Complications with pancreatic stenting can occur. Occlusion was seen with the passage of time and migration was present in 10% of patients<sup>[30]</sup>. Distal migration and impaction on the opposite duodenal wall can cause perforation while proximal migration into the pancreas is a technical challenge for the endoscopist. The possibility of stent induced fibrosis has raised concerns<sup>[31]</sup>. However with the preexisting fibrosis of MPD there has been no significant clinical impact. The search for an ideal pancreatic stent continues and a new "wing stent" to prevent clogging as well as an "S" shaped stent to prevent migration are undergoing evaluation<sup>[32,33]</sup>. The use of covered metal stents (CSEMS) for pancreatic strictures is also under evaluation. The initially used CSEMS had the disadvantage of stent migration. Subsequently a new "bumpy stent" has been tried for MPD strictures in 32 patients<sup>[34,35]</sup>. The stent had antimigratory properties and its contours adapted to the MPD. These were extracted at 3 mo and were effective in resolving the MPD strictures. However they were associated with the formation of de novo strictures and further trials are needed to evaluate their long term efficacy and safety.

European Society of Gastrointestinal Endoscopy (ESGE) guidelines state that dominant PD strictures be treated by placing a single 10 Fr stent with stent exchanges planned for 1 year. Multiple plastic stents should be deployed in a stricture which persists after 1 year of single stent placement<sup>[36]</sup>. Uncovered SEMs should not be placed in MPD. ESGE guidelines also state that tem-

porary placement of fully covered SEMs should only be performed in the setting of trials<sup>[36]</sup>.

## ENDOTHERAPY OF PANCREATIC DUCTAL CALCULI

Pancreatic ductal calculi are a consequence of CP and tend to aggravate or produce pain by obstructing pancreatic ducts and producing upstream hypertension. They can occur in 50% of patients with CP<sup>[8]</sup>. Stones seen in the tropics and of the non-alcoholic type of CP tend to be larger and denser than those seen in the alcoholic variety<sup>[37,38]</sup>. The large size could also be due to delay in reporting for therapy<sup>[2]</sup>. Stones > 5 mm in size can usually be extracted with a Dormia basket, or balloon trawl following EPS. However stones > 5 mm in size are often impacted and difficult to extract by the standard techniques<sup>[2,37,39]</sup>. Large calculi need to be fragmented prior to extraction or spontaneous expulsion from the MPD. ESWL is now accepted as the standard of care in the management of large PD calculi not amenable to routine endotherapy<sup>[2,36,37,40-45]</sup>. ESWL is very effective in fragmenting both radio-opaque and radio-lucent calculi in the MPD. A meta-analysis of 17 studies with a total of 491 patients revealed a clearance rate between 37%-100% and good pain relief<sup>[46]</sup>. Another review of 11 studies with over 1100 patients showed successful stone fragmentation in 89%<sup>[47]</sup>. Our own single center study of over 1000 patients shows complete clearance in 76% patients and partial clearance in another 17% patients following ESWL and endotherapy for large calculi<sup>[2]</sup> (Figures 1 and 2).

The following protocol is followed at our center for patients with large PD calculi<sup>[2]</sup>. Patients with large calculi in the head or body and with pain as the main complaint are subjected to ESWL. Patients with isolated calculi in the tail, multiple MPD strictures, extensive calculi in head, body and tail, associated head mass, pseudocysts and pregnancy are excluded from ESWL. The procedure is performed with a III generation electromagnetic lithotripter with bi-dimensional fluoroscopy and ultrasound targeting facility. (Delta compact-Dornier MedTech Wessling Germany). Epidural anesthesia is preferred in most patients<sup>[48]</sup>. It is effective and offers many advantages as reported in our study of over 1500 patients. Radio-opaque calculi are subjected to ESWL under fluoroscopic guidance. For radio-lucent calculi, a NPT is placed and contrast is passed through this tube to help localize the calculi. The aim of fragmentation is to break the calculi to 3 mm or less to facilitate their extraction or expulsion<sup>[2,49]</sup>. An average of 3 sessions is generally required (5000-6000 shocks per session). The protocol is shown in Figure 3. A few studies have advocated use of ESWL alone followed by spontaneous expulsion of fragments<sup>[50]</sup>. A randomized controlled trial of 55 patients compared results of ESWL and ERCP with ESWL alone. The only difference was higher cost and longer stay in the ESWL and ERCP group<sup>[51]</sup>. At our center, we prefer to extract

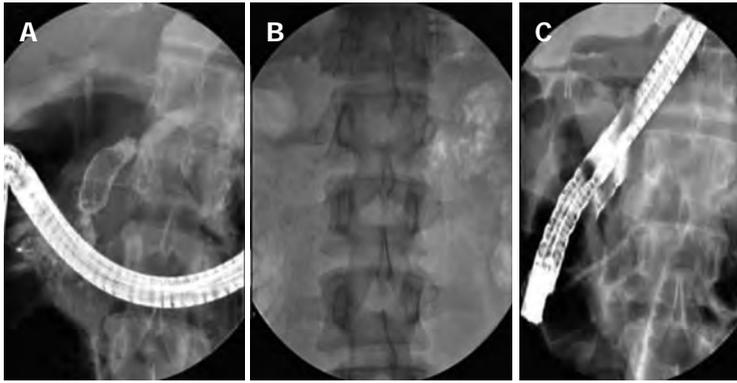

Figure 1 Large pancreatic calculi in head (A), genu in a patient with pancreas divisum (B) and chronic pancreatitis cleared by extracorporeal shockwave lithotripsy followed by pancreatic stenting<sup>[49]</sup> (C).

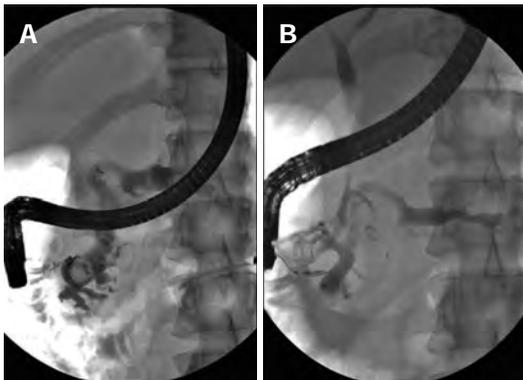

Figure 2 Large pancreatic calculi in head. Post extracorporeal shockwave lithotripsy reduction in diameter of main pancreatic duct<sup>[49]</sup> (A, B).

the fragments from the MPD by ERCP following the ESWL procedure as fragments tend to be denser and adherent and do not clear spontaneously<sup>[2,49]</sup>.

Short term pain relief following ESWL was seen in 84% of our patients<sup>[2]</sup> and similar results have been reported by others<sup>[39]</sup>. Very few long term follow up studies are available. Two-thirds of patients were found to be pain free on long term follow up<sup>[8,52]</sup>. A recent study showed pain relief in 85%, complete pain relief with no narcotic use in 50% and avoidance of surgery in 84% of 120 patients on long term follow up after ESWL<sup>[53]</sup>. Our own data on long term follow up is encouraging and over 60% of patients are pain free on follow up of more than 5 years<sup>[54]</sup>. In conclusion, in properly selected group of patients with large PD calculi, ESWL is a useful tool and provides adequate long term pain relief. A few patients also benefit in exocrine and endocrine dysfunction though the numbers are too small to be significant<sup>[54]</sup>. ESWL is a safe procedure and well tolerated. Minor side effects such as transient pain and bruising of skin at the site of shock delivery have been described<sup>[2,37,49]</sup>. The incidence of pancreatitis is not higher following ESWL.

Other techniques for extraction of large PD calculi include intraductal laser or electro hydraulic lithotripsy through a pancreatoscope or spyscope<sup>[55,56]</sup>. Experience with these modalities is small and success rates are discordant. These procedures are technically difficult and require non standard equipment. At present, they are only

to be considered as second line management after failed ESWL<sup>[36]</sup>.

## CHRONIC PANCREATITIS RELATED BENIGN BILIARY STRICTURES

CBD strictures occur in 3%-46% of patients with CP<sup>[30]</sup>. Strictures can be reversible due to inflammation or compression with a pseudocyst. They are irreversible following fibrosis. ESGE guidelines recommend treating CP related benign biliary strictures (BBS) in cases with symptoms, secondary biliary cirrhosis, biliary stones, asymptomatic elevation of serum alkaline phosphates > 2-3 times upper limit of normal or raised serum bilirubin persisting for over 1 mo<sup>[36]</sup>. Placement of a single plastic stent in the CBD is associated with poor success rates. Long term results have disappointing and sustained benefit is seen in around 25% of patients on follow up of 46 mo<sup>[57]</sup>. Single plastic stents are associated with poor resolution and higher relapse rate. The presence of pancreatic head calcification is an important factor for failure of this therapy<sup>[58]</sup>. Placement of multiple plastic stents in CP related BBS is technically successful in over 95% of patients and offers the best results. Complete therapy requires approximately four ERCP procedures and stents exchanges performed every 3 mo for 1 year. Single stents provided relief in 31% of 350 patients as compared to 62% in 50 patients who received multiple stents<sup>[36]</sup>. Catalano *et al*<sup>[59]</sup> performed a non-randomized study comparing single and multiple plastic stents in CP related BBS. Clinically, success was reported in 92% with multiple stents as compared to 24% with single stents. Uncovered SEMs for BBS are not advocated and partially or fully covered SEMs have been used with a success rate of 50%-80% on follow up for 22-28 mo<sup>[60,61]</sup>. A recently conducted multicenter trial using fully covered SEMs (FCSEMS) in BBS included 127 patients of CP. It concluded that FCSEMS may be useful for treatment of BBS particularly in patients with CP<sup>[62]</sup>. There has been no head to head study comparing single or multiple plastic stents and metal stents in BBS due to CP and surgery. The choice and option of surgery depends upon patient preference, expertise at the treating center and the presence of co morbidities such as cirrhosis or collaterals.

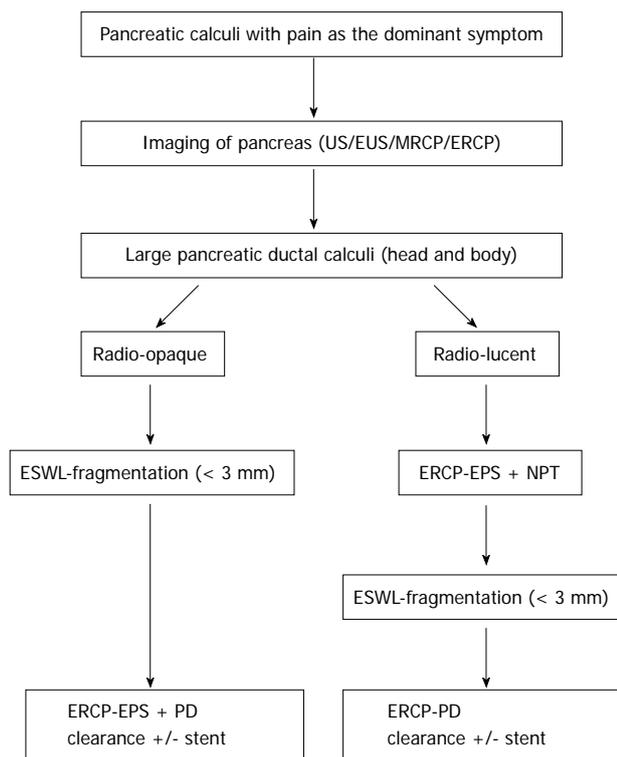

Figure 3 Protocol followed for extracorporeal shockwave lithotripsy in chronic calcific pancreatitis. NPT: Naso pancreatic tube; EPS: Endoscopic pancreatic sphincterotomy; ERCP: Endoscopic retrograde cholangiopancreatography; ESWL: Extracorporeal shockwave lithotripsy; US: Ultrasonography; PD: Pancreatic duct; EUS: Endosonography; MRCP: Magnetic resonance cholangiopancreatography.

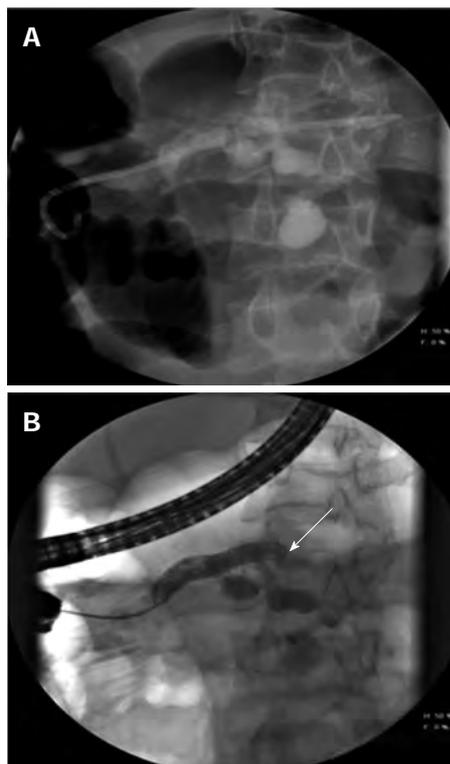

Figure 4 Mid body leak (arrow) with extravasated contrast in a patient with chronic pancreatitis (A) and dilated pancreatic duct (B). Stent placed across the leak.

## PANCREATIC DUCTAL LEAKS

Leaks from the MPD or side branches can occur following blow out of the ducts due to obstruction by stone or strictures. PD leak is defined as extravasation of contrast material from the ductal system at ERCP<sup>[63]</sup>. Disruption may be partial or complete and leads to fluid collection, pseudocysts, ascites, pleural effusion and external or internal fistulas<sup>[9,27]</sup>. Placement of transpapillary stents offers the best treatment in patients with PD disruption as it converts the high pressure ductal system into a low pressure one with preferential flow across the stents<sup>[27]</sup>. Resolution of leak was seen in 92% of patients when the stent bridged the disruption, 50% when placed proximal to the disruption and 44% when a short transpapillary stent was placed<sup>[63]</sup> (Figure 4). In patients with complete transection where stenting is not feasible a multidisciplinary approach with a help of interventional radiologist or the surgeon may be required.

## ENDOSCOPY OF PSEUDOCYSTS

Pancreatic pseudocyst (PPC) in CP is the result of disruption of the MPD or its side branches and occurs in 20%-40% of patients<sup>[64]</sup>. Disruption generally follows obstruction by stones or strictures. Treatment is indicated for symptomatic PPC or those which increase in size.

Symptoms result due to compression of adjacent structures or due to infection. It has also been suggested that prophylactic treatment be performed in certain specific situations to prevent complications. These include Pancreatic-pleural fistula, cysts > 5 mm lasting for over 6 wk, compression of major vessels or presence of large pancreatic stones in MPD<sup>[65]</sup>. There is generally a low rate of spontaneous resolution of PPC in patients with CP though small asymptomatic cysts can be followed up<sup>[66]</sup>. Drainage of pseudocysts can be transmural (transgastric or transduodenal) or transpapillary. Transmural drainage is ideal for PPC which bulge into the lumen of stomach or duodenum. Transduodenal drainage offers the best success when compared to transgastric drainage<sup>[67]</sup>. This is because cystoduodenal fistulas tend to remain patent longer than cystogastric fistulas. Placement of one or more pig tailed stents is better when compared to straight stents. Straight stents are associated with a higher rate of bleed (around 7%) as well as migration<sup>[68]</sup>. Stents should be left in place for a longer duration as their removal within 2 mo is associated with a higher incidence of PPC recurrence<sup>[36]</sup>. Pseudoaneurysm can complicate management of PPC because of the associated haemorrhage and consequent high mortality<sup>[69]</sup>. Delhaye *et al*<sup>[27]</sup> recommend prophylactic embolization of pseudoaneurysms prior to drainage of an adjacent PPC.

Transpapillary drainage is reserved for small cysts (< 6 cm size) and those in communication with the MPD. The role of EUS guided drainage for nonbulging PPC

will be discussed in the next section. Comparison of EUS guided drainage with surgery in an RCT revealed that endoscopic drainage was significantly better than surgery in terms of cost and length of stay over a 3 mo follow up<sup>[70]</sup>. Complications include bleed, infection and leak of around 4% each with a mortality of 0.5%<sup>[71]</sup>. Infection is more likely with transpapillary drainage and leak is more likely with transmural drainage. Routine antibiotic administration is recommended for drainage of PPC<sup>[72]</sup>. With a success rate of 80%-95% at most centers, a recurrence rate of 10%-20% and results comparative or better than surgery, endoscopy is the preferred first line of management for patients with PPC in the background of CP<sup>[27,36]</sup>.

## ENDOSONOGRAPHY IN CP

EUS is an excellent diagnostic modality especially in patients with early CP. It also has a definite therapeutic role in the following situations and these are discussed briefly.

### PPC drainage

EUS is ideal for drainage of nonbulging PPC and cysts as far as 4 cm from the stomach or duodenal wall have been drained<sup>[73]</sup>. Around 44%-53% of PPCs belong to this category. In the presence of collaterals the site of drainage is better identified with EUS, thus making the procedure safer. The complication rate is however similar when PPCs are drained with or without EUS guidance<sup>[74]</sup>. A recent randomized trial comparing EUS guided and surgical cystogastrostomy for pseudocysts revealed shorter hospital stay, lower cost and better physical and mental health in the endoscopy group. None in the endoscopy group had pseudocyst recurrence and therapy was successful in all the patients<sup>[75]</sup>.

### EUS guided access of MPD

EUS guided access or drainage is indicated following failed conventional drainage of MPD. It can be *via* the stomach (pancreatogastric) or duodenum (pancreatobulbar). The duodenal route is preferred because of better stability of the EUS scope<sup>[9]</sup>. A guidewire can be passed into the duodenum for a rendezvous procedure or transmural drainage can be performed. Success rates of 77%-92% have been reported<sup>[76,77]</sup>. Complications include pain, bleeding, perforation and hematoma and morbidity of 0%-44% has been reported<sup>[76-78]</sup>. EUS guided access of the MPD is a technically challenging procedure and should always be performed by experts and under radiological guidance<sup>[9]</sup>.

### EUS guided celiac block

Patients who have failed to respond to intensive medical or endoscopic therapy and are not candidates suitable for surgery can be provided relief from pain by EUS guided celiac block. A combination of corticosteroids (triamcinolone) and anesthetic agents (bupivacaine) is injected in and around the celiac plexus under EUS guidance. A recent meta analysis has reported pain relief in 50%-55%

of patients though the pain relief is transient<sup>[79,80]</sup>. Patients who are younger than 45 years or have previous pancreatic surgery are less likely to benefit<sup>[81]</sup>. EUS guided celiac block is shown to be superior to fluoroscopy guided celiac block for pain relief and pain preference in our study<sup>[82]</sup>. EUS guided nerve block can produce diarrhea, hypertension due to sympathetic blockade and unopposed parasympathetic activity<sup>[11,80]</sup>.

## CONCLUSION

In conclusion, management of CP is a multidisciplinary task involving the physician, endoscopist, interventional radiologist and surgeon. Their roles are complementary to each other. As mentioned earlier endotherapy is effective, less invasive than surgery, offers good results and is associated with low morbidity and mortality. It can be repeated and does not interfere with any subsequent surgical procedure. It is therefore advisable to offer endotherapy as the first line treatment in properly selected patients with CP.

**Core tip:** Approaches for treatment advanced gastric cancer are object of interesting debates toward scientific community worldwide over the last 20 years. Chemotherapy based on platinum and fluoropyrimidine agents remained up to now the standard of care for those patients, otherwise triplet therapy either an anthracycline or taxane may be considered. Herein we provide an additional discussion regarding the role of biologic agents, such as trastuzumab and novel therapies for improve survival in this field.

### Abstract

Gastric cancer usually is diagnosed in advanced stages and thus current medical practice affords limited therapeutic options. However, recent studies established the role of human epidermal growth factor receptor 2 (HER2) in clinical management. Trastuzumab, an anti-HER2 monoclonal antibody, acquired a main role in advanced gastric cancer harboring HER2 overexpression and/or amplification improving survival to 17.1 mo according to trastuzumab for gastric cancer phase III trial results. Also, new promising drugs, such as c-Met inhibitors, are in development and assessment for this setting. Certainly, novel drugs will emerge in the next few years for help oncologists improve clinical management of advanced gastric cancer providing higher survival and quality of life. In this mini-review we will discuss some issues in this regard and provide an actual overview of this setting.

### INTRODUCTION

Gastric cancer (GC) is one of the leading types of cancer worldwide. Although the trend in death rates<sup>[1]</sup> for GC is decreasing, this tumor continues to have a poor prognosis and few efficacious therapeutic options particularly in advanced stages. Since most of symptoms for this type of cancer are nonspecific and screening strategies in many countries are absence, GC is usually diagnosed in advanced stages. The predominant histological type of GC is adenocarcinoma (95% of tumors) and the main adenocarcinomas sub-types are intestinal, diffuse and mixed type. Recent studies showed the human cancer is the human epidermal growth factor receptor in advanced GC personalizing treatment<sup>[2-5]</sup>. Herein we will discuss issues concerning novel biologic agents for advanced gastric cancer, focusing in anti-human epidermal growth factor receptor 2 (HER2) therapies, such as trastuzumab, and promising novel agents.

## HER2 AND GASTRIC CANCER

Treatment depends on the site and extent of the tumor<sup>[4,6,7]</sup>. Treatment objectives vary from through curative approaches, such as curative surgery, radiotherapy and perioperative chemotherapy, that may improve the survival rate of operable GC patients; to palliative approaches in advanced stage patients or those who are subject to relapse after prior curative surgery<sup>[7,8]</sup>. For advanced patients, 5-fluorouracil (5-FU) plus platinum remain standard treatment regimens, with or without an anthracycline or taxane<sup>[9]</sup>. This therapeutic regimen offers a response rate of 30%-50% with 9-11 mo median overall survival (OS)<sup>[10]</sup>. Given these poor results, an investment in new treatment weapons is required. One of the most considerable innovative targets in human cancer is the human epidermal growth factor receptor (EGFR) family<sup>[11]</sup>. The human HER family includes four structurally related members, HER1 (ErbB1, also known as EGFR), HER2 (ErbB2), HER3 (ErbB3) and HER4 (ErbB4)<sup>[12]</sup>. Relatively to HER2, this is highly expressed in a significant proportion of GC<sup>[13]</sup> and thus it is nowadays considered an excellent therapeutic target. GC harboring HER2 overexpression was shown to have a worse prognosis<sup>[14]</sup>. In HER2-amplified patients the median survival was 5.5 mo compared with 12.6 mo in non-amplified patients. HER2 overexpression was more commonly seen in the intestinal-type than diffuse-type cancers (32% *vs* 6%)<sup>[15-17]</sup>.

## HER2 MOLECULAR TESTS AND TRASTUZUMAB

HER2 overexpression can be determined by immunohistochemistry (IHC) using a monoclonal antibody or by the detection of HER2 gene amplification through fluorescent *in situ* hybridization (FISH)<sup>[18-20]</sup>. Thus, it is current practice to test all new diagnoses of GC for HER2 by IHC<sup>[21,22]</sup>. Tumors can be classified by IHC as IHC 0/1+, negative resulted; IHC2+, equivocal resulted and it is recommended FISH testing, and IHC3+, positive resulted<sup>[18,23]</sup>.

In the trastuzumab for gastric cancer (ToGA) trial<sup>[2]</sup>, trastuzumab, a recombinant humanized monoclonal antibody that targets the extracellular domain IV of the HER2 protein, was evaluated in HER2 overexpressing gastric and gastroesophageal junction (GEJC) cancer. In the mentioned study, patients with GC or GEJ that showed HER2 overexpression were eligible for the analysis and randomized in two arms. To one arm standard chemotherapy alone (5-FU/capecitabine plus cisplatin) was administered while to the other arm it was administered chemotherapy plus trastuzumab. Median OS was 13.8 mo in those assigned to trastuzumab plus chemotherapy compared with 11.1 mo in those assigned to chemotherapy alone<sup>[24]</sup>. The median of progression-free survival (PFS) was increased with the addition of trastuzumab to standard chemotherapy: 6.7 mo in the trastuzumab arm and 5.5 mo in the chemotherapy alone

arm. The overall response rate was 47.3% *vs* 34.5% in trastuzumab plus chemotherapy and chemotherapy, respectively. The toxicity did not increased substantially with trastuzumab addition; however, the most common grade 3/4 adverse reactions associated with trastuzumab in metastatic GC were neutropenia, diarrhea, fatigue, anemia, stomatitis, weight loss, upper respiratory tract infections, fever, thrombocytopenia, mucosal inflammation, nasopharyngitis and dysgeusia. Thus, the ToGA trial showed that trastuzumab in combination with chemotherapy can be considered as a new standard option for patients with HER2-positive advanced GC or GEJC. So, trastuzumab was approved by the Food and Drug Administration and the European Medicines Agency (EMA) for patients with HER2-positive metastatic GC or GEJ who have not received previous anticancer therapy for metastatic disease.

## NOVEL AGENTS AND PROMISING MOLECULES

Nevertheless, others monoclonal antibodies have been developed as an alternative to trastuzumab<sup>[25-28]</sup>. For example, HER dimerization inhibitor, such as pertuzumab, which in combination with the trastuzumab has shown to have a promising effect in experimental models of GC<sup>[29,30]</sup>. In addition, some studies with anti-HER2 combination treatments indicate that the use of more than one HER2-targeted therapy was superior to one of these agents alone, particularly in breast cancer (BC) HER2 positive<sup>[31-33]</sup>. For instance, the CLEOPATRA<sup>[34]</sup> phase III trial compared the efficacy and safety of pertuzumab, trastuzumab, and docetaxel with placebo, trastuzumab, and docetaxel in patients with HER2-positive first-line metastatic breast cancer, showed a significant improvement in OS with addition of pertuzumab. So, there is need for planning studies to assess the safety and efficacy of the pertuzumab in the GC HER2 positive<sup>[35,36]</sup>.

However, when the patients acquire resistance to trastuzumab, what to do? The molecular mechanisms underlying trastuzumab resistance in GC are still unknown, but intra-tumoral heterogeneity of this tumor may contribute to this resistance<sup>[12,37-39]</sup>. There are some mechanist theories in a study that attempted to explain this phenomenon, *e.g.*, that catecholamine-induced  $\beta$ 2-AR activation mediates desensitization of GC cells to trastuzumab through up regulation of the MUC4 expression<sup>[40,41]</sup>, or that interaction between HER2 and insulin-like growth factor 1 receptor in trastuzumab-resistant breast cancer cells and involved in cross-talk that results in p27 downregulation<sup>[42]</sup>. Furthermore, hepatocyte growth factor (HGF) and its receptor, the trans-membrane tyrosine kinase c-Met, promote cell proliferation, survival, motility and invasion as well as morphologic changes that stimulate tissue repair and regeneration in normal cells but can be co-opted during tumor growth<sup>[28]</sup>. Previous studies reported that high levels of HGF or c-Met are associated with poor prognosis in gastric can-

cer, due to gene amplification and protein overexpression of c-Met drive resistance to epidermal growth factor receptor family inhibitors, both in preclinical models and in patients<sup>[21,27,28,43,44]</sup>. Only a few phase I - II trials<sup>[26,45]</sup> recently assessed the role of c-Met inhibitors, such as crizotinib<sup>[46]</sup> and foretinib<sup>[26]</sup>, in gastric cancer setting. In a study by Lennerz *et al.*<sup>[46]</sup> two patients harboring MET amplification were treated with crizotinib and presented tumor shrinkage (-30% and -16%) and experienced progression after 3.7 and 3.5 mo. Shah *et al.*<sup>[26]</sup> reported 67 advanced gastric cancer patients who were treated with foretinib irrespective of c-Met status. Best response was stable disease (SD) in 10 (23%) patients receiving intermittent dosing and 5 (20%) receiving daily dosing; SD duration was 1.9-7.2 mo (median 3.2 mo). Of 67 patients with tumor samples, 3 had MET amplification, one of whom had SD. Treatment-related toxicity occurred in 91% of patients<sup>[26]</sup>. Thus, the response to this dilemma is not so simple and current there are many options for explore in this regard.

In this regard, others classes of targeted drugs, including tyrosine kinase inhibitors, such as lapatinib<sup>[47]</sup> and dacomitinib<sup>[48]</sup>, mammalian target of rapamycin pathway inhibitors, such as everolimus<sup>[49]</sup>, have also been investigated. Lapatinib inhibits the catalytic activity of the EGFR and it is also a HER2 inhibitor; thus, it is a dual tyrosine kinase inhibitor of both EGFR and HER2. The SWOG S413 trial<sup>[47]</sup> analyzed lapatinib in the first line therapy in patients with advanced or metastatic GC showing 9% response rate (11% overall response rate) and a median OS of 4.8 mo. In summary, lapatinib as a single agent presents reduced responses, but in combination with other chemotherapeutic agents may have additional benefits. Dacomitinib<sup>[18]</sup> is a pan-HER inhibitor with potential use in cancer treatment via mutations or overexpression/amplification of HER family members or their target molecules alone or in combination with chemotherapeutic and/or molecular-targeted agents, however, there are no clinical trials phase II / III to justify its use in GC patients.

## CONCLUSION

Nowadays, an interesting biologic option is available, such as trastuzumab, for combination with platinum-5-FU for prolongs OS in a sub-set of patients. However, only 20% of advanced GC harbor with HER2 overexpression and thus a large number of patients will not acquire benefit from this innovative option. Thus, further alternatives are warranted for overcome this issue. Others biological agents are under investigation, but without immediate results for the current clinical practice. Crizotinib, foretinib and pertuzumab seems to be promising due to preliminaries small studies. However, results from larges phase III trials are still need to determine whether those innovative agents would be place in the current scenario. In conclusion, HER2 targeted therapy is responsible for a significant increase in survival of patients with GC in

advanced stages. Unfortunately, the GC continues to still have a poor prognosis. In the future it is intended to develop new trials and look for other genetic alterations that may be highly specific therapeutic targets and less toxic as well.

## ACKNOWLEDGMENTS

Authors would like to acknowledge Luis Moreira Gonçalves, PhD, Post-Doc fellow at Faculty of Sciences, University of Porto (Portugal), for the language review of this manuscript.

### Abstract

**AIM:** To investigate the effect of retinoblastoma protein-interacting zinc finger gene 1 (*RIZ1*) upregulation in gene expression profile and oncogenicity of human esophageal squamous cell carcinoma (ESCC) cell line TE13.

**METHODS:** TE13 cells were transfected with pcDNA3.1(+)/*RIZ1* and pcDNA3.1(+). Changes in gene expression profile were screened and the microarray results were confirmed by reverse transcription-polymerase chain reaction (RT-PCR). Nude mice were inoculated with TE13 cells to establish ESCC xenografts. After two weeks, the inoculated mice were randomly divided into three groups. Tumors were injected with normal saline, transfection reagent pcDNA3.1(+) and transfection reagent pcDNA3.1(+)/*RIZ1*, respectively.

Tumor development was quantified, and changes in gene expression of *RIZ1* transfected tumors were detected by RT-PCR and Western blotting.

**RESULTS:** DNA microarray data showed that *RIZ1* transfection induced widespread changes in gene expression profile of cell line TE13, with 960 genes upregulated and 1163 downregulated. Treatment of tumor xenografts with *RIZ1* recombinant plasmid significantly inhibited tumor growth, decreased tumor size, and increased expression of *RIZ1* mRNA compared to control groups. The changes in gene expression profile were also observed *in vivo* after *RIZ1* transfection. Most of the differentially expressed genes were associated with cell development, supervision of viral replication, lymphocyte costimulatory and immune system development in esophageal cells. *RIZ1* gene may be involved in multiple cancer pathways, such as cytokine receptor interaction and transforming growth factor beta signaling.

**CONCLUSION:** The development and progression of esophageal cancer are related to the inactivation of *RIZ1*. Virus infection may also be an important factor.

Alteration in gene expression profile and oncogenicity of esophageal squamous cell carcinoma by *RIZ1* upregulation. *World J Gastroenterol* 2013; 19(37): 6170-6177 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i37/6170.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i37.6170>

## INTRODUCTION

Esophageal cancer is one of the most common forms of cancer in the world and is a leading cause of cancer deaths in China and other developing countries. To date, the mechanisms of esophageal cancer are unclear. Tumor occurrence and development are regulated by a variety of oncogenes and tumor suppressor genes<sup>[1-3]</sup>, including the putative tumor suppressor gene, Retinoblastoma protein-interacting zinc finger gene 1 (*RIZ1*). The *RIZ* gene has two expression products: *RIZ1*, which is believed to be a histone methyltransferase and acts on the locus of H3K9; and *RIZ2*, which lacks the PR-domain of *RIZ1*. Abnormal expression of *RIZ1* has been found to be associated with tumor invasion and malignancy<sup>[4-10]</sup>.

Our group has previously reported that *RIZ1* expression level is lower in esophagus carcinoma than in adjacent noncancerous tissues<sup>[11]</sup>, and is related to methylation of CpG islands<sup>[12]</sup>. In addition, by constructing human *RIZ1* eukaryotic expression vectors to transfect human esophageal squamous cell carcinoma (ESCC) cell line TE13, we were able to report that upregulation of *RIZ1* can recover tumor suppression activity and that treatment of cell line TE13 by methyltransferase inhibitor 5-aza-CdR reverses the methylation status of the promoter region<sup>[13]</sup>. In order to investigate *RIZ1*-mediated changes in gene expression of esophageal cancer, we compared the gene expression profile of TE13 cells transfected with *RIZ1* with those of negative control cells. The resulting changes in oncogenicity were analyzed *in vitro* and by animal experimentation.

## MATERIALS AND METHODS

### Ethics

The animal study proposal was approved by the Tianjin Medical University General Hospital Ethics Committee with the permit number: 2012-021. All mouse experimental procedures were performed in accordance with the Regulations for the Administration of Affairs Concerning Experimental Animals approved by the State Council of People's Republic of China.

### Cell culture and transfection

Human ESCC cell line TE13 was purchased from ATCC (Rockville, MD, United States) and cultured in RPMI-1640 (HEPES 4.76 g/NaCO<sub>3</sub> 2.0 g/RPMI-1640

10.4 g/ddH<sub>2</sub>O 1000 mL) media supplemented with 10% new-born bovine serum, 2 mmol/L 1 × L-glutamine, 100 U/mL penicillin and 100 µg/mL streptomycin (Gibco, Life Technologies; NY, United States). Cells were maintained at 37 °C in a humidified atmosphere with 5% CO<sub>2</sub>. *RIZ1* eukaryotic expression vector pcDNA3.1(+)/*RIZ1* plasmid had been prepared previously and stored at -80 °C. Cultivated TE13 cells were passaged in 12-inch orifice plates. Passaging was repeated every 2-3 d at 1:10 dilution, and cells were lifted by trypsin digestion. When the cells were at the log phase, they were transfected using the classical liposome method by adding 2 µL Lipofectamine 2000 (Life Technologies; NY, United States). Experimental and control groups were transfected with pcDNA3.1(+)/*RIZ1* and pcDNA3.1(+), respectively. The media were changed after 6 h and the cells were washed in phosphate buffered saline (PBS), harvested and counted. After mixing with Trizol Reagent (Life Technologies, NY, United States), the cells were incubated at room temperature for 5 min, then transferred to liquid nitrogen. The resultant cDNA was taken and 0.75 µL was mixed with 2 × SYBR Premix Ex Taq™ (Takara). The following primer sets (10 µmol/L) were used: *RIZ1*, forward 5'-TCTGCTGTTGACAAGACCC-3', reverse 5'-GCATCAATGCACATCCATC-3'; glyceraldehyde 3-phosphate dehydrogenase (*GAPDH*), forward 5'-ACCCAGAAGACTGTGGATGG-3', reverse 5'-TTCAGCTCAGGGATGACCTT-3'. Amplification was carried out using LightCycler real-time polymerase chain reaction (PCR) system (Roche, United States), according to the manufacturer's protocol. Each sample was run in triplicate for each gene. An initial denaturation step at 95 °C for 5 min was followed by 40 denaturation cycles at 94 °C for 30 s, annealing at 56 °C for 30 s, and extension at 72 °C for 30 s. A solubility temperature curve assay was constructed and the *RIZ1* and *GAPDH* Ct-values for each group were recorded and compared. The *RIZ1* mRNA relative quantitation formula: ( $2^{-\Delta\Delta Ct}$ , × 100%), was applied to evaluate whether transfection was successful. Duplicate detections were performed in triplicate, through  $2^{-\Delta\Delta Ct}$ , to calculate mean ± SD.

### Microarray analysis

Total RNA was extracted using Trizol Reagent (Life Technologies; NY, United States). Quality control was achieved by utilizing the Agilent Bioanalyzer 2100 (Agilent Technologies; United States). Purification was achieved using the RNeasy mini kit and RNase-Free DNase Set (QIAGEN, Germany). Agilent's Low Input Quick Amp Labeling Kit, one-color and full genome chip (4 × 44K, design ID: 014850) were used to amplify and mark the mRNA according to the manufacturer's protocols. The cRNA was purified and conjugated using the RNeasy mini kit. Agilent's Gene Expression Hybridization Kit with a sample quantity of 1.65 µg cRNA was employed for gene chip hybridization for 17 h in a hybridization oven at < 65 °C and 10 rpm, following Agilent's protocol. Slides were washed in staining dishes (Thermo Shandon,

PA, United States) with Gene Expression Wash Buffer Kit. After completion of hybridization, gene chip scanning was performed using an Agilent Microarray Scanner. The software was adjusted to set the Dye channel to Green; scan resolution to 5  $\mu\text{m}$ ; and PMT to 100%, 10%, 16 bit. Data was read by Feature Extraction software v.10.7 and Gene Spring Software v.11.0, and uniformly processed by a Quantile algorithm. Data analysis was carried out using an online analysis system (SAS) (Shanghai Bohao Company, China). Fold changes  $\geq 2$  (upregulated) or  $\leq 0.5$  (downregulated) were set to select differentially expressed genes. Gene ontology (GO) functional analysis, chromosomal assignment, and pathway analysis were then performed. Several representative genes were selected for verification of the gene chip scan results by reverse transcription PCR (RT-PCR).

### Animal experimentation

**Purchase and feeding:** Eighteen BALB/c nude mice (female; aged 4–6 wk; weight, 17–21 g), were purchased from the Experimental Animal Center of the Academy of Military Medical Sciences, Chinese People's Liberation Army, under license No. SCXK-(army)-2007-004. Nude mice were fed in the Tianjin Medical University General Hospital SPF rearing chamber with sterilized standard feed and sterile water. Animal experimentation and protocol were carried out in accordance with medical ethical standards.

**Subcutaneous transplantation:** Cultured cells were adjusted to a final concentration of  $1 \times 10^7$  cells/mL in sterilized PBS; 0.2 mL was injected into the right armpit of each nude mouse and their general condition and tumor growth after inoculation were observed. The large and small tumors in diameter were measured every three days, tumor size was calculated and a tumor growth curve plotted. The antitumor rate was calculated using the following formulae: Volume =  $0.5 \times \text{small diameter} \times (\text{large diameter})^2$ ; antitumor rate =  $(1 - \frac{\text{the experimental group volume}}{\text{the control group volume}}) \times 100\%$ .

**Animal grouping and treatment:** The nude mice were divided into three groups using a random digital method. Five mice from each group, with the maximum and minimum tumor volumes, were separated and the remaining mouse was removed. The blank control group was injected with 100  $\mu\text{L}$  normal saline. The pcDNA3.1(+) group was injected with 20  $\mu\text{L}$  liposome, to which 20  $\mu\text{g}$  empty plasmid, adjusted to a final volume of 100  $\mu\text{L}$  in DMEM, was added. The pcDNA3.1(+)/RIZ1 recombinant plasmid group was injected with 20  $\mu\text{L}$  liposome to which 20  $\mu\text{g}$  RIZ1 recombinant plasmid, adjusted to a final volume of 100  $\mu\text{L}$  in DMEM, was added. Each group was injected every two days using the multi-point injection method, and the treatment was repeated 5 times. Seven days after the final injection, the mice were killed by cervical dislocation and the tumor tissue was removed, weighed and used for subsequent experimentation.

### RT-PCR

RT-PCR was carried out as described above, and 12 mL of the reaction products were analyzed by electrophoresis on a 20 g/L agarose gel. The electrophoresis images were scanned by UV spectrophotometry (Beckman Coulter Inc., Brea, CA, United States).

### Western blotting

Tissue from each group was homogenized in RIPA buffer (50 mmol/L Tris-HCl, pH 7.4; 150 mmol/L NaCl; 1% Nonidet P-40; 0.5% sodium deoxycholate; 0.1% SDS; 1 mmol/L EDTA; 1 mmol/L PMSF; 1 mg/mL Aprotinin). The supernatant was collected and protein concentrations were determined by a bicinchoninic acid (BCA) protein assay kit (Pierce; IL, United States); 30  $\mu\text{g}$  of whole-cell lysate was separated on 8% SDS-PAGE gels, transferred to nitrocellulose (NC) membranes (Amersham Biosciences; New Jersey, United States), and immunoblotted with the following antibodies: anti- $\beta$ -actin (ABCAM; United Kingdom), control; primary antibodies, 1:2000 dilution (ABCAM; United Kingdom); secondary antibodies Goat Anti-Mouse, 1:5000 dilution (ABCAM; United Kingdom). The films were analyzed by a PowerLook scanner (UMAX) and quantified by Image Quant software (GE; United States). The control experiments (TE13 cells; TE-13 cells transfected with blank plasmid) were treated by the same method. Relative expression of RIZ1 = gray value of RIZ1 protein/gray value of  $\beta$ -actin.

## RESULTS

### Transfection

The melting curve peaks for RIZ1 and GAPDH transcript products were at 80  $^{\circ}\text{C}$  and 82.5  $^{\circ}\text{C}$ , respectively (Figure 1), giving Ct-values for the two groups. The relative expression levels were calculated using the real-time PCR relative quantitative formula. RIZ1 gene expression levels were compared with SPSS v.13.0 statistical software. The results showed that the mRNA expression level in the experimental group was higher than in the control groups (Figure 2), indicating that transfection had been successful ( $P \leq 0.01$ ).

### Alteration of gene expression profile

Table 1 gives the 2100 results for  $RIN \geq 7.0$  and  $28S/18S \geq 0.7$ , therefore qualifying the samples without degradation. The initial scanned single fluorescence chip data (Figure 3A) were standardized and converted to logarithmic values. A scatter plot was constructed with a two-dimensional rectangular coordinate plane (Figure 3B).

### GO and microarray analysis

The SAS system was used for GO analysis of the differentially expressed genes and  $P \leq 0.05$  was considered to be statistically significant (Table 2). The microarray data showed that 2123 genes were differentially expressed in the pcDNA3.1(+)/RIZ1 transfected cells with fold

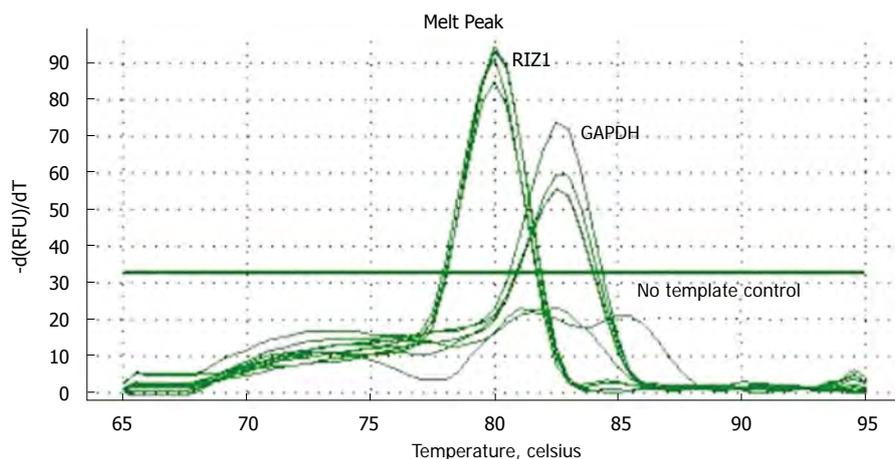

Figure 1 Solubility temperature curves for RIZ1 and glyceraldehyde 3-phosphate dehydrogenase showing that transfection was successful. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

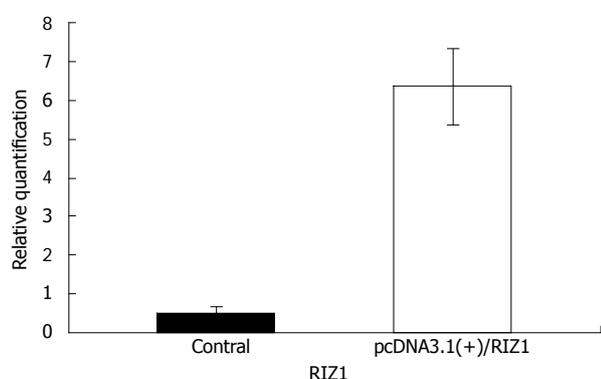

Figure 2 Histogram of RIZ1 gene mRNA expression levels in the blank control group and pcDNA3.1(+)/RIZ1 recombinant plasmid group, clearly showing that gene expression is higher in the pcDNA3.1(+)/RIZ1 group ( $P \leq 0.01$ ).

Table 1 Sample qualification					
Sample number	Concentration ( $\mu\text{g}/\mu\text{L}$ )	$A_{260}/A_{280}$	2100 result		Results
			RIN	28S/18S	
1	0.816	1.94	8.9	1.5	Qualified
2	0.865	1.93	8.9	1.5	Qualified

changes  $> 2$  ( $P < 0.05$ ) compared to control samples. Of these, 960 genes were upregulated, of which 654 were known genes (1.70%, 654/38500) and 306 were unknown; 1163 genes were downregulated, of which 719 were known genes (1.87%, 719/38500) and 444 were unknown. Subsequent analyses were primarily carried out on annotated genes. The gene chip results were confirmed by RT-PCR (Figure 4).

### Pathway analysis

Many of the identified genes are associated with cell development, virus replication supervision, costimulatory molecule, and immune system development. Further analysis indicated that the RIZ1 gene may participate in multiple signaling pathways ( $P < 0.01$ ), some of which

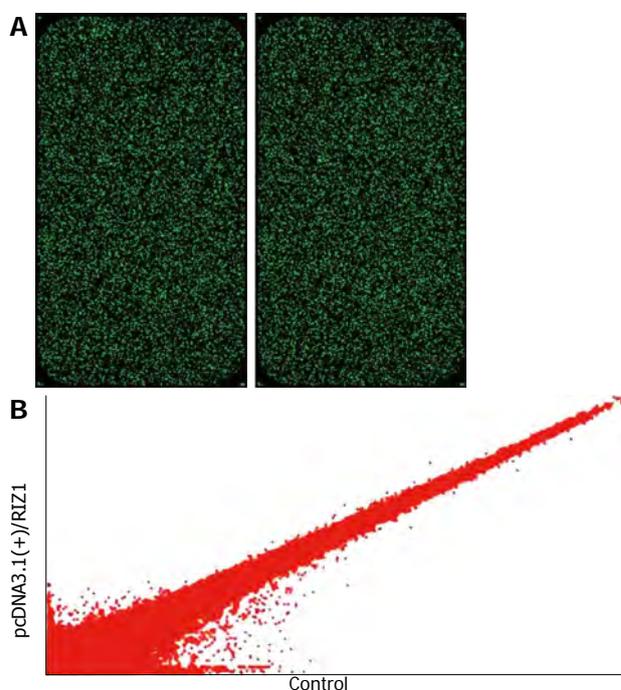

Figure 3 Alteration of gene expression profile. A: Single fluorescence chip images for microarray analysis; B: The data were used to construct the scatter plot. Hybridization signal strength scatter diagram. Each point in the scatter diagram represents a probe point on the chip. The position of each point is identified by an  $x$  and  $y$  coordinate: the  $x$ -coordinate gives the standardized signal value on the control chip; the  $y$ -coordinate gives the standardized signal value on the sample chip. The scatter plot is used to assess the centralized tendency of two sets of data.

are given in Table 3.

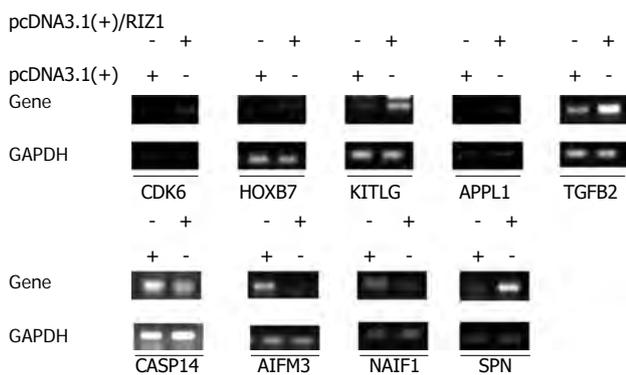

### Transplantation and tumor growth

Transplantation of human esophageal cancer TE13 cells into nude mice was successful as shown in Figure 5. Tumor volumes were compared among the three groups (Figure 6A). The tumor growth rate curves revealed that tumor growth was slower in the pcDNA3.1(+)/RIZ1 group, with a shallower growth rate curve, than in the

**Table 2** Gene ontology analysis of differentially expressed genes

GO ID	Name	Hits	Total	Percentage	P value
GO: 0048468	Cell development	81	832	9.74%	0.0288
GO: 0050792	Regulation of viral reproduction	5	20	25.00%	0.0304
GO: 0031294	Lymphocyte costimulation	3	8	37.50%	0.0397
GO: 0002520	Immune system development	38	358	10.61%	0.0428

Hits: Number of differentially expressed genes in the pathway; Total: The total number of genes in the pathway; Percentage: Percentage hits in the pathway (Hits/Total); P: Enrichment P value; GO: Gene ontology.

**Figure 4** Comparison between results from the gene chip and the reverse transcription-polymerase chain reaction. Out of the nine genes tested, eight yielded consistent results for both reverse transcription-polymerase chain reaction and gene chip. The five upregulated genes are CDK6, HOXB7, KITLG, APPL1, TGFB2; and the three downregulated genes are CASP14, AIFM3 and NAIF1; however, in the case of service principal name (SPN), the reverse transcription-polymerase chain reaction results indicate upregulation, whereas the gene chip results indicate downregulation.

other two groups (Figure 6B). The following tumor volumes were recorded after 26 d:  $1.025 \pm 0.018 \text{ cm}^3$  for the pcDNA3.1(+)/RIZ1 group,  $2.208 \pm 0.092 \text{ cm}^3$  for the blank control group, and  $1.980 \pm 0.089 \text{ cm}^3$  for the pcDNA3.1(+) group, showing that the tumor volume of the pcDNA3.1(+)/RIZ1 group was significantly lower than that of the other two groups ( $P < 0.05$ ). In contrast, there was no significant difference between the blank control and pcDNA3.1(+) groups ( $P > 0.05$ ).

**Electrophoresis**

RNA was extracted from the transplanted tumors for RT-PCR, and the products were analyzed by electrophoresis: GAPDH was identified at 125 base pairs (bp) and RIZ1 at 167 bp. The intensity of the GAPDH band was similar among the three groups; however, the intensity of the RIZ1 band was greatest in the pcDNA3.1(+)/RIZ1 group, showing that RIZ1 expression level was higher than in the other two groups (Figure 7).

**Western blotting**

The housekeeping gene,  $\beta$ -actin, was used as a control for Western blot analysis (Figure 8). The results showed no

**Table 3** RIZ1 pathway analysis (selected pathways)

Name	Hits	Total	Percentage	P value	q

obvious difference in density of the  $\beta$ -actin bands among the three groups. In contrast, the density of the RIZ1 band was higher in the pcDNA3.1(+)/RIZ1 group than in the blank control and pcDNA3.1(+) groups, indicating that RIZ1 had been successfully expressed in the tumor tissues.

**DISCUSSION**

Esophageal cancer is the world's most common cancer of the digestive system, with 70% of incidences occurring in China. China also has the highest incidence and mortality rates for both men and women. Recent statistics on morbidity and mortality for cancer patients show that esophageal cancer is the 6<sup>th</sup> most common form of cancer, and the 4<sup>th</sup> highest cause of cancer death-related in China<sup>[14-18]</sup>. Furthermore, the incidence rate is higher in rural areas than in urban areas. Esophageal cancer can be divided into two pathological types: ESCC and esophageal adenoid carcinoma. In China, ESCC accounts for 90% of esophageal cancers, in contrast to Western countries.

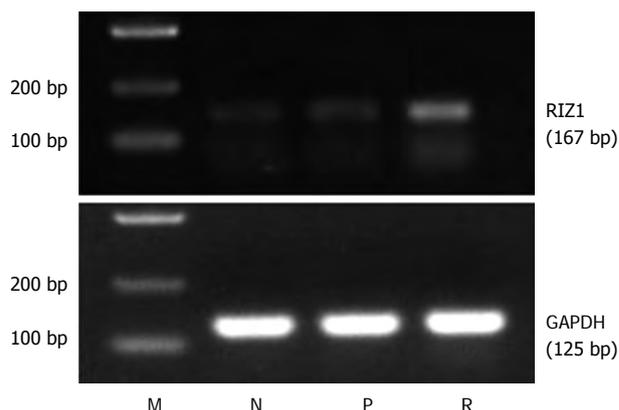

Treatment of esophageal carcinoma is a long-term project; however, by combining several different treatment types, the quality of life of the patients can be greatly improved. The purpose of our study is to enhance the understanding of ESCC development and mechanisms at the genetic level in order to advance clinical therapies. RIZ1 is one of the most effective tumor sup-

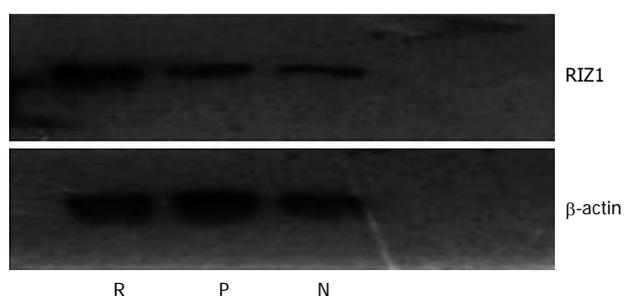

**Figure 6** Transplantation and tumor growth. A: Photograph comparing esophageal squamous cell carcinomas removed from nude mice of the three groups after 26 d; B: Growth rate curves showing the increase in tumor volumes with time. The shallower curve in the pcDNA3.1(+)/RIZ1 group, compared to the blank control and pcDNA3.1(+) groups, indicates slower growth.

pression genes, therefore failure of RIZ1 expression can lead to the development of many forms of cancer<sup>[19-25]</sup>. Our group has carried out a number of studies on the *RIZ1* gene<sup>[11,12]</sup>; however, further research is required. One key research area is the introduction of a foreign gene into the tumor tissue, which is then able to express stably; eukaryotic expression vector is an ideal choice. The liposome mediated method was adopted because it has the advantages of high transfection efficiency, low immunogenicity, simple manipulation, and can be applied to a wide variety of cells.

We constructed the *RIZ1* gene eukaryotic expression vector pcDNA3.1(+)/RIZ1 using an established molecular biology technique; empty plasmid, pcDNA3.1(+), was used as a negative control. After transfection into ESCC cell line TE13, *in vivo* experiments and gene chip analyses were carried out, as described in Materials and Methods. Our results showed that the xenograft in nude mice had a slower growth rate, and lower tumor volume and mass, in the pcDNA3.1(+)/RIZ1 group than in the blank control and pcDNA3.1(+) groups. This suggests that RIZ1 has a restraining effect on ESCC tumor growth. In contrast, the growth curves for the blank control and pcDNA3.1(+) groups were approximately parallel, indicating that these groups had no restraining effect. Secondly, after transfection, the gene expression profile of the cell line TE13 underwent extensive changes, with a total of 2123 differentially expressed genes, including 1163 downregulated and 960 upregulated. We found that

**Figure 7** Electrophoresis gel image showing bands for glyceraldehyde 3-phosphate dehydrogenase (125 bp) and RIZ1 (167 bp). The intensity of the RIZ1 band is greatest in the pcDNA3.1(+)/RIZ1 group. M: Marker (D2000); N: Blank control; P: pcDNA3.1(+); R: pcDNA3.1(+)/RIZ1; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

**Figure 8** Western blot image for RIZ1 protein expression with  $\beta$ -actin as the control. The density of the RIZ1 band in the pcDNA3.1(+)/RIZ1 group is higher than in the other groups, indicating increased expression. R: pcDNA3.1(+)/RIZ1; N: Blank control; P: pcDNA3.1(+).

many of these genes are involved in cell development, lymphocyte costimulatory, immune system development, and interestingly, in the supervision of viral replication. This is consistent with the results from Dąbrowski *et al.*<sup>[13]</sup> who reported that low-risk type human papilloma virus may be one of the auxiliary activated or carcinogenic factors in ESCC occurrence and development. Vaiphei *et al.*<sup>[26]</sup> also found that the infection rates of human papilloma virus in ESCC patients was as high as 87%, especially in patients with two or more types of phenotypic mixed infection. Persson *et al.*<sup>[27]</sup> reported that HIV infection increases the risk of esophageal cancer. All these reports indicate that the occurrence and development of esophageal cancer may be related to virus infection; however, the pathophysiological mechanisms are poorly understood and require further research.

In conclusion, we propose that the occurrence of esophageal cancer is a consequence of widespread alterations in gene expression, involving multiple functions and signaling pathways with roles in tumor development, some of which are synergistic or antagonistic. We also speculate that the most probable signaling pathways in ESCC affected by these genes are the cytokine receptor interaction and transforming growth factor pathways.

Therefore, we recommend that future research should be directed towards better understanding of the relationship between the *RIZ1* gene and ESCC and the mechanism and role of virus infection in ESCC occurrence and development.

## COMMENTS

### Background

Esophageal cancer is one of the most common forms of cancer in the world and is a leading cause of cancer deaths in many developing countries. China is a country with a high incidence of esophageal cancer, and the pathological type is mainly the squamous cell carcinoma, which is different from the Western countries where adenocarcinoma is reported to be the main pathological type. To date, the mechanisms of esophageal cancer are unclear. Tumor occurrence and development are regulated by a variety of oncogenes and tumor suppressor genes, including the putative tumor suppressor gene, retinoblastoma protein-interacting zinc finger gene 1 (*RIZ1*).

### Research frontiers

*RIZ1* expression is lower in esophagus carcinoma and is related to methylation of CpG islands. In addition, by constructing human *RIZ1* eukaryotic expression vectors to transfect human esophageal squamous cell carcinoma (ESCC) cell line TE13, the authors were able to report that upregulation of *RIZ1* can recover tumor suppression activity and that treatment of cell line TE13 by methyltransferase inhibitor 5-aza-CdR reverses the methylation status of the promoter region.

### Innovations and breakthroughs

In order to investigate *RIZ1*-mediated changes in gene expression of esophageal cancer, the authors compared the gene expression profile of TE13 cells transfected with *RIZ1* with that of negative control cells. The resulting changes in oncogenicity were analyzed *in vitro* and by animal experimentation. They found that the development and progression of esophageal cancer are related with the inactivation of *RIZ1*. In addition, virus infection may also be an important factor.

### Applications

*RIZ1* is one of the most effective tumor suppression genes, therefore failure of *RIZ1* expression can lead to the development of ESCC, which is expected to be a molecular biological parameter for early diagnosis.

### Peer review

This paper reports that the development and progression of esophageal cancer is relevant to the inactivation of *RIZ1*. In addition, virus infection may also be an important factor.

### Abstract

**AIM:** To investigate cytokeratin 8 (*CK8*) overexpression during hepatitis C virus (HCV) infection and its pathogenesis, and the effect of ectopic *CK8* expression on hepatoma cell lines.

**METHODS:** We successfully established an *in vitro* HCV cell culture system (HCVcc) to investigate the different expression profiles of *CK8* in Huh-7-HCV and Huh-7.5-HCV cells. The expression of *CK8* at the mRNA level was determined by real-time polymerase chain reaction (RT-

PCR). The expression of *CK8* at the protein level was evaluated by Western blotting. We then constructed a eukaryotic expression combination vector containing the coding sequence of human full length *CK8* gene. *CK8* cDNA was amplified by reverse transcription-PCR and inserted into pEGFP-C1 and the positive clone pEGFP-*CK8* was obtained. After confirming the sequence, the recombinant plasmid was transfected into SMMC7721 cells with lipofectamine2000 and *CK8* expression was detected using inverted fluorescence microscopy, RT-PCR and Western blotting. Besides, we identified biological function of *CK8* on SMMC7721 cells, including cell proliferation, cell cycle and apoptosis detection.

**RESULTS:** RT-PCR showed that the expression level of *CK8* in Huh-7-HCV and Huh-7.5-HCV cells was 2.88 and 2.95 times higher than in control cells. Western blot showed that *CK8* expression in Huh-7-HCV and Huh-7.5-HCV cells was 2.53 and 3.26 times higher than that in control cells, respectively. We found that *CK8* at mRNA and protein levels were both significantly increased in HCVcc. *CK8* was up-regulated in SMMC7721 cells. *CK8* expression at the mRNA level was significantly upregulated in SMMC7721/pEGFP-*CK8* cells. *CK8* expression in SMMC7721/pEGFP-*CK8* cells was 2.69 times higher than in SMMC7721 cells, and was 2.64 times higher than in SMMC7721/pEGFP-C1 cells. *CK8* expression at the protein level in SMMC7721/pEGFP-*CK8* cells was 2.46 times higher than in SMMC7721 cells, and was 2.29 times higher than in SMMC7721/pEGFP-C1 cells. Further analysis demonstrated that forced expression of *CK8* slowed cell growth and induced apoptosis of SMMC7721 cells.

**CONCLUSION:** *CK8* up-regulation might have a functional role in HCV infection and pathogenesis, and could be a promising target for the treatment of HCV infection.

**Key words:** Hepatitis C virus cell culture system; Cytoker-

atin 8; Up-regulation; Eukaryotic expression; Apoptosis

**Core tip:** In this study, we observed that cytokeratin 8 (CK8) levels are elevated in hepatitis C virus (HCV) cell culture system and its ectopic expression decreased the proliferation and induced apoptosis of SMMC7721 cells. CK8 up-regulation might have a functional role in HCV infection and pathogenesis, and could be a promising target for the treatment of HCV infection.

Sun MZ, Dang SS, Wang WJ, Jia XL, Zhai S, Zhang X, Li M, Li YP, Xun M. Cytokeratin 8 is increased in hepatitis C virus cells and its ectopic expression induces apoptosis of SMMC7721 cells. *World J Gastroenterol* 2013; 19(37): 6178-6187 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i37/6178.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i37.6178>

## INTRODUCTION

Hepatitis C virus (HCV) infection is a significant global healthcare burden<sup>[1]</sup>. Current estimation suggests that a minimum of 3% of the world's population is chronically infected, with a prevalence of up to 170 million people<sup>[2,3]</sup>. However, the mechanism of HCV infection is not fully understood. Recently, the development of HCV replicon technology has accelerated the understanding of the mechanism underlying HCV infection<sup>[4,5]</sup>. It has been reported that there were more than 100 abnormal expression proteins in HCV infected cells and hepatitis C patients<sup>[6-10]</sup>. Studies determining the changes in protein expression associated with HCV infection will help elucidate host/virus interactions, and provide further insight to HCV pathogenesis.

Cytokeratin 8 (CK8) is the major component of the intermediate filament cytoskeleton, belonging to the type-II keratin, and is primarily expressed in the epithelia of liver, intestine, and exocrine pancreas<sup>[11,12]</sup>. CK8 plays a crucial role in maintaining the structural integrity and the mechanical properties of cells<sup>[13]</sup>. Recent studies have suggested that CK8 is involved in several liver diseases. CK8 knock-out mice develop liver hemorrhage and are more susceptible to liver injury<sup>[14,15]</sup>. Some variants of CK8 are associated with disease severity and progression in patients with chronic liver diseases<sup>[16,17]</sup>. Thus, we hypothesized that CK8 contributed to cellular pathological processes and the infection and pathogenesis of HCV, leading to liver injury and chronic liver diseases.

In this study, we established an *in vitro* HCV cell culture system (HCVcc) and investigated whether HCV affects CK8 levels. Simultaneously, we established eukaryotic expression recombination vector containing the full length coding sequence of CK8, then transfected into hepatoma cells *in vitro* and investigated the biological and functional role of CK8 in hepatoma cells.

## MATERIALS AND METHODS

### Construction and identification of HCVcc

Huh-7 and Huh-7.5 cells were maintained in Dulbecco's modified Eagle's medium (DMEM) containing 10% heat-inactivated fetal bovine serum, 0.1 mmol/L nonessential amino acids and 1 × penicillin-streptomycin-glutamine. Plasmid pFL-J6/JFH, containing a chimeric full length HCV genome, was kindly provided by Professor Charles M Rice from Rockefeller University. Plasmid pFL-J6/JFH, containing a single Xba I restriction site and T7 RNA polymerase start site, is the chimera of HCV J6 strain (5'-NCR-NS2) and JFH strain (NS3-3'-NCR). Subsequently, plasmid pFL-J6/JFH encoding the full length HCV chimeric genome was transcribed to HCV RNA *in vitro*. HCVcc was established by electroporation of HCV RNA into Huh-7 and Huh-7.5 cells.

Huh7 and Huh-7.5 were used as negative controls of HCVcc. Huh-7-HCV and Huh-7.5-HCV cells were maintained under the same condition as Huh-7 and Huh-7.5 cells. Cells were cultured in an incubator at 37 °C supplemented with 5% CO<sub>2</sub>. During the cell culture, the supernatant of cell culture was collected at 24, 72 and 96 h after electroporation in order to determine the HCV copies. Quantitative real-time polymerase chain reaction (qRT-PCR) was used to determine HCV copy number. At approximately 72 h after transfection, cells were washed three times with 1 × phosphate-buffered saline (PBS) and then harvested. In addition, indirect immunofluorescence was used to observe the expression of HCV core protein. Mouse monoclonal HCV core protein antibody (Novus Biologicals, United States) was used as the primary antibody, and goat anti-mouse conjugated with Fluorescein Isothiocyanate (FITC) was used as the secondary antibody. The harvested cells were fixed with 3% glutaraldehyde at 4 °C for 24 h, then washed twice by 0.1 mol/L arsenic acid dimethyl sodium buffer (pH 7.4) at 4 °C, fixed by 1% osmium tetroxide for 1 h, gradient acetone dehydration, embedded by Epon812, sliced by ultra-thin LKB-V slicer. H-7650 transmission electron microscope (HITACHI, Japan) was also used to observe the morphology of the viral particles and intracellular ultrastructure changes.

### Total RNA isolation, cDNA synthesis and RT-PCR

Total RNA was extracted from cells by TRIzol reagent (Invitrogen, United States) according to the manufacturer's protocol. A two-step reverse transcription PCR was performed. The first-strand cDNA was synthesized from 1 µg of total RNA with AMV Reverse Transcriptase<sup>b</sup> (TAKARA, Japan). To investigate the expression of CK8 at the mRNA level, the expression of CK8 and glyceraldehydes-3-phosphate dehydrogenase (GAPDH) genes was quantified by RT-PCR, and GAPDH was used as an internal control. A total of 20 ng cDNA was used as template in the reaction. All RT-PCR assays were performed

**Table 1 Primers used for real-time polymerase chain reaction and high fidelity**

Name	Forward primer (5'-3')	Reverse primer (5'-3')
CK8 (172 bp)	AGCTGGAGICTCGCTGGAA	TGTGCCTTGACCTCAGCAATG
GAPDH (138 bp)	GCACCGTCAAGGCTGAGAAC	TGGTGAAGACGCCAGTGGA
CK8 (1465 bp)	ATGTCGACATGTCCATCAGGGTGAC	TAGGATCCCTTGGCAGGACGTC

CK8: Cytokeratin 8; PCR: Polymerase chain reaction; GAPDH: Glyceraldehydes-3-phosphate dehydrogenase.

in triplicate using SYBR green incorporation method with Bio-Rad IQ5 Multicolor RT-PCR Detection System (Bio-Rad, United States) based on the manufacturer's protocol. Table 1 shows the sequences of the primer sets for CK8 and GAPDH. Briefly, following a denaturation at 95 °C for 5 s, RT-PCR was carried out with 50 cycles at a melting temperature of 95 °C for 30 s, an annealing temperature of 65 °C for 30 s, and an extension temperature of 72 °C for 10 s. Data analysis was performed using the Sequence Detector System software. The relative quantification was calculated by the  $2^{-\Delta\Delta Ct}$  method with GAPDH as the housekeeping gene and the control cells as the baseline, and the results were expressed as fold-change.

#### Protein extraction, SDS-PAGE and Western blotting

Total proteins were prepared by RIPA cell lysate. Proteins of interest were separated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) with a 10% polyacrylamide gel, and 1 mg/mL protein was loaded onto a SDS-PAGE gel. Proteins were transferred to nitrocellulose membranes and then detected by Western blotting under the recommended conditions. Mouse anti-human CK8 IgG (Abcam, United States) was used as the primary antibody, goat anti-mouse IgG conjugated with horseradish peroxidase (HRP) was used as the secondary antibody, and GAPDH was used as the control. The antigen-antibody complex was detected by an enhanced chemiluminescence (ECL) kit following the manufacturer's protocol. The experiments were repeated in triplicate. The chemiluminescent signal of each band was analyzed by gel image analysis system (Syngene, United States).

#### Construction of pEGFP-CK8 recombination vector

The *Bam*H I and *Sal* I restriction sites were introduced into the CK8 coding sequence (CDS) by high fidelity PCR (Thermo, United States). Sequences for the primers are listed in Table 1, with the amplified product being 1465 bp. The CK8 CDS was purified by gel extraction. CK8 CDS and pEGFP-C1 vector (TAKARA, Japan) were digested respectively by the restriction enzyme *Sal* I and *Bam*H I (TAKARA, Japan). The digestion products were examined on 1% agarose gel by electrophoresis. The ligation reaction (Ligation Kit, TAKARA, Japan) was carried out between both of the DNA fragments, followed by transformation into competent *Escherichia coli* DH5 $\alpha$  cells at 37 °C overnight (12-16 h). Colony selection was performed by PCR, and the amplicons were examined on 1% agarose gel by electrophoresis. Plasmid extraction (E.Z.N.A.<sup>®</sup> Endo-Free Plasmid Midi Kit, Omega, United

States) was carried out for positive colonies, and then sequenced and matched by Blast method.

#### Transfection of pEGFP-CK8 vector into SMMC 7721 cells

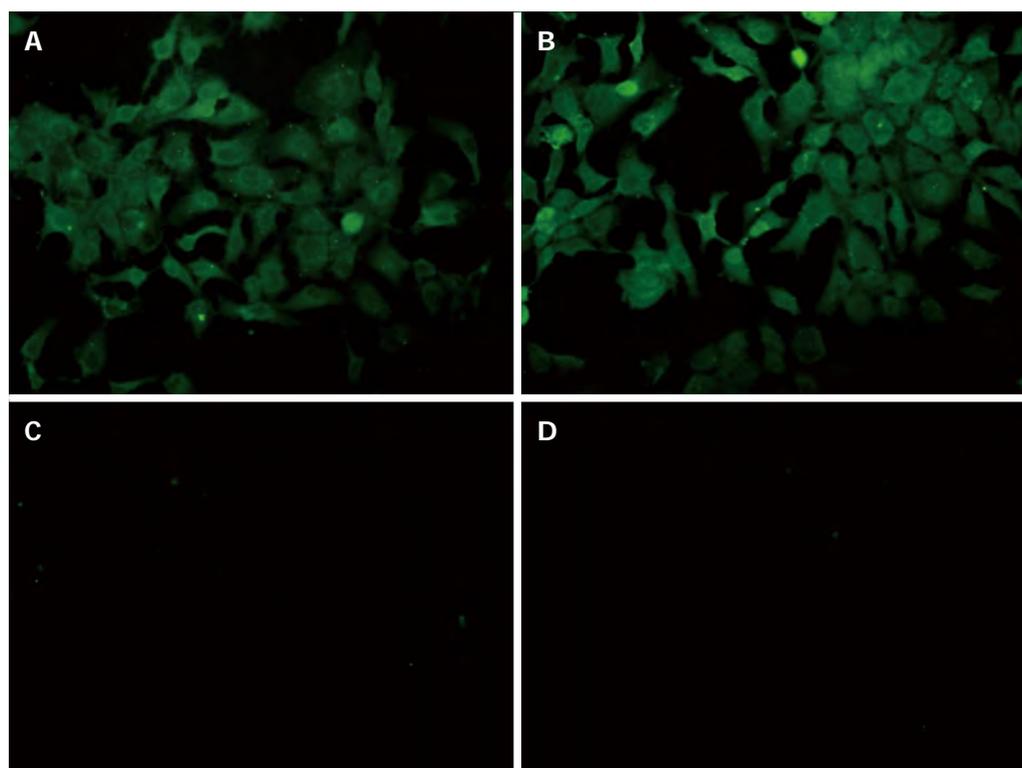

SMMC7721 cells were seeded in 6-well plates in 4 mL of growth medium for 24 h prior to transfection. In each well,  $0.8 \times 10^5$ - $4.0 \times 10^5$  adherent cells were seeded. Four microgram (4.0  $\mu$ g) of DNA (pEGFP-CK8 vector or pEGFP-C1 vector) was diluted in 250  $\mu$ L of serum-free DMEM. Lipofectamine2000 (Millipore, United States) was added (10  $\mu$ L) to the diluted DNA and mixed immediately by pipetting. The mixture was incubated for 25 min at room temperature. The lipofectamine2000/DNA mixture (500  $\mu$ L) was added dropwise to the four wells containing the pEGFP-CK8 plasmid, and another two wells to control cells containing the pEGFP-C1 plasmid. The plate was then gently rocked to achieve even distribution of the complexes and incubated at 37 °C in a 5% CO<sub>2</sub> incubator.

#### Detection assay

The expression and distribution of CK8 was observed under an inverted fluorescence microscope (Nikon eclipse Ti, Japan) 24 h after transfection. Forty-eight hours after transfection, cellular RNA and total cellular proteins were determined by RT-PCR and Western blotting, respectively. Total RNA was extracted from SMMC7721, SMMC7721/ pEGFP-C1, and SMMC7721/pEGFP-CK8 cells by TRIzol reagent. Total proteins were prepared by RIPA cell lysate. Real time PCR assays (SYBR<sup>®</sup> Premix Ex Taq<sup>™</sup> II, TAKARA, Japan) were performed in triplicate with Bio-Rad iQ5 Multicolor RT-PCR Detection System according to the manufacturer's protocol. Rabbit anti-human IgG (Santa, United States) was used as the primary antibody, goat anti-rabbit IgG conjugated with HRP was used as the secondary antibody and  $\beta$ -actin (Abcam, United States) was used as control. Cells were collected after 24, 48 and 72 h transfection to perform a proliferation assay by MTT reaction (MTT cell proliferation Assay kit, Trevigen, United States). Cells were also collected 48 h after transfection to detect apoptosis (Annexin V-FITC Apoptosis Detection Kit, Abcam, United States) using Flow Cytometry (guava easyCyte HT, Millipore, United States).

#### Statistical analysis

All experiments were performed in triplicate. Representative graphical data are presented as mean  $\pm$  SD. Statistical analyses were performed using the SPSS 10.0 software

**Figure 1** Indirect immunofluorescence detection of hepatitis C virus core proteins (400 ×). A: Huh-7-HCV cells appeared bright green fluorescent, they are HCV core proteins which were labeled with GFP; B: Huh-7.5-HCV cells appeared bright green fluorescent, they are HCV core proteins which were labeled with GFP; C and D: In Huh-7 and Huh-7.5 control cells, there were no green fluorescent, HCV core proteins were not expressed in them.

**Table 2** Detection of hepatitis C virus at RNA level in transfected cellular supernatant

24 h	$5.73 \times 10^5$	$9.48 \times 10^5$
48 h	$1.38 \times 10^6$	$6.40 \times 10^6$
72 h	$3.00 \times 10^4$	$9.29 \times 10^4$
96 h	$6.62 \times 10^5$	$1.43 \times 10^4$

HCV: Hepatitis C virus.

package (SPSS Inc.). We used Student's *t* test. *P* values below 0.05 were considered to be significant.

## RESULTS

### Detection of HCV RNA copies, HCV core protein, and HCV particles

We determined HCV RNA copy number by performing qRT-PCR of viral supernatants obtained from HCV-transfected cells. High-level viral copies in the supernatant of transfected cells were observed at different time-points and reached its peak value at 48 h after transfection (Table 2). Indirect immunofluorescence also showed high expression of HCV core protein in the HCV-transfected cells. Huh-7-HCV and Huh-7.5 HCV cells were also labeled with GFP, further indicating that HCV core protein has been expressed in these cells compared to control cells (Figure 1). Transmission electron microscopy (TEM)

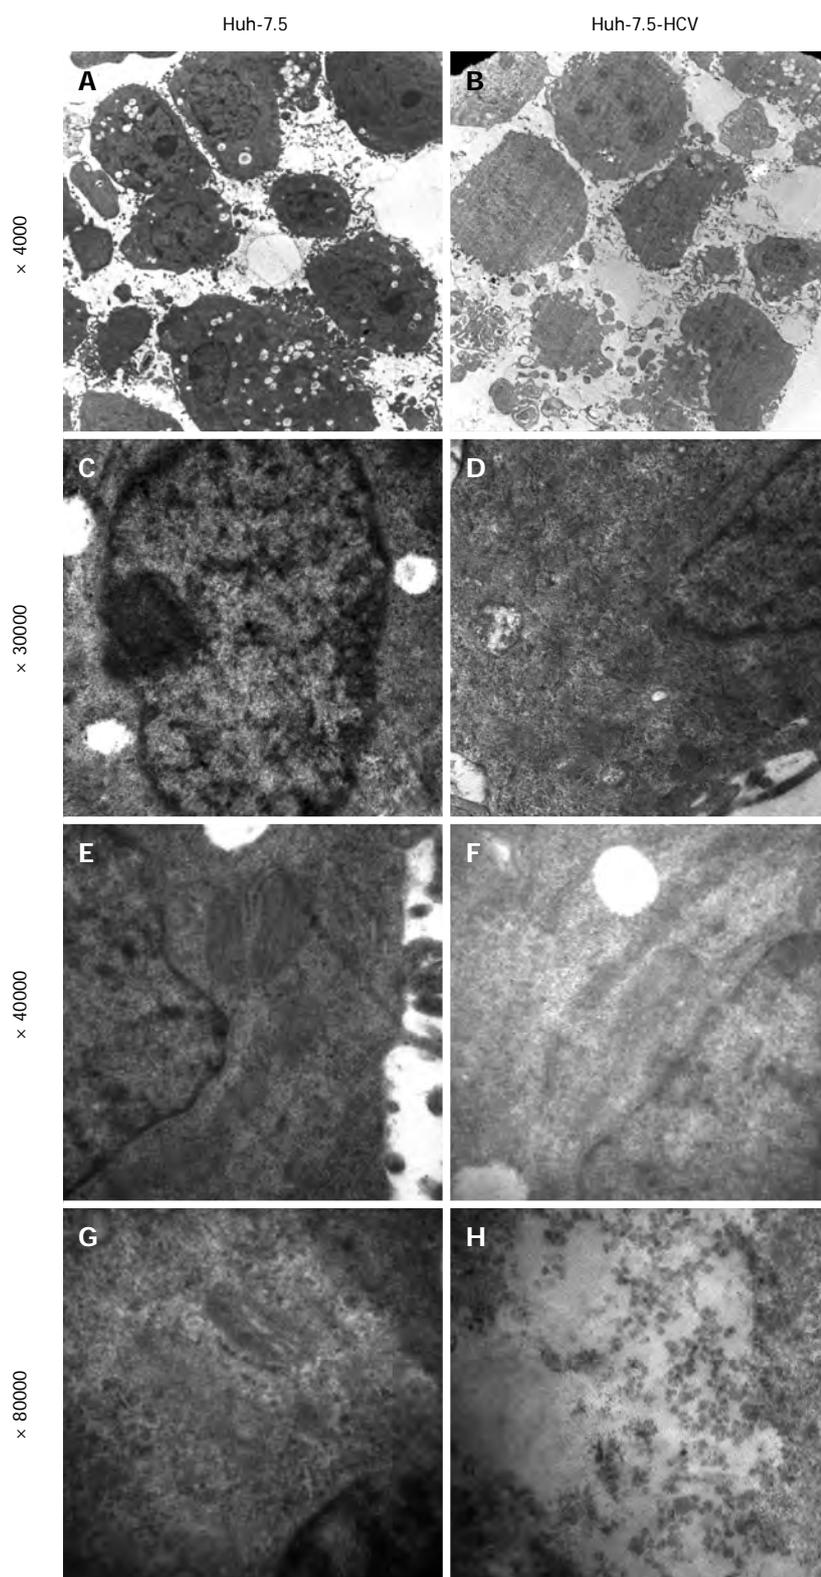

revealed a large number of enveloped or unenveloped virus-like particles (VLPs) in HCVcc. Some characteristic structures of *Flaviviridae* virus infection were observed, including an increased number of endoplasmic reticulum, mitochondrial swelling, cristae disappearance, and cytoplasmic vacuolar structures. Also, a large number of HCV nucleocapsid-like particles of inclusion body were presented in HCVcc cells (Figure 2). Viral-like particles were not seen in the control cells. Moreover, hyperplasia, vacuolar membrane structure, and formation of inclusion bodies were not observed in the control cells.

### Increased CK8 levels in HCVcc cells by RT-PCR

Extracted total cellular RNA was examined by electrophoresis on a 0.8% non-denaturing agarose gel. A 172 bp fragment of *CK8* was successfully amplified by PCR without unspecific amplification. The melting and amplification curves of *CK8* expression indicated that the primers were properly designed. *CK8* expression in Huh-7-HCV cells was 2.88 times higher than that in Huh-7 cells, and *CK8* expression in Huh-7.5-HCV cells was 2.95 times higher than that in Huh-7.5 cells (Figure 3). Therefore, *CK8* was significantly highly expressed in HCVcc cells.

### Increased CK8 levels determined by Western blotting of HCVcc cells

By Western blotting, we showed that the ratio of *CK8*/GAPDH was  $0.079 \pm 0.004$  and  $0.031 \pm 0.003$  in Huh-7-HCV cells and Huh-7 cells, respectively, which was 2.53

**Figure 2** Transmission electron microscopy of hepatitis C virus-transfected Huh7.5 cells ( $\times 4000$ ,  $\times 30000$ ,  $\times 40000$ ,  $\times 80000$ ). A, C, E, G: Control human hepatoma cells, no virus-like particles, mitochondrial and endoplasmic reticulum are normal; B, D, F, H: HCV-transfected human hepatoma cells, human hepatoma cells have large deformed nuclei, and cultured cells prone to exist large vacuoles; D shows mitochondrial swelling and cristae disappearance; F shows the rough endoplasmic reticulum increased; H shows spherical structures of electron density, diameter is between 30-50 nm.

times higher. Furthermore, the ratio of *CK8*/*GAPDH* was  $0.105 \pm 0.004$  in Huh-7.5-HCV cells, which was significantly higher than in Huh-7.5 cells ( $0.032 \pm 0.002$ )

and expression was 3.26 times higher (Figure 4). Therefore, we confirmed that HCVcc cells do have increased *CK8* expression.

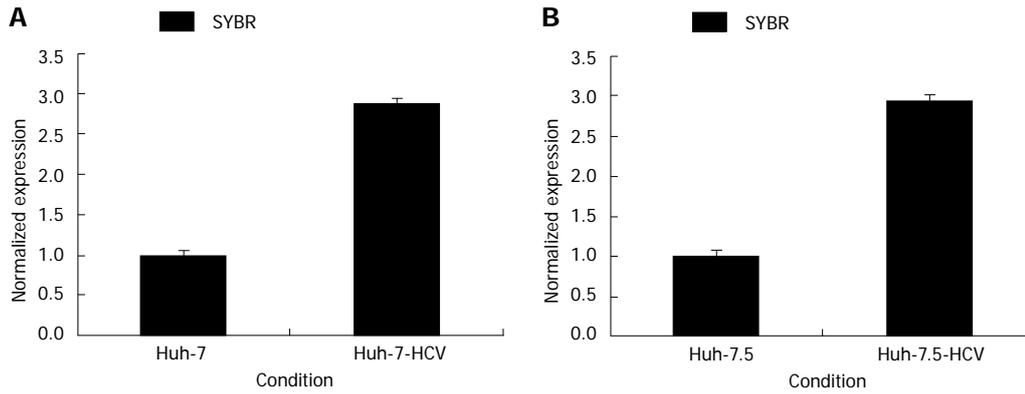

Figure 3 Relative cyokeratin 8 mRNA expression in Huh-7 and Huh-7- hepatitis C virus cells (A), or Huh-7.5 and Huh-7.5- hepatitis C virus cells (B).

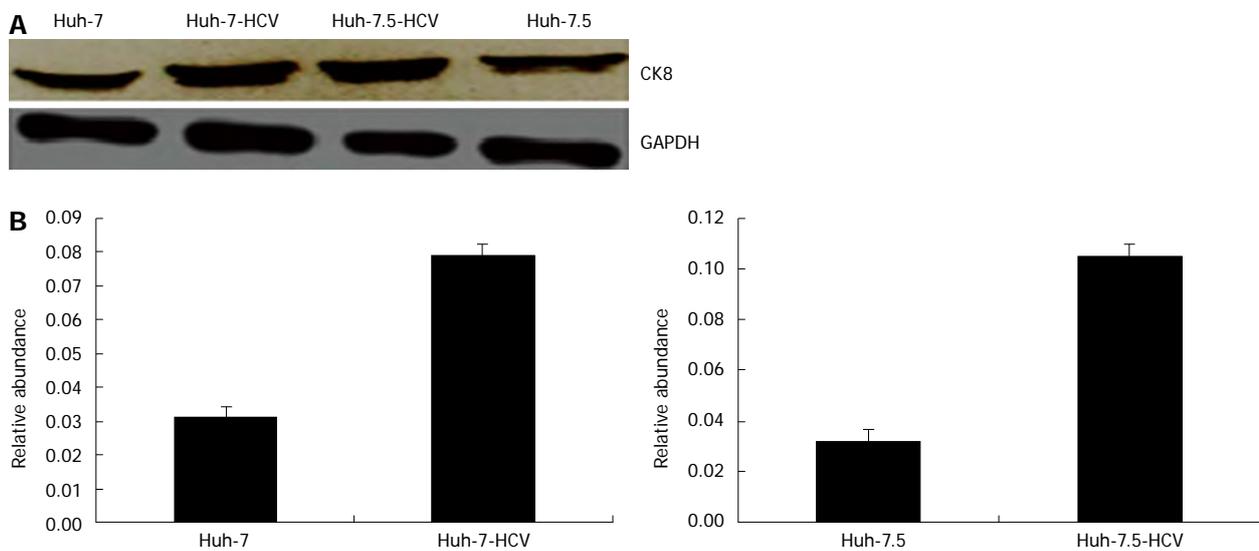

Figure 4 Cyokeratin 8 expression determined at the protein level by Western blotting in Huh-7 and Huh-7-hepatitis C virus cells (A), or Huh-7.5 and Huh-7.5-hepatitis C virus cells (B). HCV: Hepatitis C virus; CK8: Cyokeratin 8; GAPDH: Glyceraldehydes-3-phosphate dehydrogenase.

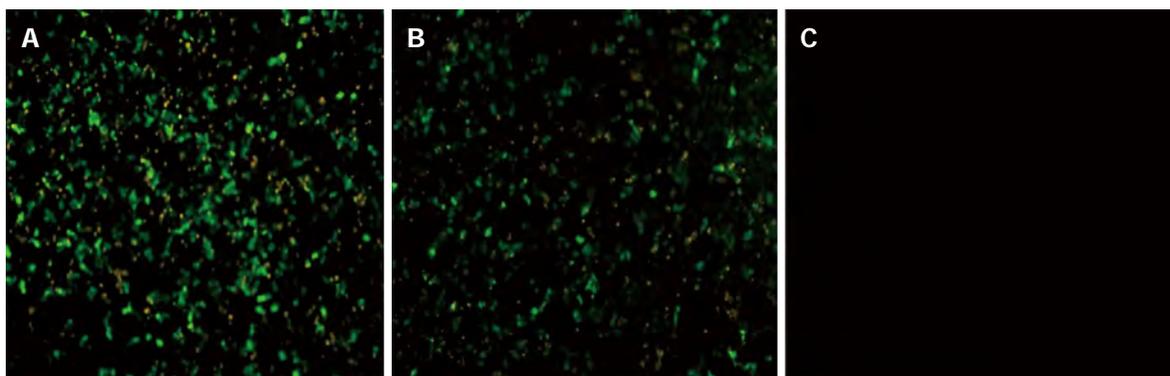

Figure 5 Inverted fluorescence microscopic observation 24 h after cyokeratin 8 transfection ( $\times 200$ ). A: SMMC7721 cells transfected by pEGFP-CK8 recombination vector; B: SMMC7721 cells transfected by pEGFP-C1 vector; C: SMMC7721 cells without transfection. CK8: Cyokeratin 8.

**Inverted fluorescence microscopic observation**

We next ectopically expressed CK8 in SMMC7721 cells. We confirmed the overexpression of CK8 in cells under inverted fluorescence microscope 24 h after transfection. Since the CK8 expression vector contains an EGFP marker, we observed that SMMC7721/pEGFP-C1 and SMMC7721/pEGFP-CK8 cells appeared bright

green compared to control SMMC7721 cells (Figure 5). This data indicated that ectopic expression of CK8 was achieved in SMMC7721 cells.

**CK8 mRNA expression by qRT-PCR**

The  $2^{-\Delta\Delta Ct}$  value of CK8 mRNA levels in SMMC7721, SMMC7721/pEGFP-C1, and SMMC7721/pEGFP-CK8

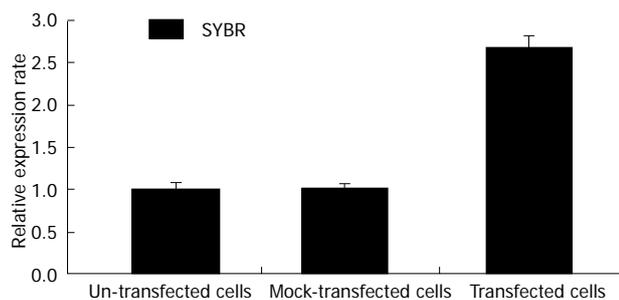

Figure 6 Cytokeratin 8 relative expression at the mRNA level.

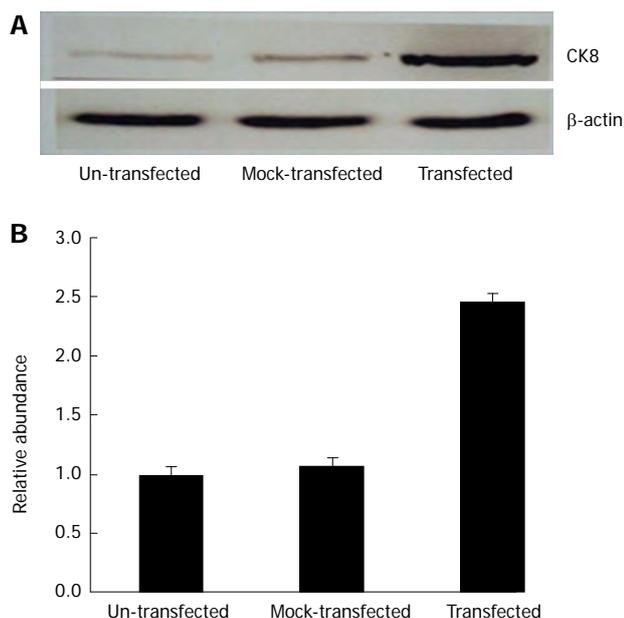

Figure 7 Cytokeratin 8 expression at the protein level 48h after transfection. CK8: Cytokeratin 8.

cells are shown in Figure 6. Beta-actin was used as the housekeeping gene, while SMMC7721 cells were used for baseline detection. The results were expressed as fold-change. *CK8* expression at the mRNA level was significantly upregulated in SMMC7721/pEGFP-*CK8* cells. *CK8* expression in SMMC7721/pEGFP-*CK8* cells was 2.69 times higher than in SMMC7721 cells, and was 2.64 times higher than in SMMC7721/pEGFP-C1 cells.

#### Ectopic expression of *CK8* determined by Western blot analysis

Using Western blotting, we compared the chemiluminescent signals of *CK8* and  $\beta$ -actin in SMMC7721, SMMC7721/pEGFP-C1, and SMMC7721/pEGFP-*CK8* cells. The ratio between *CK8* and  $\beta$ -actin were reflective changes in *CK8* expression. *CK8* expression in SMMC7721/pEGFP-*CK8* cells was 2.46 times higher than in SMMC7721 cells, and 2.29 times higher than in SMMC7721/pEGFP-C1 cells. This demonstrated that ectopic expression of *CK8* was observed at the protein level in SMMC7721/pEGFP-*CK8* cells (Figure 7). Therefore, we confirmed that *CK8* expression was increased

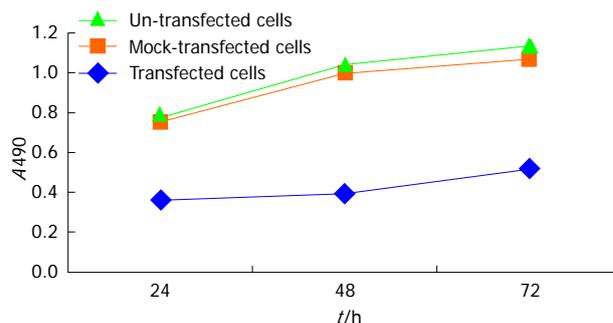

Figure 8 Growth chart after transfection in three groups of cells.

in SMMC7721 cells after transfection with pEGFP-*CK8* vector.

#### Effects of ectopic *CK8* overexpression on cell proliferation

Using MTT detection, we determined the effects of ectopic *CK8* expression on SMMC7721 cells 72 h after transfection. *CK8* overexpression decreased the growth and proliferation of SMMC7721 cells compared to control cells and mock-transfected cells (Figure 8). This data indicated that ectopic *CK8* expression decreased cell growth and proliferation of SMMC7721 cells.

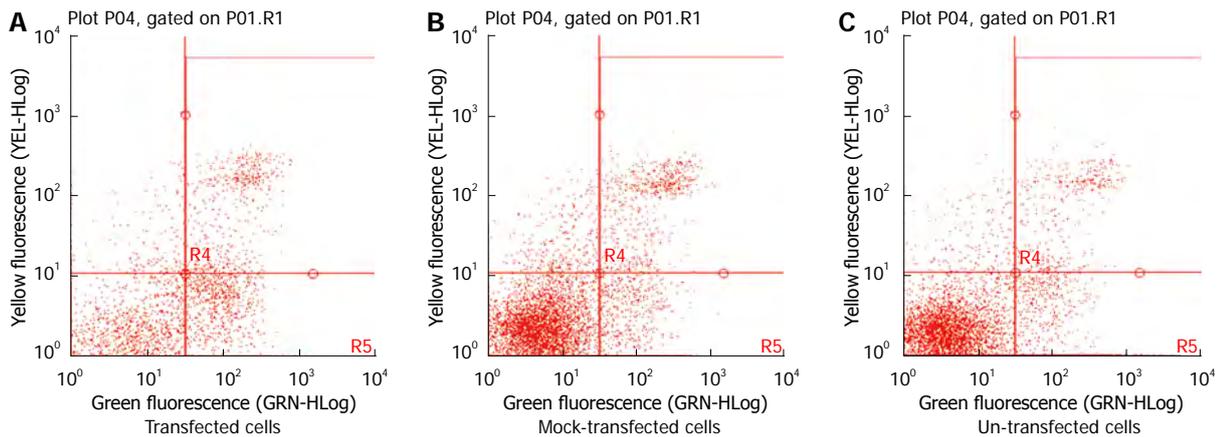

#### Effects of ectopic *CK8* expression on the apoptosis of SMMC7721 cells

We determined the effects of ectopic *CK8* expression on the apoptosis of SMMC7721 cells 48 h after transfection. Using flow cytometry, ectopic *CK8* expression increased the apoptotic rate of SMMC7721 cells, compared to untransfected and mock-transfected cells (Figure 9).

## DISCUSSION

In this study, we established a full-length HCV genomic replication in Huh-7 and Huh-7.5 cells. Lohmann *et al.*<sup>[18]</sup> reported that subgenomic HCV RNA replicons are capable of autonomously replicating in Huh7 cells. These dicistronic replicons include the neomycin-resistant gene, making them selectable by G418, and most or all of the viral nonstructural genes<sup>[19,20]</sup>. This system provides a novel and powerful tool for the study of HCV replication mechanisms and for study of the interaction between host and viral factors involved in viral progression<sup>[21,22]</sup>. In our study, we transfected Huh-7 and Huh-7.5 cells to express HCV RNA and generated the HCVcc cell line. We used qRT-PCR, immunofluorescence, and TEM to detect HCV RNA, HCV core protein, and HCV particles, respectively. The results confirmed that HCV expression in Huh-7 and Huh-7.5 cells led to the production of HCV particles.

*CK8* is a cytoskeletal intermediate filament protein that abundantly expresses in hepatocytes to maintain cell integrity, and prevent mechanical and non-mechanical cell injury<sup>[23,24]</sup>. Previous studies showed that *CK8* was upregulated in HBV-infected liver tissues from p21-HBx mice<sup>[25]</sup>,

**Figure 9 Cell flow cytometry.** A: SMMC7721/pEGFP-cytokeratin 8 cells; B: SMMC7721/pEGFP-C1 cells; C: SMMC7721 cells without transfection. Cells were collected and washed twice with PBS, suspended in 200  $\mu$ L binding buffer and 10  $\mu$ L annexin V-FITC for 20 min in the dark, and thereafter, 300  $\mu$ L binding buffer and 5  $\mu$ L propidium iodide (PI) were added to each sample. The apoptotic cells were determined using a flow cytometer by staining with Annexin V-FITC. Representative dot plots show annexin V-FITC staining in cells. Results are representative of 3 independent experiments. FITC: Fluorescein isothiocyanate; PBS: Phosphate-buffered saline.

and that its upregulation contributed to the development and progression of HCC-induced HBV. Tai DI found that *CK8* was focally positive in a patient with a malignant liver patient infected with HCV<sup>[26]</sup>. Toivola *et al*<sup>[17]</sup> found that in chronic HCV infection, *CK8* phosphorylation is a progression marker during HCV progression and regression. Furthermore, Strnad *et al*<sup>[27]</sup> found that a number of *CK8* gene variants are increased in patients with chronic HCV infection. However, it is unclear about the relation between *CK8* expression and HCVcc cells. We observed a concomitant increase in *CK8* levels, which was confirmed by RT-PCR and Western blot analysis. *CK8* mRNA expression in Huh-7-HCV and Huh-7.5-HCV cells was 2.88 and 2.95 times higher than in Huh-7 and Huh-7.5 cells, respectively. At the protein level, *CK8* expression was 2.53 and 3.26 times higher in Huh-7-HCV and Huh-7.5-HCV cells, respectively, than Huh-7 and Huh-7.5 cells. This suggests that HCV up-regulates *CK8* expression in HCVcc cells, and that *CK8* expression is significantly associated with HCV.

*CK8* plays a role in maintaining cellular structural integrity, signal transduction, and cellular differentiation<sup>[28-32]</sup>. Snider NT demonstrated that acetylation of *CK8* was up-regulated in diabetic human livers<sup>[33]</sup>. We showed that HCV up-regulates *CK8* expression in HCVcc cells. However, the biological function of ectopic *CK8* in tumor cells is not fully elucidated. To further investigate the biological function of aberrant *CK8* expression, we cloned the full length CDS of *CK8* to establish the eukaryotic expression recombination vector pEGFP-*CK8*. To study the biological function of increased *CK8* on cells independently, we chose another cell line called SMMC7721 cells in our laboratory. SMMC7721 cells were transfected by pEGFP-*CK8* recombination vector, and under an inverted fluorescence microscope we observed the expression and distribution of GFP-tagged *CK8*. In addition, by RT-PCR and Western blot analysis, we found that *CK8* mRNA levels in SMMC7721/pEGFP-*CK8* cells was 2.69 and 2.64 times higher than in SMMC7721

cells and SMMC7721/pEGFP-C1 cells, respectively. At the protein level, *CK8* expression in SMMC7721/pEGFP-*CK8* cells was 2.46 and 2.29 times higher than in SMMC7721 and SMMC7721/pEGFP-C1 cells, respectively. These observations showed that *CK8* gene was transcribed and expressed in SMMC7721 cells.

*CK8* abnormal expression and mutations can lead to acute or sub-acute liver injury and promote tumor cells apoptosis<sup>[34,35]</sup>. The persistent expression of *CK8* can induce tumor cell apoptosis through a number of transcription factors that regulate a large number of oncogenes<sup>[36]</sup>. In SMMC7721 transfected by pEGFP-*CK8*, we further observed the biological effects of increased *CK8* on cells. We detected proliferation and apoptosis by MTT reaction and flow cytometry, respectively. We found that ectopic *CK8* expression decreased cell growth and proliferation, and increased apoptosis of SMMC7721 cells. Therefore, we concluded that the abnormal expression of *CK8* regulates cellular pathological injury. However, it is unclear what the mechanisms are by which *CK8* affects cell cycle and apoptosis. In conclusion, these results suggest *CK8* up-regulation might have a functional role during HCV infection and pathogenesis, and it could be a promising target for the treatment of HCV infection.

In summary, we successfully established and identified HCVcc and observed that *CK8* is upregulated in HCVcc. Overexpression of *CK8* in SMMC7721 cells inhibited cell proliferation and induced apoptosis. *CK8* could be a potential target for the treatment of HCV infection. Future studies will (1) identify the interactions of *CK8* with other proteins to mediate its effects; (2) assess how *CK8* expression regulates a number of known oncogenes in HCV; and (3) determine how *CK8* promotes apoptosis.

## COMMENTS

### Background

Currently, several proteins have been identified to be overexpressed during hepatitis C virus (HCV) infection and pathogenesis. Studies have suggested

that cytokeratin 8 (*CK8*) is closely related to a number of liver diseases. *CK8* knock-out mice develop liver hemorrhage and are more susceptible to liver injury. However, it remains unknown whether HCV affects *CK8* levels in their established *in vitro* HCV cell culture system (HCVcc) and the biological and functional role of *CK8* in hepatoma cells.

### Research frontiers

It has been reported that there are more than 100 abnormal proteins expressed in HCV-infected cells and hepatitis C patients. Studies determining the changes in protein expression associated with HCV infection will help to elucidate host/virus interactions, and provide further insight to HCV pathogenesis. *CK8* plays a crucial role in maintaining the structural integrity and the mechanical properties of cells. Recent studies have suggested that *CK8* is involved in several liver diseases. Much interest is shown to understand *CK8* overexpression during HCV infection and to investigate the role of ectopic *CK8* expression in hepatoma cell lines.

### Innovations and breakthroughs

In this study, the authors transfected Huh-7 and Huh-7.5 cells to express HCV RNA and generated the HCVcc cell line. Previous studies showed that *CK8* is upregulated in HBV-infected liver tissues from p21-HBx mice and in a patient with a malignant liver infected with HCV. However, it is unclear what the relation between *CK8* expression and HCVcc cells is. The authors observed a concomitant increase in *CK8* levels by real-time Polymerase chain reaction and Western blot analysis. The results show that HCV up-regulates *CK8* expression in HCVcc cells. However, the biological function of ectopic *CK8* in tumor cells is not fully elucidated. The authors found that ectopic *CK8* expression decreased cell growth and proliferation, and increased apoptosis of SMMC7721 cells. Therefore, the authors concluded that the abnormal expression of *CK8* regulates cellular pathological injury.

### Applications

The results of this study suggest that *CK8* up-regulation might have a functional role during HCV infection and pathogenesis, and it could be a promising target for the treatment of HCV infection.

### Peer review

This is a very well written manuscript. In this paper, the authors show the over-expression of *CK8* in an *in vitro* HCV cell culture system. Large-scale proteome analyses of the *in vitro* HCV infection model have also been performed. Thus new hopes characterize the HCV field and new advances are reasonably expected. Here, *CK8* is found up-regulated in Huh7 and Huh7.5 cells infected with chimeric full length HCV genome. The methodology is acceptable. The conclusions are interesting.

### Abstract

**AIM:** To determine if esophageal capsule endoscopy (ECE) is an adequate diagnostic alternative to esophagogastroduodenoscopy (EGD) in pre-bariatric surgery patients.

**METHODS:** We conducted a prospective pilot study to assess the diagnostic accuracy of ECE (PillCam ESO2, Given Imaging) vs conventional EGD in pre-bariatric surgery patients. Patients who were scheduled for bariatric surgery and referred for pre-operative EGD were prospectively enrolled. All patients underwent ECE followed by standard EGD. Two experienced gastroenterologists blinded to the patient's history and the findings

of the EGD reviewed the ECE and documented their findings. The gold standard was the findings on EGD.

**RESULTS:** Ten patients with an average body mass index of 50 kg/m<sup>2</sup> were enrolled and completed the study. ECE identified 11 of 14 (79%) positive esophageal/gastroesophageal junction (GEJ) findings and 14 of 17 (82%) combined esophageal and gastric findings identified on EGD. Fisher's exact test was used to compare the findings and no significant difference was found between ECE and EGD ( $P = 0.64$  for esophageal/GEJ and  $P = 0.66$  for combined esophageal and gastric findings respectively). Of the positive esophageal/GEJ findings, ECE failed to identify the following: hiatal hernia in two patients, mild esophagitis in two patients, and mild Schatzki ring in two patients. ECE was able to identify the entire esophagus in 100%, gastric cardia in 0%, gastric body in 100%, gastric antrum in 70%, pylorus in 60%, and duodenum in 0%.

**CONCLUSION:** There were no significant differences in the likelihood of identifying a positive finding using ECE compared with EGD in preoperative evaluation of bariatric patients.

**Key words:** Capsule endoscopy; Bariatric; Moderate sedation; Esophagogastroduodenoscopy; Esophageal capsule endoscopy

**Core tip:** This is the first prospective study that shows in pre-bariatric patients, capsule endoscopy can be used to identify positive esophageal disorders when compared to a sedated esophagogastroduodenoscopy. Further studies are needed to help define the role of esophageal capsule endoscopy as a tool for pre-operative evaluation.

## INTRODUCTION

In patients with morbid obesity, surgery is a treatment option associated with good medium and long-term results with procedures such as gastric banding, sleeve gastrectomy, gastric bypass, and biliopancreatic diversion<sup>[1]</sup>. These operations can be performed laparoscopically in most obesity centers<sup>[2-4]</sup>. Preoperative esophagogastroduodenoscopy (EGD) is useful to detect pathological findings that might preclude or delay bariatric surgery<sup>[5]</sup>.

Patients referred for bariatric surgery often have comorbidities including obstructive sleep apnea, arterial hypertension, coronary heart disease or diabetes mellitus which puts them at risk for any procedure that involves conscious sedation. The risk of EGD in these patients includes aspiration, hypoxemia, hypoventilation, airway obstruction, vasovagal episodes, and arrhythmias. Esophageal capsule endoscopy (ECE) offers a less invasive diagnostic alternative in evaluating diseases of the esophagus. ECE does not require sedation and is therefore better tolerated by patients. Several studies have shown that ECE is an adequate alternative diagnostic method for esophageal variceal screening and diagnosis of Barrett's esophagus in patients with chronic gastroesophageal reflux<sup>[6-8]</sup>. Delvaux *et al*<sup>[9]</sup> concluded that capsule endoscopy showed a moderate sensitivity and specificity in detecting esophageal diseases such as esophagitis, hiatal hernias, varices and Barrett's esophagus. They determined the overall positive predictive value of capsule endoscopy was 80%. In this study we aim to determine if capsule endoscopy is adequate in identifying specific esophageal and gastric pathology for patients undergoing bariatric surgery as compared to EGD.

## MATERIALS AND METHODS

This was a prospective pilot study. Patients from 2010 to 2012 who were scheduled to undergo bariatric surgery at University of California San Diego Medical Center and referred for pre-operative EGD were prospectively enrolled to assess the diagnostic accuracy of the ECE (PillCam ESO2, Given Imaging) *vs* conventional EGD. A total of ten patients were enrolled in the study. Patients were enrolled after Human Subjects Research Protection Committee approved consent was obtained. All patients underwent ECE followed by standard EGD performed under moderate sedation with fentanyl and versed. All patients underwent ECE followed by standard EGD performed by a single endoscopist that was video recorded.

Demographic data was collected on each patient including age, sex, weight in kilograms (kg), and body mass index (BMI) per patient's medical chart. Co-morbidities on each patient were documented including obstructive sleep apnea, coronary artery disease hypertension, type II diabetes mellitus, chronic kidney disease, and non-alcoholic fatty liver disease (NAFLD). Two experienced gastroenterologists reviewed the ECE and EGD videos and documented their findings. Both gastroenterologists were blinded to patients' history. Findings on ECE were then compared with the findings on EGD. Findings were categorical variables where 0 represented a normal finding and 1 represented an abnormal finding. Abnormal findings included esophagitis, Schatzki ring, and hiatal hernia. Fisher's exact test was used to compare the findings between the two modalities with the findings on the EGD considered the gold standard.

## RESULTS

Table 1 provides baseline demographic information and co-morbidities on each patient. The mean age was 46.2 years with the majority of patients being female (6/10). The average BMI was 50.12 kg/m<sup>2</sup> and average weight of 141.85 kg. Eight out of ten patients and nine out of ten patients suffered from obstructive sleep apnea and hypertension respectively. Forty percent of patients suffered from diabetes and 30% of patients had a diagnosis of NAFLD. Two out of ten patients had chronic kidney disease with a glomerular filtration rate of 55 and 48 mL/min/1.73 sqm.

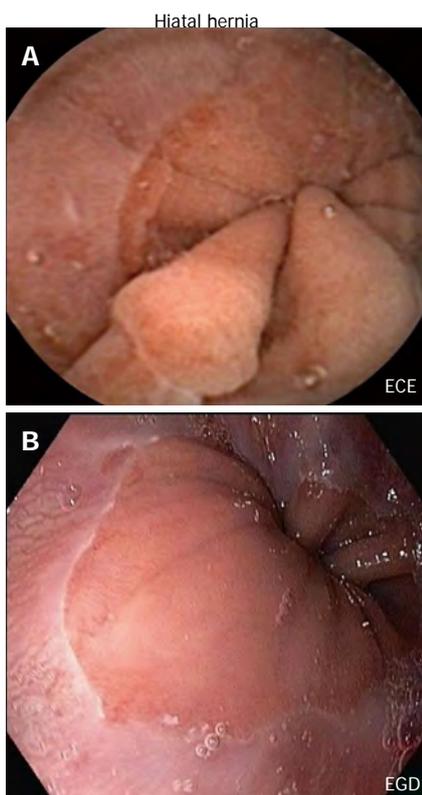

Visualization of the esophagus, GE junction, and gastric body were seen 100% of the time on ECE. The antrum and pylorus were identified 70% and 60% of the time respectively. The gastric cardia and the duodenum were not able to be identified on any capsule endoscopies. The majority of the capsules (9/10) were retained in the stomach (Table 1).

Esophageal findings on EGD included Schatzki ring, hiatal hernia and esophagitis. Two patients were noted to have gastric findings. One patient was found to have mild gastropathy and the other patient was described as having a watermelon stomach at the pylorus.

ECE identified 11 of 14 (79%) positive esophageal/gastroesophageal junction (GEJ) findings and 14 of 17 (82%) combined esophageal and gastric findings identified on EGD. Correctly identified abnormal findings on ECE as seen on EGD in the esophagus included hiatal hernia in seven out of ten patients (Figure 1), Schatzki ring in one out of three patients and felinization rings were correctly identified in one patient on both ECE and EGD. Gastric findings seen on ECE as well as EGD included gastropathy in the body of the stomach in three out of three patients. Erosions were correctly identified on ECE and EGD in one patient. There was a trend toward agreement among ECE and EGD findings in the esophagus *vs* stomach (35/40 findings in agreement in the esophagus *vs* 30/40 findings in agreement in the

tively) (Figure 2B). Of the positive esophageal/GEJ findings, ECE failed to identify the following: hiatal hernia in two patients, mild esophagitis in two patients, and mild Schatzki ring in two patients. Conversely, ECE identified a Schatzki ring in one patient, an irregular Z-line in another patient, and a hiatal hernia in a third patient not identified on EGD. There were no adverse events related to ECE.

## DISCUSSION

Bariatric surgery is increasingly performed to treat morbid obesity and its complications. Pre-operative EGD can help identify useful pathology that can negatively influence post-operative outcomes. However EGD is an invasive procedure requiring the use of conscious sedation that can carry risks of cardiopulmonary complications, hypoxemia, aspiration and cardiac arrhythmias<sup>[10-13]</sup>. Quine *et al*<sup>[10]</sup> showed in a prospective study of 14149 upper endoscopies that 31 patients experienced cardiopulmonary complications related to moderate sedation. Similar studies have shown the rate of cardiopulmonary complications to range from 1.3 per thousand to 5.4 per thousand<sup>[11,14]</sup>. Sharma *et al*<sup>[15]</sup> showed that the risk of developing unplanned cardiopulmonary events following

upper endoscopy was 0.6%. Multiple studies have determined that the risks of moderate sedation in patients undergoing endoscopy increase with co-morbidities such as advanced age, obstructive sleep apnea, underlying heart disease, and obesity<sup>[10-12,14,16]</sup>. Sharma *et al*<sup>[15]</sup> found that an increased American Society of Anesthesiologists classification (ASA class score) was attributed to an increase risk of developing cardiopulmonary complications. Odds ratio ranged from 1.1 with an ASA II score to 1.8 with ASA class III and 7.4 with class V. Many bariatric surgery patients will generally have higher ASA scores.

Endoscopic capsule was initially approved by the Food and Drug Administration in 2001 for evaluation of the small bowel. It is increasingly being used for the evaluation of obscure GI bleeding, Crohns' disease, and suspected small bowel tumors<sup>[17-21]</sup>. Several studies have shown that capsule endoscopy can be used to identify esophageal disorders such as Barrett's esophagus/esophagitis, hiatal hernia, and esophageal varices<sup>[22-26]</sup>.

Our study shows that in pre-bariatric patients, capsule endoscopy can be used to identify positive esophageal disorders when compared to a sedated EGD. Capsule endoscopy was correctly able to identify hiatal hernias, Schatzki rings and esophagitis when compared with EGD. However in our study ECE failed to identify gastric pathology the majority of the time. The gastric cardia was not visualized during ECE and the gastric antrum and pylorus were identified 30% and 40% of the time respectively. The duodenum also could not be correctly identified by ECE due to the short capsule recording time of 20 min.

Esophageal findings seen on ECE but not noted on EGD included a Schatzki ring in one patient, an irregular Z-line in another patient, and a hiatal hernia in a third patient. This might be explained by changes in body position between the upright ECE and left lateral decubitus EGD.

Further limitations of this pilot study include a small patient size. Only ten patients were enrolled in the trial. Despite this, results trended towards no significant difference in the likelihood of identifying a positive finding using ECE compared with EGD.

In conclusion, this is the first study to suggest that ECE may be a safer alternative than sedated EGD for evaluation of esophageal disorders prior to bariatric surgery. However ECE cannot consistently evaluate for gastric or duodenal pathology. Further studies are needed to help define the role of ECE as a tool for pre-operative evaluation.

## COMMENTS

### Background

In patients with morbid obesity, bariatric surgery is a treatment option associated with good medium and long-term results. Prior to surgery, many patients undergo an endoscopic examination to determine if they have any pathology to prevent or delay them from undergoing bariatric surgery. Esophagogastroduodenoscopy (EGD) however is an invasive procedure which comes with risks including the risk of sedation associated with morbidly obese patients. Small bowel capsule endoscopy has been used to identify pathology in the small

bowel for years. Esophageal capsule endoscopy (ECE) uses the same technology to examine the esophagus and stomach. Several studies have shown that ECE is able to identify pathology and anatomic variations in the esophagus and stomach, and can be performed without the risks of moderate sedation. No studies to date have been done to determine whether capsule endoscopy is equivalent to EGD in screening pre-bariatric surgery patients.

### Research frontiers

Small bowel capsule endoscopy was developed as a means to non-invasively examine the small bowel for pathology. ECE was subsequently developed and food and drug administration approved using the same technology to examine the esophagus and stomach. There have been several studies to suggest that ECE is comparable to EGD in the diagnosis of upper gastrointestinal disorders such as Barrett's esophagus and esophageal varices.

### Innovations and breakthroughs

Small bowel capsule endoscopy is a useful tool to non-invasively examine the small bowel. ECE uses the same technology to examine the esophagus and stomach. Recent studies have shown that ECE is comparable EGD in diagnosing esophageal pathology such as esophagitis, Barrett's esophagus and esophageal varices as well as stomach pathology such as gastric cancers. However ECE has never been compared to EGD in pre-screening patients for pathology which may preclude them from bariatric surgery. This study is the first study to date to compare the two in this patient population.

### Applications

The study results indicate that ECE may be a safer alternative than sedated EGD for evaluation of esophageal disorders prior to bariatric surgery, but cannot consistently evaluate for gastric or duodenal pathology. Further studies are needed to help define the role of ECE as a tool for pre-operative evaluation.

### Terminology

Bariatric surgery: Surgery is performed on the stomach and/or intestines in order to facilitate weight loss in obese patients. This could be achieved either through restrictive alone or both restrictive and malabsorptive mechanisms. EGD: An imaging test that involves visually examining the lining of the esophagus, stomach, and upper duodenum with a flexible fiberoptic endoscope; ECE: A small camera inside a capsule shaped and sized like a pill which is used to take video images of the digestive tract to help in evaluation of symptoms such as gastrointestinal bleeding or abdominal pain; Moderate sedation: Drug induced consciousness (typically carried out with a combination of a narcotic such as fentanyl and benzodiazepine such as midazolam) during which patients respond purposefully to verbal commands, either alone or by light tactile stimulation. No interventions are needed to maintain a patent airway, patient is able to spontaneously breathe during moderate sedation. Used in a wide variety of medical procedures.

### Peer review

The results suggest that ECE may be a safer alternative than sedated EGD for evaluation of esophageal disorders prior to bariatric surgery. The paper would be desirable to specify

### Abstract

**AIM:** To determine whether an increased number and duration of non-acid reflux events as measured using the multichannel intraluminal impedance pH (MII-pH) is linked to gastroparesis (GP).

**METHODS:** A case control study was conducted in which 42 patients undergoing clinical evaluation for continued symptoms of gastroesophageal reflux disease (both typical and atypical symptoms) despite acid suppression therapy. MII-pH technology was used over 24 h to detect reflux episodes and record patients' symptoms. Parameters evaluated in patients with documented GP and controls without GP by scintigraphy included total, upright, and supine number of acid and non-acid reflux episodes (pH < 4 and pH > 4, respectively), the duration of acid and non-acid reflux in a 24-h period, and the

number of reflux episodes lasting longer than 5 min.

**RESULTS:** No statistical difference was seen between the patients with GP and controls with respect to the total number or duration of acid reflux events, total number and duration of non-acid reflux events or the duration of longest reflux episodes. The number of non-acid reflux episodes with a pH > 7 was higher in subjects with GP than in controls. In addition, acid reflux episodes were more prolonged (lasting longer than 5 min) in the GP patients than in controls; however, these values did not reach statistical significance. Thirty-five patients had recorded symptoms during the 24 h study and of the 35 subjects, only 9% ( $n = 3$ ) had a positive symptom association probability (SAP) for acid/non-acid reflux and 91% had a negative SAP.

**CONCLUSION:** The evaluation of patients with a documented history of GP did not show an association between GP and more frequent episodes of non-acid reflux based on MII-pH testing.

**Key words:** Gastroparesis; Non-acid gastroesophageal reflux; Acid gastroesophageal reflux; Multi-channel intraluminal impedance; Functional bowel disorder

**Core tip:** Gastroparesis (GP) has been thought to occur in about 8%-10% of patients who suffer from refractory gastroesophageal reflux disease (GERD). There have been no formal studies to date that have evaluated whether patients with refractory GERD additionally suffer from GP. Our study aimed to investigate whether patients who experience continued symptoms of GERD despite acid suppression therapy also concurrently have gastroparesis. By using multichannel intraluminal impedance pH technology, we were not able to find an association between patients with refractory GERD and gastroparesis.

## INTRODUCTION

Gastroparesis (GP) is a chronic gastrointestinal (GI) motility disorder characterized by delayed gastric emptying in the absence of mechanical outlet obstruction<sup>[1]</sup>. The most common etiologies of GP include those secondary to chronic disease states such as diabetes mellitus and collagen-vascular diseases, post-surgical causes, medication induced, and idiopathic causes<sup>[1,2]</sup>. Symptoms of GP include early satiety, nausea, vomiting, abdominal pain, bloating, and gastroesophageal reflux<sup>[1-3]</sup>. Notably, GP has been rising in prevalence across the United States, which as a result, has led to an increase in GP related hospitalizations and increasing health care costs<sup>[1,4]</sup>.

Gastroesophageal reflux disease (GERD) is a very common disease in the United States and has recently been shown to be the most common GI diagnosis among clinical visits in the United States<sup>[5]</sup>. The mainstay of treatment for GERD includes proton pump inhibitors (PPIs) but several studies have shown that upwards of 40% of patients who suffer from heartburn have either a partial or complete lack of response to PPIs taken once a day<sup>[6-8]</sup>. A number of causes for PPI failure have been investigated, including medication non-compliance, undiagnosed functional bowel disorders, and GP<sup>[9]</sup>.

GP has been reported to be present in a variable subset of patients who suffer from refractory GERD and studies have shown that anywhere between 8%-10% of patients with refractory GERD additionally suffer from GP<sup>[10-14]</sup>. It is unknown whether the hypothesized link between GP and refractory GERD actually exists in clinical practice. The aim of our study was to determine whether there is an increased number and duration of non-acid reflux events when comparing patients with GP and without GP using multichannel intraluminal impedance pH (MII-pH). Given the delayed gastric emptying of food in patients with GP, we hypothesized that patients with GP will experience a greater number of non-acid reflux episodes for a longer duration of time when compared to controls without GP.

## MATERIALS AND METHODS

The University of Florida Health Science Center Institutional Review Board approved the collection and analysis of MII-pH data obtained in this study.

### Patient population

From July 2009 to September 2010, all patients who underwent MII-pH analysis for continued symptoms of

GERD despite PPI therapy were enrolled after signing informed consent ( $n = 66$ ). The patients' health records were reviewed for evidence of a prior gastric emptying scintigraphy (GES) done at the University of Florida ( $n = 39$ ) or the results were documented in a recent clinic note from a prior GES done at an outside institution ( $n = 3$ ). Patients were then included in this study if a GES was previously done (abnormal at University of Florida if  $t^{1/2} > 90$  min) and they were scheduled to or had undergone a MII-pH study at the gastric motility laboratory at University of Florida. Patients were excluded from the study if they had no prior GES or history of one documented in a recent clinical note. However, patients were not excluded if they were currently on anti-acid therapy. All patients underwent a physical examination and upper endoscopy prior to undergoing the ambulatory MII-pH testing to exclude any mechanical obstruction.

Patients were considered refractory to PPI therapy at the discretion of the clinician who had referred them to receive MII-pH analysis. Patients were defined as "refractory" if they continued to have symptoms of GERD despite anti-acid therapy. All patients remained on their previously prescribed PPI therapy during the duration of the study.

### MII-pH monitoring

Subjects presented to the motility laboratory after an overnight fast. The Sleuth ambulatory system (Sandhill Scientific, Inc; Highlands Ranch, CO, United States) was used to perform the impedance testing. The catheter has an antimony pH electrode measuring the pH 5 cm from the distal tip and 6 impedance electrodes that measure impedance at 3, 5, 7, 9, 15 and 17 cm above the distal tip. The catheter was placed transnasally with its tip 5 cm above the lower esophageal sphincter.

Subjects then underwent a 24-h monitoring in which their symptoms were electronically recorded and the patients kept a diary of their food intake. All 42 subjects were continued on their current acid suppression therapy for the entire duration of the study. All prokinetic agents, including bethanechol, domperidone, metoclopramide, and azithromycin were discontinued.

Symptoms recorded in the electrical diaries included both typical GERD symptoms (heartburn, regurgitation, and chest pain) and atypical GERD symptoms (cough, hoarseness, abdominal discomfort, nausea, belching, globus sensation, and dysphagia). After the 24-h ambulatory period, subjects returned to the motility laboratory where the data was transferred and analyzed using a single investigatory dedicated software (BioView Analysis; Sandhill Scientific, Inc.). Two investigators in the motility laboratory manually reviewed tracings and electronic diary entry of symptoms. Meal periods were marked and excluded from the analysis. Only liquid and mixed liquid/gas reflux episodes were evaluated for this study.

The parameters obtained from the MII-pH device included the total, upright, and supine number of acid and non-acid reflux episodes, the duration of acid and non-

EGD: Esophagogastroduodenoscopy; GERD: Gastroesophageal reflux disease; IBD: Inflammatory bowel disease; *H. pylori*: *Helicobacter pylori*; PPI: Proton pump inhibitor.

acid reflux in a 24-h period, and the number of reflux episodes lasting longer than 5 min. The MII-pH detected reflux episodes that were classified as acidic when the esophageal pH fell below 4, non-acidic if the pH was between 4-7, and alkaline if the pH rose above 7.

Based on the MII-pH data, we evaluated each separate symptom and determined their association with a reflux episode. The symptom association probability (SAP) was electronically calculated using the BioView Analysis Software. The 24-h pH data was divided into 2-min segments and each of the 2 min segments were studied to determine whether a reflux event and a symptom occurred during that segment. A 2  $\times$  2 table was made in which the number of two minute segments with and without reflux and with and without symptoms were tabulated. A  $\chi^2$  test was then used to determine whether the occurrence of the symptoms and reflux could have occurred by chance. The SAP was then calculated using the formula  $SAP = (1 - P) \times 100\%$  and it was considered positive if  $> 95\%$ <sup>[15]</sup>.

### Statistical analysis

The impedance pH data was compared using the Wilcoxon non-parametric analysis of variance for means and the 2-sided Fisher exact test for proportions. All values are expressed as a mean  $\pm$  SD. The null hypothesis assumes that no significant difference in the number of non-acid reflux events will be seen when comparing impedance pH data between the GP group and the control group.

## RESULTS

### Demographics and medical conditions

The study included 42 participants chosen based on their GES results and then divided into two groups: subjects with gastroparesis and subjects with normal GES both undergoing MII-pH for continued symptoms of GERD despite PPI therapy.

The GP group included 16 patients with a mean age of 54  $\pm$  14 years (age range: 24-76 years) with a mean GES half-time ( $t^{1/2}$ ) of 134  $\pm$  59 min (normal defined at UF as  $t^{1/2}$  between 45-90 min). The control group consisted of 26 patients with a mean age of 51  $\pm$  13 years (age range: 24-77 years) with a mean GES ( $t^{1/2}$ ) of 65  $\pm$  13 min (Table 1). Among the GP group, 6 patients had a normal esophagogastroduodenoscopy (EGD) and 7 patients had biopsy proven *Helicobacter pylori* (*H. pylori*) negative gastritis (Table 1). In the control group, 11 patients had a normal EGD and 6 patients had biopsy proven *H. pylori* negative gastritis (Table 1).

Symptoms on presentation among both the GP and control group included heartburn, bloating, nausea/vomiting chest pain, and hoarseness. Concurrent medical diagnoses included GERD, irritable bowel syndrome, type II diabetes mellitus, and chronic constipation. Prior surgical procedures in both populations included cholecystectomy and Nissen fundoplication.

### MI-pH data

No statistical difference was seen between subjects with GP and controls with respect to the total number and duration of acid reflux events [13.3  $\pm$  17.1 (95%CI: 4.2-22.4) in GP *vs* 12.0  $\pm$  14.8 (95%CI: 6.0-18.0) in controls,  $P < 0.79$ ], total number and duration of non-acid reflux events [21.6  $\pm$  24.6 (95%CI: 8.5-34.7) in GP *vs* 25.7  $\pm$  29.3 (95%CI: 13.9-37.5) in controls,  $P < 0.64$ ], or the total number and duration of reflux events [30.8  $\pm$  36.5 (95%CI: 11.3-50.2) in GP *vs* 37.9  $\pm$  35.7 (95%CI: 23.48-52.29) in controls,  $P < 0.54$ ] (Figure 1). The number of non-acid reflux episodes with a pH  $> 7$  were higher in subjects with GP [5.3  $\pm$  5 (95%CI: 2.6-8.0) *vs* 4.5  $\pm$  5.6 (95%CI: 2.3-6.9) in controls,  $P < 0.67$ ] and the acid reflux episodes were more prolonged (lasting longer than 5 min) in the GP group [0.95  $\pm$  2.0 (95%CI: -1.1-2.0) *vs* 0.25  $\pm$  0.7 (95%CI: -1.1-0.5) in controls], but these values did not reach statistical significance ( $P < 0.12$ ) (Figure 1).

### Symptom association probability

Of the 42 subjects who were evaluated, 35 subjects (83%)

**Table 2** Symptom association probability for patients with gastroparesis and controls

MII-pH symptoms	Gastroparesis (n)	Controls (n)	Positive SAP (n)	Negative SAP (n)
Chest pain	3	5	1	7
Nausea/vomiting	2	4	1	6
Regurgitation	3	4	0	14
Hoarseness	0	4	0	6
Heartburn	5	9	0	4
Globus sensation	2	2	0	4
Dysphagia	4	4	1	7
Cough	3	7	1	9
Abdominal pain	7	3	0	10
Belching	6	8	0	14
Bloating	0	2	0	2

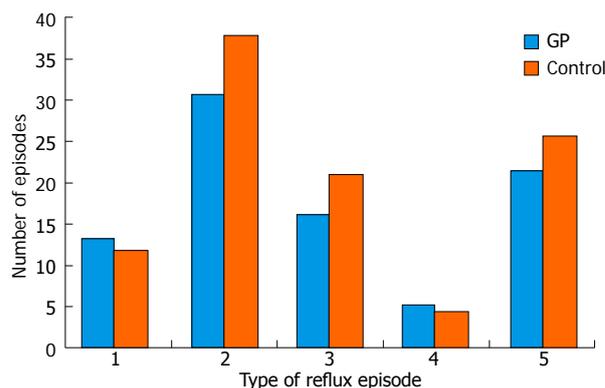

SAP: Symptom association probability; MII-pH: Multichannel intraluminal impedance pH.

recorded symptoms during the 24-h study period and 7 patients did not have any recorded symptoms. There were 87 total symptoms recorded by the 35 subjects and 33% were typical symptoms and 67% were atypical symptoms of GERD. The GP group accounted for 38% ( $n = 11$ ) of the total typical symptoms reported and the control group accounted for 62% ( $n = 18$ ) of typical symptoms. Atypical symptoms of GERD were also more commonly recorded in the control group than the GP group (59% *vs* 41% respectively) (Table 2).

Of the 35 subjects who had recorded symptoms during their MII-pH testing, only 9% ( $n = 3$ ) had a positive SAP for acid/non-acid reflux and 91% ( $n = 32$ ) had a negative SAP. Similarly, of the total typical symptoms that were recorded, 7% ( $n = 2$ ) had a positive SAP and 93% ( $n = 27$ ) had a negative SAP. Of the 58 atypical symptoms recorded, 3% ( $n = 2$ ) had a positive SAP and 97% ( $n = 56$ ) had a negative SAP. Among the 16 subjects with GP, a total of 35 symptoms were recorded and all had a negative SAP. Among the 26 controls, 52 symptoms were recorded, and 8% of those had a positive SAP with the majority (92%) having a negative SAP.

## DISCUSSION

Resistance to acid suppression therapy such as PPIs is the most common presentation of GERD in the tertiary care GI practices<sup>[16]</sup>. A survey of GERD patients receiving PPI therapy shows that 25%-42% of patients are refractory to a once-daily PPI dose, of which only 25% would respond to an increase in PPI dosing to twice daily<sup>[17,18]</sup>. In addition, 42% of GERD patients surveyed are dissatisfied with their PPI treatment outcomes<sup>[19]</sup>. GP has long been thought of as a risk factor for refractory GERD due to the impaired gastric accommodation, delayed gastric emptying and the subsequent loss of lower esophageal sphincter tone. Furthermore, as our study shows, symptoms of GP and GERD often overlap as

**Figure 1** Comparison of the number of reflux episodes for subjects with gastroparesis and controls. 1: Total reflux events; 2: Total acid reflux events; 3: Total non-acid reflux events; 4: Non-acid reflux events pH 4-7; 5: Non-acid reflux events pH > 7. GP: Gastroparesis.

both patients can complain of epigastric pain, abdominal bloating, nausea, and vomiting making it difficult to distinguish between the two disease processes. Given this observed overlap of symptoms, our study aimed to determine whether patients with GP and concurrent symptoms of reflux despite concurrent PPI therapy have an increased frequency and duration of non-acid reflux using impedance pH technology, as compared to those with normal gastric emptying.

Our results indicate that the total number and duration of acid, non-acid, and total reflux events was similar in GP and non-GP cases. While the number of alkaline events was slightly higher in the GP group, these alkaline reflux events represented a small percentage of the total non-acid reflux events observed (20%). Moreover, among the 35 patients who recorded symptoms during the 24 h MII-pH study, only 3 patients had a positive SAP for acid/non-acid reflux. Our findings do not support some prior studies indicating up to 40%-50% of patients with GERD have GP<sup>[12,20]</sup>, and we believe that GP likely accounts for a small percentage of refractory GERD cases than previously evaluated based on conventional pH testing. Our findings based on MII-pH testing indicate that neither acid nor non-acid reflux occur more frequently in patients with GP than those without.

Since only 3 of 35 patients had a positive SAP for acid and non-acid reflux, and given our lack of statistical correlation between GP and acid or non-acid reflux, other causes of refractory GERD need to be explored to explain patients' persistent symptoms. Notably, even the control group with refractory GERD symptoms had a poor symptom correlation with acid and non-acid reflux events. One possible explanation may be the presence of esophageal hypersensitivity, which has been proposed previously as an underlying mechanism in this patient population<sup>[16,18,21]</sup>. Esophageal distention occurs due to increased reflux volume exposing the esophagus to acidic/non-acid components of the refluxate, which in turn leads to persistent impairment of esophageal mucosa and thus results in esophageal hypersensitivity<sup>[21]</sup>. In our study, 67% of the reflux events recorded were non-acid with no

correlation to patients' symptoms, making esophageal hypersensitivity a plausible explanation for their continued symptoms.

Our study has some limitations. First, this study was limited to one tertiary care center and the small sample size ( $n = 42$  total with 16 subjects with GP) compromised the overall generalizability of the study, leading to a statistical type II error. This may account for our negative findings indicating a lack of difference in acid and non-acid reflux in patients with and without GP. Based on the mean number of acid reflux events in GP and control groups ( $P = 0.09$ ), the statistical power in the current study is 8%. *Post hoc* power analysis suggests that to achieve 90% statistical power, a sample size of 2592 for each group is necessary. In addition, the GES testing done was not based on the current national standard protocol for obtaining GES and some of the GES studies were not obtained at our institution therefore the accuracy of the measurements may influence our results<sup>[22]</sup>. This lack of uniformity of GES testing across multiple centers introduces a potential area for error, as patients with or without GP might have been misdiagnosed given lack of standardization. Furthermore, performing the MII-pH study on PPI therapy, as done in our study, may have affected our results in terms of delaying gastric emptying as shown in several studies which could lead to a type II error. By delaying acid-dependent peptic activity, PPIs impair hydrolytic digestion and therefore delay gastric emptying<sup>[23]</sup>. This finding may have clinical implications in the management of GERD in our subjects. Future studies evaluating the effect of GP on acid and non-acid reflux should be done with subjects strictly off PPI therapy 5 d prior to testing. Another limitation is that not all patients were maxed out on PPI therapy prior to the MII-pH study, making continued reflux a potential cause of their continued symptoms. Lastly, GES and MII-pH studies were completed on separate days and in most cases months apart and as a considerable intra-individual variability exists with gastric motility, this may also have contributed to achieving the negative results seen in this study<sup>[22]</sup>.

Our study has several important strengths. This is the first study evaluating whether an association exists between GP and non-acid reflux analyzed by MII-pH monitoring. While GP may have been thought to be associated with refractory GERD, studies have not validated this finding using MII-pH to diagnose acid and non-acid reflux. In addition, the idea that delayed gastric emptying is associated with GERD has been the basis of using prokinetic drugs for the treatment of GERD<sup>[20]</sup>. Considering our results, it might not be necessary to start these patients on prokinetic agents in addition to acid suppression therapy, unless evidence of esophageal dysmotility is found on esophageal manometry testing, given these drugs have significant side effects and drug-drug interactions. Other medications that improve LES pressure or decrease transient relaxations of the lower esophageal sphincter may be more beneficial for patients with any

type of reflux, acid or nonacid, than perhaps improving their gastric emptying. Moreover, our study illustrates that patients with weakly acidic and alkaline reflux likely suffer from esophageal hypersensitivity rather than continued reflux or GP as the main cause of their typical and atypical GERD symptoms. Finally, our study justifies a larger study in which a population of patients with refractory GERD off PPI therapy is evaluated for GP in close proximity to their initial MII-pH analysis combined with manometric esophageal testing. A larger study using the MII-pH as the gold standard for diagnosing non-acid reflux would better delineate whether GP and non-acid reflux are clearly associated.

In conclusion, whether gastroparesis contributes to refractory reflux remains to be established. However, based on our pilot study, a clear relationship does not exist but further studies using larger populations of patients undergoing impedance testing for refractory reflux would help to delineate this relationship.

## COMMENTS

### Background

Up to 40% of patients with gastroesophageal reflux disease (GERD) have either a partial or incomplete response to proton-pump inhibitors. Gastroparesis has been hypothesized to be a potential cause of refractory GERD in a subset of patients.

### Research frontiers

In a case-control study, 42 patients undergoing clinical evaluation for continued heartburn and regurgitation despite acid suppression therapy were evaluated with multi-channel intraluminal impedance pH monitoring and for evidence of gastroparesis.

### Innovations and breakthroughs

Their results did not show a difference between acid and non-acid reflux events among patients with gastroparesis and those without the disease process.

### Applications

While a clear relationship between gastroparesis and refractory GERD was not shown in their study, the results could be used to conduct further studies using larger populations of patients to help further delineate the relationship.

### Terminology

Multi-channel intraluminal impedance pH monitoring is a new technology that can detect intraluminal bolus movement without radiation. When it is combined with pH testing, it can detect both acid and non-acid reflux.

### Peer review

The current study is a relevant paper dealing with a difficult to treat and often poorly assessed patient population.

**RESULTS:** Thirty-two SEMS were implanted in 20 patients. In all patients, endoscopic stent implantation was successful. Stent migration was observed in 9 of 16 cSEMS (56%) in comparison to 0/16 SEMS (0%) implantations ( $P = 0.002$ ). Stent overgrowth did not significantly differ between the two stent types (SEMS: 3/16, 19%; cSEMS: 2/16, 13%). One cSEMS dislodged and had to be recovered from the jejunum by way of laparotomy. Time until migration between SEMS and cSEMS in patients with and without concomitant biliary stents did not significantly differ (HR = 1.530, 95%CI 0.731-6.306;  $P = 0.556$ ). The mean follow-up was  $57 \pm 71$  d (range: 1-275 d).

**CONCLUSION:** SEMS and cSEMS placement is safe in small bowel tumor obstruction. However, cSEMS is accompanied with a high rate of migration in comparison to uncovered SEMS.

**Key words:** Endoscopy; Digestive system; Intestinal neoplasms; Self-expandable metal stents; Tumor obstruction; Self-expandable metal stents complications

**Core tip:** Gastrointestinal obstruction is a complication of advanced cancer disease. It heavily impacts on patients' general condition. Endoscopic implantation of self-expanding metal stents (SEMS) is a safe and established procedure for palliative treatment of tumor obstruction. Covered SEMS are considered favorable concerning reobstruction by inhibiting tumor ingrowth. In contrast, uncovered SEMS might harbor a lower risk of migration and dislocation. In the present study covered SEMS were retrospectively compared with uncovered SEMS in patients with small bowel or duodenal obstruction. Significantly higher migration rates were observed in the covered SEMS group without observing significant increase of the rate of patients with tumor ingrowth indicating that uncovered SEMS should be

### Abstract

**AIM:** To compare clinical success and complications of uncovered self-expanding metal stents (SEMS) vs covered SEMS (cSEMS) in obstruction of the small bowel.

**METHODS:** Technical success, complications and outcome of endoscopic SEMS or cSEMS placement in tumor related obstruction of the duodenum or jejunum were retrospectively assessed. The primary end points were rates of stent migration and overgrowth. Secondary end points were the effect of concomitant biliary drainage on migration rate and overall survival. The data was analyzed according to the Strengthening the Reporting of Observational Studies in Epidemiology guidelines.

avored for palliative treatment of tumor obstruction of the duodenum or the small bowel.

## INTRODUCTION

Endoscopic placement of self-expandable metal stents (SEMSs) has become a broadly accepted first line treatment option for patients with advanced malignant intestinal stenosis. Reconstitution of the intestinal transit is paramount in palliation of tumor obstruction, and endoscopic SEMS insertion is weighed against surgical intervention in terms of clinical relief, complication rate, and length of hospital stay of the patient. In the small bowel, duodenal tumor obstruction has increasingly been treated by SEMS placement<sup>[1,2]</sup>, but SEMS insertion in the lower small bowel is less often performed<sup>[3,4]</sup>. Duodenal SEMS insertion is technically feasible in more than 90% of interventions; it is safe and comes along with a faster start of oral intake, shorter length of hospital stay, lower morbidity and probably reduced in-hospital mortality as compared to surgical treatment<sup>[5-13]</sup>. SEMS may as well be preferred over surgical treatment in the lower small bowel and at anastomotic small bowel obstructions in case of recurrent malignancy<sup>[4]</sup>.

Tumor in- or over-growth can limit long-term outcome of SEMS in 12% to 21% of cases, but stent occlusion might be reduced by covering the SEMS with silicone or plastic membranes (covered SEMS, cSEMS)<sup>[1,2]</sup>.

Aim of this study was to compare outcome of SEMS vs cSEMS in small bowel tumor obstruction and to identify technical feasibility, safety, clinical impact, complications and patient's outcome at follow-up.

## MATERIALS AND METHODS

All patients who underwent endoscopic placement of SEMS or cSEMS for small bowel tumor obstruction (duodenum or jejunum) between August 2009 and September 2012 were retrospectively analyzed. Due to advanced or metastatic disease or comorbidity, none of the patients were considered candidates for curative surgical treatment of the tumor. All patients included into this study were symptomatic and were admitted to the hospital because of their obstructive symptoms including nausea, vomiting, bloating, or abdominal pain. At least for some time all patients were suffering from postprandial vomiting. No patient was treated for non-symptomatic stenosis. Indication for jejunal placement of stents was only given in cases of unilocular stenosis by circumscribed peritoneal

carcinomatosis. Histology was obtained by endoscopic biopsy from the intestinal tumor or percutaneous needle biopsy from liver metastasis. The therapeutic procedures were ascertained in an interdisciplinary conference with senior physicians from the departments of surgery, gastroenterology and medical oncology and the recommendation to treat by endoscopic stent placement was given in consent.

We retrospectively reviewed the prospectively collected records on technical success of the procedure, clinical benefit, and the incidence of complications including migration and stent occlusion. The patients' outcome at follow-up was additionally registered.

Patients were advised to resume oral intake of liquids within 24 h and to advance to a low-residue diet as tolerated. The status of oral food intake was monitored at one-month intervals on an outpatient basis. In case of recurrence of dysphagia, radiographic imaging (iodine or barium upper gastrointestinal series) and/or upper gastrointestinal endoscopy was performed. Patients who had recurrent symptoms caused by tumor overgrowth were treated by placement of a second intestinal stent.

### Endoscopic technique and stent selection

Stents were placed by very experienced gastroenterological endoscopists using a therapeutic gastroscope (GIF-1TQ 160), or a duodenoscope (TJF-Q180V, TJF-160 VR; all Olympus medical Europe, Hamburg, Germany) with a working channel of 3.7 or 4.2 mm, respectively. All stents were inserted through-the-scope (TTS) in combination with over-the-wire technique, and all stents were placed under fluoroscopic guidance. Selection of SEMS vs cSEMS was at the appraisal of the endoscopist and cSEMS was preferably chosen in case of advanced tumors with subtotal or complete obstruction intending to avoid later tumor ingrowth. SEMS was preferred over cSEMS in case that the investigator was in fear of blocking biliary outflow by crossing the duodenal papilla by the stent. If complications (migration or overgrowth) occurred, new stents were placed and the stenting procedure in the patient was switched from a covered to an uncovered stent and vice versa. The stents used in this study were self-expandable Nitinol uncovered SEMS (Niti-S, D-Type, TaeWoong medical, South Korea) and covered SEMS [cSEMS; Niti-S pyloric duodenal covered stent (End Bare Type), TaeWoong medical, South Korea]. A stent diameter from 18 to 28 mm and a stent length from 40 to 120 mm were used. The cSEMS provides a silicone covering and has a retrieval suture for preventing tumor-ingrowth and easy removal. It contains a fixed-cell braided structure. The SEMS is a fine mesh tubular prosthesis that facilitates immediate and continuous wall apposition due to the so-called D-weaving technology, *i.e.*, stent cells are unfixed resulting in a high flexibility and retaining its shape even in bending sections of the intestinal tract. In case that a stent did not cover the entire tumor obstruction, two overlapping stents were implanted to bridge the entire obstructed bowel segment and this was accounted

as a single application in this study.

### Definition

Tumor overgrowth of the stent was defined as deterioration of the patient's condition (recurrence of dysphagia) and detection of narrowing of the stent lumen within or adjacent to the proximal or distal end of the stent mesh as a result of tumor growth, as shown by endoscopic and/or radiologic findings. Tumor ingrowth was defined as tumor obstruction through the stent mesh as a reason for as deterioration of the patient's condition (recurrence of dysphagia). Improvement of vomiting or the intake of fluids or food was assessed qualitatively. Postinterventional complication rate was defined as occurrence of complications within 24 h after stent placement, all other complications were observed until the end of the follow-up period.

### Ethics

The retrospective study was approved by the institutional review board (Ethikkommission) of the Johann Wolfgang Goethe-University Hospital.

### Statistical analysis

The present study is a retrospective cohort study. The primary endpoints were complications due to stent implantation including tumor overgrowth and stent migration. The secondary end points were effect of concomitant biliary stenting on migration rates and overall survival. Statistical analyses were performed with SPSS (Version 22.0, IBM, NY, United States). Predictors of survival were determined using a univariate Cox regression hazard model. Death was recorded as event. Survival curves with the estimated hazards were calculated with the Cox regression model. The patients at risk at the individual time points are shown in the figures. The data was analyzed according to the Strengthening the Reporting of Observational Studies in Epidemiology guidelines<sup>[14]</sup>.

## RESULTS

Thirty-two cases of stent insertion were included in this study: 16 cSEMSs and 16 SEMSs were placed in 20 patients. Patient characteristics are shown in Table 1. Five patients received two overlapping stents; in the remaining 27 interventions a singular stent was put in place. Whereas all covered SEMS were implanted in the duodenum, 3 of 16 uncovered SEMS were inserted into the jejunum. The main etiology of gastric outlet obstruction was pancreatic cancer, followed by cholangiocellular carcinoma or gallbladder carcinoma (Table 1). All three jejunal SEMS were placed due to an obstruction that was caused by a circumscribed manifestation of peritoneal carcinomatosis in gastric cancer patients. Nine of the SEMS (56%) and eight of the cSEMS (50%) were placed in patients who presented with concomitant biliary tract stenosis; all these patients were treated with placement of plastic stents or SEMS/cSEMS into the common bile duct (CBD), and plastic endoprosthesis were replaced by biliary SEMS at the time of duodenal SEMS insertion in all patients.

We observed technical success of SEMS placement in all cases without occurrence of peri-interventional complications. In three (SEMS) and two (cSEMS) stent placements, respectively, balloon dilatation was needed for complete expansion of the stents. The duration of endoscopic procedure did not significantly differ between SEMS and cSEMS (Table 2). The clinical condition ameliorated in 14 of 16 (87.5%) cases treated with SEMS and intake of fluids or food improved. In contrast, in patients treated with cSEMS the clinical condition improved in 12 of 16 (75%) cases only. However, this difference was not statistically significant ( $P = 0.564$ ).

The mean follow-up time  $\pm$  SD was 57  $\pm$  71 d with a range of 1-275 d. In patients with gastric outlet obstruction and concomitant biliary obstruction no migration or occlusion of the bile duct stents was observed. Nine of the 16 cSEMS (56%) migrated within the observation time. In one of the patients the dislodged stent had to be recovered from the jejunum by laparotomy. The patient

**Figure 1** Self-expanding metal stents insertion in duodenal tumor obstruction. A: Retention of secretions and food in the stomach; B: Duodenal self-expanding metal stents (SEMS) together with biliary SEMS in X-ray; C: SEMS in endoscopic imaging.

was dismissed from hospital treatment after recovery from the surgery. On the contrary none of the SEMS dislocated. SEMS placement was superior to cSEMS for duodenal location of obstructions concerning migration rate (0% *vs* 56%). However, although none of the three SEMS placed in the jejunum migrated within time no further conclusion can be drawn for a superiority of SEMS in the jejunal location as no cSEMS was placed in the jejunum. The mean time until migration  $\pm$  SD was  $30 \pm 52$  d with a range of 1-161 d.

As stents in situ of the CBD might give hold to the duodenal SEMS/cSEMS and might be associated with a reduced rate of stent migration, we analyzed the group of patients with CBD SEMS/cSEMS and concomitant duodenal SEMS/cSEMS placement separately. In 17 of 32 cases, a combined biliary and duodenal SEMS/cSEMS insertion had been undertaken. Comparing the time until migration of stents in patients with and without biliary SEMS/cSEMS, there was no difference in migration of duodenal stents (HR = 1.530, 95%CI: 0.731-6.306;  $P = 0.556$ ). In those 17 patients in whom a biliary SEMS was in place, all six events of stent migration were observed in patients with duodenal cSEMS, whereas no migration was seen in patients with uncovered duodenal SEMS ( $P = 0.008$ ). A representative example of duodenal stent with concomitant biliary metal stent implantation is shown in Figure 1.

Overgrowth of a SEMS by progressive cancer occurred in three cases, whereas this complication was seen in two of the cSEMS patients. There was no tumor ingrowth into any of the stents (SEMS or cSEMS) observed. In case of tumor overgrowth or migration, a new stent was placed into the stenosis and migrated cSEMS were replaced by uncovered SEMS. A flow chart demonstrating the algorithm of stent treatment is displayed in Figure 2.

Thirteen patients died within the observation time. The median overall survival was 74 d (Figure 3A). To assess the influence of the stent type on survival, overall survival times for the two kinds of stents were compared. There was no significant difference between SEMS and cSEMS concerning overall survival according to a uni-

variate Cox regression model (Figure 3B).

## DISCUSSION

In this comparative study, we observed a high rate (> 50%) of stent migration in the covered SEMS group in comparison to the non-covered SEMS group (0%) in palliation of duodenal or small bowel obstruction. Concurrently, technical feasibility of stent placement (TTS technique) was similar, and relief of symptoms was equal in both patient groups. Insertion of SEMS was as safe as cSEMS implantation during peri-interventional surveillance of the patient. Thereby, biliary SEMS did not prevent migration of duodenal cSEMS migration, and the migration rate in patients with and without concomitant biliary stents was similar. We did not observe clinically significant tumor ingrowth in the SEMS or cSEMS group. However, the overall survival times were quite short and in patients with longer survival times cSEMS might show advantages concerning tumor ingrowth rates.

Randomized trials comparing SEMS *vs* cSEMS treatment in the small bowel has not been reported up to date, but an increased risk of stent migration in covered SEMS has been reported in colonic tumor palliation: Stent migration was four times as common in the covered SEMS group as in the non-covered stent group in a recent meta-analysis<sup>[15]</sup>. In patients with inoperable gastric cancer, comparison of cSEMS *vs* SEMS yielded similar results: Migration was observed in 26.0% of patients, in comparison to 2.8% in non-covered SEMS in a randomized trial<sup>[16]</sup>. Our results suggest that migration rate in the small bowel is even higher than in the stomach or large bowel. Technical success rate and clinical success was similar in cSEMS *vs* SEMS in both studies, and immediate complications were near to zero. Migration rates are low (1%-3% of cases) in other studies reporting on SEMS insertion in the duodenum and small bowel<sup>[1,17]</sup>.

As the duration of the endoscopic treatments and the responsible endoscopists did not differ between the two cohorts, we consider two factors to contribute mainly on migration in cSEMS *vs* SEMS study: First, the stent cover minimizes hyperplastic tissue to get hold of the stent

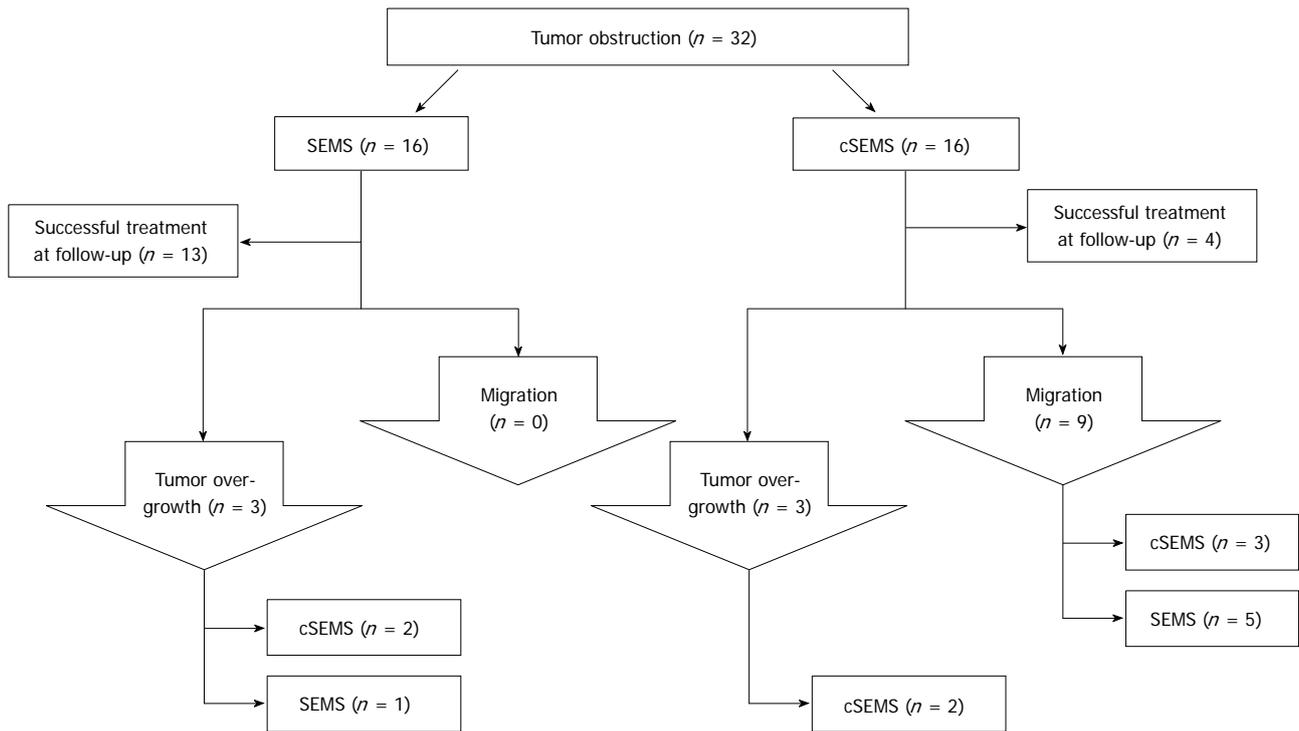

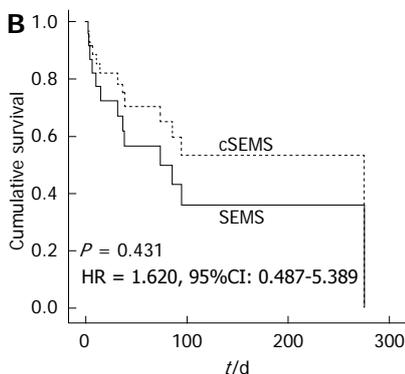

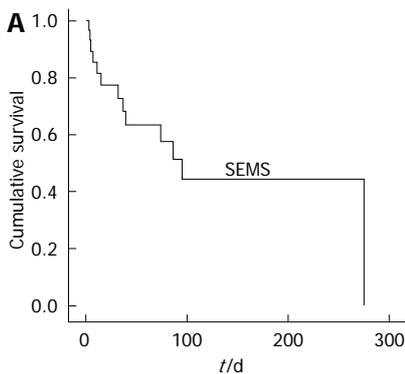

Figure 2 The treatment algorithm for self-expanding metal stents placement. SEMS: Self-expanding metal stents; cSEMS: Covered SEMS.

mesh and partial ingrowth of tumorous and hyperplastic tissue is prevented, thus minimizing any anti-migration effect that the stent may provide against the natural motility of the small bowel. Moreover, we think that the fixed-cell braided structure of the SEMS we used might have significantly contributed to migration by causing the stent to straighten itself by use of its axial expansion force. In opposite, the so-called D-weaving technology of the SEMS with unfixed stent cells might have resulted in a higher flexibility and retention of its shape even at bending sections of the intestinal tract, such as the duodenum. The motility of the small bowel contributes to the progression of the stent. Stent migration can be reduced by endoscopic clip fixation of stents in the duodenal position<sup>[18]</sup>. This procedure might be impracticable and only short-lasting, though, as clips usually dislodge in the short term.

The use of SEMS in duodenal obstruction might be compromised by concomitant biliary obstruction. However, combined endoscopic treatment is safe and successful in the majority of cases with only minor complications (0%-16% of cases)<sup>[19-23]</sup> even if others report found much higher incidence of complications (up to 52%)<sup>[24]</sup>. In our cohort of patients there were no treatment related complications of biliary drainage by duodenal stents. Migration rates were also not affected by the existence of biliary stenting. However, all events of migration of duodenal stents in patients receiving combined biliary and duodenal stenting happened in patients who had obtained cSEMS. Therefore, biliary stenting may protect from duodenal stent migration, if the biliary stents are placed in between the meshes of uncovered SEMS. The

advantage of SEMS in comparison to cSEMS might be lower rates of tumor occlusion<sup>[1,2,19]</sup>. In contrast in patients receiving cSEMS recurrence of tumor occlusion is rarely observed<sup>[19]</sup>. The rate of stent occlusion did not significantly differ between patients with SEMS (19%) and cSEMS (13%) in our study, though. Also in another report no differences were found between SEMS and SEMS concerning necessity of re-interventions<sup>[25]</sup>. An overview of literature concerning complications of SEMS placements is provided in Table 3.

The limitation of the current study is the retrospective non-randomized approach. However, in conclusion, technical feasibility, tumor overgrowth, and overall survival of the patients are comparable in SEMS vs cSEMS, but migration rate is much higher in cSEMS as migration was observed in none of the SEMS group patients.

We prefer SEMS over cSEMS insertion as first choice for malignant duodenal and small bowel obstruction and restrict use of cSEMS in cases with fast tumor ingrowth. Prospective randomized trials are needed to compare SEMS and cSEMS for small bowel obstruction.

comparing covered SEMS and uncovered SEMS in for tumor related stenosis has been reported. The authors hypothesized, that covered SEMS and uncovered SEMS differ concerning complications in the indicated localization.

### Innovations and breakthroughs

The authors learnt that covered SEMS showed significant higher migrations rates than uncovered SEMS when placed in the duodenal position. In contrast, no significant differences concerning re-obstruction of the lumen or overall survival after SEMS implantation were found.

### Applications

The authors conclude that uncovered SEMS should be preferred when SEMS implantation in the duodenum is performed.

### Terminology

SEMS are self-expanding metal stents which are often made of nitinol alloyings and are placed by guide wired and under fluoroscopic control in endoscopic procedures. SEMS can be used uncovered or covered with silicone or other materials.

### Peer review

The authors showed in their retrospective analysis for the first time that uncovered SEMS might be preferred for malignant duodenal or small stenosis, as covered SEMS show much higher rates of migration. The results may help to reduce complications raised by migrated SEMS.

## COMMENTS

### Background

Duodenal and small bowel obstructions are complications of advanced cancer disease. Endoscopic implantation of nitinol based self-expanding metal stents (SEMS) is a safe and established procedure for palliative treatment of tumor obstruction. Covered and uncovered SEMS differ in their characteristics concerning risk of tumor ingrowth and overgrowth or migration and dislocation. But up to now, there is no data provided that covered or uncovered SEMS should be favored for treatment of tumor stenosis in the duodenum or small bowel.

### Research frontiers

Endoscopic treatment of duodenal or small bowel obstruction is an established treatment procedure for malignant stenosis. However, no thorough analysis

### Abstract

**AIM:** To study serological antibodies in Caucasians and Asians, in health and inflammatory bowel disease (IBD), in Australia and Hong Kong (HK).

**METHODS:** Anti-glycan antibodies [anti-chitobioside (ACCA), anti-laminaribioside (ALCA)], and anti-mannobioside (AMCA), anti-*Saccharomyces cerevisiae* (gASCA); and atypical perinuclear anti-neutrophil cytoplasmic antibody (pANCA) were tested in IBD patients, their unaffected relatives, and healthy controls in Australia and HK (China). Antibody status (positive or negative) and titre was compared between subjects of different

geography, ethnicity and disease state.

**RESULTS:** Ninety subjects were evaluated: 21 Crohn's disease (CD), 32 ulcerative colitis (UC), 29 healthy controls, and 8 IBD patient relatives. Forty eight subjects were Australian (29 Caucasian and 19 ethnic Han Chinese) and 42 were from HK (all Han Chinese). Caucasian CD patients had a significantly higher antibody prevalence of gASCA (67% vs 3%,  $P < 0.001$ ), ALCA (44% vs 6%,  $P = 0.005$ ), and AMCA (67% vs 15%,  $P = 0.002$ ), whereas HK CD patients had a higher prevalence of only AMCA (58% vs 25%,  $P = 0.035$ ), when compared with UC and healthy subjects in both countries. Caucasian CD had significantly higher gASCA prevalence (67% vs 0%,  $P < 0.001$ ) and titre (median 59 vs 9,  $P = 0.002$ ) than HK CD patients. Prevalence and titres of ALCA, ACCA and AMCA did not differ between CD in the two countries. Presence of at least one antibody was higher in Caucasian than HK CD patients (100% vs 58%,  $P = 0.045$ ). pANCA did not differ between countries or ethnicity.

**CONCLUSION:** Serologic CD responses differ between HK Asian and Australian Caucasian patients. Different genetic, environmental or disease pathogenic factors may account for these differences.

**Key words:** Crohn's disease; Ulcerative colitis; Serological antibodies; Asia; Ethnic; Anti-*Saccharomyces cerevisiae* antibodies; Anti-chitobioside antibodies; Anti-laminaribioside antibodies; Anti-mannobioside antibodies; Atypical perinuclear anti-neutrophil cytoplasmic antibodies

**Core tip:** Serological antibodies to enteric antigens are a hallmark of inflammatory bowel disease (IBD) and may carry pathogenic and prognostic significance. There is limited information about their role and prevalence in Asian patients. We evaluated anti-glycan antibodies (anti-chitobioside, anti-laminaribioside, and anti-mannobioside), anti-*Saccharomyces cerevisiae*; and atypical

perinuclear anti-neutrophil cytoplasmic antibody in IBD patients, their unaffected relatives, and healthy controls in Australia and Hong Kong (China). Serologic responses were found to differ between Asian and Caucasian patients. Different genetic, environmental or disease pathogenic factors may account for these differences.

## INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are related to a mucosal immune response to antigenic stimulation from the gut microbiota on a background of genetic susceptibility<sup>[1]</sup>. Serological antibodies for inflammatory bowel disease (IBD) have a role as diagnostic markers for IBD and assist in disease stratification<sup>[2]</sup>.

Glycans are carbohydrate surface components, which can be found on immune cells, erythrocytes, tissue matrices and microorganisms. They likely reflect the interaction between the immune system and glycosylated cell wall components of microbiota such as fungi, yeast, and bacteria<sup>[3]</sup>. Anti-*Saccharomyces cerevisiae* (gASCA) (IgA and IgG) antibodies are directed against the cell wall mannan of the yeast *Saccharomyces* that shares homology with intestinal bacteria<sup>[4]</sup>. gASCA (antibodies against covalently immobilized mannan)<sup>[5]</sup> have been found to be comparable to "conventional" ASCA<sup>[6]</sup>. Anti-laminaribioside carbohydrate IgG antibodies (ALCA), anti-chitobioside carbohydrate IgA antibodies (ACCA), anti-mannobioside carbohydrate IgG antibodies (AMCA) were first reported in 2006<sup>[5]</sup> and discovered using GlycoChip glycan array technology<sup>[7]</sup>. These antibodies may allow differentiation of IBD from health, define between IBD subtypes, and have been associated with a more complicated CD behaviour<sup>[2,5]</sup>. Atypical perinuclear anti-neutrophil cytoplasmic antibody (pANCA) is regarded as a marker of UC, as it has a higher prevalence in UC than in CD or healthy controls<sup>[8]</sup>.

Until two decades ago IBD was rare in Asia<sup>[9]</sup>, but recent population-based and referral centre cohorts<sup>[10,11]</sup> have shown a rising incidence and prevalence of IBD in Asia<sup>[12]</sup>. These temporal trends in disease incidence and prevalence may provide insights into possible etiologic factors, such as genetic *vs* environmental. As serologic antibodies may represent an interface between a patient's genetic make-up and their environment, we hypothesised that evaluation of serologic responses in areas of increasing incidence may provide an insight into these complex interactions. Most data on serological antibodies are derived from North American or European cohorts. There are no publications of the prevalence of the anti-glycan

antibodies in Asian cohorts, either in Asia or in Asians abroad.

This study aimed to provide an initial insight into the prevalence and magnitude of the anti-glycan antibodies, and pANCA in IBD, compared to control groups, in Han Chinese (referred to as Asian) and Caucasian subjects in Australia and in Han Chinese subjects in Hong Kong (China).

## MATERIALS AND METHODS

### Patient population

Serum samples were obtained from consented consecutive subjects, regardless of disease extent or duration, from IBD centres in Melbourne, Australia and Hong Kong (China).

IBD diagnosis and differentiation into UC and CD was made based on accepted clinical, endoscopic, histopathological, and radiological findings. Patient characteristics are shown in Table 1. The healthy subjects consisted of patients undergoing a colonoscopy for a family history of cancer or polyps, with a subsequent normal colonoscopy. Eight first degree relatives of IBD subjects (2 of UC, 6 of CD) who were undergoing a colonoscopy for cancer screening were also studied. Signed informed consent was obtained from all participants. The study was approved by the Ethics Committees of St Vincent's Public and Private Hospitals Melbourne, and The Chinese University of Hong Kong.

### Serological analysis

After blood was taken, serum was immediately separated by centrifugation and then frozen at -80 °C until use. All sera were processed anonymously.

The IBDX ELISA kit was used to detect gASCA IgG, ALCA IgG, ACCA IgA, AMCA IgG, following the manufacturer's recommendations (Glycominds Ltd, Lod, Israel). The cutoff values were those supplied by the manufacturer: 50, 90, 60, 100 EUs for gASCA IgG, ACCA, ALCA, and AMCA, respectively. pANCA was performed using indirect immunofluorescence on ethanol and formalin-fixed neutrophil substrate slides.

For the titre of immune response of the anti-glycan antibodies, quartile scores for each serologic antibody were calculated, as described previously<sup>[6,13,14]</sup>. For each patient each antibody titre was assigned to a quartile score of 1 (lowest), 2, 3, or 4 (highest). By adding individual quartile scores for each glycan antigen a semi-quantitative quartile sum score (QSS) (range 4-16), representing the cumulative quantitative immune response toward all four antigens for each patient, was obtained.

### Statistical analysis

Using the suggested cut-off values for each antibody, positive or negative status was determined for each subject. In addition, antibody titres were divided into four groups based on the quartiles (see description above). Discrete parameters were assessed as percentages and

**Table 1 Subject demographics and disease characteristics n (%)**

Country	Group	Ethnicity	Group No.	Age (yr) mean ± SD	Female	Never smoker	Family history of IBD	CD (severe behaviour)	CD (ileocolonic location)	UC proctitis

CD: Crohn's disease; UC: Ulcerative colitis; Severe behaviour: Strictureing or penetrating disease.

compared using Fisher's exact or  $\chi^2$  test where appropriate. Continuous parameters were assessed as means if normally distributed (compared using one way ANOVA), and medians if not normally distributed (compared using Mann-Whitney *U* test). The software Graphpad Prism 5 and SPSS 21 were used for analyses. *P* < 0.05 was considered statistically significant.

## RESULTS

### Demographics

Ninety participants (21 CD, 32 UC, 29 healthy controls, and 8 relatives of IBD patients) were divided according to geography, ethnicity and disease (Table 1). All Asian patients were Han Chinese. There was no significant difference when comparing age or gender distribution between countries (Australian *vs* HK subjects), or ethnicities (Asian *vs* Caucasian subjects).

### CD vs non-CD (UC, healthy subjects and relatives)

**Anti-glycan antibody prevalence and number of antibodies positive:** As the anti-glycan antibodies are known to be associated with CD, we compared each CD *vs* non-CD groups in combined Australian and HK cohorts. Three (gASCA, ALCA, AMCA) of the four anti-glycan antibodies were present in a significantly higher proportion of Australian Caucasian CD compared to all non-CD subjects combined [6/9 (67%) *vs* 2/69 (3%), *P* < 0.001; 4/9 (44%) *vs* 4/69 (6%), *P* = 0.005; and 6/9 (67%) *vs* 10/69 (15%), *P* = 0.002, respectively]. In contrast, in the HK Asian CD group only AMCA had a significantly higher proportion of subjects positive compared to all non-CD groups combined [7/12 (58%) *vs* 10/69 (15%), *P* = 0.002] (Table 2).

The proportion of subjects with at least one, and at least two, antibodies positive was significantly higher in the Australian Caucasian CD group than all non-CD groups combined [9/9 (100%) *vs* 17/69 (25%), *P* < 0.001; 6/9 (67%) *vs* 5/69 (7%), *P* = 0.001]. The HK Asian CD group had a significantly higher proportion of subjects with at least one antibody positive compared to all non-CD groups combined, [7/12 (58%) *vs* 17/69 (25%), *P* =

0.035], however, only 2/12 (17%) had at least two antibodies positive. All subjects in the HK Asian CD group that had an antibody positive had AMCA as one of the antibodies.

**Anti-glycan antibody titres:** The titres of three of the four anti-glycan antibodies (gASCA, ALCA, and AMCA), and the quartile sum score (QSS), were significantly higher in the Australian Caucasian CD group than all non-CD groups combined (median titres 59 *vs* 9, *P* < 0.001; 45 *vs* 18, *P* = 0.002; 111 *vs* 67, *P* = 0.002; 14 *vs* 9, *P* < 0.001, respectively). Two of the four anti-glycan antibodies (ALCA, and AMCA), and the QSS, had significantly higher titres in the HK Asian Crohn's group than all non-CD groups combined (median titres 27 *vs* 18, *P* = 0.029; 121 *vs* 67, *P* = 0.003, 13 *vs* 9, *P* = 0.022, respectively). HK relatives did not have a significantly higher number of antibodies positive, or a higher antibody titre, than other healthy subjects.

### CD in Australian Caucasians and Hong Kong Asians

**Anti-glycan antibody prevalence and number of antibodies positive:** The proportion of subjects with positive gASCA was significantly higher in the Australian Caucasian CD group than the HK Asian CD group [6/9 (67%) *vs* 0/12 (0%), *P* < 0.001]. Prevalence of ALCA, ACCA and AMCA in Australian Caucasian CD patients [4/9 (44%), 2/9 (22%), and 6/9 (67%)] was not significantly different to the HK CD patients [1/12 (8%), 1/12 (8%) and 7/12 (58%)]. The proportion of subjects with at least one antibody, or at least two antibodies, positive was significantly higher in Australian Caucasian CD patients than the HK Asian CD patients [9/9 (100%) *vs* 7/12 (58%), *P* = 0.045; 6/9 (67%) *vs* 2/12 (17%), *P* = 0.032].

**Anti-glycan antibody titres:** A significant difference was seen when comparing gASCA titres of Australian Caucasian CD to HK Asian CD patients (median titres 59 *vs* 9, *P* = 0.002). There was no significant difference in any other antibody titre, or the QSS, between the CD patients in the two countries.

<sup>a</sup>Significantly higher than all non-Crohn's disease (CD) groups combined ( $P < 0.05$ ); <sup>b</sup>Significantly higher than Hong Kong Asian CD ( $P < 0.05$ ); <sup>c</sup>Significantly higher than all non-ulcerative colitis (UC) groups combined ( $P < 0.05$ ). gASCA: Anti-*Saccharomyces cerevisiae*; ALCA: Anti-laminaribioside carbohydrate IgG antibodies; ACCA: Anti-chitobioside carbohydrate IgA antibodies; AMCA: Anti-mannobioside carbohydrate IgG antibodies; pANCA: Atypical perinuclear anti-neutrophil cytoplasmic antibody; QSS: Quartile sum score.

### pANCA presence

The proportion of subjects with a positive pANCA in the Australian Caucasian UC group (7/10, 70%) did not differ significantly from the Australian Asian UC (5/10, 50%) and the HK Asian UC (4/12, 33%) patients. pANCA was present in 3/12 (25%) of the HK Asian CD group, but was virtually absent from all other non-UC groups. When comparing the Australian Caucasian UC patients, Australian Asian UC patients, and the HK Asian UC patients, to all non-UC subjects combined, each UC group had a statistically higher proportion of subjects with a positive pANCA ( $P < 0.001$ ,  $P = 0.002$ ,  $P = 0.025$ , respectively).

## DISCUSSION

There are very few studies reporting the prevalence of antibodies to microbial antigens in non-Western countries and between different ethnicities. This is the first report investigating anti-glycan antibodies in an Asian cohort, and the first report investigating pANCA in an Asian cohort residing in a country outside of Asia.

The prevalence of anti-glycan antibody in Australian Caucasian CD patients was consistent with previous published Western CD cohorts<sup>[14]</sup>, and were more prevalent than in all other subjects studied. The exception was ACCA which had a high prevalence in the healthy Australian Asian (33%) and Caucasian (20%) subjects, in contrast to a previously reported lower prevalence (0.5%-12%) in other healthy cohorts<sup>[2]</sup>.

gASCA was not present in any HK Asian CD subjects studied. This is in contrast to Asian data showing a similar prevalence of ASCA in Japanese<sup>[15]</sup> and South Korean<sup>[16,17]</sup> CD patients to that of Caucasian CD cohorts. A low gASCA titre was present in HK subjects. Chinese

patients in HK may not raise an antibody response to this antigen, or may do it only in low titre. Lawrence *et al*<sup>[18]</sup> directly compared a HK IBD cohort with an Australian Caucasian IBD cohort and found ASCA IgG detection was similar but IgA was lower in Chinese CD patients. This IgG detection may differ from the gASCA IgG we measured, although the two antibody measurements have been said to correlate well<sup>[6]</sup>.

Differences in prevalence of the anti-glycan antibodies may reflect true pathogenic differences in different populations. However they may still be present in some populations in low titre; this may need to be taken into account in non-Caucasian ethnicities.

AMCA was prevalent in Asian IBD patients and healthy Asian subjects. This antibody has low specificity for differentiating IBD from health in an Asian population. Bernstein *et al*<sup>[19]</sup> demonstrated a similar lack of specificity in a Canadian study of Caucasian and First Nations cohorts. He found a relatively high prevalence of IBD associated antibodies (pANCA, ASCA, anti-OmpC, anti-I2, and anti-CBir-1) in all First Nations cohorts (including controls). They concluded that these antibodies are unlikely to be of pathogenic significance.

pANCA was less prevalent in Asian UC than Caucasian UC patients. The lack of significance may relate to the small number of subjects studied and the modest difference observed. These findings are consistent with Asian UC studies from Japan (35%)<sup>[20]</sup>, South Korea (22%)<sup>[21]</sup>, and HK (44%)<sup>[18]</sup>. The prevalence in our Caucasian UC cohort was consistent with other Western UC cohorts<sup>[2]</sup>.

Our study included 8 first-degree relatives of IBD patients (all Asian from HK), six related to CD patients, and 2 to UC patients. The only 2 relatives with a positive anti-glycan antibody were related to a CD patient, and for both it was a positive AMCA. There have been no studies of

antibodies in relatives of IBD patients in Asian cohorts, however several studies have shown ASCA is present in 20%-56% of Caucasian healthy relatives of patients with CD<sup>[22-28]</sup>. None of the 8 relatives had a positive pANCA. Early studies of Caucasians demonstrated pANCA presence in 15%-30% of first degree relatives of patients with UC<sup>[29,30]</sup>, however this has not been replicated<sup>[31-36]</sup>, or not been significant when comparing to healthy non-related controls<sup>[37]</sup>.

This study has a number of limitations. Sample sizes were small; however these data provide a basis for larger confirmatory studies. Australian Caucasian CD patients had more severe disease than Hong Kong Asian CD patients which could be contributing to differences in antibodies<sup>[38]</sup>, however, because of the small numbers, comparisons between antibodies and CD phenotype were not made, but should be considered in further studies. Our lack of Australian Asian CD subjects limited our ability to separately determine the effects of ethnicity and geography. A cross sectional study on serological antibodies may be limited by changes in antibody status over time, although it appears that seropositive/seronegative antibody status remains relatively stable over time for the individual antibodies ASCA<sup>[13,14,23,38-41]</sup>, ALCA, ACCA and AMCA<sup>[14,38,42]</sup>.

In conclusion serological antibodies associated with IBD appear to differ in their presence and titre between the West and Chinese IBD patients. Caution should therefore be exercised in attributing pathogenic importance or using them as prognostic markers in different ethnic and geographic patient populations<sup>[43-45]</sup>.

## COMMENTS

### Background

Serological antibodies to enteric antigens are a hallmark of inflammatory bowel disease (IBD) and may carry pathogenic and prognostic significance.

### Research frontiers

Until two decades ago IBD was rare in Asia, but recent population-based and referral centre cohorts have shown a rising incidence and prevalence of IBD in Asia.

### Innovations and breakthroughs

Although there has been previous research on serological antibodies in Caucasian patients with IBD, there is limited information about their role and prevalence in Asian patients in Asia, or in Asian migrants to the West.

### Applications

This study has found that serological antibodies associated with IBD appear to differ in their presence and titre between Western and Chinese IBD patients. Caution should therefore be exercised in attributing pathogenic importance or using them as prognostic markers in different ethnic and geographic patient populations.

## Terminology

Anti-*Saccharomyces cerevisiae* antibodies, which are directed against the cell wall mannan of the yeast *Saccharomyces*, that shares homology with intestinal bacteria; Antigliyan antibodies, which are directed against carbohydrates found on immune cells, erythrocytes, tissue matrices and microorganisms, and likely reflect the interaction between the immune system and glycosylated cell wall components of microbiota. The anti-glycan antibodies include: anti-chitobioside, anti-laminaribioside and anti-mannobioside; Perinuclear anti-neutrophil cytoplasmic antibody is widely regarded as a marker of ulcerative colitis.

## Peer review

This is interesting data of a little studied area in inflammatory bowel disease. The subject matter may be a spring board to further studies and understanding of the pathogenesis and prognosis of IBD.

### Abstract

**AIM:** To investigate characteristics of hepatitis B virus (HBV) implicated in HBV reactivation in patients with hematological malignancies receiving immunosuppressive therapy.

**METHODS:** Serum samples were collected from 53

patients with hematological malignancies negative for hepatitis B surface antigen (HBsAg) before the start of and throughout the chemotherapy course. HBV reactivation was diagnosed when the HBsAg status changed from negative to positive after the initiation of chemotherapy and/or when HBV DNA was detected by real-time detection polymerase chain reaction (RTD-PCR). For detecting the serological markers of HBV infection, HBsAg as well as antibodies to the core antigen (anti-HBc) and to the surface antigen were measured in the sera by CEIA. Nucleic acids were extracted from sera, and HBV DNA sequences spanning the S gene were amplified by RTD-PCR. The extracted DNA was further subjected to PCR to amplify the complete genome as well as the specific genomic sequences bearing the enhancer II/core promoter/pre-core/core regions (nt 1628-2364). Amplicons were sequenced directly.

**RESULTS:** Thirty-five (66%) of the 53 HBsAg-negative patients were found to be negative serologically for anti-HBc, and the remaining 18 (34%) patients were positive for anti-HBc. Five of the 53 (9.4%) patients with hematologic malignancies experienced HBV reactivation. Genotype D1 was detected in all five patients. Four types of mutant strains were detected in the S gene product of HBV strains and were isolated from 3 patients with HBV reactivation: T/S120, L143, and I126. HBV DNA was detected in the pretreatment HBsAg-negative samples in one of the five patients with HBV reactivation. In this patient, sequences encompassing the HBV full genome obtained from sera before the start of chemotherapy and at the time of *de novo* HBV hepatitis were detected and it showed 100% homology. Furthermore, in the phylogenetic tree, the sequences were clustered together, thereby indicating that this patient developed reactivation from an occult HBV infection.

**CONCLUSION:** Past infection with HBV is a risk factor for HBV reactivation in Egypt. Mandatory anti-HBc

screening prior to chemotherapy in patients with hematological malignancies is recommended.

© 2013 Baishideng. All rights reserved.

**Key words:** Hepatitis B virus; Occult infection; Reactivation; Hepatitis B surface antigen

**Core tip:** The study aimed to investigate characteristics of hepatitis B virus (HBV) implicated in HBV reactivation in patients with hematological malignancies receiving immunosuppressive therapy in Egypt. Fifty-three hepatitis B surface antigen (HBsAg)-negative patients treated with chemotherapy were included in the study. The incidence of HBV reactivation was 9.4% among the studied cohort, and all of the affected individuals were positive for HBsAg as well as antibodies to the hepatitis B core antigen. The present study provides further evidence via molecular evolutionary analysis of the development of HBV reactivation from an occult HBV infection. Past infection with HBV is a risk factor for HBV reactivation in Egypt. Mandatory antibodies to the core antigen screening prior to chemotherapy in patients with hematological malignancies is suggested.

## INTRODUCTION

Infection with hepatitis B remains one of the major causes of acute and chronic liver disease. An estimated 350-400 million people are chronically infected with hepatitis B virus (HBV) worldwide<sup>[1]</sup>.

The reactivation of hepatitis B infection has been recorded in many clinical settings: chronic HBV infection after the cessation of HBV treatment, patients with malignant disease who receive immunosuppressant or chemotherapy, patients with end stage renal failure, and patients co-infected with human immunodeficiency virus (HIV)<sup>[2-6]</sup>. Patients with resolved HBV infection are diagnosed serologically by clearance of serum hepatitis B surface antigen (HBsAg) and the appearance of the hepatitis B core antibody (anti-HBc), with or without antibodies to hepatitis B surface antigen (anti-HBs)<sup>[7]</sup>. These patients are at risk of hepatitis B reactivation due to any factor that can suppress the immune system<sup>[8,9]</sup>. *De novo* hepatitis B is of particular concern in this subset of patients because it commonly leads to severe liver dysfunction and fatal hepatitis<sup>[10,11]</sup>.

Occult hepatitis B is defined by the presence of HBV DNA in the serum or the liver in the absence of HBsAg,

with or without anti-HBc or anti-HBs. In these patients, a low level of HBV replication has been shown to persist in the liver and in peripheral blood mononuclear cells for decades<sup>[12]</sup>. Occult HBV infection is observed worldwide, and its prevalence is related closely to the endemicity of HBV infection.

Large scale geographic heterogeneity in the prevalence of HBV had been reported worldwide. Africa is one of the highly endemic regions of HBV, and an intermediate endemicity of HBV infection had been recorded in Egypt<sup>[13,14]</sup>.

The aim of this study was to investigate the incidence of HBV reactivation and the underlying risk factors of hepatitis B reactivation in Egyptian patients who received cytotoxic chemotherapy for hematological malignancies.

## MATERIALS AND METHODS

### Patients

Fifty-nine consecutive patients with hematological malignancies were admitted to the oncology department of Sohag Faculty of Medicine and South Egypt Cancer Institution from November 2010 to October 2011. After admission, all patients underwent physical examination and blood and serum biochemistry analyses. All of patients received chest computed tomography and ultrasonography of the abdomen as an initial evaluation.

In clinical practice, patients are monitored during chemotherapy using liver function tests. HBsAg and HBV DNA are tested in patients with elevated liver enzymes. For the purpose of this study, serum samples were collected before and after the start of the chemotherapy course. The collected sera were stored at -80 °C for future examination of HBsAg, anti-HBs, and anti-HBc. HBV reactivation was diagnosed when the HBsAg status changed from negative to positive after the initiation of chemotherapy and/or when HBV DNA was detected as measured by real-time detection polymerase chain reaction (RTD-PCR) using stored samples from patients, as described latter.

### Serological markers of HBV infection

HBsAg was measured by enzyme immunoassay (EIA) (AxSYM; Abbott Japan, Tokyo, Japan) or chemiluminescence enzyme immunoassay (CLEIA) (Fujirebio, Tokyo, Japan). Anti-HBc of the IgG class was determined by radioimmunoassay (Abbott Japan). All serologic assays were performed according to the manufacturer's instructions.

### Detection and quantitation of serum HBV DNA

HBV-DNA sequences spanning the S gene were amplified by RTD-PCR according to the previously described protocol with a slight modification and a detection limit of 100 copies/mL (equivalent to 20 IU/mL)<sup>[15]</sup>.

### Sequencing and molecular evolutionary analysis of HBV

Nucleic acids were extracted from serum samples (200 µL) using the QIAamp DNA extraction kit (Qiagen, Hilden,

**Table 1 Characteristics of 53 patients with malignant hematologic disease who were negative for hepatitis B surface antigen *n* (%)**

Characteristics	Total ( <i>n</i> = 53)	Anti-HBc positive ( <i>n</i> = 18)	Anti-HBc negative ( <i>n</i> = 35)	<i>P</i> value
Age yr, mean ± SD	27.8 ± 26.2	34.4 ± 27.9	27.7 ± 25.4	0.42
Gender (male)	26 (49.1)	10 (55.6)	16 (45.7)	0.56
Diagnosis				
Malignant lymphoma	26 (40.1)	9 (50.0)	17 (48.6)	1.00
Acute leukemia	25 (47.2)	9 (50.0)	15 (42.9)	0.77
Chronic leukemia	1 (1.9)	0 (0.0)	1 (2.9)	1.00
Multiple myeloma	1 (1.9)	0 (0.0)	1 (2.9)	1.00

Anti-HBc: Antibody to hepatitis B core antigen.

Germany).

Extracted DNA was subjected to PCR for amplifying the complete genome and the specific genomic sequences bearing enhancer II /core promoter/pre-core/core regions (nt 1628-2364), as described previously<sup>[16]</sup>.

Amplicons were sequenced directly using the ABI Prism Big Dye ver. 3.1 kit in the AMI 3100 DNA automated sequencer (Applied Biosystems; Foster City, CA, United States).

All sequences were analyzed in both the forward and reverse directions. HBV genotypes were determined by molecular evolutionary analysis. Reference HBV sequences were retrieved from the DDBJ/EMBL/GenBank database and aligned by CLUSTALX, and genetic distances were estimated with the 6-parameter method in the Hepatitis Virus Database (<http://s2as02.genes.nig.ac.jp/>)<sup>[17]</sup>. Based on the obtained distances, phylogenetic trees were constructed by the neighbor-joining (NJ) method with the mid-point rooting option. To confirm the reliability of the phylogenetic trees, bootstrap resampling tests were performed 1000 times for analysis by the ODN program of the National Institute of Genetics.

**Ethical consideration**

This study was conducted in accordance with the guidelines of the Declaration of Helsinki and its subsequent amendments, and informed consent was obtained from all patients.

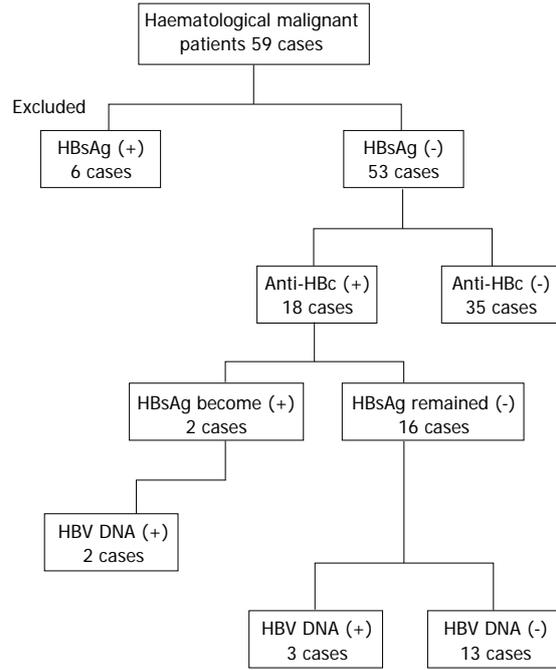

**Statistical analysis**

Statistical analysis was performed with the Fisher’s exact probability test and the independent *t* test for the continuous variables using the SPSS software package (SPSS, Chicago, IL, United States). *P* values (two-tailed) less than 0.05 were considered statistically significant.

**RESULTS**

**Patient characteristics**

Six of the 59 patients with hematologic malignancies were found to be HBsAg positive and were excluded from the analysis. Therefore, a total of 53 HBsAg-nega-

**Figure 1 Longitudinal representation of hepatitis B reactivation after chemotherapy in patients with hematological malignancies.** HBsAg: Hepatitis B surface antigen; anti-HBc: Antibody to hepatitis B core antigen; HBV: Hepatitis B virus.

tive patients were checked for the serological markers of infection with hepatitis B. The background general characteristics of the 53 HBsAg-negative patients are presented in Table 1. The mean age of the analyzed cohort was 27.8 ± 26.2 years old. Thirty-five (66%) of 53 HBsAg-negative patients were found to be anti-HBc-negative, and 18 (34%) patients were serologically positive for anti-HBc. The predominance of male patients was observed in both the anti-HBc-positive and -negative patient groups. Twenty-six patients (40.1%) were diagnosed with malignant lymphoma, whereas 25 patients (47.2%) were diagnosed with acute leukemia. Solitary cases of chronic leukemia and multiple myeloma were also included in the studied cohort. An insignificantly higher incidence of acute leukemia cases was observed in the anti-HBc-positive patients (9/18; 50%) compared with the anti-HBc-negative patients (15/35; 42.9%).

**Consequences of HBV serology after receiving anti-cancer treatment**

After the initiation of systemic chemotherapy, examination of the HBV serology revealed that two (3.8%) of the HBsAg-negative patients became serologically positive for HBsAg. In addition, 3 more patients (5.8%) exhibited detectable HBV DNA in their sera after the start of the anticancer therapy (Figure 1). Interestingly, none of the serologically negative patients for anti-HBc became serologically positive for HBsAg or molecularly detectable for HBV DNA. In contrast, 2 of the 18 anti-HBc-positive patients (11.1%) became serologically positive for the HBsAg, and 3 (16.7%) became molecularly detectable for the HBV DNA. In brief, 5 of the 53 HBsAg negative

M: Male; F: Female; NHL: Non-Hodgkin lymphoma; AML: Acute myeloid leukemia; ALL: Acute lymphoblastic leukemia; HBsAg: Hepatitis B surface antigen; Anti-HBs: Antibody to hepatitis B surface antigen; CVP: Cyclophosphamide, vincristine, prednisone; ALT: Alanine amino transferase enzyme. <sup>1</sup>St Jude protocol: (1) prephase: vincristine + steroid; (2) induction: vincristine + fludarabine + aracytine + etoposide, intrathecal; (3) consolidation: high dose methotrexate + mercaptopurine; (4) continuation: methotrexate + mercaptopurine.

patients (9.4%), representing 27.8% (5/18) of the anti-HBc-positive patients in the studied cohort, manifested the criteria of HBV reactivation (Figure 1).

### Clinical and virological criteria of the patients who manifested HBV reactivation

Five of the 53 patients (9.4%) treated for hematologic malignancies manifested HBV reactivation throughout the anti-cancer therapy regimen. The demographic, clinical and virological criteria of the HBV infection of the five patients who experienced HBV reactivation are summarized in Table 2 (cases 1-5). The mean age of the five patients was  $24.6 \pm 30.9$  years old. Three of the patients were males (cases 2, 4 and 5), and two were females. Four patients were diagnosed with acute leukemia (cases 2-5), and only one patient (case 1) was diagnosed with malignant lymphoma. All of the 5 patients received a steroid regimen as a part of their anticancer therapy. All 5 patients were positive for anti-HBc. Three patients were positive for anti-HBs (cases 1, 2 and 4), and only one patient was serologically negative for the anti-HBs (case 3). Because of small volume of serum sample obtained from case 5, anti-HBs could not be tested. After HBV reactivation, two cases (cases 2 and 4) exhibited abnormal ALT levels, and one patient (case 2) experienced a more than 3-fold increase in the ALT level, indicating the emergence of hepatitis in this patient. None of the 5 cases who experienced had the HBV reactivation after cancer chemotherapy received an antiviral treatment for HBV.

The virological and molecular criteria are summarized in Table 2. The infecting genotype of the HBV strains was HBV genotype D, subtype D1 in all five cases. Two core promoter HBV variants were detected in 2 patients.

The two variants were T1764/G1766 and A1764 in cases 2 and 3, respectively. The stop codon pre-core HBV mutant (A1896) was detected in one patient (case 1).

Infection with HBV mutant strains in the S gene product was detected in 3 patients. The amino acid escape mutant strains are as follows: S120 and L143 (case 1), T120 (case 2) and I126 (case 4). Four types of mutant strains (T/S120, L143, and I126) were detected in the S gene strains of 3 patients (cases 1, 2 and 4, respectively).

### DNA sequencing and phylogenetic analysis

HBV DNA was quantified retrospectively by RTD-PCR in the stored samples of the five patients with HBV reactivation. Evidence of occult HBV infection at the time of the HBsAg-negative status (before the start of anti-cancer therapy) was detected by RTD-PCR in one patient (case 1). To determine the source of HBV infection, sera from case 1 before (case 1-A) and at the time of HBV reactivation (case 1-B) were subjected to HBV full genome amplification and sequencing. Sequences encompassing the HBV full genome obtained from sera before the start of chemotherapy and at the time of *de novo* HBV hepatitis revealed 100% homology, and the two sequences clustered together in the phylogenetic tree (Figure 2). These results demonstrate that case 1 developed reactivation from an occult HBV infection.

## DISCUSSION

This study is considered the first step in documenting and characterizing the reactivation of hepatitis B in Egypt among patients negative for the HBsAg who received immunosuppressive therapy. The current study presented

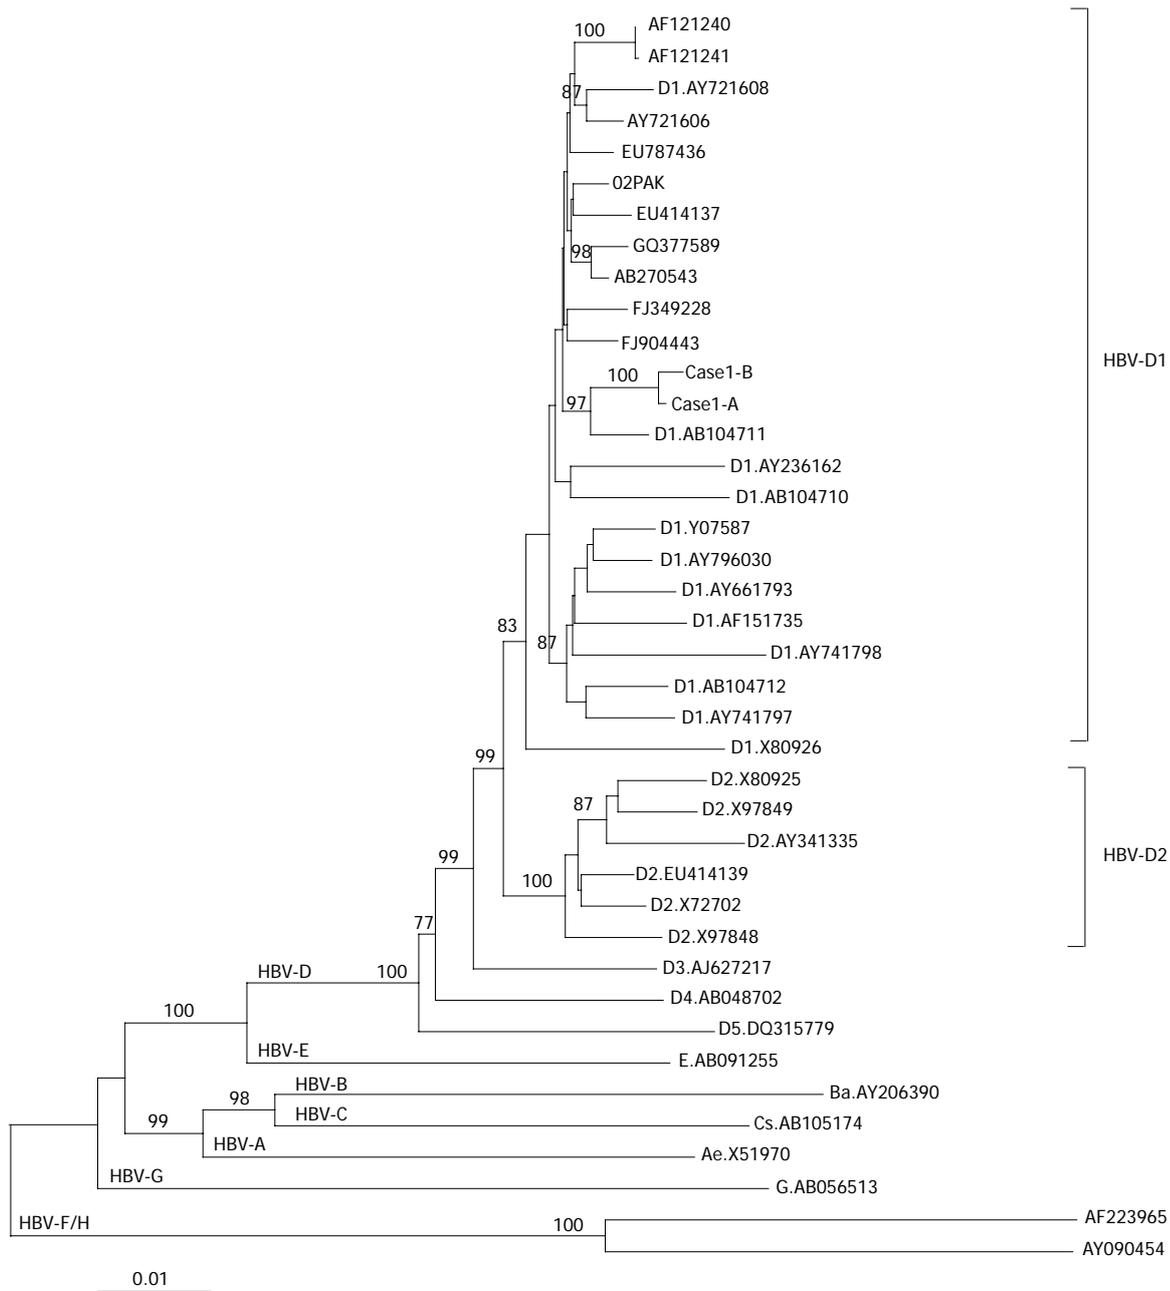

Figure 2 The complete genome of the hepatitis B virus was isolated and sequenced (case 1) prior to the start of chemotherapy (case 1-A) and after the emergence of hepatitis B virus reactivation (case 1-B). The phylogenetic analysis demonstrated that the patient (case 1) developed an hepatitis B virus (HBV) reactivation of an occult HBV infection.

further evidence that resolved hepatitis B infection and occult HBV infection may represent a hidden risk factor for the development of *de novo* hepatitis B.

The incidence of hepatitis B reactivation in the HBsAg-negative group was 9.4%, and all cases of reactivation occurred in patients with resolved or past infection with hepatitis B, as evidenced by the absence of HBsAg and the serological detection of anti-HBc. The patients who had HBV reactivation represent 27% of the HBsAg-negative/anti-HBc-positive patients. This incidence was comparable to the incidence that was described by Hui *et al.*<sup>[18]</sup>. In their study, Hui *et al.*<sup>[18]</sup> described an HBV reactivation incidence of 3.3% (8/244) in their studied cohort,

which included HBsAg-negative lymphoma patients receiving systemic chemotherapy. Of note, all 8 patients were seropositive for either anti-HBc or anti-HBs antibody. Recently, Matsue *et al.*<sup>[19]</sup> conducted a retrospective study on consecutive patients with CD20-positive B cell lymphoma before and after rituximab-containing treatment. In the latter study, 5 out of 230 patients negative for HBsAg (2.2%) experienced HBV reactivation, representing an incidence of 8.9% of the anti-HBc-positive patients<sup>[19]</sup>. In a prospective observational study of patients with hematological malignancies (a study cohort similar to the current study), Francisci *et al.*<sup>[20]</sup> reported the incidence of HBV reactivation was (18%), which is close

to that detected in the present study. The reasons for the difference in the incidence in HBV reactivation among different studies remain to be elucidated. However, the intensity of treatment, patient characteristics, and geographic differences in HBV prevalence and its genotypes may account for these differences<sup>[21]</sup>. Furthermore, the lack of a clear definition of HBV reactivation should not be ignored as a possible explanation for this variation in the incidence. In this study, the inclusion of patients who had detectable HBV DNA after cancer chemotherapy plus patients who exhibited HBsAg seroconversion after receiving the anticancer therapy dramatically increased the incidence of HBV reactivation among the studied cohort. This criterion of including cases with detectable HBV DNA after cancer chemotherapy as a sign of HBV reactivation was not used to define cases with HBV reactivation in the related studies<sup>[18,19]</sup>. The variations in the cohort size among the different studies cannot be ignored as a possible factor that may be implicated in such discrepancy.

Occult HBV infection is defined by the detection of HBV DNA in the sera or in the livers of serologically HBsAg-negative patients<sup>[14]</sup>. Until recently, the clinical effects of occult HBV infection were unclear regarding the influence on the progression of liver disease, the development of hepatocellular carcinoma, the risk for HBV reactivation, and the transmission of HBV infection<sup>[22]</sup>. The underlying mechanisms for the pathogenesis of occult HBV infection may be due to either viral or host factors<sup>[23]</sup>. One of the important viral factors is the presence of mutations in the HBV DNA sequence, which may interfere with the detection of HBsAg by the commercial assays, *i.e.*, “escape mutations”<sup>[24]</sup>. In the present study, 4 types of possible escape mutants were detected in 3 of the 5 patients who experienced HBV reactivation<sup>[25]</sup>. Previous *in vitro* studies have reported that escape mutations are associated with an increased immune evasive capacity and are capable of causing symptomatic flare up and high viral loads<sup>[26]</sup>. Furthermore, studying the viral genome isolated from case 1 revealed a complete match of the sequences obtained before the start of chemotherapy and at the time of reactivation. The present study provides further evidence of the emergence of HBV reactivation of occult hepatitis B as confirmed by the molecular evolutionary analysis<sup>[27]</sup>. Furthermore, two amino acid escape mutations in the S gene product, P120S and S143L, were detected in the HBV viral genome isolated from case 1.

Patients with malignancies in Egypt are monitored only by testing ALT levels throughout the chemotherapy course. Therefore, the present study, which is the first to explore HBV reactivation in Egypt, suggests mandatory serological screening for anti-HBc and anti-HBs in patients planning to receive immunosuppressant therapy. Patients found to be positive for anti-HBc, particularly patients who are negative for anti-HBs, should be closely monitored with HBsAg, HBV DNA and serum biochemistry during chemotherapy and for at least 6 mo after the completion of therapy. Further prospective multicenter studies are needed to explore the incidence

and risk factors of HBV reactivation in Egypt. Further studies are recommended to determine whether specific genomic mutations are implicated in *de novo* hepatitis in this subset of patients infected with HBV genotype D1.

## COMMENTS

### Background

The reactivation of hepatitis B is a syndrome characterized by an abrupt appearance or rise of the hepatitis B virus (HBV) DNA in the sera of patients with resolved or inactive hepatitis B infection. Reactivation can be spontaneous but is typically triggered by cancer chemotherapy, immune suppression or alterations in immune system function. Hepatitis B reactivation is of special clinical concern in immunocompromised patients because it leads to severe liver dysfunction and hepatic failure. However, hepatitis B reactivation is easy to prevent by introducing a prophylactic oral antiviral therapy. Occult hepatitis B is defined by the presence of HBV DNA in the serum or the liver in the absence of Hepatitis B surface antigen (HBsAg) with or without hepatitis B core antibody (anti-HBc) or antibodies to HBV surface antigen (anti-HBs). These patients are at risk of developing hepatitis B reactivation due to any factor suppressing the immune system. In Egypt, patients receiving cancer chemotherapy are typically monitored by liver function tests, with no screening for HBsAg or HBV DNA except in cases with elevated liver enzymes. This study aimed to investigate the incidence of HBV reactivation and the underlying risk factors of reactivation in Egyptian patients with hematological malignancies who were receiving cancer chemotherapy.

### Research frontiers

In a cohort of 53 patients with hematological malignancies receiving cancer chemotherapy who were negative for HBsAg, 18 patients (34%) were found to be positive for the anti-HBc, and five of the 53 (9.4%) patients with hematologic malignancies experienced HBV reactivation. All five patients were positive for anti-HBc. HBV DNA was detected in pretreatment HBsAg-negative samples in one of the five patients with HBV reactivation. In this patient, sera were obtained before the start of chemotherapy and at the time of *de novo* HBV hepatitis; the molecular evolutionary analysis of the sequences encompassing the HBV full genome obtained from the sera revealed that this patient developed reactivation from an occult HBV infection.

### Innovations and breakthroughs

This study is the first in Egypt to characterize HBV reactivation in Egypt. The study introduces more evidence through molecular evolutionary analysis that occult HBV infection is a risk factor for reactivation of hepatitis B in patients with hematological malignancies receiving cancer chemotherapy.

### Applications

The study strongly recommends mandatory serological screening for anti-HBc and anti-HBs in this subset of patients before the commencement of chemotherapy. Patients found to be positive for anti-HBc, particularly patients who are negative for anti-HBs, should be closely observed for signs of HBV reactivation through the regular monitoring of HBsAg and HBV DNA.

### Peer review

In the study, performance of sequencing and molecular analysis of HBV genomes seems relevant in characterization of the strains associated with HBV reactivation. Their findings are significant and beneficial for the readers.

### Abstract

**AIM:** To evaluate the efficacy and safety of grasper type scissors (GTS) for endoscopic submucosal dissection (ESD) of gastric epithelial neoplasia.

**METHODS:** The study was performed by 4 endoscopists in 4 institutions affiliated to The Catholic University of Korea. ESD was performed in 76 consecutive patients with gastric epithelial neoplasia by using the GTS (37 patients) or the hook knife plus coagrasper (HKC) (39 patients). The complete resection rate, complication rate, total time elapsed and elapsed time per

square centimeter of the dissected specimen were analyzed between the GTS and HKC group.

**RESULTS:** The mean age of the GTS group was  $62.3 \pm 11.4$  years and mean age of the HKC group was  $65.6 \pm 10.1$  years. Differentiated adenocarcinoma was found in 32.4% in the GTS group and 33.3% in the HKC group. The procedures were performed without interruption in every case in both groups. The *en bloc* resection rates of both groups were 100%. The total time elapsed during the procedure was  $44.54 \pm 21.72$  min in the GTS group and  $43.77 \pm 21.84$  min in the HKC group ( $P = 0.88$ ) and the time elapsed per square centimeter of the resected lesion was  $7.53 \pm 6.35$  min/cm<sup>2</sup> in the GTS group and  $6.92 \pm 5.93$  min/cm<sup>2</sup> in the HKC group ( $P = 0.66$ ). The overall complication rate was not significantly different between the two groups.

**CONCLUSION:** GTS is a safe and effective device for ESD compared with HKC. ESD can be performed with GTS alone, which can reduce the costs for ESD.

**Key words:** Gastric epithelial neoplasia; Endoscopic submucosal dissection; Grasper type scissors; Hook knife; Coagrasper

**Core tip:** Many types of knives have been developed and used for endoscopic submucosal dissection (ESD). We modified the grasping type scissors forceps and developed a novel grasper type scissors (GTS). The aim of this study was to evaluate the efficacy and safety of GTS compared to hook knife plus coagrasper (HKC) for ESD of gastric epithelial neoplasia. The procedures were performed without interruption in every case in both groups. GTS is a safe and effective device for ESD of gastric epithelial neoplasia compared with HKC. ESD can be performed with GTS alone, which can reduce the costs for ESD.

## INTRODUCTION

Endoscopic mucosal resection (EMR) is an endoscopic technique developed for removal of sessile or flat neoplasms confined to the superficial layers (mucosa and submucosa) of the gastrointestinal tract. EMR is typically used for removal of lesions smaller than 20 mm. *En bloc* resection of lesions larger than 20 mm is difficult by EMR thus increasing the risk of local recurrence<sup>[1-4]</sup>. Newly developed endoscopic techniques and devices have helped to overcome the limitations of EMR in terms of lesion size, location, and presence of fibrotic scarring.

Endoscopic submucosal dissection (ESD) allows *en bloc* resection of larger (usually more than 20 mm) lesions as well as subepithelial gastrointestinal lesions<sup>[5]</sup>. Various cutting devices - insulated tipped (IT) knife, hook knife, flex knife, triangular knife, and fork knife and so on-have been developed. Grasping-type scissors forceps (GSF) have a 0.8-mm-wide and 6-mm-long serrated cutting edge to facilitate the grasping of tissues. The outer side of the forceps is insulated and the forceps are able to rotate to the desired location. GSF can be used for excision by accurately gripping the submucosal tissue of the target lesion<sup>[6-8]</sup>. This device has been used safely and effectively for ESD in other organs such as the colorectum and duodenum<sup>[9-12]</sup>. However, it was not designed for cutting tissues and sometimes it was not optimal when used for dissecting lesions. Furthermore, rotating the GSF to the desired location is frequently difficult.

The newly developed grasper type scissors (GTS) can grasp and cut a piece of tissue using an electrosurgical current. Unlike GSF, the tip of the knife is not insulated and has a thin cutting blade to facilitate submucosal dissection. Theoretically, it possesses both advantages of the GSF and the flex knife.

The aim of this study was to evaluate the efficacy and safety of the novel GTS knife, which can be used for both dissection and hemostasis, for ESD of gastric epithelial neoplasia and compare it to hook knife plus coagrasper (HKC), which is one of the most commonly used knives in South Korea.

## MATERIALS AND METHODS

### Ethical consideration

The advantages and disadvantages of ESD with GTS, as well as alternative endoscopic options (*e.g.*, ESD with a conventional device, EMR) were discussed with each pa-

tients. All patients gave their written informed consent to the designated intervention. This study protocol was approved by the Institutional Review Board of The Catholic University of Korea.

### Patients

Patients with gastric epithelial neoplasia were consecutively enrolled between May 2010 and April 2012. The study was a prospective, randomized, multi-center, comparative trial. It was performed by 4 endoscopists in 4 institutions affiliated with The Catholic University of Korea (Incheon St. Mary's Hospital, St. Vincent's Hospital, Seoul St. Mary's Hospital, and Bucheon St. Mary's Hospital). All of the endoscopists were experienced with ESD and had performed ESD in over 200 cases. Before this study, two endoscopists (Kim BW, Lim CH) had used hook knife as the main device and the other two endoscopists (Chung WC, Kim TH) had used flex knife as the main device.

Adults (> 18 years) with histopathologic diagnosis of gastric epithelial neoplasia and without evidence of lymph-node involvement documented by abdominal computed tomography (CT) and/or endoscopic ultrasound (EUS) were included in this study. The lesions met the expanded criteria for local resection proposed by Gotoda<sup>[5,13,14]</sup>. Differentiated mucosal cancers of any size without ulceration or scarring, differentiated mucosal cancers < 30 mm in diameter with ulceration or scarring, or differentiated cancers with minimal submucosal invasion (< 500  $\mu$ m deep in the submucosa starting from the muscularis mucosae) were enrolled. The diameter of the lesions without ulcers was limited to a maximum of 60 mm. Patients with conditions that might have substantial effects on our study results (*e.g.*, serum creatinine > 2.5 mg/dL, total bilirubin > 3.0 mg/dL, platelet < 100000/mm<sup>3</sup>), patients who were consuming anti-platelet agents, patients with a history of previous gastric surgery and patients who did not consent to the study were excluded.

### Sample size

An estimated sample size of 37 subjects per group would give an 80% power to detect a difference in resection rate of the GTS compared to the HKC (assumed to have a complete resection rate of 90%), with a two-sided  $\alpha = 0.05$ . With a 10% drop out rate, 40 patients had to be recruited for each group.

### Randomization

All patients were randomly assigned to receive one of the knives-hook knife (Olympus; Tokyo, Japan) plus coagrasper (Olympus; Tokyo, Japan) or grasper type scissors (Alton Medical Instruments; Shanghai, China) (Figure 1) after evaluation with abdominal CT and/or EUS. Randomization codes (A-1 to A-10, B-1 to B-10) were packed into sealed opaque envelopes by an individual, who was not involved in screening and enrolment of the subjects to ensure concealment of allocation. In each of the study institute, twenty patients were enrolled.

Figure 1 Distal tip of the grasper type scissors. GTS has teeth inside the device and the outer side is not insulated. GTS: Grasper type scissors.

### Grasper type scissors

The diameter of the scissors is 2.4 mm and the serrated cutting edges are 4-mm-long. The outer side of the forceps except the tip is insulated so that electrosurgical current energy is concentrated at the blade to avoid burning the surrounding tissue. Unlike GSF, the tip of this knife is not insulated and has a thin cutting blade, so that it can facilitate the dissection of submucosal layer such as a flex knife. Furthermore, the forceps can be rotated to the desired location.

### Endoscopic submucosal dissection

A conventional gastroscope (GIF-Q240J or GIF-H260Z; Olympus, Tokyo, Japan) fitted with a transparent distal attachment (D-201-11304, Olympus) was used for the ESD procedures regardless of the ESD devices. Patients were sedated with intravenous midazolam (0.1 mg/kg) while in the endoscopic suite, and conscious sedation was maintained with additional injections during the procedure. After spraying indigo carmine dye, circumferential markings using argon plasma coagulation were made at 5 mm distances around the outside margin of the lesion, with 2 mm intervals between each marking dot. Hypertonic saline/epinephrine solution (1:10000) and indigo carmine mixture was injected into the submucosal layer until the mucosa was raised and additional injections were repeated as necessary during the procedure. After the lesion was lifted, mucosal incision was performed by using each type of knife and an electrosurgical generator (Erbe; Tübingen, Germany). Electrical current was set as endocut-I for hook knife and as endocut-Q for GTS. After incision around the lesion, dissection was conducted with either the hook knife or GTS (Figure 2).

Electrical current was set as forced coagulation for hook knife and as swift coagulation for GTS. When bleeding occurred during dissection, saline irrigation was performed. If the endoscopist performed the procedure with a hook knife, coagrasper was used for hemostasis according to the endoscopists' instructions, with an electrical current of 80 W for soft coagulation. With GTS, hemostasis was performed with an electrical current of

80 W for soft coagulation mode.

### Measurements

We compared the endoscopic appearance of tumors, location of tumors, *en bloc* resection rate, complete resection rate, size of resected specimens, histopathologic findings, operation time, and complication rates between the two groups. Complete resection was defined as lateral and vertical margins of the specimen being free from tumor involvement. Marking of the first dot and withdrawal of the endoscope were measured as the procedure time.

Bleeding was identified when melena, hematochezia, or the presence of fresh bloody vomitus along with a decreased hemoglobin levels of more than 2 g/dL were present after the resection. Perforation was identified by endoscopy during or just after the procedure and/or by the presence of intraperitoneal free air on plain abdominal radiography after the procedure.

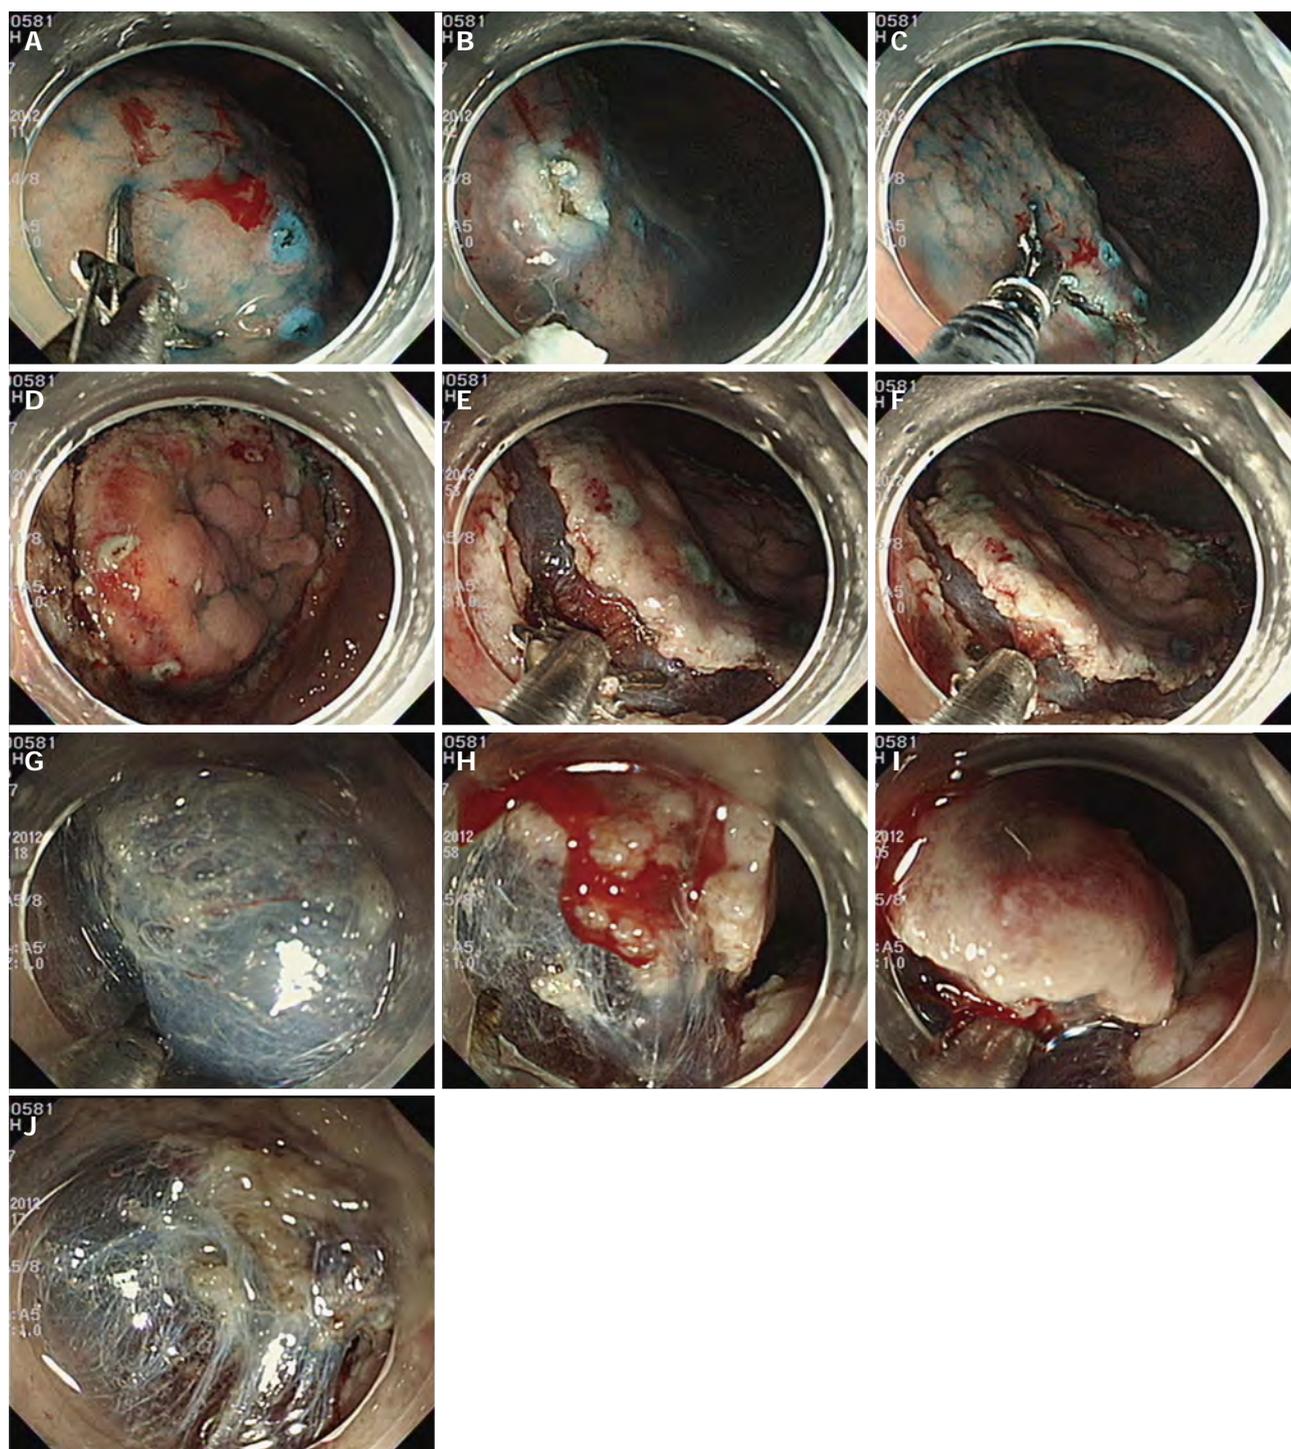

### Statistical analysis

All data were recorded on standard forms and computer analyzed. The Student *t* test was used to compare continuous variables between the groups. Differences between dichotomous variables were evaluated with the  $\chi^2$  test. The calculations were performed with the SPSS software (SPSS version 12.0, Chicago, IL, United States). Null hypotheses of no difference were rejected if *P* values were less than 0.05.

## RESULTS

A total of 78 patients were enrolled and 76 patients (37 patients of GTS knife group and 39 patients with HKC group) completed this study. Since over 37 patients in each group completed this protocol, additional enrollment was not conducted. One patient dropped out of the study because undifferentiated cancer was found in the resected specimen. Another patient with extensive submucosal infiltration ( $> 500 \mu\text{m}$  deep in the submucosa starting from the muscularis mucosae) was also dropped out of the study. Both patients underwent additional surgery after ESD.

The mean age of the GTS group was  $62.3 \pm 11.4$  years and mean age of the HKC group was  $65.6 \pm 10.1$  years (Table 1). There was no significant difference in age and sex ratio between the two groups. Differentiated adenocarcinoma was found in 32.4% in the GTS group and 33.3% in the HKC group. The pathologic distribution and mean size of the resected specimens were not different between the two groups. The area of the resected specimens was  $8.30 \pm 4.52 \text{ cm}^2$  in GTS group and  $8.59 \pm 4.43 \text{ cm}^2$  in HKC group. The depth of tumor distribution was not different between the two groups (94.6% of mucosal layer in the GTS group, 92.3% in the HKC group). With regard to tumor location, 64.9% (24/37 cases) were located at the antrum in the GTS group and 71.8% (28/39 cases) in the HKC group. The locations were not significantly different between the two groups. The total time

**Figure 2** Procedure of endoscopic submucosal dissection with distal tip of the grasper type scissors. A: Grasper type scissors (GTS) is ready for puncture; B: Puncture was completed with GTS; C: Incision is conducted with GTS; D: Complete incision was performed with GTS; E: Submucosal dissection is ready with GTS; F: Submucosal dissection is conducted by grasping the submucosal layer; G: Submucosal dissection is conducted with blade of the GTS just like a flex knife; H: Hemorrhage from the submucosal layer is noted; I: Bleeding focus was grasped with GTS; J: Bleeding was controlled after coagulation with GTS.

elapsed during the procedure was  $44.54 \pm 21.72$  min in the GTS group and  $43.77 \pm 21.84$  min in the HKC group ( $P = 0.88$ ). The time elapsed per square centimeter of the resected lesion was  $7.53 \pm 6.35$  min/cm<sup>2</sup> in the GTS group and  $6.92 \pm 5.93$  min/cm<sup>2</sup> in the HKC group ( $P = 0.66$ ). The *en bloc* resection rate was 100% in both groups. The overall complication rate was 5.41% (2/37 cases)

in the GTS group and 7.69% (3/39 cases) in the HKC group ( $P = 0.68$ ).

In Korea, the prices of the knives used for ESD are the same. GTS and hook knife cost about 199240 Won (about 185 dollars) and coagrasper cost about 210000 Won (about 191 dollars). HKC are about double in cost compared to GTS alone.

**Table 1** Characteristics of the enrolled patients *n* (%)

Characteristics	GTS	HKC	<i>P</i> value

## DISCUSSION

Conventional EMR was previously recommended as a curative local treatment for early gastric cancer<sup>[15,16]</sup>. To achieve curative resection with adequate margins, the excisions need to be large enough. When piecemeal resection occurs, electro-cautery across the specimens could affect the accuracy of assessment of the lateral margins and this could result in a higher risk of local recurrence. ESD is intended to perform large mucosal resections and improves the rate of successful *en bloc* resection of an early stage gastrointestinal neoplasia<sup>[17,18]</sup>. To date, novel devices have been developed for the completion of *en bloc* resection with adequate margins. However, many endoscopists are eager for the development of devices that allow more effective and faster procedures. In this study, we aimed to introduce and to evaluate the efficacy and technical aspects of the GTS.

Since GSF is ideally designed for both incising the targeted tissue and hemostasis, we tried to improve the device by improving its effect during dissection. Theoretically, the advantage of GSF for ESD is that the device can prevent unexpected incisions. By elevating the lesion during dissection, GSF provides good visualization of

the submucosal layer. However, GSF has the disadvantage that it cannot be opened when using a conventional cap because of the small cap diameter. Therefore, a special hood is required when using the GSF. We modified the GSF and developed the GTS, which can accurately grasp and incise the targeted tissue using electrosurgical current. It is smaller than GFS so that it can be used with the conventional transparent cap. The most important difference between GTS and GSF is that the tip of GTS is not insulated and has a thin cutting blade, so that it can facilitate the dissection of the submucosal layer.

Most of the knives are designed for cutting or dissection, but they are not adequate for hemostasis during the ESD procedure. The use of additional instruments increases the cost and requires more procedure time because it takes time to change the instruments. The scissor-type device makes it possible to perform dissection and hemostatic procedures without changing the devices. In this study, we compared the novel GTS, which can be used for both dissection and hemostasis, with HKC for ESD of gastric epithelial neoplasia. We compared these knives because HKC is one of the most commonly used devices for ESD in Korea. In our results, the elapsed time did not differ significantly between GTS and HKC and the procedure time was not saved by using the GTS. This result may have been caused by various factors such as the fact that the endoscopists of this study were not experienced with the new instrument. Furthermore, 2 of the endoscopists had been using the HKC and were familiar with this device which may have affected the procedure time. It is known that there is a learning curve for ESD and that experience of the procedure shortens the procedure time<sup>[19,20]</sup>. We believe that increased experience with the GTS will reduce the procedure time. Nonetheless all the lesions were removed successfully with the GTS by the 4 endoscopists, which suggest that any experienced endoscopists can complete the whole ESD procedure with the GTS. Feasibility of ESD for gastric epithelial neoplasia with the GTS in beginners should be elucidated in the future.

One case of perforation occurred in the GTS group which might have been prevented if a knife with an insulated body such as GSF was used. The perforation rates of ESD while using different types of knives were reported to be 4%-10%<sup>[21-24]</sup>, which is similar to the perforation rates of our result. A decrease in hemoglobin level over 2 g/dL per day after the procedure was the same in both groups. Thermal and mechanical tissue damage at the GTS-tissue interface was expected because GTS is larger compared to the hook knife. However, contrary to our expectations, GTS did not interfere with the pathologists' interpretation of the specimens and complete resections with adequate margins were obtained pathologically with GTS.

There are some limitations in this study. We designed this device to reduce the procedure time, but the sample size was limited and we could not figure it out. Four experienced endoscopists participated in this study and the

procedure times by beginners also should be examined. Further studies with larger sample sizes are anticipated to show other benefits of this device.

In conclusion, ESD for gastric epithelial neoplasia can be performed with GTS alone regardless of size and location of the lesion when the endoscopists are experienced. GTS is a safe and effective device for ESD of gastric epithelial neoplasia when compared to HKC. ESD can be performed with GTS alone, which can reduce the costs. Further experiences and large scaled studies would be anticipated to compare the various devices.

## COMMENTS

### Background

Various cutting devices have been developed for endoscopic submucosal dissection (ESD). Most of these knives are designed for dissection of the submucosa and sometimes are not adequate for control hemorrhages developed during the procedure. The authors recently designed a new device, grasper type scissors (GTS) both for dissection and control hemorrhages.

### Research frontiers

Grasping-type scissors forceps (GSF) was developed by Akahoshi *et al* for dissection and control hemorrhages. However, it requires a special hood and rotating the device is frequently difficult because of the size. The safety and effectiveness of GSF was performed in a single center.

### Innovations and breakthroughs

The most important difference between GTS and GSF is that the tip of GTS is not insulated and has a thin cutting blade, so that it can facilitate the dissection of the submucosal layer. The safety and effectiveness of GTS was evaluated in multi-centers in this study.

### Applications

This study suggests that ESD for gastric epithelial neoplasia can be performed with GTS alone regardless of size and location of the lesion when the endoscopists are experienced.

### Peer review

The authors developed a novel device which was modified from GSF, GTS, for ESD of gastric neoplasia. In this study, GTS resolved several disadvantage of GSF and clearly succeeded to reduce the cost of ESD. This study is very interesting, exciting and useful for all endoscopists.

### Abstract

**AIM:** To isolate biliary lipid-carrying vesicles from isolated perfused rat livers after taurohyodeoxycholic acid (THDC) infusion. Biliary lipid vesicles have been implicated in hepatic disease and THDC was used since it increases biliary phospholipid secretion.

**METHODS:** Rat livers were isolated and perfused *via* the hepatic portal vein with THDC dissolved in Krebs Ringer Bicarbonate solution, pH 7.4, containing 1 mmol/L CaCl<sub>2</sub>, 5 mmol/L glucose, a physiological amino acid mixture, 1% bovine serum albumin and 20% (v/v) washed human erythrocytes at a rate of 2000 nmol/min for 2 h. The livers were then removed, homogenized and subjected to centrifugation, and the microsomal fraction was obtained and further centrifuged at 350000 *g* for 90 min to obtain subcellular fractions. These were analyzed for total phospholipid, cholesterol, protein and alkaline phosphodiesterase I (PDE).

**RESULTS:** No significant changes were observed in the total phospholipid, cholesterol and protein contents of the gradient fractions obtained from the microsomal preparation. However, the majority of the gradient fractions ( $\rho = 1.05-1.07$  g/mL and  $\rho = 1.95-1.23$  g/mL) obtained from THDC-infused livers had significantly higher PDE activity compared to the control livers. The low density gradient fraction ( $\rho = 1.05-1.07$  g/mL) which was envisaged to contain the putative vesicle population isolated from THDC-perfused livers had relatively small amounts of phospholipids and protein when compared to the relevant control fractions; however, they displayed an increase in cholesterol and PDE activity. The phospholipids were also isolated by thin layer chromatography and subjected to fractionation by high performance liquid chromatography; however, no differences were observed in the pattern of the fatty acid composition of the phospholipids isolated from THDC and control perfused livers. The density gradient fractions ( $\rho = 1.10-1.23$  g/mL) displayed an increase in all the parameters measured from both control and THDC-infused livers.

**CONCLUSION:** No significant changes in biliary lipids were observed in the fractions from THDC-infused livers; however, PDE activity was significantly increased compared to the control livers.

© 2013 Baishideng. All rights reserved.

**Key words:** Taurohyodeoxycholic acid; Phospholipids; Biliary cholesterol; Bile; Vesicles

**Core tip:** Bile contains various constituents including cholesterol and phospholipid, mainly phosphatidylcholine with a unique fatty acid composition of 1-palmitoyl 2-linoleyl (16:0-18:2) phosphatidylcholine and 1-palmitoyl 2-oleoyl (16:0-18:1). These biliary lipids are transported in vesicles from a specific intra-hepatic pool and an increase in biliary lipid-carrying vesicles may have

implications for hepatic diseases such as gallstone formation. Taurohyodeoxycholic acid (THDC) stimulates the secretion of biliary phospholipids; hence THDC-infused rat livers were subjected to ultracentrifugation in order to isolate these phospholipid-carrying vesicles. The isolation of these biliary lipid-carrying vesicles was not successful; however, vesicles enriched in PDE activity were obtained.

## INTRODUCTION

Phospholipids and cholesterol are synthesized in the hepatocytes and are thought to be transferred into bile by vesicular and non-vesicular mechanisms. Biliary lipids mainly consist of cholesterol and phospholipids and their secretion into bile is effected by secretion of bile salts<sup>[1]</sup>. Hepatocytes acquire biliary lipid by three pathways namely biosynthesis, lipoproteins and existing lipid molecules drawn from intracellular membranes and newly synthesized biliary lipids; these account for less than 20% of the total lipids<sup>[2]</sup>.

The majority of biliary phospholipid is phosphatidylcholine (PC) with distinct fatty acid composition, namely 1-palmitoyl 2-linoleyl (16:0-18:2) PC and 1-palmitoyl 2-oleoyl (16:0-18:1), whereas hepatocyte PC contains significant amounts of different phospholipid classes<sup>[3,4]</sup>. Very few studies have been performed on biliary lipid transport in hepatocytes<sup>[5,6]</sup>, whereas numerous studies have been performed on bile, its formation and composition especially related to lipids, and these studies have identified several physical forms of lipid carriers, including biliary vesicles<sup>[7,8]</sup>.

The main source of biliary lipid, before its appearance in bile, has been suggested to be the bile canalicular membrane where it is removed by the detergent action of bile salts. These lipids are then thought to be continuously replaced from within the cell, probably *via* vesicular transport, for biliary lipid secretion to continue without damage to the liver and canalicular membrane<sup>[9]</sup>. In support of this, inhibitors of microtubular function such as colchicine and vinblastine have been shown to reduce biliary lipid secretion<sup>[10-12]</sup>. Such vesicles supplying lipids to the plasma membrane have also been shown and isolated in other cell types, thus, it can be postulated that biliary lipid is probably supplied to the canalicular membrane *via* such vesicles. This is supported by the fact that increased numbers of vesicles have been observed accumulating near the bile canaliculus during extensive bile acid secretion<sup>[2,9,13-15]</sup>. The isolation of putative biliary lipid-carrying vesicles, however, is difficult due to the wide range of

vesicle types in hepatocytes, and the difficulty of identifying them because of inadequate criteria.

Hepatic ATP-binding cassette half-transporter genes 5/8 (*ABCG5* and *ABCG8*) are expressed in the canalicular membrane of hepatocytes and have an essential role in biliary cholesterol secretion<sup>[16-19]</sup>. However, the pathways involved in trans-hepatic cholesterol trafficking into bile are still not clear and a specific cholesterol transport protein has not been confirmed in hepatocytes. Biliary cholesterol secretion is important for the two important disease complexes of atherosclerotic cardiovascular disease (CVD) and gallstone disease<sup>[1]</sup>. In atherosclerotic CVD, biliary cholesterol secretion is thought to be the final step in the completion of the reverse cholesterol transport pathway which includes the transport of peripheral cholesterol back to the liver for excretion into bile. Increase in biliary cholesterol secretion can lead to the supersaturation of bile and under the right conditions this may lead to the formation of cholesterol gallstones<sup>[1]</sup>. Taurohyodeoxycholic acid (THDC) is a natural 6 $\alpha$ -hydroxylated bile acid with hydrophilic properties, causing more secretion of PC into bile compared to taurosoxycholic acid and taurocholic acid, whereas no significant differences were found in the biliary secretion of cholesterol<sup>[20]</sup>. Due to its relatively high hydrophilicity, THDC has been proposed for use instead of other bile acids for the treatment of cholesterol gallstone dissolution<sup>[21]</sup>. Angelico *et al.*<sup>[20]</sup> showed by the use of electron microscopy that increased recruitment of vesicles and lamellar bodies around and within bile canaliculi in the liver occurred with THDC infusion. The identification of biliary lipid-carrying vesicles may have implications for the treatment of hepatic disorders such as cholesterol gallstone formation.

The aim of this study was to isolate these biliary lipid-carrying vesicles in hepatocytes by using a novel gradient centrifugation technique and to verify their origin by separating PC by thin layer chromatography (TLC) and measuring its unique fatty acid pattern by high-performance liquid chromatography (HPLC). Cholesterol was measured by gas liquid chromatography (GLC).

## MATERIALS AND METHODS

### Chemicals

All chemicals were purchased from Sigma Chemical Co., Poole, Dorset, United Kingdom, except for cannulation tubing PP10 (internal diameter 0.28 mmol/L) which was obtained from Portex Ltd., Hythe, United Kingdom.

### Animals and treatments

Animals used throughout this study were male Wistar rats (250-300 g), bred within Liverpool John Moores University, Life Services Support Unit, and they were allowed free access to standard laboratory diet in powdered form.

### Perfusion of isolated liver

Rats were anaesthetized with sodium pentobarbitone (6 mg/100 g body weight, intraperitoneally) before starting

the experiment. Once isolated, livers were perfused in the absence and presence of THDC infusion *in situ* using the method of Rahman and Coleman<sup>[22]</sup>. Heparin (2500 units/0.5 mL) was injected into the vena cava and after 2 min, the hepatic portal vein was cannulated with a Wallace 17.5 G cannula and the perfusion was commenced immediately with 150 mL of Krebs ringer bicarbonate buffer, pH 7.4, containing 1 mmol/L CaCl<sub>2</sub>, 5 mmol/L glucose, a physiological amino acid mixture, 1% bovine serum albumin and 20% (v/v) washed human erythrocytes, and the abdominal aorta was severed. The inferior vena cava was then cannulated with a Wallace 16 G cannula and a recycling perfusion commenced by returning the efferent perfusate to the original perfusate pool which was gassed continuously with O<sub>2</sub>/CO<sub>2</sub> (19:1, v/v). The livers were maintained in a thermostatically controlled cabinet at 37 °C throughout the experiment. As soon as the liver perfusion was established, THDC infusion was commenced into the hepatic portal cannula at a rate of 2000 nmol/min for 2 h to stimulate delivery of lipid-carrying vesicles to the canalicular membrane.

### Liver homogenization

At the end of perfusion livers were removed, weighed and transferred to 3 vol. (w/v) of ice-cold buffered sucrose (0.25 mol/L containing 1 mmol/L HEPES pH 7.4). They were then cut into several large pieces and swirled around in the buffer to remove as much blood as possible. The livers were then minced finely with sharp scissors, transferred to an ice-cold homogenizing vessel and were finally homogenized with about six strokes of the pestle at full speed. Finally, the homogenate was made up to 4 vol. (w/v) with sucrose buffer solution.

### Fractionation of liver homogenate

The homogenate from the liver was used to produce subcellular fractions based on the method of Ford and Graham<sup>[23]</sup>. A sample of homogenate (3-4 mL) was removed for analysis and the remainder was centrifuged in a fixed angle rotor at 4 °C for 10 min at 1000 *g* to pellet the nuclei and heavy mitochondria. The pellet was then suspended in sucrose buffer and stored frozen at -20 °C until analysis.

Further centrifugation was performed at 4000 *g* for 10 min to produce the mitochondrial fraction, followed by 15000 *g* for 20 min to produce the light mitochondrial and lysosome fraction. A final centrifugation step at 100000 *g* for 45 min was then performed and the microsomal fraction was obtained. All fractions were assayed for cholesterol, phospholipids, protein and PDE activity

### Purification of vesicles from microsomal fraction

The microsomal pellet was then dissolved in sucrose buffer solution up to 8 mL and then loaded onto 2 mL of OptiPrep<sup>TM</sup> (1.32 g/mL) in a Beckman Vti65 vertical tube rotor and centrifuged at 350000 *g* for 90 min at 4 °C. At the end of the centrifugation, the gradient was fractionated by upward displacement into 10 × 1 mL samples and these fractions were analyzed for cholesterol, phos-

pholipids, protein and PDE activity.

### Lipid analysis

Cholesterol was analyzed by GLC as trimethylsilyl ether derivatives as described by Zak *et al.*<sup>[24]</sup>. Phospholipid was extracted from the liver fractions as described by Bligh and Dyer<sup>[25]</sup> in a method by which lipid is extracted into a chloroform-methanol-water mixture. Addition of further chloroform and water forms a biphasic system with non-lipids passing into the methanol-water phase. The phospholipid in the chloroform phase was then assayed by the method of Bartlett<sup>[26]</sup> in which organic phosphate is digested and the resulting orthophosphate is determined by converting it to phosphomolybdic acid, which is reduced to a blue complex allowing spectrophotometric measurement at 830 nm.

### Alkaline phosphodiesterase I analysis

PDE (EC 3.1.4.1) was measured at 37 °C, essentially as described by Trams and Lauter<sup>[27]</sup>.

### Thin layer chromatography of phospholipids

**Sample extraction:** 200 µL of sample was added to 200 µL of distilled water in a 2 mL (microcentrifuge) tube followed by the addition of 750 µL of chloroform then methanol (1:2 v/v) to each tube, vortex mixed and left to stand for 20 min. After this time, 250 µL of chloroform and 250 µL of distilled water were added and the tubes were vortex mixed and then centrifuged for 1 min. The lower organic phase was then transferred to a clean tube and placed in a water bath at 37 °C to evaporate the chloroform<sup>[25]</sup>. Samples were finally redissolved in 30 mL of chloroform, vortex mixed and loaded on to the TLC plates.

**Solvent for running phospholipid plates:** The plates were developed in a solvent mixture containing chloroform/methanol/glacial acetic acid/water (75:45:12:1.5 by volume). These solvent ratios were poured into a tank containing a filter paper layered against the wall of the chamber and the lid was replaced; the tank was then left to saturate for at least 30 min prior to running the plates. The plates were left to run until solvent reached the scored solvent front line (approximately 75 min) and were then removed and air dried in a fume cupboard.

**Developing the TLC plates:** The dried plates were developed in an iodine tank and the position of the phospholipid was marked with a needle. The PC bands were scraped and the silica transferred to extraction tubes; at the same time silica was scraped from a similar area without any phospholipids to act as a control. Phospholipids were extracted with 2 × 1 mL methanol (HPLC grade) and vortex mixed for 5 min, vortexed again, centrifuged and the methanol extract was then transferred to clean glass tubes and dried at 37 °C under nitrogen. The dried lipids were redissolved in 1 mL of methanol (HPLC grade) and 2 × 10 µL aliquots were removed for phospholipids assay. The remainder was filtered, dried at 37 °C

under nitrogen and stored cool and in the dark until required for HPLC analysis. At least 20 nmol of PC was injected onto the HPLC column.

### HPLC

HPLC analysis was performed using a Bio-Rad HPLC 2700, Series 8000 Gradient System V 2.30.1a liquid chromatograph equipped with an oven column module, and a spectrophotometric detector, Bio-Rad Model 1801 UV monitor. The sample was injected onto the column by a Rheodyne injector equipped with a 20  $\mu$ L sample loop. An HPLC column of 100 mmol/L  $\times$  4.6 mmol/L *id*, packed with a Spherisorb ODS2 bonded phase, and with a 3  $\mu$ L particle size was used and the mobile phase consisted of 20 mmol/L choline chloride in methanol/water/acetonitrile (90:8:3, by vol.). The operating conditions were: column temperature, 60  $^{\circ}$ C; chromatographic profile: initial flow, 1 mL/min, held for min and then a linear increase to 2 mL/min over 20 min; the final flow of 2 mL/min being held for 10 min.

### Protein estimation

Protein estimation was determined by the method of Winterbourne and all samples were assayed in duplicate<sup>[28]</sup>. A sheet of 3 mmol/L Whatman chromatography paper was divided into 1 cm  $\times$  1 cm squares. Standard protein concentration BSA ranged from 0.5-8 mg/mL and the standards were prepared by spotting corresponding amounts onto the center of the squares on the sheet. 3  $\mu$ L of sample was carefully spotted onto the center of individual squares and blank squares were left for the determination of background staining. The standards and samples were then left to dry and were later fixed by immol/Lersing into 10% TCA solution for 15 min and the sheet was then transferred to a working dye solution (0.04% w/v Coomassie Blue, 25% v/v ethanol and 12% v/v acetic acid) and left to stain for 1 h. The sheet was then destained by immersing in three changes of destaining solution 10% (v/v) methanol and 5% (v/v) glacial acetic acid for 10 min, and it was then left to dry in the oven at 80  $^{\circ}$ C. The grid was then cut into its individual component squares and was placed into small plastic vials containing 1 mL eluent, 1 mol/L potassium acetate in 70% (v/v) ethanol for 1 h and finally the absorbance of the eluted dye solution was read at 590 nm against the background dye measurements.

### Statistical analysis

Data were subjected to 2-tailed paired *t* test and *P* values  $\leq$  0.05 were considered as statistically significant.

## RESULTS

### Total phospholipids and total cholesterol in the subcellular fraction of isolated perfused rat livers in the absence and presence of THDC infusion

Total phospholipids and cholesterol in the subcellular fractions from isolated perfused rat livers in the absence

and presence of THDC infusion are shown in Figure 1A and B. The total lipids have been expressed as  $\mu$ mol/g of liver due to the differences in liver weight of the animals. No significant differences were found in total phospholipids and cholesterol content of subcellular fractions from control and THDC-infused rat livers (Figure 1A and B).

### Total protein and PDE activity in subcellular fractions of liver homogenate

Total protein and PDE activity in subcellular fractions of isolated perfused rat livers in the absence or presence of THDC infusion are depicted in Figure 1C and D. No significant differences were found in total proteins in the subcellular fractions of isolated perfused rat livers in the absence or presence of THDC infusion (Figure 1C). However, PDE activity was significantly higher in fraction P3 II from THDC-infused livers (Figure 1D).

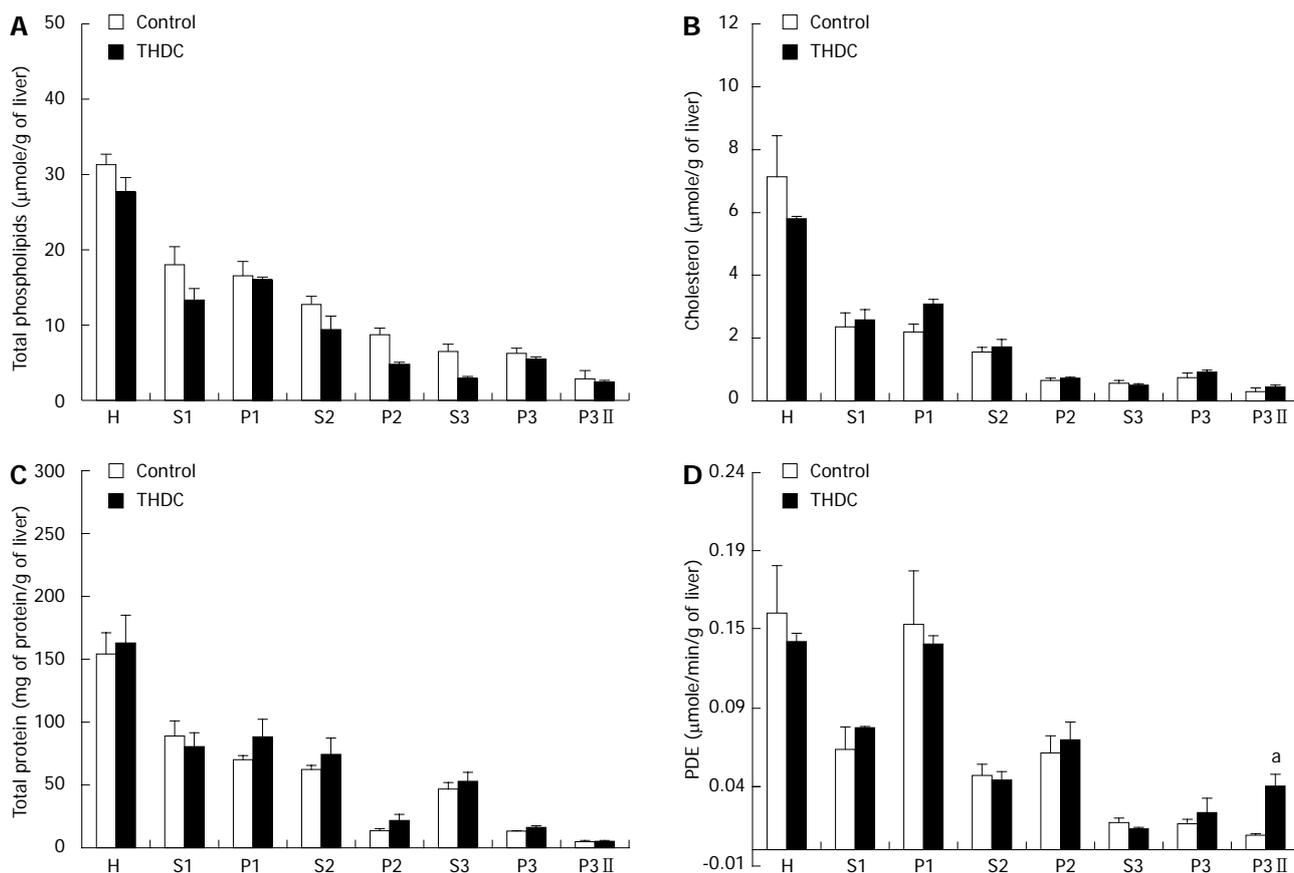

### Analysis of the subfractions of the microsomal fraction

The microsomal fractions were subjected to self-generating density gradient centrifugation and the fractions were analyzed for total phospholipids, cholesterol, protein and PDE activity. The results are presented in Figure 2. Enzyme activity in THDC-infused liver fractions 1, 2, 8, 9 and 10 was significantly higher when compared to the control values. However, no significant differences were observed in total phospholipids, cholesterol and protein in the subcellular fractions of isolated perfused rat livers in the absence or presence of taurohyodeoxycholic acid infusion.

Biliary PC has a unique fatty acid pattern, 1-palmitoyl 2-linoleyl (16:0-18:2) PC, 1-palmitoyl 2-oleoyl (16:0-18:1) PC, which is distinct from that of membrane PC fatty acid pattern 1-stearoyl 2-arachidonyl (16:0-20:4). No differences in the level of subfractions of PC were found (Table 1). It was not possible to identify peak 1 due to lack of relevant standards (Figure 3).

## DISCUSSION

The liver is the site of many important biochemical functions including formation of bile which contains many solutes including phospholipids and cholesterol, both of which are synthesized in the liver and have been implicated in liver and cholestatic disease<sup>[29]</sup>. Many studies have been performed in which the physical forms of lipids have been isolated in bile; however, very few studies have addressed this problem in the liver. Attempts to isolate vesicles containing biliary type PC and cholesterol have largely been unsuccessful in hepatocytes<sup>[5]</sup>. However, Gilat and Sömjen<sup>[7]</sup> and Sömjen *et al*<sup>[8]</sup> have identified three forms of biliary lipid carriers in bile, namely unilamellar vesicles, stacked lamellae and micelles. The sources of biliary phospholipids may be numerous: *de novo* synthesis, microsomes, Golgi, bile canalicular membrane and preformed hepatic and extrahepatic pool<sup>[30]</sup>. The extrahepatic pool may contribute about 40% of the biliary phospho-

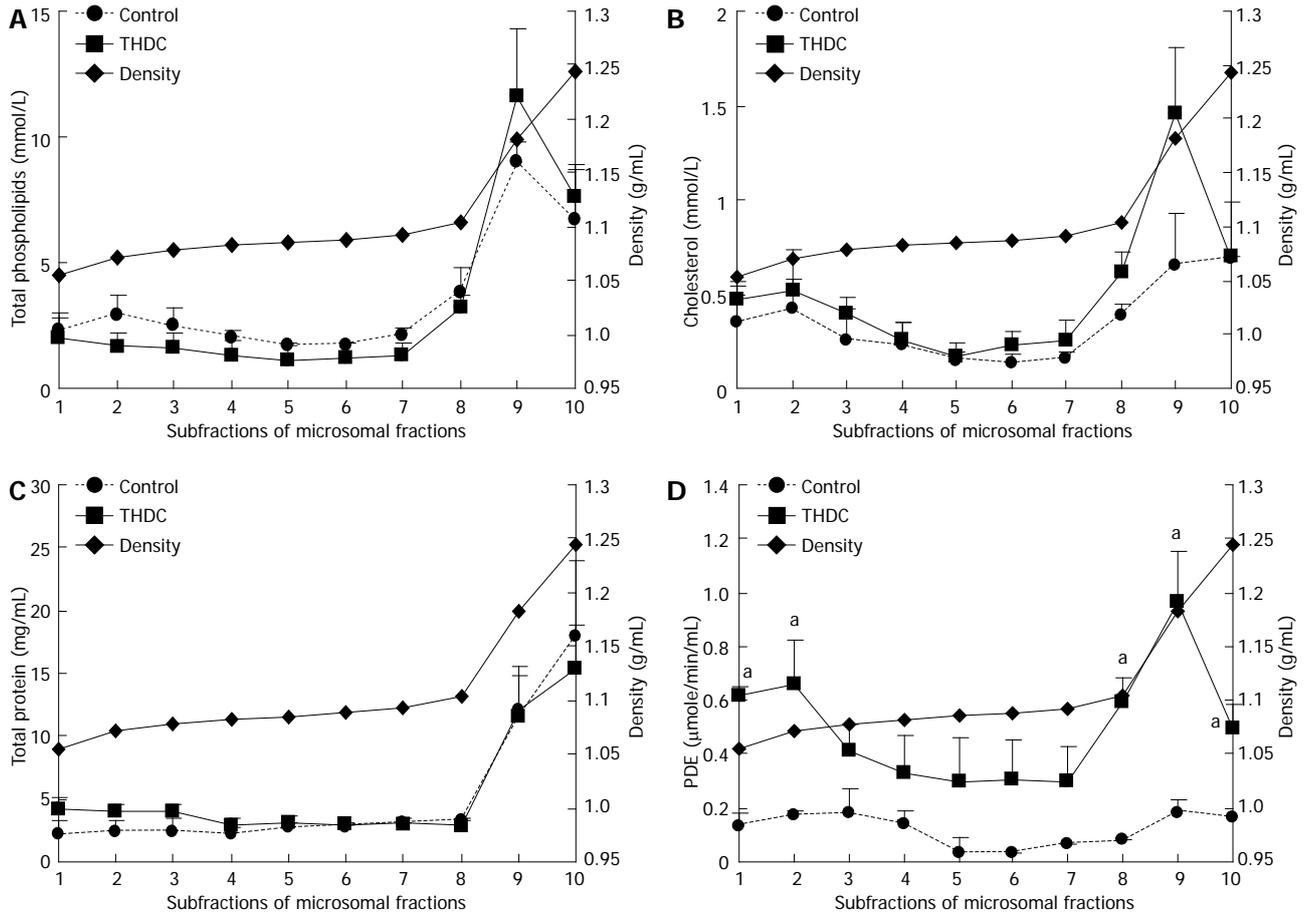

**Figure 1** Total phospholipids, cholesterol, protein and phosphodiesterase I activity in subcellular fractions of liver homogenate. A: Phospholipids; B: Cholesterol; C: Protein; D: Phosphodiesterase I activity (PDE). THDC: Taurohyodeoxycholic acid. Symbols are homogenate (H), supernatant 1 (S1), pellet 1 (P1), supernatant 2 (S2), pellet 2 (P2), supernatant 3 (S3), pellet 3 (P3) and pellet 3 (P3 II) diluted with sucrose and KCl. Results are presented as mean  $\pm$  SE ( $n = 6$ ). Significant differences from controls were assessed by student's *t*-test and are indicated by (<sup>a</sup> $P < 0.05$  vs control group).

lipids secreted in the basal state in rats and is associated with high density lipoprotein<sup>[31]</sup>, also bile acid activates a specific cytosolic PC transfer protein in the hepatocytes which then transfers PC to the canalicular membrane. It has also been reported that a PC transmembrane translocator (*flippase*) exists in the canalicular membrane and may be involved in the membrane translocation of specific PC to the biliary side of the canalicular membrane<sup>[32]</sup>. Most of the cholesterol secreted in bile is derived from circulating plasma lipoprotein, mainly low-density lipoprotein, high-density lipoprotein and chylomicron remnants. Cholesterol is transported probably in vesicles and binds to protein such as sterol carrier protein 2 present in the hepatocytes and, under physiological conditions, biliary bile acid secretion is the driving force behind the secretion of phospholipid and cholesterol in bile<sup>[33,34]</sup>.

THDC is a hydrophilic bile acid, causing more secretion of biliary PC compared to tauroursodeoxycholic acid and taurocholic acid, whereas this bile acid does not significantly increase biliary secretion of cholesterol and protein when compared to the control<sup>[20]</sup>. It was thought that increased biliary PC carrier vesicles would be present in the hepatocytes in this experiment. This concept was initiated by the study of Angelico *et al*<sup>[20]</sup>, who observed by electron microscopy that increased recruitment

of vesicles and lamellar bodies around and within bile canaliculi in the liver occurred with THDC infusion. It is possible that mechanisms at a molecular level include stimulation by THDC of the PC transfer protein and/or of the phospholipid translocator involved in the transmembrane canalicular transport of phospholipids. It has also been reported from physical-chemical and imaging studies that bile salts stimulate the biliary secretion of unilamellar vesicles from the external hemileaflet of the canalicular membrane<sup>[31]</sup>.

However, no significant differences were observed between control and THDC-infused rat liver sub-fractions in total phospholipids and cholesterol (Figure 1A and B). There was no significant difference in total proteins in the subcellular fractions of isolated perfused rat livers in the absence of THDC infusion (Figure 1C). However, PDE activity in the subcellular fraction P3II was significantly higher than in the corresponding fraction from the control experiment. Within the liver, PDE is a membrane-bound enzyme and would be expected to be associated with vesicles, hence this enzyme was assayed and results may indicate that there is more membrane material in this fraction. This is in contrast to the results reported by Lanzarotto *et al*<sup>[35]</sup> who observed that chronic administration of THDC in humans with intact

**Figure 2** Analysis of the subfractions of the microsomal fraction. A: Phospholipids; B: Cholesterol; C: Protein; D: Phosphodiesterase I activity (PDE). Livers were removed and the microsomal fraction was prepared and subjected to centrifugation and sub-fractions obtained. The sub-fractions were analyzed for total phospholipids, total cholesterol, protein and PDE activity. Results are presented as mean  $\pm$  SE ( $n = 6$ ). THDC: Taurohydoxychoic acid. Significant differences from controls were assessed by student's *t* test and indicated by <sup>a</sup> $P < 0.05$  vs control group.

Fractions	PC (nmol)	C16:0 C20:4	C16:0 C18:2	C16:0 C18:1
Control perfused fed rat livers				
1	0.171 $\pm$ 0.001	41.147% $\pm$ 3.02%	11.048% $\pm$ 0.8%	8.327% $\pm$ 0.92%
2	0.223 $\pm$ 0.003	42.219% $\pm$ 2.8%	10.223% $\pm$ 0.7%	6.49% $\pm$ 0.5%
8	0.214 $\pm$ 0.007	41.545% $\pm$ 3.09%	11.281% $\pm$ 0.8%	6.436% $\pm$ 0.9%
9	1.02 $\pm$ 0.05	43.59% $\pm$ 1.5%	8.68% $\pm$ 1%	6.61% $\pm$ 0.73%
10	1.34 $\pm$ 1.1	44.64% $\pm$ 0.27%	8.19% $\pm$ 0.64%	6.84% $\pm$ 0.33%
THDC-perfused rat livers				
1	0.193 $\pm$ 0.001	44.424% $\pm$ 3.29%	7.864% $\pm$ 0.92%	10.239% $\pm$ 1.52%
2	0.208 $\pm$ 0.004	44.796% $\pm$ 2.09%	8.177% $\pm$ 0.8%	8.507% $\pm$ 0.93%
8	0.444 $\pm$ 0.008	43.735% $\pm$ 0.98%	9.373% $\pm$ 1.76%	8.298% $\pm$ 1.35%
9	1.47 $\pm$ 0.16	44.94% $\pm$ 1.2%	8.07% $\pm$ 0.3%	8.23% $\pm$ 0.95%
10	1.17 $\pm$ 0.4	43.94% $\pm$ 2.8%	7.94% $\pm$ 0.52%	7.74% $\pm$ 1.7%

Phosphatidylcholine was isolated and separated by thin layer chromatography and then subjected to high-performance liquid chromatography (HPLC) for the sub-fractionation of the fatty acid composition as described in the methods section for control perfused livers and in livers perfused with taurohydoxychoic acid (THDC). Results are presented as mean  $\pm$  SE ( $n = 6$ ). No significant differences were found between the fatty acid composition of livers perfused with THDC when compared to the control; PC: Phosphatidylcholine.

enterohepatic circulation has little effect on biliary lipid composition and secretion. In contrast, Sinhal *et al.*<sup>[36]</sup> and Cohen *et al.*<sup>[37]</sup> showed that feeding THDC to hamsters and prairie dogs increased hepatic HMG-CoA reductase activity and thus an increase in vesicles carrying cholesterol. It is speculated that a similar increase in the activity

of PDE is caused in this experiment by THDC.

Analysis of the microsomal fraction gave an interesting profile of total phospholipids, cholesterol, protein and PDE, as presented in Figure 2. The results indicate that there may be two different populations of the parameters measured. The first population isolated from

**Figure 3** A typical high-performance liquid chromatography chromatogram of a liver homogenate. Phospholipids were separated by thin layer chromatography (TLC) and the phosphatidylcholine band was scraped off the TLC plate and extracted with 2 × 1 mL methanol [high-performance liquid chromatography (HPLC) grade]. After determination of the phospholipid, 20 nmol was injected onto HPLC for the analysis of the fatty acid composition of the phosphatidylcholine as described in the methods section. Results are presented as mean ± SE ( $n = 6$ ). A typical chromatogram is presented. Peak 1: Not identified; peak 2: 1-palmitoyl 2-arachidonoyl (16:0-20:4) phosphatidylcholine; peak 3: 1-palmitoyl 2-linoleoyl (16:0-18:2) phosphatidylcholine; peak 4: 1-palmitoyl 2-oleoyl (16:0-18:1) phosphatidylcholine; peak 5: 1-stearoyl 2-arachidonoyl (18:0-20:4) phosphatidylcholine.

fractions 1-2 ( $\rho = 1.05$ - $1.07$  g/mL) had relatively small amounts of cholesterol and PDE activity, whereas the population isolated from fractions 8-10 ( $\rho = 1.09$ - $1.23$  g/mL) had higher concentrations of phospholipids, cholesterol, protein and PDE activity (Figure 2A-D). Some putative vesicles may be present in fractions 8-10 ( $\rho = 1.09$ - $1.23$  g/mL) since these had more total phospholipids, cholesterol, protein and PDE activity. Enzyme activity in THDC-infused liver microsomal sub-fractions ( $\rho = 1.05$ - $1.07$  g/mL and  $\rho = 1.95$ - $1.23$  g/mL) was significantly higher than that observed in control values (Figure 2D). No significant difference was found in PC molecular species in the C16:0-C18:2, C16:0-C18:1 between control and THDC-infused liver subfractions.

In the experiments reported in this study, the isolation of biliary type vesicles was achieved by using the novel gradient medium, Iodixanol, which is a nonionic medium that has an advantage over sucrose in that it rapidly forms self-generated gradients in vertical or near-vertical rotors<sup>[38]</sup>. Increased lipid transfer vesicles might be present in the microsomal fraction<sup>[39,40]</sup>; however, subfractions of microsomal fraction on density gradient with Iodixanol failed to identify biliary transfer vesicles.

Crawford *et al.*<sup>[32,41]</sup> reported that vesicles are secreted from the outer leaflet of the canalicular membrane by ABCB4 transporter and subsequently, bile salt/phospholipid micelles in bile extract cholesterol from these vesicles. Vesicular secretion is compatible with the function of ABCG5/ABCG8, and several studies<sup>[7,32,42,43]</sup> have suggested that vesicular secretion of cholesterol is one of the mechanisms by which sterols appear in bile.

According to the results of this study no significant changes in biliary lipid-carrying vesicles were observed;

however, a significantly different profile of PDE was seen. However, the observation of increased vesicle accumulation during bile salt secretion by electron microscopy<sup>[44]</sup> and inhibition of the vesicle transport by colchicine, vinblastine and valproate still require explanation<sup>[45]</sup>. The changing of lipid content in any subcellular compartment might be prevented by analysis of the whole liver. However, the subcellular fraction of the livers which was also an initial fraction resulted in no significant difference between control and THDC-perfused rat livers (Figure 1A and B). Some putative biliary lipid transfer vesicles may exist but techniques used in this study have failed to identify them. The identification and regulation of biliary lipid-carrying vesicles may lead to an improvement in the treatment of hepatic disorders.

In conclusion, the present study failed to identify an increase in biliary lipid-carrying vesicles in THDC-infused rat livers probably due to the limitation of the techniques. However, PDE activity was significantly increased in the microsomal sub-fractions isolated from THDC-infused livers when compared to control values and needs further investigation.

## COMMENTS

### Background

Bile contains many constituents, including cholesterol and phospholipids, and these are reported to be transported from the hepatocytes to the bile canaliculus in vesicles. An increase in biliary lipid secretion can have implications for hepatic disorders such as cholesterol gallstone formation. Hence, the isolation of biliary lipid-carrying vesicles may lead to a better understanding of such hepatic disorders.

### Research frontiers

Taurohyodeoxycholic acid (THDC) is reported to increase biliary lipid-carrying vesicles (mainly phosphatidylcholine) and ultracentrifugation techniques are now available which can be used to separate vesicle type material relatively quickly.

### Innovations and breakthroughs

Biliary phosphatidylcholine has a unique fatty acid composition compared to hepatic phosphatidylcholine and can be identified by high-performance liquid chromatography (HPLC). Since THDC induces an increase in biliary phosphatidylcholine it was thought that increased biliary phosphatidylcholine carrier vesicles would be present in the hepatocytes and could be separated by ultracentrifugation. Electron microscopy has confirmed the presence of increased vesicles and lamellar bodies around and within the bile canaliculus after THDC infusion.

### Applications

Although the present study failed to identify an increase in biliary lipid-carrying vesicles in THDC-infused livers, probably due to the limitation of the techniques employed, vesicles enriched in phosphodiesterase I (PDE) activity were present in THDC livers compared to controls.

### Terminology

THDC is a natural 6 $\alpha$ -hydroxylated bile acid displaying hydrophilic properties and causes more secretion of phosphatidylcholine into bile compared to other bile acids. The microsomal fraction was obtained and subjected to further ultracentrifugation using a novel gradient centrifugation technique. The phosphatidylcholine was separated and subjected to HPLC fractionation since biliary phosphatidylcholine has a unique fatty acid composition.

### Peer review

In this study the authors have isolated rat livers and have subjected them to THDC infusion, which is reported to increase biliary phospholipid secretion. The livers were then homogenized and the microsomal fraction was subjected to ultracentrifugation by using a novel gradient technique in order to isolate putative vesicles destined for biliary secretion. The results show that the density

gradient fraction envisaged to contain the putative vesicle population isolated from THDC-perfused livers had relatively small amounts of phospholipids and protein when compared to the relevant control fractions. However, the vesicles isolated from the THDC-perfused livers displayed an increase in cholesterol and PDE activity.

### Abstract

**AIM:** To investigate the effects of nilotinib in a rat model of trinitrobenzene sulfonic acid (TNBS)-induced colitis.

**METHODS:** Twenty-one Wistar albino female rats obtained from Dokuz Eylul University Department of Laboratory Animal Science were categorized into a control ( $n = 7$ ), TNBS ( $n = 7$ ) and nilotinib group ( $n = 7$ ). Saline was administered orally for 14 d to the control and the TNBS group. The TNBS group received rectal TNBS on the first day while saline was administered to the control group. The nilotinib group received 20 mg/kg nilotinib for 14 d in 2 divided doses, starting the

same day as TNBS administration. For 14 d, the rats were fed a standard diet, and their weights were recorded daily. After sacrifice, colon tissue samples from each group were scored for macroscopic and microscopic pathology. Apoptotic indices were determined by the terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling method. Platelet-derived growth factor receptor (PDGFR) alpha and beta levels were assessed through immunohistochemistry staining scores and compared among the groups. Tissue and serum tumor necrosis factor (TNF) alpha levels were determined by enzyme-linked immunosorbent assay.

**RESULTS:** Between days 1 and 14, the nilotinib group rats lost significantly less weight than the TNBS group rats ( $-0.7$  g *vs*  $-14.0$  g,  $P = 0.047$ ). The difference in weight between the control and nilotinib groups was also statistically significant ( $+8.3$  g *vs*  $-0.7$  g,  $P = 0.031$ ). From day 7 to day 14, the weight differences of the control group *vs* the TNBS group, the TNBS group *vs* the nilotinib group, and the control group *vs* the nilotinib group were all statistically significant ( $+8.0$  g *vs*  $-11.1$  g,  $P = 0.007$ ;  $-11.1$  g *vs*  $+2.9$  g,  $P = 0.015$ ;  $+8.0$  g *vs*  $+2.9$  g,  $P = 0.042$ , respectively). Macroscopic and microscopic scores were significantly lower in the nilotinib group than in the TNBS group ( $0.00 \pm 0.00$  *vs*  $1.43 \pm 0.65$ ,  $P = 0.009$ ;  $2.86 \pm 0.55$  *vs*  $7.71 \pm 1.48$ ,  $P = 0.030$ , respectively). However, these scores were similar between the nilotinib and control groups. While no significant difference for the nilotinib *vs* control groups could be determined for PDGFR alpha and beta scores, PDGFR alpha and beta scores were lower in the nilotinib group than in the TNBS group. Furthermore, the TNF alpha levels in the serum, tissue and apoptosis scores were similar between the nilotinib and TNBS groups.

**CONCLUSION:** Nilotinib prevents weight loss, facilitates mucosal healing by improving the pathological scores without introducing variation into the apoptotic scores or TNF alpha levels.

**Key words:** Inflammatory bowel disease; Platelet-derived growth factor receptor; Tumor necrosis factor alpha; Tyrosine kinase inhibitor; Mucosal healing

**Core tip:** Unresponsiveness to medical treatment in refractory inflammatory bowel disease (IBD) still poses a therapeutic challenge. To detect an alternative treatment option, we selected nilotinib based on the fact that tyrosine kinases inhibitors affect several key components in the pathogenesis of IBD, including tumor necrosis factor (TNF) alpha, platelet-derived growth factor receptor (PDGFR), and apoptosis. In a trinitrobenzene sulfonic acid-induced colitis rat model, we concluded that nilotinib has a significant effect on weight loss and on macroscopic and microscopic pathological scores, leading to significant mucosal healing. Although nilotinib caused a decrease in the PDGFR alpha and PDGFR beta levels, it did not have a significant effect on the apoptotic scores or TNF alpha levels.

Nilotinib-mediated mucosal healing in a rat model of colitis. *World J Gastroenterol* 2013; 19(37): 6237-6244 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i37/6237.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i37.6237>

## INTRODUCTION

Chronic intestinal inflammation is characterized by the pathological responses of the adaptive and innate immune systems. These responses are central to the pathological mechanisms that lead to inflammatory bowel disease (IBD)<sup>[1]</sup>. Genetic and environmental factors, infectious agents, the structure of the enteric flora, and immune system dysfunctions are key elements in the pathogenesis of IBD, and thus, these are targets for many drugs developed to treat IBD<sup>[2,3]</sup>. However, unresponsiveness to medical treatment in IBD still poses a therapeutic challenge. Previous studies examining the therapeutic effectiveness of selecting drugs in patients with ulcerative colitis (UC) reported the rates of remission to be 47%-81% with rectal 5-aminosalicylic acid (5-ASA), 9%-30% with oral 5-ASA, and 42%-82% with thiopurines<sup>[4-6]</sup>.

Monoclonal tumor necrosis factor (TNF) alpha inhibitors are currently the treatment of choice, especially in severe and resistant cases of IBD. However, decreased responses or resistance to the TNF alpha inhibitor infliximab have been reported. Previous studies have reported an average clinical remission rate at week 8 of 33% (range, 27.5%-38.8%) with the use of infliximab in IBD patients<sup>[7]</sup>. Clinical remission was maintained in 33% (range, 25.6%-36.9%) of patients treated with infliximab at week 30<sup>[7]</sup>. In a randomized, placebo-controlled 52-wk study examining the effectiveness of adalimumab, another anti-TNF agent, the IBD remission rate was significantly

higher than the placebo, regardless of treatment with steroids (13.3% and 5.7%, respectively;  $P = 0.035$ )<sup>[8]</sup>.

Mucosal healing has emerged as a key therapeutic objective in the treatment of IBD and is able to predict sustained clinical remission and resection-free survival in patients. Mucosal healing is achieved in approximately 30% of IBD patients receiving corticosteroid therapy and in as many as 60% of IBD patients receiving anti-TNF therapies<sup>[9-11]</sup>. Approximately 20% of IBD patients, however, do not respond to anti-TNF therapy and require surgical intervention<sup>[12]</sup>. These findings emphasize the importance of discovering new medical treatment options for IBD because the currently available treatments are insufficient for a substantial number of patients.

Tyrosine kinases (TKs) are enzymes that play a role in normal cell function, metabolism, growth, differentiation, and apoptosis. TK inhibitors are drugs that block the action of these enzymes. Although they are typically used as anticancer drugs, they have recently been considered for use in noncancer proliferative diseases and for inflammatory conditions. Imatinib, the best-known member of this class of drugs, is specific for TK receptor sites and suppresses the Abelson proto-oncogene (ABL), the c-kit proto-oncogene, platelet-derived growth factor receptor (PDGFR), macrophage colony-stimulating factor receptor, TNF alpha, and inducible nitric oxide synthase<sup>[13]</sup>. Nilotinib is a more potent inhibitor of TKs than imatinib. In studies involving patients with lung fibrosis, nilotinib has been shown to reduce interleukin (IL)-6, IL-1 beta, TNF alpha, tumor growth factor beta 1, and PDGFR beta levels more significantly than imatinib and had a potent antifibrotic effect<sup>[14]</sup>.

In the literature, there are a few reports suggesting that TK inhibitors may be effective in IBD. In a case report by Magro *et al.*<sup>[15]</sup>, a patient diagnosed with Crohn's disease (CD) and chronic myeloid leukemia (CML) remained in remission for 3 years on imatinib therapy alone, without the use of mesalamine or steroids. Cuzzocrea *et al.*<sup>[16]</sup> demonstrated that the development of colitis in dinitrobenzene sulfonic acid (DNBS)-induced colitis animal models was reduced by the TK inhibitor tyrphostin AG126.

The present study was planned based on the demonstrated success of nilotinib in previous studies and on the fact that TK inhibitors affect several key components in the pathogenesis of IBD, including TNF alpha, PDGFR, and nitric oxide (NO) synthesis. For this purpose, we evaluated the efficacy of nilotinib on weight, macroscopic and microscopic pathological scores, TNF alpha levels, PDGFR levels, and the apoptotic index in a rat model of trinitrobenzene sulfonic acid (TNBS)-induced colitis. This study is the first to evaluate the efficacy of nilotinib in a rat colitis model.

## MATERIALS AND METHODS

### Experimental design

Approval was obtained from the animal ethics council of Dokuz Eylul University Medical Faculty (DEUTF). The

DEUTF Hospital Experimental Research Laboratory provided 21 female Wistar albino rats weighing 200-250 g (mean weight:  $209.43 \pm 8.92$  g) for use in this study.

The rats were maintained in a room at a temperature of  $23 \pm 2$  °C under a 12-h light/dark cycle at the DEUTF Experimental Animal Laboratory. Before and during the study, they were fed a standard diet, and their weights were monitored daily. The animals were also allowed water *ad libitum*.

The rats were divided into 3 groups, each consisting of 7 rats: the control group, TNBS group and nilotinib group. After 24 h of fasting, 0.25 mL of the physiological serum was intracolonic administered to the control group rats through a cannula inserted 8 cm proximal to the anus, using a rectally inserted flexible polypropylene catheter. To induce colitis, the rats in the other 2 groups received an intracolonic solution treated with 0.5 mL of 100 mg/mL TNBS (Sigma, Germany) dissolved in 30% ethanol and administered through a cannula. Before catheter insertion, short-term sedation was provided through ether anesthesia. Neither group of rats treated with TNBS encounter any instance of perforation or death due to colonic ulceration. The TNBS and control groups received a saline placebo for 14 d through an orogastric tube. Nilotinib 20 mg/kg/d (Novartis Pharma AG, Basel, Switzerland) was administered in 2 divided doses to the nilotinib group for 14 d through an orogastric tube, beginning on the same day as TNBS administration.

Blood and tissue samples for pathological examination were obtained from all of the rats under ether anesthesia at the end of the 14-d period. All of the animals were then sacrificed by decapitation. The abdominal cavities were opened by a midline incision, and the entire length of the large intestines was dissected from the distal ileum to the rectum. After washing with saline, the large intestinal tissues were fixed with buffered formalin.

### Pathological examination

A pathologist blinded to the group identity of the intestinal samples performed pathological evaluations of all of the tissue samples. Each intestinal column was opened longitudinally, according to the method reported by Vilaseca *et al.*<sup>17</sup>, and macroscopic scoring was performed. Tissue sections of the gross ulcerative lesions and surrounding normal mucosa were then stained with hematoxylin-eosin (HE). The pathologist then performed microscopic scoring according to the method reported by Dieleman *et al.*<sup>18</sup>.

### Apoptosis

The pathologist stained all tissue samples using the TUNEL method. Mucosal crypts and apoptotic cells were counted along the surface epithelium under a microscope (Olympus DX51) at a magnification of  $\times 400$ . Using the TUNEL technique, all of the cut sections were preserved with lysine for 3 nights at 37 °C and then for 1 night at 60 °C in an incubator. Thereafter, deparaffinization was performed with 3 cycles of xylene. The tissue sections

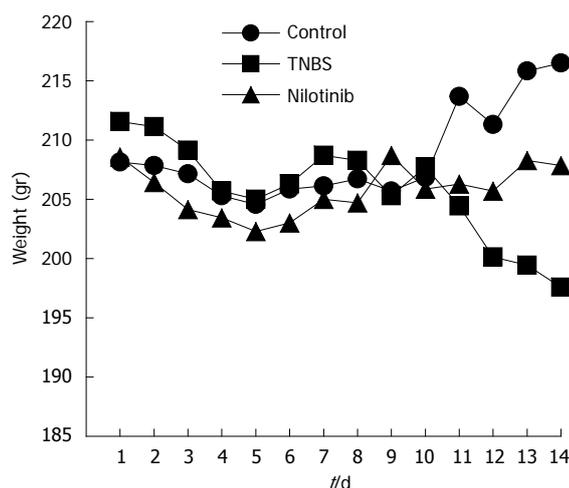

were then rehydrated by flushing with a series of alcohol solutions of decreasing degrees (absolute, 96%, 80%, and 70%) and then stored in distilled water for 5 min. Proteinase K (Proteinase K, Invitrogen, Carlsbad, CA, United States) was applied for 10 min at room temperature. The sections were then washed twice with phosphate-buffered solution (PBS) for a period of 2 min each. After drying the cross-sections, 3% H<sub>2</sub>O<sub>2</sub> (Merck, Germany) was applied for 5 min, and the sections were then washed with PBS twice for 5 min each. The cross-sectional slices were then dried, and an equilibration buffer (ApopTag Plus peroxidase kit, Millipore, Billerica, MA, United States) was applied for 10 min at room temperature. A total of 55  $\mu$ L of the enzyme terminal deoxynucleotidyl transferase was then applied to each cross-section. The cross-sections were closed with a coverslip (ApopTag Plus peroxidase kit, Millipore, Billerica, MA, United States) and incubated for 1 h at 37 °C. Stop/wash buffer (ApopTag Plus peroxidase kit, Millipore, Billerica, MA, United States) was then applied to the sections removed from the incubator for 10 min at room temperature. The sections were then washed with PBS at room temperature 3 times for 1 min each, dried, and incubated with anti-streptavidin-peroxidase (ApopTag Plus peroxidase kit, Millipore, Billerica, MA, United States) at room temperature for 30 min. The sections were then washed with PBS 4 times for 2 min to determine the visibility of the TUNEL reaction before being stained with diaminobenzidine (DAB) (DAB-PLUS kit; Invitrogen, Carlsbad, CA, United States). After washing with distilled water, ground staining was performed using methyl green. After three changes of the searing process with xylene for 20 min, it was closed with Entella.

### Tissue homogenization and measurement of tissue serum TNF alpha

The tissue samples obtained from the ileum were introduced into 2 mL microcentrifuge tubes and stored at -80° C until the day of the study. These tissues were then removed and warmed to 4 °C. Next, 60-80 mg pieces were obtained from these samples and placed into a tube containing 5-mm-diameter stainless steel beads and a phosphate buffer with a 1:7 ratio (pH 7.2). Microcentrifuge tubes were introduced into a pre-chilled TissueLyser LT device and replaced into a TissueLyser (Qiagen-Germany) tissue homogenization device. Next, an enzyme-linked immunosorbent assay (ELISA) was performed on tissue supernatants, and serum was obtained via centrifugation for the identification of TNF alpha in accordance with the manufacturer's recommendations (Invitrogen Rat TNF-alpha, Carlsbad, CA, United States). Finally, the ELISA plates were spectrophotometrically evaluated at 450 nm (Biotech Synergy HT; Winooski, VT, United States).

### PDGFR alpha and beta levels

PDGFR alpha and beta levels were assessed through staining scores and compared among the groups by im-

**Figure 1** Trends of weight changes among the experimental groups. Control group (circle), Trinitrobenzene sulfonic acid (TNBS) group (square), and nilotinib group (triangle). The TNBS group lost an average weight of 14 g, while the nilotinib group lost 0.7 g in 14 d ( $P = 0.047$ ). The nilotinib group gained an average weight of 2.9 g between day 7 and day 14, while the TNBS group lost an average weight of 11.1 g ( $P = 0.015$ ).

munohistochemistry. For immunohistochemical staining, 2-3 micron sections were stored overnight in an incubator at 40 °C. The following day, the sections were washed with xylene, a descending alcohol series, and distilled water for 20 min. They were then boiled for 20 min in EDTA solution at pH 8. Next, they were stored in DakoFlex peroxidase solution for 5 min and washed again with Tris-buffered saline. A primary antibody was then applied. PDGFR alpha in a 1:100 dilution (NOVUS Biologicals, NBP1-19 423, Littleton, CO, United States) and PDGFR beta in a 1:50 dilution (NOVUS Biologicals, NBP1-19 473; Littleton, CO, United States) were stored for 30 min, washed with Tris buffer, stored in DakoFlex HRP solution for 20 min, washed with Tris buffer again, and stored in DakoFlex DAB for 7 min. The samples were again washed with Tris-buffered saline, kept under tap water for 5 min, stained with Mayer's hematoxylin solution for 10 min, washed with tap water for 1 min, rinsed in an alcohol series, and cleaned with xylene for 5-10 min.

PDGFR alpha and beta positivity was determined according to a devised scoring system. According to this system, a score of 1 was assigned if PDGFR alpha and beta positivity was confirmed in inflammatory cells and in the cells of the lamina propria, stroma, and submucosal endothelium. A score of 2 was assigned if increased expression of PDGFR alpha and beta was confirmed in the lamina propria and submucosa. A score of 3 was assigned if PDGFR alpha and beta positivity was confirmed with widespread staining in the ulcerated areas or in the inflammatory cells, fibroblasts, endothelial cells, submucosa, and mucosa of the surrounding tissue.

### Statistical analysis

All statistical procedures were performed using SPSS software (version 15.0). The Kruskal-Wallis test was used

for multigroup comparisons, and the Mann-Whitney *U* test was used to compare the means of 2 groups. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

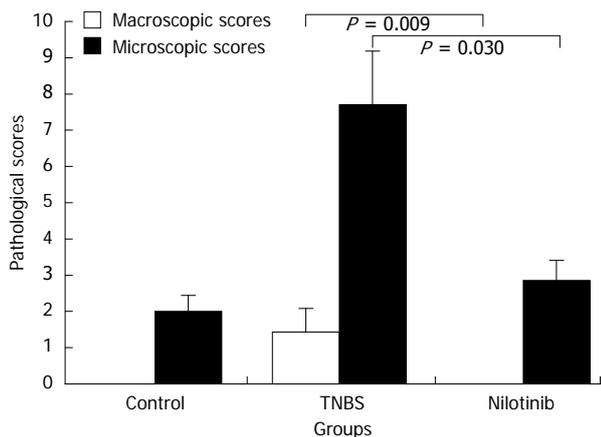

Bloody diarrhea was observed on day 1 of rectal TNBS administration in all 14 of the rats in the 2 experimental groups; no bloody diarrhea was observed in the control group. In the TNBS and nilotinib groups, the diarrhea was semi-solid on day 5. In the nilotinib group, normal stools were observed after day 7. During rectal saline administration under ether anesthesia in the control group, respiratory arrest developed in 1 rat, which remained stable after CPR. However, the animal's general condition deteriorated over the next few d, and the animal died on day 6 of the experiment. An autopsy was not performed on this rat.

On the first experimental day, the average weights were similar among all of the study groups ( $P > 0.05$ ), and the average weights were examined daily (Figure 1). The average weight of the control group increased to 8.3 g at the end of 14 d. The TNBS group, however, lost an average of 14 g throughout the study, and the nilotinib group lost an average of 0.7 g. There was a significant difference among the groups with regard to the average weight change throughout the study ( $P = 0.006$ ). The difference in weight between the control and nilotinib groups was statistically significant (+8.3 and -0.7 g, respectively,  $P = 0.031$ ). The TNBS group lost significantly more weight than the nilotinib group (-14.0 and -0.7 g, respectively;  $P = 0.047$ ) and the control group (-14.0 and +8.3 g, respectively,  $P = 0.008$ ).

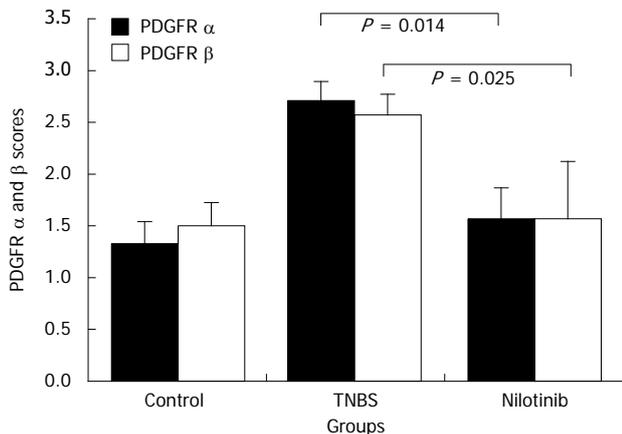

Between day 7 and day 14, the weights of the control group increased by an average of 8 g; those of the nilotinib group increased by an average of 2.9 g; and those of the TNBS group decreased by an average of 11.1 g. Comparing the average increase in weights over this time period among all 3 of the groups, there was a significant difference observed ( $P = 0.004$ ). From day 7 to day 14, the weight differences of the control rats *vs* the TNBS rats, the TNBS rats *vs* the nilotinib rats, and the control rats *vs* the nilotinib rats were statistically significant (+8.0 and -11.1 g,  $P = 0.007$ ; -11.1 and +2.9 g,  $P = 0.015$ ; +8.0 and +2.9 g,  $P = 0.042$ , respectively).

The mean macroscopic pathological scores of the control and nilotinib groups were 0, while the macroscopic pathological score in the TNBS group was  $1.43 \pm 0.65$ . When the distribution of macroscopic scores based on rats was examined, all scores from the control and nilotinib group rats were "0", which is noteworthy. The control and nilotinib groups were similar in terms of macroscopic scores ( $P > 0.05$ ). Macroscopic scores were significantly lower in the control and nilotinib groups than in the TNBS group ( $0.00 \pm 0.00$  and  $1.43 \pm 0.65$ ,  $P = 0.014$ ;  $0.00$  and  $1.43 \pm 0.65$ ,  $P = 0.009$ , respectively) (Figure 2).

The mean microscopic scores in the control, TNBS, and nilotinib groups were  $2.0 \pm 0.45$ ,  $7.71 \pm 1.48$ , and  $2.86 \pm 0.55$ , respectively. The mean microscopic scores were significantly lower in the control and nilotinib groups than

**Figure 2** Microscopic and macroscopic pathological scores among the experimental groups. The results are the mean ± SD. Macroscopic and microscopic pathological scores were similar in the control and nilotinib groups, while the scores in the nilotinib group were significantly lower than those in the trinitrobenzene sulfonic acid (TNBS) group (TNBS vs nilotinib,  $P = 0.009$ ; TNBS vs nilotinib,  $P = 0.030$ ).

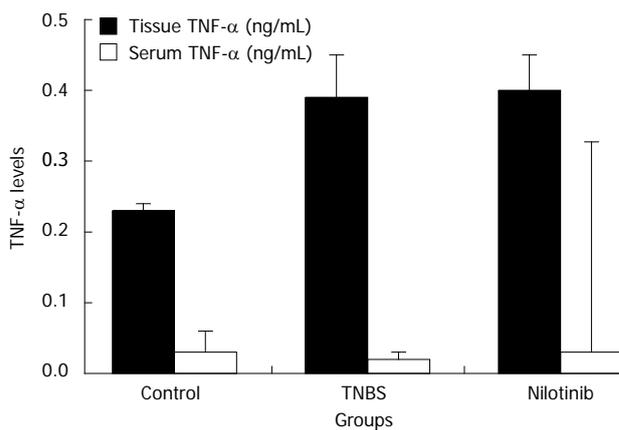

**Figure 3** Platelet-derived growth factor receptor alpha and beta scores among the experimental groups. The results are the mean ± SD. Platelet-derived growth factor receptor (PDGFR) alpha and beta scores were similar in the control and nilotinib groups, while the scores in the nilotinib group were significantly lower than those in the trinitrobenzene sulfonic acid (TNBS) group (TNBS vs nilotinib,  $P = 0.014$ ; TNBS vs nilotinib,  $P = 0.025$ ).

in the TNBS group ( $2.0 \pm 0.45$  and  $7.71 \pm 1.48$ ,  $P = 0.034$ ;  $2.86 \pm 0.55$  and  $7.71 \pm 1.48$ ,  $P = 0.030$ , respectively). The control and nilotinib groups were similar in terms of the mean microscopic scores ( $P > 0.05$ ) (Figure 2).

With regard to the PDGFR alpha and beta scoring system, the PDGFR alpha scores in the control, TNBS, and nilotinib groups were  $1.33 \pm 0.21$ ,  $2.71 \pm 0.18$ , and  $1.57 \pm 0.30$ , respectively. There was a significant difference among the groups ( $P = 0.007$ ). The PDGFR alpha scores were significantly lower in the control and nilotinib groups than in the TNBS group ( $1.33 \pm 0.21$  and  $2.71 \pm 0.18$ ,  $P = 0.004$ ;  $1.57 \pm 0.30$  and  $2.71 \pm 0.18$ ,  $P = 0.014$ , respectively). The control and nilotinib groups were similar in terms of the PDGFR alpha scores ( $P > 0.05$ ) (Figure 3).

The mean PDGFR beta scores in the control, TNBS,

**Figure 4** Tissue and serum tumor necrosis factor α levels among the experimental groups. The results are the mean ± SD. Serum tumor necrosis factor (TNF) and tissue TNF α levels were similar between the trinitrobenzene sulfonic acid (TNBS) and nilotinib groups.

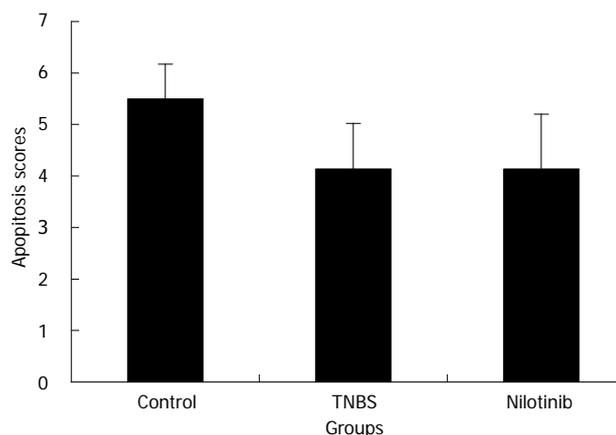

and nilotinib groups were  $1.50 \pm 0.22$ ,  $2.57 \pm 0.20$ , and  $1.57 \pm 0.30$ , respectively. There was a statistically significant difference among all of the groups in terms of the mean PDGFR beta scores ( $P = 0.020$ ). The PDGFR beta scores were significantly lower in the control and nilotinib groups than in the TNBS group ( $1.50 \pm 0.22$  and  $2.57 \pm 0.20$ ,  $P = 0.011$ ;  $1.57 \pm 0.30$  and  $2.57 \pm 0.20$ ,  $P = 0.025$ , respectively). The PDGFR beta scores of the control and nilotinib groups were similar ( $P > 0.05$ ) (Figure 3).

The mean serum TNF alpha levels in the control, TNBS, and nilotinib groups were  $0.03 \pm 0.03$ ,  $0.02 \pm 0.01$ , and  $0.03 \pm 0.01$  pg/mL, respectively. There was no statistically significant difference observed among the groups in terms of the mean serum TNF alpha levels ( $P > 0.05$ ) (Figure 4). The average tissue TNF alpha levels in the control, TNBS, and nilotinib groups were  $0.23 \pm 0.01$ ,  $0.39 \pm 0.06$ , and  $0.40 \pm 0.05$  ng/mL, respectively. There was a significant difference observed among the groups ( $P = 0.002$ ). TNF alpha levels were significantly lower in the control group than in the TNBS or nilotinib groups ( $0.23 \pm 0.01$  and  $0.39 \pm 0.06$  ng/mL,  $P = 0.002$ ;  $0.23 \pm 0.01$  and  $0.40 \pm 0.05$  ng/mL,  $P = 0.003$ , respectively). However, there was no statistically significant difference between the TNBS and nilotinib groups in terms of the mean tissue TNF alpha levels ( $P > 0.05$ ) (Figure 4).

The mean number of apoptotic cells detected by the TUNEL method in the control, TNBS, and nilotinib groups was  $5.50 \pm 0.67$ ,  $4.14 \pm 0.88$ , and  $4.14 \pm 1.06$ , respectively. The difference among the groups was not statistically significant ( $P > 0.05$ ) (Figure 5).

## DISCUSSION

IBDs, such as CD and UC, are chronic recurrent intestinal inflammatory conditions. Genetic, environmental, microbial, and immune factors play a role in the etio-pathogenesis of IBDs. Despite the development of biological therapies and advancements in genetic technology, treatment options remain limited for refractory cases.

**Figure 5 Apoptosis scores among the experimental groups.** The results are the mean  $\pm$  SD. Apoptosis scores were similar among the groups. TNBS: Trinitrobenzene sulfonic acid.

Mucosal healing has emerged as a key treatment goal for IBD and allows the prediction of sustained clinical remission and resection-free survival in affected patients. Mucosal healing can be achieved in approximately 30% of patients receiving corticosteroid therapy and in 60% of patients receiving anti-TNF agents<sup>[9-12]</sup>. Approximately 20% of IBD patients do not respond to anti-TNF therapy and require surgical intervention<sup>[12]</sup>. Thus, the currently available medical treatment options are ineffective in a substantial group of patients with IBD.

Nilotinib, which was used in this study, is a strong TK inhibitor that was initially approved for use in patients with imatinib-intolerant and imatinib-resistant Philadelphia chromosome-positive chronic or accelerated phase-CML and has since been approved as a frontline therapy in chronic phase CML<sup>[19]</sup>. Nilotinib is more potent than imatinib, which inhibits the autophosphorylation of various kinases, such as BCR-ABL, PDGFR, and c-KIT<sup>[19]</sup>. Nilotinib is generally well tolerated. Due to the lack of Src family kinase inhibition, myelosuppression is an infrequent adverse event that occurs less frequently with nilotinib than with other TK inhibitors<sup>[19]</sup>. The most common manageable adverse events are rash, pruritus, fatigue and headache. Neutropenia, anemia, thrombocytopenia, elevations of liver enzymes, cardiac toxicity, namely QT prolongation, fluid retention, edema, and weight gain are among the less common side effects<sup>[19]</sup>. TK inhibitors affect several key components in the pathogenesis of IBD, including TNF alpha, PDGFR, and NO synthesis. In this study, we evaluated the efficacy of nilotinib on weight, macroscopic and microscopic pathological scores, TNF alpha and PDGFR levels, and the apoptotic index in rat models with TNBS-induced colitis. There are no previous reports in the literature evaluating the efficacy of nilotinib in either a rat model of colitis or in human colitis.

In the present study, the weights of the control and experimental rats were monitored daily. At the end of 14 d, rats in the nilotinib group had lost significantly less weight than rats in the TNBS group ( $P = 0.047$ ). These results are similar to those obtained in the study by Cuzzocrea *et al*<sup>[16]</sup>, in which weight loss was significantly

reduced by 7 d of treatment with the TK inhibitor tyrophostin AG126 in a DNBS-induced colitis animal model. The TK inhibitor used in the study by Cuzzocrea *et al*<sup>[16]</sup> is different from that used in our study. However, our study indicates that nilotinib does have a positive effect on weight in animal models with colitis.

The first therapeutic target in drug studies for the treatment of IBD was the regression of disease-related symptoms. The most important reason for this was that the agents used in the treatment of IBD were not disease-modifying drugs. In more recent studies, however, the primary endpoint in evaluating the therapeutic efficacy of drugs used to treat IBD has been “mucosal healing”<sup>[20]</sup>. With mucosal healing as the therapeutic target, continuous clinical remission and survival without surgery can be achieved<sup>[21]</sup>. The mucosal healing rates of anti-TNF agents have been reported at approximately 60% in the active ulcerative colitis trials (ACT)-1 and ACT-2 studies<sup>[7,10]</sup>. In the present study, the effects of nilotinib on mucosal healing and pathological macroscopic and microscopic scores yielded quite remarkable results. The macroscopic and microscopic pathological scores of intestinal tissue from the nilotinib group were similar to those of the control group ( $P > 0.05$ ) but significantly lower than those of the TNBS group ( $P = 0.009$ ;  $P = 0.030$ , respectively). In our study, the similar microscopic and macroscopic scores of the nilotinib and control groups constituted the most important evidence of the mucosal healing effect of nilotinib. Indeed, in the study conducted by Cuzzocrea *et al*<sup>[16]</sup>, the rats treated with the TK inhibitor showed significant histological improvements after treatment compared with the control rats. This result parallels the results of our study. Although there are no human studies investigating the use of TK inhibitors in patients with IBD, the case report by Magro *et al*<sup>[15]</sup> representing a case of long-standing remission from Crohn’s disease under imatinib therapy supports these results. However, a number of caveats should be noted regarding the present study. This is the first study of nilotinib in a rat colitis model. The current study was unable to compare the efficacy of nilotinib with that of other IBD agents or to assess the adverse events of nilotinib. Generally, as found in previous studies on CML, nilotinib has been a well-tolerated agent with manageable adverse effects. The findings of this study have a number of important implications for future practice. Further experimental investigations could provide more definitive evidence for human studies.

In our study, to determine the effectiveness of nilotinib on colitis, the PDGFR alpha, PDGFR beta, TNF alpha, and apoptosis levels were compared among the groups. Similar to the results observed in the macroscopic and microscopic pathological scores, the PDGFR alpha and beta scores were significantly lower in the nilotinib group than in the TNBS group ( $P = 0.014$ ,  $P = 0.025$ ) but were similar to the control group. There are no other studies investigating the effects of TK inhibitors on the levels of PDGFR alpha and beta in a colitis animal model. Histologically, in IBD, the intestinal microvascula-

ture shifts into a tight angiogenic structure characterized by the increased secretion of angiogenic integrins and mediators into the inflamed mucosa<sup>[22]</sup>. PDGF alpha and beta are 2 of the angiogenic mediators whose levels increase in IBD<sup>[23]</sup>. Increased PDGF alpha and beta activity can be found in the fibrotic areas adjacent to the active ulcer areas in IBD. Kumagai *et al.*<sup>[24]</sup> detected the increased expression of PDGF and PDGFR in the areas with active fibrosis in IBD, and they considered that this contributes to the development of IBD. The macrovascular results of this process were demonstrated as endothelial dysfunction in study of Principi *et al.*<sup>[25]</sup> due to decreased brachial artery flow-mediated vasodilatation in patients with IBD. The results of our study suggest that nilotinib enacts its effect on mucosal healing in colitis by blocking PDGFR alpha and beta.

TNF alpha is a protein that plays a role in cell proliferation, differentiation, and cell survival. It is responsible for the expression of adhesion molecules, fibroblast proliferation, the release of procoagulant substances, the initiation of cytotoxic apoptosis, and the acute phase response<sup>[26]</sup>. It has a clearly defined role in the pathogenesis of IBD, and anti-TNF agents are currently being used in the successful treatment of IBD<sup>[10]</sup>. In IBD, induced apoptosis can be triggered by TNF alpha, which causes much larger leaks in the intestinal barrier<sup>[27]</sup>. Previous studies have demonstrated that TNF alpha and IL-1 beta, both proinflammatory cytokines synthesized in the colon, are reduced with TK inhibition<sup>[16,28]</sup>. In our study, the apoptotic indices and serum and tissue levels of TNF alpha were evaluated. The serum and tissue levels of TNF alpha and the apoptotic index in the nilotinib group were found to be similar to those in the TNBS group. Previously, it has been shown that TNF alpha levels on day 7 are significantly higher in acute models of colitis established through a single dose application of TNBS, compared to the model of chronic colitis using weekly TNBS administrations<sup>[29,30]</sup>. That the serum and tissue TNF alpha levels were similar in the nilotinib and TNBS groups in our study might be explained by the length of the experiment (14 d), during which a TNF alpha peak could not be obtained. Additionally, the apoptosis indices were similar between both groups in our study. D'Argenio *et al.*<sup>[31]</sup> demonstrated the apoptotic cells and expressions of apoptotic proteins in TNBS-induced colitis over 4 wk. According to the results of this study, the apoptotic cell count was detected to be significantly decreased after first week by the TUNEL method<sup>[31]</sup>. The similar apoptotic scores detected in our study might be because the apoptotic cell peak could not be obtained after 14 d. Furthermore, the similar results of the TNF alpha levels and apoptosis scores in our study might also suggest that nilotinib has no significant effect on TNF alpha levels and apoptosis.

In conclusion, nilotinib has a significant effect on weight loss, as well as on the macroscopic and microscopic pathological scores in rats with TNBS-induced colitis, leading to significant mucosal healing. Although nilotinib caused a decrease in PDGFR alpha and PDGFR

beta levels, it did not have a significant effect on apoptotic scores or TNF alpha levels.

## COMMENTS

### Background

Genetic and environmental factors, infectious agents, the structure of enteric flora, and immune system dysfunction are key elements in the pathogenesis of inflammatory bowel disease (IBD); thus, these are the targets for many drugs developed to treat IBD. Unresponsiveness to medical treatments in refractory IBD still poses a therapeutic challenge. Tyrosine kinases (TKs) are enzymes that play a role in normal cell function, metabolism, growth, differentiation, and apoptosis. To establish an alternative treatment option, they selected nilotinib based on the fact that TK inhibitors affect several key components in the pathogenesis of IBD, including tumor necrosis factor (TNF) alpha, platelet-derived growth factor receptor (PDGFR), and apoptosis.

### Research frontiers

Nilotinib is a TK inhibitor that is typically used as an anticancer drug. Recently, it has been considered for use in noncancerous proliferative diseases and for inflammatory conditions. Authors concluded that nilotinib has a significant effect on weight loss and macroscopic and microscopic pathological scores while leading to significant mucosal healing. Although nilotinib caused a decrease in the PDGFR alpha and PDGFR beta levels, it did not have a significant effect on apoptotic scores or TNF alpha levels.

### Innovations and breakthroughs

Genetic, environmental, microbial, and immune factors play a role in the etio-pathogenesis of IBDs. The currently available medical treatment options are ineffective in a substantial group of patients with IBD. Nilotinib, as used in this study, is a strong TK inhibitor. TK inhibitors affect several key components in the pathogenesis of IBD, including TNF alpha, PDGFR, and nitric oxide synthesis. Before this study, there were no reports in the literature evaluating the efficacy of nilotinib in a rat colitis model. One previous study showed that the use of a different TK inhibitor could successfully treat rat colitis. There are no human studies investigating the use of TK inhibitors in patients with IBD.

### Applications

The results of this study suggest that nilotinib has a significant effect on weight loss, as well as on the macroscopic and microscopic pathological scores of rats with Trinitrobenzene sulfonic acid (TNBS)-induced colitis. Additionally, this treatment leads to significant mucosal healing and caused a decrease in PDGFR alpha and PDGFR beta levels, although it did not have a significant effect on apoptotic scores or TNF alpha levels. These results suggest that *nilotinib* may be effective in patients with IBD. The findings of this study have a number of important implications for the future practice. Therefore, further studies are needed to draw firm conclusions.

### Terminology

IBD are chronic inflammatory disorders of the gastrointestinal tract that have characteristic clinical, pathological, endoscopic and radiological features. TKs are enzymes that play a role in normal cell function, metabolism, growth, differentiation, and apoptosis. TK inhibitors are drugs that block the action of these enzymes. TNBS-induced colitis is a well-established animal model of mucosal inflammation that has been used for over 2 decades in the study of IBD pathogenesis, as well as in preclinical studies.

### Peer review

This is an excellent basic research animal study using a well-known model of TNBS-induced colitis in rats. The authors explored the ability of a tyrosine kinase inhibitor, nilotinib, to treat various clinical (weight determination), laboratory (TNF levels, apoptotic index) and pathological parameters (macroscopic and microscopic pathologic scores, PDGFR levels) and to quantify results. They were basically able to demonstrate mucosal healing effects, clinical improvements and decreased PDGFR alpha and beta levels; however, significant drops in the TNF peaks and apoptotic indices were not clearly shown.

with lymphadenectomy in the Department of Surgery, Xin Hua Hospital and Rui Jin Hospital of Shanghai Jiaotong University Medical School between November 2001 and May 2012. Both the surgical procedure and extent of lymph node dissection were based on the recommendations of Japanese gastric cancer treatment guidelines. Univariate and multivariate analyses of lymph node metastases and the clinicopathological features were undertaken.

**RESULTS:** The rate of lymph node metastases in male patients with gastric cardiac adenocarcinoma was 72.1%. Univariate analysis showed an obvious correlation between lymph node metastases and tumor size, gross appearance, differentiation, pathological tumor depth, and lymphatic invasion in male patients. Multivariate logistic regression analysis revealed that tumor differentiation and pathological tumor depth were the independent risk factors for lymph node metastases in male patients. There was an obvious relationship between lymph node metastases and tumor size, gross appearance, differentiation, pathological tumor depth, lymphatic invasion at pN<sub>1</sub> and pN<sub>2</sub>, and nerve invasion at pN<sub>3</sub> in male patients. There were no significant differences in clinicopathological features or lymph node metastases between female and male patients.

**CONCLUSION:** Tumor differentiation and tumor depth were risk factors for lymph node metastases in male patients with gastric cardiac adenocarcinoma and should be considered when choosing surgery.

## INTRODUCTION

Although its incidence and mortality have declined over the past 50 years, gastric cancer (GC) remains the fourth most common cancer and the second most frequent cause of cancer death worldwide<sup>[1-3]</sup>. In China, GC is the second most common malignancy and the third most frequent cause of cancer-related death, with an annual age-adjusted mortality rate of 24.34 deaths per 100000 people<sup>[4]</sup>. As GC incidence declines, the frequency of proximal gastric and gastroesophageal junctional adenocarcinomas continues to rise, and has become a significant clinical challenge<sup>[5-7]</sup>. The reasons for this rapid increase in aggressive proximal malignancies remain unclear. Tumors in the upper third of the stomach might spread *via* the lymphatic system through the lower esophageal channel to the mediastinum, through the suprapancreatic channel to the abdomen, or through the abdominal para-aortic channel to the retroperitoneum. Surgery is currently the only treatment that can lead to a cure. However, the optimal surgical strategy for tumors in the cardiac area of the stomach, especially tumors invading the lower esophagus, remains controversial<sup>[6]</sup>. The development of effective therapeutic strategies for these tumors requires information on patient characteristics, patterns of lymph node metastasis, and the efficacy of lymph node dissection. Adenocarcinoma of the cardia generally has a low curative resection rate and a poor prognosis; worse than carcinoma of the other regions of the stomach, mainly because the disease is at a more advanced stage at diagnosis<sup>[6-8]</sup>. The 5-year survival rate in resected cases is  $\leq 20\%$ <sup>[9]</sup>.

The role of lymphadenectomy in GC surgery has been hotly debated during the past three decades. Although there is still no standard approach, it is obvious that an adequate lymphadenectomy, removing all the possible metastatic nodes, remains a milestone in GC surgery<sup>[10]</sup>. The most recent edition of the tumor, node, metastasis (TNM) classification states that at least 15 lymph nodes must be examined to form an accurate eval-

uation of the node status. The optimal extent of lymphadenectomy (D2) for this cancer has been defined in the Japanese Classification of Gastric Carcinoma<sup>[11]</sup>, based on the retrospective historical data of the involved nodes in patients with gastric carcinoma. The optimal extent of lymph node dissection for Siewert type II esophagogastric junction (EGJ) carcinoma is poorly defined in this classification. Rüdiger Siewert *et al*<sup>[12]</sup> uncovered the distribution of metastatic nodes in patients with type II adenocarcinoma. In their cohort of 186 patients, they found that the disease mainly involved the paracardial and lesser curve nodes, followed in frequency by the nodes in the lower mediastinum, and suprapancreatic nodes and nodes along the greater curve were involved in patients with Siewert type II EGJ cancers. Furthermore, they found positive parapyloric nodes in three of their patients, which lends support to their recommended strategy of extended total gastrectomy for type II EGJ carcinoma.

Therefore, in the present study, we reevaluated retrospectively the clinicopathological features and distribution of metastatic nodes in a two-center cohort of 146 patients with gastric cardiac adenocarcinoma. Univariate and multivariate analyses were applied to confirm the clinicopathological factors associated with lymph node metastases, and to provide a basis for choosing the optimal surgical treatment and for determining the appropriate range of lymph node dissection.

## MATERIALS AND METHODS

### Patients

Data were collected from a prospectively maintained database of patients with histologically confirmed gastric cardiac carcinoma who had curative gastrectomy (R0) with lymphadenectomy in the Department of Surgery, Xin Hua Hospital and Rui Jin Hospital of Shanghai Jiaotong University Medical School between November 2001 and May 2012. The clinicopathological characteristics and lymph node metastasis of gastric cardiac adenocarcinoma were compared in male and female patients (Table 1).

### Surgery

All operations were performed with curative intent. Curative surgery was defined as the removal of all gross tumor and the demonstration of tumor-negative surgical margins by microscopic examination of the entire circumference. Subtotal or total gastrectomy was performed according to the tumor size, tumor location, and the status of the resection margins. Proximal gastrectomy involved resection of the proximal half of the stomach *via* an abdominal or thoracic approach, with an esophago-gastric anastomosis. Following total gastrectomy with D2 lymph node dissection, an esophagojejunostomy was used routinely for Roux-en-Y reconstruction. Proximal resection margins were evaluated intraoperatively to confirm freedom from disease. Resection of adjacent organs was undertaken to achieve clear margins when deemed necessary. Both the surgical procedure and the extent of

lymph node dissection were based on the recommendations of the Japanese GC treatment guidelines<sup>[13]</sup>. No patient received neoadjuvant chemotherapy or postoperative radiotherapy.

### Pathological examination

In both hospitals, the surgical team immediately examined the lymph nodes macroscopically, which were then divid-

ed and classified into lymph node stations, as defined by the Japanese Classification of Gastric Carcinoma<sup>[14]</sup>. No size limitation was imposed for lymph node harvesting. Specimens were fixed in formalin, stained with hematoxylin and eosin, and sent for histopathological evaluation, following which the number of histologically confirmed lymph nodes was recorded for each lymph node station. Each lymph node was embedded in paraffin and at least two sections were taken. Immunohistochemistry for micrometastasis was not performed.

Tumor size was recorded as the maximum diameter. The depth of infiltration was measured at the deepest point of penetration of the cancer cells. In this study, we referred to the classifications established by the Japanese Classification of Gastric Carcinoma: 3<sup>rd</sup> English edition<sup>[14]</sup>, which define T1 as a tumor confined to the mucosa (M) or submucosa (SM); T2 as a tumor that invades the muscularis propria (MP); T3 as a tumor that invades the subserosa (SS); and T4 as tumor invasion that is contiguous to or exposed beyond the serosa (SE) or tumor invades adjacent structures (SI). The macroscopic type was classified as type 0 (superficial), type 1 (mass), type 2 (ulcerative), type 3 (infiltrative ulcerative), type 4 (diffuse infiltrative) or type 5 (unclassifiable). We evaluated the tumor histology according to the classification established by the Japanese Research Society for GC<sup>[11]</sup>. Well- and moderately differentiated tubular adenocarcinoma, and papillary adenocarcinoma were classified as differentiated-type carcinomas; and poorly differentiated adenocarcinoma, signet ring cell carcinoma and mucinous carcinoma were classified as undifferentiated-type carcinomas.

The nodal classification was classified into four groups: pN<sub>0</sub>, no metastasis; pN<sub>1</sub>, one or two positive regional lymph nodes; pN<sub>2</sub>, 3-6 positive regional lymph nodes; and pN<sub>3</sub>, ≥ 7 positive regional lymph nodes. We conducted the tumor staging according to the Japanese Classification of Gastric Carcinoma: 3<sup>rd</sup> English edition<sup>[14]</sup>. The ratio of lymph node metastasis was calculated by determining the number of patients with a metastasized lymph node in a particular station divided by the number of patients who underwent dissection of that lymph node. The metastatic incidence is the ratio of metastatic nodes to the total number of dissected nodes and was recorded for each nodal station for all regional lymph nodes.

### Ethics

This study was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. The Institutional Review Board of Shanghai Jiaotong University gave ethical approval for this study. All patients provided written informed consent.

### Statistical analysis

Descriptive data are presented as the mean ± SD. For between group comparisons, continuous variables were analyzed using Student's *t* test, and categorical variables with the  $\chi^2$  test. Factors found to be significant (*P* <

0.05) in univariate analysis were included in subsequent multivariate logistic regression analysis, to identify independent variables associated with lymph node metastases. All statistical analyses were undertaken using SPSS for Windows, version 18.0 (SPSS, Chicago, IL, United States). For all analyses,  $P < 0.05$  was considered statistically significant.

## RESULTS

### *Demographics and clinicopathological features of gastric cardiac adenocarcinoma*

The clinicopathological characteristics of gastric cardiac cancer are illustrated in Table 1. Among the 146 patients, there were 111 men and 35 women, ranging in age from 16 to 84 years (mean  $63.9 \pm 11.6$  years). Surgical procedures comprised 93 proximal gastrectomies and 53 total gastrectomies. Splenectomy was required in 8 (5.5%) of the 146 patients undergoing curative resections. The total splenectomy patients were all male. Mean tumor length was 5.54 cm. Of the 146 patients, 6 (4.1%), 13 (8.9%), 105 (71.9%), 13 (8.9%) and 8 (5.8%) were type 0, 1, 2, 3 and 4, respectively. Tumors were differentiated in 76 patients and undifferentiated in 70. The number of lymph

nodes retrieved was  $22.88 \pm 9.16$ , and 104 patients had positive lymph node metastases (71.2%). There were eight cases with a T1 tumor, 16 with a T2 tumor, 4 with a T3 tumor, and 118 with a T4 tumor. Lymph node involvement according to the Japanese Classification of Gastric Carcinoma: 3<sup>rd</sup> English edition<sup>[14]</sup> included 43 patients with N0 disease, 27 with N1 disease, and 76 with N2-3 disease (Table 2). Evidence of lymphatic invasion, venous invasion and neural invasion was seen in 24 (16.4%), 5 (3.4%) and 22 patients (15.1%), respectively. On pathological examination, the tumors of 31 patients (21.2%) were found to have invaded the lower esophagus. None of the clinicopathological factors, such as age, type of gastrectomy, tumor size, gross appearance, tumor differentiation, pathological tumor depth, node status, pTNM staging, lymphatic invasion, venous invasion, nerve invasion and esophagus involvement were different between male and female patients ( $P > 0.05$ ).

### *Univariate analysis of lymph node metastasis in gastric cardiac cancer and clinicopathological factors*

Univariate analysis was performed on the relationship between lymph node metastases and clinicopathological factors. The findings revealed a close relationship between

tumor size, gross appearance, differentiation, pathological depth, lymphatic invasion and lymph node metastases in all patients ( $P = 0.011$ ,  $P = 0.000$ ,  $P = 0.000$ ,  $P = 0.000$  and  $P = 0.001$ , respectively) and in male patients ( $P = 0.011$ ,  $P = 0.000$ ,  $P = 0.000$ ,  $P = 0.000$  and  $P = 0.003$ , respectively). However, there was no obvious correlation between lymph node metastases and clinicopathological features in female patients, nor between male and female patients (Table 3).

#### Multivariate analysis of lymph node metastases in gastric cardiac cancer for the entire study population and male patients

Multivariate analysis revealed that only tumor differentiation was an independent risk factor for lymph node metastases in gastric cardiac cancer for the entire study population ( $P = 0.001$ ). Tumor size, gross appearance, pathological depth and lymphatic invasion had no significant effect on nodal involvement rates (Table 4). Multivariate analysis revealed that tumor differentiation and pathological depth were independent risk factors for lymph node metastases in gastric cardiac cancer for male patients ( $P = 0.001$ ,  $P = 0.020$ ). Tumor size, gross appearance and lymphatic invasion had no significant effect

on nodal involvement rates (Table 4).

#### Relationship between sex and number of metastatic lymph nodes

There was no significant difference between female and male patients in terms of the number of retrieved lymph nodes, using the independent sample  $t$  test ( $P = 0.878$ ). The number of metastatic lymph nodes in female patients was higher than that in male patients ( $6.20 \pm 7.49$  vs  $4.84 \pm 5.44$ ). However, the difference was not significant ( $P = 0.243$ ).

**Retrieved lymph nodes, lymph node metastases, lymph node metastasis ratios and incidence for involved lymph nodes at each station in gastric cardiac adenocarcinoma**  
Lymph nodes ( $n = 3340$ , median 22.88; range 15-62) were removed from the 146 patients and examined, and 754 (median 5.16; range 0-30) were metastatic. For female patients, 807 (median 23.06; range 15-61) lymph nodes were examined and 217 (median 6.20; range 0-30) contained metastases. For male patients, 2533 (median 22.82; range 15-62) lymph nodes were examined and 537 (median 4.84; range 0-26) contained metastases (Table 5).

According to the Japanese Classification of Gastric Carcinoma: 3<sup>rd</sup> English edition<sup>[14]</sup>, 103 cases (70.5%) were at N1, 23 cases (15.8%) at N2, 15 cases (10.3%) at N3, and four cases (2.7%) at M. A direct skip to N3, without moving through N2, occurred in 10 cases (6.8%). There were no skips to N2 without going through N1. Nodal metastases were frequent in the abdominal nodes, followed in frequency by involvement of the No. 3 (59.6%), No. 1 (26.7%), No. 2 (18.5%), and No. 4 (16.4%) nodes, and thereafter by mediastinal lymph nodes, which were affected only in a small number in our series (No. 110, 0.7%). The frequency of the metastatic involvement of the supra- and infra-pyloric nodes was low (4.1% and 3.4%, respectively), and no cases with metastasis to Nos. 13-15 were found. Only four patients received station No. 16 lymph node dissection, and three of them had metastasis (Table 5).

The extent of metastases in female cases was as follows: 24 cases were at N1 (16.4%, 24/146), representing a metastatic rate of 68.6% (24/35); 5 cases were at N2 (3.4%, 5/146), with a metastatic rate of 14.3% (5/146); and 4 cases were found at N3 (2.7%, 4/146), with a metastatic rate of 11.4% (4/146). The extent of metastases in male patients was as follows: 79 cases (54.1%) occurred at N1, with a metastatic rate of 71.2%; 18 cases occurred at N2 (12.3%), with an incidence of 16.2%; and 11 cases occurred at N3 (7.5%), with an incidence of 9.9% (Table 5).

**Correlation between lymph node metastases at pN<sub>1</sub>, pN<sub>2</sub> and pN<sub>3</sub> and clinicopathological factors, using the Japanese GC association classification for the entire study population and between male and female patients**  
Univariate analysis of variance revealed a close relationship between tumor size, gross appearance, differentiation, pathological depth and lymphatic invasion and

lymph node metastases at pN<sub>1</sub> in all patients ( $P = 0.020$ ,  $P = 0.000$ ,  $P = 0.000$ ,  $P = 0.000$  and  $P = 0.001$ , respectively) and male patients ( $P = 0.021$ ,  $P = 0.000$ ,  $P = 0.001$ ,  $P = 0.001$  and  $P = 0.002$ , respectively) (Table 6). However, there was no obvious correlation between lymph node metastases and clinicopathological features in female patients (Table 6) and between male and female patients (Table 7).

There was obvious relationship between the lymphatic invasion and lymph node metastases at pN<sub>2</sub> in all patients ( $P = 0.048$ ) and male patients ( $P = 0.046$ ) (Table 6). There was no significant correlation between clinicopathological features and the presence of lymph node metastases at pN<sub>2</sub> in female patients (Table 6) nor between male and female patients (Table 7).

There was an obvious relationship between lymphatic invasion and nerve invasion and lymph node metastases at pN<sub>3</sub> in all patients ( $P = 0.009$ ,  $P = 0.001$ ) (Table 6). There was a significant correlation between lymphatic invasion in female patients (Table 6) and neural invasion in

male patients (Table 6) and the presence of lymph node metastases at pN<sub>3</sub>. There was no significant correlation between clinicopathological features and the presence of lymph node metastases at pN<sub>3</sub> between male and female patients (Table 7).

## DISCUSSION

According to some clinicians, true carcinoma of the cardia may be considered a distinct clinical entity, with different biological behavior and a more aggressive natural history than subcardial gastric carcinoma<sup>[15-17]</sup>. Strangely enough, the location, extent and even the existence of the gastric cardia are controversial<sup>[18]</sup>. Anatomists have applied the term cardia to that part of the stomach that lies around the orifice of the tubular esophagus. The American Joint Committee on Cancer describes the EGJ as the first part of the stomach, which is located immediately below the diaphragm and is often called the cardia<sup>[19]</sup>. The definition of the cardia commonly employed in Japan is

the area within 2 cm above and below the EGJ, and tumors whose center is situated in this area are considered to be cancer of the cardia; such cancers are distinguished from upper GCs. Siewert *et al*<sup>[20]</sup> proposed a topographical classification for cardiac carcinomas. In contrast to the previously described classification system, Siewert and Stein<sup>[20]</sup> attempted to resolve the problem of splitting up EGJ tumors into esophageal and gastric tumors by creating a third entity. These tumours show a high rate of early lymphatic dissemination and lymph node metastases<sup>[12,21]</sup> and are usually related to poorer prognosis<sup>[12,21]</sup>. The reasons for this sudden increase of gastric cardia carcinomas are not clear, but changing risk factors such as smoking, alcohol use, presentation at a more advanced stage, salty foods, pollution and increases in gastroesophageal reflux diseases might explain it partially<sup>[5,7,23]</sup>.

It is crucial that the therapeutic strategy for gastric cardiac adenocarcinoma be clarified through evaluation of both the pattern of lymph node metastasis and the efficacy of lymph node dissection in this region. According to Siewert *et al.*<sup>[20]</sup>, metastases already exist in 72.0% of the cases at the time of surgery on tumors of the distal esophagus and the cardia. Lymphogenous metastases were present in 73.5% of the cases in our study. The cause of the frequent invasion of lymph nodes is the density of the lymph duct supply both to the stomach and to the lower esophagus, such that the cancers at the EGJ invade the regional lymph nodes concerned at an early stage<sup>[24]</sup>.

Previous studies have proved that the number of lymph nodes retrieved has a significantly impact in pN category, which resulted in a “stage-migration” phenomenon<sup>[25-27]</sup>; therefore, in the present study the quality of lymphadenectomy was adequate because the median number of resected lymph nodes was clearly more than 15, as recommended by the Japanese Classification of Gastric Carcinoma: 3<sup>rd</sup> English edition<sup>[14]</sup>. Furthermore, the median number of 23 lymph nodes in our study is comparable with other prospective studies on the treatment of GC<sup>[27,28]</sup>. The number of dissected lymph nodes is closely associated with the pathological stages and prognosis. A

population-based study by Bouvier *et al.*<sup>[29]</sup> showed that the error rate was 47.1% if the pathological stages were classified according to the identical TNM stages for the patients with < 10 or > 15 detected lymph nodes. Thus, the pathological stages are not reliable for patients with < 10 detected lymph nodes in GC surgery. On TNM stages, Union for International Cancer Control version 5 states that the number of dissected lymph nodes in advanced GC must be ≥ 15 to ensure the reliability of pathological stages and prognosis judgment. In a study reported by Karpeh *et al.*<sup>[30]</sup>, 27 patients with GC classified as stage II and III disease, and having < 15 lymph nodes examined, had significantly lower 5-year survival rates than those who had ≥ 15 lymph nodes examined. In a similar analysis, Bouvier *et al.*<sup>[29]</sup> concluded that > 10 lymph nodes should be analyzed per specimen to allow for valid N staging.

The sex distribution in this study showed an absolute male predominance (3.2:1) in gastric cardiac adenocarcinoma, which is similar to previous studies<sup>[23,31,32]</sup>. The sex ratio for cancer of the pylorus is only 1.5<sup>[33]</sup>. Although the exact reason for the male predominance of this type of cancer remains unknown, it seems to be a definite feature of this type of tumor, irrespective of the origin of the population<sup>[7,34]</sup>. Some scholars pointed out that this

may be because sex hormones such as estrogen affect the incidence rate of GC<sup>[35,36]</sup>. In our group, 98.6% of patients had tumors > 2 cm. Larger tumors have higher rates of lymph node metastases. Of the 104 cases with lymph node metastases, all the tumor sizes were > 2 cm, accounting for all metastases. Morphological classification was mainly of the ulcerative type (71.9%). Otherwise, type 0, 1, 3 and 4 accounted for 4.1%, 8.9%, 8.9% and 5.5%, respectively. Histologically, there were slightly more undifferentiated tumors (52.1%) than differentiated tumors (47.9%), and > 83.6% of patients had T3 or T4 tumors.

Toward the latter, the seventh edition of the TNM classification of malignant tumors defines rules for classifying carcinomas arising within the vicinity of the EGJ to end the imprecise regulation of earlier editions, where carcinomas around the EGJ could be staged according to either the classification of esophageal carcinomas or the classification of gastric carcinomas. However, neither of the two staging systems has proven to be clearly superior to the other, and neither of them is perfect for so-called cardiac adenocarcinomas. For the N classification of the so-called cardiac adenocarcinomas, both schemes are monotone and distinct, with continuously decreasing and significantly different prognosis with an increasing number of lymph node metastases<sup>[37]</sup>. Huang<sup>[38]</sup> pointed out that the Version 7 manual would predict the prognosis of patients more effectively than the Version 6 manual according to the staging of GC. The staging of lymph nodes (pN) can predict the prognosis better than the invasion depth of cancer tissue (pT), while the lymph node status in the axial area of the celiac artery is particularly critical. The Version 7 manual defined the EGJ-involved gastric cardia cancer staging improperly and this should be corrected. Of course, their research results are to be updated and verified with more large-sample studies. Huang *et al.*<sup>[39]</sup> postulated that type II EGJ adenocarcinomas are more adequately staged as GC by the seventh edition of the American Joint Committee on Cancer classification.

Many researchers have attempted to investigate the relationship between nodal involvement and clinicopathological factors. The factors related to lymph node metastasis include age, sex, clinical staging of tumor, pathological tissue type, invasion depth of lesion, tumor size, and typing. As expected, we found tumor characteristics such as tumor size, gross appearance, differentiation, pathological depth and lymphatic invasion were associated with lymph node metastases in all patients and male patients, and could represent a selection indicator of lymph node dissection. However, there was no obvious correlation between lymph node metastases and clinicopathological features in female patients. In gastric cardiac adenocarcinoma, the clinicopathological features and lymph node metastasis patterns did not differ significantly between male and female patients. These results were similar to those reported by previous studies<sup>[40]</sup>. Male patients had lymph node metastasis in 72.1%;

slightly higher than that in female patients. The present study discovered that the metastasis rate of lymph nodes increased with the maximum diameter of the lesion; nevertheless, it is not advisable to simply take the tumor size as the correlation factor for predicting the lymph node metastasis because of variations in the period of tumor growth. Borrmann typing is also related to lymph node metastasis. The metastasis rate of lymph nodes in type III and IV GC was significantly higher than in type I and II in this paper. This could be explained by the main invasion growth of the former types and the limited growth of the later types, because weak or strong invasion ability may lead to differences in the metastasis rate of lymph nodes. Histological type is closely related to nodal status. In our group, the rate of lymph node metastases in undifferentiated tumors was higher than that observed in differentiated cancer: 85.7% (60/70) and 67.9% (44/76), respectively. The tumor differentiation extent decides the biological behavior of GC. A larger extent of cell differentiation possibly causes a larger metastasis rate of lymph nodes. Some scholars have found that poorly differentiated GC cells produced more type IV collagenase, which can degrade the basilar membrane, reduce the ability to resist cancer cell infiltration, and cause the rate of lymph node metastasis to be higher than that for differentiated adenocarcinoma. Moreover, there is an increasing rate of node involvement as the T stage increases; in our series, 12.5% of T1, 50.0% of T2, 75.0% of T3 and 78.0% of T4 cases had positive nodes. This suggests a correlation between T stage factor and the presence of positive nodes. The results of this study showed that lymphatic duct invasion is closely related to the lymph node metastasis; the metastasis rate of lymph nodes was up to 100% in the LVI (+) group, but 0% in the LVI (-) groups. Many studies have shown that metastasis of lymphatic duct invasion occurs before lymph node metastasis. The presence of lymphatic duct invasion or cancer cells indicates the prophase of lymph node metastasis or a manifestation of lymph node metastasis. The above factors should be the focus of preoperative gastric cardia treatment options. The appropriate degree of lymph node dissection must be selected to improve the surgical efficacy in gastric cardia cancer.

In this study, multivariate analysis revealed that tumor differentiation was the only independent risk factor for lymph node metastases in all patients, and revealed that tumor differentiation and pathological depth were independent risk factors for lymph node metastases in male patients. By logistic methods, Liu *et al.*<sup>[41]</sup> also confirmed that the tumor length, invasion depth, blood vessel invasion and specimen stump had a significant effect on lymph node metastasis. With the increase of tumor length and invasion depth, the appearance of blood vessel invasion and specimen stump cancer cells, the risk of lymph node metastasis increased significantly.

The new nodal staging in the 7<sup>th</sup> TNM classification is based on the number of metastatic nodes. In our group, all 146 cases of gastric cardiac adenocarcinoma

received radical gastrectomy. Postoperatively, 3340 regional lymph nodes were located. Seven hundred and fifty-four lymph nodes were found in 104 cases with lymph node metastases - an average of 7.25 per case. It had been considered that all the regional nodes of the stomach were potentially involved in metastasis in patients with adenocarcinoma of the gastric cardia<sup>[42]</sup>. Lymphogenous metastasis by cancer of the cardia frequently affects the lymph nodes at the greater and lesser curvature of the stomach. Less frequent involvement of the lymph nodes at right cardiac and left cardiac lymph nodes has been observed<sup>[39,43,44]</sup>. In line with previous findings<sup>[12,45,46]</sup>, the Mine *et al*<sup>[47]</sup> confirmed that nodal station numbers 3 (lesser curvature), 1 (right cardia), 2 (left cardia) and 7 (left gastric artery) were most frequently involved in type II junctional cancers. The study of Hosokawa *et al*<sup>[40]</sup> came to a similar conclusion. The present study discovered that the perigastric lymph nodes (in Groups 3, 1, 4 and 2) in patients with the cardia cancer ranked the top four positions by metastasis rate, suggesting that the cardiac lymph node is a key dissection object in the reasonable radical operation.

Even after a precise anatomical-topographical differentiation of this tumor entity, Siewert *et al*<sup>[20]</sup> found a small number of patients with parapyloric node metastasis in their cohort with type II adenocarcinoma. Consistent with their finding, in our patient series we found 4.1% of patients with suprapyloric node metastasis and 3.4% with infrapyloric node metastasis. Wang *et al*<sup>[48]</sup> reported that the pathological examination after total gastrectomy showed metastasis rates of lymph nodes in No. 5 and No. 6 of 9.1%-13.6%. They believed that it was difficult to remove all tumor tissues (including metastatic lymph nodes) without total gastrectomy.

Yamashita *et al*<sup>[34]</sup> clearly indicated that dissection of the paracardial and lesser curve lymph nodes offered significant therapeutic benefit, suggesting that these lymph nodes were possibly peritumoral. Furthermore, the number of metastatic nodes in these stations and the total number of metastatic nodes in all stations were equally predictive of the clinical outcome. Dissection of other perigastric nodes, such as Nos. 4sb, 4d, 5, and 6, offered only marginal therapeutic benefit as determined by calculating the index of estimated benefit of nodal dissection. Thus, involvement of the lymph nodes in these stations appeared to represent distant rather than locoregional metastasis<sup>[34]</sup>. Therefore, both esophagectomy with gastric tube reconstruction and gastrectomy with Roux-en-Y reconstruction seem to be valid procedures clinically.

Most series report 7%-40% of mediastinal nodal involvement for type II and III esophagogastric cancer even though abdominal nodes are more affected<sup>[49]</sup>. In our series, mediastinal lymph nodes were affected only in a small number (No. 110, 0.7%), lower than that reported in the literature<sup>[40,49,50]</sup>. The necessity of a prophylactic mediastinal nodal dissection remains controversial. Mine *et al*<sup>[47]</sup> suggested that lower mediastinal lymph nodes,

and station numbers 16A2lat (left renal vein), 11 (splenic artery) and 9 (celiac axis) were the second most frequently involved, and positivity here influenced survival. Hiroharu's data<sup>[34]</sup> suggested that extensive mediastinal lymph node dissection *via* thoracotomy offers no survival benefit over para-periesophageal node clearance alone by the transhiatal approach, which is associated with a lower morbidity, consistent with Sasako' and Hulscher' finding<sup>[51,52]</sup>. Phase III trials in The Netherlands (Dutch trial) and Japan (JCOG 9502) also suggested that an extended transthoracic resection was more hazardous surgery, in terms of morbidity, than a transhiatal esophagectomy. Extended surgery could not be recommended for patients with type II tumors<sup>[52]</sup>. In addition, nodal recurrence was the most frequent in the para-aortic nodes, and less frequent in the mediastinal nodes in Hiroharu's series<sup>[34]</sup>. These results mostly consistent with another report<sup>[40]</sup> support the hypothesis that complete mediastinal nodal clearance is not essential for local control of this disease. Nevertheless, Reeh *et al*<sup>[53]</sup> showed that the presence of lower mediastinal lymph nodes in AOG(oesophago-gastric junction) type II suggests that at least a lower mediastinal dissection should be performed.

Lymph node Nos. 10 and 11 (splenic hilum and splenic artery) belong to pN<sub>2</sub> cardia cancer and have a higher metastatic rate. The high risk factors include female sex, Borrmann type IV, tumor size > 5 cm, poorly differentiated adenocarcinoma, signet ring cell carcinoma, Lauren's diffuse type, vascular lymphatic invasion, and perineural invasion. Some authors believe that a splenectomy must be included for patients with the above high-risk factors<sup>[54]</sup>. Okajima *et al*<sup>[55]</sup> reported that the metastasis rates for lymph node Nos. 10 and 11 in cardia cancer were 15.5% and 12.1%, respectively, and Sakaguchi *et al*<sup>[56]</sup> estimated the rate at 24%. This reflects the status of lymph node metastasis; however, these data were derived from the pathological examination of surgical specimens, mostly based on the corresponding radical operation, and was subject to the understanding of radical surgical indications. Sakaguchi *et al*<sup>[56]</sup> believed that the lymph node metastasis of Nos. 10 and 11 in a larger tumor (> 4 cm), with deeper lesions (T3 and T4) and infiltrative lesions occurred easily. Thus, these clinical characteristics may provide a reference for understanding the indications for combined splenectomy. In our study, the metastasis rates for lymph node No. 10 lymph 1.4%, and for No. 11 it was 2.7%, which are lower than those reported in the literature<sup>[59,40,57]</sup>. Metastasis in these lymph nodes was mainly observed in advanced GC. Therefore, it would be prudent to select the combined resection of distal pancreatectomy and splenectomy for lymph node dissection in patients with cardia cancer<sup>[58,59]</sup>.

The present study showed that the most common sites of the pN<sub>1</sub> lymph node metastasis were Nos. 1-4; the most common sites of the pN<sub>2</sub> lymph nodes were Nos. 7-9; and the most common sites of the pN<sub>3</sub> lymph nodes were Nos. 5 and 6. Lymph node metastasis occurred mostly in the abdominal cavity and lymph node

metastasis of cardia cancer is more similar to that seen for GC. The lymph node metastasis in cardia cancer observed in this study suggests that: (1) for lymph nodes Nos. 1-9, conditions must be focally examined in preoperative ultrasound endoscopic and computed tomography examination; and (2) the superior paragastric fatty tissues should be thoroughly removed in the radical operation for GC and the total lymph node should be dissected in the regions; the celiac trunk and common hepatic artery must be skeletonized and the left gastric artery must be cut to remove the Nos. 7-9 lymph nodes thoroughly.

One analysis showed that 32.9% of type II tumors had involvement of the lymph nodes along the major branched arteries (the left gastric artery, common hepatic artery, splenic artery and celiac axis), and the rate was 50% in type III tumors<sup>[60]</sup>. Siewert *et al*<sup>[61]</sup> also reported similar results; 25% nodal involvement in type II tumors and 39% in type III tumors. These reports clearly indicate that abdominal nodal metastases are frequently observed in adenocarcinoma of the esophagogastric junction type II/III tumors, as in true gastric cancer. Therefore, the extent of a nodal dissection for AEG type II/III should be same as that applied for GC, and an abdominal D2 lymphadenectomy is recommended for patients with type II/III tumors, unless D2 increases the surgical risk<sup>[32]</sup>. Siewert types II and III cancers could be removed safely with an abdominal approach<sup>[45]</sup>. Our results agree with the conclusion of Husemann, that carcinoma of the cardia is a type of carcinoma of the stomach that must be treated according to the criteria of GC surgery<sup>[50]</sup>.

In our study, of 104 patients with lymph node metastases, all were N1, 23 were N2, and 15 were N3. Investigating the correlation between pN<sub>1</sub>, pN<sub>2</sub> and pN<sub>3</sub> lymph node metastases and clinicopathological factors, we found that tumor size, gross appearance, differentiation, pathological depth and lymphatic invasion were associated with lymph node metastases in all patients and male patients at pN<sub>1</sub>. There was an obvious correlation between lymph node metastases and lymphatic invasion in all patients at pN<sub>2</sub>. Univariate analysis of variance revealed a close relationship between lymph node metastases and lymphatic invasion and neural invasion in all patients and lymphatic invasion in female patients at pN<sub>3</sub>. Study of Di Leo *et al*<sup>[10]</sup> study of the treatment of advanced gastric cancer showed that T2 tumors were consistently associated with pN<sub>2</sub> stations nodal infiltration. Such behavior, although less frequent than in T3/4 tumors, does not allow conservative surgery in terms of nodal resection<sup>[10]</sup>.

There were limitations to the present study. First, it was a retrospective study based on postoperative examination of resected specimens. Second, the number of patients was low. Thus, further study with a larger sample size should be carried out to confirm our results. Otherwise, the extent of nodal involvement was most likely underestimated. The lack of information of nodal status at specific remote sites in some cases also made the investigation of nodal stage migration impossible. The retrospective nature of this study meant that there was

some selection bias, such as the surgeon's preference for a thoracoabdominal or transabdominal approach.

In conclusion, the findings in this study indicate that the clinicopathological features and risk factors for lymph node metastasis of male and female patients with gastric cardia adenocarcinoma did not differ significantly. Therefore, the effect of male sex on the clinical course of gastric cardia adenocarcinoma had a weak impact in comparison to female sex once a curative resection had been performed. However, further evaluations should be performed. The outcome should improve if male patients, as well as female patients, undergo careful diagnosis of malignancy and early multimodality treatment.

## COMMENTS

### Background

As gastric cancer incidence declines, the frequency of proximal gastric and gastroesophageal junctional adenocarcinomas continues to rise, and has become a significant clinical challenge. Adenocarcinoma of the cardia generally has a low curative resection rate and a poor prognosis; worse than carcinoma of other regions of the stomach, mainly because the disease is at a more advanced stage at diagnosis. It is crucial that the therapeutic strategy for gastric cardia adenocarcinoma be clarified through evaluation of both the pattern of lymph node metastasis and the efficacy of lymph node dissection in this region.

### Research frontiers

The optimal surgical strategy for tumors in the cardia area of the stomach, especially tumors invading the lower esophagus, remains controversial. The development of effective therapeutic strategies for these tumors requires information on patient characteristics, patterns of lymph node metastasis, and the efficacy of lymph node dissection.

### Innovations and breakthroughs

Univariate analysis showed an obvious correlation between lymph node metastases and tumor size, gross appearance, pathological depth and lymphatic invasion in male patients. Multivariate logistic regression analysis revealed that tumor differentiation and pathological depth were independent risk factors for lymph node metastases in male patients. There was an obvious relationship between lymph node metastases and tumor size, gross appearance, differentiation, pathological depth, lymphatic invasion at pN<sub>1</sub>, and lymphatic invasion at pN<sub>2</sub> and neural invasion at pN<sub>3</sub> in male patients. There were no significant differences in clinicopathological features or lymph node metastases between female and male patients.

### Applications

Tumor differentiation and depth were risk factors for lymph node metastases in male patients with gastric cardia adenocarcinoma and should be considered when choosing surgery.

### Terminology

The definition of the cardia commonly employed in Japan is the area within 2 cm above and below the esophagogastric junction, and tumors whose center is situated in this area are considered to be cancer of the cardia; such cancers are distinguished from upper gastric cancers. Siewert and Stein proposed a topographical classification for cardia carcinomas.

### Peer review

Congratulate the authors for an excellent effort. As rightly highlighted, a future attempt in expanding the population size should hopefully provide further insights.

### Abstract

**AIM:** To investigate the stress-induced apoptosis of natural killer (NK) cells and the changes in their killing activity in mouse livers.

**METHODS:** A restraint stress model was established in mice. Flow cytometry was employed to measure the percentage of NK cells and the changes in their absolute number in mouse liver. The cytotoxicity of hepatic and splenic NK cells was assessed against YAC-1 target cells *via* a 4 h <sup>51</sup>Cr-release assay.

**RESULTS:** The restraint stress stimulation induced the apoptosis of NK cells in the liver and the spleen, which decreased the cell number. The number and percentage of NK cells in the spleen decreased. However, the number of NK cells in the liver decreased, whereas the percentage of NK cells was significantly increased. The apoptosis of NK cells increased gradually with prolonged stress time, and the macrophage-1 (Mac-1)<sup>+</sup> NK cells were more susceptible to apoptosis than Mac-1<sup>-</sup> NK cells. Large numbers of Mac-1<sup>-</sup> NK cells in the liver, which are more resistant to stress-induced apoptosis, were observed than the Mac-1<sup>-</sup> NK cells in the spleen. The stress stimulation diminished the killing activity of NK cells in the spleen was significantly decreased, but the retention of numerous Mac-1<sup>-</sup> NK cells in the liver maintained the killing ability.

**CONCLUSION:** Significant stress-induced apoptosis was observed among Mac-1<sup>+</sup> NK cells, but not Mac-1<sup>-</sup> NK cells in the mouse liver. Stress stimulation markedly decreased the killing activity of NK cells in the spleen but remained unchanged in the liver.

**Key words:** Restraint stress; Natural killer cells; Cell apoptosis; Killing activity

**Core tip:** Hepatic natural killer (NK) cells are classified into macrophage-1 (Mac-1)<sup>+</sup> and Mac-1<sup>-</sup> cells, and the different functional characteristics of Mac-1<sup>+</sup> or Mac-1<sup>-</sup> NK cells in response to stress stimulation are confirmed. This study further proves the heterogeneity of NK cell function, and the results provide a reference for preventing the immune system damage caused by stress.

## INTRODUCTION

In the modern society, the acceleration of work and life style and the deterioration of the environment, as well as natural disasters and frequent traffic accidents, expose people to increasing stress. Prolonged or intense stress that overwhelms autoregulation, causes nervous, endocrine, and immune system dysfunction<sup>[1-3]</sup>, as well as the apoptosis of lymphocytes such as natural killer (NK) cells, B cells and T cells. Immune system dysfunction is the direct cause of infectious diseases, cancers and self-deterioration<sup>[4-6]</sup>.

NK cells are an important type of lymphocytes, accounting for 10% to 15% of total lymphocytes and play a crucial role in body resistance to against infections and tumours, as well as immune and hematopoietic regulation<sup>[7,8]</sup>.

This study aims to determine the effects of persistent and intense stress on the apoptosis of hepatic and splenic NK cells and change in their function in mice.

## MATERIALS AND METHODS

### Experimental animals

Eight-week-old clean grade C57BL/6 mice were purchased from the Animal Centre of The 3<sup>rd</sup> Affiliated Hospital of Harbin Medical University.

### Mouse model preparation

The protocol used has been described in the published literature<sup>[9]</sup>. The mice were placed in a 50 mL Falcon tube with 4 to 5 drilled holes at the bottom to maintain ventilation. Sufficient amounts of absorbent cotton were placed inside the tube to immobilise the mouse, and then the lid was screwed shut. The tube was kept at room temperature for 24 h, and the mouse was not fed any food and water. The mice in the control group were left in the original cage without any disturbance.

### Mouse lymphocyte preparation

The protocol used has been described in the published literature<sup>[10]</sup>. The mouse was anaesthetised with ether and sacrificed *via* heart puncture. Subsequently, the mouse liver and spleen were collected and minced. The tissue sample was washed with phosphate-buffered saline (PBS) and filtered with 200 mesh strainer, and then the cell suspension was collected. After gradient centrifugation, the cells were lysed with 0.83% NH<sub>4</sub>Cl-Tris buffer (pH 7.6). The resulting cell suspension was collected and the concentration was adjusted to  $1.0 \times 10^6$ /mL.

### Immunofluorescence labelling

Lymphocytes were isolated from mouse liver and spleen, and then double or triple immunofluorescence staining was performed to identify the CD<sub>3</sub><sup>+</sup>NK<sub>1.1</sub><sup>+</sup> cells as NK

cells. Fluorescein-isothiocyanate (FITC)-labelled antibodies: CD<sub>3</sub> (145-2C11 clone); PE-labelled antibody: NK<sub>1.1</sub> (PK136 clone); Biotin-labelled antibody: macrophage-1 (Mac-1) (M1/70 clone) CD<sub>69</sub> (H1.2F3 clone), Ly49C/I (5E6 clone). All the monoclonal antibodies were purchased from BD Biosciences Pharmingen in San Diego, United States.

Cell suspension was transferred in centrifuge tube (cell number  $< 2 \times 10^6$ ). After 2 min of centrifugation at 2500 r/min and 4 °C, the supernatant was removed, followed by vibration. Then, 10 μL of 2.4 G2 was added (anti-FcγR II / III). After incubation at 4 °C for 10 min, 10 μL of various monoclonal antibodies (CD<sub>3</sub>, NK<sub>1.1</sub>, Mac-1, CD<sub>69</sub>, and Ly49C) were added, accordingly. After vortex and incubation at 4 °C for 20 min, the cells were washed once with PBS (2500 r/min at 4 °C). For double staining, the cells were diluted with 0.5 mL of PBS and filtered with nylon mesh, and then 5 μL of propidium iodide (PI) was added for flow cytometry analysis. When subjected for triple staining, cells were incubated with 10 μL of biotin-labelled secondary antibody at 4 °C for 20 min, and then washed with PBS once (2500 r/min at 4 °C). After diluting with 0.5 mL of PBS and filtration with a nylon mesh, the stained cells were analyzed *via* flow cytometry<sup>[11]</sup>. Flow Cytometer was FAC sort from BD-United States and software was Cell Quest 3.0.

### Detection of killing activity of NK cells

The cytotoxicity of NK cells was assessed against YAC-1 target cells. Target cells were continuously cultured for 24 h in RPMI 1640 containing 200 mL/L FCS. YAC-1 cells were collected at exponential phase and counted through trypan blue staining. Viable cells were considered as targets cells when their percentage exceeded 95%. The cell concentration was adjusted to  $1 \times 10^5$  /mL with RPMI 1640. After incubation with <sup>51</sup>Cr for 2 h, the cells were washed three times with RPMI 1640 to remove free <sup>51</sup>Cr. The target cell concentration was adjusted to  $1.0 \times 10^4$ /mL or  $2.0 \times 10^4$ /mL. The cells were divided into three groups: NK cell group, target cell maximum release group, and target cell spontaneous release group. Subsequently, the cells were seeded in U-bottom microplates (96-well). Lymphocytes in the mouse liver and spleen were utilized as effector cells, which were added into the U-bottom microplates at an effector:target ratio of 50:1, 25:1, and 12.5:1 in a volume of 100 μL/well. The cells were incubated at 37 °C with 5% CO<sub>2</sub> for 4 h and the microplates were centrifuged at 1500 r/min for 5 min. About 100 μL of supernatant was collected from each well, and its radioactivity (CPM) was measured with gamma counter<sup>[12]</sup>.

The specific killing rate was calculated using the following formula: specific killing rate (%) = (experimental cell release - target cell spontaneous release)/(target cell maximum release - target cell spontaneous release) × 100%.

### Statistical analysis

The data are presented as mean ± SD and percentage.

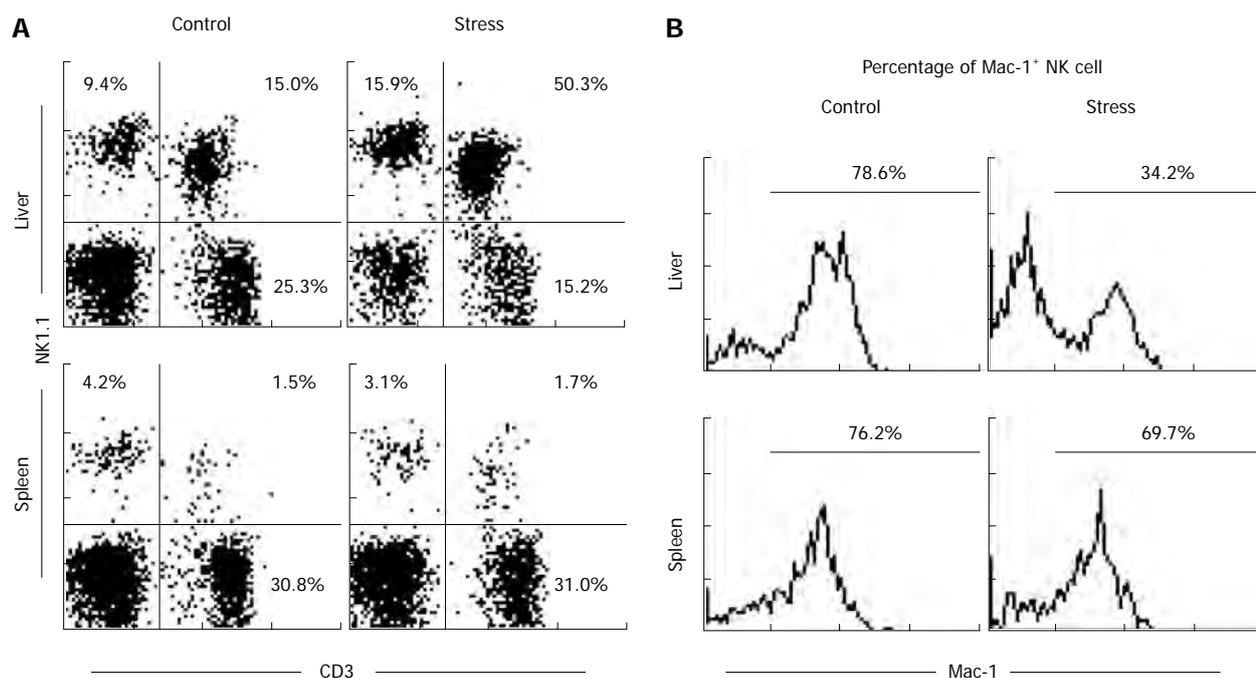

Figure 1 Percentage of natural killer cells and macrophage-1<sup>+</sup> natural killer cells in mouse liver and spleen after 24 h of restraint stress. A: Natural killer cells; B: Macrophage-1<sup>+</sup> natural killer cells. NK: Natural killer; Mac-1: Macrophage-1.

Significant differences between two samples were analyzed with Student's *t* test.

## RESULTS

### Stress stimulation and the change of NK cell number

The percentage of splenic NK cells in total lymphocytes did not change significantly ( $3.9\% \pm 1.2\%$  vs  $2.6\% \pm 1.1\%$ ,  $P > 0.05$ ), whereas the percentage of hepatic NK cells increased ( $8.6\% \pm 1.3\%$  vs  $14.9\% \pm 1.5\%$ ,  $P < 0.05$ ; Figure 1).

After restraint stress stimulation, the numbers of lymphocytes in the experimental and control groups were  $(53.1 \pm 9.7) \times 10^5$  vs  $(19.7 \pm 4.6) \times 10^5$  ( $n = 6$ ,  $P < 0.05$ ) in liver,  $(87.7 \pm 9.6) \times 10^6$  vs  $(36.4 \pm 7.1) \times 10^6$  ( $n = 6$ ,  $P < 0.05$ ) in spleen. The number of NK cells in the experimental and control groups were  $(57.4 \pm 8.9) \times 10^5$  vs  $(24.6 \pm 7.3) \times 10^5$  ( $n = 6$ ,  $P < 0.05$ ) in the liver,  $(29.7 \pm 6.5) \times 10^6$  vs  $(8.6 \pm 1.4) \times 10^6$  ( $n = 6$ ,  $P < 0.05$ ) in the spleen (Figure 2).

### Number of Mac-1<sup>+</sup> and Mac-1<sup>-</sup> NK cells

NK cells were isolated from mouse liver and spleen after 24 h of restraint stress stimulation, followed by immunofluorescence staining with FITC: Mac-1 and PE: NK1.1. The cells were analyzed *via* flow cytometry. The results show that the percentage of hepatic Mac-1<sup>+</sup> NK cells in the experimental group was significantly higher than that of the control group ( $77.2\% \pm 1.7\%$  vs  $33.9\% \pm 1.1\%$ ,  $P < 0.05$ , Figure 1B), whereas the percentage of hepatic Mac-1<sup>-</sup> NK cells relatively increased. The percentage of splenic Mac-1<sup>+</sup> NK cells was slightly decreased ( $75.1\% \pm 1.1\%$  vs  $68.5\% \pm 1.6\%$ ,  $P > 0.05$ ).

After 24 h of stress stimulation, the number of Mac-1<sup>+</sup> NK cells in the liver and spleen in the stress group was significantly lower than those in the control group: liver,  $(37.7 \pm 9.8) \times 10^4$  vs  $(8.4 \pm 1.7) \times 10^4$  ( $n = 6$ ,  $P < 0.05$ ); spleen,  $(23.5 \pm 6.3) \times 10^5$  vs  $(8.7 \pm 1.9) \times 10^5$  ( $n = 6$ ,  $P < 0.05$ ). The results are shown in Figure 3.

### Stress stimulation and apoptosis of NK cells

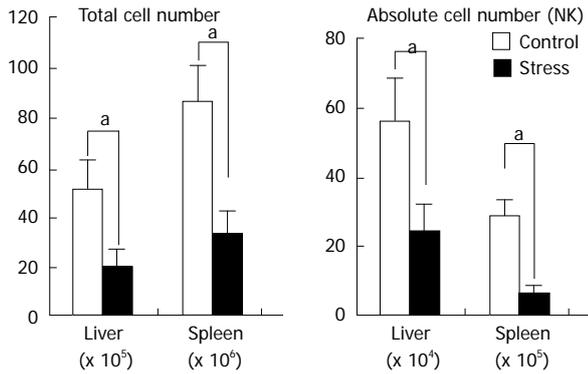

NK cells were isolated from mouse liver after 24 h of restraint stress stimulation, followed by immunofluorescence staining with Annexin V-FITC and PI. The cells were analyzed *via* flow cytometry. The results revealed significant apoptosis of NK cells ( $9.5\% \pm 1.4\%$  vs  $19.3\% \pm 1.3\%$ ,  $P < 0.05$ ), especially the Mac-1<sup>+</sup> NK cells ( $5.2\% \pm 1.8\%$  vs  $19.3\% \pm 1.4\%$ ,  $P < 0.05$ ), whereas the apoptosis of Mac-1<sup>-</sup> NK cells did not significantly change ( $13.4\% \pm 1.3\%$  vs  $7.4\% \pm 1.7\%$ ,  $P > 0.05$ ; Figure 4).

### Stress stimulation and the change of killing activity mediated by NK cells

The killing activity of NK cells was markedly decreased in the spleen ( $16.7\% \pm 1.4\%$  vs  $8.9\% \pm 1.1\%$ ,  $P < 0.05$ ), but was sustained in the liver even after 24 h of restraint stress stimulation (Figure 5).

## DISCUSSION

With the development of modern medical technology, increasing attention has been focused on the relationship between stress and health. The response of the body to stress is a dynamic balance, which allows the body to recover to its original state through autoregulation after stress reaction. However, persistent stress may overwhelm

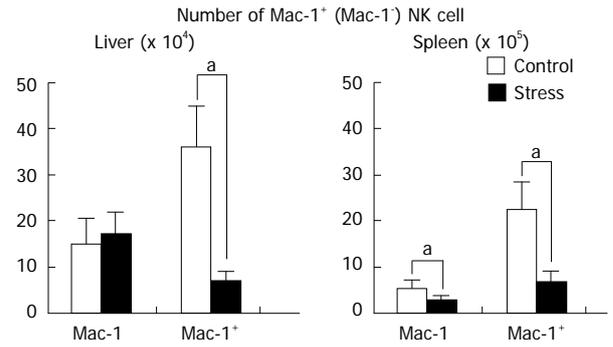

**Figure 2** The number of lymphocytes and of natural killer cells in mouse liver and spleen after 24 h of restraint stress. NK: Natural killer. <sup>a</sup>*P* < 0.05 vs control group.

autoregulation and cause psychosomatic damage<sup>[13,14]</sup>.

Numerous studies have demonstrated that acute stress stimulation causes distinctly reduced number of lymphocytes in the thymus, spleen, peripheral blood, and liver, as well as disrupt the function of T, B and NK cells. Moreover, the decrease in lymphocytes mainly results from apoptosis.

Our research shows that the number of splenic lymphocytes was significantly decreased, but their percentage did not change significantly. We speculate that various lymphocytes in spleen decreased with the same percentage, which is consistent with the results of previous studies<sup>[10,15]</sup>. Moreover, the results showed that the number of hepatic lymphocytes significantly declined but the percentage of NK cells dramatically increased (Figures 1A and 2). Therefore, the number of NK cells in the liver and the spleen were determined. Although both the liver and the spleen had fewer NK cells, the number of NK cells was relatively high in the liver, dramatically increasing the percentage of NK cells in the liver (Figure 2). These results indicate that the hepatic NK cells differed from splenic NK cells after stress stimulation. A recent study reported that NK cells have organ specificity, which allows liver to be considered as immune organ and NK cells possess unique functional characteristics<sup>[16,17]</sup>.

Mac-1 was employed to distinguish the subtypes of NK cells with different functions. Mac-1 (CD11b/CD18) is an adhesion molecule of the integrin family, highly expressed in most myeloid hematopoietic cells, such as neutrophils, monocytes/macrophages, eosinophils and B cells. Mac-1 is closely correlated with cell phagocytosis and adhesion, as well as a marker for myeloid and lymphoid hematopoietic cells. NK cells are the only lymphoid cells that express Mac-1. Some researchers have considered Mac-1 as a marker for mature NK cells, which have cell killing activity and are able to secrete cytokines, whereas Mac-1<sup>-</sup> NK cells are immature, with limited cell killing activity and cytokine production<sup>[18-20]</sup>. Mac-1 is expressed by 80% to 90% of mature NK cells in the liver, spleen, and peripheral blood. Therefore, current research on NK cells is mainly focused on Mac-1<sup>+</sup> NK cells. Our previous study discovered numerous Mac-1<sup>-</sup> NK cells

**Figure 3** Determination of macrophage-1<sup>+</sup> and macrophage-1<sup>-</sup> natural killer cells in mouse liver and spleen after 24 h of restraint stress. Mac-1<sup>+</sup>: Macrophage-1 positive; Mac-1<sup>-</sup>: Macrophage-1 negative; NK: Natural killer. <sup>a</sup>*P* < 0.05 vs control group.

in the liver and demonstrated that Mac-1<sup>+</sup> NK cells and Mac-1<sup>-</sup> NK cells have different functional characteristics and cell phenotypes<sup>[11]</sup>. Therefore, hepatic NK cells were classified into Mac-1<sup>+</sup> and Mac-1<sup>-</sup> subtypes according to Mac-1 expression.

Our study shows that the number of Mac-1<sup>+</sup> and Mac-1<sup>-</sup> NK cells in the spleen decreases with same percentage after stress stimulation, which results in sustained Mac-1 expression in splenic NK cells. The number of hepatic Mac-1<sup>+</sup> NK cells significantly decreased, whereas the number of Mac-1<sup>-</sup> NK cells did not change significantly, which accounts for the reduced Mac-1 expression in hepatic NK cells (Figures 1B and 3). Therefore, we speculate that Mac-1<sup>+</sup> hepatic NK cells are resistant to the apoptosis induced by stress stimulation.

A large number of studies have demonstrated that acute stress stimulation causes distinctly reduced number of lymphocytes in the thymus, spleen, peripheral blood, and liver, as well as disrupts the function of T, B and NK cells. Moreover, the decrease in lymphocytes is mainly caused by the apoptosis of lymphocytes.

Intracellular Annexin V expression was measured to assess the degree of apoptosis of hepatic NK cells induced by stress stimulation<sup>[21]</sup>. The results revealed significant NK cell apoptosis, especially Mac-1<sup>+</sup> NK cells, whereas Mac-1<sup>-</sup> NK cell apoptosis remained unchanged (Figure 4).

To determine the effects of stress on NK cell function, we employed YAC-1 as target cells to measure killing activity of NK cells. The results imply that stress stimulation decreases the killing activity of splenic NK cells, which accords with the results of previous research. Our study also discovered that stress stimulation does not affect the killing activity of hepatic NK cells, which contrasts with the conclusion of previous investigations. We concluded that Mac-1<sup>+</sup> NK cells had stronger killing activity than that of Mac-1<sup>-</sup> NK cells<sup>[11]</sup>. We also believed that the number of hepatic Mac-1<sup>+</sup> NK cells declined because of cell apoptosis, which allowed apoptosis-resistant Mac-1<sup>-</sup> NK cells to survive, and to exhibit relatively strong cell killing activity.

In conclusion, our research preliminarily demon-

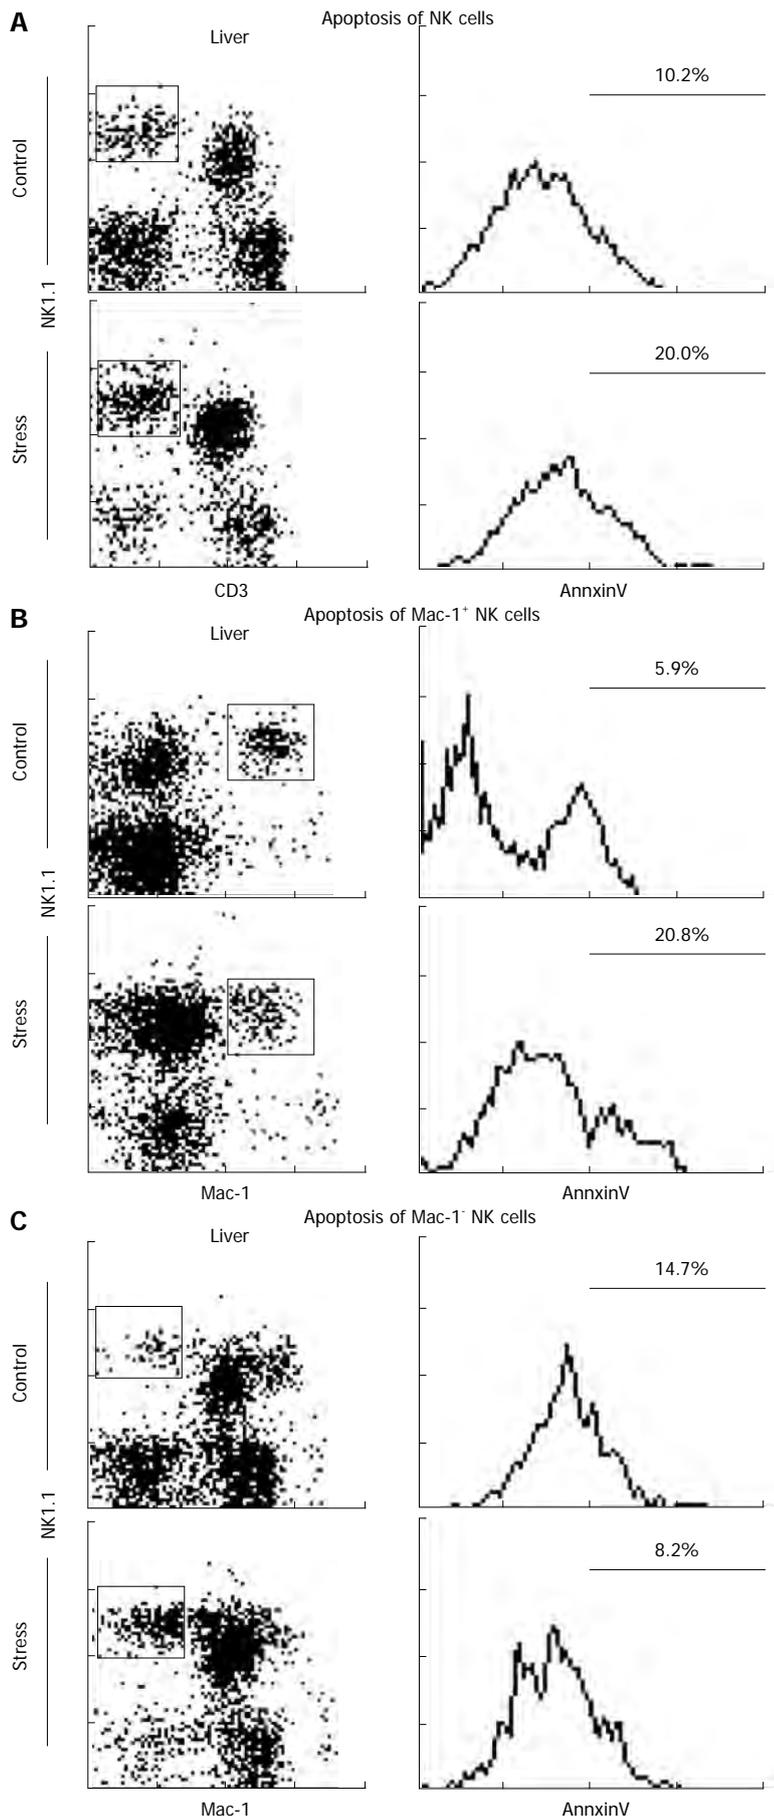

Figure 4 Apoptosis of natural killer cells after 24 h of restraint stress. A: Apoptosis of NK cells; B: Apoptosis of Mac-1<sup>+</sup> NK cells; C: Apoptosis of Mac-1<sup>-</sup> NK cells. NK: Natural killer; Mac-1: Macrophage-1.

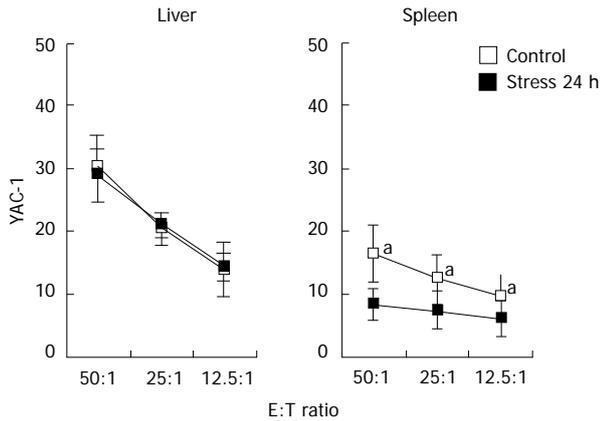

Figure 5 Cytotoxicity of natural killer cells in mouse liver and spleen after 24 h of restraint stress. NK: Natural killer; E:T Ratio: Effector-target ratio. <sup>a</sup> $P < 0.05$  vs spleen after 24 h of stress.

states that intense stress stimulation induces the apoptosis of Mac-1<sup>+</sup> hepatic NK cells instead of Mac-1<sup>-</sup> NK cells, which requires further investigation to understand the underlying mechanisms and the role of the liver in stress-triggered immune function.

## COMMENTS

### Background

Stress refers to non-specific systemic reactions to strong stimulus on the body. Intense and prolonged stress stimulation causes immune function disorders, volume shrinkage, and dysfunction of immune organs such as the liver, spleen, and thymus gland. In addition, stress stimulation causes the apoptosis and dysfunction of lymphocytes such as natural killer (NK), T, and B cells in the peripheral blood and immune organs. Most studies have demonstrated that strong stress stimulation may decrease NK cell killing activity in the peripheral blood and spleen, which weakens the immune system.

### Research frontiers

NK cells are a class of lymphocytes in the innate immune system that account for about 10% to 15% of all lymphocytes. They have anti-infective, anti-tumour, and immunomodulatory functions, and they regulate hematopoiesis. NK cells mainly function in killing cells and cytokine secretion. NK cells are divided into two subtypes according to surface antigens and functional cell expression, namely, NK<sub>1</sub> and NK<sub>2</sub>. Previous investigations have studied NK cells in the peripheral blood and the spleen. The results confirm that the liver generates NK cells during embryogenesis and the function of NK cells in the liver is different from that in the peripheral blood and the spleen.

### Innovations and breakthroughs

This study confirms that stress stimulation significantly decreases the number of splenic NK cells, with significantly decreased killing activity, whereas some NK cells survive in the liver. Further research proves that these surviving cells are macrophage-1 (Mac-1<sup>-</sup>) NK cells that resist stress-induced cell apoptosis. By contrast, the killing activity of Mac-1<sup>+</sup> NK cells is unaffected by stress stimulation.

### Applications

This study proves the anti-stress ability of Mac-1<sup>-</sup> hepatic NK cells. This finding suggests that Mac-1<sup>-</sup> NK cells maintain immune functional stability under stress conditions. Further studies should investigate how to characterize Mac-1<sup>-</sup> NK cells and utilize them for preventing the immune dysfunction caused by stress.

### Terminology

NK cells are important immune cells with anti-tumour, anti-viral, and immune regulation function, but also participate in the hypersensitivity and occurrence of autoimmune diseases in some cases. Mac-1 (CD11b/CD18) is an adhesion molecule (integrins), and is expressed in most myeloid hematopoietic cells such as neutrophils, monocyte-macrophages, eosinophils, and B cells.

## Peer review

Authors investigated the stress-induced apoptosis of NK cells and the changes in their killing activity in mouse livers. NK cell is an important type of lymphocytes. The authors made an interesting research on NK cell. This study proves the anti-stress ability of Mac-1<sup>-</sup> hepatic NK cells. This finding suggests that Mac-1<sup>-</sup> NK cells maintain immune functional stability under stress conditions. Further studies should investigate how to characterize Mac-1<sup>-</sup> NK cells and utilize them for preventing the immune dysfunction caused by stress.

### Abstract

**AIM:** To investigate the mechanisms of how cyclooxygenase-2 (COX-2) regulates E-cadherin in gastric cancer cells.

**METHODS:** COX-2 expression in human gastric cancer cell lines SGC-7901, BGC-823, MGC-803 and AGS were measured at the mRNA and protein level. COX-2 rich cell line SGC-7901 was chosen for subsequent experiments. siRNA mediated gene knockdown was used to investigate the impact of COX-2 on nuclear factor- $\kappa$ B

(NF- $\kappa$ B), Snail, and E-cadherin in gastric cancer cells. Gene expression was determined by Western blot and real-time polymerase chain reaction. To analyze whether NF- $\kappa$ B inhibition could interrupt the modulatory effect of COX-2 or prostaglandin E2 (PGE2) on E-cadherin, gastric cancer cells were treated with celecoxib or PGE2, in the presence of NF- $\kappa$ B specific siRNA.

**RESULTS:** Highest expression level of COX-2 was found in SGC-7901 cells, both at mRNA and protein levels. siRNA mediated down-regulation of COX-2 led to a reduced expression of NF- $\kappa$ B and Snail, but an increased expression of E-cadherin in SGC-7901 cells. siRNA mediated down-regulation of NF- $\kappa$ B also led to a reduced expression of E-cadherin and Snail in SGC-7901 cells. However, COX-2 expression did not alter after cells were treated with NF- $\kappa$ B specific siRNA in SGC-7901 cells. Treatment of SGC-7901 cells with celecoxib led to a reduced expression of Snail but an increased expression of E-cadherin. In contrast, treatment of SGC-7901 cells with PGE2 led to an increased Snail and a decreased E-cadherin. However, siRNA-mediated knockdown of NF- $\kappa$ B partially abolished the effect of celecoxib and PGE2 on the regulation of E-cadherin and Snail in SGC-7901 cells.

**CONCLUSION:** COX-2 likely functions upstream of NF- $\kappa$ B and regulates the expression of E-cadherin *via* NF- $\kappa$ B/Snail signaling pathway in gastric cancer cells.

**Key words:** Cyclooxygenase-2; E-cadherin; celecoxib; Prostaglandin E2; Gastric cancer

**Core tip:** Cyclooxygenase-2 (COX-2) plays an important role in transcriptional regulation of E-cadherin in gastric cancer and other malignancies. On the contrary, prostaglandin E2 (PGE2) promotes invasion of tumor cells through down-regulating the expression of E-cadherin.

Our study has provided further evidence that COX-2 functions upstream of nuclear factor- $\kappa$ B in the regulation of Snail and E-cadherin in gastric cancer cells. Blockade of COX-2 activity or inhibition of PGE2 production may offer some benefit in the chemoprevention and treatment of gastric cancer.

## INTRODUCTION

Cyclooxygenase-2 (COX-2) is an inducible isozyme of cyclooxygenase and catalyzes prostaglandin E2 (PGE2) formation in response to various inflammatory stimuli or growth factors<sup>[1]</sup>. PGE2 plays an important role in regulating diverse cellular functions under physiological and pathological conditions<sup>[2]</sup>. Overexpression of COX-2 is related to invasion and metastasis of tumor cells<sup>[3-5]</sup>. To further support the role of COX-2 in tumor promotion, it was reported that PGE2 was able to facilitate the invasion of tumor cells through down-regulation of E-cadherin<sup>[6]</sup>. On the other hand, celecoxib, a selective inhibitor of COX-2, could inhibit migration and metastasis of tumor cells by up-regulating E-cadherin<sup>[7]</sup>. Many studies have suggested that COX-2 is generally overexpressed in gastric cancer tissues, and it was thought to play a crucial role in the development and invasion of gastric cancers<sup>[8]</sup>. In contrast, the expression of E-cadherin, an important cell adhesion molecule, is usually low, mutated, or even lost in gastric cancer tissues<sup>[9,10]</sup>. Thus, COX-2 and E-cadherin appear to exhibit totally different expression patterns. Our group had previously reported an inverse correlation between COX-2 and E-cadherin and suggested that Snail is likely to be responsible for the regulation of COX-2 on the expression and function of E-cadherin in gastric cancer tissues<sup>[11,12]</sup>.

Snail is a transcription factor and was reported to down-regulate the expression of E-cadherin, causing disruption to cell-to-cell adhesion and thereby facilitates tumor progression and metastases<sup>[13,14]</sup>. Meanwhile, it was reported that nuclear factor- $\kappa$ B (NF- $\kappa$ B) promotes tumor cell migration and invasion in many human cancers through up-regulating Snail and subsequent suppression of E-cadherin<sup>[15-17]</sup>.

Therefore, it is very likely that the interaction between COX-2, Snail, and E-cadherin may play a key regulatory role in invasion and metastasis of gastric cancer. Our group is interested in understanding the possible interaction between COX-2, Snail, and E-cadherin during the development, progression, invasion, and metastasis of gastric cancer. Thus, the aim of this study is to investigate if COX-2 modulates E-cadherin expression *via* Snail and

NF- $\kappa$ B in gastric cancer cells.

## MATERIALS AND METHODS

### Reagents and cell lines

RPMI 1640 medium and PGE2 were purchased from Sigma-Aldrich (St. Louis; MO, United States). Opti-MEM I Reduced Serum Medium, Lipofectamine 2000, BLOCK-iT™ Fluorescent Oligo, and negative control for RNAi were purchased from Invitrogen (Carlsbad, CA, United States). Fetal calf serum was purchased from Hyclone Laboratories (Logan, UT, United States). Reverse transcription kit and quantitative polymerase chain reaction (qPCR) kit were purchased from Takara Biotechnology Co. Ltd. (Dalian, China). celecoxib was purchased from Cayman Chemical (Ann Arbor, MI, United States). Polyclonal antibodies against COX-2, NF- $\kappa$ B p65, E-cadherin, and  $\beta$ -actin were from BioWorld Corporation (CA, United States). Polyclonal antibody against human Snail was purchased from Abcam (Cambridge, United Kingdom). All primers were synthesized by Takara Biotechnology Co. Ltd. (Dalian, China). Double strand (ds) RNAi Stealth™ oligos, the specific siRNA against COX-2 and NF- $\kappa$ B (p65) were designed and synthesized by Invitrogen (Carlsbad, CA, United States).

Human gastric cancer cell lines SGC-7901, BGC-823, MGC-803 and AGS were purchased from Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences (Shanghai, China).

### Cell culture

Gastric cancer cell lines (SGC-7901, BGC-823, MGC-803 and AGS) were cultured in RPMI 1640 supplemented with 10% fetal bovine serum, 1% penicillin and streptomycin, and maintained at 37 °C in a humidified atmosphere containing 50 mL/L CO<sub>2</sub>. Before transfection, the culture medium RPMI 1640 was replaced by Opti-MEM I.

### Baseline expression of COX-2 in gastric cancer cells

SGC-7901, BGC-823, MGC-803 and AGS were plated respectively at a concentration of 10<sup>5</sup> cells/ well in a 6-well plate and incubated overnight. Total RNA and protein were extracted to determine the basal expression level of COX-2 at the mRNA by PCR and protein level by Western blot, respectively.

### siRNAs design, transient transfection of SGC-7901 cells with COX-2 and NF- $\kappa$ B siRNA oligonucleotides

As the SGC-7901 cells showed the highest expression level of COX-2, we used siRNA knockdown approach to investigate the impact of COX-2 on NF- $\kappa$ B, Snail, and E-cadherin in this cell line. Three pairs of siRNA oligos against COX-2 and NF- $\kappa$ B p65, and a control (scrambled) siRNA were initially designed and commercially synthesized. The sequences of these siRNAs were shown in Table 1.

For transfection, cells were seeded into a 6-well plate at a density of 3 × 10<sup>5</sup> cells per well and incubated overnight. Cells were then transfected with siRNA oligos

**Table 1** Sequences of the specific siRNA against cyclooxygenase-2 and nuclear factor- $\kappa$ B p65 used in the study

siRNA against	Forward	Reverse

using Lipofectamine 2000 and incubated for 24 to 72 h before further analysis. Transfection efficiency was determined by transfecting the cells with FITC labeled Oligo and counting the number of positive cells under the fluorescent microscopy. More than 80% of cells were routinely successfully transfected. The expression of COX-2, NF- $\kappa$ B, Snail and E-cadherin were analyzed by qPCR and Western blot in successfully transfected cells.

#### Co-treatment of SGC-7901 cells with NF- $\kappa$ B specific siRNA, celecoxib, and PGE2

To analyze whether NF- $\kappa$ B inhibition could interrupt the modulation effect of COX-2 or PGE2 on E-Cadherin, SGC-7901 cells were treated with 40  $\mu$ mol/L celecoxib for 24 h alone or with NF- $\kappa$ B specific siRNA. Cells were also treated with 10  $\mu$ mol/L PGE2 for 4 h alone or with NF- $\kappa$ B specific siRNA. The optimal dosages for celecoxib and PGE2 were based on our preliminary study. The expression of NF- $\kappa$ B, Snail and E-cadherin were measured by qPCR and Western blot.

#### Western blotting for COX-2, NF- $\kappa$ B, Snail and E-cadherin expression

Whole-cell extracts were prepared from the treated cells with 2 mL of RIPA buffer containing protease inhibitors. Cell lysates were centrifuged at 8000 rpm for 10 min and the supernatant was collected. Cell lysates were electrophoretically separated by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) gels. Proteins were transferred to nitrocellulose membrane and the membrane was blocked with 5% fat-free milk in TBS plus 0.1% Tween-20 (TBST). The membranes were then incubated with respective primary antibodies (rabbit polyclonal COX-2, NF- $\kappa$ B p65, Snail, E-cadherin, all at 1:1000 dilution) and the corresponding horseradish peroxidase-conjugated secondary antibody for 1 h. The membranes were incubated with enhanced chemiluminescence system and exposed to X-ray film for signal detection.  $\beta$ -actin was used as a control for equal loading of samples.

#### Real-time PCR for COX-2, NF- $\kappa$ B, Snail and E-cadherin expression

Total RNA was extracted with Trizol reagent according to the manufacturer's instructions. Approximately 30 ng of total RNA was transcribed into cDNA. The synthesized cDNA samples were subjected to qPCR using SYBR<sup>®</sup>

**Table 2** The sequences of the primers used in this study

Primers	Sense primer	Antisense primer

COX-2: Cyclooxygenase-2; NF- $\kappa$ B: Nuclear factor- $\kappa$ B.

Green Quantitative PCR kit. Amplification was carried out in a total volume of 20  $\mu$ L for 40 cycles of 15 s at 95  $^{\circ}$ C, 20 s at 60  $^{\circ}$ C, and 30 s at 72  $^{\circ}$ C. Samples were run in triplicate and their relative expression was determined by normalizing expression of each target to  $\beta$ -actin. The amplification was monitored on a Roter-Gene realtime PCR apparatus (Roter-Gene, Australia). Primers used in these experiments were shown in Table 2.

#### Statistical analysis

Data analysis was performed using SPSS11.0. All data were expressed as mean  $\pm$  SD. Comparison of the differences between each group was performed by  $\chi^2$  test. A *P* value of < 0.05 was considered statistically significant.

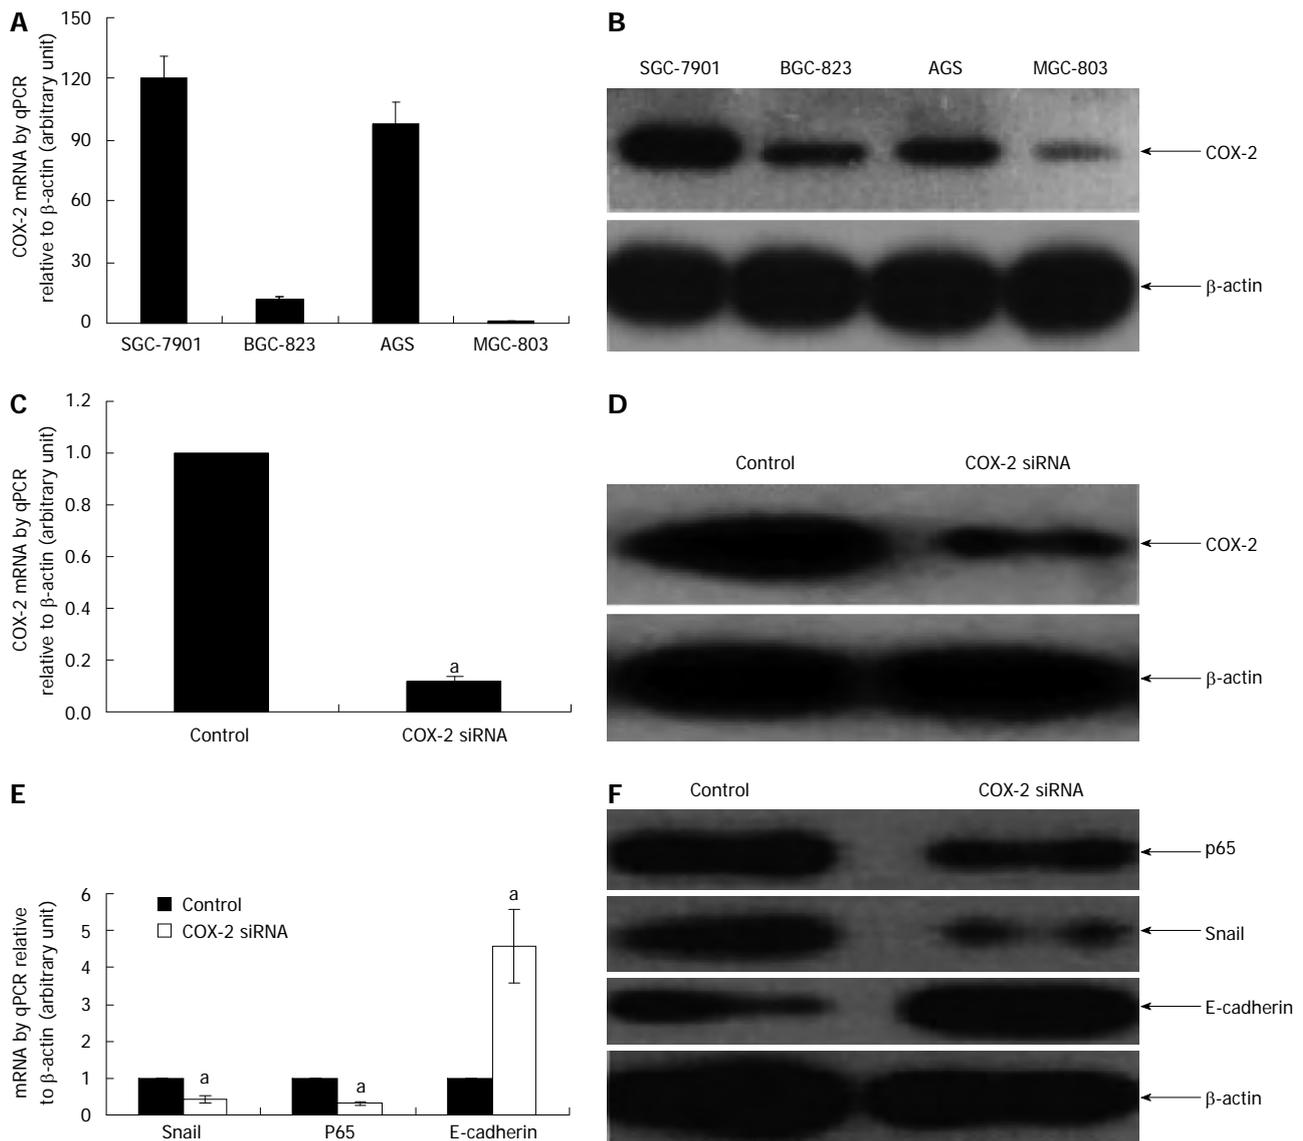

## RESULTS

#### COX-2 baseline expression in human gastric cancer cell lines

We first examined the basal level of COX-2 expression in several human gastric cancer cell lines using qPCR and Western blot. The cell lines tested include SGC-7901 (moderately differentiated), BGC-823 (poorly differentiated), MGC803 (undifferentiated), and AGS (well differentiated). Highest expression level of COX-2 was found in SGC-7901 cells, both at mRNA and protein levels (Figure 1A and B) (*P* < 0.05). Thus, the subsequent experiments were performed in SGC-7901 unless otherwise stated.

#### Effect of COX-2 silencing on NF- $\kappa$ B, Snail, and E-cadherin in SGC7901 cells

In order to test the effect of siRNA-mediated down-regulation of COX-2 on NF- $\kappa$ B, Snail and E-cadherin, SGC-7901 cells were incubated with COX-2 specific siRNA (COX-2-siRNA) and the target gene expression was examined by qPCR and Western blot. As shown in Figure 1, knockdown of COX-2 (Figure 1C and D) led to a 3-fold and 2.3-fold decrease but a 4.6-fold increase in the mRNA expression of NF- $\kappa$ B, Snail, and E-cadherin, respectively (Figure 1E) (*P* < 0.05, compared to their respective controls). These changes were confirmed at the protein level: COX-2-siRNA led to 2.3-fold and 2.8-fold

**Figure 1** Effect of cyclooxygenase-2 knockdown on the expression of nuclear factor- $\kappa$ B, Snail, and E-cadherin in gastric cancer cells. Among the four human gastric cancer cell lines, SGC-7901 has the highest expression level of cyclooxygenase-2 (COX-2) at mRNA (A) and protein level (B). Thus, this cell line was used to study the regulatory effect of COX-2 on nuclear factor- $\kappa$ B (NF- $\kappa$ B), Snail, and E-cadherin. Successful knockdown of COX-2 was confirmed at mRNA (C) and protein (D) levels. Down-regulation of COX-2 led to a reduction of NF- $\kappa$ B subunit p65 and Snail but an increased E-Cadherin, both at the mRNA (E) and protein (F) levels. mRNA expression was examined by quantitative polymerase chain reaction (qPCR) and expressed as a relative arbitrary unit against that of  $\beta$ -actin. Protein expression was examined by Western blot ( $^*P < 0.05$  vs their respective controls).

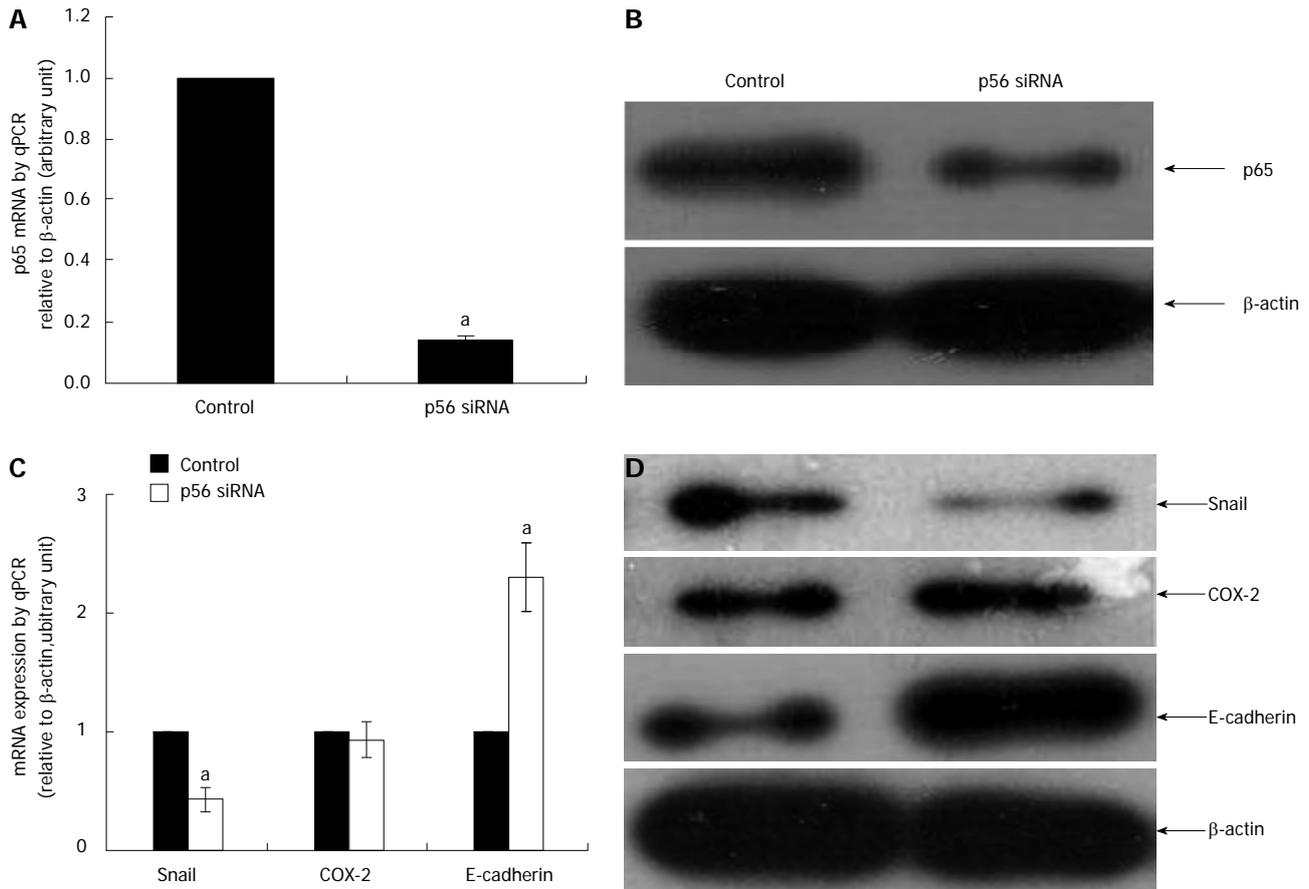

decrease but a 2.5-fold increase in the expression of NF- $\kappa$ B, Snail, and E-cadherin, respectively (Figure 1F) ( $P < 0.05$ , compared to their respective controls).

**Effect of NF- $\kappa$ B silencing on COX-2, Snail and E-cadherin in SGC7901 cells**

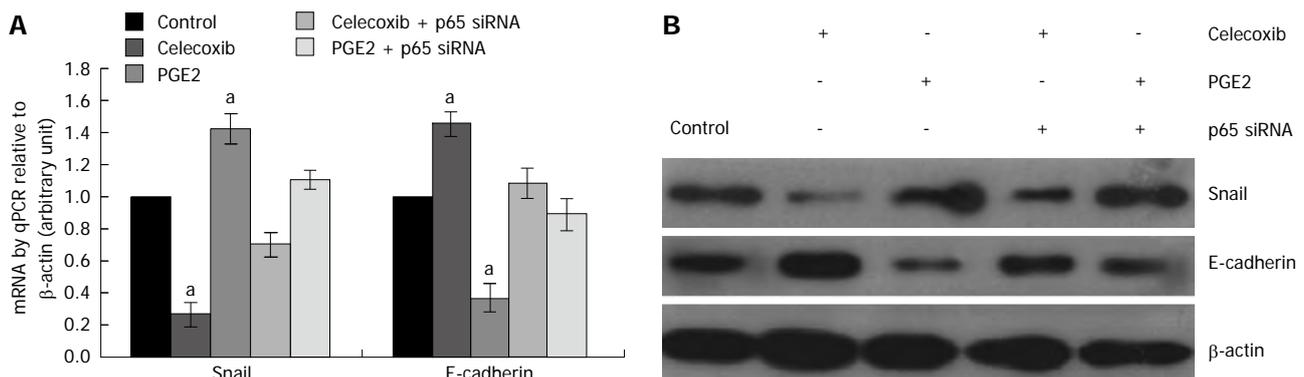

As noted above, siRNA mediated down-regulation of COX-2 led to a reduced expression of NF- $\kappa$ B and Snail in SGC-7901 cells. In order to confirm if COX-2 functions upstream of NF- $\kappa$ B, we examined if NF- $\kappa$ B was able to modulate COX-2 expression in SGC-7901 cells. As shown in Figure 2, knockdown of NF- $\kappa$ B subunit p65 using its specific siRNA (p65-siRNA) (Figure 2A and B) did not affect the expression of COX-2 at both

mRNA and protein levels (Figure 2C and D) ( $P < 0.05$ , compared to their respective controls).

We then proposed that NF- $\kappa$ B could regulate the expression of E-cadherin *via* the transcription factor Snail. Therefore, the effect of NF- $\kappa$ B silencing on Snail and E-cadherin were further examined in SGC-7901 cells. As shown in Figure 2, knockdown of NF- $\kappa$ B (Figure 2A and B) was associated with a reduced expression of Snail at both mRNA and protein levels (Figure 2C and D) ( $P < 0.05$ , compared to their respective controls). On the other hand, blockade of NF- $\kappa$ B with p65-siRNA rendered an increase in the expression of E-cadherin at both mRNA and protein levels (Figure 2C and D) ( $P < 0.05$ , compared to their respective controls).

**Figure 2** Effect of nuclear factor- $\kappa$ B knockdown on the expression of cyclooxygenase-2, Snail, and E-cadherin in SGC-7901 cells. Cells transfected with specific siRNA against nuclear factor- $\kappa$ B (NF- $\kappa$ B) subunit p65 (p65-siRNA) showed a marked down-regulation of p65 at mRNA (A) and protein (B) levels. p65-siRNA led to a reduction of Snail but an increased E-cadherin, both at the mRNA (C) and protein (D) levels. However, p65-siRNA mediated down-regulation of NF- $\kappa$ B did not significantly alter the expression of COX-2, both at the mRNA (C) and protein (D) levels. mRNA expression was examined by polymerase chain reaction (qPCR) and expressed as a relative arbitrary unit against that of  $\beta$ -actin. Protein expression was examined by Western blot. ( $^eP < 0.05$  vs their respective controls).

**Figure 3** Down-regulation of nuclear factor- $\kappa$ B by p65-siRNA reversed the regulatory effect of celecoxib and prostaglandin E2 on Snail and E-cadherin in SGC-7901 cells. Treatment of SGC-7901 cells with celecoxib led to a reduced expression of Snail but an increased expression of E-cadherin both at mRNA (A) and protein (B) levels. In contrast, treatment of SGC-7901 cells with prostaglandin E2 (PGE2) led to an increased Snail and a decreased E-cadherin at mRNA (A) and protein (B) levels. However, when the cells were pre-treated with p65-siRNA, the observed effects of Celecoxib and PGE2 were reversed (A, B). mRNA expression was examined by polymerase chain reaction (qPCR) and expressed as a relative arbitrary unit against that of  $\beta$ -actin. Protein expression was examined by Western blot ( $^eP < 0.05$  vs their respective controls).

**NF- $\kappa$ B inhibition interrupted the effects of celecoxib and PGE2 on E-cadherin and Snail in SGC-7901 cells**

To further determine the regulatory role of NF- $\kappa$ B on E-cadherin, we used celecoxib, a potent COX-2 inhibitor,

and PGE2, a principal COX-2 substrate with reported role in promoting cell migration and invasion in tumors, to treat SGC-7901 cells in the presence or absence of p65-siRNA.

As shown in Figure 3, treatment of SGC-7901 cells with celecoxib led to a reduced expression of Snail but an increased expression of E-cadherin both at mRNA (Figure 3A) and protein (Figure 3B) levels. In contrast, treatment of SGC-7901 cells with PGE2 led to an increased Snail and a decreased E-cadherin at mRNA (Figure 3A) and protein levels (Figure 3B). However, when the cells were pre-treated with p65-siRNA, the observed effects of celecoxib and PGE2 were reversed (Figure 3A and B) ( $P < 0.05$ , compared to their respective controls).

## DISCUSSION

Abnormal down-regulation of E-cadherin is an important event involved in epithelial-mesenchymal transition, a critical process in the malignant transformation of epithelial cancers including gastric cancer<sup>[10,18]</sup>. Previous studies, including our own, have demonstrated that COX-2 has a modulatory effect on expression of E-cadherin in gastric cancer and other malignancies<sup>[12]</sup>. The regulatory role of COX-2 on the expression of E-cadherin is also reflected by the observed chemopreventive effect of the selective COX-2 inhibitor celecoxib which was shown to inhibit the migration and metastasis of tumor cells by up-regulating E-cadherin<sup>[19]</sup>, and further supported by the fact that PGE-2 was able to promote the tumor invasion through down-regulating E-cadherin<sup>[20]</sup>. However, the mechanisms responsible for the regulatory effect of COX-2 on E-cadherin have not been well defined.

E-cadherin is usually lost in gastric cancer tissues and this appeared to be mediated by COX-2<sup>[21]</sup>. In our previous study, we found that inhibition of COX-2 activity by celecoxib was not only associated with a reduced expression of Snail, but also a marked reduction in NF- $\kappa$ B subunit p65<sup>[12]</sup>. In the current study, we explored the same regulatory effect based on RNAi technique. The results showed that COX-2 mediated down-regulation of E-cadherin appeared to be dependent on a functional NF- $\kappa$ B pathway, as blockade of COX-2 activity, either by COX-2-siRNA or celecoxib, restored the expression of E-cadherin. This was associated with a marked down-regulation of NF- $\kappa$ B and Snail expression. These findings are in agreement with previous reports that NF- $\kappa$ B up-regulates Snail and consequently represses E-cadherin in tumor cells<sup>[21,22]</sup>. Snail has been firmly established as a repressor of E-cadherin and it down-regulates E-cadherin transcription through an interaction with proximal E-boxes of the E-cadherin promoter<sup>[23]</sup>. In our current study, we further revealed that blockade of NF- $\kappa$ B by p65-siRNA did not alter the expression of COX-2 in SGC-7901 cells. However, the effect of celecoxib and PGE2 on Snail and E-cadherin was reversed by p65-siRNA, suggesting that a functional COX-2 was necessary for regulating NF- $\kappa$ B and Snail signaling in gastric cancer.

The regulatory role of NF- $\kappa$ B on COX-2 has been reported in other human tumors<sup>[24]</sup>. For example, NF- $\kappa$ B was found to enhance the expression of COX-2 and promote cells proliferation in human colorectal carci-

noma cells<sup>[25]</sup>. In our study, NF- $\kappa$ B p65 was not found to regulate the expression of COX-2. This inconsistency may reflect a cell type specific difference. Additionally, the regulatory role of NF- $\kappa$ B on COX-2 in gastric cancer through other subunits could not be excluded. More studies are needed to unveil the possible mechanisms of how COX-2 and NF- $\kappa$ B interact during gastric cancer formation.

In conclusion, this study has provided further evidence that COX-2 functions upstream of NF- $\kappa$ B in the regulation of Snail and E-cadherin in gastric cancer cells. Blockade of COX-2 activity or inhibition of PGE2 production may offer some benefit in the chemoprevention and treatment of gastric cancer.

## COMMENTS

### Background

Cyclooxygenase-2 (COX-2) plays an important role in transcriptional regulation of E-cadherin in gastric cancer and other malignancies. celecoxib, a selective inhibitor of COX-2, inhibits migration and metastasis of tumor cells by up-regulation of E-cadherin. On the contrary, prostaglandin E2 (PGE2) promotes invasion of tumor cells through down regulating the expression of E-cadherin. This study aims to explore how COX-2/PGE2 regulates E-cadherin expression and further to determine whether COX-2/PGE2 reduces the expression of E-cadherin via nuclear factor- $\kappa$ B (NF- $\kappa$ B)/ Snail signal pathway in gastric cancer cells.

### Research frontiers

Although the correlation between COX-2 and E-cadherin is always inverse in tumor cells, the mechanism of how COX-2 regulates E-cadherin is not clear yet.

### Innovations and breakthroughs

The authors firstly found COX-2 baseline expression was significantly higher in SGC-7901 cells in comparison to that in BGC-823, MGC-803 and AGS cells. celecoxib or COX-2 specific RNAi both down-regulated NF- $\kappa$ B and Snail expression, and up-regulated E-cadherin expression, in contrast to PGE2, in SGC-7901 cells. Next, they found that NF- $\kappa$ B specific RNAi did not influence the expression of COX-2 in SGC-7901 cells. Therefore, they can conclude preliminarily that NF- $\kappa$ B and Snail are the downstream molecules in COX-2 modulated E-cadherin signaling pathway in SGC-7901 cells.

### Applications

This study has provided further evidence that COX-2 functions upstream of NF- $\kappa$ B in the regulation of Snail and E-cadherin in gastric cancer cells. Blockade of COX-2 activity or inhibition of PGE2 production may offer some benefit in the chemoprevention and treatment of gastric cancer.

### Terminology

Epithelial-mesenchymal transition (EMT): The epithelial-mesenchymal transition is a process by which epithelial cells lose their cell polarity and cell-cell adhesion, and gain migratory and invasive properties to become mesenchymal cells. EMT is essential for numerous developmental processes including mesoderm formation and neural tube formation. EMT has also been shown to occur in wound healing, in organ fibrosis and in the initiation of metastasis for cancer progression. COX-2: COX-2 is an inducible isozyme of cyclooxygenase and catalyzes PGE2 formation in response to various inflammatory stimuli or growth factors; E-cadherin: E-cadherin is an important cell adhesion molecule and is usually low, mutated, or even lost in gastric cancer tissues. COX-2 and E-cadherin appear to exhibit totally different expression patterns in tumor cells.

### Peer review

This is a very interesting paper on the molecular biology of COX-2 and E-cadherin via the NF- $\kappa$ B and Snail pathways. The methodology and reasoning is

sound along with the results and logical discussion at the end.

### Abstract

**AIM:** To compare short- and long-term outcomes of laparoscopic vs open distal pancreatectomy for solid pseudopapillary tumor (SPT) of the pancreas.

**METHODS:** This retrospective study included 28 patients who underwent distal pancreatectomy for SPT of the pancreas between 1998 and 2012. The patients were divided into two groups based on the surgical approach: the laparoscopic surgery group and the open surgery group. The patients' demographic data, operative results, pathological reports, hospital courses, morbidity and mortality, and follow-up data were compared between the two groups.

**RESULTS:** Fifteen patients with SPT of the pancreas underwent laparoscopic distal pancreatectomy (LDP), and 13 underwent open distal pancreatectomy (ODP). Baseline characteristics were similar between the two groups except for a female predominance in the LDP

group (100.0% vs 69.2%,  $P = 0.035$ ). Mortality, morbidity (33.3% vs 38.5%,  $P = 1.000$ ), pancreatic fistula rates (26.7% vs 30.8%,  $P = 0.728$ ), and reoperation rates (0.0% vs 7.7%,  $P = 0.464$ ) were similar in the two groups. There were no significant differences in the operating time (171 min vs 178 min,  $P = 0.755$ ) between the two groups. The intraoperative blood loss (149 mL vs 580 mL,  $P = 0.002$ ), transfusion requirement (6.7% vs 46.2%,  $P = 0.029$ ), first flatus time (1.9 d vs 3.5 d,  $P = 0.000$ ), diet start time (2.3 d vs 4.9 d,  $P = 0.000$ ), and postoperative hospital stay (8.1 d vs 12.8 d,  $P = 0.029$ ) were significantly less in the LDP group than in the ODP group. All patients had negative surgical margins at final pathology. There were no significant differences in number of lymph nodes harvested (4.6 vs 6.4,  $P = 0.549$ ) between the two groups. The median follow-up was 33 (3-100) mo for the LDP group and 45 (17-127) mo for the ODP group. All patients were alive with one recurrence.

**CONCLUSION:** LDP for SPT has short-term benefits compared with ODP. Long-term outcomes of LDP are similar to those of ODP.

**Key words:** Solid pseudopapillary tumor; Pancreatic tumor; Laparoscopic surgery; Distal pancreatectomy

**Core tip:** Solid pseudopapillary tumor (SPT) of the pancreas is a rare neoplasm. Laparoscopic distal pancreatectomy (LDP) and open distal pancreatectomy (ODP) for SPT have not previously been compared. We compared the short-term and long-term outcomes among patients undergoing either LDP or ODP for SPT. Our results showed that LDP for SPT had the advantages of minimally invasive surgery, less intraoperative blood loss, and rapid recovery. The mortality, morbidity, oncological outcome, and long-term outcome of LDP were similar to those of open surgery.

## INTRODUCTION

Solid pseudopapillary tumor (SPT) of the pancreas is a rare neoplasm, accounting for 0.17%-2.7% of all pancreatic tumors, and affecting predominantly young women<sup>[1]</sup>. Frantz<sup>[2]</sup> first described the tumor in 1959 as a papillary tumor of the pancreas. The tumor has been named as a papillary epithelial neoplasm, solid and cystic tumor, solid and papillary tumor, papillary cystic tumor, and solid and papillary epithelial neoplasm depending on its histological features including cystic, solid, and pseudopapillary structures<sup>[1,3]</sup>. In 1996, the World Health Organization renamed this tumor as SPT<sup>[4]</sup>. SPT is of unclear histopathogenesis, and low-grade malignancy, malignant degeneration and lymph node metastasis rarely occur<sup>[1,5]</sup>. Surgical resection of this tumor could result in long-term survival<sup>[1]</sup>.

Laparoscopic resection of the pancreas, including enucleation, pancreaticoduodenectomy, and distal and central pancreatectomy, has been recently described; some of the patients could have benefited from these procedures<sup>[6-10]</sup>. Until April 2013, about 86 cases of laparoscopic/robot-assisted resection for SPT have been reported in the English-language literature. Most of these are case reports and small series. However, there are few reports comparing short-term and long-term outcomes among patients who underwent laparoscopic distal pancreatectomy (LDP) vs open distal pancreatectomy (ODP) for SPT of the pancreas.

The goal of the present study was to compare short-term and long-term outcomes in patients undergoing either LDP or ODP for SPT of the pancreas.

## MATERIALS AND METHODS

### *Patient sample and data collection*

Between May 1998 and December 2012, 55 patients underwent pancreatectomy for SPT of the pancreas at Sir Run Run Shaw Hospital, Hangzhou, China. We retrieved 29 patients who underwent distal pancreatectomy. One patient with liver metastasis and colon cancer was excluded from the study, and 28 patients were included in this study. The medical records of all patients were retrospectively reviewed, including demographics, clinical presentation, operative results, hospital course, morbidity and mortality, pathological findings, and long-term follow-up data. The Institutional Review Board of Sir Run Run Shaw Hospital of Zhejiang University approved this study protocol.

### *Surgical procedure*

All operations were performed by four experienced surgeons using our institution's standardized technique. Laparoscopic pancreatic surgery was adopted in 2003 at our institution, therefore, all of the patients who underwent surgery from 1998 to 2003 were included in the open surgery group. After 2003, the surgeons could decide whether to perform laparoscopic or open surgery with the informed consent of the patients.

### *Operative technique used for distal pancreatectomy*

The operative procedure for LDP has been described previously<sup>[11,12]</sup>. Briefly, the patient was placed in supine position with the head slightly elevated. The surgeon and the second assistant who held the laparoscope stood on the right side of the patient and the first assistant stood on the left. One initial 10-mm trocar was placed for laparoscopy below the umbilicus. A 30-degree telescope was inserted to examine the peritoneal cavity to rule out metastatic disease. After general examination, the other four trocars (one 12 mm, three 5 mm) were inserted into the left upper flank, left flank, right upper flank, and right flank quadrants; and the five trocars were arranged in a V shape. Under pneumoperitoneum, the gastrosplenic ligament was divided for entrance to the lesser sac using a harmonic scalpel (Harmonic Ace; Ethicon Endo-Surgery, Cincinnati, OH, United States). The mobilization of the pancreas began at the superior border until the proximal splenic artery was visualized. The pancreas was mobilized at the inferior border to visualize the superior mesenteric and splenic veins. After creating a tunnel behind the neck of the pancreas, the pancreas was transected with an endoscopic linear stapler (Endocutter 60 stapler, white or blue cartridge; Ethicon Endo-Surgery, Cincinnati, OH, United States). For spleen-preserving procedures, the distal pancreas was freely dissected from the splenic vessels by ligation of the small branches connected to the pancreas using small titanium vascular clips or a harmonic scalpel. In the case of DP with splenectomy, the splenic artery and splenic vein were divided. The spleen was resected with the pancreas.

ODP was performed in the same manner as LDP through an upper midline incision. However, a variety of techniques, including suturing and/or stapling, were used to control the pancreas stump, according to the preference of the individual surgeon.

### *Postoperative management*

Diet was started after the first flatus had been passed. Patients were discharged if they considered themselves sufficiently recovered; tolerated food without any significant discomfort; and had no major complications. Postoperative pancreatic fistula was defined as any measurable volume of drainage fluid (amylase > 3 times the upper limit of normal serum value) on or after postoperative day 3<sup>[13]</sup>. Three different grades of postoperative pancreatic fistula (A-C) were defined according to the clinical impact on the patient's hospital course<sup>[13]</sup>. Postoperative mortality

**Table 1** Baseline characteristics of patients undergoing laparoscopic distal pancreatectomy or open distal pancreatectomy for pancreatic solid pseudopapillary tumor *n* (%)

Characteristics	LDP ( <i>n</i> = 15)	ODP ( <i>n</i> = 13)	<i>P</i> value
Age (yr)	35.4 ± 13.0	35.2 ± 16.6	0.965
Sex			0.035
Male	0 (0.0)	4 (30.8)	
Female	15 (100.0)	9 (69.2)	
BMI (kg/m <sup>2</sup> )	20.8 ± 2.3	22.4 ± 6.1	0.392
Symptoms			0.255
No	10 (66.7)	5 (38.5)	
Yes	5 (33.3)	8 (61.5)	
Comorbidity	4 (26.7)	4 (30.8)	1.000
ASA score			1.000
1	9 (60.0)	8 (61.5)	
2	6 (40.0)	5 (38.5)

Data are expressed as *n* (%) or mean ± SD or unless otherwise specified. BMI: Body mass index; ASA: American Society of Anesthesiologists; LDP: Laparoscopic distal pancreatectomy; ODP: Open distal pancreatectomy.

was defined as death occurring within 30 d after surgery.

### Patient follow-up

Patients were followed up as outpatients by telephone. We included data up to the last follow-up in March 2013. Recurrence or distant metastasis was diagnosed pathologically by surgical resection, biopsy, or cytology and/or radiological examination. The fasting blood glucose level (normal ≤ 110 mg/dL) was used to evaluate pancreatic endocrine function. The clinical evaluation was used to assess the pancreatic exocrine function. Patients with diarrhea, weight loss, and fatty stools were considered to have pancreatic exocrine insufficiency.

### Statistical analysis

Continuous clinicopathological data were expressed as median (range) or mean ± SD as appropriate. Categorical variables were reported as number and percentage. Continuous clinicopathological data were analyzed with Student's *t* test (or Mann-Whitney *U* test). Categorical variables were analyzed with the  $\chi^2$  test (or Fisher's exact test). All statistical analyses were performed using SPSS version 16.0. *P* < 0.05 was considered statistically significant.

## RESULTS

### Baseline characteristics

Table 1 summarizes the baseline characteristics of the LDP and ODP groups. Fifteen patients underwent LDP and 13 ODP. The two groups were balanced in terms of their baseline characteristics: age, body mass index (BMI), symptoms, comorbidity, American Society of Anesthesiologists (ASA) score, tumor size, spleen preservation

**Table 2** Surgical outcomes of laparoscopic distal pancreatectomy and open distal pancreatectomy for pancreatic solid pseudopapillary tumor *n* (%)

Outcomes	LDP ( <i>n</i> = 15)	ODP ( <i>n</i> = 13)	<i>P</i> value
Operating time (min)	171 ± 54	178 ± 75	0.755
EBL (mL)	149 ± 127	580 ± 400	0.002
Transfused patients	1 (6.7)	6 (46.2)	0.029

Reoperation	0 (0.0)	1 (7.7)	0.464
Percutaneous drainage	2 (13.3)	2 (15.4)	1.000
Mortality	0 (0.0)	0 (0.0)	-

Data are expressed as *n* (%) or mean ± SD or unless otherwise specified. EBL: Estimated blood loss; LDP: Laparoscopic distal pancreatectomy; ODP: Open distal pancreatectomy.

rate, and combined resection rate, except for a significant female predominance in the LDP group: 100% women (*n* = 15) compared with 69.2% (*n* = 9) in the ODP group (*P* = 0.035).

### Surgical outcomes in the LDP and ODP groups

Table 2 summarizes the operative outcomes and hospital courses of the LDP and ODP groups. There were no significant differences in the operating time (171 min *vs* 178 min, *P* = 0.755) between the two groups. LDP produced a significantly lower amount of intraoperative blood loss (149 mL *vs* 580 mL, *P* = 0.002), lower transfusion requirement (6.7% *vs* 46.2%, *P* = 0.029), shorter first flatus time (1.9 d *vs* 3.5 d, *P* = 0.000), shorter diet start time (2.3 d *vs* 4.9 d, *P* = 0.000), and shorter postoperative hospital stay (8.1 d *vs* 12.8 d, *P* = 0.029) than ODP.

There were no significant differences in postoperative complication rates (33.3% *vs* 38.5%, *P* = 1.000), pancreatic fistula rates (26.7% *vs* 30.8%, *P* = 0.972), and reoperation rates (0.0% *vs* 7.7%, *P* = 0.464) between the two groups. One patient underwent laparotomy for acute peritonitis after open spleen-preserving DP. We found biliary and pancreatic fistulas from the pancreatic stump. A calculus (diameter 6 mm) was incarcerated in the distal common bile duct, which led to bile regurgitation through the pancreaticobiliary common channel. The procedure consisted of cholecystectomy, common bile duct exploration, T tube drainage, and suture of the pancreatic remnant. The patient was discharged 24 d after the second operation. No perioperative mortality was recorded.

### Pathological characteristics

Table 3 shows the pathological characteristics of the two groups. All patients had negative surgical margins at final

**Table 3** Pathological characteristics of patients undergoing laparoscopic distal pancreatectomy or open distal pancreatectomy for pancreatic solid pseudopapillary tumor *n* (%)

Characteristics	LDP ( <i>n</i> = 15)	ODP ( <i>n</i> = 13)	<i>P</i> value

Data are expressed as *n* (%) or mean ± SD or unless otherwise specified. LDP: Laparoscopic distal pancreatectomy; ODP: Open distal pancreatectomy.

pathology. An average number of 5.3 lymph nodes were resected without metastases. There was no significant difference in the number of harvested lymph nodes (4.6 *vs* 6.4, *P* = 0.549) between the two groups. In seven (25%) patients, the pathological findings were consistent with malignant features of SPT<sup>[14]</sup>. The malignant features included local invasion of peripancreatic tissue (*n* = 6), perineural invasion (*n* = 2), no liver metastasis, invasion of adjacent organs and angioinvasion. There were no significant differences in the pathological characteristics between the two groups.

### Long-term outcomes

The median follow-up was 33 (3-100) mo for the LDP group and 45 (17-127) mo for the ODP group. All patients were alive with one recurrence. A 57-year-old female patient underwent ODP, and the pathology report revealed SPT with peripancreatic tissue invasion and perineural invasion. Six years after surgery, she developed peritoneal recurrence, which was treated by open tumorectomy and traditional Chinese medicine. At a follow-up of 15 mo after the second operation, no tumor recurrence was found. After surgery, six patients developed pancreatic exocrine or endocrine insufficiency; two received pancreatic enzyme therapy; and one developed diabetes and received insulin therapy. There were three cases of hyperglycemia with diet control.

## DISCUSSION

SPT is an uncommon pancreatic neoplasm with nonspecific symptoms or completely asymptomatic<sup>[1]</sup>. A review of 718 patients with SPT showed that the most common localization of the tumor was the distal pancreas [tail (247 patients, 35.9%), body (102 patients, 14.8%), and body and tail (71 patients, 10.3%)]<sup>[1]</sup>. This was also demonstrated in our series (29 patients, 52.7%). Therefore, DP with/without splenectomy is the most common surgical procedure for SPT. Complete resection of SPT offers benefits in almost all patients, and extensive lymphatic dissection is not indicated<sup>[1,15]</sup>. With the feasibility

and safety of LDP being proven<sup>[16,17]</sup>, it seems that LDP is thought to be more appropriate for SPT of the distal pancreas.

The first surgical resection of a pancreatic SPT was performed in 1970 and laparoscopic SPT resection in 2003<sup>[18,19]</sup>. The first series of laparoscopic SPT resection (10 cases) was published by Cavallini *et al*<sup>[20]</sup> in 2011. They regarded that LDP was a safe and feasible procedure for patients with SPT. However, no comparative analysis with open surgery was done. Kang *et al*<sup>[21]</sup> found smaller tumor size, earlier oral intake, and shorter hospital stay, without increasing morbidity in the laparoscopic (8 cases)/robot-assisted (3 cases) surgery group (*P* < 0.05) compared with open surgery group. To the best of our knowledge, the present series is the largest comparison of LDP and ODP for SPT. Our results indicated that LDP for SPT was associated with less operative blood loss and transfusion requirement, earlier first flatus and diet start, and shorter hospital stay compared to ODP, without increasing surgery-related risks (Table 2). The pathological examination showed that LDP for SPT provided similar oncological outcomes (harvested lymph nodes and margin status) as compared with ODP (Table 3). Long-term outcomes of laparoscopic surgery were comparable to those of open surgery. We believe that LDP for SPT could produce better short-term outcomes than ODP, without affecting oncological and long-term outcomes.

Our data and literature<sup>[1]</sup> showed that patients with SPT are expected to have a long-term survival after resection. At a median follow-up of 39 mo, 6 patients developed pancreatic exocrine or endocrine insufficiency. Thus, quality of life should be considered when choosing surgical procedure. Function-preserving laparoscopic pancreatectomy, including laparoscopic central pancreatectomy (LCP), spleen-preserving (SP)-LDP is thought to be an ideal procedure for this tumor. Some experts have reported the surgical technique of LCP with operative outcomes in small case series<sup>[9,10]</sup>. Three patients with SPT underwent LCP in our center. Nevertheless, the number of patients was too small to draw any conclusion. With the advances in instrumentation and accumulating experience, LCP would be an alternative procedure for SPT in the neck or proximal body of the pancreas.

As compared with SP-LDP, LDP with splenectomy tends to impair quality of life, with frequent higher-grade complications and prolonged hospital stays<sup>[22]</sup>. Butturini *et al*<sup>[23]</sup> compared the results of patients who underwent SP-LDP with or without splenic vessel conservation, and showed that postoperative morbidity did not differ between the two groups. The rate of perigastric varices was 60.0% after splenic vessel resection and 21.7% after splenic vessel conservation (*P* = 0.123)<sup>[23]</sup>. No gastrointestinal bleeding occurred at a median follow-up of 69 (37-139) mo<sup>[23]</sup>. In our series, only two patients underwent SP-LDP with splenic vessel conservation and 13 patients underwent LDP with splenectomy. For the small number of cases, there was no comparability between SP-LDP with splenic vessel conservation group and LDP with

splenectomy group. Considering the low malignancy of SPT and high rate of perigastric varices after splenic vessel resection, it is best to try to preserve the spleen with splenic vessels.

Recently, Fais *et al*<sup>[24]</sup> reported three patients with recurrences within 3 years after resection for SPT (laparoscopic biopsy with resection in one case, and laparoscopic biopsy and open resection in two cases). They considered that recurrence after laparoscopic biopsy may be due to diffusion of tumor cells caused by gas insufflation<sup>[24]</sup>. In our series, 15 patients underwent LDP without biopsy or broken specimen. At a median follow-up of 33 mo, all patients were alive without recurrence. In our opinion, laparoscopic biopsy should not be performed in patients with SPT. During laparoscopic surgery, we should make sure that the integrity of the specimen is not broken.

The limitations of this study were its retrospective design and low number of patients. These problems can be overcome only by a large, prospective randomized trial, which would be difficult to accomplish owing to the infrequent diagnosis of patients with SPT of the distal pancreas. We believe that this study could provide useful evidence in clinical practice.

In conclusion, LDP for SPT is feasible and safe, and has short-term benefits compared with ODP. Long-term outcomes are similar for LDP and ODP.

## COMMENTS

### Background

Solid pseudopapillary tumor (SPT) of the pancreas is a rare neoplasm. Some patients have benefited from laparoscopic pancreatectomy. Laparoscopic distal pancreatectomy (LDP) has not previously been compared with open distal pancreatectomy (ODP) for SPT.

### Research frontiers

Recently, several case reports and small series have shown less intraoperative blood loss and rapid recovery after LDP for SPT. However, the short-term and long-term outcomes of LDP compared with ODP for SPT required further assessment.

### Innovations and breakthroughs

In the present study, the authors compared the short-term and long-term outcomes of LDP and ODP for SPT, and showed that LDP was suitable and minimally invasive for treating SPT and could achieve similar oncological outcomes (harvested lymph nodes and margin status) and long-term outcomes as ODP.

### Applications

This study showed that LDP for SPT had the advantages of minimally invasive surgery, less intraoperative blood loss, and rapid recovery. The mortality, morbidity, oncologic outcomes and long-term results of LDP were similar to those of ODP. These findings are helpful in decision-making for the treatment of SPT of the distal pancreas.

### Peer review

The topic is interesting, and despite the rarity of SPT, the study includes a large series of patients.

### Abstract

**AIM:** To compare efficacy of combined lamivudine (LAM) and adefovir dipivoxil (ADV) therapy with that of entecavir (ETV) monotherapy for hepatitis B virus (HBV)-related decompensated liver cirrhosis.

**METHODS:** A total of 120 naive patients with HBV-related decompensated cirrhosis participated in this study. Sixty patients were treated with combined LAM and ADV therapy (LAM + ADV group), while the other 60 were treated with ETV monotherapy (ETV group) for two years. Tests for liver and kidney function, alpha-

fetoprotein, HBV serum markers, HBV DNA load, prothrombin time (PT), and ultrasonography or computed tomography scan of the liver were performed every 1 to 3 mo. Repeated measure ANOVA and the  $\chi^2$  test were performed to compare the efficacy, side effects, and the cumulative survival rates at 48 and 96 wk.

**RESULTS:** Forty-five patients in each group were observed for 96 wk. No significant differences in HBV DNA negative rates and alanine aminotransferase (ALT) normalization rates at weeks 48 ( $\chi^2 = 2.12$  and 2.88) and 96 ( $\chi^2 = 3.21$  and 3.24) between the two groups were observed. Hepatitis B e antigen seroconversion rate in the LAM + ADV group at week 96 was significantly higher in the ETV group (43.5% vs 36.4%,  $\chi^2 = 4.09$ ,  $P < 0.05$ ). Viral breakthrough occurred in 2 cases (4.4%) by week 48 and in 3 cases (6.7%) by week 96 in the LAM + ADV group, and no viral mutation was detected. In the ETV group, viral breakthrough occurred in 1 case (2.2%) at the end of week 96. An increase in albumin ( $F = 18.9$  and 17.3), decrease in total bilirubin and in ALT ( $F = 16.5$ , 17.1 and 23.7, 24.8), reduced PT ( $F = 22.7$  and 24.5), and improved Child-Turcotte-Pugh and the model for end-stage liver disease scores ( $F = 18.5$ , 17.8, and 24.2, 23.8) were observed in both groups. The cumulative rates of mortality and liver transplantation were 16.7% (10/60) and 18.3% (11/60) in the LAM + ADV and ETV groups, respectively.

**CONCLUSION:** Both LAM + ADV combination therapy and ETV monotherapy can effectively inhibit HBV replication, improve liver function, and decrease mortality.

**Key words:** Chronic hepatitis B; Decompensated liver cirrhosis; Lamivudine; Adefovir dipivoxil; Combination therapy; Entecavir

**Core tip:** This study compared the *de novo* efficacy of combined lamivudine (LAM) and adefovir dipivoxil (ADV) therapy with that of entecavir (ETV) monotherapy for patients with hepatitis B virus (HBV)-related decompensated liver cirrhosis. Both LAM + ADV combination therapy and ETV monotherapy can effectively inhibit HBV replication, improve liver function, and decrease mortality. The data obtained in this study demonstrate the efficacy and the safety of these treatment regimens for 96 wk in patients with HBV-related decompensated liver cirrhosis.

## INTRODUCTION

Cirrhosis is the end stage of chronic liver damage and is characterized by fibrosis resulting in the distortion and destruction of normal liver architecture. Functional liver tissue is destroyed and replaced by regenerating nodules that do not fully restore lost liver function. Cirrhosis may be due to various causes, including hepatitis B virus (HBV) infection, hepatitis C (HCV) and alcohol consumption<sup>[1,2]</sup>. Chronic infection with HBV accounts for 30% of hepatic cirrhosis globally<sup>[3]</sup>. In China, about 93 million people are carriers of HBV, with 20 million people chronically infected. Within a five-year period, 10% to 20% of patients with chronic hepatitis B develop cirrhosis<sup>[4]</sup>. The five-year survival rates of patients with compensated cirrhosis and of those with decompensated cirrhosis (determined by the presence of ascites, hepatoencephalopathy, and/or history of variceal bleeding) were 84% and 14%, respectively<sup>[5]</sup>. Cirrhosis precedes most cases of hepatocellular carcinoma (HCC), with 70% to 90% of HCC developing from liver cirrhosis or inflammation<sup>[6]</sup>. Antiviral agents are assumed to reduce decompensated cirrhosis and HCC development<sup>[7]</sup>, however, agents such as lamivudine (LAM) and telbivudin show high drug resistance. The latest chronic hepatitis B prevention and treatment guidelines suggest the selection of a higher genetic barrier to resistant antivirals, such as entecavir (ETV) and tenofovir, for patients with HBV-related liver cirrhosis<sup>[8,9]</sup>. However, based on the paradigm that drug combination therapy is more effective than monotherapy for the treatment of human immunodeficiency virus and HCV, the same approach may be appropriate for chronic hepatitis B. This study was designed to compare the two-year efficacy of *de novo* combination therapy of LAM and adefovir dipivoxil (ADV) with that of ETV monotherapy in patients with decompensated liver cirrhosis.

## MATERIALS AND METHODS

### Study patients

From January 2008 to March 2009, 120 patients diagnosed with HBV-related decompensated liver cirrhosis at the First Affiliated Hospital of the Zhejiang University School of Medicine (Hangzhou, China) were recruited into this study. The diagnosis was based on medical history, the results of physical examination, biochemical, endoscopic and ultrasound findings, and radiological signs of cirrhosis. All patients were 18 to 65 years old, with  $\geq 10^3$  copies/mL HBV DNA, 7 to 12 (inclusive) Child-Turcotte-Pugh (CTP) score,  $\geq 50$  mL calculated serum creatinine clearance,  $\geq 75$  g/L hemoglobin,  $\geq 2.5 \times 10^9$ /L total white blood cells,  $\leq 20$  ng/mL  $\alpha$ -fetoprotein, and no evidence of HCC. None of the patients had been treated with antiviral drugs, including interferon- $\alpha$  or nucleos(t)ides. Patients with hepatitis delta virus, hepatitis C virus, or had human immunodeficiency virus (HIV) co-infection were excluded. Patients with HCC, autoimmune hepatitis, alcoholic liver cirrhosis, hepatorenal syndrome, grade 3 or 4 hepatic encephalopathy, spontaneous bacterial peritonitis, and severe heart, renal, and brain diseases were also excluded. All patients who participated in this study provided informed consent and were aware of the procedures to be conducted. The protocol was approved by the Ethics Committee of the First Affiliated Hospital of Zhejiang University.

### Study design

The study was designed as a prospective case-control study. The patients were randomly assigned to the ETV monotherapy (60 patients) group and the *de novo* LAM and ADV combination therapy (60 patients) group. Baseline data of the two groups were compared to ensure comparability. Patients in the combination therapy group were prescribed 100 mg LAM and 10 mg ADV per day, while the monotherapy group received 0.5 mg ETV per day.

### Follow-up studies

Serum hepatitis B viral markers, including hepatitis B surface antigen (HBsAg), antibody to HBsAg, hepatitis B e antigen (HBeAg), antibody to HBeAg and antibody to hepatitis B core antigen, were detected by commercially available enzyme immunoassays (Abbott Laboratories; Chicago, IL, United States). Serum HBV DNA was measured by polymerase chain reaction with a linear range between  $1 \times 10^3$  and  $5 \times 10^8$  copies/mL (Shanghai ZJ Bio-Tech Co., Ltd., China).

Follow-up observations in the two groups were performed at the start and during weeks 4, 12, 24, 36, 48, 60, 72, 84, and 96. Follow-up clinical assessments included physical examination, HBeAg and antibodies to the e antigen, quantitative HBV DNA, serum biochemistry, alpha-fetoprotein, renal function, prothrombin time (PT), and ultrasonography or computed tomography scan. The lower limit of detection of DNA used in this study was  $1.0 \times 10^3$  copies/mL (Shanghai ZJ Bio-Tec Co., Ltd, Chi-

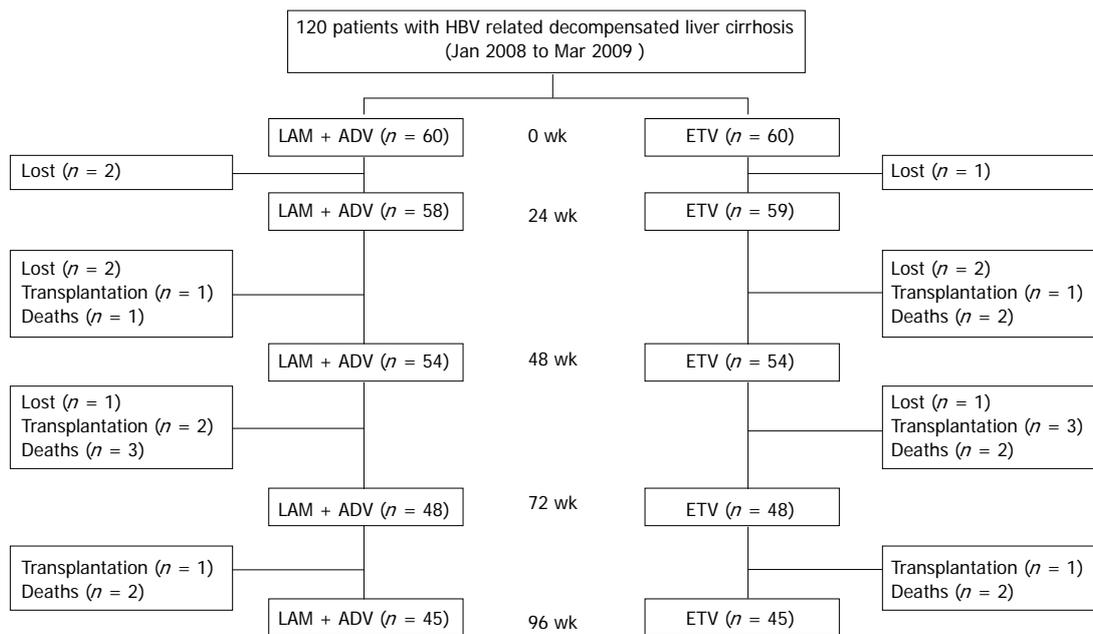

Figure 1 Flow chart of patient conditions following treatment with *de novo* lamivudine and adefovir dipivoxil combination therapy and entecavir monotherapy for 96 wk. LAM: Lamivudine; ADV: Adefovir dipivoxil; ETV: Entecavir.

na). The condition of the patients after 96 wk is shown in Figure 1.

### Statistical analysis

SPSS 16.0 software was used for data analysis. Measurements were presented as mean  $\pm$  SD and comparisons were conducted following analysis of the results using the Student's *t* test. Proportions were presented as percentage (%). Rate comparisons were performed using the  $\chi^2$  test. A *P* value < 0.05 was considered significant.

## RESULTS

### Baseline characteristics

In the two years of follow-up observations, of the 60 patients who received LAM and ADV combination therapy, 5 cases were lost, 4 cases underwent liver transplantation, 6 cases died, and 45 cases survived until the end of the observation period. The 45 remaining cases comprised 16 females and 29 males. The mean patient age was  $53.1 \pm 8.8$  years. Of the 60 patients who received ETV monotherapy, 4 cases were lost, 5 cases underwent liver transplantation, 6 cases died, and 45 cases survived until the end of the observation period. The 45 remaining cases comprised 17 females and 28 males. The mean patient age was  $53.2 \pm 7.4$  years. The baseline characteristics of the patients were similar, and no statistically significant differences were observed (Table 1).

### Virological, serological and biochemical response

Of the 45 patients in the LAM and ADV combination group, 51.1% (23/45) and 86.7% (39/45) achieved undetectable HBV DNA by weeks 48 and 96, respectively. Of the 45 patients in the ETV group, 60% (27/45) and

88.9% (40/45) achieved undetectable HBV DNA by weeks 48 and 96, respectively. No statistical differences were observed between the two groups by weeks 48 and 96 (*P* > 0.05).

In the LAM and ADV combination therapy group, 71.1% (32/45) and 88.9% (40/45) of patients achieved ALT normalization by week 48 and 96, respectively. In the ETV treatment group, 68.9% (31/45) and 91.1% (41/45) achieved ALT normalization by week 48 and 96, respectively. No statistical difference was observed between the two groups at week 48 and 96 (*P* > 0.05).

Of the 45 patients who received the LAM and ADV combination treatment, 30.4% (7/23) and 43.5% (10/23) achieved HBeAg seroconversion by weeks 48 and 96, respectively. Similarly, 27.3% (6/22) and 36.4% (8/22) of the patients who received ETV monotherapy achieved HBeAg seroconversion by weeks 48 and 96, respectively. No statistical difference was observed between the two groups at week 48, while the HBeAg seroconversion rate in the LAM and ADV combination group at week 96 was significantly higher than that in the ETV monotherapy group (43.5% vs 36.4%,  $\chi^2 = 4.09$ , *P* < 0.05).

Of the respondents, 2 and 3 patients in the LAM and ADV combination group and 1 and 2 patients in the ETV monotherapy group developed virological breakthrough by weeks 48 and 96, respectively. No genetic mutations were detected in either patient group. The obtained differences were not statistically different (*P* > 0.05).

### Changes in liver function in patients with decompensated cirrhosis

After 96 wk of treatment, the albumin level in patients in the LAM and ADV combination group increased sig-

**Table 1** Baseline characteristics of patients with HBV-related decompensated cirrhosis *n* (%)

Variables	LAM + ADV ( <i>n</i> = 45)	ETV ( <i>n</i> = 45)	<i>t</i>	$\chi^2$	<i>P</i> value
Age (yr)	53.1 ± 8.8	53.2 ± 7.4	0.23		> 0.05
Male/female	29/16	28/17		3.10	> 0.05
HBV DNA (log <sub>10</sub> copy/mL)	6.56 ± 1.13	6.61 ± 1.15	0.33		> 0.05
ALT (U/L)	98.1 ± 21.6	99.8 ± 17.2	0.23		> 0.05
TBil (μmol/L)	51.6 ± 8.9	49.2 ± 6.8	0.31		> 0.05
Alb (g/L)	29.2 ± 0.7	29.5 ± 1.2	0.24		> 0.05
PT (s)	16.3 ± 2.3	16.5 ± 1.9	0.21		> 0.05
CTP score	8.4 ± 1.7	8.6 ± 2.1	0.16		> 0.05
MELD score	13.7 ± 3.5	12.9 ± 6.7	0.25		> 0.05
HBeAg positive rate	23 (51.1)	22 (48.9)		2.13	> 0.05
Ascites	22 (48.9)	21 (46.7)		2.46	> 0.05
HE	6 (13.3)	7 (15.5)		3.13	> 0.05
UGB	9 (22.2)	8 (17.8)		3.35	> 0.05

ALT: Alanine aminotransferase; TBil: Total bilirubin; Alb: Albumin; PT: Prothrombin time; CTP: Child-Turcotte-Pugh; MELD: Model for end-stage liver disease; HE: Hepatic encephalopathy; UGB: Upper gastrointestinal bleeding; HBeAg: Hepatitis B e antigen.

nificantly compared with the baseline level ( $F = 18.9$ ,  $P < 0.05$ ), whereas ALT and TBil decreased significantly compared with the baseline levels ( $F = 16.5$  and  $23.7$ , respectively,  $P < 0.05$ ). In addition, PT was significantly shortened ( $F = 22.7$ ,  $P < 0.05$ ), and both CTP and MELD scores decreased significantly compared with the baseline scores ( $F = 18.5$  and  $24.2$ , respectively,  $P < 0.05$ ). A decrease of more than 2 points in the CTP score in 31 (68.9%) cases was observed and is shown in Table 2.

After 96 wk, patients who received ETV treatment exhibited a significant increase in albumin level compared with the baseline level ( $F = 17.3$ ,  $P < 0.05$ ). In contrast, ALT and TBil decreased significantly compared with baseline levels ( $F = 17.1$  and  $24.8$ ,  $P < 0.05$ ). PT was significantly shortened ( $F = 24.5$ ,  $P < 0.05$ ), and CTP and MELD scores decreased significantly compared with the baseline levels ( $F = 17.8$  and  $23.8$ ,  $P < 0.05$ ). A decrease in the CTP score by more than 2 points was evident in 30 (66.7%) cases.

The LAM and ADV combination group and the ETV monotherapy group showed no significant differences in albumin level or in ALT, TBil, PT, CTP, and MELD scores by weeks 48 and 96 (Table 2).

### Adverse events

All patients in this study responded well to both LAM and ADV combination therapy and ETV monotherapy. Creatinine levels in four cases in the LAM and ADV combination therapy group and in one case in the ETV monotherapy group were more than twice the baseline values, but were still lower than upper limit of normal. No patient developed lactic acidosis in either group.

In the combination group, the cumulative mortality (including liver transplantation) was 16.7% (10/60) during the follow-up period, and included 2 cases of upper gastrointestinal bleeding, 2 cases of hepatic encephalopathy, 1 case of secondary bacterial infection, and 1 case of

hepatorenal syndrome. Four patients had undergone liver transplantation in this group. In the ETV monotherapy group, the cumulative mortality (including liver transplantation) was 18.3% (11/60), and included 3 cases of upper gastrointestinal bleeding, 2 cases of secondary bacterial infection, and 2 cases of hepatorenal syndrome. Three patients had undergone liver transplantation. These findings are illustrated in Figure 2.

## DISCUSSION

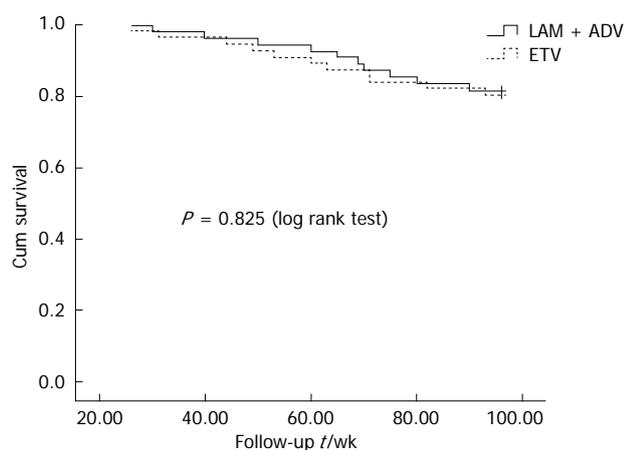

Increasing evidence shows that suppression of HBV replication results in the reduction of hepatic necroinflammation and consequently, improvement of liver function in patients with HBV-related decompensated liver cirrhosis. Antiviral therapy associated with improved outcomes in patients with HBV-related decompensated cirrhosis, including postponement or prevention of liver transplantation, reducing the incidence of HCC<sup>[10-12]</sup>.

LAM was the first oral agent approved for the treatment of chronic hepatitis B (CHB) and currently has a well-established safety and efficacy profile. Liaw *et al*<sup>[13]</sup> reported that continuous treatment with LAM delays clinical progression of CHB infection in patients by significantly reducing the incidence of hepatic decompensation and HCC. ADV benefits pre- and post-transplant patients with LAM-resistant CHB, including decompensated cirrhotics, by suppressing HBV DNA and by improving the CTP score<sup>[14,15]</sup>. In China, ADV is relatively cheap and a large number of CHB patients, including cirrhotics, have received LAM and ADV combination therapy. According to the latest guidelines, the patients with liver cirrhosis and those who have received a liver graft for HBV-related cirrhosis should be considered for *de novo* combination therapy because of the risk of clinical deterioration if they develop drug resistance<sup>[16]</sup>. But the data to support a role of combination therapy in these patients were limited. On the other hand, ETV demonstrates very low rates of resistance in nucleoside-naïve patients and is recommended for patients with HBV-related decompensated cirrhosis<sup>[8,17]</sup>. Therefore, a comparison of the efficacy and safety between LAM and ADV combination therapy and ETV monotherapy for patients with HBV-related decompensated cirrhosis is urgent. Our study showed that 51.1% and 86.7% of patients in the LAM and ADV combination group achieved undetectable HBV DNA by weeks 48 and 96, respectively, while 60% and 88.9% of patients in the ETV treatment group achieved undetectable HBV DNA by weeks 48 and 96, respectively. In addition, both *de novo* combination of LAM and ADV therapy and ETV monotherapy significantly increased albumin level and decreased TBil, PT, CTP, and MELD scores compared with baseline. More importantly, 68.9% of patients in the combination group and 66.7% of patients in the monotherapy group had a decrease in their CTP score of more than 2 points after 96 wk of treatment. A total of 73.7% of patients in the combination group and 71.1% of patients in the monotherapy group exhibited an increase in the CTP score at the end of 96

**Table 2** Comparison of changes in hepatic function

Characteristics	LAM + ADV combination group			ETV monotherapy group		
	0 wk	48 wk	96 wk	0 wk	48 wk	96 wk
Alb (g/L)	29.2 ± 0.7	32.2 ± 0.5	36.7 ± 0.2 <sup>a</sup>	28.9 ± 1.2	31.9 ± 0.4	36.4 ± 0.6 <sup>a</sup>

ALT (U/L)	98.1 ± 21.6	56.1 ± 21.3	34.7 ± 12.8 <sup>a</sup>	99.8 ± 17.2	54.2 ± 15.7	32.5 ± 11.5 <sup>a</sup>
PT (s)	16.3 ± 2.3	14.3 ± 1.6	12.6 ± 2.1 <sup>a</sup>	16.5 ± 1.9	13.8 ± 2.0	12.9 ± 3.7 <sup>a</sup>
CTP score	8.4 ± 1.7	6.8 ± 1.9	5.5 ± 3.7 <sup>a</sup>	8.6 ± 2.1	6.7 ± 2.5	5.7 ± 1.3 <sup>a</sup>
MELD score	13.7 ± 3.5	9.8 ± 3.1	7.6 ± 1.8 <sup>a</sup>	12.9 ± 6.7	9.6 ± 4.3	7.9 ± 2.3 <sup>a</sup>

<sup>a</sup>*P* < 0.05 vs baseline. ALT: Alanine aminotransferase; TBil: Total bilirubin; Alb: Albumin; PT: Prothrombin time; CTP: Child-Turcotte-Pugh; MELD: Model for end-stage liver disease; LAM: Lamivudine; ADV: Adefovir dipivoxil; ETV: Entecavir.

**Figure 2** Kaplan-Meier analysis of cumulative survival rate in patients with hepatitis B virus-related decompensated cirrhosis treated with lamivudine and adefovir dipivoxil combination therapy and entecavir monotherapy for 96 wk. LAM: Lamivudine; ADV: Adefovir dipivoxil; ETV: Entecavir.

wk. No genetic mutations in either treatment group were detected. In this study, no statistically significant difference was observed between the LAM and ADV combination therapy group and the ETV monotherapy group in terms of the serological conversion rate by 48 wk, while the HBeAg seroconversion rate in the LAM and ADV combination group at week 96 was significantly higher than that in the ETV group. This finding is similar to the results of previous studies<sup>[18]</sup>.

HBV-related decompensated cirrhosis requires a longer duration of antiviral therapy and consideration of the effect and safety of these drugs are essential. LAM has been shown to be safe. ADV, in contrast, is mainly excreted by the kidney and has an impact on renal function during long-term antiviral therapy<sup>[19]</sup>. Our study confirms that ADV treatment of decompensated cirrhosis is safe and effective. However, in the subsequent stages of treatment, doctors should closely monitor kidney function and adjust the treatment plan as soon as renal function is found to be abnormal.

The best treatment method for late-stage HBV-related decompensated liver cirrhosis is liver transplantation. However, transplantation is very expensive and there is a worldwide donor shortage. Liver transplantation is considered in the treatment of decompensated cirrhosis only

when the CTP score for grade C or the MELD score is more than 20 points. Upon detection of HBV DNA, patients with decompensated cirrhosis should be immediately treated with antiviral therapy to improve liver function and to reduce the need for liver transplantation.

Lange *et al*<sup>[20]</sup> reported on 16 patients with liver cirrhosis and chronic hepatitis B who were treated with ETV. Five of these patients developed lactic acidosis (all with MELD scores > 20) during ETV treatment. Lactic acidosis was lethal for one patient, while for other patients, the symptoms were resolved after termination/interruption of ETV treatment. In the present study, no cases of lactic acidosis were observed during the follow-up period of 96 wk.

In conclusion, both *de novo* LAM and ADV combination therapy and ETV monotherapy are effective in patients with HBV-related decompensated cirrhosis, with no differences in the level of HBV DNA suppression, liver function improvement, resistance rate, and on confirmed changes in renal parameters and in cumulative survival rate. The data obtained in this study demonstrate the efficacy and the safety of these treatment regimens for 96 wk in patients with HBV-related decompensated liver cirrhosis, as well as their evident therapeutic benefits in both groups.

## COMMENTS

### Background

The mortality rate of hepatitis B virus (HBV)-related decompensated cirrhosis is very high. Recommended treatment options are monotherapy with high genetic barrier nucleos(t)ide analogues or combination therapy with no cross resistance nucleos(t)ide analogues. There has been no report regarding the entecavir monotherapy or *de novo* lamivudine and adefovir dipivoxil combination therapy in these patients.

### Research frontiers

*De novo* combination therapy with lamivudine and adefovir dipivoxil is better than lamivudine monotherapy in patients with HBV-related decompensated liver cirrhosis. But there is no head to head research to compare the entecavir, a high genetic barrier nucleoside analogue monotherapy with *de novo* lamivudine and adefovir dipivoxil combination therapy for those patients. In this study, the authors demonstrated that both entecavir monotherapy and *de novo* lamivudine and adefovir dipivoxil combination therapy were effective for patients with HBV-related decompensated liver cirrhosis.

### Innovations and breakthroughs

Many clinical studies showed that the combined therapy is effective for patients with human immunodeficiency virus and hepatitis C virus infection. And entecavir is effective for patients with HBV-related decompensated liver cirrhosis.

This is the first head to head study to report that both *de novo* lamivudine and adefovir dipivoxil combination therapy and entecavir monotherapy are effective for patients with HBV-related decompensated liver cirrhosis.

### Applications

By understanding that both *de novo* lamivudine and adefovir dipivoxil combination therapy and entecavir monotherapy are effective for patients with HBV-related decompensated liver cirrhosis, this study may represent a future strategy for therapeutic intervention in patients with HBV-related decompensated liver cirrhosis.

### Terminology

*De novo* combination therapy means combination with two or more drugs from the beginning of the treatment. Monotherapy means use one drug from the beginning of the treatment. The diagnosis of decompensated liver cirrhosis was based on clinical, laboratory, previous histological, ultrasonographic and radiological signs of cirrhosis with Child-Turcotte-Pugh (CTP) score. The CTP score is a system to assess the disease stage for decompensated cirrhotic patients.

### Peer review

This is a good clinical study in which the authors compared the effects of *de novo* lamivudine and adefovir dipivoxil combination therapy with entecavir monotherapy for HBV-related decompensated liver cirrhosis patients. The authors concluded that both *de novo* lamivudine and adefovir dipivoxil combination therapy and entecavir monotherapy are effective for patients with HBV-related decompensated liver cirrhosis.

### Abstract

**AIM:** To evaluate the accuracy of endoscopic ultrasound (EUS) elastography for differentiating between pancreatic ductal adenocarcinoma (PDAC) and pancreatic inflammatory masses (PIM).

**METHODS:** Electronic databases (updated to December 2012) and manual bibliographical searches were carried out. A meta-analysis of all diagnostic clinical trials evaluating the accuracy of EUS elastography in differentiating PDAC from PIM was conducted. Heterogeneity was assessed among the studies. The meta-analysis was performed to evaluate the accuracy of EUS elastography in differentiating PDAC from PIM in homogeneous studies.

**RESULTS:** Ten studies involving 781 patients were included in the analysis. Significant heterogeneity in

sensitivity was observed among the studies (Cochran  $Q$  test = 24.16,  $df = 9$ ,  $P = 0.0041$ ,  $I^2 = 62.8\%$ ), while heterogeneity in specificity was not observed (Cochran  $Q$  test = 5.93,  $df = 9$ ,  $P = 0.7473$ ,  $I^2 = 0.0\%$ ). The area under the curve under the Sports Rights Owners Coalition was 0.8227. Evaluation of heterogeneity suggested that the different diagnostic standards used in the included studies were the source of heterogeneity. In studies using the color pattern as the diagnostic standard, the pooled sensitivity, specificity, positive likelihood ratio (LR), negative LR and diagnostic OR were 0.99 (0.97-1.00), 0.76 (0.67-0.83), 3.36 (2.39-4.72), 0.03 (0.01-0.07) and 129.96 (47.02-359.16), respectively. In studies using the hue histogram as the diagnostic standard, the pooled sensitivity, specificity, positive LR, negative LR and diagnostic OR were 0.92 (0.89-0.95), 0.68 (0.57-0.78), 2.84 (2.05-3.93), 0.12 (0.08-0.19) and 24.69 (12.81-47.59), respectively.

**CONCLUSION:** EUS elastography is a valuable method for the differential diagnosis between PDAC and PIM. And a preferable diagnostic standard should be explored and improvements in specificity are required.

© 2013 Baishideng. All rights reserved.

**Key words:** Endoscopic ultrasound; Elastography; Pancreatic adenocarcinoma; Meta-analysis

**Core tip:** Pancreatic inflammatory masses (PIM) are easily confused with pancreatic ductal adenocarcinoma (PDAC). Endoscopic ultrasound (EUS) elastography is a promising noninvasive method for differentiating between PDAC and PIM and may prove to be a valuable supplemental method to EUS-guided fine-needle aspiration.

Li X, Xu W, Shi J, Lin Y, Zeng X. Endoscopic ultrasound elastography for differentiating between pancreatic adenocarcinoma and

inflammatory masses: A meta-analysis. *World J Gastroenterol* 2013; 19(37): 6284-6291 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i37/6284.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i37.6284>

## INTRODUCTION

Pancreatic cancer is a highly lethal disease, and approximately 90% of pancreatic tumors are pancreatic ductal adenocarcinoma (PDAC) which has an extremely poor prognosis<sup>[1,2]</sup>. The 5-year survival rate of PDAC is as low as 0.2%<sup>[3]</sup>. The only potentially curable treatment which is surgical resection, relies on early diagnosis<sup>[4]</sup>. Pancreatic inflammatory masses (PIM) are confused with PDAC<sup>[5]</sup>. The differential diagnosis between PDAC and PIM is currently still difficult due to non-specific symptoms, signs or imaging presentations<sup>[6]</sup>.

Endoscopic ultrasound (EUS) elastography is a recently developed technique for the differential diagnosis of benign and malignant pancreatic masses and measures the mechanical properties of tissues<sup>[7-14]</sup>. The tissue elasticity modulus is represented by a transparent color superimposed on the conventional gray-scale B-mode scans. The nature of the tissue is analyzed either by a qualitative method where blue-predominant represents malignancy or a quantitative method where a value of more than 175 represents malignancy.

Pancreatic masses include PDAC, PIM, neuroendocrine tumors, metastatic tumors, lymphoma, sarcoma, insulinoma and lipoma. Several meta-analyses have evaluated the accuracy of EUS elastography in the diagnosis of pancreatic masses. The overall accuracy of EUS elastography in differentiating between PDAC and PIM has not been assessed. The aim of this study was to perform a meta-analysis of existing studies to assess the accuracy of EUS elastography in differentiating between PDAC and PIM.

## MATERIALS AND METHODS

### Study selection

Studies were selected according to the inclusion and exclusion criteria which were delineated prior to the literature search. The inclusion criteria were: (1) diagnostic clinical trials assessing the accuracy of EUS elastography for differentiating between PDAC and PIM; (2) cytology of EUS-guided fine-needle aspiration (FNA) samples, histopathology of surgical specimens or a follow-up period of at least 6 months as a reference standard; and (3) sufficient data to construct a  $2 \times 2$  table for true-positive, false-positive, false-negative and true-negative findings.

Studies were excluded if they met the following criteria: (1) studies without complete data available for constructing a  $2 \times 2$  table for true-positive, false-positive, false-negative and true-negative findings; (2) studies

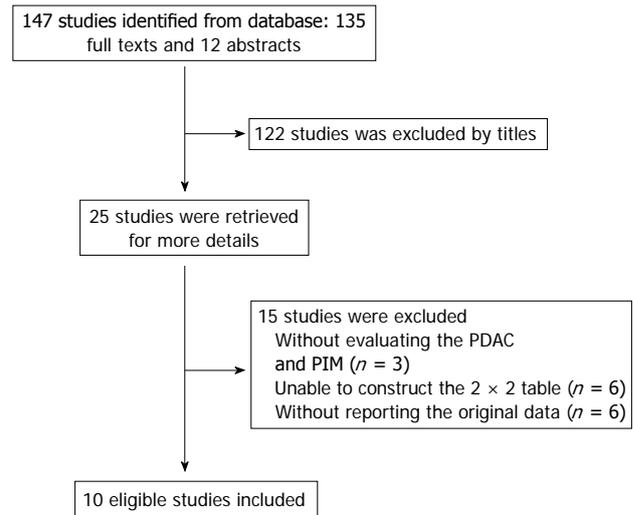

Figure 1 Literature search flow diagram.

updated or duplicated; (3) studies which did not report their own data such as editorials, reviews, corresponding letters; and (4) case reports.

### Literature search

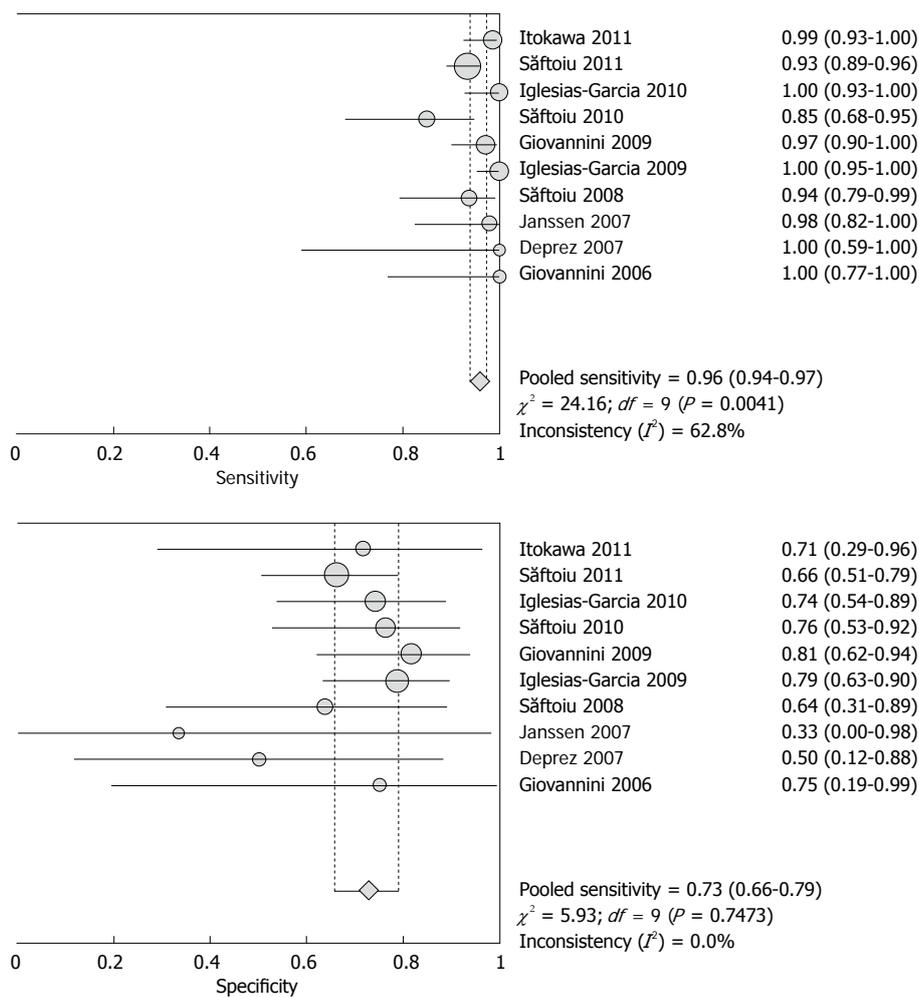

Using the Medline, Embase, Web of Science, and Cochrane Central Trials databases up to Dec. 2012, a systematic literature search was conducted. The search strategy was (“elastogram” or “elastography” or “elastonoendoscopy” or “sonoelastography”) and (“pancreatic” or “pancreas” or “adenocarcinoma” or “inflammatory mass”). To expand the search, we also performed a manual search of abstracts presented at the United European Gastroenterology Week (UEGW) congresses and the American Digestive Disease Week (DDW) from 2000 to 2012. The bibliographies of each peer-reviewed paper were screened for other potentially relevant studies. If missing data were needed, we contacted the appropriate authors by mail.

### Statistical analysis

Data on the differentiation between PDAC and PIM were extracted. The Cochrane  $Q$  test was used to assess heterogeneity with a  $P$  value  $< 0.10$ <sup>[15]</sup>.  $I^2$  was used to describe the percentage variability attributable to heterogeneity rather than sampling errors.  $I^2 > 25\%$  indicated the presence of heterogeneity. The Spearman  $\rho$  between the logit of sensitivity and logit of 1-specificity was calculated to assess the presence of a threshold effect. A strong correlation (Spearman  $\rho < -0.4$ ) suggested the presence of a threshold effect<sup>[16]</sup>. The source of heterogeneity, with the exception of the threshold effect, was explored by meta-regression analysis<sup>[17,18]</sup>. The subgroups were predefined, and included diagnostic standard (color pattern *vs* hue histogram), blind (yes *vs* unclear), sample size ( $\geq 50$  *vs*  $< 50$ ), type of publication (full text *vs* abstract), and design of study (single center *vs* multicenter). A  $P$  value  $< 0.05$  indicated significance. Pooling was only

**Figure 2** Forest plot (random-effect model) of the meta-analysis for sensitivity (upper) and specificity (lower) in differentiating between pancreatic ductal adenocarcinoma and pancreatic inflammatory masses.

conducted within the homogeneous groups using the fixed-effect model (Mantel-Haenszel method<sup>[19]</sup>). Pooling the results with corresponding 95%CI included sensitivity, specificity, positive likelihood ratio (LR), negative LR and diagnostic odds ratio (DOR).

In order to analyze the presence of publication bias, funnel plots were constructed using the Harbord<sup>[20]</sup> and Egger indicator and Begg<sup>[21]</sup> and Mazumdar indicator. Asymmetric funnel plots or a *P* value < 0.1 suggested the presence of publication bias. The quality of the se-

lected studies was assessed using the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) questionnaire<sup>[22]</sup>. Items were rated as yes, no, or unclear.

The pooled weighted sensitivity, specificity, positive LR, negative LR, DOR, Sports Rights Owners Coalition (SROC) curve and Spearman analysis were performed using Meta-Disc version 1.4 (Unit of Clinical Biostatistics, Ramon y Cajal Hospital, Madrid, Spain)<sup>[23]</sup>. Meta-regression and publication bias analyses were performed using Stata version 10.0 (Stata Corporation, College Sta-

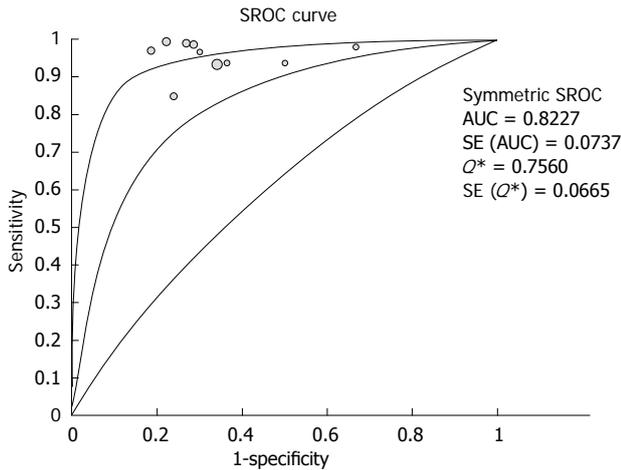

Figure 3 Sports Rights Owners Coalition, with 95%CI, for differentiating between pancreatic ductal adenocarcinoma and pancreatic inflammatory masses.

tion, TX, United States).

## RESULTS

The initial literature search identified a total of 147 studies (Figure 1). Of these 147 studies, 25 potentially relevant studies were retrieved for further evaluation. Ten studies involving 781 patients were finally included in this meta-analysis. The baseline characteristics of the selected studies are listed in Table 1. Nine studies were published as full texts, and 1 as an abstract. Seven studies used the color pattern as the diagnostic standard, while the other three used the hue histogram value.

### Differentiating PDAC and PIM

The pooled sensitivity and specificity (random-effect model) of EUS elastography for differentiating between PDAC and PIM were 96% (95%CI: 94-97) and 73% (95%CI: 66-79), respectively. Significant heterogeneity in sensitivity was observed among the studies (Cochran *Q* test = 24.16, *df* = 9, *P* = 0.0041, *I*<sup>2</sup> = 62.8%), while heterogeneity in specificity was not observed (Cochran *Q* test = 5.93, *df* = 9, *P* = 0.7473, *I*<sup>2</sup> = 0.0%) (Figure 2). The AUC under the SROC was 0.8227 (Figure 3).

By excluding the study reported as an abstract, the pooled sensitivity and specificity (random-effect model) were 96% (95%CI: 94-97) and 73% (95%CI: 66-80), respectively. There was significant heterogeneity in sensitivity among the studies (Cochran *Q* test = 23.56, *df* = 8, *P* = 0.0027, *I*<sup>2</sup> = 66.1%), while heterogeneity in specificity was not observed (Cochran *Q* test = 5.50, *df* = 8, *P* = 0.8090, *I*<sup>2</sup> = 0.0%). The AUC under the SROC was 0.8188.

### Test of heterogeneity

The source of heterogeneity was explored. A Spearman  $\rho$  of -0.29 (*P* = 0.41) between the logit of sensitivity and the logit of 1-specificity did not suggest the presence of

Table 2 Meta-regression analysis for the potential source of heterogeneity

Study characteristics	Z	P value	95%CI
Diagnostic standard (color pattern vs hue histogram)	2.90	0.00	0.68-3.50
Blind (yes vs unclear)	1.36	0.17	-0.87-4.82
Sample size ( $\geq 50$ vs $< 50$ )	0.13	0.90	-1.90-2.17
Type of publication (full text vs abstract)	1.28	0.20	-1.33-6.37
Design of study (single center vs multicenter)	0.04	0.97	-1.35-1.40

Table 3 Subgroup analysis on the basis of the diagnostic standards

Pooled estimate	Color pattern (n = 426) <sup>1</sup>		Hue histogram (n = 355) <sup>2</sup>	
	Pooled result (95%CI)	<i>I</i> <sup>2</sup>	Pooled result (95%CI)	<i>I</i> <sup>2</sup>
Sensitivity	0.99 (0.97-1.00)	0.00%	0.92 (0.89-0.95)	20.10%
Specificity	0.76 (0.67-0.83)	0.00%	0.68 (0.57-0.78)	0.00%
Positive LR	3.36 (2.39-4.72)	17.90%	2.84 (2.05-3.93)	0.00%
Negative LR	0.03 (0.01-0.07)	0.00%	0.12 (0.08-0.19)	0.00%
Diagnostic OR	129.96 (47.02-359.16)	0.00%	24.69 (12.81-47.59)	0.00%

<sup>1</sup>Studies using the color pattern as the diagnostic standard and the total number of patients involved; <sup>2</sup>Studies using the hue histogram as the diagnostic standard and the total number of patients involved. OR: Odds ratio; LR: Likelihood ratio.

a threshold effect. The meta-regression analysis showed that the different diagnostic standards used in the selected studies were the source of heterogeneity (*P* = 0.00). In addition, the characteristics of blinding, sample size, type of publication and design of study were not related to heterogeneity (Table 2).

### Meta-analysis based on diagnostic standards

The evaluation of heterogeneity suggested that the different diagnostic standards used in the included studies were the source of heterogeneity. As a result, the meta-analysis was performed on the studies using the same diagnostic standards. The pooled results showed good homogeneity. Pooling was conducted using the fixed-effect model (Mantel-Haenszel method<sup>[22]</sup>). In studies using the color pattern as the diagnostic standard, the pooled sensitivity, specificity, positive LR, negative LR and DOR were 0.99 (0.97-1.00), 0.76 (0.67-0.83), 3.36 (2.39-4.72), 0.03 (0.01-0.07) and 129.96 (47.02-359.16), respectively. In studies using the hue histogram as the diagnostic standard, the pooled sensitivity, specificity, positive LR, negative LR and DOR were 0.92 (0.89-0.95), 0.68 (0.57-0.78), 2.84 (2.05-3.93), 0.12 (0.08-0.19) and 24.69 (12.81-47.59), respectively (Table 3).

### Quality assessment using the QUADAS questionnaire

The quality of the selected studies according to the QUADAS questionnaire is shown in Figure 4. The overall quality of the studies was good. Eight studies were rated as “yes” in all items. In the study by Janssen *et al*<sup>[9]</sup>

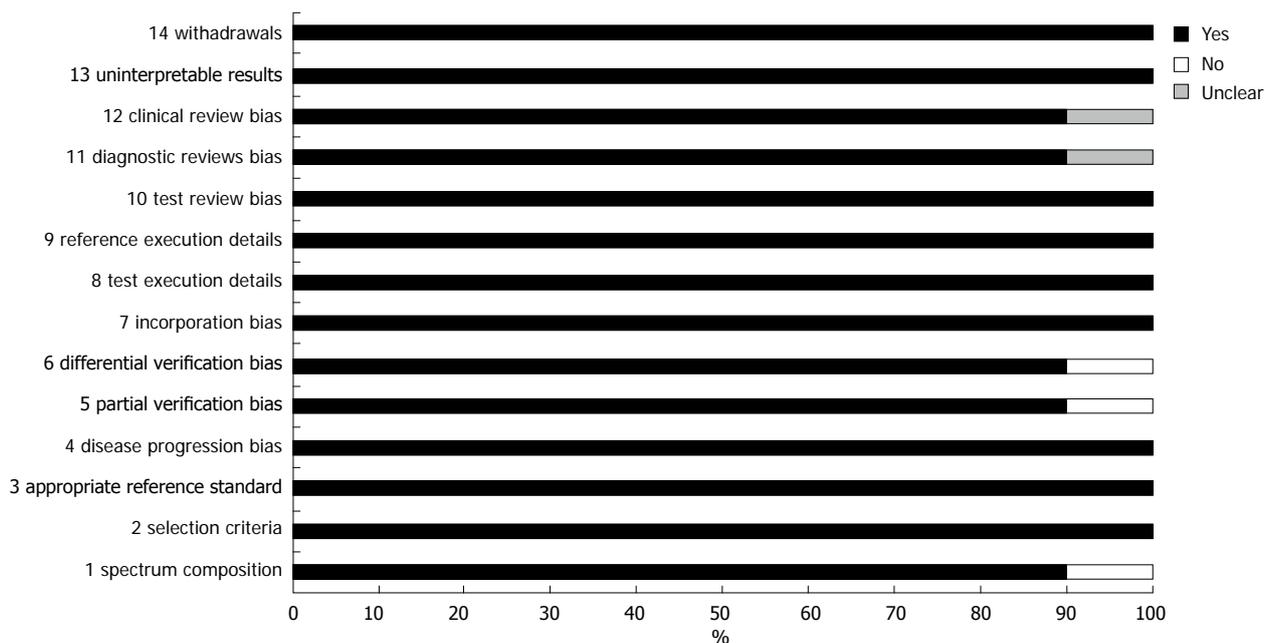

Figure 4 The Quality Assessment of Diagnostic Accuracy Studies scores of the selected studies are summed up per item and presented in a bar chart.

all selected patients were referred for EUS-guided FNA or surgery and one of the selected patients was diagnosed with lipoma by CT densitometry without histological proof. As a result, QUADAS question 1, 5 and 6 were rated as “no”. In addition, Jassen *et al*<sup>[9]</sup> and Itokawa *et al*<sup>[24]</sup> did not mention whether blinding was used in their study. As a result, QUADAS question 11 was rated as “unclear”.

**Publication bias**

The Harbord-Egger indicator for publication bias provided a value of 1.65 (95%CI: -0.43-2.59, *P* = 0.14) and the Begg-Mazumdar indicator gave a Kendall’s tau *b* value of 9 (*P* = 0.47) for the selected studies, which suggested no publication bias (Figure 5).

**DISCUSSION**

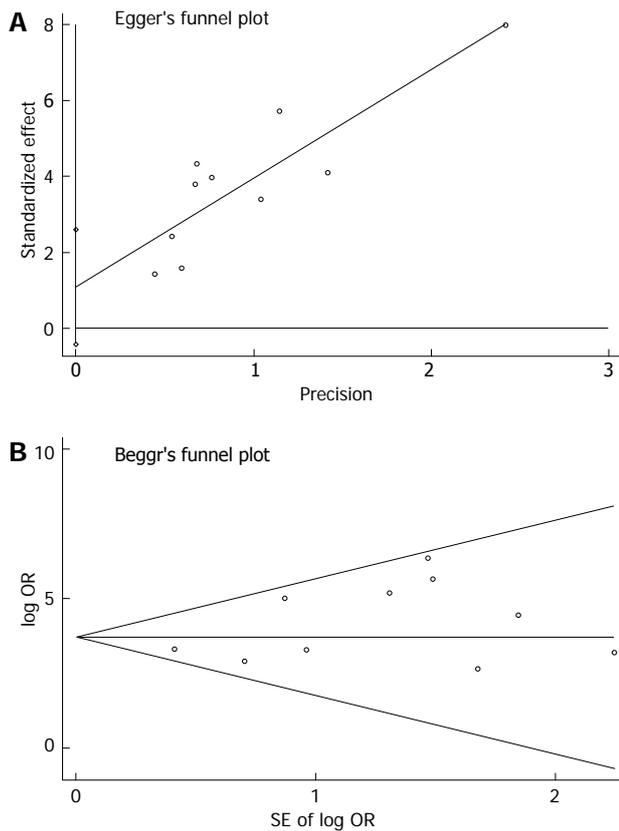

Pancreatic cancer is the fourth leading cause of cancer-related death in the USA, and the second among gastrointestinal tumors<sup>[25]</sup>. Early diagnosis may allow patients to receive the only potentially curable treatment which is surgical resection. PDAC is found in more than 90% of patients with pancreatic cancer and most of the lesions confused with PDAC are benign PIM<sup>[5]</sup>. PDAC is frequently associated with secondary inflammatory changes caused by obstruction of the pancreatic duct. In addition, chronic pancreatitis can markedly increase the risk of PDAC<sup>[26]</sup>. As a result, the differential diagnosis between PDAC and PIM is essential for clinical decision-making.

Despite considerable advances in imaging techniques, the diagnosis of PDAC, particularly in the setting of chronic pancreatitis, remains a challenge. There are no

characteristic findings to differentiate pancreatic masses on transabdominal ultrasound (TAS) and its accuracy is very low<sup>[27]</sup>. Computed tomography (CT) and magnetic resonance imaging (MRI) may be used for staging and detecting metastasis, however, these techniques have limited ability in differentiating between PDAC and PIM<sup>[28,29]</sup>. Endoscopic retrograde cholangiopancreatography (ERCP) has an increased risk of complications, the most important being pancreatitis<sup>[30]</sup>.

EUS, which provides high-resolution images of the pancreas, has become an indispensable tool in the management of pancreatic diseases. However, an important limitation of EUS examination is its low capacity to determine the exact nature of pancreatic masses<sup>[31]</sup>. EUS-FNA allows pathological diagnosis. It is currently considered an accurate and safe method for the diagnosis of pancreatic disease. However, EUS-FNA is an invasive procedure and the sensitivity of EUS-FNA is less than 75% in the presence of coexistent chronic pancreatitis or “pseudotumoral” pancreatitis<sup>[32,33]</sup>.

EUS elastography is a newly developed technique which assesses the mechanical properties of tissues during conventional EUS examination. In this meta-analysis, no significant publication bias was detected using the Harbord-Egger and Begg-Mazumdar indicators. The meta-regression analysis demonstrated that the different diagnostic standards used in the included studies may be the source of heterogeneity. This meta-analysis indicated that EUS elastography could achieve a very high sensitivity and a moderate specificity for differentiating between PDAC and PIM. As EUS elastography showed good sensitivity it may be an appropriate method for monitoring patients with PIM in whom malignancy has been excluded. In addition, it could also be used to fol-

**Figure 5** Funnel plots. A: Funnel plot of the Harbord-Egger indicator for the selected studies; B: Funnel plot of the Begg-Mazumdar indicator for the selected studies.

low patients with PDAC after surgery.

The pooled specificity of EUS elastography may not be satisfactory for differentiating between PDAC and PIM compared with the 100% specificity of EUS-FNA. This may be due to the following reasons: first, diagnostic studies preferred maximal sensitivity in order to reduce the false negative rate when setting up the cutoff value. This reduced the specificity of individual studies. Second, this study focused on the differentiation between PDAC and PIM. The data from normal controls and chronic pancreatitis patients without focal masses, which could easily be excluded from malignancy by EUS elastography, were excluded from this study. This would markedly reduce the number of true negative cases, and thereby decrease specificity.

As an imaging method with moderate specificity, EUS elastography could not replace EUS-FNA which provides a pathological diagnosis. However, it may be a valuable supplemental method to EUS-FNA. EUS elastography and FNA could be performed sequentially during the same EUS procedure. It could be used to guide FNA to reduce the number of false negative cases, especially in patients with coexisting pancreatitis. Moreover, EUS elastography may provide additional information for differentiating between PDAC and PIM when a negative EUS-FNA result is obtained or the patients are

unsuitable for FNA.

The diagnostic standard used for the analysis of mechanical properties was correlated with the accuracy of EUS elastography in the differentiation of pancreatic masses. The qualitative color pattern and quantitative hue histogram value are two currently used diagnostic standards. In general, the quantitative diagnostic standard would be considered better because it is an objective method. Based on unified samples (PDAC and PIM), a subgroup analysis was performed to compare these two standards. The results showed that studies using the color pattern as the diagnostic standard showed preferable pooled estimates than those using the hue histogram. This may be due to the fact that both the overall stiffness and the distribution of stiffness were associated with the nature of the tissue. The color pattern diagnostic standard takes the predominant color and the distribution of the color into consideration simultaneously, while the hue histogram value only gives overall stiffness.

There were some limitations in this meta-analysis. One of the selected studies was published as an abstract, and some details were not available. A small number of studies were included in this study which may have reduced the power of the analysis.

In conclusion, EUS elastography is a valuable method for the differential diagnosis between PDAC and PIM. And a preferable diagnostic standard should be explored and improvements in specificity are required.

## COMMENTS

### Background

Endoscopic ultrasound (EUS) elastography is a recently developed technique for the differential diagnosis of benign and malignant pancreatic masses and measures the mechanical properties of tissues. The overall accuracy of EUS elastography in differentiating between pancreatic ductal adenocarcinoma (PDAC) and pancreatic inflammatory masses (PIM) has not been assessed.

### Research frontiers

Several meta-analyses on the accuracy of EUS elastography in the diagnosis of pancreatic masses have been carried out. The overall accuracy of EUS elastography in differentiating between PDAC and PIM has not been assessed.

### Innovations and breakthroughs

Previous studies have mainly focused on the differential diagnosis of benign and malignant pancreatic masses. This analysis suggested that EUS elastography could achieve a very high sensitivity and a moderate specificity for differentiating PDAC from PIM. Such findings were not presented clearly in previous studies.

### Applications

This analysis suggested that EUS elastography could achieve a very high sensitivity and a moderate specificity for differentiating PDAC from PIM. Due to good sensitivity, EUS elastography may be an appropriate method for monitoring patients with PIM in whom malignancy has been excluded. In addition, it could be used to follow patients with PDAC after surgery.

### Peer review

This is a well-performed meta-analysis of currently available studies on the accuracy of EUS elastography in the differential diagnosis between PDAC and PIM. The authors found that EUS elastography is a promising noninvasive method for differential diagnosis of PDAC and PIM and may prove to be a valuable supplemental method to EUS-guided fine-needle aspiration. This is a good meta-analysis and the authors have included many relevant issues missed by other research groups.

### Abstract

Primary adult hypertrophic pyloric stenosis is a rare but important cause of gastric outlet obstruction that may be misdiagnosed as idiopathic gastroparesis. Clinically, patients present with early satiety, abdominal fullness, nausea, epigastric discomfort and eructation. Permanent gastric retention of a video capsule endoscope is diagnostic in differentiating between the two diseases, in the absence of an organic gastric outlet obstruction. This case presents the longest video capsule retention in the medical literature to date. It is also the first case report of adult hypertrophic pyloric stenosis diagnosed with video capsule endoscopy or a computed tomography scan. Finally, an unusual "plugging" of the gastric outlet with free floating capsule has an augmented effect on disease physiology and on patient's symptoms.

### INTRODUCTION

Video capsule endoscopy is an important tool in our ever growing arsenal in detecting bowel related abnormalities. Its wide use has led to the significant improvement of our ability to understand and diagnose a variety of gastrointestinal (GI) diseases. Retention of the capsule is one of the feared complications of the procedure, however, its location can often point to the identifiable pathology in a patient with an obscure GI condition. In this case report, we present a truly unique situation in which a discovery of a retained capsule led to the correct diagnosis of adult hypertrophic pyloric stenosis in a patient previously diagnosed with idiopathic gastroparesis. Interestingly, freely floating video capsule intermittently "plugged" already compromised gastric outlet, resulting in worsening of the patient's symptoms.

## CASE REPORT

A 53-year-old female presented to our office for a second opinion evaluation of a progressive history of early satiety, weight loss, and postprandial abdominal fullness of over 10-year duration, with notable exacerbation of her symptoms over last 3 years. Her symptoms would typically worsen toward the evening. Her past medical history included depression, surgically excised breast cancer, gastroesophageal reflux disease, and eradication of *Helicobacter pylori* in the absence of peptic ulcer disease. Several prior esophagogastroduodenoscopies performed at different clinics were notable for persistent retention of solid food in the stomach despite overnight fasts and nuclear studies showed prolonged gastric emptying. The patient was diagnosed with gastroparesis, however, she failed to respond to trials of metoclopramide, domperidone, or erythromycin. Part of her previous work up also included a video capsule endoscopy in 2008 that commented on delayed gastric transit and an erroneous conclusion of a capsule entering small bowel after 7 h. On our initial physical exam, the patient appeared in no distress. Abdominal evaluation was unremarkable, including absence of a succession splash. Laboratory values were all within normal limits. A scout abdominal roentogram revealed a retained capsule in the gastric antrum, and a barium upper GI series demonstrated pronounced delay in gastric emptying with a narrowed slightly elongated pylorus and a distended gastric antrum (Figure 1A, B). Computed tomography (CT) enterography of the abdomen verified retained video capsule in the distended antrum of the stomach and visualized abnormally dense, eccentric, and significantly narrowed pylorus measuring 15 mm in thickness and 24 mm in length (Figure 1C). Endoscopic findings were remarkable for retained semi-digested food particles despite a two day liquid diet, and confirmed the presence of a 3-year-old video capsule freely floating in the gastric fundus. A notably fixed and narrow (7 mm pre-instrumentation) thickened pyloric channel was successfully traversed with a standard 10 mm endoscope applying moderate pressure (Figure 2). The pyloric mucosa appeared unremarkable with no mass lesion or ulceration. Evaluation of the proximal duodenum was unremarkable. Four quadrant biopsies of the pyloric channel did not reveal malignancy. The video capsule was endoscopically retrieved with a Roth Net<sup>®</sup>. The patient was diagnosed with adult hypertrophic pyloric stenosis that accounted for her symptoms. She refused possible endoscopic interventions with balloon dilation or Botox injection, and declined a surgical pyloroplasty. During follow-up at three and 6 mo, the patient appeared well and reported mild improvement in her symptoms.

## DISCUSSION

Video capsule endoscopy (VCE) has revolutionized noninvasive evaluation of small intestinal mucosa since its approval for clinical use in the United States in 2001. Initially utilized for the assessment of patients with GI

bleeding of obscure origin, its indications have expanded to include evaluation for small bowel tumors, polyposis syndromes, inflammatory bowel disease, and enteropathies, including celiac disease<sup>[1]</sup>. Contraindications for the study include motility disorders, obstruction, known stenotic area in the GI tract, pregnancy<sup>[2]</sup>. Today, capsule endoscopy is used in evaluation of some esophageal and colonic disorders as well.

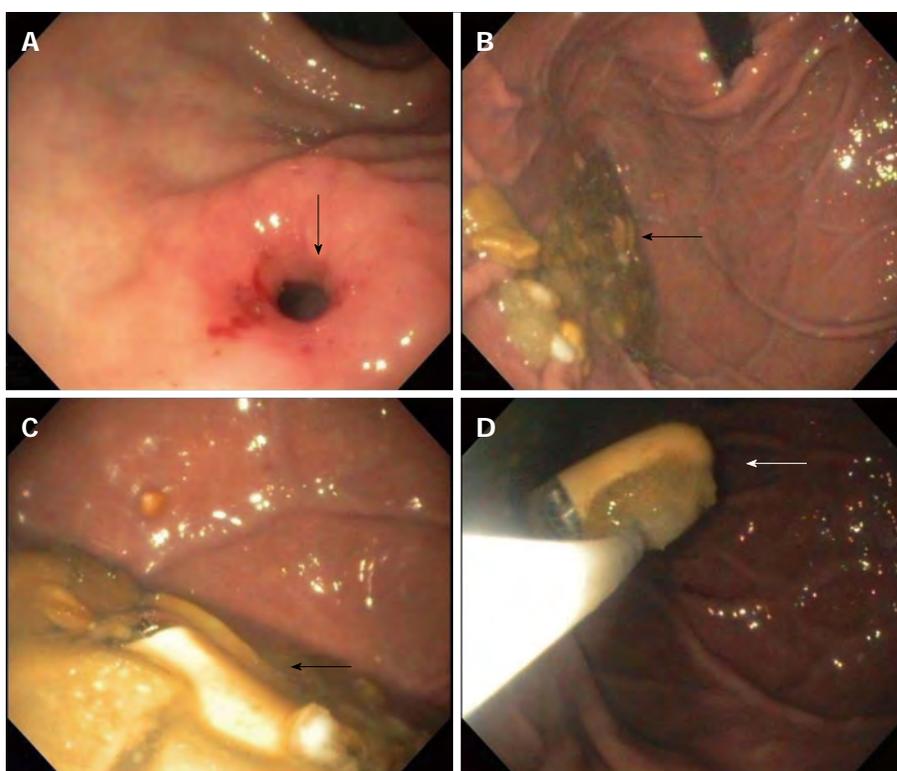

The PillCam<sup>®</sup> capsule (Given Imaging, Yoqneam, Israel) is 11 mm in diameter and 26 mm in length. Although VCE is generally regarded as safe<sup>[3,4]</sup>, capsule retention is recognized as a major complication of the procedure, potentially leading to bowel obstruction requiring its surgical removal. The 4<sup>th</sup> International Conference on Capsule Endoscopy (ICCE) in 2005 defined capsule retention as “having a capsule endoscope remain in the digestive tract for a minimum of 2 wk”. It was further defined as a “capsule remaining in the bowel lumen unless directed medical, endoscopic, or surgical intervention was instituted”<sup>[5]</sup>. The ICCE consensus did not set a time limit for removing retained capsules. In fact, asymptomatic retention and a possibility of reversing the cause of obstruction by directed medical management of the underlying condition may permit cautious non-surgical observation in select cases. Alternatively, double balloon enteroscopy may be helpful in removing retained capsule. The exact incidence of retained capsules varies widely from 0%<sup>[6]</sup> to 13%<sup>[7]</sup>, depending on the indication for the study. Patients with obscure GI bleeding are considered low risk, in contrast to patients with active Crohn’s disease or suspected small bowel obstruction where higher incidence of capsule retention was noted<sup>[7,8]</sup>. Careful history taking and small bowel radiologic evaluation will lead to anticipation of a potential obstruction, and use of biodegradable patency capsule may effectively assist in its precise localization. In general, a capsule retention requiring surgical intervention occurs at a rate of 0.75%<sup>[9]</sup>, ultimately leading to correct diagnosis of the underlying pathology.

Review of the medical literature to date shows that the duration of asymptomatic capsule retention varies greatly from few weeks to several years. Anatomically, the video capsule is most often retained in the ileum<sup>[5,10]</sup>. Until now, the longest reported case was 38 mo in a patient with small bowel Crohn’s disease<sup>[8]</sup>. To the best of our knowledge, our report describes the first case of a retained capsule in the stomach for over three years. It is also the first case report of adult hypertrophic pyloric stenosis diagnosed with video capsule endoscopy or a CT scan. In addition, we postulate that the physiologic worsening of our patient’s symptoms over last three years was due to the added degree of gastric flow obstruction secondary to intermittent proximal “plugging” of the pyloric channel with a retained video capsule.

Hypertrophic pyloric stenosis (HPS) is a rare cause of gastric outlet obstruction. Infantile HPS is suspected in a neonate with projectile non-bilious vomiting and weight loss, and occurs in 0.2%-0.5% of births. Classically, “ol-

ive sign” of a prominent pyloric muscle is palpated on physical examination and transabdominal ultrasound is diagnostic. Surgical intervention provides excellent prognosis. In contrast, adult HPS is a rare disorder that is further characterized as primary (idiopathic) or secondary (in association with peptic ulcer disease, malignancy, or hypertrophic gastropathy). To date, only over 200 cases of primary adult HPS have been described in the medical literature<sup>[11]</sup>, although its prevalence is likely under-reported. Males are more likely to be affected, and although affected patients range from 14 to 85 years of age, it is mostly diagnosed in fourth and fifth decades of life<sup>[12]</sup>. It has been traditionally accepted that primary

idiopathic adult HPS is likely a delayed presentation of a pediatric subclinical HPS. Histologically, there is marked hypertrophy and hyperplasia of the circular pyloric muscle. Grossly, pyloric channel greater than 1 cm in length and over 8 mm of muscular wall thickness is considered hypertrophic<sup>[13]</sup>. Expected diameter of normal pyloric orifice ranges from 1.2 to 1.5 cm<sup>[12]</sup>. Endoscopic findings may include “cervix sign” - a fixed narrowed pylorus with smooth borders that may preclude normal duodenal intubation with a standard gastroscope. Pyloric channel may also be eccentric in relation to the antrum with slight tenting towards lesser curvature. Upper GI series may demonstrate “Kirklín’s sign” - a mushroom-like

deformity at the base of the duodenal bulb<sup>[11]</sup>. Clinically, patient may present with early satiety, abdominal fullness, nausea, epigastric discomfort and eructation. Vomiting of undigested foods may provide symptomatic improvement. Due to outlet obstruction, a gastric scintigraphy may show delayed emptying, leading to a common misdiagnosis of gastroparesis and a delay in effective treatment. Management of symptomatic adult idiopathic HPS includes endoscopic balloon dilatation<sup>[14]</sup>, surgical pyloroplasty or Billroth I or II resection<sup>[11]</sup>. Potential benefit of Botulinum toxin injection in the pyloric sphincter may be of clinical interest, although its use in HPS has never been reported.

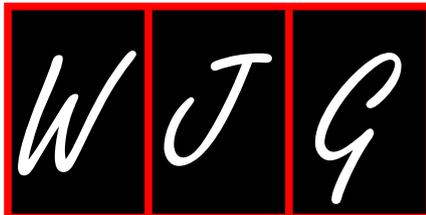

In conclusion, we report a first case in the medical literature of idiopathic adult HPS diagnosed by unusual finding of a retained video capsule endoscope in the stomach of the patient for over 3 years. This case raises a reasonable speculation that the use of a standard patency video capsule may, in certain cases, be applied to establish a diagnosis of occult HPS, differentiating it from an idiopathic gastroparesis, in which normal pyloric opening will eventually permit passage of the capsule into the small bowel. Permanent gastric retention of an 11 mm capsule may be detected by an abdominal roentogram and the device may be easily retrieved with an endoscope. It should be also noted that, specific to primary adult HPS, as large free floating capsule follows normal food bolus propagation it may effectively block an already compromised pyloric channel proximally, thus causing transient gastric outlet obstruction and appreciable worsening of patient's chronic symptoms. GI community should be aware of unique findings of capsule endoscopy in patients with HPS and use them to our advantage in arriving to correct diagnosis. In addition, advances in radiologic imaging have brought an important tool in CT enterography that, with better spatial resolution, may replace upper GI series as a test of choice in diagnosing primary HPS. Finally, this case raises clinical awareness of adult HPS, an uncommon medical condition that may mimic idiopathic gastroparesis, and importantly points out the need to vigilantly review antecedent workup in a complex patient with chronic GI symptoms to arrive to correct diagnosis.

### Abstract

A 49 years old Vietnamese male with a history of thalassemia, presented with gastrointestinal symptoms and signs of hemolysis. He was diagnosed with *Yersinia enterocolitis*. *Yersinia* is a gram-negative rod that most frequently occurs in children especially during the winter months. In the current case, the bone marrow biopsy showed hemophagocytosis along with positive cultures for *Yersinia*. The microorganism likely triggered hemophagocytosis. This syndrome, also known as, hemophagocytic lymphohistiocytosis, is defined by fever for more than 7 d, cytopenia of two or more cell lines, hemophagocytosis, hepatitis, serum ferritin greater than 500, jaundice, lymphadenopathy, and hepatosplenomegaly. This disorder can be either familial or secondary to a strong immunologic activation. Both have an overwhelming activation of T-cells and macrophages.

### INTRODUCTION

*Yersinia* is a gram-negative rod that most frequently occurs in children especially during the winter months. Transmission is largely food and waterborne. Pigs are frequently colonized with strains that cause human illness. Incubation typically lasts 2-6 d followed by a diarrheal period that can last up to three weeks. Symptoms include nausea, vomiting, and abdominal pain. Most strains of *Yersinia* grow poorly in typical agar solutions because the bacteria lack a mechanism for the efficient uptake of iron. Individuals who have iron overload due to either primary or secondary hemochromatosis are at increased risk of infection, and are also at higher risk to develop severe infections. Complications of severe infection can include diffuse ulcerating ileitis and colitis, intussusception, perforation, toxic megacolon, cholangitis, mesenteric vein

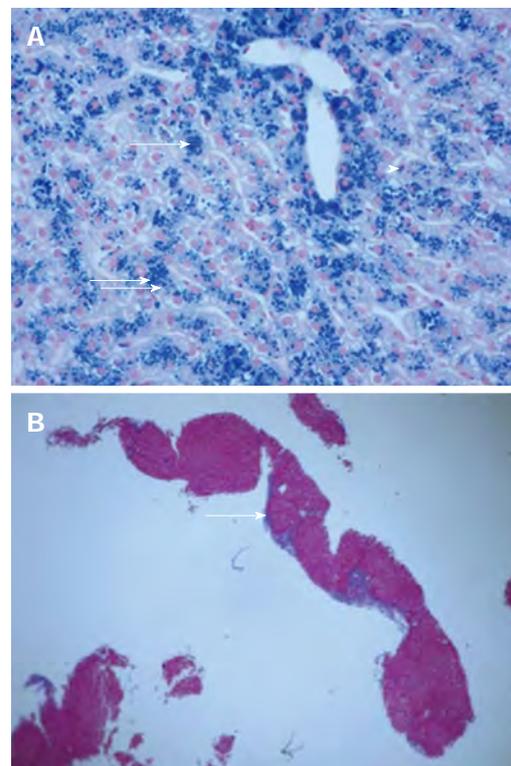

thrombosis, and hemophagocytic lymphohistiocytosis. Post-infectious complications include erythema nodosum and reactive arthritis. Treatment, reserved only for severe systemic infections, should consist of a 3<sup>rd</sup> generation cephalosporin and gentamicin for 3 wk. Genetic studies on this patient showed a loss of three alpha globin genes indicating the presence of Hb H disease. This lack of alpha globin causes a relative increase in the number of beta globin chains which can aggregate to form unstable tetramers. The tetramers have abnormal oxygen dissociation curves reflected in poor delivery of oxygen to the periphery, as well as precipitation of the hemoglobin tetramers as Heinz bodies. These precipitants can induce phagocytosis of red blood cells and a chronic hemolytic anemia which in turn leads to an increase in serum hep- cidin levels with resultant elevated iron transport across the gut mucosa. Over time, this leads to a systemic iron overload which can also be exacerbated iatrogenically by blood transfusions.

## CASE REPORT

A 49-year-old Vietnamese male, with a history of malaria 27 years ago was well until 5 d prior to admission when he developed dark urine associated with fevers, chills, and night sweats. This was followed by non-bloody diarrhea, and right upper quadrant abdominal pain as well as nausea and non-bloody vomiting. He denied any IV drug abuse, sick contacts, or travel history. He drank alcohol socially, but not to excess. On physical exam, he had a temperature of 104.3 °C, Blood pressure of 102/59 mmHg, heart rate of 100 beats/min, and saturation of 92% on room air. Generally, he was pale, diaphoretic, and sclerae were icteric. Abdominal examination revealed some right upper quadrant tenderness, but no rebound or guarding, and no hepatosplenomegaly. He had no rashes or stigmata of chronic liver disease. His laboratory studies showed a hemoglobin of 6.1 (13.8-18.0) g/dL with an MCV of 58 (80-100) fL, a white cell count of 10.6 (4.8-10.5) 10<sup>3</sup>/μL, and a platelet count of 75 (150-400) 10<sup>3</sup>/μL. Aspartate aminotransferase and alanine aminotransferase were 168 and 160 (5-40 and 7-56) U/L, respectively with a total bilirubin of 3.3 (0.3-1.9) mg/dL, and a direct bilirubin of 1.1 (0-0.3) mg/dL. Haptoglobin was < 15 (41-165). A peripheral smear demonstrated marked anisopoikilocytosis with schistocytes and target cells. Iron saturation was initially normal, 29%, with a ferritin of 6148 (12-300) mg/dL. Subsequent testing revealed persistently high iron saturation, 80%, and ferritin levels > 1000 mg/dL. Glucose and electrolytes were normal. Computerized tomography (CT) of the abdomen showed a normal biliary tree, proximal ascending colon mural thickening with surrounding adenopathy and pericolic stranding as well as bilateral pleural effusions (Figure 1). Stool, blood, and bone marrow cultures were all positive for *Yersinia enterocolitica*. The patient was positive for HBsAg with a viral load of 270000 IU. Genetic testing revealed mutations of three alpha globin genes making a diagnosis of alpha thalassemia (Hb H). A liver biopsy showed 3+ iron in hepatocytes

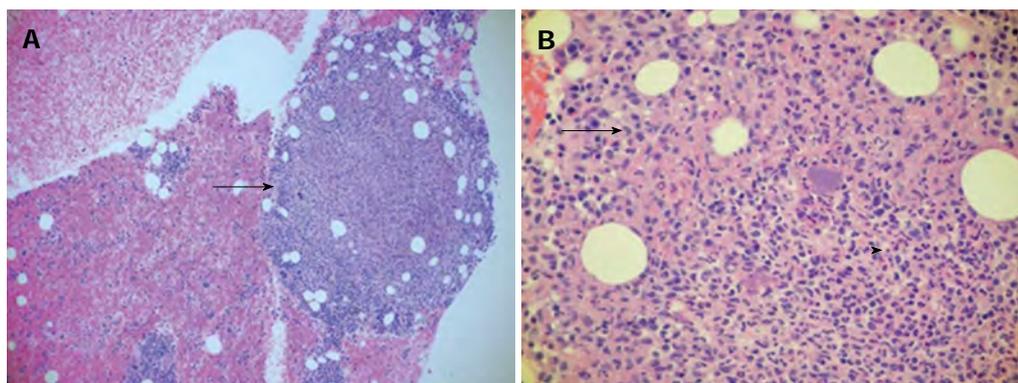

**Figure 1** A computer tomography of the abdomen without contrast performed on the day of admission. There was moderate mural thickening of the proximal ascending colon (arrow) with surrounding adenopathy and mild pericolic stranding. Also visible are mesenteric, pericolic and retroperitoneal lymph nodes (arrowheads) with the largest measuring 1.6 cm in short axis in the right pericolic region.

**Figure 2** Liver biopsy. A: There is marked, 3+, accumulation of iron primarily in the hepatocytes (arrows), but also in Kupfer cells (arrow head), and bile duct epithelium in association with moderate lobular hepatitis (Prussian Blue stain for iron, × 400); B: There is increased fibrosis with focal portal-to-portal and occasional central-portal septum formation (arrow) indicating progression towards early cirrhosis (Masson Trichrome stain, × 40).

with a portal to central gradient (Figure 2A), and chronic inflammation with early septum formation (Figure 2B). Bone marrow biopsy revealed iron overload, and a granuloma (Figure 3A), and hemophagocytic lymphohistiocytosis (Figure 3B)<sup>[1]</sup>. The patient was started on piperacillin/tazobactam/gentamicin and transfused to a hemoglobin level of 10 g/dL with rapid clinical improvement. He was discharged on a 3-wk course of oral ciprofloxacin, and a

**Figure 3 Bone marrow biopsy.** A: A necrotizing granuloma (arrow) with trilineage maturation and markedly increased iron storage [hematoxylin and eosin (HE) stain, ×100]; B: An area of necrosis (arrowhead) with erythrophagocytosis typical, but not diagnostic of *Yersinia* infection (HE stain, ×400).

follow up CT of the abdomen showed resolution of the bowel thickening and disappearance of the fat stranding. In addition, he was treated with oral deferasirox (Exjade) and entecavir. His ferritin level decreased to 842 by 12 wk. His liver enzyme levels returned to normal, and his HBV viral load became undetectable.

## DISCUSSION

In the current case, the bone marrow biopsy showed hemophagocytosis along with positive cultures for *Yersinia*. The microorganism likely triggered hemophagocytosis<sup>[2]</sup>. This syndrome, also known as, hemophagocytic lymphohistiocytosis, is defined by: fever for more than 7 d, cytopenia of two or more cell lines, hemophagocytosis, hepatitis, serum ferritin greater than 500, jaundice, lymphadenopathy, and hepatosplenomegaly. This disorder can be either familial or secondary to a strong immunologic activation. Both have an overwhelming activation of T-cells and macrophages.

In this patient, the chronic anemia due to thalassemia, or anemia in combination with the hepatitis B caused a secondary hemochromatosis<sup>[3]</sup>. This increased the risk of

*Yersinia* infection, and likely was responsible for the severity of the systemic infection<sup>[4]</sup>.

This patient will need iron chelation therapy and close monitoring for development of hepatocellular carcinoma because of the heightened risk with his coexisting HBV infection.

### Abstract

Plasmablastic lymphoma (PBL) is a very rare B-cell lymphoproliferative disorder with an aggressive clinical behavior that recently characterized by the World Health Organization. Although PBL is most commonly observed in the oral cavity of human immunodeficiency virus (HIV)-positive patients, it can also be observed at extra-oral sites in HIV-negative patients. Epstein-Barr virus (EBV) may be closely related to the pathogenesis of PBL. PBL shows different clinicopathological characteristics between HIV-positive and -negative patients. Here, we report a case of PBL of the liver in a 79-year-old HIV-negative male. The patient died approximately 1.5 mo after examination and autopsy showed that the main lesion was a very large liver mass. Histopathological examination of the excised lesion showed large-cell lymphoma with plasmacytic differentiation diffusely infiltrating the liver and involving the surrounding organs. The neoplastic cells were diffusely positive for CD30,

EBV, Bob-1, and CD38. The autopsy findings suggested a diagnosis of PBL. To our knowledge, the present case appears to be the first report of PBL with initial presentation of the liver in a patient without HIV infection.

### INTRODUCTION

Plasmablastic lymphoma (PBL) is a distinct, aggressive B-cell neoplasm that shows a diffuse proliferation of large neoplastic cells resembling B-immunoblasts with

an immunophenotype of plasma cells. PBL was initially described in 1997 as a rare subtype of diffuse large B-cell lymphoma (DLBCL) and has an aggressive clinical behavior arising in the oral cavity of human immunodeficiency virus (HIV)-infected individuals<sup>[1]</sup>. There have been several reports of PBL in HIV-negative patients, mainly at extra-oral sites including the stomach, small intestine and colon<sup>[2-6]</sup> but not in the liver. Interestingly, most cases of PBL occur without HIV infection in Japan and Korea, where the prevalence of HIV infection is low in comparison to Western countries<sup>[7,8]</sup>. In the present study, we describe the first case of liver PBL in a 79-year-old HIV-negative Japanese patient.

## CASE REPORT

A 79-year-old Japanese man was admitted to our hospital with the chief complaint of abdominal pain and icterus. Upon physical examination, jaundice was found to be prominent, which gradually worsened without relief of symptoms. Abdominal examination revealed the liver was palpable about 10 cm below the costal margin. The transaminase, gamma glutamyl transpeptidase, alkaline phosphatase, and bilirubin levels all notably exceeded normal values. An abdominal ultrasound showed dilatation of the intrahepatic bile ducts and a heterogeneous large mass that was 15 cm in diameter located in the right hepatic lobe. Radiographs and computed tomography (CT) of the chest, oral, and peri-oral sites showed no abnormalities, and no peripheral lymphadenopathy was observed. Serological tests to detect specific antibodies against hepatitis B and C virus were negative. The carcinoembryonic antigen and alpha-fetoprotein levels were normal, but soluble interleukin-2 receptor was high (5760 U/mL), and the patient tested negative for an anti-HIV antibody. The examination of the serum levels of Bence-Jones protein and rheumatoid factor was also negative. The patient's medical history included a gastrectomy for a gastric ulcer 20 years earlier and a hepatectomy for a liver abscess 5 years earlier. Plain (Figure 1A) and enhanced (Figure 1B) abdominal CT revealed a liver tumor and hepatomegaly with the same lesion present on ultrasonography (US).

Following examination, a US percutaneous-guided fine needle liver biopsy was performed. Histopathological examination of the biopsy smears showed a dense infiltrate composed of diffuse and proliferative large immunoblast cells with a typical morphological appearance of high-grade non-Hodgkin's lymphoma. However, we were unable to make a diagnosis due to poor immunostaining and a low number of specimens. During the detailed examination, CT and US revealed tumor progression with jaundice, despite continued percutaneous transhepatic biliary drainage.

Considering the high tumor burden and poor prognosis, the patient chose not to receive chemotherapy. He received palliative care and passed away due to multiple

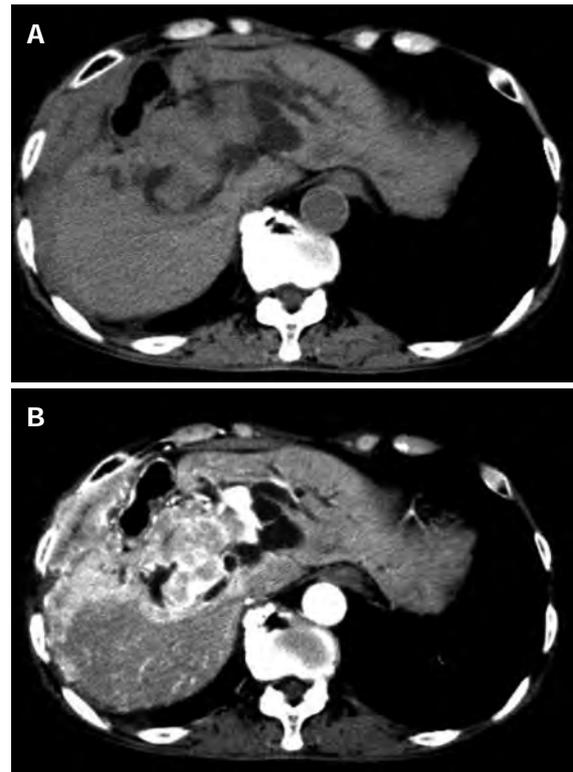

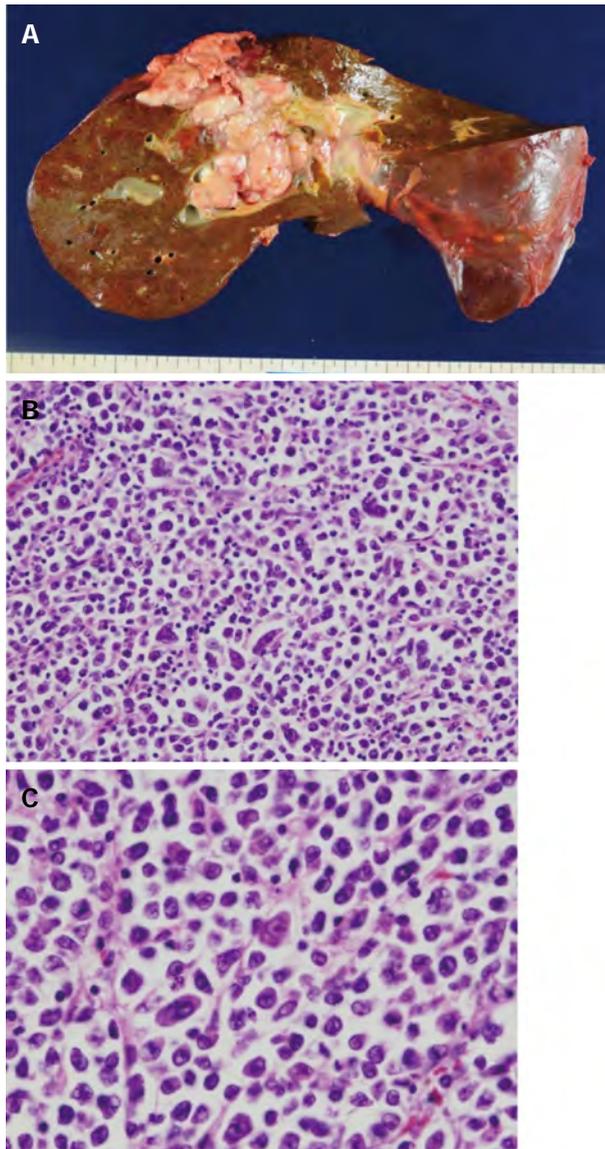

Figure 1 Computed tomography showing dilatation of the intrahepatic bile ducts and a heterogeneous large mass 15 cm in diameter located in the right hepatic lobe. A: Plain computed tomography (CT); B: Contrast-enhanced CT.

organ failure 1.5 mo after his initial clinical presentation. An autopsy was performed immediately after his death. Gross findings included a white, soft solid tumor of approximately diameter of 10 cm in the liver that involved the diaphragm and parietal peritoneum (Figure 2A). Histologically, large tumor cells with abundant basophilic cytoplasm were diffusely proliferative, and large nuclei were sporadically or centrally located and contained one or two conspicuous nucleoli in the central portion (Figure 2B). Specifically, the tumor cells had plasmablast- or immunoblast-like morphology, and there were almost no mature plasma cells present (Figure 2C). Additionally, binucleated or multinucleated tumor cells were scattered throughout the specimen, tumor cell proliferation in lymphatic vessels was conspicuous, and tumor cell invasion was found in some blood vessels.

Immunohistochemical examination revealed that the tumor cells were negative for B-cell markers CD20 (Figure 3A) and CD3 (Figure 3B) but positive for CD30 (Figure 3C), Epstein-Barr virus (EBV) (Figure 3D), and Bob-1 (Figure 3E). Although over 90% of the tumor cells were positive for Ki-67, they were negative for epithelial cell markers such as AE1/AE3, S100 protein, CD43, CD56, PAX-5, and human herpes virus (HHV)-8. Almost all tumor cells were highly positive for EBV virus-encoded RNA *in situ* hybridization (EBER-ISH). Based on these results, a diagnosis of PBL was made.

**Figure 2** Gross appearance of the primary tumor lesion at autopsy and histological appearance. A: A large tumor (diameter of 10 cm) is present in the liver. The cut section shows that the tumor is white and solid, with marked necrosis; B: Diffuse infiltration in the liver by monotonous large atypical lymphoid cells (HE staining; original magnification  $\times 200$ ); C: These atypical cells have an abundant basophilic cytoplasm, eccentrically located pleomorphic nuclei, and single, centrally located prominent nucleoli (HE; original magnification  $\times 400$ ).

## DISCUSSION

DLBCL is currently considered to be a heterogeneous group of rare tumors primarily occurring in the presence of HIV infection<sup>[9,10]</sup>. DLBCL with plasmablastic features has recently been categorized into the following subtypes: PBL of the oral cavity, PBL with plasmacytic differentiation, classic primary effusion lymphoma (PEL), extracavitary/solid PEL or HHV8-associated DLBCL, and anaplastic lymphoma kinase-positive DLBCL<sup>[10,11]</sup>.

PBL is a rare lymphoma accounting for approximately 2.6% of AIDS-related neoplasms<sup>[12]</sup> and typically occurs in the oral cavity of HIV-infected patients. Recently, however, PBL has been reported in patients without HIV

infection, and several cases have been reported in extra-oral locations, such as skin, subcutaneous tissue, stomach, anal mucosa, lung, and lymph node regions<sup>[3-6,13,14]</sup>. PBL has also been observed in immunocompromised individuals such as organ transplant patients and the elderly. PBL with HIV infection primarily affects men at a young age, while the clinical characteristics of PBL without HIV infection are typically old age with a slight male predominance<sup>[15]</sup>. This difference reflects the epidemiology of HIV infection. In addition, over one-third of all cases with PBL were first noted at extra-oral locations<sup>[16]</sup>. Interestingly, although the gastrointestinal tract has been observed to be the most common extraoral site (10.6%), the liver is a rare extra-oral location in PBL patients<sup>[16]</sup>. Only one case of liver PBL patient with HIV infection has been reported<sup>[17]</sup>.

PBL is a distinct, aggressive B-cell neoplasm that shows a diffuse proliferation of large neoplastic cells resembling B-immunoblasts with an immunophenotype of plasma cells. PBL cells predominantly exhibit the morphological features of plasmablasts/immunoblasts and are immunohistologically negative or slightly positive for B-cell markers such as CD20 and CD79a but positive for plasmacyte markers such as CD38 and CD138. PBL cells are highly reactive to the cell proliferation marker Ki67, and 2 in 3 patients carry an integrated EBV genome, while HHV8 is negative. EBER-ISH is highly positive in PBL cells; in particular, EBER-ISH has a positive predictive value of close to 100% in HIV-positive PBL patients with presentation in the oral cavity<sup>[18,19]</sup>.

Differential diagnosis is needed for poorly differentiated carcinomas and malignant melanomas, in addition to malignant lymphomas, such as anaplastic (plasmablastic) plasmacytoma (AP), Burkitt's lymphoma, and DLBCL-NOS<sup>[20]</sup>. Although a differential diagnosis of AP is especially difficult because of tumor cell morphology and immunohistochemical results that are similar to other subtypes, AP cases are usually preceded by a plasmacytoma such as multiple myeloma.

Because the positive value of EBER is significantly high in PBL patients, it has been suggested to use this value as a diagnostic tool<sup>[18]</sup>. However, some plasmacytomas with no signs of immune system abnormalities exhibit plasmablast-like morphology with a particularly high EBER-positive rate<sup>[21]</sup>. To differentiate the two diseases, it is important to use clinical findings (such as the presence of multiple myeloma and M protein) in addition to histopathological and immunohistological findings. The overall prognosis of PBL is poor<sup>[12,15]</sup>; however, the prognosis of PBL in HIV-positive patients has improved with the enhanced management of HIV symptoms, but it has worsened in HIV-negative patients, which include a large elderly population<sup>[7,15]</sup>. MYC/IgH translocation is observed in 70% of EBER-positive PBL patients, and, interestingly, these patients have a notably worse PBL prognosis, presenting with an endemic Burkitt lymphoma-like phenotype and symptoms<sup>[22,23]</sup>.

The management of PBL is based mainly on early

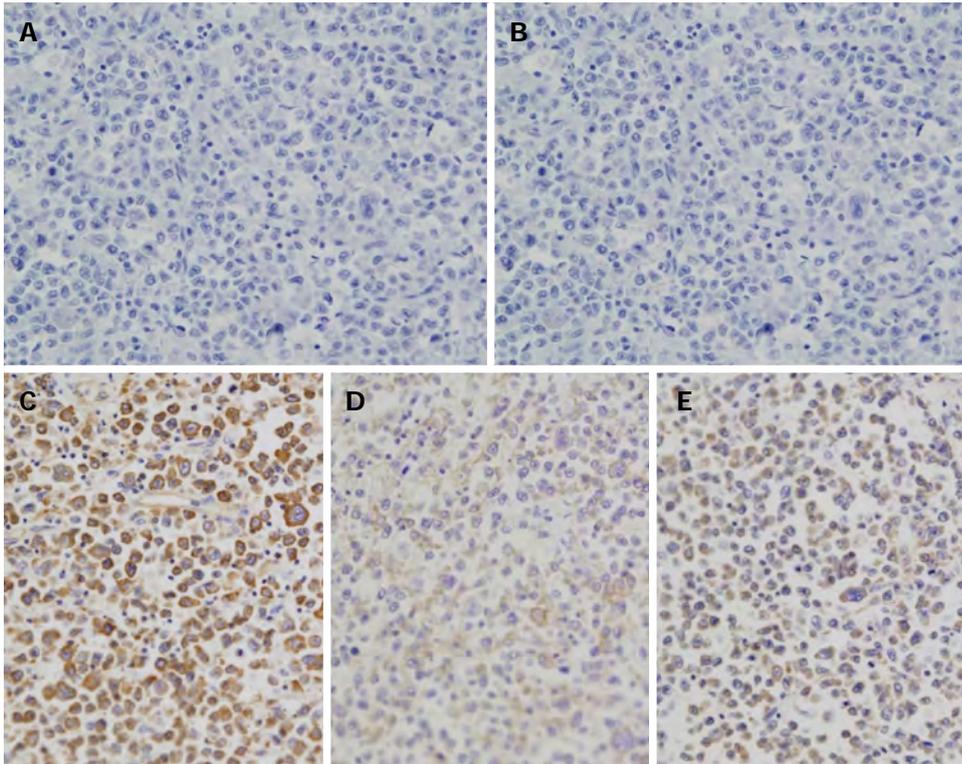

Figure 3 Immunohistochemical staining showing tumor cells with a negative expression of CD20 (A) and CD3 (B), positive expression of CD30 (C), Epstein-Barr virus (D), and Bob-1 (E).

aggressive chemotherapy. Cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) and CHOP-like regimens are commonly used with a good overall response rate but have a high relapse rate and poor overall survival<sup>[24]</sup>.

In our case, no primary carcinoma was detected in any organs at autopsy. In cases of malignant melanoma, tumor cells are immunohistochemically positive for melanosomes and S-100 protein, and Burkitt's lymphomas expresses LCA, CD20, and CD79a. A differential diagnosis between PBL and plasmacytoma is often difficult without histological examination. Because PBL is composed almost entirely of blast cells, plasmacytoma typically consists of mature plasma cells. Therefore, the morphology and immunophenotype of both tumor cells, as well as clinical features, are essential for an accurate diagnosis of PBL.

The condition of the patient rapidly deteriorated because we failed to provide proper treatment due to the unsuccessful initial histopathological examination of the liver biopsy. If biopsy specimens show similar pathological features to those presented in this study, a differential diagnosis of PBL and an immunohistochemical analysis of CD138 and EBER are urgently needed. Although there is one reported case of PBL originating in the liver<sup>[17]</sup>, to our knowledge, this is the first case report of PBL that occurred in the liver without HIV infection. Because extra-oral PBL can occur in HIV-negative patients and has a poor prognosis, it should be included as a differential diagnosis in cases of suspected hepatic lymphoma.

### Abstract

The combination of classical Hodgkin's lymphoma (cHL) and non-Hodgkin lymphoma coexisting in the same patient is not common, especially in one extranodal location. Here we present a rare case of composite diffuse large B-cell lymphoma (DLBCL) and cHL occurring simultaneously in the stomach of a 53-year-old female who presented with upper abdominal discomfort and gas pain. Surgery was performed and the disease was diagnosed pathologically as composite lymphoma of DLBCL and cHL using hematoxylin-eosin and immunohistochemical staining. Epstein-Barr virus (EBV) infection was not detected by *in situ* hybridization for EBV-encoded RNA or immunohistochemistry for EBV latent membrane protein-1. Polymerase chain reaction analysis from the two distinct components of the tumor demonstrated clonal immunoglobulin  $\kappa$  light chain gene rearrangements. The patient died approximately 11 mo after diagnosis in spite of receiving eight courses of the CHOP and two courses of the rituximab-CHOP (RCHOP)

chemotherapy regimen. This case report showed that the two distinct components, DLBCL and cHL, appeared to originate from the same clonal progenitor cell, and that EBV infection was not essential for transformation during the course of tumorigenesis.

### INTRODUCTION

Composite lymphoma (CL), which is defined as the coexistence of two or more morphologically and phenotypically distinct lymphoma types in a single anatomic organ or tissue, is unusual<sup>[1]</sup>. Almost all the primary stomach

Figure 1 Gastroscopy showing an irregular ulcer covered with white exudates (A) and multiple mucosal nodularities in the gastric corpus (B) and a circular ulcer in the gastric pyloric canal (C).

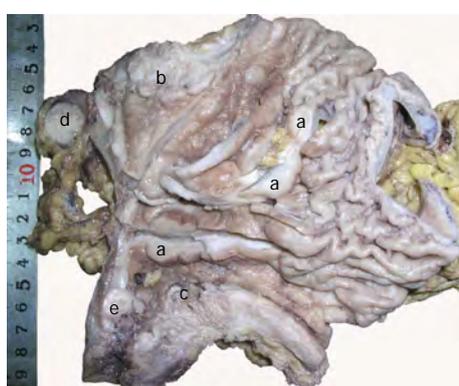

Figure 2 Macroscopic findings of the lesions. Multiple mucosal nodularities (a) and an ulcer (b) in the gastric corpus, a circular ulcer in the gastric pyloric canal (c), perigastric (d) and parapyloric (e) swollen lymph nodes.

lymphomas are non-Hodgkin's lymphoma (NHL), the majority of which are of B-cell origin, and mucosa-associated lymphoid tissue lymphoma and diffuse large B-cell lymphoma (DLBCL) account for over 90%<sup>[2]</sup>. Classical Hodgkin's lymphoma (cHL) commonly manifests in lymph nodes whereas primary extranodal cHL in the gastrointestinal tract is very rare, estimated at 0.025% of all cHL, and only single cases of primary gastric cHL have been reported in the literature<sup>[3]</sup>. The combination of cHL and NHL coexisting in the stomach is extremely rare. Here we present a rare case of composite DLBCL and mixed cellularity cHL involving the stomach, and present a review of the literature.

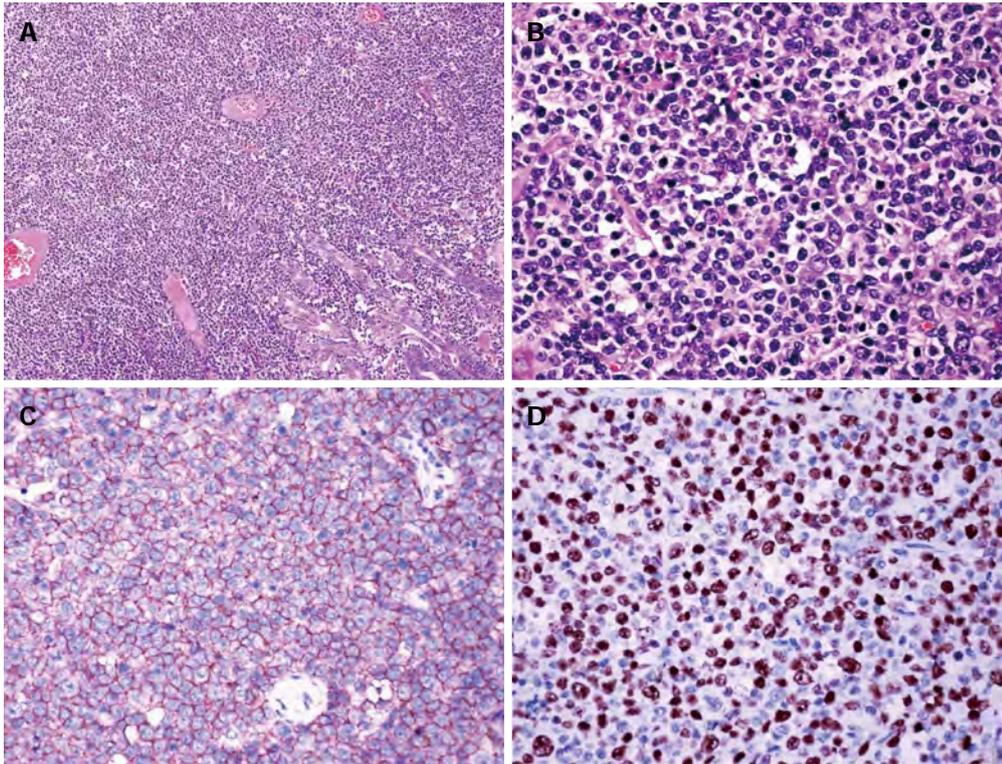

## CASE REPORT

A 53-year-old female presented with upper abdominal discomfort and flatulent pain for over an 8-mo period and her condition became gradually worse. She also described a substantial weight loss and anorexia over the preceding 6 mo. Computed tomography (CT) scans of the abdomen showed thickening of the wall in the gastric pylorus and gastric corpus, and uneven enhancement could be seen after intravenous administration of contrast agent. Gastroscopy revealed an irregular ulcer

covered with white exudates (Figure 1A) and multiple mucosal nodularities in the gastric corpus (Figure 1B). Another circular ulcer covered with white exudates and effusion was simultaneously found in the gastric pyloric canal (Figure 1C). Biopsy specimens were obtained from the two ulcers. A histologic diagnosis of small round cell malignant tumor, indicating lymphoma, was made. Routine blood examination showed hemoglobin 115 g/L, white blood cell count  $5.32 \times 10^9/L$ , neutrophils 52.3%, lymphocytes 19.6%, monocytes 12.1%. Serological testing demonstrated negativity for hepatitis B virus and human immunodeficiency virus infections. The lactate dehydrogenase level (185 U/L) was in the normal range. Abdominal ultrasonography and computed tomography scans of the chest did not show any other abnormalities. No superficial lymphadenopathy was noted.

The patient underwent distal stomach resection because of aggravated symptoms of obstruction. Grossly, the greater and lesser curvatures of the resected stomach measured 17.0 and 7.5 cm respectively. The gastric wall was diffusely thickened and multiple different sizes of mucosal nodularities ranging from 1 cm to 2.5 cm in diameter (Figure 2, a) and a well circumscribed ulcer measuring 4 cm  $\times$  3.5 cm  $\times$  0.5 cm (Figure 2, b) were identified in the gastric corpus. The gastric pyloric canal presented with increased thickness and stenosis, and a circular ulcer measuring 3 cm  $\times$  3 cm  $\times$  0.8 cm was also found (Figure 2, c). The cut surface of the neoplastic ulcers and mucosal nodularities were grey and soft. Perigastric (Figure 2, d) and parapyloric (Figure 2, e) swollen lymph nodes were identified. Selected tumor tissues were fixed in formalin and embedded in paraffin and cut into sections then stained with hematoxylin and eosin for routine histology. Additional sections of paraffin-embedded tissue were used for immunohistochemical staining and *in situ* hybridization analysis. Genomic DNA was isolated from CD30<sup>+</sup> Hodgkin and Reed-Sternberg (RS) cells and CD20<sup>+</sup> DLBCL cells by micromanipulation, and polymerase chain reaction (PCR) procedures were performed for analysis of immunoglobulin heavy and  $\kappa$  light chain rearrangements.

Microscopically, there were two morphologically and

**Figure 3** Diffuse large B-cell lymphoma of the stomach. A: Large lymphoid cells diffusely infiltration the gastric corpus wall (HE,  $\times 100$ ); B: Nucleoli and frequent mitotic figures (HE,  $\times 400$ ); C: Neoplastic cells diffusely positive for CD20 (immunoperoxidase stain,  $\times 400$ ); D: Nuclear proliferation rate as assessed by Ki-67 staining was approximately 80% (immunoperoxidase stain,  $\times 400$ ). HE: Hematoxylin and eosin.

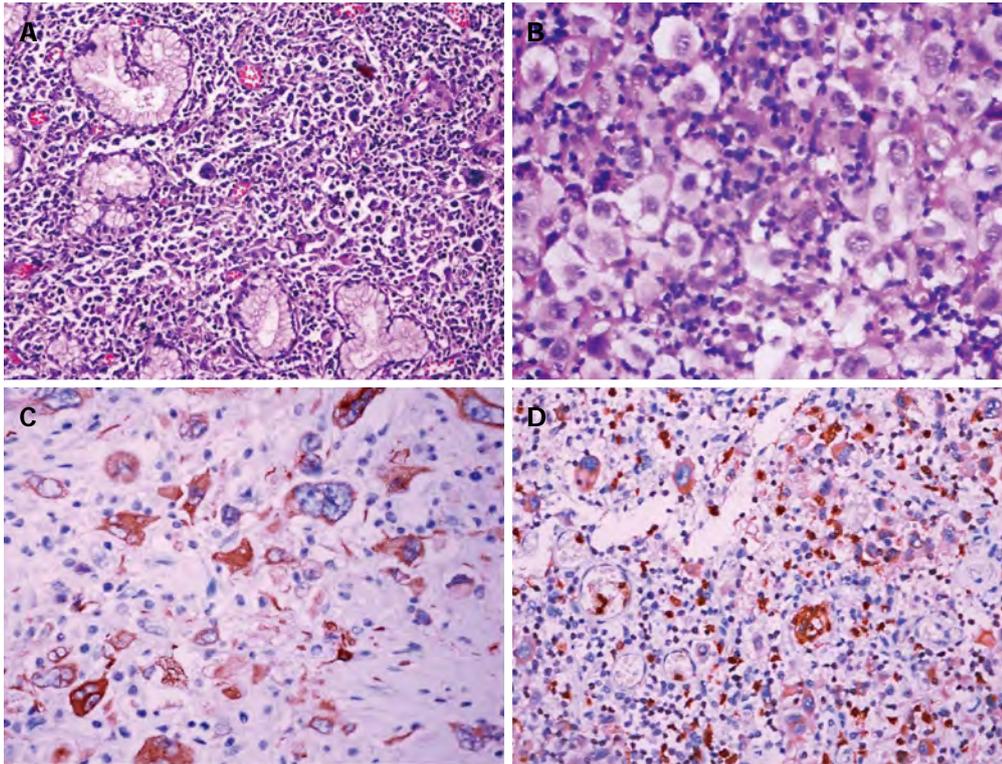

immunophenotypically distinct components in different locations of the stomach. The ulcer and multiple mucosal nodularities in the gastric corpus exhibited a homogeneously uniform population of large lymphoid cells infiltration all layers of the gastric wall (Figure 3A). The nuclei were round or multilobated, with finely dispersed chromatin and evident nucleoli. Frequent mitotic figures were noted (Figure 3B). The neoplastic cells showed uniform expression of CD45, CD20 (Figure 3C), CD79a, Pax-5, MUM1, and absence of CD3, Bcl-6 and CD10. The nuclear proliferation rate as assessed by Ki-67 staining was approximately 80% (Figure 3D). Additional immunohistochemistry displayed tumor cells negative for cytokeratin, CD30, CD15 and other T-cell antigens. The ulcer in the gastric pylorus showed typical mixed lymphocyte, eosinophil granulocyte and neutrophil granulocyte infiltration with fibrosis (Figure 4A), and contained numerous large atypical lymphoid cells, including Hodgkin and RS cells (Figure 4B). The Hodgkin and RS cells were positive for CD30 (Figure 4C), CD15 (Figure 4D), MUM1 and Oct-2, and weakly positive for Pax-5, but negative for CD45, CD20, CD79a, CD3, CD10 and BOB.1. Interestingly, the perigastric and parapyloric swollen lymph nodes were infiltrated by tumor cells of DLBCL and cHL, respectively. Neither cell population showed markers of Epstein-Barr virus (EBV) infection by *in situ* hybridization for EBV-encoded RNA or immunohistochemistry for EBV latent membrane protein-1. On the basis of these morphologic and immunohisto-

chemical characteristics, the pathological diagnosis of composite DLBCL and mixed cellularity cHL was made. PCR analysis from the two distinct components of the tumor demonstrated clonal immunoglobulin  $\kappa$  light chain gene rearrangements (Figure 5).

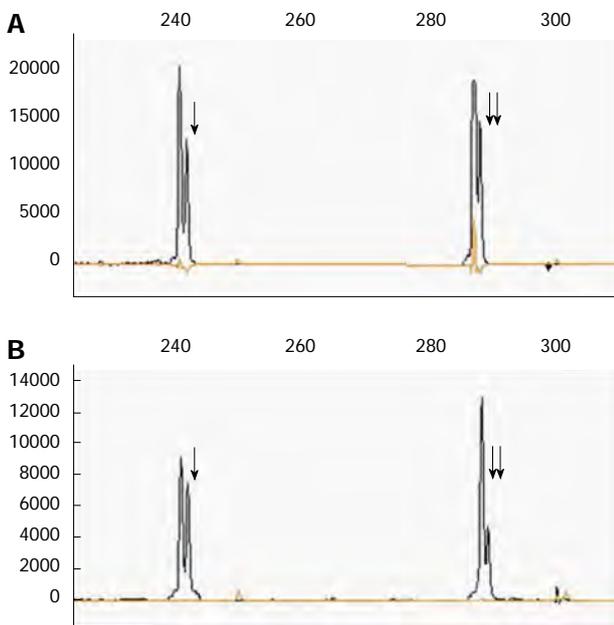

After surgery, the patient was treated with eight courses of a standard CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy regimen, after which she showed an excellent response with normal brain, thoracic and abdominal CT scans. Unfortunately, repeat CT scans and ultrasonography revealed tumor recurrence with abdominal tumor load 7 mo after chemotherapy. Then the patient received a further two cycles of rituximab-CHOP (RCHOP) chemotherapy. Unfortunately, she died of multiple organ failure due to lymphoma recurrence on the 11<sup>th</sup> postoperative month. An autopsy was not performed.

## DISCUSSION

The concept of CL was first put forward by Custer<sup>[4]</sup> to explain the occurrence of more than one histological type of lymphoma in the same patient. In the study of more than 1000 cases for the International Working Formulation for NHL, the incidence of CL varied between 1% and 4.7%<sup>[5]</sup>. cHL and NHL are morphologically and clinically distinct neoplasms. The combination of cHL and NHL coexisting in the same tissue is rare and much more uncommon than other combinations<sup>[3]</sup>. According

**Figure 4 Classical Hodgkin's lymphoma of the stomach.** A: Mixed lymphocyte, eosinophil granulocyte and neutrophil granulocyte infiltrating the gastric pyloric canal wall (HE,  $\times 200$ ); B: Hodgkin and Reed-Sternberg (RS) cells are present (HE,  $\times 400$ ); C, D: Hodgkin and RS cells positive for CD30 and CD15, respectively (immunoperoxidase stain,  $\times 400$ ). HE: Hematoxylin and eosin.

A: DNA from the dissected diffuse large B-cell lymphoma component. B: DNA from the dissected classical Hodgkin lymphoma component.

to our literature review, a total of 10 cases, including the present case, reported a combination of DLBCL and cHL within the same site simultaneously<sup>[6-13]</sup>. The clinical data of all previously published cases of composite DLBCL and cHL are listed in Table 1. In these cases, there were five cases of combination of DLBCL and cHL in the lymph nodes, three cases in the stomach, one case in the small intestine and one case in the anterior mediastinum, indicating that the gastrointestinal tract is the most common extranodal site involved in this kind of composite lymphoma. Prochorec-Sobieszek *et al*<sup>[9]</sup> firstly reported localized gastric DLBCL and cHL as secondary neoplasms in two patients with chronic lymphocytic leukemia. To the best of our knowledge, this is the first case report of composite DLBCL and cHL coexisting in the stomach with no history of lymphoma or leukemia.

The pathogenesis of CL is inconclusive. Viral infections, genetic susceptibility, genetic mutations, and immune suppression are CL pathogenic factors. However, no single definite mechanism has been proposed to explain the pathogenesis of different types of CL as the etiology is variable, complex and differs according to the types of lymphomas involved<sup>[14-16]</sup>. In general, cHL is associated with EBV; on the other hand, NHL is infrequently associated with EBV. When cHL and NHL are present in the same anatomic site, there is a higher correlation with the presence of EBV in both lymphoma

cells than when two lymphomas occur at different times and/or at different sites. If the two components demonstrate positivity for EBV, it would be suggested that a commonly infected progenitor cell might be responsible for both lymphomas<sup>[17,18]</sup>. From assessment of the data in Table 1, composite DLBCL and cHL often showed EBV positivity, suggesting an origin from a commonly EBV-infected progenitor cell; however, two components from two cases including our patient were all negative for EBV, indicating EBV infection did not seem to be the primary event in this tumorigenesis.

Lymphoma, generally, is defined as monoclonal proliferation of lymphocytes (T cell, B cell or natural killer cell). Coexistence of DLBCL and cHL in the same anatomic location has been reported occasionally; studies using molecular techniques have proved that they may be clonally related (*i.e.*, derived from the same lymphoid progenitors) or not related (*i.e.*, different lymphoid progenitors)<sup>[7-10]</sup>. Controversy about this issue may reflect the lack of a full understanding of the pathogenesis of these lymphomas or the heterogeneity of Hodgkin lymphoma and NHL. In the present case, identical immunoglobulin  $\kappa$  light chain gene rearrangements were seen in the two distinct components, indicating that both components, despite their distinctly different morphologic features and immunophenotype, were indeed derived from the same clone. Thus, DLBCL and cHL coexisting in the stomach in our case can be considered a true CL with two distinctive presentations.

The pathological differential diagnosis of composite DLBCL and cHL in the present case mainly included cHL transformation to DLBCL, anaplastic variant of DLBCL, T cell/histiocyte-rich large B-cell lymphoma (THRLBCL), anaplastic large cell lymphoma (ALCL) and grey zone lymphoma. The characteristic morphology and immunophenotype of the tumor cells in conjunction with clinical features aid in the differential diagnosis. cHL

transformation to DLBCL may be differentiated from the current case as the two distinct lymphoma occurred simultaneously within different sites of the stomach without a histological mixing zone. An anaplastic variant of DLBCL is characterized by large tumor cells with bizarre pleomorphic nuclei that may resemble Hodgkin and/or RS cells, and it may be differentiated according to its consistent immunological staining for B-cell markers, such as CD20 and CD79. THRLBCL is comprised of scattered, single, large B cells embedded in a background of T cells and a variable number of histiocytes. These large B cells may mimic Hodgkin and RS cells in cHL, but they express pan B-cell markers with no expression of CD15 and CD30. The "Hodgkin-like pattern" accounts for 3% of ALCL cases, which is characterized by morphological features mimicking nodular sclerosing cHL. CD15 expression is rarely observed and when present only a small proportion of the neoplastic cells are stained; however, Hodgkin and RS cells in cHL are always weakly positive for Pax-5, which is different from ALCL. The most presentation of grey zone lymphoma is a large anterior mediastinal mass with rare involvement of non-lymphoid organs. Some areas may more closely resemble DLBCL and others appear more like cHL. In cases that morphologically resemble cHL, uniform strong expression of CD20 and other B-cell markers and absence of CD15 would favor the diagnosis of grey zone lymphoma. Other histological differential diagnoses, including leukocytopenia, poorly differentiated carcinoma, sarcoma, reactive lymphoid proliferation and collision tumor should be cautiously considered<sup>[19]</sup>.

To conclude, we report a rare case of composite DLBCL and cHL involving the stomach and describe the histologic and immunophenotypic findings. The contribution of immunohistochemistry plays an important role in differential diagnosis. Using molecular techniques, we further proved that the two different components ap-

peared to originate from the same clonal progenitor cell, and that EBV infection was not essential for transformation during the course of tumorigenesis.

### Abstract

Biliary cystadenoma (BCA) is a rare hepatic neoplasm. Although considered a benign cystic tumor of the liver, BCA has a high risk of recurrence with incomplete excision and a potential risk for malignant degeneration. Correct diagnosis and complete tumor excision with negative margins are the mainstay of treatment. Unfortunately, due to the lack of presenting symptoms, and normal laboratory results in most patients, BCA is hard to distinguish from other cystic lesions of the liver such as biliary cystadenocarcinoma, hepatic cyst, hydatid cyst, Caroli disease, undifferentiated sarcoma, intraductal papillary mucinous tumor, and hepatocellular carcinoma. Ultrasound (US), computed tomography (CT) and magnetic resonance imaging (MRI) may be necessary. They demonstrate intrahepatic cystic lesions with features such as mural nodules, varying wall thickness, papillary projections, and internal septations. Nevertheless, surgery is still the only means of accurate diagnosis. Definitive diagnosis requires histological examination following formal resection. We describe a 57-year-old woman initially diagnosed with polycystic liver who was subsequently diagnosed with giant intra-

hepatic BCA in the left hepatic lobe. This indicates that both US physicians and hepatobiliary specialists should attach importance to hepatic cysts, and CT or MRI should be performed for further examination when a diagnosis of BCA is suspected.

### INTRODUCTION

Biliary cystadenoma (BCA) is a rare hepatic neoplasm. Although considered a benign cystic tumor of the liver, BCA has a high risk of recurrence with incomplete excision and a potential risk for malignant degeneration. Correct diagnosis and complete tumor excision with negative margins are the mainstay of treatment. Unfortunately, due to the lack of presenting symptoms, and normal laboratory results in most patients, it is hard to distinguish BCA from other cystic lesions of the liver. Definitive diagnosis requires histological examination following for-

mal resection. We describe a 57-year-old woman initially diagnosed with polycystic liver who was subsequently diagnosed with a giant intrahepatic BCA in the left hepatic lobe. This indicates that importance should be attached to hepatic cysts in the ultrasound (US) examination, and computed tomography (CT) or magnetic resonance imaging (MRI) should be performed for further examination when a diagnosis of BCA is suspected.

## CASE REPORT

A 57-year-old woman was admitted to our hospital with intermittent abdominal discomfort and pain for almost 2 years. Discomfort and pain were not related to meals, defecation or change in position, and could be tolerated. Initially, she underwent an US examination of the abdomen at a local hospital. This revealed multiple small cysts in the liver, which caused no particular concern. She had not experienced diarrhea, nausea, vomiting, fever or chills since the onset of symptoms. However, she noticed that her abdominal girth appeared to be slowly increasing in size 1 mo ago, and repeat US examination at an outside institution showed a left hepatic multiloculated cystic mass measuring 21.0 cm × 9.1 cm × 13.6 cm with internal septations and multiple small cysts in the left liver lobe.

She visited our hospital for further treatment. On physical examination, it was significant for abdominal tenderness and the abdomen was distended, with a large, soft, non-mobile mass in the left half of the abdomen. The patient had no history of intravenous drug use or tattoos or body piercing, no history of excessive alcohol use or obesity, and no history of working with toxic chemicals. She had no prior history of surgery, medical illness, and no known allergies. She was not using any medication. There was no significant family history of biliary or liver diseases.

CT imaging performed at our institution demonstrated a left hepatic multiloculated cystic mass measuring 15.0 cm × 9.1 cm, occupying the majority of the upper abdomen, and normal liver structure had disappeared. The internal septations were visible and enhanced after intravenous administration of contrast medium. The mass cranially displaced the liver. The gallbladder and pancreas were compressed. Simultaneously, multiple sizes of hypoattenuating shadows without enhancement were seen in the right liver lobe (Figure 1). Abdominal MRI was ordered and revealed a large cystic tumor measuring approximately 18.0 cm × 9.0 cm originating from the left liver lobe (Figure 2). On T1-weighted imaging (T1WI), low signal intensity was apparent within the cystic spaces. On corresponding T2-weighted imaging (T2WI), the tumor was characterized by a medium-high intensity signal clearly delineated from the surrounding liver tissue with internal septal structures separating the fluid-filled spaces.

Laboratory tests were within normal limits, and serology for hepatitis B virus infection was negative, and serum carcinoembryonic antigen (CEA), carbohydrate

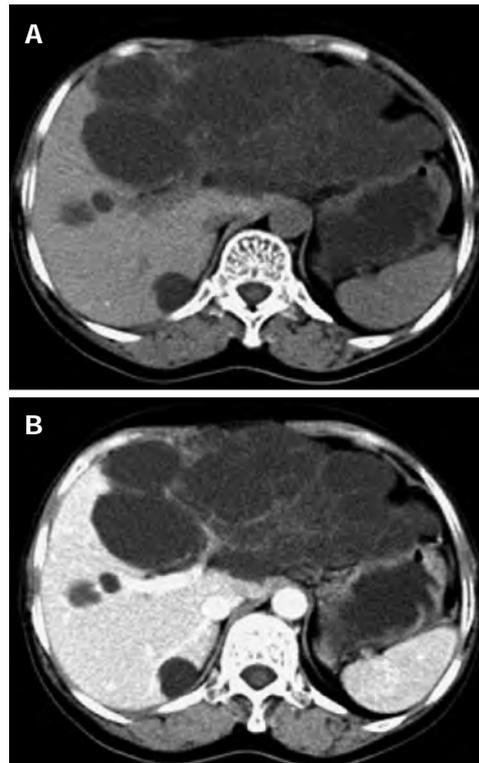

Figure 1 Transverse computed tomography scan showed a left hepatic multiloculated cystic mass measuring 15.0 cm × 9.1 cm (A) and contrast computed tomography showing enhanced septum of the tumor (B). Simultaneously, multiple sizes of hypoattenuating shadows without enhancement were seen in the right liver lobe.

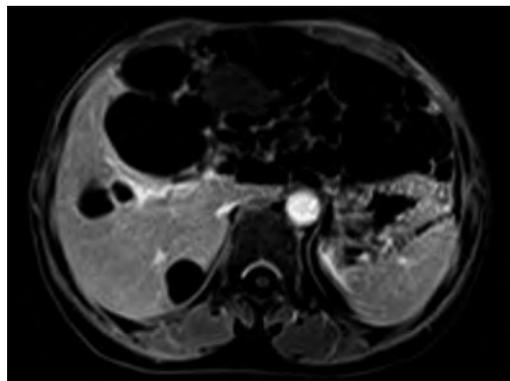

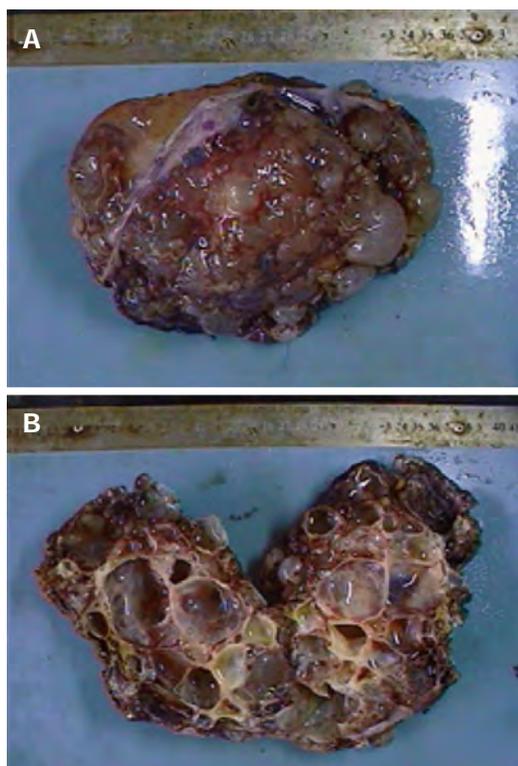

Figure 2 T1-weighted imaging revealed a large cystic tumor measuring approximately 18.0 cm × 9.0 cm originating from the left liver lobe.

antigen (CA) 19-9, CA-125 and  $\alpha$ -fetoprotein (AFP) levels were normal. On the basis of these findings, the patient was diagnosed with a hepatobiliary cystadenoma and polycystic liver.

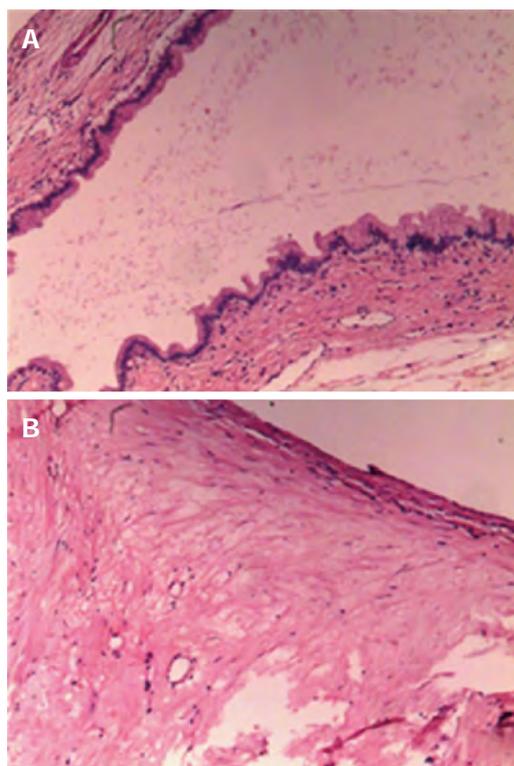

The patient underwent an exploratory laparotomy with left hepatic lobectomy, right liver cyst fenestration, and cholecystectomy through a right subcostal incision. A large cystic mass presenting with grape-like blisters was located on the surface of the left lobe of the liver. It was well encapsulated and essentially without invasion into any other structures, and it was completely excised.

**Figure 3** Resected left liver specimen showed a multilocular cystic lesion measuring 15 cm × 9 cm × 8 cm, covered with bullate nodules on the cut surface (A), and opened specimen filled with grayish yellow but clear fluid, the inner surface was smooth without any masses or excrescences (B).

On gross examination, the resected left liver specimen showed a multilocular cystic lesion measuring 15 cm × 9 cm × 8 cm, covered with bullate nodules on the cut surface (Figure 3A). The cyst contained grayish yellow but clear fluid with no connection to the bile duct, and the wall was smooth. No masses or excrescences were noted on the inner surface (Figure 3B). Microscopically, the cystic lesion was lined by a single layer of cuboidal to columnar epithelial cells (Figure 4A). The cell morphology was normal and not pleomorphic. A stroma with proliferating fibrous tissue and a small number of inflammatory cells was underlying the epithelium (Figure 4B). Typical ovarian-like stroma was absent. The histopathology was homogeneous and uniform throughout the lesion. The surgical margins were negative and a final diagnosis of hepatobiliary cystadenoma was established. It also showed chronic inflammation of the gallbladder of the excised specimen.

The patient was seen 1 mo after surgery in the clinic. She was able to eat normally and had no abdominal discomfort. She was monitored with abdominal US for recurrence after operation. The abdominal US revealed some small cysts in the right liver lobe, whereas serological tests for CEA, CA19-9, CA-125 and AFP were within normal ranges. She was scheduled for a repeat US in 3 mo.

**Figure 4** Microscopic evaluation showed a single layer of cuboidal to columnar epithelial cells (A) with underlying stroma with proliferating fibrous tissue and a small number of inflammatory cells (B) (hematoxylin and eosin stain, × 100).

## DISCUSSION

BCA is a cystic benign tumor which that originates from intrahepatic or extrahepatic biliary ducts, and it is also called hepatobiliary cystadenoma. BCA represents < 5% of cystic liver disease cases<sup>[1]</sup>. The cystadenoma is predominantly intrahepatic in origin and rarely seen in extrahepatic bile ducts or the gallbladder<sup>[2]</sup>. About 90% of BCAs are located intrahepatically, with a slight predilection for the right hepatic lobe. Its size varies from 3-4 cm to a giant cyst of 20-30 cm<sup>[3]</sup>. Here, we reported a giant intrahepatic BCA located in the left hepatic lobe in a 57-year-old woman.

The etiology of BCA is still unclear, although abnormal embryonic development resulting in ectopic foregut or gonadal epithelium sequestered in the liver has been proposed recently<sup>[4]</sup>. It seems that BCA has specific epidemiological characteristics. Wang *et al.*<sup>[5]</sup> reported that the majority of intrahepatic BCA cases occurred in women aged ≤ 60 years, which was consistent with our patient's presentation. However, 11 cases of BCA have been reported in the pediatric population<sup>[2,6,7]</sup>.

Histologically, there are three described subtypes of BCA, based on the underlying type of stroma seen beneath the cuboidal or columnar epithelium. In the first subtype, BCA, microscopically, has a dense, ovarian-like

mesenchymal stroma. This group is the most common and also occurs exclusively in women at a mean age of 40 years. The second subtype has non-ovarian-like stroma and is characterized by the absence of a mesenchymal layer. This group may instead have fibrous, hyaline, or myxoid stroma and is more frequently seen in men with a mean age of 50 years. The third subtype is a cystadenoma that also lacks mesenchymal stroma, but is lined by eosinophilic epithelial cells, which resemble hepatocytes. This group is rare, occurs only in men, and may be a semimalignant histological variant<sup>[6]</sup>. Our patient lacked a mesenchymal stroma but instead had fibrous stroma, and was classified into the second group.

It is difficult to make an accurate diagnosis of BCA before surgery, and to date no publication has established presenting symptoms that differentiate BCA from other benign or malignant hepatic cystic diseases such as biliary cystadenocarcinoma, hepatic cyst, hydatid cyst, Caroli disease, undifferentiated sarcoma, intraductal papillary mucinous tumor, and hepatocellular carcinoma. Patients may present with abdominal pain, abdominal distention, indigestion, nausea, vomiting, and jaundice, yet patients may be asymptomatic at presentation<sup>[8]</sup>. On physical examination, an abdominal mass can be identified occasionally. Laboratory results are normal in most patients with BCA, although serum liver enzyme and bilirubinemia levels may be mildly elevated occasionally. Serum AFP, CA19-9, CA-125 and CEA levels are usually within the normal range. It was recently reported that CA19-9 may be elevated in the cystic fluid and contributes to the diagnosis of BCA before surgery<sup>[9]</sup>. US, CT and MRI play an important role in the diagnosis and antidiastole of the disease. Medical imaging demonstrates intrahepatic cystic lesions with features such as mural nodules, varying wall thickness, papillary projections, and internal septations, which could help to distinguish BCA from other cystic lesions of the liver. On color Doppler US, BCA may appear as a multiloculated anechoic cystic structure with irregular shape and intact membranes. Dense and scattered echogenic dots can be seen in the echo-free area with partitions in between, and solid and papillary echo which is connected to the cystic wall can be seen on the partition wall. Abdominal CT scan may further characterize the multilocular cystic lesion with enhanced, thin internal septations and surrounding normal liver parenchyma, whereas the intraluminal content is usually hypoattenuating. Its fibrous capsule and internal septations are often visible and help distinguish the lesion from a simple cyst. Convex papillae can be seen on the septation, although they are more common in cystadenocarcinoma. MRI may improve tissue characterization because of its high contrast resolution. On MRI, BCA appears as a hypoattenuating lesion on T1WI and hyperintensity cystic fluid on T2WI, but the signal intensity may vary depending on the properties of the cyst fluid<sup>[10,11]</sup>. On T1WI, the signal intensity may increase with protein concentration. The signal intensity of serous fluid and bile is low. In rare cases, the intensity of serous cystic content can be raised

by intracystic hemorrhage and fluid-fluid level can be present. On T2WI, septations with low signal intensity are better visualized in contrast to the high signal intensity of the cystic fluid. If jaundice is present, magnetic resonance cholangiopancreatography or endoscopic retrograde cholangiopancreatography may be considered to evaluate biliary obstruction. Most commonly, displacement and extrinsic compression of the bile ducts by the tumor is seen, and rarely, communication between the cyst and biliary tree may be observed<sup>[12]</sup>. With the development of US contrast agent in recent years, contrast-enhanced ultrasonography has become increasingly useful in the diagnosis of liver lesions. BCA manifests as a non-homogeneous rich blood supply cystic masses, the solid part and the wall nodules show strong enhancement in the arterial phase, decreased enhancement in the delayed phase, and equivalent enhancement in the portal phase. Nevertheless, the wall nodules are a little more sharply enhanced in the three phases, making it difficult to differentiate from cystadenocarcinoma. It is well known that US-guided biopsy is the most commonly used method for preoperative pathological diagnosis, and cyst fluid cytology and enzymes can be detected, but carcinomatosis may occur following cyst biopsy<sup>[9]</sup>.

Although imaging is the major diagnostic method for BCA at present, surgery is still the only means of accurate diagnosis. Definitive diagnosis requires histological examination following formal resection, liver transplant, or enucleation<sup>[13]</sup>. Resection or enucleation with clear margins is the treatment of choice for suspected BCA. Malignant degeneration and recurrence are 30% and 90%, respectively, for incompletely excised lesions<sup>[14]</sup>. Therefore, patients who only undergo treatment such as aspiration or laparoscopic fenestration would have a poor prognosis. Surgical resection is still necessary when there is diagnostic uncertainty, especially when the patient was complicated with simple or multiple liver cysts. Sometimes, intraoperative frozen sectioning should be performed, in order not to miss a neoplastic condition, such as cystadenocarcinoma. It is important for surgeons to determine the scope of the operation and for patients to receive timely surgery.

Our patient was complicated with polycystic liver disease, which was initially only diagnosed as polycystic liver. This indicates that such cases should be brought to the attention of US physicians and hepatobiliary specialists. In outpatients with diagnosis of hepatic cysts, especially multiple cysts, CT or MRI should be performed when a diagnosis of BCA is suspected.

### Panitumumab

**Core tip:** Metastatic colorectal cancer (mCRC) remains a challenge for oncologists worldwide. Despite a very aggressive disease profile, mCRC's outcomes are improving toward last decades. Target drugs, such as cetuximab and panitumumab, acquired a main role in this scenario whether phase III trials showed interesting results in overall survival and disease control. Thus, we will briefly in this paper discuss some issues and pitfalls concerning this framework.

### Abstract

Colorectal cancer (CRC) has high incidence and mortality worldwide. In 2012, CRC was the second most prevalent cancer among males (9%) and the third among females (8%). In recent decades, standard chemotherapy protocols combining 5-fluorouracil, leucovorin, irinotecan and oxaliplatin were important for improve survival in this set of patients. Further, biological drugs throughout epidermal growth factor receptor (EGFR) pathways showed interesting results in metastatic disease (mCRC) control when in association to standard chemotherapy regimens. Cetuximab and panitumumab are two cornerstones for mCRC treatment and are both approved in Europe and United States based on previous results phase III trials. This paper will briefly summarize those anti-EGFR therapies framework in mCRC and discusses some issues in this regard.

### INTRODUCTION

Colorectal cancer (CRC) has high incidence and mortality worldwide. In 2012, CRC was the second most prevalent cancer among males (9%) and the third among females (8%)<sup>[1]</sup>. The survival rates, in advanced CRC remain low; therefore, the development of new therapeutic weapons becomes a real need. Targets therapies through epidermal growth factor (EGF) and its receptor (EGFR) and also *KRAS* pathways modulation acquired a main role whether in association with standard chemotherapy<sup>[2]</sup>. Since its discovery, EGFR has been considered a good candidate for targeted cancer therapy<sup>[3,4]</sup>. It is over expressed in many types of cancers, especially CRC<sup>[5]</sup>.

### EPIDERMAL GROWTH FACTOR RECEPTOR

Although EGFR remains a controversial prognostic fac-

**Table 1** Mainly clinical trial and target therapies

Study	Design	Median PFS (mo)	Median OS (mo)	Toxicity (grade 3/4)	Genetic analyses	Response rate
PACCE trial <sup>[18]</sup>	PMAB + Bev/Ox-CT	10	19.4	Skin rash, diarrhea, infections and pulmonary embolism	KRAS status was determined in 82% tumor samples. Mutations were found in 40%	46%
	PMAB + Bev/Iri-CT + Bev/Ox-CT	11.4	24.5			48%
Peeters <i>et al</i> <sup>[22]</sup>	Panitumumab-FOLFIRI (in the WT KRAS subpopulation)	5.9	14.5 <sup>1</sup>	Toxicities associated with anti-EGFR therapy	KRAS status was available for 91% of patients: 597 (55%) with wild-type KRAS tumors, and 486 (45%) with mutant KRAS tumors	Improved to 35% vs 10% with the addition of panitumumab
	FOLFIRI (in the WT KRAS subpopulation)	3.9	12.5 <sup>1</sup>			
PRIME study <sup>[28]</sup>	Wild-type KRAS stratum Panitumumab + FOLFOX (4)	9.6	23.9 <sup>1</sup>	Toxicities associated with anti-EGFR therapy	KRAS results were available for 1100 (93%) patients	55%
	Mutant KRAS stratum Panitumumab + FOLFOX (4)	8.0	19.7 <sup>1</sup>			48%
	Panitumumab + FOLFOX (4)	7.3	15.5 <sup>1</sup>			40%
	FOLFIRI (4)	8.8	19.3 <sup>1</sup>			40%
COIN trial <sup>[29]</sup>	Ox and 5FU (arm A) in KRAS wild-type tumours	8.6 <sup>1</sup>	17.9 <sup>1</sup>	NA	565 (43%) had KRAS mutations	57%
	Ox and 5FU plus cetuximab (arm B) in KRAS wild-type tumours	8.6 <sup>1</sup>	17.0 <sup>1</sup>	Skin rash and gastrointestinal toxic effects		64%
NORDIC-VII <sup>[20]</sup>	Standard Nordic FLOX (arm A)	7.9 <sup>1</sup>	20.4 <sup>1</sup>	The regimens were well tolerated	KRAS and BRAF mutation analyses were obtained in 498 (88%) and 457 patients (81%) respectively	41%
	Cetuximab and FLOX (arm B)	8.3 <sup>1</sup>	19.7 <sup>1</sup>			49%
	Cetuximab combined with intermittent FLOX (arm C)	7.3 <sup>1</sup>	20.3 <sup>1</sup>			47%

<sup>1</sup>Without statistical significance. PFS: Progression-free survival; OS: Overall survival; PMAB: Panitumumab; Bev: Bevacizumab; Ox:CT: Oxaliplatin-based chemotherapy; Iri-CT: Irinotecan-based chemotherapy; 5FU: 5-fluorouracil; FOLFOX/FLOX: Fluorouracil, leucovorin and oxaliplatin; FOLFIRI: Fluorouracil, leucovorin and irinotecan; NA: Not applicable.

tor, this expression-stage association may play a crucial role in the decision to initiate an adjuvant treatment toward *KRAS* mutation assessment<sup>[6]</sup> as it will be discussed below.

However, not all patients have a good response to anti-EGFR monoclonal antibodies, and given the risks for adverse effects associated with their use and their substantial cost, there is particular interest in identifying predictors of treatment benefit or lack thereof<sup>[2]</sup>. Genetic alterations may explain the resistance to anti-EGFR therapies<sup>[7]</sup>. In current clinical practice, *KRAS* mutation (codon 12 and 13) is mainly responsible for primary resistance to the EGFR target drugs, particularly cetuximab and panitumumab<sup>[8]</sup>. Thus the advantages of anti-EGFR monoclonal antibody treatment of colorectal cancer may be limited to *KRAS* wild-type patients<sup>[9]</sup>.

## METASTATIC COLORECTAL CANCER

Currently, we know that many monoclonal antibodies has been approved by Food and Drugs Administration (FDA) and European Medicine Agency for the treatment of mCRC: cetuximab and panitumumab in *KRAS* wild-type patients<sup>[5,9]</sup> and bevacizumab for those harbor codon 12 or 13 mutation<sup>[10,11]</sup>. These drugs are used in association with

chemotherapy in patients with mCRC or maintenance therapies in chemorefractory tumors (Table 1). In overall, current guidelines advocate the use of the following regimens as initial standard chemotherapy for mCRC: fluorouracil, leucovorin, and oxaliplatin-based chemotherapy (FOLFOX), fluorouracil, leucovorin, and irinotecan-based chemotherapy (FOLFIRI), capecitabine plus oxaliplatin (CapeOx or XELOX)<sup>[12,13]</sup>, and fluorouracil, leucovorin, oxaliplatin and irinotecan-based chemotherapy (FOLFOXIRI)<sup>[14]</sup>. The addition of a biological agent, such as anti-vascular endothelial growth factor (bevacizumab)<sup>[15]</sup> or anti-EGFR (cetuximab or panitumumab), in *KRAS* wild-type, will depends on patients *KRAS* profile, fitness and related- clinical co-morbidities.

However, we should be aware for the toxicity profile. Most common anti-EGFR adverse events<sup>[16]</sup> are the skin acneiform rash, xeroderma, hypomagnesemia, diarrhea and nausea<sup>[17]</sup>. Hecht *et al*<sup>[18]</sup> assessed panitumumab plus bevacizumab versus regular chemotherapy (oxaliplatin and irinotecan-based) as first line treatment for mCRC and showed no outcomes benefit, but only increase in toxicity profile, particularly diarrhea, infections and pulmonary embolism<sup>[19]</sup>. The increased in the toxicity can be explicated by dual-pathway inhibition in combination with chemotherapy<sup>[18]</sup>. In this study the patients were

enrolled onto one of two cohorts per investigator arm: a fluorouracil, leucovorin, and oxaliplatin-based chemotherapy (FOLFOX) cohort or a fluorouracil, leucovorin, and irinotecan-based chemotherapy (FOLFIRI) cohort, each with bevacizumab. Anyway, panitumumab given with FOLFOX or with FOLFIRI in the absence of bevacizumab appears to be well tolerated in other studies.

Tveit *et al.*<sup>[20]</sup> evaluated in mCRC patients the efficacy of cetuximab plus bolus fluorouracil/folinic acid and oxaliplatin, administered continuously or intermittently as first line regimen. This study did not show significant benefit compared with the FOLFOX regime. For another hand in third-line treatment of patients with chemotherapy-refractory mCRC, cetuximab provides a substantial prolongation of progression-free-survival (PFS) and overall survival<sup>[21]</sup>. Similarly, panitumumab plus FOLFIRI has shown significantly improved in PFS and was well-tolerated as second-line treatment in patients with wild-type *KRAS* mCRC<sup>[22]</sup>.

Plus, the combination of cetuximab plus FOLFIRI as first-line chemotherapy in wild-type *KRAS* tumors also can reduce the risk of progression of mCRC as compared with FOLFIRI alone<sup>[23]</sup>. Moreover, we should note that the toxicity of FOLFIRI plus cetuximab combination was superior to FOLFIRI regimen alone (notably skin reactions). Notwithstanding, patients with *KRAS* wild-type locally advanced rectal cancer with the addition of cetuximab to chemoradiation regimen based on irinotecan plus capecitabine showed no benefit compared to the use of chemoradiation alone<sup>[24]</sup>. Further, in spite of we have focused our attention to *KRAS* mutations; there are others biomarkers that are also implicated in colorectal cancer outcomes, such as *BRAF* mutation. *BRAF*-mutant tumors have worse prognosis<sup>[25]</sup>. Recently *BRAF* inhibitor, vemurafenib, was approved by the FDA for treatment of patients with *BRAF*-mutant metastatic melanoma<sup>[26]</sup>. It is expected that in the near future other *BRAF* inhibitors are developed and maybe directed to mCRC.

## CONCLUSION

In summary, the most recent studies aim to demonstrate not only the efficacy and safety of the target molecules discussed above, in particular cetuximab and panitumumab, but also how these new agents act in conjunction with conventional chemotherapy. Currently, mCRC molecular profile assessments acquired a main role for oncologists worldwide due to the possibility of personalizing treatments approaches for mCRC patients and thus improve survival outcomes as well as quality of life<sup>[27-29]</sup>. In addition, the choice to use bevacizumab, cetuximab or panitumumab in association with standard chemotherapy (FOLFOX or FOLFIRI) for mCRC framework run toward patients fitness, acceptable toxicities profiles, survival outcome and mainly pharmaco-economic evaluation of those drugs in this setting.

### Abstract

Chronic pancreatitis (CP) continues to be a clinical challenge. Persistent or recurrent abdominal pain is the most compelling symptom that drives patients to seek medical care. Unfortunately, in spite of using several treatment approaches in the clinical setting, there is no single specific treatment modality that can be earmarked as a cure for this disease. Traditionally, ductal hypertension has been associated with causation of pain in CP; and patients are often subjected to endotherapy and surgery with a goal to decompress the pancreatic duct. Recent studies on humans (clinical and laboratory based) and experimental models have put forward several mechanisms, including neuroimmune alterations, which could be responsible for pain. This might explain the partial or no response to single modality treatment in a significant proportion of patients. The current review discusses the recent concepts of pain generation in CP and evidence based therapeutic approaches (other than ductal decompression) to handle persistent or recurrent pain. We focus primarily on parenchymal and neural components; and discuss the role of antioxidants

and the existing controversies, drugs that interfere with neural transmission, pancreatic enzyme supplementation, celiac neurolysis, and pancreatic resection procedures. The review concludes with the treatment approach that we follow at our institute.

**Key words:** Pain; Chronic pancreatitis; Nociception; Neuroplasticity; Antioxidant micronutrients; Pregabalin; Pancreatic enzymes

**Core tip:** Pain in chronic pancreatitis (CP) has multiple but simultaneously occurring mechanisms. Recent data have shown expression of nociceptors and neurotrophic factors in different neural locations. The expression of these and other neural chemokines (fractalkine) have positive correlation with pain. Pain also results from global sensitization. Among the therapeutic modalities, beneficial effects have been demonstrated with methionine containing antioxidant micronutrients supplements and pregabalin. Of the pancreatic enzymes, only non-enteric coated preparations might benefit a subgroup of patients. The threshold for performing celiac neurolysis should be high in view of variable response across clinical trials.

Talukdar R, Reddy DN. Pain in chronic pancreatitis: Managing beyond the pancreatic duct. *World J Gastroenterol* 2013; 19(38): 6319-6328 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6319.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6319>

### INTRODUCTION

Pain in chronic pancreatitis (CP) is as enigmatic as the disease itself. There is currently no definitive cure for the illness; and treatment usually centers on pain relief and

management of exocrine and endocrine dysfunction. 85%-90% patient will have abdominal pain at presentation<sup>[1]</sup>; and in our experience over two-third of patients would present with ductal calculi and/or stricture (unpublished data). Traditionally, pain in CP has been largely associated with ductal hypertension. However, as evident from the literature, recurrence of pain is common even after ductal decompression in the form of extracorporeal shock wave lithotripsy (ESWL), endoscopic retrograde cholangiopancreatography (ERCP) or lateral pancreaticojejunostomy. Over the past several years, a host of pain mechanisms have been proposed and demonstrated directly or indirectly in humans<sup>[2]</sup>. Most important among these are oxidative stress and inflammation induced pancreatic nociception, pancreatic neuropathy/neuroplasticity and central neuroplasticity. There appears to be significant cross talk among the different mechanisms, which could explain the partial or no success of single modality treatment approaches. This mandates a holistic and conceptualized approach to pain management in CP, aided by the little evidence available.

This review addresses the current concepts of genesis of pain in CP and evidence based management approaches focusing primarily on the parenchymal and neural components.

## PAIN MECHANISMS

### Nociception

Nociception refers to the perception of pain sensation as a result of activation of pain receptors (nociceptors). The proteinase-activated receptor 2 (PAR-2) and the transient receptor potential vanilloid 1 receptors are two discrete types of nociceptors that have been shown to be present in the pancreas specific sensory nerves and dorsal root ganglia<sup>[3,4]</sup>. It is now known from experimental models that even sub-inflammatory doses of trypsin could bind to the PAR-2 receptor, thereby suggesting trypsin as a potential nociceptive stimulus, independent of its inflammatory role<sup>[4]</sup>. Other nociceptive stimuli that have been proven or speculated to stimulate pancreatic nociceptors include trypsin, alcohol metabolites, protons, bradykinin, hydrogen sulphide, serotonin and calcium<sup>[5]</sup>. The primary sources of intrapancreatic trypsin are the mast cells that infiltrate the pancreatic nerves in CP. The latter mediators are known to be released by injured acinar cells. Recently, another nociceptor namely the ligand-gated cation channel Transient receptor potential ankyrin 1 has also been shown to cause pancreatic inflammation and visceral hypersensitivity<sup>[6]</sup>.

Other than the above-mentioned ligands, several neurotrophic factors like nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), glial-derived neurotrophic factor and artemin are expressed locally in the pancreas in response to inflammation and bind to specific receptors at different regions within the nerves (Figure 1)<sup>[7-10]</sup>. These factors, after binding to the respective receptors cause nociceptive sensitization and neural

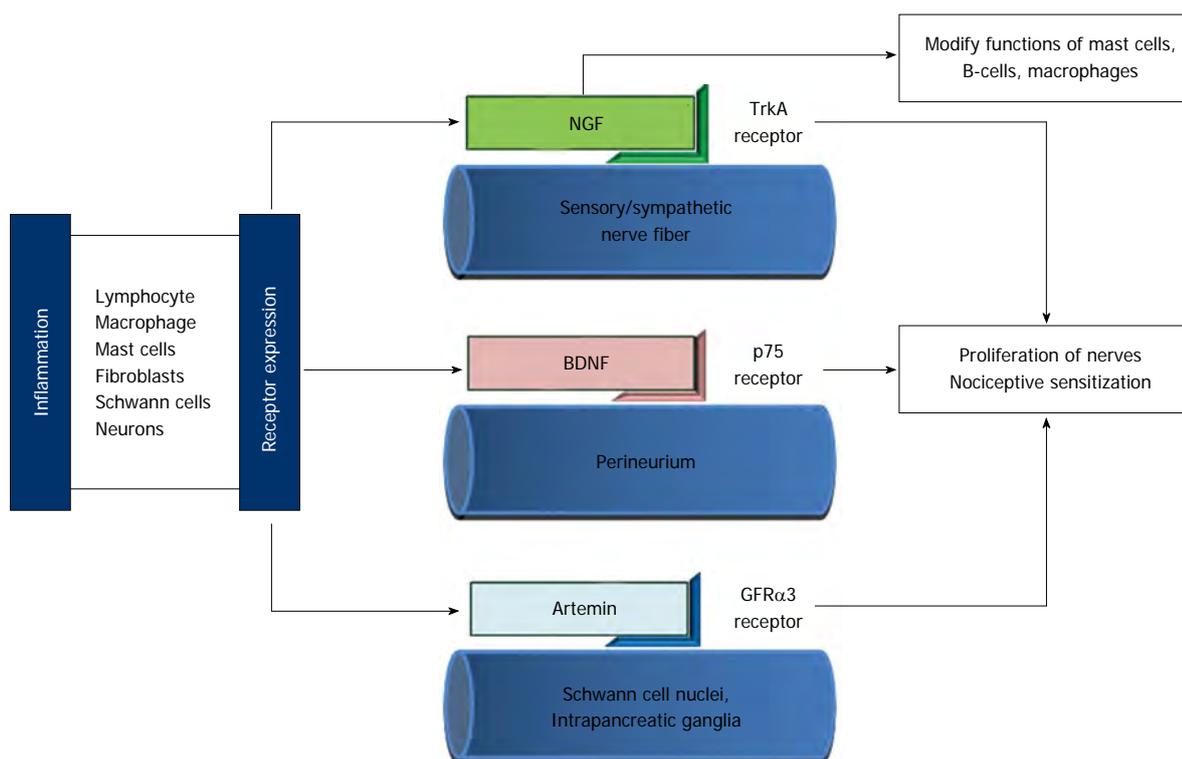

proliferation. Interestingly, the expression of TrkA, BDNF and artemin has been found to correlate with the severity of pain in patients with CP<sup>[2]</sup>.

Even though ductal hypertension had been considered to be a major cause of pain in CP, the mechanism was not known clearly. Recently, it was shown in experimental models that increase in pressure can activate pancreatic stellate cells (PSC), which in turn can generate oxidative stress<sup>[11]</sup>. Furthermore, ethanol and smoking can by itself lead to oxidative stress within the PSCs<sup>[12,13]</sup>. Oxidative stress is capable of generating a pro-inflammatory state by means of activating immune cells, increasing expression of pro-inflammatory cytokines, and activating cytokine receptors and transcription factors (*e.g.*, tumor necrosis factor alpha, NF- $\kappa$ B)<sup>[2]</sup>. This could indirectly or directly sensitize the intrapancreatic pain receptors. The response of pain in CP along with normalization of circulating oxidant stress markers after treatment with high-dose anti-oxidants is a testimony to this.

Once activated, the pain receptors generate an action potential in the first order sensory neurons of spinal levels T5 to T9. The action potential travel forward (antegrade) to the dorsal horn (gray matter) of the spinal cord where it results in the release of the neurotransmitters glutamate, calcitonin gene related peptide (CGRP) and substance P<sup>[14]</sup>, which subsequently excites the second order neurons in the dorsal horn *via* N-methyl D-aspartate,  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors and the neurokinin 1 (NK-1) receptors<sup>[15]</sup>. The nociceptive transmission is then propagated through the ascending pathways in the spinal cord white matter to the thalamus, from where third order neurons relay to the sensory cortex, limbic system and the thalamus for cognitive and affective integration of pain. The sympathetic efferent cell body is the other sensory component to which the first order pancreatic nociceptive neurons project. This in turn relays to the celiac plexus *via* the greater splanchnic nerves and finally synapses with the second order sympathetic neurons. Axons of these sympathetic neurons then travel cephalad in the vagal trunks<sup>[2]</sup>.

### Neural mechanisms

Several neuroimmune and neuroplastic mechanisms have been described in CP pain over the recent years in humans and experimental models. The most conspicuous neural changes in the intrapancreatic nerves include: (1) infiltration of inflammatory cells (especially mast cells and eosinophils)<sup>[16]</sup>; (2) neural edema and perineural disruption<sup>[17]</sup>; (3) Schwann cell (glial cell in peripheral nerves) proliferation<sup>[18]</sup>; and (4) neural hypertrophy and sprouting<sup>[19]</sup>, to name a few. The magnitude of these changes has been shown to correlate with the severity of pain, thereby ascribing them a causal role for neuropathic pain in CP. Possible factors that could be responsible for neural inflammation in the pancreatic nerves include glutamine, CGRP, substance P, and fractalkine. Some of these mediators can travel retrograde (antidromic) from the dorsal horn to the intrapancreatic nerve end-

**Figure 1** Schematic diagram representing neuroimmune mechanisms of pain in patients with chronic pancreatitis. The TrkA receptors (for nerve growth factor, NGF) are expressed on the sensory and sympathetic nerve fibres, p75 (for brain derived neurotropic factor, BDNF) on the perineurium and glial cell line-derived neurotrophic factor receptor  $\alpha 3$  (GFR $\alpha 3$ ) (for Artemin) on the Schwann cell nuclei and intrapancreatic ganglia. The receptor expression is mediated by inflammation involving inflammatory cells and neural elements.

ing and induce chemotaxis of inflammatory cells<sup>[2,20,21]</sup>. Furthermore, overexpression of two important markers, namely, nestin and growth-associated protein-43 has been demonstrated in pancreas of human CP<sup>[19]</sup>. These two are markers of neuroplasticity/neural regeneration and are responsible for Schwann cell and neural growth. The composite of these findings and the associated pain clearly points towards profound neural remodeling within the pancreas (pancreatic neuroplasticity). These changes have important bearing on pain processing in central nervous system both at the level of the spinal cord and higher centers. Continuous sensitization of the intrapancreatic nociceptors due to persistent inflammation results in continuous stimulation of second order neurons present the dorsal horn of the spinal cord, a phenomenon called global sensitization<sup>[22]</sup>. The clinical surrogate of global sensitization is an increase in the area of referred pain due to convergence of afferent fibres from different visceral and somatic organs on the same hyperexcitable secondary spinal neurons. This has been demonstrated recently in patients with CP, in whom the areas involved in referred pain in response to esophageal, gastric and duodenal stimulation were significantly higher than those in controls<sup>[23]</sup>. Global sensitization results in two important phenomenon, mechanical allodynia (generation of pain after a physiological or non-noxious stimulus) and inflammatory hyperalgesia (amplified pain response to normal or minimal pain stimuli). The other manifestation of global sensitization is an increasingly painful response

to repetitive but isointense stimuli. This is known as temporal summation, which has been clearly demonstrated in patients with CP<sup>[24,25]</sup>. It has also been demonstrated that early event-related brain potentials are altered in several key pain processing areas in the cerebral cortex in response to visceral stimulation in patients with CP<sup>[23]</sup>. This, along with a posteromedial shift in the electrical dipoles indicates significant neural reorganization in the cerebral cortical pain processing architecture. This is central neuroplasticity. Other evidence of central neuroplasticity in CP has come from clinical studies that have shown increase in theta activity on electroencephalogram (EEG) and increased activity in the right secondary somatosensory area on magnetic resonance spectroscopy<sup>[26,27]</sup>. Furthermore, abnormalities have been demonstrated in the descending inhibitory pathways from the cortex, which tilts the balance between these and ascending excitatory pathways in favour of more central pain processing abnormalities<sup>[28]</sup>.

Figure 2 depicts a conceptual model of pain in patients with CP.

## CLINICAL EVALUATION

Even though different mechanisms for pain in CP have been proposed and demonstrated, there are currently no easily available and clinically validated tools to identify the type of pain. A clinical history of new or wider areas of referred pain could be an indicator of the develop-

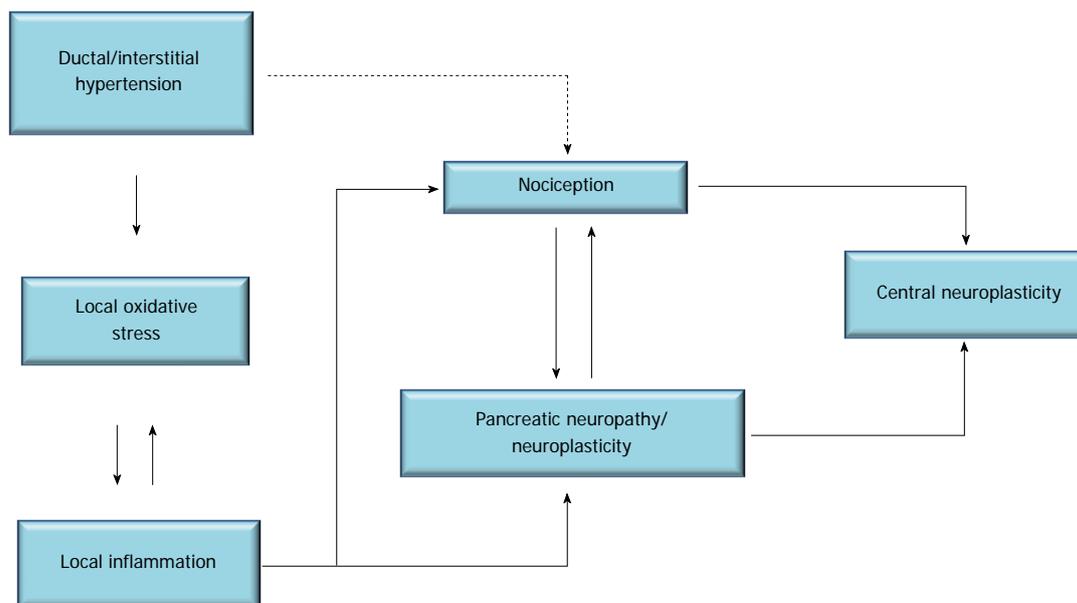

Figure 2 Schematic representation of the conceptual framework of pain mechanisms in chronic pancreatitis.

ment of neuropathy. An objective questionnaire based tool namely painDETECT has been used to evaluate neuropathic pain in the context of radiculopathy<sup>[29]</sup>. This questionnaire evaluates components pertaining to neuropathic pain (for *e.g.*, burning/tingling nature of pain); and could have a potential use in patients with CP to assess the neuropathic component of the total pain. Persistence of theta wave on EEG is another proven feature of development of central neuroplasticity<sup>[26]</sup>. However, this has not been tested and validated in large multicenter studies to be recommended for use in the routine clinical setting. Furthermore, even though few groups have used quantitative sensory testing for evaluation of pain in CP, this may not be feasible widely<sup>[30]</sup>.

## PAIN MANAGEMENT BEYOND DUCTAL DECOMPRESSION

In routine pancreatology practice, usually three broad categories of CP patients with recurrent or persistent pain are encountered, namely those with ductal obstruction (with calculi or stricture), those after ductal decompression (post-endothrapy/surgery) with a dilated duct and those with a non-dilated duct but only parenchymal changes. In the first category, ductal decompression in the form of endothrapy (ESWL with/without ERCP and ductal stenting) is the current standard of care<sup>[31,32]</sup>. Discussion of management of this group of patients is out of the scope of the current review. In the second category, it is important to rule out recurrent stones (which may be radiolucent), stricture, local complications (like inflammatory mass, biliary obstruction, pseudocysts), and cancer. In the absence of these, recurrent pain in this group of patients (and also in the third group) is most likely to be associated with predominant neural mechanisms resulting from interstitial hypertension, tissue

ischaemia, and neural inflammation. For the management of chronic and recurrent pain in CP, following treatment modalities have been practiced.

### Analgesics

For short-term relief of pain in CP, the World Health Organization pain ladder, starting with an nonsteroidal anti-inflammatory drugs may be followed<sup>[33]</sup>. It is a common practice in many western countries to use opiates long-term to ameliorate chronic and recurrent pain. However, even though high potency opiates like morphine and analogues are effective, they should be avoided as a first line drug as far as possible due to the risk of drug dependence and potentiation of side effects, including narcotic bowel syndrome. Furthermore, morphine and codeine can cause activation and degranulation of mast cells, thereby overriding the beneficial effect while worsening the inflammation and pain<sup>[34]</sup>. Tramadol, though a low potency selective  $\mu$ -opiate receptor agonist, has been shown to be as effective as higher potency narcotics but with a significantly better safety profile<sup>[35]</sup>. Other effective alternatives for severe continuing pain include epidural buprenorphine and transdermal fentanyl (patch)<sup>[36]</sup>.

### Antioxidant micronutrients

The primary aim of antioxidant micronutrient therapy in CP is to supply methyl and thiol moieties for the transsulfuration pathway, which is essential for protection against reactive oxygen species (ROS) mediated electrophilic stress<sup>[37]</sup>. It has been demonstrated in clinical studies that there is a significant reduction in antioxidant defense in patients with CP. Studies from the United Kingdom, India and Spain have used a antioxidant cocktail consisting of methionine, organic selenium, ascorbic acid,  $\beta$ -carotene, and  $\alpha$ -tocopherol; out of which 2-4 g/d of methionine (which preserves the transsulfuration path-

**Table 1** Studies evaluating the role of antioxidant micronutrients on clinical outcomes, including pain, in patients with chronic pancreatitis

Ref.	Study type	Antioxidant micronutrients used	Indications; study duration	Outcomes

way in acinar cells) is believed to be the most important. Table 1 shows the clinical trials that have evaluated the effect of antioxidant micronutrient supplementation on pain relief in CP<sup>[38-43]</sup>. The largest randomized controlled trial (from India) with 127 patients that used organic selenium (600 µg), ascorbic acid (0.54 g), β-carotene (6000 IU), α-tocopherol (270 IU) and methionine (2 g) for six months demonstrated a significant reduction in the number of painful days compared to placebo ( $7.4 \pm 6.8$  d *vs*  $3.2 \pm 4.0$  d, respectively;  $P < 0.001$ ) and use of analgesic tablets per month<sup>[42]</sup>. There was also significant concomitant reduction in markers of oxidative/electrophilic stress like TBARS and improvement in antioxidant capacity. However, the clinical efficacy found in this trial was negated by the most recent randomized trial from Manchester (ANTICIPATE study), which concluded that even though micronutrients increased the antioxidant levels in blood, they did not produce adequate pain relief<sup>[43]</sup>. It is important to note that in contrary to the Indian study, patients in the ANTICIPATE study were on high dose of narcotics, many continued to consume alcohol and many did not respond to other forms of therapy either<sup>[44,45]</sup>. We believe that the optimal dose of antioxidant micronutrients confers definite benefit in terms of pain relief in carefully selected patients with CP. Even though it is advisable to monitor plasma glutathione and micronutrient concentrations, and titrate doses accordingly, in practice this may not be feasible.

In addition to the fixed dose antioxidant cocktail regimen, it is also important to give dietary advise on intake of anti-oxidant rich diet, and avoid practices that can adversely affect the bioavailability of dietary antioxidants (*e.g.*, vegetables cooked in high temperature)<sup>[46]</sup>. Folate deficiency can hinder with methionine recovery for the transsulfuration pathway<sup>[2,47]</sup>. Therefore folic acid supplementation could provide additional benefits especially to the alcoholic CP patients.

#### Drugs that interfere with neural transmission

In clinical practice, tricyclic antidepressants (like amitryp-

tiline) and serotonin-norepinephrine reuptake inhibitors (like duloxetine) are frequently used for refractory pain in CP, based on the observed benefits in other neuropathic states. Similarly, anticonvulsants like gabapentin and pregabalin, which are first line drugs for diabetic neuropathy have also been used. However, among all these agents, only pregabalin have been tested in a randomized controlled setting. A recent randomized controlled trial (RCT) evaluated the effect of increasing doses (150-600 mg/d) of pregabalin for three weeks on pain in 64 patients with CP; and demonstrated that there was significant reduction in pain score in the pregabalin arm [ $-36\%$  (95%CI:  $-43 - -29$ )] *vs*  $-24\%$  (95%CI:  $-31 - -16$ );  $P = 0.02$ ]<sup>[48]</sup>. Significant improvement was also observed in the patient's global impression of change at the end of the study. Ninety-one percent of patients had some adverse events in this trial, of which the most common were neurological (feeling drunk in 35%, and light-headedness in 12%). Rest of the adverse events was similar to those in the placebo arm. The number (proportion) of patients with serious adverse events in the pregabalin and placebo patients was 4 (12%) and 2 (7%) respectively; and this difference was not statistically significant. Pregabalin is α2δ receptor blocker that decreases presynaptic release of glutamate, noradrenaline and substance P; and has been shown to improve pain in CP by inhibiting central sensitization<sup>[49]</sup>. Studies have shown that the inhibition of central sensitization is manifested by normalization of the theta band on EEG, particularly in the parietal lobe<sup>[50]</sup>. These studies does give a comprehensive mechanistic insight of the beneficial role of pregabalin on chronic pain in CP. Further long-term follow-up studies would complement the current evidence and provide data on the long term efficacy of the drug.

#### Pancreatic enzymes

Pancreatic enzymes have been often used to control pain in CP. This is based on the hypothesis that proteases in the enzyme supplement would inhibit overstimulation of duodenal cholecystokinin (CCK) receptors, which will

in turn inhibit the food induced feedback loop thereby putting the pancreas to rest. However, meta-analysis of six double-blinded RCTs from 1983-1995 involving 186 patients concluded that pancreatic enzymes confer no benefit in pain relief<sup>[51]</sup>. Similarly, a Cochrane Systematic Review of 10 RCTs (2 parallel design and 8 cross over) involving 361 patients found equivocal pain relief, fecal fat excretion and improvement in quality of life in the pooled analysis<sup>[52]</sup>. However, the individual trials in the two studies that used non-enteric coated preparations did show significant improvement in pain<sup>[53,54]</sup>, thereby fitting into the notion of reducing post-prandial pancreatic secretion by CCK receptor inhibition. This does not happen with the enteric-coated preparations because the release of these enzyme preparations (which should happen at a pH of 5.5) in the duodenum is erratic and non-uniform due to reduced ductal bicarbonate secretion in CP. The enzymes from the enteric-coated preparations are generally released more distally in the jejunum and ileum. Unfortunately, almost all currently available enzyme preparations are enteric coated and should not be prescribed for pain relief as a sole indication. Non-enteric coated enzyme preparations (wherever available) can be of some benefit to a subgroup of patients with post-prandial pain. It is important to prescribe non-enteric preparations along with a proton pump inhibitor or H<sub>2</sub> receptor blocker in order to prevent gastric acid mediated degradation of the enzymes in the stomach.

### **Celiac plexus block**

Celiac plexus block with a local anesthetic (bupivacaine) with or without a combination of steroid (triamcinolone) is another modality for treatment for pain in chronic pancreatitis. Even though this can also be performed percutaneously, endoscopic ultrasound (EUS) based procedure has better results and negligible risk of developing paraplegia, which is associated with the percutaneous technique<sup>[55]</sup>. However, the overall benefits of celiac plexus block are about 55% after 4-8 wk and a dismal 26% and 10% after 12 and 24 wk respectively<sup>[56]</sup>. Therefore, this modality should be kept as rescue therapy for patients who do not respond to conventional medical and endoscopic therapy and are not ideal surgical candidates. EUS guided celiac ganglion neurolysis with absolute alcohol is another option, but is too extreme for a benign disease, especially in the presence of additional central mechanisms of chronic pain<sup>[57]</sup>.

Side-effects of celiac block are seen in 10%-33% of patients. The most common side effects include transient self-limiting diarrhea and orthostatic hypotension, owing to the sympathetic blockade with relatively unopposed visceral parasympathetic activity<sup>[56,58]</sup>. Diarrhea usually settles in 48 h. Occasionally the patient may complain of an increase in the pain. Serious complications like retroperitoneal bleeding and peripancreatic abscess have infrequently been reported. An additional problem with the use of alcohol is the development of dense desmoplasia, which might make future pancreatic surgery difficult.

### **Surgery**

Other than drainage procedures, surgical interventions for pain control in CP includes resectional procedures like classical (Kausch Whipple) or pylorus preserving (Traverso-Longmire) pancreaticoduodenectomy, distal pancreatectomy and total pancreatectomy. Pancreaticoduodenectomy is particularly useful in pain with an associated inflammatory head mass. Even though long-term pain relief has been demonstrated in 75%-95% of patients, this procedure is associated with worsening of exocrine and endocrine functions<sup>[59,60]</sup>. Similarly, endocrine and exocrine insufficiency is seen in 80%-95% patients undergoing distal pancreatectomy<sup>[61]</sup>; and is therefore currently performed only for recurrent pain with localized disease (such as a stricture in the upstream duct not amenable to endotherapy). Total pancreatectomy is also infrequently performed in view of the associated significant morbidity. However, with the development of islet transplantation, there has been a renewed interest in select centers in total pancreatectomy with autoislet transplantation in patients with end stage CP. However, it should be borne in mind that even after removing the entire pancreas, as high as 40% of patients could still require analgesics even after 2 years of follow-up<sup>[62]</sup>. Many a time, a resectional procedure is combined with a drainage procedure, like Frey's, Beger's, Berne's and the V-shaped procedure, in order to provide the benefit of both ductal decompression and removal of a part of the inflamed pancreas (especially an inflammatory mass).

Bilateral thoracic splanchnicectomy is yet another infrequently used surgical modality that could ameliorate chronic pain in patients with CP; and have recently been shown to inhibit pain by predominantly impairing adrenomedullary function<sup>[63]</sup>.

### **Miscellaneous**

Both short and long acting octreotide have been attempted in pain management in advanced CP in small-scale studies<sup>[64,65]</sup>. Even though satisfactory pain relief has been documented, the results need to be verified in larger trials. Furthermore, whether the pain relief is better in patients with or without ductal obstruction also needs to be examined. Other than octreotide, secretin infusion has also been evaluated in a recent phase II trial with equivocal results<sup>[66]</sup>. Few of the modalities that have been used as adjuncts to medical/surgical therapy include spinal cord stimulation<sup>[67]</sup>, cognitive-behavioral therapy, and other alternative approaches for chronic pain states. However, none of these are backed by sufficient good-quality evidence to be currently recommended specifically for pain in CP.

---

## **HURDLES IN MANAGING PAIN IN CP**

---

Even though much have been understood on pain mechanisms in CP, there are still several hurdles in pain management in clinical practice. Firstly, several mechanisms might be simultaneously operating at any particular time

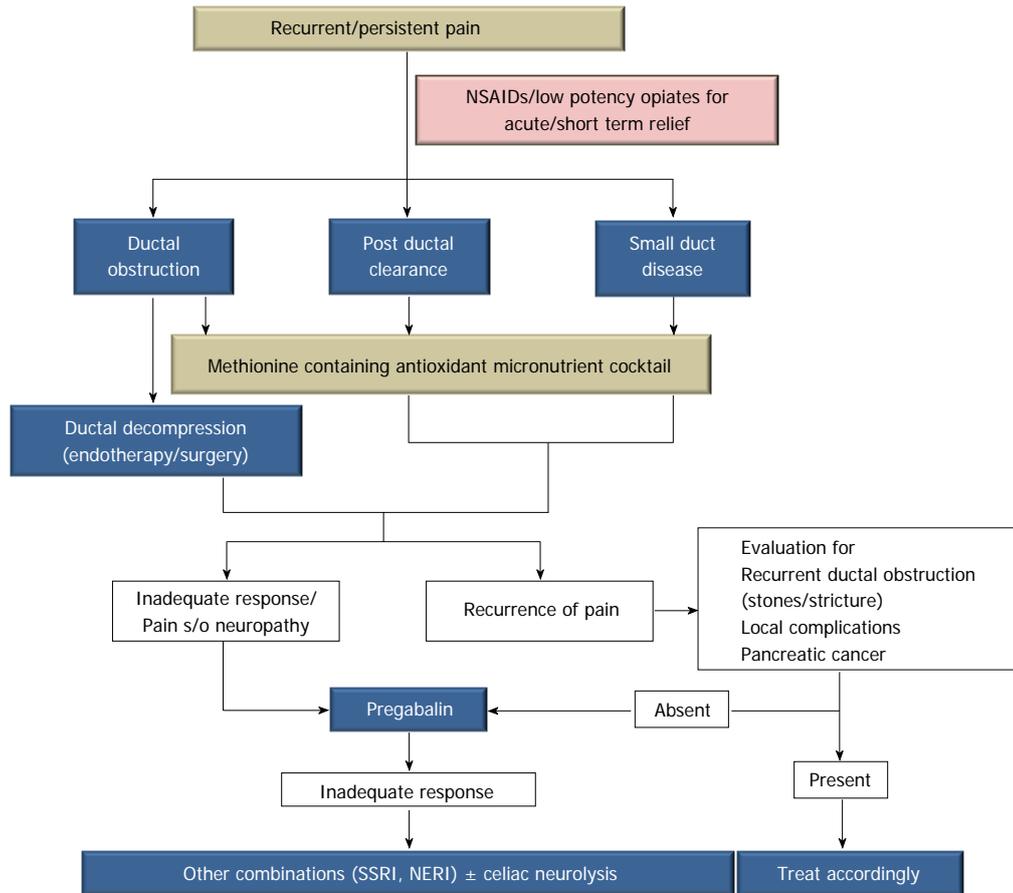

Figure 3 Management approach for recurrent and/or persistent pain in patients with chronic pancreatitis at the Asian Institute of Gastroenterology. SSRIs: Selective serotonin reuptake inhibitors; NERI: Norepinephrine reuptake inhibitor; NSAIDs: Nonsteroidal anti-inflammatory drugs.

point in a particular patient, thereby posing a question on selecting the most appropriate and optimal modality. Secondly, there are no validated objective tools that can identify the pain type, thereby precluding a fixed treatment regimen. Thirdly, there are no data to suggest an optimal duration of treatment with antioxidant and/or pregabalin in order to achieve long-term pain relief; as a result of which patients might run the risk of undertreatment or of building up excessive antioxidant micronutrients in circulation, which could impede with the physiological roles of ROS. Finally, there are no data on the efficacy or adversity of combination therapy for refractory pain.

### APPROACH TO PAIN MANAGEMENT IN CP AT ASIAN INSTITUTE OF GASTROENTEROLOGY

Figure 3 shows the treatment approach that is followed at Asian Institute of Gastroenterology. This is a composite of clinical evidence; concepts build on experimental data; and clinical experience. Methionine containing antioxidants micronutrient cocktail is started early on after the diagnosis of CP. Dose and duration of treatment is titrated according to clinical response and patient's tolerance to treatment. Patient with recurrent pain with

ductal obstruction are subjected to ductal clearance by endotherapy (ESWL with or without ERCP) or surgery (in select patients). Pregabalin is added to the regimen for patients who do not show satisfactory response to antioxidant micronutrient therapy and ductal decompression; and in those who shows clinical signs suggestive of neuropathy. In patients who have recurrence of intractable pain are evaluated for recurrence of ductal obstruction, development of local complications or cancer; and treated with additional pregabalin in the absence of these. Patients who respond sub-optimally to these regimens are treated additionally with combination of SSRI and NERI like duloxetine with or without celiac plexus block. It is important to counsel the patients thoroughly on diet and lifestyle changes like quitting alcohol and smoking all along the treatment sessions.

### CONCLUSION

Pain in CP is complex, and several independent and interdependent mechanisms may manifest simultaneously in a patient. Therefore, pain management in CP should be individualized for each patient rather than follow a fixed regimen. Recent laboratory data from human and experimental CP have opened up avenues to explore new and target specific antagonists against TRPV1, NGF, PAR2,

NK-1, CGRP and substance P.

### Abstract

Recently the European Federation of Societies for Ultrasound in Medicine and Biology Guidelines and Recommendations have been published assessing the clinical use of ultrasound elastography. The document is intended to form a reference and to guide clinical users in a practical way. They give practical advice for the use and interpretation. Liver disease forms the largest section, reflecting published experience to date including evidence from meta-analyses with shear wave and strain elastography. In this review comments and illustrations on the guidelines are given.

### INTRODUCTION

Non-invasive methods for liver stiffness (LS) assessment have been researched over decades, often mirroring the development of new drugs in the treatment of chronic liver disease. So far, two main forms of elastography have become established in clinical practice. The first is known as quasi-static or strain elastography (SE). Imaging of strain and elastic modulus distributions in soft tissues based on external tissue compression, with subsequent computation of the strain profile along the transducer axis, was first described by Ophir *et al.*<sup>[1,2]</sup>. Strain imaging can be applied to the liver by inducing probe pressure<sup>[3]</sup>. The temporal derivative of strain, *i.e.*, the strain rate, is a measure of the rate of deformation<sup>[4]</sup>. Strain Rate Imaging is a Doppler-based method that can be used to mea-

sure strain of moving tissue<sup>[5,6]</sup>. The second form is shear wave elastography (SWE). Shear waves are generated in the tissues when a directional force is applied to the tissue which causes shear deformation. Shear waves are rapidly attenuated by tissue, they travel much more slowly (between 1 and 10 m/s) and they are not supported by liquids of low viscosity<sup>[7]</sup>.

The use of different ultrasound methods to estimate liver fibrosis have been published, such as transient elastography (TE) (FibroScan<sup>TM</sup>)<sup>[8-10]</sup>, strain elastography (*e.g.*, Hitachi Aloka Medical)<sup>[11-14]</sup> and SWE using acoustic radiation force impulse (ARFI) (Siemens *et al.*)<sup>[14-16]</sup>. Other techniques including 2D-SWE (Supersonic, Siemens) and 3D-SWE (Supersonic) have since been introduced<sup>[17-19]</sup>.

Recently the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) Guidelines and Recommendations have been published assessing the clinical use of ultrasound elastography<sup>[7,20]</sup>. The document is intended to form a reference and to guide clinical users in a practical way. The guidelines also give practical advice on its use and interpretation. Liver disease forms the largest section, reflecting the published experience to date, including evidence from meta-analyses with shear wave and strain elastography. This article comments on the EFSUMB elastography guidelines, discusses the multivariate factors that have an influence on LS, and the current techniques of ultrasound elastography as well as magnetic resonance elastography (MRE).

## LS AS A DYNAMIC AND MULTIFUNCTIONAL PROCESS

LS (elasticity) is a dynamic and multifunctional process. This means that factors influencing the stiffness and elasticity of a healthy liver are different to the factors in advanced fibrosis. However, many studies have examined the grade of liver fibrosis as the sole indicator of LS<sup>[21-25]</sup> (Table 1); a few others have evaluated more factors<sup>[26-29]</sup> (Table 1).

In patients with chronic liver disease, the assessment of the patient should include age, liver-related comorbidity, aetiology and duration of the liver disease, grading (inflammation), fatty infiltration, risk of malignant transformation, fibrosis, general comorbidity and many other factors. Such factors are important as they guide management and indicate prognosis. Therefore, the assessment of liver fibrosis is only one of many other important factors to determine before treatment. However, the focus on the assessment of liver fibrosis seems to be overstated and many studies lack the design of multivariate analysis.

Factors influencing liver elasticity in healthy subjects depend mainly on blood volume and perfusion parameters that are reported by surgeons during daily routine. Studies have reported a positive correlation of LS with central venous pressure<sup>[30]</sup>, therefore knowledge of co-existing cardiac and pulmonary disease is necessary for interpretation of results.

In addition, it is also reported that food intake could

significantly increase the LS in adults<sup>[31,32]</sup>, children<sup>[33]</sup> and the patients with chronic or resolved hepatitis C virus (HCV) infection<sup>[34]</sup>, therefore, elastography should be performed in fasting conditions. However, there is controversy on the influence of respiration on LS. Yun *et al.*<sup>[35]</sup> reported that LS was significantly elevated during expiration especially in patients without liver cirrhosis while Goertz *et al.*<sup>[32]</sup> did not find differences on the LS in deep inspiration, deep expiration and during Valsalva maneuver.

In liver cirrhosis, the degree and architecture of fibrosis is presumed to be the most important factor influencing LS (elasticity). The factors influencing liver elasticity in intermediate (significant) fibrosis are still not known in detail.

The factors influencing liver elasticity in patients with inflammatory disease (at least to some degree), independent of fibrosis, are acute hepatitis, any flare of transaminase values, acute-on chronic hepatitis<sup>[36,37]</sup>, cholestasis<sup>[38]</sup> and acute liver failure<sup>[39]</sup>. In a recent study of 104 patients with chronic hepatitis B (CHB) and 453 patients within chronic hepatitis C (CHC), histological necro-inflammatory activity was found to be an independent risk factor for the overestimation of LS in HCV and hepatitis B virus (HBV), while histological steatosis was a risk factor in HCV patients only<sup>[40]</sup>.

Other factors influencing liver elasticity in patients with fatty liver (hepatic steatosis) with or without inflammatory activity, with or without fibrosis, have also been described<sup>[41-47]</sup>.

The multivariate intercorrelation of factors influencing liver elasticity under different circumstances is not known. Since multiple factors have shown to influence LS measurements, interpretation of results has to be performed taking into account all these risk factors.

## DIAGNOSIS OF LIVER FIBROSIS

### Liver biopsy

Liver biopsy (LB) has been considered the “gold-standard” for grading and follow-up of necro-inflammatory activity and staging of fibrosis for more than fifty years<sup>[48,49]</sup>.

However, substantial limitations are obvious. Firstly, it is an invasive method with a significant complication rate<sup>[50]</sup>. A review of the literature regarding possible complications has recently been published<sup>[51]</sup>. Secondly, LB has shown some sampling variability<sup>[52]</sup>. The specimen obtained by LB represents a very small part of the liver (about 1/50000) but inflammatory and fibrotic activity is known to be patchy within the liver. The sampling variability can be reduced by mini-laparoscopic guided biopsy with the ability to evaluate the liver surface<sup>[53-57]</sup>, however, it has been shown that the sampling error using mini-laparoscopic guided biopsy is still about 30%<sup>[58]</sup>. LB has also shown some intra- and inter-observer variability<sup>[58,59]</sup>. Thirdly, there is a high inter-observer variability during microscopic evaluation<sup>[58]</sup>.

Therefore, one difficulty for the evaluation of non-

Table 1 Examples of studies

Title	Comment	Ref.
Univariate approach		
Elastographic assessment of liver fibrosis in children: A prospective single center experience	Pearson's correlation	[21]
Is it better to use two elastographic methods for liver fibrosis assessment?	Spearman rank correlation	[22]
Is ARFI elastography reliable for predicting fibrosis severity in chronic HCV hepatitis?	Spearman rank correlation	[23]
Factors that influence the correlation of acoustic radiation force impulse, elastography with liver fibrosis	Spearman rank correlation	[24]
Liver stiffness measurement using acoustic radiation force impulse elastography and effect of necroinflammation	Pearson product-moment correlation	[25]
Multivariate approach		
Liver stiffness measurements in patients with different stages of non-alcoholic fatty liver disease: Diagnostic performance and clinicopathological correlation	Spearman's correlation (no attention paid to Bonferroni or alpha correction) 6 factors (higher age, serum albumin, serum AST, serum cholesterol, diabetes mellitus, LSM), LSM is the only independent predictor of advanced fibrosis (odds ratio = 1.47, 95%CI: 1.23-1.77, $P < 0.001$ )	[26]
Assessment of liver fibrosis using transient elastography in patients with alcoholic liver disease	Spearman's correlation (with Bonferroni test). In multivariate analysis including fibrosis, HAH, and steatosis, fibrosis was the only histological parameter significantly correlated with LSM	[27]
FibroScan and ultrasonography in the prediction of hepatic fibrosis in patients with chronic viral hepatitis	Pearson correlation (no attention paid to Bonferroni or alpha correction) 12 factors. Multivariate analysis showed that LSM positively correlates with hepatic fibrosis, necro-inflammatory activity and ultrasound scores	[28]
Performance of unidimensional transient elastography in staging non-alcoholic steatohepatitis	Spearman's correlation (no attention paid to Bonferroni or alpha correction) 4 factors (fibrosis, ballooning, Lobular inflammation, steatosis). Multivariate analysis found fibrosis as the only factor influencing independently liver stiffness in NASH patients	[29]

LSM: Liver stiffness measurement; HAH: Hepatic abscess of hydatid origin; AST: Aspartate aminotransferase; NASH: Non-alcoholic steatohepatitis.

invasive markers of fibrosis is the use of LB as a reference method. Taking into account the limitations of LB, a perfect non-invasive method cannot be distinguished from an unacceptable fibrosis marker. Thus a new reference marker is needed. Studies have shown that non-invasive tests for liver fibrosis with FibroTest, enhanced liver fibrosis (ELF) and TE can predict 5-10 year survival of patients with CHC<sup>[60-64]</sup>. However, more studies using liver related mortality as the endpoint are still awaited to identify the best non-invasive methods<sup>[3]</sup>.

### Serum marker of liver fibrosis

One important non-invasive method for assessment of the severity of fibrosis includes serum markers<sup>[65-68]</sup>. So far, many serum biomarkers, both direct and indirect, have been evaluated for their ability to stage liver fibrosis<sup>[69-71]</sup>. Direct serum markers, reflecting either the deposition or the removal of extracellular matrix in the liver, include: (1) collagens such as type IV collagen, procollagen III N-peptide, collagenases; (2) inhibitors of collagens such as matrix metalloproteases and tissue inhibitory metalloprotease-1; and (3) glycoproteins such as serum hyaluronate, laminin, and YKL-40. So-called indirect markers include factors that can be measured from routine blood tests, such as platelet count, prothrombin index, and aspartate aminotransferase/alanine aminotransferase (AST/ALT), which indicate alterations in hepatic function. The usefulness of these markers has been assessed mostly in patients with CHC<sup>[70-72]</sup> and hyaluronate has been the most extensively studied direct marker<sup>[73,74]</sup>. These direct and indirect markers, when

used individually, are useful for the diagnosis or the exclusion of cirrhosis but have limited accuracy for the diagnosis of clinically significant fibrosis<sup>[75]</sup>. Therefore, more sophisticated algorithms or indices combining the results of groups of markers have been developed to improve the diagnostic accuracy. The FibroTest™ (proprietary formula; Biopredictive, Paris, France) was the first algorithm that combined these data<sup>[76]</sup>. Thereafter, several other indices, such as Fibrosure™ in the United States (LabCorp, Burlington, NC, United States), the Fibrometers™ (BioLiveScale, Angers, France), the FibroSpect II™ (Prometheus Laboratory Inc., San Diego, CA, United States), the ELF™ (Enhanced Liver Fibrosis Test, iQur Ltd, Southampton, United Kingdom) and the Hepascore™ (PathWest, University of Western Australia, Australia), have been developed. They are mainly for patients with CHC<sup>[77-80]</sup>, but can also be used in patients with hepatitis B<sup>[81,82]</sup> and human immunodeficiency virus (HIV)-HCV co-infection<sup>[83,84]</sup>. Among these indices, Fibrotest has been the one most extensively studied<sup>[69]</sup>.

In a prospective cohort of 537 HCV-infected patients, Fibrotest had a 5 year prognostic value (HCV-related complications and death) similar to that of LB<sup>[61]</sup>. In a meta-analysis<sup>[85]</sup> which included 6378 subjects with both FibroTest and biopsy (3501 HCV and 1457 HBV), the mean standardized area under the receiver operator curve (AUROC) for diagnosing significant fibrosis was 0.84 (95%CI: 0.83-0.86), without differences between HCV, 0.85 (95%CI: 0.82-0.87) and HBV, 0.80 (95%CI: 0.77-0.84). ELF has been evaluated in a recently published study<sup>[86]</sup> that included 196 patients. The ELF panel

had an AUROC of 0.90 for distinguishing severe fibrosis, 0.82 for moderate fibrosis, and 0.76 for no fibrosis, and it was improved to 0.98, 0.93 and 0.84, respectively, by the addition of simple markers. The clinical utility model showed that 82% and 88% of liver biopsies could potentially be avoided for the diagnosis of severe fibrosis using ELF and the combined panel, respectively<sup>[62,64]</sup>.

### Advantages and limitations

The practical advantages of analysing serum biomarkers to measure fibrosis include their high applicability and high inter-laboratory reproducibility<sup>[87,88]</sup>. However, the direct markers of liver fibrosis are not routinely available in most hospital settings, and none of the serum markers are liver specific—their results can be influenced by comorbidity. For example, FibroTest and Hepascore produce false-positive results in patients with Gilbert's syndrome or haemolysis as these patients have hyperbilirubinaemia<sup>[89]</sup>. Similarly, acute hepatitis can produce false-positive results in the marker measuring the level of aminotransferases, such as aspartate-to-platelet ratio index (APRI), Forns index, FIB-4, or Fibrometer tests.

### Magnetic resonance elastography

In recent years, magnetic resonance elastography (MRE) has been developed as a non-invasive functional magnetic resonance imaging (MRI) method for assessing and staging liver fibrosis, using a modified phase-contrast method to image the propagation characteristics of shear waves in the liver<sup>[90,91]</sup>. Elasticity is quantified by MRE and expressed in kilopascals (kPa) using a formula that determines the shear modulus, equivalent to one-third of the Young's modulus which is estimated with TE<sup>[72,92]</sup>. So far, there is only limited data on the accuracy of MRE. Several studies<sup>[92-96]</sup> have evaluated the usefulness of MRE for the assessment of LS among patients with chronic liver disease and have shown that increased shear stiffness measured on MRE is associated with increased severity of the fibrotic process. In addition, MRE has relatively high sensitivity and specificity for predicting the stage of hepatic fibrosis. It has shown at least equivalent diagnostic performance in fibrosis staging compared with TE with fewer limitations regarding its application in patients with a large amount of ascites or who are obese<sup>[92-95]</sup>. Yin *et al.*<sup>[95]</sup> reported sensitivity of 86% and 78%, and specificity of 85% and 96%, with cut-off values of 4.89 and 6.47 kPa, respectively. Huwart *et al.*<sup>[93]</sup> showed similarly high sensitivity of 98% and 95%, and specificity of 100% and 100%, for discrimination, but lower cut-off values of 2.5 and 3.1 kPa were used. The reason for the difference in cut-off values obtained in the two studies may potentially be explained by the differently manufactured scanners used for MRE acquisition, case mixes, imaging protocols, and post-processing procedures. A meta-analysis has been recently published<sup>[97]</sup>.

### Advantages and limitations

Compared with TE, dynamic MRE has the potential

to assess larger volumes (almost the entire liver) and to provide full three-dimensional information about the viscoelastic properties of tissues<sup>[98]</sup>, moreover, due to the theoretical advantages, MRE is capable of application to patients with obesity or ascites. However, MRE cannot be performed on the liver of patients with iron overload because of signal-to-noise limitations and it is too costly and time-consuming to use in routine practice<sup>[72]</sup>.

## INTRODUCTION TO ULTRASOUND ELASTOGRAPHY

### TE

TE (FibroScan<sup>®</sup>) was the first tool introduced for routine clinical use (Echosens, Paris, France) (Figure 1). TE does not display a conventional ultrasound image. TE has been mainly evaluated in patients with chronic viral hepatitis C and also in a few patients with HIV/viral hepatitis C co-infection and some other liver diseases (see below)<sup>[99]</sup>.

### Technique

**Basic principles:** TE is an ultrasound-based non-invasive method. It is characterized by the material's strain response to external stress according to the principle of Hooke's law<sup>[9]</sup>. Briefly, an ultrasound transducer probe is mounted on the axis of a vibrator. Vibrations of mild amplitude and low frequency (50 Hz) are transmitted by the transducer from a right intercostal space, inducing an elastic shear wave that propagates through the liver. Pulse-echo ultrasound acquisition is used to follow the propagation of the shear wave and to measure its speed. This speed is proportional to the tissue stiffness, with faster wave progression occurring through stiffer material. The elastic modulus  $E$  is expressed as  $E = 3qV^2$ , where  $V$  is the shear wave speed and  $q$  is the material density (assumed constant for tissues): the stiffer the tissue, the faster the shear wave propagates<sup>[100]</sup>. TE measures LS in a cylindrical volume approximately 10 mm wide and 40 mm long, between 25 and 65 mm below the skin surface with the standard M-probe, and between 35 and 75 mm for the recently developed XL probe, recommended for obese patients<sup>[101,102]</sup>. This volume is at least 100 times bigger than a biopsy sample and it has been suggested, therefore, that the results compared to LB are more representative of the hepatic parenchyma. However, TE does not work for the left liver lobe or from a subcostal approach and the measurement is only feasible *via* a few intercostal spaces. Therefore, the technique is limited. Inter- and intra-observer variability depend on the intercostal space used, the presence of ascites, musculoskeletal habitus, depth of subcutaneous tissue, position of the patient, and many other factors<sup>[47,103]</sup>.

**How to perform?** The measurements with FibroScan<sup>®</sup> are taken from the right liver lobe *via* an intercostal space, while the patient lies flat on his/her back, with the right arm tucked behind the head to facilitate access to the liver parenchyma. The tip of the probe is covered with

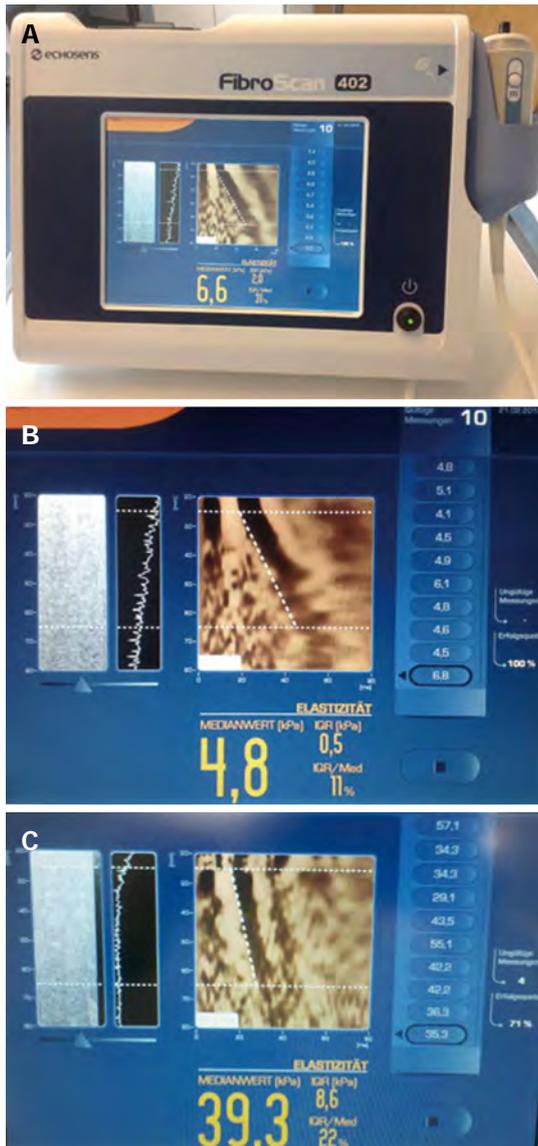

Figure 1 Transient elastography (FibroScan<sup>®</sup>, A) for the evaluation of normal liver (B) and liver cirrhosis (C).

coupling gel and placed on the skin between the ribs at the level of the right lobe where LB would be performed. Once the measurement area has been located, the operator presses the probe button (shot) to start an acquisition. When a shot is unsuccessful, the machine does not give a reading. Measurement of LS is measured in kilopascals (kPa) (range is between 2.5 and 75 kPa)<sup>[100]</sup>.

**Advantages:** TE with FibroScan<sup>®</sup> is a rapid procedure (less than 5 min), painless, and easy to perform even in the outpatient clinic or at the bedside. The results are immediately available<sup>[103]</sup>. The examination can be performed by a nurse after a short learning curve (about 100 examinations)<sup>[104]</sup>. In addition, TE analysis has excellent inter- and intra-observer agreement, which makes it suitable for widespread application in clinical practice<sup>[103,105,106]</sup>.

**Limitations:** TE provides only a regional elasticity measurement (determined by the width of the ultrasound beam and depth of the shear wave penetration), but no anatomical images or elastograms. Other drawbacks include limited depth (several cm), the inability of the shear wave to propagate beyond fluid collections (ascites) and difficulty in obtaining sufficient signal in obese patients. Recently, a new probe (XL probe; Echosens, Paris, France) has been proposed for overweight and obese patients<sup>[107]</sup>, and a so-called S-probe has been developed for patients with narrow intercostal spaces, especially children<sup>[108]</sup>. However, it remains impossible to obtain TE results from patients with ascites<sup>[105]</sup>.

The validity of the TE result also depends on two important parameters: (1) the success rate (the ratio of the number of successful measurements to the total number of acquisitions) should be at least 60%; and (2) the interquartile range (IQR), which reflects the variability of the validated measurements, should not exceed 30% of the median value<sup>[109]</sup> (Figure 1). Both the feasibility and reproducibility of the TE measurement may be affected by high body mass index (BMI). In a study with 13369 TE measurements, a failure rate of 3.1% was reported. Unreliable results were reported in 15.8% of measurements and were associated with a BMI > 30 kg/m<sup>2</sup>, age > 52 years, female sex, operator experience and type 2 diabetes<sup>[47]</sup>.

The clinical interpretation of TE results should always be made by an expert clinician and with reference to the patient's history, disease aetiology and essential laboratory parameters Castera *et al*<sup>[110]</sup>.

**Intra- and inter-observer variability:** Several studies<sup>[103,105,106]</sup> have shown that the intra- and inter-observer reproducibility of TE measurements are good, at least in non-obese subjects. In the study by Sandrin *et al*<sup>[105]</sup> intra- and inter-observer variation in TE was investigated in 15 patients and was around 3%, but with a wide variation (2%-18%). The sample size of this study was small, and therefore inadequate to draw firm conclusions on host- and disease-related co-variables that may interfere with TE performance. Another study by Fraquelli *et al*<sup>[103]</sup> with a larger sample obtained similar results; 800 TE examinations were performed by two operators in 200 patients with various chronic liver diseases. Both inter- and intra-observer agreement was high and TE reproducibility was excellent, with an intraclass correlation coefficient (ICC) of 0.98. However, inter-observer agreement was significantly reduced in patients with mild hepatic fibrosis, and hepatic steatosis.

The probe location during the TE measurement may affect its reproducibility. In a recent study<sup>[111]</sup> TE was performed on 625 consecutive patients with chronic liver disease at three different sampling sites. Sampling variability according to probe location was seen in approximately 30% of patients and it was suggested that TE should be performed from various sites to minimize the sampling error.

### Review of the literature

**Chronic viral hepatitis:** For patients with CHC, LS values  $> 6.8$ - $7.6$  kPa are indicative of significant fibrosis ( $F \geq 2$ ) using the gold standard of LB, and the cut-off values for predicting complete cirrhosis ( $F = 4$ ) range between 11.0 and 13.6 kPa<sup>[20,112,113]</sup>. TE is able to distinguish mild fibrosis from advanced liver fibrosis and cirrhosis, which is important for decision making<sup>[114]</sup>. In contrast, TE does not allow differentiation between the contiguous stages of liver fibrosis. In a meta-analysis including 40 studies<sup>[114]</sup>, the pooled sensitivity and specificity of TE was 79% and 78% for the diagnosis of significant fibrosis; 82% and 86% for diagnosing severe fibrosis; and 83% and 89% for the diagnosis of liver cirrhosis.

It might be of interest to remember that conventional ultrasound techniques can also distinguish between liver cirrhosis and early liver disease in approximately 70% of patients with high specificity but low sensitivity<sup>[115-124]</sup>. However, TE had an acceptable diagnostic accuracy for detecting early compensated cirrhosis in patients with CHB who did not fulfil the clinical and ultrasound criteria for cirrhosis<sup>[125]</sup>. Conventional ultrasound techniques are helpful in the detection of complications of liver cirrhosis including portal hypertension<sup>[126,127]</sup> and can also give important information about fatty infiltration<sup>[128-132]</sup> and inflammation<sup>[133-136]</sup>. In a study with 90 patients with suspected liver cirrhosis, liver surface nodularity on conventional ultrasound and TE showed comparable results for diagnosis and exclusion of liver cirrhosis, with the best results when both methods were combined. Liver surface nodularity was better for the diagnosis of liver cirrhosis, while TE was better at ruling out cirrhosis<sup>[137]</sup>.

The performances of TE, when compared, have been shown to be similar between patients with HBV and HCV<sup>[138]</sup>. Several studies have investigated the performance of TE in an Asian population with CHB<sup>[125,139-144]</sup> and concluded that TE is a promising and accurate tool for the early detection of cirrhosis. It is demonstrated that the optimal cut-off values for diagnosing HBV-related cirrhosis were between 9.0 and 10.1 kPa in the Asian population<sup>[125,140,142,145]</sup>, which is lower than that in patients with CHC<sup>[146,147]</sup>. Since there is an increasing number of evidence on the usefulness of TE in patients with CHB, especially in the Asian population, TE should also be recommended in patients with CHB, though the evidence is more limited compared to CHC. Future and updated guidelines have to include this recommendation.

It would be interesting to know in what percentage of patients TE can give important additional information which is of relevance to the treatment, over and above sophisticated ultrasound technology in the hand of an expert hepatologist<sup>[43,148]</sup>.

### EFSUMB recommendations

TE can be used to assess the severity of liver fibrosis in patients with chronic viral hepatitis, provided that confounding factors are taken into account, and especially to distinguish patients with nil/mild fibrosis from those with

significant fibrosis, and to identify those with cirrhosis. TE is useful for assessment of liver fibrosis in patients with non-alcoholic fatty liver disease (NAFLD), alcoholic liver diseases, and in patients co-infected with HIV and HCV. Other types of chronic liver disease might also have been investigated, but the evidence is more limited. TE is useful for assessment of liver fibrosis in patients with post-transplant recurrence of CHC. TE has some value for predicting the occurrence of complications of liver cirrhosis, portal hypertension, hepatocellular carcinoma (HCC) and liver-associated mortality. It cannot replace upper gastrointestinal endoscopy for identifying patient with varices<sup>[20]</sup>.

## POINT SHEAR WAVE ELASTOGRAPHY WITH ACOUSTIC RADIATION FORCE IMPULSE IMAGING

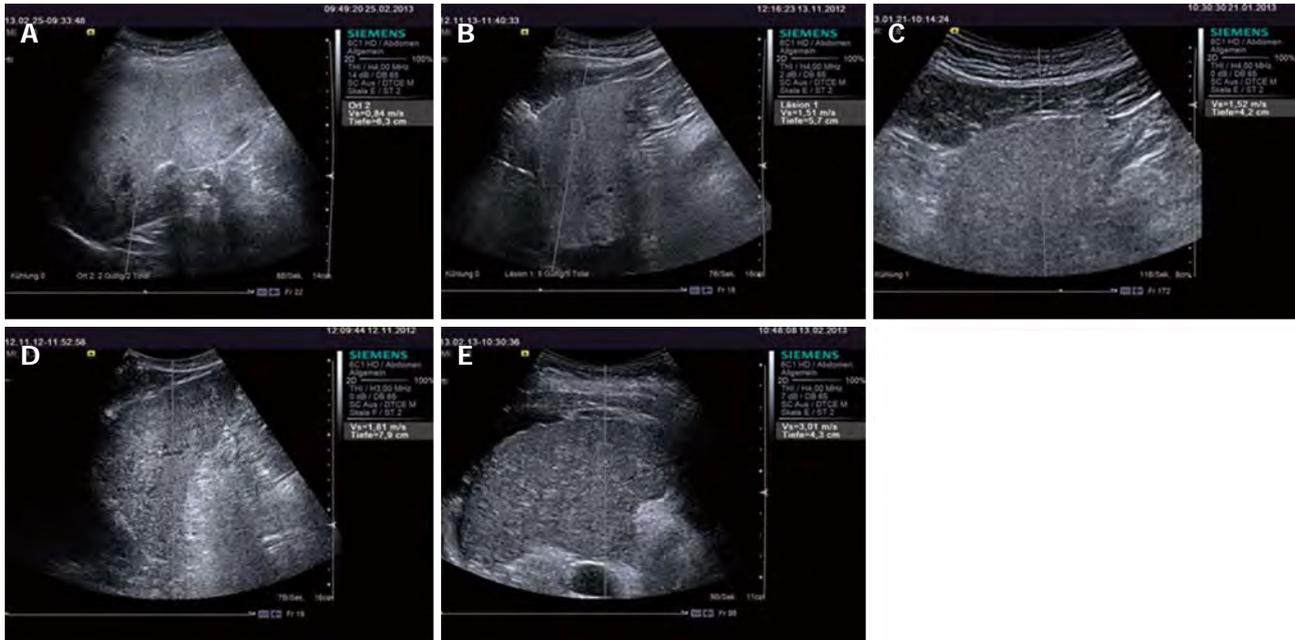

Point shear wave elastography (pSWE) has been introduced by different companies, each currently at different stages of development<sup>[7,20]</sup>. Acoustic radiation force impulse (ARFI) was the second method to be introduced as a tool for liver fibrosis assessment in a clinical setting. ARFI has a significant advantage over TE in that it simultaneously displays a conventional ultrasound image. The accuracy of both methods has been shown to be similar in the differentiation of normal liver parenchyma from liver cirrhosis<sup>[15,149,150]</sup>. ARFI has been mainly evaluated in patients with chronic viral hepatitis C and in a few other liver diseases.

### Technique

**Basic principles:** ARFI quantification has been developed by two companies (Siemens and Philips) according to the guidelines<sup>[7,20]</sup>, almost all reported studies were done with a conventional high-end ultrasound machine (Siemens S2000). It uses a region of interest (ROI) cursor to interrogate the elastic properties of a specific anatomic region, while real-time B-mode imaging of the abdomen being performed. Short-duration acoustic pulses with a fixed transmit frequency of 2.67 MHz, are generated in the vicinity of the ROI and the subsequent mechanical excitation of the tissues results in tissue displacement and the formation of shear waves that propagate away from the region of excitation. Ultrasound tracking beams laterally adjacent to the single push-beam are used to estimate the shear wave speed in the tissue by the measurement of the time to peak displacement at each lateral location<sup>[151]</sup>. The shear wave speed is estimated in the central window 5 mm long by 4 mm wide within a graphically displayed ROI of size 10 mm long by 6 mm wide. The results are expressed in meters per second (m/s) (range: 0.5-4.4 m/s with  $\pm 20\%$  accuracy over the range), the shear wave propagation speed being proportional to the square root of the tissue elasticity<sup>[152,153]</sup>. The ARFI imaging examination takes approximately 5 min. Unlike FibroScan<sup>®</sup>, ARFI can be utilized in patients with ascites. No limitations

**Table 2 Mean shear wave velocities (VirtualTouch values) of the left and right liver lobes (mean  $\pm$  SD)**

Ref.	n	Subjects	Left lobe (m/s)	Right lobe (m/s)
Karlas <i>et al.</i> <sup>[158]</sup>	50	Healthy individuals	1.28 $\pm$ 0.19	1.15 $\pm$ 0.17
Karlas <i>et al.</i> <sup>[158]</sup>	23	Patients with F1, F2 fibrosis	2.1 $\pm$ 0.73	1.75 $\pm$ 0.89
Toshima <i>et al.</i> <sup>[159]</sup>	103	24 healthy volunteers, 79 patients with chronic liver disease	1.90 $\pm$ 0.68	1.61 $\pm$ 0.51
Piscaglia <i>et al.</i> <sup>[157]</sup>	14	Healthy individuals	1.29 (1.00-1.60)	1.15 (0.80-1.74)
Piscaglia <i>et al.</i> <sup>[157]</sup>	114	Patients with chronic liver disease	1.79 (0.80-4.00)	1.67 (0.45-3.76)

**Figure 2** Point-shear wave elastography with acoustic radiation force impulse for the evaluation of histologically proved liver fibrosis and cirrhosis. A: F0; B: F1; C: F2; D: F3; E: F4 = cirrhosis.

concerning measurement are known<sup>[154]</sup>.

**Tips and tricks:** When scanning the right lobe (especially segment VIII), an optimal window should be used. To reduce the variance of the measurement, it is recommended to apply minimal scan pressure and for the patient to minimize breathing, the influence of cardiac motion should also be avoided. In general, the best and most consistent results will occur when the “normal” state of the liver is measured. When scanning intercostally, no pressure should be applied to the liver and the patient should be asked to just stop breathing for a moment (instead of deep inspiration and breath hold).

In difficult patients, several measurement attempts are needed to “average” out the readings, and data that varies significantly should be excluded. It is recommended to put the patient in a left lateral decubitus position with right arm behind the head in order to get better access to the liver without excessive pushing or the need for breath holds<sup>[155]</sup>. However, it may still not be possible to get reliable readings in 5.3 % of patients<sup>[156]</sup>.

**Intra- and inter-observer variability:** Reproducibility of ARFI is also an important pre-requisite for its widespread application in clinical practice. Good inter-observer vari-

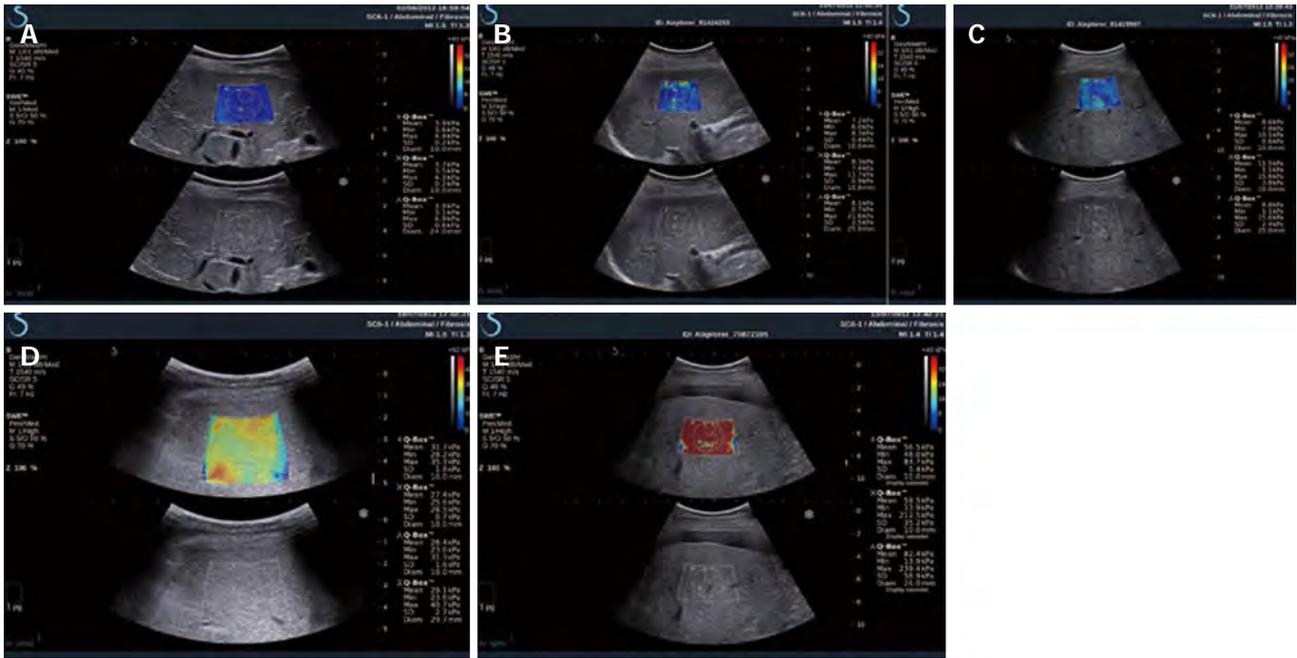

ability has been reported<sup>[157]</sup>. Since ARFI allows different measurement sites, comparison of measurements in the right and left liver lobes have been made, and have shown a trend toward higher values in the left lobe<sup>[157-159]</sup>. However, results in the right lobe revealed higher diagnostic accuracy compared to the left (AUROC: for diagnosis of F1, F2, F3, F4, right lobe: 0.92; 0.83; 0.86; 0.80; left lobe: 0.77; 0.71; 0.78; 0.84; sensitivity, specificity, positive predictive value and negative predictive value of right lobe: 0.88; 0.81; 0.74; 0.92; left lobe: 0.80; 0.75; 0.87; 0.68)<sup>[159]</sup> (Table 2).

### Clinical applications

**Chronic viral hepatitis:** In patients with significant fibrosis ( $F \geq 2$ ) the ARFI cut-off values published have been between 1.21-1.34 m/s (AUROCs 0.85-0.89)<sup>[23,149,150]</sup> and in patients with cirrhosis, 1.55-2 m/s (AUROC's 0.89-0.93)<sup>[15,23,149,160]</sup> (Figure 2). Similar to TE, SWE has not proved accurate enough to distinguish between contiguous stages of fibrosis<sup>[20]</sup>.

**Other liver diseases:** ARFI has also been evaluated in patients with NAFLD and NASH<sup>[161,162]</sup> and in patients after liver transplantation<sup>[163]</sup>.

**Meta-analysis:** Friedrich-Rust *et al.*<sup>[154]</sup> published a meta-

**Figure 3** 2D-shear wave elastography with supersonic shear imaging for the evaluation of histologically proved liver fibrosis and cirrhosis. A: F0; B: F1; C: F2; D: F3; E: F4 = cirrhosis.

analysis which included 9 studies with a combined total of 518 patients with chronic liver disease and evaluated the diagnostic performance of ARFI imaging for the staging of liver fibrosis. The diagnostic accuracy of ARFI quantified by the AUROC was 87% for predicting significant fibrosis ( $F \geq 2$ ), 91% for the diagnosis of severe fibrosis ( $F \geq 3$ ) and 93% for the diagnosis of liver cirrhosis. The meta-analysis revealed good diagnostic accuracy for ARFI in the diagnosis of significant liver fibrosis and excellent diagnostic accuracy for the diagnosis of liver cirrhosis.

It was also shown that a comparison of ARFI with TE in the four studies that included 312 patients, resulted in comparable diagnostic accuracies for both methods in the diagnosis of severe fibrosis, and slightly, but significantly, higher diagnostic accuracies of TE for the diagnosis of significant fibrosis and liver cirrhosis. However, a recent study showed superior results for ARFI elastography<sup>[150]</sup>. Future multicentre studies are necessary to compare the different methods before any conclusions can be drawn.

#### Advantages and limitations

In contrast to TE, ARFI has been shown to be less influenced by obesity and ascites<sup>[151]</sup>. One study showed that valid LS measurement (LSM) were obtained in all 23 patients with morbid obesity (mean BMI was higher than  $44 \text{ kg/m}^2$ )<sup>[164]</sup>. In addition, it can be easily added to a commercial ultrasound machine.

However, in contrast to TE values, ARFI values have a narrow measurement range (0.5-4.4 m/s), which limits the definition of cut-off values required for decisions on patient management. In addition, inflammatory activity

and elevated aminotransferase levels may lead to overestimation of ARFI-LS values<sup>[15,25]</sup> as has been shown for TE. Moreover, since this is a new technique, the quality criteria are not yet well-defined.

#### EFSUMB recommendations

pSWE with ARFI can be used to assess the severity of liver fibrosis in patients with chronic viral hepatitis, especially with hepatitis C. pSWE with ARFI is promising for liver fibrosis assessment in patients with NAFLD, and post-transplant patients<sup>[7,20]</sup>.

## 2D SWE

SWE [Aixplorer<sup>®</sup>, SuperSonic Imagine (SSI), France] has been introduced as a 2D and also 3D-technique. So far, only 2D-SWE has been evaluated in studies on the liver. The studies of 3D-SWE have mainly focused on the breast<sup>[165,166]</sup>.

#### Technique

This technique is based on the combination of a radiation force induced in the tissues by focused ultrasonic beams and very high frame rate (up to 5000 f/s) ultrasound imaging capable of catching, in real time, the transient propagation of the resulting shear waves<sup>[167,168]</sup>. The local shear wave speed is recovered using a dedicated time-of-flight estimation technique and enables the 2-D quantitative mapping of elasticity. This imaging modality can be performed using a conventional ultrasound probe, during a standard intercostal ultrasound examination. Three supersonic shear wave imaging sequences are applied successively to the left, middle and right parts of

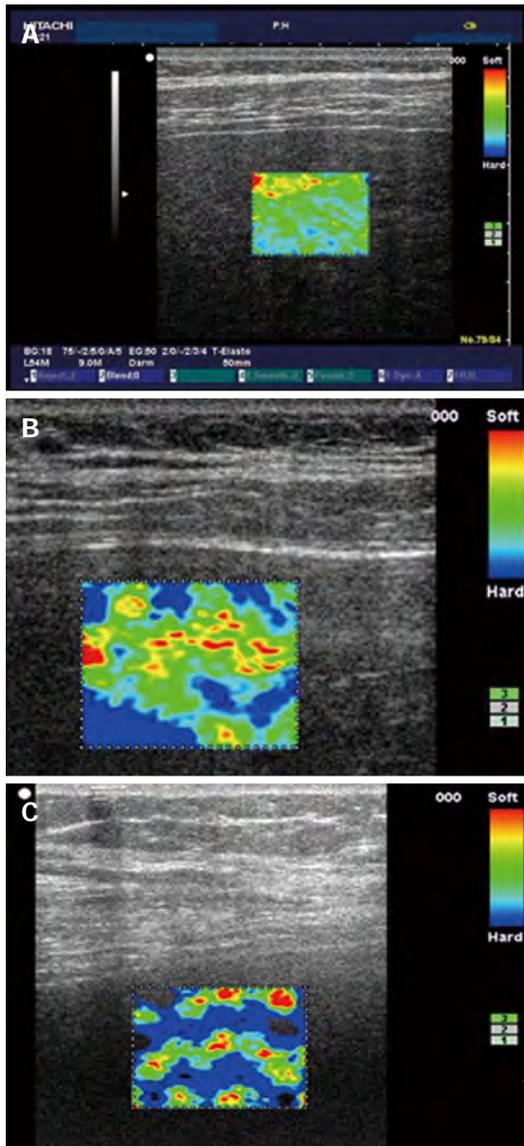

Figure 4 Strain elastography for the evaluation of histologically proved liver fibrosis and cirrhosis. A: F0; B: F2; C: F4 = cirrhosis.

the 2-D ultrasound image. The resulting elasticity images in the three regions are concatenated to provide the final image covering the entire region-of-interest. The ability of the SWE technique to provide a quantitative and local estimation of liver shear modulus with a millimetric resolution has been proven in a pilot study in 15 healthy volunteers<sup>[18]</sup>. Liver moduli extracted from *in vivo* data from healthy volunteers, were consistent with those reported in the literature (Young's modulus ranging from 4 to 7.5 kPa). Moreover, LSM using the SWE mode was fast (less than one second), repeatable (5.7% standard deviation) and reproducible (6.7% standard deviation)<sup>[3]</sup>.

**Intra- and inter-observer variability:** To date, there has only been one study<sup>[169]</sup> aimed at assessing the intra- and inter-observer precision of 2D-SWE measurements in the evaluation of liver elasticity. It was reported that the

reproducibility was good with high intra- and inter-observer agreement. In this study, 2D-SWE was performed on 60 volunteers (42 cases with 10 consecutive measurements, 18 cases with 2 measurements) on 2 different days by 2 operators (one expert and one novice). The intra-observer agreement between measurements performed in the same subject on the same day (day 1 or day 2) showed intraclass correlation coefficient (ICC) values of 0.95 and 0.93 for the expert operator and novice, respectively, and the ICC values for intra-observer agreement between measurements performed in the same subject on different days were 0.84 and 0.65, respectively. The inter-observer agreement was 0.88. Therefore, real-time 2D-SWE has been shown to be a reproducible method to measure liver elasticity, but the novice operator showed lower measurement reproducibility over time than the expert operator.

### Clinical application

**CHC:** 2D-SWE might be used in assessing liver fibrosis for patients with CHC, as has been proved in two large studies. Ferraioli *et al.*<sup>[170]</sup> assessed the accuracy of 2D-SWE in comparison with transient elastography in 121 patients with CHC using LB as the reference standard, and found that LS values increased in parallel with the degree of liver fibrosis both with 2D-SWE and TE. The AUROC was 0.92 for 2D-SWE and 0.84 for TE ( $P = 0.002$ ); 0.98 for 2D-SWE and 0.96 for TE ( $P = 0.14$ ); 0.98 for 2D-SWE and 0.96 for TE ( $P = 0.48$ ), when comparing F0-F1 *vs* F2-F4, F0-F2 *vs* F3-F4, and F0-F3 *vs* F4, respectively (Figure 3). Therefore, the real-time 2D-SWE was more accurate than TE in assessing significant fibrosis ( $\geq F2$ ). In the other study which included 113 hepatitis C virus patients, a good agreement was shown between 2D-SWE and TE, the AUROC for elasticity values assessed by 2D-SWE were 0.948, 0.962 and 0.968 for patients with predicted fibrosis levels  $F \geq 2$ ,  $F \geq 3$  and  $F = 4$ , respectively. However, LB was only available in 39 patients<sup>[17]</sup>.

### EFSUMB recommendations

2D-SWE can be used to assess the severity of liver fibrosis in patients with chronic viral hepatitis, especially with hepatitis C<sup>[7,20]</sup>.

## STRAIN ELASTOGRAPHY

Strain elastography (SE), also termed as quasi-static strain imaging, has been developed by several manufacturers, however, only Hitachi ultrasound system has been evaluated for use in liver.

### Technique

SE is based upon the fact that soft tissue can be more easily compressed than hard tissue. When subtle compression is applied with probe, SE shows the relative degree of tissue strain, but not demonstrates the physical elasticity directly. SE calculates the strain response of the tissue

**Table 3** Advantages and disadvantages of non-invasive methods to evaluate liver fibrosis

Parameters	Transient elastography	ARFI	2D-SWE	MR Elastography	Serum biomarkers
Advantages	High and rapid performance Reproducibility Easy to learn	High and rapid performance Reproducibility Easy to learn	High and rapid performance Reproducibility Easy to learn, large ROI	High performance (applicability) Reproducibility Examination of the whole liver	Availability Reproducibility Low cost
Disadvantages	Technical requirements (equipment) without additional use Intermediate cost Limited recognition of intermediate stages of fibrosis Blind selection of region of interest Restricted value in obese patients and ascites False positive values in patients with acute hepatitis, cholestasis, and heart failure	Combined with conventional ultrasound Obesity and ascites are not limiting Technical requirements (ultrasound equipment) Intermediate cost Limited recognition of intermediate stages of fibrosis Narrow range of values, small ROI Quality criteria not well defined	Combined with conventional ultrasound Ascites are not limiting Technical requirements (ultrasound equipment) Intermediate cost Limited recognition of intermediate stages of fibrosis Quality criteria not well defined	Combined with conventional MRI obesity and ascites are not limiting Technical requirements (MRI equipment) Extremely high cost, time consuming Limited recognition of intermediate stages of fibrosis Not applicable in case of iron deposition	Non-specific (hyperbilirubinemia, hemolysis, inflammation, others) Relatively high cost, limited availability (patent) Limited recognition of intermediate stages of fibrosis Results not immediately available

ARFI: Acoustic radiation force impulse; SWE: Shear wave elastography; ROI: Region of interest; MRI: Magnetic resonance imaging.

to stress (relative tissue elasticity) and displays it as a colour overlay [ranges from red (soft) to blue (hard)] on the B-mode image<sup>[171]</sup>. The echo signals could be captured in real-time by incorporating a high speed algorithm, in addition, both the B-mode image and corresponding tissue elasticity image could be simultaneous displayed<sup>[172]</sup>. Semi-quantitative elastography techniques are based on quantification of the strain distribution within a defined ROI.

Because the pressure generated by the operator's compression may influence both the image of elasticity and the resulting elasticity score, Hitachi medical system has recently developed an elastography method that did not require extra external stress. The required liver distortion for future analysis would be achieved from the rhythmic pulsations of the abdominal aorta or the heart.

### Clinical application

In 2007, Frederich-Rust *et al*<sup>[111]</sup> reported the clinical application of SE in the liver. They developed an elasticity score by assessing the colour-coded strain image using the computer program Matlab. The diagnostic accuracy for F2, F3 and F4 were 0.75, 0.73 and 0.69, respectively. In 2009, the same group<sup>[173]</sup> compared SE with TE (Fibroscan) and serum fibrosis marker (Fibrotest), and concluded that SE in its evaluated format could not replace TE for non-invasive assessment of liver fibrosis at the time of the study. After the software for elastography was developed by Hitachi medical systems, good results were published by several studies. Morikawa *et al*<sup>[174]</sup> transferred the pixel data in the ROI into a histogram and a binary

image for semi quantification with a devised system, and found that the mean value on the histogram and the percentage of hard tissue may directly represent liver elasticity. The diagnostic accuracy of SE for liver fibrosis was also compared with TE, the author felt SE compared favourably with TE and suggested SE could potentially be used as a routine imaging tool to evaluate liver fibrosis. A Chinese group<sup>[175]</sup> utilized a new Hitachi ultrasound system (HI VISION Preius) and concluded that there was a strong positive correlation ( $r = 0.81$ ) between the elasticity index and fibrosis stage. Diagnostic accuracies of SE for the diagnosis of F1, F2, F3, F4 were 0.93, 0.92, 0.84 and 0.66, respectively. Koizumi *et al*<sup>[176]</sup> performed a semi-quantitative analysis using the elastic ratio method (ratio of strain distribution in two selected ROI) on 70 patients with CHC and with the hepatic vein as the internal control and found that the AUROC curves for elastic ratio were superior to serum fibrosis markers and scores of fibrotic change based on blood results (Figure 4).

More studies including meta-analysis about the use of SE for the evaluation of liver fibrosis are required to establish a protocol for accurate imaging and to standardize analysis.

### Advantages

The main advantage of this technique is the relatively large region of interest that can be interrogated in the right liver lobe, plus the quantification method that can measure the change from the diffuse soft uniform architecture of the liver to a patchy hard pattern as hepatic

fibrosis progresses.

**Intra- and inter-observer reproducibility**

The intra-observer variability and intra-observer agreement of SE for the assessment of liver fibrosis have been criticized in several studies<sup>[173,177,178]</sup>. In a more recent study, a Japanese group<sup>[176]</sup> used a semi-quantitative method (elastic ratio) and found that the measurements obtained from four separate locations had no observed variation between the two operators ( $K = 0.835$ ,  $ICC = 0.966$ ).

**EFSUMB recommendations**

The evidence with this approach is still too limited to allow recommendation for its clinical use, at least in European patients<sup>[7,20]</sup>.

**ADVANTAGES AND DISADVANTAGES OF CURRENT NON-INVASIVE METHODS IN EVALUATING LIVER FIBROSIS**

Advantages and disadvantages of currently available non-invasive methods in patients with chronic viral hepatitis C are summarized in Table 3.

**ELASTOGRAPHY FOR DETECTION AND CHARACTERIZATION OF FOCAL LIVER LESIONS**

Elastography methods have been also applied for detection and characterisation of focal liver lesions (FLL).

Although the method so far cannot be applied to all segments and the limited depth of penetration is so far disappointing, several studies have evaluated the performance of ARFI to differentiate FLL, and the results are encouraging. ARFI has shown a high accuracy for the identification of malignant FLL. In a meta-analysis by Ying *et al.*<sup>[179]</sup> including 590 lesions in eight studies, the summary sensitivity and specificity for identification of malignant liver lesions were 0.86 and 0.89, respectively. The hierarchical summary receiver operating characteristic (HSROC) was 0.94. However, one paper showed that ARFI did not permit differentiation between benign and malignant FLL because high ARFI values occur in benign as well as in malignant lesions<sup>[180]</sup>. In another study by Gallotti A, the mean shear wave speed of HCC, haemangioma, adenoma, metastasis, FNH was 2.17, 2.30, 1.25, 2.87, 2.75 m/s, respectively. Adenoma showed similar stiffness to the surrounding liver, and was significantly softer than the other four types of lesion. FNH showed different stiffness to HCC and metastasis, however, haemangioma showed no difference to HCC, metastasis and FNH<sup>[181]</sup> (Figures 5 and 6). The performance of ARFI is summarized in Table 4.

#### EFSUMB recommendations

Although promising results have been reported, more research is needed, especially in comparison to CEUS, before recommendations on its use in clinical practice can be made. So far, elastography cannot be recommended for the differential diagnosis of benign from malignant liver lesions<sup>[7,20]</sup>.

### Abstract

Iatrogenic bile duct injuries (IBDI) are still a challenge for surgeons. The most frequently, they are caused by laparoscopic cholecystectomy which is one of the commonest surgical procedure in the world. Endoscopic techniques are recommended as initial treatment of IBDI. When endoscopic treatment is not effective, surgery is considered. Different surgical biliary reconstructions are performed in most patients in IBDI. Roux-Y hepaticojejunostomy is the commonest biliary reconstruction for IBDI. In some patients with complex IBDI, hepatectomy is required. Recently, Li *et al* analyzed the factors that had led to hepatectomy for patients with IBDI after laparoscopic cholecystectomy (LC). Authors concluded that hepatectomy might be necessary to manage early or late complications after LC. The study showed that proximal IBDI (involving hepatic confluence) and IBDI associated with vascular injuries were the two independent risk factors of hepatectomy in this series. Authors distinguished two main groups of patients that require liver resection in IBDI: those with an injury-induced liver necrosis necessitating early intervention, and those in whom liver resection is indicated for treatment of liver atrophy following long-term cholangitis. In this commentary, indications for hepatectomy in patients with IBDI are discussed. Complex biliovascular injuries as indications for hepatectomy are presented. Short- and long-term results in patients fol-

lowing liver resection for IBDI are also discussed. Hepatectomy is not a standard procedure in surgical treatment of IBDI, but in some complex injuries it should be considered.

### COMMENTARY ON HOT TOPICS

I have read with great interest the recent article Li *et al*<sup>[1]</sup> analyzing the factors that had led to hepatectomy for patients with bile duct injuries after laparoscopic cholecystectomy (LC). I would strongly recommend this article to the readers.

Iatrogenic bile duct injuries (IBDI) are still a chal-

lenge for surgeons. The most frequently, they are caused by laparoscopic cholecystectomy which is one of the commonest surgical procedure in the world<sup>[2,3]</sup>. The early and proper diagnosis of IBDI is very important for surgeons and gastroenterologists, because unrecognized IBDI lead to serious complications such as biliary cirrhosis, hepatic failure and death<sup>[3,4]</sup>. Endoscopic techniques are recommended as initial treatment of IBDI. When endoscopic treatment is not effective, surgery is considered. Different surgical biliary reconstructions are performed in most patients in IBDI. Roux-Y hepaticojejunostomy is the commonest biliary reconstruction for IBDI. However, in some patients with complex IBDI, hepatectomy is required. Complex IBDI involve disruption of hepatic confluence and injuries associated with concomitant vascular damage<sup>[1,5]</sup>. The incidence of arterial injury in patients in IBDI ranges between 12% and 47%<sup>[6,7]</sup>. Distal IBDI are accompanied by damage of axial arteries (10%-15%) and proximal IBDI are usually associated with damage of the proper hepatic artery and its branches (most frequently right hepatic artery) (40%-60%)<sup>[2,6]</sup>. The incidence of complex biliovascular injuries has risen since the introduction of LC<sup>[8]</sup>. According to Li *et al*<sup>[1]</sup>, most complex IBDI such as Strasberg types E4 and E5 IBDI, either as an isolated condition or in combination with injury to vascular structures, can be effectively repaired by Roux-Y hepaticojejunostomy. However, in some patients with liver necrosis or lobar atrophy and fibrosis, hepatectomy is required<sup>[1]</sup>.

In their study, Li *et al*<sup>[1]</sup> analyzed the medical records of 76 patients who had received surgery for IBDI following LC from April 1998 to September 2007. Hepatectomy was performed in 10 of 76 patients (13.2%), with IBDI either as isolated damage or in combination with vascular injury (VI). Proximal IBDI (defined as disruption of the biliary confluence) and injury to the right hepatic artery were found to be independent risk factors of hepatectomy. When both injuries occurred, 72.7% (8/11) of their referred patients required hepatectomy. Five patients required early liver resection (within 5 wk post-LC) to control sepsis caused by confluent liver necrosis or bile duct necrosis. In five patients, hepatectomy was indicated during long-term follow-up (over 4 mo post-LC) to effectively manage recurrent cholangitis and liver atrophy. Based on their own observation, authors distinguished two groups of patients with IBDI that require hepatectomy: those with an injury-induced liver necrosis necessitating early intervention, and those in whom liver resection is indicated for treatment of liver atrophy following long-term cholangitis.

Another interesting aspect of this study is analysis of short- and long-term results in 10 patients undergoing hepatectomy. Authors noted high postoperative morbidity (60%) and mortality (10%), and satisfactory long-term results (with median follow-up of 34 mo) with either no or only transitory symptoms in 67% of the patients<sup>[1]</sup>.

There are a number of publications regarding the

use of hepatectomy in surgical treatment of complex IBDI<sup>[5,22]</sup>. Hepatectomy is one of therapeutic possibilities in patients with complex IBDI. Right hepatectomy is the most frequently performed liver resection in patients with IBDI because of the highest incidence injuries of the right hepatic artery<sup>[5,6,22]</sup>. Li *et al*<sup>[1]</sup> presented the following indications for hepatectomy in patients with IBDI: vascular injury causing liver necrosis without the possibility of vascular reconstruction, uncontrolled bile leakage due to a destructed segmental or sectional hepatic duct without the possibility of biliary reconstruction and recurrent cholangitis (more than four episodes) refractory to endoscopic management and not effectively amenable to bilioenteric anastomosis due to imaging evidence of atrophy or cirrhotic changes of the liver parenchyma. These indications are similar to literature data<sup>[5,22]</sup>. Most frequently, liver atrophy or necrosis, sepsis, and unreconstructable hepatic ducts, as complications of complex IBDI, and multiple failed previous repairs are indications for hepatectomy. Liver resection removes the fibrotic, atrophic segment and the diseased biliary confluence and allows good access to the remnant bile duct for a safe healthy anastomosis<sup>[5,6]</sup>.

Laurent *et al*<sup>[5]</sup> presented aims of hepatectomy in patients with complex IBDI involving biliary confluence (Bismuth IV, Strasberg E4). The aim of partial liver resection in patients with complex IBDI was to remove fibrotic and atrophic liver parenchyma with a high risk of secondary complications because of vascular or septic lesions. The other aim of hepatectomy was to remove completely the biliary stricture at the early stages of the disease for preventing progressive liver damage and potential malignancy caused by bile stasis and repeated cholangitis. Authors presented the following indications for hepatectomy: simultaneous ipsilateral portal and arterial injuries, stenosis of the hilar confluence involving secondary biliary confluence; presence of liver atrophy and presence of metallic stent.

Mercado *et al*<sup>[9]</sup>, based on their 20 years experience in surgical treatment of IBDI including 512 patients with complex IBDI (Strasberg E), performed major hepatectomy in patients with chronic biliary obstruction, liver atrophy, and persistent or recurrent cholangitis, with 1 to 3 previously failed attempts of surgical repair before arriving at their hospital. In remaining patients, Roux-Y hepaticojejunostomy without major liver resection was possible to perform. Authors pointed that in 2 patients, acute recurrent cholangitis, with pericholangitic abscess involving one hemi-liver that had not responded to medical and radiologic treatment, was the indication for major liver resection. In these cases, the liver parenchyma was not possible to rehabilitation, in spite of absence of disruption of hepatic influence. Based on the above mentioned two studies<sup>[8,9]</sup>, complex IBDI involving hepatic influence without vascular injury can be managed successfully with Roux-Y hepaticojejunostomy without major liver resection.

According to Thomson *et al*<sup>[10]</sup>, most patients are managed successfully with a Hepp-Couinaud hepaticojejunostomy because the left hepatic duct remains readily accessible. However, complications such as hepatic infarction, sepsis, anastomotic stricture, and intrahepatic stone formation can require hepatic resection, or even transplantation. Authors presented the following indications for hepatectomy in patients with IBDI: vascular injuries leading to partial liver devascularization, major injuries to the right hepatic duct that could not be repaired by conventional methods, and severe atrophy or sepsis of the hepatic lobe resulting from vascular injury or prolonged biliary obstruction that could not be drained effectively by Roux-Y hepaticojejunostomy. Liver transplantation was performed in combined biliary and vascular injuries leading to acute liver failure and in secondary biliary fibrosis with chronic liver failure.

In studies conducted in 1994 by Madariaga *et al*<sup>[14]</sup>, and in the year 1996 by Majno *et al*<sup>[15]</sup>, they indicated hepatectomy in cases of liver-infected necrosis. Sauvanet *et al*<sup>[16]</sup> described the following indications for hepatectomy: injuries from the confluence or higher with unilateral portal injury, right pedicle destruction, and liver atrophy. de Santibañes *et al*<sup>[21]</sup> presented algorithm for management of lobar atrophy including patients with IBDI. In asymptomatic cases of lobar atrophy, authors recommended control. Liver resection was indicated for symptomatic lobar atrophy caused by vascular injury, combined vascular and biliary injury, and biliary stenosis not responded to balloon dilatation. According to Truant *et al*<sup>[22]</sup> large review, the presence of a Strasberg type E4 or E5 BDI associated with hepatic artery injury was an independent risk factor for hepatectomy. Based on the analyzing studies in PubMed database authors presented the following indications for hepatectomy: recurrent biliary sepsis, biliary strictures caused by continuous cholangitis, intrahepatic abscesses, non-visualization and/or unsuitability of the proximal stump of the injured bile duct(s) for anastomosis, intrahepatic injuries of an aberrant right hepatic duct, anastomotic strictures and intrahepatic lithiasis, right hepatic lobar atrophy, secondary biliary cirrhosis, primary non-diagnosed Klatskin tumor.

It should be emphasized that immediate arterial reconstruction of biliovascular injuries recognized intraoperatively or at least within 4 d is recommended in order to avoid liver devascularization<sup>[8]</sup>. In another study, Li *et al*<sup>[11]</sup> presented hepatic rearterialization, with vascular reconstruction with or without vascular graft, when it was technically possible. Authors carried out hepatic resection only in patients with partial liver atrophy or necrosis. Only early recognition of vascular injury allows to perform rearterialization. In late recognized injuries, partial hepatectomy is required.

Partial hepatectomy is not only performed in patients with damaged liver parenchyma, such as liver ischemia, atrophy and necrosis. A minor partial hepatectomy is

used in order to improve biliary reconstruction in high intrahepatic IBDI. Mercado *et al*<sup>[23-27]</sup> described partial liver resection of segments IV and V that allowed adequate exposure of the bile duct at its bifurcation with an anterior approach of the ducts in order to perform a high quality anastomosis. The first partial-segment IV resection was performed in 1994.

The interesting phenomenon described by Li *et al*<sup>[11]</sup> was a higher incidence of vascular injuries, involving a right hepatic artery, in proximal IBDI compared to distal ones. In this series, 11/33 high injuries were associated with arterial injury but only 9/43 distal injuries were. Authors explained this phenomenon by the fact that the high biliary injury involving the confluence was more likely to damage the hilar component of the choledochal hilar plexus and thus prevent compensatory flow from the left artery. A high risk of concomitant vascular injury in patients with proximal IBDI has been also reported in other studies on LC-related complications<sup>[11,12,28-32]</sup>. Two arterial plexuses play important roles in adequate vascularization of the extrahepatic biliary system. One is the arterial plexus on the surface of the common bile duct and the common hepatic duct, connecting the posterosuperior pancreaticoduodenal artery and the right hepatic artery (most frequently, the 3 o'clock and 9 o'clock axial arteries). The other one (described by Vellar<sup>[33]</sup>) is located within hilar plate on the inferior surface of the hilum of the liver. It is formed by the collateral vessels coming from the right hepatic left hepatic arteries<sup>[33,34]</sup>. In patients with an occluded right hepatic artery combined with major bile duct injury, the arterial plexus on the bile duct is totally transected, and the hilar plate plexus might be jeopardized. In these cases, necrosis of the bile duct, dehiscence and stenosis of the biliary anastomosis, or a syndrome of multiple peripheral strictures within the biliary tree with jaundice and recurrent cholangitis, can occur<sup>[11]</sup>.

In the commented study, high morbidity and mortality rates and good long-term results were reported. It is associated with presence of serious complications in patients with complex IBDI requiring hepatectomy, such as peritonitis, sepsis with multi-organ insufficiency, and liver failure. Good long-term results show that liver resection should be considered in patients with complex IBDI that do not respond to other treatment. According to literature, hepatic resections in patients with IBDI can be performed successfully with low (0%) mortality, although with significant morbidity (50%-60%), and with excellent long-term success of 94%<sup>[6]</sup>.

In conclusion, depending on the time of surgical intervention, two groups of indications (early and late) can be distinguished. In the early postoperative period after cholecystectomy, hepatectomy is necessary in patients with liver necrosis or abscesses and bile leakage, in order to control peritonitis and sepsis. In remaining patients, hepatectomy is required in cases of recurrent cholangitis, that do not respond to standard therapy, and

symptomatic lobar atrophy. Although hepatectomy is not a standard procedure for patients with IBDI, it should be considered as a part of the surgical armamentarium for the repair of a selected group of patients in post-cholecystectomy injuries.

### Abstract

Mini invasive techniques are taking over conventional open liver resections in the setting of left lateral segmentectomy for living liver donation, and hydride procedure are being implemented for the living related right hepatectomy. Our center routinely performs laparoscopic left lateral segmentectomy for pediatric recipient and has been the first in the Europe performing an entirely robotic right hepatectomy. Great emphasis is posed on living donor safety which is the first priority during the entire operation, then the most majority of our procedures are still conventional open right hepatectomy (RHLD), defined as removal of a portion of liver corresponding to Couinaud segments 5-8, in order

to obtain a graft for adult to adult living related liver transplant. During this 10 years period some changes, herein highlighted, have occurred to our surgical techniques. This study reports the largest Italian experience with RHLD, focused on surgical technique evolution over a 10 years period. Donor safety must be the first priority in right-lobe living-related donation: the categorization of complications of living donors, specially, after this "highly sensitive" procedure, reflects the need for prompt and detailed reports.

### INTRODUCTION

In July 2013 we have been communicated by the edito-

rial board of the *World Journal of Gastroenterology* that our paper “Analysis of Surgical and Perioperative Complications in Seventy-five Right Hepatectomies for Living Donor Liver Transplantation” published in May 2008<sup>[1]</sup>, had been cited, up to now, more than 27 times in the world English literature. This figure supported by data banks such as Scopus and ISI web of Science, made this scientific article entering in the 1% most cited papers of ever. Prompted by this achievement we reviewed our 12 years single Italian center experience with hepatic right lobe living donation. Indeed, we were particularly glad to contribute with this retrospective clinical report, to the special number of the *World Journal of Gastroenterology*, published to celebrate the 50<sup>th</sup> year’s anniversary of liver transplantation<sup>[2]</sup>.

Although in the last 6 years the number of procedures performed each year has been dramatically fallen down, our center is still, by far, the busiest living related liver transplant program in Italy (Table 1).

Herein, we will focus our attention on live donor of conventional right lobe (Coineaud segment 5-8) and only marginally on live donor of open left lateral segments (Coineaud segments 2-3)<sup>[3,4]</sup>. To further improve the outcome of these complex procedures, refinements in the surgical technique and better comprehension of the interrelations between post resectional liver regeneration, and donor nutritional status is, in our opinion, needed.

We individualized three area of interest where we accomplished remarkable goals over a 12 years period: nutritional status and rescue of steatotic donors<sup>[5]</sup>; analysis of liver regeneration in donors<sup>[1]</sup>; technical developments in conventional open resection for living donation<sup>[6]</sup>.

## PATIENTS POPULATION

At the “Istituto Mediterraneo per i Trapianti e Terapie ad Alta Specializzazione” in Palermo, Italy, from January 2002 to April 2013, we performed an overall of 107 live donor hepatectomy of which in details: 95 for adult patients and 12 for pediatric recipients. One additional case of potential right hepatectomy was aborted after the beginning of the surgery because of an abnormal venous outflow discovered at the intra-operative ultrasound and not previously detected at the pre operative imaging.

In the early phase of our experience two of the adult patients received a full left lobe (Coineaud segment 2-4), while the others adult recipients received a right lobe (Coineaud segments 5-8); in one case the right hepatic graft was harvested using a totally robotic procedure of retrieval. This case, the first performed in Europe and the second in the world, will not be treated here.

The pediatric recipients always received an anatomical left lateral segmentectomy (Coineaud segments 2, 3); in 8 cases we have performed entirely laparoscopic harvesting procedures and details of these procedures will not be discussed here<sup>[7]</sup>.

No living donor mortality, neither administration of heterologous blood transfusion were reported; 25 (27.1%)

living donors presented 1 or more episodes of complication in the post-operative period.

One case of HCV infection was revealed after donation<sup>[8,9]</sup>.

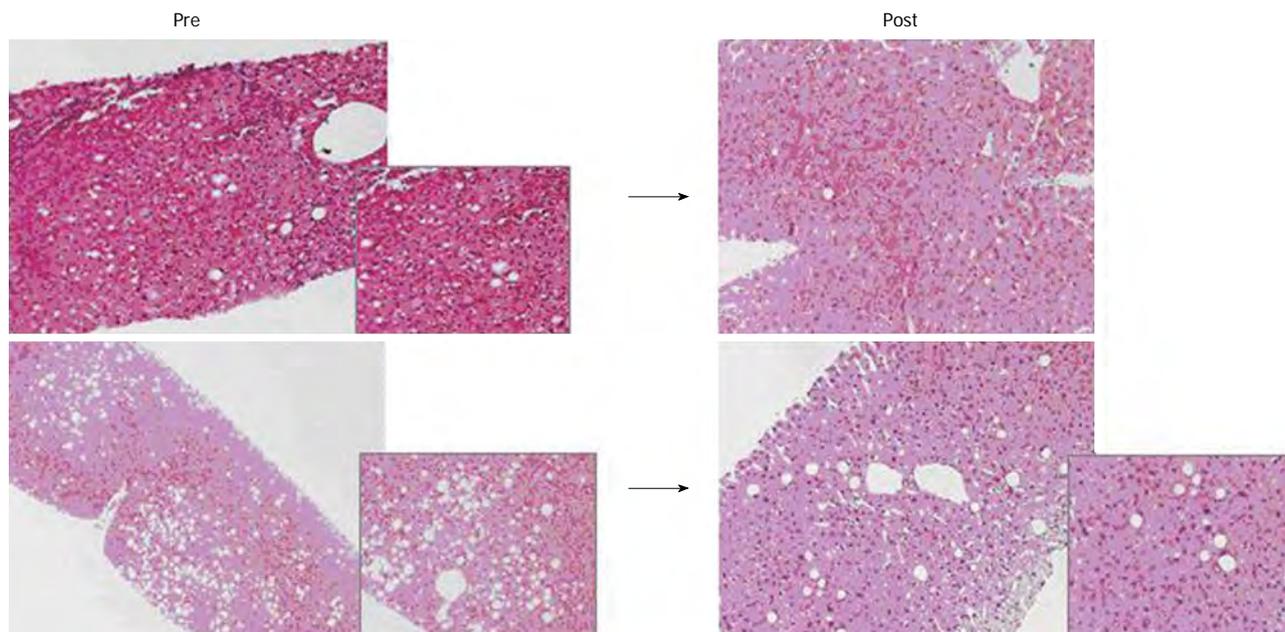

Regarding recipients, the patient and graft survival at 1, 3 and 5 year after right hepatectomy (RHLT) were 89.3%, 83.2%, 77.8% and 83.4%, 77.3%, 71.9% respectively.

## NUTRITIONAL STATUS AND RESCUE OF STEATOTIC DONORS

In our center a comprehensive step-by-step donor work-up protocol is designed to ensure donor and recipient safety.

Donors with hepatic steatosis > 30% are excluded from donation, due to reported impairment of both graft and patient survival after living donor liver transplantation (LDLT)<sup>[10]</sup>.

Donors with body mass index (BMI)  $\geq$  30 kg/m<sup>2</sup>, a significant correlation between BMI and overall grade of steatosis is well known<sup>[11]</sup> and/or steatosis at imaging

**Figure 1** Two histologic examinations of liver parenchyma with steatosis, before and after intensive dietary treatment in the same donor. 10/18 donors successfully completed the 3-mo treatment (body mass index < 30 kg/m<sup>2</sup>). In all 10 treated donors, hepatic macrosteatosis < 30% was found (range: 2%-15%) and therefore they were considered eligible for donation.

(ultrasonography, computed tomography or magnetic resonance imaging) or at histology underwent dietician consult and then re-evaluated within 3 mo.

After nutritional assessment [nutritional and dietary anamnesis, life-style evaluation and resting energy expenditure (REE) calculation] the dietician arranged a personal diet (carbohydrates 55%-57%, proteins 17%-19%, and lipids 24%-27%) and encouraged the donor to do physical activity.

Dietetic compliance of the donor was monthly reassessed.

Acceptable monthly weight loss was considered 2-4 kg, with a final gained BMI of < 30 kg/m<sup>2</sup>.

Eighteen potential living donors (age 27-59 years, male/female 14/4) were treated with diet. Nine out of 18 donors didn't complete the 3-mo dietary follow-up for donor-unrelated reasons. In 9 donors who successfully completed the 3-mo treatment a liver biopsy was performed. In all cases a hepatic steatosis degree < 30% was found and they became eligible as donors (Figure 1).

After LDLT, none of them experienced life-threatening complications or died. Liver function in both remnant liver donors and transplanted grafts showed a good outcome, with no differences (in terms of hospital length of stay, liver function parameter normalization after resection, and liver regeneration) between them and other LDLT without hepatic steatosis.

Surprisingly, in a very recent multicentric study, according to data maintained in the LiverMetSurvey database, a paradoxical survival advantage was observed in patients with steatosis undergoing liver resection for colorectal liver metastases (CLM)<sup>[12]</sup>.

This data has generated a fascinating hypothesis that

of excess body adiposity has a survival protective effect, concept which warrants further research.

## DONOR LIVER REGENERATION

Based on the evidence that an exposure of a small graft to persisting hyperdynamic circulation and high portal blood inflow may induce impairment of liver regeneration, and hepatic dysfunction<sup>[13,14]</sup>, we have translated in a population of 70 donors who underwent right hepatectomy the analysis of the impact of the donor regeneration predictors on post hepatectomy outcomes<sup>[1]</sup>.

Liver regeneration was evaluated with multidetector computed tomography (MDCT) at a mean of 61.07 d after surgery.

We have examined the possible impact of pre-surgical variables (*e.g.*, age, weight, height, BMI, liver function tests, creatinine levels, platelet counts, international normalized ratio, and glucose levels) and variables detected with preoperative MDCT imaging [*e.g.*, main portal vein diameter, steatosis, original liver volume, and spleen volume (SV)]. The future remnant liver volume (FRLV) was preoperatively calculated with a virtual surgical cut. Donor BMI was  $23.7 \pm 2.9$  kg/m<sup>2</sup>, and was used to physiologically assess nutritional status.

In 26 of the 70 donors analyzed (37.14%), 100% or greater hepatic regeneration had occurred at 2 mo.

There was no association between the clinical outcome and the liver regeneration rate. A stepwise multiple regression analysis showed that a higher BMI (coefficient = 0.035,  $P < 0.0001$ ) and preoperative parameters such as a smaller FRLV (coefficient = -0.002,  $P < 0.0001$ ) and a

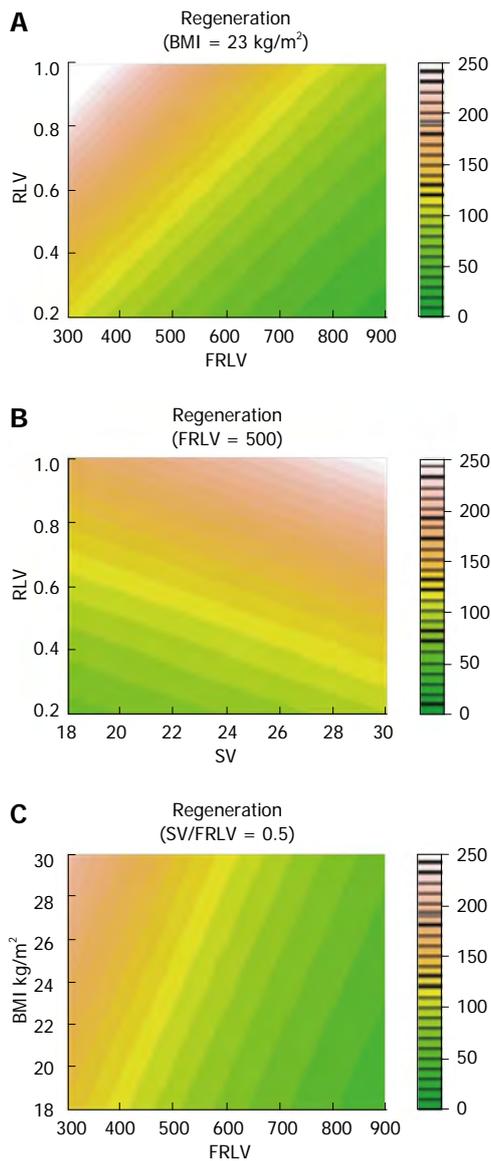

Figure 2 Locally Weighted Scatterplot Smoother graphics of the overall population, evidencing the association of percentage of liver regeneration with levels of body mass index (A), future remnant liver volume (B) and spleen volume/future remnant liver volume (C). FRLV: Future remnant liver volume; SV: Spleen volume; BMI: Body mass index.

greater SV/FRLV ratio (coefficient = 1.196,  $P < 0.0001$ ) were predictors of greater liver regeneration (Figure 2).

## TECHNICAL UPDATES

The most majority of our procedures are still conventional open RHLT, defined as removal of a portion of liver corresponding to Couinaud segments 5-8, in order to obtain a graft for adult to adult living related liver transplant.

While in the setting of the left lateral segment procurement open procedures are reserved only to rare cases presenting vascular anomalies.

During this 12 years period some changes, herein highlighted, have occurred to our surgical techniques. In

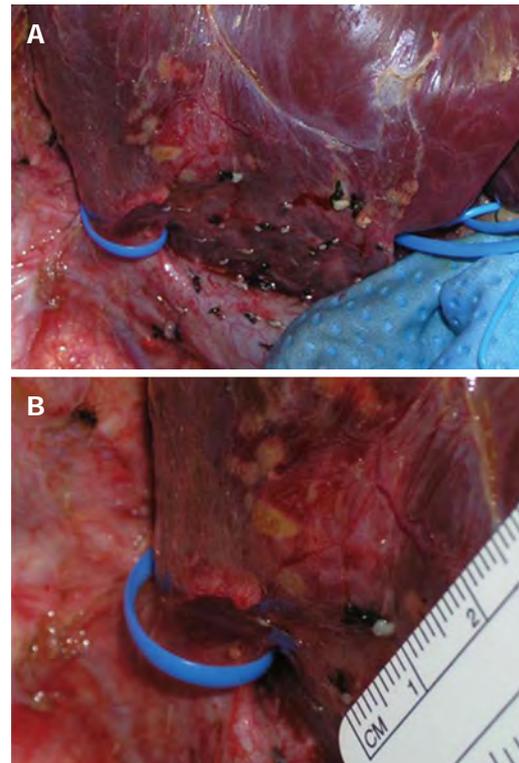

Figure 3 A large accessory hepatic vein draining the right lobe along with the right hepatic vein is encircled using a vessel loop (A). The measurement of the accessory hepatic vein [major of 5 mm, (B)] was performed for decision making to transect it with a vascular stapler, only when transections of liver parenchyma and of the structures of hepatic pedicle were almost complete.

particular we felt that the modifications we adopted concerning the transection of the accessories veins and final severing of the vascular stumps contributed to fasten, ameliorate and make safer the entire procedure.

Those technical development were possible using tools, strategies and experiences gained in laparoscopic surgery.

The operation is lately (after March 2008) being performed (last 10 cases, 9.2%) with a right renal flap incision while we were used to start with a bilateral subcostal incision, with upper midline extension (Mercedes incision). In the setting of the left lateral donation even an upper midline incision has been employed. For the right hepatectomy our original technique has been described elsewhere<sup>[15]</sup>.

We later adapted our technique to all type of anatomic variants. In the case of a right dominant hepatic vein, when a tributary of the hepatic venous system larger than 5 mm was encountered in the transection plane a test clamp was performed in order to see whether the liver parenchyma became dusky, after which a decision was made as to whether to preserve the branch.

This practice was lately substituted by the preoperative use of the MEVIS Hepavision<sup>®</sup> system in order to obtain a more detailed analysis of the outflow venous drainage.

In case of preservation we severed the accessory he-

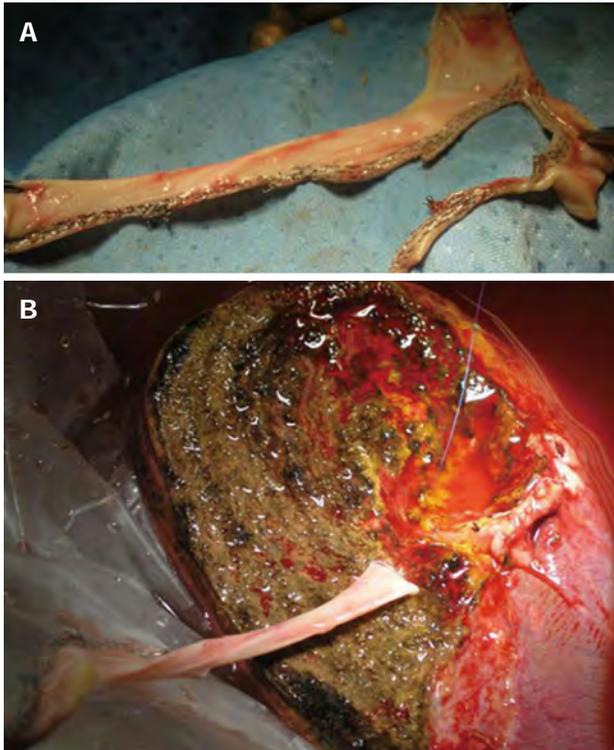

Figure 4 Usage of several vascular staplers were crucial to shapes and employees a heterologous venous conduit (A), previously harvested from a deceased donors, for a back-table reconstruction of a large accessory hepatic vein (B) to be connected to the recipient inferior vena cava in the LRLT.

patric vein, regardless was anterior or posterior, with the Endopath vascular staples (35 mm long, 12.3 mm wide; Ethicon Inc., Somerville, NJ) (Figure 3).

This step was originally taken using straight pediatric Pott vascular clamp and then suturing the two stumps of the vein.

This ultimate practice allowed us to avoid a complex manual suture especially in case of medial tributary when the parenchyma is not yet completely transected. Subsequently, once the parenchyma had been completely divided, the vascular stumps of the right branch of the portal vein, of the right hepatic vein and of the ipsilateral hepatic artery were sectioned with the Endopath vascular staples (35 mm long, 12.3 mm wide; Ethicon Inc., Somerville, NJ), while before the traditional Satinsky and Pott vascular clamps with subsequent manual suture were used.

In the setting of the left lateral segmentectomy, after mobilization of the left anatomic lobe and after performing the parenchymal transection as described above for the right counterpart, we lately substituted the conventional use of vascular Satinsky clamps with endo-vascular stapler.

In particular, while the vascular stumps of the left portal vein and of the left hepatic artery were treated with the Endopath vascular staples (35 mm long, 12.3 mm; Ethicon Inc., Somerville, NJ), the left or the common middle and left stumps of the hepatic veins was

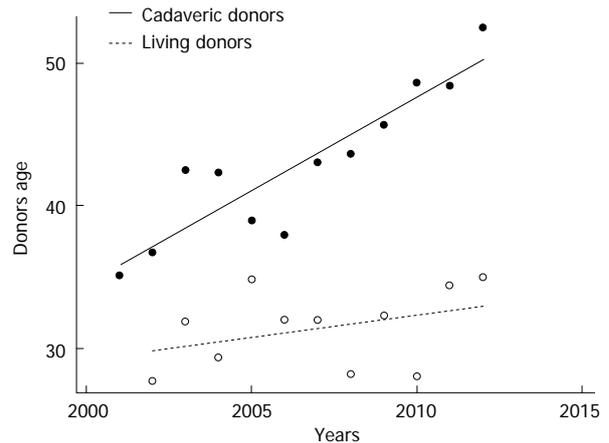

Figure 5 Linear regression models were used for explaining differences in terms of age between deceased and living liver donors over the last decade at the Mediterranean Institute for Transplantation and Advanced Specialized Therapies, and the University of Pittsburgh Medical Center in Italy. In our series of 677 cadaveric liver transplantation and 105 living donor liver transplantation, the deceased donor age has been increasing with a significant difference of average values between deceased and living liver donor age (95%CI: 0.9-1.3),  $P < 0.0001$ .

treated with Endo GIAT<sup>TM</sup> Universal 12 mm vascular stapler (Covidien, New Haven, CT).

Eventually we like to report on the utility of vascular endo-stapler into the open transplantation surgery, in the setting of the use of vascular graft. Indeed in few cases, the usage of several vascular staplers were crucial to shapes and employees a heterologous venous conduit, previously harvested from a deceased donors, for a back-table reconstruction of a large accessory hepatic vein which was connected to the recipient inferior vena cava of a LRLT (Figure 4).

## DISCUSSION

Deceased donor quality is worsening in Italy, the average of donor age in our center is much better in the living counterpart (Figure 5). However living donation carries a special risk and donor safety must be the first priority in liver living-related donation.

Indeed, the categorization of complications, the developments of new surgical tips, the changes matured over time in terms of donor selection and match needs to be promptly reported in details<sup>[16]</sup>.

Herein, we separately analyzed three area of interest in live donor hepatectomy that have been exposed to some changes and ameliorations since the beginning of our practice.

We found that the reduction of hepatic steatosis to a values of  $< 30\%$ , could be obtained with a strategic nutritional assessment and arranging an adequate personal diet. This concept is guiding our strategy in order to expand the live donor pool without affecting donor and recipient safety.

At this regard, the paradoxical survival advantage observed in patients with steatosis undergoing liver resec-

tion for CLM might create a new fascinating scenario, in which overweight living donor could be suitable for transplantation<sup>[12]</sup>.

However it is too early to conclude that peri-diagnosis overweight is a good prognosticator after a major liver resection, because its impact upon long-term survival is less well documented.

Further clinical studies with large series, comparing patients and potential live donors with different BMI, grade of liver steatosis and nutritional marker, will be necessary to obtain convincing evidence.

Assuming that preoperative nutritional status is one of the key points for successful resection in living-related liver donors, we have recently put emphasis not only on the evaluation of the ratio between donor and recipient liver volume but also on the predictors of optimal early liver regeneration in the donors.

Historical series suggested that in adult-to-adult living related liver transplantation one of the most challenging tasks is to match an optimal size graft, balancing the clinical condition of the sick recipient and the safety of the healthy donor. In this setting, particularly care must be taken in the pre operative imaging evaluation of liver and spleen volume<sup>[17-19]</sup>.

Eventually, in the scenario of the surgical refinements obtained over a 12 years period the adoption into the open conventional surgery of tools created for laparoscopic surgery such as the endo-mechanical stapler for vascular structures allowed us to make safer a unique surgical operation such as the living donor hepatectomy.

At this regard, we like to mention that traditionally one of the most stress full point of the operation is the positioning of the vascular clamp around the right hepatic vein or the common trunk of the middle and left hepatic vein and the subsequent manual suture of a potentially long vascular stump. Indeed, no matter how safely the clamp is placed the length of remnant vein to be sutured in the donor side might be short, and any moment the clamps could be displaced with detrimental consequences.

On the other hand, using the vascular stapler will make this step faster and safer with no consequence on the recipient side, once the stumps are opened on the back-table and the graft is flushed.

Adult-to-Adult Living-related Donor Liver Transplantation remains the greatest most recent and challenging evolution of liver transplantation, both from a technical and ethical point of view, which has contributed to reduce donor shortage<sup>[20]</sup>. Stringent criteria of donor selection criteria and peri-operative care were implemented following one of the first reported case of living donor death in 2002, and a smaller number of centers with large experience refined the surgical technique, selection and clinical management of both donors and recipients<sup>[21]</sup>.

### Abstract

Hospitalized patients with inflammatory bowel disease (IBD) are at high risk for morbidity, mortality, and health care utilization costs. While the literature on trends in hospitalization rates for this disease is conflicting, there does appear to be significant variation in the delivery of care to this complex group, which may be a marker of suboptimal quality of care. There is a need for improvement in identifying patients at risk for hospitalization in an effort to reduce admissions. Moreover, appropriate screening for a number of hospital acquired complications such as venous thromboembolism and *Clostridium difficile* infection is suboptimal. This review discusses areas of inpatient care for IBD patients that are in need of improvement and outlines a number of potential quality improvement initiatives such as pay-for-performance models, quality improvement frameworks, and healthcare information technology.

### INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic gastrointestinal condition characterized by relapsing inflammation. Most patients with IBD are managed in the outpatient setting, however as disease severity progresses and complications arise, hospitalization is often required. Patients admitted to hospital are at increased risk for a variety of complications including venous thrombotic events (VTE), hospital acquired infections, *Clostridium difficile*, and death<sup>[1-3]</sup>. Moreover, hospitalized patients are more likely to require surgery<sup>[5,6]</sup>. There have been

conflicting reports on trends in hospitalization rates for IBD over the last decade and the literature has revealed significant variation in care and disease outcomes among hospitalized IBD patients. The heterogeneous nature of IBD severity, location, and phenotype as well as limited evidence to guide some therapeutic domains make standardization of IBD care delivery difficult. However, given that hospitalized patients are at the highest risk for morbidity, mortality, and health care utilization costs, quality improvement initiatives aimed at reducing variation, a known surrogate marker of poor performance, are well suited to this subset of patients<sup>[7,8]</sup>. This review outlines recent trends in rates of hospitalization for IBD and highlights areas of inpatient care that are in need of improvement.

## HOSPITALIZATION RATES FOR IBD

Most IBD care is delivered in the ambulatory setting. However, a significant proportion of patients will require hospitalization at some point in their disease course. Reports on overall trends in hospitalization rates for IBD over the past two decades are conflicting. Among a large cohort of patients followed across an integrated care network in Northern California, Herrinton *et al*<sup>[8]</sup> noted a 33% decline in hospitalization rates for Crohn's disease ( $P = 0.02$ ) and a 29% decline among those with ulcerative colitis ( $P = 0.0009$ ) from 1998-2005. However, a report using the National Hospital Discharge Survey (NHDS) showed that between the years 1970-2004, the rates of hospitalization for both Crohn's disease and ulcerative colitis in the United States increased<sup>[9]</sup>. Moreover, readmission is not uncommon, as demonstrated by Bernstein *et al*<sup>[10]</sup>, whereby 20% of patients with IBD were readmitted within the same calendar year. The most important advance in IBD care over the last ten years has been the increasing use of anti-tumour necrosis factor (TNF) therapy. The true impact of this on hospitalization rate may not have been completely captured in all these reports, thus more data is needed to evaluate the impact of anti-TNF on recent hospitalization trends.

While the literature on hospitalization rates is conflicting, most studies clearly show variation in practice patterns among hospitalized IBD patients. For example, in the cohort from Northern California discussed above, variability in surgery rates and immunomodulator use depending on the number of gastroenterologists and colorectal surgeons at each site was noted among the 16 medical centers included in the study<sup>[8]</sup>. Similarly, Spiegel *et al*<sup>[11]</sup> demonstrated significant variation among community and expert gastroenterologists in a number of care areas including patients admitted to hospital with severe ulcerative colitis. Expert gastroenterologists had a lower threshold to consult a surgeon for patients with severe steroid refractory disease. Outcomes following colectomy based on surgical volumes have also been shown in several studies, with high volumes centers having lower mortality rates<sup>[12,13]</sup>. Differences in outcomes based on the

type of admitting physician have also been demonstrated. Murthy *et al*<sup>[14]</sup> showed that patients with ulcerative colitis admitted to non-gastroenterologists had higher in-hospital mortality rates compared to those admitted under the care of a gastroenterologist (1.1% *vs* 0.2%,  $P < 0.0001$ ). Colectomy rates have also shown to be subject to geographic variation across the United States, with rates in the Midwest and West regions being three fold higher than those in the Northeast<sup>[15]</sup>. These studies underscore the need for improvement efforts focused on minimizing variation and bridging the gap between ideal and true performance in caring for the hospitalized inpatient with IBD.

## VENOUS THROMBOEMBOLISM PROPHYLAXIS

The risk of venous thromboembolism (VTE) has been shown to be increased among patients with IBD. Multiple studies have shown patients with IBD have a 2-3.5 fold increased risk for VTE compared to the general population and a recent meta-analysis confirmed a relative risk of 2.2 (95%CI: 1.83-2.65)<sup>[16-18]</sup>. In fact, one study showed that among 17 chronic illnesses, only heart failure and cancer carried a greater risk of VTE than IBD<sup>[19]</sup>. Moreover, it appears the prevalence of VTE among this group of patients is rising<sup>[1]</sup>. A number of risk factors for VTE among IBD patients have been identified. In a review of the Nationwide Inpatient Sample (NIS) between 1998-2004, Nguyen *et al*<sup>[11]</sup> identified increasing age, co-morbidities, ulcerative colitis (as opposed to Crohn's disease), surgery, and the need for public health assistance as important risk factors for the development of VTE. Disease activity has also been shown to be an important predictor, with one study showing a 4.5 fold increased risk of developing VTE during times of disease flare compared to remission<sup>[20]</sup>. Hospitalized IBD patients, particularly those with ulcerative colitis, appear to be at very high risk of VTE. Hospitalized IBD patients have been shown to have nearly a 6 fold increased absolute risk of VTE compared to an ambulatory IBD population<sup>[17]</sup> and an increased adjusted odds ratio of 1.85 (95%CI: 1.7-2.1) compared to those non-IBD patients admitted to hospital<sup>[11]</sup>. Moreover, VTE has been shown to be a marker of worse outcomes and higher health resource utilization. A review of a large database of hospital discharges in the United States found an odds ratio (OR) of 2.5 (95%CI: 1.83-3.43) for in-hospital mortality compared to IBD patients without VTE<sup>[1]</sup>. Mortality rates for ulcerative colitis were particularly high (37.4 per 1000 hospitalizations *vs* 9.9 per 1000 hospitalizations,  $P < 0.0001$ ). Patients with IBD and VTE also had a longer average length of stay (11.7 d *vs* 6.1 d,  $P < 0.0001$ ) and higher hospital charges compared to IBD patients without VTE.

Given the morbidity and mortality associated with inpatient VTE, the utility of VTE prophylaxis to prevent this complication is clear. Prophylaxis with heparin has been shown to significantly and safely decreased

the incidence of deep-vein thrombosis and pulmonary embolism<sup>[21]</sup>. However, despite the efficacy and ease of administering VTE prophylaxis, a significant percentage of IBD patients admitted to hospital are not receiving it and remain at risk. In a retrospective review of a tertiary IBD center in the United States, Tinsley *et al*<sup>[22]</sup> noted that the overall prophylaxis rate was only 67.6%. Variation was noted depending on the admitting service, with significantly higher rates noted among those admitted to a surgical service compared to a medical service (93.5% *vs* 57.4%). Even among those in which VTE prophylaxis was ordered, up to 34% of doses were not given. The lower prevalence for prophylaxis of IBD patients may in part be due to lack of awareness of their increased risk, as they are often young and mobile. This was suggested by a survey of gastroenterologists who were members of the American Gastroenterological Association<sup>[23]</sup>. Only 45% of respondents were aware that guidelines recommending VTE prophylaxis were published and a third surveyed reported working in a hospital with no protocols for VTE prophylaxis. Significant variation in practice was noted. However, contributors other than lack of awareness are suggested by studies of IBD experts. At a large Canadian tertiary IBD center, rates of VTE prophylaxis were lowest for patients admitted to the gastroenterology run IBD service compared to those admitted to general internal medicine or surgery<sup>[24]</sup>. Moreover, a survey of Canadian IBD experts found that almost 20% did not routinely use VTE prophylaxis and there was inconsistency among respondents regarding the indication for prophylaxis for patients in remission<sup>[25]</sup>. These studies underscore tremendous variation and suboptimal quality of care in preventing this morbid IBD related extra-intestinal manifestation. Given the uniform increased risk among hospitalized IBD patients, the presence of readily available and safe prophylactic agents, and the identification of important predictors for lack of prevention, this area of IBD care is a “low hanging fruit” that is very amenable to quality improvement initiatives.

## CLOSTRIDIUM DIFFICILE TESTING

A substantial body of evidence has emerged to implicate IBD as an important risk factor for *Clostridium difficile* infection (CDI). IBD patients have been shown to have higher infection rates with CDI compared to non-IBD patients. In an analysis of administrative data using a large registry of hospital discharges in the United States, Nguyen *et al*<sup>[4]</sup> noted that patients with ulcerative colitis (UC) had a prevalence of CDI that was 8 times that of non IBD patients admitted with a gastrointestinal problem (37.3 cases/1000 discharges *vs* 4.8 cases/1000 discharges,  $P < 0.001$ ). This finding was supported by a systematic review of 42 articles that showed CDI was more common among IBD patients than non IBD controls<sup>[26]</sup>. In addition to the higher prevalence of CDI among IBD patients, the incidence of CDI appears to be increasing over the last decade, particularly among hospitalized IBD patients. A review of discharges

among hospitalized IBD patients showed that the percentage of IBD admissions complicated by CDI had increased from 1.4% to 2.9% between the years 1998 and 2007 ( $P < 0.001$ )<sup>[27]</sup>. This increase was most marked for the subset with UC in which CDI complicated 5.3% of admissions. Similarly, in a retrospective review of hospitalized patients, Rodemann *et al*<sup>[28]</sup> showed that while CDI rates doubled among Crohn's disease patients between the years 1998 and 2004, they tripled among those with UC.

Not only does the literature support a true rise in CDI incidence and prevalence among individuals with IBD, but CDI also may confer worse outcomes. In-hospital mortality was four fold higher among IBD patients with CDI compared to those with IBD alone in a retrospective review of the NIS<sup>[27]</sup>. Similarly, a retrospective cohort study from Ontario, Canada showed a higher in-hospital mortality rate among hospitalized UC patients with CDI compared to those with UC alone (3.3% *vs* 0.38%,  $P < 0.0001$ )<sup>[29]</sup>. This increased mortality rate persisted out to five years of follow up in which the cumulative 5 years mortality rate was 27% for the CDI group and 14% for those with UC alone ( $P = 0.0073$ ). CDI has also been shown to increase length of stay and hospitalization costs among those with concomitant IBD. A review of a large administrative database of hospital discharges from the United Kingdom showed that median length of stay was 26 d among those with both CDI and IBD compared to only 5 d for those with IBD alone, a difference that was statically significant<sup>[30]</sup>. This translates into increased health care costs as shown by Nguyen *et al*<sup>[4]</sup>, whereby average hospital charges were \$35606 for a UC patient with CDI compared to \$23856 for those with UC alone ( $P < 0.0001$ ). The impact of CDI on colectomy is less clear. Jen *et al*<sup>[30]</sup> showed an increased risk of in-hospital colectomy among hospitalized UC patients with CDI as compared to UC alone (OR = 1.7, 95%CI: 1.4-2.1). This conflicts with the finding of Nguyen *et al*<sup>[4]</sup>, who showed a lower risk of colectomy in IBD patients with CDI (OR = 0.44, 95%CI: 0.34-0.55). Studies evaluating long term risk of colectomy after CDI are also conflicting. Navaneethan *et al*<sup>[31]</sup> showed that one year following hospitalization for UC, the colectomy rate was 35% for those with CDI during that hospitalization compared to 9.9% for those without infection ( $P < 0.001$ ). This was in keeping with a study from a large, tertiary IBD center in which one year colectomy rates for those with IBD and CDI were higher compared to those with IBD alone (44.6% *vs* 25%,  $P = 0.04$ )<sup>[32]</sup>. However, no difference in the risk of colectomy at 5 years was seen in the Canadian study cited above<sup>[29]</sup>.

The literature supports the finding that CDI among patients with IBD is a significant and increasingly prevalent problem, particularly for those with UC. Moreover, CDI confers increased short and long term mortality risk and increased health care utilization costs and may increase short and long term risk of colectomy. The majority of CDI is diagnosed within 48 h of admission, suggesting most patients acquire CDI in the community<sup>[28]</sup>. Given the high incidence and potential poor outcomes

associated with CDI and the fact that it is most often acquired before admission, routine testing of patients presenting with exacerbation of IBD for *Clostridium difficile* is a reasonable and potentially powerful intervention. In fact, a single center study showed a reduction in the number of colectomies after routine testing on admission was introduced<sup>[33]</sup>. While more evidence evaluating the benefits of routine testing is indicated, the literature thus far supports its use. Nonetheless, it appears routine testing is not widespread. A study of 34 European countries found tremendous variation in the incidence of CDI across hospitals and suggested difference in testing behavior was most likely responsible for these results<sup>[34]</sup>. Moreover, despite the rising prevalence of CDI, there is variation in approaches management in terms of antibiotic selection and practices regarding IBD specific immunosuppressive therapy. A survey of gastroenterologists in Canada and the United States found that nearly half of respondents add antibiotics to ongoing immunosuppressive therapy while the other half routinely held all immunosuppressants during antibiotic treatment<sup>[35]</sup>. The lack of consensus even among IBD experts highlights the need for more studies aimed at bringing clarity to the commonly encountered clinical “grey area”.

## INTERVENTIONS AIMED AT IMPROVEMENT

In order to adequately address gaps in care, an understanding of the contributing factors to the target problem is essential. It is important to tailor a quality improvement (QI) initiative to the local context and implement according to the resources, infrastructure, and QI culture available. A variety of methods to improve identified deficiencies in the quality of care of hospitalized IBD patients are already underway and discussed in detail below.

### Pay-for-performance program

Guidelines have outlined algorithmic approaches for following this complex group of patients. However, the uptake of IBD guidelines by gastroenterologists has been shown to be variable<sup>[36,37]</sup>. Therefore, other improvement approaches are necessary. A pay-for-performance (P4P) funding model has been advocated by some, whereby hospital and/or physician reimbursement is tied to meeting certain predetermined care benchmarks. This model is increasingly being used, although its impact on patient outcomes remains controversial. A review of over 7000 primary care physicians in the United Kingdom Quality and Outcomes Framework Pay for Performance Program found significant improvements in outcomes of a number of chronic diseases such as diabetes and coronary artery disease<sup>[38]</sup>. Similarly, a large study from the National Health Services in England compared mortality in a region of the country that had uniformly adopted a P4P model in all hospitals to the remainder of the country which did not use this model<sup>[39]</sup>. In the 24 hospitals that did use the P4P model, an absolute reduction in

mortality of 1.3% (95%CI: 0.4-2.1,  $P = 0.006$ ) and a relative reduction of 6% (95%CI: 260-1500) was observed. However, an American study evaluating the impact of the Centers for Medicare and Medicaid Services strategy that relies primarily on financial penalties through not providing hospitals with additional payment for health care-acquired or preventable complications found no significant changes in performance before or after this policy was adopted<sup>[40]</sup>. Therefore, while P4P programs hold promise, more study is needed before there is universal adoption of these models. Moreover, there is a need to evaluate the impact of these programs on IBD patient, given their complexity and unique needs. The American Gastroenterology Association has developed IBD specific quality indicators eligible for reimbursement through the Physician Quality Reporting System (PQRS) (Table 1)<sup>[41]</sup>. The impact of the PQRS on improving the quality of inpatient IBD care needs to be further characterized.

While not designed for the purposes of a reimbursement program, the Crohn's and Colitis Foundation of America have recently sponsored the publication of a set of quality indicators<sup>[42]</sup>. Both process and outcome indicators were developed that encompass a variety of domains in IBD care including treatment, surveillance, and health care maintenance. A number of inpatient IBD care process indicators are defined such as “IF a hospitalized patient with severe colitis is not improving on intravenous steroids within 3 d, THEN sigmoidoscopy with biopsy should be performed to exclude cytomegalovirus, AND surgical consultation should be obtained” as well as “IF a patient in whom a flare of IBD is suspected with new or worsening diarrhea THEN the patient should undergo *Clostridium difficile* testing at least once” and inpatient related outcomes measures including: (1) Number of days per year in the hospital attributable to IBD; and (2) Number of emergency room visits per year for IBD. It is important for gastroenterologists to become familiar with these quality indicators as they can be expected to become increasingly incorporated into the accreditation processes of health care institutions.

### Quality improvement frameworks

As the quality improvement movement continues to build momentum, there are increasing calls for innovative changes to the way health care is delivered. System rede-

sign is a fundamental principal in QI and there has been a particular focus on healthcare provided in the hospitalized setting as this is associated with significant morbidity and cost. Examples of new frameworks in IBD care are increasing. For example, a program in Australia implemented a new model of care consisting of a designated IBD service aimed at reducing hospitalizations<sup>[43]</sup>. The service consisted of a team of gastroenterologists, a designated weekly IBD clinic, a joint gastroenterology-surgery clinic, and a nurse practitioner (NP). The NP performed a variety of tasks including standardized protocols for monitoring patients on immunomodulator and biologic therapy, a 24-h help line, routine post-discharge follow up phone calls, and a routine education session at discharge. Outcomes were compared before and after adopting this framework. Following the implementation of the IBD service, the mean number of admissions per patient, mean length of stay, and total cost for inpatient care decreased. While this simple before and after design does not clearly control for biases, it does highlight the potentially valuable role of designated chronic care teams, particularly the role of the NP. NPs have been shown to improve outcomes in other chronic diseases, however their use in IBD has lagged behind other fields<sup>[44-46]</sup>. More studies are needed to evaluate their role in participating in IBD care.

Centralizing care delivery of certain disease into designated tertiary centers of excellence has also become a model employed by some jurisdictions. A number of large studies using administrative data have shown outcomes may be improved in high volume IBD referral centers. For example, United States hospital discharges were reviewed using the Nationwide Inpatient Sample between 1998-2004<sup>[6]</sup>. IBD patients admitted to high volume centers had lower in-hospital mortality compared to non-high volume hospitals. Similarly, Ananthakrishnan *et al*<sup>[13]</sup> found that patients admitted to high volume centers were more likely to undergo IBD surgery and had lower post-operative mortality rates compared to those in average volume hospitals. These studies support the designation of IBD centers of excellence whereby complicated IBD patients can be referred to for expert opinion and management. However, these centers must have the resources in place to handle such a complex cohort of patients and to be able to accommodate a large number of referrals to be seen in a timely fashion by gastroenterology and/or surgery.

### **Advancing healthcare information technology**

Hospitals have been increasingly incorporating healthcare information technology (HIT) into patient care. Many QI experts link HIT with improved quality, safety, efficiency, and coordination of care<sup>[47]</sup>. Hospitalized patients are at increased risk of harm in the form of hospital acquired infections, preventable complications (*e.g.*, VTE), medication errors, and lapses in communication at discharge regarding follow-up. Therefore, initiatives aimed at reducing these harms are needed, and HIT is one avenue that may

achieve improvements. If designed well and appropriately adapted to the context of a given institution, an electronic health record has the potential to improve efficiency, safety, and communication. Computerized provider order entry has the potential to decrease medication errors, link providers to clinical decision support, and address the underuse or overuse of certain resources<sup>[47]</sup>. For example, standardized admission order sets involve a collection of orders or investigations that when designed well, are effective through improving efficiency, decreasing variation, enhancing workflow, and improving communication of evidence based practices<sup>[48,49]</sup>. Fields can be customized to an admitting service (*e.g.*, general surgery, gastroenterology, *etc.*) or disease specific (*e.g.*, IBD). An IBD admission order set has the potential to address areas in which the quality of care is suboptimal. For example, including *Clostridium difficile* testing on the admission order may be expected to increase the rates of screening for IBD patients presenting to hospital with new or worsening diarrhea. While the impact of such initiative on IBD outcomes is not yet known, it would increase adherence to recently defined QI benchmarks and potentially identify a high risk group for bad outcomes<sup>[42]</sup>. Similarly, an electronic order set that automatically defaults to ordering VTE prophylaxis on admission may improve the underuse of VTE prophylaxis outlined above. The physician would deliberately have to remove this order if it is not desired. These “forcing functions” are regarded among the most effective patient safety interventions available<sup>[50]</sup>. This strategy has been shown to be effective in increasing prophylaxis rates in several studies of non-IBD patients and overcomes barriers to ordering VTE prophylaxis such as the knowledge gaps outlined above<sup>[51,52]</sup>. However, other barriers to VTE prophylaxis have also been identified that may not be adequately addressed by an order set. Moreover, evidence in support of VTE order sets in IBD is lacking. This underscores the importance of a clear understanding of the local context before implementing an initiative and to ensure that it is well tailored to the patients, resources, and providers at a given institution. Nonetheless, the theory behind order set effectiveness is sound and more study is needed to evaluate their impact on IBD outcomes.

## **CONCLUSION**

In summary, hospitalized patients with inflammatory bowel disease are at risk of harm and increased healthcare utilization resources. More attention needs to be placed on reducing hospital admissions and re-admissions and preventable inpatient complications such as VTE. A number of potential improvement strategies may benefit both patients and providers including pay-for-performance programs, quality improvement frameworks, nurse practitioners, and healthcare information technology. While the true impact of these interventions on IBD outcomes still needs to be elucidated, quality indicators are expected to become increasingly measured in all aspects

of clinical care and it is therefore important that IBD providers familiarize themselves with these concepts.

### Abstract

In recent years, pediatric health care has embraced the concept of quality improvement to improve patient outcomes. As quality improvement efforts are implemented, network collaboration (where multiple centers and practices implement standardized programs) is a popular option. In a collaborative network, improvement in the conduct of structural, process and outcome quality measures can lead to improvements in overall health, and benchmarks can be used to assess and compare progress. In this review article, we provided an overview of the quality improvement movement and the role of quality indicators in this movement. We reviewed current quality improvement efforts in pediatric inflammatory bowel disease

(IBD), as well as other pediatric chronic illnesses. We discussed the need to standardize the development of quality indicators used in quality improvement networks to assess medical care, and the validation techniques which can be used to ensure that process indicators result in improved outcomes of clinical significance. We aimed to assess current quality improvement efforts in pediatric IBD and other diseases, such as childhood asthma, childhood arthritis, and neonatal health. By doing so, we hope to learn from their successes and failures and to move the field forward for future improvements in the care provided to children with IBD.

**Key words:** Inflammatory bowel disease; Colitis; Ulcerative; Crohn's disease; Child; Adolescent; Quality of health care; Review

**Core tip:** This review article provides an overview of the quality improvement movement and the role of quality indicators. Active quality improvement efforts in pediatric inflammatory bowel disease are discussed, and the need for standardizing the development of quality indicators across all fields of healthcare is emphasized. This article also discusses the importance of incorporating validation techniques when developing and selecting quality indicators. Examples of quality improvement efforts in other areas of pediatric chronic illnesses are presented, with important lessons highlighted to guide future quality improvement initiatives.

## INTRODUCTION

The inflammatory bowel disease (IBD) are a group of chronic gastrointestinal diseases caused by inflammation of the gastrointestinal tract and resulting in malabsorption of nutrients, failure to thrive, abdominal pain, and extraintestinal manifestations<sup>[1]</sup>. They consist of two main subtypes: Crohn's disease (CD) and ulcerative colitis (UC), and patients who do not fall into either subtype are deemed IBD type unclassified (IBD-U)<sup>[1]</sup>. Adult and pediatric onsets of IBD differ in some regards, with one of them being in regards to the degree of psychosocial burden. Quality of life is significantly affected, with children being frequently affected by psychosocial issues as a result of stunted growth, weight gain from drug therapy and the inability to feel confident around peers due to associated bowel issues<sup>[2]</sup>.

Incidence and prevalence of pediatric IBD have been increasing worldwide. A recent systematic review with the aim of describing international trends for pediatric IBD rates found that 60% and 20% of relevant publications reported statistically significant increases in CD and UC incidence, respectively<sup>[3]</sup>. The findings represented data from 32 countries, thereby providing evidence that pediatric IBD has become a global disease affecting a multitude of countries<sup>[3]</sup>. Several developed countries had released reports characterizing incidence rates within their pediatric population. In Ontario, Canada, there was a 5% and 7.6% increase per year in incidence for children aged 0-4 years and 5-9 years, respectively<sup>[4]</sup>. Similar increases have been demonstrated in Spain and Northern California, United States<sup>[5,6]</sup>.

With increasing incidence and prevalence comes greater economic burden, both on the healthcare system and on patients' families. Based on 2003-2004 data, the direct healthcare costs of IBD in the United States was \$3.1 billion for CD and \$2.1 billion for UC<sup>[7]</sup>. Children had the highest cost of direct medical care, and lengths of hospital stay were also high, with an average of 8.1 d for CD patients who were  $\geq 5$  years of age<sup>[8]</sup>. While the average pediatric patient with IBD costs significantly more in direct medical costs than the average adult, a high degree of variability in care and outcomes has been noted in the literature<sup>[7]</sup>. A study from the United States demonstrated variation in care provided to children in a network of pediatric IBD centers, including a large degree of variation in use of immunosuppressive medications at diagnosis<sup>[9]</sup>. Similarly, we have previously described variation in surgical outcomes in Canadian children based on family income, despite a universal access healthcare environment<sup>[10]</sup>. In addition, we described a high degree of variability in medication prescription rates in children with IBD from three countries<sup>[11]</sup>. This variation in care may be unwarranted, and indicate room for improvement in the quality of care<sup>[12]</sup>. The description of unwarranted variation in care has therefore spurred quality improvement efforts in pediatric IBD<sup>[13]</sup>.

In addition, with increasing burden of pediatric IBD,

the issue of quality of care becomes more important. Improved quality of care should lead to improved outcomes, and therefore lower long-term burden as well as medical and psychosocial benefits. While the motivation for improving processes involved in providing high quality medical care is clear, such quality improvement efforts should be based in evidence and undergo validation to ensure efficient resource allocation.

Recognizing the disparities present in modern-day healthcare systems, the Institute of Medicine released two reports highlighting current issues affecting quality<sup>[14,15]</sup>. Both reports have argued that quality of care is sub-optimal across all aspects of health regardless of disease type, and have proposed that healthcare systems be reformed to prevent mis-use of healthcare services<sup>[16]</sup>. As a result of these reports, many providers, including pediatric IBD specialists, have worked with quality improvement experts to improve the quality of care for their patients by implementing quality improvement programs. We have reviewed current published quality improvement efforts in pediatric IBD, and the evidence that they have improved outcomes. In addition, we have examined evidence from quality improvement work in other fields to inform future pediatric IBD efforts and improved their likelihood of success.

## WHAT IS QUALITY IMPROVEMENT?

Quality improvement in medicine is defined as the effort to change care using an evidence-based approach in order to make tangible positive changes to the delivery healthcare<sup>[17]</sup>. With origins stemming from the field of industry and production, quality improvement efforts have slowly been introduced into the field of healthcare delivery over the past few decades. Definitions used to describe common quality improvement terms can be found in Table 1.

The plan-do-study-act (PDSA) has been used as a paradigm for quality improvement efforts<sup>[18,19]</sup>. With this framework, at the plan stage, quality indicators are developed to measure the quality of care provided. During the do stage, these indicators are implemented into practice and quantitative measures are collected. At the study stage, the statistics gathered in the previous stage are used to evaluate the progress that this action has on healthcare delivery. At the act stage, a feed-back loop is utilized such that quality indicators which have produced sub-optimal results are re-examined and cycled back through the PDSA cycle. Quality indicators which have improved quality of care are also re-examined to ensure that additional modifications cannot be added to ensure optimal care is being provided<sup>[20]</sup>. The National Health Services(NHS) in the United Kingdom has recommended that the PDSA be used in trial phase and then implemented fully once outcomes have been satisfied<sup>[20]</sup>. A modified PDSA cycle can be found in Figure 1, and is adapted from Langley *et al*<sup>[19]</sup>.

In general, many efforts for quality improvement have been unsuccessful due to the lack of a trial phase,

**Table 1** Definitions of common quality improvement terms<sup>[17,18,22,23]</sup>

Term	Definition
Quality improvement	The overall framework used to describe the process of implementing evidence-based interventions to bridge the disparities currently present in various healthcare systems
Quality indicators	A set of measures used to assess the appropriateness and quality of health care. Quality indicators are considered the fundamental building blocks of quality improvement efforts
Structural indicators	Indicators having to do with the structure of the healthcare system ( <i>e.g.</i> , staffing, equipment, environment, electronic health records)
Process indicators	Indicators having to do with the process of providing care ( <i>e.g.</i> , investigations, treatments, interaction with patients)
Outcome indicators	Indicators having to do with assessing the outcome of patients ( <i>e.g.</i> , mortality, morbidity, quality of life, patient satisfaction)

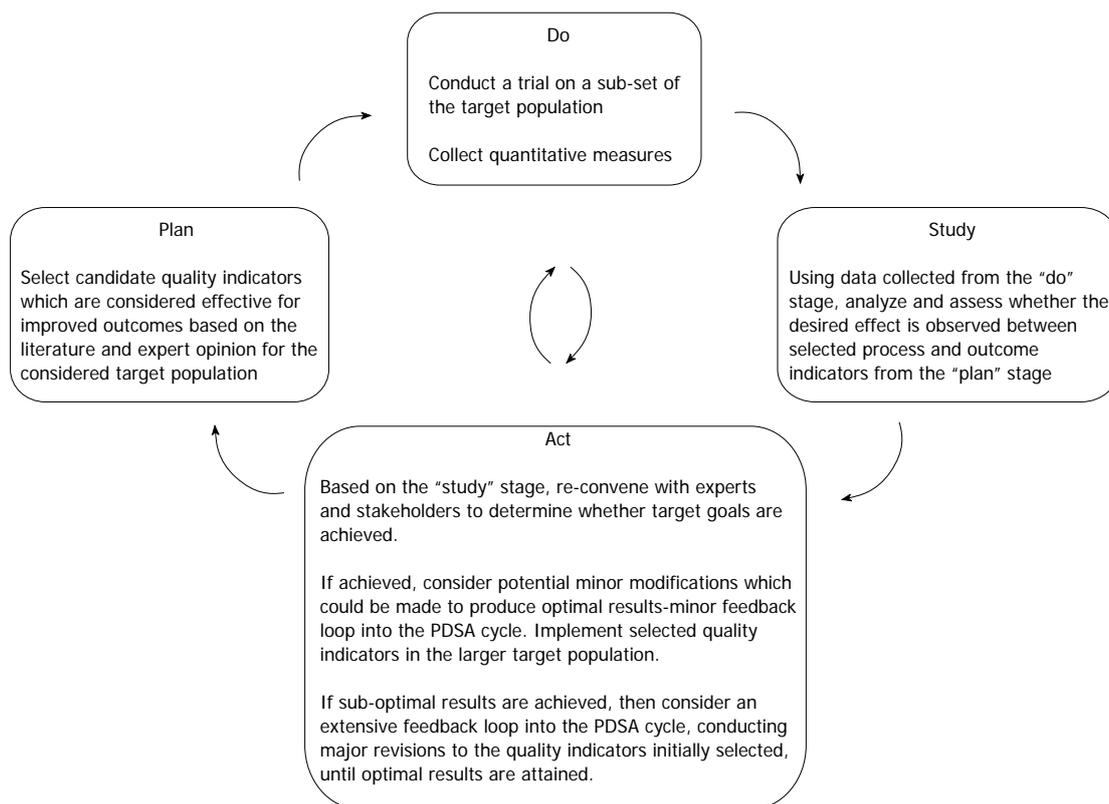

Figure 1 Modified plan-do-study-act cycle. PDSA: Plan-do-study-act.

and the lack of feed-back and change. Too often, quality indicators are developed and measures are extracted, but the process does not extend further beyond that point<sup>[21]</sup>.

### WHAT ARE QUALITY INDICATORS?

The process of quality improvement of medical care requires markers of adequate and inadequate care. The essential building blocks for quality improvement efforts are the proper identification and implementation of effective quality indicators<sup>[22]</sup>. These quality indicators are measurable elements of practice performance for which there is evidence or consensus that they may be applied to assess and improve the quality provided<sup>[23]</sup>. The types of quality indicators have been broadly categorized as follows: (1) Structural measures-[indicators to do with the structure of the health system (*e.g.*, staffing, equipment, electronic medical records)]; (2) Process measures-[indicators to do with the process of providing care (*e.g.*,

investigations, treatment, interactions with patients)]; and (3) Outcomes measures-[indicators which assess the outcome of patients (*e.g.*, mortality, morbidity, quality of life, patient satisfaction)]<sup>[18]</sup>. While improvement in all categories of indicators is desirable, process measures have garnered the majority of the attention, as they are most easily modified. To serve their intended purpose, process measures should predict facility-level outcomes, predict patient-level outcomes, and specify changes in care that are supported by the scientific evidence while being acceptable to patients and clinical staff<sup>[24]</sup>.

### QUALITY IMPROVEMENT IN PEDIATRIC IBD

Understanding the benefits associated with standardized quality improvement efforts, an initiative called ImproveCareNow (ICN) was implemented amongst several

centers in the United States, and is rapidly expanding<sup>[25]</sup>. It consists of a network of IBD centers engaged in a well-designed quality improvement program with an overall aim to determine whether measuring and decreasing variability would improve remission rates and other outcomes<sup>[25]</sup>. Patient details and center practices are inputted prospectively into a registry, with quality indicator compliance rates fed back to centers on a regular basis. This feedback mechanism forms the basis of well-planned quality improvement efforts, including comparative reports, knowledge sharing activities, and clinical pre-visit planning mechanisms. The participating centers can then use their own results as benchmarks and compare future results as markers of improvement. They can also compare their performance to other participating centers<sup>[26]</sup>. Initial results from ICN activities are promising, with improved compliance and remission rates demonstrated in the earliest years of the program. Crandall *et al*<sup>[27]</sup> reported improvement in adherence to the selected quality indicators based on prospectively collected data from 6 participating centers. This was associated with a higher proportion of patients with inactive disease by Physician Global Assessment (PGA). However, improvements were relatively modest (13% improvement in remission rates for CD, 11% improvement for UC, based on statistical process control methods). These improvements were associated with a decreased proportion of patients with mild active disease. The proportion of patients with moderate to severely active disease remained stable over time. In addition, improvements in remission rates measured by the more objective short Pediatric Crohn's Disease Activity Index (sPCDAI) were smaller than those measured with PGA<sup>[13,28]</sup>. This raises the issue of disease activity measurement in IBD. As evidence grows that clinical remission is insufficient to predict long-term prognosis, the use of measures which correlate strongly with mucosal healing and complete remission becomes especially important<sup>[29]</sup>.

In another study, Cincinnati Children's Medical Centre, one of the original participating centers in ICN with a long history of quality improvement efforts, published preliminary results of their quality improvement program in a separate report<sup>[30]</sup>. As with ICN, a registry was developed, and indicators and outcomes were measured. To assess remission rates, PGA was used, along with patient-reported symptoms. Other variables measured included use of azathioprine and corticosteroids. They also assessed the use of vitamin D supplementations and serum 25-hydroxyvitamin D levels. Process and outcome indicators were chosen based on available guidelines and expert consultation. The institution reported improved remission rates of 59% to 76%, ( $P < 0.05$ ), and a decreased use of repeated steroid courses of 17% to 10%, ( $P < 0.05$ ). Investigators also found significant associations between decreased disease activity and vitamin D supplementations as well as disease activity and serum 25-hydroxyvitamin D levels ( $P = 0.02$ ), although there was no control for confounders such as overall medica-

tion adherence and frequency of clinic visits<sup>[30]</sup>.

While ICN has become the first large-scale pediatric IBD quality improvement network to demonstrate successful changes in practice, some lessons can be learned from their methods (as well as those of quality improvement efforts in other pediatric patient groups) to further increase the likelihood of success in future quality improvement efforts.

## QUALITY INDICATOR DEVELOPMENT AND VALIDATION

The indicators developed by ICN formed the basis of the measurement and feedback system, and therefore were developed with the assumption that improvement in the care provided and outcomes achieved would follow improved compliance with these indicators.

The initial set of indicators developed by ICN were not considered adequate and were revised<sup>[25]</sup>. The initial 19 measures initially deemed appropriate for improving pediatric IBD quality were implemented amongst multiple centers. As these measures were being used in routine practice, it became obvious that several quality indicators needed further clarification, and some measures were not appropriate or feasible for inclusion<sup>[25]</sup>. Flexibility is therefore required in the development and implementation of a quality improvement network, and the allowance for revision is an important part of the quality improvement process.

A pilot phase, as conducted by ICN is also important to ensure that intervention in the population being studied will produce a desirable effect. While quality indicators in quality improvement efforts are typically derived using RAND appropriateness methodology, which integrates expert opinion and review of the evidence, the literature may not be representative of the centers involved in the network<sup>[24]</sup>. For example, a quality improvement network could consist of centers whose patients are mostly from low income neighborhoods. Measurement and control for these confounding factors is paramount. Without a pilot phase, and assessment of confounding, a formal quality improvement network may use imprecise process measures, leading to wasted resources and possibly misleading information<sup>[24]</sup>. Following development of a second set of indicators for ICN, various mechanisms were put into place to provide clarification (such as a manual detailing strategies for accurate and complete measurement by participating centers). Of the 19 quality indicators developed, the quality indicators assessed by Crandall *et al*<sup>[25,27]</sup>, through ICN can be found in Table 2.

Both sets of ICN quality indicators were developed using RAND appropriateness methodology. Briefly, experts convene twice, before and after a meeting to rate importance of items derived from existing medical literature<sup>[31]</sup>. Median scores are calculated and a final list is developed<sup>[32]</sup>. Although reliability, feasibility and validity of indicators using the RAND appropriateness method have been established, improvement in the performance of

**Table 2** ImproveCareNow quality indicators assessed in Crandall *et al*<sup>[25,27]</sup> (of 19 total indicators developed)

Original set of quality indicators	Modified set of quality indicators	Results of quality improvement
Process: Diagnostic evaluation, disease phenotype, disease severity, body mass index including height and weight are all presented as separate measures under the domain titled: "Initial Diagnostic Evaluation"	Process: Assessing disease phenotype, disease severity, body mass index including height and weight were combined into a single "bundled" domain titled: Model classification	Increase in complete disease classification through the "bundled" measures: CD 38% <sup>b</sup> increase, UC 27% <sup>b</sup> increase
Outcome: Nutritional and growth status (those "at risk" with evaluation plans and those currently experiencing "failure" with treatment plans) are presented as separate domains	Outcome: Nutritional and growth status (those "at risk" and those currently experiencing "failure") are combined into the same domain, with no reference to further intervention plans based on the assessed status	Nutritional status: No changes in BMI z-scores for CD, however there was a 0.11 decrease in BMI z-score for UC ( $P = 0.01$ ) Growth status did not change for CD and UC
Process: Treatment measures listed consist of measuring TPMT levels to ensure appropriate doses of thiopurine are prescribed	Process: Several other treatment quality indicators were included under the domain titled Treatment Measures which were not included in the original set such as anti-TNF therapy, skin test, screening for tuberculosis, appropriate infliximab and methotrexate dosage, among several others  Outcome: Remission as an outcome measure was added (overall remission, prednisone free remission and sustained remission) The absence of prescribing prednisone was also an added outcome measure	Improved compliance with TPMT status assessment before prescribing thiopurines: CD 20% <sup>b</sup> increase, UC 23% increase Improvement in appropriate dose: CD 8% <sup>b</sup> increase, UC 41% <sup>b</sup> increase  Only those with mild disease had significant changes to disease activity for CD and UC Remission rate (sPCDAI) increased 4% ( $P < 0.0001$ ) Proportion with inactive disease improved: CD 13%, UC 11% Proportion who were not on prednisone increased by 4% for CD

<sup>b</sup> $P < 0.01$ . CD: Crohn's disease; UC: Ulcerative colitis; BMI: Body mass index; TPMT: thiopurine methyltransferase; TNF: Tumor necrosis factor; sPCDAI: Short pediatric Crohn's disease activity index.

the selected indicators do not necessarily correlate with improved outcomes<sup>[33]</sup>.

The typical indicator development process does not include a validation stage to ensure that the effects on outcomes are desirable. An alternative to the RAND appropriateness method incorporating a validation stage was proposed by Harris *et al*<sup>[24]</sup> in the context of an alcohol addiction program. First, outcomes were collected and compared from pre- and post-treatment in a large sample of the target population. The goal of this stage was to determine whether implementing an effort to improve the completion of selected quality indicators would improve scores from baseline<sup>[24]</sup>. A candidate set of quality indicators were selected from available literature, and association between selected indicators and outcomes were evaluated, using statistical methods and controlling for important confounding variables. As several predictors were tested for effects, true positives were maximized and false positives were minimized to avoid detection of spurious associations<sup>[24]</sup>. Finally, those indicators which demonstrated the highest statistical correlation with outcomes were cross-validated with another subset of patients from the target population to determine whether the effect is sustained. Lastly, expert consultation was re-convened and indicators were re-evaluated<sup>[24]</sup>. This approach may result in indicators that are more closely correlated with outcomes, thereby maximizing the cost-benefit ratio of implementing a formal quality improvement network.

Ideally process measures which indicate quality should be associated with both facility-level and patient-outcomes<sup>[24]</sup>. Outcomes chosen by ICN as important

measures of success include remission rates (as measured by both PGA and PCDAI), nutritional status [measured by body mass index (BMI) z-score], linear growth velocity, and steroid-free treatment rates<sup>[27]</sup>. Some of the indicators chosen would not directly correlate with these outcomes. For example, thiopurine methyltransferase (TPMT) genotype status would dictate safety of use of azathioprine or 6-mercaptopurine and risk of adverse events, but may not directly affect remission or growth velocity. In addition, completion of TPMT genotype is restricted to certain regions with some centers preferring TPMT phenotypic expression testing, and others preferring to monitor complete blood count and/or serum azathioprine metabolite levels. Therefore, TPMT genotype measurement may predict avoidance of serious adverse events, but may not be associated with either patient-level or facility-level outcomes<sup>[34]</sup>.

In summary, while ICN has successfully demonstrated improved documentation and compliance with select indicators, only modest benefits in patient outcomes have been achieved. Rigorous pilot work, with assessment and validation of correlation between indicators and outcomes could improve success. Elimination of indicators that are unassociated with outcomes would reduce the burden on participating centers and improve the cost benefit balance of a quality improvement network.

## LESSONS LEARNED IN OTHER PEDIATRIC QUALITY IMPROVEMENT PROGRAMS

As the idea of quality improvement in health care has

become increasingly significant, several network collaboratives have been created with the overall goal of improving child health. A recent review by Billett *et al*<sup>[35]</sup> highlighted five well-established and impactful regional and national pediatric quality improvement networks in the United States. The networks were in the fields of IBD (ICN), childhood asthma care, perinatal care, patient safety, and central line associated blood stream infection prevention in intensive care patients.

Although the review identified five examples of successful collaboratives, there are many other collaboratives in existence which have been able to demonstrate successes in their endeavors as well. The Canadian Neonatal Network (CNN) is a large network which includes upwards of 30 neonatal centers across Canada, with the goal of improving care in intensive care units, and therefore improving neonatal outcomes. Information on patients are collected in a database, which is then subsequently used to inform selection of indicators and to benchmark progress. Quality improvement is a priority of the CNN, as demonstrated by the creation of evidence-based practice for improving quality (EPIQ) cluster randomized controlled trial<sup>[36]</sup>. EPIQ aimed to reduce nosocomial infections and bronchopulmonary dysplasia (BPD). Results demonstrated significantly reduced nosocomial infections and BPD in the quality improvement intervention group compared with control centers<sup>[36]</sup>. In EPIQ, evidence based literature is used to inform the selection of quality indicators and information collected from the database is used to inform the use of the most appropriate indicators<sup>[37]</sup>. Based on the EPIQ trial to assess the association between indicators and outcomes, the collaborative is now confident that these indicators can be used to determine high quality care in all centers involved in the CNN.

Another pediatric collaborative network aimed to improve the quality of care received by children with asthma presenting to emergency departments<sup>[38]</sup>. Process and outcome quality indicators were chosen from an existing adult quality initiative, where associations between the selected process indicators and outcomes were observed<sup>[39]</sup>. Unfortunately, preliminary results from the pediatric collaborative did not find an association between these process indicators and outcomes, indicating the importance of validation of indicators in the specific patient group to which they will be applied prior to their widespread application<sup>[38]</sup>.

Another quality improvement network in pediatric asthma based their quality improvement efforts on the chronic care model<sup>[40,41]</sup>. Indicators were selected from existing guidelines, a pilot study was conducted to collect data before and after the intervention in cases and controls, and results of the pilot study were used to refine the processes used for quality improvement. After the rigorous initial process, the network was expanded to additional centers. Initial research from this network demonstrated significant improvement in the completion of processes, which resulted in improved outcomes<sup>[41]</sup>.

IBD practitioners and researchers are certainly not

the only specialists dealing with these issues in chronic inflammatory conditions. No fewer than four sets of quality indicators have been developed for arthritis care<sup>[42-45]</sup>, including one set for juvenile idiopathic arthritis<sup>[43]</sup>. While quality improvement efforts are planned for arthritis care (including by the eumusc.net network), care providers also struggle with issues of measurement and validation<sup>[46]</sup>.

## CONCLUSION

The increased availability of routinely-collected health data (including disease registries, electronic health records, and health administrative data) has resulted in a spotlight on unnecessary variability in the medical care of children with IBD. Quality improvement efforts have therefore never been more relevant, and reduction in negative outcomes in children with chronic diseases such as IBD could save healthcare costs and improve long-term quality of life for patients and families. While quality improvement programs in pediatric IBD are more advanced than those in other pediatric diseases, continually learning from the successes and limitations of networks such as ICN will allow for more rapid improvement in outcomes. The development and validation of quality indicators that are more strongly associated with outcomes will allow for more efficient implementation of quality improvement efforts, thereby reducing costs while improving the quality of life of children with IBD. We are at the beginning of a revolution in health care improvement, and we must therefore continuously learn from and improve upon the methods currently employed by our current quality improvement efforts.

### Abstract

Over the past decade, there has been increasing focus on improving the quality of healthcare delivered to patients with chronic diseases, including inflammatory bowel disease. Inflammatory bowel disease is a complex, chronic condition with associated morbidity, health care costs, and reductions in quality of life. The condition is managed primarily in the outpatient setting. The delivery of high quality of care is suboptimal in several ambulatory inflammatory bowel disease domains including objective assessments of disease activity, the use of steroid-sparing agents, screening prior to anti-tumor necrosis factor therapy, and monitoring thiopurine therapy. This review outlines these gaps in performance and provides potential initiatives aimed at improvement including reimbursement programs, quality improvement frameworks, collaborative efforts in quality improvement, and the use of healthcare information technology.

### INTRODUCTION

Over the past decade, there has been increasing focus on improving the quality of healthcare. Much of this interest was inspired through the publication of *To Err is Human* by the Institute of Medicine (IOM) in 2000, that painted a portrait of a health care system full of preventable morbidity and mortality in desperate need for change<sup>[1]</sup>. This has led to the reinvigoration of the quality improvement (QI) movement, the foundation of which had developed over the last century.

QI is defined by the IOM as "the degree to which health services for individuals and populations increase

the likelihood of desired health outcomes and are consistent with current professional knowledge<sup>[2]</sup>. Fundamental principles of the study of QI include reflection on individual and peer performance in delivering high quality care, transparency in reporting performance, and implementing changes to improve deficiencies with the ability to measure successes and failures. Variation in practices may also be a marker of suboptimal performance. This had led to the resurrection and refinement of measures, study designs, and statistical analyses that are uniquely suited to QI.

Chronic disease management has become a significant focus of QI initiatives given their associated morbidity and cost. Some of this may be due to gaps in delivering evidence-based care. This was demonstrated in a landmark trial that showed that only 57% of outpatients regularly receive recommended standard of care for a variety of conditions<sup>[3]</sup>. As a result, there has been significant focus on improving delivery of evidence based care and preventative measures to patients with chronic disease in order to decrease complications, hospitalizations, and death. Moreover, quality indicators are increasingly becoming incorporated in the accreditation and funding models of healthcare institutions. Inflammatory bowel disease (IBD) is a chronic gastrointestinal condition characterized by relapsing inflammation. Crohn's disease (CD) and ulcerative colitis (UC) are the major subtypes of IBD. In North America, the incidence of CD ranges from 3.1-20.2 cases per 100000 population and 2.2-19.2 cases per 100000 population for UC<sup>[4,5]</sup>. While the incidence is less in Asia and the Middle East, the incidence and prevalence have been noted to be rising in many different regions of the world<sup>[5]</sup>. As in other chronic diseases, IBD patients are at increased risk of morbidity due to symptoms, hospitalizations, and complications of disease or therapy<sup>[6]</sup>. Moreover, there are significant health care costs and reduction in quality of life associated with IBD<sup>[7,8]</sup>. The economic burden of IBD is significant, with high disability rates among this young cohort of patients<sup>[9]</sup> and one cost analysis of eight European cohorts showing a mean total health care cost of 1871 euros per patient-year over 10 years<sup>[10]</sup>. Patients requiring hospitalization had 10 fold higher costs. Most patients with IBD are managed in the outpatient setting. However as disease severity progresses and complications of disease or therapy arise, hospitalization is often required. Unlike some other chronic conditions, IBD is a heterogeneous disease with a wide spectrum of disease phenotypes and management strategies. This makes disease wide QI strategies particularly challenging. Nonetheless, there are several areas of IBD care that are amenable to QI study and change. This review outlines current gaps in quality in a number of outpatient domains and provides potential initiatives aimed at improvement.

## ASSESSMENT OF DISEASE ACTIVITY

A challenging management issue in patients with IBD is how to best assess disease activity. This assessment has

traditionally been based on clinical symptoms. However, with the increasing number of more objective tools to assess disease activity now available, such as serum inflammatory markers and fecal calprotectin, the use of symptoms alone may no longer be the best approach to follow these patients. Reliance solely on symptoms can potentially miss ongoing inflammation that may not be clinically apparent. In a Groupe d'Etudes Therapeutiques des Affections Inflammatoires Digestives (GETAID) study of 121 patients with CD, there was weak correlation between clinical symptoms and endoscopic activity<sup>[11]</sup>. This puts patients at risk of disease complications and may make treatment more difficult once symptoms ultimately develop. Alternatively, active inflammation may not always be the cause of persistent gastrointestinal symptoms in patients with IBD. A meta-analysis of 13 studies containing 1703 IBD patients found the pooled prevalence for symptoms meeting criteria for IBS was 39%, with an OR compared to healthy controls of 4.89 (95%CI: 3.43-6.98)<sup>[12]</sup>. Similarly, a pediatric study found significant overlap between functional abdominal pain and CD, with almost half of the patients meeting criteria for functional pain classified as having active IBD according to the Pediatric CD activity index<sup>[13]</sup>. This often leads to patients being inappropriately treated with immunosuppressants, with a low likelihood of improvement in symptoms and exposure to unnecessary risk. Therefore, there is a clear need for routine objective assessments of patients with IBD both at diagnosis and during follow up. While regular endoscopic evaluation, the gold standard to assess disease activity, has well established barriers such as cost and invasiveness, incorporating other objective tools such as erythrocyte sedimentation rate, C-reactive protein, and fecal calprotectin may facilitate more accurate and targeted approaches to managing these patients. A recent comparison of these tools noted a sensitivity and specificity of C-reactive protein > 6 mg/L of 68% and 72%, respectively as compared to a sensitivity and specificity of fecal calprotectin of 91% and 90%, respectively for the detection of endoscopically active disease<sup>[14]</sup>. More studies such as this are needed to provide more insight on the most valuable and cost-effective non-invasive approach to monitor disease activity in patients.

## STERIODS SPARING AGENTS

Corticosteroids are effective in inducing remission among patients with CD and UC<sup>[15]</sup>. However, they have not been shown to be helpful in long-term maintenance<sup>[16]</sup>. Moreover, their poor safety profile and tolerability makes avoidance of prolonged use a priority. Nonetheless, a significant proportion of patients treated with corticosteroids remain on extended courses. A retrospective review of patients referred to a tertiary IBD center in the United States found that over 75% of patients had been on corticosteroids for over 3 mo, including patients classified as having "mild" disease<sup>[17]</sup>. There was no attempt to consider steroid sparing medications, such as immunomod-

lators, in almost 60% of patients. Similarly, in a study of time trends in therapy among 16 medical centers between the years 1998 and 2005, there was a 27% increase in prolonged corticosteroid use (defined as > 120 d) among patients with UC<sup>[18]</sup>. Significant variation in the use of steroid-sparing agents was noted among centers. This was also demonstrated among 10 North American pediatric centers whereby the use of immunomodulators as a steroid sparing-agent varied significantly, ranging from 30%-95% of patients followed at the center<sup>[19]</sup>. Corticosteroids are a well-established risk factor for osteoporosis and as such, patients on extended courses should undergo bone density measurement. Despite this recommendation, a practice audit at a large tertiary IBD center found that almost 80% of patients referred had not received the appropriate screening for metabolic bone disease<sup>[17]</sup>. Clearly there is significant variation in practice patterns regarding the recognition of the need to minimize steroid exposure and highlights the underuse of steroid-sparing agent such as immunomodulators and anti-TNF therapy.

## SCREENING PRIOR TO ANTI-TUMOR NECROSIS FACTOR THERAPY

Anti-tumor necrosis factor therapy (anti-TNF) has emerged as an effective treatment for IBD<sup>[20-23]</sup>. It, however, carries risk of infection due to immunosuppression. The incidence of reactivation of latent tuberculosis infection (LTBI) has been shown to be increased among individuals treated with anti-TNF. A review of the United States Food and Drug Administration Adverse Event Reporting System found an incidence of 24 cases of tuberculosis per 100000 per year among those treated with anti-TNF, which translates into a 4 fold increased risk<sup>[24]</sup>. Similarly, the incidence of hepatitis B virus (HBV) reactivation is also increased among these patients<sup>[25-27]</sup>.

In order to minimize this risk, screening measures have been recommended prior to initiating anti-TNF therapy. Screening for LTBI and HBV prior to treatment has been recommended by the United States Food and Drug Administration, Health Canada, and all gastrointestinal societies<sup>[28-31]</sup>. Screening is effective in reducing infections complications, is easy to perform, and has minimal risks to patients<sup>[32-34]</sup>. This involves tuberculin skin testing and chest-X-ray for LTBI and a panel of three serological blood tests for HBV (HBsAg, HBsAb, HBcAb). Adherence to screening with tuberculin skin testing and chest x-ray has been shown to reduce the risk of tuberculosis by 78%-90%<sup>[32,33]</sup>. Screening for HBV with subsequent vaccination or chemoprophylaxis if indicated has also been shown to be effective<sup>[34]</sup>.

Despite these recommendations, cases of severe and sometimes fatal infection with tuberculosis or hepatitis B have been described, and many of these can be attributed to lack of screening<sup>[34-36]</sup>. A retrospective review of over 200 patients followed at a large United States academic IBD center revealed only 65% of patients were appropriately screened for tuberculosis and 25% screened for

hepatitis B<sup>[37]</sup>. Similarly, a study from Australia showed that only 50% of gastroenterologists were routinely screening for HBV prior to starting anti-TNF<sup>[38]</sup>. This underscores the problem in provider's adherence to screening. The development of tuberculosis or hepatitis B while on anti-TNF has the potential for high morbidity and mortality. Given the ease and effectiveness of screening and the consequences of lack of screening, one can argue that anti-TNF screening rates less than 100% are unacceptable.

There is growing literature exploring contributors to this safety problem. In their review of 287 IBD patients starting anti-TNF, Vaughn *et al.*<sup>[37]</sup> identified factors most often associated with lack of screening for tuberculosis: previous exposure to anti-TNF [OR = 5.3 (95%CI: 2.8-10.3)], health care providers in practice for more than 10 years [2.5 (95%CI: 1.4-4.5) and treatment at a non-IBD center [1.9 (95%CI: 1-3.4)]. The factors contributing to lack of HBV screening were the same. These reasons highlight the role of lack of knowledge, as physicians in practice longer or those at a non-IBD center may be less likely to be up to date with current guidelines. Previous exposure to anti-TNF may falsely reassure the prescribing physician that the appropriate work up had already been completed. This highlights the contribution of confusion as to who is responsible for screening. Uncertainty as to how and when to screen is also an important contributor, as evident in a gastroenterology practice audit that showed that while most knew that screening was indicated, there was significant heterogeneity in the type and timing of screening<sup>[38]</sup>. Thus, knowledge gaps as to the need for screening, confusion surrounding responsibility for screening, and details regarding how to screen appear to be major contributors to this problem.

## MONITORING THIOPURINE THERAPY

Thiopurines, including azathioprine and 6-mercaptopurine, are commonly used in patients with IBD. While most patients tolerate these medications with minimal side effects, ongoing monitoring is required once therapy commences. Regular complete blood counts (CBC) are recommended by all published guidelines to monitor for myelosuppression<sup>[39-42]</sup>, for example weekly CBC within the first month of therapy, every other week for the following two months, and every 3 mo thereafter. While the routine checking of thiopurine S-methyltransferase (TPMT) genotype and phenotype status prior to therapy remains controversial, it is strongly recommended by the United States Food and Drug Administration and has recently been listed as a quality indicator<sup>[31,43]</sup>. Regular monitoring of liver chemistries is also recommended by some, although the frequency of which is less clear<sup>[42]</sup>. Despite tremendous experience with this class of medication that has been available for over 5 decades, variation in monitoring patients while on this medication is significant and lapses in many best-practice recommendations are noted. A survey of members of the Canadian Association of Gastro-

**Table 1 American Gastroenterology Association Physician Quality Reporting System inflammatory bowel disease measures**

1	IBD type, location and activity all documented
2	Corticosteroid sparing therapy after 60 d
3	Bone loss assessment
4	Influenza immunization

6	Testing for latent tuberculosis before initiating anti-TNF therapy
7	Assessment of Hepatitis B status before initiating anti-TNF therapy
8	Tobacco use: screening and cessation intervention

IBD: Inflammatory bowel disease; TNF: Tumor necrosis factor.

enterology revealed that while all providers acknowledged the need to monitor blood counts, there were differences in the frequencies of monitoring<sup>[44]</sup>. Forty-two percent of those surveyed checked CBC weekly after starting therapy while 26% said they checked monthly and 23% biweekly during the initial period of treatment. Moreover, only 62% of respondents routinely monitored liver chemistries. In terms of routine TPMT testing, an international questionnaire sent to experts in the use of thiopurines in IBD found that only 30% and 43% routinely ordered genotype and phenotype testing, respectively<sup>[45]</sup>. Lack of reimbursement for testing was the most important predictor of not ordering the test, and almost half of respondents felt that they would incorporate routine testing into their practice if it was reimbursed.

More recently, an association with thiopurine use and non-melanoma skin cancer (NMSC) has been noted. In a review of over 1000 South African IBD patients, a strong association was noted between thiopurine exposure and NMSC (OR = 5.0, 95%CI 1.1-22.8)<sup>[46]</sup>. This was similar to the association noted by Peyrin-Biroulet *et al*<sup>[47]</sup> in which ongoing thiopurine use had a hazard ratio for NMSC development of 5.9 (95%CI: 2.1-16.4). Lifelong, regular dermatologic screening has therefore been recommended<sup>[48]</sup>. Nonetheless, a recent survey of dermatologists and gastroenterologist found that only 46% of gastroenterologists were aware of the association between NMSC and immunosuppression<sup>[49]</sup>. This implies that at least half of IBD patients are not receiving the recommended screening.

## INTERVENTIONS AIMED AT IMPROVEMENT

In order to adequately address gaps in care, an understanding of the contributing factors to the target problem is essential. While the evidence in support of a potential intervention is often regarded as the most important factor when choosing between potential initiatives focused on improving care, there is often limited supporting research available. As a result, other factors also need to be considered when choosing QI interventions including the prevalence and severity of the problem, the potential for undesirable outcomes as a result of the intervention, cost, complexity, and the ability to generate momentum

for future related initiatives<sup>[50]</sup>. Moreover, once an intervention has been selected, continuous measurement is essential in order to know if an observed change represents an improvement. Thus, prior to implementing an initiative, well defined measures need to be developed and measured continuously. This will provide support that the initiative is responsible for any observed improvements in performance or alternatively, negative outcomes and unattended consequences.

### Reimbursement programs

Guidelines have outlined algorithmic approaches for following this complex group of patients. However, the uptake of IBD guidelines by gastroenterologists has been shown to variable<sup>[51,52]</sup>. Therefore, other improvement approaches are necessary. In 2006, the American Gastroenterology Association began to develop quality indicators that would be eligible for reimbursement through the Physician Quality Reporting System (PQRS)<sup>[53]</sup>. Recently, IBD specific measures have been added to this growing list of indicators, and documentation of disease activity was the first such IBD indicator implemented. Other IBD indicators eligible for reimbursement through this program include recommending steroid-sparing therapy after 60 d of corticosteroid, assessment of tuberculosis and hepatitis B status prior to anti-TNF therapy, vaccinations, bone loss assessment, and addressing tobacco cessation (Table 1). While the impact of the PQRS on increasing objective assessment of disease activity is not yet known, data extrapolated from other disease states shows promise for the potential beneficial impact of similar reimbursement programs<sup>[54]</sup>. Nonetheless, prior to implementing such an intervention, careful study is required as the literature showing the benefits of reimbursement programs on quality are conflicting and some studies identifying unintended consequences, such as providers avoiding the most severely ill patients, a phenomenon known as “adverse selection”<sup>[54-57]</sup>.

Although not designed for the purposes of a reimbursement program, the Crohn’s and Colitis Foundation of American have recently sponsored the publication of a set of quality indicators<sup>[43]</sup>. Both process and outcome indicators were developed that encompass a variety of domains in IBD care including treatment, surveillance, and health care maintenance. A number of corticosteroid related indicators are defined such as “IF a patient with IBD requires at least 10 mg prednisone (or equivalent) for 16 wk or longer, THEN an appropriately dosed steroid-sparing agent or operation should be recommended” and steroid related outcomes measures including; (1) proportion of patients with steroid-free clinical remission for a 12 mo period; and (2) the proportion of patients currently taking prednisone. Screening for latent tuberculosis and hepatitis B prior to therapy with anti-TNFs and TPMT testing prior to thiopurine therapy are also included. As more quality indicators develop and become increasingly incorporated into the accreditation processes of health care institutions, it is likely that more reimbursement models, or alternatively citations and pen-

alties for under performance, can be expected over the coming years.

### **Quality improvement frameworks**

It does not appear that knowledge gaps are solely responsible for barriers in delivering high quality, evidence-based care. In terms of the underuse of steroid sparing agents, for example, the avoidance of prolonged corticosteroid and the importance of transitioning to steroid-sparing agents are not new concepts, have been endorsed by all gastrointestinal societies, and have been highlighted in guidelines for many years. This was borne out in a survey of gastroenterologists from 36 countries whereby 100% of those surveyed agreed that there is minimal evidence for continuing high dose corticosteroids for more than 3 wk and that steroid-sparing agents should begin to be considered after 2-4 wk of therapy<sup>[58]</sup>. Therefore other contributors beyond physician knowledge base need to be addressed. Patients often initiate or modify steroid doses on their own without consultation with their health care provider. This may be due to poor access to a timely visit to a gastroenterologist when symptoms first present or when disease activity flares. Early referral to a specialist has been shown to improve IBD outcomes and initiatives aimed at improving access to gastroenterology have been shown to reduce steroid use and increase the use of early steroid-sparing therapy<sup>[59]</sup>. A Swedish gastroenterology unit implemented a quality improvement framework whereby a registry of quality metrics was established and performance tracked<sup>[60]</sup>. All routine visits were initiated by the clinic, rather than the patients and regular reminders to contact a designated IBD nurse for problems was provided. The program resulted in 98% of patients receiving regular IBD follow up visits, less than 3 wk between primary care referral and specialist visit, and less than 2 d to schedule an acute patient visit during disease flares. This experience highlights that implementing well designed frameworks, which are common place in other chronic diseases, has the potential to improve quality of care in IBD<sup>[61]</sup>. Frameworks need to be developed with the appropriate local context in mind with and some have argued that frameworks do nothing to improve quality but rather improve documentation alone<sup>[62]</sup>. This underscores the importance of continuous measurement after implantation to ensure the effort and costs associated are translating to improvements.

### **Collaborative efforts in quality improvement**

Another potential motivator for change is collaborative efforts between institutions. These involve multiple sites working together towards a common improvement goal through receiving training in quality improvement methods, defining QI metrics, tracking performance, and transparency in reporting<sup>[63]</sup>. While the use of improvement collaboratives in inflammatory bowel disease lags behind other chronic diseases, early outcomes of such initiatives have been promising. The ImproveCareNow Network consists of 51 pediatric hospitals across the United States and Europe that adopted the Chronic Ill-

ness Care Model and developed standardized practices and measures<sup>[64,65]</sup>. Process and outcomes measures were prospectively collected and shared between sites. Early data has shown significant improvements in processes of care and patient outcomes in a variety of care areas. The use of a classification bundles to assess disease location, phenotype, activity, and nutritional/growth parameters at every visits has allowed for standardization between sites. Not only does this improve care, but also allows for collaborative clinical research efforts. Other outcomes already reported by the network include a decrease in the number of patients with CD on corticosteroids and an increase in the number of patients starting thiopurines with TPMT activity measured. These improvements in process measures are likely responsible for the increased remission rates noted in the participating sites. While more data on the efficacy of this and other such collaboratives are needed, given that an overarching theme of QI is to improve care delivery throughout the entire health care system, more widespread adoption of such broad, multi-site quality improvement initiatives should be considered.

### **Advancing healthcare information technology**

The widespread incorporation for healthcare information technology (HIT) has been identified as essential in order to improve quality, safety, efficiency, and coordination of care by many leaders in the field of QI and patient safety<sup>[66]</sup>. Many of the organizations regarded as leaders in the field of QI, such as the Veterans Affairs (VA) system in the United States or the Intermountain Healthcare Network in Utah attribute their success to the early adoption of electronic medical records and ongoing refinement of HIT resources<sup>[67]</sup>. Providers delivering care to IBD patients have the potential to benefit from a variety of HIT related interventions including an electronic health record, computerized provider order entry (CPOE), and clinical decision support. If designed well and appropriately adapted to the context of a given institution, an electronic health record has the potential to improve efficiency, safety, and communication. It also has the potential to engage patients as platforms in which patients are able to access their own health record are increasingly being developed<sup>[66]</sup>. This is important in IBD as patients are often young and may travel or move frequently for school and work. An electronic record also lends well to automated reminders which could address many areas of care that have been shown to have suboptimal performance such as monitoring blood work on thiopurines and bone density assessments<sup>[63]</sup>. CPOE is another HIT intervention that in addition to decreasing medication errors, has the potential to enable drug interaction warnings, monitoring tests, and linkage to decision support systems<sup>[66]</sup>. For example, order sets involve a collection of orders or investigations at one location that when designed well, are effective through improving efficiency, decreasing variation, enhancing workflow, and improving communication of evidence based practices<sup>[68,69]</sup>. Traditionally, order sets have been paper-based, but

electronic order sets have become increasingly popular and have already been evaluated extensively in the patient safety literature. Compared to traditional paper order sets, electronic order sets have been shown to be more readily accessible, easier to link with other relevant order sets, and can be updated in real time<sup>[70]</sup>. A number of areas within IBD patient care may be improved with electronic order sets, such as pre anti-TNF screening. While the evidence for order sets improving anti-TNF screening is lacking, examples in other fields support their utility. A pediatric study showed that an order set improved adherence to evidenced based asthma medication behaviors by almost 25%<sup>[71]</sup>. While these results are encouraging, the quality of most studies evaluating order sets is not high and often employ simple before and after designs with poor control of biases<sup>[72]</sup>. Moreover, some studies have shown unintended consequences of HIT. For example, one study aimed at using an electronic reminder to improve adherence to colon cancer found that following the intervention was unveiled, colon cancer screening adherence actually declined as a result of ineffective reminders and increased fecal occult blood screening rather than colonoscopy<sup>[73]</sup>. Nonetheless, the theory behind order set effectiveness is sound and addressed several of the contributors to the anti-TNF safety problem identified above including knowledge gaps and confusion with details as to how to screen.

## CONCLUSION

Caring for patients with IBD can be challenging due to the heterogeneous nature of the disease and the lack of consensus in many areas of practice. Variation in practice is therefore unavoidable and does not necessarily imply deficiencies in quality. Nonetheless, there are several aspects of IBD care whereby suboptimal performance has been documented and may be amenable to quality improvement initiatives including regular objective assessments of disease activity, recommending steroid sparing therapy, and appropriate monitoring of patients initiating and ongoing immunomodulator and anti-TNF therapy. Reimbursement programs, chronic disease frameworks, QI collaboratives, and health information technology resources are several potential interventions that may benefit IBD patient care. Quality performance indicators are expected to increasingly become incorporated into accreditation and funding models and it is therefore important that gastroenterologists become familiar with QI concepts and consider implementing initiatives where warranted.

### Abstract

Globally, gastric cancer is the 4<sup>th</sup> most frequently diagnosed cancer and the 2<sup>nd</sup> leading cause of death from cancer, with an estimated 990000 new cases and 738000 deaths registered in 2008. In the advanced setting, standard chemotherapies protocols acquired an important role since last decades in prolong survival. Moreover, recent advances in molecular therapies provided a new interesting weapon to treat advanced gastric cancer through anti-human epidermal growth factor receptor 2 (HER2) therapies. Trastuzumab, an anti-

HER2 monoclonal antibody, was the first target drug in the metastatic setting that showed benefit in overall survival when in association with platinum-5-fluorouracil based chemotherapy. Further, HER2 overexpression analysis acquired a main role in predict response for trastuzumab in this field. Thus, we conducted a review that will discuss the main points concerning trastuzumab and HER2 in gastric cancer, providing a comprehensive overview of molecular mechanisms and novel trials involved.

**Key words:** Gastric cancer; Human epidermal growth factor receptor 2; Biomarkers; Target therapies; Trastuzumab; Lapatinib; Pertuzumab; Trastuzumab-DM1; Afatinib

**Core tip:** Advanced gastric cancer is a very aggressive disease though the standard chemotherapy protocols available. In 2010, Trastuzumab for Gastric Cancer trial showed that the combination of trastuzumab, could be considered a new standard option for patients with human epidermal growth factor receptor 2 (HER2) positive advanced gastric and gastro-esophageal junction cancer. Thus, a new era emerged for those patients due to the interesting possibility in prolong survival in a personalized setting (HER2 positive). Our manuscript will provide an overview of the molecular mechanisms involved and also promising targeted therapies in this field.

## INTRODUCTION

Gastric cancer has been described since 3000 BC in ancient Egypt. One of the first epidemiologic studies on cancer, with data spanning from 1760 to 1839, pointed gastric cancer as the most common and lethal. In modern times, it remains one of the most important forms of cancer, with different geographic, ethnic and socio-economic distributions. Incidence is particularly high in Japan, China, South Korea, Chile and Costa Rica. The large regional variations in incidence possibly reflect different prevalences of *Helicobacter pylori* infection, which is responsible for more than 60% of gastric cancer globally. Globally, gastric cancer is the 4<sup>th</sup> most frequently diagnosed cancer and the 2<sup>nd</sup> leading cause of death from cancer, with an estimated 990000 new cases and 738000 deaths registered in 2008<sup>[1]</sup>. The human epidermal growth factor receptor 2 (HER2) protein, a 185 kDa protein (p<sup>185</sup>) encoded by a gene located on chromosome 17q21 is a transmembrane tyrosine kinase receptor with an extracellular ligand-binding domain; a short transmembrane domain and an intracellular domain with kinase activity (Figure 1). It belongs to the epidermal growth factor receptor (EGFR) family of growth factors comprising four structurally related members, HER1 or ErbB1, also known as EGFR, HER2 or ErbB2, HER3 or ErbB3 and HER4 or ErbB4. Activation occurs through homo- or heterodimerization induced by ligands. HER2 is designated an orphan receptor which is believed to homodimerize independently of a ligand or to heterodimerize with another ligand-bound member of the EGFR family. Activation triggers a cascade of events that involves autophosphorylation and activation of the tyrosine kinase domain, Ras/Raf/mitogen-activated protein kinase pathway, phospholipase C- $\gamma$  and phosphatidylinositol-3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) (Figure 2). HER2 receptors have also been found in nuclear localization, where they act as transcription factors for cyclin D1 and p53<sup>[2,3]</sup>. Therefore, *HER2* (also known as *c-erbB-2/neu*) acts as an oncogene involved in the regulation of cell proliferation, differentiation, motility and apoptosis<sup>[4-8]</sup>. Heterodimers of HER2 with other members of the HER family, particularly with HER3, are the most mitogenic dimers and HER2 increases the affinity of EGFR, HER3 and HER4 to their ligands<sup>[9-12]</sup>.

Analysing the molecular structure of HER2 allows new insights into approaching it as a potential therapeutic target (Figures 1 and 3). The extracellular domain of the receptor is subdivided into four subdomains. Whereas subdomains II and IV are involved in the process of dimerization, subdomains I and III are the binding sites for pertuzumab and trastuzumab respectively, two of the most well studied HER2 inhibitors which will be discussed further on. The transmembrane domain of HER2 plays an important role in the process of dimerization and oncogenic mutations in this region were described. The intracellular domain contains the active enzyme site which activates different downstream pathways by phosphorylation<sup>[13-16]</sup>.

The importance of addressing HER2 as a therapeutic target is underscored by a number of molecular and pathological findings. Amplified HER2 relates to processes of carcinogenesis and adverse pathologic features such as tumor size, invasion and metastatic spread; the level of *HER2* gene expression is much higher in cancer cells than that in non-malignant adult cells<sup>[17]</sup>. HER2 overexpression has been reported in breast, lung, salivary gland, ovary, colon, prostate and pancreatic cancers<sup>[18,19]</sup>.

About 10%-34% of invasive breast cancers present HER2 overexpression. Trastuzumab has shown survival advantage in early and metastatic disease and is now a part of standard care. HER2 overexpression stands as a poor prognosis marker for chemo- and endocrine therapy but at the same time as a positive predictive marker for treatment with trastuzumab. Furthermore, trastuzumab proved to be effective as adjuvant treatment in breast cancer with HER2 overexpression, with different chemotherapy regimens<sup>[20-26]</sup>. In gastric cancer, the prognostic role of HER2 overexpression remains controversial. The most important prognostic factor for gastric cancer is the tumor node metastasis (TNM) stage<sup>[20,27]</sup>. Initial works addressing the prognostic significance of HER2 overexpression reported a negative effect on overall survival (OS)<sup>[28,29]</sup>. However, conflicting results regarding the prognostic value of HER2 have been published more recently. Some studies found a negative effect of HER2 on prognosis with reduction in OS<sup>[17,20,29-36]</sup>, others found no relationship<sup>[37-40]</sup> and a trend towards improved survival was found in one cohort<sup>[41]</sup>. A comprehensive review by Jørgensen *et al.*<sup>[42]</sup> found that the majority of publications that fulfilled the selection criteria for the analysis, associated HER2-positive status with poor survival and clinicopathological characteristics such as serosal invasion, lymph node metastases, disease stage or distant metastases. Chua *et al.*<sup>[43]</sup> recently reviewed 49 studies with data regarding the relation of HER2 with clinicopathological variables and survival and concluded that HER2 overexpression is associated with poor survival; results pertaining other variables were not conclusive. HER2 overexpression has also been suggested as a molecular abnormality in the development of intestinal type gastric cancer and HER2 expression increases with disease progression, leading to the suggestion that the initial timing of this event probably occurs in early stages. Barros-Silva *et al.*<sup>[20]</sup> found overexpression and amplification in both components of mixed tumors (intestinal and diffuse components) and *HER2* amplification in early stages, supporting this idea of amplification in an early stage of carcinogenesis. Further support arises from the high levels of concordance between primary tumors and paired metastatic sites found by some authors, suggesting HER2 amplification as an early event and not acquired at a later moment by cells with metastatic potential<sup>[44]</sup>. Kataoka *et al.*<sup>[45]</sup> found no HER2 positivity in the diffuse component of mixed type cases, but also found HER2 overexpression in early TNM T1a cases, pointing towards an early event<sup>[30,46]</sup>. Although these data tend to establish

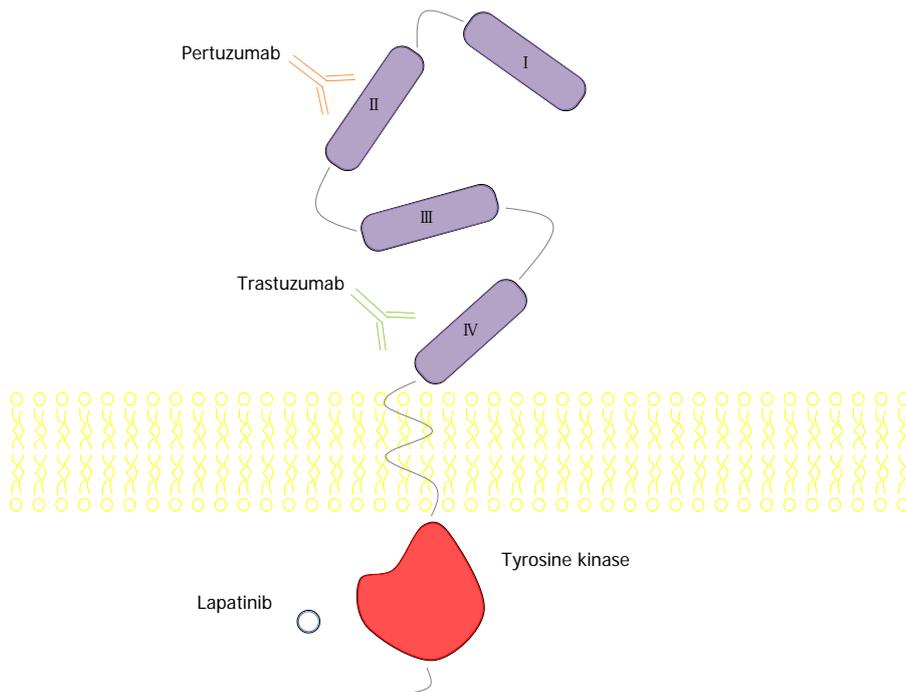

Figure 1 Human epidermal growth factor receptor 2 and binding sites. I-IV: Epidermal growth factor receptor 1-4.

HER2 as a potential negative prognostic factor in gastric cancer, the relation seems not to be as consistent as in breast cancer<sup>[42]</sup>. In fact, more recent studies demonstrate no significant prognostic relationship. In a study involving 381 metastatic gastric cancer patients, Yanjigian *et al*<sup>[47]</sup> found that patients with HER2-positive gastric cancer had longer median OS compared with HER2-negative gastric cancer patients, but on multivariate analysis HER2 status was not an independent prognostic factor. Terashima *et al*<sup>[48]</sup> found no correlation with OS in 829 stage II/III resected gastric cancer patients. Hsu *et al*<sup>[49]</sup> investigated 1036 gastric cancer patients undergoing curative-intent resection. Although HER2 positivity emerged as a favourable prognostic factor for stage III-IV gastric cancer on univariate analysis, it did not on multivariate adjustment.

Despite these conflicting results, it seems likely that HER2 is not associated with an adverse prognosis in gastric cancer in an extent similar to breast cancer; nevertheless, inhibition of the HER2 pathway in patients with HER2 amplification demonstrated clinical benefits. In this review, we will address the main advances in the treatment of advanced gastric cancer, focusing on the novel biomarkers and target therapies concerning HER2 signalling pathways.

## HER2 TESTING IN GASTRIC CANCER

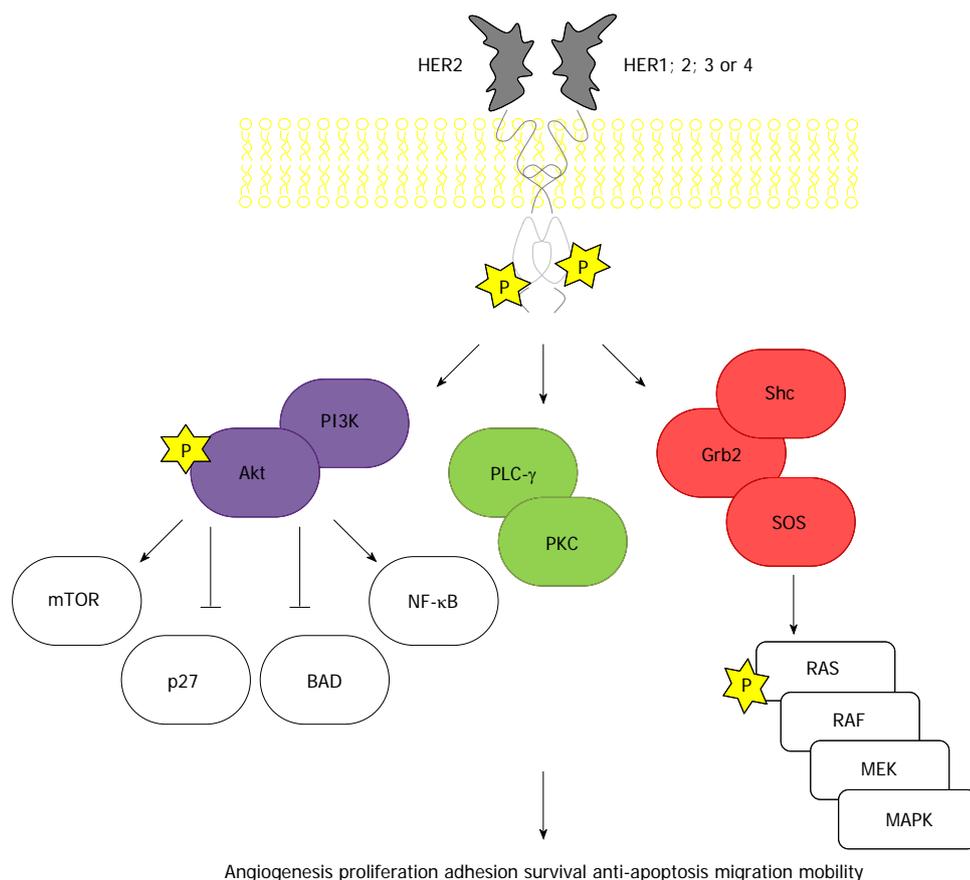

A precise analysis is necessary in order to address the status of HER2 expression in gastric cancer, which constitutes an essential step to select the patients feasible to treatment with HER2 target therapies. Techniques include primarily immunohistochemistry (ICH) and *in situ* hybridization (ISH), which constitute standard techniques

also used in the current practice of HER2-status determination in breast cancer. Current evidence suggests the need to adopt the methods used in breast cancer in order to address HER2 expression in gastric cancer<sup>[50]</sup>. Considering the different biologic origin of the tissue, the high density of glandular structures needs to be understood in its context. In gastric tissue, ICH staining for HER2 occurs typically on the basolateral membrane and less so on the luminal aspect of the cell, conferring an U-shaped appearance to the staining whereas completeness of the membrane staining is the rule for higher scores in breast cancer. Another difference concerns the heterogeneity of immunostaining which is rare in breast, but frequent in gastric tumors. ICH should be used as primary test; cases with ICH score 3+ are candidates for HER2 directed therapy, 2+ scoring cases should be re-tested using ISH; in the case of ISH positivity patients are eligible for these therapeutic modality<sup>[51]</sup>.

## HER2-DIRECTED THERAPIES IN GASTRIC CANCER

In January 2010, the European Medicines Agency granted approval to trastuzumab plus chemotherapy in the treatment of with IHC 3+ or 2+/metastatic adenocarcinoma of the stomach or gastro-esophageal junction (GEJ)<sup>[52]</sup>. The United States Food and Drug Administration approved trastuzumab for HER2 overexpressing patients, without further specification<sup>[53]</sup>.

Trastuzumab is a fully humanized monoclonal antibody that binds to the extracellular domain of the receptor, acting by blockage of the HER2 receptor cleavage, inhibition of dimerization, as well as by the induction

**Figure 2 Human epidermal growth factor receptor 2 signalling pathways.** HER: Human epidermal growth factor receptor; PI3K: Phosphoinositide 3-kinase; BAD: Bcl-2-associated death promoter protein; NF-κB: Nuclear factor κB; PLC-γ: Phospholipase C gamma 1; PKC: Protein kinase C; Grb2: Growth factor receptor-bound protein 2; SOS: Son of Sevenless; MEK: Mitogen-activated protein kinase 1; MAPK: Mitogen-activated protein kinase; mTOR: Mammalian target of rapamycin; RAS: Rat sarcoma viral oncogene; RAF: Rapidly accelerated fibrosarcoma.

of antibody-dependent cellular cytotoxicity (ADCC), increasing endocytosis of the receptor and possibly through anti-angiogenic effects<sup>[54-56]</sup>. It was developed in the 1990s, after murine monoclonal antibodies directed to the extracellular domain of HER2 were produced and evaluated in cell lines and xenografts<sup>[57-59]</sup>.

**Preclinical data**

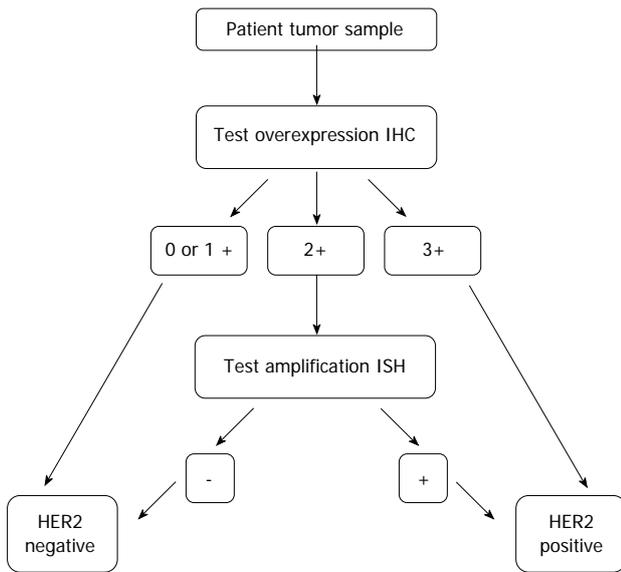

Overexpression of HER2 in gastric cancer cells was first reported in 1986 by Sakai *et al*<sup>[60]</sup> and Fukushima *et al*<sup>[61]</sup>. Preclinical models of gastric cancer were successful in demonstrating the inhibitory effect of trastuzumab on human gastric cancer cell lines *in vitro* and in mice xenografts *in vivo*, with additive and synergistic antineoplastic effects in combination with chemotherapy<sup>[59,62-65]</sup>. A study by Tanner *et al*<sup>[17]</sup> points out a gastric cancer cell line that was as sensitive to trastuzumab as a breast cancer cell line, both of them with amplified *HER2*, while Matsui *et al*<sup>[63]</sup> reported suppression of tumor growth in a xenograft model. Enhanced antineoplastic effects were observed with capecitabine, cisplatin, docetaxel, paclitaxel and irinotecan<sup>[62]</sup>, and a further synergistic effect with cisplatin has been found by Kim *et al*<sup>[64]</sup>.

**Clinical data**

Although information on the specific pathways involved

is scarce, *HER2* has been shown to be amplified in gastric cancer and *HER2* is progressively regarded as an important biomarker and driver of cancerization in gastric cancer, with studies pointing out amplification or overexpression in 7%-34% of tumors, mainly in the intestinal type and in GEJ and proximal tumors<sup>[17,27,66]</sup>.

Cortés-Funes *et al*<sup>[67]</sup> presented preliminary results of a phase II study involving 21 chemotherapy-naïve patients with *HER2* overexpressing locally advanced or metastatic gastric cancer. Trastuzumab at a loading dose of 8 mg/kg and maintenance dose of 6 mg/kg and cisplatin 75 mg/m<sup>2</sup> were administered every 21 d until progression, unacceptable toxicity or withdrawal of consent. Response rate was of 35%, with 17% of patients achieving stabilization. The tolerability profile was favourable; no grade 4 toxicity was observed and most the frequent grade 3 events were asthenia, nausea or vomiting, diarrhea, hyporexia and neutropenia. Data from another preliminary phase II study involving 16 gastric cancer patients were presented by Egamberdiev *et al*<sup>[68]</sup>. Trastuzumab 6 mg/kg was administered once in addition to cisplatin 100 mg/m<sup>2</sup> during 3 d + fluorouracil (5-FU) 1000 mg/m<sup>2</sup> 3 d + leicovirin 100 mg/m<sup>2</sup> 3 d, every 3 wk. Authors reported an objective response rate of 54.5% in the combined therapy group *vs* 33.3% in the chemotherapy-only group and a median remission duration of 8.3 mo *vs* 5.2 mo. In a recent phase

**Figure 3** Human epidermal growth factor receptor 2 testing algorithm. IHC: Immunohistochemistry; HER2: Human epidermal growth factor receptor 2; ISH: *In situ* hybridization.

II study carried out by Grávalos *et al.*<sup>[69]</sup>, chemo-naïve patients with non-resectable advanced or metastatic gastric or GEJ adenocarcinoma overexpressing HER2 were treated with trastuzumab 8 mg/kg as loading dose and 6 mg/kg in subsequent cycles + cisplatin 75 mg/m<sup>2</sup> every 3 wk. Twenty-two out of 228 patients (9.6%) enrolled had HER2 overexpression. An overall response rate of 32% was found, with disease control achieved in 64% of patients; median time to progression was 5.1 mo. No grade 4 toxicities occurred, whereas most frequent grade 3 adverse events were asthenia, neutropenia, anorexia, diarrhoea and abdominal pain. Interestingly, higher baseline HER2 extracellular domain levels associated with better response to therapy.

In more recent studies, HER2 overexpression was found to be lower than previously reported, especially in distant gastric cancers<sup>[70]</sup>. Resectable gastric cancer has reported HER2-positive ratios of 8.1% and 11.7%, suggesting that in resectable gastric cancer HER2 positive status might be less frequent than in advanced gastric cancer<sup>[71,72]</sup>.

The phase III ToGA trial constitutes a milestone, establishing trastuzumab as the first biological therapy that demonstrated survival benefits in gastric cancer<sup>[62,63]</sup>. ToGA was a multicenter, international trial, undertaken in 24 countries<sup>[73]</sup>. It evaluated the combination of trastuzumab with standard chemotherapy (cisplatin + either capecitabine or 5-FU) in advanced (inoperable locally advanced, recurrent or metastatic) HER2-positive gastric cancer as a first-line therapy *vs* chemotherapy alone. Patients were treated with six cycles of chemotherapy in both treatment arms, with patients in the experimental arm continuing to be treated with trastuzumab until disease progression. Cisplatin 80 mg/m<sup>2</sup> was given on day 1 by intravenous infusion. Capecitabine 1000 mg/m<sup>2</sup> was given orally twice a day for 2 wk followed by a 1-wk rest

or 5-FU 800 mg/m<sup>2</sup> per day was given by continuous infusion on days 1-5 of each cycle. Trastuzumab was given intravenously at a loading dose of 8 mg/kg on day 1 of the first cycle, followed by 6 mg/kg afterwards.

The primary objective of the study was to compare OS in both arms, and the secondary objectives were to compare progression-free survival (PFS), time to progression, overall response rate, disease control, duration of response and quality of life between the two treatment arms. Among 3665 tumor tissue specimens screened for HER2 positivity, 22% were HER2 positive (34% of the intestinal type *vs* 6% of diffuse and 20% of mixed types). Assessment was done with IHC and fluorescence ISH (FISH), according to Figure 3. The highest rate was observed in 34% of GEJ cancer and 20% of gastric cancer samples<sup>[74]</sup>, which is in conformity with other studies where positivity rates for the GEJ are between 24%-35% and in gastric cancer samples comprise 9.5%-21.0%<sup>[17,27,75-77]</sup>.

The combination of trastuzumab with chemotherapy in advanced HER2-positive cancer patients led to significantly better OS compared to the same chemo-therapeutic regimen alone (median OS in the combination therapy group was 13.8 mo against 11.1 mo in the chemotherapy-alone group). This effect was observed in patients with intestinal type gastric cancer but not in those with diffuse type gastric cancer<sup>[73,78]</sup>. Median PFS (6.7 mo *vs* 5.5 mo) and radiological response rate (47% *vs* 35%), also improved with trastuzumab therapy. Exploring these data further, a sub-group analysis of the ToGA study which excluded patients with IHC 0-1+ FISH+ disease, found a main gain in median survival of 4.2 mo, comparable to the figures in breast cancer<sup>[28]</sup>. In fact, patients with strongest HER2 expression (IHC 3+ FISH+) gained the greatest benefit, with a median survival of 17.9 mo in patients treated with trastuzumab *vs* 12.3 mo with chemotherapy alone.

A summary of selected clinical trials of trastuzumab in gastro-esophageal cancer can be found in Table 1.

### Adjuvant treatment

In this behalf, it is important to consider the possible benefits of trastuzumab in the adjuvant setting for earlier stages of the disease; however activity of targeted therapeutics in advanced disease should not automatically be extrapolated into the adjuvant setting, as results may be misleading<sup>[79]</sup>. Trials have been initiated which intend to investigate anti-HER2 therapeutics in this setting<sup>[80,81]</sup>. Early onset gastric cancer (presenting at or under the age of 45) seems to have lower HER2 overexpression than in late onset cases, with possible different molecular genetic pathways<sup>[82-84]</sup>. Ongoing clinical trials with trastuzumab can be found in Table 2.

### Maintenance therapy

From a clinical perspective, data known from breast cancer suggest that trastuzumab administration after disease progression might have benefits in OS<sup>[23,85]</sup>. In an observational study of 623 patients, median time to progression was longer in patients who continued trastu-

ID, NCT identification (information available at <http://clinicaltrials.gov>, as accessed June 28, 2013). OS: Overall survival; PFS: Progression-free survival; 5-FU: 5-fluorouracil; RR: Response rate; CR: Complete response; PR: Partial response; NA: Not available.

zumab beyond progression than in those who stopped (10.2 mo *vs* 7.1 mo)<sup>[86]</sup>. Data from an interventional study involving 156 patients revealed OS rates of 20.4 mo *vs* 25.5 mo and response rates of 27.0% *vs* 48.1% in patients who stopped and continued trastuzumab beyond progression, respectively. Continuation of trastuzumab beyond progression was not associated with increased toxicity<sup>[87]</sup>. However, the issue is still a matter of debate, as increasing therapeutic options pose a challenge on the best possible sequencing and combinations of these interventions<sup>[88-90]</sup>.

### Perioperative treatment

Perioperative chemotherapy regimens have shown promising results in gastric cancer. The MAGIC trial randomized over 500 patients to either surgery alone or perioperative chemotherapy consisting of epirubicin, cisplatin and fluorouracil (3 cycles before and 3 cycles after surgery). This triplet therapy demonstrated a decrease in tumor size and improved PFS and OS in comparison with surgery alone<sup>[91,92]</sup>. In addition, some data indicate that response to neoadjuvant treatment is a major predictive factor of survival after curative surgical resection<sup>[93]</sup>.

Although there is no trial so far reporting results on the role of trastuzumab in the neoadjuvant setting, a number of case reports with trastuzumab-containing neoadjuvant chemotherapy regimens have been published, with interesting outcomes; complete pathological

responses were attained in 2 cases and a partial response with tumor mass reduction allowing for an extensive surgery in another case<sup>[94-96]</sup>.

### Pharmacokinetics and pharmacodynamics

Most data regarding the pharmacokinetic and pharmacodynamic profiles of trastuzumab stem from studies in breast cancer. A low systemic clearance ( $5.15 \pm 2.45$  mL/kg per day) and volume of distribution (44 mL/kg) have been described. Serum minimum concentrations of 10 µg/mL are needed to attain anti-proliferative effects and ADCC. With the usual loading dose of 4 mg/kg followed by 2 mg/kg per week, trastuzumab achieves and maintains serum minimum concentrations greater than 20 µg/mL. Recent results demonstrate that trastuzumab 6 mg/kg every 3 wk lead to the same plasma trough levels as trastuzumab 2 mg/kg weekly. Trastuzumab has been found not to exhibit dose-related nonlinear pharmacokinetics and the value of half-life of trastuzumab has an estimated value of 28.5 d<sup>[97,98]</sup>. No relevant drug interactions have been reported to date and elimination pathways remain largely unknown<sup>[99]</sup>. An extensive review about the pharmacodynamic and pharmacokinetic profiles, tolerability and dosage of trastuzumab in gastric cancer has been elaborated by Croxtall *et al*<sup>[100]</sup>. Targeted delivery systems involving anti-HER2 antibody mediated nano-scaled systems, drug conjugates, and fusion proteins are under active investigation<sup>[4,101,102]</sup>.

### Safety

The most commonly described adverse events with trastuzumab are infusion-related, described as fever, rigors, chills, nausea, dyspnea, and hypotension, and are present in about 40% of patients after the first administration and in 5% with subsequent treatment<sup>[103]</sup>. Trastuzumab has been extensively evaluated in breast cancer with a wide range of chemotherapeutic agents showing no significant overlapping toxicity, with one important exception, regarding an increased risk of cardiotoxicity. Trastuzumab-related cardiac dysfunction is largely reversible on withdrawal of the antibody. However, significant cardiopathy such as valvular heart disease, angina pectoris, previous transmural infarction and heart failure with left ventricular ejection fraction (LVEF) < 50% are generally regarded as counter-indications for trastuzumab use<sup>[28]</sup>. With the chemotherapy doublet regimen evaluated in the ToGA trial, trastuzumab contributed with little added toxicity; no increase in chemotherapy related grade 3-4 toxicities (68% both arms) or cardiac events (6% both arms) were found. Nonetheless the number of patients with cardiac dysfunction (considered a  $\geq$  10% drop in LVEF to an absolute value < 50%) was low in both arms (5% trastuzumab + chemotherapy *vs* 1% chemotherapy alone). The European Society for Medical Oncology<sup>[104]</sup>, issued a statement regarding the cardiac monitoring of patients receiving trastuzumab. Clinical evaluation and assessment of cardiovascular risk factors and comorbidities should be performed in every patient proposed for treatment with trastuzumab<sup>[105]</sup>. While screening algorithms for trastuzumab-induced cardiomyopathy provide guidance, patient-based strategies of surveillance remain important. Many clinical trials involving patients with metastatic breast cancer include a screening study to document the baseline LVEF, followed by serial monitoring at 8- to 16-wk intervals<sup>[106]</sup>.

In the ToGA trial, serious adverse events were reported in 32% of patients treated with trastuzumab + chemotherapy and 28% in the chemotherapy group; with treatment-related mortality of 3% and 1% respectively. The adverse events were similar between both groups, with no difference in the overall rate of adverse events. Nausea, neutropenia, vomiting, and anorexia were the most frequently reported adverse events. Patients treated with trastuzumab + chemotherapy had slightly higher rates of diarrhoea, stomatitis, anemia, thrombocytopenia, fatigue, chills, weight loss, pyrexia, mucosal inflammation, and nasopharyngitis<sup>[73]</sup>. In a phase II study with trastuzumab and cisplatin as first-line therapy in GEJ and gastric cancer, trastuzumab showed a favourable toxicity profile<sup>[69]</sup>.

### Resistance to trastuzumab

Whilst data regarding mechanisms of resistance to trastuzumab in gastroesophageal cancer is scarce, important information can be retrieved from previous knowledge in the treatment of breast cancer. Primary resistance to single-agent trastuzumab in HER2-overexpressing

metastatic breast carcinomas is described in 66%-88% of cases, with resistance eventually ensuing after a relatively short treatment period; in fact, the majority of patients who achieve an initial response to trastuzumab-based regimens develop resistance within 1 year (PFS between 6.7 and 7.4 mo)<sup>[85,107-109]</sup>.

Proposed resistance mechanisms include aberrations in the PI3K/AKT/mTOR pathway with or without loss of the phosphatase and tensin homologue protein (PTEN) tumor suppressor gene, accumulation of truncated forms of the HER2 receptor that lack the extracellular trastuzumab-binding domain (collectively known as p95HER2), loss of phosphatase, activation of other tyrosine kinase receptors including the insulin-like growth factor receptor (IGF-1R), increased expression of membrane-associated glycoprotein (MUC1 and MUC4) and cyclin E overexpression<sup>[85,109-111]</sup>.

PTEN inhibits PI3K, thereby inhibiting the PI3K/AKT/mTOR pathway. Loss of this tumor suppressor gene leads to at least partial resistance to trastuzumab. Indeed, both PIK3 mutations and PTEN loss were associated with inferior PFS and OS in a retrospective study of 256 HER2-positive metastatic breast cancer patients treated with trastuzumab<sup>[112]</sup>. A potential role for PI3K, AKT or mTOR inhibitors seems to exist, since these agents preclude the constitutive activation of this pathway, reversing PTEN loss-induced trastuzumab resistance<sup>[113-116]</sup>.

Truncated forms of HER2 which arise through the proteolytic shedding of the extracellular domain of full-length HER2 or by alternative translation initiation from two methionine residues are the predominant HER2 forms in some tumors. The biological function of p95HER2 has not been fully characterized, though overexpression of p95HER2 has been shown to lead to growth of tumor xenografts in nude mice. The p95HER2 protein has kinase activity, and this activity is required for tumor growth; however, the mechanisms involved and its possible relationship with those used by full-length HER2 are still unknown. Importantly, since p95HER2 lacks the binding site for trastuzumab, it conveys resistance to this antibody. p95HER2 is expressed in approximately 30% of HER2-positive breast tumors and is correlated with poor disease-free survival and increased nodal metastasis when compared with patients that express full-length HER2<sup>[110,117]</sup>. p95HER2 can therefore be seen as a prognostic and predictive biomarker in breast cancer. In one study analysing 93 metastatic breast tumors, patients overexpressing p95HER2 were found to have a higher incidence of lung metastases and had significantly shorter PFS and OS with trastuzumab treatment in comparison with patients expressing only the full-length receptor<sup>[118]</sup>. Tumors that express p95HER2 may be resistant to trastuzumab but sensitive to the inhibitory effects of lapatinib, a low-molecular-weight dual tyrosine kinase inhibitor (TKI) of HER1/2 that has activity in patients with HER2-expressing tumors that are resistant to trastuzumab. Combination of trastuzumab

with lapatinib has been evaluated in women with HER2-positive, trastuzumab-refractory metastatic breast cancer. Lapatinib with trastuzumab was superior to lapatinib alone in clinical benefit: complete response, partial response, and stable disease for  $\geq 24$  wk was observed in 24.7% of patients in the combination arm *vs* 12.4% in the monotherapy arm<sup>[119,120]</sup>. According to some authors this combination could provide a chemotherapy-free option after first line chemotherapy + trastuzumab<sup>[109]</sup>.

Increased signalling through other receptor TKIs including EGFR, HER3, MET and IGF-1R has been found in cells resistant to HER2-targeting treatments<sup>[109]</sup>. PI3K/AKT/mTOR pathway activation through up-regulation of HER3 signalling was demonstrated after exposure of breast cancer cells to HER TKIs<sup>[121]</sup>. On the other hand, pertuzumab, a HER2-HER3 dimerization inhibitor has demonstrated activity against trastuzumab resistant breast cancer cells<sup>[122]</sup>. Taking this findings into account, HER3 seems to play an important role in the mechanism of trastuzumab resistance.

In preclinical studies, co-expression of HER2 and IGF-1R in breast cancer cells resulted in loss of sensitivity to trastuzumab, conversely, inhibiting ligand-mediated activation of IGF-1R restored sensitivity to trastuzumab, therefore pointing towards a possible strategy to reduce or delay trastuzumab resistance<sup>[123,124]</sup>.

### Overcoming resistance to trastuzumab

Strategies to overcome trastuzumab resistance imply the important fact that many HER2-positive gastric tumors retain dependency on downstream signalling *via* the HER2 pathway. Therefore, besides other anti-HER2 agents (described in the following section), a focus on targeting these downstream signalling molecules has emerged<sup>[125,126]</sup>. Implied targets include mTOR inhibitors, HSP90 inhibitors and MET inhibitors; particularly interesting data exists concerning the possibility to combine some of these agents with anti-HER2 agents on which a patient has progressed, as the potential to reverse resistance to trastuzumab has been demonstrated<sup>[127-129]</sup>.

## OTHER ANTI-HER2 AGENTS

### Lapatinib

Lapatinib is a dual TKI active on both EGFR and HER2, with known activity in trastuzumab resistant advanced breast cancer; data suggests that there is no cross-resistance with trastuzumab and lapatinib restored trastuzumab sensitivity in preclinical models<sup>[28,130,131]</sup>. Wainberg *et al*<sup>[132]</sup> evaluated the effect of lapatinib in HER2-amplified cell lines and xenograft models, concluding that lapatinib inhibits the growth of HER2-amplified cancer cell lines, induces cell cycle arrest and apoptosis and acts synergistically with trastuzumab.

It is approved as combination therapy with capecitabine for patients with HER2-overexpressing breast cancer with prior progression on trastuzumab, an anthracycline and a taxane<sup>[133]</sup>. In a phase II trial conducted by Galsky

*et al*<sup>[134]</sup>, patients with HER2 amplified gastro-esophageal, bladder, ovarian, or uterine tumors were enrolled into a double-blinded randomized discontinuation study of lapatinib 1500 mg *per os* a day. Of a total of 141 patients screened, 32 patients with HER2 amplified tumors were enrolled in the study. At 3 mo, 1 (3%) patient had a complete response (CR), 9 (28%) had stable disease, 20 (63%) had progressive disease, and 2 (6%) were unknown. Unfortunately, due to low response rate and slow enrolment, the study had to be closed early. Concerning gastro-esophageal cancer, a modest CR rate of 6.25% was reported. A phase II study with lapatinib as first-line therapy in 47 patients with advanced gastric cancer showed modest single-agent activity, with 12% response rate, 20% disease stabilization, 7% of patients experiencing partial response and a median OS of 5 mo, less than that seen with conventional cytotoxic chemotherapy<sup>[135]</sup>. Another phase II study of lapatinib monotherapy in patients with HER2-overexpressing GEJ or esophageal cancer reported limited single-agent activity, with no objective responses and stable disease in 8% of patients<sup>[136]</sup>. Lapatinib in conjunction with capecitabine in the first line treatment of HER2 positive metastatic gastric cancer setting was addressed in a multicenter phase II trial, reporting a response rate of 22% and stable disease rate of 45%<sup>[137]</sup>. In another phase II trial, partial response of 24% and stable disease in 34% of patients was reported with lapatinib + capecitabine. Most frequent grade 3 and 4 side effects were anorexia, hand-foot syndrome, anemia and nausea; no significant cardiotoxicity was reported<sup>[138]</sup>. Two phase III studies evaluating the role of lapatinib in combination with chemotherapy in advanced esophago-gastric cancer are currently being conducted, the LOGIC trial<sup>[139,140]</sup> (combination of lapatinib with oxaliplatin and capecitabine as first-line treatment) and the TYTAN trial<sup>[141,142]</sup> (lapatinib in combination with weekly paclitaxel in second-line setting). OS results from the LOGIC trial are expected in 2014. Data from the TYTAN trial were presented at ASCO GI 2013. 430 patients were randomized, with an OS of 11 mo for the experimental arm *vs* 8.9 mo for the paclitaxel-alone arm; the subgroup of patients with HER2 3+ expression score attained an OS of 14 mo.

As previously stated, dual blockade with lapatinib and trastuzumab in metastatic breast cancer patients that progressed on trastuzumab-containing regimens improved PFS and clinical response rate<sup>[120]</sup>; a clinical case reported durable stable disease in a patient treated with this strategy despite progression during prior chemotherapy with trastuzumab<sup>[143]</sup>.

### Pertuzumab

Pertuzumab is a monoclonal antibody targeting HER2 in domain II (Figure 1), preventing formation of the highly mitogenic HER2/HER3 dimer. Available data stem mostly from breast cancer. As with trastuzumab, the antibody is not effective in patients without amplification of HER2<sup>[144]</sup>. In the phase III CLEOPATRA

**Table 3 Clinical trials with other anti-human epidermal growth factor receptor 2 agents**

Setting, therapy line	ID	Phase	n	Treatment	Primary EP	Status
Operable disease	NCT00450203	III	370	Lapatinib, epirubicin, cisplatin, capecitabine	OS	Recruiting
Advanced first line	NCT00680901	III	535	Lapatinib, oxaliplatin, capecitabine	OS	Active, not recruiting
	LOGiC					
	NCT01395537	II	43	Lapatinib, carboplatin, paclitaxel	Safety, RR	Active, not recruiting
	NCT01123473	II	192	Lapatinib, epirubicin, cisplatin, capecitabine, 5-FU	PFS	Unknown
	NCT00526669	II	67	Lapatinib, capecitabine	RR	Active, not recruiting
Advanced second line	NCT00486954	III	273	Lapatinib, paclitaxel	OS	Completed
	TYTAN					
	NCT01522768	II	27	Afatinib	RR	Recruiting
	NCT01152853	II	28	Dacomitinib	PFS	Unknown
	NCT01145404	II	76	Lapatinib, capecitabine	RR	Active, not recruiting

OS: Overall survival; PFS: Progression-free survival; 5-FU: 5-fluorouracil; RR: Response rate; CR: Complete response; PR: Partial response; NA: Not available.

study, 808 patients with HER2-positive metastatic breast cancer received placebo + trastuzumab + docetaxel (control group) or pertuzumab + trastuzumab + docetaxel (pertuzumab group). Median PFS was 12.4 mo in the control group *vs* 18.5 mo in the pertuzumab group. The hazard ratio for the addition of pertuzumab to docetaxel + trastuzumab for PFS was 0.62, with moderate toxicity added by the second antibody<sup>[145]</sup>. Pre-clinical results show potentiation of trastuzumab antitumour activity when combined with pertuzumab<sup>[146]</sup>. Pertuzumab is currently under investigation in a phase II study, in the first line gastric setting in combination with trastuzumab and platinum-fluoropyrimidine based chemotherapy<sup>[147]</sup>.

### Trastuzumab emtansine

Trastuzumab emtansine (T-DM1) is an antibody-drug conjugate, which combines trastuzumab with the targeted delivery of the cytotoxic agent DM1, a derivative of maytansine, and a potent antimicrotubule agent. As systemic therapy, gastrointestinal toxicity limits the therapeutic usefulness of the agent<sup>[109]</sup>. In xenograft models, T-DM1 was found more effective than trastuzumab alone, with positive results independent of the tumor burden at therapy initiation, or preceding treatment with trastuzumab<sup>[101]</sup>. In a phase II study by Burris *et al*<sup>[148]</sup>, T-DM1 had robust single-agent activity in patients with heavily pre-treated, HER2-positive metastatic breast cancer, with a favourable toxicity profile. In breast cancer, the EMILIA trial assigned patients with HER2-positive advanced breast cancer, previously treated with trastuzumab and a taxane, to T-DM1 or lapatinib + capecitabine. Median PFS was 9.6 mo with T-DM1 *vs* 6.4 mo with lapatinib plus capecitabine; with an objective response rate of 43.6% for T-DM1<sup>[149]</sup>. Taken together, results from preclinical studies and breast cancer clinical trials point out T-DM1 as a promising agent to be evaluated in gastro-esophageal cancer. Currently, a phase II-III study is ongoing to evaluate T-DM1 *vs* taxane in patients with previously treated locally advanced or metastatic HER2+ gastric and GEJ cancer.

### Pan-HER TKIs

Irreversible small molecule pan-HER TKIs causes tumor

regression in HER2-overexpressing human gastric cancer xenograft models. They act by inhibition of HER family receptor phosphorylation and blocking of hetero-dimerization among them. Pre-clinical data reveal a synergistic effect with other molecular targeted agents (including trastuzumab) and chemotherapeutic agents. Currently investigated pan-HER TKIs include dacomitinib and afatinib<sup>[150,151]</sup>.

Selected ongoing clinical trials exploring other anti-HER2 agents can be found in Table 3.

## OTHER HER2-DIRECTED STRATEGIES

HER2 vaccines, both DNA and peptide-based, are actively researched in the field of breast cancer and results indicate a possible future role for this modality in combination with other HER2 targeted therapies. A phase I study carried out by Hamilton *et al*<sup>[152]</sup> combined HER2 immunization with lapatinib found this combination to be safe and immunogenic, however, the anticancer activity of immunization-induced antibodies is still not well characterized. Successful repression of the HER2 gene by the means of adenovirus constructs rises expectations for possible applications in cancer treatment<sup>[153]</sup>. Radioimmunotherapy is another possible application of HER2 directed homing, with authors currently evaluating 212Pb immunoconjugates with trastuzumab in intraperitoneal application after preclinical studies showed interesting results<sup>[154,155]</sup>.

## CONCLUSION

Now, times are changing. New strategies had been developed and implemented for advanced gastric cancer treatment. HER2 acquired a main role in gastric cancer management and current is also mandatory in order to predict trastuzumab response in association with standard platinum-based chemotherapy. Furthermore, others drugs are in developing to overcome resistance to trastuzumab, serious treatment-related toxicities and also help oncologists to improve treatments approaches. In future, genomic profiles will probably be part of clinical routines

for personalizing therapies and improve outcomes of those patients.

### Abstract

Bilirubin, a major end product of heme breakdown, is an important constituent of bile, responsible for its characteristic colour. Over recent decades, our understanding of bilirubin metabolism has expanded along with the processes of elimination of other endogenous and exogenous anionic substrates, mediated by the action of multiple transport systems at the sinusoidal and canalicular membrane of hepatocytes. Several inherited disorders characterised by impaired bilirubin conjugation (Crigler-Najjar syndrome type I and type II, Gilbert syndrome) or transport (Dubin-Johnson and Rotor syndrome) result in various degrees of hyperbilirubinemia of either the predominantly unconjugated or predominantly conjugated type. Moreover, disrupted regulation of hepatobiliary transport systems can explain jaundice in many acquired liver disorders. In this review, we discuss the recent data on liver bilirubin handling based on the discovery of the molecular basis of Rotor syndrome. The data show that a substantial fraction of bilirubin conjugates is primarily secreted by

MRP3 at the sinusoidal membrane into the blood, from where they are subsequently reuptaken by sinusoidal membrane-bound organic anion transporting polypeptides OATP1B1 and OATP1B3. OATP1B proteins are also responsible for liver clearance of bilirubin conjugated in splanchnic organs, such as the intestine and kidney, and for a number of endogenous compounds, xenobiotics and drugs. Absence of one or both OATP1B proteins thus may have serious impact on toxicity of commonly used drugs cleared by this system such as statins, sartans, methotrexate or rifampicin. The liver-blood cycling of conjugated bilirubin is impaired in cholestatic and parenchymal liver diseases and this impairment most likely contributes to jaundice accompanying these disorders.

**Key words:** Hyperbilirubinemia; Hereditary jaundice; UGT1A1; ABCC2; Organic anion transporting polypeptide 1B1; Organic anion transporting polypeptide 1B3

**Core tip:** Experiments with *Oatp1a/1b*-null mice and *Oatp1a/1b*; *Abcc3* combination knockout mice plainly demonstrated that even under physiologic conditions a substantial portion of bilirubin glucuronides is not excreted directly into bile but is transported back to the blood by *Abcc3*. *Oatp1a/1b* activity accentuated in downstream (centrizonal) hepatocytes allows efficient reuptake of bilirubin conjugates, with a subsequent possibility being safely eliminated by excretion into bile. This and molecular findings in Rotor syndrome suggest that human transporters MRP3 and OATP1Bs form a sinusoidal liver-to-blood cycle which mediates shifting (hopping) of bilirubin and other substrates from periportal to centrizonal hepatocytes (References 18, 19, 22, 125).

## INTRODUCTION

Bilirubin is the end product of heme breakdown. About 80% of bilirubin originates from degradation of erythrocyte haemoglobin in the reticuloendothelial system; the remaining 20% comes from inefficient erythropoiesis in bone marrow and degradation of other heme proteins<sup>[1-4]</sup>. Water insoluble, unconjugated bilirubin (UCB) bound to albumin is transported to the liver where it is removed from the plasma. The exact mechanism of UCB uptake is unknown; however, passive transmembrane diffusion seems to be combined with active transport mediated by several sinusoidal transporters (see below). Within the cytoplasm of hepatocytes, bilirubin is bound to ligandin and transported to endoplasmic reticulum where conjugation with glucuronic acid takes place. Conjugation is catalysed by the enzyme uridine diphosphate glycosyltransferase 1A1 (UGT1A1; EC2.4.1.17), a member of an enzyme family in the endoplasmic reticulum and nuclear envelope of hepatocytes<sup>[5-8]</sup>. In addition to the liver, UGT activity has also been detected in the small intestine and kidney<sup>[9,10]</sup>. *UGT1A1* gene (ID: 54658) is a part of a complex locus encoding 13 UDP-glucuronosyltransferases<sup>[11]</sup>. The locus contains a series of thirteen unique alternate promoters and first exons, followed by four common exons No. 2-5. Theoretically, each of the unique first exons is spliced to the first of the four shared exons. The unique first exons encode different substrate binding domains whereas the other functional domains encoded by the shared exons 2-5 are the same<sup>[11-15]</sup>. In reality, only 9 of the 13 predicted *UGT1As* are active genes encoding functional enzymes; four are nonfunctional pseudogenes.

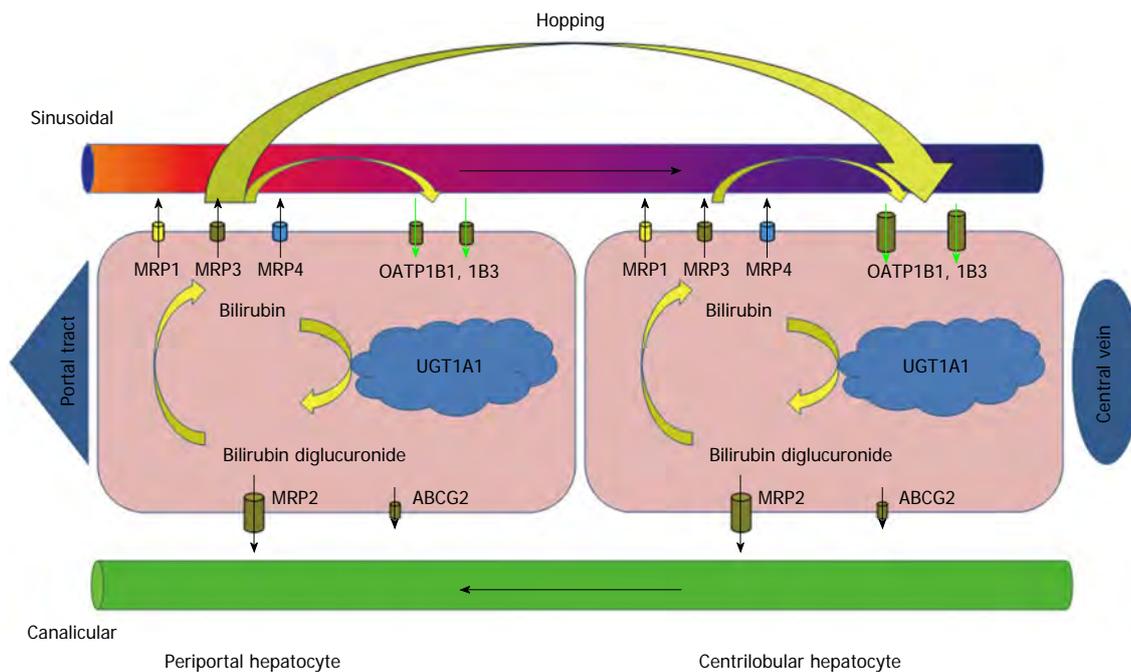

The excretion of conjugated bilirubin into bile is mediated by an ATP-dependent transporter identified as the multidrug resistance-associated protein MRP2/cMOAT and, to a lesser extent, also by ATP-binding cassette (ABC) efflux transporter ABCG2. MRP2 is encoded by *ABCC2* and expressed under physiologic conditions at the apical (canalicular) membrane of hepatocytes and, to a much lesser extent, in the kidney, duodenum, ileum, brain and placenta<sup>[16]</sup>. Since the MRP2 mediated export represents an important step in detoxification of many endogenous and exogenous substrates, the absence of functionally active MRP2 prevents the secretion of these conjugates into bile. Absence of MRP2 mediated transport is followed by upregulation of the basolateral MRP2 homologues at the sinusoidal membrane of hepatocytes and conjugated bilirubin flow is redirected into sinusoidal blood<sup>[17]</sup>. Aside from MRP2 mediated transport of conjugated bilirubin into bile, recent studies have shown that a significant fraction of the bilirubin conjugated in the liver is, under physiologic conditions, secreted into sinusoidal blood and subsequently reuptaken by hepatocytes for fi-

nal biliary excretion<sup>[18,19]</sup>. The process is mediated by sinusoidal transporters MRP3 and organic anion-transporting polypeptides OATP1B1 and OATP1B3. OATP1B transporters facilitate sodium-independent uptake of numerous endogenous and exogenous substrates<sup>[20,21]</sup>. Since expression of OATP1Bs is higher in centrilobular hepatocytes, the MRP3-OATP1B1/3 loop is likely responsible for shifting (hopping) of conjugated bilirubin and other substrates from the periportal to the centrilobular zone of the liver lobule (Figure 1). Such intralobular substrate transfer may protect periportal hepatocytes against elevated concentrations of various xenobiotics<sup>[22]</sup>. In addition, the OATP1B proteins mediate hepatic clearance of bilirubin conjugated in splanchnic organs and may represent an important alternative pathway in enterohepatic circulation<sup>[18]</sup>.

OATP1Bs may also contribute to liver uptake of UCB since complete absence of both OATP1Bs in Rotor syndrome (RS, see below) is associated with elevated levels of UCB and single nucleotide polymorphisms in genes encoding OATP1B proteins have been shown to influence serum bilirubin level<sup>[23,24]</sup>. Furthermore, results of functional studies demonstrate that OATP1B3, but not OATP1B1, may play an important role in the carrier-mediated uptake of foetal UCB by the placental trophoblast and contribute to elimination of UCB across the placental barrier<sup>[25,26]</sup>.

Mild or moderately elevated serum bilirubin seems to be beneficial: Bilirubin is known as a strong antioxidant<sup>[27,28]</sup> and the protective effects of bilirubin on atherogenesis and cancerogenesis have been demonstrated in both *in vitro* and *in vivo* studies<sup>[29-33]</sup>. On the other hand, patients with profound unconjugated hyperbilirubinemia are at risk for bilirubin encephalopathy (kernicterus)<sup>[34,35]</sup>. The toxic effects of bilirubin are explained by inhibition of DNA synthesis<sup>[36]</sup>. Bilirubin may also uncouple oxidative phosphorylation and inhibit adenosine triphosphatase (ATPase) activity of brain mitochondria<sup>[37,38]</sup>. Bilirubin mediated inhibition of various enzyme systems, RNA synthesis and protein synthesis in the brain and liver, and/or alteration of carbohydrate metabolism in the brain can also contribute to its toxicity<sup>[39-43]</sup>. The accumulation of bilirubin in plasma and tissues results in characteristic yellow discoloration of tissues known as icterus or jaundice.

Inherited disorders of bilirubin excretory pathway played the key role in understanding the individual steps of the bilirubin excretory pathway. Disrupted regulation of hepatobiliary transport systems explained jaundice in many acquired liver disorders<sup>[44-48]</sup>. Additional information was obtained from a number of animal models of hereditary jaundice. These include the Gunn rat and *Ugt1(-/-)* mouse mimicking the Crigler-Najjar syndrome type I<sup>[49-51]</sup>, the Bolivian population of squirrel monkeys mimicking Gilbert syndrome (GS)<sup>[52,53]</sup> and mutant TR or GY (Groningen yellow) rats with organic anion excretion defect (TR *-/-*), Eizai hyperbilirubinuria rats (EHBR), mutant Corriedale sheep, and *Mrp2(-/-)* mice, all modelling the Dubin-Johnson syndrome (DJS)<sup>[54-58]</sup>.

**Figure 1** Liver cycle of conjugated bilirubin. Bilirubin conjugated in endoplasmic reticulum of hepatocytes is secreted into the bile. This process is mediated by MRP2/ABCC2 with possible minor contribution of other transporters (ABCG2) at the canalicular membrane of hepatocytes. In addition, even under physiologic conditions, a fraction of bilirubin conjugates is secreted by MRP3 across the sinusoidal membrane into the blood, from where they can be subsequently reuptaken by sinusoidal membrane-bound OATP1B1 and OATP1B3 transporters. The highest overall expression of OATP1Bs has been demonstrated at the centrilobular hepatocytes. The process of substrate shifting (hopping) from periportal to centrilobular hepatocytes may act as a protection of the periportal hepatocytes against elevated concentrations of various xenobiotics. MRP: Multidrug resistance-associated protein; OATP: Organic anion transporting polypeptide; UGT: Uridine diphosphate glucuronosyltransferase; ABC: ATP-binding cassette.

## HEREDITARY PREDOMINANTLY UNCONJUGATED HYPERBILIRUBINEMIA

Conjugation of bilirubin in endoplasmic reticulum is catalysed by the enzyme UGT1A1. Mutations in *UGT1A1* can lead to decreased expression or partial or even complete inactivation of the enzyme<sup>[59]</sup>. By contrast, expression of *UGT1A1* can be increased by phenobarbital (PB) administration. PB response activity is delineated to a 290-bp distal enhancer module sequence (-3483/-3194) glucuronosyltransferase phenobarbital response enhancing motif (gtBPREM) of the human *UGT1A1*<sup>[59,60]</sup>. gtBPREM is activated by the nuclear orphan receptor, human constitutive active receptor (hCAR). CAR is a cytoplasmic receptor which, after treatment with activators such as PB, translocates into the nucleus, forms a heterodimer with the retinoid X receptor and activates the PB response enhancer element.

Three types of inherited, predominantly unconjugated hyperbilirubinemia with different levels of UGT1A1 activity are recognised: Crigler-Najjar syndrome type I (CN1), type II (CN2) and GS.

CN1 (MIM#218800), the most deleterious form, described in 1952 by Crigler and Najjar<sup>[61]</sup>, is characterised by complete or almost complete absence of UGT1A1 enzyme activity with severe jaundice<sup>[62]</sup>. Icterus occurring shortly after birth is complicated by bilirubin encephalopathy (kernicterus). Until the introduction of phototherapy and plasmapheresis, kernicterus was fatal in almost all cases during the first two years of life or caused seri-

ous brain damage with permanent neurologic sequelae. Intermittent phototherapy is lifelong and it results in a thorough elimination of water-soluble photoisomers of unconjugated bilirubin *via* bile. The effectiveness of phototherapy may decrease gradually with age and patients are at higher risk of sudden brain damage<sup>[63]</sup>.

Although new treatment modalities such as hepatocyte or hepatic progenitor cell transplantation have already been used to treat CN1 patients, liver transplantation is still considered to be the only definitive treatment for CN1<sup>[63-67]</sup>. Gene therapy seems to be a promising therapeutic possibility for the patients with CN1 in the near future<sup>[68,69]</sup>.

CN2 (Arias syndrome, MIM #606785), described by Arias in 1962<sup>[70]</sup>, is characterised by reduced UGT1A1 enzyme activity with a moderate degree of nonhemolytic jaundice. Bilirubin levels do not exceed 350  $\mu\text{mol/L}$  and CN2 is only rarely complicated by kernicterus<sup>[71]</sup>. Virtually all the mutations responsible for the syndrome are autosomal recessive, as in CN1, but several observations have also suggested the possibility of autosomal dominant pattern of inheritance<sup>[72-74]</sup>.

An important clinical difference between CN type I and type II is the response to PB treatment, with no effect in type I (complete loss of the UGT1A1 enzyme activity) and a decrease of serum bilirubin levels by more than 30% in CN type II (some residual UGT1A1 activity is preserved). Moreover, bilirubin glucuronides are present in bile in CN2. However, the method of choice for the diagnosis of CN syndrome is mutation analysis of

*UGT1A1*<sup>[75]</sup>.

GS (MIM #143500), described in 1901 by Gilbert and Lereboullet<sup>[76]</sup>, is characterised by fluctuating mild, unconjugated nonhemolytic hyperbilirubinemia < 85 µmol/L without overt haemolysis, usually diagnosed around puberty, and aggravated by intercurrent illness, stress, fasting or after administration of certain drugs<sup>[77,78]</sup>. Physical examination and the results of routine laboratory tests are normal apart from elevated serum bilirubin and jaundice. The clinical diagnosis of GS can be established if patients have a mild, predominantly unconjugated hyperbilirubinemia and normal activity of liver enzymes. The reduced caloric intake test and phenobarbital stimulation test have low diagnostic specificity in GS subjects<sup>[79]</sup>. Histological findings in GS are mild, with a slight centrilobular accumulation of pigment with lipofuscin-like properties<sup>[80]</sup>. Ultrastructurally, hepatocytes reveal hypertrophy of smooth endoplasmic reticulum<sup>[81,82]</sup>. Since the morphological picture of GS is completely non-specific and the disorder is benign, liver biopsy is not indicated.

GS is characterised by reduced levels of *UGT1A1* activity to about 25%-30% caused by homozygous, compound heterozygous, or heterozygous mutations in the *UGT1A1* with autosomal recessive transmission<sup>[80]</sup>.

GS is the most frequent hereditary jaundice affecting nearly 5%-10% of the Caucasian population<sup>[83]</sup>. The genetic basis of GS was first disclosed in 1995<sup>[84]</sup> as presence of the allele *UGT1A1\*28*, characterised by insertion of TA in the TATAA box (A[TA]<sub>n</sub>TAA) in the proximal promoter of *UGT1A1*. *UGT1A1\*28* has been identified as the most frequent mutation in Caucasian GS subjects<sup>[85]</sup>. The insertion is responsible for reduction of transcription of *UGT1A1* to 20% from normal and for a decrease of hepatic glucuronidation activity by 80% in a homozygous state<sup>[86]</sup>. In Caucasians and African Americans, the frequency of *UGT1A1\*28* allele is about 35%-40%, but it is much lower in Asians, including Koreans (13%), Chinese (16%), and Japanese (11%)<sup>[87-89]</sup>. Moreover, in the majority of Caucasian GS subjects, expression of *UGT1A1* is further decreased by the presence of the second mutation T>G in *gtPBREM*<sup>[59,60]</sup>. In addition to the mutations in the promoter, GS may be caused by mutations in structural regions of the *UGT1A1*. In Asians, other variants, such as *UGT1A1\*6* characterised by a missense mutation involving G to A substitution at nucleotide 211 (c.211G>A) in exon 1 (also known as p.G71R), *UGT1A1\*7* (p.Y486D), *UGT1A1\*27* (p.P229Q), and *UGT1A1\*62* (p.F83L) have been detected<sup>[60,87-90]</sup>.

In addition to biochemical defect leading to reduced glucuronidation, other factors, such as impaired hepatic (re)uptake of bilirubin (see Rotor syndrome below for the possible mechanism) or an increased load of bilirubin, seem to be necessary for clinical manifestation of GS<sup>[86,91,92]</sup>.

GS is benign and GS carriers present with no liver disease. However, the mutations in the *UGT1A1* identical to those recognised in GS subjects may contribute to the

development of prolonged neonatal hyperbilirubinemia in breast-fed infants<sup>[93,94]</sup>.

Moreover, since the process of glucuronidation is an important step in elimination of numerous endogenous and exogenous substrates, GS subjects may be more susceptible to the adverse effects of some drugs metabolised by *UGT1A1*, such as indinavir, atazanavir<sup>[95-99]</sup> or irinotecan<sup>[100-102]</sup>.

## HEREDITARY PREDOMINANTLY CONJUGATED HYPERBILIRUBINEMIA

Two types of hereditary conjugated jaundice are known as Dubin-Johnson and Rotor syndrome. Both are characterised by the presence of mixed, predominantly conjugated hyperbilirubinemia, with conjugated bilirubin more than 50% of total bilirubin.

DJS (MIM # 237500), a benign autosomal recessive disorder described in 1954 by Dubin *et al*<sup>[103]</sup> and Sprinz *et al*<sup>[104]</sup>, is characterised by fluctuating mild, predominantly conjugated hyperbilirubinemia, with typical manifestation in adolescence or young adulthood. Most patients are asymptomatic except of occasional slight abdominal pain and fatigue. Urine excretion of total coproporphyrin in 24 h is normal, but 80% are represented by coproporphyrin I. Biliary excretion of anionic dyes including bromosulfophthalein (BSP), indocyanine green and cholescintigraphy radiotracers is delayed with absent or delayed filling of the gallbladder<sup>[105]</sup>. BSP clearance in DJS subjects is normal at 45 min with the second peak at 90 min<sup>[106]</sup>. Liver histology in DJS shows an accumulation of distinctive melanin-like lysosomal pigment in an otherwise normal liver that gives the organ a characteristic dark pink or even black colour. The pigment is positive in PAS and Masson-Fontana reaction with marked autofluorescence. In contrast to melanin, DJS pigment does not reduce neutral silver ammonium solution<sup>[103,107]</sup>. The amount of pigment may vary and possible transient loss may occur in coincidence with other liver diseases<sup>[108,109]</sup>. The molecular mechanism in DJS is absence or deficiency of human canalicular multispecific organic anion transporter MRP2/cMOAT caused by homozygous or compound heterozygous mutation in *ABCC2* (gene ID: 1244) on chromosome 10q24<sup>[110-114]</sup>. The *ABCC2* mutation alters not only MRP2-mediated transport of conjugated bilirubin but also transport of many anionic substrates as well as a wide range of drugs, such as chemotherapeutics, uricosurics, antibiotics, leukotrienes, glutathione, toxins and heavy metals. Absence of MRP2/cMOAT may result in impaired elimination and in subsequent renal toxicity of the substrates mentioned above<sup>[115-120]</sup>.

A rare type of hereditary mixed hyperbilirubinemia caused by the simultaneous presence of mutations characteristic for DJS and GS has been classified as dual hereditary jaundice<sup>[121]</sup>. Serum direct bilirubin concentrations in dual hereditary jaundice reach only 20%-50% of total bilirubin.

RS (MIM #237450), described in 1948 by Rotor *et al*<sup>[122]</sup>,

is characterised by mild, predominantly conjugated hyperbilirubinemia with delayed excretion of anionic dyes without re-increase of their concentration. Total urinary coproporphyrin excretion is significantly increased and the proportion of coproporphyrin I in urine is approximately 65% of the total in homozygotes and 43% in heterozygotes<sup>[123,124]</sup>. By histopathological examination, the liver tissue does not display any marked architectural or cytomorphological abnormalities and pigment is not present.

The presence of homozygous mutations in both *SLCO1B1* and *SLCO1B3* neighbouring genes located on chromosome 12 with complete and simultaneous deficiency of proteins OATP1B1 and OATP1B3 has recently been identified as the molecular mechanism of the syndrome<sup>[125]</sup>. The complete absence of both transporters OATP1B1 and OATP1B3 has been confirmed by immunohistochemistry in all studied Rotor subjects. Interestingly, the presence of a single functional allele of either *SLCO1B1* or *SLCO1B3* prevented the jaundice.

RS does not require any therapy but, with regard to the impact of OATP1B transporters on pharmacokinetics of a broad spectrum of commonly used drugs such as penicillins, statins, sartans, rifampicin, methotrexate and many others, it is assumed that RS subjects and also those with the deleterious mutations in either of the *SLCO1B* genes, even without full clinical expression of the syndrome, may be at increased risk for drug toxicity<sup>[125-129]</sup>.

## BILIRUBIN HANDLING PROTEINS IN CHOLESTASIS

Animal models of obstructive and intrahepatic cholestasis help us to discover and understand the main principles of acquired defects in hepatobiliary transport of bile salts and other organic anions. Up and down regulation of these mechanisms can explain impaired liver uptake and excretion of the biliary constituents resulting in the cholestasis and icterus which accompanies many common acquired liver disorders<sup>[48,130,131]</sup>. A general pattern of response to cholestatic liver injury is initiated by down-regulation of the basolateral membrane bound transporters NTCP and OATP1B1. The expression of several canalicular export pumps is relatively unaffected [bile salt export pump (BSEP), multidrug resistance protein 2 (MDR2)] or even upregulated (MDR1). Decreased expression of MRP2 in sepsis or in obstructive cholestasis is followed by upregulation of several MRP homologues at basolateral membrane of hepatocytes that may extrude bile salts back to the sinusoidal blood and systemic circulation. Most of these changes are believed to help prevent an accumulation of potentially toxic bile components and other substrates in the liver.

Similar patterns of expression of the bilirubin and bile salts handling proteins and mRNA are observed in cholestatic liver diseases in humans. At the stage I and II of primary biliary cirrhosis (PBC), expression and localisation of OATP1B1, OATP1B3, NTCP, MRP2, MRP3

and MDR3 are unchanged. At stage III, immunostaining intensities of the sinusoidal uptake transporters and their mRNA levels decrease. Irregular MRP2 immunostaining suggests redistribution of MRP2 into intracellular structures in the advanced stages of PBC; however, at stage III and IV, basolateral uptake transporters NTCP and OATP1B1 are downregulated. Expression of the canalicular export pumps for bile salts (BSEP) and bilirubin (MRP2) remains unchanged and the canalicular P-glycoproteins MDR1 and MDR3 and the basolateral efflux pump MRP3 are upregulated<sup>[132-135]</sup>.

At the early-stages of cholestasis in extrahepatic biliary atresia, BSEP, MDR3, MRP2, NTCP/SLC10A1, SLCO1A2 and nuclear receptor farnesoid X receptor are downregulated. At the late-stages of cholestasis, farnesoid X receptor and BSEP levels returns to normal, MDR3 and MDR1 are upregulated and MRP2 is downregulated<sup>[136]</sup>.

In primary sclerosing cholangitis, the level of OATP1B1 mRNA in liver tissue has been demonstrated to represent 49% of controls and the level of MRP2 mRNA dropped to 27% of controls<sup>[137]</sup>.

## CONCLUSION AND PERSPECTIVES

Over the last decades, molecular basis of hyperbilirubinemia syndromes has been elucidated and mutations affecting the basolateral and apical membrane transporters responsible for accumulation of either conjugated or unconjugated bilirubin have been identified.

Except for GS, the majority of inherited hyperbilirubinemia syndromes are rare autosomal recessive disorders with a low prevalence in the general population and, apart from CN syndrome type I and some cases of CN type II in neonatal period, mostly not requiring further therapy. Nonetheless, the enzyme and transport systems involved in bilirubin metabolism may play an important role in the elimination and disposition processes of many other endogenous and exogenous substrates including hormones, drugs, toxins and heavy metals<sup>[102,138]</sup>. Dysfunction or absence of these systems, including selected ABC transporters and OATPs, may alter pharmacokinetics and pharmacodynamics of many biologically active agents, affect penetration of the substrates into various tissues and lead to their intracellular accumulation with a subsequent increase of organ toxicity<sup>[126,127,128]</sup>. In addition, the absence of the functional transport proteins involved in hepatobiliary and enterohepatic circulation may involve drug disposition, drug-drug or drug-food interactions and result in decreased effectiveness or even resistance to a diverse spectrum of chemotherapeutic agents and xenobiotics<sup>[139-141]</sup>. Individuals with mutations in the responsible gene or genes with the fully expressed phenotype of the corresponding hyperbilirubinemia syndrome, as well as subjects carrying mutations without clinical manifestation of hyperbilirubinemia under normal conditions, may be more susceptible to the adverse effects of some drugs and metabolites<sup>[142,143]</sup>.

Clarifying the molecular genetic basis of hereditary hyperbilirubinemia syndromes together with the discoveries of the major systems essential for the metabolism and transport of bilirubin and other endogenous and exogenous substrates represent a substantial contribution to the current knowledge of the heme degradation pathway. Further investigation of how bilirubin transport proteins and their variations affect pharmacokinetics of drugs may be of significant clinical importance.

### Abstract

**AIM:** To assess the esophageal motility in patients with irritable bowel syndrome (IBS) and to compare those with patients with autoimmune disorders.

**METHODS:** 15 patients with IBS, 22 with systemic lupus erythematosus (SLE) and 19 with systemic sclerosis (SSc) were prospectively selected from a total of 115 patients at a single university centre and esophageal motility was analysed using standard manometry (Mui Scientific PIP-4-8SS). All patients underwent esophago-gastro-duodenoscopy before entering the study so that

only patients with normal endoscopic findings were included in the current study. All patients underwent a complete physical, blood biochemistry and urinary examination. The grade of dysphagia was determined for each patient in accordance to the intensity and frequency of the presented esophageal symptoms. Furthermore, disease activity scores (SLEDAI and modified Rodnan score) were obtained for patients with autoimmune diseases. Outcome parameter: A correlation coefficient was calculated between amplitudes, velocity and duration of the peristaltic waves throughout esophagus and patients' dysphagia for all three groups.

**RESULTS:** There was no statistical difference in the standard blood biochemistry and urinary analysis in all three groups. Patients with IBS showed similar pathologic dysphagia scores compared to patients with SLE and SSc. The mean value of dysphagia score was in IBS group 7.3, in SLE group 6.73 and in SSc group 7.56 with a  $P$ -value  $> 0.05$ . However, the manometric patterns were different. IBS patients showed during esophageal manometry peristaltic amplitudes at the proximal part of esophagus greater than 60 mmHg in 46% of the patients, which was significant higher in comparison to the SLE (11.8%) and SSc-Group (0%,  $P = 0.003$ ). Furthermore, IBS patients showed lower mean resting pressure of the distal esophagus sphincter (Lower esophageal sphincter, 22 mmHg) when compared with SLE (28 mmHg,  $P = 0.037$ ) and SSc (26 mmHg,  $P = 0.052$ ). 23.5% of patients with SLE showed amplitudes greater as 160 mmHg in the distal esophagus (IBS and SSc: 0%) whereas 29.4% amplitudes greater as 100 mmHg in the middle one (IBS: 16.7%, SSc: 5.9% respectively,  $P = 0.006$ ). Patients with SSc demonstrated, as expected, in almost half of the cases reduced peristalsis or even aperistalsis in the lower two thirds of the esophagus. SSc patients demonstrated a negative correlation coefficient between dysphagia score, amplitude and velocity of peristaltic activity at middle and lower esophagus [ $r = -0.6$ ,  $P <$

0.05].

**CONCLUSION:** IBS patients have comparable dysphagia-scores as patients with autoimmune disorders. The different manometric patterns might allow differentiating esophageal symptoms based on IBS from other organic diseases.

**Key words:** Irritable bowel syndrome; Systemic lupus erythematosus; Systemic sclerosis; Esophageal manometry; Dysphagia

**Core tip:** This is the first comparative study concerning esophageal motility among functional and autoimmune disorders. Patients in irritable bowel syndrome (IBS)-group showed comparable dysphagia-scores as patients with systemic lupus erythematosus and systemic sclerosis. Nevertheless, different manometric patterns between the three examined groups were observed, which might allow differentiating esophageal symptoms based on IBS from other organic diseases.

## INTRODUCTION

Irritable bowel syndrome (IBS) is a functional disorder of the gastrointestinal tract characterized mainly by symptoms as diarrhoea, constipation and diffuse abdominal pain<sup>[1]</sup>. The prevalence of IBS in the western population varies between 15% and 20%<sup>[2-7]</sup> with an overall 2:1 female predominance<sup>[5]</sup>. In 2006 the Rome III criteria for diagnosis and classification of IBS were established<sup>[8]</sup>. According to these criteria IBS is defined as recurrent abdominal pain or discomfort associated with altered defecation.

Dyspepsia and dysphagia are commonly reported of IBS patients. However, there are no comparative data available dealing with esophagus motility in IBS patients compared to autoimmune disorders. Analyses of peristaltic changes of the esophagus in patients with IBS have led to controversial findings<sup>[9-13]</sup>. Reduced resting pressure and relaxation of the lower esophageal sphincter (LES)<sup>[9,11]</sup>, abnormal contractions up to 150 mmHg<sup>[10]</sup> as well as normal peristaltic motility in patients with IBS<sup>[12]</sup> have been described.

Systemic sclerosis (SSc) and systemic lupus erythematosus (SLE) show a variety of visceral manifestations. Skin, joints, lungs, nervous system and internal organs

can be affected. Dysfunction of esophagus motility is reported in about 70%-90% of patients with SSc<sup>[14-18]</sup>. In patients with SLE the percentage varies between 1.5% and 25%<sup>[19]</sup>. Aim of the present study was to assess the esophageal motility function in patients with IBS compared to organic diseases (SLE and SSc).

## MATERIALS AND METHODS

### Subjects

Patients were prospectively invited to participate at this single centre study. Patients were identified based on the database of our outpatient clinic of gastroenterology and rheumatology at the University Mainz. Patients with IBS, SLE and SSc were able to participate. The database showed 115 patients with one of the mentioned diseases. 74 patients were screened and 56 patients agreed to participate in the study and were included (15 patients with IBS, 22 with SLE and 19 with SSc).

All SLE and SSc patients met the criteria established by the American Rheumatism Association for autoimmune diseases, whereas the patients in IBS group were included on the basis of Rome III process<sup>[8,20,21]</sup>. Patients with uncertain diagnosis, with known other severe diseases of the upper gastrointestinal tract and pregnant and lactating women were excluded from the study. All patients gave their written consent. The study was approved by the local ethics committee of Rheinland-Pfalz (No. 837.432.09).

### Methods

Besides thorough history and physical examination, the following diagnostic methods were performed:

**Blood biochemistry analysis:** A complete blood biochemistry examination including blood count and biochemical analysis were performed in each patient. Furthermore, the following parameters were examined: Complement factors C3 and C4, ANA, ENA, dsDNA, CRP and ESR.

**Upper endoscopy:** All patients underwent esophago-gastro-duodenoscopy (EGD) before entering the study. Only patients with normal endoscopic findings were included in the current study.

**Esophageal manometry:** Esophageal manometry was performed after 8 h of fasting. All medications which potentially could affect the esophageal motility were paused 48 h before manometry.

The measurements were performed using a 60 cm long, 8 channel lumen catheter (Sierra Scientific Instruments, Germany) with 5 distal openings separated 1 cm vertically and 3 proximal openings distributed at 5 cm distance apart.

Each of the catheter lumens was perfused with distilled water at a rate of 1.36 mL/min. The catheter was connected to an infusion system (Mui Scientific, Canada) with attached pressure converters. The catheter was ini-

**Table 1** Demographic data of the three examined groups *n* (%)

	Diarrhoea	Constipation	Diarrhoea + Constipation	
Total	8 (53.3)	4 (26.7)		
Male	3 (100)	0	0	2 (9.01)
Female	8 (66.7)	1 (8.3)	3 (25)	20 (90.9)
Age (yr)	42 ± 16	56 ± 15	34 ± 18	48 ± 10
				55 ± 9

IBS: Irritable bowel syndrome; SLE: Systemic lupus erythematosus; SSc: Systemic sclerosis.

tially inserted transnasally into the patient’s stomach. The patients remained in a sitting position during insertion of the catheter.

After the lumen reached the stomach, patients were brought to a horizontal position and then the pressure of the LES was measured by using the station and rapid pull-through technique<sup>[22,23]</sup>.

Subsequently, the catheter was slowly withdrawn at 1 cm intervals with wet (10 mL water) and dry swallows at each level, so that a complete analysis of esophagus motility could be obtained. Ineffective swallows were not included in detailed measurements of manometric parameters.

The resulting esophageal parameters were: position, length, resting pressure and relaxation of the LES und upper esophageal sphincter (UES), mean peristaltic pressure, simultan or retrograde contractions, duration and velocity of the peristaltic waves at the proximal, medial and distal third of esophagus.

**Questionnaires**

Patients were asked to complete the following questionnaires:

**SLEDAI:** The disease activity in patients of SLE was assessed *via* the SLEDAI-Index<sup>[24]</sup>.

**Rodnan score:** The disease activity in patients with SSc was assessed *via* the modified Rodnan score<sup>[25]</sup>.

**Dysphagia score:** The intensity and frequency of the esophageal symptoms was assessed as an accumulation score as described before<sup>[26]</sup>. Specifically all patients were evaluated for symptoms such as odynophagia, difficulty in swallowing, chest pain, dysphagia etc in relation to frequency, need for treatment and weight loss.

**Statistical analysis**

The statistical analysis was conducted using SPSS program (version 19.0). Data were analyzed using the Mann-Whitney *U*-test to compare group means. A *P*-value < 0.05 was considered to represent a significant difference. Sample size estimation: Distinct sample size estimation could not be performed because of lack of comparative data. However, we hypothesised that IBS patients have at least 30% different manometric outcome parameters

**Table 2** Disease activity scores in patients with systemic lupus erythematosus and systemic sclerosis *n* (%)

Activity	Modified Rodnan score (average score)			SLEDAI (average score)		
	No activity	0	7 (39)	No activity	0	4 (19)
Mild	7.2	10 (55)		Mild	3	10 (48)
Moderate	18	1 (6)		Moderate	7.4	5 (24)
Severe	-	-		Severe	11	2 (9)
Total	5.2	18 (100)		Total	4.2	21 (100)

SLEDAI-score: 0: No activity; 2-5: Mild activity; 6-9: Moderate activity; 10-12: Severe activity. Modified Rodnan score: 0: No activity; 1-14: Mild activity; > 14: Moderate-severe activity.

compared to patients with autoimmune disorders, which lead to a sample size of 15 patients per group (Power 80%).

**RESULTS**

**Lab analysis**

There was no statistical difference in the standard lab values in all three groups. Patients with SLE and SSc showed as expected higher incidence in expression of autoimmune antibodies such as ANA, ENA, dsDNA or altered complement concentrations.

**Patient’s characteristics**

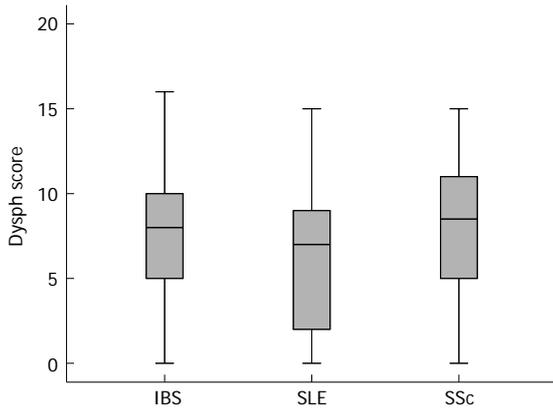

Patients with IBS showed higher prevalence of diarrhoea compared to constipation or to the combination of diarrhoea and constipation (Table 1). Patients with SLE and SSc reported a great variety of symptoms including weakness, difficulty in swallowing or non-specific musculoskeletal tenderness that can be explained due to secondary fibromyalgia. Gender and age showed no statistical significant changes within the three groups (Table 1).

**Disease activity in SLE and SSc**

The disease activity of SLE and SSc are shown in Table 2. SSc patients tend to have a milder disease activity compared to SLE patients. However, dysphagia score was similar in all three groups without any statistical difference. The mean value of dysphagia score was in IBS group 7.3, in SLE group 6.73 and in SSc group 7.56 with a *P*-value > 0.05 (Figure 1).

**Manometric analysis**

In the manometric studies we observed significant differences concerning the quality of the peristaltic waves (amplitude, duration and velocity) among the three groups (Figure 2). IBS patients showed increased peristalsis in the lower two thirds of esophagus in comparison to patients with SSc who in almost 50% of the cases manifested wide peristalsis with reduced amplitude and velocity (Figure 3). There was no significant difference between the amplitude, duration and velocity of the peristaltic movements in the lower two thirds of esophagus among

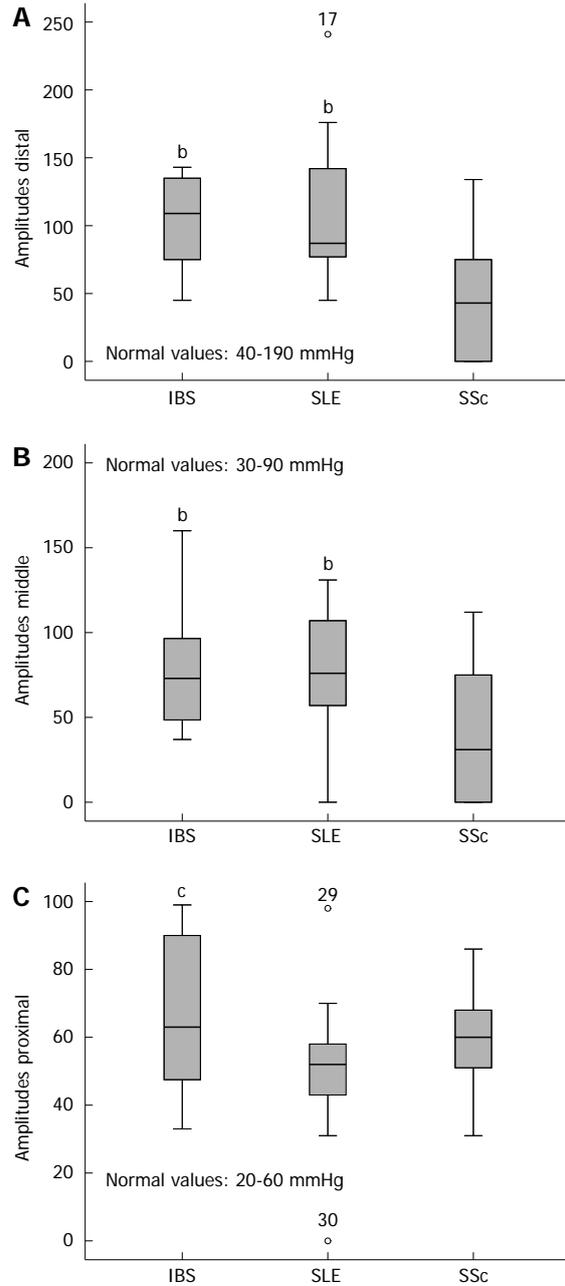

**Figure 1** Dysphagia score in patients with irritable bowel syndrome, systemic lupus erythematosus and systemic sclerosis. All groups showed similar abnormal dysphagia scores. The mean value of dysphagia score was in IBS group 7.3, in SLE group 6.73 and in SSc group 7.56. IBS: Irritable bowel syndrome; SLE: Systemic lupus erythematosus; SSc: Systemic sclerosis.

patients with IBS and patients with SLE. Nevertheless 23.5% of patients with SLE showed distal amplitudes greater as 160 mmHg and 29.4% middle amplitudes greater as 100 mmHg. At the proximal esophageal part patients with IBS showed significant higher peristaltic waves also when compared with patients in the SLE group (Table 3, Figure 2). Particularly, 45.5% of IBS patients showed amplitudes greater as 60 mmHg whereas in the SLE and SSc group the rates were 11.8% and 0% respectively (Figure 3). Measurements concerning the LES showed that patients with IBS had significant lower resting pressure in comparison to patients with autoimmune disorders (Table 3). Though, no significant difference could be observed when other manometric measures between the 3 groups were examined, such as length and relaxation of the lower esophageal sphincter as well as duration of distal and middle peristalsis. Regarding the UES we found a significant higher resting pressure and length by patients in IBS group in comparison to SLE and SSc (Table 3). Interestingly, 58.8% of patients with SLE and 56.35% of patients with SSc showed resting pressure less than 40 mmHg (Figure 3).

Correlation coefficient tests revealed a negative relation between dysphagia score, amplitude and velocity of peristaltic activity at middle and lower esophagus in SSc patients ( $r = -0,6, P < 0.05$ ). A connection between dysphagia and peristaltic abnormality in IBS and SLE groups was not observed. Furthermore, there was no association between the three subgroups of IBS, the score of dysphagia and manometric findings, as well as between the presence of autoantibodies and dysphagia among patients with SLE and SSc (data not shown).

## DISCUSSION

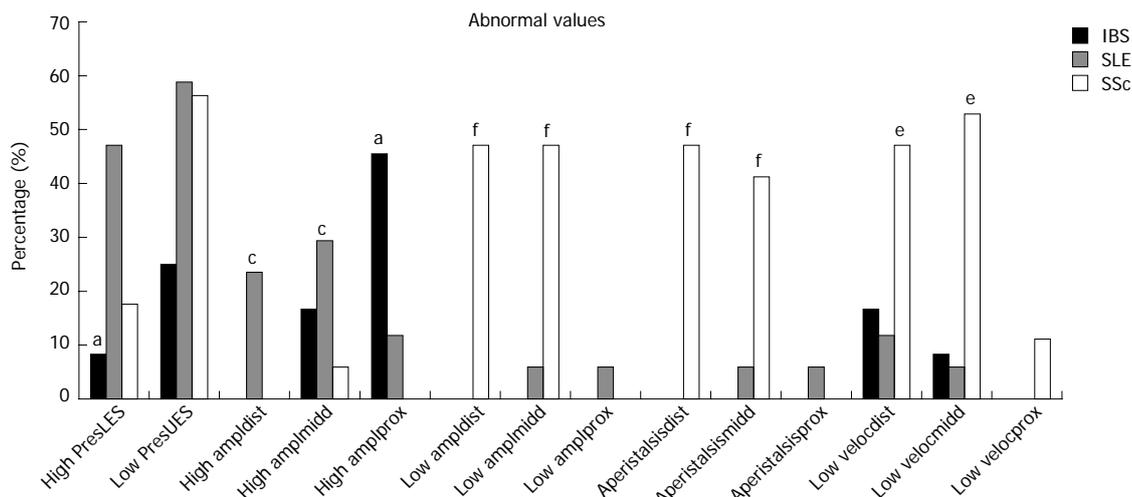

We conducted a comparative analysis of the peristalsis of the esophagus between patients with IBS and patients with SLE and SSc. The groups consisted in 66.7% IBS, 91% SLE and 84.2% SSc of female patients mainly be-

**Figure 2** Amplitudes of the peristaltic waves throughout esophagus. The mean value of amplitudes in patients with SSc was significant lower comparing to subjects with SLE and IBS in the middle (B) and distal (A) esophagus ( $P < 0.01$  vs SSc). In the proximal part (C) IBS patients showed higher peristaltic amplitudes in comparison to the other groups ( $P = 0.05$  vs SLE). Normal values as previously described. IBS: Irritable bowel syndrome; SLE: Systemic lupus erythematosus; SSc: Systemic sclerosis.

tween 40 and 60 years, which is completely in accordance with the epidemiology of the examined diseases<sup>[27-29]</sup>.

We found significant different manometric patterns in IBS patients compared to those with autoimmune disorders. It was interesting to notice that patients in the IBS group, as seen in the derived dysphagia scores, showed the same intensity and frequency of swallowing problematic as subjects in the two other categories. Specifically, patients with IBS complained about difficulties in swallowing, retrosternal sore and heartburn as frequent as pa-

**Figure 3** Comparative analysis of pathological manometric parameters in patients with irritable bowel syndrome, systemic lupus erythematosus and systemic sclerosis. 47.1% of SLE patients showed pressure of lower esophagus sphincter > 30 mmHg. 58.8% of SLE patients and 56.35% of SSc patients showed resting pressure of the upper esophageal sphincter < 40 mmHg. 23.5% of patients with SLE showed distal amplitudes > 160 mmHg and 29.4% middle amplitudes > 100 mmHg, whereas in the proximal part 45.5% of IBS patients had amplitudes > 60 mmHg. The majority of SSc patients showed as expected reduced peristaltic activity in the lower two thirds of esophagus. <sup>a</sup>*P* < 0.05 vs SLE and SSc; <sup>c</sup>*P* < 0.05 vs IBS and SSc; <sup>e</sup>*P* < 0.05, <sup>f</sup>*P* < 0.01 vs IBS and SLE. High PresLES: Pressure lower esophageal sphincter (LES) > 30 mmHg; Low PresUES: Pressure upper esophageal sphincter (UES) < 40 mmHg; High ampldist: Distal amplitude > 160 mmHg; High amplmidd: Middle amplitude > 100 mmHg; High amplprox: Proximal amplitude > 60 mmHg; Low ampldist: Distal amplitude < 50 mmHg; Low amplmidd: Middle amplitude < 40 mmHg; Low amplprox: Proximal amplitude < 30 mmHg; Low velocdist: Distal velocity < 2 cm/s; Low velocmidd: Middle velocity < 2 cm/s; Low velocprox: Proximal velocity < 2 cm/s. IBS: Irritable bowel syndrome; SLE: Systemic lupus erythematosus; SSc: Systemic sclerosis.

tients with SLE and SSc (Figure 1). It was speculated that esophageal symptoms are mainly caused due to esophageal reflux<sup>[30,31]</sup>. However, in our study only patients with normal EGD were included and retrosternal burning was treated with PPI prior entering our study.

The most significant finding in our manometric study was that IBS patients showed very high peristaltic amplitudes in the proximal esophageal part and reduced

resting pressure of the lower esophagus sphincter (Figure 3) which was statistically significant different to SSc and SLE patients.

The analysis of esophageal peristaltic activity in patients with IBS showed controversial results. Diffuse peristaltic dysfunction with amplitudes > 150 mmHg and duration > 7 s<sup>[10,32]</sup>, simultan peristaltic<sup>[11]</sup> or also normal findings<sup>[12,33,34]</sup> have been reported. Reduced resting pres-

sure of LES has already been confirmed by others studies<sup>[9,11,30]</sup>. A pathophysiologic explanation or underlying pathomechanism is not known to date, however a correlation between small bowel or colonic dysfunction has been suggested<sup>[33,35]</sup>.

Our study clearly shows that IBS patients have pathologic motility patterns which are comparable to organic disorders (like SLE or SSc). However, the distribution of changes is different in IBS patients compared to SLE and SSc. A hypermotility of the proximal esophagus > 60 mmHg was seen in almost 50% of the patients. Our data suggest that altered esophageal motility is a common feature in IBS. Taken into consideration the small invasiveness of this method, esophageal manometry may have a place in the diagnostic work up of patients with suspected IBS, especially in the presence of dysphagic symptoms.

SLE patients showed significantly higher incidence of pathological manometric measurements concerning the resting pressure of LES (> 30 mmHg), the amplitudes of distal and middle peristalsis (> 160 mmHg and > 100 mmHg respectively) and the resting pressure of UES (< 40 mmHg) in comparison to IBS group. These findings, with exception to the resting pressure of the UES, are in contrast with the manometric findings in SSc, where most of the patients showed reduced peristaltic activity in the lower two thirds of esophagus (Figures 2 and 3).

Hyperperistalsis has been described from Peppercorn *et al.*<sup>[36]</sup> reporting cases of SLE with manometric features similar to diffuse esophageal spasm. In our study, we noticed peristaltic motility similar to nutcracker esophagus with biphasic waves and amplitudes up to 241 mmHg. Hypoperistalsis or aperistalsis, as previously described<sup>[37,38]</sup>, even in a small percentage, were not observed. These findings are consistent with Gutierrez *et al.*<sup>[38]</sup>. They described that such abnormalities are more often in SSc and mixed connective tissue diseases than in SLE.

In conclusion, this is - to the best of our knowledge - the first comparative study concerning esophageal motility among functional and autoimmune disorders. Although IBS, SLE and SSc patients showed different motility patterns, the intensity and frequency of dysphagia were comparable.

The esophageal peristalsis in patients with IBS appears to be more affected in the proximal part, whereas in the autoimmune disorders in the middle and distal one. Thus, smooth muscle changes might be associated with autoimmune diseases whereas striated muscles might be more affected in patients with IBS as suggested previously<sup>[39,40]</sup>. However, the absence of direct correlation between dysphagia score and manometric parameters in patients with IBS implies that, apart from motor dysfunction, visceral hypersensitivity plays an additional role to the pathology in IBS. In deed, visceral hypersensitivity in IBS patients has been documented in older and recent studies<sup>[34,41-45]</sup> pointing various lines of evidence for its relevance in the pathophysiology of IBS. Future studies are needed to further verify our data and to evaluate whether

different motility patterns can be used to diagnose IBS related motility changes of the esophagus.

## COMMENTS

### Background

Irritable bowel syndrome (IBS) is a functional disorder of the gastrointestinal tract with a still unclear pathophysiology. Although patients with IBS complain predominantly about manifestations concerning the lower gastrointestinal tract, esophageal symptoms are not uncommon.

### Research frontiers

Esophageal dysmotility is frequent in patients with autoimmune diseases, such as systemic lupus erythematosus (SLE) and systemic sclerosis (SSc). However, there is no comparative data available concerning esophageal motility between IBS patients and those with autoimmune disorders.

### Innovations and breakthroughs

This is the first comparative study concerning esophageal motility among functional and autoimmune disorders. Patients with IBS appear to have similar grade of dysphagia in comparison to patients with autoimmune disorders such as SLE and SSc. This study shows that IBS patients have pathologic esophageal motility patterns which are comparable to organic disorders.

### Applications

Esophageal manometry might have a place in the diagnostic work up of patients with suspected IBS.

### Terminology

Irritable bowel syndrome: Functional disorder of the gastrointestinal tract characterized mainly by symptoms as diarrhoea, constipation and diffuse abdominal pain. Systemic lupus erythematosus and systemic sclerosis are autoimmune diseases with esophageal and multiple other visceral manifestations.

### Peer review

The authors compared the esophageal motility between patients with IBS and patients with autoimmune disorders, such as SLE and SSc, at a single university prospective study. The outcome was calculating correlation coefficient between amplitudes, velocity and duration of the peristaltic waves throughout esophagus and patients' dysphagia for all three groups. It revealed that IBS patients showed similar pathologic dysphagia scores but were characterized from different motility patterns when compared to patients with autoimmune diseases. The results are interesting and suggest that esophageal manometry may have a place in the diagnostic work up of patients with suspected IBS, especially in the presence of dysphagic symptoms.

### Abstract

**AIM:** To investigate the effect of quercetin supplementation on the myenteric neurons and glia in the cecum of diabetic rats.

**METHODS:** Total preparations of the muscular tunic were prepared from the ceca of twenty-four rats divided into the following groups: control (C), control supplemented with quercetin (200 mg/kg quercetin body weight) (CQ), diabetic (D) and diabetic supplemented with quercetin (DQ). Immunohistochemical double staining technique was performed with HuC/D (general population)/nitric oxide synthase (nNOS), HuC-D/S-100 and VIP. Density analysis of the general neuronal population HuC/D-IR, the nNOS-IR (nitrergic subpopulation) and the enteric glial cells (S-100) was performed, and

the morphometry and the reduction in varicosity population (VIP-IR) in these populations were analyzed.

**RESULTS:** Diabetes promoted a significant reduction (25%) in the neuronal density of the HuC/D-IR (general population) and the nNOS-IR (nitrergic subpopulation) compared with the C group. Diabetes also significantly increased the areas of neurons, glial cells and VIP-IR varicosities. Supplementation with quercetin in the DQ group prevented neuronal loss in the general population and increased its area ( $P < 0.001$ ) and the area of nitrergic subpopulation ( $P < 0.001$ ), when compared to C group. Quercetin induced a VIP-IR and glial cells areas ( $P < 0.001$ ) in DQ group when compared to C, CQ and D groups.

**CONCLUSION:** In diabetes, quercetin exhibited a neuroprotective effect by maintaining the density of the general neuronal population but did not affect the density of the nNOS subpopulation.

© 2013 Baishideng. All rights reserved.

**Key words:** Diabetes; Myenteric plexus; Neuroprotection; Neuronal nitric oxide synthase; Vasoactive intestinal polypeptide; Enteric glia

**Core tip:** The present study is the first to report a neuroprotective effect of the flavonoid quercetin in the general population of enteric neurons in the cecum of rats with experimental diabetes mellitus. Quercetin did not reduce the loss of nitrergic neurons in the diabetic rats. This observation suggests that selective changes in the neurochemical code of enteric neurons occur in the presence of quercetin. We propose a causal link between the area and number of glial cells and the size of VIP-IR (reduction in varicosity population) varicosities. Although this link is not fully understood, these observations provide a basis for further studies to clarify the link between glia and VIP-IR varicosities.

## INTRODUCTION

Diabetes affects the gastrointestinal tract causing changes in its motility, such as diarrhea, constipation and gastroparesis<sup>[1]</sup>. These symptoms are related to damage to the Enteric Nervous System (ENS) caused by diabetic neuropathy. Diabetes affects subpopulations of enteric neurons differently<sup>[2,3]</sup>, causing changes in neuronal size and density<sup>[2-6]</sup> and altering neurochemical code and neurotransmitters release<sup>[7]</sup>. The etiology of diabetic neuropathy is complex; hyperglycemia, which through various metabolic pathways including mitochondrial dysfunction and osmotic stress, can induce toxicity in neurons<sup>[8]</sup>; and oxidative stress, which results in a decrease in antioxidant capacity<sup>[9]</sup> through glucose oxidation, protein glycosylation and a decrease in the formation of reduced glutathione<sup>[10]</sup>, are among the causative factors. Reductions in the levels of non-enzymatic antioxidants such as ascorbic acid<sup>[11]</sup> and vitamin E enhance oxidative stress<sup>[12]</sup>.

Antioxidants are promising therapies for preventing and alleviating the debilitating clinical symptoms of diabetic neuropathy. Flavonoids, a family of polyphenolic compounds with a high antioxidant capacity<sup>[13]</sup>, might effectively protect against the pathology of diabetes. Quercetin is a flavonoid that is naturally present in various foods, such as onions, apples, broccoli, tea and red wine<sup>[14,15]</sup>. Quercetin has shown several beneficial pharmacological properties, such as antiperoxidative, anticarcinogenic, anti-inflammatory and antioxidant activities<sup>[16]</sup>. Ganglion neurons and their bundles of nerve fibers in the ENS are surrounded by numerous glial cells<sup>[17]</sup>. These glial cells play an important role in gastrointestinal physiology and pathophysiology, contributing to intestinal homeostasis, serving as a link between the nervous and immune systems<sup>[18]</sup> and influencing neurochemical phenotype<sup>[19]</sup>. The number of glial cells and neurons in the ENS are reduced by diabetes<sup>[2]</sup>.

The use of a potent antioxidant, such as quercetin, could mitigate this damage and alleviate the clinical symptoms of the disease. Because diabetes affects enteric neurons subpopulations differently<sup>[2,3]</sup>, the aim of this study was to investigate the potential for quercetin to mitigate of neuropathy. This aim was achieved by comparing the areas of the varicosities of vasoactive intestinal polypeptide (VIP)-containing neurons and the distributions of neuronal nitric oxide synthase (nNOS) and HuC/D (general population) containing neurons and glial cells in the ceca of diabetic and control rats.

## MATERIALS AND METHODS

### Animals

All the procedures involving animals were conducted in accordance with the ethical principles adopted by the Brazilian College of Animal Experimentation (COBEA) and were reviewed and approved by the Ethics Committee on Animal Experiments (CEEA) at the Universidade Estadual de Maringá (State University of Maringá). For the present study, twenty-four adult male Wistar rats (Central Animal Facility at the State University of Maringá) were used. At 88 d of age, weighing 360 g on average, the animals were transferred to the vivarium Sector of the Morphological Sciences Department, where they were housed in individual cages maintained under controlled environmental temperature conditions of  $(22 \pm 2 \text{ }^\circ\text{C})$  and light/dark cycle (12/12 h) with *ad libitum* access to a water fountain and food (Nuvilab<sup>®</sup>).

After a 2-d period of adaptation to the new environment, rats were weighed and the 120-d trial period monitoring began. At this time, rats were divided randomly into four groups, each containing 6 animals, that received the following treatments: control (C), control supplemented with quercetin (200 mg/kg quercetin body weight) (CQ), diabetic (D) and diabetic supplemented with quercetin (DQ).

To induce diabetes, rats from the D and DQ groups were fasted for fourteen hours and then received an intravenous injection (penile vein) of streptozotocin (STZ) (Sigma, St. Louis, MO) at a dose of 35 mg/kg body weight, dissolved in citrate buffer 10 mmol/L (pH 4.5). Four days after the induction, blood glucose was measured (Accu-Chek Active, Roche Diagnostics GmbH, Mannheim, BW, Germany) to confirm the establishment of experimental diabetes. All the animals in the D and DQ groups had glucose levels above 210 mg/dL.

Starting on the fourth day of the experiment, animals in the CQ and DQ groups were weighed weekly and their water intake was measured. These measurements were used to calculate the dilutions required to ensure each animal in the CQ and DQ groups received 200 mg/kg per day of quercetin in their drinking water. Animals in C and D groups received water without supplementation. After 120 d (210-d-old), the rats were euthanized following anesthesia with Thiopental<sup>®</sup> (40 mg/kg *ip*; Abbott Laboratories, Chicago, IL). Blood was collected by cardiac puncture and blood glucose concentration measured using the glucose oxidase method<sup>[20]</sup>.

### Cecum collection and processing

The ceca were removed, washed in phosphate buffered saline (PBS; 0.1 mol/L pH 7.4) and filled with and immersed in Zamboni fixative solution<sup>[21]</sup> for 18 h at 4 °C. Following fixation, ceca were opened along their mesenteric borders and washed with 80% alcohol until the excess fixative was removed. Then, dehydration was performed in 95% and 100% EtOH, followed by diaphanization in xylene and sequential rehydration in 100%, 90%, 80% and 50% EtOH and finally PBS. Individual

ceca were cut into small segments (approximately 2 cm<sup>2</sup>) that were subsequently microdissected under a stereomicroscope to remove the mucosa and submucosa and reveal the tunica muscularis.

### Immunohistochemistry

Three tissues sections per animal underwent immunohistochemical staining. One section was double-labeled to reveal immunoreactivity for HuC/D (general population) and nNOS. A second section was stained for HuC/D and S-100 (a glial protein), and a third section was stained to reveal immunoreactivity for vasoactive intestinal peptide (VIP). Tissues were washed twice in PBS containing 0.5% Triton X-100 for 10 min followed by one hour incubation in a blocking solution of PBS containing 2% BSA and 10% goat serum at room temperature under constant agitation. Tissues were then incubated for 48 h under agitation at room temperature in solutions of PBS containing primary antisera at the dilutions indicated in Table 1, 2% BSA, 0.5% Triton X-100 and 2% goat serum. Tissues were washed in PBS containing 0.5% Triton X-100 and incubated for 2 h at room temperature in solutions of PBS containing the appropriate secondary antisera at the dilutions indicated in Table 1, 2% BSA, 0.5% Triton X-100 and 2% goat serum. Tissues were then washed in PBS containing 0.5% Triton X-100 three times for 10 min and mounted on slides with 10% PBS in glycerol.

### Quantitative analysis of immunoreactive myenteric neurons

Analysis was performed by sampling the antimesenteric

basal region<sup>[22]</sup>. High-resolution micrographs of stained tissue were captured using an AxioCam MRC camera (Carl Zeiss, Jena, Germany) coupled to an Axioshop Plus fluorescence microscope (Carl Zeiss, Jena, Germany) with Axio Vision software (v. 4.6). Images were subsequently analyzed using Image-Pro Plus (v. 4.5.029; Media Cybernetics, Silver Spring, MD) to quantify the neurons and glia. For each animal, all the neurons and glial cells present in 30 images captured at  $\times 20$  magnification were manually identified and counted. The area of each image was approximately 0.2041 mm<sup>2</sup> and the total quantified area was 6.123 mm<sup>2</sup>. The results were expressed per square centimetre.

### Neuronal density correction

According to Cowen *et al.*<sup>[23]</sup>, pathological processes can change organ size, which can scatter the neurons. Therefore, the results of the neuronal and glial quantification were corrected for the changes in cecum size caused by diabetes (Table 2). For this correction, the cecum of each animal was outlined on cardboard and the images were transferred to the Image-Pro Plus software to measure the perimeter of each animal's cecum. The average area in cm<sup>2</sup> of the cecum in each group was used to calculate the correction factor and the factor was then applied to the quantitative results for each animal in the CQ, DQ and D groups (Tables 2 and 3).

### Morphometric analysis of immunoreactive myenteric neurons

Images of ganglia were captured using a 20  $\times$  objective for HuC/D-, nNOS- and S-100-immunoreactivity and a 40  $\times$  objective for VIP-immunoreactivity. Morphometric analyses were performed using the image analysis software Image Pro-Plus. The areas of 100 neuronal cell bodies (HuC/D-IR, nNOS-IR) and glial cells (S-100-IR) were measured per animal. For VIP, the areas of 400 varicosities per animal were measured. Varicosity measurements were performed using a digital zoom of  $\times 800$ , maintaining the original calibration of the captured image.

### Statistical analysis

Statistical analysis of the quantitative data was performed

using Statistica 7.1 and GraphPad Prism 3.1, with data expressed as the means  $\pm$  SEM. Morphometric data were set in delineation blocks and analyzed by Tukey's test. For the other results, we performed one-way analysis of variance (ANOVA) followed by Tukey's test. The level of significance was 5%.

## RESULTS

Diabetes was induced by STZ administration in the D and DQ groups, as demonstrated by the assessment of blood glucose (Table 4). Hyperglycemia was accompanied by a significant reduction in the body weights in the D and DQ groups when compared with the control (C) group. Other symptoms typical of diabetes, such as polydipsia (increased water intake) and polyuria (increased urine output), were also observed (Table 4). In addition, the D group demonstrated a significant dilatation (61%) of the cecum compared with the C group ( $P < 0.01$ ). Treatment with quercetin helped to reduce the diabetes-associated dilation of the cecum in DQ group to 34% of the controls (Table 2), which was not significantly different from the C group ( $P > 0.05$ ). However, quercetin treatment did not affect the hyperglycemia, polydipsia or polyurea induced by STZ (Table 4).

### Morphology of HuC/D, nNOS, S-100 and VIP immunoreactivity in the cecum myenteric plexus

HuC/D-IR and nNOS-IR neuronal cell bodies were observed within the ganglia and along the interganglionic nerve tracks. The intensity of the immunofluorescence in neurons was heterogeneous within the four groups studied (Figure 1). We observed that the nitrergic population was usually located peripherally in the ganglion. Glial cells were present in all ganglia and along the nerve tracks. However, more glial cells were found in the nerve tracks of the CQ group than the other groups (Figure 2E and F). The VIP-IR varicosities were distributed throughout the tunica muscularis. However, in the D and DQ groups a reduction in the number of nerve fibers was observed (Figure 3C and D).

### Neuronal and glial density

After correction for cecum dilatation (Table 2), we ob-

**Table 4** Animal parameters (mean  $\pm$  SEM)

Groups	Starting weight (g)	Final weight (g)	Blood glucose (mg/dL)	Water intake (mL/d)	Feed intake (g/d)	Urine volume (mL/d)
C	341 $\pm$ 9	517 $\pm$ 13	138 $\pm$ 5	42 $\pm$ 3	37 $\pm$ 3	11 $\pm$ 2

<sup>a</sup> $P < 0.05$  vs C group. C: Control; CQ: Control supplemented; D: Diabetic; DQ: Diabetic supplemented with quercetin.

served a reduction in the general population (HuC/D) of myenteric neurons in the ceca of diabetic rats compared with the C group ( $P < 0.001$ ). The CQ and DQ groups were not significantly different from the C group ( $P > 0.05$ ) (Table 3). There was a significant reduction in nNOS-IR neurons in D and DQ groups compared with the C group ( $P < 0.05$ ). Quercetin supplementation did not alter the cell densities between the D and DQ groups in this subpopulation ( $P > 0.05$ ). Double labeling showed that the ratio of HuC-D/nNOS was similar in the C, D and CQ groups but was significantly reduced in the DQ group (Table 3). Quantitative analysis of glia (S-100-IR) showed a significant increase in the CQ group compared with the C group ( $P < 0.001$ ). The D and DQ groups were not different from the C group ( $P > 0.05$ ). The ratio of glial cells to neurons (HuC-D/S-100) were similar in groups C, D and DQ, but were significantly increased in the CQ group when compared with the C and DQ groups ( $P < 0.05$ ) (Table 3).

### Morphometric analysis

**Neuronal population HuC/D-IR and nNOS-IR and glial cells:** The average HuC/D-IR and nNOS-IR neuronal areas in the C and CQ groups were not significantly different ( $P > 0.05$ ). However, there was an increase in the neuronal area in the D group when compared with the C group ( $P < 0.05$ ) and an even larger increase in the average area of the DQ group when compared with the D group ( $P < 0.05$ ). The mean areas of the HuC/D-IR and nNOS-IR neuron cell bodies are shown in Table 5. We observed a significant increase in the average area of the glia in the D group compared with the C, CQ and DQ groups, and a significant decrease in the DQ group compared with the C, CQ and D groups (Table 5).

**VIP-IR varicosities:** Fluorescence intensity was lower in VIP-IR varicosities in the DQ group compared with the other groups (Figure 3). We found significant differences in the diameter of the varicosities among the four groups studied; the CQ group had an increase in the average area of varicosities compared with the C group ( $P < 0.01$ ), a larger increase was observed in the D group compared with the C and CQ groups ( $P < 0.01$ ). In contrast, a decrease in the area of varicosities was found in the DQ group compared with all the other groups ( $P < 0.001$ ) (Table 5).

## DISCUSSION

STZ administration to animals in the D and DQ groups promoted typical characteristics of diabetes mellitus, including hyperglycemia, polyuria, polydipsia and weight loss. Quercetin treatment did not affect these measurements in control or diabetic rats suggesting that supplementation with this antioxidant did not influence metabolic pathways linked to weight gain or the mobilization of energy substrates in these animals.

Rats in the D group exhibited 61% cecum dilation compared with animals in the C group, so we used a correction factor to quantify neuronal density. The correction factor was required to ensure the results presented reflected real changes in the neuronal/glial population

density rather than the dispersion of these populations as a consequence of the dilation. Previous studies have shown that diabetes promotes dilation of the small intestine<sup>[6,24]</sup> and the large intestine<sup>[4,25,26]</sup>.

A reduction (25%) in the density of myenteric neurons that were immunoreactive to HuC/D in the D group compared with the C group was observed. Earlier studies in our laboratory showed neuronal loss in different gastrointestinal segments, including the stomach<sup>[27]</sup>, duodenum<sup>[28]</sup>, ileum<sup>[6]</sup>, proximal colon<sup>[29]</sup> and cecum<sup>[4,26]</sup>. These alterations may be attributed to the reduction in antioxidant defenses and the concomitant intensification of oxidative stress in the cells<sup>[10]</sup>. Free radicals can react with DNA, proteins and lipids and these reactions could cause nerve damage<sup>[30]</sup>, which results in the gastrointestinal motility disorders that are typical of diabetes<sup>[31]</sup>.

In the DQ group, quercetin promoted a preservation of neuronal density (HuC/D-IR) of 18% compared with the D group. The density in the DQ group was similar that observed in the C group. This preservation may be attributed to the antioxidant potential of quercetin<sup>[16]</sup>, which would minimize oxidative stress, preventing cell death by necrosis or apoptosis<sup>[32]</sup>. The ability of quercetin to reduce superoxide anions ( $\text{O}_2^{\cdot-}$ ), singlet oxygen and hydroxyl radicals ( $\text{HO}^{\cdot}$ ), could also prevent lipid peroxidation caused by these molecules<sup>[33]</sup>. Finally, quercetin may induce the gene expression of antioxidant enzymes, increasing glutathione levels (GSH) and conferring neuroprotection<sup>[34]</sup>. In the present study, we

found a significant reduction in the density of nitrergic neurons in the cecum of the rats from the D group (25%) and the DQ group (26%) compared with the C group. These decreases in nitrergic density may be attributed to the duration of the diabetes (17 wk). Previous studies have shown an accumulation of advanced glycation end-products, which result in oxidative stress and in neuronal apoptosis, begins in the twelfth week of diabetes<sup>[35,36]</sup>. Reductions in the number of neurons and/or nNOS activity were also observed in the stomach of diabetic rats<sup>[37,38]</sup>. However, depending on the model, the duration of diabetes and the techniques used to assess these changes, we can find an increase<sup>[39]</sup>, a decrease<sup>[35,37]</sup>, or no change<sup>[6]</sup> in the number of nitrergic neurons and/or nNOS levels and activity in different regions of the gastrointestinal tract. According to Shotton and colleagues<sup>[3]</sup>, these inconsistencies may be explained by regional or neuronal subpopulation differences and/or by the existence of multiple stages in the development of neuropathy. In the current study, quercetin treatment did not prevent the reduction of nitrergic neurons compared with D group as it did for the general neuronal population (HuC/D-IR). These findings are of great interest, as quercetin seems not only to prevent neuronal loss but also to direct the chemical coding of the neurons it protects.

In the CQ group, we observed an increase in the VIP-IR varicosity areas compared with the C group ( $P < 0.01$ ), similar data were obtained by Alves *et al.*<sup>[40]</sup> who studied the effect of supplementation with L-glutamine in the jejunum of normoglycemic and diabetic rats. VIP is an inhibitory neuropeptide that has an important role in regulating glial cell proliferation, modulating cell plasticity, stimulating the release of neuroprotective factors and secreting gliotransmitters/gliopeptides that are involved in intercellular communication<sup>[41]</sup>. In the present study, there was a significant increase (36%) in the number of glial cells in the CQ group compared with the C group ( $P < 0.001$ ). In the CNS, VIP promotes astrocytic proliferation<sup>[41,42]</sup>; a quercetin-induced increase in VIP may cause an increase in enteric glia in the same way. Furthermore, VIP is capable of stimulating the production of neurotrophic factors by glia in the CNS<sup>[43]</sup>. An interesting finding in the present study was that there was a greater increase in the number of glia within the fiber tracts rather than within the ganglia in the CQ group. Fiber tracts also contain numerous VIP-IR varicosities.

However, the observation that diabetic rats (group D) demonstrated an increase in the area of VIP-IR varicosities compared with the C group ( $P < 0.01$ ), without a concomitant increase in the density of glial cells argues against the hypothesis of a direct causal relationship between VIP and glia. These seemingly conflicting observations may be explained by other factors that might be present in the diabetic state. There are published reports of increased expression and release of interleukin (IL)-1 beta in STZ-induced diabetic rats<sup>[44]</sup> and in human monocytes treated *in vitro* with different concentrations of glu-

cose<sup>[45]</sup>. Studies by Rühl and colleagues<sup>[46]</sup> demonstrated a combined response of IL-1 beta and IL-10 that lead to a reduction in glial cell proliferation. Thus, despite an increase in IL-10 resulting from increased VIP expression the diabetic state could also be promoting an increase of IL-1 beta and together these two cytokines would inhibit glial cell proliferation in the D group. Regardless of the relationship between VIP and glia, which requires further study, the increase in the size of the VIP-IR varicosities in the diabetic rats may be explained by an increased expression of VIP as a compensatory effect due to neuronal loss<sup>[47]</sup>, or it may be a reflection of neuronal plasticity to maintain the survival of the neurons in response to the pathophysiological conditions of diabetic neuropathy<sup>[48]</sup>. This conclusion could be supported by studies demonstrating an important role for VIP in neuroprotection<sup>[49,50]</sup>, perhaps by scavenging reactive oxygen species as demonstrated *in vitro*<sup>[49]</sup> and *in vivo*<sup>[51]</sup>.

Morphometric analysis of the general neuronal population (HuC/D-IR) and the nitrergic (nNOS-IR) subpopulation showed a significant increase in the neuronal area in the D group compared with the C group. An increase in neuronal area is a frequent finding in diabetic animals<sup>[4,6]</sup>. Hypertrophy was also observed in subpopulations of enteric neurons in the diabetic rats, including the VIP-IR neurons<sup>[40,47]</sup>, nNOS-IR<sup>[5]</sup> and NADH diaphorase-positive neurons<sup>[52]</sup>. In the present study, we observed a significant increase in the neuronal area of the general (HuC/D) and nitrergic (nNOS-IR) populations in the DQ group when compared with the other studied groups (Table 5). This event could be explained a the reduction in glial function and metabolism, which was suggested by the decrease in glial cell area and which could reduce the production of neurotrophic factors leading to a loss of control over the processes of synthesis, potentially changing the neurochemical phenotype of the neurons. Evidence that enteric glial cells can produce neurotrophic factors, such as nerve growth factor, brain derived neurotrophic factor and neurotrophin 3, that modulate neuronal gene expression and possibly the enteric neurophenotype has been observed<sup>[53]</sup>. Additionally, neurotrophic factors play a critical role in regulating the synthesis of neurotransmitters and neuropeptides and in influencing neuronal morphology<sup>[54]</sup>.

In summary, we concluded that in diabetic rats, quercetin exhibited a neuroprotective effect due to its antioxidant action. This action is independent of diabetes-induced changes in hyperglycemia, polydipsia, polyurea and weight loss. Interestingly, while quercetin was able to reduce the loss of myenteric neurons, it did not reduce the loss of nitrergic neurons suggesting a selective change in the neurochemical coding of the enteric neurons during quercetin treatment. Quercetin treatment increased the area of VIP-IR varicosities and concurrently increased the density of enteric glia in control animals. In diabetic rats, there is a disconnection between these observations: quercetin does not increase glial density, but does decrease VIP-IR varicosity area. While there are

data in the literature to support a causal link between VIP and glia and to suggest a connection to neuronal loss and changes in chemical coding, the molecular mechanisms and the relationships between these observations remain to be elucidated.

## ACKNOWLEDGMENTS

The authors thank Juliana Vanessa Colombo Martins Perles and Flavia Freiz for their assistance with the animal care and Mariana Cristina Vicente Umada Zapater, Angélica Soares, Maria Eurides do Carmo Cancino and Maria dos Anjos Fortunato (UEM-Maringá, Brazil) for their excellent technical support.

## COMMENTS

### Background

Hyperglycemia from diabetes mellitus (DM) may cause long-term neuropathic abnormalities that affect the autonomic nervous system. In the gastrointestinal tract, neurodegeneration and morphological changes in the neurons and glia cells of the enteric nervous system (ENS) are observed. These changes are related to the oxidative stress of diabetes. Hyperglycemia is responsible for an increase in oxidative stress and a decrease in antioxidant capacity. In this context, the use of flavonoids, a family of polyphenolic compounds with a high antioxidant capacity, might be effective in protecting against the pathology of diabetes. Quercetin is a flavonoid that is present in various foods, such as grapes, and their derivatives. Several studies have revealed the beneficial pharmacological effects of quercetin in biological systems, including its potent antioxidant effect. Thus, the use of quercetin is a promising therapy for the prevention of neurological disorders and can reduce the pathological conditions of diabetes.

### Research frontiers

Currently, diabetes is considered an epidemic that affects more than 300 million people worldwide. Its chronic nature combined with the severity of its complications and the necessary means to control them, makes diabetes a very costly disease for patients and for the healthcare system. Autonomic neuropathies, which are among the complications of diabetes, can trigger a wide range of gastrointestinal problems, such as nausea, vomiting, diarrhea, constipation and fecal incontinence, that cause discomfort and deeply affect the quality of life of patients with DM. In this context, studies evaluating therapeutic strategies that have the potential to improve or mitigate the degenerative damage to the enteric nervous system, such as the use of the flavonoid quercetin, may eventually contribute to an improved quality of life for these patients.

### Innovations and breakthroughs

Previous studies in their research group, using simple neuronal marking techniques, reported the absence of an effect of antioxidants on the cecum of rats with experimental DM. In this study, using immunohistochemical techniques, the authors could observe an effect of antioxidant treatment on the cecum in a rat DM model. In addition, using these techniques we observed this effect in both the general neuronal population and in specific neuronal subpopulations of the cecum ENS. Although, studies suggest a neuroprotective effect of quercetin in the central nervous system, there are only a few studies examining the effect of quercetin in the ENS of rats with experimental DM.

### Applications

The present study shows that quercetin could improve antioxidant capacity and thus protect the enteric nervous system in the cecum of streptozotocin-induced diabetic rats *in vivo*. When these effects are confirmed by further research, future application of quercetin as a therapeutic in the treatment of diabetic neuropathy may be merited. Another aspect of the present study is the identification of an apparent causal relationship between VIP and glia. This observation could provide a basis for the clarification of other research.

### Terminology

ENS is made of sensory neurons, interneurons and motoneurons and is divided into two major plexuses in the gastrointestinal tract: the myenteric and submucosal. VIP and the enzyme Nitric Oxide Synthase are neuronal sub-

populations of the ENS that express inhibitory neurotransmitters and are non-adrenergic and non-cholinergic. Enteric glia: a set of cells, which are similar to the astrocytes of the CNS, that are adhered to the ENS ganglion neurons and their nerve fiber bundles.

### Peer review

This paper concerns an interesting issue, however introduction is repetitive, and discussion is too long and should be reduced.

### Abstract

**AIM:** To evaluate the feasibility and safety of full robot-assisted gastrectomy with intracorporeal robot hand-sewn anastomosis in the treatment of gastric cancer.

**METHODS:** From September 2011 to March 2013, 110 consecutive patients with gastric cancer at the authors' institution were enrolled for robotic gastrectomies. According to tumor location, total gastrectomy, distal or proximal subtotal gastrectomy with D2 lymphadenectomy was fully performed by the da Vinci Robotic Surgical System. All construction, including Roux-en-Y jejunal limb, esophagojejunal, gastroduodenal and gastrojejunal anastomoses were fully carried out by the intracorporeal robot-sewn method. At the end of surgery, the specimen was removed through a 3-4 cm incision at the umbilicus trocar point. The details of the surgical technique are well illustrated. The benefits in terms of

surgical and oncologic outcomes are well documented, as well as the failure rate and postoperative complications.

**RESULTS:** From a total of 110 enrolled patients, radical gastrectomy could not be performed in 2 patients due to late stage disease; 1 patient was converted to laparotomy because of uncontrollable hemorrhage, and 1 obese patient was converted due to difficult exposure; 2 patients underwent extra-corporeal anastomosis by minilaparotomy to ensure adequate tumor margin. Robot-sewn anastomoses were successfully performed for 12 proximal, 38 distal and 54 total gastrectomies. The average surgical time was  $272.52 \pm 53.91$  min and the average amount of bleeding was  $80.78 \pm 32.37$  mL. The average number of harvested lymph nodes was  $23.1 \pm 5.3$ . All specimens showed adequate surgical margin. With regard to tumor staging, 26, 32 and 46 patients were staged as I, II and III, respectively. The average hospitalization time after surgery was 6.2 d. One patient experienced a duodenal stump anastomotic leak, which was mild and treated conservatively. One patient was readmitted for intra-abdominal infection and was treated conservatively. Jejunal afferent loop obstruction occurred in 1 patient, who underwent re-operation and recovered quickly.

**CONCLUSION:** This technique is feasible and can produce satisfying postoperative outcomes. It is also convenience and reliable for anastomoses in gastrectomy. Full robotic hand-sewn anastomosis may be a minimally invasive technique for gastrectomy surgery.

## INTRODUCTION

Although laparoscopic gastrectomy has been widely performed worldwide, its role is still a matter of debate due to inherent difficulties in specific node dissection and intracorporeal anastomosis<sup>[1,2]</sup>. Recently, robotic surgery has been demonstrated to overcome the intrinsic limitations of a traditional laparoscopic approach, where the anatomical and operative conditions are similar to those encountered during gastric resection<sup>[3,4]</sup>. Several recent retrospective studies have reported that robotic surgery for the treatment of gastric cancer is feasible and can produce satisfying postoperative outcomes<sup>[5-7]</sup>. However, most studies have reported that anastomosis after robotic gastrectomy was carried out by extracorporeal hand-sewn sutures or an intracorporeal stapler.

Wristed instruments that allow seven degrees of freedom, tremor filtering, the ability to scale motions, and stereoscopic vision improve the surgeon's dexterity when fine manipulation of tissues in a close, fixed operating field or when hand-sewn sutures and knot tying are required<sup>[8]</sup>. In robotic surgery for other complex robotic procedures, such as urethral anastomosis in radical prostatectomy or valve replacement in cardiac surgery, several studies have reported that robot hand-sewn anastomosis was possible within a narrow space due to these distinct advantages<sup>[9-11]</sup>. Therefore, we believe that a robotic approach would also be relevant for laparoscopic D2 dissection and intracorporeal anastomosis by a full robot hand-sewn method.

To the best of our knowledge, no study has assessed the reliability of this hand-sewn technique or described its technical details, although it is a classic and feasible method. The current study aimed to assess the feasibility and safety of full robot-assisted total and subtotal gastrectomy with extended lymphadenectomy and intracorporeal robot-sewn anastomosis.

Here, we present the results of a preliminary study in which anastomosis after gastrectomy was successfully achieved by a robot-sewn technique. All procedures, including lymph node dissection and anastomosis, were completed by the robot, the so-called "full robot-assisted gastrectomy", which was different from previous robotic surgery for the treatment of gastric cancer.

## MATERIALS AND METHODS

All procedures were performed by the da Vinci Surgical System (Intuitive Surgical, Inc, Mountain View, CA, United States). We began using this system for gastric cancer surgery in May 2010 at Jinglin Hospital, affiliated to Nanjing University, China. From September 2011 to

March 2013, we conducted a prospective evaluation of the feasibility and safety of robot-assisted gastrectomy with intracorporeal robot hand-sewn anastomosis. During this time, all patients with histologically proven gastric cancer without organ invasion (T4) underwent preoperative work-up and examination. One hundred and ten consecutive patients diagnosed with gastric cancer were enrolled in this trial (details in Figure 1). Robotic anastomosis was performed by a surgeon (Dr. Jiang ZW) who had been involved with more than 100 cases of robotic-assisted gastrectomy before this trial. We obtained informed consent from all patients for administration of this robotic surgery anastomotic method.

Perioperative management was performed by adopting the measures of fast track surgery<sup>[12,13]</sup>. Preoperative short-time fasting and carbohydrate loading were introduced. Nasogastric decompression tubes were abandoned in all patients, unless absolutely necessary. When able, patients were given water from postoperative day 1, liquid diet was started on postoperative day 2, and soft diet was started on postoperative day 3. After 1 d of soft diet without complications, patients were discharged.

All data were collected prospectively. Operative time was calculated as the time between pneumoperitoneum induction and port-site closure. Intraoperative blood loss was measured by subtraction. Tumor staging and lymph node harvest rate were assessed by the pathology department. Surgical and oncologic outcomes were well documented. Patients were evaluated weekly with clinical examinations during the 30 d after discharge and then followed-up every 3 mo. We evaluated feasibility and safety of the procedure with the Clavien-Dindo classification, which categorizes surgical complications from grade 1 to 5 based on the invasiveness of the treatment required. Grade 1 requires no treatment; grade 2 requires medical therapy; grade 3a requires surgical, endoscopic, or radiologic intervention, but not general anesthesia; grade 3b requires general anesthesia; grade 4 represents life-threatening complications that require intensive care; and grade 5 represents death of the patient.

### *Patient and robot position, port placement*

The patient is moved to the 20° reverse Trendelenburg position under general anesthesia. The camera port (C) is inserted into the infra-umbilical area for a 12 mm trocar. After establishing 12-mmHg pneumoperitoneum, the other four ports are placed with the aid of camera visualization.

Two 8-mm Intuitive cannulae for robotic devices are placed under direct visualization 2-3 fingerbreadths below the costal margin at the right and left anterior axillary line, respectively (Figure 2, trocar A and E). The last 8-mm Intuitive cannula (B) is placed in the right paraumbilical area below the level of port A and at least one handbreadth away from the camera port.

One 12-mm trocar (D) is placed along the left mid-clavicular line, in the left paraumbilical area and at least

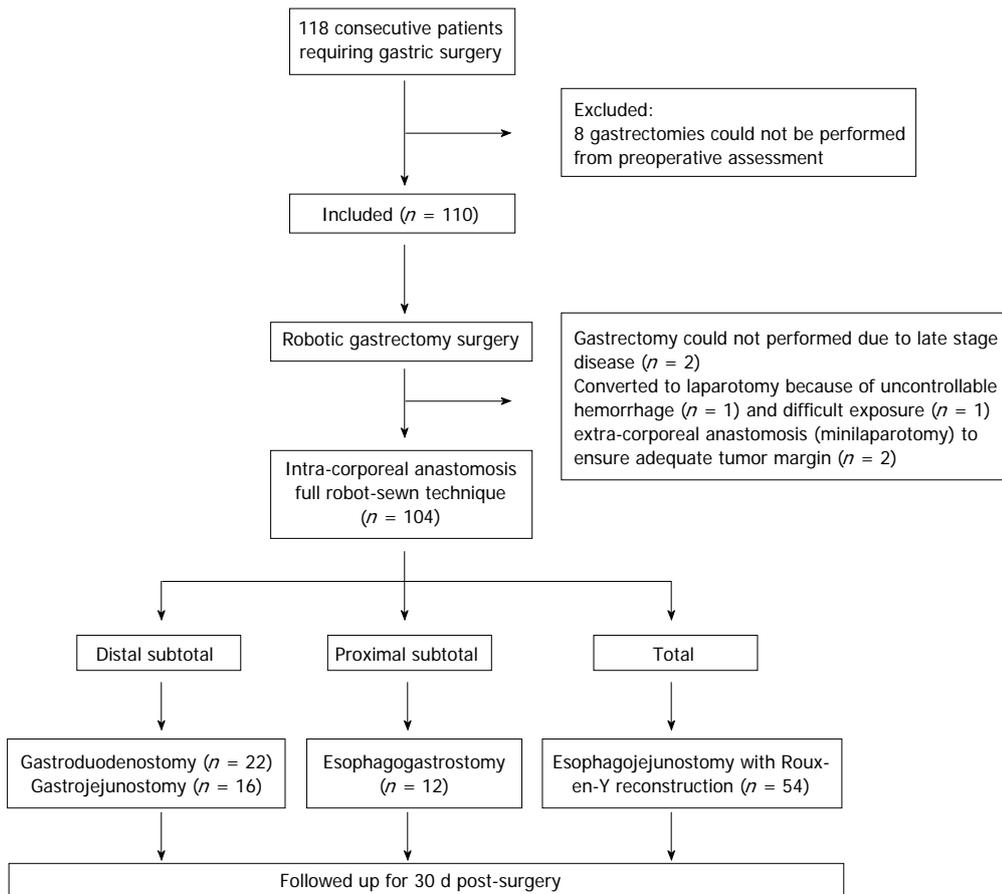

Figure 1 Flow diagram.

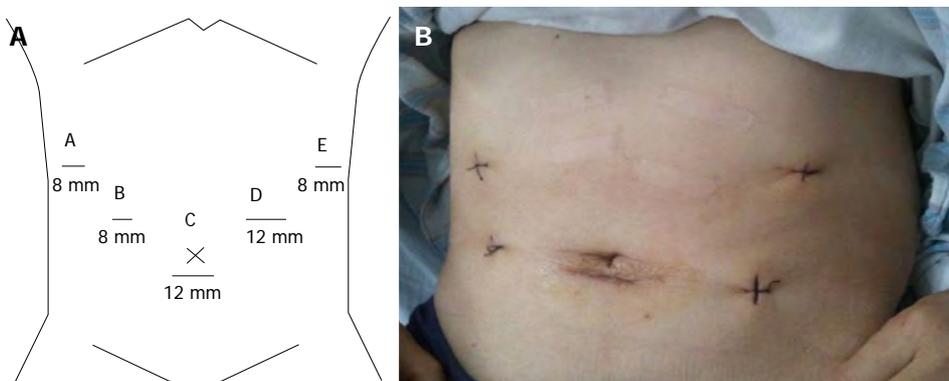

Figure 2 Placement of surgical ports. For A, B and E 8-mm ports were used. For C and D 12-mm ports were used. Port C was extended to 3 cm for specimen extraction from the abdominal cavity.

one handbreadth away from the camera port (C). The assistant who works on the patient's left side uses this port (D) to aid the surgeon during the robotic operation, such as insertion of an endo-stapler for resection of the duodenum, the stomach, or the abdominal esophagus and for placement of gauze or a suction device for clearing the operative field (Figure 2). After port placement, the robotic cart is installed from the patient's head.

In Japan and Europe, extended lymph node dissection (D2) is the standard of care for gastric cancer<sup>[14-16]</sup>.

Robotic gastrectomy with D2 lymph node dissection were performed according to the rules of the Japanese Research Society for Gastric Cancer<sup>[17,18]</sup>. Total gastrectomy, distal or proximal subtotal gastrectomy was decided according to tumor location. The lymphatic tissues are removed *en bloc* along the hepatic, splenic, left gastric artery and celiac trunk using an ultrasonic shear. The origins of these arteries are clearly identified and skeletonized, and the lymphatic tissue dissected away from the adventitia. The left gastric artery is then clipped or tied at its origin

Figure 3 Lymphatic tissues are removed *en bloc* along the hepatic, splenic, left gastric artery and celiac trunk using an ultrasonic shear. The origins of these arteries are clearly identified and skeletonized, and the lymphatic tissue dissected away from the adventitia. The left gastric artery is then clipped or tied at its origin.

(Figure 3). Once the lymphadenectomy is complete, the assistant divides the stomach, intestine or esophagus using multiple endostapler applications (Ethicon Endo-Surgery, Cincinnati, United States) from the 12 mm trocar D. The specimen, including the stomach, omentum, and the lymphatic tissue, are wrapped by an endobag. The specimen was extracted from the abdominal cavity through the intraumbilical port site extended to 3 cm.

#### **Distal subtotal gastrectomy with gastroduodenostomy (Billroth I) and gastrojejunostomy (Billroth II)**

After distal subtotal gastrectomy, 38 patients underwent gastroduodenostomy or gastrojejunostomy reconstruction. For gastroduodenostomy, the duodenum was resected by an endo-linear stapler inserted into the assistant's 12 mm trocar D. The remnant portion of the lesser curvature was resected by an endo-linear stapler, and the completely resected stomach was then wrapped by an endobag. The posterior walls of the duodenum and the stomach were approximated by continuous seromuscular sutures (Figure 4B and C); the duodenal stump was then opened by an ultrasonic shear. A continuous suture with interlocking of the full intestinal layers of the posterior and anterior wall of the duodenum and the stomach was then made (Figure 4D and F). Finally, the anterior wall of the anastomosis was reinforced by interrupted seromuscular sutures (Figure 4G). Sometimes, the duodenum was not transected until the posterior wall suturing of the gastroduodenostomy was finished. This method can facilitate pulling up the duodenum for anastomosis. The duodenum was totally dissected using an ultrasonic scalpel (Figure 4C and E). For gastrojejunostomy reconstruction, the jejunum which is about 20 cm away from the Treitz was brought up just below the remnant stomach for antecolic end-to-side anastomosis, which was achieved using the hand-sewn technique in the same manner.

#### **Proximal subtotal gastrectomy with esophagogastrostomy**

For esophagogastrostomy reconstruction after proxi-

mal subtotal gastrectomy, the remnant distal stomach in which the gastroepiploic arcade was preserved was brought up just below the dissociated esophagus for end-to-end anastomosis. Robotic interrupted suturing was performed to fix the distal gastric-remnant and esophagus together. A continuous suture with interlocking of the full layers of the posterior and anterior wall of the esophagus and the stomach was then made (Figure 5). Finally, the anterior wall of the anastomosis was reinforced by interrupted seromuscular sutures.

#### **Total gastrectomy with esophagojejunostomy and Roux-en-Y reconstruction**

Fifty-four esophagojejunostomies were performed using methods similar to those described above (Figure 6). After the total stomach was divided, the assistant aids the console surgeon in manipulating the bowel to identify the ligament of Treitz. The small bowel which is 15-20 cm away from the Treitz was brought up just below the dissociated esophagus for antecolic end-to-side anastomosis. Robotic needle holders are loaded with 3-0 absorbable sutures and interrupted suturing is performed to fix the jejunum and esophagus together. Then continuous interlocking suturing is performed between the posterior esophageal wall and seromuscular layer of the jejunum. A 2-3 cm incision is made in the jejunum to be anastomosed. The posterior wall of the esophagus is dissected for the half ring at about 1-2 cm above the cardia. The posterior esophageal and jejunal walls are sutured by a continuous interlocking suture (Figure 6).

Sometimes, especially when the tumor is small or adjacent to the cardia, the tumor cutting edge must be clearly identified. The esophagus is not transected until the posterior wall suturing of the esophagojejunostomy is finished (Figure 6K and L). This strategy can facilitate not only identification of the tumor cutting edge, but also pulling down the esophagus for anastomosis. The remaining half ring of the anterior wall of the esophagus is dissected using an ultrasonic scalpel.

After the anterior wall is clearly exposed, a continuous interlocking suture anterior of the anastomosis wall is performed. Finally, the anterior esophageal wall and anterior seromuscular layer of the jejunum are sutured using interrupted sutures (Figure 6D and E). The proximal jejunum 5 cm away from the esophagojejunal anastomotic stoma, is then transected by the assistant using a 45-mm cartridge endostapler (gold loads, Ethicon Endo-Surgery). The side-to-side jejunojunction and jejunal stump are achieved using the hand-sewn technique in the same manner (Figure 6F-J).

## **RESULTS**

Of the 110 patients enrolled in this trial, two patients could not undergo radical gastrectomy due to late stage disease; 1 patient was converted to laparotomy because of uncontrollable hemorrhage, and 1 obese patient was

**Figure 5** Proximal gastric resection with esophagogastrostomy. A: The terminal esophagus fully mobilized. Diaphragmatic crura are exposed and freed from the surrounding adipose and lymphatic tissue. The esophagus was stitched to the crura for better exposure; B-G: The remnant distal stomach was brought up just below the dissociated esophagus for end-to-end anastomosis; H: Complete anastomosis.

converted due to difficult exposure; 2 patients underwent extra-corporeal anastomosis by minilaparotomy to ensure adequate tumor margin. There were no cases of pancreatic or spleen injury during surgery.

Robot-assisted gastrectomy with total robot-sewn anastomosis were successfully performed in 104 cases,

including 66 males and 38 females with an average age of  $58.2 \pm 12.6$  years (range: 40-76 years) and body mass index (BMI) of  $22.12 \pm 4.64 \text{ kg/m}^2$  (range: 16-26  $\text{kg/m}^2$ ). Patient characteristics are presented in Table 1.

Fifty-four esophagojejunostomies with Roux-en-Y reconstruction for 54 total gastrectomies, 22 gastroduo-

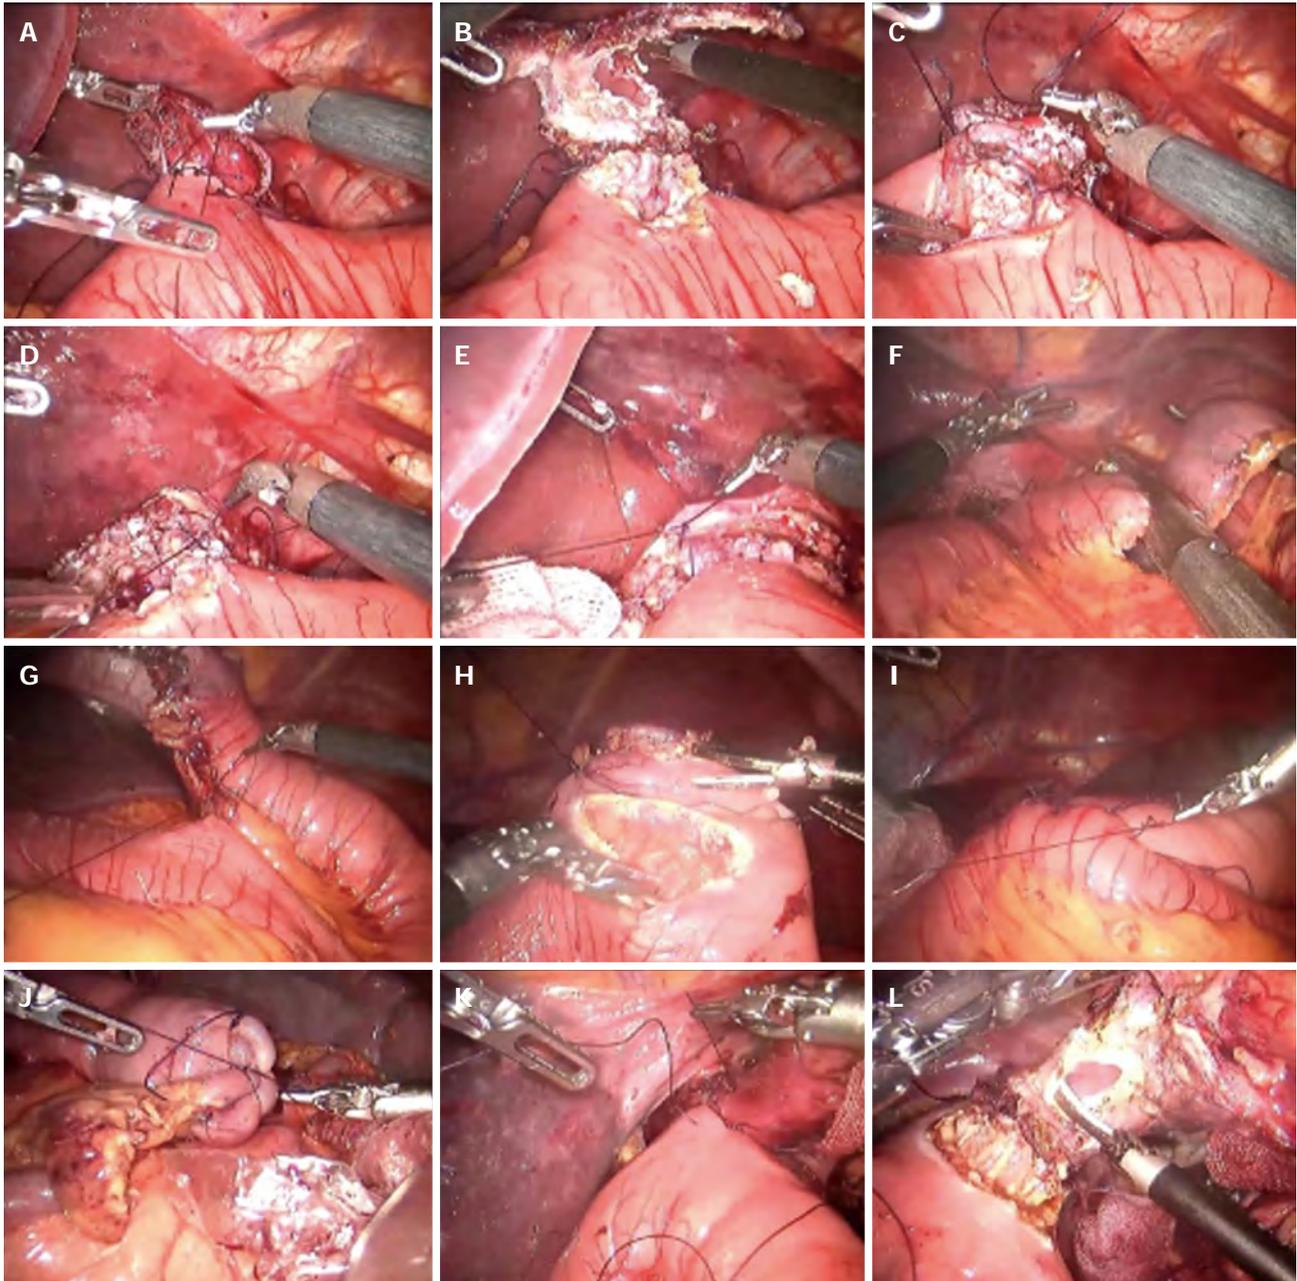

Figure 6 Total gastrectomy with esophagojejunostomy and Roux-en-Y reconstruction. A-E: The small bowel which is 15-20 cm away from the Treitz was brought up just below the dissociated esophagus for antecolic end-to-side anastomosis. Robotic anastomosis for esophagojejunostomy was performed in the same manner; F: The proximal jejunum 5 cm away from the esophagojejunal anastomotic stoma is transected by a 45-mm cartridge endostapler; G-I: The side-to-side jejunojunction and jejunal stump were achieved using the hand-sewn technique in the same manner; J: Jejunal stump was achieved using the hand-sewn technique in the same manner; K, L: Sometimes, the esophagus was not transected until the posterior wall suturing of the esophagojejunostomy was finished.

denostomies and 16 gastrojejunostomies for 38 distal subtotal gastrectomies, and 12 esophagogastromies for 12 proximal subtotal gastrectomies were successfully performed. The average operation time was  $272.52 \pm 53.91$  min, and median reconstruction time was  $45.8 \pm 26.0$  min (Table 2). The average amount of bleeding during surgery was approximately  $80.78 \pm 32.37$  mL. From the pathologic findings, the average number of harvested lymph nodes was  $23.1 \pm 5.3$ . No tumor specimens showed positive surgical margins. The final pathological staging was as follows: stage I, 26 cases; stage II, 32

cases; stage III, 46 cases.

The average time to first flatus and semi-liquid diet after surgery was  $2.5 \pm 0.7$  and  $4.1 \pm 1.3$  d, respectively. The average length of postoperative hospital stay was 6.2 d. Postoperative complications were observed in 12 (11.5%) patients and included anastomotic leakage in 1 (0.96%) patient, gastroplegia in 2 (1.9%) patients, prolonged ileus in 2 (1.9%) patients and poor wound healing in 2 (1.9%) patients. Postoperative complications are shown in Table 3. The anastomotic leak was mild and occurred in the duodenal stump. The patient recovered

Distal subtotal gastrectomy	266.54 ± 35.26
Proximal gastrectomy	264.82 ± 40.33
Construction time (min)	45.8 ± 26.0
Total number of retrieved lymph node	23.1 ± 5.3
Estimated blood loss (mL)	80.78 ± 32.37
Hospital stay after surgery (d)	6.2 ± 2.5

fully following treatment with continuous irrigation drainage for 12 d. One patient underwent re-operation on post-operative day 14 due to jejunal afferent loop obstruction and recovered 10 d later. Another patient who underwent distal gastrectomy with gastroduodenostomy was readmitted due to intra-abdominal infection after surgery. She was treated with abdominal puncture and drainage and recovered.

## DISCUSSION

The first robotic cholecystectomy was performed by Cadière *et al*<sup>[19]</sup>. Currently, robotic surgery is widely applied in most operations. Recent studies have shown that robotic gastrectomy is feasible for patients with gastric cancer<sup>[20,21]</sup>.

A recent trend in minimally invasive surgery for the treatment of gastric cancer has attempted to reduce the length of the skin incision. The fact that minilaparotomy

itself can cause traumatic stress to surgical patients led to the development of a totally laparoscopic technique in which all of the surgical procedures, including reconstruction, are performed intraabdominally under a laparoscopic field<sup>[22]</sup>. Various methods have been established to facilitate intracorporeal anastomosis<sup>[23-25]</sup>. A recent study in a large volume center showed that extracorporeal anastomosis can be changed to intracorporeal anastomosis using a stapling device. However, this laparoscopic method, especially in esophagojejunal anastomosis, presented many technical problems including exposure difficulty, impossible reinforced suturing, variation in the diameter of the esophagus and a weak point in double stapling<sup>[26-28]</sup>. Due to the technical difficulties of laparoscopic anastomosis and concern regarding anastomotic complications using the stapling method<sup>[29]</sup>, many surgeons still prefer extracorporeal reconstruction. However, with the advance of robotic surgery, the da Vinci system has become a minimally invasive cutting edge surgical technique. Since articulating instruments of the robotic device may provide complete wrist dexterity, allowing fine control with precision when performing intracorporeal sutures, a robot-sewn anastomosis in robotic gastric cancer surgery could avoid minilaparotomy and additional laparoscopic techniques, and provide surgeons with a reduced risk of anastomotic complications similar to hand sewing<sup>[22]</sup>.

Robotic operations improved the time to completion and the quality of choledochojejunostomy compared with laparoscopy in an *ex vivo* bench model, especially for surgeons with less experience with minimally invasive surgery<sup>[30]</sup>. Compared with standard laparoscopy, robotic assistance significantly improved intracorporeal suturing performance and the safety of novices in the operating room, thus significantly shortening the learning curve<sup>[31]</sup>. Three dimensional vision allows significant improvements in performance times and error rates for both inexperienced residents and advanced laparoscopic surgeons<sup>[32]</sup>. Hur *et al*<sup>[33]</sup> reported 2 cases of successful esophagojejunostomy using the full robot-sewn technique after total gastrectomy with lymph node dissection. The study further confirmed that all types of hand-

sewn anastomoses in gastrectomy, which are performed in the deep and narrow space of the abdominal cavity, were technically feasible<sup>[33]</sup>. Our study of 104 cases also demonstrated that full robotic hand-sewn anastomosis was technically feasible and safe.

Recent studies have demonstrated that the robotic approach does not provide an advantage over laparoscopy<sup>[34-37]</sup>. Twenty of the initial robot-assisted gastrectomies had similar results to those for experienced laparoscopically-assisted gastrectomies in one report. Other studies have shown that patients who undergo a robot-assisted gastrectomy have a larger number of dissected lymph nodes and a smaller amount of bleeding during radical surgery for early gastric cancer than those who undergo a laparoscopically-assisted gastrectomy<sup>[38,39]</sup>, but not in terms of hospitalization time after surgery<sup>[32]</sup>. Some scholars have indicated that one reason for the insufficient demonstration of this surgical system's advantages is that full robot-assisted reconstruction of the alimentary tract<sup>[40]</sup> was not performed in these studies. Before this clinical trial, we performed more than 100 cases of robot-assisted gastrectomy with minilaparotomy for anastomosis<sup>[41]</sup>. According to our experience, hospitalization time after robotic surgery with full intracorporeal anastomosis decreased by approximately 1 d compared to that with minilaparotomy for anastomosis. The rate of incision infection was sharply reduced in robotic surgery with full intracorporeal anastomosis. However, to achieve a definite result, a large number of robot-assisted gastrectomy cases and well-designed research are needed. As the number of robot-assisted gastrectomy cases increase, surgical outcomes may improve.

Although this trial showed many benefits in terms of clinical outcomes, limitations were still encountered. As a result of full robotic intracorporeal surgery, the tumor location may not be identified as easily as extra-corporeal anastomosis. Thus, preoperative examination with gastro-endoscopy and computed tomography is obligatory to determine the location of the tumor and the type of gastrectomy. As the specimen was extracted from the abdominal cavity through the extended intraumbilical port site, the stomach was opened to ensure the tumor margin was adequate. As in our study, 2 cases were diagnosed with early stage tumor in the middle part of stomach and the precise location of tumor was not palpable even with 3-D vision during surgery. Thus, these two cases were converted to extra-corporeal anastomosis *via* minilaparotomy to ensure adequate tumor margin.

The optimal method for full intracorporeal anastomosis remains to be established. It is probable that there is not one single optimal method. As we have shown, full robot hand-sewn anastomosis can be safely and rapidly performed by surgeons familiar with intracorporeal suturing and knot-tying techniques. This technique is feasible and can produce satisfying postoperative outcomes, and may be a minimally invasive technique in future gastrectomy surgery.

## COMMENTS

### Background

To achieve a minimally invasive method in gastrectomy surgery, a minimal gastroenteral anastomosis must be completed intracorporeally. Various modified procedures for reconstruction have been reported, but an optimal method has not been established due to technical difficulties. Robotic surgery has theoretical advantages such as increased degrees of freedom of instruments and a three-dimensional view. The aim of this study was to determine the feasibility and effectiveness of full robot-assisted total gastrectomy using intracorporeal robot hand-sewn anastomosis in the treatment of gastric cancer.

### Research frontiers

Hand-sewn suturing is technically demanding, but with the advantages of robotic surgery it can be performed safely by trained surgeons. This technique is feasible and can produce satisfying postoperative outcomes. Its convenience and reliability in anastomosis for gastrectomy were confirmed in the study. This is the first large scale report on full robot-assisted gastrectomy with intracorporeal robot-sewn anastomosis.

### Innovations and breakthroughs

The details of the surgical technique were well illustrated in this article. This technique is feasible and can produce satisfying postoperative outcomes, and may be a minimally invasive technique in future gastrectomy surgery.

### Applications

Intracorporeal robot-sewn anastomosis can be widely used in robotic surgery centers. It may be a minimally invasive technique in future robotic gastrectomy surgery.

### Terminology

Robotic surgery: Computer-assisted surgery and robotically-assisted surgery are terms used for technological developments which use robotic systems to aid surgical procedures. Robotically-assisted surgery was developed to overcome the limitations of minimally invasive surgery and to enhance the capabilities of surgeons performing open surgery. Minilaparotomy: A small abdominal incision for surgical procedures, such as liver biopsy, open transhepatic cholangiography, or alimentary anastomosis to ensure minimal traumatic stress.

### Peer review

Authors present their prospective experience with full robotic-assisted gastrectomy. They performed 104 successful operations ranging from distal gastrectomy with intracorporeal gastroduodenotomies or gastrojejunostomies to total gastrectomy with esophagojejunostomy. The average surgical time was 272 min and blood loss was 81 cc. Patients averaged 6.2 d in hospital. The authors conclude that robotic gastrectomy with intracorporeal anastomosis is feasible and safe. Further case-control studies need to be conducted to investigate the advantage of intracorporeal robot's hand sewn anastomosis.

### Abstract

**AIM:** To compare the performance of three commercially available anti-human epidermal growth factor re-

ceptor 2 (HER2) antibodies in whole-tissue sections and tissue microarrays (TMAs) of a series of gastric tumors.

**METHODS:** We present a comparative analysis of three anti-HER2 antibodies (HercepTest, 4B5 and SP3) using TMA and whole-tissue sections prepared from the same paraffin blocks of 199 gastric adenocarcinomas operated upon between January 2004 and December 2008 at a Brazilian cancer hospital. The data on the patients' age, sex, the anatomical location of the tumor and the Lauren's histological classification were collected from clinical and pathological records. The immunohistochemical (IHC) results were examined by two pathologists and the cases were classified as positive (3+), equivocal (2+) and negative (0 or 1+), according to the criteria of the IHC scoring system of gastric cancer. TMAs and whole-tissue sections were evaluated separately and independently. All cases yielding discordant IHC results and/or scored as 2+ were subjected to dual-color *in situ* hybridization in order to determine the final HER2 status. Besides determining the sensitivity and predictive value for HER2-positive status, we measured the accuracy of each antibody by calculating the area under the receiver operating characteristic (ROC) curve. The agreement between the results obtained using the TMAs and those obtained using the whole-tissue sections was assessed by means of Kappa coefficient.

**RESULTS:** Intratumoral heterogeneity of HER2 expression was observed with all antibodies. HER2-positive expression (3+) in the whole-tissue sections was observed in 23 cases (11.6%) using the 4B5 antibody, in 18 cases (9.1%) using the SP3 antibody and in 10 cases (5.1%) using the HercepTest antibody. In the TMAs, 11 positive cases (5.6%) were identified using SP3 antibody, 9 (4.6%) using the 4B5 antibody and 6 (3%) using the

HercepTest antibody. The sensitivity using whole-tissue sections and TMA, respectively, was 95.2% and 42.9% with 4B5, 90.5% and 66.7% with SP3 and 47.6% and 42.9% with HercepTest. The accuracy, calculated from the area under the ROC curve, using whole-tissue sections and TMA, respectively, was 0.91 and 0.79 by 4B5, 0.86 and 0.80 by SP3 and 0.73 and 0.71 by HercepTest. The concordance of the results obtained using whole-tissue sections and TMA was 97.4% (Kappa 0.75) using HercepTest, 85.6% (Kappa 0.56) using SP3 and 84.1% (Kappa 0.38) using 4B5.

**CONCLUSION:** The use of the 4B5 antibody on whole-tissue sections was the most accurate IHC method for evaluating HER2 expression in gastric adenocarcinoma.

**Key words:** Gastric cancer; Human epidermal growth factor receptor 2; Immunohistochemistry; Whole-tissue sections; Tissue microarray; Trastuzumab

**Core tip:** This is the first study to compare the three widely used anti-human epidermal growth factor receptor 2 (HER2) antibodies 4B5, SP3 and HercepTest in tissue microarrays and whole-tissue sections prepared from paraffin blocks of a single series of gastric tumors. We aimed to find the best method to assess HER2 expression in gastric cancer, facilitating the choice of the antibody with the greatest ability to identify the most patients who could benefit from the use of trastuzumab. Besides, we demonstrated that HER2 expression in small samples of gastric cancer (such as tissue microarrays and biopsies) should be evaluated cautiously because these tumors exhibit intratumoral heterogeneity that may influence the results.

Abrahão-Machado LF, Jácome AAA, Wohnrath DR, Santos JS, Carneseca EC, Fregnani JHTG, Scapulatempo-Neto C. HER2 in gastric cancer: Comparative analysis of three different antibodies using whole-tissue sections and tissue microarrays. *World J Gastroenterol* 2013; 19(38): 6438-6446 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6438.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6438>

## INTRODUCTION

The incidence of gastric cancer (GC) is gradually decreasing; however, it remains one of the leading causes of cancer-related death worldwide because the vast majority of GC patients are diagnosed with advanced disease<sup>[1-4]</sup>. Despite the improvement in surgical techniques and the use of multimodal treatments, the prognosis for GC is generally poor and treatment continues to be a challenge for physicians<sup>[1,4]</sup>. Recently, several oncogenes and tumor suppressor genes were studied in an attempt to clarify the process of gastric carcinogenesis, and specific monoclonal antibodies were developed as a potential form of adjuvant treatment for patients with advanced disease.

The HER2 (CerbB-2) or human epidermal growth factor receptor 2 (HER2) gene is a proto-oncogene located on chromosome 17q21 that encodes a transmembrane protein that is a member of the HER receptor family. These receptors possess tyrosine kinase activity and are typically involved in signal transduction pathways that lead to cell growth and differentiation<sup>[5]</sup>. Amplification of the *HER2* gene and overexpression of its product have been identified in several tumors and have been widely studied in breast cancer<sup>[6]</sup>. In GC, however, the reported frequency of HER2 overexpression ranges from 8.2% to 53.4%, and its clinical significance and prognostic value remain controversial, although HER2-positive tumors are usually associated with more aggressive biological behavior and tumor recurrence<sup>[7-13]</sup>. A recent meta-analysis showed that in 7 of the 15 papers evaluated, HER2 positivity was correlated with a worse prognosis<sup>[14]</sup>.

New advances in molecular targeting therapy have identified HER2 as an important target for anti-cancer therapy of gastric tumors. The ToGa study recently indicated improved survival of patients with advanced GC who were treated with trastuzumab (a chimeric anti-HER2 targeted drug) combined with chemotherapy compared with those treated with chemotherapy alone<sup>[15]</sup>. This randomized clinical trial achieved the longest median survival to date of patients with advanced gastric carcinomas. The mechanism by which trastuzumab acts is not completely understood, but the likely possibilities are that it prevents the dimerization of HER2 with other members of the HER family, activates the immune response by promoting antibody-dependent cell-mediated toxicity and induces endocytosis of HER2<sup>[16,17]</sup>. Given the demonstration of its clinical benefits and its approval for use in systemic therapy by the Food and Drug Administration (FDA), trastuzumab is the new standard treatment option for patients with HER2-positive advanced GC. Therefore, it is crucial to determine the HER2 status of GCs to select patients who may benefit from this promising targeted therapy.

Several assays are available to determine HER2 status; however, many of them require fresh tissue, involve complicated procedures and are costly. The most commonly used method is immunohistochemistry (IHC), which is a low-cost technique that can be performed on small samples, even formalin-fixed and paraffin-embedded tissues. Fluorescent *in situ* hybridization (FISH) is considered the gold standard and can be used to analyze this type of sample. However, because of its higher cost and the need for a fluorescence microscope, as well as the high concordance between FISH and IHC reported in literature<sup>[18-21]</sup>, generally only equivocal cases are subjected to FISH. An alternative for equivocal cases is provided by the use of other *in situ* hybridization methods such as silver *in situ* hybridization (SISH), including dual-color *in situ* hybridization (DISH), which allows the use of an ordinary light microscope and has shown excellent correlation with results obtained using FISH<sup>[18,22,23]</sup>.

Although a widely used and FDA/CAP-approved IHC scoring system already exists for HER2 in breast

cancer, it was necessary to develop a suitable scoring system for gastric tumors, mainly because of morphological differences and the intratumoral heterogeneity of HER2 expression in GC<sup>[8,9,11,18,24]</sup>. The system proposed by Hoffmann *et al*<sup>[9]</sup> for GC and incorporated as standard by CAP and FDA differentiates between surgical specimens and biopsies.

Currently, commercially available IHC antibodies include the HercepTest and A0485 (Dako, Glostrup, Denmark) rabbit polyclonal antibodies, the SP3 (Labvision; Thermo Fisher Scientific, Fremont, CA, United States) and 4B5 (Ventana Medical Systems, Tucson, AZ, United States) rabbit monoclonal antibodies and the CB11 mouse monoclonal antibody (Novocastra, Newcastle upon Tyne, England). Only the HercepTest, 4B5 and CB11 antibodies are approved by the FDA, although the international literature also shows high-quality of the SP3 antibody in samples of breast cancer<sup>[20,25]</sup>.

In the present study, HER2 expression in 199 GC was investigated by IHC on whole-tissue sections and tissue microarrays (TMA) using HercepTest, 4B5 and SP3. To date, no published results have compared these three antibodies. Moreover, this is the first study of GC to compare HER2 expression using both TMAs and whole-tissue sections prepared from samples of the same paraffin blocks, *i.e.*, the same tumors. All cases yielding divergent IHC results or results considered equivocal (2+) were subjected to DISH. We hypothesized that if the TMA samples were considered to be biopsies because they are small tissue samples, the reproducibility of the HER2 scoring system for GC could be tested using the two types of specimens.

Given that HER2 expression in the stomach is heterogeneous, the main purpose of our study was to compare the performance of three commercially available anti-HER2 antibodies. Furthermore, we aimed to determine the concordance of results obtained from whole-tissue sections and TMAs from the same tumors to evaluate the feasibility of TMA as an alternative method for assessing HER2 expression in GC.

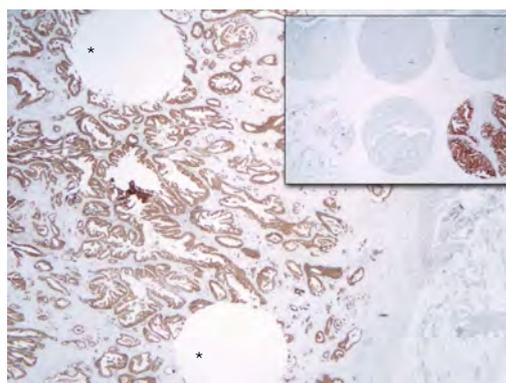

## MATERIALS AND METHODS

### Patients

In the present study, we selected 199 cases of surgically resected primary gastric or gastro-esophageal adenocarcinomas. All the patients were operated upon between January 2004 and December 2008 at the Barretos Cancer Hospital. Clinical data were collected from medical charts and pathology reports, including sex and patient age as well as the anatomical location of the tumor and its Laurén histological classification.

### TMA construction and IHC

Paraffin blocks containing representative samples of the tumors were selected by reviewing all of the hematoxylin and eosin (HE) stained slides. For the TMAs, two tissue cores with a diameter of 0.6 mm were extracted from

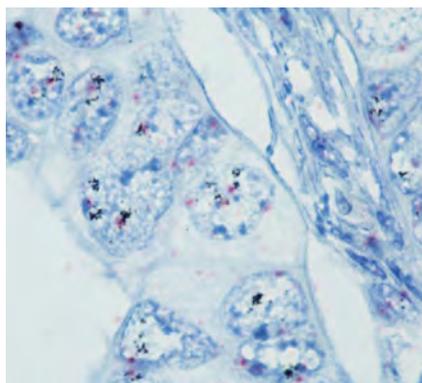

**Figure 1** Photomicrograph of immunohistochemistry ( $\times 100$ ) in a whole-tissue section. Asterisks indicate two round voids where the tissue microarray cores (inset) were extracted.

each tumor using the TMA arrayer MTA1 (Estigen, Tartu, Estonia). The tumor cores were sequentially placed in molds, embedded in paraffin and cooled to form the tissue array blocks. Each TMA also contained various non-gastric tissue samples as control tissues.

Sections of a thickness of 4  $\mu\text{m}$  were obtained from the whole-tissue paraffin blocks and TMA blocks and used for IHC (Figure 1). The slides were stained using automatic staining devices: the Benchmark XT (Ventana Medical Systems, Tucson, AZ) for the 4B5 and SP3 antibodies and the Autostainer Link 48 (Dako, Glostrup, Denmark) for the HercepTest. After antigen retrieval processing for 60 min (at pH 8.4), 4B5 (prediluted form as provided by the manufacturer) and SP3 (diluted 1:100) were applied for a 32 min incubation period. Antibody visualization was enabled using the Ventana Ultraview DAB detection kit. The HercepTest was performed according to the manufacturer's guide provided with the kit, using the prediluted "ready-to-use" form for all of the steps and incubation periods preprogrammed in the stainer software. The kit also contained the visualization reagent. All the slides were subsequently counterstained with hematoxylin.

The criteria suggested by Hoffmann *et al*<sup>[9]</sup> were used to evaluate the expression of HER2. Sections of the surgical specimens were considered HER2-positive (3+) when strong complete or basolateral membranous staining was detected in  $\geq 10\%$  of the neoplastic cells; equivocal (2+) when moderate/weak complete or basolateral membranous staining was detected in  $\geq 10\%$  of the cells; 1+ (negative) when the staining was weak or detected in only one part of the membrane in  $\geq 10\%$  of the cells and 0 (also negative) in cases in which there was no membranous staining or staining of  $< 10\%$  of the tumor cells. The criteria for evaluating biopsies were applied to the TMAs, and the percentage above (10%) was replaced by a cellular group of at least 5 cells. Full-tissue sections or TMA cores with excessive tissue fragmentation, scant invasive tumor and excessive cytoplasmic or background staining were rejected, and IHC was repeated on more suitable samples.

**Figure 2** Dual-color *in situ* hybridization (× 1000), human epidermal growth factor receptor 2 amplification. Black dots: Human epidermal growth factor receptor 2 gene; Pink dots: Chromosome 17.

### ***In situ hybridization***

DISH was performed in all cases that were scored 2+ in either of the samples stained with any of the antibodies, in accordance with the guidelines recommended by CAP and routine laboratory practice. In addition, all of the cases with discordant IHC results were tested by DISH. The tissue sections used for DISH were obtained from the whole-tissue paraffin blocks. HER2 DISH was performed using the Ventana Benchmark XT-machine (Ventana Medical System, Tucson, AZ) following its standardized protocol. DISH is dual-color *in situ* hybridization in which the *HER2* gene is labeled using silver to produce a black dot, and the centromere of chromosome 17 (Chr 17) is labeled with alkaline phosphatase to produce a pink dot. Therefore, the *HER2* gene and Chr 17 are both simultaneously stained on the same slide (Figure 2). The DISH slides were examined using an HE slide to assist with the tumor location and morphology within each section. At least 40 tumor cell nuclei were scored for the Chr 17 signal and HER2 signal in different areas of the tumor. Only nuclei displaying both signals were scored, and a HER2/Chr 17 ratio was obtained for each specimen. HER2 amplification was defined as a ratio of HER2/Chr 17  $\geq 2$ . Chromosome 17 polysomy was defined as  $\geq 3$  Chr 17 signals per cell on average<sup>[26]</sup>.

### ***Statistical analysis***

The statistical analysis was conducted using SPSS version 19.0 software (SPSS Inc., Chicago, IL). The IHC results were compared with a final variable of positivity or negativity for HER2 protein expression. In equivocal cases or cases of nonconcordant results obtained with the three antibodies, *HER2* gene amplification was assayed by DISH, and the DISH results determined the definitive HER2 status. Therefore, the results considered final, *i.e.*, the gold standard for statistical analysis, were those that were identical for the three antibodies, in addition to the results of DISH. The area under the receiver operating characteristic (ROC) curve (AUC) for each test was used to measure the accuracy of antibody labeling. To verify the agreement between the results obtained using the TMAs and those obtained using the whole-tissue sec-

tions, we employed the Kappa coefficient<sup>[27]</sup>. We defined  $P < 0.05$  as statistically significant.

## **RESULTS**

### ***Patients and tumor characteristics***

There were 123 male and 76 female patients, and their age ranged from 27 to 87 years (median: 60.7 years). The location of the tumor was in the antrum in 86 cases (43.2%), in the body in 26 cases (13%), in the fundus in 2 cases (1%), in the cardia in 38 cases (19%) and multicentric (in more than 2 regions) in 47 cases (23.6%). Fifty-five cases were histologically classified as the diffuse type (27.6%), 123 as the intestinal type (61.8%), 17 as the mixed type (8.5%) and four as not otherwise classified (2%).

### ***Immunohistochemistry***

HER2-positive expression (3+) in the whole-tissue sections was observed in 10 cases (5.1%) using the HercepTest, in 23 cases (11.6%) using the 4B5 antibody and in 18 cases (9.1%) using the SP3 antibody. Using the TMAs, 6 HER2-positive cases (3%) were identified using the HercepTest, 9 (4.6%) using the 4B5 antibody and 11 (5.6%) using SP3 antibody. The immunohistochemistry results are shown in Table 1.

The HercepTest demonstrated the lowest number of positive cases in both the whole-tissue sections and the TMAs. The SP3 antibody yielded the highest number of equivocal (2+) cases for both types of samples. The frequency of a score of 2+ was higher among the whole-tissue sections than among TMAs, except when using the HercepTest, which showed the opposite pattern.

The overall concordance between the results obtained using the TMAs and those obtained using the whole-tissue sections was 97.4% with the HercepTest, 84.1% with the 4B5 antibody and 85.6% with the SP3 antibody. According to the values of the Kappa coefficient, HercepTest provided substantial agreement between the TMAs and whole-tissue sections, the SP3 antibody provided moderate agreement and the 4B5 antibody provided fair agreement (Table 2).

Stronger membrane staining in positive cases was observed for the 4B5 antibody than for the other two antibodies (Figure 3). The diffuse cytoplasmic staining in the gastric foveolar epithelium and intestinal metaplasia that was observed when using 4B5 antibody was less pronounced when using the SP3 antibody and not observed when using the HercepTest antibody. Heterogeneous HER2 expression within the tumors was observed with all antibodies (Figure 4). All the positive cases were classified as intestinal type. Nuclear staining with the 4B5 and SP3 antibodies was observed in some of the diffuse adenocarcinomas.

### ***DISH and final HER2 status***

Cases with divergent results and those considered equivocal by IHC (scored as 2+) were subjected to DISH; there

**Table 1 Results of HER2 immunostaining using the three antibodies on whole-tissue sections and tissue microarrays *n* (%)**

Score	Whole-tissue sections			TMAs		
	HercepTest	4B5	SP3	HercepTest	4B5	SP3
0	179 (90.9)	125 (63.1)	128 (65.2)	185 (93.5)	174 (88.8)	162 (82.6)
1+	7 (3.5)	30 (15.2)	17 (8.5)	3 (1.5)	10 (5.1)	8 (4.1)
2+	1 (0.5)	20 (10.1)	34 (17.2)	4 (2.0)	3 (1.5)	15 (7.7)
3+	10 (5.1)	23 (11.6)	18 (9.1)	6 (3.0)	9 (4.6)	11 (5.6)
Total	197 (100.0)	198 (100.0)	197 (100.0)	198 (100.0)	196 (100.0)	196 (100.0)

TMA: Tissue microarray.

**Table 2 Concordance between the tissue microarrays and whole-tissue sections staining results using the HercepTest, 4B5 and SP3 antibodies**

Antibody	Overall concordance	Kappa coefficient (95%CI)
HercepTest	97.40%	0.75 (0.54-0.96)
4B5	84.10%	0.38 (0.22-0.53)
SP3	85.60%	0.56 (0.43-0.70)

were 58 (29.1%) such cases, of which 14 cases (24.1%) exhibited *HER2* gene amplification and 44 cases (76.9%) did not exhibit *HER2* gene amplification. Chr 17 polysomy was present in 5 cases (8.6%), but it was not related to amplification in our study. Table 3 shows the *HER2* gene status in the cases that presented an IHC score of 2+.

A final positive *HER2* status (either by IHC or DISH) was obtained in 20 of the 199 cases tested (10%). The sensitivity using whole-tissue sections was 47.6% with HercepTest, 95.2% with 4B5 and 90.5% with SP3 in cases with an immunoscore of 2+/3+. The sensitivity using TMA was 42.9% with HercepTest, 57.1% with 4B5 and 66.7% with SP3 (Table 4).

Table 5 demonstrates the accuracy of each antibody. The 4B5 and SP3 antibodies gave similar AUC values in whole-tissue sections (Table 5), and both were significantly more accurate than HercepTest ( $P = 0.002$  and  $0.035$ , respectively). Although the 4B5 and SP3 antibodies both gave greater AUC values than HercepTest in TMAs, the difference was not statistically significant. Based on the AUC of each antibody for both types of samples and the respective  $P$  values (Table 6), we determined that the use of the 4B5 antibody on whole-tissue sections was the most accurate method. SP3 staining of whole-tissue sections was also more accurate than the HercepTest using TMAs ( $P = 0.013$ ).

### Histological type and anatomical location

Of the 123 adenocarcinomas of the intestinal type, nine (7.3%) were given a final positive *HER2* status. None of the 76 cases of the other histological types was positive.

Of the 86 carcinomas located in the antrum, nine (10.4%) had a final positive *HER2* status. Eight (21%) of the 38 tumors situated in the cardia and three (6.4%) of the 47 multicentric tumors were positive.

## DISCUSSION

With the demonstration of the benefits of trastuzumab therapy for advanced GC<sup>[15]</sup>, the clinical demand for *HER2* assessment is rapidly increasing. The use of trastuzumab in association with platinum and capecitabine or 5-FU for *HER2*-positive GC has shown the longest median survival in GC patients<sup>[15]</sup>. Because IHC appears to be the easiest, least expensive and most widely used method, our goal was to compare three commercially available antibodies. Although the use of different clones can be problematic for GC, only two other reports in the literature have compared the performance of *HER2* antibodies<sup>[18,28]</sup>. An ideal antibody test would be sufficiently sensitive to identify all possible treatment candidates and would have a low false-positive rate to minimize over-treatment.

Variability in performance among commercially available anti-*HER2* antibodies has been demonstrated in several studies, although most of these studies were performed in breast tumors<sup>[29,30]</sup>. Cho *et al.*<sup>[28]</sup> compared the HercepTest, A0485, 4B5 and CB11 antibodies in TMAs of gastric carcinomas, and they found that the sensitivity and specificity were 78.9% and 96% with HercepTest, respectively, 86.5% and 94.4% with the A0485 antibody, 76.3% and 95.6% with 4B5 and 60.5% and 98.4% with the CB11 antibody. Boers *et al.*<sup>[18]</sup> tested the SP3 and 4B5 antibodies on biopsy specimens of gastro-esophageal adenocarcinomas, and they showed sensitivities of 77% and 96% as well as specificities of 100% and 98.4%, respectively. The latter result is consistent with the results we obtained when comparing the SP3 and 4B5 antibodies. In the present study, however, the difference in sensitivity among antibodies was much higher, as the sensitivity ranged from 47.6% to 95.2% when whole-tissue sections were analyzed and ranged from 42.9% to 66.7% when TMAs were analyzed. The sensitivity of HercepTest was far lower than that of the other two tests, which contributed to this difference. The specificity ranged from 81.2% to 99.4% for the whole-tissue sections and from 93.1% to 100% for the TMAs. For all the antibodies, lack of staining (score 0) was highly predictive of a negative/nonamplified case as confirmed by DISH, and positive staining (score 3+) was highly predictive of an amplified case as confirmed by DISH.

The 4B5 and SP3 antibodies exhibited similar perfor-

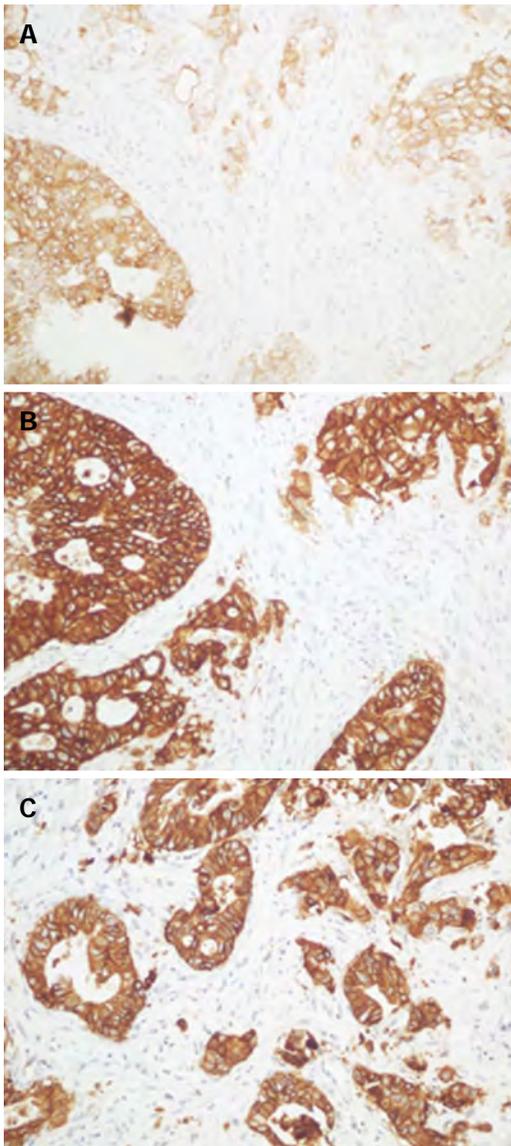

Figure 3 Comparison of positivity (3+) using the HercepTest (A), 4B5 (B) and SP3 (C) antibodies ( $\times 200$ ).

mance, with high NPV values and AUC values that indicated higher accuracy, compared to HercepTest, although the difference was only statistically significant ( $P < 0.05$ ) for whole-tissue sections. Even though HercepTest had high values for PPV and specificity, it presented the lowest sensitivity. Thus, this antibody provided the highest number of tumors with immunoscores of 0 or 1+ that were positive for HER2 amplification using DISH, which agrees with the report of Dekker *et al.*<sup>[29]</sup> for breast tumors. Thus, in our view, HercepTest is not the best antibody to use as a first-line test to assess the HER2 status of GC because the ideal antibody should be highly sensitive, even though high sensitivity could increase the number of equivocal cases (2+) and the need for *in situ* hybridization tests. The 4B5 and SP3 antibodies were highly sensitive; therefore, these two antibodies appear to be more reasonable for first-line tests than HercepTest.

Another issue that we wanted to address was the use

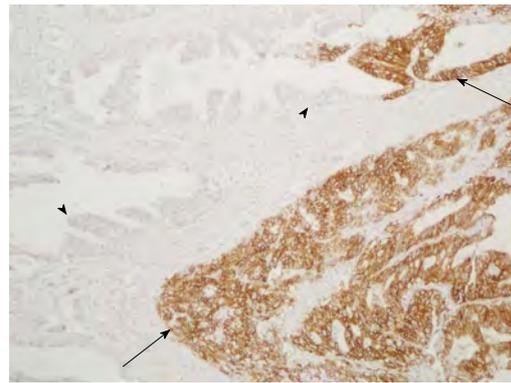

Figure 4 Representative image of the intratumoral heterogeneity of HER2 expression ( $\times 100$ ). Arrows indicate areas with strong continuous membranous staining (score 3+) and arrowheads indicate negative areas (score 0).

of TMAs for assessment of HER2 and, by analogy, the reliability of testing endoscopic biopsies. The use of TMAs permits the inclusion of several different tumors in the same assay on a single slide. This cost-effective technique has become a standard procedure for many contemporary IHC studies. Dekker *et al.*<sup>[29]</sup> found that TMAs were reliable for retesting large volumes of previously HER2-classified breast carcinomas. Similarly, Drev *et al.*<sup>[31]</sup> observed a high concordance between whole-tissue sections and TMAs for breast tumors. Despite these favorable results for TMAs of breast cancers, HER2 assessment of gastric adenocarcinomas is more problematic. The obvious disadvantage of TMAs is that this preparation enables the analysis of only a limited sample of the tumor and for GCs, TMAs are even more unfavorable because of the generally observed heterogeneous expression of HER2 within these tumors.

Intratumoral heterogeneity can be defined as areas with different HER2 scores within the same tumor. This is the predominant pattern for GCs but not for breast tumors, and may thus cause sampling error when randomly sampled TMA cores of GCs are used<sup>[8,9,11,24]</sup>. The difference in HER2 status between primary and metastatic tumor samples is still a matter of debate, and although the few studies in the scientific literature have demonstrated high concordance among the results obtained using these samples, some cases gave discordant results<sup>[32,33]</sup>, which suggests an effect of intratumoral heterogeneity.

Conspicuously heterogeneous HER2 staining on the whole-tissue sections and TMA core samples from most of the tumors was noted in our study. To minimize the discrepancy with results obtained with whole-tissue sections, we included two core samples from different areas of each tumor in the TMAs. Regardless, the TMA staining was much less sensitive than the staining of whole-tissue sections (mean values for the antibodies: 55.5% *vs* 77.7%, respectively). Although the HercepTest provided greater agreement between the TMAs and the whole-tissue sections, with a substantial Kappa value, its sensitivity was low for both types of sample, as mentioned above. The difference in HER2 expression detected in

AUC: Area under the receiver operating characteristic curve; TMA: Tissue microarray.

our study between TMAs and whole-tissue sections was caused by the prominent heterogeneity of HER2 staining. The 4B5 antibody results in whole-tissue sections were significantly different from the results of the three antibodies in TMAs. Because 4B5 antibody staining of whole-tissue sections had the highest accuracy, which was much different from that obtained for TMAs, our results suggest that TMA staining is less accurate and lacks sufficient sensitivity to reliably assess the HER2 status in GC. Two tissue cores for the TMA were definitely not sufficient to prevent sampling error and minimize false results because of the intratumoral heterogeneity and the small amount of tissue in the cores. Therefore, studies in the literature that used TMA to test the HER2 status of GCs must be carefully analyzed, and it must be noted that this technique does not seem to reflect the real status of the HER2 gene in GCs.

Endoscopic biopsies with few fragments, such as those used in the TMA, may underestimate the incidence of HER2-amplification, as Yang *et al*<sup>[24]</sup> demonstrated in a recent study in which large surgical specimens had higher rates of HER2 positivity than biopsy specimens. We believe that endoscopic biopsies are not optimal to identify the maximal number of patients who could be eligible for treatment. Therefore, to represent the tumor better and reduce misinterpretation, it is important to examine as many pieces of a biopsy as possible. We also suggest that all excisional specimens that had a previous HER2-negative result in a biopsy specimen should be retested to increase the chance of classifying the tumor as HER2-positive. Because the intratumoral heterogeneity of HER2 expression also seems to cause divergent results for primary and metastatic tumor samples<sup>[32]</sup>, is highly advisable to analyze the HER2 status of both primary and metastatic specimens when possible.

Thus, among the HercepTest, 4B5 and SP3 antibodies, HercepTest was the least sensitive and therefore had the lowest ability to identify a large number of patients eligible for trastuzumab treatment. According to our results, the most accurate IHC method to assess HER2 expression in GC is the use of the 4B5 antibody on whole-tissue sections. Intratumoral heterogeneity appears to be a major limitation for the use of TMA because TMA does not reflect the true HER2 status of many tumors. Because the number of cells that respond to a targeted therapy directly affects the tumor's responsiveness to treatment, there must be a great difference between cases that are diffusely positive and those that are only focally positive but still meet the criteria of positivity. Given the promising results from the use of trastuzumab and the particularities of HER2 expression in the stomach, further trials are needed to determine the clinical significance of the intratumoral heterogeneity and its impact on treatment outcome.

## COMMENTS

### Background

The vast majority of patients with gastric cancer are diagnosed with advanced disease and the prognosis is generally poor. Human epidermal growth factor receptor 2 (HER2)-positive tumors are usually associated with more aggressive biological behavior and recurrence. In view of the recently demonstrated clinical benefit of the anti-HER2 drug trastuzumab in the treatment of advanced gastric cancer, reliable HER2 testing is of key importance. HER2 status is usually determined by immunohistochemistry (IHC) and occasionally by *in situ* hybridization (ISH). However, little is known regarding the performance difference among the commercially available anti-HER2 immunohistochemical antibodies in gastric adenocarcinomas. This study compared three anti-HER2 antibodies (HercepTest, 4B5 and SP3) using two different arms: samples prepared in tissue microarray (TMA) device and whole-tissue sections counterpart prepared from paraffin blocks of a series of 199 gastric adenocarcinomas.

### Research frontiers

HER2 is a member of the family of tyrosine kinase receptors. Overexpression of the HER2 receptor has been identified in various cancers and is most widely studied in breast cancer. Like in breast cancer, HER2-positive gastric tumors are correlated with worse prognosis. An important difference in HER2 immunoreactivity between breast cancer and gastric adenocarcinomas is the striking heterogeneity of HER2-positivity in the latter, which can affect the determination of HER2 status in small samples such as biopsies and TMA.

### Innovations and breakthroughs

Many studies have compared anti-HER2 antibodies in breast cancer, however only few reports have done it in gastric cancer. Gastric adenocarcinomas exhibit intratumoral heterogeneity of HER2 expression and have a unique IHC scoring system. This is the first study to compare HercepTest, 4B5 and SP3 in a series of gastric tumors. Most contemporary studies use the cost-effective TMA technique for testing HER2 expression; however, given the high incidence of heterogeneous HER2-immunoreactivity and the risk of underestimating the incidence of HER2-amplification rate; we also aimed to compare the results obtained from TMA to those obtained from whole-tissue sections.

### Applications

The study results indicate the best method to assess HER2 expression in gastric cancer, facilitating the choice of the antibody with the greatest ability to identify the most patients who could benefit from the use of trastuzumab. The results also demonstrated that HER2 expression in small samples of gastric cancer should be cautiously evaluated because the intratumoral heterogeneity may influence the results.

### Terminology

According to the four-tiered IHC scoring system for gastric cancer, samples scored as 0 and 1+ are negative, 2+ as equivocal and 3+ as positive. Intratumoral heterogeneity is defined as areas with different HER2 scores within the

same tumor.

### Peer review

This is a highly stringent study in which the authors examined HER2 immunostaining in a series of gastric cancers, using three different commercially available anti-HER2 antibodies in samples of TMA and whole-tissue sections. The sensitivity, predictive value for HER2 amplification and accuracy of each antibody were determined. The results are provoking and indicate the most accurate IHC method for HER2 evaluation, emphasizing the limitations of the TMA technique. The results of the study should encourage a more judicious assessment of the HER2 status in gastric cancers, especially in small tissue samples.

### Abstract

**AIM:** To study a retrospective analysis of patients who presented to the emergency departments (ED) with complaints related to foreign body ingestions.

**METHODS:** Patients older than 16 years of age who presented to the ED between January 1<sup>st</sup> and December 31<sup>st</sup> of 2010 with complaints related to swallowed foreign bodies were identified from electronic health records and patient charts.

**RESULTS:** A total of 100 patients presented with a complaint of foreign body ingestion during the study period. Overall, an X-ray was performed on 75 patients, and a fiberoptic evaluation was performed on 45 patients. A foreign body was detected in 46 (46%) patients. The diagnostic yield of the X-ray was 27 (36%)

out of 75 patients, while the diagnostic yield of the fiberoptic evaluations was 21 (47%) out of 45 patients. The detected foreign bodies were mostly located in the esophagus (17 out of 46 foreign bodies detected). When the types of ingested foreign bodies were evaluated, 52 (52%) patients reported ingesting food, and 19 (19%) patients reported swallowing pins. An X-ray was performed on 33 patients with accidental food ingestions but yielded a positive result in only two cases. In 12 out of 21 patients with accidental food ingestion who underwent fiberoptic evaluation, the foreign material was detected and removed.

**CONCLUSION:** Plain radiography is helpful in the localization of radiopaque swollen foreign bodies, while fiberoptic methods are useful as both diagnostic and therapeutic tools, regardless of radiopacity.

**Key words:** Foreign body; Ingestion; Gastrointestinal tract; Endoscopy; Emergency

**Core tip:** The majority of foreign bodies swallowed by patients who present to the emergency departments cannot be detected using standard imaging studies and evaluation. Plain radiography is especially useful in the localization of radiopaque foreign bodies, while fiberoptic methods can be used as both diagnostic and therapeutic tools, regardless of the radiopacity of the foreign body ingested.

Emergency admissions due to swallowed foreign bodies in adults. *World J Gastroenterol* 2013; 19(38): 6447-6452 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6447.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6447>

## INTRODUCTION

Visits related to gastrointestinal foreign bodies are relatively common causes of admission to emergency departments (ED)<sup>[1,2]</sup>. The ingestion or insertion of a foreign body into the gastrointestinal (GI) tract can be a clinically serious condition with associated risks for morbidity and mortality<sup>[2,3]</sup>. An estimated 1500 to 1600 patients die in the United States each year as a result of complications related to the ingestion or insertion of foreign bodies into the GI tract<sup>[1,3-5]</sup>. Although this problem can be encountered in every age group, almost 80% of cases comprise patients in early childhood (18-48 mo), with a majority of cases resulting from swallowing coins, toys, crayons, or pen caps<sup>[3,4]</sup>. The ingestion of foreign bodies is rarely seen in adults, is generally accidental and is commonly seen in the form of food (meat and bones) ingestion. Other risk groups for this type of injury include patients with psychiatric disorders, adults without teeth, prisoners and patients under the influence of substances that obscure judgment<sup>[3,5-7]</sup>. The clinical presentation, symptoms and management of foreign bodies depend on their location within the GI tract. Depending on the size and shape, almost 80%-90% of such foreign bodies pass freely from the GI tract without any complication<sup>[4,7,8]</sup>.

The purpose of the present study was to conduct a retrospective analysis of patients who presented to our ED with complaints related to foreign body ingestions.

## MATERIALS AND METHODS

Patients older than 16 years of age who presented to the Emergency Department between January 1<sup>st</sup> and December 31<sup>st</sup> of 2010 with complaints related to swallowed foreign bodies were analyzed retrospectively using the data obtained from electronic health records and patient charts. The patients' present complaints, demographic characteristics, previous medical history and medication use, physical exam findings, diagnostic studies performed, type and location of the foreign body, treatment provided, need for conservative or invasive/surgical treatment, complication rates, radiological findings and rate of survival/mortality were all recorded.

## RESULTS

During the study period, we identified a total of 100 patients (42 male, 58 female; mean age 38 years, range 16-88 years) who were admitted with a complaint of foreign body ingestion. Of those, 65 (65%) localized their complaints to the pharynx, while 35 (35%) told us that they had ingested the foreign bodies. Among the list of complaints, 53 (53%) patients had difficulty swallowing; 33 (33%) had pain in the throat; 6 (6%) had difficulty breathing; 5 (5%) had abdominal pain; 4 (4%) had vomiting; 4 (4%) had bleeding from the mouth; 2 (2%) had a foreign body sensation in the throat; 2 (2%) had coughing; and 1 (1%) had chest pain. The incident was self-reported as

accidental in all patients. When facilitating factors were considered, 3 (3%) patients were undergoing dental interventions, and another 3 (3%) patients had dental plates. None of the study patients had any established diagnosis of psychiatric disease or history of substance abuse, alcohol or sedative use. Physical examination revealed oropharyngeal foreign bodies in 7 patients, epigastric tenderness in 1 patient, and rhonchus in 1 patient.

The diagnostic approaches to our patients are summarized in Figure 1. A foreign body was detected in 46 (46%) patients. The diagnostic yield of X-rays was 27 (36%) among the 75 patients evaluated by lateral neck, chest or abdominal X-ray. The foreign bodies were detected for 10 out of 51 patients using the chest X-ray, for 14 out of 29 patients using the abdominal X-ray and for 3 out of 52 patients using the lateral neck X-ray. The diagnostic yield was 21 (47%) out of 45 for all patients undergoing fiberoptic evaluations (Figure 1). The detected foreign bodies were mostly located in the esophagus (17 out of 46 foreign bodies detected) (Table 1). When the types of ingested foreign bodies were evaluated, 52 (52%) patients reported ingesting food, and 19 (19%) patients reported swallowing pins (Figure 2, Table 2). With respect to the types of ingested food, 20 were fish bones, 9 were bone fragments (Figure 3), and 23 were unknown food parts.

In 53 (53%) of the patients, a conservative approach for management was considered. Nineteen (19%) patients were followed with serial radiological examinations. In 21 patients, of whom 17 were undergoing upper GI endoscopy, 2 were undergoing laryngoscopy and 2 were undergoing bronchoscopy, the foreign body was removed by fiberoptic means. In total, 19 (19%) of the study patients were admitted for further evaluation and treatment. Out of all the patients, the clinical course was complicated by aspiration (food material) in two patients, by GI bleed (pin) in 1 patient and by mediastinitis (food material) secondary to perforation in 1 patient.

## DISCUSSION

The medical history obtained from the patient is highly critical in the diagnosis of swollen GI foreign bodies. Therefore, the planning of the diagnostic work-up and the extent and urgency of a possible intervention are decided according to the information provided by the patient regarding the type of foreign body ingested, together with the clinical complaints and physical examination<sup>[6,9-12]</sup>. Most GI foreign-body ingestions occur in pediatric patients aged between 6 mo and 6 years<sup>[5,7,9]</sup>. GI foreign body exposure tends to be accidental in adults, with food particles and bones constituting the majority of the foreign bodies<sup>[4,13]</sup>. The rest of the cases occur in the setting of facilitating factors, such as adults without teeth or with dental plates, prisoners and psychiatric patients<sup>[4,6,9,14,15]</sup>. Our results were also similar among all of the patients evaluated in the study reporting accidental intake. Patients who suffer foreign body ingestion can present with a wide range of symptoms, which can vary

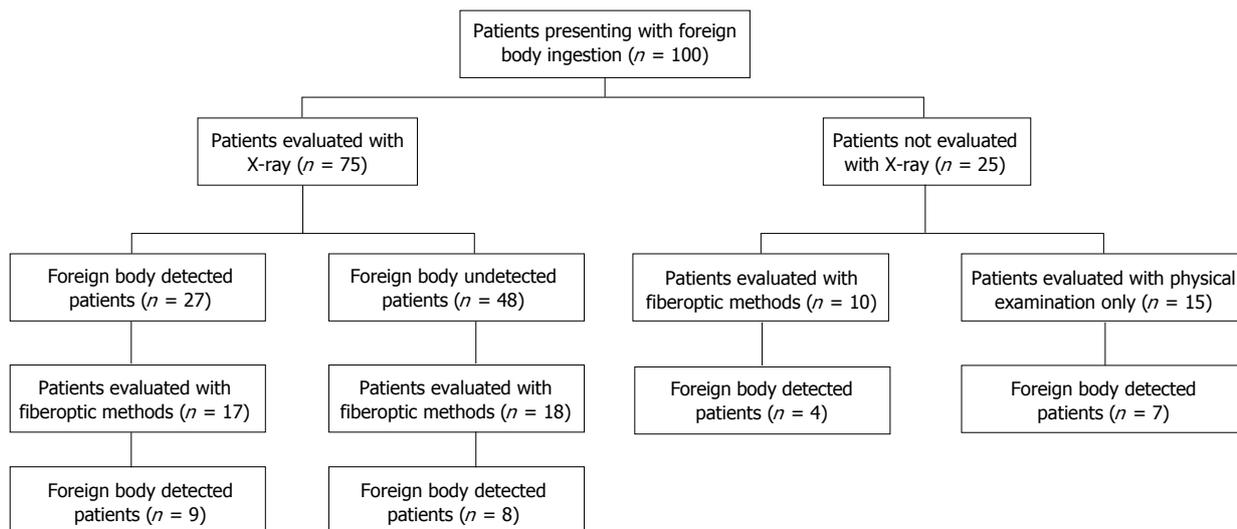

Figure 1 Diagnostic approach to patients presenting with foreign body ingestions.

Table 1 Location of the foreign bodies (n = 100)	
Foreign body location	n (%)
Esophagus	17 (17)
Oropharynx	8 (8)
Small intestine	6 (6)
Stomach	6 (3)
Trachea	2 (2)
Larynx	3 (3)
Colon	3 (3)
Undetermined location	1 (1)
Undetected	54 (54)

based on the physical characteristics and the content that is absorbed in the GI tract. Diagnosis is based on the patient’s history and complaints, which typically include the sudden onset of difficulty of swallowing during eating, chest pain, odynophagia or insufficiency in tolerating secretions. However, symptoms range from mild to life-threatening, including shortness of breath, abdominal pain, vomiting, hematemesis, foreign body sensation, coughing and chest pain<sup>[3,5,9,11,16,17]</sup>. In agreement with the literature, the majority of patients in our cohort presented with difficulty in swallowing and foreign body sensations in the throat.

Different types of foreign bodies are observed in the GI tract based on the age group. During childhood, swallowed coins, small toys, crayons or batteries are observed, whereas during adulthood, food, bones and dental-related foreign bodies are more common<sup>[4,6,7,9,13,16,17]</sup>. The types of foreign bodies may also differ by country. The high number of pin ingestions in our study group is thought to be related to the regional dress code, which results in women holding pins between their lips before attaching their headscarves. While certain conditions, such as parental attitudes and dietary habits, can provide clues for the types of foreign bodies that are ingested, prevention strategies are also dependent on various cultural, social,

religious and economic factors<sup>[7,11,17-19]</sup>.

The presentation, clinical findings, and management of foreign bodies are distinct and based upon the anatomical region where the foreign body is located<sup>[4,9,11,17]</sup>. Determining the type and location of the foreign body in the ED changes the treatment approach<sup>[5,9,16]</sup>. In our study, most of the foreign bodies were detected in the upper GI tract. The majority of the radiopaque foreign bodies in the GI tract can be detected using radiography. This simple modality provides crucial information, such as the number, size, location and direction of the foreign body, as well as the presence of sharp edges<sup>[2,3,6,8]</sup>. However, the presence of fish bones, chicken bones, glass, wood and thin metals cannot be ruled out by plain radiographies<sup>[2,3,6,11,13,20]</sup>. Neck, chest and abdominal radiographies are able to show perforations as well as metal objects and bones<sup>[6,13]</sup>. In our study, we detected a foreign body with plain radiography in 27 (36%) out of 75 patients evaluated by X-rays; all of these foreign bodies were radiopaque. All of the 19 patients with radiopaque foreign bodies in whom an emergency intervention was not planned were admitted for serial radiographic evaluations to determine the passage of the foreign body. Serial radiographic studies can be used to determine the passage of the foreign body and the complications resulting from it. If perforation is suspected based on the clinical or radiological findings, neck, chest or abdominal computed tomography is then indicated<sup>[13]</sup>. Computed tomography (CT) is especially useful when radiolucent materials cannot be detected with plain X-rays. A three-dimensional reconstruction with CT also increases the sensitivity of the detection modality<sup>[2,6,21-23]</sup>. CT can also be useful in determining, treatment options and complications.

Foreign bodies in the GI tract are typically treated conservatively, based on the type of foreign body and the patient’s clinical condition. Between 80% and 90% of foreign bodies pass through the GI tract freely, while 10% to 20% require an endoscopic intervention, and 1%

Figure 2 Plain abdominal X-ray showing a pin (white arrow) in the bowel in an adult. The pin passed spontaneously.

Figure 3 Lateral neck X-ray showing a bone fragment (white arrow). The fragment was removed by fiberoptic means.

**Table 2 Types of foreign bodies swallowed**

	Foreign body type	Total detected foreign bodies	Patients underwent X-ray	Foreign bodies detected with X-ray	Patients who underwent fiberoptic evaluation	Foreign bodies detected with endoscopy
	<i>n</i>	<i>n</i>	<i>n</i>	<i>n</i>	<i>n</i>	<i>n</i>

require surgery<sup>[4,6-9,11,13,17,24,25]</sup>. Physicians should determine if and when an intervention is needed. The patient management strategies depend on a patient’s age and clinical condition, the type and size of the foreign body, the presence of sharp edges, the anatomical location and the endoscopic capability of the treating unit<sup>[2,3,5]</sup>. In general, foreign bodies larger than 2.5 cm in diameter cannot pass the pylorus, while objects longer than 6 cm cannot pass the duodenal curve. Therefore, these objects require endoscopic removal<sup>[2,6,19,26]</sup>. Endoscopic intervention is also indicated if the patient’s condition is not stable or if the foreign body is impacted or presents risks of further damage to the patient<sup>[13,27]</sup>. An emergent endoscopic removal should be performed in patients with esophageal obstruction (*e.g.*, cannot swallow secretions), those with disc batteries in the esophagus and those who have swallowed pointed objects<sup>[6,13]</sup>. However, endoscopic removal is contraindicated if the foreign body is above the upper esophageal sphincter or if there is clinical or radiological evidence of perforation. Objects containing illegal drugs must be removed with endoscopy, but this technique should be avoided in cases where ruptured cocaine pack-

ages are present in the GI tract<sup>[6,13]</sup>. Objects located proximal to the upper esophageal sphincters are suggested to be removed by ear-nose-throat specialists<sup>[6,13]</sup>. Emergent endoscopy should be performed to remove magnets if they are within the reach of the technique<sup>[6]</sup>. Monitoring of the spontaneous passage of coins in asymptomatic patients is recommended. If there is no spontaneous passage, then removal within 24 h of ingestion is recommended<sup>[6,9]</sup>. We conducted conservative monitoring in slightly over half of our patients (53 out of 100). The diagnostic yield was 21 (47%) out of 45 for all patients undergoing fiberoptic evaluations. Endoscopic treatment options for meat or other food impactions included food extraction and advancement of the bolus into the stomach<sup>[6,9]</sup>. In our study, an X-ray was performed on 33 patients with accidental food ingestions but yielded a positive result in only two cases. By contrast, among 21 patients with accidental food ingestion who underwent fiberoptic evaluation, 12 patients were found to have a foreign material, and the material was removed. Food ingestion, a subjective feeling of foreign body sensation, and other properties of foreign bodies may have resulted

in the poor yield of standard imaging studies and endoscopic and physical examinations<sup>[11,27]</sup>.

An alternative radiological tool that was not systematically assessed in our study was ultrasonography, which is uncommonly used to diagnose GI foreign bodies in adults<sup>[28]</sup>. However, there are reports in the literature where ultrasonography proves to be useful in the detection of abdominal foreign bodies<sup>[9,29]</sup>. However, abdominal ultrasonography can be used as an initial imaging modality in the diagnosis of GI foreign bodies in pediatric patients<sup>[30]</sup>.

Conditions such as acute abdomen due to intestinal perforations are seen in nearly 1% of patients who have ingested foreign bodies<sup>[8,31]</sup>. This condition can lead to severe complications and even death<sup>[32]</sup>. The most common complication of foreign body ingestion is perforation<sup>[33]</sup>; the ingestion of a sharp and pointed object is more likely to cause perforations<sup>[9,33,34]</sup>. Approximately 30%-35% of such objects can penetrate the GI tract, requiring endoscopic management<sup>[35]</sup>. In the presence of complications or in the case of unsuccessful endoscopic interventions, emergency surgery is preferred<sup>[35,36]</sup>. The majority of foreign bodies pass through the GI tract freely, without any complication, and only a small percentage of these cases require intervention<sup>[4,9]</sup>.

In conclusion, a majority of the swallowed foreign bodies in patients presenting to the ED cannot be detected using standard imaging studies and evaluation. Plain radiography is especially useful in the localization of radiopaque foreign bodies, while fiberoptic methods can be used both as diagnostic and therapeutic tools, regardless of the radiopacity of the foreign body ingested. The goal of ED management is to refer patients with clinical significance to the appropriate departments for further evaluation and treatment. It is therefore important to evaluate the type and location of the foreign body and to identify complications that might develop as a result of this entity.

## COMMENTS

### Background

Ingestions or insertions of foreign bodies are rarely seen in adults, are generally accidental and are commonly seen in the form of food ingestion (such as meat and bones). Nonetheless, foreign body ingestions into the gastrointestinal tract can lead to clinically serious conditions with significant morbidity and mortality. Approximately 80%-90% of the foreign bodies pass through the gastrointestinal tract freely, while 10%-20% require an endoscopic intervention, and 1% require surgery.

### Research frontiers

The majority of swallowed foreign bodies in patients presenting to emergency departments cannot be detected using standard imaging tools. The research hotspot discussed here is that fiberoptic methods were implemented in both the diagnosis and treatment of gastrointestinal foreign bodies.

## Innovations and breakthroughs

The most common approach for the detection of ingested foreign bodies in the gastrointestinal tract is physical examination combined with radiological studies. While radiological examinations are especially helpful in the detection of radiopaque foreign bodies, these studies are unyielding in a significant proportion of patients, depending on the timing of presentation and the nature of the ingested foreign body. Early evaluation with fiberoptic methods helps not only in the diagnosis and localization of the foreign body but also in its removal.

## Applications

Dietary habits and various cultural factors can provide clues for the types of foreign bodies likely to be ingested. Fiberoptic methods can be used to diagnose and treat accidental foreign body ingestions in an emergency department setting.

## Peer review

The present study is a retrospective analysis of 100 patients with complaints related to foreign body ingestions. The data suggest that plain radiography is especially useful in the localization of radiopaque foreign bodies, while fiberoptic methods can be used as both diagnostic and therapeutic tools, regardless of the radiopacity of the foreign body ingested. This study highlights interesting points regarding the clinical treatment of complaints related to foreign body ingestions.

### Abstract

**AIM:** To investigate whether nonalcoholic fatty liver disease (NAFLD) affects coronary artery disease (CAD) and identify candidate mediators.

**METHODS:** Patients who underwent coronary angiography were consecutively recruited. The patients were classified into four groups by coronary artery stenosis: A, insignificant; B, one-vessel disease; C, two-vessel disease; and D, three-vessel disease. Abdominal ultrasonography was performed to determine the presence of a fatty liver and categorize by grade: 0, no evidence; 1, mild; 2, moderate; and 3, severe. We measured not only known CAD risk factors, but also serum insulin, HOMA-index, adiponectin, interleukin-6, tumor necrosis factor- $\alpha$  and high-sensitivity C-reactive protein levels.

**RESULTS:** Of the 134 patients who met the inclusion criteria, 82 (61.2%) had ultrasonographically diagnosed NAFLD. Among the 46 patients with CAD, 37 (80.4%) had evidence of a fatty liver. The two groups (A vs B-D) were significantly different in terms of age, total cholesterol, triglycerides, low-density lipoprotein levels and fatty liver. Coronary artery stenosis was strongly associated with fatty liver in a grade-dependent manner ( $P = 0.025$ ). In binary logistic regression, NAFLD was a significant independent predictor of CAD ( $P = 0.03$ , OR = 1.685; 95%CI: 1.051-2.702). Among the candidate mediators, the serum adiponectin level showed a trend toward lowering based on CAD progression ( $P = 0.071$ ).

**CONCLUSION:** NAFLD is an independent risk factor for CAD in a grade-dependent manner. Moreover, adiponectin might be related to the pathogenesis of NAFLD.

**Key words:** Nonalcoholic fatty liver disease; Coronary artery disease; Coronary angiography; Adiponectin; Insulin resistance

**Core tip:** This article shows that angiographically proven coronary artery stenosis is strongly associated with nonalcoholic fatty liver disease (NAFLD) in a grade-dependent manner. Although many recent studies used coronary artery calcification score, carotid artery intima-media thickness, or carotid artery plaque measurements as surrogate markers for coronary artery disease (CAD), we evaluated the interaction between fatty liver and cardiovascular outcomes using coronary angiograms in a prospective case-controlled study. Because the pathogenesis of NAFLD and CAD is not fully elucidated, we attempted to identify mediators of these diseases and believe that adiponectin might be related to the development and progression of CAD in patients with NAFLD.

## INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is a common disorder with an increasing prevalence of approximately 34% of the adult population in the United States<sup>[1]</sup>. Patients with NAFLD can progress to more aggressive forms of nonalcoholic steatohepatitis (NASH), which can progress to cirrhosis, end-stage liver disease, and eventually hepatocellular carcinoma<sup>[2]</sup>. Because NAFLD is related to metabolic syndrome and obesity, many patients with NAFLD have coronary artery disease (CAD). Several studies have reported that NAFLD is a strong independent risk factor for CAD<sup>[3,4]</sup>. However, these studies have some clinical application limitations because of the use of indirect modalities, such as coronary artery calcification or intima-media thickness despite coronary artery imaging. Authors of these studies suggested that the presence of CAD was indicated by coronary artery calcification or intima-media thickness despite conducting coronary artery imaging<sup>[5,6]</sup>. Many NAFLD studies conducted in Western populations have found a relationship between NAFLD and CAD in relatively obese patients, which has not been found in Asian populations<sup>[6,7]</sup>. Therefore, the relationship between NAFLD and CAD in relatively thin Asian people must be evaluated. This study was conducted to evaluate whether NAFLD independently affects angiographically proven CAD in Asians and, if so, which mediator is responsible for this association.

## MATERIALS AND METHODS

### Subjects and study design

From January 2009 to June 27, 2011, 184 adult patients who underwent elective coronary angiography (CAG) at Kangwon National University Hospital were consecutively recruited. Indications for CAG included Canadian Cardiovascular Society class III or IV angina upon medical treatment, high-risk findings upon noninvasive testing, acute coronary syndrome, or a chest pain evaluation according to the American College of Cardiology/American Heart Association recommendations<sup>[8]</sup>. Standard selective CAG was performed by three experienced cardiologists and reviewed by another cardiologist. CAD was defined as the presence of at least a 50% stenosis in at least one major coronary artery. The patients were classified into four groups according to the number of major coronary arteries affected by CAD: A, insignificant coronary artery stenosis; B, one-vessel disease; C, two-vessel disease; and D, three-vessel disease.

We excluded patients with viral hepatitis (positive for

hepatitis B surface antigen and anti-hepatitis C virus), history of alcohol ingestion (> 30 g/d for men and > 20 g/d for women), history of drug use reported to cause steatosis (steroids, estrogens, tamoxifen, amiodarone, valproic acid, diltiazem, or methotrexate), improved steatosis (metformin, statins, or glitazones) within 3 mo of enrollment, or other history of chronic liver disease. Hypertension was defined as systolic blood pressure  $\geq$  140 mmHg, diastolic blood pressure  $\geq$  90 mmHg or using antihypertensive medications. Diabetes was defined as fasting blood sugar  $\geq$  126 mg/dL or using glucose-lowering medications (oral agents or insulin). Of the 184 patients, we excluded 50 with at least one potential cause for chronic liver disease. Altogether, 134 patients were enrolled and underwent abdominal ultrasonography within 2 d after CAG by a single experienced physician to determine the presence of four fatty liver grades: 0, no evidence of fatty liver; 1, mild; 2, moderate; and 3, severe degree. The presence of a fatty liver was identified by characteristic echo patterns such as a diffuse increase in the echogenicity of the liver compared with that of the kidney according to conventional criteria<sup>[9]</sup>. We measured not only known risk factors (*i.e.*, age, male gender, high low-density lipoprotein, low high-density lipoprotein, triglyceride, body mass index, diabetes, and hypertension) for CAD but also serum insulin, HOMA index, adiponectin, interleukin (IL)-6, tumor necrosis factor (TNF)- $\alpha$  and high-sensitivity C-reactive protein (hs-CRP) levels. This study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Institutional Review Board of Kangwon National University Hospital.

### Statistical analysis

Clinical and biochemical variables were compared between the two groups (A vs B-D). Continuous variables were assessed with the unpaired Student's *t*-test, and nominal variables were compared with the chi-square test. Variables that were significantly different between the two groups were extracted and included as covariates in a binary logistic regression with CAD as the dependent and NAFLD as the independent variable. Correlations between CAD severity and NAFLD degree were analyzed using Pearson's correlation analysis. A *P*-value < 0.05 was considered significant. All analyses were conducted using the SPSS for Windows 12.0.1 statistical software (SPSS, Inc., Chicago, IL, United States).

## RESULTS

A total of 134 (37 males and 97 females) patients met the inclusion criteria for the study. Table 1 demonstrates the demographic, clinical and laboratory data of the subjects without CAD (A) and those with CAD (B-D). The two groups were significantly different in terms of age, total cholesterol, triglycerides, low-density lipoprotein levels and presence of NAFLD. In addition, there tended to be more clinical features associated with metabolic syndrome in the CAD group, but the difference was not significant. In each

Data are expressed as mean ± SD or n (%). DM: Diabetes mellitus; HTN: Hypertension; BMI: Body mass index; WHR: Waist-hip ratio; HDL: High density lipoprotein; LDL: Low density lipoprotein; BP: Blood pressure; FBS: Fasting blood sugar; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; PT: Prothrombin time; HOMA-index: Homeostatic model assessment of insulin resistance, fasting insulin (mU/L) × fasting glucose (mmol/L)/22.5; NAFLD: Nonalcoholic fatty liver disease.

group, women were predominant, and all subjects were post-menopausal except for one person in the CAD group.

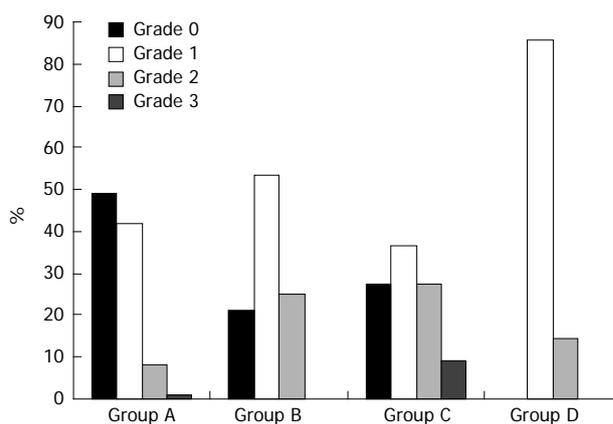

An analysis of the relationship between NAFLD and the presence of CAD is shown in Table 2. In addition to the significantly different variables between the two groups in Table 1, well-known established risk factors for CAD, such as age, gender, glucose, HbA1c and body mass index, were considered as covariates in conducting the multivariate analysis. In those models, as shown in Table 2, NAFLD was the significant independent predictor for CAD ( $P = 0.03$ , OR = 1.685; 95%CI: 1.051-2.702).

Next, we evaluated the correlation between the NAFLD degree and CAD severity. The proportion of patients with NAFLD increased from 51.1% in group A to 100% in group D. In group A, most of the fatty livers were grade 1. However, in the higher grade CAD group, the proportion of patients with more severe fatty livers was increased. No subject in group D (three-vessel

**Table 2** Multivariate analysis of coronary artery disease with age, nonalcoholic fatty liver disease and metabolic risk factors

	OR (95%CI)	P value

disease) had a normal liver. Figure 1 shows that angiographically proven coronary artery stenosis was strongly associated with NAFLD in a grade-dependent manner by Pearson's correlation analysis ( $P = 0.002$ ).

In addition, we measured the serum level of candidate mediators of metabolic syndrome, such as insulin, the HOMA index, IL-6, TNF- $\alpha$ , and hs-CRP (Table 3). In our results, none of the factors assessed were found to be related to CAD. However, serum adiponectin level demonstrated a trend toward lowering based on CAD progression ( $P = 0.071$ ).

## DISCUSSION

Our findings demonstrate that NAFLD is strongly associated with coronary artery stenosis in a grade-dependent manner. Our results also demonstrate that NAFLD is a significant predictor of CAD independent of traditional risk factors in Asians. Furthermore, we suggest that adiponectin might have a potential pathogenic role in the development and progression of CAD in patients with NAFLD.

Because NAFLD is a hepatic manifestation of metabolic syndrome, many studies have suggested that NAFLD results in increased cardiovascular risk and mortality<sup>[7,10]</sup>. The risk for developing cardiovascular morbidity and mortality is thought to be higher than the risk for developing hepatic disease because of its slow progression. Therefore, many studies have investigated the association between NAFLD and cardiovascular diseases. As a result,

**Table 3 Comparison of candidate mediators between subjects with and without coronary artery disease (mean  $\pm$  SD)**

	Group A Insignificant stenosis (n = 88)	Group B-D Significant stenosis (n = 46)	P value
Adiponectin ( $\mu\text{g}/\text{mL}$ )	8.40 $\pm$ 5.97	6.95 $\pm$ 5.85	0.071
IL-6 (pg/mL)	4.55 $\pm$ 7.75	4.71 $\pm$ 7.41	0.894
TNF- $\alpha$ (ng/mL)	4.00 $\pm$ 3.95	4.85 $\pm$ 4.73	0.273
hs-CRP(mg/dL)	0.45 $\pm$ 1.70	0.74 $\pm$ 1.18	0.366

IL: Interleukin; TNF: Tumor necrosis factor; hs-CRP: High sensitive C-reactive protein.

a number of studies have demonstrated that NAFLD is an independent risk factor for CAD<sup>[4,5,11-13]</sup>. However, most studies used coronary artery calcification score, carotid artery intima-media thickness, carotid artery plaque measurements, or circulatory endothelial dysfunction as surrogate markers for CAD<sup>[5,6,14]</sup>. Despite the fact that the coronary calcification score is a well-known marker for an increased risk of coronary events, the direct relationship between the presence of NAFLD and clinical CAD must be evaluated for use in the clinical setting<sup>[3]</sup>. Recently, Wong *et al*<sup>[15]</sup> evaluated the interaction between fatty liver and cardiovascular outcomes using coronary angiograms in a prospective cohort study and demonstrated that fatty liver is associated with CAD independently of other metabolic factors, which is consistent with our results. In contrast, our study was different from that study because we demonstrated that angiographically proven coronary artery stenosis was strongly associated with fatty liver in a grade-dependent manner.

Although the pathogenesis of NAFLD and CAD has not been fully elucidated, several explanations are present for the relationship between NAFLD and CAD. One widely accepted hypothesis implicates low-grade inflammatory conditions as key factors leading to hepatic steatosis and atherosclerosis<sup>[16,17]</sup>. Moreover, oxidative stress is presumed to play a role in NASH pathogenesis. Many investigators have studied additional mechanisms that might be associated with NAFLD, which are supported by the levels of various biomarkers, such as reactive oxygen species, adipocytokines (leptin and adiponectin), CRP, and caspase-generated cytokeratin-18<sup>[18-21]</sup>. In this study, we also tried to find candidate mediators of the mechanism of this relationship. We investigated several mediators, including adiponectin, IL-6, TNF- $\alpha$ , and hs-CRP. Among these candidate mediators, adiponectin may have been related to the development and progression of CAD in patients with NAFLD in our study. Adiponectin is the most abundant adipose-specific adipokine, and decreases hepatic insulin resistance and attenuates liver inflammation<sup>[22]</sup>. Low levels of serum adiponectin might play an important role in the pathogenesis of clinical CAD and NAFLD. In contrast, NAFLD is also characterized by increased insulin resistance<sup>[23]</sup>. We measured fasting serum insulin levels and calculated the HOMA index to confirm this relationship in our study. Because we included obese Asians, which in contrast with previous

Asian-Pacific NAFLD studies that included non-obese subjects, our study subjects had relatively high insulin resistance<sup>[24]</sup>. However, fasting serum insulin levels and HOMA-IR were not different between our two groups (with/-without CAD and with/-without a fatty liver).

Some limitations of our study merit comment. First, our results were not based on a biopsy-proven NAFLD. There is no histology or staging of fibrosis by use of elastography to determine the liver fibrosis. We diagnosed NAFLD using hepatic ultrasonography. This technique does not identify fatty infiltration < 30% although it is a safe and confirmed reliable noninvasive method<sup>[25]</sup>. This technique also has additional weak points, which are intra- and interobserver differences when making a diagnosis. However, to overcome these limitations, ultrasonography was performed by a single experienced physician to determine the presence of the four fatty liver grades. In addition, standard selective CAG was performed to diagnose and measure CAD severity by three experienced cardiologists in our study. To reduce interobserver variability for CAG, another cardiologist also reviewed all of the data. Second, this study was conducted at a single center in a rural area, which increased the chance for selection bias. Women were predominant in the included subject. A possible explanation for this gender imbalance is that men in this area had a high prevalence of alcohol intake and were excluded based on a history of alcohol ingestion.

Because NAFLD is considered a hepatic manifestation of metabolic syndrome, many studies have investigated the association between NAFLD and cardiovascular diseases. As a result, our study demonstrates that NAFLD is an independent risk factor for angiographically proven CAD in a grade-dependent manner. Because the pathogenesis of NAFLD and CAD are not fully elucidated, we also attempted to identify mediators and believe that adiponectin might be related to the development and progression of CAD in patients with NAFLD. Therefore, future large-scale studies are needed to elucidate the precise mechanism of this relationship.

## COMMENTS

### Background

Although recent many studies used coronary artery calcification score, carotid artery intima-media thickness, or carotid artery plaque measurements as surrogate markers for coronary artery disease (CAD), this study evaluated the interaction between fatty liver and cardiovascular outcomes using coronary angiograms in a prospective case-control study of Asians.

### Research frontiers

The relationship between nonalcoholic fatty liver disease (NAFLD) and CAD in relatively thin Asian people must be evaluated. Moreover, because the pathogenesis of NAFLD and CAD are not fully elucidated, the authors attempted to identify candidate mediators.

### Innovations and breakthroughs

This article show that angiographically proven coronary artery stenosis was strongly associated with NAFLD in a grade-dependent manner. In addition, the authors attempted to identify mediators and believe that adiponectin might be related to the development and progression of CAD in patients with NAFLD.

### Applications

By understanding the association between NAFLD and CAD, patients with a se-

vere degree of fatty liver disease have to be concerned about CAD to improve their prognosis.

### Peer review

This is a prospective single center study, which investigate the relationship between NAFLD and CAD and seeks candidate mediators. Future large-scale studies are needed to elucidate the precise mechanism of this relationship.

### Abstract

**AIM:** To investigate the diet of pouch patients compared to healthy controls, and to correlate pouch patients' diet with disease behavior.

**METHODS:** Pouch patients were recruited and prospectively followed-up at the Comprehensive Pouch Clinic at the Tel Aviv Sourasky Medical Center. Pouch behavior was determined based on clinical, endoscopic and histological criteria. Healthy age- and sex-matched volunteers were selected from the "MABAT" Israeli

Nutrition and Public Health Governmental Study and served as the control group. All the participants completed a 106-item food frequency questionnaire categorized into food groups and nutritional values based on those used in the United States Department of Agriculture food pyramid and the Israeli food pyramid. Data on Dietary behavior, food avoidance, the use of nutritional supplements, physical activity, smoking habits, and body-mass index (BMI) were also obtained. Pouch patients who had familial adenomatous polyposis ( $n = 3$ ), irritable pouch syndrome ( $n = 4$ ), or patients whose pouch surgery took place less than one year previously ( $n = 5$ ) were excluded from analysis.

**RESULTS:** The pouch patients ( $n = 80$ ) consumed significantly more from the bakery products food group ( $1.2 \pm 1.4$  servings/d vs  $0.6 \pm 1.1$  servings/d,  $P < 0.05$ ) and as twice as many servings from the oils and fats ( $4.8 \pm 3.4$  servings/d vs  $2.4 \pm 2$  servings/d,  $P < 0.05$ ), and the nuts and seeds food group ( $0.3 \pm 0.6$  servings/d vs  $0.1 \pm 0.4$  servings/d,  $P < 0.05$ ) compared to the controls ( $n = 80$ ). The pouch patients consumed significantly more total fat ( $97.6 \pm 40.5$  g/d vs  $84.4 \pm 39$  g/d,  $P < 0.05$ ) and fat components [monounsaturated fatty acids ( $38.4 \pm 16.4$  g/d vs  $30 \pm 14$  g/d,  $P < 0.001$ ), and saturated fatty acids ( $30 \pm 15.5$  g/d vs  $28 \pm 14.1$  g/d,  $P < 0.00$ )] than the controls. In contrast, the pouch patients consumed significantly fewer carbohydrates ( $305.5 \pm 141.4$  g/d vs  $369 \pm 215.2$  g/d,  $P = 0.03$ ), sugars ( $124 \pm 76.2$  g/d vs  $157.5 \pm 90.4$  g/d,  $P = 0.01$ ), theobromine ( $77.8 \pm 100$  mg/d vs  $236.6 \pm 244.5$  mg/d,  $P < 0.00$ ), retinol ( $474.4 \pm 337.1$   $\mu$ g/d vs  $832.4 \pm 609.6$   $\mu$ g/d,  $P < 0.001$ ) and dietary fibers ( $26.2 \pm 15.4$  g/d vs  $30.7 \pm 14$  g/d,  $P = 0.05$ ) than the controls. Comparisons of the food consumption of the patients without ( $n = 23$ ) and with pouchitis ( $n = 45$ ) showed that the former consumed twice as many fruit servings as the latter ( $3.6 \pm 4.1$  servings/d vs  $1.8 \pm 1.7$  servings/d, respectively,  $P < 0.05$ ). In addition, the pouchitis patients consumed significantly fewer liposoluble antioxidants, such as cryptoxanthin ( $399 \pm 485$

$\mu\text{g/d}$  vs  $890.1 \pm 1296.8 \mu\text{g/d}$ ,  $P < 0.05$ ) and lycopene ( $6533.1 \pm 6065.7 \mu\text{g/d}$  vs  $10725.7 \pm 10065.9 \mu\text{g/d}$ ,  $P < 0.05$ ), and less vitamin A ( $893.3 \pm 516 \mu\text{g/d}$  vs  $1237.5 \pm 728 \mu\text{g/d}$ ,  $P < 0.05$ ) and vitamin C ( $153.3 \pm 130 \text{ mg/d}$  vs  $285.3 \pm 326.3 \text{ mg/d}$ ,  $P < 0.05$ ) than the patients without pouchitis. The mean BMI of the pouchitis patients was significantly lower than the BMI of the patients with a normal pouch:  $22.6 \pm 3.2$  vs  $27 \pm 4.9$  ( $P < 0.001$ ).

**CONCLUSION:** Decreased consumption of antioxidants by patients with pouchitis may expose them to the effects of inflammatory and oxidative stress and contribute to the development of pouchitis.

© 2013 Baishideng. All rights reserved.

**Key words:** Ulcerative colitis; Dietary reference intake; Body mass index; Ileal-pouch anal anastomosis; Pouch surgery; Food frequency questionnaire

**Core tip:** The diet of patients who had pouch surgery differed significantly from that of healthy individuals. Patients with pouchitis consumed significantly fewer fruit servings and antioxidants than patients with normal pouches, thus possibly exposing the former to inflammatory and oxidative stress. The body mass index of patients with pouchitis was significantly lower than patients with normal pouches, probably as a result of the continuous inflammatory burden.

Ianco O, Tulchinsky H, Lusthaus M, Ofer A, Santo E, Vaisman N, Dotan I. Diet of patients after pouch surgery may affect pouch inflammation. *World J Gastroenterol* 2013; 19(38): 6458-6464 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6458.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6458>

## INTRODUCTION

Total proctocolectomy and the formation of a small bowel reservoir-ileal pouch anal anastomosis (IPAA, “pouch surgery”) is the surgery of choice for the treatment of severe, refractory or complicated ulcerative colitis (UC)<sup>[1,2]</sup>. Pouch surgery has good short- and long-term outcomes and is associated with improved quality of life<sup>[2]</sup>. Inflammation of the pouch (“pouchitis”) is the most common long-term complication, with a reported incidence of up to 60%<sup>[3]</sup>. Nutrition is increasingly incorporated into the management of inflammatory bowel disease (IBD)<sup>[4]</sup>. However, few studies have assessed the influence of nutrition on the health status of pouch patients. Rather most have focused on patients’ subjective feelings after consuming specific food products<sup>[5]</sup>. Nevertheless, the potential contribution of nutrition to the development of inflammation in the pouch, as well as to IBD in general, remains unclear. Studies have shown that probiotic supplements, such as various strains of lactobacilli 3

(VSL#3), may prevent pouchitis after closure of the ileostomy, shorten the duration of the inflammation, and maintain remission<sup>[6,7]</sup>. Several nutritional imbalances may also result from pouch surgery itself, including vitamin B12 and iron deficiency, fat malabsorption and electrolyte and trace element deficiencies<sup>[8-11]</sup>. Such deficiencies may, in turn, cause or increase inflammation by mechanisms such as increased tissue oxidative stress<sup>[10]</sup>.

We hypothesized that diet modification and nutritional imbalance may occur after pouch surgery and that these could be associated with and predispose pouch patients to the development of pouchitis. We further assumed that such major changes might be related to the consumption of essential vitamins, minerals, antioxidants or fibers, which could thus potentially contribute to pouch inflammation<sup>[11-15]</sup>. The purpose of the current investigation was thus to gather and analyze the detailed intake of food groups and nutrients as well as examine the nutritional and lifestyle habits of pouch patients, and test for correlations between these parameters and the occurrence of pouchitis.

## MATERIALS AND METHODS

### Study population

Pouch patients were recruited from the Comprehensive Pouch Clinic at the Tel Aviv Sourasky Medical Center (Tel Aviv, Israel), a tertiary referral center for IBD and the national referral center for pouch patients. Both an IBD-oriented gastroenterologist (Dotan I) and a colorectal surgeon (Tulchinsky H) examined all pouch patients. Healthy age- and sex-matched volunteers were selected from the “MABAT” Israeli Nutrition and Public Health Governmental Study cohort<sup>[16]</sup>. Pouchitis was diagnosed by accepted clinical, endoscopic and histological criteria (the pouchitis disease activity index, PDAI<sup>[17]</sup>). Pouch status was further defined as normal or pouchitis (recurrent acute pouchitis and chronic pouchitis) as previously described<sup>[2]</sup>. Briefly, normal pouch status was defined as no clinical, endoscopic or histological criteria for pouchitis during the previous 2 years and no antibiotic or anti-inflammatory therapy of any type. Chronic pouchitis was defined by clinical, endoscopic and histological criteria that called for chronic administration of antibiotics or anti-inflammatory therapies for more than one month or when there were more than 5 flares of pouchitis within a year<sup>[2,18,19]</sup>. Recurrent acute pouchitis was defined as  $\leq 5$  flares of pouchitis responding to a 2-wk course of antibiotics/year. The data on pouch patients who had familial adenomatous polyposis ( $n = 3$ ), irritable pouch syndrome ( $n = 4$ ), or patients who had had their pouch for less than one year ( $n = 5$ ) were excluded.

Since there was no significant difference in the food and nutrient consumption between the patients with chronic pouchitis and those with recurrent acute pouchitis, they were combined into a single “pouchitis” group. The data for all of the enrolled pouch patients were compared to those of the healthy controls. Patients with a normal pouch status ( $n = 23$ ) were further compared to

**Table 1 Food group consumption in pouch patients and healthy controls (mean  $\pm$  SD)**

Food group	Consumption healthy controls ( <i>n</i> = 80, servings/d)	Consumption pouch patients ( <i>n</i> = 80, servings/d)	Recommendation <sup>1</sup>	<i>P</i> value

<sup>1</sup>Serving recommendations according to food pyramid (*n* = 20); <sup>2</sup>6-11 servings are recommended for the grains, baked goods or potato categories; <sup>3</sup>2-3 servings are recommended for the meat, fish and poultry, eggs, and legume categories.

patients with pouchitis (*n* = 45). All participants gave their informed consent. The study complied with the Helsinki Declaration and the ethical guidelines of our institution.

### Questionnaires

All participants were prospectively interviewed using a food frequency questionnaire (FFQ). The 106 items on the FFQ were categorized into food groups according to those defined in the United States Department of Agriculture (USDA) food pyramid<sup>[20]</sup> and the Israeli food pyramid<sup>[21]</sup>. The questionnaire also included sub-food groups defined in the "MABAT" Israeli Nutrition and Public Health Governmental Study<sup>[16]</sup>. The nutritional values of the food items were taken from the USDA FNDD, version 4.1<sup>[22]</sup>. The nutritional values of several specific Israeli food items that do not appear in the USDA FNDD database were taken from the Israeli Ministry of Health food consumption and nutrients "TZAMERET" database, version 2<sup>[23]</sup>. Pouch patients were also asked about their dietary behavior, food avoidance, and the use of nutritional supplements, as well as physical activity, smoking habits, and body-mass index (BMI). Assessment of the questionnaires was based on the recommended range of values established by the USDA FNDD<sup>[22]</sup> and Israeli Health Ministry "TZAMERET"<sup>[23]</sup> databases. The nutrient consumption of all participants was compared to the upper limits for daily nutrient recommendations for healthy males and females between the ages of 31-50 years as indicated in the USDA Dietary Reference Intake (DRI) 2010<sup>[24]</sup>.

### Statistical analysis

Statistical analyses were conducted using SPSS software version 19.0 (SPSS Inc. Headquarters, S Wacker Drive, Chicago, IL, United States). A *P* value of < 0.05 was considered significant. Data are presented as mean  $\pm$  SD for continuous variables, and frequencies and percentages for categorical variables. Independent *t*-tests were used to compare pouch patients *vs* healthy controls for

food group and nutrient consumption. Fisher's exact test and independent *t*-tests were used to compare normal pouch patients to recurrent acute and chronic pouchitis patients for the categorical and continuous variables, respectively.

## RESULTS

### Diets of pouch patients vs controls

Eighty adult pouch patients were recruited and compared to 80 healthy adult volunteers. Subjects from both groups were matched for sex and age. Differences in their nutritional intake were first examined by comparing their consumption of servings of the main food groups. The major food groups were divided into subgroups based on the "MABAT" study distribution<sup>[16]</sup>. The pouch patients consumed significantly more bakery, oils and fats, and nuts and seeds compared to the controls (Table 1). The consumption of other food groups was comparable. The total nutrient content of foods<sup>[25]</sup> consumed by the patients and the control groups is shown in Table 2. The pouch patients' increased consumption of fat servings included significantly more total fat and fat components; *i.e.*, mono-unsaturated fatty acids and saturated fatty acids, than the controls. The pouch patients also consumed significantly higher amounts of several nutrients than the controls, *e.g.*, niacin, zinc, and vitamins C and D (Table 2). These higher levels were usually attributed to external supplements rather than to the diet itself. In contrast, the pouch patients consumed significantly fewer carbohydrates, sugars, theobromine, retinol and dietary fibers compared to the controls. Interestingly, neither the controls nor the pouch patients met DRI recommendations for dietary fiber intake (38 g/d<sup>[24]</sup>).

### Normal pouch vs pouchitis patients' diets

The pouch patients were divided into a normal pouch group (*n* = 23) and a pouchitis group (*n* = 45) (both recurrent acute and chronic). The demographic parameters of

DRI: Dietary reference intakes.

**Table 3** Demographic characteristics of pouch patient subgroups

	Normal pouch ( <i>n</i> = 23)	Recurrent acute and chronic pouchitis ( <i>n</i> = 45)	<i>P</i> value
Male/female	11/12	22/23	0.56
Age (yr)	53.2 $\pm$ 13.7	43.0 $\pm$ 14.9	< 0.001
Mean time since surgery (yr)	7.8 $\pm$ 4.4	11.0 $\pm$ 6.3	0.04
Operation stages (1/2/3)	4/16/3	4/34/7	0.4
Body mass index (kg/m <sup>2</sup> )	27 $\pm$ 4.9	22.6 $\pm$ 3.2	< 0.001
Food avoidance	60.90%	73.30%	0.21
Probiotics consumption	30.40%	31.10%	0.6
Vitamins/supplement consumption	43.50%	66.70%	0.06
Smokers	4.30%	13.30%	0.24

the two groups are shown in Table 3. Comparison of the food consumption of the normal pouch patients to that of patients with pouchitis revealed significant differences in two main food groups; namely, fruits and vegetables (Table 4). Patients with a normal pouch consumed twice as many fruit servings as patients with pouchitis ( $P < 0.01$ ) and tended to consume more vegetable servings than the pouchitis patients ( $P < 0.01$ ). The consumption of other food groups was comparable regardless of pouch status. We hypothesized that these findings would be reflected in significantly less consumption of antioxidants. As predicted, pouchitis patients consumed significantly less liposoluble antioxidants, such as cryptoxanthin and lycopene, as well as less vitamins A and C than the normal pouch patients. Taken together, these data suggest that patients with pouchitis may be more exposed to oxidative stress as a result of their consumption of fewer fruits and vegetables. Interestingly, two-thirds of the patients with pouchitis supplemented their diet with vitamins and minerals, compared to 43.5% of the patients with a normal pouch ( $P = 0.06$ ). Nevertheless, even after this supplementation, the total consumption of antioxidants was still significantly lower in the pouchitis group than in the normal pouch group. Seventy percent of all pouch

patients reported some type of food avoidance. The most frequently avoided foods were milk, citrus fruits, and spicy foods. Although up to 25% of all pouch patients avoided milk products, they met the recommended calcium intake level, mostly through supplements.

Only 26.2% ( $n = 21$ ) of all pouch patients in the cohort used probiotics; 30.4% ( $n = 7$ ) in the normal pouch group and 31.1% ( $n = 14$ ) in the pouchitis group. Most of these were over-the-counter probiotics, and only 4 patients used the probiotic VSL#3.

### BMI comparisons

Despite the comparable mean energy intake of patients with normal pouches and those with pouchitis, the mean BMI of both groups was significantly different, with the former having a significantly higher BMI than the latter. In terms of the normal BMI range for the healthy population (18.5-25 kg/m<sup>2</sup>)<sup>[26]</sup>, 15 patients (65%) in the normal pouch group fell into the overweight range compared to 35 patients (77%) the pouchitis group who were categorized in the normal or underweight range. This may suggest that inflammatory activity itself, rather than decreased caloric intake, plays a role in the significantly lower BMI of patients with pouchitis.

**Table 4 Food group consumption in patients with recurrent acute and chronic pouchitis *vs* patients with a normal pouch (mean  $\pm$  SD)**

Food group	Consumption normal pouch patients ( <i>n</i> = 23, servings/d)	Consumption recurrent acute and chronic pouchitis patients ( <i>n</i> = 45, servings/d)	Recommendation <sup>1</sup>	<i>P</i> value

## DISCUSSION

Increased attention has been paid in recent years to the role of nutrition in the treatment of IBD patients<sup>[4,27]</sup>, and its putative contribution to inflammation continues to be a topic of considerable interest<sup>[14,15]</sup>. UC patients undergoing pouch surgery are exposed not only to the consequences of total removal of the large bowel and reconstruction of an ileal reservoir, but also to the potential influence of nutrition on inflammatory processes. Thus it is surprising that there are no nutritional guidelines for these patients. Moreover, there is only sparse information on nutrition among pouch patients and its relationships to the development, treatment, and prevention of pouch inflammation. In this prospective cross-sectional study, we employed the FFQ to characterize pouch patients' dietary consumption to analyze correlations between diet and pouch inflammation. We hypothesized that nutrition could be significantly impaired in these patients, which would have possible implications for the inflammation of the pouch.

The results indicate major differences in the diet of pouch patients as compared to healthy individuals and, more importantly, between patients with normal pouches and those with pouchitis. In particular, pouch patients

consumed significantly higher servings of fats and oils compared to healthy controls, and patients with pouchitis consumed fewer fruit servings and antioxidants than patients with a normal pouch. These findings on fat and oil consumption may be crucial since USDA nutritional guidelines recommend that fats should be consumed sparingly<sup>[20,28]</sup>. Sakamoto *et al.* for instance found that high consumption of fats and oils is associated with increased risk of CD<sup>[12]</sup>. The same may apply to the development of pouchitis, which, similar to CD, is an inflammation of the small bowel in an IBD patient.

Our patients with normal pouches consumed twice as many servings from the fruit food group than the pouchitis patients (Table 4). They also tended to consume more servings from the vegetable food group. Low consumption of fruits and vegetables has been shown to be inversely related to inflammation, as reflected by higher CRP levels<sup>[29]</sup>. El Muhtaseb *et al.*<sup>[10]</sup> for instance showed that pouch patients have significantly lower plasma concentrations of liposoluble antioxidants such as beta carotene, and that they have increased oxidative stress in plasma compared to healthy controls. This may imply that the low consumption of antioxidants and vitamin C observed in the pouchitis patients here may contribute to their low serum levels. According to D'Odorico *et al.*<sup>[30]</sup>

this may lead to further oxidative damage. When DRI consumption of dietary fibers is below the recommended level, several mechanisms may lead to a similar effect<sup>[31]</sup>. Intestinal bacteria ferment soluble fibers, producing short chain fatty acids such as butyrate<sup>[31,32]</sup> as well as lactic acid<sup>[32]</sup>. A shortage in butyrate was shown to be associated with the development of pouchitis<sup>[32]</sup>. Second, lactic acid decreases fecal pH<sup>[31]</sup>, which may contribute to protection from pouchitis<sup>[31]</sup> by inhibiting the proteolytic activity of bacterial glycosidases<sup>[33]</sup>.

Taken together, these results on the low consumption of antioxidants, vitamins and dietary fibers by pouchitis patients support our hypothesis that these imbalances may both predispose and be associated with the development of pouchitis in pouch patients. Whether the consumption of more antioxidants and vitamins can prevent further intestinal inflammation or even reverse it is an open question reserved for future studies. Notably, probiotic supplements were consumed by 26.2% of our pouch patients, but the probiotic formula VSL#3 that has been reported to be beneficial for the prevention of pouchitis<sup>[34]</sup> was consumed by only 5%. This low rate of use may change in the near future since 2011 VSL#3 has now been included in the Israeli MOH health basket as a supplement for patients with pouchitis<sup>[35]</sup>.

A major finding of the current work is the correlation between BMI and the inflammatory state. Patients with normal pouches had significantly higher BMI ratios than patients with pouchitis, even to the point of being in the “overweight” range<sup>[26]</sup>. This finding is intriguing given that there was no difference in energy intake between the normal pouch and the chronic pouchitis patient groups. Thus, differences in BMI might be due to increased malabsorption<sup>[3]</sup>, increased energy expenditure<sup>[3]</sup> or differences in microbiota composition, which may lead to differential utilization of nutrients<sup>[36]</sup>. This correlation between BMI and pouch inflammatory state also suggests that the inflammation itself contributes to energy expenditure, as we reported elsewhere for CD patients<sup>[3]</sup>.

In conclusion, the results of this study revealed significant differences in the consumption of food groups and nutrients between healthy controls and pouch patients, and between patients with normal pouches and those with pouchitis. These differences correlated, in part, with pouchitis and affected the patients’ BMI levels. Further studies on the mechanistic effects of nutrition on pouch inflammation are needed to help provide guidelines for nutritional counseling and interventions to alleviate the symptoms of pouchitis and modify its course.

## COMMENTS

### Background

Total proctocolectomy and the formation of a small bowel reservoir-ileal pouch anal anastomosis (IPAA, “pouch surgery”) is the surgery of choice for the treatment of severe, refractory or complicated ulcerative colitis (UC). Inflammation of the pouch (“pouchitis”) is the most common long-term complication, with a reported incidence of up to 60%. Nutrition has been increasingly incorporated into the management of inflammatory bowel disease (IBD). However, few studies have assessed the influence of nutrition on the health of pouch patients.

Moreover, the potential contribution of nutrition to the development of inflammation in the pouch, as well as in IBD in general, remains under-researched.

### Research frontiers

The characteristics of pouch patients’ nutrition were prospectively evaluated using a food frequency questionnaire. The questionnaire data were analyzed for correlations between pouch disease behavior, as determined by clinical, endoscopic and histological criteria. Most previous nutritional studies on pouch patients have focused on their subjective feelings after consuming specific food products rather than on the overall relationships between various food groups and nutrients and pouch disease behavior.

### Innovations and breakthroughs

The dietary intake and nutrient composition of pouch patients was analyzed for relationships with pouch disease behavior. The key finding shows that the diet of patients with pouch surgery differed significantly from that of healthy individuals. Moreover, patients with pouchitis consume significantly fewer fruit servings and antioxidants compared to patients with normal pouches, possibly exposing the former to inflammatory and oxidative stress. The body mass index of patients with pouchitis was significantly lower than patients with normal pouches, probably as a result of the continuous inflammatory burden.

### Applications

The findings suggest that the consumption of fruits and vegetables, as well as supplementation with specific vitamins, minerals and antioxidants may be beneficial for patients with pouchitis. Specific nutritional consultation for pouch patients is advisable.

### Terminology

Pouch surgery: This is the surgery of choice for the treatment of severe, refractory or complicated UC. The large bowel and the rectum are removed (total proctocolectomy), and a reservoir (“pouch”) constructed of the normal small bowel is created and connected to the anus (IPAA). Pouchitis: Inflammation of the small bowel (that was originally normal, not inflamed) creating the pouch.

### Peer review

This research compares the dietary and nutritional treatment of pouch patients and pouchitis. This manuscript is a meaningful and enlightening study in general because it reveals the dietary differences between pouch patients and controls as well as between patients with or without pouchitis, which can guide further investigations on this topic.

### Abstract

**AIM:** To explore the association between consumption

of spicy foods and prevalence of irritable bowel syndrome (IBS) among Iranian adults.

**METHODS:** In this cross-sectional study, data from 4763 Iranian adult participants were used. Consumption of spicy foods was estimated using a dietary habits questionnaire that included a question on spicy foods consumption: "how frequently do you use spicy foods (pepper, curry, ginger, cinnamon and turmeric) during a week?" Participants could respond to the question by choosing one of these choices: never, 1-3 times, 4-6 times, 7-9 times, or more than 10 times per week. A modified Persian version of the Rome III questionnaire was used to determine the prevalence of IBS.

**RESULTS:** IBS was prevalent in 21.7% (18.6% of men and 24.1% of women) of the study population. After controlling for potential confounders including dietary behaviors, those consuming spicy foods  $\geq 10$  times per week were 92% more likely to have IBS compared with those who never consumed spicy foods (OR = 1.92; 95%CI: 1.23-3.01,  $P_{\text{trend}} < 0.01$ ). The association remained significant even after taking lactose intolerance into account (OR = 1.85; 95%CI: 1.18-2.90,  $P_{\text{trend}} < 0.01$ ). Stratified analysis by gender revealed that the association between consumption of spicy foods and IBS was not significant in men; however, a significant association was found among women after taking potential cofounders, including meal regularity and lactose intolerance, into account. Women who consumed spicy foods  $\geq 10$  times per week were two times more likely to have IBS compared with those who never consumed spicy foods (OR = 2.03; 95%CI: 1.09-3.77,  $P_{\text{trend}} = 0.02$ ).

**CONCLUSION:** Consumption of spicy foods is directly associated with IBS, particularly in women. Further, prospective studies are warranted to (1) examine this association in other populations; and (2) evaluate whether dietary interventions, for example a reduction

in spice consumption, would improve IBS symptoms.

**Key words:** Spice; Diet; Condiments; Red pepper; Irritable bowel syndrome; Functional gastrointestinal disorders

**Core tip:** The role of dietary habits, including consumption of spicy foods, in the development of functional gastrointestinal disorders remains controversial. In this cross-sectional study in a large sample of Iranian adults, we found that women with high consumption of spicy foods had a two-fold increased risk of developing irritable bowel syndrome compared with women who reported not to consume spicy foods. The results underline the need for further studies to characterize potential relationships between diet-related practices and the risk of functional gastrointestinal disorders, in order to design appropriate, and effective, diet-based interventions.

## INTRODUCTION

Functional gastrointestinal disorders (FGIDs) are characterized by chronic and recurrent gastrointestinal (GI) symptoms with ambiguous pathophysiology<sup>[1]</sup>. The most common FGID is irritable bowel syndrome (IBS), which is characterized by abdominal pain and changes in stool consistency and/or frequency<sup>[2-5]</sup>. It has been estimated that 5%-10% of the adult population in Asian countries<sup>[6]</sup> and 10%-20% of the population in developed countries<sup>[7]</sup> are affected by IBS. In Iran, the prevalence of IBS has been reported to be 1.1%-25% based on different studies<sup>[8]</sup>. Since there is no established medical therapy to alter the natural history of IBS in the longer term, the disorder represents a considerable financial burden to the health service, owing to medical consultations and consumption of other valuable resources<sup>[9]</sup>.

Diet appears to play an important role in the etiology of FGIDs<sup>[10-12]</sup>. Dietary intake of carbohydrates and fatty foods along with caffeine, alcohol and spices have been linked to IBS<sup>[13,14]</sup>. Consumption of other foods and nutrients has also been implicated in the induction of symptoms in IBS<sup>[15-20]</sup>. Some studies have suggested that IBS symptoms might result from food sensitivities rather than altered diet composition<sup>[10]</sup>.

The consumption of spicy foods has received attention in relation to FGIDs<sup>[21,22]</sup>. Earlier studies have shown that chili, with its pungent ingredient, capsaicin,

exacerbates abdominal pain and burning in IBS patients. In contrast, chronic consumption of chili has been found to result in an improvement in IBS-related symptoms<sup>[11]</sup>. Six-week administration of four pills per day each containing 150 mg of red pepper powder was reported to be effective in improving the intensity of abdominal pain in IBS patients<sup>[21]</sup>. Other studies have also reported the beneficial effects of spicy foods in the management of FGID symptoms<sup>[22]</sup>. However, most previous studies have focused on chili and its ingredients, and no information is available on other spicy foods. Furthermore, earlier investigations have mostly used high doses of spices as a treatment, and limited data are available examining the habitual consumption of spicy foods and its relationship to the prevalence of IBS.

The traditional Iranian diet contains large amounts of spicy foods, including turmeric, saffron, and ginger, providing an opportunity to assess consumption of spicy foods in relation to health. In addition, few data exist about the association between diet and FGIDs, and available evidence has mostly been reported from small samples, thus, no data are available from large populations. The Study on the Epidemiology of Psychological, Alimentary Health and Nutrition (SEPAHAN), which has been performed in a large group of Iranian adults, provides a unique opportunity to investigate the epidemiological aspects of FGIDs and their relationship with different lifestyles, including nutritional factors<sup>[23]</sup>. Here, we present the sub-study that aimed to explore the association between consumption of spicy foods and the prevalence of IBS among Iranian adults.

## MATERIALS AND METHODS

### Study population

This cross-sectional study was carried out within the framework of the SEPAHAN project. This project was conducted in two main phases in a large sample of Iranian adults working in 50 different healthcare centers across Isfahan province, Iran<sup>[23]</sup>. In the first phase of SEPAHAN, questionnaires on demographic information, medical history, anthropometric measures, lifestyle and nutritional factors were sent to 10087 persons, and 8691 subjects returned the completed questionnaires (response rate: 86.16%). In the second phase, another set of questionnaires was sent out to obtain data on gastrointestinal health of participants. After linking data from both phases and considering missing data, 4763 people who provided complete information on diet and FGIDs were included in the current analysis. The Bioethics Committee of Isfahan University of Medical Sciences, Isfahan, Iran, approved the study.

### Assessment of spicy foods consumption

We used a dietary habits questionnaire that contained detailed questions about meal frequencies, regularity of meals and drinking fluids before and after meals, as well as a question relating to the consumption of spicy foods:

“how often do you use spicy foods (chili pepper, curry, ginger, cinnamon, and turmeric) during a week?” Participants could respond to this question by choosing one of the following choices: never, 1-3 times, 4-6 times, 7-9 times, or more than 10 times per week. Responses to this question were used as the main exposure variable in the current study.

### Assessment of IBS

A modified Persian version of the Rome III questionnaire, as part of the main comprehensive questionnaire, was used for the identification of FGIDs, including IBS<sup>[23]</sup>. During the face validation of the questionnaire, we found that most participants were unable to distinguish between the descriptors used in the original Rome III questionnaire (never, less than one day a month, one day a month, two to three days a month, one day a week, more than one day a week, every day). We, therefore, modified the rating scales to consist of only four descriptors (*i.e.*, never or rarely, sometimes, often, always)<sup>[23]</sup>. Participants were also asked about the presence of each symptom in the previous three months. IBS was defined according to Rome III criteria as recurrent abdominal pain or discomfort at least sometimes in the previous 3 months associated with two or more of the following criteria: (1) improvement with defecation at least sometimes; (2) pain onset associated with a change in stool frequency; and (3) pain onset associated with a change in form (appearance) of stool at least sometimes.

### Assessment of other variables

Standard questionnaires were distributed to collect information on age, gender and educational status. Weight, height and the presence of diabetes mellitus were evaluated by a self-administered questionnaire. Data on smoking were collected through self-reported responses to the questionnaire and participants were categorized as non-smokers, ex-smokers and current smokers. The use of dietary supplements (yes/no) and oral contraceptive pills (OCP) (yes/no) as well as patterns of tea consumption (never or less than 1 cup/mo, 1-3 cups/mo, 1-3 cups/wk, 4-6 cups/wk, 1 cup/d, 2-4 cups/d, 5-7 cups/d, 8-11 cups/d, or at least 12 cups/d) were also assessed by a pre-tested questionnaire. Fluid intake was evaluated through questions on the consumption of water, soft drinks, yogurt drink (“dough”) and other beverages, before, after or during meals, which participants could answer as never, sometimes, often, or always. Regularity of meals was also assessed and quantified as never, sometimes, often, or always having regular meals. Study subjects were also categorized in terms of dental status as fully dentate, lost 1-3 teeth, lost 4-5 teeth, or lost half or more teeth. Quality of chewing was also evaluated (How thoroughly do you chew food?), with responses including: not very well, well, or very well. We also asked participants to describe their feelings/symptoms after milk intake. Lactose intolerance was defined as the existence of abdominal pain, bloating, diarrhea or belching after milk consumption<sup>[24]</sup>.

### Statistical analysis

We categorized participants based on their reported frequency of consumption of spicy foods *i.e.*, never, 1-3 times, 4-6 times, 7-9 times, or 10 times or more during a week. Comparison of continuous variables across different categories of spicy foods consumption was performed using one-way analysis of variance. Distribution of study participants in terms of categorical variables across different categories of intake of spicy foods was compared using  $\chi^2$  test. To assess the relationship between spicy foods consumption and IBS, logistic regression analysis was performed in different models. First, we adjusted for age (continuous) and gender (categorical). We further controlled for smoking (non-smoker, ex-smoker and current smoker), dietary supplement (yes/no) and OCP use (yes/no), self-reported diabetes (yes/no) and body mass index (continuous) in the second model. Additional adjustments were made for meal regularity (never, sometimes, often and always), quality of chewing foods (not very well, well and very well), intra-meal fluid intake (never, sometimes, often and always), dental status (fully dentate, lost 1-3 tooth, lost 4-5 tooth, lost half or more tooth) and pattern of tea consumption (never or < 1 cup/mo, 1-3 cups/mo, 1-3 cups/wk, 4-6 cups/wk, 1 cup/d, 2-4 cups/d, 5-7 cups/d, 8-11 cups/d or at least 12 cups/d). In the final model, a further adjustment was made for lactose intolerance (yes/no). In all analyses, the category of never consuming spicy foods was considered as the reference category. To assess the trend of odds ratios across increasing categories of spicy foods intake, we applied Mantel-Haenszel extension chi-square. A stratified analysis by gender was also performed to examine gender-specific associations. All analysis was performed using SPSS version 16 (SPSS Corp, Chicago, IL, United States). *P* values less than 0.05 were considered statistically significant.

## RESULTS

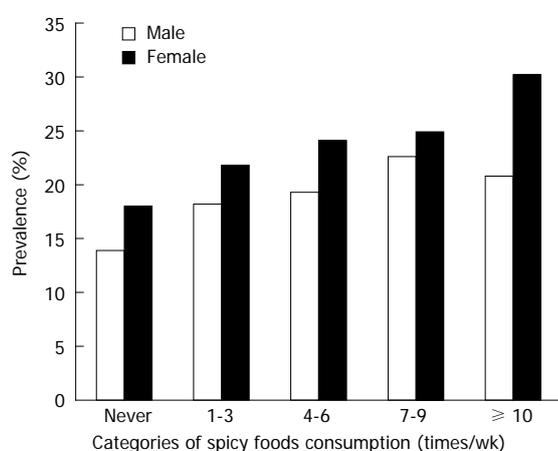

IBS was prevalent among 21.7% (18.6% of men and 24.1% of women) of the study population. General characteristics of study participants across different categories of spicy food consumption are summarized in Table 1. Those consuming spicy foods  $\geq 10$  times/wk were younger, had lower weight and were more likely to be women, married and highly educated compared with those who never consumed spicy foods. High consumption of spicy foods was associated with a lower prevalence of smoking and high prevalence of dietary supplement consumption and OCP use. There was no significant difference in the prevalence of self-reported diabetes among different groups of spicy food intake.

The prevalence of IBS across different categories of spicy foods consumption in the entire study population and each gender is shown in Figure 1. Consumption of spicy foods was associated with an increased prevalence of IBS among women, so that those consuming spicy foods  $\geq 10$  times/wk were more likely to have IBS com-

**Table 1** General characteristics of study participants across different categories of spicy foods consumption

	Consumption of spicy foods (times/wk)					<sup>1</sup> P value
	Never	1-3	4-6	7-9	≥ 10	
Age (yr)	38.0 ± 8.3	37.4 ± 8.4	36.5 ± 7.8	35.1 ± 7.3	33.9 ± 7.6	< 0.001
Weight (kg)	70.3 ± 15.2	70.7 ± 13.4	68.2 ± 12	66.9 ± 14.0	65.4 ± 11.7	< 0.001
BMI (kg/m <sup>2</sup> )	25.1 ± 5.3	25.2 ± 5.0	24.9 ± 4.0	25.0 ± 5.0	24.5 ± 3.8	0.16
Female	38.10%	41.30%	63.50%	73.50%	76.50%	< 0.001

All values are mean ± SD; <sup>1</sup>Obtained from ANOVA or  $\chi^2$  test, as appropriate. BMI: Body mass index; OCP: Oral contraceptive pill.

**Figure 1** Prevalence of irritable bowel syndrome across different categories of spicy food consumption in men and women. Irritable bowel syndrome (IBS) was defined according to the Rome III criteria. Consumption of spicy foods was associated with an increased prevalence of IBS among women ( $P < 0.05$ ). A trend for greater prevalence of IBS with consumption of spicy foods was also seen in men; however, a slight drop in its prevalence was evident in the top category.

pared with those who never consumed spicy foods (30.2% *vs* 18.0%,  $P < 0.05$ ). A trend for greater prevalence of IBS with consumption of spicy foods was also seen in men; however, a slight drop in its prevalence was evident in the top category.

Multivariable adjusted odds ratio (OR) for IBS in the entire study population among different categories of spicy foods intake are illustrated in Table 2. Increased consumption of spicy foods was associated with a greater chance of having IBS in the crude model. After controlling for age and gender, those consuming spicy foods  $\geq 10$  times/wk were two times more likely to have IBS compared with those who never consumed spicy foods. The association remained significant even after taking other cofounders into account (OR = 1.92, 95%CI: 1.23-3.01). Further adjustment for dietary behaviors and lactose intolerance slightly attenuated the association, but it remained significant (OR = 1.85, 95%CI: 1.18-2.90).

Stratified analysis by gender revealed that the association between consumption of spicy foods and IBS

was not significant in men, even after controlling for cofounders (Table 3); however, a significant association was found among women after taking potential cofounders, including meal regularity and lactose intolerance, into account. Those who consumed spicy foods  $\geq 10$  times/wk were twice as likely to have IBS compared with those who never consumed spicy foods (OR = 2.03, 95%CI: 1.09-3.77,  $P_{\text{trend}} = 0.02$ ).

## DISCUSSION

We found that consumption of spicy foods was associated with increased prevalence of IBS among Iranian adults. This association remained significant even after adjustment for potential cofounders, including dietary behaviors. After stratified analysis by sex, the associations remained significant only in women. To the best of our knowledge, our study is among the first population-based studies that assessed habitual intake of spicy foods as a major exposure variable in relation to IBS.

Associations between the consumption of spicy foods and FGIDs, including IBS, have been examined previously<sup>[11,13,14,21,22]</sup>. However, most studies have attempted to use spices to alleviate pain in these patients<sup>[4,25,26]</sup>, and limited data are available on the relationship between habitual consumption of spicy foods and symptoms of IBS<sup>[11]</sup>. Furthermore, prior studies have mostly focused on pepper<sup>[11,13,14,21,22]</sup>, and effects of other spicy foods on IBS remain to be identified. In the current study, we found a significant, and direct, association between consumption of spicy foods and IBS. Our findings are in line with a population-based study in China, which showed a significant association between excessive intake of pepper and prevalence of IBS in adolescents<sup>[14]</sup>. The link between spicy food consumption and IBS symptoms is also supported by an acute, meal-based study<sup>[27]</sup>, in which administration of a standard meal containing 2 g chili, either mixed into the meal or given separately in capsules, caused more abdominal pain and burning in IBS patients than in healthy participants. In contrast, in other studies, ingestion of 4 enteric-coated pills per day (each containing 150 mg of capsaicin-equivalent) for 6 wk, signifi-

cantly improved abdominal pain and bloating in IBS patients<sup>[21]</sup>; ginger was found to be the most common type of complementary and alternative medicine used for IBS treatment<sup>[4]</sup>; cinnamon administration has been found to reduce the number of IBS symptoms<sup>[25]</sup>; and beneficial effects of turmeric on abdominal pain and discomfort in IBS patients have also been reported<sup>[26]</sup>. While the causes for the discrepant study outcomes are not clear, there are a number of potential reasons. Different spices may have different modes of action; almost all studies that reported beneficial effects of individual spices used high doses in the form of supplements, and study designs and methodologies varied markedly between studies. It appears that the current study is the first observational study in an adult population, in which habitual consumption of spicy foods has been linked to IBS, although, due to the use of a single question to assess spicy food intake, it is not possible to distinguish between the potential effects of individual spices.

The mechanisms through which consumption of spicy foods might affect IBS are unknown. The effect of red pepper has been related to its pungent ingredient, capsaicin, which can modify gastrointestinal sensation

*via* transient potential vanilloid 1 (TRPV1) receptors<sup>[11,27]</sup>. Increased TRPV1 receptors are associated with visceral hypersensitivity in the proximal gut and colon<sup>[11,27]</sup>. It seems that capsaicin intake in IBS patients can lead to hypersensitivity, which in turn can result in TRPV1 up-regulation<sup>[4,11,28]</sup>. However, few studies have postulated that intermittent and chronic ingestion of capsaicin or capsaicin containing chili can improve FGID symptoms by desensitization of TRPV1 receptors<sup>[11]</sup>. This can be explained by the action of capsaicin, which when administered chronically, depletes nerve terminals of substance P, while acute application leads to maximal release of transmitters, resulting in pain. Further research is required to prove this hypothesis. The mechanisms of other spices remain to be identified.

This study has several strengths. Firstly, it is a large population-based study, which examined habitual intake of spicy foods, rather than the effects of high doses of spices. Earlier studies have mostly been performed in small sample sizes. Secondly, we performed rigorous statistical analyses, including adjustments for several potential contributing factors to IBS. Therefore, the associations we identified are independent of many factors,

including dietary behaviors. Nevertheless, the findings need to be interpreted in the light of some limitations. We used a pre-tested questionnaire for assessing dietary intakes of spicy foods; misclassification is a potential concern in our study as in any epidemiological studies. In addition, high consumption of spicy foods was associated with a complex pattern of lifestyles that may not have been accurately captured and controlled in our analysis, resulting in residual confounding. The significant direct association of spicy foods intake and IBS may be attributed to the other factors (*e.g.*, having irregular meals, not chewing foods very well, *etc.*) associated with higher intake of these foods. That said, the apparently 1 direct effect of spicy food consumption persisted in multivariate models accounting for known potential confounders. Furthermore, some intermediate factors might lead to changes in diet and may, therefore, confound the association between spicy food intake and IBS. In addition, the observed association may not apply to other sections of the Iranian population, including the young, elderly or those from different socio-economic backgrounds. However, participants in the current study were selected from different areas of Isfahan province with diverse socio-economic status and their dietary intakes covered a broad range of dietary habits. Given these characteristics, it is unlikely that this type of bias could explain the observed associations between spicy food intake and IBS.

In conclusion, we found evidence indicating that spicy food consumption was positively associated with IBS, particularly in women. Further studies, in particular of a prospective nature, are required to examine this association in more detail and to potentially develop novel dietary approaches to manage IBS and other FGIDs.

## ACKNOWLEDGMENTS

We wish to thank all staff of Isfahan University of Medical Sciences (MUI) who participated in our study. We also appreciate staff of the Public Relation Unit, MUI and other authorities of MUI for their excellent cooperation.

## COMMENTS

### Background

The relationship between dietary factors and irritable bowel syndrome (IBS) remains yet to be clearly defined. Some research suggests that carbohydrate, protein, fiber, or water all may play a role. However, currently there are many controversial findings regarding the relationship between diet-related practices and different gastrointestinal disorders including IBS.

### Research frontiers

While some studies have indicated that acute chili ingestion can aggravate abdominal pain and burning symptoms in functional gastrointestinal disorders, chronic ingestion of chili was found to improve functional dyspepsia and gastroesophageal reflux disease symptoms in small controlled studies. It is worth noting that most previous studies focused on one type of spice (*e.g.*, chili pepper), and there are few studies that have investigated the relationships between habitual intake of spicy foods and functional gastrointestinal disorders.

### Innovations and breakthroughs

In a large cross-sectional study, information on habitual spicy food intake and symptoms related to IBS were gathered from 4763 adults using standard questionnaires. Individuals with a high intake of spicy foods ( $\geq 10$  times/wk) had an

almost two-fold increased risk of having IBS compared with those who reported a lower intake of spicy foods. After taking into account different variables that might distort the association between spicy food intake and IBS, the relationship was significant only among women.

### Applications

The findings of the current study, if confirmed in well-designed prospective studies, may assist with the design of novel dietary therapies that take into account, and modify, the dietary intake of spicy foods and, thus, may be useful in the management of IBS related symptoms.

### Peer review

In this interesting manuscript, the authors explored the association between consumption of spicy foods and prevalence of IBS among Iranian adults. They performed a cross-sectional study from 4763 Iranian adult participants. Consumption of spicy foods was estimated using a dietary habits questionnaire, and the prevalence of IBS was estimated using a modified Persian version of the Rome III questionnaire. The study has concluded that consumption of spicy foods is directly associated with IBS, particularly in women. This article is interesting and the readers will get some beneficial information from this.

**RESULTS:** The median follow-up was 30 mo (range, 30-46 mo). Late postoperative complications occurred in 11 (14.7%) patients. Three of these patients required procedure-related reintervention (one diverticulectomy and two excision of staple granuloma). Although the recurrence rate was 10.7%, constipation scores (CSS, ODS score and SSS) significantly improved after STARR ( $P < 0.0001$ ). Significant reduction in ODS symptoms was matched by an improvement in the PAC-QOL and VAS ( $P < 0.0001$ ), and the satisfaction index was excellent in 25 (33.3%) patients, good in 23 (30.7%), fairly good in 14 (18.7%), and poor in 13 (17.3%). Nevertheless, the WS increased after STARR ( $P = 0.0169$ ). Incontinence was present or deteriorated in 8 (10.7%) patients; 6 (8%) of whom were new onsets. Univariate analysis revealed that the occurrence of fecal incontinence (preoperative, postoperative or new-onset incontinence;  $P = 0.028, 0.000, \text{ and } 0.007$ , respectively) was associated with the success of the operation.

**CONCLUSION:** STARR is an acceptable procedure for the surgical correction of ODS. However, its impact on symptomatic recurrence and postoperative incontinence may be problematic.

### Abstract

**AIM:** To assess midterm results of stapled transanal rectal resection (STARR) for obstructed defecation syndrome (ODS) and predictive factors for outcome.

**METHODS:** From May 2007 to May 2009, 75 female patients underwent STARR and were included in the present study. Preoperative and postoperative workup consisted of standardized interview and physical examination including proctoscopy, colonoscopy, anorectal manometry, and defecography. Clinical and functional results were assessed by standardized questionnaires for the assessment of constipation constipation scoring system (CSS), Longo's ODS score, and symptom severity score (SSS), incontinence Wexner incontinence score (WS), quality of life Patient Assessment of Constipation-Quality of Life Questionnaire (PAC-QOL), and patient satisfaction visual analog scale (VAS). Data were collected prospectively at baseline, 12 and 30 mo.

**Core tip:** As a less-invasive surgical procedure, stapled transanal rectal resection (STARR) is becoming an important option in the treatment of obstructive defecation syndrome. However, its clinical and functional outcomes are still conflicting and controversial. The present study assessed the midterm results after STARR performed by the same team in our department to identify factors for predicting outcome. Our data provide evidence to attest the clinic benefits of this pro-

cedure, but its impact on symptomatic recurrence and postoperative incontinence may be problematic.

Midterm outcome of stapled transanal rectal resection for obstructed defecation syndrome: A single-institution experience in China. *World J Gastroenterol* 2013; 19(38): 6472-6478 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6472.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6472>

## INTRODUCTION

Obstructed defecation syndrome (ODS) is defined as the normal desire to defecate but with an impaired ability to evacuate the rectum satisfactorily<sup>[1]</sup>. The anatomical and physiological disturbances underlying ODS are complex and only partly understood, but rectocele and intussusception have been identified as the two most important organic causes of ODS<sup>[2]</sup>.

Although a variety of surgical approaches has been described in the literature for correction of ODS, most of these have high recurrence and complication rates. Stapled transanal rectal resection (STARR) was introduced in 2003 by Longo<sup>[3]</sup> as a minimally invasive transanal operation for ODS associated with rectocele and intussusception. The novel procedure is carried out using double circular stapler devices to resect a full-thickness segment of rectal wall and subsequently to restore normal rectal anatomy. In contrast to traditional techniques, STARR addresses correction of both rectocele and intussusception.

Several multicenter trials have demonstrated that STARR significantly improves constipation with low morbidity and high comfort for patients<sup>[4-8]</sup>. In addition, the procedure could even offer long-term clinical benefits<sup>[9-11]</sup>. Nevertheless, worrisome complications and unsatisfactory functional results have been described<sup>[12,13]</sup>. There are also reports of high rates of reintervention for both symptomatic recurrence and procedure-related complications after this surgery<sup>[14,15]</sup>. As a consequence, although STARR is increasingly being accepted as an important option for surgical treatment of ODS, its clinical and functional outcomes are still conflicting and controversial.

We have shown previously that STARR can be performed safely and is effective for eligible patients with ODS secondary to rectocele and intussusceptions<sup>[16,17]</sup>. The objective of this study was to assess midterm clinical and functional results and to identify factors for predicting outcome after STARR.

## MATERIALS AND METHODS

### Patients

From May 2007 to May 2009, a consecutive series of 86 female patients was treated with STARR for ODS in our Department of Colorectal Surgery at the Second Artillery General Hospital, Beijing, China. A total of 75 (87.2%)

patients completed the scheduled follow-up and formed the study population. All patients were prospectively included in a database. Study protocol was approved by the institutional ethics committee of our hospital. Written informed consent was obtained from all patients enrolled in the study. Preoperative assessment included symptom evaluation, clinical and gynecological examinations, and investigations with proctoscopy, colonoscopy, colonic transit time study, anorectal manometry, and defecography. Anorectal manometry was performed as previously described<sup>[17]</sup>. Patients were carefully selected according to the inclusion and exclusion criteria for STARR proposed by the consensus recommendations<sup>[18]</sup> and the decision-making algorithm<sup>[2]</sup>.

### Surgical procedures

Polyethylene glycol electrolyte solutions were preoperatively prescribed for bowel preparation. Patients received routine broad-spectrum antibiotics immediately after anesthesia induction. Under spinal anesthesia, patients were placed in the lithotomy position with a catheter in the bladder. The STARR procedure was performed using the circular stapler (PPH-01; Ethicon Endo-Surgery, Inc., New Brunswick, NJ, United States) as described previously<sup>[4]</sup>. Subsequent bleeding from the staple line was controlled with full-thickness 2-0 Vicryl stitches (Ethicon Endo-Surgery). All STARR procedures were conducted by the same surgical team.

### Outcome measures

The severity of ODS was quantified by the validated constipation scoring system (CSS; range: 0-30 at increments of 1; no symptoms = 0)<sup>[19]</sup>; Longo's ODS score (range: 0-40 at increments of 1; no symptoms = 0)<sup>[16]</sup>; and symptom severity score (SSS; range: 0-36 at increments of 1; no symptoms = 0)<sup>[7]</sup>. Patient's fecal incontinence was assessed by the Wexner incontinence score (WS; range: 0-36 at increments of 1; perfect continence = 0)<sup>[20]</sup>. The validated Patient Assessment of Constipation-Quality of Life Questionnaire (PAC-QOL) was used to measure the quality of life in patients with ODS<sup>[21]</sup>. The first three subscales of the self-reported questionnaire were used to assess the patient dissatisfaction index, with an overall score ranging from 0 to 96 (lower scores corresponding to better quality of life). The satisfaction subscale included four items with a global score ranging from 0 to 16 (high scores corresponding to better quality of life)<sup>[22]</sup>. Moreover, the index of patient satisfaction was also measured by the visual analog scale (VAS) with scores from 0 to 10, and a higher score suggested an improvement in patient satisfaction with surgery.

### Postoperative follow-up

The patients were followed up in our clinic at 3, 6, 12 and 30 mo postoperatively. At each visit, digital rectal examination was used to assess the anal sphincter, and proctoscopy or colonoscopy to evaluate the anastomosis and the presence or absence of local complications (stenosis,

<sup>1</sup>Unpaired *t* test; <sup>2</sup>Pearson's  $\chi^2$  test; <sup>3</sup>Fisher's exact test. STARR: Stapled transanal rectal resection; CSS: Constipation scoring system; SSS: Symptom severity score; ODS: Obstructed defecation syndrome.

granulomas or mucosal prolapse). We also recorded the occurrence of postoperative complications, which were considered to be early if they occurred within 1 mo after surgery and late if they occurred after this period. A complete clinical reassessment including anorectal manometry and defecography was performed at 12 mo after surgery. Functional results were further updated at 30 mo of follow-up using the same standardized questionnaires (CSS, ODS score, SSS, WS, PAC-QOL and VAS). The STARR procedure was considered successful at 30 mo when PAC-QOL (satisfaction index) scores were classified as excellent, good, or fairly good, defined as follows: 13-16 classified as excellent, 9-12 as good, 5-8 as fairly good, and 0-4 as poor.

### Statistical analysis

Statistical analysis was performed using SPSS 16.0 for Windows XP (SPSS Inc. Chicago, IL, United States). The variation of total scores of the CSS, ODS, SSS, WS, PAC-QoL and VAS were expressed as mean values with 95%CI. Data were compared between groups using the two-sample *t* test, paired *t* test, Pearson's  $\chi^2$  test, Fisher's exact test, and Wilcoxon signed-rank test, as indicated. *P* < 0.05 was considered statistically significant.

## RESULTS

### Preoperative data

Of the 75 female patients (mean age, 54.3 years; range, 29-75 years) included in this study, 60 (80%) had experienced vaginal delivery and 31 (41.3%) were multiparous. Sixty-four (61.3%) patients underwent previous anorec-

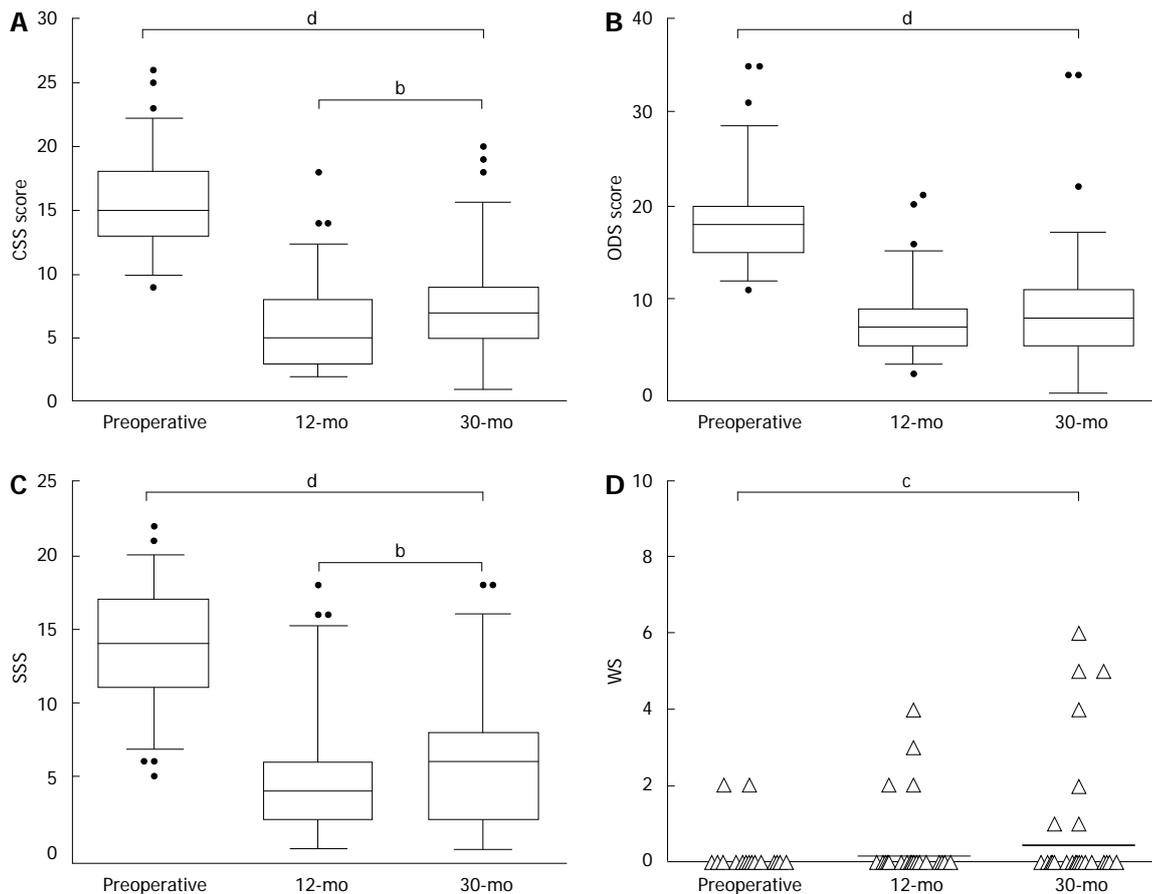

tal/gynecological surgery, including episiotomy (18 patients), hemorrhoidectomy (14 patients), fistulectomy (3 patients), sphincterotomy (1 patient), and hysterectomy (10 patients). Defecographic and manometric findings are detailed in Table 1.

### Perioperative data

A staple-line dehiscence necessitating handsewn suturing was the only intraoperative complication that we observed. There were no major complications, rectovaginal fistula, pelvic sepsis, or deaths. The operative data, early postoperative complications, and short-term results were described in our previous studies<sup>16,17</sup>.

### Late postoperative complications

A total of 12 late complications occurred in 11 patients, giving an overall morbidity rate of 14.7%. The most frequently reported complication was postoperative incontinence, which was present or deteriorated in eight (10.7%) patients. Although defecatory urgency vanished spontaneously in most patients within the first 3 mo postoperatively, one (1.3%) patient reported this complaint at the time of the latest interview. Two (2.7%) patients suffered from inflammatory granulomas on the staple line, which had to be removed because of chronic pain or bleeding. Additionally, there was one (1.3%) case of iatrogenic rectal diverticulum with impacted fecalith confirmed 34 mo after surgery. It presented as severe recurrence of obstructed defecation and was treated by transanal diverticulectomy<sup>123</sup>. Thus, 3 (4%) patients required transanal reintervention for procedure-related complications after STARR.

**Figure 1** Preoperative and postoperative assessment in 75 patients with obstructed defecation syndrome undergoing stapled transanal rectal resection. A: CSS scores (paired *t* test, <sup>b</sup>*P* < 0.01, <sup>d</sup>*P* < 0.01); B: Longo's ODS scores (paired *t* test, <sup>d</sup>*P* < 0.01); C: SSS (paired *t* test, <sup>b</sup>*P* < 0.01, <sup>d</sup>*P* < 0.01); D: WS (paired *t* test, <sup>c</sup>*P* < 0.05). CSS: Constipation scoring system; ODS: Obstructed defecation syndrome; SSS: Symptom severity score; WS: Wexner incontinence scores.

### Follow-up data

Changes in the constipation scores (CSS, ODS score and SSS) and the incontinence scores (WS) are presented in Figure 1. Globally, a significant reduction in the CSS, ODS score and SSS was observed at 12 mo as compared with baseline, and this reduction was maintained at 30 mo [CSS at baseline *vs* 30 mo: 15.57 (95%CI: 14.78-16.36) *vs* 7.07 (95%CI: 6.16-7.98); ODS score: 18.39 (95%CI: 17.27-19.51) *vs* 8.55 (95%CI: 7.12-9.97); SSS: 13.69 (95%CI: 12.74-14.64) *vs* 6.16 (95%CI: 5.12-7.20); *P* < 0.0001 in each group]. However, these scores started to increase slightly after 12 mo [CSS at 12 mo *vs* 30 mo: 5.99 (95%CI: 5.28-6.70) *vs* 7.07 (95%CI: 6.16-7.98); SSS: 4.59 (95%CI: 3.73-5.45) *vs* 6.16 (95%CI: 5.12-7.20), *P* < 0.01; ODS score: 7.49 (95%CI: 6.65-8.34) *vs* 8.55 (95%CI: 7.12-9.97), *P* = 0.07]. Overall, the symptoms of ODS had persisted or recurred in 8 (10.7%) patients with adequate follow-up. Two patients who had initial improvement presented with persistence of ODS symptoms 3 mo after surgery, and another 6 patients developed symptomatic recurrence after 12 mo.

Although the WS rose slightly after STARR, two cases of new-onset fecal incontinence and two of worsened incontinence were observed during 12 mo follow-up, there was no significant difference before and after surgery [WS

at baseline *vs* at 12 mo: 0.05 (95%CI: -0.02-0.13) *vs* 0.15 (95%CI: -0.003-0.30), *P* = 0.052]. However, another four patients had new-onset incontinence after 12 mo and the WS increased significantly at 30 mo follow-up [WS at baseline *vs* at 30 mo: 0.05 (95%CI: -0.02-0.13) *vs* 0.43 (95%CI: 0.09-0.76), *P* = 0.017]. On the whole, incontinence was present or deteriorated in 8 (10.7%) patients, 6 (8%) of whom had new onset.

As shown in Table 2, improvement in the constipation scores was matched by an overall improvement in quality of life as assessed by the PAC-QOL and VAS scores at both 12 and 30 mo follow-up [PAC-QOL (dissatisfaction index) at baseline *vs* 30 mo: 44.45 (95%CI: 41.15-47.76) *vs* 13.21 (95%CI: 10.36-16.07); PAC-QOL (satisfaction index): 0 *vs* 10.12 (95%CI: 9.21-11.03); VAS: 3.83 (95%CI: 3.54-4.11) *vs* 7.07 (95%CI: 6.69-7.46); *P* < 0.0001]. At the end of follow-up, the self-reported definitive outcome was reported as excellent by 25 (33.3%) patients, good by 23 (30.7%), fairly good by 14 (18.7%), and poor by 13 (17.3%). Symptomatic recurrence and postoperative incontinence were the main reasons for a poorer outcome.

### Predictive factors for outcome

In accordance with the patient's assessment of the clini-

**Table 2** Preoperative and postoperative scores of quality-of-life questionnaires and visual analog scale in 75 patients undergoing stapled transanal rectal resection

Items	Median		
	Preoperative	12 mo	30 mo
PAC-QoL (dissatisfaction index)	44	7 <sup>b</sup>	9 <sup>b</sup>
PAC-QoL (satisfaction index)	0	12 <sup>b</sup>	10 <sup>b</sup>
VAS satisfaction index	4	8 <sup>b</sup>	7 <sup>b</sup>

The Wilcoxon signed-rank test was used; All the comparisons *vs* the preoperative data were statistically significant; <sup>b</sup>*P* < 0.01. PAC-QoL: Postoperative scores of quality-of-life questionnaires; VAS: Visual analog scales.

cal outcome at 30 mo follow-up, 17 patient- and disease-related factors were used to compare 65 patients who acquired any improvement after STARR with 13 patients who considered an absence of success for further statistical analyses (Table 1). The result of the univariate analysis revealed that lack of improvement was more likely in patients with fecal incontinence (preoperative, postoperative or new-onset incontinence; *P* = 0.028, 0.000, and 0.007, respectively). However, multiparous, hysterectomy, previous anorectal operation, CSS, ODS score, SSS, and defecographic or manometric findings were not correlated with the functional success of the operation.

## DISCUSSION

Controversy exists in the literature regarding the results after STARR, therefore, this study aimed to evaluate the midterm results and predictive factors for outcome. We assessed a series of 75 patients before and 30 mo after STARR, in which late postoperative complications were seen in 14.7% and reintervention was required in 4%. Despite the recurrence rate of 10.7%, clinical and functional outcome scores (CSS, ODS, SSS, PAC-QOL, and VAS) significantly improved after surgery. Nevertheless, the significant reduction in ODS symptoms was not matched by impairment of the WS. The success of the STARR procedure was associated with the occurrence of fecal incontinence, which was present or deteriorated in 10.7% of patients after surgery.

Several studies have indicated the midterm efficacy of STARR in relieving ODS symptoms with high patient satisfaction rates<sup>[4,5,24-27]</sup>. Similar clinic benefits were obtained in the present study; we were able to demonstrate that defecation difficulties were significantly improved after STARR. Improvement remained stable at 30 mo follow-up as compared with baseline, albeit the constipation scores started increase 12 mo after surgery. Meanwhile, the satisfaction index was reported as excellent in 25 (33.3%), good in 23 (30.7%), fairly good in 14 (18.7%), and poor in 13 (17.3%). Hence, our midterm follow-up suggests that early postoperative benefits were maintained. Other reports, however, showed that ODS symptoms may not improve or even deteriorate after STARR<sup>[13,14]</sup>. The main reason for these conflicting observations may be the patient selection criteria. Inadequate

indications for this operation will necessarily result in poor outcome. The outcomes of an Italian multicenter study were worse in none-selected patients and improvement after STARR was noted in only 65% of the patients<sup>[14]</sup>. In our series, all patients were carefully selected on the basis of the consensus recommendations and the decision-making algorithm<sup>[2,18]</sup>, but further observations should evaluate whether the midterm efficacy deteriorates with time.

Although STARR produced good midterm results, eight (10.7%) patients in our study presented with persistent or recurrent symptoms of ODS. In the literature, the incidence of midterm recurrences is between 4.3% and 17.1%<sup>[5,8,14,28]</sup>. More recently, however, it has been shown that none of the patients who underwent STARR by the curved Contour Transtar stapler had recurrence of ODS symptoms during a 36-mo follow-up<sup>[29]</sup>. This discrepancy may be attributed to the limited capacity of PPH-01 casing with risk of leaving residual disease, especially in patients with large rectocele and intussusception. It should also be stressed that rectocele and intussusception are only the emerging tip of the ODS iceberg syndrome; pelvic floor pathology caused by the “underwater rocks” or occult lesions are likely to persist and contribute to persistent or recurrent symptoms after surgery<sup>[30]</sup>.

Some series therefore have been designed to define predictive factors for outcomes after STARR. Gagliardi *et al*<sup>[14]</sup> have suggested that the results were worse in patients with preoperative digitation, puborectalis dyssynergia, enterocele, larger rectocele, lower bowel frequency, and sense of incomplete evacuation. Contrary to this observation, a subsequent study showed that the number of pelvic floor changes was associated with the success of the operation<sup>[11]</sup>. Another study demonstrated that factors for an unfavorable outcome after STARR included small rectal diameter, low sphincter pressure, and increased pelvic floor descent<sup>[8]</sup>. In the present study, we only indicated that the occurrence of fecal incontinence, including preoperative, postoperative or new-onset incontinence, was associated with poorer midterm outcome. In addition, postoperative incontinence was one of the main reasons for patient dissatisfaction. No doubt more evidence is needed to clarify this issue.

Fecal incontinence after STARR is one of the main concerns of surgeons. Postoperative incontinence and urgency have been reported as being transient and disappeared within 6 mo<sup>[4]</sup>, but were still present after 30 mo in some of our patients. Incontinence may be caused by reduced rectal volume or by muscle stretching and transient sphincter dysfunction secondary to the 36-mm dilator<sup>[4,31]</sup>. We did not systematically evaluate the anal sphincter using ultrasound, but there was no evidence of sphincter dysfunction according to our manometry results. Intriguingly, 6 (8%) patients in our study had new-onset incontinence after the STARR procedure. A possible explanation is that intussusception in the anal canal may function as a barrier with a subsequently beneficial effect on fecal continence. After its removal, fecal incontinence becomes

uncovered<sup>[31]</sup>. Consequently, a careful patient selection with the awareness of occult incontinence is crucial. It is noteworthy that incontinence improves in some patients, which is attributed to improved internal sphincter function after STARR<sup>[6,7,25,28]</sup>. Few patients with preoperative incontinence were enrolled, thus, it could not be assessed in our study.

In the current study, STARR was confirmed as a safe procedure for the treatment of ODS. Nevertheless, an unexpected major complication was observed in one patient who developed an iatrogenic rectal diverticulum after STARR. Concordant with previous findings<sup>[12,32]</sup>, the diverticulum was located along the lateral wall of the rectum, an area of weakness, where anterior and posterior suture lines cross over one another. Iatrogenic diverticulum may also occur as a consequence of technical failure in that the lateral part of the rectal wall remained outside the staple casing during the second resection, or an incomplete section of the mucosal band was retained after STARR<sup>[32]</sup>. To the best of our knowledge, no patient has developed rectal diverticulum after Transtar for the surgical correction of ODS; therefore, this major complication may be the inherent drawbacks of the PPH-01 stapler that could be avoided by using the new device.

We conclude that STARR may be an acceptable procedure for the treatment of patients with ODS caused by rectocele and intussusception, but its impact on symptomatic recurrence and postoperative incontinence may be problematic. In this study, patients were strictly selected and systematically assessed prospectively. However, there were still some limitations such as the lack of a control group. Moreover, postoperative defecography or magnetic resonance imaging with longer follow-up is also crucial for providing more details on pelvic floor anatomy as well as physiology. Finally, this was a midterm follow-up study. Further studies are needed to assess long-term results and to optimize patient selection, which is required to enhance and maintain patient satisfaction after surgery.

## COMMENTS

### Background

Obstructed defecation syndrome (ODS) is a frequent but multifactorial disease that usually afflicts middle-aged women. Although a variety of surgical procedures has been proposed to correct ODS, no one has found unanimous consensus. Stapled transanal rectal resection (STARR) was recently introduced as a minimally invasive transanal procedure, the advantage of which is the simultaneous treatment of rectocele and rectal intussusception, both representing the main anatomical cause of ODS.

### Research frontiers

In recent years, STARR is increasingly being accepted as an important option for surgical treatment of ODS. However, the clinical and functional outcomes after STARR are still conflicting and controversial. In the area of treatment of ODS by the STARR procedure, the research hotspots are how to optimize patient selection and to predict the functional outcome after surgery.

### Innovations and breakthroughs

The authors assessed midterm results and predictive factors for outcome after STARR. Even though the recurrence rate was 10.7%, the clinical and functional outcome scores significantly improved after surgery. In addition, symptomatic recurrence and postoperative incontinence were the main reasons for a poorer

outcome.

### Applications

The study results suggest that STARR may be an acceptable procedure for the treatment of ODS, but its impact on symptomatic recurrence and postoperative incontinence may be problematic.

### Peer review

This study assessed the midterm outcome of STARR for ODS. This topic has been previously studied, and the results of several studies have been discordant. Nevertheless, the topic is interesting for the readers of the journal and suitable to be published.

### Abstract

**AIM:** To develop a fuzzy classification method to score the texture features of pancreatic cancer in endoscopic ultrasonography (EUS) images and evaluate its utility in making prognosis judgments for patients with unresectable pancreatic cancer treated by EUS-guided interstitial brachytherapy.

**METHODS:** EUS images from our retrospective database were analyzed. The regions of interest were drawn, and texture features were extracted, selected, and scored with a fuzzy classification method using a C++ program. Then, patients with unresectable pancreatic cancer were enrolled to receive EUS-guided iodine 125 radioactive seed implantation. Their fuzzy

classification scores, tumor volumes, and carbohydrate antigen 199 (CA199) levels before and after the brachytherapy were recorded. The association between the changes in these parameters and overall survival was analyzed statistically.

**RESULTS:** EUS images of 153 patients with pancreatic cancer and 63 non-cancer patients were analyzed. A total of 25 consecutive patients were enrolled, and they tolerated the brachytherapy well without any complications. There was a correlation between the change in the fuzzy classification score and overall survival (Spearman test,  $r = 0.616$ ,  $P = 0.001$ ), whereas no correlation was found to be significant between the change in tumor volume ( $P = 0.663$ ), CA199 level ( $P = 0.659$ ), and overall survival. There were 15 patients with a decrease in their fuzzy classification score after brachytherapy, whereas the fuzzy classification score increased in another 10 patients. There was a significant difference in overall survival between the two groups (67 d vs 151 d,  $P = 0.001$ ), but not in the change of tumor volume and CA199 level.

**CONCLUSION:** Using the fuzzy classification method to analyze EUS images of pancreatic cancer is feasible, and the method can be used to make prognosis judgments for patients with unresectable pancreatic cancer treated by interstitial brachytherapy.

**Key words:** Digital image processing; Fuzzy classification; Endoscopic ultrasonography; Pancreatic cancer; Interstitial brachytherapy; Prognosis

**Core tip:** Digital image processing (DIP) of endoscopic ultrasonography (EUS) images has been proven to be useful in diagnosis of malignant tumor. Currently commonly used method of DIP is only to concludes the dif-

ferential diagnosis of solid tumors (“yes” or “no”), can not provide the numerical data describing the texture parameters in the EUS image. EUS-guided brachytherapy has been applied preliminarily in the study of advanced pancreatic cancer. However, prognosis judgment of these patients was still difficult. So we develop a fuzzy classification method to score texture features of pancreatic cancer in EUS images to supply more information and validated its utility in prognosis judgment of patients with unresectable pancreatic cancer treated by EUS-guided interstitial brachytherapy.

Xu W, Liu Y, Lu Z, Jin ZD, Hu YH, Yu JG, Li ZS. A new endoscopic ultrasonography image processing method to evaluate the prognosis for pancreatic cancer treated with interstitial brachytherapy. *World J Gastroenterol* 2013; 19(38): 6479-6484 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6479.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6479>

## INTRODUCTION

The application of digital image processing (DIP) in endoscopic ultrasonography (EUS) images and other imaging scenarios has been proven to be a useful adjunct to endoscopic diagnoses and often comparable with specialists’ interpretation in different pathologic settings<sup>[1-3]</sup>. The texture parameters of EUS images are extracted and classified from the returned echoes to identify the tissue type present in the images. One effective approach is to use DIP based on a support vector machine (SVM), which is a computer algorithm that learns by example to assign labels to objects<sup>[4,5]</sup>. The SVM technique, as a subfield of digital signal processing, has been applied to a series of pathologically proven diseases<sup>[6-12]</sup>.

The typical method of SVM, which is only able to provide a differential diagnosis for solid tumors (“yes” or “no”), cannot provide numerical data describing the texture parameters in the EUS image. In this study, a new DIP method based on fuzzy classification is applied to obtain the feature value of texture parameters in EUS images of pancreatic cancer and observe the change of texture parameters to evaluate its utility in making prognosis judgments for patients with unresectable pancreatic cancer after EUS-guided interstitial brachytherapy.

## MATERIALS AND METHODS

The whole study protocol was approved by the Institutional Review Board and Ethics Committees of the Second Military Medical University. All patients had provided their written informed consent before the study. DIP of EUS images using the fuzzy classification method was retrospective, whereas its application in the prognosis evaluation was prospective.

### Principle of fuzzy classification

Given that the unidentified object  $u$  had  $p$  classes, which

meant there were  $p$  cases that such an object could be classified to, a number of features were extracted from the object  $u$ , and the sum of these features had a membership degree  $\mathcal{A}$  to every class. Therefore, the membership degree of the unidentified object  $u$  to each class was  $\mathcal{A}_1(u), \mathcal{A}_2(u), \dots, \mathcal{A}_p(u)$ . It is generally assumed that the larger the membership degree’s value of a certain class is, the greater the feature value of the objects belonging to this class will be.

Given that the  $j$ th feature extracted from the unidentified object  $u$  was  $u_j$ , its membership degree to the  $j$ th feature of class  $i$  was:

$$\mathcal{A}_{ij}(u) = (1 + (u_j - a_{ij})^2 / \sigma_{ij}^2)^{-1} \quad (1)$$

where  $a_{ij}$  was the  $j$ th feature’s mean value for the training data belonging to class  $i$ , and  $\sigma_{ij}$  was the variance.

Thus, every feature of the unidentified object  $u$  could obtain a membership degree to class  $i$ . In addition, a corresponding weight  $\alpha_j$  was also assigned to it. Therefore, the membership degree of belonging to class  $i$  should be:

$$\mathcal{A}_i(u) = \left| \sum_{j=1}^m (\alpha_j \times \mathcal{A}_{ij}(u)) \right| \quad (2)$$

The weights could be optimized by taking advantage of the training data.

In terms of the application object in this study, there were two classes: pancreatic cancer and non-pancreatic cancer. For an unidentified case, its membership degree to the two categories  $\mathcal{A}_1$  and  $\mathcal{A}_2$  was computed, and then the feature value was obtained according to the following normalized evaluation function:  $Eval = [\mathcal{A}_1 / (\mathcal{A}_1 + \mathcal{A}_2)] \times 100\%$ . The object is more likely to be a cancer as the feature value gets closer to 100%, and vice versa. Thus, the fuzzy classification of pancreatic cancer was achieved.

### Processing of the fuzzy classification method

The analysis database of EUS images was compiled from data collected between March 2005 and December 2007, which was described in a previous study of our group<sup>[14]</sup>. All EUS procedures were performed with an Olympus GF-UM2000 at 7.5 MHz. Regions of interest (ROIs) of all EUS images were manually outlined by endoscopic specialists who were blind to the final diagnosis. Texture features were extracted from every ROI and analyzed using a C++ program. Texture features generally referred to the spatial arrangement and interconnection of the basic elements of images<sup>[15]</sup>. The sequential forward search algorithm was applied to select the features after extracting the feature. Then, a few optimum feature combinations were obtained<sup>[16,17]</sup>. Finally, real time was taken into account, and 22 features falling into three categories were selected. First, the mean feature value of the image was extracted. It was a first-order statistical feature. Second, the gray level co-occurrence matrix (GLCM) features were selected, which were based on the second-order joint feature distribution matrix of the images proposed by Haralick *et al*<sup>[18]</sup>. GLCMs for four directions (0°, 45°, 90°, and 135°) were constructed. For each matrix, five features were extracted, which were energy, entropy, moment of inertia, correlation, and local stationary. Finally,

the fractal feature was obtained. Recently, the fractal dimension feature has been widely used in pattern recognition and texture analysis. In this study, the second-order multi-fractal dimension feature was used, and the differential box-counting approach was applied to calculate the fractal dimension<sup>[19,20]</sup>. The previously described fuzzy classification method assessed all the features contained in the ROI of the EUS image and estimated a score between 0 and 100. Given that two states existed - cancer and a normal pancreas - 0 represented all the features of a “normal pancreas” that were contained in the ROI with no “cancer” features, whereas 100 represented all the features of “cancer” with no “normal pancreas” features.

### Application of the fuzzy classification method

Written informed consent for EUS-guided interstitial brachytherapy (EUS-guided iodine 125 radioactive seed implantation) was required from all included patients. Patient eligibility criteria included histologically confirmed unresectable pancreatic adenocarcinoma. To be included in the study, patients had to have a Karnofsky performance status score  $\geq 60$  and be expected to survive for more than 2 mo after diagnosis; in addition, they had to exhibit adequate bone-marrow function (absolute neutrophil count  $\geq 1.5 \times 10^9$  cells/L, platelet count  $\geq 100 \times 10^9$ /L, and hemoglobin  $\geq 100$  g/L), kidney function (serum creatinine  $\leq 132.6$   $\mu$ mol/L), and a prothrombin time within 3 s of the control. Exclusion criteria included the inability to give informed consent. Abdominal pain and other accompanying diseases had to be controlled in all patients before inclusion in the study. While receiving implantation treatment, the patients received other necessary treatments such as chemotherapy or biological therapy. The procedure used for radioactive seed implantation was the same one detailed in our previous description<sup>[21]</sup>.

All patients received repeated EUS before and after brachytherapy. All images were reviewed by endoscopists who were blinded to the prognosis. A total of 10 EUS images, 5 images each before and after brachytherapy, were chosen for each patient. The boundary of the ROI was manually delineated, and all the feature values within the ROIs were averaged together. By setting the appropriate range for the estimated scores, the influences of necrotic tissue and radioactive seeds on the calculation results were avoided. The fuzzy classification method calculated two scores for every patient.

All patients were evaluated by weekly physical examinations, complete blood counts, and chemistry profiles. The serum level of carbohydrate antigen 199 (CA199) was measured every 3 wk after the therapy. Standard WHO response criteria were used to define the best anti-tumor effects, toxicities, complications, and adverse events<sup>[22]</sup>. Tumor assessment by the same endoscopic expert with an EUS scan was required every 3 mo. The largest and smallest diameters were recommended to be measured by EUS, and the tumor volume was estimated according the following formula:  $V = 1/2 ab^2$ , where  $a$  and  $b$  are the largest and smallest tumor diameters, re-

spectively, and  $V$  is the tumor volume. Overall survival (OS) was calculated from the day of treatment until the date of death.

### Statistical analysis

The descriptive results of continuous variables were presented as the median (interquartile range, IQR). The relationships between the change of fuzzy classification score, tumor volume, CA199 level, and overall survival were assessed using the Spearman rank correlation test. The patients were divided into two groups according to an increase or decrease in the fuzzy classification score. The overall survival rates of the two groups were compared using the log-rank test. The inter-group comparison of the change of tumor volume and CA199 level was conducted by a Mann-Whitney  $U$  test. The results were considered statistically significant at  $P < 0.05$ . Statistical analyses were performed using the Statistical Package for Social Sciences software (SPSS version 18.0).

## RESULTS

### Database of EUS images

Between March 2005 and December 2007, 153 patients with pancreatic cancer and 63 non-cancer patients with a normal pancreas (20 patients) or chronic pancreatitis (43 patients) were included in the analysis database. All EUS images of these patients were analyzed. The ROIs were drawn, and texture features were extracted and selected.

### Characteristics of the included patients

From April 2007 to March 2009, a total of 25 consecutive patients were enrolled. There were fourteen men and eleven women, with a median age of 67 years (range 54-80 years) and a median KPS score of 80 (range 60-90). Five patients were in stage III, and twenty were in stage IV. The average number of seeds (0.5 mCi per seed) implanted was 14.6 per patient (range 5-30 per patient). All patients tolerated the brachytherapy well without any complications throughout the study.

### Change of the fuzzy classification score

A total of 250 EUS images from the 25 patients were analyzed using the fuzzy classification method, and every patient was scored twice. There was a correlation between the change in the fuzzy classification score and overall survival ( $r = 0.616$ ,  $P = 0.001$ ), whereas no correlation was found to be significant between the change of tumor volume ( $P = 0.663$ ), CA199 level ( $P = 0.659$ ), and overall survival. There were 15 patients with a decrease in the fuzzy classification score after the brachytherapy, whereas the fuzzy classification score increased in other 10 patients (Table 1). There was a significant difference in the overall survival between the two groups (67 d *vs* 151 d,  $P = 0.001$ , Figure 1). There was no significant difference in the change of tumor volume ( $P = 0.345$ ) and CA199 level ( $P = 0.371$ ) between the two groups (Table 1).

**Table 1** The change in the fuzzy classification result and clinical parameters after brachytherapy in 25 unresectable pancreatic cancer patients

No.	FCS before brachytherapy	FCS after brachytherapy	FCS <sup>1</sup>	Tumor volume <sup>1</sup>	CA199 <sup>1,2</sup>	Survival time (d)

<sup>1</sup>The parameter change was calculated by (pre-post)/pre; <sup>2</sup>When the levels of carbohydrate antigen 199 (CA199) were larger than 1000 μmol/L before and after treatment, 0% meant no improvement; <sup>3</sup>*P* = 0.001. FCS: Fuzzy classification score; NA: Not available.

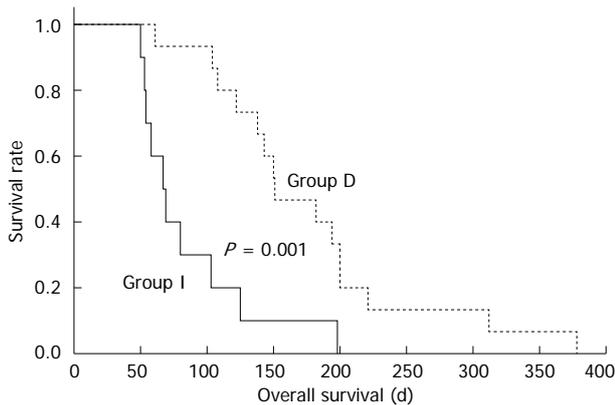

## DISCUSSION

The analysis of texture features is the core of DIP of digital images. Texture features are helpful for classifying lesions on sonography, and the potential of sonographic texture analysis to improve tumor diagnosis has already been demonstrated<sup>[23-27]</sup>. However, only a few reports exist about the application of DIP techniques to EUS. For the diagnosis of pancreatic cancer, research using DIP and pattern recognition remains rare. Two recent studies successfully used neural network analysis of EUS images to differentiate pancreatic cancer from chronic pancreatitis<sup>[1,3]</sup>. Das *et al.*<sup>[3]</sup> reported high sensitivity (93%) and specificity (92%), with excellent positive predictive values (87%) and negative predictive values (96%). An SVM model was evaluated as a potential method to differentiate between malignant and benign lesions with excellent accuracy rates<sup>[28]</sup>. Its performance characteristics in differentiating pancreatic cancer from benign lesions or normal tissue of the pancreas are closely rivaled by those of EUS-FNA.

In our study, the feature extraction and selection based on fuzzy classification was applied to EUS images of pancreatic cancer patients. All the work was carried out by the developed C++ program. According to the fuzzy algorithm, the classification result was not just “yes” or “no”, but a score from 0 to 100<sup>[2,13,29]</sup>. Compared with the SVM method<sup>[13]</sup>, the fuzzy classification method

proposed in our study could additionally give the precise numerical difference between a cancer case and a non-cancer case.

EUS-guided brachytherapy has been applied preliminarily in the study of advanced pancreatic cancer<sup>[30]</sup>. Two clinical series showed that pancreatic cancer could be treated safely with EUS-guided brachytherapy with pain control<sup>[31,32]</sup>. The number of patients enrolled in these two series was 22 and 100, respectively, with stage III or IV pancreatic cancer in a majority of cases. The estimated median overall survival in the two studies was 9.0 and 7.0 mo. The brachytherapy’s effect on overall survival was uncertain because of the lack of a control. Meanwhile, making prognosis judgments for these patients is still difficult. Given that brachytherapy aims to destroy the tumor closely, if it were effective, the EUS images of pancreatic cancer ought to change to be more similar to those from a normal pancreas, and the fuzzy classification score of EUS images after the brachytherapy ought to show a decrease. Thus, the change of the fuzzy classification score most likely reflected the treatment effect to some extent and the prognosis after brachytherapy. Our study results validated this hypothesis. First, the change of the fuzzy classification score was significantly correlated with overall survival, which meant the more the score decreased, the longer the patient survived. Second, 15 of 25 patients (60%) had a decreased fuzzy classification score after the

**Figure 1** Survival curve of two groups of patients with pancreatic cancer treated with endoscopic ultrasonography-guided interstitial brachytherapy. Group I ( $n = 10$ ): Patients whose fuzzy classification score increased after the brachytherapy. Group D ( $n = 15$ ): Patients whose fuzzy classification score decreased after the brachytherapy.

brachytherapy. The median overall survival was nearly 5 mo. As a control, the fuzzy classification results increased in 10 patients after treatment, and the median overall survival was only approximately 2 mo. The log-rank test indicated a significant difference between these two groups.

The tumor volume is an important candidate for making prognosis evaluations for pancreatic cancer. In our study setting, the metal package of radioactive seeds made it difficult to measure the tumor volume by computed tomography. Thus, the EUS scan was a more suitable and convenient way to measure the volume. Meanwhile, as a diagnostic marker, CA199 is also another candidate for prognosis evaluation<sup>[53]</sup>. However, our results found no association between the change of tumor or CA199 and the overall survival, which meant they were not a suitable prognosis marker in the patient population.

There were some limitations in our study. The new method can distinguish pancreatic cancer from chronic pancreatitis or a normal pancreas, but it cannot differentiate different cancer types. The probable approach to overcome this problem is to train multiple, 1-*vs*-all classifiers<sup>[19]</sup>. Furthermore, enlarging the sample size and selecting new effective features are future possibilities for further study to improve the practicability of the technique.

In conclusion, the fuzzy classification method to score texture features of pancreatic cancer in EUS images is feasible and can be used as an effective tool to judge the prognosis of patients with unresectable pancreatic cancer treated by interstitial brachytherapy.

## COMMENTS

### Background

The application of digital image processing (DIP) in endoscopic ultrasonography (EUS) images and other imaging scenarios has been proven to be a useful adjunct to endoscopic diagnoses and is often comparable with specialists' interpretations in different pathologic settings. The typical method of support vector machine, which is only able to provide a differential diagnosis for solid tumors

("yes" or "no"), cannot provide numerical data describing the texture parameters in the EUS image. Thus, authors applied a new DIP method based on fuzzy classification to quantify the images and supply more information about the status of pancreatic cancer.

### Research frontiers

The prognosis for pancreatic cancer is poor, and the effects of all currently available therapies are poor. EUS-guided brachytherapy has been applied preliminarily in the study of advanced pancreatic cancer as a potential new therapy. However, making prognosis judgments for these patients after brachytherapy is still difficult. EUS has become a useful tool to monitor cancer lesions. DIP of the change in EUS images after brachytherapy may be useful for making prognosis judgements.

### Innovations and breakthroughs

Making prognosis judgments for patients with unresectable pancreatic cancer after EUS-guided interstitial brachytherapy is difficult. Authors developed a new DIP method based on fuzzy classification to analyze EUS images of pancreatic cancer, and they validated its utility in making prognosis judgements.

### Applications

The new DIP method based on using fuzzy classification to analyze EUS images supplies more information than other DIP methods and has a significant potential to assist in clinical decision making in terms of diagnosis, prognosis, and diseases monitoring, especially for solid tumors.

### Terminology

Fuzzy classification is the process of grouping elements into a fuzzy set whose membership function is defined by the truth value of a fuzzy propositional function.

### Peer review

This study provided a new method to evaluate the effect of EUS-guided interstitial brachytherapy on unresectable pancreatic cancer. Through digital image processing of EUS images, the current study indicates that using the fuzzy classification method to score the texture features of pancreatic cancer in EUS images is useful for making prognosis judgments for patients with unresectable pancreatic cancer treated by interstitial brachytherapy.

### Abstract

Developmental abnormalities are rare in the liver. This study presents two case reports of ectopic liver. The first case was a 31-year-old male with clinical indication for laparoscopic appendectomy. Laparoscopy identified a perforated appendix and an unknown tumorous lesion in the ligamentum hepato umbilicalis. The patient underwent a laparoscopic appendectomy, intraoperative lavage of the peritoneal cavity, and extirpation of the lesion in the ligamentum hepato umbilicalis. Histopathological examination of the excised tumor revealed that it comprised liver tissue with fibrinous changes. The tumor was completely separate from the liver with no connection. It was classified as an ectopic liver. No further therapy was required. The second case was a 59-year-old male with a tumor on the upper pole of the spleen, incidentally diagnosed in an ultrasound examination. The biopsy raised suspicion of hepatocellular carcinoma. A positron emission tomography-computed

tomography examination revealed accumulation of F-18 fluorodeoxyglucose only in the tumor. The patient underwent a splenectomy with a resection and reconstruction of diaphragm. After the hepatocellular carcinoma was confirmed, adjuvant therapy (sorafenib) was initialized. The operations and postoperative recoveries were uncomplicated in both cases. Despite the low incidence of ectopic liver and rare complications, it is necessary to maintain awareness of this possibility. The potential malignancy risk for ectopic liver tissue is the basis for radical surgical removal. Therapy for hepatocellular carcinoma in an ectopic liver follows the same guidelines as those followed for treating the "mother" liver.

**Key words:** Ectopic; Liver; Hepatocellular carcinoma; Diagnostic; Treatment

**Core tip:** Ectopic liver presents a rare clinical finding resulting from liver tissue migration to various organs during embryogenesis. Although the condition is typically asymptomatic, it can lead to different clinical manifestations such as intraabdominal bleeding or hepatocarcinogenesis. The potential malignancy risk is the basis for radical surgical removal; which represents the only correct solution. Therapy for hepatocellular carcinoma in an ectopic liver follows the same guidelines (National Comprehensive Cancer Network Guidelines) as those followed for treating the "mother" liver. Despite the low incidence of ectopic liver and rare complications, it is necessary to maintain an awareness of this possibility.

## INTRODUCTION

The liver is the largest abdominal organ. It occupies a substantial portion of the upper abdominal cavity. Abnormalities in the position or number of liver parts are considered rare developmental anomalies. They are typically asymptomatic, and incidental detection, though extremely rare, may occur during an operation or autopsy. The incidence of ectopic liver is 0.24%-0.56%, according to data described in laparoscopic or autopsy studies<sup>[1-3]</sup>, but this estimate seems high. Most authors distinguish two types of ectopic liver. The first is an accessory liver lobe connected to the liver, and the second is a truly ectopic liver. Collan classified four types. The first is the ectopic liver, which is not connected to the mother liver, but is typically attached to the gallbladder or intra-abdominal ligaments. The second is a microscopic ectopic liver, which is occasionally found in the gallbladder wall. The third is a large accessory liver lobe, attached to the mother liver by a stalk (pedunculated liver). The fourth is a small, accessory liver lobe attached to the mother liver<sup>[4]</sup>. Here, we presented two manifestations of ectopic livers.

## CASE REPORT

### Case 1

A 31-year-old male patient was admitted with an 8-h history of pain in the right lower abdominal quadrant with a gradual onset. The patient reported nausea, but no vomiting, normal bowel function, and normal miction. He was subfebril, but no infection was observed. His medical history included pollinosis. He took no regular medication and had no previous surgeries.

The clinical examination showed right lower quadrant abdominal pain with tenderness. The bowel sounds were diminished. The patient was hemodynamically stable without any signs of sepsis (temperature 37.5 °C, noninvasive blood pressure 120/80 mmHg, heart rate 76 beats/min, respiratory rate 14 breaths/min). The white blood count was 14800 cells/mL and C-reactive protein was 12.3 mg/L. Other biochemical results were normal and the urinalysis revealed no pathological findings. An abdominal ultrasound showed a small amount of pericapsular fluid. No other abnormal findings were identified by ultrasound in other parts of the abdomen or pelvis.

The signs and symptoms suggested appendicitis; therefore, we performed an acute laparoscopic appendectomy. First, antibiotic therapy was introduced. Initially, the routine diagnostic laparoscopy revealed perforated appendicitis with circumscribed peritonitis. Incidentally, a small oval tumor (3 cm × 2 cm × 2 cm) was found in the ligamentum hepato umbilicalis next to the liver (Figure 1). No other pathological signs were observed. The appendectomy was performed, followed by an intraoperative lavage of the peritoneal cavity. The tumor was excised. The operation and the postoperative recovery were uncomplicated. The patient was discharged on the third postoperative day. The histology of the appendix revealed an ulcerophlegmonous appendix. The histopath-

Figure 1 Small oval tumor (3 cm × 2 cm × 2 cm) was found in the ligamentum hepatoumbilicalis next to the liver.

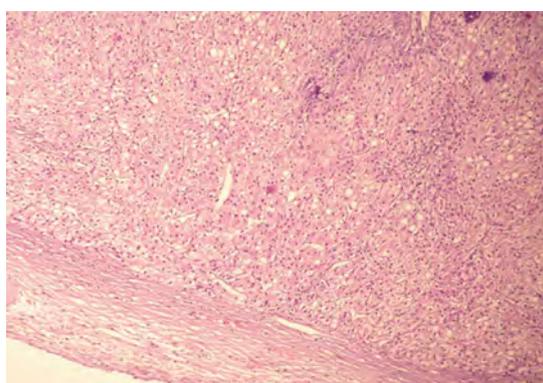

Figure 2 Histopathology of the tumor from the ligamentum hepatoumbilicalis (liver tissue with moderate steatosis and a thick fibrotic capsule).

ological examination of the tumor from the ligamentum hepato umbilicalis revealed liver tissue with moderate steatosis and a thick fibrotic capsule (Figure 2). The specimen examination showed that the tumor was completely separate, with no connection to the liver. It was classified as the first type of ectopic liver according to the Collan classification. No further therapy was required.

### Case 2

During an ultrasound examination, a 59-year-old male was incidentally diagnosed with a tumor (10 cm × 8 cm × 6 cm) on the upper pole of the spleen. The finding was confirmed with a computed tomography (CT) scan (Figure 3), and a biopsy was performed. A histological examination of the biopsy specimen, including immunohistochemistry, raised the suspicion of a metastatic hepatocellular carcinoma, but bile production was not caught and renal carcinoma could not be reliably ruled out. To detect the primary tumor location, we performed a positron emission tomography-computed tomography examination. This showed a localized accumulation of F-18 fluorodeoxyglucose only in the suspicious tumor. There was no other pathological finding in the abdominal or thoracic cavities. The medical history included toxic-nutritive hepatopathy (alcoholic liver disease) and chronic gastritis. The biochemical results were within normal

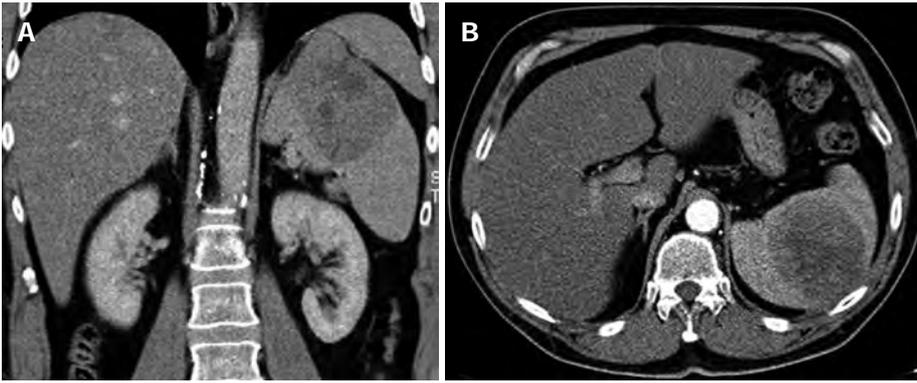

Figure 3 Tumor (10 cm × 8 cm × 6 cm) on the upper pole of the spleen. A: Computed tomography scan, arterial phase with a coronal reconstruction; B: Computed tomography scan, arterial phase - axial orientation.

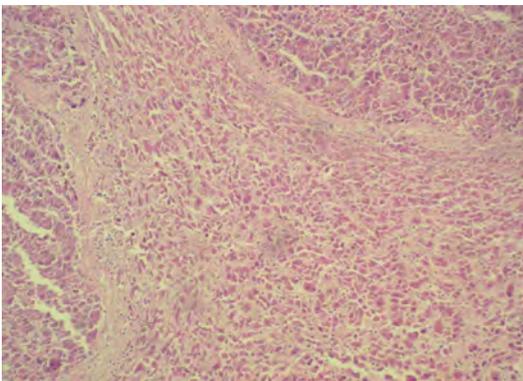

Figure 4 Histopathology of the hepatocellular carcinoma found in an ectopic liver in the spleen.

limits, and oncomarkers (carcinoembryonic antigen, alfa-fetoprotein, CA 19-9) were negative. A perioperative examination confirmed that the tumor was located on the upper pole of the spleen and was connected to diaphragm, but did not invade other surrounding tissues. It was classified as the first type of ectopic liver according to the Collan classification. No other pathology was found in the abdomen. A splenectomy was performed, with partial diaphragm resection and reconstruction. The postoperative recovery was uneventful. A definitive histological examination, including immunohistochemistry, confirmed a hepatocellular carcinoma (HCC) in the spleen tissue (Figure 4). Two small additional tumor sites (satellite tumors) were found in addition to the main lesion. Several investigations showed that the orthotopic liver tissue was negative for HCC, but a histological verification (a biopsy of the mother liver tissue) was not performed. Due to the high risk of tumor recurrence (additional tumor sites were found), we initialized a targeted adjuvant therapy with sorafenib. The American Association for the Study of Liver Diseases (AASLD) practice guidelines on the management of hepatocellular carcinoma do not recommend the routine use of adjuvant therapy with sorafenib (recurrence rates reduction was not reliably proven)<sup>[5]</sup>, nevertheless, there are data available that indicate that sorafenib was effective for treating patients with advanced HCC<sup>[6,7]</sup>.

## DISCUSSION

In development, the hepatic diverticulum comprises the liver and biliary tree, and it appears late in the third week or early in the fourth week of gestation. The foregut endoderm of the hepatic diverticulum develops into the liver parenchyma (hepatocytes) and the epithelial lining of the biliary tract. The hepatic diverticulum divides to form a small ventral portion, the future gall bladder, and a larger cranial portion, the liver primordium. Developmental errors are relatively rare in the liver. Other errors in foregut development are more frequently observed, like errors in pancreas or duodenum formation<sup>[8]</sup>. Liver tissue can migrate to various organs during embryogenesis. Sites of ectopic liver include the gallbladder, spleen, retroperitoneum, pancreas, adrenal gland, portal vein, diaphragm, thorax, gastric serosa, testes, and umbilical vein<sup>[9]</sup>. Most authors distinguish ectopic and accessory liver formations, based on whether there is a connection to the mother liver. The Collan Classification mentioned above is not widely used. In many cases, it is difficult to make a clear distinction between ectopic liver and accessory liver. The precise incidence of ectopic liver or accessory liver is unknown. Examination of several studies indicated that the incidence is approximately 0.24%-0.56%. Watanabe's series of 1060 patients revealed an incidence of 0.47% for ectopic liver and 0.09% for accessory liver. These numbers could be over-estimated, because histological verification was not performed in all cases. Ectopic and accessory liver are typically asymptomatic, but occasionally they cause unexpected problems, like intra-abdominal bleeding or hepatocarcinogenesis. The first clinical sign of ectopic or accessory liver could be an acute complication that leads to acute surgery and diagnosis of ectopic liver. Various clinical symptoms, like recurrent abdominal pain and impaired liver function could be caused by ectopic or accessory liver, but in the majority of cases, an ectopic/accessory liver remains undetected.

In some cases, the ectopic or accessory liver may undergo torsion, infarction, rupture, or other disorders. Torsion and subsequent infarction of an accessory liver lobe has been described in children and adults<sup>[10-14]</sup>. Ladurner

presented a very interesting case of a patient with hepatic ischemia caused by complete vascular occlusion due to a twisted accessory liver lobe. In that case, the accessory liver lobe produced serious, life-threatening problems, and an orthotopic liver transplantation was performed<sup>[15]</sup>. Ito reported a small omphalocele that involved an accessory liver lobe embedded in the cranial portion of the amniotic sac. In that case, the pedicle of liver tissue was markedly elongated<sup>[16]</sup>.

An ectopic or accessory liver can lead to benign or malignant diseases. Benign cases in the literature report hemangiomas, adenomas, or focal nodular hyperplasia associated with an ectopic or accessory liver<sup>[17-19]</sup>. Benign lesions seem to be less frequent; however, the higher frequency of malignancies could be based on the fact that many benign lesions remain undiagnosed because they are asymptomatic. Moreover, due to their abnormal locations, asymptomatic lesions may be misdiagnosed in the absence of histology.

The ectopic liver has been associated with malignancies more often than with benign lesions. Many authors have pointed out that ectopic liver tissue is more predisposed to malignancy than normal liver tissue. Ectopic livers have completely functional architecture, but may be metabolically handicapped; this may facilitate carcinogenesis. Ectopic liver tissue also has increased neoplastic potential compared to orthotopic liver tissue. This may have given rise to the hypothesis that ectopic livers are particularly predisposed to the development of hepatocellular cancer. A high incidence of hepatocellular cancer in ectopic livers was described in Japan<sup>[20]</sup>. In most cases, a malignant tumor was found in the ectopic liver, but not in the mother liver. Ectopic or accessory livers with cancer may be amenable to surgical resection. Many case reports have described surgical treatments. Some authors suggested that the outcome after resection to remove hepatocellular cancer was superior when it involved an ectopic or accessory liver, compared to when it involved the mother liver. However, long-term follow-up data are poor.

Many anatomical locations have been described for ectopic livers with cancer<sup>[20-23]</sup>. The favorable outcome after resection of ectopic livers could depend on the specific anatomical location<sup>[24,25]</sup>. Shigemori described a case of ectopic hepatocellular carcinoma in the jejunum<sup>[26]</sup>. Cardona *et al.*<sup>[27]</sup> reported a case of a primary, well-differentiated hepatocellular carcinoma arising from ectopic liver tissue in the pancreas. Leone presented interesting data regarding three cases of hepatocellular carcinomas that arose in ectopic livers. The clinical presentations were very interesting; one patient reported dull epigastric pain; the second reported abrupt onset with signs and symptoms of acute abdomen caused by intra-abdominal bleeding; and the third presented with an unexplained, progressive increase in alpha-fetoprotein serum levels<sup>[28]</sup>. Seo *et al.*<sup>[29]</sup> reported a case of hepatocellular carcinoma that arose from hepatic parenchyma located in the left subphrenic space in the upper portion of the gastrosplenic

ligament. The preoperative diagnosis was a nonspecific stomach mass, with suspicion of gastrointestinal stromal tumor. An operation was performed laparoscopically. Takavasu reported another case with high serum alpha-fetoprotein combined with a suspicion of a submucosal stomach tumor<sup>[30]</sup>. The two latter cases diagnosed the ectopic liver postoperatively, after histological examination.

It is important to consider an ectopic/accessory liver when evaluating perihepatic lesions. It is common to misdiagnose an ectopic liver as a malignant tumor. Stat-taus suggested that the diagnosis should be based on a biopsy of ectopic liver or a NMR with liver specific contrast<sup>[31]</sup>. However, all investigative imaging methods are limited for diagnosing an ectopic/accessory liver, due to its limited volume. Despite the low incidence and rare complications of ectopic/accessory liver, it is necessary to maintain an awareness of this possibility. Because this entity presents with a broad spectrum of clinical symptomatology, it is rarely diagnosed; thus, most discoveries of ectopic and accessory liver are incidental. An elevation in serum alpha-fetoprotein and lack of focus in liver CT image may be the first signs of malignant transformation in an ectopic liver. The suspicion of hepatocellular carcinoma in an ectopic liver is substantial reason for radical surgical removal of an ectopic liver found incidentally. When hepatocellular carcinoma is definitely, histologically confirmed in an ectopic liver, it should be treated with the same approaches used for treating carcinoma in the mother liver (National Comprehensive Cancer Network Guidelines).

### Abstract

Duodenal duplication cysts are benign rare congenital anomalies reported mainly in the pediatric population, but seldom in adults. Symptoms depend on the type and location and can present as abdominal pain, distension, dysphagia or dyspepsia. They have been reported to be responsible for duodenal obstruction, pancreatitis and, in rare cases, gastrointestinal bleeding. We present a case of a duodenal duplication cyst in a 43-year-old man presenting as melena. Initial gastroduodenoscopy and colonoscopy did not reveal any bleeding focus. However, the patient began passing melena after 3 d, with an acute decrease in hemoglobin levels. Subsequent studies revealed a duplication cyst in the second portion of the duodenum which was surgically resected. Histology revealed a duodenal duplication cyst consisting of intestinal mucosa. There was no further bleeding and the patient recovered completely. In rare cases, duodenal duplication cysts might cause gastrointestinal bleeding and should be included in the differential diagnosis.

### INTRODUCTION

Duplication cysts are rare congenital anomalies of the gastrointestinal (GI) tract. Duodenal duplication cysts are extremely rare, representing only 2%-12% of GI tract duplications<sup>[1]</sup>. Most duplication cysts are detected in children and fewer than 30% of all duplications are diagnosed in adults<sup>[2]</sup>. They are difficult to diagnose, as the presenting symptoms are nonspecific and are closely related to the type, size and location of the lesion<sup>[1]</sup>. We report a rare case of duodenal duplication with duodenoduodenal intussusception presenting as GI bleeding.

### CASE REPORT

A 43-year-old man was admitted to the emergency department complaining of melena. He had complained of recurrent burning, nonradiating upper abdominal pain,

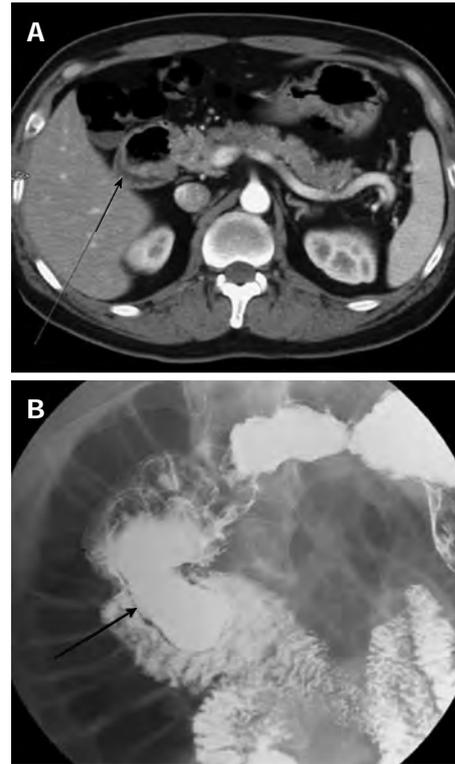

usually lasting for several minutes, irregular in nature and relieved by taking food since childhood. Ten years previously, he had been diagnosed with a gastric ulcer and had taken medications for 1 year.

His vital signs upon admission were a blood pressure of 120/80 mmHg and a heart rate of 105 beats/min. Initial laboratory studies revealed a hemoglobin level of 9.7 g/dL (normal range, 14-18 g/dL), hematocrit 28.8% (normal range, 42.0%-52.0%) and mean red corpuscular volume 88.4 fL (normal range, 80-94 fL). A nasogastric tube was inserted, but no blood was aspirated.

An initial gastroduodenoscopy showed no evidence of active bleeding or obvious focus. A colonoscopic examination was unremarkable, except for the presence of internal hemorrhoids. After a blood transfusion of 220 mL packed red blood cells, his hemoglobin level rose to 10.3 g/dL and there was no clinical evidence of further bleeding.

On the third day of hospitalization, the patient passed about 200 mL of melena and his hemoglobin levels fell to 7.6 g/dL. Gastroduodenoscopy revealed fresh blood oozing without a definite bleeding focus in the second portion of the duodenum. As there was no obvious bleeding focus, a high-resolution computed tomography (CT) scan of the abdomen was done. It revealed a circumferential cystic lesion in the proximal duodenum arising from a duodenoduodenal intussusception (Figure 1). As the patient did not have any symptoms except for melena and physical examinations did not reveal any palpable sausage-shaped abdominal mass suggestive of intussusception, an upper GI series was done. This demonstrated a large elongated sac-like 10 cm long mass in the second and proximal third portion of the duodenum (Figure 2). The junction of the first and second portions of the duodenum, where the mass began, was narrowed locally and the second portion of the duodenum was enlarged. This feature suggested a large elongated communicating duplication cyst (about 10 cm long) in the second and proximal third portion of the duodenum with duodenoduodenal intussusception.

As rare cases of GI cysts with malignancies have been reported in the literature, bleeding from a cancer could not be ruled out. Because of the recurrent bleeding symptoms and the possibility of a cancer being present, we chose surgical resection. This revealed a mass attached to the second and third portion of the duodenum. After duodenotomy, the cyst was opened and blood clots were found in its cavity. Subtotal resection of the cyst was done followed by primary closure of the duodenum. A macroscopic examination showed an irregular, flat mass measuring 4 cm × 4 cm × 0.5 cm, covered with intestinal mucosa and with hemorrhagic contents (Figure 3). Microscopy revealed showed the cyst wall to be composed of two mucosal layers sharing a common muscle layer (Figure 3). The patient had an uneventful recovery and was discharged 12 d later. Follow-up visits at our outpatient clinic have revealed no sign of further GI bleeding.

**Figure 1** Computed tomography image. A: A high resolution computed tomography image of the abdomen reveals a circumferential cystic lesion (arrow) in the vicinity of the second part of the duodenum; B: Upper gastrointestinal series showing an large elongated sac-like mass (about 10 cm in length, arrow) arising from the second and proximal third portion of the duodenum.

## DISCUSSION

GI duplication cysts are rare congenital anomalies formed during the embryonic development of the alimentary tract. They are defined by a smooth muscle coat, an intimate attachment to the native GI tract and a GI mucosal lining<sup>[3]</sup>. They can occur anywhere along the GI tract, with varying types, shapes and sizes. GI duplication cysts are most commonly found in the distal ileum, followed by the esophagus, colon and jejunum<sup>[4]</sup>.

Duodenal duplication cysts are among the rarest of all intestinal duplications. Most are located in the second or third portion of the duodenum. The cysts are usually filled with clear fluid, but might contain gallstones, bile or pancreatic fluid depending on communication with the biliary or pancreatic systems<sup>[5]</sup>. Most are diagnosed in childhood, with diverse, nonspecific clinical presentations<sup>[6]</sup>. The most common symptoms reported are abdominal pain and nausea/vomiting. The most common complication is pancreatitis, reported in up to 53% of patients. Other manifestations such as intussusceptions, infection or weight loss have also been reported<sup>[1]</sup>. Though rare, GI bleeding can result from peptic ulceration of the ectopic gastric mucosa within the cyst and be a cause of unexplained GI bleeding<sup>[3]</sup>. The bleeding can be painless, brisk and life threatening, as shown in our patient. The bleeding in our case was made more interesting by the

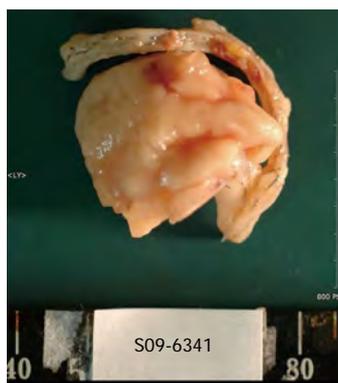

Figure 2 Gross specimen of the excised duodenal duplication cyst.

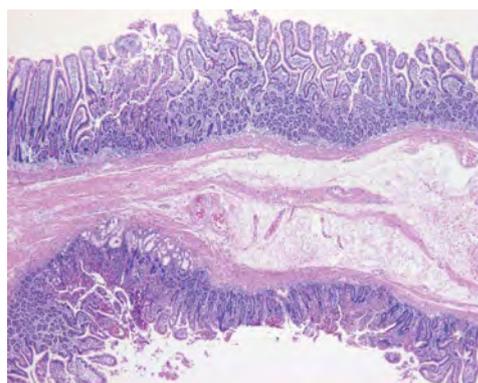

Figure 3 Histology of the duplication cyst showing two mucosal layers sharing a submucosal layer with muscular layer. Some of the mucosa are comprised of duodenal mucosa and the majority are jejunal mucosa (hematoxylin and eosin stain,  $\times 40$ ).

fact that histology did not reveal any ectopic gastric mucosa within the cyst, contrary to previous reports<sup>[1,7,8]</sup>.

The diagnosis of duodenal duplication cysts is difficult. The site of origin, such as an intraluminal or intramural position, and the presence or absence of luminal communication has to be taken into account. If the cyst is intraluminal, differentiation must be made between a pedunculated neoplastic lesion or a duodenal diverticulum. In the case of an intramural mass, a distended duodenal duplication has to be differentiated from other cystic masses belonging to the duodenal-choledochal-pancreatic area such as cystic dystrophy of the duodenal wall, choledochal cyst, pseudocysts, cystic tumors of the pancreas, cystic lymphangiomas, or mesenteric cysts. An empty duodenal duplication shows a solid structure and has to be differentiated from neoplastic or inflammatory duodenal or pancreatic lesions<sup>[9]</sup>.

The preoperative diagnosis of duodenal duplications is often inaccurate. Diagnosis is usually done using imaging modalities such as ultrasonography or CT scans. On ultrasonography, duodenal duplication is seen as having an echogenic inner mucosa surrounded by a hypoechoic outer muscular layer<sup>[4]</sup>. CT scans often reveal a cystic mass associated with the alimentary tract and is more useful in demonstrating the precise anatomical relationship between the cyst and surrounding structures<sup>[4]</sup>. Magnetic resonance images as well as endoscopic ultrasonography allow us to suspect duplications and are useful in evaluating upper GI tract masses<sup>[3,9]</sup>. On contrast CT series of the GI, duodenal duplication cysts can present as smooth submucosal or extrinsic masses, or as oval filling defects in the duodenum, as can be seen in our case. In case of bleeding, the most sensitive tool is gastroduodenoscopy, which can locate the bleeding duplication in the duodenum<sup>[8]</sup>. However, all modalities allow us only to suspect the presence of an abnormal lesion, and diagnostic confirmation is possible only after resection.

Treatment of duodenal duplication has classically involved surgical resection. However, cases of endoscopic treatment have been reported, especially in cases where the duplication is in close proximity to the adjacent structures such as the major duodenal papillae<sup>[10]</sup>. In our case,

endoscopic treatment was not possible because the duplication was not visible by endoscopy, leading to the need for surgical excision. Treatment of asymptomatic cases remains controversial. However, as neoplasms have been reported within duodenal duplication cysts, surgical resection must be considered<sup>[1]</sup>.

In conclusion, duodenal duplication cysts are rare congenital anomalies that are seldom reported in adults. Clinical presentations are diverse, but there are a few reports of GI bleeding. Here we report a case of a duodenal duplication cyst with overt GI bleeding and suggest that such cysts should be considered in cases of undiagnosed GI bleeding.

### Abstract

Warfarin is a widely used anticoagulant. Interindividual differences in drug response, a narrow therapeutic range and the risk of bleeding render warfarin difficult to use clinically. An 18-year-old woman with antiphospholipid syndrome received long-term warfarin therapy for a recurrent deep vein thrombosis. Six years later, she developed right flank pain. We diagnosed intrahepatic and subgaleal hemorrhages secondary to anticoagulation therapy. After stopping oral anticoagulation, a follow-up computed tomography showed improvement in the hemorrhage. After restarting warfarin because of a recurrent thrombosis, the intrahepatic hemorrhage recurred. We decided to start clopidogrel and hydroxychloroquine instead of warfarin. The patient has not developed further recurrent thrombotic or bleeding

episodes. Intrahepatic hemorrhage is a very rare complication of warfarin, and our patient experienced intrahepatic and subgaleal hemorrhage although she did not have any risk factors for bleeding or instability of the international normalized ratio control.

Simultaneous intrahepatic and subgaleal hemorrhage in antiphospholipid syndrome following anticoagulation therapy. *World J Gastroenterol* 2013; 19(38): 6494-6499 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i38/6494.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i38.6494>

### INTRODUCTION

Antiphospholipid syndrome (APS) is characterized by

venous or arterial thrombosis or pregnancy morbidity, in the presence of antiphospholipid antibodies (aPL). A venous thrombosis is the most common presenting complication of APS<sup>[1]</sup>. Long-term anticoagulation therapy is recommended for the secondary prevention of thromboembolism.

Warfarin is a widely used anticoagulant prescribed for patients with venous thrombosis, pulmonary embolism, chronic atrial fibrillation, and prosthetic heart valves. Interindividual differences in drug responses, a narrow therapeutic range and the risk of bleeding render warfarin difficult to use clinically. During treatment with oral anticoagulants, the risk of severe bleeding has been estimated to be 0.6%-1.0% per treatment year<sup>[2,3]</sup>. In a retrospective study of hemorrhagic complications in 184 patients, gastrointestinal bleeding was the most common complication, and liver or splenic hemorrhage was identified in only 3 patients<sup>[4]</sup>. Only a few cases of liver hematomas have been reported in the literature following anticoagulant therapy<sup>[5]</sup>. We report a woman with primary APS who presented with a simultaneous intraparenchymal hemorrhagic complication in the liver and a subgaleal hematoma with anticoagulation treatment, without any risk factors of bleeding or an elevated international normalized ratio (INR). This type of condition has not been previously described.

## CASE REPORT

An 18-year-old woman visited Dong-A University Hospital with swelling and tenderness of the left lower leg in March 2004. She had no past history of serious illness. Doppler ultrasonography (US) of her lower legs showed deep vein thromboses (DVT) in the left popliteal vein and the right common femoral vein. She received anticoagulation treatment with warfarin for 2 years. After 2 years, a follow-up US showed nearly complete improvement of the DVT, and anticoagulation therapy was stopped.

She returned four months later, in November 2006, with edema and tenderness of the right lower leg. US of her lower legs showed a chronic DVT in the right popliteal vein. We reexamined her for other conditions leading to a hypercoagulable state. The clinical lab values were as follows: white blood cell count (WBC) 4570/mm<sup>3</sup>, segmental neutrophils 29%, hemoglobin (Hb) 11.9 g/dL, platelets (PLT) 91000/mm<sup>3</sup>, prothrombin time (PT) 13.9 s, INR 1.23 and activated partial thromboplastin time (aPTT) 31.3 s. Tests for antinuclear antibodies were positive (at 1:40 dilution), and the particular types of immunofluorescence pattern were negative. An anti-double-stranded DNA antibody enzyme-linked immunoabsorbent assay test was moderately positive (326.7 WHO unit/mL). Anti-Smith antibody and anti-ribonucleoprotein antibody test were negative. Immunoglobulin (Ig)G anti- $\beta_2$ -glycoprotein I (anti- $\beta_2$  GPI) was positive (98.8 GPL), and IgM anti- $\beta_2$ -GPI was positive (95.5 GPL). IgG anticardiolipin antibodies (aCL) were highly positive (95.6 GPL),

and IgM aCL was positive (37.9 MPL). Lupus anticoagulant testing (diluted russell viper venom test, DRVVT) was positive (185.5 s). The patient was diagnosed with primary APS according to the revised Sapporo criteria for APS diagnosis<sup>[6,7]</sup>, and oral anticoagulation treatment was initiated.

After forty months of anticoagulation therapy, the patient was admitted in April 2010 with epigastric pain, headache, fever and chills. On physical examination, she had epigastric tenderness and body temperature of 38.2 °C. The laboratory findings were: WBC 17111/mm<sup>3</sup>, segmental neutrophils 82.9%, Hb 9.7 g/dL, PLT 136000/mm<sup>3</sup>, C-reactive protein (CRP) 8.38 mg/dL, alkaline phosphatase 211 I/U, PT INR 1.82 and aPTT 31.4 s. An abdominal computed tomography (CT) showed multiple low attenuated lesions without peripheral enhancement and perilesional edema of the liver on contrast-enhanced image (Figure 1). A brain magnetic resonance imaging (MRI) showed a crescentic high signal in the posterior parietal scalp on the T2 weighted image, a low signal on the T1 weighted image and mild enhancement on the contrast-enhanced scan images (Figure 2). We suspected intraparenchymal hemorrhage in the liver and a subgaleal hematoma in the posterior parietal scalp because of bleeding complications from anticoagulation. We stopped the warfarin treatment and administered antibiotics because there was the potential for an infected intrahepatic hemorrhage. After 2 wk of supportive care, a follow-up US on day 16 showed resolution of a previous hepatic lesion. We decided to restart warfarin because of her recurrent thrombotic episodes.

She was readmitted in June 2010 with right flank pain. On physical examination, she had abdominal tenderness in the right upper quadrant and her body temperature was normal. The WBC was 13250/mm<sup>3</sup>, the segmental neutrophils were 80.8%, the Hb was 10.2 g/dL and the PLT were 88000/mm<sup>3</sup>. The CRP was 7.93 mg/dL. The PT INR was 1.53, and the aPTT was 29.8 s. Liver and kidney function tests were unremarkable. An abdominal CT showed a low attenuated lesion in the S2/4 and S5 segments of the liver on the contrast-enhanced image (Figure 3A and B). We diagnosed the patient with intraparenchymal hemorrhage of the liver from the anticoagulation therapy and stopped warfarin treatment. Follow-up CT scanning on day 17 showed nearly complete improvement of intraparenchymal hemorrhage in the S2/4 and S5 segments of the liver (Figure 3C and D). After 1 mo, a follow-up US showed the previous intrahepatic lesions were completely resolved. We decided to initiate clopidogrel and hydroxychloroquine instead of warfarin. Subsequently, the patient has not developed recurrent thrombotic episodes or bleeding complications.

## DISCUSSION

APS is characterized by the occurrence of venous or arterial thromboses or by specific pregnancy morbidity in the presence of laboratory evidence of aPL. According

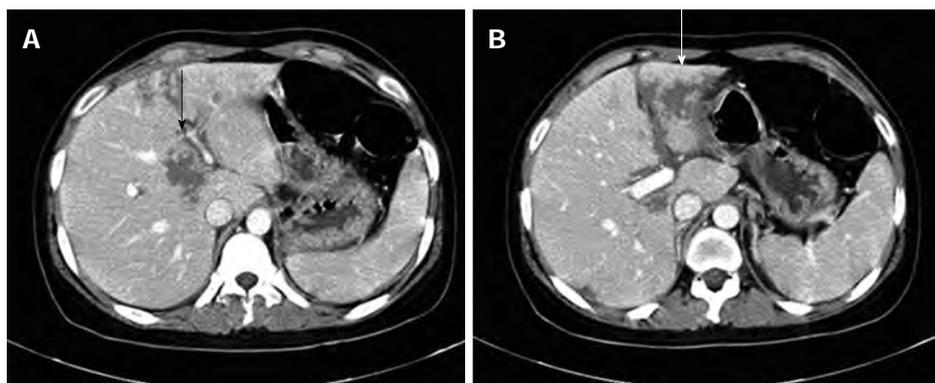

Figure 1 Intraparenchymal hemorrhage in the liver (arrows). An abdominal computed tomography showed multiple low attenuated lesions without peripheral enhancement (A) and perilesional edema of the liver on the contrast-enhanced image (B).

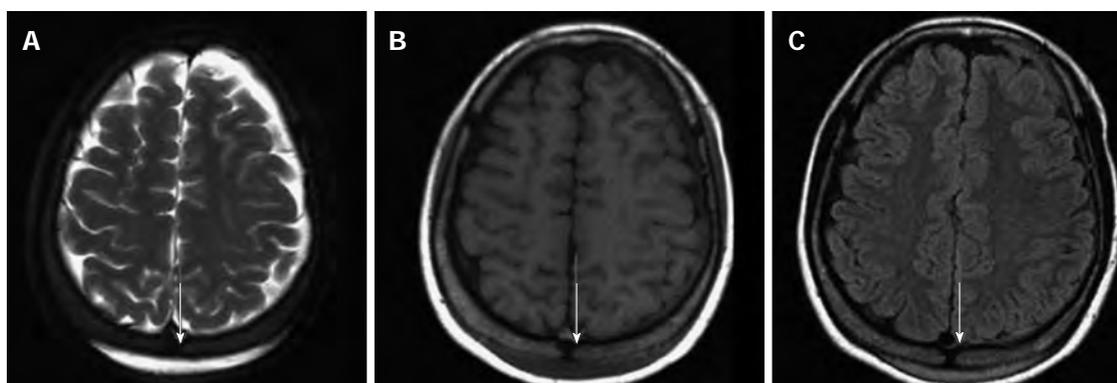

Figure 2 Subgaleal hematoma at the posterior parietal scalp (arrows). A brain magnetic resonance imaging showed a crescentic high signal in the posterior parietal scalp on the T2 weighted image (A), a low signal on the T1 weighted image (B) and mild enhancement on the contrast-enhanced image (C).

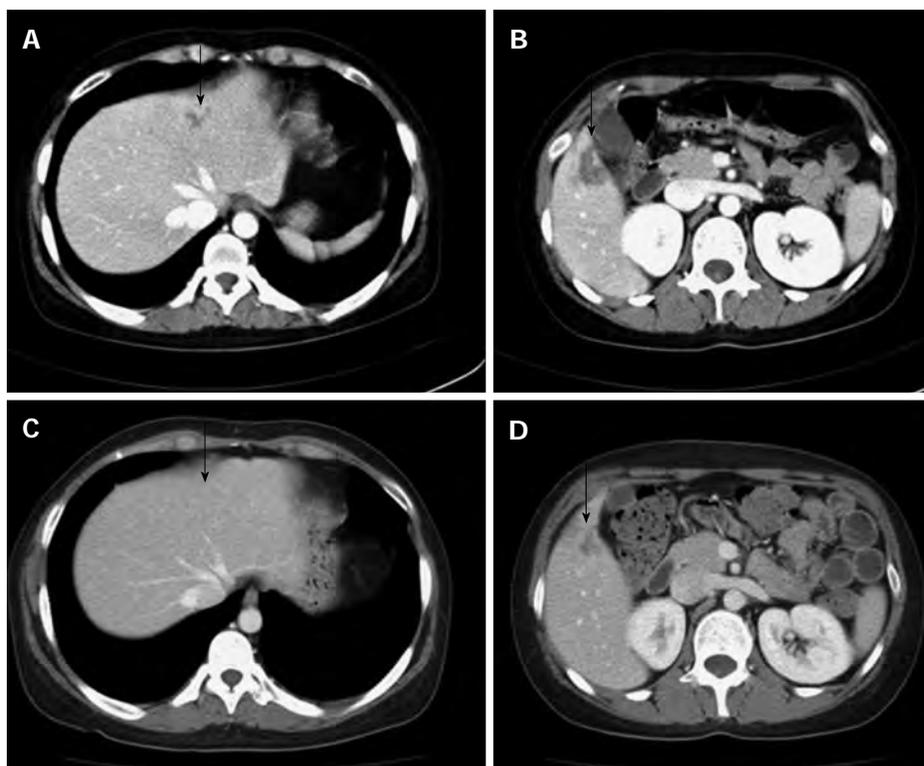

Figure 3 Recurrent and nearly complete resolution intraparenchymal hemorrhage in the liver (arrows). A, B: An abdominal computed tomography showed a low attenuated lesion (arrow) in the S2/4 (A) and S5 segments (B) of the liver on the contrast-enhanced image; C, D: An abdominal computed tomography showed resolution of the parenchymal hemorrhage in S2/4 (C) and the healing process in S5 (D) of the liver.

to the revised Sapporo criteria<sup>[6,7]</sup>, definite APS is considered if at least one of the clinical criteria and at least one of the laboratory criteria are satisfied. APS occurs either as a primary or secondary condition in the setting of an underlying disease, usually systemic lupus erythematosus. In the largest prospective cohort study of patients with APS, venous thromboembolism was the most common presenting complication, including DVT (31.7%), pulmonary embolism (9.0%), and superficial thrombophlebitis (9.1%)<sup>[11]</sup>. Warfarin is the standard of care for the chronic management of patients with APS who are not pregnant.

Warfarin is an oral anticoagulant used in a variety of clinical settings. The anticoagulant effect of warfarin is mediated through inhibition of the vitamin K-dependent gamma-carboxylation of coagulation factors II, VII, and X. Warfarin is among the top 10 drugs with the largest number of serious adverse event reports submitted to the United States Food and Drug Administration, because it has a high incidence of adverse effects as well as variable interactions with diet or medications through a mechanism of altered platelet function, altered vitamin K synthesis in the gastrointestinal tract and interference with vitamin K metabolism<sup>[8-11]</sup>. In a prospective observational study, life-threatening bleeding occurred in 32 of 1999 patients. The gastrointestinal tract was the most common site, with bleeding occurring in 21 (66%) of the 32 patients<sup>[12]</sup>. In another study of hemorrhagic complications in 184 patients, gastrointestinal bleeding was the most common complication and unusual hemoperitoneum and/or soft tissue bleeding were reported<sup>[4]</sup>. Liver hemorrhage following anticoagulation therapy has been rarely reported in the literature<sup>[5,13-15]</sup>. It is sometimes difficult to distinguish hepatic hemorrhage from a liver abscess. Liver abscesses appear as low attenuated lesions with peripheral enhancement or perilesional edema<sup>[16,17]</sup>. We diagnosed a patient with an intrahepatic hemorrhage because these characteristics were not observed in our patient. We discussed the possibility of a microaneurysm in the liver and brain with radiology specialists who said that it was very unlikely.

There are many risk factors associated with bleeding complications following the use of vitamin K antagonist. These risk factors have been associated with a significantly increased risk of bleeding in one or more multivariate analyses: old age, diabetes mellitus, the presence of malignancy, hypertension, acute or chronic alcoholism, liver disease, severe chronic kidney disease, elevated creatinine, anemia, the presence of bleeding lesions or episodes, a bleeding disorder, concomitant use of aspirin, nonsteroidal anti-inflammatory drugs, antiplatelet agents, antibiotics, amiodarone, statins or fibrates, and instability of the INR (INR > 3.0, pre-treatment INR > 1.2)<sup>[18,19]</sup>.

In previously reported spontaneous liver hemorrhages, Erichsen *et al.*<sup>[14]</sup> addressed the severe drug interaction between warfarin and trimethoprim-sulfamethoxazole. Dizadji *et al.*<sup>[13]</sup> and Roberts *et al.*<sup>[15]</sup> showed the two risk factors of old age and high INR at the time of admission. Behranwala *et al.*<sup>[5]</sup> suggested multiple risk factors, including; old age, hypertension, instability of INR control, and drug interactions with statins and omeprazole. Our patient had a simultaneous intraparenchymal hemorrhage in the liver and subgaleal hematoma despite the absence of risk factors for bleeding and a therapeutic range of warfarin with a PT INR of 1.53 (Figure 4). This type of case has not been previously reported.

One study suggested risk factors that could be used in estimating the probability of major bleeding in outpatients treated with warfarin. The risk factors include the following; age  $\geq$  65 years, history of stroke, history of gastrointestinal bleeding, and one or more the following (recent myocardial infarction, hematocrit < 30%, serum creatinine > 1.5 mg/dL, and diabetes mellitus<sup>[20]</sup>). The cumulative incidence of major bleeding at 48 mo in the low (no risk factor), intermediate (1 to 2), and high (3 or more) risk groups was 3%, 12% and 53% respectively. Our patient belonged to the low risk group with a cumulative incidence of only 3%. Some recent reports showed that APS could be correlated to a transient hemorrhagic event without anticoagulation therapy<sup>[21,22]</sup>. Lupus anticoagulant-hypoprothrombinemia syndrome is a rare clinical

entity that can occur in association with systemic lupus erythematosus. It is characterized by prolongation of the coagulation test that is not corrected by normal fresh plasma because of non-neutralizing antibodies against Factor II. Our patient did not have this abnormal laboratory finding.

There are very few randomized studies comparing the treatment options for patients with an elevated INR and/or bleeding complications following the use of warfarin. If significant or life-threatening bleeding occurs, rapid reversal of excessive anticoagulation should be undertaken at any degree of anticoagulation<sup>[23-26]</sup>. Warfarin should be stopped, and 10 mg of vitamin K should be administered by a slow intravenous infusion, supplemented by fresh frozen plasma for less urgent situations. For more urgent situations, recombinant human factor VIIa or prothrombin complex concentrate may be used. If needed, angiography may help with embolization in cases of severe major bleeding. In the majority of cases, bleeding is improved by stopping warfarin and conservative care. Restarting of warfarin is not recommended, and changing the drug used for maintaining long-term anticoagulation is suggested<sup>[5]</sup>.

In studies of the bleeding risk during antithrombotic therapy, the odds ratio is generally lower for clopidogrel than warfarin, and we decided to start clopidogrel instead of warfarin<sup>[27,28]</sup>. We added hydroxychloroquine because limited data showed that it might be useful for thrombosis in patients with APS although there were no randomized controlled trials<sup>[29,30]</sup>. After starting clopidogrel and hydroxychloroquine, our patients did not experience additional bleeding complications or recurrent thromboses.

Our patient had a simultaneous intrahepatic hemorrhage and a subgaleal hematoma despite the absence of risk factors and a therapeutic range of warfarin. This is the first case with simultaneous bleeding in the liver and brain in an APS patient treated with warfarin.

Patients with intrahepatic bleeding might experience right upper quadrant or epigastric pain and pain that radiates into the shoulder or flank. Fever might develop when an infection accompanies the intrahepatic hemorrhage. If a patient experience pain and/or fever during anticoagulation therapy, we should consider the possibility of abdominal bleeding such as an intrahepatic hemorrhage in any patient receiving oral anticoagulants, even though this circumstance remains unlikely. CT or US should be adopted for early diagnosis.

**Key words:** Ileal duplication cyst; Adulthood; Computed tomography enterography; Tc-99m pertechnetate scintigraphy

**Core tip:** We reported a case of duplication of the alimentary tract involving the ileum, which mimicked intestinal intussusception, Meckel's diverticulum (MD) and Crohn's disease, in a young man. Computed tomography enterography identified the intussusception in the right lower quadrant, and the disease was positive on Tc-99m pertechnetate scintigraphy. Exploratory laparotomy and surgical pathology showed ileal duplication cyst with complicating ectopic gastric mucosa. Differential diagnosis of ileal duplication cyst was made, especially from MD.

### Abstract

Intestinal duplication is an uncommon congenital condition in young adults. A 25-year-old man complained of chronic, intermittent abdominal pain for 3 years following previous appendectomy for the treatment of suspected appendicitis. Abdominal discomfort and pain, suggestive of intestinal obstruction, recurred after operation. A tubular mass was palpable in the right lower quadrant. Computed tomography enterography scan identified suspicious intestinal intussusception, while Tc-99m pertechnetate scintigraphy revealed a cluster of strip-like abnormal radioactivity in the right lower quadrant. On exploratory laparotomy, a tubular-shaped ileal duplication cyst was found arising from the mesenteric margin of the native ileal segment located 15 cm proximal to the ileocecal valve. Ileectomy was performed along with the removal of the duplication disease, and the end-to-end anastomosis was done to restore the gastrointestinal tract continuity. Pathological examination showed ileal duplication with ectopic gastric mucosa. The patient experienced an eventless postoperative recovery and remained asymptomatic within 2 years of postoperative follow-up.

### INTRODUCTION

Gastrointestinal tract duplication is a rare congenital gastrointestinal malformation reported in 1733 for the first time, and termed as duplication of the alimentary tract (DAT) by Fiorani *et al*<sup>[1]</sup>. The exact etiology of DAT remains unknown, while multiple theories have been postulated, including "abortive twinning theory", "persistent embryonic diverticula theory", "split notochord theory", "intrauterine vascular accident theory" and more popular "aberrant luminal recanalization theory". More than 80% of DAT cases are diagnosed in children under 2 years but rarely in adults<sup>[2,3]</sup>. DAT can arise from any segment of the gastrointestinal tract from the mouth to the anus, but involves the ileum in most cases (44%)<sup>[4]</sup>. Clinical manifestations of DAT are highly variable, especially in adults, de-

pending on the type, size, location, and mucosal lining of the duplication. An intestinal DAT may be asymptomatic, while chief complaints consist mainly of belly pain, abdominal mass, intestinal obstruction, and hematochezia<sup>[5]</sup>. Ileal duplication occasionally becomes symptomatic until adulthood and requires subsequent medical intervention. However, ileal duplication cannot be overlooked in adult patients due to its serious complications, such as refractory bleeding, gastrointestinal perforation, and possible malignant transformation if with complicating gastric mucosa heterotopia<sup>[5]</sup>. Ileal duplication is also a diagnostic challenge in adults as it is almost impossible in the clinical setting to differentiate it from other common gastrointestinal malformations or inflammatory diseases, such as Meckel's diverticulum (MD), noncomplicating intestinal intussusception, and Crohn's disease<sup>[6]</sup>. We report a case of ileal duplication mimicking intestinal intussusception in a young man in his mid 20s, which was previously misdiagnosed as appendicitis, Crohn's disease or MD.

## CASE REPORT

A 25-year-old Han Chinese man complained of chronic abdominal pain and weight loss for 3 years. In previous hospitalization, contrast gastrointestinal radiography showed multiple mucosal filling defects in the terminal segment of the ileum, while abdominal contrast-enhanced computed tomography (CT) scan revealed localized dilation, effusion, thickening, and edema of the intestinal wall in the right lower quadrant with concomitant enlargement of multiple mesenteric lymph nodes. Ileal Crohn's disease was initially suspected but subsequently excluded due to the fact that colonoscopy only identified mild chronic inflammation. Moreover, the abdominal symptoms could not be alleviated by the medication with oral salicylazo-sulphapyridine but omeprazole. Open appendectomy was performed as indicated by a serious attack of right lower quadrant pain, and postoperative pathology showed mild simple appendicitis. However, intermittent abdominal pain free of hematochezia or melena, suggestive of intestinal obstruction, still recurred following appendectomy. The patient was referred to our department in November 2010 due to the consistently worsening abdominal symptoms in the absence of any clinically evident predisposing factors.

Physical examination revealed a 10 cm × 3 cm, tubular-shaped, soft, tender, mobile mass located in the right lower quadrant. Routine hematology and clinical chemical tests showed no clinically significant abnormalities. Repeated abdominal contrast-enhanced CT scan revealed a suspicious intestinal intussusception located in the right lower quadrant (Figure 1). Repeated contrast gastrointestinal radiography and colonoscopy identified clinically insignificant results. Tc-99m pertechnetate scintigraphy also showed a cluster of strip-like abnormal radioactivity in the right lower quadrant (Figure 2). Explorative laparotomy was indicated for suspicious MD in this patient with a history of previous abdominal surgery.

Intraoperative exploration showed no clinically sig-

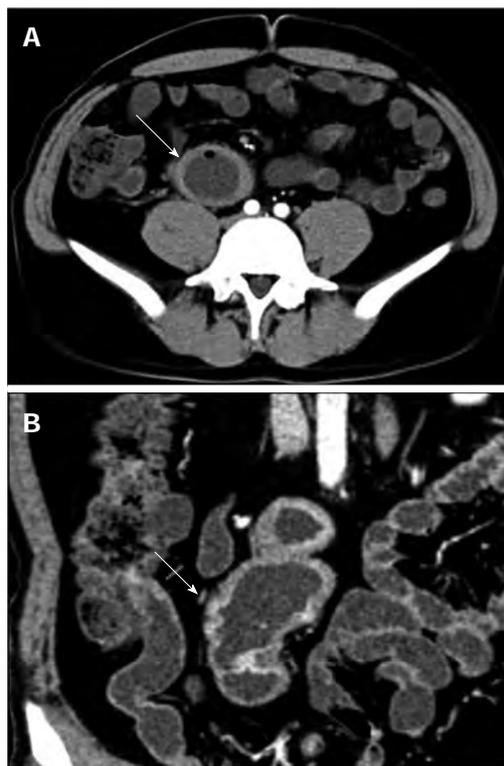

Figure 1 Computed tomography enterography scan. A: Transverse view showed suspicious ileal intussusception (white arrow) in the right lower quadrant; B: Coronal view revealed a similar result (white arrow).

nificant abnormalities, except for moderate intestinal adhesions, in the peritoneal cavity. However, a duplicating, tubular-shaped intestinal segment, 15.5 cm in length and 4 cm in diameter (Figure 3A), was found arising from the mesenteric margin of the native ileal segment located 15 cm proximal to the ileocecal valve (Figure 3B). The distal part of the ileal duplication cyst had a 2-cm, completely patent orifice into the native ileal lumen, while the proximal part ended in a blind pouch (Figure 3C). The ileal duplication cyst was easily resected along with a 7.5 cm native ileal segment, and an end-to-end ileal anastomosis was performed to restore the gastrointestinal continuity. The resection specimen showed no signs of inflammation, infection, ulceration, hemorrhage, obstruction or malignant transformation (Figure 4A). Additionally, gross pathology (Figure 4B) and histology (Figure 4C) showed that the duplication cyst was lined with ileal mucus glands and heterotopic gastric mucosae. Therefore, this disease was diagnosed as ileal duplication cyst with complicating gastric mucosa heterotopia. The patient experienced an eventless postoperative recovery, and he was discharged from hospital on postoperative day 7. The patient was followed up at the outpatient clinic and remained asymptomatic throughout a two-year follow-up period until the time of drafting this manuscript.

## DISCUSSION

DAT was firstly reported by Fitz<sup>[7]</sup> and subsequently defined by Ladd *et al*<sup>[8]</sup> as a spherical- or tubular-shaped

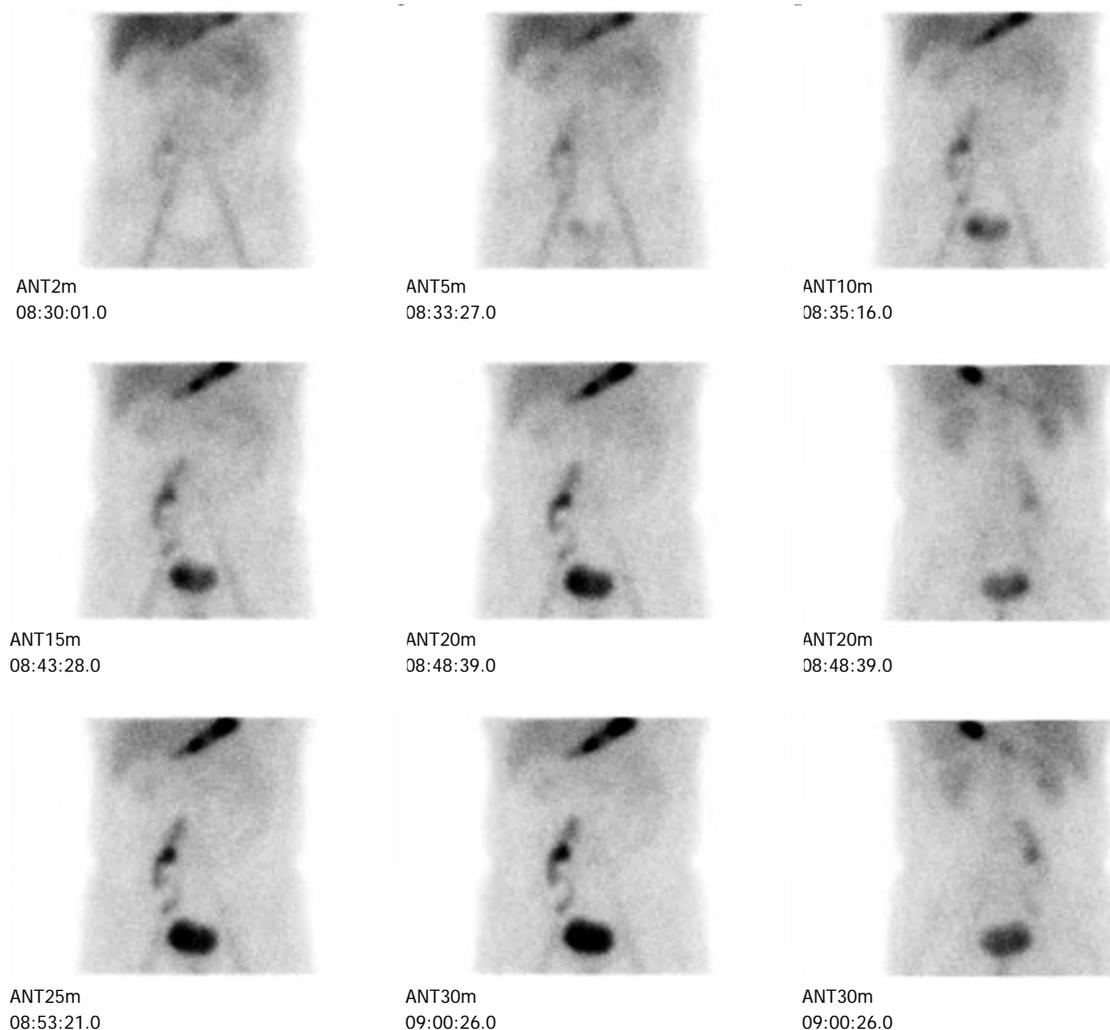

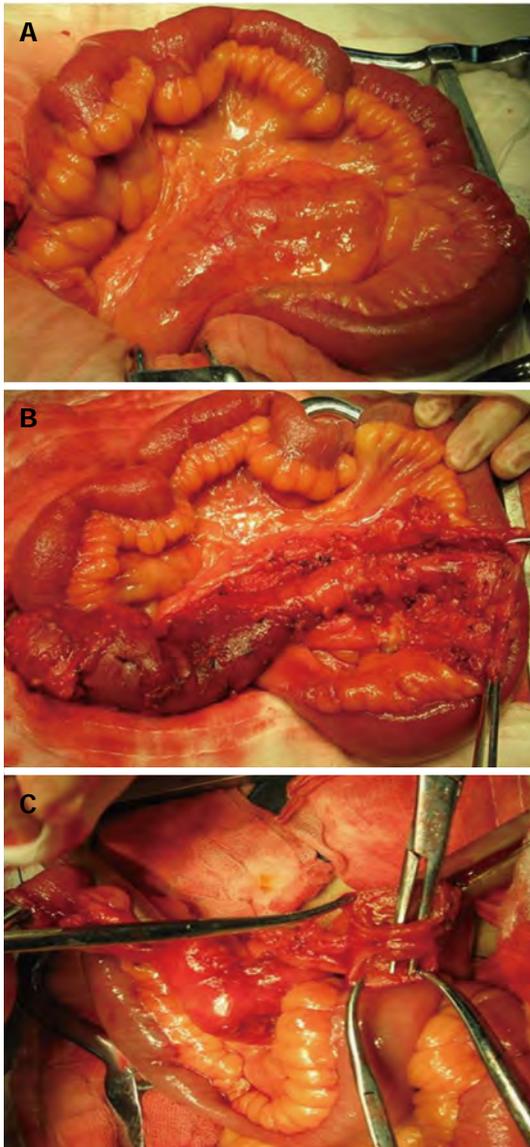

Figure 2 Tc-99m pertechnetate scintigraphy. A cluster of stripy abnormal radio-activity was located in the right lower quadrant.

anomaly that was attached or adherent to and shared the identical phenotypic characteristics with the normal alimentary tract. Although DAT is known as a rare congenital malformation (1/10000 live births), this anomaly can occur anywhere along the gastrointestinal tract, with the ileum being the most frequently affected segment<sup>[2,6]</sup>, either on the mesenteric margin or the contralateral side<sup>[9,10]</sup>. Daudet *et al*<sup>[11]</sup> reviewed 764 DAT cases, the majority of which occurred at infancy but rarely at adulthood, with a male dominance.

Ileal duplication normally exhibits highly variable and nonspecific clinical manifestations in adults. The most frequent complaints consist mainly of symptoms suggestive of gastrointestinal bleeding and intestinal obstruction<sup>[5,6,12,13]</sup>; and abdominal pain and palpable abdominal mass are also reported by approximately 50% of patients<sup>[13]</sup>. Furthermore, gastrointestinal bleeding and refractory abdominal pain may be underlain with heterotopic gastric mucosae lining the duplication cyst. Therefore, antacids can be effective in relieving abdominal pain as shown in this patient.

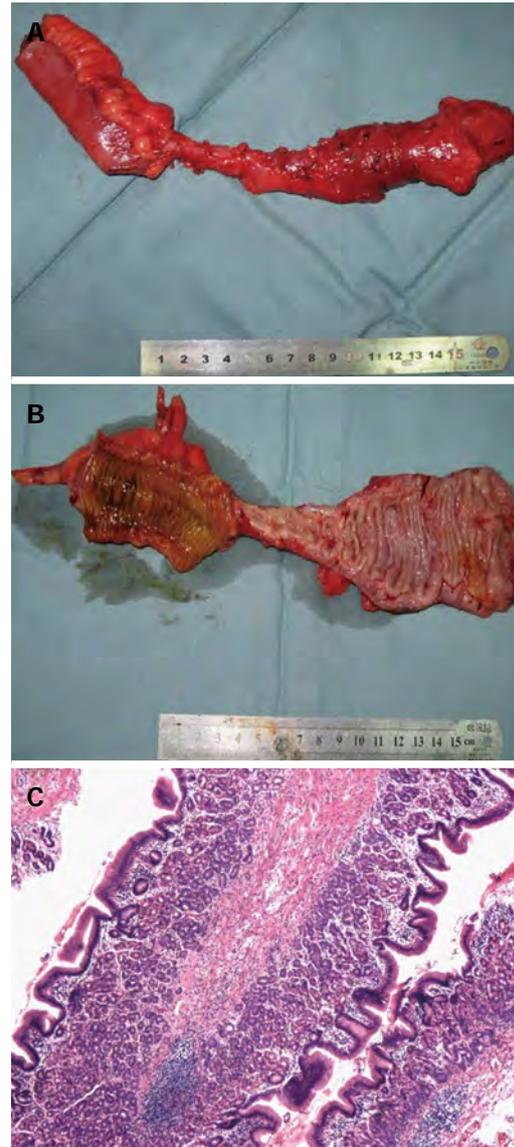

Multiple diagnostic tools are reported to be useful in the investigation of DAT, including contrast-enhanced

gastrointestinal ultrasonography and radiography, abdominal CT scan, and gastrointestinal endoscopy<sup>[14,15]</sup>. Moreover, Tc-99m pertechnetate scintigraphy is recommended as the first-line option of choice for the workup of DAT<sup>[16]</sup>. The positive result depends mainly on the abnormal enrichment of radionuclides accumulated by the heterotopic gastric mucosae. Ileal DAT mainly needs to be differentiated from MD. In pathogenesis, MD is a true congenital diverticulum deriving from the remnant of the omphalomesenteric duct during the development of the terminal ileum, while DAT can occur anywhere along the gastrointestinal tract but most frequently in the ileum; MD is normally located on the contralateral side of the mesenteric margin, while ileal duplication cyst occurs either on the mesenteric margin or the contralateral side. MD is often complicated with ectopic gastric mucosa; therefore, abdominal pain responsive to antacids is more frequently present in MD patients than in ileal DAT patients. Furthermore, MD is known to often cause a series of complications, such as diverticulitis, gastrointestinal bleeding or perforation, and intestinal obstruction, whereas these complications are relatively less common in ileal DAT. However, it is almost impossible to distinguish DAT from

**Figure 3 Exploratory laparotomy findings.** A: A 25-cm duplicating, tubular small intestinal segment was found arising from the ileal mesenteric margin; B: This duplication cyst was intimately attached to the native ileal segment located 15 cm proximal to ileocecal valve; C: this cyst had a blind end proximally and a completely patent orifice into the native ileal lumen distally.

MD prior to operation if the ileum is involved. A previous study conducted in Japan reported that only 11.2% of ileal duplication cases could be correctly diagnosed before operation, 18.2% misdiagnosed as ileal intussusception, 15.1% as ileal mass, 14.4% as ileus, and 26.7% as abdominal pain of unknown cause<sup>[17]</sup>. Therefore, it will easily lead to the misdiagnosis of ileal DAT as MD. As MD is the most frequent gastrointestinal malformation, a suspected diagnosis of MD was made and indicated for exploratory laparotomy in our case. Appendicitis also needs to be excluded as the primary complaint was right lower quadrant pain in this patient, especially if complicating infection occurred in the duplication cyst. Unfortunately, the ileal duplication, which located 15 cm proximal to the ileocecal valve, was missed in previous appendectomy. The possibility of ileal duplication should be excluded for a patient

**Figure 4 Gross and histological pathology of the resection specimen.** A: The resection specimen showed no signs of inflammation, infection, ulceration, hemorrhage, obstruction, or malignant transformation; B: The mucosal layer of the duplication cyst was lined with both small intestinal and gastric mucosae; C: Histology revealed that the duplication cyst was lined with ileal mucus glands and heterotopic gastric mucosae (hematoxylin-eosin,  $\times 100$ ).

diagnosed with suspicious MD or appendicitis but exhibiting gastrointestinal bleeding and/or intestinal obstruction. Use of laparoscopy may be helpful in identifying any suspicious ileal diseases when a diagnosis of MD or appendicitis is doubtful. Double-balloon enteroscopy may be another effective investigational technique for the diagnosis of ileal DAT if an additional ileal luminal orifice is visualized<sup>[4,18,19]</sup>.

Symptomatic treatment, such as acid-suppressing medications, may be effective in some cases if the symptoms are primarily associated with ectopic gastric mucosae. Like the possibility of adenocarcinoma in MD with complicating ectopic gastric mucosa, malignant transformation of ileal duplication cyst with complicating gastric mucosa heterotopia is also a major concern in adult patients as

epithelial instability is seen in long-standing duplication cysts. A historic review published by Johnson and his colleagues<sup>[5]</sup> reported that three out of 13 (23.1%) adult ileal DAT patients had ileal cancer, including adenocarcinoma in two patients and squamous cell carcinoma in one patient. Thus, radical resection of the duplication cyst along with the affected native intestinal segment remains the mainstay modality of definitive treatment<sup>[5,20]</sup>.

In conclusion, our report described ileal DAT, a rare congenital gastrointestinal malformation uncommonly seen in adults. This rare condition exhibits no specific manifestations although CT enterography scan and Tc-99m pertechnetate scintigraphy may identify some characteristic appearance of intussusception and MD. Surgical resection is thought to be the most effective treatment modality. Use of laparoscopy will allow a direct visualization and concomitant resection of possible ileal DAT.

### Abstract

A patient with stent embedding after placement of an esophageal stent for an esophagobronchial fistula was treated with an ST-E plastic tube inserted into the esophagus to the upper end of the stent using gastroscopy. The gastroscopy was guided into the esophagus through the ST-E tube, and an alligator forceps was inserted into the esophagus through the ST-E tube alongside the gastroscopy. Under gastroscopy, the stent wire was grasped with the forceps and pulled into the ST-E tube. When resistance was met during withdrawal, the gastroscopy was guided further to the esophageal section where the stent was embedded. Biopsy forceps were guided through a biopsy hole in the gastroscopy to the embedded stent to remove silicone membranes and connection threads linking the Z-shaped wire mesh. While the lower section of the Z-shaped stent was fixed by the biopsy forceps, the alligator forceps were used to pull the upper section of the metal wire until the Z-shaped metal loops elongated. The wire mesh of the stent was then removed in stages through

the ST-E tube. Care was taken to avoid bleeding and perforation. Under the assistance of an ST-E plastic tube, an embedded esophageal metal stent was successfully removed with no bleeding or perforation. The patient experienced an uneventful recovery after surgery. Plastic tube-assisted gastroscopic removal of embedded metal stents can be minimally invasive, safe, and effective.

### INTRODUCTION

The use of fully covered self-expandable esophageal metal stents has favorable results in treating a variety of

**Figure 1** Disordered stent structure as a result of failure of repeated attempts at gastroscopic removal of the stent. A-D: Enhanced chest computed tomography scan performed showed the stent was situated in the middle section of the esophagus after esophageal stent placement, the wall of the middle and inferior segments of the esophagus thickened noticeably, part of the stent was embedded into the esophageal wall, borders between the stent and surrounding fat were blurred, and the upper end of the stent pressed against the trachea carina.

benign and malignant esophageal strictures and esophageal fistulae<sup>[1-6]</sup>. However, stent placement over a prolonged period can result in hyperplastic tissue overgrowth on both ends of the stent, leading to in-stent restenosis<sup>[7-9]</sup>. Therefore, stents should be removed after an appropriate period after treatment of benign esophageal strictures and fistulae<sup>[10-12]</sup>. Notable tissue hyperplasia can occur at both stent ends, causing difficulty in stent removal and sometimes requiring surgical treatment. This procedure has a high risk of trauma<sup>[13,14]</sup>. Therefore, a minimally invasive, low-risk method is needed for removal of embedded esophageal stents. Here, we report our experience with a novel approach to gastroscopic removal of an embedded esophageal stent.

## CASE REPORT

The patient was a 15-year-old girl who had experienced coughing after drinking since early March 2012. The imaging of iodinated contrast-enhanced radiological examination showed an esophagobronchial fistula arising from the left bronchus to the middle portion of the esophagus. Under gastroscopy on May 30, 2012, a fully covered Z-shaped metal stent measuring 2 cm × 6 cm was placed within the esophagus to cover the fistula opening. After the procedure, the coughing after drinking disappeared. However, the patient developed esophageal obstruction. Gastroscopy on August 13, 2012 showed tissue hyperplasia on both stent ends, luminal stenosis, and embedding of both stent ends in the hyperplastic tissue.

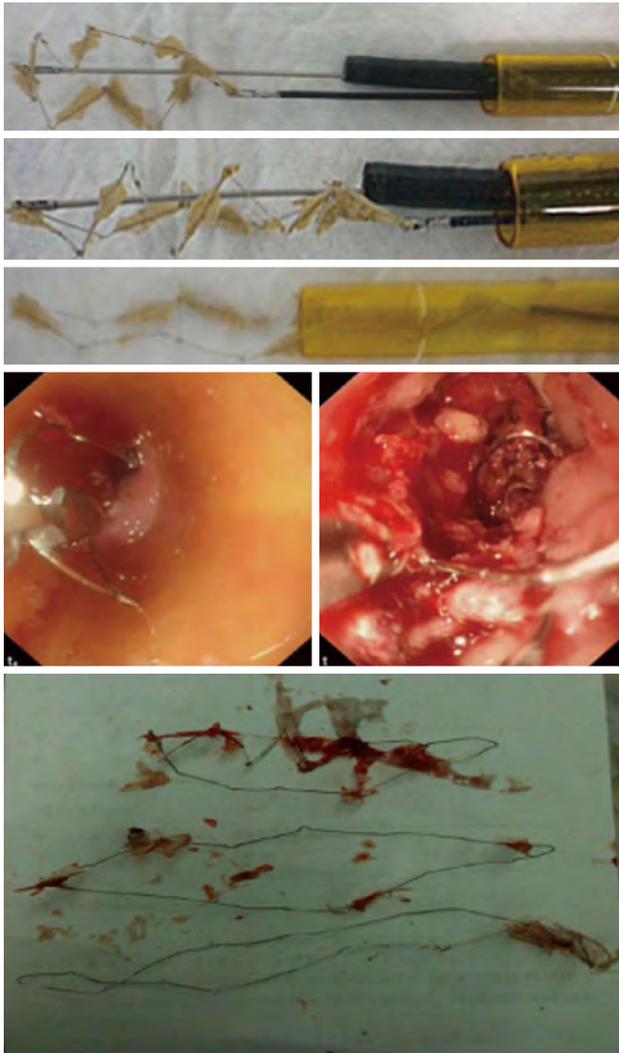

Attempts to remove the stent under endoscopy failed and led to a disorganized stent structure. Enhanced chest computed tomography scan showed the wall of

the middle and inferior segment of the esophagus were noticeably thickened. Part of the stent was embedded in the esophageal wall, the boundary between the stent and surrounding fat was blurred, and the upper end of the stent was pressed against the trachea carina (Figure 1). After consultation with thoracic surgeons, we decided to perform gastroscopic removal on August 31, 2012.

Under the guidance of gastroscopy, an ST-E plastic tube (3 cm × 40 cm) was inserted into the esophagus to the upper end of the stent. A gastroscope was guided into the esophagus through the ST-E tube, and an alligator forceps was inserted into the esophagus through the ST-E tube alongside the gastroscope. Under gastroscopy, the stent wire was gripped with the forceps and pulled into the ST-E tube. When resistance was met during withdrawal, the gastroscope was guided further to the esophageal section where the stent was embedded. Biopsy forceps were sent through a biopsy hole in the gastroscope and inserted near the embedded stent to remove the silicone membranes and connection threads linking the Z-shaped stent wire. Next, while the lower section of the Z-shaped stent was fixed by the biopsy forceps, the alligator forceps were used to pull the upper section of the metal wire until the Z-shaped metal loops elongated. The wire mesh of the stent was then removed in stages through the ST-E tube (Figure 2).

## DISCUSSION

Benign esophagobronchial fistulae are rare and often result from trauma, esophageal spontaneous rupture, tuberculosis, and Crohn's disease<sup>[2,4,5]</sup>. Treatment is usually difficult and surgical interventions involve a high risk of

**Figure 2** An alligator forceps was inserted into an ST-E tube alongside a gastroscop and, under the guidance of gastroscopy, the stent wire was gripped and pulled up into the ST-E tube. Biopsy forceps were inserted into the lower section of the Z-shaped stent through a biopsy hole in the gastroscop to fix the stent; in the meantime, the alligator forceps continued to be used to pull up the stent wire until the Z-shaped metal loops became elongated strips. All the stent wire was removed in stages through the ST-E tube.

trauma. Placement of fully covered self-expanding metal stents has become a viable treatment option. However, stent placement over a prolonged period can result in hyperplastic tissue overgrowth on both ends of the stent, leading to in-stent re-stenosis. Removing embedded stents is difficult. One study attempted to remove a stent by placing a secondary stent within the primary stent<sup>[13]</sup>. However, in this case, the stent structure was compromised and became disordered during attempts to remove the stent under endoscopy, with the result that sharp parts of the stent were entering the esophageal wall. Thus, placement of another stent might have caused esophageal perforation and damage to surrounding organs.

In our view, two goals must be achieved to successfully remove a structurally disordered Z-shaped metal stent embedded in the esophageal wall under

gastroscopy. First, the esophageal entrance and throat must be protected from scratching by the stent wire during removal; second, each of the Z-shaped stent loops needs to be pulled outward until it is elongated. Gastroscopic procedures conducted through a ST-E tube meet these requirements, as the plastic tube fully protects the upper portion of the esophagus and throat from scratching by the stent wire. A two-handed operation is possible with an ST-E tube: with one hand, an alligator forceps is inserted into the esophagus through the ST-E tube alongside the gastroscop. Under the guidance of gastroscopy, the stent wire is gripped and pulled outward into the ST-E tube. If resistance is met during pulling, the gastroscop can be sent further to the esophageal section where the stent is embedded and biopsy forceps guided with the second hand through a biopsy hole in the gastroscop to insert into the embedded stent to remove silicone membranes and connection threads linking the Z-shaped stent. While the lower section of the Z-shaped stent is fixed by the biopsy forceps, the alligator forceps can be used to pull the upper section of the metal wire until the Z-shaped metal loops are elongated, to enable the wire mesh of the stent to be removed through the ST-E tube. The wire mesh of the stent is removed in stages by repeating the above procedures.

In our view, plastic tube-assisted gastroscopy is a minimally invasive, safe, and effective method for removal of esophageal embedded metal stents.

## ACKNOWLEDGMENTS

We got the study approval for the paper from Southwest Hospital.

**AIMS AND SCOPE** *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup>, and 28<sup>th</sup> each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

**INDEXING/ABSTRACTING** *World Journal of Gastroenterology* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2012 Impact Factor: 2.547 (34/74); Total Cites: 19145 (6/74); Current Articles: 944 (1/74); and Eigenfactor® Score: 0.06035 (6/74).

### Abstract

Esophagectomy, the surgical removal of all or part of the esophagus, is a surgical procedure that is associated with high morbidity and mortality. Pulmonary complications are an especially important postoperative problem. Therefore, many perioperative strategies to prevent pulmonary complications after esophagectomy have been investigated and introduced in daily clinical practice. Here, we review these strategies, including improvement of patient performance and technical advances such as minimally invasive surgery that have been implemented in recent years. Furthermore, interventions such as methylprednisolone, neutrophil elastase inhibitor and epidural analgesia, which have been shown to reduce pulmonary complications, are discussed. Benefits of the commonly applied routine nasogastric decompression, delay of oral intake and prophylactic mechanical ventilation are unclear, and many of these strategies are also evaluated here. Finally, we will

discuss recent insights and new developments aimed to improve pulmonary outcomes after esophagectomy.

**Key words:** Esophagectomy; Complications; Pneumonia; Acute lung injury; Acute respiratory distress syndrome

**Core tip:** Pulmonary complications following esophagectomy significantly contribute to postoperative morbidity and mortality. Over the years many strategies aimed at reducing pulmonary complications have been investigated. In the current article, we discuss these strategies, specifically minimally invasive surgical techniques; anti-inflammatory therapies and optimization of patient performance.

Strategies to reduce pulmonary complications after esophagectomy. *World J Gastroenterol* 2013; 19(39): 6509-6514 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6509.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6509>

### INTRODUCTION

Esophageal cancer is the sixth leading cause of cancer related mortality, and its incidence is increasing rapidly<sup>[1]</sup>. For patients with loco-regional disease the best chance for long-term survival is offered by a transthoracic esophagectomy after neoadjuvant therapy<sup>[2-4]</sup>. However, esophagectomy is considered to be one of the most invasive and complex gastrointestinal procedures with a high post-operative morbidity and mortality<sup>[5]</sup>. Concentration of surgical treatment in high volume centers and improvements in perioperative care have led to significant reductions in postoperative mortality and improved long-

term survival<sup>[5,6]</sup>.

Respiratory complications are most common after esophagectomy, with up to a 60% incidence rate; respiratory failure due to pulmonary complications remains the major cause of postoperative morbidity and mortality after esophagectomy<sup>[7,8]</sup>. A wide range of perioperative strategies have been introduced in order to reduce these pulmonary complications. In this editorial we will discuss several of these strategies.

## DEFINITIONS

The most severe pulmonary complications following esophagectomy are pneumonia, adult respiratory distress syndrome (ARDS) and acute lung injury (ALI). Pneumonia is the most common complication and is significantly associated with need for re-intubation, prolonged hospital stays and in hospital mortality<sup>[9]</sup>. Although ARDS and ALI have been clearly defined during American-European consensus conferences, criteria for pneumonia differ widely<sup>[10-12]</sup>. In a recent systematic review, pneumonia rates were reported by 56 studies and defined by 18 studies. However, 16 different definitions were used, resulting in a wide range of reported pneumonia rates (between 1.5% and 38.9%). Consequently, this variation makes it difficult to compare study results<sup>[10]</sup>. Therefore, generating a consensus on the definition of pneumonia after esophagectomy is an important step in improving the quality and comparability of research. Despite the heterogeneity in definitions, several interesting strategies to reduce pulmonary complications after esophagectomy have been described.

## OPTIMISATION OF PERFORMANCE STATUS

### Nutrition

Improvement of performance status of patients undergoing esophagectomy is important in reducing pulmonary complications. Adequate enteral nutrition is an important tool to achieve this in the pre-operative and postoperative phase. When nutrition is inadequate, leading to malnutrition, this is associated with expiratory muscle weakness and pulmonary complications after major upper abdominal surgery<sup>[13]</sup>. Preoperative malnutrition also increases the risk for overall complications after esophagectomy (OR = 3.50, 95%CI: 1.89-6.49)<sup>[14]</sup>. Furthermore, when all patients undergoing esophagectomy receive preoperative intensive nutritional support by a dietician, fewer postoperative complications are observed (OR = 0.23, 95%CI: 0.05-0.97)<sup>[15]</sup>. This is supported by another prospective cohort study that investigated preoperative nutritional support for malnourished patients<sup>[16]</sup>. Despite the fact that preoperative nutritional support seems a logical and promising strategy to prevent postoperative pulmonary complications, clear evidence is lacking.

An important role for nutrition also exists in the postoperative phase. Early enteral nutrition after gastro-

intestinal surgery improves patient recovery and reduces morbidity and mortality<sup>[17]</sup>. However, commonly a nil-by-mouth regimen is still applied after esophagectomy. The rationale for this regimen is the concern that early oral intake would result in vomiting with subsequent aspiration pneumonia. Furthermore sequelae of anastomotic leakage are thought to be more severe if leaked fluids contain food besides to saliva. However, benefits of a nil-by-mouth regimen are theoretical and evidence is lacking<sup>[18]</sup>.

Jejunal tube feeding can be started early to ensure enteral nutrition following esophagectomy. Compared to total parenteral nutrition or fasting this reduces postoperative pneumonia rates by 50% or more<sup>[19,20]</sup>. Drawbacks are frequent dislocation of nasojejunal tubes, and serious complications such as leakage<sup>[21]</sup>.

The risks of artificial feeding, combined with the lack of evidence concerning effects of a nil-by-mouth regimen, are reasons to investigate the feasibility and safety of starting oral intake early after esophagectomy. Interestingly, for major upper abdominal surgery early oral intake has already been demonstrated to be feasible and safe<sup>[22]</sup>. However, further research is needed to provide more evidence in patients undergoing esophagectomy.

### Inspiratory muscle training

Another method to optimize performance status is through physical exercise. If postoperatively compromised, respiratory muscle strength will result in reduced lung function and insufficient coughing. This might induce atelectasis, which, acting in combination with postoperative pain and sedation, might result in hypoxia<sup>[23]</sup>. For this reason, several studies have been performed to prevent postoperative decrease in muscle function by preoperative physiotherapy. For example, a large-scale randomized controlled trial (RCT) demonstrated that inspiratory muscle training (IMT), for two or more weeks before coronary artery bypass graft surgery reduced the incidence of all pulmonary complications from 35% to 18%, and for pneumonia from 16% to 7%<sup>[23]</sup>. Preoperative IMT is also feasible for patients undergoing esophagectomy, and even preserves postoperative respiratory muscle strength<sup>[24,25]</sup>.

### Minimizing irradiated lung volume

Patients with esophageal cancer are mostly treated neoadjuvant with radiotherapy and chemotherapy<sup>[4]</sup>. However, these multimodality treatments are often correlated with an increase in postoperative pulmonary complications and mortality<sup>[26]</sup>. An adjustable factor in these treatments is the amount of radiation on the lung. For example, when  $\geq 40\%$  of the lung volume received  $\geq 10$  Gy, the incidence of pneumonia and ARDS significantly increased from 8% to 35%<sup>[26]</sup>. Multivariate analysis of various dosimetric factors has shown that the total amount of lung spared from doses  $> 5$  Gy is significantly correlated with reduced pulmonary complications<sup>[27]</sup>. Though this correlation is not found in all studies, it seems reasonable to reduce the amount of irradiated healthy lung

**Table 1 Advantages of prone positioning**

Alveolar recruitment
Improved redistribution of ventilation
Redirection of compressive force of the heart
Better clearance of secretion

tissue from an oncological viewpoint.

## PEROPERATIVE STRATEGIES

### *Minimally invasive surgery*

Minimally invasive surgery has rapidly evolved in recent years. Since minimally invasive approaches reduce factors associated with pulmonary complications (*e.g.*, blood loss, pain, and inflammation), minimally invasive esophagectomy would be especially beneficial with respect to pulmonary complications<sup>[28]</sup>. Recently, a prospective RCT demonstrated the benefits of a minimally invasive approach regarding pulmonary complications for the first time<sup>[29]</sup>. Fifty-nine patients undergoing thoracoscopic esophagectomy in prone positioning were compared to 56 patients undergoing open transthoracic esophagectomy in a left semi-lateral position. The pneumonia (clinical diagnosis confirmed by radiologic investigation and a positive sputum culture) rate within the first two postoperative weeks was 9% *vs* 29% in the open group (RR = 0.30, 95%CI: 0.12-0.60). Since a sputum culture is often negative in case of pneumonia, this study may underestimate the true pneumonia rate. However, the observed reduction in postoperative pneumonia by the minimal invasive approach is significant<sup>[29]</sup>.

It is questionable whether the minimally invasive approach, the prone positioning, or a combination of both caused the outcomes in this trial. Traditionally, patients undergo an open transthoracic esophagectomy in a left lateral decubitus position with double lumen tube intubation for one-lung ventilation. However, with the development of minimally invasive, thoracoscopic techniques, patient positioning was no longer restricted to a lateral decubitus position giving rise to minimally invasive, thoracoscopic, prone position techniques<sup>[30]</sup>. There are several advantages to a prone positioning, including partial or intermittent single lumen ventilation, as opposed to total lung collapse by a double lumen intubation in lateral decubitus position (Table 1). Further, perioperative distribution of pulmonary ventilation and circulation might be improved, leading to better oxygenation<sup>[30]</sup>. These advantages translate in improved postoperative outcomes, as shown by two studies that demonstrated an advantage of prone positioning compared to left lateral decubitus positioning<sup>[31,32]</sup>.

Despite these advantages, prone positioning has not been adopted widely. Surgeons question whether or not safety is compromised due to the difficulty of an emer-

gency conversion in prone position to left lateral with subsequent difficult airway management. However, a recent systematic review concluded prone positioning to be safe<sup>[30]</sup>. Furthermore in the previously mentioned trial during thoracoscopic dissection all patients were in prone position<sup>[29]</sup>.

### *Corticosteroids and neutrophil elastase inhibitors*

Pulmonary complications can be reduced by dampening the inflammatory response through medication. Sato *et al.*<sup>[33]</sup> found a pre-operative single dose of methylprednisolone (10 mg/kg) significantly reduced postoperative inflammation and subsequent pulmonary complications (from 30% to 9%). Other studies found similar benefits of methylprednisolone, without observing adverse effects<sup>[34]</sup>.

However, even with pre-operative methylprednisolone administration, pulmonary complications occur frequently<sup>[35]</sup>. This might be caused by the systemic inflammatory response on esophagectomy, leading to accumulation of neutrophils in the lungs. Subsequently local release of neutrophil elastase injures the lung<sup>[36]</sup>. Since glucocorticoids do not affect the release or function of neutrophil elastase, additional selective inhibition of neutrophil elastase might be beneficial<sup>[37]</sup>. Indeed, adding a selective neutrophil elastase inhibitor to methylprednisolone improves oxygenation during the first seven postoperative days<sup>[38]</sup>. Furthermore, perioperative selective neutrophil elastase inhibition prevented ALI after minimally invasive esophagectomy<sup>[36]</sup>.

The results of perioperatively administered methylprednisolone and neutrophil elastase inhibitors are encouraging. However, all trials were conducted in Eastern populations. Because genomic factors might influence results, trials should be conducted in other populations in order to determine whether these results can be extrapolated to all populations.

### *Protective ventilation*

Protective ventilation can reduce the amount of mechanically induced pulmonary injury during esophagectomy. During protective ventilation, tidal volumes are reduced and a moderate positive end-expiratory pressure is applied<sup>[39]</sup>. This strategy reduces inflammation and improves oxygenation compared to conventional ventilation. Though pneumonia rates have shown to be lower after protective ventilation, this was not significantly different<sup>[39]</sup>.

### *Goal-directed fluid therapy*

Goal directed fluid administration reduces postoperative pulmonary complications in other types of surgery such as major (upper) abdominal and major vascular surgery (RR = 0.7, 95%CI: 0.6-0.9)<sup>[40]</sup>. With this strategy, fluids are administered to achieve predefined, patient-specific hemodynamic goals, avoiding excessive resuscitation or under-resuscitation as seen with liberal or restrictive fluid administration<sup>[40]</sup>. Increased volume of perioperative fluid administration increases the risk for pulmonary complica-

tions following esophagectomy<sup>[41]</sup>. Therefore, it would be interesting to determine if this can be prevented by goal-directed fluid administration. However, because instruments that adequately measure hemodynamic parameters to guide fluid administration are invasive or difficult to use, they are not commonly applied. As a consequence several simple, minimally invasive instruments have been developed. Further research should first compare these devices in order to determine which impacts outcomes most<sup>[42]</sup>.

## POSTOPERATIVE STRATEGIES

Strategies to reduce pulmonary complications that are applied postoperatively are analgesia, prolonged postoperative ventilation, and nasogastric decompression. Adequate postoperative analgesia is important after esophagectomy, because postoperative pain from thoracic and upper abdominal wounds compromises pulmonary function, coughing, and mobilization, resulting in atelectasis and pneumonia. In patients undergoing esophagectomy, thoracic epidural analgesia is more effective than intravenous opioid analgesia<sup>[43]</sup>. Furthermore, thoracic epidural analgesia facilitates early extubation and reduces the risk for respiratory failure, overall pulmonary complications and mortality<sup>[9,44]</sup>.

Postoperative pain, aspiration and airway edema were the main rationale for routinely performing prolonged postoperative ventilation for many years. Mechanical ventilation could cause barotrauma, ventilator acquired pneumonia and endotracheal tube related problems. Early extubation, based on individual clinical factors, does not increase pulmonary complications<sup>[45]</sup>. After early extubation, routine bronchoscopic clearance of secretions was associated with reduced mortality, possibly due to preventing of postoperative pulmonary complications<sup>[44]</sup>. However, further studies are needed to substantiate this retrospectively found effect.

Another commonly applied strategy to reduce pulmonary complications due to postoperative aspiration is routine nasogastric decompression. However, a recent meta-analysis showed that after major upper abdominal surgery this strategy increased pulmonary complications (OR = 1.49, 95%CI: 1.01-2.21)<sup>[46]</sup>. Routine insertion of a nasogastric tube six to ten days following a esophagectomy is not beneficial compared to early removal of the nasogastric tube (second day postoperative)<sup>[47]</sup>. Furthermore, the commonly used single lumen nasogastric tube does not reduce aspiration compared to the situation in which no tube is routinely inserted<sup>[48,49]</sup>. In addition, routine nasogastric decompression failed to reduce pneumonia rates<sup>[48,49]</sup>. However, trials that have investigated routine nasogastric tube insertion did not specifically investigate pulmonary complications, highlighting a need for a trial to detect a clinically significant reduction in pulmonary complications is needed.

## CONCLUSION

Pulmonary complications are an important problem after esophagectomy. However, many advances have been made in recent years. Proven effective strategies are minimally invasive surgery, thoracic epidural analgesia and early enteral nutrition. Perioperative methylprednisolone and neutrophil elastase inhibitor administration can be added to these strategies if their benefits are confirmed in additional studies.

Preoperative optimization of performance status, prone positioning and targeted fluid therapy are promising for further research. While new interventions are extensively investigated before application, it seems unjust to apply invasive interventions without proven benefits. Therefore several commonly applied strategies (*e.g.*, routine nasogastric decompression, delay of oral intake, prophylactic mechanical ventilation) are currently being re-evaluated.

## Abstract

Chronic hepatitis B (CHB)-related hepatocellular carcinoma (HCC) is a major health problem in Asian-Pacific regions. Antiviral therapy reduces, but does not eliminate the risk of HCC. It would be a heavy financial burden in most low and middle economic countries if all CHB patients received antiviral therapy and HCC surveillance. Thus, there is a need for accurate risk prediction to assist prognostication, decisions on the need for antiviral therapy and HCC surveillance. A few well-established risk factors for HCC, namely advanced age, male gender, high viral load, cirrhosis *etc.*, are the core components of three HCC risk scores: CU-HCC, GAG-HCC and REACH-B scores. These 3 scores were confirmed to be accurate in predicting HCC up to 10 years in treatment-naïve patients. Their validity and applicability have recently been demonstrated in a large cohort of entecavir treatment patients. A decrease in risk scores after antiviral therapy translates to a lower risk of HCC. These findings support the application of HCC risk scores in all CHB patients. Different levels of care and different intensities of HCC surveillance should be offered according to the risk profile of patients. Patients at risk of HCC should undergo regular HCC surveillance,

even when they are receiving antiviral treatment.

© 2013 Baishideng. All rights reserved.

**Key words:** Antiviral therapy; Cirrhosis; Hepatitis B virus DNA; Hepatocellular carcinoma; Risk prediction score; Transient elastography

**Core tip:** CU-hepatocellular carcinoma (HCC), GAG-HCC and REACH-B scores accurately predict subsequent HCC development in both treatment-naïve patients with chronic hepatitis B and those receiving antiviral therapy. At the recommended cutoff values, baseline CU-HCC and REACH-B scores had high sensitivity, while the GAG-HCC score had high specificity in predicting HCC. Patients persistently in the low-risk category have the lowest risk of HCC; those "downgraded" in risk category have significantly lower, but a small risk of HCC compared to those in the high-risk category. Patients in the high-risk category either at baseline or after treatment should undergo HCC surveillance.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the second leading cause of cancer death in men worldwide<sup>[1]</sup>. Chronic hepatitis B virus (HBV) infection is one of the major causes of HCC, and it is estimated that over 350 million people are chronically infected with HBV worldwide<sup>[2]</sup>. Globally, HBV accounts for 53% of all cases of HCC<sup>[3]</sup>. Due to the high preva-

lence of HBV infection, the incidence of HCC in Eastern Asia and Southeast Asia is the highest in the world<sup>[4]</sup>.

In the last two decades, the development of antiviral therapy was a major breakthrough in the management of chronic hepatitis B (CHB), which modifies the natural history of the disease and reduces the risk of HCC<sup>[5-7]</sup>. Nonetheless, there is still a low, but clinically relevant risk of HCC in patients receiving antiviral therapy. It would be a heavy financial burden, particularly in low and middle economic countries, if all CHB patients received antiviral therapy and HCC surveillance. Thus, there is a need for accurate risk prediction to assist prognostication, decisions on the need for antiviral therapy and HCC surveillance.

## RISK FACTORS FOR HBV-RELATED HCC

### Treatment-naïve patients

A handful of factors have been repeatedly shown to increase the risk of HCC when studying the natural history of chronic HBV infection. In general the risk factors can be categorized into host factors, liver factors and viral factors (Table 1). Host factors include advanced age<sup>[8-10]</sup>, male gender<sup>[9,10]</sup>, family history of HCC<sup>[11]</sup>, and possibly single-nucleotide polymorphisms at different human genomic loci [*e.g.*, chromosome 1p36.22, chromosome 6 of human leukocyte antigen (HLA)-DP and HLA-DQ loci, and chromosome 8p12]<sup>[12,13]</sup>. Immunosuppressed conditions like human immunodeficiency virus co-infection is another risk factor<sup>[14]</sup>. Liver factors consist of advanced fibrosis and cirrhosis<sup>[11]</sup>; poor liver function as evidenced by hypoalbuminemia and hyperbilirubinemia<sup>[8]</sup>; active hepatitis as evidenced by high alanine aminotransferase (ALT) and active necroinflammation demonstrated on liver biopsy<sup>[9]</sup>; and other concomitant liver diseases such as co-infection with hepatitis C virus or hepatitis delta virus, alcoholic liver disease and nonalcoholic fatty liver disease<sup>[11]</sup>. Viral factors include high serum HBV DNA level<sup>[8,15]</sup>, hepatitis B virus e antigen (HBeAg) seropositivity<sup>[16]</sup>, HBV genotype C<sup>[17]</sup> and subgenotype Ce<sup>[18]</sup>, core promoter mutations<sup>[10]</sup> and probably high serum hepatitis B surface antigen (HBsAg) level<sup>[19]</sup>.

### Patients receiving antiviral therapy

The natural history of chronic HBV infection is altered by antiviral therapy. Therefore, the risk factors for HCC may be different in treated patients compared to untreated patients. The landmark Asian lamivudine trial did not specifically determine the risk factors for HCC, however, baseline Child-Pugh and Ishak fibrosis score, as well as genotypic resistance *YMDD* mutation were risk factors for disease progression<sup>[6]</sup>. The drug-resistant mutant did not increase the risk of HCC (both 4% in patients with or without *YMDD* mutation). Nonetheless, the significance of *YMDD* mutation might be masked by the short follow-up duration (study prematurely terminated at 32 mo) and the unspecified interval between emergence of drug resistance and HCC development.

**Table 1 Risk factors for hepatitis B virus-related hepatocellular carcinoma**

Host factors	Liver factors	Viral factors
Advanced age	Advanced fibrosis	High serum HBV DNA
Male gender	Cirrhosis	Positive HBeAg
Family history of HCC	Hypoalbuminemia	HBV genotype C
SNP at human genomic loci, <i>e.g.</i> Chromosome 1p36.22	Hyperbilirubinemia	HBV subgenotype Ce
Chromosome 6 of HLA-DP/Q loci	High ALT	Core promoter mutations
Chromosome 8p12	Active necroinflammation	High serum HBsAg level
Immunosuppressed condition, <i>e.g.</i>	Concomitant liver diseases, <i>e.g.</i>	
Human immunodeficiency virus co-infection	Hepatitis C virus co-infection	
	Hepatitis delta virus co-infection	
	Alcoholic liver disease	
	Nonalcoholic fatty liver disease	

ALT: Alanine aminotransferase; HBeAg: Hepatitis B virus e antigen; HBsAg: Hepatitis B surface antigen; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; HLA: Human leukocyte antigen; SNP: Single-nucleotide polymorphism.

In a retrospective study of 2795 Japanese CHB patients (657 lamivudine-treated *vs* 2138 untreated patients), the absence of treatment, male gender, family history of HBV carriage, age greater than 40 years, fibrosis more than grade 2 of 4, albumin level below 40 g/L, and platelet count of < 150000/mm<sup>3</sup> were independent risk factors for HCC<sup>[20]</sup>. The risk factors identified in this study appeared to be no different from those identified from studies on the natural history, probably because more than 75% of patients were untreated.

In a nationwide study from Greece retrospectively analyzing 818 HBeAg-negative patients treated with lamivudine, advanced age and cirrhosis were risk factors for HCC<sup>[21]</sup>. On-therapy virologic remission (*i.e.*, undetectable on-treatment serum HBV DNA level) did not significantly affect the incidence of HCC (although there was a trend for lower risk of HCC in the absence of cirrhosis). As all patients with on-therapy virologic remission who developed HCC (8 of 228; 3.6%) occurred within 30 mo of lamivudine treatment, some of these tumors might have been pre-existing HCC.

A recent large-scale cohort study of 1531 entecavir treatment CHB patients demonstrated the importance of maintained virologic response<sup>[22]</sup>. Old age, cirrhosis, and virologic remission for 24 mo or more were independent factors associated with HCC in the entire cohort; whereas advanced age and hypoalbuminemia were predictors in non-cirrhotic patients. Although maintained virologic response was important, 30 out of 47 patients (64%) who achieved this virologic target still developed HCC. This can be explained by the early integration of HBV into the host genome and the presence of cirrhosis, such that

even with very effective suppression of viral replication with antiviral agents, HCC may still develop<sup>[23]</sup>.

Summarizing the findings of these studies, advanced age and cirrhosis are the two major risk factors consistently demonstrated in patients receiving antiviral therapy. While maintained virologic response is likely a protective factor, baseline HBV DNA level is no longer important in these treated patients as it is usually much reduced after treatment. Theoretically HBsAg level, which reflects the amount and transcriptional activity of covalently closed circular DNA inside the liver, might have a role in predicting HCC in treated patients when serum HBV DNA is no longer detectable<sup>[24]</sup>. However, this was not confirmed in patients receiving entecavir<sup>[22]</sup>. The probable reason for this is that these patients had active disease to start with; those with lower HBsAg levels were more likely to be cirrhotic. In other words, there were no “inactive HBV carriers” at very low risk of HCC as in untreated natural history cohorts<sup>[19]</sup>.

## APPROACHES TO DEVELOP RISK SCORES

There are different approaches to developing a risk score for HCC, however, the first common step is to identify important independent factors associated with HCC in a training cohort. After statistical analysis, scores are assigned to different parameters in the equation to make up the final score. In order to demonstrate the applicability and reproducibility of the score, it should be validated in an independent cohort. If this independent cohort is not available, the leave-one-out cross-validation can be applied to assess the performance of the score in new data<sup>[25]</sup>. This validation involves using a single observation from the original sample as the validation data, and the remaining observations as the training data. This is repeated such that each observation in the sample is used once as the validation data.

Take the CU-HCC score as an example, significant variables were first identified in the multivariable Cox proportional hazards model<sup>[8]</sup>. A score was attributed to each variable according to its relative contribution in the model, as determined by the  $\chi^2$  score. Furthermore, different cutoff values of the score were determined to categorize patients into different levels of risk (*i.e.*, low-, medium-, and high-risk categories). The performance of the cutoff can be assessed in terms of discriminatory ability and monotonicity by the linear trend  $\chi^2$  test<sup>[26]</sup>.

Validation of the score usually involves two steps: discrimination and calibration. Discrimination can be assessed with the receiver operating characteristic (ROC) curve, *i.e.*, area under ROC (AUROC) curves, sensitivity, and specificity. Calibration is evaluated by estimating the observed HCC risk using the Kaplan-Meier method with the same cumulative risk scores. A combination of neighboring groups of cumulative risk scores will be performed if the observed HCC risk in a group with the same cumulative risk score is low<sup>[9]</sup>.

## EXISTING PREDICTION SCORES FOR HCC

The three most commonly applied HCC risk scores are described below (Tables 2 and 3).

### CU-HCC score

The CU-HCC score<sup>[8]</sup> was first derived from a cohort of 1005 Chinese CHB patients from a prospective study on the surveillance of HCC in chronic HBV carriers from The Chinese University of Hong Kong (abbreviated as CU in the name of the score)<sup>[18]</sup>. It was validated in an independent cohort of 424 Chinese CHB patients<sup>[27]</sup>. Both cohorts were from tertiary referral clinics. While all patients were treatment-naïve at baseline, 15.1% and 25.0% of patients from the training and validation cohort, respectively, received antiviral therapy during the long-term follow up to 10 years. The CU-HCC score is composed of 5 parameters: age, albumin, bilirubin, HBV DNA, and cirrhosis; it ranges from 0 to 44.5 (Table 2). The investigators identified two cutoff values (5 and 20) which best discriminated HCC risk into three categories. The 5-year HCC-free survival rates were 98.3%, 90.5%, and 78.9% in the low-, medium-, and high-risk groups, respectively. By applying the lower cutoff value, this score has high negative predictive value of 97.8% to exclude future HCC development.

### GAG-HCC score

The GAG-HCC score<sup>[10]</sup> was first developed from a cohort of 820 Chinese CHB patients from tertiary referral clinics. The name was abbreviated from “Guide with Age, Gender, HBV DNA, Core promoter mutations and Cirrhosis”. All patients were treatment-naïve at baseline and censored at the time of initiation of antiviral therapy. As an independent cohort was not included, the investigators adopted the leave-one-out cross-validation mentioned above<sup>[25]</sup>. There are two versions of the score. The original version is composed of gender, age, core promoter mutations, HBV DNA level and cirrhosis. There is a simplified version which omits core promoter mutations, as they may not be easily available in some centers. The score ranges widely to above 100, as age (in years) is one of the components in the formula. A cutoff value of 101 was found to have good sensitivity and specificity of 84.1% and 76.2% for 5-year prediction, and 88.0% and 78.7% for 10-year prediction, respectively. The negative predictive values were as high as 98.3% to 100% to exclude future HCC development.

### REACH-B score

The REACH-B score<sup>[9]</sup> was first derived from a cohort of 3584 Chinese CHB patients from the community-based prospective Taiwanese REVEAL-HBV study<sup>[15]</sup>, and then validated in a cohort of 1505 patients from three hospitals in Hong Kong and South Korea tertiary referral clinics. The name was the abbreviation of “Risk Estimation for HCC in CHB”. All patients in the training

**Table 2 Components of the risk scores**

Factor	Risk score			
	CU-HCC	GAG-HCC (yr)	REACH-B	
Age (yr)	≤ 50: 0		30-34: 0	
	>50: 3		35-39: 1	
			40-44: 2	
			45-49: 3	
			50-54: 4	
			55-59: 5	
Sex	NA	Male: 16 Female: 0	Male: 2 Female: 0	
	Albumin (g/L)	≤ 35: 20	NA	NA
		> 35: 0		
Bilirubin (mmol/L)	≤ 18: 0	NA	NA	
	> 18: 1.5			
ALT (U/L)	NA	NA	< 15: 0	
			15-44: 1	
			≥ 45: 2	
HBeAg	NA	NA	Positive: 2 Negative: 0	
	HBV DNA (copies/mL)	< 4 log: 0	3 × in log	< 4 log: 0
4-6 log: 1		4-5 log: 3		
> 6 log: 4		5-6 log: 5		
(lack of maintained virologic suppression: 4)		≥ 6 log: 4		
		(lack of maintained virologic suppression: 4)

ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen; NA: Not applicable; HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus.

cohort did not have cirrhosis according to ultrasonography at the time of recruitment, and remained treatment-naïve throughout the follow-up period which was as long as 12 years. In contrast, 18.4% (277/1505) of patients in the validation cohort had cirrhosis. The REACH-B score consists of 5 parameters: gender, age, ALT level, HBeAg status and HBV DNA level. The score ranges from 0 to 17 and is primarily designed for patients without cirrhosis. The authors did not categorize patients into different risk levels, instead the 3-, 5- and 10-year risk of HCC was determined for each particular risk score. The HCC risk ranged from 0% to 23.6% at 3 years, 0% to 47.4% at 5 years, and 0% to 81.6% at 10 years for patients with the lowest (0 point) and highest HCC risk (17 points), respectively. As the risk increased significantly starting at 8 points, it could be used as an arbitrary cutoff value to categorize patients into different level of risks.

## IMPACT OF ANTIVIRAL THERAPY ON RISK PREDICTION

Most of the patients involved in the development of the risk scores did not receive antiviral therapy. This raised a concern regarding their validity and applicability to patients receiving treatment. This is particularly relevant to

**Table 3 Comparison of the CU-hepatocellular carcinoma, GAG-hepatocellular carcinoma and REACH-B scores**

Score	Patients	Components	Cutoff value	Performance
CU-HCC	Clinic patients: 1005 in training cohort, 424 in validation cohort	Age, albumin, bilirubin, HBV DNA, cirrhosis	5	97% NPV at 10 yr
GAG-HCC	820 clinic patients (leave-one-out cross-validation method)	Age, gender, HBV DNA, cirrhosis	101	99% NPV at 10 yr
REACH-B	Non-cirrhotic patients: 3584 in training cohort, 1505 in validation cohort	Age, gender, ALT, HBV DNA, HBeAg	8	98% NPV at 10 yr

ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; NPV: Negative predictive value.

those at risk of HCC as they most often receive antiviral therapy. Antiviral therapy modifies the natural history of CHB by decreasing the serum HBV DNA levels, and altering other laboratory parameters (*e.g.*, lowering ALT, raising albumin and lowering bilirubin level). This leads to another question on the clinical significance of dynamic changes in the risk scores during longitudinal follow-up.

These important concerns have been addressed in a recent cohort study of 1531 entecavir treatment CHB patients followed up for 42 ± 13 mo<sup>[22]</sup>. All patients received entecavir 0.5 mg daily for at least 12 mo. The importance of maintained viral suppression was emphasized in this study as virologic remission for 24 mo or more, together with advanced age and cirrhosis, were independent factors associated with HCC in this cohort. The CU-HCC, GAG-HCC and REACH-B scores were found to be accurate in predicting HCC in 3 and 5 years. Of these scores, the CU-HCC score had the highest AU-ROC at baseline (0.80 *vs* 0.76 and 0.71, respectively). At the recommended cutoff values, baseline CU-HCC and REACH-B scores had high sensitivity (93.6% and 95.2%, respectively), while the GAG-HCC score had high specificity (78.9%) in predicting HCC.

After antiviral therapy, the risk scores change due to decreased viral load (*i.e.*, lower HBV DNA) and even HBeAg-seroconversion, improvement in liver function (high albumin, lower bilirubin) and necroinflammation (lower ALT). Therefore, a significant proportion of patients would have decreased risk scores following treatment. From this cohort study, 14.0%, 8.2% and 38.3% of patients had their risk category changed from high risk to low risk as defined by the CU-HCC, GAG-HCC and REACH-B score, respectively, after 2 years of entecavir<sup>[22]</sup>. One unresolved issue is the regression of cirrhosis, which may occur after long-term antiviral therapy<sup>[28,29]</sup>. However, as this regression take years to happen, its effect on the dynamic change in risk level can only be evaluated in a study with at least 8 to 10 years of follow up.

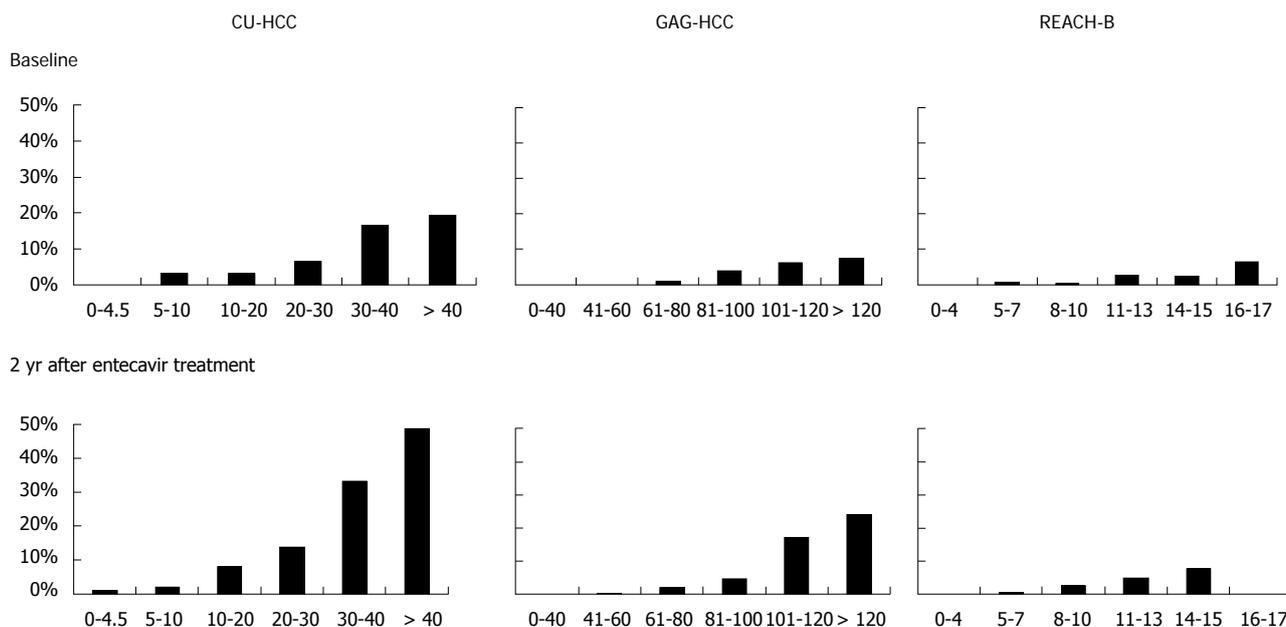

Figure 1 Risk of hepatocellular carcinoma in the next 3 years by risk scores. Results adopted from Wong *et al*<sup>[22]</sup>. HCC: Hepatocellular carcinoma.

**Table 4** Dynamic changes in risk scores and 5-year risk of hepatocellular carcinoma

Risk score	Baseline	2 yr	HCC in 5 yr		
			CU-HCC	GAG-HCC	REACH-B <sup>1</sup>
Low	Low	Low	0.4%	1.4%	0.0%
Low	Low	High	0.0%	NA	0.0%
High	High	Low	2.1%	5.1%	0.0%
High	High	High	12.9%	26.4%	2.1%

<sup>1</sup>Only patients without cirrhosis were analyzed for the REACH-B score. Results adopted from Wong *et al*<sup>[22]</sup>. HCC: Hepatocellular carcinoma; NA: Not available.

The dynamic changes in risk scores after antiviral therapy had a significant meaning on HCC risk. For all three risk scores, patients persistently in the low-risk category had the lowest risk of HCC; those “downgraded” in risk category had a significantly lower risk of HCC compared to those in the high-risk category (Table 4)<sup>[22]</sup>. Only 0.4% of patients who remained at low risk at baseline and 2 years according to the CU-HCC score would develop HCC in 5 years; the corresponding figures were 2.1% and 12.9% in those who changed from high risk to low risk, and those who remained at high risk at both time points, respectively. With the GAG-HCC score, 1.4%, 5.1% and 26.4% of patients who remained at low risk, changed from high to low risk, and remained at high risk developed HCC in 5 years, respectively. The results from both the CU-HCC and GAG-HCC score showed that downgrading of risk score reduces, but does not eliminate the risk of HCC (Figure 1).

## CLINICAL APPLICATION OF RISK SCORES

The risk scores discussed above are simple to use as they combine a few widely available clinical variables for the estimation of HCC risk within a specific timeframe. However, the version of the GAG-HCC score which includes core promoter mutations as a component may not be preferred by clinicians, as tests for these mutations are not easily accessible in the primary care setting and general practitioners taking care of the majority of CHB patients. The simple calculations in these scores facilitate implementation in routine clinical use. However, the complexity of these calculations is less of a concern as web-based or smart phone apps which include calculators for some of these scores are now available<sup>[30,31]</sup>. The major limitation of these scores is that all studies only involve Asian (mostly Chinese) patients, therefore, the validity and applicability in other ethnic groups remain uncertain. These risk scores can potentially be incorporated into a clinical risk-prediction instrument that could improve patient management through appropriate and timely intervention. Clinicians could use the scores to assess the risk of progression, and subsequently make evidence-based decisions about the clinical management of these patients. A recent Japanese study showed that patients in the high-risk categories according to these risk scores would benefit most from entecavir<sup>[5]</sup>. Another long-term follow-up study of 641 patients receiving tenofovir for 6 years showed that the observed incidence of HCC was lowered compared to the predicted risk us-

ing the REACH-B score<sup>[32]</sup>. This is indirect evidence that antiviral therapy reduces the risk of HCC.

We advocate estimating the risk scores for all CHB patients. For treatment-naïve patients, the results of these scores may guide the need for antiviral therapy complementary to the treatment guidelines. The scores should be monitored regularly every 1 to 2 years. Patients remaining at low risk are suitable for regular monitoring in the primary care setting. Those at high risk should be referred for specialist care and appropriate treatment should be considered.

For patients receiving antiviral therapy, the risk scores should be monitored yearly. Those who respond well to treatment, *i.e.*, achieve maintained virologic remission, and remain in the low-risk category have a minimal risk of HCC. Therefore, they may also be referred to family physicians who are experienced in monitoring such patients. Patients with risk downgraded after treatment would have a lower, but 2% to 5% risk of HCC in 5 years. Therefore, they should undergo regular HCC surveillance<sup>[33]</sup>. Those in the high-risk category despite antiviral therapy may require more intensive HCC surveillance, as the risk of HCC can be as high as 12.9% to 26.4% in 5 years (Table 3). On the other hand, patients who fail to achieve maintained viral suppression should consider alternative treatment regimes in order to reduce the risk of HCC<sup>[34]</sup>.

## FUTURE DIRECTION

One potential problem with these risk scores is that heavy weighting is assigned to cirrhosis in CU-HCC and GAG-HCC. In the study of the REACH-B score, liver cirrhosis was excluded by ultrasonography. As early cirrhosis may be missed by ultrasonography, this limitation may lead to substantial prediction errors if the presence or absence of cirrhosis is misclassified<sup>[35]</sup>. Transient elastography is one of the most widely validated non-invasive tools to detect early liver cirrhosis in various chronic liver diseases<sup>[36]</sup>. Liver stiffness measurement (LSM) with this tool may be useful to refine the diagnosis of cirrhosis and substitute clinical cirrhosis as a component in the risk score to predict HCC. There is evidence that LSM can predict HCC<sup>[37]</sup>, patient survival<sup>[38]</sup> as well as complications after hepatic resection<sup>[39]</sup>. Therefore, it is reasonable to believe that LSM would be an important parameter in a HCC risk score.

A recent Korean study of 1250 CHB patients developed a predictive model for HCC using four clinical parameters, which included age, gender, HBV DNA and LSM value<sup>[40]</sup>. The probability equals  $1 - P^A$ ; where  $A = \exp(0.05306 \times \text{age} + 1.106 \times \text{male gender} + 0.04858 \times \text{LSM values} + 0.50969 \times \text{HBV DNA} \geq 20000 \text{ IU/L})$ . This model was found to have a moderately good discrimination capability, with an AUROC of 0.81. The predicted risk of HCC development correlated fairly well with the observed risk ( $r = 0.91$ ). More data concerning the role of LSM in the HCC risk score is now evolving<sup>[41]</sup>.

## CONCLUSION

In conclusion, HCC risk scores can accurately predict subsequent HCC development in both treatment-naïve patients and in those receiving antiviral therapy. Different levels of care and different intensities of HCC surveillance should be offered according to the risk profile of patients. Patients in the high-risk category should be one of the indications for antiviral therapy, as well as appropriate HCC surveillance. For patients receiving antiviral therapy, maintained virologic response should be the treatment target, particularly in patients with cirrhosis. Patients at risk of HCC should undergo regular HCC surveillance, even when they are receiving antiviral treatment.

### Abstract

Although gastroesophageal reflux disease (GERD) is a common disorder in Western countries, with a significant impact on quality of life and healthcare costs, the mechanisms involved in the pathogenesis of symptoms remain to be fully elucidated. GERD symptoms and complications may result from a multifactorial mechanism, in which acid and acid-pepsin are the important noxious factors involved. Prolonged contact of the esophageal mucosa with the refluxed content, probably caused by a defective anti-reflux barrier and luminal clearance mechanisms, would appear to be responsible for macroscopically detectable injury to the esophageal squamous epithelium. Receptors on acid-sensitive nerve endings may play a role in nociception and esophageal sensitivity, as suggested in animal models of chronic acid exposure. Meanwhile, specific cytokine and chemokine profiles would appear to underlie the various esophageal phenotypes of GERD, explaining, in part, the genesis of esophagitis in a subset of patients. Despite these findings, which show a significant production of inflammatory mediators and neurotransmitters

in the pathogenesis of GERD, the relationship between the hypersensitivity and esophageal inflammation is not clear. Moreover, the large majority of GERD patients (up to 70%) do not develop esophageal erosions, a variant of the condition called non-erosive reflux disease. This summary aims to explore the inflammatory pathway involved in GERD pathogenesis, to better understand the possible distinction between erosive and non-erosive reflux disease patients and to provide new therapeutic approaches.

**Key words:** Gastroesophageal reflux disease; Mucosal inflammation; Heartburn; Esophagitis; Hypersensitivity

**Core tip:** The present study aimed to explore the mechanisms involved in the pathogenesis of gastroesophageal reflux disease (GERD) symptoms and complications, which remain to be fully elucidated. Despite recent evidence confirming the important production of inflammatory mediators and neurotransmitters in the pathogenesis of GERD, the interplay between esophageal inflammation and hypersensitivity is not clear. Based on the literature and on personal experimental studies, this paper attempts to summarize the evidence concerning the inflammatory pathway involved in GERD pathogenesis, to better define the possible distinction between erosive and non-erosive reflux disease patients and to provide new therapeutic approaches.

## INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common disorder in Western countries, with 10%-30% of the individuals affected every week by symptoms that have a significant impact on quality of life and healthcare costs<sup>[1-3]</sup>. In GERD, the mechanisms involved in the pathogenesis of heartburn and chest pain remain to be completely elucidated; however, acid and pepsin can induce macroscopically detectable injury to the esophageal squamous epithelium<sup>[4]</sup>. Injured or inflamed tissues release inflammatory mediators that can be detected by the immune system. Moreover, in response to these chemical insults, endothelial cells produce adhesion molecules, which recruit and activate leukocytes, thus mediating inflammatory conditions<sup>[5]</sup>. In an experimental model of reflux esophagitis and in patients affected by GERD, some of the mediators considered to be critical in the etiology of esophagitis are classic inflammatory products, such as prostanoids and reactive oxygen species (ROS)<sup>[6,7]</sup>. Several studies have also suggested that the mucosal immune and inflammatory responses, characterized by specific cytokine and chemokine profiles, may underlie the various esophageal phenotypes of GERD<sup>[8-11]</sup>. Indeed, the large majority of GERD patients (up to 70%) do not develop esophageal erosions, a variant of the condition called non-erosive reflux disease (NERD)<sup>[12,13]</sup>. Although several studies report the progression of NERD to erosive esophagitis (erosive reflux disease, ERD), structural and functional characteristics differentiate these two important GERD groups: NERD patients usually have a normal lower esophageal sphincter resting pressure, minimal esophageal body motility abnormalities, low esophageal acid exposure profile and minimal night-time esophageal acid exposure<sup>[14,15]</sup>. The symptom response, in NERD patients, to acid suppressive therapy is lower than that in patients with ERD<sup>[14]</sup>. In fact, in these patients, esophageal visceral hypersensitivity, sustained esophageal contractions or impaired tissue resistance, have been identified as possible mechanisms responsible for reflux symptoms and proton pump inhibitor (PPI) resistance<sup>[16-18]</sup>.

This brief summary focuses on the inflammatory pathway involved in the pathogenesis of GERD, to better understand the distinction between ERD and NERD patients and, thus, to provide better therapeutic approaches.

## DAMAGE INDUCED BY REFLUXATE

GERD is a complex disorder with the potential for developing esophagitis, esophageal strictures and Barrett's esophagus<sup>[2]</sup>. GERD symptoms and complications may result from a multifactorial mechanism in which acid and acid-pepsin are the important noxious factors involved. Prolonged contact of the esophageal mucosa with the refluxed content, possibly caused by a defective anti-reflux barrier and luminal clearance mechanisms, would appear to be responsible for the morphological changes in the esophageal epithelium of GERD patients<sup>[19,20]</sup>.

A well studied ultra-structural alteration, *i.e.*, dilated intercellular spaces (DIS), demonstrated both in ERD and NERD patients<sup>[21,22]</sup>, could explain the genesis of symptoms triggered by the activation of intra-mucosal chemo-sensitive nociceptors and, at the same time, the inflammatory cascade generated by luminal acid diffusing into the tissue. In conditions not associated with severe inflammation, it is unclear how, in the presence of these symptoms, an injurious process initiating in the normal mucosa may lead to macroscopic injuries in a subset of patients (30%-40%), namely the ERD group.

The increased paracellular permeability, associated with the presence of DIS, and the resulting breakdown in the epithelial barrier, do not necessarily result only from excessive acid exposure, as suggested by the normal acid contact time at pH-monitoring in NERD patients, in which the symptoms are generated in the absence of esophageal epithelial erosions<sup>[23]</sup>. At the same time, the esophageal mucosa would appear to play a pivotal role in the development of esophageal inflammation and pain. Unlike intestinal inflammation, in which the role of the mucosa has been studied, as far as concerns the esophagus, it has only recently been suggested that gastric juice reflux does not directly damage the esophageal mucosa, but instead stimulates the esophageal epithelial cells to secrete chemokines that attract and activate the immune cells, causing damage to the esophageal squamous epithelial cells<sup>[23]</sup>. Microscopic inflammation, characterized by neutrophilic and eosinophilic infiltration of the esophageal mucosa and submucosa, is observed more frequently in ERD than in NERD patients<sup>[24-26]</sup>.

Therefore, the different esophageal phenotypes of GERD could possibly reflect the presence of various inflammatory mediators responsible for mucosal immune responses in these groups of patients<sup>[8,27,28]</sup>.

In a recent investigation, we observed that levels of cytokines, such as interleukin-8 (IL-8) and platelet activating factor (PAF), are significantly higher in the esophageal mucosa of ERD patients compared with those in the NERD group, in whom the expression of these inflammatory mediators is comparable to those of controls<sup>[11]</sup>. The acid-induced production of IL-8 and other inflammatory mediators by the esophageal mucosa have been shown to promote migration and activation of peripheral blood leukocytes<sup>[29]</sup>. These findings would corroborate the hypothesis that a cytokine-mediated mechanism, rather than a direct effect of gastroesophageal reflux, is responsible for the mucosal injury in the ERD subgroup.

Growing evidence shows that NERD patients are characterized by enhanced esophageal sensitivity to chemical and mechanical stimuli caused by enhanced excitability of visceral sensory neurons, possibly associated with overexpression of acid-sensing receptors in the epithelial layer and in the afferent fibers of the *lamina propria*<sup>[30,31]</sup>.

In particular, the transient receptor potential channel vanilloid subfamily member-1 (TRPV1) is overexpressed in the esophageal mucosa of ERD and NERD patients,

**Table 1** Cytokines and Chemokines involved in the pathophysiology of gastroesophageal reflux disease

Patients	Cytokines	Chemokines
GERD	IL-6 <sup>[8,23]</sup> , and IL-8 <sup>[8-11,23,25,29]</sup> , IL-1 $\beta$ <sup>[23,28,32,38]</sup> , INF- $\gamma$ <sup>[8]</sup> , TNF- $\alpha$ <sup>[20,38]</sup>	
ERD	IL-6 <sup>[32,37]</sup> , IL-8 <sup>[8-11,25,28]</sup> , IL-1 $\beta$ <sup>[28,32,37,38]</sup>	PAF <sup>[11,36,37]</sup> , MCP-1 <sup>[9-11,36,38]</sup> , RANTES <sup>[9,36]</sup> , MIP-1 $\alpha$ <sup>[11,36,38]</sup> , Eotaxin-1, Eotaxin-2 and Eotaxin-3 <sup>[11,36]</sup> , CINC-2 $\alpha$ <sup>[38]</sup> , and ICAM-1 <sup>[38]</sup>
NERD	IL-8 <sup>[10,25,28]</sup> , IL-1 $\beta$ <sup>[28]</sup>	
Barrett's esophagus	IL-8 <sup>[8]</sup> , IL-4 <sup>[8]</sup> , TNF- $\alpha$ <sup>[34]</sup> , IL-6 <sup>[34]</sup> , IL-8 <sup>[35]</sup>	

GERD: Gastroesophageal reflux disease; ERD: Erosive reflux disease; NERD: Non-erosive reflux disease; IL-6: Interleukin-6; IL-8: Interleukin-8; IL-1 $\beta$ : Interleukin-1 $\beta$ ; INF- $\gamma$ : Interferon-gamma; TNF- $\alpha$ : Tumor necrosis factor- $\alpha$ ; PAF: Platelet-activating factor; MCP-1: Monocyte chemoattractant protein; MIP-1 $\alpha$ : Macrophage inflammatory protein-1 $\alpha$ ; CINC-2 $\alpha$ : Cytokine-induced neutrophil chemoattractant-2 $\alpha$ ; ICAM-1: Intercellular Adhesion Molecule-1; RANTES: Regulated upon activation normal T cell expressed and presumably secreted.

compared with healthy controls, which may explain the similar severity of reflux symptoms in both groups, regardless of the presence or absence of inflammation and erosions<sup>[25]</sup>.

## INFLAMMATORY MEDIATORS AND GERD PATHOGENESIS

The mucosa of GERD patients produces significantly larger amounts of various cytokines compared with that of healthy controls<sup>[8-10,26,28,32]</sup>. These inflammatory mediators activate immune cell recruitment and migration, and may be involved in the pathophysiology of GERD (Table 1).

IL-8, one of the most important neutrophil chemoattractants<sup>[33]</sup>, is overexpressed in the mucosa of GERD patients<sup>[8-10]</sup>, and increased IL-8 levels in the esophageal mucosa of these patients correlate with the endoscopic and histological severity of the disease<sup>[8-10]</sup>. Moreover, IL-8 levels decrease following PPIs<sup>[34]</sup> and following anti-reflux surgery<sup>[35]</sup>, possibly indicating a role of this chemokine in mucosal damage. Acid-induced production of IL-8 and PAF by the esophageal mucosa promotes the migration of peripheral blood leukocytes. PAF also induces the production of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) by peripheral blood leukocytes<sup>[29]</sup>.

In a previous study, we have shown that acid-induced inflammation of the esophagus begins with activation of the TRPV1 receptors in the mucosa and synthesis of PAF by the epithelial cells<sup>[36]</sup>. Furthermore, the sensory neurotransmitters, calcitonin-gene related peptide (CGRP) and substance P, are produced by sensory neurons located in the esophageal mucosal layer<sup>[29]</sup>.

PAF diffuses from the mucosal layer, stimulating the production of H<sub>2</sub>O<sub>2</sub> in leukocytes and the production of IL-6 in the circular muscle, where IL-6 causes production of additional H<sub>2</sub>O<sub>2</sub> through activation of NADPH oxidases present in the circular muscle layer<sup>[37]</sup>. In turn, H<sub>2</sub>O<sub>2</sub> triggers the formation of IL-1 $\beta$ , which may induce the production of PAF in the muscle, probably supporting a self-sustaining cycle of inflammatory mediator production. Indeed, in an animal model of chronic esophagitis, significantly increased expressions of other inflammatory mediators, among which IL-1 $\beta$ , tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), monocyte chemoattractant protein-1 (MCP-1),

macrophage inflammatory protein-1  $\alpha$  (MIP-1 $\alpha$ ) and eotaxins, were detected in esophageal lesions compared with the normal esophagus<sup>[11,38]</sup>. In agreement with these previous reports, we recently confirmed, in biopsies from ERD patients, a significant increase in the expression of IL-8, PAF and several chemokines, compared with controls<sup>[25]</sup>. Interestingly, unlike ERD patients, the esophageal mucosa of NERD patients did not exhibit enhanced expressions of various inflammatory mediators, or the significant presence of neutrophils and eosinophils in the mucosa, being comparable to asymptomatic controls<sup>[11,23,24]</sup>.

This hypothesis is supported by a multicenter, randomized, controlled trial including 514 patients affected by GERD<sup>[26]</sup>. The study revealed that “microscopic esophagitis” (dilatation of intercellular spaces, papillary elongation and basal cell hyperplasia), was found in more than 90% of ERD patients, but in only approximately 2/3 of NERD patients<sup>[26]</sup>, with significant infiltration of immune cells only in the ERD group.

These findings would indicate a key role of several soluble mediators acting as powerful inflammatory activators, contributing to the induction of esophagitis. The observation that CGRP and substance P are generated by different mechanisms and that two different pathways mediate the sensation of heartburn and inflammation, would further explain the presence of recurrent and severe symptoms, irrespective of mucosal injury.

## VISCERAL HYPERSENSITIVITY AND REFLUX PERCEPTIONS IN GERD PATIENTS

The pathogenesis of heartburn and acid regurgitation remain to be fully elucidated, particularly in the numerous NERD patients in whom the 24-h pH-test findings may be within the normal range<sup>[39]</sup>. Indeed, an enhanced sensitivity to reflux would appear to be strongly associated with the failure of PPI treatment<sup>[40]</sup>.

Although gastric acid plays a pivotal role in the pathogenesis of GERD, other stimuli have been suggested to be involved in the pathogenesis of typical symptoms. In patients with GERD, reflux may result in direct activation of pain receptors, which may be enhanced by greater acid

diffusion through the esophageal epithelium caused by impaired mucosal barrier function<sup>[19]</sup>. Furthermore, activation of pain receptors may occur following reflux-induced distention of the esophagus. Enhanced esophageal sensitivity to these stimuli may be caused by upregulation of peripheral pain receptors and central sensitization of spinal neurons<sup>[19]</sup>.

Little is known about acid-sensitive nerves. Receptors on acid-sensitive nerve endings may play a role in nociception and esophageal sensitivity, as suggested in animal models following chronic acid exposure, and include the anion-sensing ion channel (ASIC), TRPV1 and ionotropic purinergic (P2X and P2Y) receptors<sup>[4]</sup>.

The recently demonstrated presence of acid-sensitive TRPV1 receptors in sensory nerve fibers and in epithelial cells of the esophageal mucosa<sup>[41]</sup> provides an interesting mechanism to better understand the onset of neuromodulation and symptoms generation in GERD. TRPV1 activation in primary afferent neurons evokes the sensation of burning pain and may induce neurogenic inflammation following the release of substance P and CGRP<sup>[36]</sup>.

On the other hand, growing evidence from animal models during chronic acid exposure supports the involvement of purinergic receptors in nociception and hypersensitivity<sup>[38,39]</sup>. The purinergic receptors are involved in several cell functions and may be activated by purine nucleotides as ligands<sup>[42]</sup>.

Based on their pharmacological properties and molecular characteristics, two distinct classes of purinergic receptors with preferential responses to adenosine 5'-triphosphate (ATP), as well as other single nucleotides, have been identified: the family of ligand-gated cation channel P2X receptors and the G protein-coupled P2Y receptors.

P2X and P2Y receptors play an important role in signaling visceral pain<sup>[19,39,42]</sup>. A working hypothesis of purine-mediated mechano-sensory transduction has been suggested<sup>[19,39]</sup>: ATP released from the epithelial cell lining of the gastrointestinal (GI) tract, bladder and ureter might activate P2X receptors present on the sub-epithelial nerve plexus and the signal is transmitted *via* the spinal cord to the brain.

To date, a limited number of studies have been performed on changes in purinergic signaling in GI disorders. Extracellular nucleotides and their receptors have been implicated in the pathogenesis of various pathological conditions in the gut; indeed, adenosine increases vagal afferent sensitization in the esophagus and is able to activate a different type of nociceptive nerve terminal in this tissue<sup>[43]</sup>. Acid sensitizes P2X receptors to ATP, and acid-induced upregulation and activation of P2X receptors has been confirmed in animal models of esophagitis<sup>[44,45]</sup>.

However, the role of purinergic receptors in patients with GERD remains to be fully determined. In a recent investigation, we studied a signaling pathway that might be responsible for esophageal nociception, which involves ATP and purinoceptors. In an experimental model of acid-induced activation of the esophageal mucosal

nociceptors, we observed that acid exposure caused activation of TRPV1 receptors on the esophageal epithelial cells, triggering production of ATP, which acts on peripheral nerve terminals inducing the production of neurotransmitters<sup>[46]</sup>. Thus, the selective presence of purinergic receptors on esophageal epithelial cells was demonstrated, suggesting a direct effect of the acid on the epithelium and a possible autocrine effect of ATP on these cells<sup>[19]</sup>. In fact, P2X4, P2X5 and P2Y14 receptors are expressed in esophageal epithelial cells, and indeed are expressed at higher levels than all the other purinergic receptors<sup>[46]</sup>. P2Y receptors appear to be more involved in esophageal motility. Lecca *et al*<sup>[47]</sup> recently reported that purinoceptors are involved in human lower esophageal sphincter (LES) relaxation, mediated by neural nitric oxide and partially by P2Y receptors. Blockade of P2Y receptors reduced the amplitude of contractions without affecting the latency. Farrè *et al*<sup>[48]</sup> had previously demonstrated, in animals, that LES relaxation, induced by stimulation of the inhibitory motor neurons of the mesenteric plexus, was mediated by neural nitric oxide with a minor contribution of purines, acting by way of P2Y and P2X receptors.

---

## CONCLUSION

Inflammatory processes in the esophageal mucosa appear to be involved not only in the development of erosive disease, but also in the early and important phases leading to hypersensitivity to intra-luminal stimuli.

Despite considerable evidence reconfirming the important production of inflammatory mediators and/or neurotransmitters in the pathogenesis of GERD, the interplay between hypersensitivity and esophageal inflammation remains unclear. Moreover, in the pathogenesis of GERD and in the generation of symptoms, receptors on acid-sensitive nerve endings may play a significant role. Further studies are warranted to better understand the signaling pathway involved in the genesis of reflux symptoms and inflammation, to identify and establish new therapeutic approaches.

### Abstract

Gastro-esophageal reflux disease (GERD) is one of the most prevalent chronic diseases. Although proton pump inhibitors (PPIs) represent the mainstay of treatment both for healing erosive esophagitis and for symptom relief, several studies have shown that up to 40% of GERD patients reported either partial or complete lack of response of their symptoms to a standard PPI dose once daily. Several mechanisms have been proposed as involved in PPIs resistance, including ineffective control of gastric acid secretion, esophageal hypersensitivity, ultrastructural and functional changes in the esophageal epithelium. The diagnostic evaluation of a refractory GERD patients should include an accurate clinical evaluation, upper endoscopy, esophageal manometry and ambulatory pH-impedance monitoring, which allows to discriminate non-erosive reflux disease patients from those presenting esophageal hypersensitivity or functional heartburn. Treatment has been primarily based on doubling the PPI dose or switching to another PPI. Patients with proven disease, not responding to PPI twice daily, are eligible for anti-reflux surgery.

**Key words:** Gastro-esophageal reflux disease; Proton pump inhibitor; Ambulatory pH-impedance monitoring; Esophageal hypersensitivity; Gastro-esophageal reflux disease treatment

**Core tip:** The present review focuses on the subgroup of patients in whom proton pump inhibitor refractoriness more frequently occurs, on the mechanisms possibly involved in the lack of response, the diagnostic work-up and the therapeutic strategies in these patients. Various mechanisms and factors have been demonstrated and some mechanisms have also been proposed, although not yet supported by strong evidence. In the management of these patients, a careful clinical interview might conduct the diagnostic evaluation and the therapeutic approaches.

### INTRODUCTION

Gastro-esophageal reflux disease (GERD) is one of the most prevalent chronic diseases in Western countries, affecting approximately 20% of the United States adult population weekly, and 7% daily<sup>[1,2]</sup>. Although the acid-suppressive drugs have improved in efficacy over the last few decades, and proton pump inhibitors (PPIs) represent the mainstay of treatment both for healing erosive esophagitis and for symptom relief as well as for preventing complications, several studies have shown that up to 40% of GERD patients reported either partial or complete lack of response of their symptoms to a

standard PPI dose once daily<sup>[3-5]</sup>. Therefore, particularly in third referral Gastrointestinal Units, the management of refractory GERD patients is a very common, as well as a very challenging, task. Indeed, chronic heartburn is associated not only with a significant decrease in all the physical and mental domains of health-related quality of life questionnaires but, also, with a significant increase in healthcare costs, due to repeated diagnostic procedures, physician examinations and drug prescriptions<sup>[6]</sup>. The present review focuses on the subgroup of patients in whom PPI refractoriness more frequently occurs, on the mechanisms possibly involved in the lack of response, the diagnostic work-up and the therapeutic strategies adopted in these patients.

## MOST DIFFICULT PATIENTS

The clinical suspicion that the symptomatic response to PPIs is less frequent in those patients affected by the most common presentation of GERD, *i.e.*, non-erosive reflux disease (NERD), than in those presenting erosive esophagitis (ERD) has been confirmed several years ago. In one of the first reports focusing on NERD patients, treatment with omeprazole 20 mg for 4 wk resulted in complete symptom relief in only 46% of patients, in even fewer of them on 10 mg and in those receiving placebo, and symptom improvement (satisfaction) in 66%<sup>[7]</sup>. The main messages of the study were the better results obtained with higher doses, which do not support the concept of NERD as a milder form of GERD and, more important, the concept that symptom relief proves to be directly correlated with esophageal acid exposure time, that is to say, the greater the acid exposure, the higher the PPI response. So far, only a few trials have compared the outcome of PPI treatment in NERD *vs* ERD patients. Almost all of these trials were carried out using a double blind, parallel group design with a short (4 wk) follow-up period. In a study performed by Bate *et al.*<sup>[8]</sup>, relief of heartburn was achieved in 47% of NERD, and in 53% of ERD patients (the difference not being significant). Of interest, as far as concerns the non-responders, 67% became heartburn-free after an additional 4 wk of treatment<sup>[8]</sup>.

Better results, both in NERD and ERD patients, have been reported in a multicenter study by Venables *et al.*<sup>[9]</sup>: heartburn relief, was achieved after 4 wk of omeprazole, in more than 60% of NERD and in 79% of ERD patients. Galmiche *et al.*<sup>[10]</sup>, besides heartburn remission, reported semi-quantitative measures of symptom severity and their impact on quality of life: At 4 wk, heartburn was resolved in 62% of NERD and 71% of the ERD patients, even higher values being observed after an additional 4-wk treatment with omeprazole. Of interest, quality of life improved in all treatment groups, but the improvement was higher in those on full PPI dose (*vs* half-dose) group<sup>[10]</sup>. Armstrong *et al.*<sup>[11]</sup>, in a randomized, Canadian multicenter study, confirmed complete relief in a larger proportion (although not significant) of ERD,

than NERD, patients receiving pantoprazole. Although some data were not stratified for the presence/absence of esophagitis, a modified intention-to-treat analysis demonstrated, in the PPI group, a trend of increased therapeutic gain throughout the 4 wk<sup>[11]</sup>. More recently, a multicenter trial performed in Japan, has shown that, following 4-wk rabeprazole 40 mg/die, complete relief of symptoms was achieved in only 36% of the NERD and in approximately 55% of the erosive group, a response rate similar to that observed in Western countries. Here, patients were stratified according to a modified Los Angeles classification and, of interest, the more severe the esophageal mucosal injury, the more effective the therapy. The design of the study and symptom assessment could also demonstrate that the median time to the first 24- and 48-h heartburn-free intervals was significantly shorter for erosive than for non-erosive patients<sup>[12]</sup>. Before concluding the issue regarding the response to PPI treatment in non-erosive *vs* erosive reflux disease, it may be useful to re-consider a major dilemma concerning NERD, namely the lack of a standard definition, which is likely to affect the results of clinical trials, and makes interpretation of data, challenging. It is generally agreed that NERD is the most common presentation (up to 75%) of GERD, with the same symptom severity and quality of life impairment as ERD, but, at the same time, there is still lack of agreement concerning the definition of NERD: should all symptomatic patients with endoscopy-negative findings be considered to be suffering from NERD? The 24-h pH test does, indeed, distinguish patients with and without pathological esophageal acid exposure, and, more important, patients with and without significant symptom-reflux association, which can reveal hypersensitivity to non-pathological acid exposure.

Endoscopy-negative patients not presenting pathological acid exposure, with negative symptom-reflux association and without a satisfactory response to the PPI test are, indeed, affected by functional heartburn, according to the Rome III criteria, and thus do not belong to the NERD population. These “functional” patients, in whom symptoms are, by definition, not related to reflux, might be a minority but they frequently attend the outpatients units and are, often, enrolled in clinical trials. The low response to PPIs reported in NERD may be affected by including this functional subgroup in a “too heterogeneous” NERD population. Another common risk of mis-classification of NERD is due to the healing of esophagitis at the time of upper endoscopy, and, thus, a recent consensus underlines the importance not only of an appropriate pharmacological washout before endoscopy but, also, of checking for previous endoscopic findings in the same patient, if available<sup>[13]</sup>. In the attempt to better evaluate the response rate in NERD patients according to the different criteria of the participants enrolled in clinical trials, a recent meta-analysis of the literature has demonstrated that lower rates of partial or complete response are reported in the large majority of studies with a poor characterization of the patients, lacking pH-test findings

and, therefore, likely including patients with functional heartburn and functional dyspepsia<sup>[14]</sup>. Future studies, enrolling well-defined NERD patients and, hopefully, with a longer follow-up, might offer more precise data on PPI efficacy.

## MECHANISMS AND FACTORS INVOLVED IN PPI RESISTANCE

In patients with reflux symptoms refractory to medical therapy, namely those with typical GERD symptoms - heartburn and regurgitation - not responding to a standard or double dose of PPI given for at least 8 wk, various causes have been demonstrated and some mechanisms have also been proposed, although not yet supported by strong evidence. Principal mechanisms and factors involved in PPI resistance are summarized in Table 1.

Ineffective control of gastric acid secretion, in terms of excessive residual acid reflux despite adequate PPI treatment, can be due to lack of compliance, rapid PPI metabolism - due to CYP2C19 polymorphism - or hypersecretory syndromes such as Zollinger Ellison. While these two latter conditions are uncommon, non-compliance to treatment, in terms of incorrect medication dose or timing, is reported to frequently occur. Two recent meta-analyses have clearly shown that lack or non-compliance to therapy is particularly frequent in GERD patients, in whom adherence to the prescribed PPI is acceptable in only 55% of patients, at one month, and in 30% at 6 mo after prescription.

The lowest levels of compliance, in terms of daily or dose administration, were observed in NERD patients, and, of the various factors, the most frequently reported were: lack of knowledge about the treated disorder, desire for personal control, side-effects and additional medications<sup>[15]</sup>. In a study focusing on patients with persistent GERD symptoms despite prolonged PPI treatment, it was reported that in less than 46% of these patients the drug was administered in the fasting state, before breakfast<sup>[16]</sup>.

In the new era of combined pH and impedance 24-h

monitoring, it is possible to detect reflux episodes with more accuracy compared to the pH-monitoring alone, following the movement of refluxate along the esophageal body and to distinguish air/liquid component as well as acidic composition of each episode. Over the last decade, several pH-impedance investigations have been conducted on patients with NERD and, particularly, on those patients with a poor symptomatic response to PPIs. Results emerging from those studies have confirmed a condition already observed with pH-tests, namely esophageal hypersensitivity in terms of perception of not-abnormal reflux, and this enhanced sensitivity involves not only acidic reflux but, also, weakly acidic reflux and gas-containing (mixed) reflux episodes. Either cohort studies analyzing the reflux pattern and reflux-symptom association<sup>[17]</sup> or pathophysiologic investigations, looking at the perception of each reflux episode<sup>[18]</sup> have clearly shown that, in NERD patients, besides acidic reflux, weakly acidic reflux and gas-containing episodes (both of them probably associated with increased reflux volume and esophageal distension) are responsible for a significant proportion of symptoms (approximately 20%), much higher when compared to those in ERD patients. These studies have demonstrated both a possible mechanism explaining symptom persistence despite acid suppression and the higher diagnostic yield of the pH-impedance test in these patients.

Recent pathophysiological investigations have also shown that a dynamic characteristic, such as the proximal migration of reflux, an indicator of high volume refluxate, represents a major determinant of reflux perception, particularly in NERD patients. Interestingly, in large multicenter studies, these three characteristics, namely weakly acidic reflux, mixed (liquid-gas) reflux and the higher proximal extent, have also been recognized as the main mechanisms underlying failure of PPI treatment in patients with reflux-related symptoms<sup>[19-21]</sup>. Finally, experimental studies suggest that some of the NERD patients presenting PPI-resistance may also present a more generalized condition of visceral hyperalgesia<sup>[22]</sup>.

The research field focusing on the ultrastructural and functional changes in the esophageal epithelium has contributed to a better understanding of NERD and of PPI-resistance pathophysiology. In those conditions not associated with severe mucosal inflammation and/or epithelial erosions, it is not clear how severe and recurrent symptoms can occur in an apparently normal mucosa (NERD). A well studied ultra-structural alteration, *i.e.*, dilated intercellular spaces (DIS), has been demonstrated by means of Transmission Electron Microscopy both in ERD and NERD patients<sup>[23,24]</sup>, and this would explain the genesis of symptoms triggered by the activation of intramucosal chemo-sensitive pain-receptors. The increased para-cellular permeability, associated with the presence of DIS, and the resulting breakdown in the epithelial barrier, do not necessarily result from excessive acid exposure, as shown in NERD patients presenting a normal acid contact time at pH-monitoring, can be induced, in ex-

perimental models, by weakly acidic and acidified bile solutions and even occurs during acute stress situations<sup>[25]</sup>. Interestingly, the feature of DIS has been observed in patients with PPI-resistant symptoms, during treatment, but not in patients affected by functional heartburn<sup>[26]</sup>, returns to normal following PPIs, together with symptoms<sup>[27]</sup>, and, therefore, the impaired mucosal integrity would now appear to be the mechanism that best explains the enhanced sensitivity to chemical and mechanical stimulation in NERD and PPI-resistant patients. Indeed, peripheral sensory pathways, in terms of up-regulated pain receptors, central sensitization of sensory neurons and processing of ascending stimuli are now under intense investigation and may be involved in the conditions of esophageal and visceral hypersensitivity.

Several conditions not, or not directly, related to gastro-esophageal reflux, should also be considered when assessing PPI refractoriness. Infectious esophagitis, eosinophilic esophagitis and pill esophagitis may be other, not frequent, causes of refractory heartburn. Anxiety and depression, demonstrated to increase reflux perception, may also be involved.

## DIAGNOSTIC EVALUATION

### *Clinical evaluation*

As previously pointed out, lack of compliance - in terms of adherence to treatment, timing and dosing - and the presence of functional heartburn are the main findings in patients referred for refractory heartburn, therefore a careful interview, also looking at the confounding presence/co-existence of atypical - ENT and respiratory - symptoms and at their possible relation with GER, is crucial. The presence of functional disorders, such as functional dyspepsia and irritable bowel syndrome, as well as of psychological disorders, should also be assessed as these are associated with visceral hyperalgesia as well as with reduced response to acid-suppressive drugs.

### *Endoscopy*

Although the sensitivity of upper endoscopy is very low - most patients have NERD - it might be helpful for ruling out pill and infectious esophagitis, eosinophilic esophagitis (4%-6% in PPI-refractory patients, multiple biopsies should be obtained) and the rare cases of Zollinger Elison syndrome.

### *Esophageal manometry*

Conventional or high-resolution manometry should be performed in order to rule out severe motor disorders, to better locate LES for pH-sensor positioning, and, furthermore can provide useful information when a surgical anti-reflux approach is indicated.

### *Ambulatory pH [impedance] monitoring*

The only test which provides quantitative information on the esophageal exposure to reflux, also assessing its

relationship with symptoms, remains 24-h ambulatory pH-monitoring. Prolonged (48 to 96 h) wireless pH-monitoring improves the diagnostic yield of the test by improving the likelihood of a positive reflux-symptom association<sup>[28]</sup>. We have previously discussed the advantages of the combined ambulatory pH-impedance test, as well as its greater accuracy in discriminating NERD patients from those presenting esophageal hypersensitivity or functional heartburn. Indeed, typical and atypical symptoms not responding to PPIs represent the main indication for performing ambulatory pH-impedance monitoring. The test performed "off" therapy can confirm or exclude a pathological gastro-esophageal reflux and, according to a recent investigation<sup>[29]</sup> offers the best chances to detect a positive association between symptoms and reflux episodes. Recent studies have shown that refractory patients studied "off" and "on" therapy are, indeed, characterized by an abnormal number of reflux events and a higher sensitivity to all types of reflux - acidic, weakly acidic, mixed and propagated<sup>[30,31]</sup>. On the other hand, performing the test "on" PPIs, provides useful information regarding the efficacy of acid-suppressive treatment and may detect a positive association between symptoms and weakly acidic reflux episodes - the large majority of episodes during acid suppressive drug -, which is a possible indication for anti-reflux surgery<sup>[32]</sup>.

## MANAGEMENT OF PATIENTS

### *Proton pump inhibitors*

The large majority of patients with reflux symptoms receive PPI therapy once daily. If symptoms are not relieved, and after the presence of functional heartburn and CYP2C19 polymorphism have been excluded, several therapeutic strategies can be proposed. These include doubling the current PPI dosage or switching to another PPI.

Indeed, treatment failure may result from an insufficient dose of PPI. Doubling the PPI dose, giving PPI before breakfast and before dinner, is one of the most common therapeutic strategies adopted by practicing physicians having also been recommended in the 2008 American Gastroenterological Association guidelines for GERD, and confirmed by the Cochrane review<sup>[33,34]</sup>. However, is still not clear the dose-response relationship for heartburn resolution in either erosive esophagitis or non-erosive reflux disease patients<sup>[35]</sup>. Even if doubling the PPI dose has become one of the standard strategies, escalation of the PPI administration beyond the twice daily dosage, both for symptom control or for healing of erosive esophagitis, is not supported by strong clinical data. In the attempt to identify the patients who would benefit from dose escalation, Becker *et al.*<sup>[36]</sup> performed pH-impedance monitoring in patients presenting persistent symptoms despite one month of standard PPI therapy. According to the pH-impedance data, two groups, one with and one without pathological findings, received high dose PPI (or fundoplication in a few cases). Imped-

ance was pathological in 40% of the non-responders, in whom escalating therapy was significantly more successful (90% relief) than in patients with normal findings.

Switching to another PPI is a very common, cost-effective, therapeutic strategy adopted in the management of patients who failed with the PPI once daily approach. In several studies, switching those patients who had failed with a PPI to esomeprazole, resulted in significant symptom improvement<sup>[37,38]</sup>.

### Antireflux surgery

Although it is well established that patients with symptoms not responding to PPIs have a less favorable post-operative clinical outcome compared to those patients responding to treatment, refractory GERD represents the most common (88%) indication for anti-reflux surgery. In a recent long-term follow-up study, 82% of the PPI-refractory patients reported that the preoperative reflux symptoms were completely resolved, and 94% were satisfied with the results of the surgery<sup>[39]</sup>. Several studies have suggested that a positive symptom-reflux association<sup>[40,41]</sup> and/or pathological AET<sup>[42,43]</sup>, observed by impedance-pH monitoring in patients off PPI, predict a favorable response to surgery. It has been recently demonstrated that ranitidine 300 mg twice daily has a comparable efficacy respect to rabeprazole 20 mg twice daily when given on-demand for the treatment of NERD and both medications are associated with improvement of the quality of life<sup>[44]</sup>.

It should be taken into consideration that the large majority of PPI-resistant patients do not present an erosive disease, therefore, given the possible adverse events associated with surgery and the recognized benign course of NERD, anti-reflux surgery should only be considered in selected patients, in whom objective evidence of reflux is revealed upon investigation. In summary, although surgery appears to be valid therapeutic option in GERD patients with typical symptoms who failed to respond to PPIs, further outcome and controlled studies, on a larger series of patients, using combined impedance-pH monitoring are warranted in order to draw definite conclusions.

### Lifestyle modifications

It has been recently suggested that weight loss and elevation of head of the bed are effective in improving GERD symptoms in refractory patients, whilst no sufficient data support any other lifestyle modifications<sup>[45]</sup>. It has been recently reported that shorter dinner-to-bed time interval (less than 3 h) is significantly associated with persistence of GERD symptoms<sup>[46]</sup>.

However, the relevance of lifestyle modifications in GERD patients who failed PPI treatment still remains to be fully elucidated.

### Visceral pain modulators, psychological treatment

The therapeutic option represented by visceral pain modulators is highly attractive but, at present, studies specifically evaluating their efficacy in refractory GERD

patients are still lacking. Tricyclic anti-depressants and selective serotonin reuptake inhibitors have been shown to relieve esophageal pain in patients with non-cardiac chest pain<sup>[46-48]</sup>. Unfortunately, side effects of these drugs appear to be not uncommon and may hamper their usage.

It has been shown that refractory patients are more likely to have a psychosocial comorbidity<sup>[49]</sup>, therefore it is conceivable that refractory GERD patients would benefit of psychological evaluation and treatment.

**Key words:** Body mass index; Visceral obesity; Gastro-esophageal reflux; Gastro-esophageal reflux disease complication

**Core tip:** This topic is aimed to explore the potential mechanisms responsible for the association between gastro-esophageal reflux disease (GERD) and obesity, that remain to be fully elucidated. Despite numerous evidence that show an increased risk of GERD symptom and/or complication in obese patients, the interplay between GERD and obesity is not clear. Based on the literature we have tried to summarize the evidence concerning the role of obesity in the GERD pathogenesis to better understand the possible role of weight loss as a therapeutic approach for this disease.

### Abstract

The confluence between the increased prevalence of gastro-esophageal reflux disease (GERD) and of obesity has generated great interest in the association between these two conditions. Several studies have addressed the potential relationship between GERD and obesity, but the exact mechanism by which obesity causes reflux disease still remains to be clearly defined. A commonly suggested pathogenetic pathway is the increased abdominal pressure which relaxes the lower esophageal sphincter, thus exposing the esophageal mucosal to gastric content. Apart from the mechanical pressure, visceral fat is metabolically active and it has been strongly associated with serum levels of adipocytokines including interleukin-6 and tumor necrosis factor  $\alpha$ , which may play a role in GERD or consequent carcinogenesis. This summary is aimed to explore the potential mechanisms responsible for the association between GERD and obesity, and to better understand the possible role of weight loss as a therapeutic approach for GERD.

### INTRODUCTION

Gastro-esophageal reflux disease (GERD), with symptoms demonstrated to impair quality of life (QoL), appears to show important variation in its prevalence. When defined as at least weekly heartburn and/or acid regurgitation, the prevalence in the Western world generally ranges between 10% and 20% whereas in Asia the prevalence is reported to be less than 5%<sup>[1]</sup>. Longitudinal studies have addressed several risk factors for GERD, and indeed obesity is indicated as a potential risk factor<sup>[2]</sup>. Interestingly, obesity, typically defined as a body mass index (BMI) of > 30, has risen to epidemic levels in several regions of North America, Europe and Asia<sup>[3]</sup>. The confluence between the increased prevalence of GERD, in

**Table 1 Proposed mechanisms by which abdominal obesity causes reflux**

Mechanical factors	Increased intra-gastric and gastro-esophageal pressure gradient Increased risk of Hiatal Hernia Increased sensitivity to distension-induced TLESR Decreased lower esophageal sphincter pressure
Humoral factors	Increased level of adipocytokines including interleukin 6 and tumor necrosis factor $\alpha$
Motility disorders	Delayed gastric emptying rate and delayed esophageal clearing time

TLESR: Transient lower esophageal sphincter relaxation.

terms of symptoms, erosive esophagitis, Barrett's esophagus (BE), esophageal adenocarcinoma and of obesity has generated great interest in the association between these two conditions and the potential mechanisms responsible for this association.

Several studies have focused on the potential relationship between GERD and obesity and results emerging from those investigations have shown that obesity is associated with an increased risk of both GERD symptoms and complication *i.e.*, erosive esophagitis, BE and esophageal adenocarcinoma as compared to individuals with a normal BMI<sup>[4]</sup>. There was also some degree of a dose-dependent relationship between BMI and these GERD-related disorders and, moreover, a recent large cohort focusing on adult females reported a possible dose-response increase in the risk of GERD with a higher BMI even if within the normal range<sup>[5]</sup>.

## PATHOGENESIS

Even if several mechanisms by which obesity causes reflux disease have been proposed (Table 1). The pathogenetic pathway commonly suggested is the increased abdominal pressure which relaxes the lower esophageal sphincter (LES), thus exposing the esophageal mucosal to the gastric content<sup>[6,7]</sup>. Results of 24-h pH-monitoring studies have shown that obesity is associated with a significant increase in the number of reflux episodes, as well as long-lasting reflux episodes and the time with pH < 4, especially in the post-prandial period<sup>[8]</sup>. This finding has been confirmed, in a more recent study, also by means of pH-impedance monitoring: not only the acid reflux but also the number of non acid reflux episodes increased significantly as BMI increased<sup>[9]</sup>. A recent study aimed to assess the pressure morphology and function of the esophago-gastric junction, by using the high resolution manometry methodology, reported that due to obesity the gastro-esophageal pressure gradients are altered in a way that would promote the retrograde flow of gastric content into the esophagus. Both the intra-gastric pressure and the gastro-esophageal pressure gradient were clearly correlated with both the BMI and waist circumference but, when these were simultaneously analysed in a regression model, the waist circumference was found to be independently associated with the different pressure

gradients, whereas the relationship between BMI and pressure became non-significant or considerably reduced. In addition to abnormal pressure gradients, high-resolution manometry also revealed that obesity was associated with hiatus hernia (HH). There was a significant correlation between BMI, waist circumference and axial separation of the intrinsic LES and crural diaphragm, and it was postulated that this was a manifestation of pressure stress due to the increased intra-gastric pressure<sup>[10]</sup>. In agreement with this finding, in a retrospective case-control study assessing BMI in relation to esophagitis and HH, it was found that obesity is strongly associated with the combined occurrence of esophagitis and HH<sup>[11]</sup>. It is widely recognized that HH has several pathophysiological implications in the pathogenesis of GERD: increased incidence of strain-induced reflux, reduced LES pressure, impaired esophageal acid clearance and increased sensitivity to distension-induced transient lower esophageal sphincter relaxation (TLESR)<sup>[12]</sup>. Among mechanisms responsible of reflux TLESR seems to play the most important role<sup>[13]</sup>. The reflux pattern after a standard meal, has been recently evaluated in obese and overweight patients by using a combined 2 h post-prandial esophageal manometry and pH monitoring<sup>[14]</sup>. The results of this study have shown that, during the post-prandial period, both the obese and overweight patients presented a substantial increase in the rate of TLESRs and in the proportion of TLESRs with acid reflux as compared to individuals with a normal BMI. Both BMI and waist circumference showed a significant positive correlation with TLESRs and there was a dose-effect relationship. Therefore, it would appear that a higher post-prandial intra-gastric pressure causes a more intense stimulation both on the stretch and tension mechanoreceptors in the proximal stomach, which leads to more postprandial TLESRs.

## ABDOMINAL OBESITY

Abdominal or visceral fat (VAT) is strongly different in respect to peripheral or subcutaneous fat (SCAT). For example, VAT is more metabolically active, is characterized by a higher number of immune and inflammatory cells, and is more insulin-resistant thus leading to an higher overall mortality in respect to SCAT<sup>[15]</sup>.

Abdominal obesity can better explain some of the epidemiological features of BE and esophageal adenocarcinoma. The distribution of body fat tends to be more visceral than truncal in high-risk groups for BE<sup>[16]</sup>. A recent study has shown that the abdominal diameter measured as the waist circumference is a risk factor for BE independently of BMI, while the association between BMI and BE disappeared after adjustment of the abdominal diameter<sup>[17]</sup>. These studies indicate that abdominal fat is the key factor linking obesity and BE. Apart from the mechanical pressure, visceral fat is metabolically active, and has been clearly associated with serum levels of adipo-cytokines including interleukin 6 and tumor ne-

cross factor  $\alpha$ , which may play a role in GERD and/or consequent carcinogenesis<sup>[18]</sup>. In fact, in a very recent study, a large amount of visceral abdominal fat in respect to subcutaneous fat was found to be associated with a significant increase in the risk of BE<sup>[19]</sup>.

## OUTCOME

Considering the dose-response relationship between obesity and occurrence of GERD and/or the resulting complications, an inverse relationship between weight loss and GERD symptoms would be expected. The prevalence of GERD symptoms in overweight and obese subjects as well as impact of weight loss on GERD symptoms has been assessed in a recent prospective study<sup>[20]</sup>. Weight loss strategies included dietary modifications, increased physical activity as well as behavioral changes. The results coming from the study showed that weight loss led to a significant improvement in GERD symptoms, thus establishing weight loss as an important modification of life style in the treatment of GERD. Moreover, weight loss over a 6-mo period, was associated with a reduction in GERD symptoms in 81% of the patients and with complete resolution in 65% of the patients. This finding provides support for recommending weight-loss in the primary treatment of overweight reflux patients, however this clinically important finding has unfortunately not been described so far. Further investigations on the long-term effect of weight loss on reflux occurrence and on the reduction in reflux symptoms are needed before any definitive conclusions can be drawn regarding eventual beneficial effects of weight loss.

## CONCLUSION

Obesity appears to be involved not only in the development of GERD symptoms but, also in the occurrence of GERD complication such as erosive esophagitis, Barrett's esophagus and esophageal adenocarcinoma.

Despite considerable evidence confirming the important role of increased esophago-gastric pressure gradient, and of production of inflammatory mediators by abdominal adipose tissue in the pathogenesis of GERD, the interplay between obesity and GERD is still not clear. Moreover, weight loss seems to reduce GERD symptoms but further studies are warranted to better understand the exact mechanism by which obesity causes reflux disease in order to identify and establish new therapeutic approaches.

### Abstract

Oxygen free radical and lipid peroxides (oxidative stress) are highly reactive and represent very damaging compounds. Oxidative stress could be a major contributing factor to the tissue injury and fibrosis that characterize Crohn's disease. An imbalance between increased reactive oxygen species levels and decreased antioxidant defenses occurs in Crohn's patients. Decreased blood levels of vitamins C and E and decreased intestinal mucosal levels of CuZn superoxide dismutase, glutathione, vitamin A, C, E, and  $\beta$ -carotene have been reported for Crohn's patients. Increased levels of proinflammatory cytokines, such as interleukin-1 and -8 and tumor necrosis factor, have been detected in inflammatory bowel disease. Oxidative stress significantly increased the production of neutrophils, chemokines, and interleukin-8. These effects were inhibited by antioxidant vitamins and arachidonic acid metabolite inhibitors in human intestinal smooth muscle cells isolated from the bowels of Crohn's disease patients. The main pathological feature of Crohn's disease is an infiltration of polymorphonuclear neutrophils and mononuclear cells into the affected part of the intestine. Activated neutrophils produce noxious substances that cause inflammation and tissue injury. Due to the physiological and biochemical actions of reactive oxygen species and lipid peroxides, many of the clinical and pathophysiological

features of Crohn's disease might be explained by an imbalance of increased reactive oxygen species and a net decrease of antioxidant molecules. This review describes the general concepts of free radical, lipid peroxide and antioxidant activities and eventually illustrates their interferences in the development of Crohn's strictures.

**Key words:** Crohn's disease; Reactive oxygen species; Antioxidant enzymes; Lipid peroxide

**Core tip:** Crohn's disease is associated with an imbalance, comprising increased reactive oxygen species (ROS) and decreased net antioxidant activity. A deficiency in antioxidant molecules could lead to increased levels of lipid peroxides or ROS, which could act locally or be secreted into the circulation to produce different systemic effects in the patient. Future research should address the question of whether ROS are involved in increasing the production of the different extracellular proteins by enhancing the transcriptions of certain genes using specific transcription factors.

### INTRODUCTION

Crohn's disease (CD) is a debilitating illness of the bowel characterized by chronic inflammation of unknown etiology<sup>[1]</sup>. In the United States and Europe, the incidence ranges from 6-20 cases per 100000 population per year, and the prevalence, from 90-300 per 100000 population.

This disease most often occurs between the ages of 15 and 20, with a secondary peak between the ages of 55 and 60<sup>[2]</sup>. It can affect any level of the alimentary tract, but the terminal ileum and proximal colon are most frequently involved. A classical feature of CD is the sharp demarcation of the affected bowel segment from adjacent uninvolved segments<sup>[1]</sup>. This disease is characterized pathologically as a recurrent granulomatous inflammation of all layers of the bowel wall<sup>[2-4]</sup>. Patients usually suffer from abdominal pain, cachexia, anorexia, chronic diarrhea, intestinal obstruction, malnutrition, weight loss, and growth failure.

The precise etiology of CD remains unclear. It is thought that interactions among various factors, including genetic factors, host immune system and environmental factors (including diets and microbiological agents), play crucial roles in disturbing the intestinal homeostasis, leading to the dysregulated inflammatory responses of the gut. As inflammation is intimately related to the formation of reactive intermediates, including reactive oxygen species (ROS), oxidative stress has been proposed as a mechanism underlying the pathophysiology of CD. The main pathological feature of CD is an infiltration of polymorphonuclear neutrophils and mononuclear cells into the affected part of the intestine<sup>[5-10]</sup>. As the disease becomes more established, neutrophils infiltrate isolated crypts, forming abscesses in the affected mucosa and underlying tissue layers<sup>[1]</sup>. Neutrophils, like other leukocytes, produce noxious substances, such as ROS, tumor necrosis factor alpha (TNF $\alpha$ ), interleukin-1 (IL-1) and protease<sup>[11-14]</sup>. It has been shown that an imbalance in the levels of proinflammatory and anti-inflammatory cytokines occurs in CD<sup>[13,14]</sup>. Increased levels of proinflammatory cytokines, such as IL-1, IL-8 and TNF $\alpha$ , can be detected in CD.

Reactive oxygen species may play an important role in CD. As will be discussed in the following sections, the ROS generated from activated leukocytes or from other sources may affect various biological molecules, generating tissue damage that could have been prevented by dietary antioxidants. This review describes the general concepts of free radical, lipid peroxide and antioxidant activities and eventually illustrates their interference into the development of Crohn's strictures.

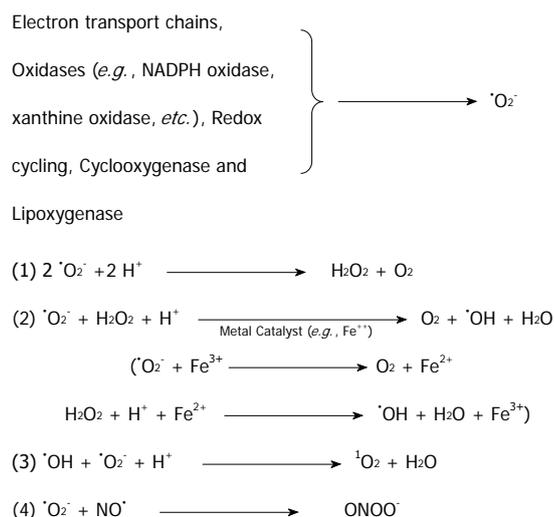

## CONCEPTS OF FREE RADICALS

A free radical can be defined as any chemical species that has one or more unpaired electrons in the outermost orbital electron shell<sup>[15]</sup>. Due to these chemical changes in the free radical atoms, they are chemically reactive. ROS include superoxide ( $\cdot\text{O}_2^-$ ), the hydroxyl radical ( $\cdot\text{OH}$ ), the hydroperoxyl radical ( $\cdot\text{O}_2\text{H}$ ), nitric oxide ( $\text{NO}\cdot$ ), and singlet oxygen ( $^1\text{O}_2$ )<sup>[16]</sup>. In general, most free radicals are derivatives of oxygen, such as superoxide.

During the normal aerobic metabolism, oxygen is the final electron acceptor at the end of the mitochondrial respiratory chain, during which it is fully reduced to water<sup>[17-19]</sup>. A small percentage of the electrons do not

travel to the end of the electron transport chain in the mitochondrial membrane (cytochrome oxidase); they escape and react directly with oxygen in the early part of the chain, forming  $\cdot\text{O}_2$ <sup>[20]</sup>. It has been estimated based on studies of isolated brain mitochondria that 1%-2% of the electrons that travel down the respiratory chain leak out and reduce oxygen to superoxide and its dismutation product, hydrogen peroxide ( $\text{H}_2\text{O}_2$ )<sup>[21,22]</sup>. Hydrogen peroxide is not a radical, but it serves as a precursor to the generation of the hydroxyl radical ( $\cdot\text{OH}$ ) in the presence of iron ions. Superoxide is also produced endogenously through the action of oxidase enzymes (*e.g.*, xanthine oxidase) in postischemic tissues<sup>[23,24]</sup>. Redox cycling substrates (*e.g.*, catecholamines), the cytochrome P450 system and soluble oxidases, such as nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase in phagocyte cells (*e.g.*, neutrophils and monocytes), are endogenous sources of superoxide production<sup>[17-19,25-27]</sup>. Arachidonic acid metabolizing enzymes (cyclooxygenase and lipoxygenase) are other sources of intracellular superoxide production<sup>[28-30]</sup>. Although superoxide serves as a precursor to many ROS (*e.g.*,  $\cdot\text{OH}$ ,  $\cdot\text{O}_2\text{H}$ ), it is not the most reactive of the species<sup>[15]</sup>. Figure 1 illustrates the chemical interconversions that are driven by  $\cdot\text{O}_2^-$ . Superoxide reacts with hydrogen to form hydrogen peroxide by nonenzymatic or by superoxide dismutase-catalyzed dismutation. One of the most important reactions for this is the  $\cdot\text{O}_2^-$  driven Fenton reaction, in which ferric or cupric ions ( $\text{Fe}^{3+}$ ,  $\text{Cu}^{2+}$ ), usually  $\text{Fe}^{3+}$ , are reduced by superoxide, and then, the reduced metal ion reacts with  $\text{H}_2\text{O}_2$  to form  $\cdot\text{OH}$ <sup>[7]</sup>. Another important free radical,  $\text{NO}\cdot$ , is synthesized from L-arginine by the enzyme nitric oxide synthase.  $\text{NO}\cdot$  can interact with  $\cdot\text{O}_2^-$  to generate another damaging molecule, peroxynitrite ( $\text{ONOO}\cdot$ ) (Figure 1). Once ROS are formed by the mechanisms explained in Figure 1, they can generate oxidative damage to a variety of biological molecules, such as lipids, proteins, and nucleic acids. The most important ROS involved in cellular oxidative damage is  $\cdot\text{OH}$ . Prime targets for ROS are the unsaturated fatty acids in membrane lipids, which will be discussed in the lipid peroxidation section. Proteins may also be damaged by ROS. This damage can be achieved through different stages, starting with site-specific lesions in the protein structure that leads to fragmentation products and cross-linked reaction products with other cellular components<sup>[25-27,31-33]</sup>. This oxidative damage to proteins by ROS can cause enzymatic dysfunction. For example, oxidation of the active site of the  $\alpha$ -protease inhibitor inactivates the protein itself, causing tissue damage<sup>[31]</sup>. Nucleic acids can also be affected by ROS. Oxidative damage to the DNA can occur after the attack of hydroxyl radicals on the sugar residues, yielding strand break products<sup>[31]</sup>. This may occur indirectly, when oxidative stress activates endonuclease, or directly, through the reaction of  $\text{H}_2\text{O}_2$  with DNA-bound metal ions and the formation of  $\cdot\text{OH}$ , which fragments the DNA at site-specific spots<sup>[15,31,34]</sup>.

ROS play an important role in increasing the intracellular levels of calcium. Ikebuchi *et al*<sup>[35]</sup> reported that the

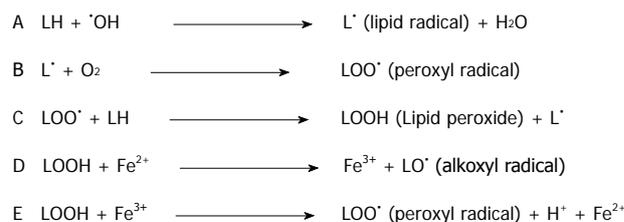

**Figure 1** Reactions of superoxide ( $\text{O}_2^-$ ) that generate highly reactive oxygen species.  $\cdot\text{O}_2^-$  can be dismutated into  $\text{H}_2\text{O}_2$ , which, in the presence of  $\text{Fe}^{2+}$ , can generate the highly reactive hydroxyl radical,  $\cdot\text{OH}$ .  $\cdot\text{O}_2^-$  may react with  $\text{NO}$  to form the strong pro-oxidant peroxynitrite ( $\text{ONOO} \cdot$ ); alternatively, it may react with  $\cdot\text{OH}$  to form singlet oxygen ( $\cdot^1\text{O}_2$ ); NADPH: Nicotinamide adenine dinucleotide phosphate.

superoxide anion activates calcium channels in human amnion cells to increase the intracellular calcium concentrations. Hirosumi *et al*<sup>[36]</sup> and others have shown that the superoxide anion also increases the intracellular calcium concentration in endothelial cells<sup>[37,38]</sup>. ROS inhibit the  $\text{Ca}^{2+}$ -ATPase, leading to elevated intracellular  $\text{Ca}^{2+}$  concentration<sup>[39]</sup>. Kimura *et al*<sup>[38]</sup> have found that  $\cdot\text{O}_2^-$  attenuated smooth muscle contraction by impairing  $\text{Ca}^{2+}$  release-activated  $\text{Ca}^{2+}$  entry (CRAC), ATP-induced  $\text{Ca}^{2+}$  transient, and  $\text{Ca}^{2+}$  sensitivity in bovine aortic smooth muscle cells. Recent studies have shown that intracellular  $\text{Ca}^{2+}$  is involved in capsaicin-induced apoptosis. However, the molecular mechanisms of these intracellular  $\text{Ca}^{2+}$  signal pathways that lead to a sensitivity for the TNF-related induction of apoptosis remain unclear<sup>[40,41]</sup>. We will see in the next section that ROS are able to increase lipid peroxidation in the cell membrane to alter its permeability to ions and proteins.

## CONCEPTS OF OXIDIZED LIPIDS

Oxidized lipids, also known as lipid hydroperoxides and lipid peroxides, can be formed in the presence of oxygen free radicals. The double bonds of polyunsaturated fatty acids (PUFA), such as linoleic acid, are most susceptible to oxidation by ROS<sup>[42]</sup>. The peroxidation chain reactions of membrane PUFA begin when oxygen free radicals extract hydrogen atoms from the methylene carbons adjacent to carbon-carbon double bonds. The presence of the double bond in the fatty acids weakens the carbon-hydrogen bonds in the carbon atoms adjacent to the double bonds, thus allowing hydrogen to be removed in the presence of ROS<sup>[15]</sup>. Because a hydrogen atom has only one electron, the loss of hydrogen from a methylene group leaves behind an unpaired electron on the carbon

**Figure 2** Initiation and propagation of the free-radical chain reaction of lipid peroxidation. Reactions D and E represent the metal-catalyzed Fenton reaction.

atom adjacent to the double bond, and the lipid becomes a lipid radical ( $\text{L} \cdot$ ). Next, the reaction of lipid radicals with oxygen ( $\text{O}_2$ ) molecules forms a peroxyl radical ( $\text{LOO} \cdot$ ). Peroxyl radicals are capable of abstracting a hydrogen atom from adjacent lipids to form lipid hydroperoxides ( $\text{LOOH}$ ), sometimes called lipid peroxides. Once the chain of lipid peroxide formation is initiated, it becomes self-propagating. These events are illustrated in Figure 2. Reduced iron ( $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ) complexes can react with lipid peroxides to form strong oxidizing agents, such as alkoxyl radicals ( $\text{LO} \cdot$ ) and  $\text{LOO} \cdot$  (Figure 2D and E).

Lipid peroxides and oxygen radicals are responsible for many of the damaging reactions in the cell. They stimulate the peroxidation reactions that are toxic to cells and cell membranes. They can damage biological membranes, make the membrane leaky, and eventually cause complete membrane breakdown<sup>[43]</sup>. Furthermore, endothelial cell injury, the enhanced adhesion and activation of neutrophils, platelet aggregation, an increased uptake of low density lipoproteins by the endothelium, increased intracellular calcium and increased production of toxic aldehydes, as well as many other cellular dysfunctions, are due to the effects of  $\text{LOOH}$  and oxygen free radicals<sup>[42]</sup>. The breakdown products of lipid peroxidation, such as malondialdehyde, can affect membrane proteins by cross-linkage, rendering them useless as receptors or enzymes<sup>[44]</sup>. These different lipid peroxide effects can lead to cellular dysfunction and may result in the deaths of the affected cells.

## CONCEPTS OF ANTIOXIDANTS

An antioxidant is any substance or compound that scavenges oxygen free radicals or inhibits the oxidation process in the cell<sup>[45]</sup>. The level of antioxidant defenses available within the cells and extracellularly should be sufficient to oppose the toxic effects of lipid peroxides and to maintain normal physiology. This balance can be lost due to the over-production of free radicals or the inadequate intake of nutrients containing antioxidant molecules. Antioxidants can be considered plasma antioxidants and intracellular antioxidants.

The major role of plasma antioxidant defense is to bind transition metal ions, such as iron and copper, thereby lowering their plasma concentration and capacity to stimulate free radical reactions<sup>[15]</sup>. This prevents the formation of hydroxyl radicals of the very potent variety that is able

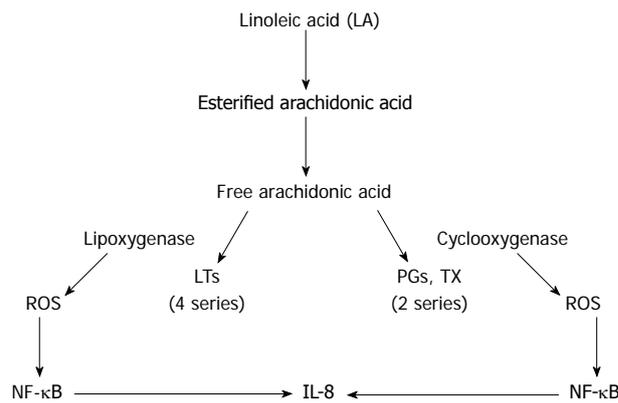

to generate lipid peroxides. This is achieved by plasma antioxidants, such as transferrin, lactoferrin, ceruloplasmin, albumin, uric acid, haptoglobins, and hemopexin<sup>[45]</sup>. Ascorbic acid is also a plasma antioxidant that can scavenge water-soluble peroxy radicals and other ROS<sup>[17-19]</sup>. This is accomplished through the completion of two reactions. First, the ascorbic acid is converted into the ascorbyl radical and then to dehydroascorbate. Ascorbic acid can also reduce  $\alpha$ -tocopheryl radicals to  $\alpha$ -tocopherol at the cell membrane surface<sup>[46]</sup>. Vitamin E ( $\alpha$ -tocopherol), a lipid peroxidation, chain-breaking antioxidant, is localized in membranes and lipoproteins<sup>[17]</sup>. It is the most important lipid-soluble antioxidant in the human plasma<sup>[47-50]</sup>. Vitamin E usually donates a hydrogen atom to the peroxy radical and prevents the propagation of the chain reaction of lipid peroxidation. Each tocopherol can react with two  $\text{LOO}^\bullet$ , the first  $\text{LOO}^\bullet$  reacts with  $\alpha$ -tocopherol to form the  $\alpha$ -tocopherol radical that reacts with the second  $\text{LOO}^\bullet$  to form a stable adduct ( $\text{LOO}-\alpha$ -tocopherol)<sup>[45]</sup>. Decreased blood and mucosal levels of vitamins A, C, E and  $\beta$ -carotene were reported in Crohn's patients<sup>[51-60]</sup>. Reimund *et al*<sup>[61]</sup> showed that antioxidants inhibited the production of inflammatory cytokines, such as IL-1 and  $\text{TNF}\alpha$ , in the colonic mucosa of inflammatory bowel disease patients. Vitamin C and E inhibited the levels of oxidative stress in human intestinal smooth muscle (HISM) cells isolated from Crohn's bowels<sup>[62]</sup>.

The main intracellular antioxidant enzymes are superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), and catalase. Human plasma has very little or no catalase, but it contains low activities of SOD and GSH-Px<sup>[15]</sup>. SOD is localized in both the cytosol (CuZn-SOD) and the mitochondria and acts to dismutate superoxides into hydrogen peroxide and molecular oxygen<sup>[17]</sup>. SOD is considered as the major intracellular enzyme because it is capable of reducing the most abundant free radical,  $\text{O}_2^\bullet$ . Catalase reacts rapidly with hydrogen peroxide, a precursor of  $\text{OH}^\bullet$  in the presence of iron, and converts it into water and molecular oxygen. Selenium glutathione peroxidase also converts hydrogen peroxide into water and lipid hydroperoxides into water and harmless fatty acid alcohols<sup>[45]</sup>. Decreased intestinal mucosal levels of CuZn superoxide dismutase and glutathione were reported in Crohn's patients<sup>[63-69]</sup>.

## OXIDANT STRESS IN CROHN'S DISEASE

Oxidant stress is a major factor in Crohn's disease. Reactive oxygen species can cause DNA modifications and damage, as briefly discussed in the previous section. The major sign of these modifications is the formation of 8-hydroxyguanine (8-OHDG). It was reported that 8-OHDG levels were significantly higher in the inflamed part of the bowel of Crohn's patient<sup>[70]</sup>. These data show an important indication of the role and existence of ROS in the pathogenesis of Crohn's disease.

There is direct and indirect evidence suggesting that the chronically inflamed intestines of Crohn's patients may be subjected to considerable oxidative stress.

**Figure 3** Two proposed mechanisms through which linoleic acid could increase the production of interleukin-8 via the activation of arachidonic acid pathways. By the generation of reactive oxygen species (ROS) from the cyclooxygenase and lipoxygenase enzymes to activate Nuclear factor- $\kappa$ B (NF- $\kappa$ B), increasing interleukin (IL)-8 production; or by the use of AA metabolites to increase IL-8 production. LTs: Leukotrienes; Tx: Thromboxane.

The direct evidence includes the demonstration of the increased production of ROS in response to various stimuli by phagocytic cells (neutrophils, monocytes, and macrophages) isolated from the inflamed bowels of patients with IBD (both Crohn's disease and ulcerative colitis)<sup>[7,71-73]</sup>. Kitahora *et al*<sup>[74]</sup> have demonstrated that monocytes from patients with Crohn's disease release large amounts of ROS during stimulation. It is well known that active IBD is characterized by persistent neutrophil infiltration into the injured site. The influx of neutrophils and macrophages into the bowel wall during inflammation causes a large degree of tissue damage due to their release of myeloperoxidase, which constitutes 5% of their total protein load. Myeloperoxidase metabolizes  $\text{H}_2\text{O}_2$  and chloride ions to form the potent oxidizing agent hypochlorous acid, commonly known as bleach, which is thought to be 100-1000 times more toxic than superoxide and hydrogen peroxide. Inflammatory phagocytes are activated by certain pro-inflammatory agents, such as leukotriene  $\text{B}_4$  ( $\text{LTB}_4$ ), platelet-activating factor (PAF), immune complexes, and bacterial products. As a result, the phagocytes release large amounts of ROS into the extracellular space<sup>[72-75]</sup>. Increased synthesis of  $\text{LTB}_4$  and PAF was detected in mucosal samples obtained from patients with active IBD<sup>[76-80]</sup>. Alzoghaibi *et al*<sup>[81]</sup> showed a significant increase in the production of the neutrophil-attracting chemokine, IL-8,  $\text{LTB}_4$  and other arachidonic acid metabolites in isolated HISM cells from Crohn's strictures after stimulation by linoleic acid or oxidized linoleic acid (OxLA). The cyclooxygenase and lipoxygenase enzymes generate ROS when activated. Both cyclooxygenase and lipoxygenase have been involved in the production of IL-8 from HISM cells (Figure 3). OxLA increased the levels of lipid peroxidation, an indicator of oxidative stress, as quantified by thiobarbituric acid reactive substances in HISM cells. These pro-inflammatory mediators activate certain receptors on the phagocytes' plasma membranes, resulting in the activation of plasma membrane-associated NADPH oxidase. NADPH oxi-

dase reduces oxygen molecules to superoxide on the cell membrane and releases the superoxide extracellularly.

Most of the evidence for the role of the ROS in Crohn's disease is indirect. Under normal physiological conditions, dietary and enzymatic antioxidants protect tissues from the damaging effects of ROS. However, a state of oxidative stress may exist when there is an imbalance in the levels of antioxidants and ROS. When the levels of antioxidants are low and ROS are high, increased cellular oxidative stress is present; such is the case in Crohn's disease<sup>[63,82-89]</sup>. The intestinal mucosa is particularly favored, as it is the location of many different enzymes necessary for the production of large amounts of ROS, such as xanthine oxidase, cyclooxygenase, and 5-lipoxygenase<sup>[75]</sup>. In addition to these sources of ROS, the number of the main sources of ROS (phagocyte cells) is increased in IBD<sup>[72,82]</sup>. For example, neutrophils account for up to 20% of the cells found in the lamina propria in active IBD<sup>[86]</sup>. On the other hand, Crohn's patients have low blood levels of vitamin C and vitamin E<sup>[63]</sup>. They also have low levels of CuZn superoxide dismutase, glutathione peroxidase, catalase, vitamin A and  $\beta$ -carotene in their intestinal mucosa, submucosa and muscularis-serosa<sup>[72,82-85,89]</sup>. This coincidence of increased levels of ROS and decreased levels of antioxidant defenses results in a state of oxidative stress in Crohn's strictures. A study of mucosal biopsies obtained from patients with IBD by Simmonds *et al*<sup>[86]</sup> demonstrated a significant increase in chemiluminescence, a very sensitive measurement for ROS, in comparison to controls. The addition of various antioxidant enzymes and scavengers, such as SOD, catalase, dimethyl sulfoxide (hydroxyl radical scavenger) and taurine (hydrochloride scavenger), confirmed that this increase in chemiluminescence was due to ROS. A study of HISM cells demonstrated a significant inhibition in TBARS after the cells had been exposed to antioxidant vitamins, such as C and E. Vitamin C and E also inhibited the effect of oxidized linoleic acid on the production of the most potent neutrophil-attracting chemokine, IL-8, from HISM cells<sup>[62]</sup>.

Clinical data suggest that ROS may play a role in the pathogenesis of Crohn's disease. Emerit and coworkers reported that intramuscular injections of bovine CuZn-SOD had a beneficial effect in attenuating mucosal inflammation and injury in Crohn's patients<sup>[90,91]</sup>. The beneficial effect of this antioxidant enzyme is a strong indication of the role of ROS in Crohn's disease. Another piece of evidence of the involvement of ROS in this disease is the use of 5-aminosalicylic acid (5-ASA) in treating patients with IBD. It is well known that the oral administration of sulfasalazine (SAZ) is capable of reducing the mucosal injury and inflammation associated with Crohn's disease. 5-ASA is the pharmacologically active moiety of SAZ<sup>[72,75]</sup>. It has been suggested that 5-ASA protects the gut mucosa by inhibiting cyclooxygenase and lipoxygenase activities. Several studies have reported that 5-ASA is a potent antioxidant and free radical scavenger. Research from several laboratories has demonstrated that 5-ASA is

very effective in scavenging hydroxyl radicals, interacting with superoxides and causing the rapid decomposition of this free radical<sup>[92,93]</sup>. Nielsen *et al*<sup>[71]</sup> demonstrated a high rate of lipid peroxidation in the gut mucosa obtained from patients with IBD. They also reported a significant inhibition in lipid peroxidation among patients who had been treated with SAZ for 5 wk<sup>[94]</sup>. These data implicate the involvement of ROS in Crohn's disease due to the antioxidant and free radical scavenging actions of 5-ASA or due to its role as an inhibitor of cyclooxygenase and lipoxygenase, which are enzymatic sources of ROS.

In summary, ROS could be an important factor in Crohn's disease. Crohn's disease is associated with an imbalance, comprising increased ROS and decreased net antioxidant activity. A deficiency in antioxidant molecules could lead to increased levels of lipid peroxides or ROS, which could act locally or be secreted into the circulation to produce different systemic effects in the patient. Obviously, more work is needed in this area to demonstrate the effects of ROS on the production of other neutrophil chemokines from different layers of Crohn's strictures. Future research should also address the question of whether ROS are involved in increasing the production of the different extracellular proteins, such as collagen, that lead to increased thickness of the bowel wall and decreased bowel diameters by enhancing the transcriptions of certain genes using specific transcription factors.

## Current position of ALPPS in the surgical landscape of CRLM treatment proposals

Marcello Donati, Gregor A Stavrou, Karl J Oldhafer

Marcello Donati, Gregor A Stavrou, Karl J Oldhafer, Department of General and Abdominal Surgery, Asklepios Hospital Barmbek, 22291 Hamburg, Germany

Marcello Donati, Department of Surgery, General and Oncologic Surgery Unit, Vittorio-Emanuele University Hospital of Catania, 95122 Catania, Italy

Author contributions: Donati M and Oldhafer KJ equally contributed to the present work; Donati M wrote the article; Donati M and Oldhafer KJ collaborated on design and conception; Donati M and Stavrou GA completed literature research, data collection and wrote the table; Stavrou GA made the first language and style revision; Donati M and Oldhafer KJ made the final critical review of article.
