above, the stenosis was very close to the secondary porta of the liver, and the placement of the stent was incorrect as it blocked the entrance of the HV into the IVC. Thus, based on our experience, surgical broadening of the stricture of the IVC is strongly advocated. With regard to our second case, it is evident that no other method is a substitute for surgical reconstruction of the HV to resolve hepatic congestion.

In conclusion, episodes of acute iatrogenic BCS following hepatectomy for hepatolithiasis are a rare occurrence. Awareness of potential hepatic outflow obstructions and timely management are critical to avoid poor outcomes when performing hepatectomy for hepatolithiasis. From our experience, prompt surgical reconstruction of the HV should be favored to salvage the congested liver.

### Abstract

In immunoglobulin G4 (IgG4)-related disease (RD), organ enlargement or nodular lesions consisting of abundant infiltration of lymphocytes and IgG4-positive plasma cells and fibrosis are seen in various organs. Although infiltration of many IgG4-positive plasma cells is detected in the gastric and colonic mucosa and major duodenal papilla of patients with autoimmune pancreatitis, it cannot be diagnosed as a gastrointestinal lesion involved in IgG4-RD, because none of the following is observed in these lesions: a mass-like formation; dense fibrosis; or obliterative phlebitis. Based on our review of the literature, there appear to be two types of IgG4-

related gastrointestinal disease. One is a gastrointestinal lesion showing marked thickening of the wall of the esophagus and stomach, consisting of dense fibrosis with abundant infiltration of IgG4-positive plasma cells, which usually show submucosal spreading. The other is an IgG4-related pseudotumor occurring in gastrointestinal regions such as the stomach, colon, and major duodenal papilla, showing polypoid or mass-like lesions. Most solitary IgG4-related gastrointestinal lesions that are not associated with other IgG4-RD appear to be difficult to diagnose. It is of utmost importance to rule out malignancy. However, these lesions may respond to steroid therapy. To avoid unnecessary resection, IgG4-related gastrointestinal diseases should be considered in the differential diagnosis.

## INTRODUCTION

Immunoglobulin G4 (IgG4)-related disease (RD) is a recently recognized systemic condition characterized by elevated serum IgG4 levels and steroid responsiveness. IgG4-RD shows organ enlargement or nodular lesions consisting of abundant infiltration of lymphocytes and IgG4-positive plasma cells and fibrosis. IgG4-RD affects various organs such as the pancreas, bile duct, gallbladder, liver, salivary gland, lacrimal gland, retroperitoneum, and lymph nodes simultaneously or metachronously. IgG4-RD frequently presents both clinically and radiologically with findings that mimic a malignancy, resulting in unnecessary resection<sup>[1-4]</sup>. According to comprehensive clinical diagnostic criteria for IgG4-RD<sup>[4]</sup>, IgG4-RD is diagnosed when there is a characteristic diffuse/localized swelling or mass in a single or multiple organs with elevated serum IgG4 levels, or there are histological findings of abundant infiltration of IgG4-positive plasma cells and lymphocytes, along with fibrosis.

Autoimmune pancreatitis (AIP) is a typical lesion of IgG4-RD, and the concept of IgG4-RD was proposed based on research on AIP<sup>[1,2]</sup>. Although it has been reported that infiltration of many IgG4-positive plasma cells was observed in the gastric mucosa, colonic mucosa, and major duodenal papillae of some AIP patients<sup>[5-10]</sup>, it is questionable whether they are the lesions involved in IgG4-RD. To clarify IgG4-related gastrointestinal disease, this article reviews the published literature about the relationships between IgG4 and gastrointestinal diseases such as esophagitis, gastritis, colitis, and duodenal papillitis with abundant infiltration of IgG4-positive plasma cells. A PubMed database search, from 1990 to April, 2013, using the terms “autoimmune pancreatitis or IgG4-related” and “esophagus, duodenum, papilla, colon” identified 116 papers. Additional sources were identified by scanning the bibliographies of original and review articles.

## IGG4-RELATED ESOPHAGEAL LESIONS

There have been two case reports of IgG4-related esophagitis<sup>[11,12]</sup>. In both cases, esophageal stricture with thickening of the esophageal wall evoked debilitating dysphagia and weight loss. Endoscopy showed esophageal stricture without a cancerous lesion. With a diagnosis of gastrointestinal stromal tumor based on endoscopic ultrasound-guided fine needle aspiration (one case) and because of concerns regarding a hidden malignancy (one case), esophageal resection was performed in both patients. On gross examination, the resected specimens showed an esophageal submucosal stricture with mucosal

ulceration and wall thickening; histologically, they showed transmural chronic fibrotic inflammation with abundant infiltration of IgG4-positive plasma cells and lymphocytes and phlebitis. There was no evidence of other IgG4-RD. The post-operative serum IgG4 level was 138 mg/dL in one case. Both lesions are considered esophageal manifestations of IgG4-RD and should be called IgG4-related esophagitis. These lesions would probably respond to steroid therapy. Thus, IgG4-related esophagitis should be kept in mind in the differential diagnosis of unexplained esophagitis with stricture.

## IGG4-RELATED GASTRIC LESIONS

It has been reported that infiltration of many IgG4-positive plasma cells was observed in the gastric mucosa in 33%-47% of AIP patients<sup>[10,13]</sup>. Shinji *et al*<sup>[14]</sup> and Uehara *et al*<sup>[15]</sup> also reported that IgG4-positive plasma cells were significantly more abundant in the gastric mucosa of AIP patients. Most of the infiltrated IgG4-positive plasma cells in the gastric mucosa disappeared in the biopsy specimen from the gastric mucosa after steroid therapy<sup>[16]</sup>. However, neither dense fibrosis nor obliterative phlebitis was observed in the gastric mucosa of AIP patients. Baez *et al*<sup>[17]</sup> reported a patient with AIP and IgG4-related sialadenitis who showed diffusely thickened (up to 1.4 cm) and nodular gastric mucosa with abundant infiltration of IgG4-positive plasma cells. The patient's serum IgG4 level was within the normal range (58 mg/dL), but the gastric lesion improved after steroid therapy. Kaji *et al*<sup>[18]</sup> reported an AIP patient (IgG4 level, 595 mg/dL) with multiple sporadic polyps in the gastric body with erosion and redness on the surface containing many infiltrated IgG4-positive plasma cells. On the other hand, two 3-cm-sized submucosal tumors that were laparoscopically wedge-resected showed histological findings of storiform fibrosis with abundant infiltration of lymphocytes and IgG4-positive cells (> 50/hpf), and they were reported as IgG4-related inflammatory pseudotumor of the stomach<sup>[19]</sup>. Both cases showed normal serum IgG4 levels and no evidence of other IgG4-RD<sup>[19]</sup>. Rollins *et al*<sup>[20]</sup> also reported a laparoscopically resected 5.6-cm IgG4-related fibrosclerosing pseudotumor of the stomach. Three cases with well-circumscribed, sclerosing nodular lesions of the stomach composed of fibrous tissue with abundant infiltration of IgG4-positive plasma cells were reported, and they were not associated with other IgG4-RD<sup>[21,22]</sup>. Fujita *et al*<sup>[23]</sup> reported a case with refractory gastric ulcers that worsened after successful *Helicobacter pylori* eradication therapy. The biopsy specimens taken from the ulcers showed abundant infiltration of IgG4-positive plasma cells (50/hpf). The patient's serum IgG4 level was elevated to 203 mg/dL, but he had no other IgG4-RD.

Bateman *et al*<sup>[24]</sup> reported a case of intractable gastric ulcer showing storiform fibrosis and abundant infiltration of IgG4-positive plasma cells (> 100/hpf). These reported lesions are considered IgG4-related gastric lesions. Anjiki *et al*<sup>[25]</sup> reported that gastric emptying assessed by

the carbon 13 acetate breath test was impaired in AIP patients and improved to the reference range after steroid therapy, and they suggested that the stomach might be a target organ of IgG4-RD.

## IGG4-RELATED MAJOR DUODENAL PAPILLARY LESIONS

It has been reported that the duodenal major papilla is swollen in 41%-65% of AIP patients<sup>[26-28]</sup>. Abundant infiltration of IgG4-positive plasma cells is reportedly detected in 55%-80% of AIP patients<sup>[8,10,26,27]</sup>. Both a swollen major papilla and abundant infiltration of IgG4-positive plasma cells have shown improvement after steroid therapy<sup>[8,29]</sup>. In the resected pancreas of AIP patients, lymphoplasmacytic inflammation with many IgG4-positive plasma cells was detected in the major duodenal papilla connected to the head of the pancreas; thus, IgG4 immunostaining of biopsy specimens obtained from the major duodenal papilla might be useful to support the diagnosis of AIP<sup>[8,26,27,30,31]</sup>. Hisa *et al.*<sup>[32]</sup> reported a resected case of a lymphoplasmacytic granuloma with abundant IgG4-positive plasma cells localized to the major duodenal papilla. The case was not associated with other IgG4-RD. This lesion is considered to be an IgG4-related pseudotumor localized to the major duodenal papilla.

## IGG4-RELATED COLONIC LESIONS

Although infiltration of many IgG4-positive plasma cells is occasionally detected in the colonic mucosa of AIP patients, dense fibrosis or obliterative phlebitis was not observed in the lesion<sup>[1,5-7,21,33]</sup>. Although Ravi *et al.*<sup>[34]</sup> suggested that inflammatory bowel disease might represent an extrapancreatic manifestation of AIP, in general, conventional AIP (type 1 AI) is rarely associated with ulcerative colitis (UC)<sup>[2,35]</sup>. IgG4-positive plasma cell infiltration is sometimes detected in the colonic mucosa of UC patients<sup>[36-40]</sup>, but the mechanisms underlying IgG4-positive plasma cell infiltration in the colonic mucosa of UC patients are unknown. Matsui *et al.*<sup>[41]</sup> reported a case of an AIP patient with a colonic polyp (ascending colon) containing many IgG4-positive plasma cells<sup>[42]</sup> who developed colonic polyposis (descending colon) containing many IgG4-positive plasma cells 1 year after complete remission of AIP with steroid therapy. The polyposis was markedly reduced with re-administration of steroids. They suggested that enhanced T helper type 2 responses to intestinal microflora may underlie the immunopathogenesis in patients with IgG4-RD<sup>[43]</sup>. Well-circumscribed sclerosing nodular lesions of the cecum and sigmoid colon composed of hyalinized fibrocollagenous tissue with abundant infiltration of IgG4-positive plasma cells were reported, and the two cases had no other IgG4-RD<sup>[21]</sup>. These polypoid or nodular lesions appear to be IgG4-related colonic lesions.

## IGG4-RELATED INFLAMMATORY PSEUDOTUMOR OF AN ILEAL CONDUIT

An ill-defined, fibrotic, tumor-like mass, histologically showing fibrosis with infiltration of lymphocytes and IgG4-positive plasma cells and marked obliterative phlebitis, occurred in an ileal conduit created as part of surgery for urinary bladder cancer<sup>[44]</sup>.

## DISCUSSION

IgG4-RD shows organ enlargement or nodular lesions consisting of abundant infiltration of lymphocytes and IgG4-positive plasma cells and fibrosis in various organs simultaneously or metachronously<sup>[3,4]</sup>. The first International Symposium on IgG4-RD held in 2011 suggested that the term "IgG4-related disease" aptly recognizes the ubiquity of IgG4 within involved organs, and proposes a style that employs "IgG4-related" as a prefix to the organ system affected and pathological guidelines for the diagnosis of IgG4-RD<sup>[3,45]</sup>. The diagnosis of IgG4-RD rests on the combined presence of the characteristic histopathological appearances and increased number of IgG4-positive plasma cells. A histologically high suspicion of IgG4-RD requires the presence of at least two of three characteristic histological features including (1) dense lymphoplasmacytic infiltration; (2) fibrosis, usually storiform in character; and (3) obliterative phlebitis. The IgG4 counts required for the diagnosis differ among affected organs, ranging from 10 to 200 cells/hpf. The diagnosis of IgG4-RD requires considering both histopathological findings and clinical information such as elevated serum IgG4 levels, other organ involvement that is consistent with IgG4-RD, and effective response to steroid therapy<sup>[45]</sup>.

Comprehensive clinical diagnostic criteria for IgG4-RD<sup>[4]</sup> were proposed in 2011. In the criteria, IgG4-RD is diagnosed when there is a characteristic diffuse/localized swelling or mass in a single or multiple organs with elevation of serum IgG4 levels or IgG4-related histological findings. However, the concept of IgG4-related gastrointestinal diseases was not included as objects of the criteria. It is unclear whether IgG4-related gastrointestinal diseases exist or what gastrointestinal lesions are regarded as IgG4-RD. To clarify these questions, this review of IgG4-related gastrointestinal diseases, the first of its kind, was conducted.

Infiltration of many IgG4-positive plasma cells is detected in the gastric and colonic mucosa and the major duodenal papillae of some AIP patients, but none of the following are observed in these lesions: a mass-like formation; dense fibrosis; or obliterative phlebitis<sup>[5-10]</sup>. They cannot be diagnosed as gastrointestinal lesions involved in IgG4-RD, because, as in many other organ systems, increased IgG4-positive plasma cells do not mean the disease is one of the family members of IgG4-RD. At this point, both the clinical finding of mass forming and histological finding of abundant infiltration of IgG4-

positive plasma cells with fibrosis would appear to be necessary to make the diagnosis of IgG4-related gastrointestinal diseases.

IgG4-related pseudotumors have been reported in several organs, such as the liver and lung<sup>[46-48]</sup>. On review of these papers, there appear to be two types of IgG4-related gastrointestinal disease. One is a gastrointestinal lesion showing marked thickening of the wall of the esophagus<sup>[11,12]</sup> and stomach<sup>[17,23,24]</sup>, consisting of dense fibrosis with abundant infiltration of IgG4-positive plasma cells, which usually show submucosal spreading. The other is an IgG4-related pseudotumor occurring in gastrointestinal regions such as the stomach<sup>[18-22]</sup>, colon<sup>[21,42]</sup>, and major duodenal papilla<sup>[52]</sup>, showing polypoid or mass-like lesions. We currently consider these lesions to be IgG4-related gastrointestinal diseases. However, this is the first review of a few cases of IgG4-related gastrointestinal diseases; further studies should be conducted to confirm this concept.

Most solitary IgG4-related gastrointestinal lesions that are not associated with other IgG4-RD appear to be difficult to diagnose. It is of utmost importance to rule out malignancy. However, these lesions may respond to steroid therapy. To avoid unnecessary resection, IgG4-related gastrointestinal diseases should be considered in the differential diagnosis.

## CONCLUSION

The concept of IgG4-related gastrointestinal disease remains unclear due to its rarity. There appear to be some IgG4-related gastrointestinal lesions that present with a mass-like lesion consisting of abundant infiltration of IgG4-positive plasma cells and lymphocytes and fibrosis.

### Abstract

Polycystic liver diseases (PLD) represent a group of genetic disorders in which cysts occur in the liver (autosomal dominant polycystic liver disease) or in combination with cysts in the kidneys (autosomal dominant polycystic kidney disease). Regardless of the genetic mutations, the natural history of these disorders is alike. The natural history of PLD is characterized by a continuous increase in the volume and the number of cysts. Both genders are affected; however, women have a higher prevalence. Most patients with PLD are asymptomatic and can be managed conservatively. Severe symptoms can affect 20% of patients who develop massive hepatomegaly with compression of the surrounding organs. Rarely, patients with PLD suffer from acute

complications caused by the torsion of hepatic cysts, intraluminal cystic hemorrhage and infections. The most common methods for the diagnosis of PLD are cross sectional imaging studies. Abdominal ultrasound and computerized tomography are the two most frequently used investigations. Magnetic resonance imaging is more sensitive and specific, and it is a valuable test for patients with intravenous contrast allergies or renal dysfunction. Different treatment modalities are available to physicians caring for these patients. Medical treatment has been ineffective. Percutaneous sclerotherapy, transarterial embolization, cyst fenestration, hepatic resection and liver transplantation are indicated to specific groups of patients and have to be tailored according to the extent of disease. This review outlines the current knowledge of the pathophysiology, clinical course, diagnosis and treatment strategies of PLD.

**Key words:** Polycystic liver disease; Hepatic; Epidemiology; Classification; Therapy; Genetic

**Core tip:** The management of patients with symptomatic polycystic liver disease is challenging. Among several treatments options, the most common interventions are: percutaneous cyst aspiration, fenestration, hepatic resection and liver transplantation. There is no consensus on the best treatment options and the optimal timing for interventions in symptomatic patients. In vision of these limitations, we reviewed the most recent literature and present a comprehensive article on this topic.

## INTRODUCTION

The association between polycystic liver disease (PLD) and autosomal dominant polycystic kidney disease (ADPKD) was described for the first time by Bristowe in 1856<sup>[1,2]</sup>. Initially, it was thought that PLD could develop only in the context of ADPKD<sup>[3]</sup>. The notion that isolated PLD might be a separate condition was proposed in the 1950s<sup>[4]</sup>. In 2003, a linkage analysis of eight Finnish families confirmed that PLD is genetically distinct from ADPKD<sup>[5]</sup>. Asymptomatic patients usually do not require any intervention<sup>[6]</sup>. In some patients, massive hepatomegaly can cause pain or compression of the adjacent gastrointestinal organs, vasculature, and diaphragm. This can have a significant effect on patients' quality of life and performance status<sup>[6,7]</sup>. For these patients, the main aim is to reduce their symptoms by decreasing the liver volume<sup>[8-10]</sup>. Current surgical options include open or laparoscopic cyst fenestration with or without hepatic resection and orthotopic liver transplantation (OLT). Significant advances in surgical techniques have improved the outcomes of PLD patients. However, the selection of the appropriate approach remains a clinical challenge, and there is no consensus on the optimal timing and what represents the best therapeutic modality.

## INCIDENCE AND GENETICS

ADPKD affects up to 0.2% of the general population<sup>[11]</sup>. On the other hand, isolated PLD has prevalence of less than 0.01%<sup>[12]</sup>. Both ADPKD and PLD are autosomal dominant and 75%-90% of patients with ADPKD have associated PLD<sup>[13]</sup>. In humans, PLD has been linked to mutations of four genes. Two genes (*PKD1*, locus 16p13.3, encoding polycystin-1 and *PKD2*, locus 4q21, and encoding polycystin-2) are predominantly associated with renal disease and less frequently with PLD. *PKD1* mutations are more common and account for 85%-90% of the cases, whereas mutations in *PKD2* affect approximately 10%-15% of patients<sup>[11]</sup>. The remaining two mutations (*PRKCSH*, locus 19p13.2, encoding the protein kinase C substrate 80K-H or hepatocystin and *SEC63*, locus 6q21, encoding the Sec63 protein) are linked only to the development of PLD<sup>[11]</sup>. However, these mutations explain just 25% to 40% of cases of PLD<sup>[14,15]</sup>. Comparative characteristics between ADPKD and PLD are summarized in Table 1.

## PATHOPHYSIOLOGY

Malformation of the hepatic ductal plate and cilia of cholangiocytes is the main characteristic linked to the pathophysiology of PLD (Figure 1).

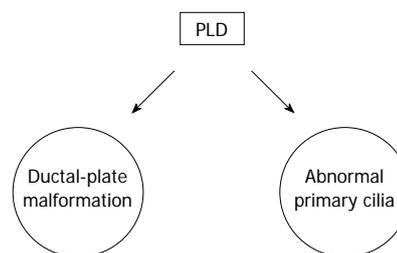

### DUCTAL-PLATE MALFORMATION

The ductal plate is the anatomical template for the development of the intra-hepatic bile ducts<sup>[16]</sup>. Normal

Chromosome locus	216p13.3; 4q21	19p13.2; 6q21

AD: Autosomal dominant; ADPKD: Autosomal dominant polycystic kidney disease; PLD: Polycystic liver disease.

**Figure 1 Pathophysiology of polycystic liver disease.** PLD: Polycystic liver disease.

bile ducts arise from the ductal plate through a complex sequence of growth and apoptosis. Complexes of disconnected intralobular bile ductules (von Meyenburg complexes) are retained because they do not undergo apoptosis in PLD<sup>[10]</sup>. As a consequence, multiple cysts arise from progressive dilatation of these abnormal ductules<sup>[17-19]</sup> that display the same epithelium and structures of functioning cholangiocytes<sup>[20,21]</sup>.

### ABNORMAL PRIMARY CILIA

Cholangiocytes are the only ciliated cells in the liver. Cilia have mechanosensory capacity and modulate the intracellular levels of cAMP and Ca<sup>2+</sup> when bent by the flow of bile. They also detect changes in osmolarity and composition of the bile<sup>[22-24]</sup>. Ciliary defects result in a decreased cytoplasmic level of Ca<sup>2+</sup> and an increased cytoplasmic level of cAMP<sup>[25]</sup>. These changes are responsible for the hyperproliferation of cholangiocytes and for the cystogenesis that is a consequence of the altered balance between fluid secretion and absorption in the lumen of the biliary ducts<sup>[25]</sup>.

## NATURAL HISTORY AND RISK FACTORS FOR PLD

The natural history of PLD is characterized by a continuous increase in the volume and the number of cysts<sup>[11,26,27]</sup>. The annual growth of affected livers is in the range of 0.9%-3.2% of the initial hepatic volume<sup>[10,28-30]</sup>. Both genders are affected; however, women have a higher

**Table 2 Risk factors for liver-cyst growth in polycystic liver disease**

Risk factors for liver-cyst growth in polycystic liver disease
Advancing patient age

Severity of renal dysfunction and renal cyst volume

OCPs: Oral contraceptive pills.

prevalence. Exposure to estrogen during pregnancies, the use of oral contraceptive pills or estrogen replacement therapy seems to accelerate the progression of the disease<sup>[1,27,31]</sup>. Other risk factors are the severity of renal dysfunction that is dependent on the volume of the cysts in the kidneys<sup>[1]</sup>. Table 2 summarizes the known factors that influence the progression of PLD.

### CLINICAL PRESENTATION

PLD is asymptomatic in 80% of patients<sup>[8,9]</sup> and is usually diagnosed incidentally. Women present with massive and symptomatic cystic liver more frequently than men<sup>[32]</sup>. For 20% of patient, symptoms are typically caused by the compression of organs surrounding the liver, bleeding or infectious complications of the cysts. Compressive symptoms include abdominal distention, early satiety that can lead to decreased oral intake and severe malnutrition, gastro-esophageal reflux, dyspnea, hepatic venous-outflow obstruction (Budd-Chiari syndrome), inferior vena cava syndrome, portal-vein and bile-duct compression. Complications of liver cysts include infections, torsions, rupture and hemorrhage<sup>[1,18,33,34]</sup> (Table 3). In asymptomatic patients, serum laboratory studies are usually normal. In the presence of symptoms, 47% of patients have elevated serum alkaline phosphatase, 70% have elevated serum levels of gamma glutamil transferase<sup>[35-38]</sup>, 27% have elevated serum levels of aspartate amino transferase and 15% have elevated serum levels of total bilirubin<sup>[35,36]</sup>. Liver synthetic function is typically preserved despite the presence of innumerable cysts<sup>[52]</sup> while 45% of patients might have elevated serum tumor marker CA19-9 without proof of malignancy<sup>[39]</sup>. Other tumor markers such as CA-125, carcinoembryonic antigen, and alpha-fetoprotein may also be elevated but less frequently than CA19-9<sup>[40-42]</sup>.

### ASSOCIATED EXTRA-HEPATIC DISEASES

Intracranial arterial aneurysms can affect 6% of patients without a family history of ADPKD and up to 16% of patients with family history of ADPKD. Other common conditions are mitral-valve prolapse and colonic diverticulosis that can be detected in 25% of patients with PLD<sup>[1,11,43-45]</sup>. Screening for intracranial aneurysm by

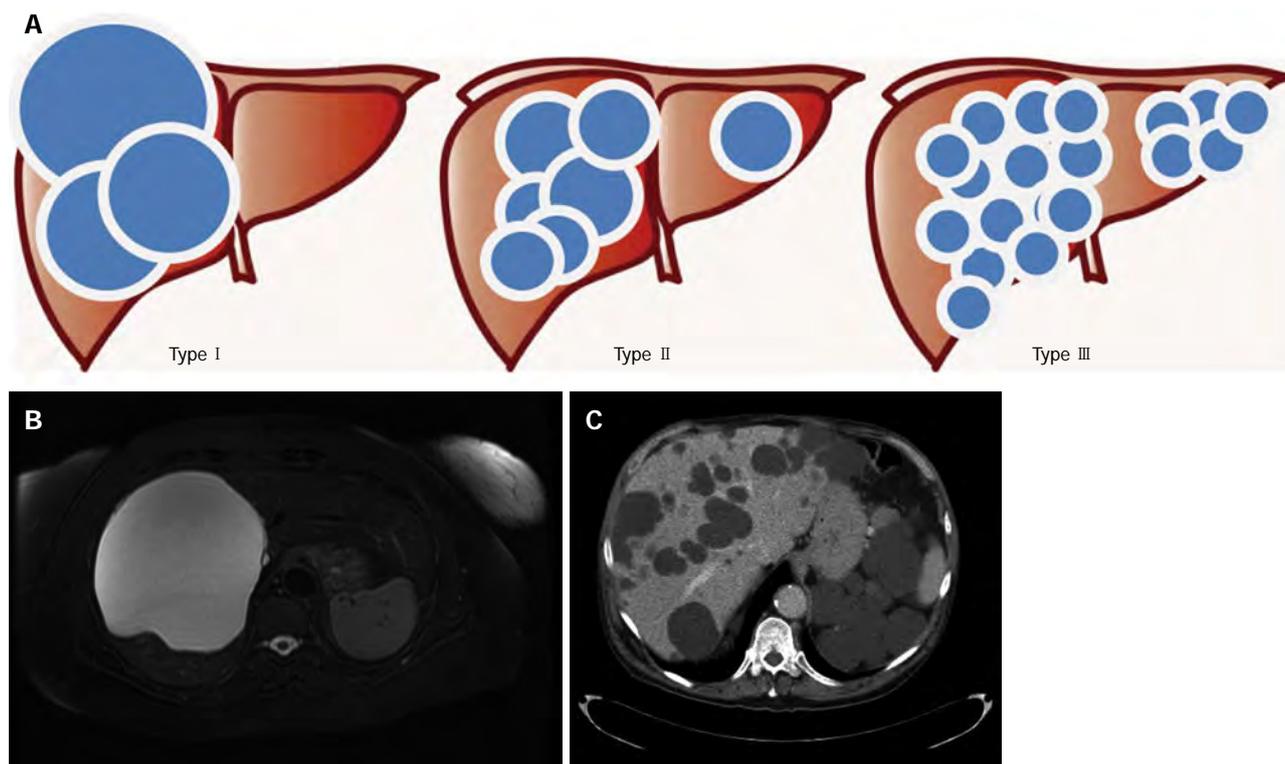

**Table 3 Summary of the most frequent symptoms caused by polycystic liver disease**

Symptoms due to mass effect	Symptoms due to complications of the cysts
Abdominal distention	Infection
Early satiety	Torsion
Postprandial fullness	Rupture

Malnutrition	
Dyspnoea	
Hepatic venous-outflow obstruction (Budd-Chiari syndrome)	
Inferior vena cava syndrome	
Portal-vein compression	
Bile-duct compression	

magnetic resonance angiography (MRA) is recommended only for patients with ADPKD, older than 30 years or for those patients with family history of hemorrhagic strokes or intracranial arterial aneurysms<sup>[46]</sup>. Screening for intracranial arterial aneurysms is also warranted in cases of a sudden severe headache, or for candidates to liver or kidney transplantation. Screening for mitral-valve prolapse is not recommended unless a cardiac murmur is ascultated during routine clinical examinations<sup>[11,47]</sup>. Finally, patients with ADPKD may have asymptomatic cysts within other organs, such as the pancreas, spleen, ovaries, and lungs<sup>[48]</sup>. Pancreatic cysts are the most common with a reported incidence of 9% among ADPKD patients older than 30 years<sup>[49-51]</sup>.

### DIAGNOSIS

The most common methods for the diagnosis of PLD are cross sectional imaging studies. Abdominal ultrasound (US) and computerized tomography (CT) are the two most frequent investigations<sup>[52,53]</sup>. For hepatic cysts, MRI is more sensitive and specific, and it is a valuable test for patients with intravenous contrast allergies or renal dysfunction or when other studies are unable to satisfy the diagnostic needs<sup>[54]</sup>. Hepatic cysts have radiological characteristics identical to benign developmental cysts. On US, they appear anechoic and well-circumscribed<sup>[55]</sup>. On CT and MRI, they have non-enhancing, well-circumscribed round walls with hypodense content<sup>[55]</sup>. On T2-weighted MRI and CT scans, they appear homogenously enhanced spherical lesions<sup>[55]</sup> (Figure 2B and C). The distinction between isolated PLD and ADPKD relies on the number of renal cysts, age at presentation and family history (Table 4). In adults, younger than 30 years with a positive family history, the diagnosis of ADPKD is established by radiologic evidence of at least two unilateral or bilateral cysts. At least two cysts in each kidney are necessary for the diagnosis of patients between the age of 30 to 59 years, and at least four cysts in each kidney for patients 60 years or older<sup>[56]</sup>. It is worth noting that at least one third of patients with isolated PLD may also have a few kidney cysts<sup>[15,56,57]</sup>. It has been proposed that

**Figure 2** Gigot's classification for polycystic liver diseases. A: Graphical representation; B: Abdominal magnetic resonance imaging of a patient affected by Gigot I cystic liver disease; C: Abdominal computerized tomography of a patient affected by Gigot II cystic liver disease.

**Table 4** The ravine diagnostic criteria for autosomal dominant polycystic kidney disease

Patient's age (yr)	Number of cysts	
	Positive family history	Negative family history
≤ 30	At least 2 cysts affecting 1 or both kidneys	At least 5 cysts
31-59	At least 2 cysts in each kidney	At least 5 cysts
≥ 60	At least 4 cysts in each kidney	At least 8 cysts

sporadic cases of PLD should be diagnosed when a patient has more than 15 to 20 cysts and no previous family history<sup>[1,18]</sup> while four cysts suffice in the presence of a positive familial history<sup>[1,18]</sup>.

### INFECTED CYSTS

Hepatic cysts may become infected, and cause life-threatening sepsis<sup>[58,59]</sup>. Often, infected hepatic cysts are responsible for recurrent episodes of fever without any other signs or symptoms. In these circumstances, the diagnosis can be quite difficult as the accuracy of imaging tests remain low due to the altered anatomy of the liver parenchyma<sup>[60]</sup>. A promising investigation technique for suspected infected hepatic cysts is In-111 WBC scan<sup>[61]</sup>. Several other tracers such as 99mTc-diphosphonates, 67Gacitrate, and 111In- or 99mTc-labeled leukocytes have also been used<sup>[62]</sup>. Although labeled leukocyte imaging is theoretically the test of choice for detecting most infections, it is labor intensive, not always available and

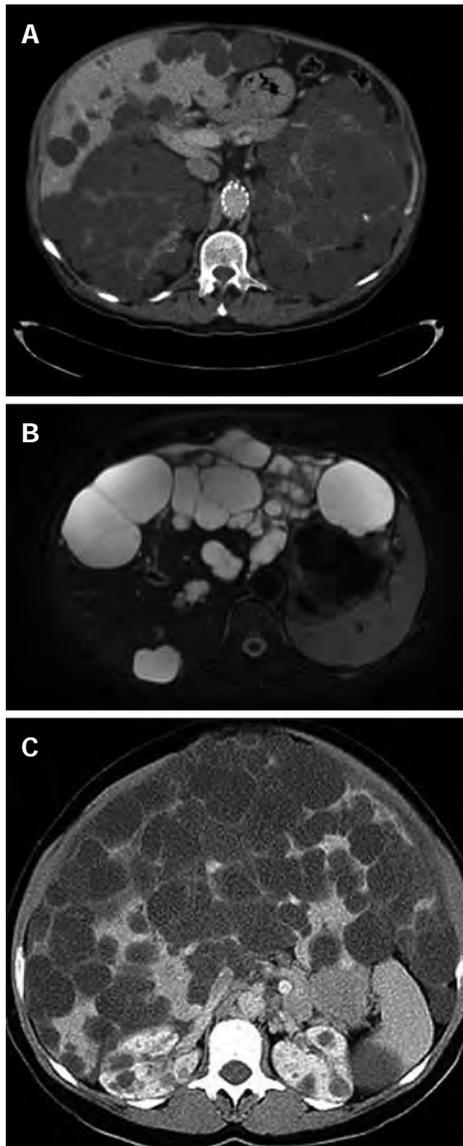

involves direct handling of potentially infected blood products. Therefore, considerable effort has been devoted to search for alternatives to this procedure such as the use of 67Gallium scintigraphy and 18F-FDG-positron emission tomography (PET). In recent years, PET has become the most commonly used diagnostic test for the detection of infected renal and hepatic cysts<sup>[60,62,63]</sup>. However, the accuracy of this technique is still under investigation. The literature on the treatment of infected cysts in PLD patients is very scarce and based only on a few case reports. Most of patients will need parenteral broad spectrum antibiotic therapy with percutaneous drainage of the content of the cyst if their symptoms persists.

### CLASSIFICATION

Several clinical classifications have been proposed to grade the severity of PLD.

### GIGOT'S CLASSIFICATION

Gigot's classification relies on imaging findings and was designed to identify the best candidates for fenestration of symptomatic cysts<sup>[38]</sup> (Figure 3): Type I : presence of less than 10 large hepatic cysts measuring more than 10 cm in maximum diameter. Type II : diffuse involvement of liver parenchyma by multiple cysts with remaining large areas of non-cystic liver parenchyma. Type III: presence of diffuse involvement of liver parenchyma by small and medium-sized liver cysts with only a few areas of

**Figure 3** Gigot's classification relies on imaging findings and was designed to identify the best candidates for fenestration of symptomatic cysts. A: Intravenous contrast enhanced computerized tomography (CT) of a patient affected by polycystic liver and renal disease. The cysts appear hypodense with smooth and regular walls; B: T2 magnetic resonance imaging of a patient with multiple hepatic cysts. The cystic fluid appears bright on T2 images; C: Abdominal CT of a patient affected by Gigot III cystic liver disease.

normal liver parenchyma.

### QUIAN'S CLASSIFICATION

Qian's classification has been used in the context of familial screening and relies on the number of cysts and the presence of symptomatic hepatomegaly<sup>[18]</sup>: (1) grade 0 - 0 cysts; (2) grade 1 - 1 to 10 cysts; (3) grade 2 - 11 to 20 cysts; (4) grade 3 - more than 20 cysts; and (5) grade 4 - more than 20 cysts and symptomatic hepatomegaly.

### SCHNELLDORFER'S CLASSIFICATION

Schnelldorfer's classification aims at differentiating pa-

tients who could benefit from resection or transplantation as summarized in Table 5<sup>[64]</sup>.

### TREATMENT

Most patients with PLD are asymptomatic and do not require any intervention<sup>[6]</sup>. However, symptomatic PLD patients might require treatment when they experience severe dysfunction of organs around the liver due to the increased hepatic volume or when one or more cysts get tormented, infected or develop intra-cystic hemorrhages (Table 6).

### AVOIDANCE OF EXPOSURE TO ESTROGENS

Observational and experimental studies have shown that PLD may worsen under the influence of estrogen during pregnancy or when patients are prescribed estrogen replacement therapy<sup>[1,27,31]</sup>. Estrogen can increase both the number of liver cysts and their volume, therefore, hormonal therapy should be stopped in most symptomatic patients when appropriate<sup>[27]</sup>.

### NON-SURGICAL TREATMENTS

Medical management may be valuable in symptomatic patients with Gigot's type II/III.

### SOMATOSTATIN ANALOGUES

Somatostatin analogues are inhibitors of cAMP and they reduce the secretion of fluid and the proliferation of many cell types, including cholangiocytes<sup>[65-69]</sup>. They also suppress the expression of insulin-like growth factor 1 (IGF-1), vascular endothelial growth factor (VEGF), and other cytogenetic growth factors<sup>[70]</sup>. In addition, somatostatin analogues inhibit the downstream signaling of these receptors<sup>[70]</sup>. Two randomized controlled trials have recently demonstrated that after 6 to 12 mo, treatment with lanreotide, a long-acting somatostatin analogue, was associated with a significant reduction of liver volume in patients with PLD compared with placebo<sup>[28,29]</sup>. However, the average hepatic volume reduction was only 3% to 5%. The severity of abdominal symptoms was also not significantly improved<sup>[28]</sup>. Currently, somatostatin analogues are indicated only for a selected group of patients with symptomatic PLD in whom the risks for surgical intervention are not justified, or in whom the surgical intervention is technically challenging.

### MAMMALIAN TARGET OF RAPAMYCIN INHIBITORS

Mammalian target of rapamycin (m-TOR) inhibitors have immunosuppressive and antiproliferative effects<sup>[71]</sup>. Sirolimus and Everolimus were studied in Phase-II prospective randomised control trials. None of the two drugs showed substantial therapeutic effects both in hu-

**Table 5 Summary of Schnelldorfer’s classification that aims at differentiating patients who could benefit from resection or transplantation**

	Type A	Type B	Type C	Type D
Symptoms	Absent or mild	Moderate or severe	Severe (or moderate)	Severe (or moderate)

mans<sup>[72-74]</sup> and in animal models<sup>[75]</sup>. Clinical prospective data on the effect of m-TOR inhibitors are currently not available, and this class of medications should not be recommended outside clinical trials.

## INTERVENTIONAL RADIOLOGY: ARTERIAL EMBOLIZATION

Trans-catheter arterial embolization has been used since the early 2000s<sup>[76]</sup>. Hepatic artery branches supplying the hepatic segments replaced by the cysts are targeted by using microcoils or polyvinyl alcohol particles measuring 150-250 μm in diameter<sup>[76,77]</sup>. For patients with advanced PLD and multilobar disease, trans-catheter arterial embolization can be technically demanding. The largest series of patients treated with this modality included 30 patients who had a significant reduction of the volume of their cysts ( $6.667 \pm 2.978 \text{ cm}^3$  down to  $4.625 \pm 2.299 \text{ cm}^3$ ), whereas the volume of the unaffected hepatic parenchyma increased<sup>[76]</sup>. After several months, patients reported improvement of their symptoms and no major complications except for occasional post-embolization syndrome<sup>[76,77]</sup>.

## PERCUTANEOUS SCLEROTHERAPY

This technique requires radiologically guided percutaneous aspiration of the content of the cysts followed by the injection of a sclerosing agent that inhibit the reaccumulation of fluid by damaging the epithelial lin-

ing the cysts<sup>[78,79]</sup>. Symptomatic patients with one to five large dominant cysts (Gigot’s type I) are suitable for percutaneous sclerotherapy. Most commonly, cysts with a diameter larger than 5 cm are candidates for this treatment<sup>[10]</sup>. Puncturing of the cyst can be done with a 5 or 7 French catheter<sup>[80]</sup> and sclerosing agents commonly used include ethanol, ethanolamine oleate, minocycline and tetracycline. Although a single session is often sufficient, some patients require more than one<sup>[81]</sup>. Aspiration with sclerotherapy has an excellent safety profile, although severe abdominal pain can be caused by peritoneal irritation due to spillage of the sclerosing agent<sup>[10]</sup>. The majority of patients who undergo percutaneous sclerotherapy has improved symptoms in the immediate period following the procedure<sup>[10]</sup>, but only 20% will have partial, or full regression of their disease<sup>[10]</sup>.

## SURGERY

Patient and treatment selection remain a clinical challenge. There is no consensus on selection criteria for surgery, the optimal timing, and technique. Current surgical options include fenestration, partial liver resection and OLT. Fenestration and partial liver resection are options for Gigot’s type I and II patients. For Gigot’s type III disease, fenestration and partial liver resection are often ineffective, and OLT should be considered as it is the only curative treatment. In general, several factors have to be considered before any surgical intervention is recommended: (1) The degree of cystic burden; (2) The distribution of the cysts; and (3) The proximity of the cysts to the main biliary ducts and portal and hepatic vein branches.

## SURGICAL PEARLS

In Gigot’s type I or II, symptoms might not be related to the size of the entire liver but to the size of one or two large cysts. These patients can be treated similarly to those with simple cysts. Some hepatic segments such as V and VI are frequently spared and, therefore, surgical resection can be performed if the spared liver parenchyma is thought to be sufficient. Frequently, the right hepatic veins are compressed by cysts causing the formation of collateral circulation between the right and the middle hepatic veins that can be responsible for intraoperative bleeding during the parenchymal transaction.

## FENESTRATION

Fenestration is a surgical technique that combines aspiration and surgical unroofing of the cyst. It has the advantage that multiple cysts can be treated in one session<sup>[48,82]</sup>. Fenestration is effective in symptomatic patients with Gigot's type I and II disease<sup>[83]</sup>. Patients with superficial and a limited number of large cysts are the best candidates for this procedure<sup>[48]</sup>. Fenestration may be achieved by laparotomy or laparoscopy<sup>[48]</sup>. Patients with the majority of their cysts located in the right posterior segments (VI, VII), or at the dome of the liver (segment VIII) may be better candidates for open fenestration because these cysts are difficult to be visualized and fenestrated by laparoscopic approach<sup>[48]</sup>. Published series describing open and laparoscopic fenestration are summarized in Table 7. Immediate symptom relief is achieved in 92% of the patients, whereas up to 25% experience recurrence of the cysts or symptoms<sup>[10]</sup>. Complication rate after fenestration is in the range of 23% while mortality is about 2%<sup>[10]</sup>. Complications include ascites, pleural effusion, hemorrhage and bile leakage<sup>[84]</sup>. Factors that predict failure of fenestration are previous abdominal procedures, deep-seated cysts, incomplete unroofing, cysts in segments VII-VIII, and the presence of diffuse PLD<sup>[10]</sup>.

## HEPATIC RESECTION WITH FENESTRATION

Hepatic resection is usually reserved for highly symptomatic patients who are incapacitated by their disease due to the massive expansion of their livers (Gigot's type II and

III)<sup>[38]</sup>. In these circumstances fenestration alone is rarely successful because the liver parenchyma is rigid and it does not collapse<sup>[10]</sup>. Symptom relief is achieved in 86% of cases although cyst recurrence is expected in one third of patients<sup>[10]</sup>. Overall, most of the patients have an improvement in their quality of life and functional status<sup>[36]</sup>. The morbidity rate associated with this procedure can be up to 50% and includes ascites, pleural effusions, biliary leakage, and hemorrhage<sup>[10]</sup>. One of the reasons for these complications is the fact that there is a significant distorsion of the intra-hepatic vasculature and biliary tree which makes these procedures technically very challenging. Mortality rate is around 3%<sup>[10]</sup>. As subsequent adhesions may complicate future OLT, this surgical treatment is usually preserved for patients with massive hepatomegaly for which OLT is not an option<sup>[85,86]</sup>. Published series describing hepatic resection with/without fenestration for symptomatic PLD are summarized in Table 8.

## LIVER TRANSPLANTATION

OLT is the only curative treatment for patients with severe PLD<sup>[87]</sup>. It is indicated in those patients with disabling symptoms that lead to decreased performance status and quality of life<sup>[10]</sup>. Patients with PLD usually have normal liver function and the current organ allocation system based on the Model for End-Stage Liver Disease (MELD) is often unable to assist this group of patients. For these patients, MELD exception criteria are needed<sup>[88,89]</sup>. Because of the shortness of available grafts, the need for life-long immunosuppression and the perioperative risks, OLT is indicated only for symptomatic patients

**Table 8 Summary of largest series published on the surgical techniques used for cystic fenestration and resection of symptomatic polycystic liver disease**

Ref.	No.	Technique	Outcome	Complications	Follow-up (mo)

with Gigot's type II and III disease<sup>[12,48,90]</sup>. For patients undergoing OLT for PLD, perioperative morbidity is 40%-50%, whereas overall mortality is 10%-17%<sup>[10]</sup>. In 3% of patients, retransplantation is required<sup>[10]</sup> and combined renal and liver transplantation are necessary in 42% of patients<sup>[91,92]</sup>. Expected survival at 1- and 5-year are 93% and 92% for patients undergoing OLT alone while for patients who undergo combined liver and kidney transplant are 86% and 80% respectively<sup>[10]</sup>. Published series reporting the outcomes of OLT for symptomatic PLD are summarized in Table 9.

## HEPATIC RESECTION VS LIVER TRANSPLANTATION

The clinical decision between performing a hepatic resection with or without cyst fenestration<sup>[93]</sup> and referring

the patient for OLT can be extremely difficult (Table 10). Hepatic resection with cyst fenestration implies leaving residual hepatic cysts that will eventually progress<sup>[94]</sup>. However, hepatic resection is associated with a lower risk of perioperative morbidity and mortality. OLT provides the only option for the cure of these patients but requires lifelong immunosuppression and has higher perioperative risks. Both resection and OLT are technically demanding, and peri-operative care can be complex. The risks and the benefits of each of the possible treatment options have to be carefully evaluated and put in the context of the clinical presentation and condition of each patient. Referral to a tertiary center with an experienced team of surgeons, hepatologists, and nephrologists is strongly recommended.

## CONCLUSION

For patients with PLD, patients' selection, timing and choice of treatments can be very challenging even for experienced physicians. For symptomatic patients, treatment strategies should be based on the degree and progression of their symptoms and the severity of other medical conditions. Symptomatic patients with large cysts or limited hepatic involvement might benefit from fenestration or sclerotherapy. Hepatic resection with or without fenestra-

tion should be favored in patients with diffuse involvement of the liver but with sufficient spared parenchyma. Finally, in the patient with diffuse disease, OLT is a valid option and should be pursued as primary therapy prior to the development of debilitating disease such as malnutrition and liver dysfunction that can significantly increase the risks of perioperative adverse events.

### Abstract

Several studies indicate a significant degree of overlap between irritable bowel syndrome (IBS) and gastroesophageal reflux disease (GERD). Likewise, both functional heartburn (FH) and IBS are functional digestive disorders that may occur in the same patients. However, data establishing a solid link between FH and IBS are lacking, mainly because the clinical definition of FH has undergone substantial changes over the years. The available literature on the overlap between GERD or FH and IBS highlights considerable heterogeneity in terms of the criteria and diagnostic procedures used to assess heartburn and IBS. In particular, several epidemiological studies included patients with concomitant IBS and GERD without any attempt to distinguish FH (as defined by the Rome III criteria) from GERD *via* pathophysiological investigations. Independent of these critical issues, there is preliminary evidence supporting a significant

degree of FH-IBS overlap. This underscores the need for studies based on updated diagnostic criteria and accurate pathophysiological classifications, particularly to distinguish FH from GERD. This distinction would represent an essential starting point to achieving a better understanding of pathophysiology in the subclasses of patients with GERD and FH and properly assessing the different degrees of overlap between IBS and the subcategories of heartburn. The present review article intends to appraise and critically discuss current evidence supporting a possible concomitance of GERD or FH with IBS in the same patients and to highlight the pathophysiological relationships between these disorders.

### INTRODUCTION

Gastroesophageal reflux disease (GERD) and irritable bowel syndrome (IBS) are gastrointestinal disorders that affect a large portion of the general population and have a relevant impact on quality of life and health care costs. Although these disturbances affect different regions of the digestive tract, it has been noted that they may occur in the same patient. In addition, recent studies have shown a concomitance between functional heartburn

(FH) and IBS. This finding is not completely unexpected because FH and IBS are both functional digestive disorders (FDDs), and the possibility of an overlap among different FDDs has been largely acknowledged<sup>[1]</sup>. Indeed, there is mounting evidence that FDDs consist of a number of heterogeneous syndromes characterized by various gastrointestinal symptoms with no evident organic cause found upon clinical investigation<sup>[2]</sup>.

Based on the above considerations, the hypothesis of an association between FH and IBS deserves careful attention and investigation. However, data establishing a solid link between FH and IBS are lacking, most likely because the disorders' clinical definitions have undergone to significant variations over the years, and their pathophysiology remains poorly understood.

The present article intends to provide a review of current evidence supporting a possible clinical and pathophysiological relationship between GERD/FH and IBS.

## DEFINITIONS

To properly address the relationship between GERD/FH and IBS, it is important to preliminarily clarify some definitions of GERD, as patients affected by FH have been often included in this category in both past and recent clinical investigations.

### GERD

GERD develops when the reflux of gastric contents into the esophagus leads to troublesome symptoms, with or without mucosal damage and/or complications<sup>[3]</sup>. A subcategory of GERD patients that displays reflux-related symptoms in the absence of erosive esophagitis at endoscopy is considered to have non-erosive reflux disease (NERD)<sup>[3]</sup>. Pathophysiological studies conducted *via* pH monitoring and, more recently, impedance-pH monitoring (MII-pH) have demonstrated that there are two main types of NERD patients: those with abnormal acid reflux and those with physiological acid exposure time (AET). In the latter group, patients showing a close temporal relationship between symptoms and acid or non-acid reflux episodes have been defined as having a "hypersensitive esophagus" and should be considered within the spectrum of GERD<sup>[4,5]</sup>. When the association between symptoms and physiological reflux is lacking, patients can be classified as having FH, which is defined in the next section.

### FH

The Rome II criteria for functional esophageal disorders defined FH as an episodic retrosternal burning in the absence of pathological gastroesophageal reflux, pathology-based motility disorders, or structural alterations<sup>[6]</sup>. In 2006, the Rome III committee modified the definition of FH as the occurrence of chronic retrosternal burning in the absence of either GERD or histopathology-based esophageal motility disorders. In particular, according to Rome III criteria, heartburn should be reported as hav-

ing persisted over the previous 3 mo, with a symptom onset dating to at least 6 mo before the diagnosis<sup>[7]</sup>. To exclude GERD, patients must undergo upper digestive endoscopy; in the absence of esophagitis, ambulatory pH monitoring should also be performed<sup>[4]</sup>. A lack of correspondence between symptoms and reflux episodes, together with normal acid exposure in the distal esophagus, would suggest a diagnosis of FH. Such a diagnosis could be further substantiated by the outcome of a therapeutic trial with a proton pump inhibitor (PPI); although it is not specific, an unsatisfactory response to acid inhibition is likely to have a negative predictive value in support of GERD<sup>[8]</sup>.

A recent study suggested that, to be diagnosed with FH, patients should have a normal upper endoscopy, a normal AET in the distal esophagus and a negative symptom association with both acid and non-acid reflux<sup>[5]</sup>.

The evaluation of the latter condition is possible only with MII-pH monitoring, which is able to recognize both acid and non-acid reflux. However, it must be considered that, to date, the exact role of non-acid reflux in the pathophysiology of symptoms in untreated GERD patients has been minimally evaluated. Therefore, the findings reported by Savarino *et al.*<sup>[5]</sup> should be viewed as preliminary in nature and should be substantiated by further studies before undergoing a critical assessment by consensus committees.

### IBS

According to the Rome III criteria, IBS is a functional bowel disorder in which recurrent abdominal pain or discomfort is associated with defecation and/or changes in bowel habits. In particular, abdominal pain or discomfort is associated with two or more of the following characteristics: improvement with defecation and onset associated with a change in the frequency and/or form of stool. The predominant stool pattern allows the classification of IBS into four clinical variants: with constipation; with diarrhea; mixed; and unsubtyped<sup>[9]</sup>.

## GERD/FH AND IBS OVERLAP

To date, several studies have reported a certain degree of overlap between GERD and IBS that cannot be explained solely by chance<sup>[10-13]</sup>. By contrast, epidemiological data regarding the possible concomitance of FH and IBS in the same patient are lacking.

In the last two decades, the assessment of the epidemiological and clinical features of IBS has gained considerable attention. At present, the overall prevalence of IBS ranges from 10% to 20% of adults and adolescents, and it predominantly affects young (20-45 years old) females<sup>[14,15]</sup>. Population-based studies suggest that GERD, defined by at least weekly heartburn and/or regurgitation, is a common condition, with a prevalence of 10%-20% in Western populations<sup>[16]</sup>. Several studies have shown that up to 70% of patients complaining of heartburn have NERD; 30%-50% of NERD patients display nor-

mal 24-h esophageal pH monitoring<sup>[17]</sup>, and approximately 60% of these patients show a negative relationship between symptoms and acid reflux events<sup>[4]</sup>. More recent studies conducted with MII-pH in NERD patients suggest an FH prevalence ranging from 19% to 26%<sup>[5]</sup>. Very little is currently known about gender prevalence among patients with FH, although the condition seems to be more common in women<sup>[18]</sup>.

The identification of a clinical overlap between FH and IBS is complicated by the fact that most studies have usually evaluated the concomitance of IBS and heartburn, irrespective of whether the latter was related to GERD or FH. In particular, most data have been collected *via* epidemiological studies conducted using validated questionnaires and endoscopy, without any pathophysiological attempt to discriminate GERD patients from FH patients. In this context, we were interested in performing an in-depth analysis of the overlap between GERD/FH and IBS by conducting a search of the available literature.

### Literature search

We identified the published studies to include in our review *via* an electronic search of three bibliographical databases: PubMed (1966-2011), EMBASE (1980-2011) and the Cochrane Library (2000-2011). Only studies that were designed as randomized-controlled, cross-sectional and case-control were included in our analysis. The search was performed by two investigators using the string “(reflux OR heartburn OR GERD OR GORD OR gastroesophageal reflux OR PPI OR 24-h pH) AND (IBS)”. A restriction was placed to collect articles in English only. The initial search yielded 371 titles of studies that were published as either full text papers or abstracts of scientific meetings, and all of the studies were screened by all authors to determine their eligibility. Based on our inclusion criteria, we selected 45 studies, which were used for an in-depth analysis of the prevalence of GERD/FH in patients with IBS and vice versa. In addition, the criteria and diagnostic procedures used to assess the presence of heartburn and IBS were recorded.

### Prevalence of GERD/FH in patients with IBS

Twenty-three studies evaluated the prevalence of GERD/FH in subjects with a previous diagnosis of IBS<sup>[10,12,19-39]</sup>. The details are shown in Table 1. The overall mean prevalence of GERD was 37.5%, although there was remarkable variability, with values ranging from 11% to 79%. Five studies assessed IBS according to the Manning criteria, 4 studies according to the Rome I criteria, 8 studies according to the Rome II criteria, and 6 studies according to the Rome III criteria. In 18 studies, IBS was diagnosed *via* a symptom questionnaire; in 4 studies, organic diseases were excluded with imaging techniques and laboratory tests; in 1 study, only laboratory tests were performed. In comparison, GERD was diagnosed *via* a symptom questionnaire in 18 studies and a symptom questionnaire combined with upper endoscopy in 3 studies. In 2 studies, pathophysiological evaluations

*via* esophageal manometry and pH-metry/MII-pH were performed in addition to the symptom questionnaire and upper endoscopy<sup>[20,39]</sup>. Overall, in patients with IBS, NERD was slightly more prevalent (42%) than erosive reflux disease (ERD, 38%). One study conducted in accordance with Rome III criteria estimated an FH prevalence of 59% among patients with IBS<sup>[39]</sup>.

### Prevalence of IBS in patients with GERD/FH

Thirty-two articles investigated the prevalence of IBS in subjects with a previous diagnosis of GERD/FH<sup>[10,12,23,25,26,31,32,35,36,38-60]</sup>. The details are shown in Table 2. In GERD patients, the overall mean prevalence of IBS was 36%, although there was considerable variability, as shown by values ranging from 8% to 71%. In 3 studies, IBS was diagnosed according to the Manning criteria (mean prevalence: 34.4%); in 8 studies, it was diagnosed according to the Rome I criteria (mean prevalence: 41.4%); in 10 studies, it was diagnosed according to the Rome II criteria (mean prevalence: 38.1%); in 8 studies, it was diagnosed according to the Rome III criteria (mean prevalence: 31.9%); in 3 studies according to the ReQuest criteria (mean prevalence: 37.3%). In all studies, IBS was diagnosed *via* a symptom questionnaire. However, in one study, hematological and stool examinations were also performed to exclude organic diseases<sup>[26]</sup>. In comparison, GERD was diagnosed *via* a symptom questionnaire in 18 studies and *via* a symptom questionnaire combined with upper endoscopy in 7 studies. In 7 studies, esophageal pathophysiological studies (*i.e.*, manometry and pH-metry) were performed in addition to the symptom questionnaire and upper endoscopy. Overall, IBS was more prevalent in patients with NERD (41%) than in those with ERD (23.9%). Two studies, which evaluated FH in accordance with the Rome III criteria, estimated prevalences of 39%<sup>[56]</sup> and 61.4% for IBS<sup>[39]</sup>. In the first study, heartburn was investigated *via* pH-metry, while the latter used MII-pH testing.

### Discussion

Large population-based studies have used validated questionnaires to investigate a possible association between GERD and IBS and have suggested that GERD can affect a considerable proportion of patients with IBS<sup>[22,27,28]</sup> or vice versa<sup>[43,49]</sup>. However, few studies specifically address the issue of overlap between FH and IBS, mainly because the definition of FH has varied substantially throughout the years. Indeed, the definition of FH has been greatly modified from the Rome II criteria (in which the definition of FH included all NERD patients with negative pH-metry) to the Rome III criteria (in which FH is defined as a functional esophageal disorder unrelated to GERD and characterized by negative pH-metry, the lack of a relationship between symptoms and reflux events, and the lack of symptom improvement after a trial of PPI therapy).

Notably, most of the available data on the association between IBS and GERD were collected in the context

GERD: Gastroesophageal reflux disease; FH: Functional heartburn; IBS: Irritable bowel syndrome; S: Symptoms; SQ: Symptom questionnaire; PE: Physical examination; HE: Hematological examinations; BE: Barium enema; BC: Bacteriological culture; SC: Stool culture; BT: Lactose/lactulose breath test; AU: Abdominal ultrasonography; UE: Upper endoscopy; LE: Lower endoscopy; SBB: Small-bowel biopsies; Sg: Sigmoidoscopy; OM: Esophageal manometry; pH: pH-metry; MII-pH: pH impedance monitoring; ERD: Erosive reflux disease; NERD: Nonerosive reflux disease.

of epidemiological studies, which were conducted on patients with heartburn using validated questionnaires and upper endoscopy without the use of any reliable pathophysiological investigation to discriminate FH (according to the Rome III criteria) from GERD.

As mentioned above, only two studies have evaluated the concomitance of FH and IBS. Lee *et al*<sup>[56]</sup> examined 95 patients with heartburn by endoscopy, pH-metry, PPI test, and psychological characteristics. The patients were classified using the Rome III criteria; therefore, FH was diagnosed based on physiological AET, a negative association between symptoms and reflux, and a negative PPI test in patients without erosive esophagitis. A higher prevalence of IBS was recorded in FH patients (39%) than in ERD (17%) or NERD (23%) patients. Furthermore, anxiety was more prevalent in FH patients than in NERD patients. Recently, we examined 92 patients with heartburn (without esophageal mucosal breaks found upon upper endoscopy) *via* pH-MII to assess, in accordance with Rome III criteria, the prevalence of NERD

subgroups and FH in two groups of patients: those with and those without IBS. For each subject, we evaluated the AET, number of reflux episodes, correlation between symptoms and refluxes, and subjective response to PPI therapy. FH was found in 59% (27/46) of the patients with IBS, compared with 37% (17/46) of the patients without IBS ( $P < 0.05$ ), indicating a higher prevalence of FH in IBS patients. In comparison, IBS was found in 39.6% (19/48) of the patients with NERD and in 61.4% (27/44) of the patients with FH, suggesting that in IBS patients, FH was more common than NERD was<sup>[39]</sup>. Although data from these two pioneering studies are not sufficient to support the concept that FH and IBS can occur in the same patient, they underscore the need for future investigations based on updated diagnostic criteria.

## PATHOPHYSIOLOGICAL SIMILARITIES IN GERD, FH AND IBS

Previous studies dealing with the overlap between GERD

and IBS have proposed that visceral hypersensitivity, motility dysfunctions, and central neural mechanisms can be the main common pathophysiological mechanisms<sup>[11,13,61]</sup>. However, following the release of Rome III criteria, an increasing number of studies have indicated the importance of a careful categorization of GERD patients *via* pathophysiological investigations to better appreciate the degrees of overlap between IBS and reflux symptoms in various subgroups of patients<sup>[39,56,62,63]</sup>. Accordingly, this section intends to appraise and critically discuss the available evidence supporting a pathophysiological relationship among GERD, FH and IBS. When attempting such a difficult task, two important points must be care-

fully considered: (1) In previous studies, GERD and IBS patients have been investigated to determine their pathophysiological and clinical features, while FH patients constitute a “new entity” for which pathophysiological studies are urgently required; and (2) Most of the available literature on the pathophysiology of FH addresses patients who were identified using old criteria (*i.e.*, criteria that have since been replaced by the Rome III classification) that also identified NERD patients with normal esophageal AET. Even when these issues are kept in mind, IBS and FH, as well as IBS and GERD, appear to share some pathophysiological features that need to be carefully considered.

### Visceral hypersensitivity

Most FDD patients display a reduced pain or discomfort threshold in response to visceral stimulation, implying that they might perceive a stimulus as uncomfortable or painful at significantly lower intensity than normal subjects would<sup>[64]</sup>. Such increased sensitivity can be usually documented throughout the whole gastrointestinal tract, suggesting diffuse, rather than site-dependent, involvement<sup>[65]</sup>.

Studies aimed at gaining pathophysiological insights irrespective of the dominant digestive disorder have extensively investigated visceral hypersensitivity to a variety of stimuli (*e.g.*, acid perfusion, balloon distension, electrical stimulation) within both IBS<sup>[66]</sup> and GERD<sup>[63]</sup>. In particular, current data suggest that NERD patients displays equivalent or increased degrees of visceral hypersensitivity as compared with ERD, but may have lower levels than those shown by patients with functional esophageal disorders (*i.e.*, FH/chest pain of presumed esophageal origin). According to recent advances in basic science, three main mechanisms are believed to underlie visceral hypersensitivity (*i.e.*, peripheral sensitization, central sensitization and psychoneuroimmune interactions), and all of these have been documented in NERD patients<sup>[63]</sup>. Nevertheless, these factors' respective roles and degrees of involvement in the pathophysiology of FH remain to be established, particularly in the light of the Rome III criteria. To verify whether FH patients have visceral hypersensitivity and to assess whether this feature is a common trait in IBS patients, some studies have investigated the presence of esophageal sensitivity to chemical or mechanical stimuli in FH and/or IBS patients.

Rodriguez-Stanley *et al.*<sup>[67]</sup> reported that 89% of patients with FH (Rome II) experienced abnormal responses to intraesophageal acid perfusion (Bernstein test), esophageal balloon distension, or both. In repeated studies using either esophageal balloon distension or electrical stimulation, patients with FH (Rome II) have consistently demonstrated a lower perception threshold for pain or discomfort compared with patients with erosive esophagitis and/or abnormal 24-h esophageal pH monitoring<sup>[68,69]</sup>. Recently, Thoua *et al.*<sup>[62]</sup> observed that patients with NERD had higher sensitivity to esophageal acid exposure than did ERD patients and controls, and this hypersensitivity was most pronounced with proximal esophageal acid exposure. Moreover, FH patients (Rome III) were more hypersensitive to excess acid exposure than NERD patients were. Of note, these authors carefully selected patients with unequivocal reflux, taking care to exclude those with minor mucosal breaks, and the condition of hypersensitivity was found to be independent from motility changes<sup>[62]</sup>. Yang *et al.*<sup>[70]</sup> found that cortical evoked potentials latencies induced by balloon distension were shorter in FH patients (Rome II) than in controls before acid perfusion, and such perfusion decreased the latencies and increased their amplitude in FH patients, but not in controls. These findings suggest that dysfunctions of visceral neural pathways and/or alterations in cortical processing might generate and mediate esophageal hypersensitivity in FH.

Consistent with the notion that visceral hypersensitivity is not site-specific, Costantini *et al.*<sup>[71]</sup> reported that during esophageal provocative testing (balloon distension and bethanechol administration), IBS patients displayed a lower threshold for esophageal symptoms compared with healthy volunteers, without any evident alteration of esophageal motility or decrease in esophageal basal pressure. In line with these observations, Trimble *et al.*<sup>[72]</sup> demonstrated that IBS patients had a lower rectal sensory threshold for pain compared with healthy controls and that IBS patients displayed concomitantly lower sensory thresholds for both esophageal perception and discomfort evoked by balloon distension.

Whether the types of sensory dysfunctions previously detected in FH patients (Rome II)<sup>[68]</sup> can also be observed in FH patients diagnosed in accordance with Rome III criteria remains to be established. When investigating this issue, it must be considered that at present, there is not a unanimous consensus on how to define and measure the condition of lowered visceral threshold. A further critical issue is that visceral thresholds for different stimuli do not necessarily display parallel alterations. In this context, some relevant questions still await conclusive answers: (1) Which is the most meaningful index of an altered sensory threshold? (2) Can different stimuli be regarded as equivalent in nature? and (3) Considering day-to-day variations in the occurrence of symptoms, is there also a day-to-day variation in the underlying biological abnormalities responsible for these symptoms? Overall, great caution will be required in future studies addressing the pathophysiological meaning of visceral hypersensitivity in GERD/FH and/or IBS.

Whether the types of sensory dysfunctions previously detected in FH patients (Rome II)<sup>[68]</sup> can also be observed in FH patients diagnosed in accordance with Rome III criteria remains to be established. When investigating this issue, it must be considered that at present, there is not a unanimous consensus on how to define and measure the condition of lowered visceral threshold. A further critical issue is that visceral thresholds for different stimuli do not necessarily display parallel alterations. In this context, some relevant questions still await conclusive answers: (1) Which is the most meaningful index of an altered sensory threshold? (2) Can different stimuli be regarded as equivalent in nature? and (3) Considering day-to-day variations in the occurrence of symptoms, is there also a day-to-day variation in the underlying biological abnormalities responsible for these symptoms? Overall, great caution will be required in future studies addressing the pathophysiological meaning of visceral hypersensitivity in GERD/FH and/or IBS.

### Motility dysfunction

Motor abnormalities might represent a common pathophysiological mechanism between GERD and IBS<sup>[61]</sup>. Consistent with this concept, some authors speculate that an overall dysfunction of smooth muscle throughout the GI tract might explain the overlap between IBS and GERD<sup>[22]</sup>.

Of note, the pattern of esophageal motility has been shown to differ between ERD and NERD patients<sup>[73]</sup>, while no significant differences have been found in LES pressure or contraction amplitude when comparing FH patients (Rome III) to NERD patients with pathological AET<sup>[62]</sup>. In unclassified subjects complaining of heartburn, Bhalla *et al.*<sup>[74]</sup> observed that acid infusion elicited an increase in symptom sensitivity in concomitance with a perturbation of esophageal contractility, as revealed by a greater increase in contraction amplitude, contraction duration, muscle thickness, and the incidence of sustained esophageal contractions during the second acid infusion in comparison with the first one.

To date, the possible contribution of motility dysfunction to the pathophysiology of FH remains unclear; however, while studying 12 unclassified subjects with heartburn using 24-h pH-metry, synchronized pressure

recording and high-frequency intraluminal ultrasound imaging of the oesophagus, Pehlivanov *et al.*<sup>[75]</sup> highlighted a close correlation between heartburn episodes (whether associated with acid reflux or not) and abnormally long longitudinal muscle contraction durations. This motor correlate might also be relevant to a better understanding of the pathophysiological bases of heartburn perception in FH patients, but it has been documented only by a preliminary investigation and requires additional studies to be confirmed. Likewise, whether esophageal and bowel motor abnormalities occur concomitantly in patients with overlapping GERD/FH and IBS is currently unclear, and studies addressing this issue are required.

### Central neural mechanisms

In FH patients, heartburn has been proposed to originate from factors other than luminal stimuli<sup>[68]</sup>. It has been speculated that central neural mechanisms related to psychological comorbidity (anxiety, depression and stress) could modulate esophageal perception and make patients prone to perceiving low-intensity esophageal stimuli as painful<sup>[69]</sup>. In particular, anxiety has been implicated as a factor that may modulate the degree of sensitization to esophageal acid testing<sup>[76]</sup>.

Johnston *et al.*<sup>[77]</sup> studied 101 patients with heartburn using esophageal pH monitoring. The subjects who showed no correlation between symptoms and refluxes displayed significantly higher levels of trait anxiety compared with patients with a positive correlation. Along the same line, Rubenstein *et al.*<sup>[78]</sup> observed that in subjects with heartburn, esophageal sensation to both acid perfusion and mechanical distension was associated with increased levels of psychiatric distress and a diagnosis of IBS.

According to Posserud *et al.*<sup>[79]</sup>, no clear relationship between pain threshold and IBS symptoms (severe pain, bloating and diarrhea) has been convincingly established, and other mechanisms, including central nervous ones, are likely to play a relevant role. In line with this contention, Elsenbruch *et al.*<sup>[80]</sup> observed that IBS patients can indeed experience a higher severity of distension-induced pain and overall discomfort despite unaltered rectal sensory thresholds, suggesting that the perception of visceral stimuli could be influenced by emotional factors. In contrast, it remains unclear what psychological factors are relevant for visceral hyperalgesia in IBS patients and how they may interact with biological mechanisms, such as peripheral/central neuroendocrine and immune processes<sup>[66]</sup>.

Another aspect that deserves attention addresses the possible impact of sleep disorders on the pathophysiology of FDD symptoms. Jung *et al.*<sup>[10]</sup> observed that self-reported insomnia and frequent abdominal pain represent two risk factors for IBS-GERD overlap compared with IBS or GERD alone. In addition, a positive association has been found between the severity of IBS symptoms and the severity of sleep disturbances. However, the pathophysiological mechanisms underlying this association are only partly understood. One possibility

is that sleep disorders induce visceral hyperalgesia, thus amplifying the patient's perception of gastrointestinal symptoms<sup>[81,82]</sup>.

### Response patterns to drugs that modulate visceral pain

Pathophysiological similarities among GERD, FH and IBS might reflect similarities in their response patterns to the drugs that influence common pathophysiological mechanisms. According to the Rome III criteria, FH patients' symptoms do not improve with PPI therapy. Consistent with this criterion, even before Rome III, some authors reported that adding or switching PPIs to a visceral pain modulator [(*i.e.*, tricyclic antidepressants (TCAs) or selective serotonin reuptake inhibitors (SSRIs)] might induce beneficial effects in FH patients (Rome II)<sup>[83]</sup>. Peghini *et al.*<sup>[84]</sup> were the first to report that imipramine can reduce esophageal pain perception in healthy male volunteers. Clouse *et al.*<sup>[85]</sup> investigated the effects of low-dose trazodone in patients with symptomatic esophageal dysmotility and obtained a significantly greater global symptom improvement compared with placebo. Broekaert *et al.*<sup>[86]</sup> observed that citalopram lowered chemical and mechanical esophageal sensitivity in healthy subjects without altering motility. Likewise, in a randomized placebo-controlled study, citalopram 20 mg/d was found to be effective in a selected group of patients with hypersensitive esophagus (*i.e.*, normal AET, positive SI)<sup>[87]</sup>. Overall, the current evidence, although preliminary in nature, suggests that SSRIs may exert beneficial effects in lowering esophageal sensitivity to chemical and mechanical stimuli. These observations encourage the performance of studies aimed at assessing the efficacy of SSRIs in patients with esophageal hypersensitivity. In this regard, it is interesting to note that antidepressants (*e.g.*, TCAs and SSRIs) have been found more effective than placebo in IBS treatment, as indicated by a recent review and meta-analysis of randomized controlled trials<sup>[88]</sup>. Thus, based on current knowledge, it can be tentatively speculated that visceral hypersensitivity might be a common trait among patients with esophageal hypersensitivity and/or IBS and that such an underlying pathophysiological condition might explain the beneficial responses to antidepressants in both these disorders. Overall, a critical appraisal of current evidence highlights the need for future clinical studies aimed at assessing the possible transverse beneficial actions of drugs in patients with concomitant ERD, NERD or FH and IBS. To date, it can be hypothesized that antidepressants have a beneficial role as visceral pain modulators.

## CONCLUSION

In the present review, we have attempted to appraise and critically discuss whether the current literature supports an association between GERD and IBS and between FH and IBS. Our literature search highlights a high heterogeneity in terms of both the criteria and diagnostic procedures used to investigate the presence of heartburn

and IBS. In particular, most of the current epidemiological data do not rely on a formal diagnostic assessment of IBS and/or GERD; rather, the studies generally evaluated these disorders *via* symptom questionnaires. Another critical issue is the inclusion of patients with concomitant IBS and GERD without any attempt to distinguish FH from GERD using pathophysiological investigations. Indeed, a very few small studies have documented an actual concomitance of FH and IBS. The main reason for this paucity of data stems from the fact that, until the release of the Rome III criteria, FH was not regarded as a distinct entity and was included in the same category as GERD. Moreover, most of current pathophysiological data refer to FH patients as defined by criteria older than the Rome III classification. Accordingly, clear evidence of an association between IBS and FH, as defined by the Rome III criteria, is presently lacking.

Independent of these critical issues, there is some evidence, though scarce and preliminary, of the concomitance of FH and IBS. In support of this contention, some studies have shown that FH and IBS may share common pathophysiological mechanisms, such as visceral hypersensitivity, and that drugs that act as visceral pain modulators (such as antidepressants) may exert beneficial effects on both disorders when tested in separate trials.

Overall, current knowledge about the GERD/FH and IBS overlap needs to be expanded *via* investigations based on updated diagnostic criteria, more accurate pathophysiological classifications, and careful categorization of patients with heartburn. To achieve these goals, future epidemiological and pathophysiological studies should be designed to properly assess the presence and extent of overlaps linking IBS with FH and various subgroups of GERD patients. In this context, it is also expected that a better pathophysiological characterization of heartburn will foster the identification of therapeutic strategies that target the common pathogenic mechanisms underlying FH and IBS.

### Abstract

Recent diagnostic and therapeutic progress for severe acute pancreatitis (SAP) remarkably decreased the case-mortality rate. To further decrease the mortality rate of SAP, it is important to precisely evaluate the severity at an early stage, and initiate appropriate treatment as early as possible. Research Committee of Intractable Diseases of the Pancreas in Japan developed simpler criteria combining routinely available data with clinical signs. Severity can be evaluated by laboratory examinations or by clinical signs, reducing the defect values of the severity factors. Moreover, the severity criteria considered laboratory/clinical severity scores and contrast-enhanced computed tomography (CE-CT) findings as independent risk factors. Thus, CE-CT scans are not necessarily required to evaluate the severity of acute pancreatitis. There was no fatal case in mild AP diagnosed by the CE-CT severity score, whereas case-mortality rate in those with SAP was 14.8%. Case-mortality of SAP that fulfilled both the laboratory/clinical and the CE-CT severity criteria was 30.8%. It is recommended, therefore, to perform CE-CT examination to clarify the prognosis in those patients who were diagnosed as SAP by laboratory/clinical severity criteria. Because the mortality rate of these patients with SAP is high, such patients should be transferred to advanced medical units.

## INTRODUCTION

Acute pancreatitis (AP) involves various clinical features from mild cases with only transient abdominal symptoms to severe fatal cases. It is important to identify patients with AP who are at risk for developing persistent organ failure early in the course of the disease<sup>[1]</sup>. Because case-mortality rate of severe AP (SAP) at the survey conducted by the Research Committee of Intractable Diseases of the Pancreas (RCIDP) supported by the Japanese Ministry of Health, Labour and Welfare was as high as 30%<sup>[2]</sup>, SAP has been designated as an intractable disease by the Japanese Ministry of Health and Welfare since 1990, and the cost of treatment for SAP is paid in full by the government<sup>[3]</sup>. With the start of the medical expense payment system for patients with SAP, the RCIDP established the criteria for the diagnosis and severity stratification of AP. The severity scoring system was revised and the 2002 version was developed in 2002 (JPN criteria 2002)<sup>[1,4-6]</sup>.

The criteria 2002 were complicated and composed of 18 items of prognostic factors; 5 clinical sign items, 10 blood test items, computed tomography (CT) findings, the presence of systemic inflammatory response syndrome (SIRS) and age<sup>[1,4-6]</sup>. The attending physician cannot remember all or even most of the factors. Moreover, these numerous parameters are not available soon enough or not available as the routine laboratory tests at all hospitals. There is a possibility, therefore, that incomplete examinations or defect values of the prognostic factors underestimated the severity of AP, resulting in insufficient and inadequate treatment of the disease, and aggravated AP<sup>[1]</sup>. There is another possibility that incomplete severity evaluation of AP overlooked the predicted serious cases to transfer to medical institutions with the high-level medical facilities and intensive care.

To decrease the mortality rate of the SAP, it is important to precisely evaluate the severity early in the disease and initiate appropriate treatment as early as possible<sup>[7-9]</sup>. The Ranson<sup>[10]</sup> and the modified Glasgow (Imrie) scores<sup>[11]</sup> represent a major advantage in the evaluation of

the disease severity in AP but require 48 h of data collection before the severity can be evaluated. Thereafter, several clinical scoring systems such as acute physiology and chronic health evaluation (APACHE II) score systems<sup>[12-15]</sup>, SIRS<sup>[16]</sup>, bedside index for severity in acute pancreatitis (BISAP)<sup>[17]</sup> and harmless acute pancreatitis score (HAPS)<sup>[18,19]</sup> for evaluating AP have been developed, but these methods to predict the development of SAP are complicated, cumbersome, and insufficiently sensitive<sup>[20]</sup>. Recently a web-based consultative process involving multiple international pancreatic societies revised and updated the Atlanta classification of AP<sup>[21-23]</sup>. Severity of the disease is classified as mild, moderate, and severe by the absence or presence of organ failure and local or systemic complications. Moderately SAP has transient organ failure of < 2 d, while SAP is defined by the presence of persistent organ failure for  $\geq$  2 d. Although the revised Atlanta classification of AP is simple and will help the clinician to predict the outcome of patients with AP, it is unable to differentiate between moderately SAP and SAP before 48 h after onset. It is expected, therefore, to develop simpler severity scoring system with routinely available data that predicts outcome, the system that clinicians can use at the bedside.

## PROBLEM OF THE PREVIOUS JPN CRITERIA FOR THE DIAGNOSIS AND STRATIFICATION OF THE SEVERITY

JPN clinical criteria for the diagnosis of AP proposed in 2002 are (1) acute abdominal pain and tenderness in the upper abdomen; (2) elevated pancreatic enzyme levels in serum, urine or ascitic fluid; and (3) ultrasonographic (US) or radiologic abnormalities characteristic of AP<sup>[1,4-6]</sup>. When at least two of the above conditions are present, then excluding other pancreatic and acute abdominal diseases of different causes can make the diagnosis of AP. Acute exacerbation of chronic pancreatitis is also included in this category. When diagnosis is confirmed by surgery and/or autopsy, the event has to be duly recorded<sup>[1,4-6]</sup>.

The JPN severity criteria 2002 consisted of 5 clinical sign items (shock, respiratory failure, mental disturbance, severe infection, hemorrhagic diathesis), 10 blood test items [base excess (BE), hematocrit (Ht), blood urea nitrogen (BUN) or creatinine, calcium concentration (Ca), fasting blood glucose, arterial oxygen saturation (PaO<sub>2</sub>), lactate dehydrogenase (LDH), total protein, prothrombin time (PT), and platelet count], and CT findings. In cases with severity scores  $\geq$  2 points, SIRS and an age over 70 had to be added to the prognostic factors<sup>[1,4-6]</sup>. These items of prognostic factors were all scored as severity scores, 1 or 2 points for each positive factor, and the highest possible total score was 27 points. However, blood glucose level, serum total protein concentrations and Ht are inappropriate for the prognostic factors after the initiation of the treatment of the disease because initial fluid resuscitation might have an influence on the

measurement value of these laboratory data. In addition, the severity criteria had redundant prognostic factors indicating similar clinical condition such as shock and the decrease in BE, and dyspnea and fall of PaO<sub>2</sub>. Bleeding tendency, platelet counts and PT also indicate similar clinical condition. Moreover, the clinical signs such as severe infection that rarely develops within 48 h after disease onset were implicated in the severity criteria. The severity criteria included CT grade by the non-enhanced plain CT scan as one of the prognostic factors. Plain CT scans can evaluate peripancreatic inflammatory changes, but are unable to identify pancreatic necrosis that is closely associated with various complications and prognosis<sup>[21,24-26]</sup>.

Usefulness of the JPN criteria 2002 for severity stratification was evaluated in 1131 consecutive patients with AP that had been admitted to high specific or intensive therapy units of the affiliated research group hospitals from January 1 1995 to December 31 1998 (survey 1998; before the establishment of the JPN criteria 2002), and in 1768 patients who visited the hospitals in the year 2003 (survey 2003; from January 1 to December 31; after the establishment of the criteria in 2002)<sup>[1,4-6]</sup>. The results revealed that the severity score have almost the same value for assessment as the APACHE II score and the Ranson score<sup>[4]</sup>.

In survey 1998, case-fatality rate of mild, moderate and SAP was 0.2%, 1.6% and 13.8%, respectively, whereas it was 0.1%, 0.7% and 9.0%, respectively, in survey 2003<sup>[1,4-6]</sup>. The case-mortality rate of mild and moderate AP was quite low, and there was little clinical significance to differentiate moderate from mild AP. The case-mortality rate of SAP at stage 2 (3.7%) was low compared with that at stage 3 (25.4%) in survey 2003<sup>[1,4-6]</sup>. Therefore, it was inappropriate to classify these patients at stage 2 as SAP and identify as applicants for the medical expense payment system<sup>[5]</sup>.

Although the previous severity criteria classified prognostic factors into 2 groups; each of the items in the first group has 2 points, while that in the second group is 1<sup>[1,4-6]</sup>, there is no significant difference in case mortality between these 2 groups with different prognostic scores. JPN severity criteria 2002 were complicated and included several prognostic factors which cannot be measured at outpatient clinic or emergency room, especially at night. In addition, multiple scoring systems of the severity criteria were very cumbersome to use and they suffer from their complexity<sup>[1,4-6]</sup>. Indeed, 56% of 1768 clinical records of AP in survey 2003 had defect values of more than 3 items of 11 laboratory examinations. Especially, BE was measured in only 25.1%, and PT and PaO<sub>2</sub> were measured in only 38.3% and 38.7%, respectively<sup>[1]</sup>. These results indicate that even if we can diagnose the patient as AP, in the presence of many defect values a correct stage classification is difficult, and it is very likely that we underestimate the severity.

Because CT grade was included as one of the prognostic factors<sup>[1,4-6]</sup>, it was required to perform CT examination repeatedly to precisely evaluate the severity and

stage of AP. However, it is unacceptable to perform CT examination repeatedly<sup>[27]</sup>, and thus one of the prognostic factors remains as a defect value. In addition, there are many hospitals that cannot perform CT examination and laboratory tests such as PT, especially at night. This might be one of the reasons for many defect values in the clinical records of AP<sup>[1]</sup>.

## NEW DIAGNOSTIC CRITERIA OF AP

JPN diagnostic criteria of AP are revised taking into account of the recent progress of imaging studies and laboratory examinations of pancreatic enzymes. The revised clinical criteria for the diagnosis of AP are (1) acute pain and tenderness in the upper abdomen; (2) elevated pancreatic enzyme levels in blood and/or urine; and (3) ultrasound (US), CT or magnetic resonance imaging (MRI) abnormalities of the pancreas characteristic of AP<sup>[1]</sup>. When at least two of the above conditions are present, the diagnosis of AP can be made by excluding other pancreatic and acute abdominal diseases of other causes than pancreatitis. Acute exacerbation of chronic pancreatitis is included in this category.

Measurement of pancreatic enzyme levels in serum has been generally adopted in clinical practice, whereas those in ascitic fluid and urine are rarely determined. Since, however, recent studies have demonstrated that urinary strip tests for trypsinogen activation peptide (TAP) and trypsinogen-2 provide a reliable early diagnosis of AP<sup>[28-35]</sup>, the revised diagnostic criteria included the elevation of the pancreatic enzymes in serum and/or urine, excluding that in ascitic fluid. It is well known, however, that some patients with AP, mostly alcoholic etiology, show normoamylasemia<sup>[28]</sup>, and that serum amylase level rises only slightly in many patients with acute exacerbations of chronic alcoholic pancreatitis<sup>[36]</sup>. Moreover, serum amylase level seldom rises in AP caused by hyperlipidemia<sup>[37,38]</sup> and in those with pancreatic insufficiency<sup>[39]</sup>. In addition, the elevation of serum amylase level is only transient and declines within 3 d after onset of AP<sup>[28,40]</sup>. On the other hand, abnormally high values of serum lipase persist for longer period than that of serum amylase and are observed even in cases of alcohol-induced pancreatitis<sup>[41]</sup>. Although a recent case report of AP has demonstrated that serum amylase and lipase remain normal throughout the acute phase of AP in a man with pancreatic insufficiency and cystic fibrosis<sup>[39]</sup>, serum lipase is considered to be a more reliable diagnostic marker of AP than serum amylase. Therefore, the revised diagnostic criteria recommend determining pancreatitis specific enzymes in serum and/or urine such as pancreatic-type amylase<sup>[42,43]</sup> and lipase<sup>[44]</sup>.

The new diagnostic criteria require the presence of clear findings indicating AP by imaging studies such as US, CT and MRI. US can visualize pancreatic enlargement, inflammatory changes around the pancreas, and abnormal findings associated with AP such as the presence of ascitic fluid and gallstones. US examination can

**Table 1 Laboratory/clinical criteria for grading the severity of acute pancreatitis**

No.	Laboratory/clinical criteria
1	Base excess $\leq$ -3 mEq/L or shock (systolic blood pressure $\leq$ 80 mmHg)
2	PaO <sub>2</sub> $\leq$ 60 mmHg (room air) or respiratory failure (artificial respiratory ventilation)
3	BUN $\geq$ 40 mg/dL or creatinine $\geq$ 2.0 mg/dL or oliguria (urinary volume $\leq$ 400 mL/d after hydration)
4	LDH: More than twice higher than the upper limit of normal ( $\geq$ 700 IU/L)
5	Serum total Ca $\leq$ 7.5 mg/dL
6	Platelet count $\leq$ $1 \times 10^5$ /mm <sup>3</sup>
7	CRP $\geq$ 15 mg/dL
8	Positive score of SIRS criteria $\geq$ 3
9	Age $\geq$ 70 yr

One point for each positive factor. Severe acute pancreatitis: total scores  $\geq$  3 points. BUN: Blood urea nitrogen; LDH: Lactate dehydrogenase; SIRS: Systemic inflammatory response syndrome; CRP: C-reactive protein.

be performed repeatedly at bedside. CT provides clear local images without being affected by the adipose tissue in the abdominal wall and abdominal cavity<sup>[14,45]</sup>. CT findings of an enlarged pancreas, inflammatory changes around the pancreas and fluid collections are useful marker for the diagnosis of AP. Thus, CT is the most important imaging procedures for the diagnosis of AP<sup>[46-48]</sup>. MRI scanning can also visualize the enlargement of the pancreas and the inflammatory changes around the pancreas<sup>[49,50]</sup>.

### SEVERITY CRITERIA OF AP BY MULTIPLE-SCORING SYSTEM

Following the correct diagnosis of AP, severity stratification should be performed promptly and repeatedly, in particular for the first 48 h after the onset of the disease<sup>[1]</sup>. Early recognition of severe disease and application of appropriate therapy require vigilance as decisions regarding management need to be made shortly after admission.

The revised severity score put the redundant factors that show similar clinical conditions together into one, and deleted the unclear clinical signs. Since the new severity criteria combined laboratory data with clinical signs, the severity of AP can be evaluated by one of these findings. BE can be substituted by shock (systolic blood pressure less than 80 mmHg), PaO<sub>2</sub> by respiratory failure (artificial respiratory ventilation), and BUN or creatinine by oliguria (urinary volume less than 400 mL/d after hydration). Thus, SAP can be properly diagnosed by reducing underestimation of severity by the defect values (Table 1).

Among several serum biochemical markers that have been developed for severity stratification of AP, C-reactive protein (CRP) remains the most useful<sup>[19,32,51-54]</sup>. Although its increase delays, peaking not earlier than 72 h after the onset of symptoms, it is accurate and widely available. According to United Kingdom guidelines for the man-

**Table 2 Contrast-enhanced computed tomography criteria for grading the severity of acute pancreatitis**

Contrast-enhanced computed tomography criteria	Scores
Extension of extrapancreatic inflammatory changes	
Anterior pararenal extraperitoneal space	0 point
Root of the mesocolon	1 point
Beyond inferior renal pole	2 points
Unenhanced area in the pancreatic parenchyma (Divide the pancreas into 3 areas for expediency, head, body and tail)	
Limited to one area or peripancreatic area	0 point
Extend over 2 areas	1 point
More than 2 areas	2 points

Severe acute pancreatitis: total computed tomography severity scores  $\geq$  2 points.

agement of AP<sup>[55]</sup> and the Working Party of the Program Committee of the Bangkok World Congress of Gastroenterology 2002<sup>[56]</sup>, CRP  $\geq$  15 mg/dL is adopted as a prognostic factor. Moreover, Gardner *et al.*<sup>[57]</sup> have demonstrated that an age above 70 years is an independent risk factor for mortality in patients admitted with SAP. Based on these previous studies, the new severity criteria included CRP and age of the patient. In spite of these changes, the new severity criteria that employ routinely available data are simple and easy to remember.

Since the contrast-enhanced CT (CE-CT) is the mainstay of imaging patients with AP and recommended for the evaluation of the severity of AP<sup>[20,24-27,34,35,49]</sup>, the revised severity criteria included the CE-CT findings of the presence and extent of pancreatic necrosis, and the extent of peripancreatic inflammatory changes (Table 2). The revised Atlanta classification provided precise definitions of CE-CT findings, including peripancreatic necrosis, walled-off-necrosis and pseudocyst<sup>[21,22]</sup>. Although the revised Atlanta classification suggested that pancreatic necrosis can rarely be identified accurately during the first several days of hospitalization, CE-CT findings help us to decide special measures such as continuous regional arterial infusion (CRAI) of protease inhibitors and antibiotics, and continuous hemodiafiltration (CHDF)<sup>[58-60]</sup>. Once it is thought that contrast medium exacerbates pancreatitis<sup>[61-63]</sup>, but denied by another studies<sup>[64,65]</sup>. Since, however, there is a possibility that intravenous contrast media extend pancreatic necrosis and exacerbate renal impairment<sup>[61-63]</sup>, vigorous intravenous hydration for the purpose of intravascular resuscitation is important during and after CE-CT examination. Attending physicians must aware of the possibility that the contrast medium aggravates renal dysfunction associated with SAP.

The new severity criteria considered laboratory/clinical symptoms and radiographic features of CE-CT scans as independent risk factors. Indeed, Leung *et al.*<sup>[14]</sup> have demonstrated that CT severity index is a useful tool in assessing the severity and outcome of AP, and superior to Ranson score<sup>[10]</sup> and APACHE II scoring system<sup>[12-15]</sup> in predicting AP outcome. Thus, the CE-CT is not necessarily required to evaluate the severity of the patients with AP. Preliminary study revealed that the case-fatality

**Table 3 Verification of the revised severity criteria**

Total severity score (points)	Revised severity criteria	Criteria 2002
0	66	77
1	51	31
2	18	15
3	11 (1)	9
4	4	7
5	4 (2)	6
6	2 (1)	3 (1)
7	0	2 (1)
8	0	0
9	0	1
10	0	2 (2)
11	0	2
12	0	1
Total	156 (4)	156 (4)

Results shown are number of patients. Number in parenthesis indicates patients died of acute pancreatitis. The same patients with acute pancreatitis were evaluated by the revised criteria and by the criteria 2002. Total severity score of the revised criteria  $\geq 3$  points, while that of the criteria 2002  $\geq 2$  points was diagnosed as severe acute pancreatitis.

**Table 5 Relationship between the laboratory/clinical and the contrast-enhanced computed tomography severity scores**

Total CE-CT severity score (points)	Total laboratory/clinical severity score (points)							Total
	0	1	2	3	4	5	6	
0	0	0	0	0	0	0	0	0
1	56	40	13	5	1	0	0	115
2	3	5	2	1	0	2 (1)	1 (1)	14 (2)
3	2	1	1	3 (1)	3	2 (1)	1	13 (2)
Total	61	46	16	9 (1)	4	4 (2)	2 (1)	142 (4)

Results shown are number of patients. Number of patients died of acute pancreatitis is indicated in parenthesis. In these 142 patients, laboratory/clinical and contrast-enhanced computed tomography (CE-CT) examinations were evaluated at the same time.

in patients with the CE-CT severity score 1 was 3.3%, while that in those with severity score 2 and 3 points was 21.9% and 33.3%, respectively. Thus, the severity scores of CE-CT  $\geq 2$  points was defined as SAP (Table 2).

Analysis of case records of 1337 consecutive patients with AP in survey 2003<sup>[1,5,6]</sup> in that more than 5 items of 9 prognostic factors of the new severity criteria were recorded revealed that case-fatality rate of patients with severity score point 0 and point 1 was nearly the same (0.2% *vs* 0.7%), whereas that of patients with severity score 2 and 3 points was greatly different (2.6% *vs* 11.1%). Thus, the new criteria divided the severity of AP into mild (severity score  $\leq 2$  points) and SAP (severity score  $\geq 3$  points). Based on this classification, case-mortality rate of mild AP and SAP was 0.83% (9/1183) and 19.5% (30/154), respectively.

## VERIFICATION OF THE NEW SEVERITY CRITERIA

Usefulness of the new severity criteria was prospectively

**Table 4 Relationship between the revised laboratory/clinical or contrast-enhanced computed tomography severity score and incidence of organ failure**

Total severity score (points)	Incidence of organ failure	
	Laboratory/clinical	CE-CT
0	1.5%	0.0%
1	7.8%	4.3%
2	5.5%	42.9%
3	36.4%	46.2%
4	50.0%	-
5	75.0%	-
6	100.0%	-

Total number of patients evaluated by laboratory/clinical examinations was 156, whereas contrast-enhanced computed tomography (CE-CT) severity score was evaluated in 142 of these 156 patients at the same time.

studied in 156 patients with AP. CE-CT severity score was evaluated in 142 of these 156 patients at the same time with laboratory examinations. Overall case-mortality of 156 patients with AP was 2.6%, and was similar to that reported in nationwide survey in 2003<sup>[1,5,6]</sup>. Although some survey sheets had defect data of laboratory examinations, most frequently BE (defect value 41.0%) and PaO<sub>2</sub> (defect value 41.0%), these data were substituted by clinical signs of shock (defect value 0%) and respiratory failure (defect value 0%), respectively. Therefore, the severity score could be precisely calculated even if these laboratory data were defect values.

The revised severity criteria (Table 1) identified 13.5% of these 156 patients with AP as SAP, whereas 30.8% were diagnosed as SAP if the criteria 2002 were adopted. Case-mortality of SAP diagnosed by the revised criteria was 19.1%, whereas that by the criteria 2002 was only 8.3% due to large number of patients who are diagnosed as SAP (Table 3). The validity of the revised classification was further revealed by the incidence of complications of organ failure. Complications of organ failure were far greater in patients with SAP than in those with mild AP (Table 4). These results clearly indicate that the patients with SAP diagnosed by the revised criteria are suitable as applicants for the medical expense payment system<sup>[3]</sup>.

Since the new severity criteria consider laboratory data/clinical symptoms, and the CE-CT severity score as independent risk factors, SAP can be diagnosed either by the laboratory/clinical severity criteria or by the CE-CT severity criteria. There was no fatal case of mild AP diagnosed by the laboratory/clinical severity score regardless of CT severity score. Similarly, there was no fatal case of mild AP diagnosed by the CE-CT severity score regardless of laboratory/clinical severity scores (Table 5). Case-mortality rate of patients with SAP diagnosed by the laboratory/clinical severity score was 21.1%, whereas that in those diagnosed by the CE-CT severity score was 14.8%. Case fatality of SAP that fulfilled both laboratory/clinical (severity score  $\geq 3$  points) and CE-CT severity criteria (severity score  $\geq 2$  points) was as high as 30.8%. It is recommended, therefore, to perform CE-CT examination to clarify the prognosis in patients who were diagnosed as SAP by laboratory/clinical severity score. Because the

mortality rate of these patients with SAP was high, such patients should be transferred to advanced medical units with physicians specializing in intensive care, endoscopic treatment, radiological intervention, and biliary-pancreatic surgery<sup>[1,5,6]</sup>.

## CONCLUSION

The new severity criteria consist of laboratory examinations combined with clinical symptoms and the CE-CT severity score. The laboratory and/or clinical symptoms and the CE-CT findings are independent risk factors. SAP can be diagnosed either by the severity score alone, or by the CE-CT findings alone. Mortality rate of SAP that fulfilled both laboratory/clinical and CE-CT severity criteria was high. It is recommended, therefore, to perform CE-CT examination in those patients who were diagnosed as SAP by laboratory/clinical severity criteria. Patients with SAP who fulfill both severity criteria should be transferred to advanced medical units. The revised criteria are extremely useful to detect SAP at an early stage of AP.

### Abstract

Achalasia is a neurodegenerative motility disorder of the oesophagus resulting in deranged oesophageal peristalsis and loss of lower oesophageal sphincter function. Historically, annual achalasia incidence rates were believed to be low, approximately 0.5-1.2 per 100000. More recent reports suggest that annual incidence rates have risen to 1.6 per 100000 in some populations. The aetiology of achalasia is still unclear but is likely to be multi-factorial. Suggested causes include environmental or viral exposures resulting in inflammation of the oesophageal myenteric plexus, which elicits an autoimmune response. Risk of achalasia may be elevated in a sub-group of genetically susceptible people. Improvement in the diagnosis of achalasia, through the introduction of high resolution manometry with pressure topography plotting, has resulted in the development of a novel classification system for achalasia. This classification system can evaluate patient prognosis and predict responsiveness to treatment. There is currently much debate over whether pneumatic dilatation is a superior method compared to the Heller's myotomy procedure in the treatment of achalasia. A recent com-

parative study found equal efficacy, suggesting that patient preference and local expertise should guide the choice. Although achalasia is a relatively rare condition, it carries a risk of complications, including aspiration pneumonia and oesophageal cancer. The risk of both squamous cell carcinoma and adenocarcinoma of the oesophagus is believed to be significantly increased in patients with achalasia, however the absolute excess risk is small. Therefore, it is currently unknown whether a surveillance programme in achalasia patients would be effective or cost-effective.

**Key words:** Epidemiology; Achalasia; Incidence; Treatment; Oesophageal cancer risk

**Core tip:** Achalasia remains a disease of unknown aetiology. Multicentre studies could help elucidate the cause, especially as it presents with a similar phenotype to Chagas disease which is much better understood. Improved understanding of aetiology could guide novel treatments. Current treat choice in fit patients lies between pneumatic dilatation and laparoscopic Heller's myotomy. Botulinum toxin is appropriate and effective for those unfit for other intervention. Novel treatments such as metal stents and natural orifice surgery are being trialled.

### INTRODUCTION

Achalasia is a motility disorder of the oesophagus, of unknown aetiology, which results in degeneration of the

myenteric nerve plexus of the oesophageal wall. The resultant abnormalities and diagnostic characteristics of achalasia include loss of oesophageal peristalsis and failure of relaxation of the lower oesophageal sphincter, particularly during swallowing<sup>[1]</sup>.

## DIAGNOSIS

Dysphagia is the cardinal symptom of achalasia. Diagnosis requires a high index of suspicion and exclusion of other causes. Diagnosis is confirmed by manometric, endoscopic and radiographic investigations. Oesophageal manometry is regarded as the gold standard in the diagnosis of achalasia, classically showing aperistalsis and failure of relaxation of the lower oesophageal sphincter<sup>[2]</sup>, as shown in Figure 1. Endoscopy is not accurate in the diagnosis of achalasia. However, it is still necessary to exclude a carcinoma at the lower end of the oesophagus<sup>[3]</sup>. Barium esophagogram can often show the pathognomonic “bird’s beak” appearance of the distal oesophagus with dilatation of the oesophagus proximally (Figure 2). However, this is often a finding in established disease and therefore a normal barium swallow does not rule out the diagnosis of achalasia. With the introduction of high resolution manometry, together with pressure topography, plotting the diagnosis of achalasia can now be classified into three subtypes; type 1 classic achalasia, type 2 achalasia with compression and pressurisation effects, and type 3 spastic achalasia<sup>[4]</sup>. This classification process can aid treatment decisions, with type 2 achalasia being the most responsive to pneumatic dilatation, Hellers myotomy and botulinum toxin and therefore having the best outcome<sup>[5]</sup>. Oesophageal emptying is determined by the distensibility of the oesophago-gastric junction. This can be assessed using an endoscopic functional luminal imaging probe (EndoFLIP). Recently, Dutch and American groups have demonstrated that this novel technique is a better predictor than lower oesophageal sphincter pressure for assessing response to treatment in achalasia, both symptomatically and when measured by gastric emptying by oesophageal emptying<sup>[6,7]</sup>.

## PATHOGENESIS

The pathogenesis of achalasia is not well understood but it is believed to be due to an inflammatory neurodegenerative insult with possible viral involvement. The measles and herpes viruses have been suggested as candidate viruses however molecular techniques have failed to confirm these claims and therefore the causative agent remains undiscovered<sup>[8]</sup>. Genetic and autoimmune components have also been suggested as origins of the neuronal damage however research to date has not found the exact cause<sup>[9]</sup>. Inflammatory changes within the oesophagus following the causative insult result in the loss of post-ganglionic inhibitory neurons in the myenteric plexus and a consequent reduction in the inhibitory transmitters, nitric oxide and vasoactive intestinal peptide. The excitatory

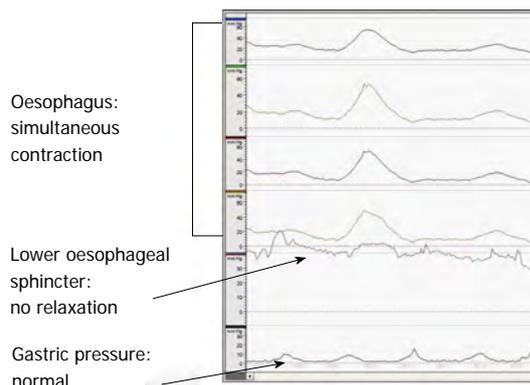

Figure 1 Oesophageal manometry demonstrating simultaneous contractions within the oesophagus and a non-relaxing lower oesophageal sphincter.

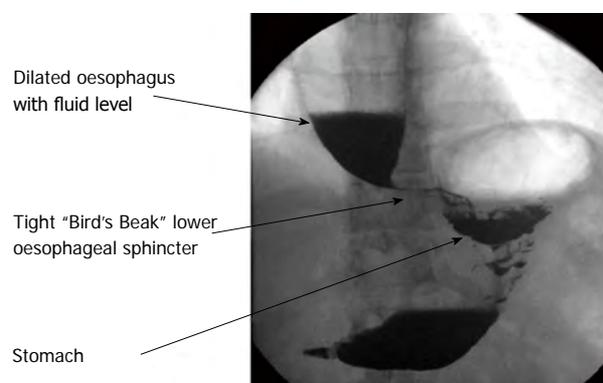

Figure 2 Barium swallow demonstrating typical “bird’s-beak” appearance of the lower oesophageal sphincter in achalasia. The oesophagus above this is dilated.

neurons remain unaffected, with the resulting imbalance between excitatory and inhibitory neurons preventing lower oesophageal sphincter relaxation<sup>[10]</sup>. Lack of peristalsis and a non-relaxing lower oesophageal sphincter cause progressive dysphagia. Regurgitation, particularly at night, with aspiration of undigested food and weight loss can be presenting features, particularly in established disease. Features which present in the early stages of the disease may be similar to that of gastro-oesophageal reflux, including retrosternal chest pain typically after eating and heartburn<sup>[11]</sup>. Due to initial non-specific symptoms in early stage disease and the low prevalence of achalasia worldwide, the condition often goes undiagnosed for many years, giving rise to features of late stage disease and their associated complications.

## EPIDEMIOLOGY

Achalasia is a relatively rare condition. A summary of studies published to date on achalasia incidence and prevalence is shown in Table 1<sup>[12-25]</sup>. The incidence of achalasia varied between studies, with reports as low as 0.03/100000 per year in Zimbabwe<sup>[22]</sup> to 1.63/100000 per year in Canada<sup>[14]</sup>. The majority of incidence rates re-

**Table 1** Summary of epidemiological studies of achalasia incidence and prevalence in adults

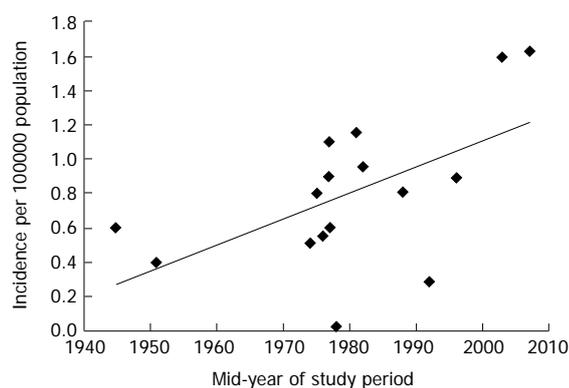

Figure 3 Achalasia incidence by mid-study time points.

ported clustered between 0.5-1.2 per 100000/year (Table 1). In an attempt to investigate changing incidence rates over time, we plotted incidence rates against the mid-timepoint within the study periods (Figure 3). As shown in Figure 3, incidence rates of achalasia appear to be rising, with most reports since the 1980s exceeding rates of 0.8/100000 per year, which has doubled to 1.6/100000 per year in post-2000 studies. Whether this reflects a true rise in incidence, or greater awareness and improved diagnosis of the condition remains uncertain though.

There are no distinct patterns of achalasia incidence in terms of age and sex distribution; it can affect both genders, all races and all ages<sup>[26]</sup>. A few studies have suggested a bimodal distribution of incidence by age, with peaks at around age 30 and 60 years<sup>[12,18,24]</sup>, while others have pointed towards a generally increased risk of achalasia with increased age<sup>[13,23,25]</sup>. Achalasia appears to affect males and females to largely equal extents<sup>[12,13,15,18,21,23-25,27]</sup>

although some investigations have detected slightly higher rates amongst females<sup>[16,19,28]</sup>. Only one study reported a higher achalasia incidence in men<sup>[14]</sup>. A study carried out by Mayberry *et al*<sup>[15]</sup> found achalasia to be significantly more common in the Republic of Ireland in comparison to its neighbouring countries (Table 1). Similarly, a study which reviewed the incidence of achalasia in New Zealand found differing incidence between ethnic groups<sup>[21]</sup>. The Pacific Islanders had an incidence of 1.3/100000 per year in comparison to those of Maori descent having an incidence of 0.2/100000 per year. This may reflect the influence of genetic factors in achalasia aetiology<sup>[21]</sup>.

A Canadian population-based study also considered the prevalence and survival rates of patients with achalasia<sup>[14]</sup>. Sadowski *et al*<sup>[14]</sup> found that the prevalence of achalasia rose from 2.51/100000 in 1996 to 10.82/100000 in 2007, despite a relatively stable incidence over the same time period (Table 1). The rise in prevalence was seen in both genders but was noted to be more pronounced in males, reflecting the fact that achalasia is a slowly progressive disease. This rise in prevalence was also evident in an Israeli study<sup>[18]</sup> and was noted in an Icelandic study between 1952 and 2002<sup>[13]</sup>. It is interesting to note that the Canadian study observed survival of achalasia patients to be significantly lower than the age-sex matched control population<sup>[14]</sup>. However, others have discerned that the majority of deaths in achalasia patients result from unrelated causes, leading to an equivalent life expectancy to the general population<sup>[29]</sup>.

## AETIOLOGY

There has been much debate over the aetiology of achalasia

lasia, with several potential triggers for the inflammatory destruction of inhibitory neurons in the oesophageal myenteric plexus being implicated. These include autoimmune responses, infectious agents and genetic factors.

### Auto-immune conditions

One recent study observed that patients with achalasia were 3.6 times more likely to suffer an autoimmune condition, compared with the general population<sup>[30]</sup>. Sjogren's syndrome, Systemic Lupus Erythematosus and uveitis were all significantly more prevalent in achalasia patients. The study also found the presence of a T-cell infiltrate and antibodies within the myenteric plexus of many patients with achalasia and an increased presence of human leukocyte antigen class II antigens<sup>[30]</sup>. Another study noted an overall higher prevalence of neural autoantibodies in patients with achalasia in comparison with a healthy control group<sup>[31]</sup>. Although no specific autoantibody was identified, this further supports the theory that achalasia has an autoimmune basis<sup>[31]</sup>.

### Infectious agents

The role of an infectious agent in the development of achalasia has been widely debated with several viral agents being implicated. For example, Chagas disease has a known infectious aetiology, and exhibits many similarities with achalasia<sup>[32]</sup>. In addition, there are several reports of varicella zoster virus and Guillain-Barre syndrome preceding the onset of achalasia<sup>[32]</sup>. Antibody studies have demonstrated increased titres to herpes and measles viruses in patients with achalasia in comparison to healthy control groups<sup>[33,34]</sup>. One study looking specifically at the link between the herpes simplex virus (HSV) and primary achalasia indicated the presence of HSV-1 reactive immune cells in the lower oesophageal sphincter of achalasia patients, suggesting that HSV-1 may be involved in the neuronal damage to the myenteric plexus leading to achalasia<sup>[35]</sup>. A further study of peripheral blood immune cells found that patients with achalasia showed an enhanced response to HSV-1 antigens<sup>[34]</sup>. In contrast, another investigation using PCR on myotomy specimens did not find any association between herpes, measles or human papilloma viruses and achalasia<sup>[36]</sup>. The current evidence for a causative infectious agent is contradictory and no clear causal relationship has yet been established.

### Genetic predisposition

The genetic basis for achalasia has not been widely investigated due to its low prevalence. One syndrome, known as the triple "A" syndrome, which consists of a triad of achalasia, alacrima and adrenocorticotrophic hormone resistant adrenal insufficiency is a known autosomal recessive disorder caused by gene mutations on chromosome 12. This syndrome, together with the prevalence of cases within children of consanguineous couples<sup>[37]</sup>, suggests the possibility for a genetic component to the aetiology of achalasia. There have been associations

with other genetic diseases including Parkinson's disease, Downs syndrome and MEN2B syndrome<sup>[10]</sup>. One recent study suggested the possibility of involvement of the rearranged during transfection gene, which is a major susceptibility gene for Hirschprung's disease (also linked with Down's syndrome)<sup>[9]</sup>. Mayberry *et al.*<sup>[38]</sup> conducted a study of first degree relatives of achalasia patients but concluded that inheritance was unlikely to be a significant causative factor due to the rarity of familial cases and exposure to common environmental and social factors within a family group may explain the presence of familial cases of achalasia.

It has been postulated that achalasia may incorporate a multi-factorial aetiology with an initiating event such as a viral or environmental insult resulting in oesophageal myenteric plexus inflammation. This inflammatory reaction may then initiate an autoimmune response in a susceptible group of genetically predisposed people, causing destruction of inhibitory neurons<sup>[39]</sup>.

## TREATMENT

The mainstay of treatment for achalasia is either pneumatic balloon dilatation or laparoscopic myotomy<sup>[40]</sup>. In pneumatic balloon dilatation, a balloon is positioned across the lower oesophageal sphincter and inflated, effectively rupturing the muscle of the affected segment. Surgical myotomy can be performed as either an open or laparoscopic procedure. The laparoscopic technique is now the most commonly performed. The procedure involves making a longitudinal division of the circular muscle of the lower oesophageal sphincter, extending this both proximally and distally onto the cardia<sup>[11]</sup>. Many surgeons advise the use of an anti-reflux procedure together with surgical myotomy, as these patients are at an increased risk of reflux following surgery<sup>[3]</sup>. A recent study compared partial anterior and partial posterior fundoplication following cardiomyotomy. It concluded that partial posterior fundoplication was superior to the anterior procedure due to significantly lower reintervention rates for postoperative dysphagia<sup>[41]</sup>.

The best comparative study between pneumatic dilatation and surgery to date has demonstrated remarkably similar outcomes in matched patients over a three year follow up period<sup>[42]</sup>. Therapeutic success at two years was noted in 86% of those treated by pneumatic dilatation and 90% of those who had laparoscopic Heller's myotomy. The regimen for pneumatic dilatation was rigorous with the option of multiple dilatations. The accompanying editorial suggests that choice should be determined by patient preference and local expertise<sup>[43]</sup>. A new endoscopic esophagomyotomy technique has been recently introduced: Peroral endoscopic myotomy involves dividing the inner circular muscle of the oesophagus. This requires sophisticated expertise and remains experimental<sup>[39]</sup>.

In patients for whom invasive procedures are not suitable, alternative treatment options may be considered including pharmacological intervention using long-acting

nitrates and calcium channel blockers. However, these are of limited benefit<sup>[44]</sup>. A further option is botulinum toxin injection into the lower oesophageal sphincter. This technique offers good short term results<sup>[45]</sup>. Most recently, metal stents have been used successfully<sup>[46]</sup>. Both of these options are generally only suited to those with several co-morbidities<sup>[9]</sup>.

## COMPLICATIONS

Patients with achalasia are at risk of developing the complications associated with disease progression as well as its treatment interventions. The complications of achalasia that can develop as a result of the natural course of the condition include aspiration-pneumonia<sup>[47]</sup>. Mega-oesophagus develops in 10% of inadequately treated cases and can ultimately require oesophagectomy<sup>[48]</sup>.

Squamous cell carcinoma is the most common oesophageal cancer in patients with achalasia and this is thought to result from the high level of nitrosamines produced by bacterial overgrowth due to stasis in the oesophagus leading to chronic inflammation and dysplasia<sup>[49]</sup>. There is considerable variation in the documented oesophageal cancer risk in achalasia. One review found that the prevalence of oesophageal cancer in achalasia was 3%, corresponding to a 50-fold increased risk<sup>[50]</sup>, while a prior review reported increased risks ranging from 0-33-fold greater than the general population<sup>[51]</sup>. Subsequent reports would also indicate a slightly more modest, but still significantly elevated, risk of oesophageal cancer 16-28-times greater than an age-sex matched control population<sup>[52,53]</sup>.

The risk of oesophageal adenocarcinoma is also increased in those with achalasia and may be a complication of longstanding reflux following successful interventional treatment<sup>[27,54]</sup>. A recent publication from The Netherlands demonstrated that 8.2% of 331 primary achalasia patients developed Barrett's oesophagus over a period of up to 25 years<sup>[55]</sup>. Two of these Barrett's cases progressed to develop oesophageal adenocarcinoma. Other studies have also reported elevated risks of Barrett's oesophagus and oesophageal adenocarcinoma in achalasia patients<sup>[27,56]</sup>.

A few studies have described even larger increased risks of oesophageal cancer amongst achalasia patients. One German study reported an risk of developing oesophageal cancer up to 140 times greater in patients with achalasia than the normal population<sup>[57]</sup>, which is equivalent to cancer risk in Barrett's oesophagus<sup>[58]</sup>. Furthermore, oesophageal cancer diagnosis in achalasia patients is often delayed, contributing to a poor mean survival after diagnosis of only 0.7 years<sup>[53,59]</sup>. These findings would support the need for endoscopic surveillance in achalasia patients.

However, despite the relative risk being increased, the absolute risk of cancer in patients with achalasia is still small and there would be a large number of examinations required to detect a single cancer. In fact it has been

estimated that for the detection of a single cancer there would need to be 681 endoscopic examinations undertaken<sup>[53]</sup>. Despite the potential complications associated with diagnosis, treatments and increased cancer risk, achalasia patients don't experience a significant compromise to overall life expectancy<sup>[29]</sup>. The most recent guidelines indicate that surveillance endoscopy is not indicated<sup>[60]</sup>.

## CONCLUSION

In conclusion, achalasia remains a relatively under-researched condition with many details on aetiology, true incidence, and risk of complications still unknown. There has been some progress over the past years into the aetiology of the condition but there is a need for further research to be carried out into this field to establish causative agents. Furthermore, clarification in relation to the need for an endoscopic screening program in patients with achalasia to detect the development of oesophageal cancer is required.

### Abstract

**AIM:** To study the subtype prevalence and the phylogenetic relatedness of hepatitis C virus (HCV) sequences obtained from the Argentine general population, a large cohort of individuals was analyzed.

**METHODS:** Healthy Argentinian volunteers ( $n = 6251$ ) from 12 provinces representing all geographical regions of the country were studied. All parents or legal guardians of individuals younger than 18 years provided informed written consent for participation. The corresponding written permission from all municipal authorities was obtained from each city or town where subjects were to be included. HCV RNA reverse transcription-polymerase chain reaction products were sequenced and phylogenetically analyzed. The 5' untranslated region (5'UTR) was used for RNA detection and initial genotype classification. The NS5B polymerase region, encompassing nt 8262-8610, was used for subtyping.

**RESULTS:** An unexpectedly low prevalence of HCV infection in the general population (0.32%) was observed. Our data contrasted with previous studies that reported rates ranging from 1.5% to 2.5%, mainly performed in selected populations of blood donors or vulnerable groups. The latter values are in keeping with the prevalence reported by the 2007 Argentinian HCV Consensus (approximately 2%). HCV subtypes were

distributed as follows: 1a (25%), 1b (25%), 2c (25%), 3a (5%), and 2j (5%). Two isolates ascribed either to genotype 1 (5%) or to genotype 3 (5%) by 5'UTR phylogenetic analysis could not be subtyped. Subtype 1a sequences comprised a highly homogeneous population and clustered with United States sequences. Genotype 1b sequences represented a heterogeneous population, suggesting that this genotype might have been introduced from different sources. Most subtype 2c sequences clustered close to the 2c reported from Italy and Southern France.

**CONCLUSION:** HCV has a low prevalence of 0.32% in the studied general population of Argentina. The pattern of HCV introduction and transmission in Argentina appears to be a consequence of multiple events and different for each subtype.

**Key words:** Hepatitis C virus NS5B subtyping; Molecular epidemiology; Hepatitis C virus; Argentina; Hepatitis C virus 5' untranslated region

**Core tip:** This study reports an unexpectedly low prevalence of hepatitis C virus (HCV) (0.32%) in the general population of Argentina, with a subgenotype distribution of 1a (25%), 1b (25%), 2c (25%), 3a (5%), and 2j (5%) while two isolates ascribed either to genotype 1 (5%) or to genotype 3 (5%) could not be subtyped. Phylogenetic analysis of the NS5B region has enabled us to define the pattern of HCV introduction and transmission in Argentina as a consequence of multiple events that differed for each (sub)genotype studied. Furthermore, this report discusses the putative sources of HCV subgenotype introduction in Argentina.

## INTRODUCTION

The analysis of extensive sets of sequences from hepatitis C virus (HCV) isolates throughout the world has revealed the existence of six major genetic groups or genotypes (named 1 to 6), and a large number of subtypes within these groups (designated a, b, c, *etc.*)<sup>[1]</sup>. Overall sequence divergence ranges from 31% to 33% among genotypes and from 20% to 25% among subtypes<sup>[1,2]</sup>; in a single patient, cloned E1/E2 sequences may differ by up to 10%. The reason for this great variation is a high mutation rate and high level of viral replication through an error prone RNA polymerase without proofreading

capacity. Consequently, in the infected individual, the virus circulates as a complex viral quasispecies<sup>[3]</sup> whose composition is subject to continuous changes due to competitive selection<sup>[4]</sup> and interactions among variants of with different levels of fitness<sup>[5]</sup>. The calculated average rate of fixation of mutations has consistently been found to range between 1.1 and  $1.5 \times 10^3$  mutations per site and per year<sup>[6,7]</sup>. The rate of fixation of mutations is not evenly distributed throughout the genome, which has highly variable regions within the envelope coding genes and well conserved regions, such as the 5' untranslated region (5'UTR). The practical consequence of the high conservation at 5'UTR for HCV genotyping is that this region contains insufficient variation to solve HCV classification at the level of viral subtypes<sup>[8]</sup>. Furthermore, genotype 6 variants other than 6a and 6b show 5'UTR sequences identical or similar to those of type 1 and, therefore, cannot be differentiated<sup>[9-11]</sup>. It has been reported that sequence analysis of the highly conserved region in NS5B known as the "Okamoto region" (nt 8282 to 8610 in the H77 reference genome)<sup>[8]</sup> provides the best concordance with the full length genome phylogeny for precise genotype identification. The same primers can amplify genotypes 1 to 5, and they are less efficient for genotype 6 isolates, but they facilitate analysis and classification of the amplified sequences<sup>[11]</sup>.

The prevalence of HCV infection in Argentina has been reported at 1.5% when all age groups are considered, and up to 2.0%-2.5% in adults<sup>[12]</sup>, a rate in keeping with the value reported by the Argentinian Consensus on Hepatitis C (approximately 2%) in 2007. A higher prevalence (4.9%-5.7%) has been described in small rural communities<sup>[13,14]</sup>. HCV genotype distribution in Argentina in groups at risk of HCV infection (*e.g.*, transfusion patients, hemodialysis patients, intravenous drug users, healthcare workers) has been reported at 53.5% for genotype 1, 23% for genotype 2 (mainly by subtype 2c [HCV-2c]), 8.6% for genotype 3, and 14.8% for mixed infections<sup>[13]</sup>. Similar results have been reported in studies on sequences deposited in GenBank (GB) and analyses by the Los Alamos database <http://hcv.lanl.gov>, with few genotype distribution changes (79.5% for genotype 1, 13.9% for genotype 2, 3.9% for genotype 3, 2.4% for genotype 4), but with some differences depending on the HCV subgroup at risk studied<sup>[16-18]</sup>. Phylogenetic characterization of genotype 4 isolates from Argentina has traced an independent origin of the three sequences studied<sup>[17]</sup>. Interestingly, HCV-2c was the most prevalent subtype (58%) in the city of Córdoba (Central geographical region of the country), followed by HCV-1b (33%), and to a lesser extent by HCV-1a (11%), HCV-3a (3%) and HCV-4a (3%)<sup>[19,20]</sup>.

Here, we report an unexpectedly low prevalence of HCV infection (0.32%) as measured by anti-HCV antibodies detected by using both a second generation enzyme immune assay (EIA) and a confirmatory immunoblotting, and HCV RNA detected by reverse transcription - nested polymerase chain reaction (RT-nested PCR)

**Table 1** Epidemiological profile of the population studied

Province/city of residence	Total number of individuals	Male/female number	Age <sup>1</sup> (yr), mean $\pm$ SE

<sup>1</sup>Data are expressed as mean  $\pm$  SE (SD, median). <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , regarding the gender distribution (male/female ratio) within the whole population studied; <sup>d</sup> $P < 0.01$  regarding the mean age  $\pm$  SD from the whole population studied. C.A.B.A.: Ciudad Autónoma de Buenos Aires, the national capital city.

targetting the 5'UTR HCV RNA in a cohort of random Argentinian volunteers. The genotypes detected and the putative origin of the HCV sequences are discussed based on both their phylogenetic clustering and on such clustering relative to other Argentinian and worldwide derived sequences deposited in GB, in an attempt to trace how HCV could have been introduced in the local community here represented by the cohort studied.

## MATERIALS AND METHODS

Throughout the 2000-2007 period, a total of 6251 serum samples were collected from healthy volunteers from 12 Argentinian provinces, as well as from the Ciudad Autónoma de Buenos Aires (C.A.B.A. - the capital city of the country) as follows: Buenos Aires province and C.A.B.A.,  $n = 1461$ ; Catamarca,  $n = 648$ ; Córdoba,  $n = 1061$ ; Chaco,  $n = 353$ ; Chubut,  $n = 172$ ; Entre Ríos,  $n = 474$ ; Jujuy,  $n = 176$ ; Río Negro,  $n = 329$ ; Salta,  $n = 561$ ; San Luis,  $n = 195$ ; Santiago del Estero,  $n = 375$ ; and Tucumán,  $n = 446$  (Table 1).

Subjects included in this study [ $n = 6251$ ; 2738 men; mean  $\pm$  SE, 37.5  $\pm$  0.2 years; mean  $\pm$  SD = 37.5  $\pm$  12.7; median age = 35 years (range 10-70 years)] were recruited as volunteers from the general population, local schools, and police stations, after being informed about the aim of the survey. All parents or legal guardians of individuals younger than 18 years provided informed written consent for participation. The corresponding written permission from all municipal authorities was obtained from each city or town where subjects were to be included.

### Serological studies

The presence of anti-HCV antibodies was determined by using a second generation EIA test according to the manufacturer's recommendations (Abbott Diagnostics, North Chicago, IL, United States). Samples were further

analyzed with a second generation recombinant immunoblot assay (RIBA 2.0: Chiron Corporation, Emeryville, CA, United States).

### HCV-RNA detection and genotyping

Samples with serologically detectable anti-HCV antibodies were subjected to either RT-nested or RT-hemi-nested PCR amplification (see below). The 5'UTR region was used for RNA detection and initial genotype classification. The NS5B polymerase region, encompassing nt 8262-8610, was used for subtyping.

### RNA extraction

RNA was extracted from 140  $\mu$ L of serum by using the QIAamp Viral RNA Mini Kit (Qiagen Hilden, Germany). The measures to prevent contamination suggested by Kwok and Higuchi were strictly applied<sup>[21]</sup>.

### 5'UTR RT-nested PCR amplification and sequencing

The 5'UTR RT-nested PCR was performed as follows. RT was carried out for 45 min at 42 °C (GeneAmp 2700 PCR system, Applied Biosystems, Foster City, CA, United States), using 50 U M-MLV reverse transcriptase, RNase H Minus, Point Mutant (200 U/ $\mu$ L Promega, Madison, WI, United States), 20 U RNase inhibitor (40 U/ $\mu$ L Promega, Madison, WI, United States), 10 mmol/L of each dNTP (Roche, Basel, Switzerland), 20 pmols of antisense PCR primer NR5 5'TGCTCATGGTGCACGGTCTACGAG3' and 1  $\times$  buffer from the high fidelity *Pfu* turbo DNA polymerase (Stratagene, San Diego, CA, United States) in a final volume of 20  $\mu$ L. Then, 80  $\mu$ L of PCR mix containing 1  $\times$  *Pfu* turbo buffer, 20 pmol of sense primer NF5 5'GTGAGGAACTACTGTCTTCACG-CAG3' and 2.5 U *Pfu* turbo DNA polymerase were added to each tube. After an initial denaturation step of 2 min at 95 °C, 5 initial cycles of 30 s at 94 °C, 30 s at 55 °C and 2 min at 72 °C were carried out, followed by 35 cycles of 30 s at 94 °C, 30 s at 60 °C and 2 min at 72 °C, finishing with a single final step of 10 min at 72 °C. Five microliters of the product were used for nested PCR, by using internal primers the internal primers, K80 5'AGCGTCTAGCCATGGCGT3' and K78 5'CACTCG-CAAGCACCTATCAGGCAGT3'. The nested PCR mix consisted of 1  $\times$  *Pfu* turbo buffer, 10 mmol/L of each dNTP, 20 pmol of internal primers, and 2.5 U of *Pfu* turbo DNA polymerase in a final volume of 100  $\mu$ L. After a single denaturation step of 2 min at 95 °C, we carried out 30 cycles of 30 s at 95 °C, 30 s at 60 °C, and 2 min at 72 °C, and then, a final single step of 10 min at 72 °C. The amplified products of 240 nucleotides length were analyzed by electrophoresis onto 2% agarose gels stained with ethidium bromide. PCR products were purified by using the QIAquick PCR purification kit for direct sequencing on an Abi Prism 310 Genetic analyser (Applied Biosystems).

### NS5B RT-heminested-PCR amplification and sequencing

Extracted RNA was reverse transcribed using the de-

generate primer NS5B8704 5'GADGAGCADGAT-GTWATBAGCTC3' (nucleotide positions 8682-8704), where D = G + A + T, W = A + T and B = G + T + C, following the same conditions as for 5'UTR (see before). PCR was carried out by using the primer NS5B8256 5'TAYGAYACCMGNTGYTTTGACTC3' (nucleotide positions 8256-8278), where Y = C + T, M = A + C, and N = A + T + G + C, with an initial denaturation step of 2 min at 95 °C, five initial cycles of 30 s at 95 °C, 30 s at 43 °C, and 2 min at 72 °C, followed by 35 cycles of 30 s at 95 °C, 30 s at 46 °C and 2 min at 72 °C, and completed with a single final step of 10 min at 72 °C. Heminested PCR was performed with an initial denaturation step of 2 min at 95 °C, 30 cycles of 30 s at 95 °C, 30 s at 48 °C, and 2 min at 72 °C, completed with a single final step of 10 min at 72 °C using primers NS5B8256 and NS5B8641 5'GARTAYCTGGTCATAGCNTCCGT3' (nucleotide positions 8641-8619), where R = A + G, to obtain a final product of 386 nucleotides. Purification and sequencing were performed as mentioned above.

### Genotyping and subtyping-GB sequences

A GB query to Nucleotide collection (nr/nt), using the Megablast programme (<http://www.ncbi.nlm.nih.gov/blast/Blast.cgi>) was performed for each of the NS5B sequences obtained in this study. The 100 GB sequences with the highest sequence similarity to each of our samples were selected. A tree was constructed by using either the Neighbor-joining or Fast Minimum Evolution algorithm from a given matrix of distances using the Jukes-Cantor method to calculate the distances. For every query, we obtained a tree that situates each sequence with the most closely related reference from the GB. The most similar sequences were downloaded for further analysis, the genotype was assigned, and a putative origin of local isolates was inferred. GB was accessed to download already published sequences of Argentine origin by searching with the words "HCV" and "Argentina" on the website: <http://www.ncbi.nlm.nih.gov/sites/gquery>. Published sequences obtained by several authors<sup>[15,17,22,25]</sup> were downloaded in Fasta format, and their length was then adjusted using the GeneDoc program<sup>[24]</sup>.

### Phylogenetic analysis

Nucleotide sequences were resized by using GeneDoc and aligned by the CLUSTALW program<sup>[25]</sup>. Sequence similarity with other sequences from Argentina and with other GB sequences was ascertained by both distance and parsimony methods. Statistical support for each node in the trees drawn by both methods was obtained by performing 100 or 1000 bootstrap replicates of the original nucleotide sequence alignment. Phylogenetic analysis was carried out with the PHYLIP package<sup>[26]</sup>. Trees were drawn by using the Treeview program, v. 1.6.5<sup>[27]</sup>.

### Genetic divergence analysis

Genetic divergences were calculated by using the DNASP program (version 3.53)<sup>[28]</sup> in three populations:

our sequences grouped as a population, the closest GB sequences as another, and other Argentine sequences as the third one. Pairwise distances were calculated by using the MEGA3.1 program.

### Statistical analysis

They were performed by using either the GraphPath Prism (version 5.0 for Windows) or the SigmaStat software. The non-paired Student's *t* test was used to analyze the statistical differences between the mean age  $\pm$  SD of the whole population of the country regarding those values recorded from each Province (therefore, examining a data set from two groups), as well as for such comparison with previous studies. When such study was performed among three or more groups, the one-way analysis of variance (ANOVA) was applied. Pairwise distances were statistically compared by using the  $\chi^2$  test with Yates' correction (SigmaStat software). *P* values lower than 0.05 were considered statistically significant.

## RESULTS

### HCV prevalence in the general population of Argentina

A total of 6251 serum samples from a cohort of random volunteers was studied. Initially, 25 samples (0.40%) tested anti-HCV antibody positive as determined by EIA. However, 5 of the 25 samples failed to exhibit specific anti-HCV antibodies by immunoblotting analysis and also tested negative by RT-nested PCR to detect HCV RNA; hence, they were discarded for further studies.

HCV RNA was detected in serum samples from 7 out of 12 provinces. The prevalence of ongoing HCV infection as determined by RT-nested PCR from 12 of 23 provinces of Argentina, representing 73% of the country's total population, was 0.32%. The highest prevalence was detected in Buenos Aires province (0.62%; 9/1461), a geographical area inhabited by 40.52% of the total population of Argentina. In the remaining provinces studied, the prevalence ranged from 0% in Chaco, Chubut, Entre Ríos, Jujuy, and San Luis, to up to 0.53% in Santiago del Estero. Intermediate values were observed in Salta (0.18%) and Córdoba (0.19%), Río Negro (0.30%), as well as in Catamarca (0.46%) and Tucumán (0.45%).

Genotype 1 was the most prevalent, accounting for 55% (11/20) of infected individuals, 25% were subtype 1a (5/20) and 25% subtype 1b (5/20). The second in prevalence was genotype 2 accounting for 35% (7/20); most sequences were ascribed to subtype 2c (*n* = 5), except one that clustered much closer to subtype 2j reference sequences. Lastly, genotype 3 accounted for the remaining 10% (2/20; Table 2). One genotype 1, one genotype 2, as well as one genotype 3 isolates (according to their initial 5'UTR genotype assignment) were excluded from further analysis because of their respective NS5B RT-heminested PCR amplification failure.

### Phylogenetic analysis and genetic divergence

NS5B phylogenetic trees and divergence analysis were

GenBank deposited sequences from Argentina	0.092	0.098	
Closest GB deposited sequences	0.076	0.080	0.076

Hepatitis C virus (HCV)-1b (Argentine general population sequences): 0.082 *vs* 0.054,  $P < 0.001$ ; 0.082 *vs* 0.074,  $P > 0.05$ ; HCV-1b [GenBank (GB) deposited sequences from Argentina]: 0.046 *vs* 0.050,  $P < 0.001$ ; HCV-2c (Argentine general population sequences): 0.087 *vs* 0.076,  $P < 0.001$ ; 0.087 *vs* 0.092,  $P > 0.05$ ; HCV-2c (GB deposited sequences from Argentina): 0.098 *vs* 0.08,  $P < 0.001$ . All  $P$  (HCV-1a)  $> 0.05$ . Genetic divergence (DNASP software), considering three separate HCV groups: our Argentine general population (sequenced in this study), Argentinian sequences already deposited in GB, and the closest GB worldwide sequences. All values obtained were statistically paired and compared by using the  $\chi^2$  test with Yates' correction.

performed by using the five HCV-1a, five HCV-1b, and five HCV-2c sequences. However, divergence could not be ruled out with those genotypes encompassing one single representative sequence (as occurred with 2j and 3a).

As expected, local NS5B sequences clustered together with their corresponding GB references (Figure

1), but the profile differed depending on the genotype. All of our HCV-1a Argentinian sequences clustered together with strong bootstrap support (92%; Figure 2A) and exhibited a low genetic divergence (0.034; Table 3). Furthermore, genetic divergence was not statistically different in comparison with other Argentinian sequences deposited in GB or with the closest non-Argentinian GB deposited sequences included in the study, suggesting a putative common source of infection/transmission.

In the case of Argentinian HCV-1b, we observed two clusters with very low bootstrapping support (19%-25%), and one sequence distantly located regarding such clusters (Figure 2B). Genetic divergence was higher (0.082) than that observed among GB deposited Argentinian 1b sequences but the differences were not statistically significant. Similarly, HCV-2c sequences were intermingled along the tree with no particular clustering (Figure 2C) and showed a high genetic divergence (0.087). Phylogenetic analysis of Argentinian HCV-1b and HCV-2c sequences suggested a different origin of infection/transmission when compared with HCV-1a sequences.

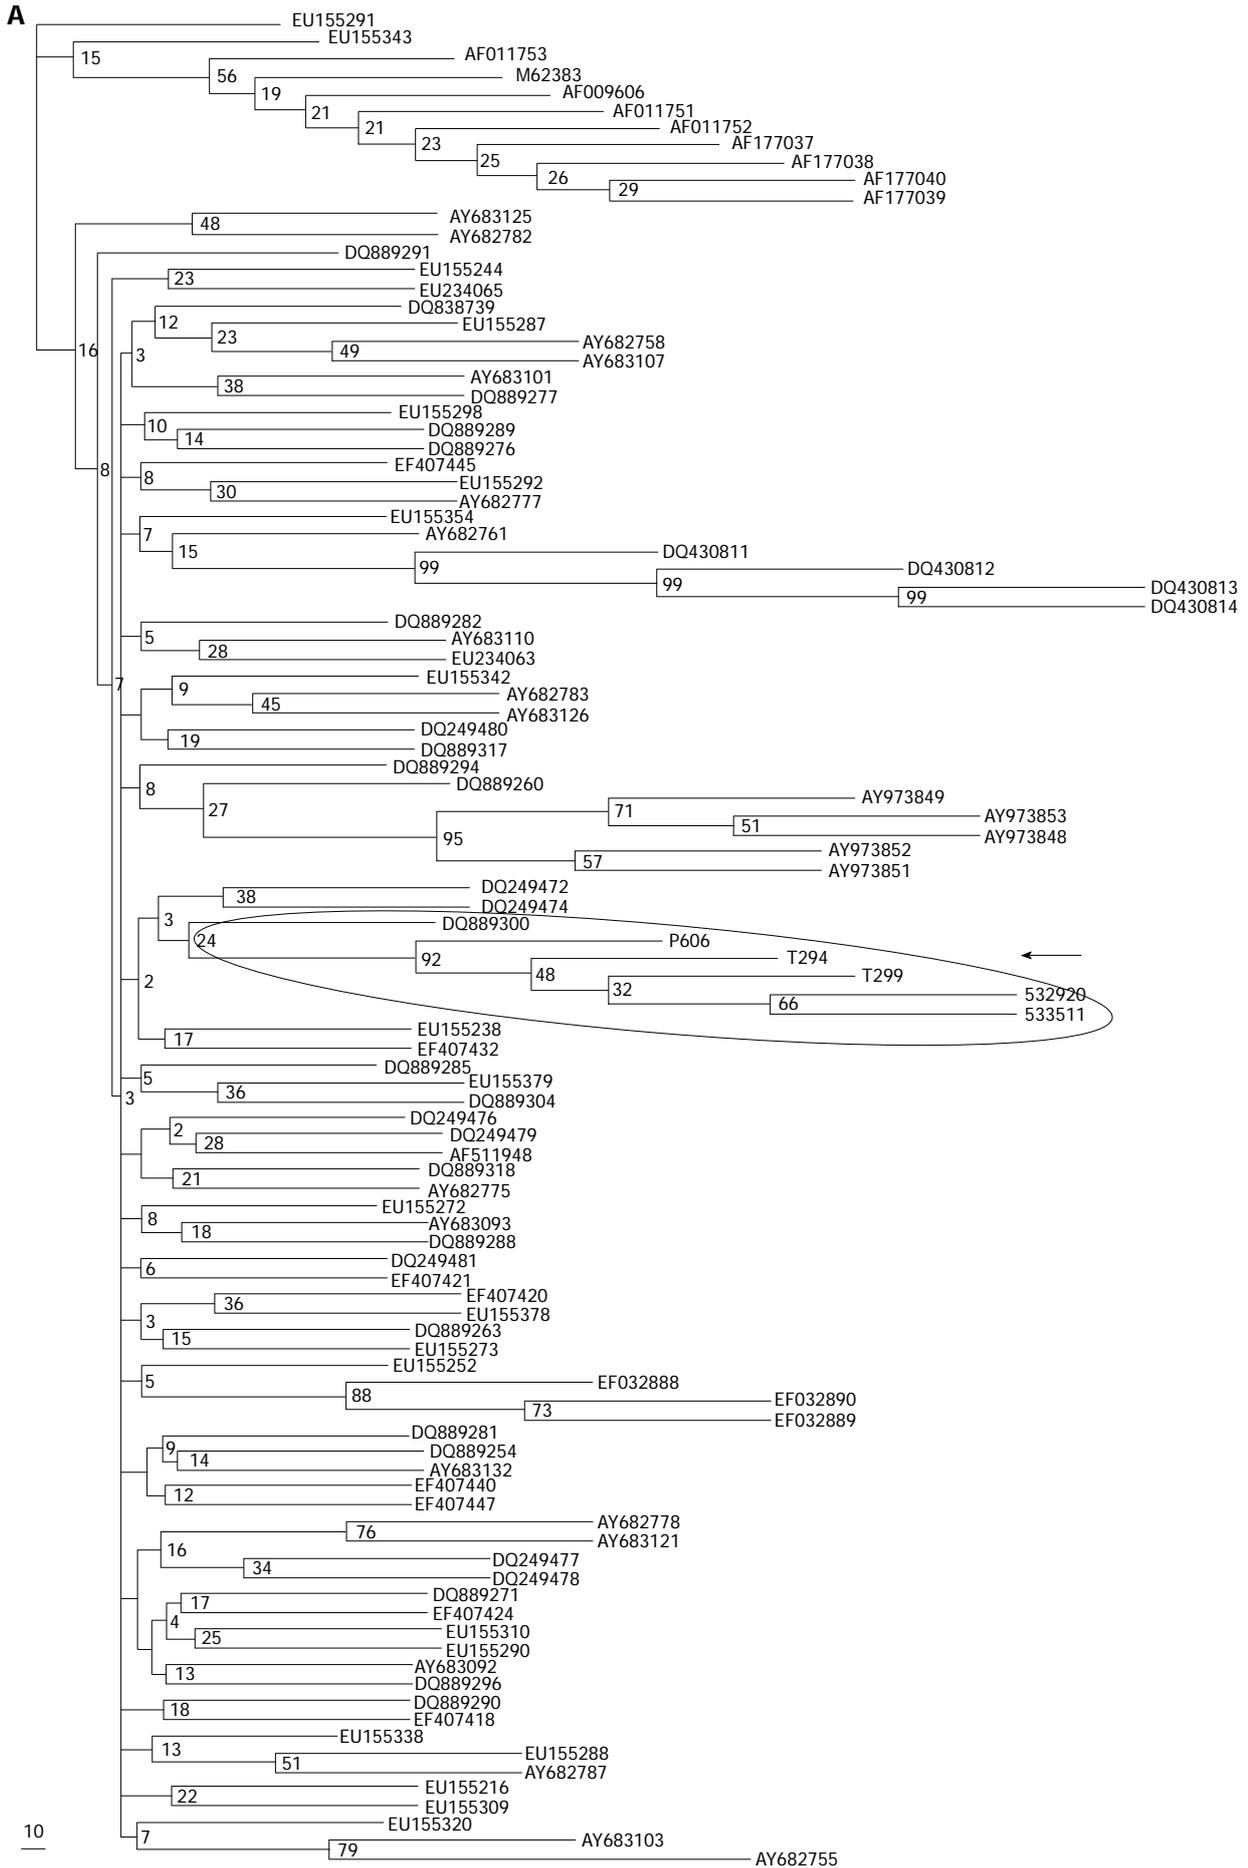

### Origin of closest GB sequences

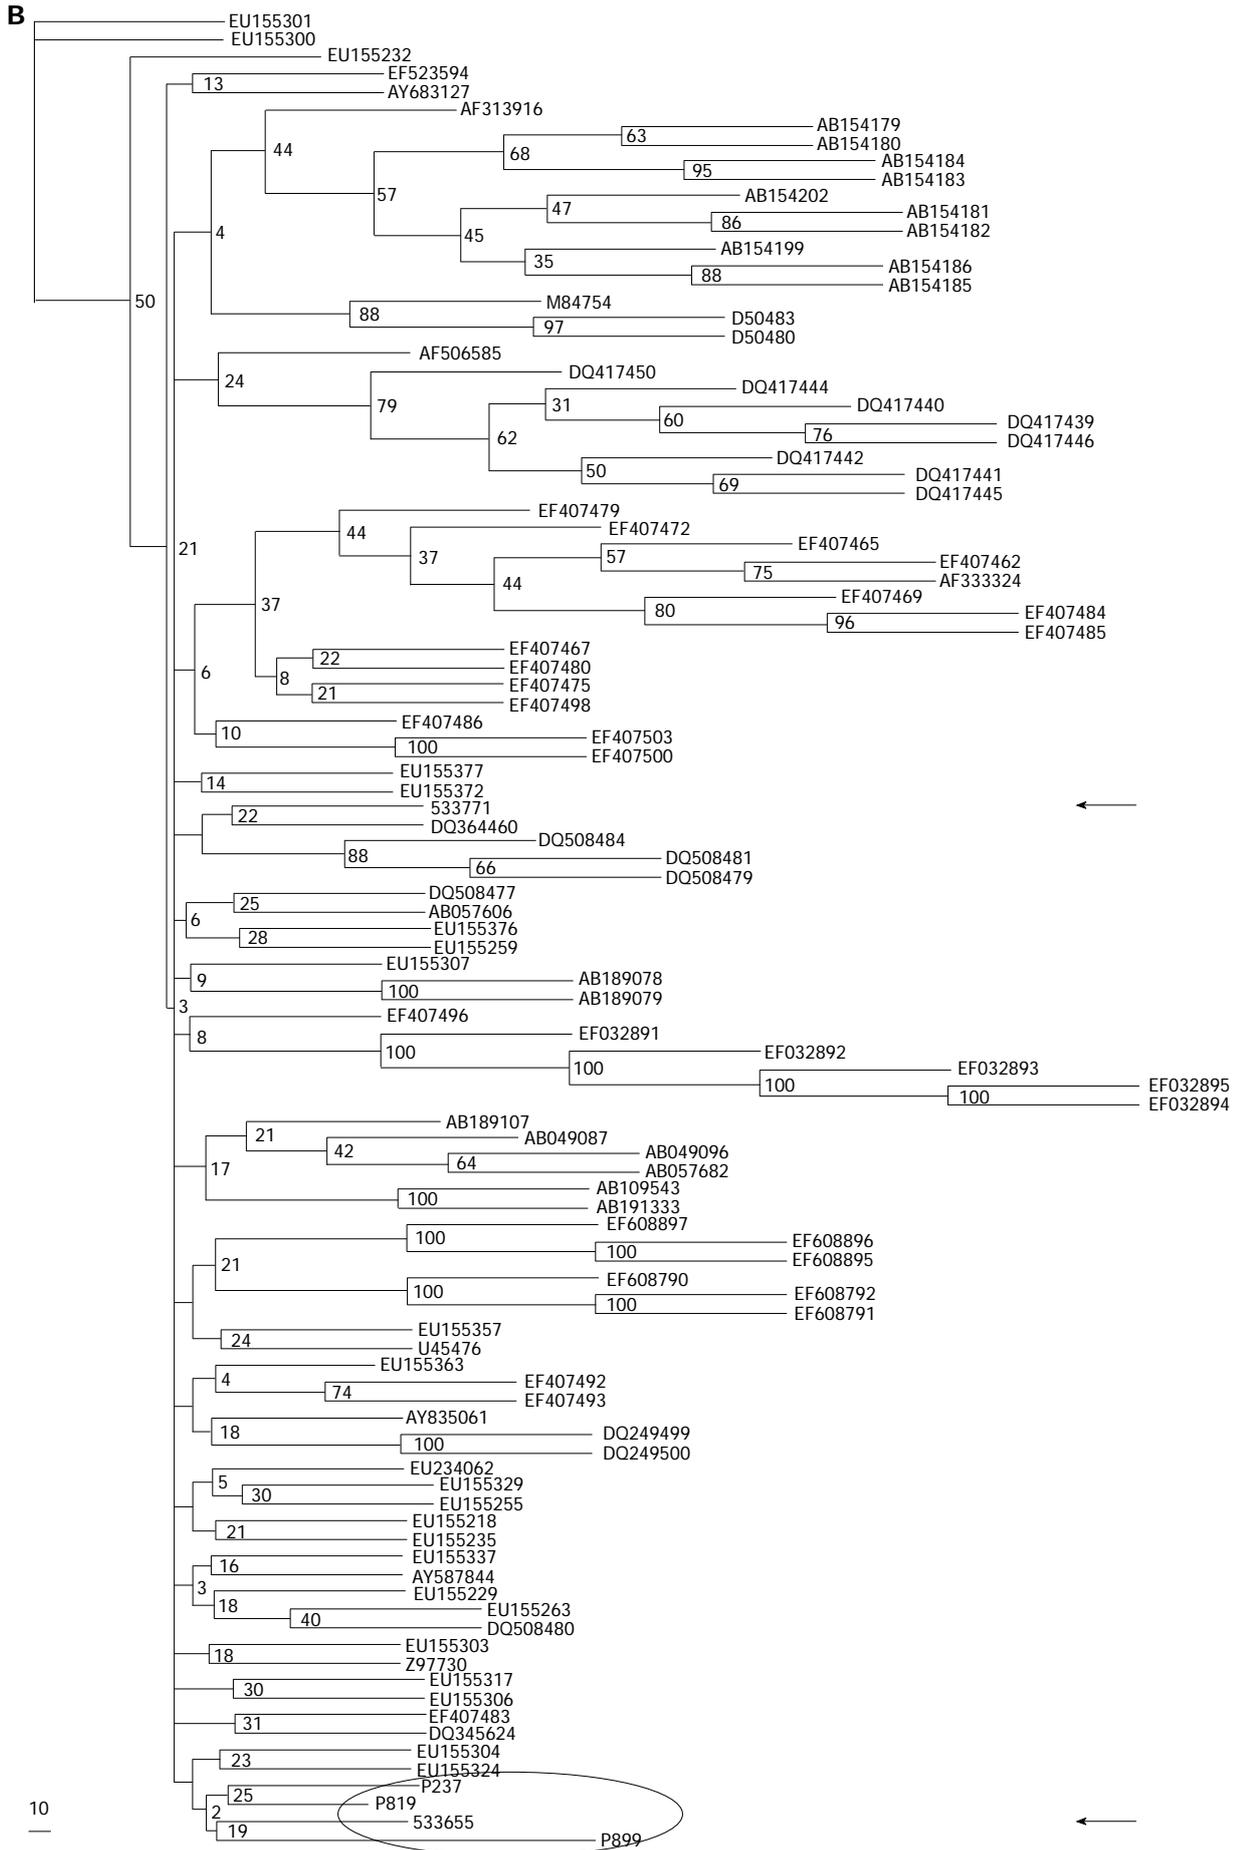

The closest GB sequences obtained by distance (UPGMA and NJ) and parsimony methods (DNAPARS) are represented in Table 4 (trees not shown). The geographic localization of the closest GB sequences is represented in Figure 3.

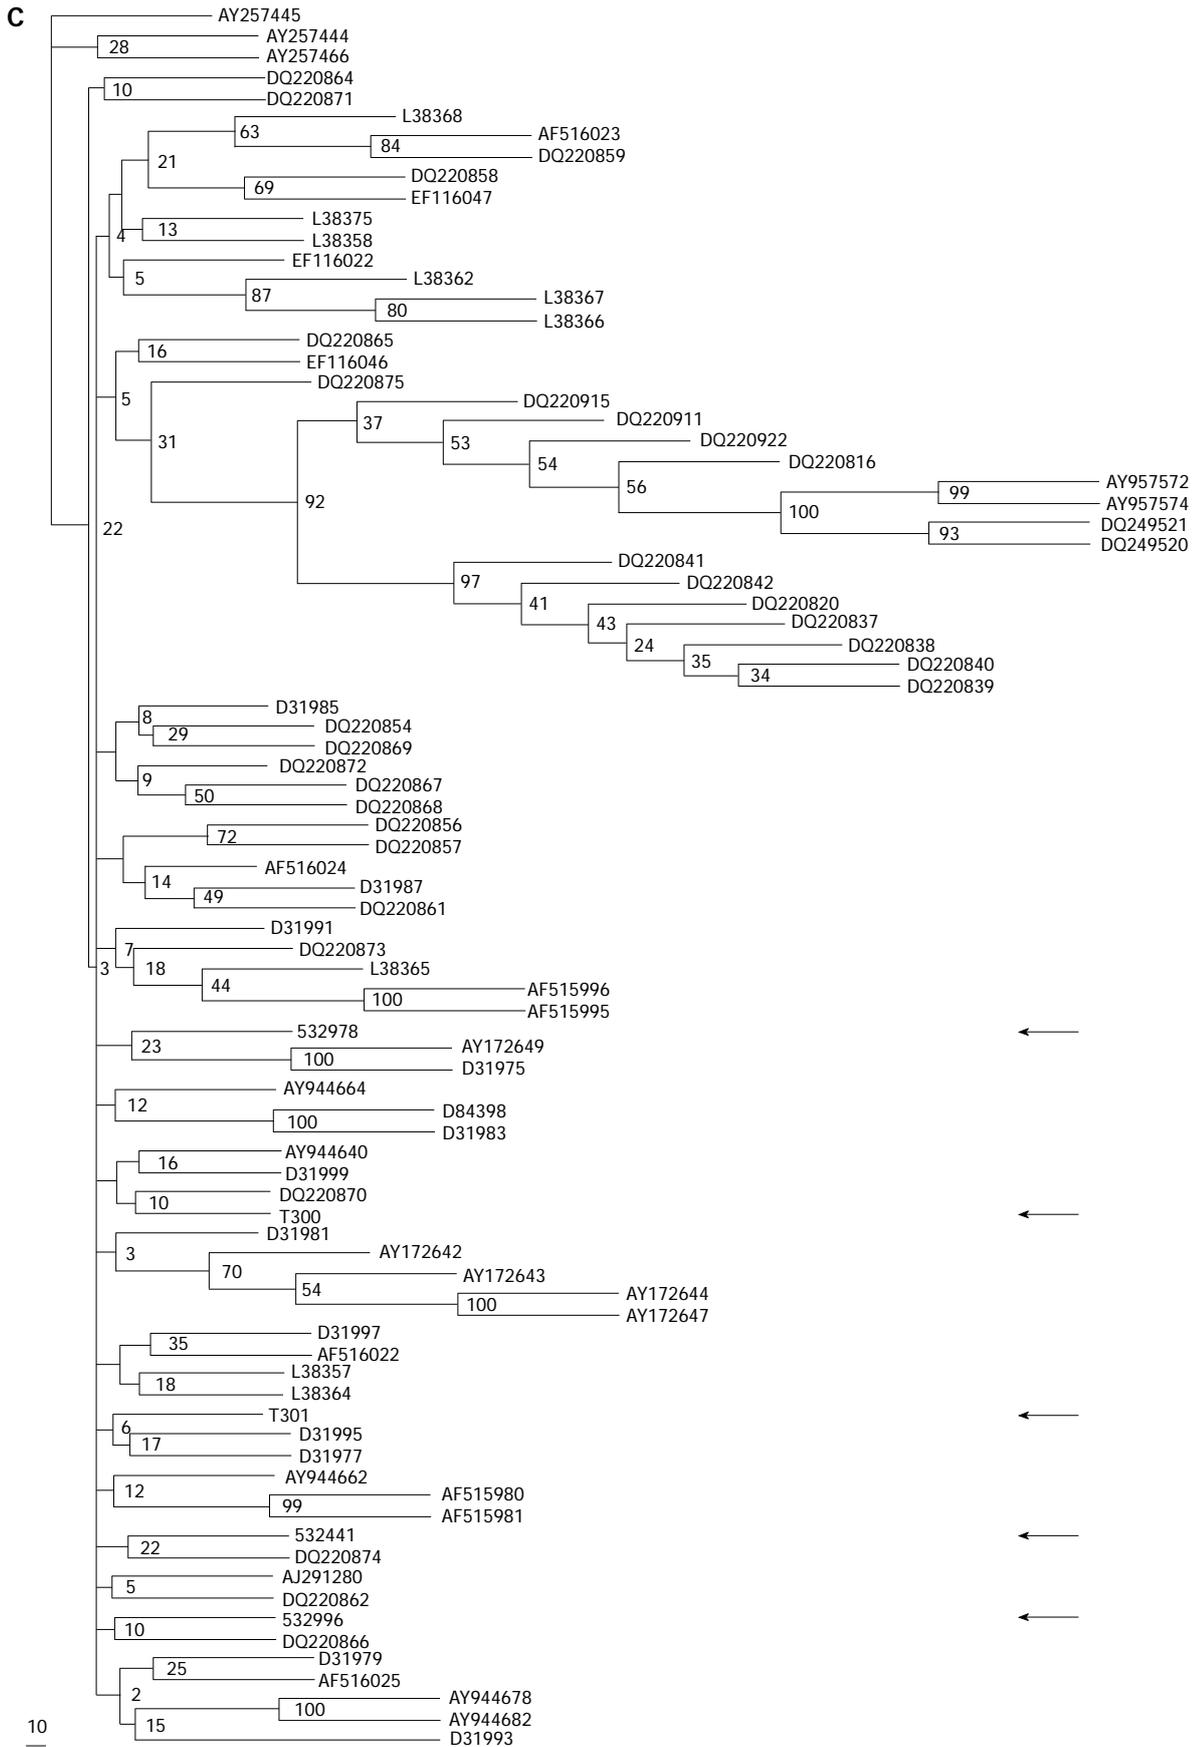

All local HCV-1a sequences grouped with GB United States sequences (St. Louis, Boston, or New York areas). The results suggest a narrow source of infection and not a multifocal event, and are consistent with the low degree of divergence found in the Argentine general population, despite the fact that the subjects studied resided in three different provinces (Buenos Aires, Córdoba, and Río Negro), and from whom serum sampling was performed, several hundred of kilometers apart from each other.

HCV-1b sequences grouped with those from all over the world, including Europe (Spain, Russia), Asia (China), Africa (Madagascar, Tunisia) and North America (United States), and represented a heterogeneous population (Table 3).

**Figure 2** Phylogenetic trees performed by the Neighbor-Joining method. NS5B sequences obtained from the volunteers whose respective hepatitis C virus (HCV) isolates had been classified as HCV-1a ( $n = 5$ ), HCV-1b ( $n = 5$ ) or HCV-2c ( $n = 5$ ) were respectively analyzed in panels A, B and C together with 100 HCV-1a, 100 HCV-1b or 81 HCV-2c sequences downloaded from the GenBank. The respective consensus trees are shown after analyzing 100 replicate trees for each HCV subtype. A distance scale (in nucleotide substitutions per position) is shown in each panel. Arrows indicate sequences obtained from Argentinian volunteers.

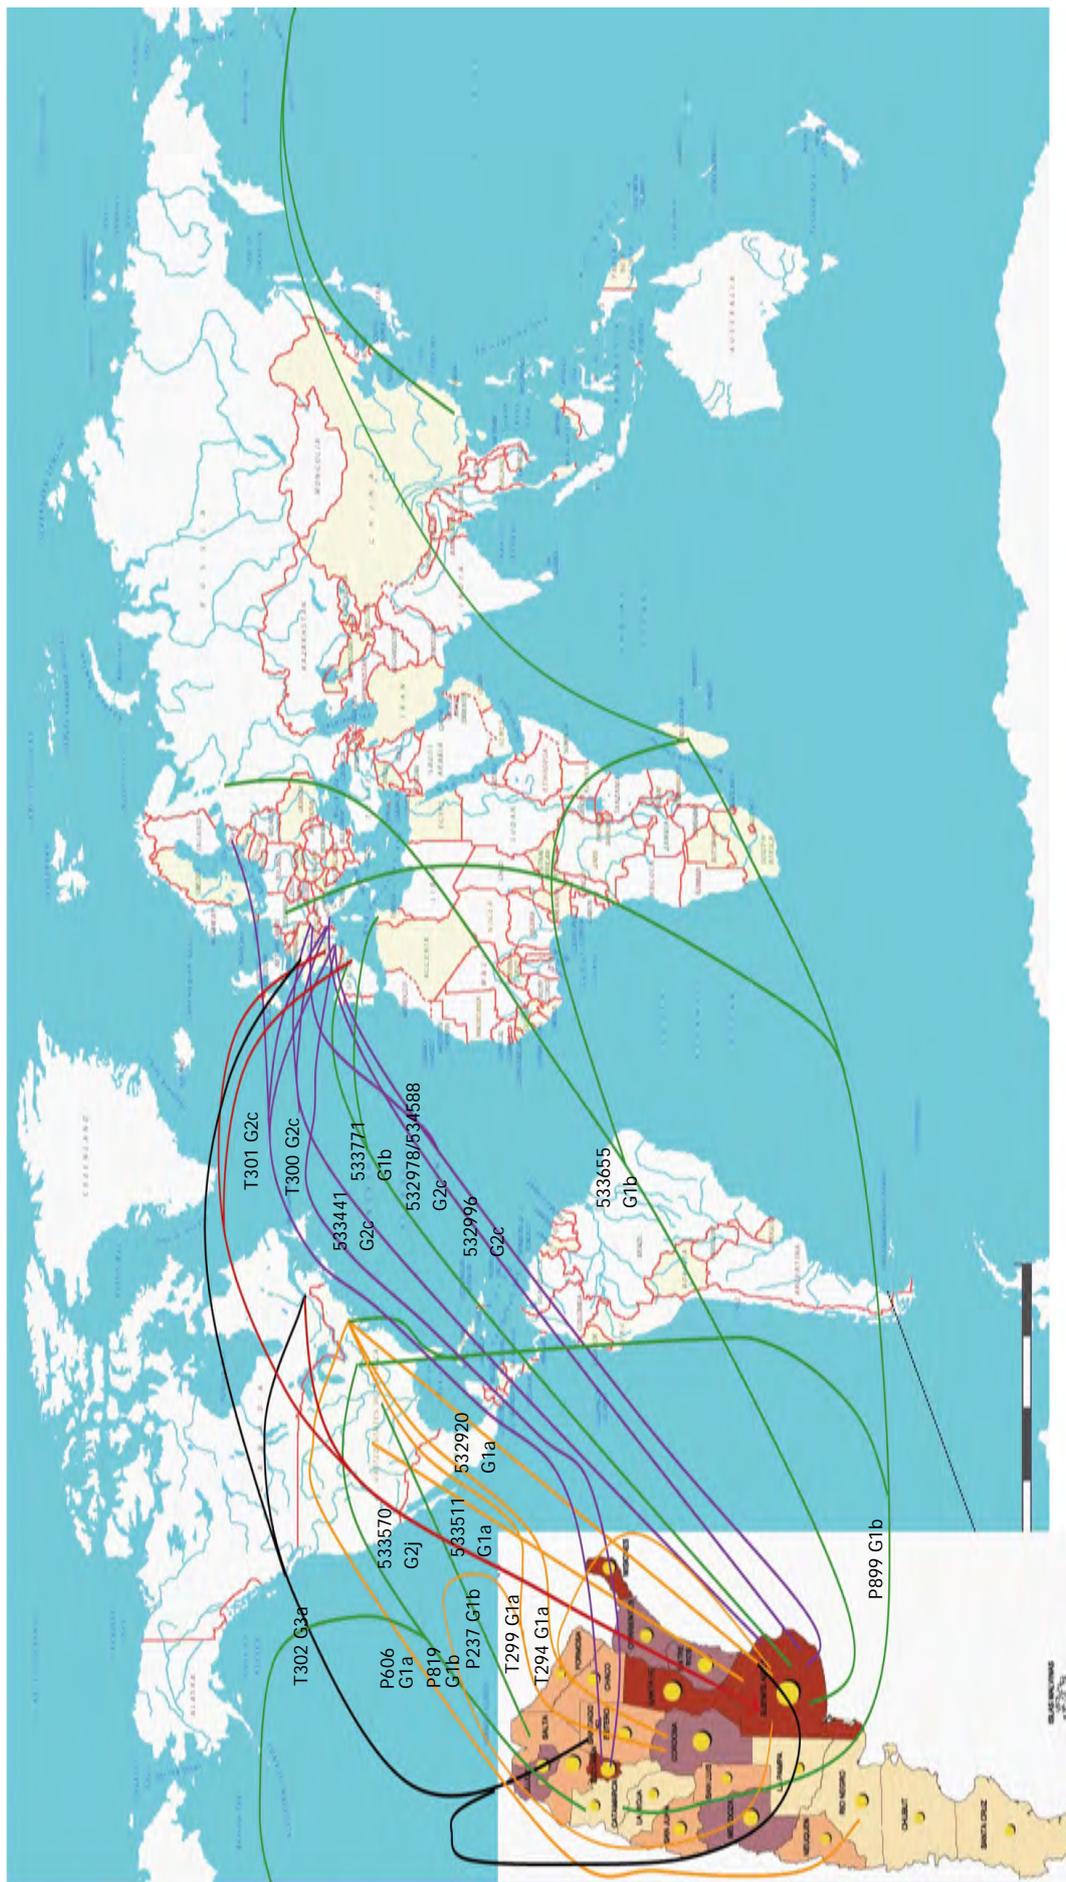

Figure 3 Each line links the Argentinian location of the sequence named on the top of the line with the world location/s of the most closely related sequence/s published in GenBank.

The 3<sup>rd</sup> column from the left shows the GenBank (GB) sequences that are most similar to each of our samples, and the 4<sup>th</sup> column from the left exhibits the origin of the GB already deposited sequences.

HCV-2c sequences from the Argentine general population formed a heterogeneous group with a completely different pattern as compared with HCV-1b. The sequences clustered with GB sequences originated from HCV patients in Italy. Even the sequences reported from Southeastern France were obtained from Italians living in this region. Only one of the clustered GB sequences was documented in Estonia. Three of our 2c sequences were detected in Buenos Aires/C.A.B.A. and two in Tucumán (approximately 1200 km from C.A.B.A.).

When blasted with GB sequences, the single sequence assigned to HCV-2j clustered with those from Canada, France, and Spain, showing the high heterogeneity among the HCV-2j sequences analyzed.

Regarding the single HCV-3a local sequence, similarities were found with one sequence from Canada and another one from France, and with an additional group of five sequences reported in Argentina.

## DISCUSSION

Here we report a very low prevalence of HCV infection (0.32%) in a large cohort of random volunteers from Argentina, contrasting with the 2% prevalence previously reported in studies based on selected populations in small communities, or even higher rates among highly vulnerable groups<sup>[12,29]</sup> (Hepatitis C Argentinian Consensus, 2007). The observed prevalence is lower than that reported in neighboring countries, such as Brazil (1.5%), Uruguay (1%), and Chile (0.85%)<sup>[12]</sup>. The highest prevalence was detected in Buenos Aires province and C.A.B.A., both making up the region that received the greatest number of European immigrants, especially during the first half of the 20<sup>th</sup> century (70.38% of all immigrants, 20.8% residing in C.A.B.A.; <http://www.mininterior.gov.ar/poblacion/estadisticas.asp> Censo2001). In this regard, recent data shows that at present most of the European immigrants from Italy and Spain are over 60-year-old ([http://www.mininterior.gov.ar/provincias/archivos\\_prv25/6-%0Perfil\\_Migratorio\\_de\\_la\\_Argentina.pdf](http://www.mininterior.gov.ar/provincias/archivos_prv25/6-%0Perfil_Migratorio_de_la_Argentina.pdf)).

The HCV isolates studied here did not form a close national cluster separate from the GB sequences. Interestingly, genetic divergence and phylogenetic analyses showed a different profile depending on the subtype analyzed. In this sense, the HCV-1a samples, detected from subjects residing in distantly placed cities/towns (hundreds of kilometers apart from each other) from three provinces, made up a highly homogeneous population, whereas the HCV-1b and HCV-2c samples were more heterogeneous, suggesting a different profile of epidemiological origin/transmission of infection for each subtype. The high homogeneity of subtype 1a and its similarity with sequences reported from United States suggest that HCV-1a was introduced in Argentina by a common infectious source from this geographic area. This finding agrees with the model of recent HCV genotype diversification in Central and South America<sup>[30-32]</sup>

compared with other continents. HCV-1b isolates formed separate clusters that were most similar to European sequences, suggesting multiple focal transmission events, likely with independent geographical origins. Interestingly, the subject whose HCV isolate showed an HCV-1b phylogenetic relationship with a Russian HCV-1b sequence stated such ethnicity. HCV-2c represents an important contribution to Argentinian HCV epidemiology (at least, 25% in this study), supporting previous observations (23%)<sup>[15]</sup>. Most of the 2c isolates clustered close to sequences reported from Italy and Southern France. In general, the 2c sequences deposited in GB represent a highly heterogeneous population with huge genetic diversity in Ghana, Guinea, Benin, and Burkina Faso in Africa<sup>[33]</sup>, suggesting that HCV-2c has long been present in human populations, especially in these parts of Africa, and that it spread to Egypt, Europe and elsewhere in the 20<sup>th</sup> century<sup>[34]</sup>. It has been proposed that the introduction of HCV-2c in Italy was a consequence of close contacts between native Africans and soldiers and colonials during the colonial wars in 1882-1896 and 1911-1912<sup>[35,36]</sup>. A high prevalence of HCV-2c was observed among individuals in Italy<sup>[37-40]</sup> and Southern France, all related with Italian immigrants<sup>[41]</sup>. Coincidentally, a substantial percentage of the Buenos Aires population descends from Italian immigrants that arrived in the 20<sup>th</sup> century. Taken together, our results suggest that the introduction of HCV-2c in Argentina may have been the result of a multiple event, likely related to waves of Italian immigration. In this regard, it is worth mentioning that a high prevalence (approximately 50%) of this genotype has been reported among chronic HCV patients from Córdoba province<sup>[19,20,29]</sup>, as compared with data from Buenos Aires and C.A.B.A. patients<sup>[15]</sup> and even higher rates (90%) from patients residing in Cruz del Eje, a small rural town located in the Northern region of Córdoba province, where HCV prevalence was reported to be 5%<sup>[29]</sup>. In contrast, the present study could not detect the circulation of such genotype from the general population studied in the city of Córdoba (encompassing the whole group from the homonymous province). Several hypothetical factors might have contributed to the observed discrepancy, among them, it seems worth mentioning: (1) the previously reported overall low prevalence of infection in the city of Córdoba<sup>[29]</sup> and in this study; (2) the lower contribution of HCV-2c to the total HCV genotype prevalence in such capital city located in the central region of the province, as compared with Cruz del Eje<sup>[20,29]</sup>; (3) the dissimilar nature of studied groups (patients versus general population), hence showing a dissimilar HCV infection prevalence, and consequently having lower probability to pick up HCV positive samples; and (4) the mean age  $\pm$  SE of all the analyzed populations ( $49.77 \pm 2.15$  for patients from Córdoba and other locations of Córdoba Province ( $n = 26$ )<sup>[29]</sup>,  $66.15 \pm 1.52$  years for patients from Cruz del Eje ( $n = 49$ )<sup>[29]</sup>, as compared with  $37.1 \pm 0.4$  in this study (SD = 12.5; median age = 35 years;  $n = 668$ ). However, the last mentioned factor failed to reach statis-

tical significance when the one way analysis of variance was carried out ( $P = 0.1177$ ).

The recorded HCV-3a sequence exhibited similarities with isolates from France and Canada and other Argentinian isolates, in concordance with a more recent, worldwide expansion of this subtype<sup>[22]</sup>. The HCV-2j sequence showed similarities with French, Canadian, and Spanish HCV sequences. No other genotypes (4, 5 or 6) were detected in the Argentine general population studied.

In conclusion, NS5B analysis allowed an accurate classification of subtypes and enabled to perform the study of the evolution and origin of HCV infection. Here, we report a very low prevalence of HCV in the Argentine general population (0.32%). Phylogenetic analysis suggests diverse profiles of epidemiological expansion of HCV in Argentina: HCV-1a might have occurred from a putative common source, whereas HCV-1b and HCV-2c might have been introduced into the country following fluxes of immigration from other endemic areas, especially from Europe. The significantly high number of HCV-2c sequences compared to the reported data from neighboring countries may be the consequence of the high percentage of Italians migrating to Argentina from an area where such subtype was (and still is) highly prevalent. Argentina is a good example of how human practices, together with global expansion and human migration flows, have increased the HCV spread over the world. Adherence to standard universal precautions to avoid transmission should be strictly followed even in countries with a low prevalence of HCV.

## ACKNOWLEDGMENTS

We are indebted to Claudio Cenetrari, Darío Ciocale, Guillermo Colazo, Patricia Chenio, Maximiliano Gomes, Marina de los Santos, Luciana Novoa and the Fresenius Medical Care Centre for providing the blood samples. We thank both Celine Cavallo and Victoria Illas for English language support and helpful suggestions.

## COMMENTS

### Background

Hepatitis C virus (HCV) is a leading cause of chronic liver disease. HCV is distributed globally, affecting all countries with an estimated worldwide prevalence of 2.3% (approximately 160 million people) of the whole general population. Comparisons of HCV nucleotide sequences derived from individuals from different geographical regions revealed the circulation of at least six major HCV genotypes and more than 50 subtypes. Accurate HCV genotyping in chronically infected patients is crucial not only for epidemiological studies but also from a clinical standpoint, since the HCV genotype orientates the treatment strategy.

### Research frontiers

Direct sequencing, also referred as "population" sequencing, is the gold standard for HCV genomic sequence analysis. The viral genome region(s) sequenced must be carefully chosen, because not all of them provide accurate typing and subtyping. Since genotyping methods based on the exclusive analysis of the 5'NCR may lead to up to 10% mistyped results, there is a need to extend the analysis to coding regions such as NS5B or core. In this regard, the knowledge of the implicated HCV genotype in each patient contributes to select the appropriate treatment. Those infected with HCV genotype 1 must be treated with a triple combination of pegylated interferon- $\alpha$  (IFN- $\alpha$ ), ribavirin and either

telaprevir or boceprevir, whereas patients infected with other genotypes must still be treated with pegylated IFN- $\alpha$  and ribavirin alone. Moreover, HCV genotyping based on phylogenetic analysis, and - in case a representative sampling of a given (sub)genotype is obtained from an area - Monte Carlo Markov Chains Bayesian coalescent analysis may respectively lead to trace the origin and if such condition is met - the putative date of the Most Recent Common Ancestor of sequences.

### Innovations and breakthroughs

This is a molecular epidemiological study performed in a large cohort of the local general population from 12 out of 23 Argentine provinces, as well as from the Autonomous city of Buenos Aires (the national capital). Unexpectedly, it shows a low prevalence of HCV (about 0.32%) in a general population cohort which included 6251 individuals. This low prevalence suggests that HCV could have been "recently" introduced in Argentina, as proposed by coalescent studies performed in restricted local areas of this country by other authors, where a predominant (sub)genotype was found, allowing such analysis. HCV subtypes were distributed as follows: 1a (25%), 1b (25%), 2c (25%), 3a (5%), and 2j (5%). HCV-1a sequences comprised a highly homogeneous population and clustered with United States sequences. HCV-1b sequences represented a heterogeneous population, suggesting that this genotype might have been introduced from different sources. Most HCV-2c sequences clustered close to the 2c reported from Italy and Southern France. Phylogenetic analysis is used by the authors to trace the putative source of HCV transmission and suggests that introduction of local HCV in this country is a consequence of multiple events that differed for each subtype studied. Diverse epidemiological patterns of HCV spread in Argentina might have occurred.

### Applications

These new data could be useful to implement suitable measures regarding HCV surveillance by Argentine Public Health authorities.

### Terminology

HCV genotype: group of HCV variants assigned to a given genetic groups (1-6) which differs from others by 31%-33% at the nucleotide level. HCV subtype (sub-genotype): group of more closely related HCV variants assigned to a given genetic group which differs from others by 20%-25% at the nucleotide level (named with lower case letters: *i.e.*, a, b, c, *etc.*).

### Peer review

This is a very well done and written molecular epidemiological study which considers the investigation of the prevalence of HCV infection and subtype frequencies among adults in Argentina. It should be underlined that authors have investigated a large amount of general population from 12 provinces representing all the geographical regions of the country.

### Abstract

**AIM:** To investigate whether transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) signaling pathway is involved in the pathogenesis of primary biliary cirrhosis (PBC).

**METHODS:** A murine model of PBC was developed by injection of polyinosinic polycytidylic acids (poly I : C) in C57BL/6 mice, and the liver expressions of TGF  $\beta$ 1, TGF- $\beta$  receptor I (T $\beta$ R I), TGF- $\beta$  receptor II (T $\beta$ R II), p-Smad2/3, monoclonal  $\alpha$ -smooth muscle actin antibody ( $\alpha$ -SMA) and  $\alpha$ 1 (I) collagen in the mouse model and control mice were evaluated by immunohistochemistry, immunoblotting and real-time polymerase chain reaction (RT-PCR). Lymphocyte subsets in liver were analyzed using flow cytometry.

**RESULTS:** The mouse model had several key phenotypic features of human PBC, including elevated levels of alkaline phosphatase, antimitochondrial antibodies, portal bile ducts inflammation, and progressive collagen deposition. Compared with control mice, protein and mRNA levels of TGF  $\beta$ 1, T $\beta$ R I, T $\beta$ R II, p-Smad2/3,  $\alpha$ -SMA and  $\alpha$ 1 (I) collagen in liver ( $1.7 \pm 0.4$  vs  $8.9 \pm 1.8$ ,  $0.8 \pm 0.2$  vs  $5.1 \pm 1.5$ ,  $0.6 \pm 0.01$  vs  $5.1 \pm 0.1$ ,  $0.6 \pm 0.3$  vs  $2.0 \pm 0.3$ ,  $0.9 \pm 0.4$  vs  $3.4 \pm 0.6$ ,  $0.8 \pm 0.4$  vs  $1.7 \pm 0.3$ ,  $1.1 \pm 1.2$  vs  $11.8 \pm 0.6$ ,  $P < 0.05$ ), and the total number and percentage of CD4<sup>+</sup> CD25<sup>+</sup> FOXP3<sup>+</sup> and CD8<sup>+</sup> lymphocytes ( $0.01 \pm 0.001$  vs  $0.004 \pm 0.00$ ,  $0.12 \pm 0.04$  vs  $0.52 \pm 0.23$ ,  $P < 0.01$ ) were higher in the mouse model.

**CONCLUSION:** TGF $\beta$ 1 might play a dual role in the development of PBC: it suppresses inflammatory response but operates to enhance fibrogenesis. The aberrant activity of TGF- $\beta$ 1 signaling contributes to the development of PBC.

**Key words:** Primary biliary cirrhosis; Transforming growth factor- $\beta$ 1; Regulatory T cell; Liver

**Core tip:** Primary biliary cirrhosis (PBC) is an autoimmune liver disease. Recent studies suggest that transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) signaling pathway might play an important role in the pathogenesis of PBC. However, whether TGF- $\beta$ 1 signaling pathway is involved in the development of PBC is still unknown. The studies have provided new data of TGF- $\beta$ 1 signaling pathway involving the pathogenesis of PBC, which will pose significant impact on our understanding of the pathogenesis of PBC. TGF- $\beta$ 1 signaling pathway is a potential target for PBC treatment.

Liu B, Zhang X, Zhang FC, Zong JB, Zhang W, Zhao Y. Aberrant TGF- $\beta$ 1 signaling contributes to the development of primary

biliary cirrhosis in murine model. *World J Gastroenterol* 2013; 19(35): 5828-5836 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5828.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5828>

## INTRODUCTION

Primary biliary cirrhosis (PBC) is a progressive autoimmune liver disease characterized by portal inflammation and immune-mediated destruction of the intrahepatic bile ducts. Damage of bile ducts is associated with cholestasis, and eventually leads to liver failure<sup>[1]</sup>.

Cytokines are involved in cell-to-cell interaction *via* specific receptors, inflammatory response amplification, immune regulation and fibrogenesis. Transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) is a prominent antiproliferative and profibrogenic cytokine that signals through TGF- $\beta$  receptor II (T $\beta$ R II), and receptor I (T $\beta$ R I), that in turn phosphorylate Smads at the mad homology 2 domain<sup>[2]</sup>. Perturbation of TGF- $\beta$ 1 signaling has been implicated in several developmental disorders and in various human diseases including cancer, fibrosis and autoimmune disease<sup>[3-5]</sup>. Mice transgenic of a dominant negative form of T $\beta$ R II, under the CD4 promoter lacking the CD8 silencer<sup>[6]</sup>, spontaneously developed features characteristic of PBC<sup>[7]</sup>. A compromised cytoarchitecture and polarized trafficking of TGF- $\beta$ 1 signaling molecules including embryonic liver fodrin and Smad3 were also noted in the pathogenesis of PBC<sup>[8]</sup>. Moreover, TGF- $\beta$ 1 was a marker for fibrosis and reflected severity of disease in patients with PBC<sup>[9,10]</sup>. Therefore, aberrant TGF- $\beta$ 1 signaling contributes to a loss of self tolerance to autoantigens in the liver, which in turn leads to autoimmunity.

We developed an animal model of PBC by polyinosinic polycytidylic acids (poly I : C) injection in genetically susceptible C57BL/6 female mice that would allow the analysis of the early cellular events of PBC<sup>[11,12]</sup>. We found that TGF $\beta$ 1 played a dual role in the development of PBC: it suppressed inflammatory response but operated to enhance fibrogenesis. The aberrant TGF- $\beta$ 1 signaling contributed to the development of PBC.

## MATERIALS AND METHODS

### PBC animal model

Adult 6-8 wk-old C57BL/6J (H-2b) mice were purchased from Institute of Laboratory Animal Sciences, Chinese Academy of Medical Sciences (CAMS) and Peking Union Medical College (PUMC, Beijing, China). They were maintained separately at the Department of Laboratory Animal, Peking Union Medical College Hospital (PUMCH), China, under controlled conditions (22 °C, 55% humidity, and 12 h day/night). All animals received adequate care according to good laboratory practice guidelines. The study protocol was approved by Committee of Animal Experimentation, PUMCH and CAMS. Female C57BL/6 mice were injected with 5 mg/kg

poly I : C (Invivogen Co. San Diego, United States) or normal saline (NS) as controls twice a week for 24 consecutive weeks, according to the protocol of Okada<sup>[11]</sup>.

At weeks 8 and 24, six mice of each group were sacrificed by cervical dislocation. Livers were fixed in buffered formalin (10%). Sera and tissue specimens were stored at -80 °C. The serum levels of alkaline phosphatase (ALP) and alanine amino-transferase (ALT) were measured by commercially available kit (WAKO Pure Chemical Industry, Osaka, Japan) exactly according to the manufacturer's protocol.

### Antimitochondrial antibodies detection

Antimitochondrial antibodies (AMA) and M2 were detected by the commercial immunofluorescence (IF), enzyme-linked immunosorbent assay (ELISA) kits (EU-ROIMMUN, Germany) and immunoblotting kits (IMTEC Corporation, Germany), according to the manufacturer's protocol. Fluorescein isothiocyanate (FITC) or horseradish peroxidase (HRP)-conjugated monoclonal goat anti-mouse IgM or IgG (Jackson ImmunoResearch Laboratories, West Grove, PA, United States) was used as the secondary antibody. Plates were read at 450 nm with a microplate reader (Bio-RAD Model 550, Tokyo, Japan). Sera with optical density (OD) values greater than the mean  $\pm$  2SD from the negative controls were regarded as AMA positive.

### Histopathology

Formalin-fixed, paraffin-embedded tissue sections were cut into 5  $\mu$ m slices for routine hematoxylin and eosin staining. Tissues were also stained with Azan to detect collagen deposition<sup>[13]</sup>. Briefly, sections were deparaffinized in xylene, dehydrated, rehydrated in distilled water, immersed in 5% potassium dichromate solution for 30 min, and stained with azocarmine G for 30 min. Sections were then immersed in 3% 12 tungsto (IV) phosphoric acid n-hydrate solution for 1 h and stained with aniline blue-orange G for 20 min.

### Immunohistochemistry

Antibodies against CD4 (1/200; L3T4, eBioscience) and CD8 (1/100; 53-6.7; Biolegend) were used for immunohistochemical staining of the portal tract infiltrates. Anticytokeratin 7 (1/50; RCK 105; BD Bioscience, San Jose, CA, United States) was used to detect biliary cell. Antibodies against TGF- $\beta$ 1 (1/200; V), T $\beta$ R I (1/200; T-19), T $\beta$ R II (1/200; C-16), p-Smad2/3 (1:50; Ser 433/435) (all obtained from Santa Cruz Biotechnology, Dallas, Texas, United States) and monoclonal  $\alpha$ -smooth muscle actin antibody ( $\alpha$ -SMA, 1:250; 1-4A; Sigma, St. Louis, MO, United States) were used to detect the expressions of TGF- $\beta$ 1 signaling proteins. Briefly, after deparaffinization, sections were incubated in a Decloaking Chamber (Biocare Medical, CA, United States) set point: SP1 123 °C for 2 min, SP2 85 °C for 10 s, SP limit 10 °C, soaked in 3% H<sub>2</sub>O<sub>2</sub> methanol solution for 5 min, then 15 min in 1  $\times$  Universal blocking solution (Bio-Genex, CA, United States) and

TGF: Transforming growth factor; T $\beta$ R: TGF- $\beta$  receptor; SMA: Smooth muscle actin; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

20 min in 10% goat serum to prevent nonspecific staining. After that, sections were incubated with primary antibodies for 1 h at room temperature in a moist chamber. After three washes with 0.1% Tween 20 in PBS (PBST) for 5 min, Envision<sup>TM</sup> (DakoCytomation, Glostrup, Denmark) was applied according to the procedure and counterstained with Mayer's hematoxylin (DakoCytomation) or DAPI (4',6-diamidino-2-phenylindole 2HCl, D9542, Sigma).

### Western blotting

Liver tissue was homogenized in an Ultra-Turrax homogenizer in RIPA buffer containing 1 mmol/L PMSF and protease inhibitors. After high-speed (12700 g) centrifugation at 4 °C, the protein in the supernatant was separated by 10% SDS-PAGE (20  $\mu$ g per lane), and transferred onto a PVDF membrane. After blocking with 1.5% bovine serum albumin (BSA) in Tris-buffered saline, TGF- $\beta$ 1, T $\beta$ R I, T $\beta$ R II, p-Smad2/3,  $\alpha$ -SMA and  $\alpha$ 1 (I) collagen were detected using rabbit polyclonal antibodies against TGF- $\beta$ 1 (1:1000), T $\beta$ R I (1:1000), T $\beta$ R II (1:1000), p-Smad2/3 (1:2000),  $\alpha$ 1 (I) collagen (1:2000), and  $\alpha$ -SMA (1:400), respectively, and then incubated with anti-rabbit and mouse IgG HRP conjugated (Promega, Madison, WI, United States). Specific binding was detected using the Super Signal West Dura Extended Duration Substrate (PIERCE, Rockford, IL, United States) with a FluorTech 8800 gel doc system (Alpha Innotech, CA, United States) equipped with a chemiluminescent filter.

### Real-time PCR

Total RNA was isolated using TRI-Reagent (Sigma). Real-time PCR was carried out as described<sup>[14]</sup>. DNase I-treated total RNA (1  $\mu$ g) was used for synthesis of the first strand of cDNA. Reverse transcription conditions were as follows: 42 °C for 15 min, 95 °C for 5 min and 5 °C for 5 min (one cycle). Real-time PCR was carried out in 25  $\mu$ L of reaction solution (2.5  $\mu$ L of 10  $\times$  buffer, 5 mmol/L of each dNTP, 10 mmol/L MgCl<sub>2</sub>, 200 nmol/L primers and 0.75 unit of platinum<sup>®</sup> Taq polymerase; all from Invitrogen) plus 1  $\mu$ L of SYBR Green (1:2000; BioWhittaker, Richland, ME, United States). No genomic DNA contamination or pseudogenes were detected by PCR in the absence of the reverse transcription step in

the total RNA used. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an invariant control. The reactions started at 95 °C for 7 min, followed by 40 cycles of 95 °C for 20 s, 54 °C for 30 s and 72 °C for 30 s. Melting peaks of PCR products were determined by heat denaturation from 60 to 95 °C at 0.2 °C/s. Fold changes in the mRNA levels of target genes relative to the endogenous GAPDH control were calculated as suggested by Schmittgen *et al.*<sup>[15]</sup>. Table 1 lists the primers used in real-time PCR.

Real-time PCR was performed for quantitative analyses according to standard protocol using the SYBR Green PCR Master Mix and ABI PRISM 7900 Sequence Detection System (Applied Biosystems, Tokyo, Japan).

### Flow cytometry

Livers were first perfused with PBS containing 0.2% BSA, passed through a nylon mesh, and resuspended in PBS/0.2% BSA (EMD chemicals, Gibbstown, NJ, United States). Hepatocytes were removed as pellets after centrifugation at 700 r/min for 60 s periods<sup>[16]</sup>. Lymphocytes from suspended liver cells were then isolated using Histopaque-1077 (Sigma Chemical Co. St. Louis, MO, United States). After centrifugation, cells were washed with PBS/0.2% BSA, and the viability of cells confirmed by trypan blue dye (Sigma Chemical Co. St. Louis, MO, United States) exclusion. Cell preparations were then pre-incubated with anti-mouse FcR blocking reagent and then incubated at 4 °C with a combination of fluorochrome-conjugated antibodies, including anti-CD4 FITC, anti-CD25 APC, anti-CD8 PECy5, anti-Foxp3 PE (all from eBioscience CA, United States). Multiple-color flow analyses were performed using a FACScan flow cytometer upregulated by Cytec Development (Fremont, CA, United States) to allow for 4-color analysis. Acquired data were analyzed with CELLQUEST Software (BD Biosciences CA, United States) and FlowJo Software (Tree star, Inc., Ashland, OR, United States).

### Statistical analysis

Results are expressed as mean  $\pm$  SD and were evaluated using Mann-Whitney *U* tests for comparison between samples from mouse model and littermates, with *P* < 0.05 considered significant.

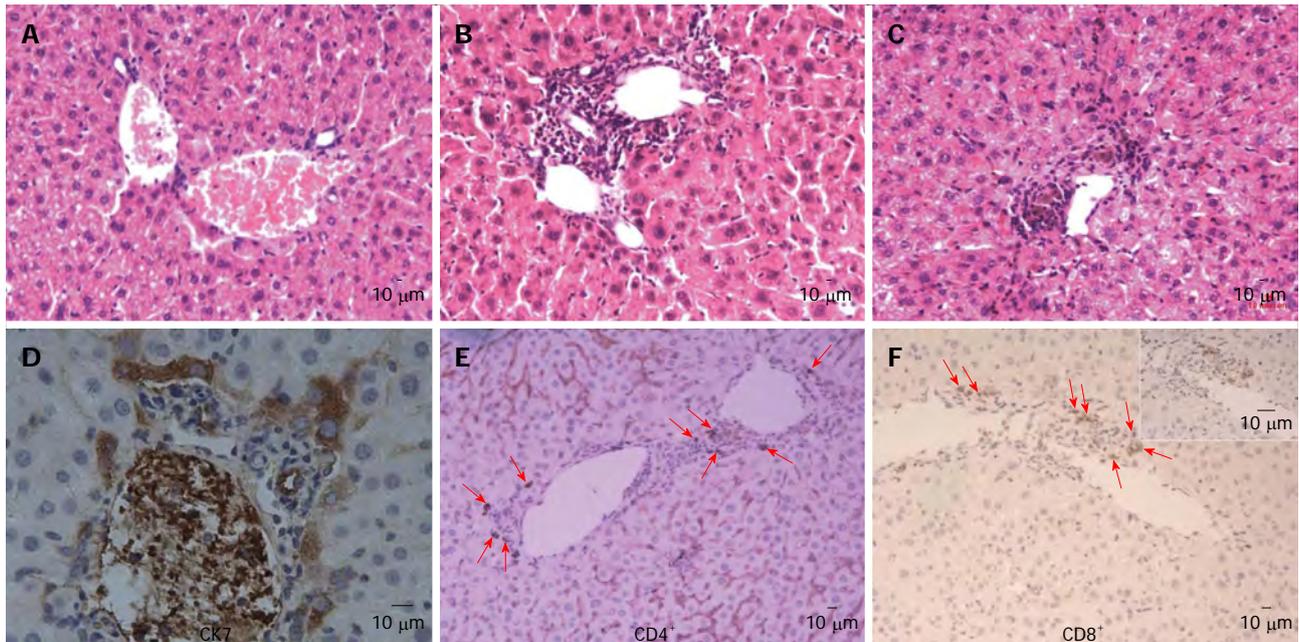

Figure 1 Histological features of the liver. A: Control mice; B-F: Mice model; B: Lymphocytic infiltration (red arrows) around the small bile ducts within the portal tracts at week 8; C: Bile plugs were seen in canaliculi at week 24; D: CK-7 expression in periportal proliferated bile ductile and intralobular hepatocytes; E: CD4<sup>+</sup> lymphocytes infiltration; F: CD8<sup>+</sup> lymphocytes infiltration (bar 10  $\mu$ m).

## RESULTS

### Histological features in Poly I : C induced animal model

The serum levels of ALT, ALP and total bilirubin in the mouse model were higher than in the control mice ( $105.5 \pm 36.9$  IU/L *vs*  $28.2 \pm 2.9$  IU/L,  $P = 0.006$ ;  $138.2 \pm 15.3$  IU/L *vs*  $74.8 \pm 18.5$  IU/L,  $P = 0.025$ ; and  $2.8 \pm 0.4$  mg/dL *vs*  $0.95 \pm 0.12$  mg/dL,  $P = 0.043$ ). Mouse model displayed an increase AMA titer over time. By week 24, serum samples of the six mouse models were all positive for AMA/M<sub>2</sub>. In the mouse model, the mean titer of anti-M<sub>2</sub> was significantly higher at week 24 than at week 8 ( $P < 0.0005$ ), while in the control mice AMA/M<sub>2</sub> was not detected. The time table of AMA in the mouse model resembled that in human PBC, of which the disease is not observed in childhood and typically develops in the fourth or fifth decade of life.

In the liver of the mouse model, moderate to severe infiltration of lymphoid cells was detected within the portal tracts in association with bile duct damage and a mild interface hepatitis (piecemeal necrosis) at week 8 (Figure 1B) and bile plugs were seen in canaliculi around portal tracts at week 24 (Figure 1C), which was absent in control mice (Figure 1A). Direct bile duct destruction was determined by the detection of scattered portal infiltration of CK-7 positive cells. Moreover, in liver tissues from some mice models, biliary cell destruction was so severe that identification of an intact bile duct structure was impossible and all biliary-type and hepatocytes were CK-7 positive, particularly in samples with cholestasis (Figure 1D). Immunohistochemical analysis demonstrated infiltration of CD4<sup>+</sup> and CD8<sup>+</sup> lymphocytes around small bile ducts that were absent in control mice (Figure 1E and F).

### In situ detection of TGF $\beta$ 1, T $\beta$ R I, T $\beta$ R II, p-Smad2/3, $\alpha$ -SMA and $\alpha$ 1 (I) collagen in liver

In mouse model, expression of TGF  $\beta$ 1 in periportal and intralobular regions became more prominent over time (Figure 2A-D). At week 8, there were positive expressions of T $\beta$ R I and T $\beta$ R II in some periportal hepatocytes and biliary ductile endothelial cells (Figure 2E-H). At week 24, distribution of T $\beta$ R I and T $\beta$ R II became more extensive and prominent (Figure 2F and I).

In mouse model, intranuclear staining of p-Smad2/3 was observed in some periportal and intralobular hepatocytes at week 8, and became more prominent at week 24 (Figure 3A-C),  $\alpha$ -SMA positive staining and collagen deposition around portal areas were observed at week 8 (Figure 3E and H), and extension into surrounding parenchyma at week 24 (Figure 3F and I), which was absent in the liver of control mice (Figure 3D and G).

### Immunoblot of TGF $\beta$ 1, T $\beta$ R I, T $\beta$ R II, p-Smad2/3, $\alpha$ -SMA and $\alpha$ 1 (I) collagen

Immunoblot analysis of TGF- $\beta$ 1, T $\beta$ R I, T $\beta$ R II, p-Smad2/3,  $\alpha$ -SMA and  $\alpha$ 1 (I) collagen of the liver homogenates from mouse model and control mice at week 8 and 24 is shown in Figure 4. Compared with that from control mice, there were increasing expressions of TGF- $\beta$ 1, T $\beta$ R I, T $\beta$ R II, p-Smad2/3,  $\alpha$ -SMA and  $\alpha$ 1 (I) collagen of the liver homogenates from mouse model as time increased.

### Real-time PCR of TGF $\beta$ 1, T $\beta$ R I, T $\beta$ R II, Smad2/3, $\alpha$ -SMA and $\alpha$ 1 (I) collagen

As shown in Table 2, the mRNA levels of TGF- $\beta$ 1, T $\beta$ R I, T $\beta$ R II, Smad2, Smad3,  $\alpha$ -SMA and  $\alpha$ 1 (I) collagen

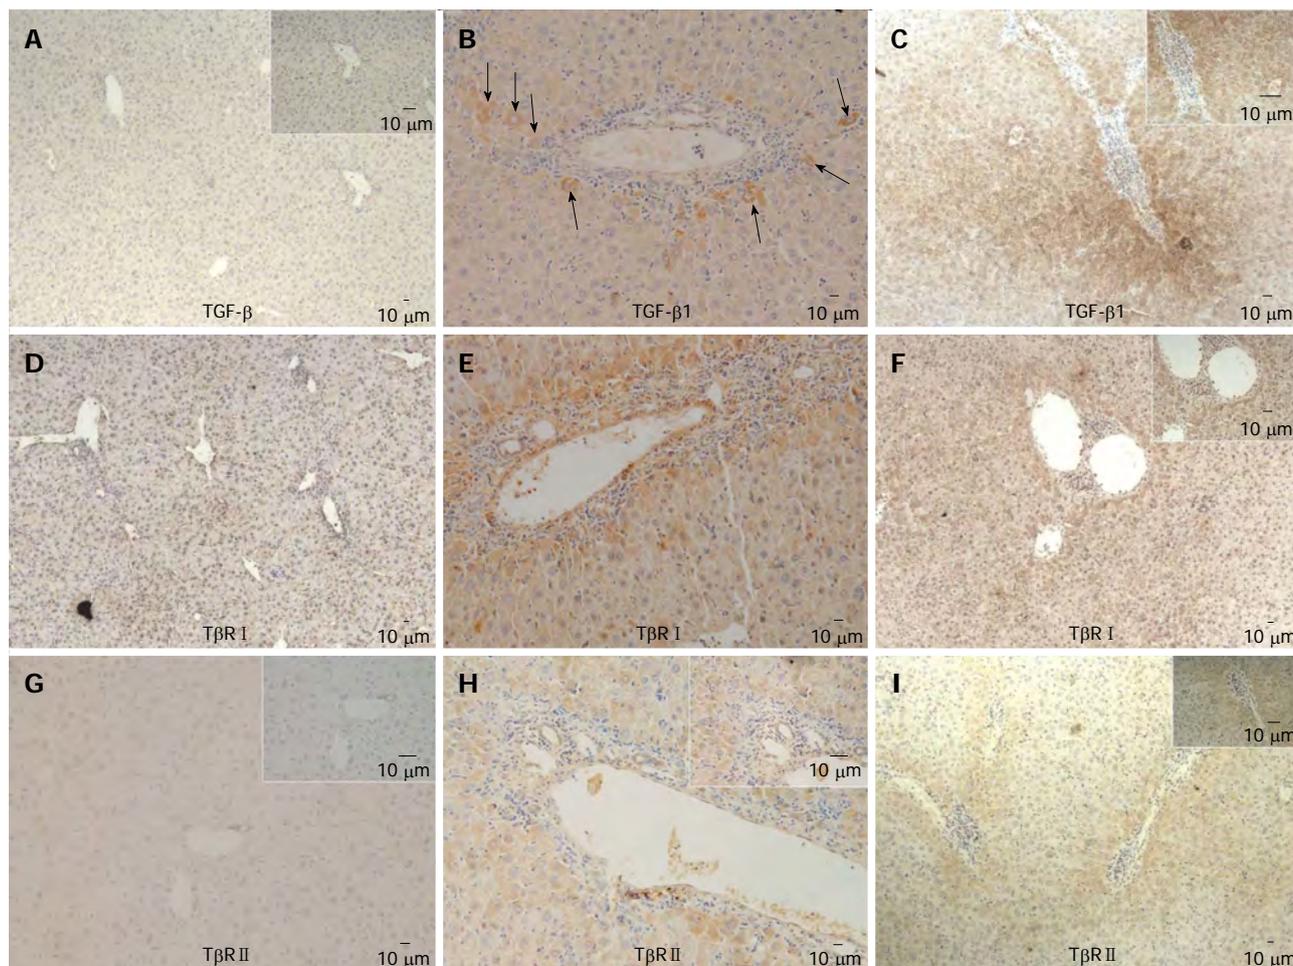

Figure 2 Expressions of transforming growth factor- $\beta$ 1, transforming growth factor- $\beta$  receptor I, transforming growth factor- $\beta$  receptor II in liver. of liver homogenates from mouse model at weeks 8 and 24 were higher than that from control mice.

**Flow cytometric analysis of lymphocyte subsets in liver**  
After poly I : C injection, the total numbers of lympho-

cytes significantly increased in the liver of mouse model (Table 3). Although the total number of intrahepatic CD4<sup>+</sup> lymphocytes increased, the percentage of CD4<sup>+</sup> cells in the lymphocytes did not (Figure 5). In contrast, the CD8<sup>+</sup> population in mouse model significantly increased in both total number and percentage compared with that in controls (Figure 5). In addition, the mouse model had a marked increase in the number as well as percentage of CD4<sup>+</sup> CD25<sup>+</sup> FOXP3<sup>+</sup> lymphocytes compared with control mice (Table 3 and Figure 5). This finding is particularly interesting, as previous studies reported a decrease in precursors of CD4<sup>+</sup> CD25<sup>+</sup> regulatory T cells (Treg) in the peripheral blood of PBC patients<sup>[7,17,18]</sup>, and several recent reports demonstrated increased infiltration of FOXP3<sup>+</sup> Treg in damaged organ or target tissues in autoimmune diseases<sup>[19-21]</sup>.

## DISCUSSION

Our study demonstrated that this mouse model mimic several key phenotypic features of human PBC. It had elevated levels of ALP, AMA, portal bile ducts inflammation, and progressive collagen deposition. In human PBC, there is a ten-fold increase in frequency of CD8<sup>+</sup>

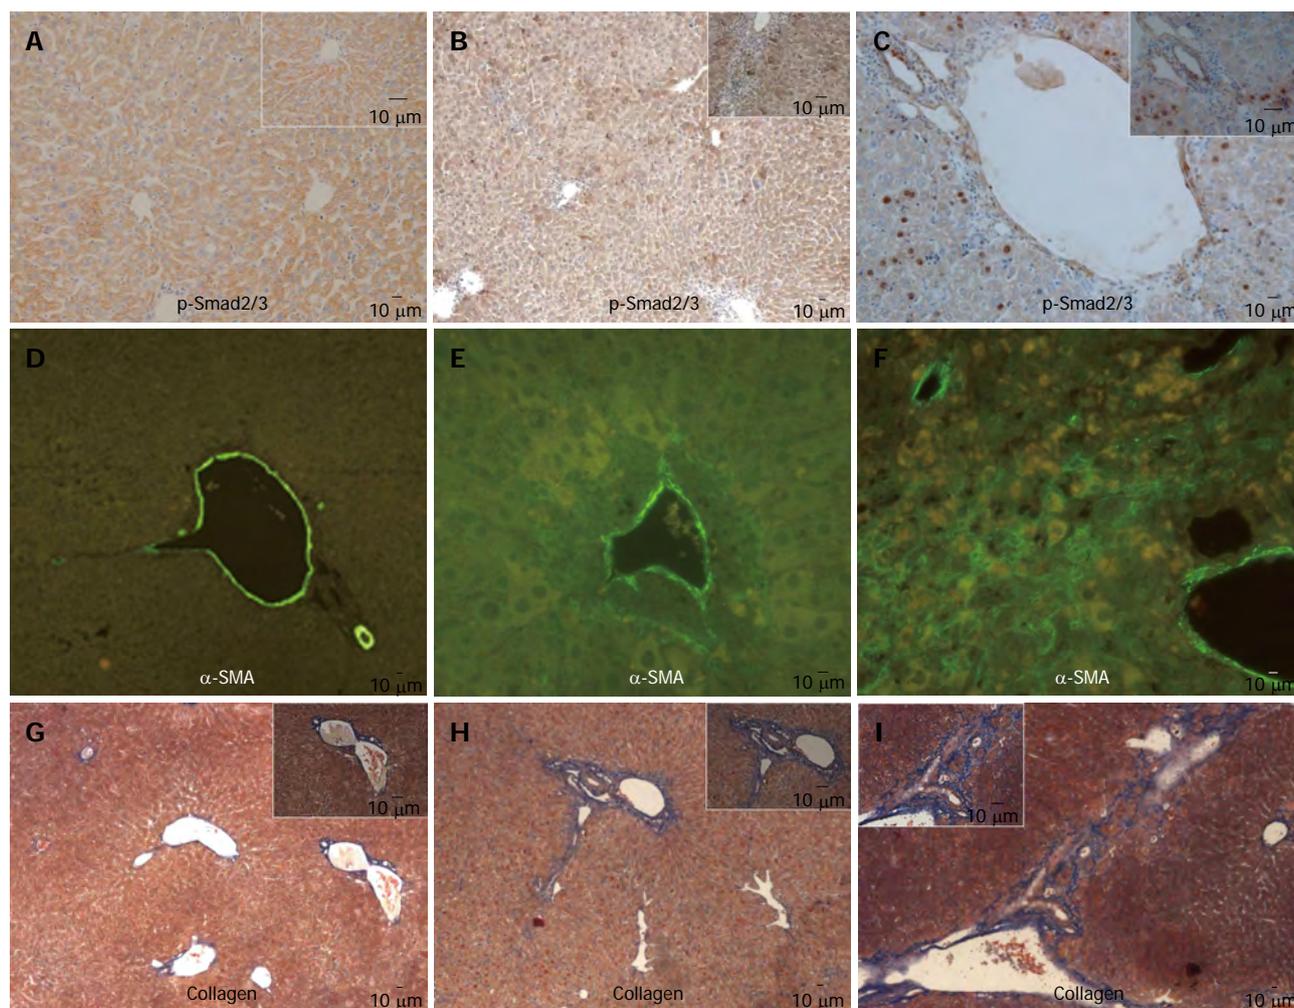

Figure 3 Expression of p-Smad2/3,  $\alpha$ -smooth muscle actin antibody and collagen in liver. A, D and G: Control mice; B, C, E, F, H and I: Mouse model. A-C: p-Smad2/3 expression; D-F:  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA) antibody expression; G-I: Collagen expression (bar 10  $\mu$ m).

**Table 3** Phenotype of mononuclear cells in the liver

	Mouse model	Control mice
Total cell number ( $\times 10^6$ )	$1.6 \pm 0.47^a$	$0.48 \pm 0.32$
CD4 <sup>+</sup> ( $\times 10^6$ )	$0.06 \pm 0.01$	$0.04 \pm 0.01$
CD8 <sup>+</sup> ( $\times 10^6$ )	$0.58 \pm 0.11^a$	$0.08 \pm 0.03$
CD4 <sup>+</sup> /CD8 <sup>+</sup>	$0.12 \pm 0.04^a$	$0.52 \pm 0.23$
CD4 <sup>+</sup> CD25 <sup>+</sup> FOXP3 <sup>+</sup> ( $\times 10^6$ )	$0.01 \pm 0.001^b$	$0.004 \pm 0.001$

<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs control mice.

T cells specific for PDC-E2 in liver compared with that in peripheral blood, and it correlates with biliary ductular damage<sup>[18,22,23]</sup>. Interestingly, our mouse model also had increased CD8<sup>+</sup> lymphocyte infiltration in liver, which is consistent with the chronic autoimmune nature of the disease. CK-7 is regarded as a histological marker for progression in PBC and indicates poor prognosis<sup>[24]</sup>. Hepatocytes do not normally express CK-7 except in the advanced stage of PBC, which was also observed in our study. Taken together, this animal model had several key phenotypic features and would allow us to analyze the early cellular events of PBC.

TGF- $\beta$ 1 is the key regulator in the pathogenesis of hepatic fibrosis, and appears to aggregate in the liver of PBC patients<sup>[25,26]</sup>. The selective abnormality of the TGF- $\beta$ 1 signaling pathway in T lymphocytes leads to impairment to peripheral tolerance and spontaneously development of features characteristic of PBC<sup>[7]</sup>. TGF- $\beta$ 1 is an essential modulator of Foxp3 expression in Tregs cells<sup>[20]</sup>, conditioning their suppressive function. Recent studies have demonstrated reduction in the number of circulating Tregs in patients with PBC<sup>[21]</sup>. In addition, it is reported that the population of Tregs coexpressing Foxp3 and TGF- $\beta$ 1 decreases with age in female NOD mice<sup>[27]</sup>. Tregs produce elevated levels of TGF- $\beta$ 1, and the fact that TGF- $\beta$ 1 signaling receptors are up-regulated on the membrane of Tregs, underscores the potential for autocrine and/or paracrine receptor-ligand interaction in these cells. TGF- $\beta$ 1 is a positive regulator of Tregs expansion and inhibits autoimmune diseases *via* regulation of the size of Tregs pool *in vivo*<sup>[28]</sup>. Our study found elevated levels of TGF- $\beta$ 1 as well as the total number of CD4<sup>+</sup> CD25<sup>+</sup> FOXP3<sup>+</sup> Treg in the liver of mouse model, which seems different from some studies<sup>[29-31]</sup>. However, there were also several reports demonstrating increased

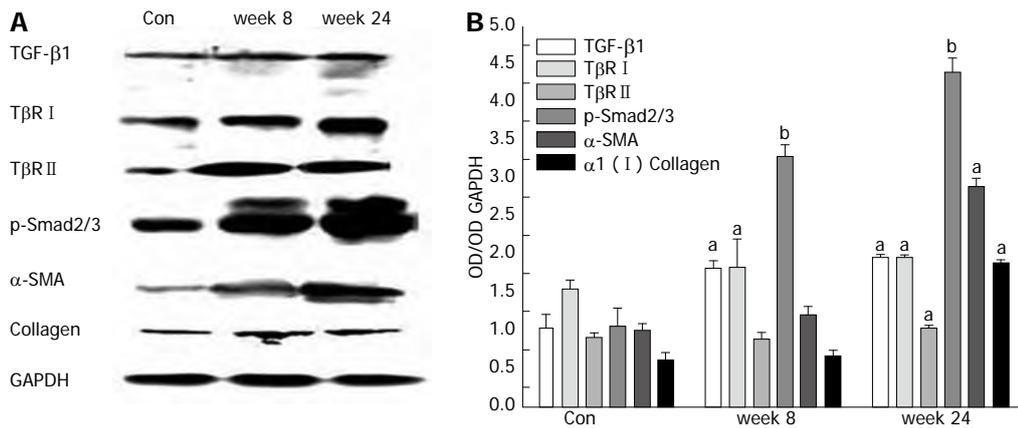

Figure 4 Immunoblot of transforming growth factor- $\beta$ 1, transforming growth factor- $\beta$  receptor I, transforming growth factor- $\beta$  receptor II, p-Smad2/3,  $\alpha$ -smooth muscle actin antibody and  $\alpha$ 1 (I) collagen. A: Western blotting analyses of transforming growth factor (TGF)- $\beta$ 1, TGF- $\beta$  receptor I (T $\beta$ R I), T $\beta$ R II, pSmad2/3,  $\alpha$ -smooth muscle actin (SMA) antibody and  $\alpha$ 1 (I) collagen expression of the liver homogenates. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was an internal control for equal loading ( $n = 6$ ); B: <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs control mice.

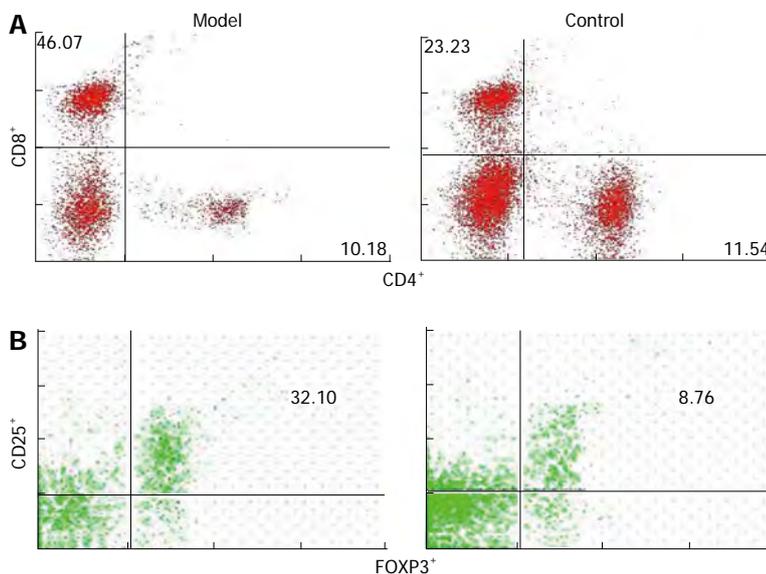

Figure 5 Lymphocytic subsets of the liver. A: The percentage of CD4<sup>+</sup> and CD8<sup>+</sup> cells in total lymphocytes population in liver; B: The percentage of CD25<sup>+</sup> FOXP3<sup>+</sup> in CD4<sup>+</sup> cells population in liver.

infiltration of FOXP3<sup>+</sup> Tregs in damaged organ or target tissues in autoimmune diseases, suggesting that suppressor cells migrate to and/or multiply at the sites of inflammation as part of immune response to combat injurious inflammation<sup>[19-21]</sup>, and in liver suppress hepatic immunity to autoantigens<sup>[32]</sup>. Taken together, our study illustrates that TGF- $\beta$ 1 regulation of FOXP3<sup>+</sup> Tregs may be involved in the maintenance of chronic inflammation in PBC.

TGF- $\beta$ 1 down-regulates potentially harmful inflammatory responses in the liver, albeit at the expense of scar formation<sup>[33]</sup>. TGF- $\beta$ 1 signaling could induce phosphorylation of Smad2 and Smad3, which translocate into the nucleus to regulate expressions of specific target genes such as  $\alpha$ 1 (I) collagen and  $\alpha$ -SMA<sup>[34]</sup>. Our study demonstrated that in the liver of mouse model, the levels of TGF $\beta$ 1 as well as T $\beta$ R I, T $\beta$ R II, p-Smad2/3,  $\alpha$ -SMA

and  $\alpha$ 1 (I) collagen increased with age. These findings revealed that TGF $\beta$ 1 may be involved in the fibrogenesis of the mice PBC model. Liver fibrosis occurs as a consequence of the differentiation of hepatic stellate cells (HSCs) into myofibroblasts, which is regulated by TGF $\beta$ 1<sup>[35]</sup>. Our study showed that the number of cells positive for  $\alpha$ -SMA, which is a marker for myofibroblast-like cells<sup>[36]</sup>, increased in aged mice in the animal model, which was coincident with increased expression of TGF $\beta$ 1 and its signal molecules, supporting the finding that TGF $\beta$ 1 signal pathway was involved in myofibroblast differentiation and subsequent liver fibrosis in the mouse PBC model.

In conclusion, although our data are derived from a murine model of PBC whose immunoregulation in PBC is likely to be far less complex than in human, the findings emphasize the role of TGF $\beta$ 1 in development of

PBC. TGF $\beta$ 1 plays a dual role in development of PBC: it suppresses inflammatory response but operates to enhance fibrogenesis. The aberrant activity of TGF- $\beta$ 1 signaling contributes to the development of PBC.

## ACKNOWLEDGMENTS

We thank Dr. Wei-Xun Zhou for the histological studies.

## COMMENTS

### Background

Primary biliary cirrhosis (PBC) is an autoimmune liver disease. Recent studies suggest that transforming growth factor (TGF)- $\beta$ 1 signaling pathway might play an important role in the pathogenesis of PBC. However, whether TGF- $\beta$ 1 signaling pathway is involved in the development of PBC is still unknown.

### Research frontiers

TGF- $\beta$ 1 plays an important role in autoimmunity and liver fibrosis, and a TGF- $\beta$ 1 receptor knockout mouse has been recently proposed as a model for PBC. There is strong experimental evidence that TGF- $\beta$ 1 is implicated in the pathogenesis of PBC, probably through deregulation of T-reg.

### Innovations and breakthroughs

An animal model of PBC was developed by polyinosinic polycytidylic acids (poly I :C) injection in genetically susceptible C57BL/6 female mice in this study. And the liver expressions of TGF- $\beta$ 1, TGF- $\beta$  receptor I (T $\beta$ R I), T $\beta$ R II, p-Smad2/3, monoclonal  $\alpha$ -smooth muscle actin antibody ( $\alpha$ -SMA) and  $\alpha$ 1(I) collagen in mouse model and control mice were evaluated. The relationship between TGF- $\beta$  and Treg was also analyzed. The study found that TGF $\beta$ 1 played a dual role in the development of PBC. The aberrant TGF- $\beta$ 1 signaling contributed to the development of PBC.

### Applications

This study has provided new data of TGF- $\beta$ 1 signaling pathway involving the pathogenesis of PBC, which will pose significant impact on the understanding of the pathogenesis of PBC. Moreover, the data is the novel result of the role of TGF- $\beta$ 1 in the development of PBC. TGF- $\beta$ 1 signaling pathway is a potential target for PBC treatment.

### Peer review

This paper finds that aberrant TGF- $\beta$ 1 signaling contributes to the development in PBC. Until now we do not have a good answer for the role of TGF- $\beta$ 1 signaling in PBC. These findings may be related to the immunological abnormalities of PBC while the role of TGF- $\beta$ 1 signaling needs further investigation.

### Abstract

**AIM:** To assess the safety and efficacy of *Aspergillus niger* prolyl endoprotease (AN-PEP) to mitigate the im-

munogenic effects of gluten in celiac patients.

**METHODS:** Patients with initial diagnosis of celiac disease as confirmed by positive serology with subtotal or total villous atrophy on duodenal biopsies who adhere to a strict gluten-free diet (GFD) resulting in normalised antibodies and mucosal healing classified as Marsh 0 or I were included. In a randomised double-blind placebo-controlled pilot study, patients consumed toast (approximately 7 g/d gluten) with AN-PEP for 2 wk (safety phase). After a 2-wk washout period with adherence of the usual GFD, 14 patients were randomised to gluten intake with either AN-PEP or placebo for 2 wk (efficacy phase). Measurements at baseline included complaints, quality-of-life, serum antibodies, immunophenotyping of T-cells and duodenal mucosa immunohistology. Furthermore, serum and quality of life questionnaires were collected during and after the safety, washout and efficacy phase. Duodenal biopsies were collected after the safety phase and after the efficacy phase. A change in histological evaluation according to the modified Marsh classification was the primary endpoint.

**RESULTS:** In total, 16 adults were enrolled in the study. No serious adverse events occurred during the trial and no patients withdrew during the trial. The mean score for the gastrointestinal subcategory of the celiac disease quality (CDQ) was relatively high throughout the study, indicating that AN-PEP was well tolerated. In the efficacy phase, the CDQ scores of patients consuming gluten with placebo or gluten with AN-PEP did not significantly deteriorate and moreover no differences between the groups were observed. During the efficacy phase, neither the placebo nor the AN-PEP group developed significant antibody titers. The IgA-EM concentrations remained negative in both groups. Two patients were excluded from entering the efficacy phase as their mucosa showed an increase of

two Marsh steps after the safety phase, yet with undetectable serum antibodies, while 14 patients were considered histologically stable on gluten with AN-PEP. Also after the efficacy phase, no significant deterioration was observed regarding immunohistological and flow cytometric evaluation in the group consuming placebo compared to the group receiving AN-PEP. Furthermore, IgA-tTG deposit staining increased after 2 wk of gluten compared to baseline in four out of seven patients on placebo. In the seven patients receiving AN-PEP, one patient showed increased and one showed decreased IgA-tTG deposits.

**CONCLUSION:** AN-PEP appears to be well tolerated. However, the primary endpoint was not met due to lack of clinical deterioration upon placebo, impeding an effect of AN-PEP.

Consumption of gluten with gluten-degrading enzyme by celiac patients: A pilot-study. *World J Gastroenterol* 2013; 19(35): 5837-5847 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5837.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5837>

## INTRODUCTION

Celiac disease (CD) is a major health care issue affecting people of all ages, with a worldwide prevalence of approximately 1%<sup>[1]</sup>. This immune-mediated small intestinal enteropathy is triggered by gluten proteins derived from wheat, barley and rye. Celiac disease is characterised by an inflammatory immune response, resulting in small-intestinal mucosal injury and malabsorption in genetically susceptible individuals<sup>[2]</sup>. Currently, the only safe and effective treatment is a strict gluten-free diet (GFD) combined with nutritional support, which improves the health and quality of life in the vast majority of patients<sup>[3]</sup>. However, a GFD is perceived as a substantial burden, particularly due to high costs, dietary restriction, reduced social activity, and increased health worries<sup>[4]</sup>.

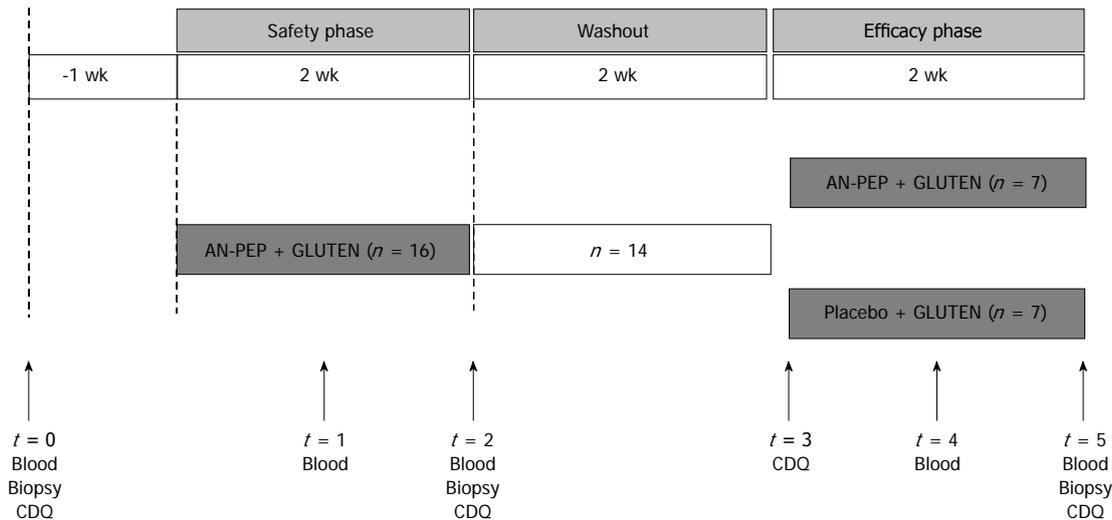

Gluten proteins are highly abundant in proline (15%) and glutamine (35%) residues, particularly in those regions identified as immunogenic in CD<sup>[5]</sup>. The proline- and glutamine-rich peptides in gluten are relatively resistant to proteolysis by gastric, pancreatic and intestinal enzymes<sup>[6,7]</sup>. Consequently, digestion-resistant proline- and glutamine-rich peptides can reach the intestinal epi-

thelium intact and can trigger an immune response that eventually results in mucosal damage. To eliminate such proline-rich gluten peptides, prolyl oligopeptidases, enzymes that can cleave after a proline residue in peptides, have been investigated by Shan and colleagues<sup>[6]</sup>. Such enzymes, derived from bacteria like *Flavobacterium meningoseptum*, *Sphingomonas capsulate* and *Myxococcus xanthus*, were capable of breaking down toxic gluten *in vitro*<sup>[6,8,9]</sup>. These prolyl oligopeptidases are however not stable and functional under acidic conditions of the stomach<sup>[9,10]</sup> and are unlikely to degrade gluten epitopes before they reach the small intestine. Alternative enzymes that can break down gluten are derived from germinating barley and the fungus *Aspergillus niger*. From the latter a prolyl endoprotease termed *Aspergillus niger*-derived prolyl endoprotease (AN-PEP) is derived which has distinct advantages over the bacterial prolyl oligopeptidase as it degrades both whole gluten and gluten peptides into non-immunogenic residues within minutes<sup>[11,12]</sup>. Moreover, the enzyme is active between pH 2 and pH 8, with an optimum activity at pH 4-5, and is therefore effective at the pH levels present in the stomach and beyond<sup>[11,13]</sup>. Importantly, the enzyme is not degraded by pepsin in the stomach and thus remains fully functional. Mitea *et al*<sup>[12]</sup> extended these findings by showing that AN-PEP degraded toxic gluten proteins in a food matrix into non-immunogenic gluten fragments in an *in vitro* digestion model that simulates the human gastrointestinal tract. After these promising *in vitro* results, it remains to be established in CD patients whether AN-PEP can reduce the clinical response to gluten. The aim of this two-phase proof of concept study was to demonstrate the safety of AN-PEP in the first phase and the ability of ANPEP to reduce antibody and histological response to gluten consumption by CD patients in the second phase of the study. This information will be important to further develop AN-PEP as a future digestive aid for unintentional ingestion of gluten by CD patients.

## MATERIALS AND METHODS

### Patients

Sixteen adults with CD were recruited at the outpatient clinic of the department of Gastroenterology and Hepatology of the VU Medical Centre Amsterdam, The Netherlands. Inclusion criteria were an initial diagnosis of CD as confirmed by histological abnormalities on duodenal biopsies classified as a Marsh III B or III C lesion and supported by positive serology; endomysium IgA antibodies (IgA-EM) and/or tissue transglutaminase IgA antibodies (IgA-tTG). Patients were required to have well-controlled CD as evidenced by Marsh 0 or I, and normalised IgA-EM and IgA-tTG on a strict GFD for at least one year. Women at fertile age were required to take adequate contraception measures. Reasons for exclusion were: use of any anticoagulant or immunoregulatory drug within the last 6 mo; clinically suspected bleeding tendency; pregnancy or breast feeding; presence of any concurrent active infection; and IgA deficiency.

**Figure 1 Study design and flowchart.** In the safety phase, 16 patients daily consumed 5 pieces of toast with *Aspergillus niger* prolyl endoprotease (AN-PEP) for 2 wk while continuing their gluten-free diet (GFD). Two patients deteriorated on Marsh scores and were excluded. After a 2-wk wash-out period during which the patients continued their usual GFD, the remainder of 14 patients were randomized to the efficacy phase to receive 2 wk of toast with either AN-PEP or placebo while continuing their GFD. CDQ: Celiac disease quality.

### Design and intervention

The intervention was performed between May 2008 and April 2009. The intervention consisted of two periods, each lasting 2 wk (Figure 1). The first study phase was an open-label period designed to assess the safety of high gluten intake with AN-PEP (safety phase). The second phase was a randomised, double-blind, placebo-controlled parallel-group study to assess the effect of AN-PEP on gluten-induced clinical response (efficacy phase). Sixteen patients with diagnosed CD were enrolled in the safety phase. Patients were asked to consume five pieces of toast (in total approximately 7 g gluten, Bolletje<sup>®</sup>, The Netherlands) with AN-PEP-containing topping daily in the morning for 2 wk. Patients were allowed to consume a glass of water (250 mL) with their toast. They were asked to continue their usual GFD. For ethical reasons, patients deteriorating  $\geq 2$  scales on the histological Marsh classification during this safety phase were not included in the efficacy phase. Between the study phases, a 2-wk washout period was introduced in which patients continued their usual GFD. Subsequently, fourteen patients were randomised in a 1:1 ratio in blocks of four in a double-blind fashion to the same amount of toast with AN-PEP-containing topping ( $n = 7$ ) or placebo topping ( $n = 7$ ) for 2 wk while remaining on their usual GFD. Patients' compliance with the product intake was checked by regular telephone contact.

Before and during the study phases, the patients visited the outpatient clinic five times (Figure 1). During the safety phase, blood was collected one week before (baseline), and one and two wk after start of gluten with AN-PEP consumption. During the efficacy phase, blood was collected at one and two wk after start of gluten with AN-PEP or placebo consumption. Duodenal biopsies were taken at baseline and at the end of the safety phase and the end of the efficacy phase. Both in the safety and

efficacy phase, participants were asked to complete a celiac disease-specific health-related quality of life questionnaire for adults<sup>[14]</sup> at baseline and after two wk of intervention. Biopsies and blood sampled at the end of the safety phase were used as baseline values to limit the burden for the patients.

### AN-PEP enzyme

The AN-PEP and placebo topping were prepared by DSM Food Specialties, Delft, The Netherlands. Both toppings (18.5 g) contained 8.2 wt% sucrose, 8.2 wt% saccharine solution (400 mg/L saccharine plus 4000 mg/L cyclamate), 0.4 wt% citric acid (Jungbunzlauer, Basel, Switzerland), 0.08 wt% potassium sorbate (Interland Chemie, Oosterhout, The Netherlands), 0.31 wt% sodium benzoate (Prolabo, Leuven, Belgium), and 1.23 wt% xanthane gum Keltrol RD (CP Kelcko, Nijmegen, The Netherlands). The AN-PEP topping contained 81.5 wt% AN-PEP enzyme concentrate corresponding with 168 Proline Protease Units of enzyme activity. The placebo topping contained 81.5 wt% distilled water with 0.06 wt% Plantex<sup>®</sup> MDA31 (colouring agent, DSM Food Specialties, Delft, The Netherlands) to match for colour differences. The aroma, flavour and consistency of the topping with AN-PEP were identical to those with placebo and both toppings could not be distinguished. Microbial counts and enzyme activity of the AN-PEP and placebo toppings were analysed monthly. All microbial counts remained below 10 CFU/g and the activity of the enzyme was maintained at  $9.1 \pm 0.3$  PPU/g topping during 12 mo shelf life at 4 °C. The AN-PEP and placebo toppings were identical in taste and appearance. They were pre-packed in containers (14 per box) by DSM and consecutively numbered for each patient according to the randomisation schedule (prepared by the DSM statistician).

**Blinding**

Each patient was assigned a random order number and received from the physician the containers in the corresponding non-transparent pre-packed box. The allocation sequence was concealed from the researcher enrolling and assessing participants in sequentially numbered sealed non-transparent envelopes. Envelopes were opened only after completion of the trial and assessments. All patients, investigators, care providers, and staff assessing outcomes were kept blind to treatment assignment.

**Measurements**

Mucosal biopsy immunohistology and immunophenotyping of lymphocytes, and serum antibodies were measured in the service laboratories of the VU University Medical Centre (Amsterdam, The Netherlands). Mucosal biopsy gluten-specific T-cell lines were measured in the research laboratory of the Leiden University Medical Centre (Leiden, The Netherlands). Mucosal biopsy IgA-tTG deposits were analysed at the University of Debrecen (Hungary).

**Adverse event reporting:** Tolerability of the gluten intake with AN-PEP or placebo was assessed by adverse event reporting to the physician during visits. All complaints were documented throughout the study. The study design did not allow for differentiation between complaints resulting from gluten or treatment. A difference in complaints between the AN-PEP and placebo group during the efficacy phase may give an indication of treatment-related effects.

**Celiac-disease quality of life:** All participants were asked to complete at home the CD quality of life questionnaire, which was translated into Dutch. The CD quality of life questionnaire included four disease-specific and health-related categories (emotional problems, social problems, disease-related worries, and gastrointestinal symptoms) with 7 items each<sup>[14]</sup>. Each question was weighed on a scale of 1-7 points, a high score corresponding to a high level of well-being. In total 196 points could be obtained, with a maximum of 49 points for each separate category. A change of 12 or more points on the total score or of 3 or more on the different categories was considered a clinically relevant change<sup>[14]</sup>.

**Mucosal biopsy immunohistology:** Twelve duodenal mucosal spike biopsies were taken through upper gastrointestinal endoscopy. Four paraffin-embedded biopsies were sectioned and hematoxylin-eosin-stained for histological evaluation according to the modified Marsh classification<sup>[15]</sup>. At least two grades increase in the Marsh scale was considered a clinically significant deterioration. Six fresh biopsies were used for flow cytometric analysis and two were snap frozen in liquid nitrogen and stored.

**Mucosal biopsy immunophenotyping of lymphocytes:** Multiparameter flow cytometric immunophenotyping of mucosal intraepithelial and lamina propria lymphocytes was performed. These lymphocytes were isolated from six duodenal biopsy specimens per time point through chemical and enzymatic dissociation<sup>[16]</sup>. The cells were stained with fluorescein isothiocyanate, phycoerythrin, peridinin chlorophyll protein and allophycocyanin-labelled monoclonal antibodies directed against CD3, CD4, CD8, CD16/56, CD19, CD45, CD45RA, HLA-DR, NKG2D, CD25 and TCR gamma-delta (all from BD Biosciences, San Jose, CA, United States), and appropriate isotype controls were included. Stained cells were analysed on a 4-colour flow cytometer (FACSCalibur™, BD Biosciences) and the data were analysed using Cellquest™ software (Becton Dickinson, San Jose, CA, United States). Care was taken to analyse only viable cellular events based on light scatter properties. The mean fluorescence intensity index as compared to isotype controls was calculated for the markers included.

**Mucosal biopsy gluten-specific T-cell lines:** Gut-resident, gluten-reactive T-cells are a hallmark of CD. To demonstrate that all patients possessed such cells, polyclonal T-cell lines were generated from small intestinal biopsies as described<sup>[17]</sup>. The resulting T-cell lines were tested for reactivity against a pepsin/trypsin digest of gluten and a pepsin/trypsin digest of gluten that had been treated with tissue transglutaminase in a T-cell proliferation assay as described<sup>[17]</sup>. In all patients gluten reactivity could be demonstrated (not shown).

**Mucosal biopsy IgA-tTG deposits:** Biopsies at the end of the randomisation study phase were stained for tTG-related extracellular IgA deposits and, in case of positivity, baseline biopsies were stained as well. Twelve unfixed, 5 µm-thick frozen sections were examined per patient by double immunofluorescent labelling of IgA (green) and tTG (red) as previously described<sup>[18]</sup>. IgA is normally detected only inside plasma cells and at the luminal surface, whereas in active CD, subepithelial deposits composed of IgA-tTG are found along the surface and crypt basement membranes and around mucosal vessels, corresponding to the intestinal localisation of tTG. The CD-type IgA-tTG deposits were graded from 0 to 3 according to their intensity along the basement membranes in the villous-crypt area. As this study of the small intestinal IgA-tTG deposits is highly subjective, it was performed by an independent specialist in this field in a blind manner to greatly increase its accuracy.

**Serum antibodies:** Blood samples were collected by venipuncture to analyse CD-associated antibodies. Levels of IgA-tTG, gliadin IgA antibodies (IgA-AG) and gliadin IgG antibodies (IgG-AG) were determined with a standard in house enzyme-linked immunosorbent assay (ELISA), using recombinant human tissue transglutamin-

GFD: Gluten-free diet; AN-PEP: *Aspergillus niger* prolyl endoprotease.

ase (Diarect AG, Freiburg, Germany) and gliadin extract (Sigma-Aldrich, Zwijndrecht, the Netherlands) as substrates, respectively. IgA-EM antibodies were determined by an in-house indirect immunofluorescence test according to Lerner using monkey oesophagus as substrate<sup>[19]</sup>. IgA deficiency was excluded to avoid false negative serology. In addition, in retrospect a combined test for IgA and IgG antibodies directed against human tissue transglutaminase and deamidated gliadin-derived peptides (IgA/G-DGP-tTG; tTG/DGP Screen ELISA, INOVA Diagnostics, San Diego, United States) was performed<sup>[20]</sup>. Reference values for antibodies were categorized into negative, dubious, weak positive, positive, and strong positive. Reference ranges for IgA-AG were < 2.4, 2.5-3.9, 4.0-20, 20-80, and > 81 U/mL, for IgG-AG, < 11, 12-20, 21-40, 41-100 U/mL, for IgA-tTG, < 2.9, 3.0-5.9, 6.0-20, 21-50, > 51 U/mL, and for IgA/G-DGP < 6.9, 7.0-10.9, 11-30, 31-100 and > 100 U/mL respectively.

### Ethical approval

The study was approved by the Medical Ethics Committee of the VU Medical Centre and conducted in accordance with the guidelines of the Declaration of Helsinki. The trial has been registered in the Dutch Trial register (NTR1281) and the FDA Clinical Trial register (NCT00810654). A written informed consent was obtained from each subject before enrolment.

### Statistical analysis

Data were analysed by OCS Biometric Support (Leiden, The Netherlands). Difference from baseline in mucosal immunohistology between the two groups after 2 wk as measured by Marsh classification was considered the primary outcome measure. All other parameters were considered secondary endpoints. Power analysis revealed that for the detection of a two-grade difference in the Marsh score with a power of 0.80 and a one-sided *a* level of 0.05, 14 patients were needed to finalise the study. Data were analysed in the SAS version 9.1, using both parametric and non-parametric tests depending on the nature of the data. The quality of life data were analysed with paired *t* tests to test for differences between data before and after the 1<sup>st</sup> (safety) and 3<sup>rd</sup> (efficacy) period of the study. Serological and histopathological outcome parameters were analysed with Wilcoxon signed-rank tests to determine differences between data before and after the 1<sup>st</sup> period and the Wilcoxon rank sum tests to test the treatment differences in change from baseline in the 3<sup>rd</sup> period of the study. In order to explore whether patients' baseline characteristics would predict their response to gluten (and hence to increase the chances of success in a future trial), rank correlations between baseline characteristics and outcome variables were explored in the placebo group using the Spearman Rank Correlation Coefficient (*r*) of the ranked data (analysed by DSM

statistician).

## RESULTS

### *Baseline characteristics*

The demographic and baseline characteristics of the patients are presented in Table 1. In total, 16 adults on a gluten-free diet diagnosed as having CD [median age: 55 (20-68) years] were enrolled in the study. The demographic characteristics of both treatment groups were comparable with exception of the median age at diagnosis of CD, which was 20 years higher in the AN-PEP compared to the placebo group. The median time on GFD treatment was similar in both groups. Two patients were excluded after the safety phase because of a histological deterioration of two and three Marsh grades, respectively, which for one patient returned to normal (Marsh 0) after four weeks of exclusion. The patient that did not return to normal started the study with high IgA/G-DGP-tTG values. However, other CD-related antibodies remained undetectable in these two patients. The remaining 14 patients entered and completed the efficacy phase.

When correlating the patients' baseline characteristics with their response to gluten, highly significant inverse relationships were found between the patients' time since diagnosis or time spent on a GFD and their response to gluten as measured by IgG-AG, IgA-tTG and IgA/G-DGP-tTG, and Marsh scores (data not shown).

### *Adverse events*

No serious adverse events occurred during the trial, patients reported no severe adverse events, and no patients withdrew during the trial. Complaints that were reported during the safety and efficacy phase were of gastrointestinal nature and mostly mild and transient. The number of reported gastrointestinal complaints did not differ between the AN-PEP and placebo group (Table 1).

### *Celiac-disease quality of life*

The mean total scores of the four categories on the CD quality of life were relatively high (145-156 out of a total score of 196) in the total group and throughout both study phases. In the safety phase, the total CD quality of life score significantly ( $P = 0.04$ ) increased by 6 points during gluten with AN-PEP treatment. This increase was however lower than the 12-point increase that is considered a clinically relevant quality of life improvement<sup>[14]</sup>. In the efficacy phase, the individual or total CD quality of life scores of patients consuming gluten with placebo or gluten with AN-PEP did not significantly deteriorate. No differences between the groups were observed. The mean score for the gastrointestinal CD quality of life was relatively high throughout the study, indicating that gluten with AN-PEP was well tolerated.

### *Mucosal biopsy immunohistology*

In the patients receiving gluten plus AN-PEP treatment

in the safety phase, several patients showed variation in Marsh scores but overall no significant change in degree of mucosal damage, as indicated by changes in the Marsh score, was observed (Table 2). Two of 16 patients were excluded from entering the efficacy phase as their mucosa showed an increase of two Marsh steps while 14 patients were considered histologically stable on gluten with AN-PEP. Also after the efficacy phase, no significant deterioration was observed in the group consuming gluten with placebo compared to the group receiving AN-PEP.

### *Mucosal biopsy immunophenotyping of lymphocytes*

Flow cytometric analysis of intestinal lymphocyte subsets showed no significant changes in the expression of the T-cell lineage associated markers CD3, CD4, CD8 and TCR  $\gamma\delta$ , in either the intraepithelial lymphocyte or the lamina propria lymphocyte populations of both treatment groups during the efficacy phase. The mean fluorescence index of the activation markers CD25, HLA-DR, the NK receptor and NKG2D as well as CD45RA, a marker for naïve T-cells, showed no significant change in either group.

### *Mucosal biopsy IgA-tTG antibody deposits*

Mucosal tTG-related extracellular IgA deposits are hypothesised to be an early marker for CD activity<sup>[21]</sup>. Despite a GFD, two of seven patients started with positive staining for IgA-tTG at baseline (Table 2). Compared to baseline, IgA-tTG deposit staining increased after 2 wk of gluten intake in four out of seven patients on placebo. In the seven patients receiving AN-PEP, one patient showed increased and one showed decreased IgA-tTG deposits (Table 2, Figure 2).

### *Serum antibodies*

Serum CD-associated antibodies (IgA-tTG, IgA-EM, IgA-AG, IgG-AG and IgA/G-DGP-tTG) were not detectable in the serum of enrolled patients at baseline (Table 2) except for one patient in which borderline levels of IgA/G-DGP-tTG were detected, which became negative after 2 wk of gluten with AN-PEP consumption. The IgA-tTG, IgG-AG, IgA/G-DGP-tTG, and IgA-EM antibody titers remained negative on gluten with AN-PEP. Three out of sixteen patients developed detectable or borderline IgA-AG levels, while 13 patients remained negative during 2-wk of gluten with AN-PEP (Table 2).

During the efficacy phase, neither the placebo nor the AN-PEP group developed significant antibody titers (Table 2). The median antibody titers after 2 wk gluten intake did not significantly differ between AN-PEP and placebo treatment. The IgA-EM concentrations remained negative in both groups.

## DISCUSSION

The enzyme AN-PEP might possibly assist in digesting

The serum EMA-A antibodies remained negative in all patients during the entire study. Mucosal tTGA-A deposits were graded from 0 to 3. Tx: Treatment; A: AN-PEP; P: Placebo; E: Excluded; IgA-tTG: Anti-tissue transglutaminase IgA antibodies; IgA-GA: Anti-gliadin IgA antibodies; IgG-GA: Anti-gliadin IgG antibodies; IgA/G-DGP-tTG: Anti-tissue transglutaminase and deamidated gliadin-derived peptide IgA and IgG antibodies; I-FABP: Intestinal fatty acid binding protein; ND: Not determined. - : Negative; +/- : Dubious; + : Weak positive; ++ : Positive; +++ : Strong positive.

unintentionally ingested amounts of gluten in those who cannot tolerate gluten. However, demonstrating a treatment effect on (small) clinical deterioration induced by small amounts of gluten in the placebo group may be difficult. Therefore, in this proof of principle study, the enzyme was given to patients consuming large amounts of gluten in a relative small period of time. A two-week safety phase (AN-PEP + gluten) preceded the randomization for AN-PEP or placebo as requested by the medical ethical commission due to concerns about such a high dose of gluten consumption. Unfortunately, the primary aim of the study was not met as the placebo arm did not show any deterioration after 2 wk of gluten consumption. With hindsight, the study should possibly have been designed for a much longer period of time with many more patients.

The baseline characteristics were balanced between groups except for median age at diagnosis, which was 20 years higher in the AN-PEP compared to the placebo group. However, this is unlikely to have influenced the study outcome as no relationship between the age of diagnosis and the response to gluten was observed (data not shown).

The safety phase showed that AN-PEP treatment, when consumed with a high dose of about 7 g of gluten for 2 wk, was safe in patients and no severe adverse events were reported. The CD quality of life scores remained relatively high during 2 wk consumption of gluten and AN-PEP indicating that patients' general well-being remained high. Serum antibodies of the sixteen patients did not increase when consuming AN-PEP with 7 g of gluten for 2 wk. Also, histology of the biopsies of the majority of patients (fourteen) showed no deterioration while two patients developed increased Marsh scores, however not accompanied by increased antibodies. The safety phase was subject to a so-called "ceiling effect" because patients entered the study on a GFD reflecting relatively healthy baseline values, limiting the ability to demonstrate any further improvement by AN-PEP.

Patients in the placebo group did not show significant deterioration on any of the measured clinical variables after a 2-wk gluten challenge, indicating that 2 wk of gluten challenge is insufficient to induce a clear clinical response in this population of celiac patients. Due to lack of response to gluten in the placebo arm, no treatment effect of

**Figure 2 Small intestinal tissue transglutaminase IgA antibody deposits (rated on a scale 0-3) in two patients at baseline and after randomization to *Aspergillus niger* prolyl endoprotease and placebo respectively.** A: Baseline evaluation of patient 1 showed preserved villous architecture (arrow), with intense, grade 3 IgA depositions (green) subepithelially and around crypts; B: This deposition merges to yellow indicating co-localisation with tTG shown in red; C: In this patient, IgA deposits diminished after 2 wk *Aspergillus niger* prolyl endoprotease (AN-PEP) treatment to grade 1, when only faint and patchy antibody deposition was seen (arrow); D: tTG appeared in red in this AN-PEP-treated patient (arrow) in the absence of IgA deposition. The cell nuclei were stained with 4',6-diamidino-2-phenylindole (DAPI) (blue); E: Baseline evaluation of patient 2 showed preserved villous architecture with faint, grade 1 IgA deposition in the deep mucosal layer around Brunner glands (arrow); F: This deposition were not sufficient to obtain a yellow colour at merging with tTG shown in red (asterisk); G: In this patient, IgA deposition increased to grade 2 subepithelially (arrow) after 2 wk placebo; H: IgA deposition increased to grade 3 in the crypt region after 2-wk placebo (arrow). IgA deposition co-localised with tTG to intense yellow (arrow). The cell nuclei were stained with DAPI (blue).

AN-PEP could be detected. The measured serum levels of IgA-tTG, IgA-EM, and IgA/G-DGP-tTG antibodies are considered sensitive markers of CD and should be able to detect subtle immunogenic effects of gluten. Similarly, the CD-specific quality of life questionnaire is considered a CD-specific measure of quality of life and should also be able to pick up relevant changes in health<sup>[14]</sup>. However, histological examination of small intestinal biopsies may be less reliable than CD-associated antibodies due to heterogeneous distribution of lesions, low grade histopathology, and intra- and interobserver variability<sup>[22]</sup>. Interestingly, measures of clinical response to gluten (Marsh scores, antibody titres, quality of life scores) did not correlate in this study, which may in part be explained by the lack of response to gluten. The IgA antibody reactivity to small intestinal mucosa tTG has been considered to be an early marker for gluten-induced pathology in CD patients<sup>[23]</sup>. It was observed that intestinal IgA-tTG deposits can be detected in latent CD patients in whom the mucosal villous architecture is still intact, and that the intensity of these mucosal deposits decreased after adherence to a GFD and increased after gluten consumption. Although numbers were low, mucosal IgA-tTG deposits increased in four patients on placebo and one on AN-PEP and decreased in one patient on AN-PEP, compared to baseline values, suggesting that AN-PEP may mitigate gluten exposure.

Some gastrointestinal-related symptoms, mostly mild and transient, were reported during gluten challenge and symptoms between the two groups were comparable suggesting no treatment-related effects on gastrointestinal symptoms. Besides the substantial gluten intake, emotional stress as a consequence of having to ingest gluten might have triggered some of the reported gastrointestinal complaints.

The celiac patients consumed approximately 7 g of gluten daily, which is about half of the average adult daily gluten intake in The Netherlands<sup>[24]</sup>. Despite this high gluten dose, no substantial histological, serological, or symptom changes were observed with placebo after 2 wk. In another study<sup>[25]</sup> in which adult CD patients consumed approximately 3.5 g/d of gluten from cracker biscuits for 2 wk, only few patients consuming gluten on placebo showed deterioration on histology, serology, and symptoms. Two other studies investigating a gluten challenge in adult patients, based on either lower gluten intake (2.5-5.0 g/d for at least 3 mo)<sup>[26]</sup> or comparable gluten intake (4 slices of white bread daily; approximately 8 g/d)<sup>[27]</sup> showed that a moderate gluten intake can be tolerated by some patients for several weeks-to-months without significant changes in symptoms<sup>[27]</sup>, serology<sup>[26]</sup> and histology<sup>[26,27]</sup>. The time to serological and mucosal relapse and recovery after gluten re-introduction and elimination, respectively, can be highly variable among adult CD patients from several weeks up to many years<sup>[27-30]</sup>. Excluding 2 out of 16 patients that may have been more sensitive to gluten from the efficacy phase may, to a small extent, have caused sample bias by select-

ing patients being less sensitive to gluten. Nevertheless, the same population of patients that entered the efficacy phase was randomly allocated to the AN-PEP or placebo arm. Also attrition bias can be excluded since all patients remained in the study. The lack of substantial clinical response to gluten observed in this study indicates that a longer gluten challenge is likely necessary to induce a significant clinical response to gluten in the majority of patients. For the same reason a longer wash-out period should be considered. Moreover, unresponsiveness to gluten of patients being diagnosed for more than 10 years ago, suggests that future studies may benefit from selecting more recently diagnosed patients.

In conclusion, AN-PEP appeared to be safe in celiac patients. More patients and gluten challenge for a longer period of time seem to be required to induce significant clinical changes and to confirm whether the tendency of AN-PEP to reduce small bowel IgA-tTG deposits is of clinical significance. These results together with previous *in vitro* evidence that AN-PEP efficiently degrades gluten under simulated gastrointestinal conditions warrant confirmation in a larger trial.

## COMMENTS

### Background

The only currently available treatment for celiac disease consists of life-long dietary exclusion of gluten, perceived as a substantial burden particularly due to high costs, dietary restriction, reduced social activity, and increased health worries. Alternative treatment modalities that reduce the need of dieting focus on modification of dietary components, enzymatic degradation of gluten, inhibition of intestinal permeability and modulation of the immune response. Following this, a previous report showed that the gluten-degrading *Aspergillus niger*-derived prolyl endoprotease (AN-PEP) degraded toxic gluten proteins in a food matrix into non-immunogenic gluten fragments in an *in vitro* digestion model that simulates the human gastrointestinal tract.

### Research frontiers

This is the first randomised double-blind placebo-controlled pilot-study evaluating the safety and efficacy of AN-PEP in celiac disease.

### Innovations and breakthroughs

The celiac disease quality of life scores remained relatively high during 2 wk consumption of gluten and AN-PEP indicating that patients' general well-being remained high. The enzyme AN-PEP might possibly assist in digesting unintentionally ingested amounts of gluten in those who cannot tolerate gluten. However, the primary aim of the study was not met as the placebo arm did not show any deterioration (small intestinal mucosa, celiac disease associated antibodies, and quality of life) after 2 wk of gluten consumption. Although numbers were low, mucosal IgA-tTG deposits increased in 4 patients on placebo and one on AN-PEP and decreased in one patient on AN-PEP, compared to baseline values, suggesting that AN-PEP may mitigate gluten exposure.

### Applications

The lack of substantial clinical response to gluten observed in this study indicates that more patients and gluten challenge for a longer period of time seem to be required to induce significant clinical changes and to confirm whether the tendency of AN-PEP to reduce small bowel IgA-tTG deposits is of clinical significance. These results together with previous *in vitro* evidence that AN-PEP efficiently degrades gluten under simulated gastrointestinal conditions warrant

confirmation in a larger trial.

### Peer review

The aim of the present study was to examine the safety and efficacy of AN-PEP to reduce the clinical response to gluten in patients with coeliac disease. The safety study showed that AN-PEP was safe and well tolerated by patients with celiac disease. Data on time to serological and mucosal relapse and recovery after gluten re-introduction and elimination show highly variable results, varying from several weeks up to many years. Even though the primary endpoint was not met, this study is of interest and warrant support for such an approach.

### Abstract

**AIM:** To evaluate the outcomes of patients who underwent laparoscopic repair of intra-thoracic gastric volvulus (IGV) and to assess the preoperative work-up.

**METHODS:** A retrospective review of a prospectively collected database of patient medical records identified 14 patients who underwent a laparoscopic repair of IGV. The procedure included reduction of the stomach into the abdomen, total sac excision, reinforced hiatoplasty with mesh and construction of a partial fundoplication. All perioperative data, operative details and complications were recorded. All patients had at least 6 mo of follow-up.

**RESULTS:** There were 4 male and 10 female patients. The mean age and the mean body mass index were 66 years and 28.7 kg/m<sup>2</sup>, respectively. All patients presented with epigastric discomfort and early satiety. There was no mortality, and none of the cases were converted to an open procedure. The mean operative time was 235 min, and the mean length of hospitalization was 2 d. There were no intraoperative complications. Four minor complications occurred in 3 patients including pleural

effusion, subcutaneous emphysema, dysphagia and delayed gastric emptying. All minor complications resolved spontaneously without any intervention. During the mean follow-up of 29 mo, one patient had a radiological wrap herniation without volvulus. She remains symptom free with daily medication.

**CONCLUSION:** The laparoscopic management of IGV is a safe but technically demanding procedure. The best outcomes can be achieved in centers with extensive experience in minimally invasive esophageal surgery.

**Key words:** Laparoscopic procedure; Hiatal hernia; Stomach; Volvulus; Mesh repair

**Core tip:** Migration of the whole stomach in to the chest cavity by rotating its longitudinal or transverse axis, namely "intra-thoracic gastric volvulus", is a very rare type of giant hiatal hernias and is associated with catastrophic complications. Laparoscopic repair of this rare condition is the most technically demanding procedure among the benign foregut surgeries. With careful attention the details, such as total excision of the hernia sac, provision of an adequate esophageal length with full mobilization of the esophagus, tensionless hiatoplasty, and a floppy fundoplication, long-term success is possible

### INTRODUCTION

It is difficult to identify the true incidence of hiatal hernia

because of the absence of symptoms in a large number of patients. Hiatal hernia is most commonly associated with gastro-esophageal reflux disease (GERD), and GERD affects millions of people worldwide<sup>[1]</sup>. Ninety-five percent of hiatal hernias are the small sliding type (type I) and are not associated with life threatening complications. The remaining 5% are classified as paraesophageal and mixed types (types II and III, respectively) both of which are known as giant hiatal hernias.

Landmark articles on giant hernias were published by Skinner *et al*<sup>[2]</sup> in 1962 and Hill<sup>[3]</sup> in 1973. They reported mortality rates exceeding 27% due to catastrophic complications of paraesophageal hernia (PEH) such as obstruction, strangulation, perforation and bleeding. Although still controversial, many surgeons recommend elective surgical repair even in elderly asymptomatic patients with PEH<sup>[4]</sup>.

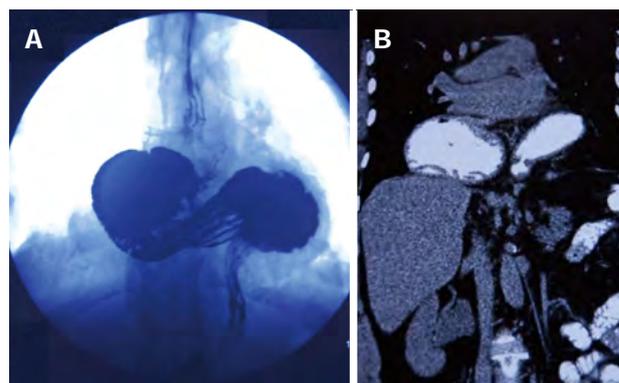

After Cuschieri *et al*<sup>[5]</sup> performed the first laparoscopic PEH repair, many surgeons reported successful results with less than 1% mortality<sup>[6,7]</sup>. All studies have shown that laparoscopic repair of giant hiatal hernias is a safe but technically demanding procedure. Because of the rarity of this disease and the lack of randomized trials comparing different surgical approaches, controversy exists regarding which surgical approach should be preferred. Choices regarding the type of surgical procedure include trans-abdominal *vs* trans-thoracic, open *vs* laparoscopic, hiatal closure with primary suture *vs* the use of meshes and whether fundoplication is necessary<sup>[8,9]</sup>.

Many previous publications addressed the management of PEH, but there is a distinct subgroup of patients who represent the end stage of all types, which occurs when the whole stomach migrates into the thorax by rotating 180 degrees around its longitudinal or transverse axis, namely “intra-thoracic gastric volvulus (IGV)”. Surgical repair of this rare disorder is most likely the most technically difficult procedure among the benign foregut diseases, even for experienced foregut surgeons. The present article focuses on this subgroup of patients who have IGV.

## MATERIALS AND METHODS

### Patient selection

The study was conducted at our anti-reflux therapy center, which is a specialized tertiary referral center for the diagnosis and treatment of GERD. A retrospective review of a prospectively collected database of patient medical records identified 14 patients who underwent laparoscopic repair for a totally intra-thoracic stomach with chronic volvulus. IGV was defined as transmigration of the whole stomach into the thorax by a 180 degree around its longitudinal or transverse axis (Figure 1). Surgical consent was obtained from all patients after detailed information was given by a senior surgeon. The preoperative evaluation included an upper gastrointestinal endoscopy, thoraco-abdominal computed tomography (CT) and a barium esophagram. We do not perform a routine

**Figure 1** Computed tomography. A: Preoperative barium swallow study shows the transmigration of the entire stomach; B: Coronal view of intra-thoracic gastric volvulus.

24-h pH study or manometry as the results do not change our treatment strategy in IGV cases. Pulmonary function testing was performed in patients with pulmonary symptoms, such as shortness of breath, to determine whether breathing problems were due to restriction of the lung by an intra-thoracic stomach or to intrinsic lung disease.

### Surgical technique

All patients were admitted on the day of the surgery and underwent a laparoscopic hiatal hernia repair procedure after an overnight fast. Patients received prophylaxis by subcutaneous low-molecular-weight heparin administered routinely during the induction of anesthesia in addition to compression stockings.

Patients were placed in the modified lithotomy position with the surgeon between the legs and the assistant on the left side. The first 10-mm optic port was placed using the open Hasson technique in the upper midline approximately one third of the way from the umbilicus to xiphoid. An additional three 10-mm and two 5-mm trocars were placed in the upper abdomen after a pneumoperitoneum was established to a pressure of 13-15 mmHg. Unlike patients who undergo an antireflux surgery, trocar placement was higher in the abdomen and was very similar to the placement in obese GERD patients we previously reported<sup>[10]</sup>.

Following liver retraction, the hiatal hernia was examined. Then the operating room table was placed in reverse Trendelenburg to allow an easier reduction. The herniated stomach was reduced into the abdomen as much as possible with atraumatic graspers in a hand-over-hand fashion. The dissection was started by dividing the gastro-hepatic ligament and exposing of the right crus. If a dominant left hepatic artery larger than 2 mm was seen, the dissection was started just above the vessel. There was no attempt to dissect the hernia sac or to find the esophagus at this stage. The hernia sac was identified at the junction of the left crus and stomach. Finding a fine areolar plane between the sac and surrounding mediastinal tissues was a landmark following the division of the hernia sac. Care was taken to identify the vagal nerves

**Table 1** Patients demographics and perioperative findings

Age, yr (range)	66.7 ± 4.7 (61-76)

and pleura to avoid any injury during the dissection of the mediastinum. Full division and removal of the sac was performed in all patients.

Following the sac removal, a circumferential dissection of the esophagus to the level of the inferior pulmonary veins was performed to achieve adequate intra-abdominal esophagus length. The final assessment of the esophageal length was conducted after careful dissection of the fat pad of the gastroesophageal junction (GEJ) with the operating table in a level position and with a 6-8 mmHg pneumoperitoneum. Collis gastroplasty (CP) was not routinely performed prior to fundoplication.

Once the esophageal dissection was completed, a crural repair with silk sutures was performed. Care was taken to avoid any tension over the crura during the repair, and we aimed to secure the integrity of the muscle. Reinforced hiatoplasty with prosthetic grafts was routinely performed. A U-shaped monofilament polypropylene graft (Prolene; Ethicon, Ltd.) was used for the reinforced hiatoplasty. The mesh was fixed to the diaphragm by a laparoscopic tacker. A fundoplication was performed during the procedure to avoid postoperative acid reflux. A partial posterior fundoplication, namely “Toupet fundoplication”, was the procedure of choice. We believe a better fixation of the gastric fundus is achieved with more sutures to the esophagus and crura using the Toupet procedure. Our partial fundoplication technique was standardized and reported elsewhere<sup>[11]</sup>. Briefly, the right side of the wrap was fixed to the esophagus using two silk sutures. The left part of the wrap was sutured to the anterior side of the esophagus by two or three sutures, and a single suture was used to fix the upper side of the wrap to the upper edge of the hiatus. There was no attempt to divide the short gastric vessels as the gastric fundus is too mobile due to long-term herniation.

### Postoperative period

The length of postoperative observation in the intensive care unit depended on patient co-morbidities and the

operation length. All patients were discharged on the second postoperative day unless problems occurred. Patients received liquids on the first postoperative day, after an esophagram was obtained. All patients were seen at intervals of 1 wk and 2 mo after surgery and yearly thereafter. A barium esophagram was performed during annual follow-up evaluations.

## RESULTS

Fourteen consecutive patients underwent a laparoscopic repair of IGV. There was no mortality, and none of the cases were converted to an open procedure. The duration of follow-up was 29.4 mo. There were 4 male and 10 female patients. The mean age and mean body mass index were 66.7 years and 28.7 kg/m<sup>2</sup>, respectively. All patients presented with epigastric discomfort and early satiety. Only 2 patients had additional reflux symptoms of heartburn and 2 had shortness of breath. The demographic characteristics of the patients are outlined in the Table 1.

The mean operative time was 234.9 min, and the mean length of hospitalization was 2.6 d. There were no intraoperative complications. Four minor complications occurred in three patients. One patient had pleural effusion and subcutaneous emphysema that spontaneously resolved within 2 wk. One patient had postoperative dysphagia that resolved within 6 wk without any intervention. One patient had postoperative delayed gastric emptying that began in the first postoperative week. She was treated with medical therapy and her complaints resolved within 6 mo. One patient presented with recurrent heartburn 6 mo postoperatively, and a wrap herniation was diagnosed with gastroscopy and barium swallow studies. She remains symptom free with daily proton pump inhibitor usage.

## DISCUSSION

An IGV is an uncommon entity and it occurs when the entire stomach migrates into the thorax through a giant hiatal defect by rotating around its longitudinal or transverse axis. Whether this rare condition is an extension of a PEH or an evolution of a longstanding sliding hernia is subject to controversy and is beyond the scope of this article. IGV is the end stage of all hiatal hernia types before catastrophic complications occur.

The clinical features of giant hiatal hernias are non-specific and the majority of patients are asymptomatic. Dysphagia, heartburn, postprandial discomfort and chest pain are the most common presenting symptoms<sup>[12]</sup>. Patients presenting with chest pain usually undergo a cardiac work-up and a PEH is incidentally found in chest scans. Patients with IGV are usually symptomatic, and in our study all patients presented with early satiety and postprandial discomfort.

We usually start with a gastroscopy in the preoperative work-up. In addition to detecting esophagitis and/or Barrett metaplasia, an upper gastrointestinal endoscopy

**Table 2** Laparoscopic repair of intra-thoracic gastric volvulus: Literature review

Ref.	n	Presentation	Follow-up	Mesh	Fundoplication procedure	Outcome

PEG: Percutaneous endoscopic gastrostomy.

can reveal other concomitant gastric neoplasias as the majority of patients are over 65 years old with non-specific symptoms. Unfortunately, total gastroscopy cannot be performed in most patients with IGV even under general anesthesia. Following gastroscopy, we obtain a radiographic evaluation with a barium swallow study and thoraco-abdominal CT. We think the barium swallow is very useful in identifying the presence and the type of volvulus, the location of the GEJ and in assessing the length of the esophagus. CT imaging is useful to determine possible associated organ herniation and to rule out of diaphragmatic hernia. Preoperative evaluation of patients with a pH meter and manometry is controversial. Fuller and co-workers reported 60% of patients with a giant hiatal hernia had pathological acid reflux despite the absence of typical symptoms<sup>[13]</sup>. Schieman *et al*<sup>[14]</sup> recommend routine pH meter and manometry to reveal possible concomitant reflux. We do not perform routine pH meter or manometry in our clinical practice as the results do not change our treatment strategy.

In 2013, there remains no consensus among foregut surgeons regarding the optimal surgical approach to giant hiatal hernias. The approaches include trans-abdominal *vs* trans-thoracic procedures, open *vs* laparoscopic procedures, hiatal closure with primary suture *vs* the use of meshes, fundoplication, gastropasty and total sac excision. Because of the rarity of this disease only small series and case reports exist in the literature (Table 2). As we had extensive experience in more than 1000 anti-reflux operations, a laparoscopic approach was the procedure of choice in our series. Some surgeons advocate the transthoracic approach especially in emergency cases<sup>[24]</sup>. The improved ability to separate adhesions between the hernia sac and pleura is the main advantage of trans-thoracic repair. In recent years, successful thoracoscopic repair of intrathoracic stomach has started to appear in the literature<sup>[25]</sup>. The surgeon's experience seems to be the most important consideration in choosing the procedure.

The debate over total excision of the hernia sac is the least controversial issue. Many surgeons believe total ex-

cision of the sac eliminates the tension on the GEJ and minimizes the risk of recurrence. Edey *et al*<sup>[26]</sup> addressed this issue and reported 20% early period recurrence in patients without sac excision. Although the total excision of the sac decreases the recurrence rates, some surgeons prefer to leave the distal part of the sac as a fail-safe measure to counter difficulties in dissecting nearby pleura and vagal nerves. We believe total excision is the critical step of the operation in patients with IGV, as reducing the volvulus can only be achieved by total excision. It may be very difficult when the vagus is partly adherent to the sac, especially anteriorly, and one of our patients had postoperative delayed gastric emptying after a demanding dissection. Her complaints spontaneously resolved after 6 mo, and we believe vagal injuries may not result in long-term clinical sequelae.

Short esophagus was first described in 1957<sup>[27]</sup>, and since then its pathophysiology, importance and management have remained a subject of clinical debate. Hypothetically, the inflammation of the posterior mediastinum due to the intra-thoracic stomach results in adhesion that causes esophageal shortening. The associated acid reflux can lead to chronic inflammation and fibrosis in the connective tissues that finally results in esophageal shortening. Despite the various attempts, specific criteria allowing surgeons to preoperatively identify short esophagus and to determine which patients will need a CP do not exist<sup>[28,29]</sup>. Although CP has become a more commonly used procedure in the past decade<sup>[30]</sup>, some surgeons believe that there is no need to perform CP with an adequate esophageal dissection<sup>[31]</sup>. If a 2.5-3 cm intra-abdominal esophagus can be achieved by mediastinal dissection, there is no need to perform a Collis procedure. There is a tendency to overestimate the esophageal length during a laparoscopy. The pneumoperitoneum elevates the diaphragm and misleads surgeons. Surgeons should keep in mind that these maneuvers can lead to an overestimate of intra-abdominal esophageal length. A CP was not needed in our experience. In one patient, we suspected an esophageal shortening based on a preoperative up-

per intestinal series. After mobilization of the esophagus and careful dissection of the fat pad over the GEJ, we thought we had achieved an adequate esophageal length. Unfortunately, she was the patient who presented with recurrence.

The use of prosthetic grafts for a reinforced hiato-plasty is another controversial issue in the treatment of giant hiatal hernias. The main point of controversy includes what shape, size and type of mesh should be used, and whether it should be used routinely, or in selected cases. Shamiyeh and co-workers addressed this issue by calculating the mean hiatal surface area (HSA)<sup>[32]</sup>. The authors found the average HSA was 5.84 cm<sup>2</sup> and suggested HSA can be used for the decision to use mesh. Although the use of a prosthetic mesh seems to significantly reduce the risk for recurrence<sup>[33,34]</sup>, it is not free of complications. Erosion into the gastrointestinal organs is the most feared complication when a mesh is used in the hiatus. Until recently, only a few mesh erosions were reported as single cases in the last 15 years<sup>[35]</sup>. In 2009, Stadlhuber *et al*<sup>[36]</sup> reported 28 patients with mesh complications by gathering case data from the expert esophageal surgeons. The authors suggested that the incidence mesh complications may be greater than estimated. Reinforced hiato-plasty has become routine in our early experience, even in GERD patients with small hiatal hernias. U-shaped polypropylene grafts were the preferred type of mesh. We did not observe a mesh complication in more than 700 patients. Because of the fear of mesh erosion, we used grafts more selectively after we read Stadlhuber's paper.

Adding a fundoplication procedure after the repair of the hiatus is also an issue of debate. Some surgeons recommend its selective application in patients with associated GERD<sup>[37]</sup>. Others advocate routine application because extensive dissection of the esophagus will result in GERD<sup>[38]</sup>. Nissen fundoplication is the most commonly used procedure. We routinely performed Toupet fundoplication in the present series. We can provide more fixation of the gastric fundus with more sutures. As the majority of these patients are over 65 years old, they have baseline esophageal dysmotility, and total fundoplication may result in dysphagia<sup>[39]</sup>.

As a result of negative intrathoracic pressure, there is always a tendency for the wrap to migrate back to the thorax following the repair of giant hiatal hernias. Anterior gastropexy was recommended to overcome this problem. Ponsky *et al*<sup>[40]</sup> reported a prospective study of 31 patients who underwent laparoscopic PEH repair. The authors did not observe recurrence during the 21 mo follow-up period. We believe gastropexy should not be an option in patients who have IGTV, as it may create a new axis that can lead to intra-abdominal volvulus.

In conclusion, laparoscopic management of IGTV is a safe procedure and should be the first option in the treatment algorithm. With careful attention the details, such as total excision of the hernia sac, provision of an adequate esophageal length with full mobilization of the

esophagus, tensionless hiato-plasty, and a floppy fundoplication, long-term success is possible. This procedure is most likely the most technically demanding procedure among the benign foregut diseases and requires advanced laparoscopic skills. The best outcomes can be achieved by surgeons with extensive experience, especially in laparoscopic anti-reflux surgery, as there is no learning curve for this rare condition.

## COMMENTS

### Background

Giant hiatal hernias are frequently associated with catastrophic complications such as obstruction, perforation and bleeding. Intra-thoracic gastric volvulus (IGV) is the rarest type and represents end stage of giant hiatal hernias before these complications occur.

### Research frontiers

Minimally invasive approaches for the treatment of foregut diseases are increasing worldwide. Laparoscopic management of IGV is probably most technically demanding procedure among the benign foregut diseases. The authors have focused on technically details and preoperative work-up in the management of this uncommon condition.

### Innovations and breakthroughs

Because of the rarity of IGV there is still no prospective randomized study which compares different surgical approaches and controversy exists regarding which surgical approach should be preferred such as; trans-abdominal vs trans-thoracic, open vs laparoscopic, hiatal closure with primary suture vs the use of meshes and the necessity of fundoplication. Laparoscopic approach was the procedure of choice as the authors have extensive experience in laparoscopic anti-reflux surgery. Total sac excision, tensionless hiato-plasty with mesh and Toupet fundoplication were performed in all patients without mortality and minimal morbidity.

### Applications

With careful attention the details, laparoscopic management of IGV is a safe procedure.

### Terminology

IGV is defined as transmigration of the whole stomach into the thorax by rotating 180 degrees around its longitudinal or transverse axis.

### Peer review

The authors have described their experience well in the management of this rare type of giant hiatal hernia.

*Salmonella enterica* (SE) and Crohn's disease (CD) and its clinical implications in Chilean patients.

**METHODS:** Ninety-four unrelated Chilean CD patients from CAREI (Active Cohort Registry of Inflammatory Bowel Disease) presenting to a single inflammatory bowel disease (IBD) unit of a University Hospital were prospectively included in this study. A complete clinical evaluation, including smoking history, was performed at the initial visit, and all the important data of clinical evolution of CD were obtained. Blood samples from these CD patients and 88 healthy sex- and age-matched control subjects were analyzed for exposure to SE and for their *NOD2/CARD15* gene status using the presence of anti-*Salmonella* lipopolysaccharide antibodies [immunoglobulin-G type (IgG)] and polymerase chain reaction (PCR), respectively. We also evaluated exposure to SE in 90 sex- and age-matched patients without CD, but with known smoking status (30 smokers, 30 non-smokers, and 30 former smokers).

**RESULTS:** CD patients comprised 54 females and 40 males, aged  $35.5 \pm 15.2$  years at diagnosis with a mean follow-up of  $9.0 \pm 6.8$  years. CD was inflammatory in 59 patients (62.7%), stricturing in 24 (25.5%) and penetrating in 15 (15.5%). Thirty cases (31.9%) had lesions in the ileum, 29 (30.8%) had ileocolonic lesions, 32 (34.0%) had colonic lesions and 23 (24.4%) had perianal disease. Sixteen CD patients (17%) were exposed to SE compared to 15 (17%) of 88 healthy control subjects ( $P = 0.8$ ). Thirty-one CD patients (32.9%) were smokers, and 7 (7.4%) were former smokers at diagnosis. In the group exposed to SE, 10 of 16 patients (62.5%) were active smokers compared to 21 of 78 patients (26.9%) in the unexposed group ( $P = 0.01$ ). On the other hand, 10 of 31 smoking patients (32%) were exposed to SE compared to 5 of 56 nonsmoking patients (9%), and one of the seven former smokers (14%) ( $P = 0.01$ ). In the group of 90 patients without CD, but whose smoking status was known, there was no differ-

### Abstract

**AIM:** To study the association between exposure to

ence in exposure to SE [3 of 30 smokers (10%), 5 of 30 non-smokers (16%), and 5 of 30 former smokers (16%);  $P = 0.6$ ]. There were no differences in disease severity between CD patients with and those without anti-SE IgG antibodies, estimated as the appearance of stricturing [2 (12.5%) *vs* 22 (28.2%);  $P = 0.2$ ] or penetrating lesions [2 (12.5%) *vs* 13 (16.6%);  $P = 1.0$ ]; or the need for immunosuppressants [11 (68.7%) *vs* 55 (70.5%);  $P = 1.0$ ], anti-tumor necrosis factor therapy [1 (6.2%) *vs* 7 (8.9%);  $P = 1.0$ ], hospitalization [13 (81.2%) *vs* 58 (74.3%);  $P = 0.7$ ], or surgery [3 (18.7%) *vs* 12 (15.3%);  $P = 0.3$ ], respectively]. No other factors were associated with SE, including *NOD2/CARD15* gene status. Seventeen CD patients (18%) had at least one mutation of the *NOD2/CARD15* gene.

**CONCLUSION:** Our study found no association between exposure to SE and CD. We observed a positive correlation between SE exposure and cigarette smoking in Chilean patients with CD, but not with disease severity.

**Key words:** Crohn's disease; *Salmonella*; Infection; Tobacco; Smoking; Environmental factors

**Core tip:** The role and clinical implications of *Salmonella enterica* (SE) in Crohn's disease (CD) are controversial and currently unknown. We evaluated the role of exposure to SE in a cohort of Chilean patients suffering from CD. Although our study showed no association between SE exposure and CD, we observed a positive correlation between SE exposure and cigarette smoking in CD patients, but not with disease severity. These data provide evidence that more precisely defines the real role of *Salmonella* infection, an important environmental factor in CD.

## INTRODUCTION

Crohn's disease (CD) is an immunological bowel disorder of unknown etiology, characterized by chronic relapsing inflammation of the gastrointestinal tract<sup>[1]</sup>. CD is a complex and heterogeneous disorder<sup>[2]</sup>, which is determined by, among other factors, the interaction between diverse environmental and genetic factors<sup>[3]</sup>. Studies on migrants have highlighted the importance of environmental factors in CD, and it is likely that there are important geographical differences<sup>[4,5]</sup>. Among the risk factors associated with CD are infections and smoking<sup>[6-12]</sup>, and both are major public health problems<sup>[13-15]</sup> (<http://www.ispch.cl/sites/>

[default/files/Vigilancia\\_Salmonella\\_spp\\_0](http://www.ispch.cl/sites/default/files/Vigilancia_Salmonella_spp_0)). Preliminary studies have suggested a correlation between CD and infectious gastroenteritis<sup>[16,17]</sup>. A previous report showed that, in some populations, the incidence of CD increases over time after an acute gastroenteritis episode caused by *Salmonella enterica* (SE)<sup>[18]</sup>. However, a recent report did not find an association between SE and CD<sup>[19]</sup>. Different gene-environmental interactions and gene-gene interactions have been studied in CD and are frequently related to the *NOD2/CARD15* gene<sup>[20-25]</sup>. Polymorphisms in this gene have been the most consistent and significant genetic factor implicated in CD susceptibility<sup>[26]</sup>. However, studies of environmental-environmental interaction and their implications are scarce<sup>[27,28]</sup>.

The reason for the possible association between SE and CD is unknown, but it is possible that mucosal immunity changes after SE exposure, promoting immune modification of the intestinal mucosa<sup>[29]</sup>. Thus, the intestinal mucosa may develop an enhanced inflammatory response when other factors affecting the immune response (genetic or environmental) are present. Moreover, the protein encoded by the *NOD2/CARD15* gene acts as an intracellular receptor that recognizes bacteria-derived molecules, including SE<sup>[30,31]</sup>. In addition, the clinical implications of SE in CD are unknown.

The aim of this study was to explore whether there is an association between SE exposure and CD and its implications in Chilean patients with CD.

## MATERIALS AND METHODS

### CD patients and clinical definitions

Ninety-four unrelated Chilean CD patients from CAREI (Active Cohort Registry of Inflammatory Bowel Disease) visiting a single inflammatory bowel disease (IBD) unit of a university referral center between December 2010 and June 2012 were included in this study. All CD patients gave written informed consent to participate in the study, and the local ethics committee approved the project. The study was performed in accordance with the principles stated in the declaration of Helsinki.

The diagnosis of CD was based on standard clinical, radiological, endoscopic, and histological criteria<sup>[32]</sup>. A complete clinical evaluation was performed at the initial visit, and all the important data of the clinical evolution of CD were obtained from a prospective clinical database of our unit. This evaluation included gender, age at diagnosis of CD, length of follow-up, location and behavior of CD, family history of IBD, previous appendectomy, smoking habit, oral contraceptive use, extra-intestinal manifestations of CD, and history of gastroenteritis caused by SE and/or vaccine for SE. The following characteristics were also documented: need for surgery or hospitalization for CD, use of steroids, use of immunosuppressants (azathioprine, 6-mercaptopurine and methotrexate) and use of anti-tumor necrosis factor (TNF) therapy.

Smokers were defined as patients who smoked more than seven cigarettes per week (one cigarette daily). A for-

mer smoker was defined as a patient who quit smoking at least 1 year before diagnosis. Nonsmokers were defined as patients who had never smoked or who smoke less than seven cigarettes per week<sup>[9]</sup>. The location and behavior of CD were determined according to X-ray and endoscopic findings; all patients underwent these procedures at least once at our center. The location and behavior of CD were defined according to criteria of the Montreal classification<sup>[2]</sup>; however, behaviors were registered as non-exclusive categories if intestinal stricturing occurred at a different time from the penetrating lesions; therefore, patients could belong to both categories. The severity of the disease was estimated as the appearance of stricturing or penetrating lesions or the need for immunosuppressants, anti-TNF therapy, hospitalization or surgery.

### Control patients

Eighty-eight unrelated Chilean healthy blood donors, matched by sex and age, were studied as control subjects to determine if there were any differences in the frequency of exposure to SE, independent of *NOD2/CARD15* gene status. In addition, we studied the frequency of SE exposure in a sample of patients without CD who were visiting a respiratory disease unit at our university center. These patients were differentiated by their smoking status and matched by sex and age. Thus, we studied 90 patients who were distributed as follows: 30 smokers, 30 non-smokers, and 30 former smokers. Smoking status was defined in the same way as in CD patients<sup>[9]</sup>.

### Determination of *Salmonella* exposure

For each subject, a venous blood sample was extracted to obtain serum, which was stored at -70 °C freezer until analysis. To evaluate previous exposure to *Salmonella*, serum samples were tested for the presence of anti-*Salmonella* lipopolysaccharide (LPS) antibodies [immunoglobulin-G type (IgG)] using an enzyme-linked immunosorbent assay (ELISA)<sup>[33]</sup>. The sensitivity and specificity of this methodology have been evaluated in a previous study<sup>[34]</sup>. Briefly, ELISA plates (Nalgene-Nunc®, Thermo Scientific, Waltham, MA, United States) were activated overnight at 4 °C with 500 ng of *Salmonella typhimurium* LPS (L7261-25MG SIGMA-ALDRICH, St. Louis, MO, United States) in 50 µL 0.1 mol/L bicarbonate buffer (NaHCO<sub>3</sub>, Merck, Whitehouse Station, NJ, United States) and blocked with 100 µL of PBS-BSA 3% for 1 h at room temperature. Then, 50 µL of serum diluted in PBS at 1/64, 1/128, and 1/256 was added to each well and incubated for 2 h at room temperature. Next, three washes with 200 µL of PBS-Tween 0.05% were performed. After the washes, 50 µL of an IgG conjugated with peroxidase (clone G18-145, Becton Dickinson, Franklin Lakes, NJ, United States) was added to each well (diluted 1/2000 in PBS) and incubated for 2 h at room temperature. Three washes with PBS-Tween 0.05% were then performed, and the positive reaction was developed using 3-3'-5'-tetramethyl-benzidine at a final concentration 100 µg/mL (Sigma-

Aldrich) as a colorimetric substrate. The enzymatic reaction was stopped with 2 mol/L H<sub>2</sub>SO<sub>4</sub>, and absorbance was recorded at 450 nm in an ELISA plate reader (Thermo Scientific). As a positive control, a group of subjects who had a previous history of gastroenteritis caused by SE or typhoid fever were included in this study and were used to standardize the methodology. As negative controls, a group of control subjects that had not been exposed to *Salmonella* were included, which comprised a serum of a pool of nine subjects up to 19 years old with no previous clinical history of gastroenteritis or typhoid fever. Both positive and negative controls were included in all the assays performed. Patients exposed to SE were defined as those patients with OD values higher than 2 SD over the value obtained for negative controls in the three dilutions tested in each determination. Those subjects not exposed to SE were all the other CD patients. As described before, this test allows the identification of patients that have been infected with either *Salmonella Typhimurium* or *Salmonella Enteritidis*<sup>[34]</sup>. These two serovars account for 80% of the cases of gastroenteritis caused by *Salmonella* in Chile ([http://www.ispch.cl/sites/default/files/Vigilancia\\_Salmonella\\_spp\\_0.pdf](http://www.ispch.cl/sites/default/files/Vigilancia_Salmonella_spp_0.pdf)).

### *NOD2/CARD15* genotyping

To detect *NOD2/CARD15* gene variants, genomic DNA from whole blood samples was isolated using standard molecular biology techniques. Specific sequences of exon 4 (missense mutation R702W), exon 8 (missense mutation G908R) and exon 11 (frameshift mutation L1007fsinsC) of the *Nod2/CARD15* gene were amplified by a polymerase chain reaction (PCR, using primers 5'- CCT TCA GAT CAC AGC AGC CTT C -3' and 5'- GGG ATG GAG TGG AAG TGC TTG -3' for exon 4; 5'- TCT AAG TCT GTA ATG TAA AGC CAC -3' and 5'- AGC TCC TCC CTC TTC ACC TGA -3' for exon 8, and 5'- CTG AGC CTT TGT TGA TGA GCT C -3' and 5'- ATT CTT CAA CCA CAT CCC CAT TC -3' for exon 11. PCR amplifications were performed in a MaxiGene Gradient Thermocycler (Axygen, Union City, CA, United States), using 250 ng of DNA, 1 nmol/mL of each primer, 0.2 mmol/L deoxynucleoside triphosphates, 1.5 mmol/L Magnesium Chloride and 50 U/mL of Taq DNA polymerase (Invitrogen, Carlsbad, CA, United States), using standard PCR amplification cycles. The PCR products obtained for exon 4 and exon 8 were digested with the restriction enzymes *Hpa* II and *Hba* I (New England Biolabs, Ipswich, MA, United States), and the digested PCR products were resolved by electrophoresis in 1% agarose gels containing 0.5 µg/mL ethidium bromide and visualized under a UV light transilluminator (UVP, Inc., Upland, CA, United States). PCR products obtained for exon 11 were gel purified and sequenced in an ABI 3100 automatic sequencer by Macrogen (<http://www.macrogen.com>). Frameshift mutations were analyzed for each sample, using the Vector NTI software (Invitrogen). CD patients positive for at least one of the

SE: *Salmonella enterica*; IBD: Inflammatory bowel disease.

*NOD2/CARD15* gene polymorphisms were categorized as gene variant carriers.

### Statistical analysis

CD patients were compared to control subjects in relation to the presence of anti-SE IgG. Among CD patients, we compared those exposed to SE *vs* unexposed in relation to the most important clinical and genetic characteristics associated with CD. Categorical variables were compared using the Fisher's exact test. Continuous variables were expressed as the mean  $\pm$  SD, and compared using Student's *t* test. A *P* value of less than 0.05 was considered to indicate statistical significance. Analysis was carried out using the StatView software package (SAS Institute Inc., Cary, NC, United States).

## RESULTS

### Patient population

The study population consisted of 94 patients with CD; 54 females and 40 males. Age at diagnosis was  $35.5 \pm 15.2$  years. Mean follow-up was  $9.0 \pm 6.8$  years, with a median of 7.0 years. Behavior of CD was inflammatory in 59 patients (62.7%), stricturing in 24 patients (25.5%) and penetrating in 15 patients (15.5%). Thirty cases (31.9%) had lesions in the terminal ileum, 29 (30.8%) were ileocolonic, 32 (34.0%) had colonic lesions and 23 (24.4%) had perianal disease. Five patients (5%) reported previous gastrointestinal infection caused by *Salmonella*, and only one patient (1%) had received a vaccine for *Salmonella*. Thirty-one CD patients (32.9%) were smokers, and seven (7.4%) were former smokers at diagnosis. The clinical characteristics of CD are shown in Table 1.

**Table 2 Comparison between Crohn's disease patients exposed and those not exposed to *Salmonella enterica***

### Exposure to SE and analysis of factors influencing exposure to SE

Sixteen CD patients (17%) were exposed to SE, as determined by the presence of anti SE-IgG in the serum. Among the 88 sex- and age-matched healthy blood donors, 15 patients (17%) were exposed to SE. There was no difference in exposure to SE between CD and control subjects (*P* = 0.8).

Comparison of the clinical characteristics between those who had been exposed to SE and those who had not, are shown in Table 2. With the exception of smoking, there were no significant differences in the clinical variables studied between the group of patients exposed to SE and those not exposed. Exposure to SE was significantly associated with cigarette smoking; in the group exposed to SE, 10 of 16 patients (62.5%) were active smokers compared to 21 of 78 patients (26.9%) in the group that was not exposed (*P* = 0.01). On the other hand, 10 of 31 smokers (32%) had exposure to SE compared with 5 of 56 nonsmokers (9%) and 1 of 7 former smokers (14%) (*P* = 0.01). No other factors were associated with exposure to SE. We also analyzed whether *NOD2/CARD15* gene variations were associated with exposure to SE, and the result was negative (*P* = 0.2, Table 2).

To assess whether increased exposure to SE was specific to CD patients who smoked, we determined the frequency of exposure to SE in smoking patients without CD. In these patients, there was no difference in exposure

to SE, defined by 3 of 30 smokers (10%) with detectable levels of anti-SE IgG compared to 5 of 30 non-smokers (16%) and 5 of 30 former smokers (16%), and the *P* value was non-significant (*P* = 0.6).

Age at diagnosis of CD, sex distribution, duration of CD, CD location, family history of IBD, and extraintestinal manifestations were similar in both groups of patients (Table 2), whereas other environmental clinical characteristics, such as use of oral contraceptives and previous appendectomy, were similar among carriers and non-carriers of anti-SE IgG (Table 2).

### CD severity according to presence of anti-SE IgG

The prevalence of several indicators of disease severity, including stricturing or penetrating lesions, the need for immunosuppressants, anti-TNF therapy, hospitalization or surgery was similar in CD patients with and those without anti-SE IgG antibodies (Table 2).

### NOD2/CARD15 genotype

Seventeen CD patients (18%) had at least one mutation of the *NOD2/CARD15* gene. All were heterozygous for these variants. The distribution of the three variants was as follows: 11 (11%) for R702W, one (1%) for G908R and five (5%) for L1007fsinsC. This frequency was higher than in control subjects, with 3 of 88 healthy blood donors (3%) displaying least 1 *NOD2/CARD15* gene mutation (*P* = 0.003).

## DISCUSSION

This study evaluated the role of *Salmonella* in CD and its interactions with genetic (*NOD2/CARD15* gene) and environmental risk factors in Chilean patients. This is a step towards unraveling the importance of environmental factors in CD and their association with other risk factors in a new population. In CD, an important part of the disease pathogenesis could be related to environmental factors and their interaction with other patient factors<sup>[1,3,11,22,27]</sup>. Our study showed no difference in the level of previous exposure to *Salmonella* between CD patients and controls. On the other hand, we observed a striking correlation between smoking and exposure to SE in CD, independent of *NOD2/CARD15* gene variants, implying a particular pattern of environment-environment interaction.

The role of microbes in CD is supported by the fact that most mouse models of IBD develop colitis only in the presence of intestinal bacteria<sup>[35]</sup>, and several human studies have shown remissions in CD patients after antibiotic therapy<sup>[36]</sup>. A growing body of evidence suggests a correlation between CD and infectious gastroenteritis<sup>[16,17]</sup> ([http://www.ispch.cl/sites/default/files/Vigilancia\\_Salmonella\\_spp\\_0.pdf](http://www.ispch.cl/sites/default/files/Vigilancia_Salmonella_spp_0.pdf)). Although a previous study implicated *Salmonella* as a risk factor for CD, in which patients with gastroenteritis caused by *Salmonella* had a higher risk for developing IBD compared to age- and sex-matched controls<sup>[18]</sup>, our study showed no difference

in previous exposure to *Salmonella* between CD patients and controls. The design of our study differs from other studies because the diagnostic criterion was based on a cross serological test to determine previous exposure to SE using the presence of anti-*Salmonella* IgG. Given the relatively low rate of history of previous typhoid fever or gastroenteritis caused by SE in our CD patient population, it is possible that independent factors of gastrointestinal infections may be more relevant in our population, including non-*NOD2/CARD15* genes, given the low frequency of mutations in this gene in our CD patients. However, our findings agree with a recent report that did not find an association between SE and CD, and this study strongly suggests that the positive associations observed in the earlier studies were the result of a detection bias<sup>[19]</sup>. The study of Jess *et al*<sup>[19]</sup> showed that the temporal risk patterns for IBD are not different following negative and positive stool tests for SE. This observation strongly suggests that increased occurrence of *Salmonella* around the time of diagnosis results from detection bias resulting from increased rates of stool testing. Moreover, the occurrence of *Salmonella* infection in patients with nonspecific gastrointestinal symptoms compatible with CD could represent a "by chance" finding and should not exclude the patients from subsequent clinical examination if gastrointestinal symptoms persist<sup>[19]</sup>.

In other autoimmune diseases, such as rheumatoid arthritis (RA), smoking is a well-established environmental risk factor<sup>[15,37,38]</sup>. In CD, smoking is also a major risk factor, and it is associated with several complications over the course of CD<sup>[9,10,39]</sup>. A meta-analysis supports the view that current smoking is associated with a significantly higher risk of CD<sup>[40]</sup>. Recent studies have reinforced the importance of smoking, suggesting that studies of risk factors for IBD should be stratified for smoking behavior, especially in cohorts of limited sample size, as in the current study<sup>[41]</sup>.

We found a significant association between *Salmonella* exposure and active smoking in a group of Chilean CD patients. These two factors may have an additive effect on the development of the disease in a subset of CD patients. To date, there is no clear biological explanation for why smoking is associated with an increased risk of CD<sup>[42]</sup>. In smokers with CD, an increased immune response against *Salmonella* could be developed, based on a greater presence of anti-*Salmonella* IgG. SE may produce a change in mucosal immunity<sup>[29]</sup>, and this change could be exacerbated in smoking patients. This could lead to tissue damage and the onset of IBD in susceptible hosts. *Salmonella* triggers an inflammatory response categorized as Th1<sup>[43]</sup>, and given that intestinal immune response in CD is classically recognized as Th1, it is conceivable that invasive bacteria, such as *Salmonella*, could trigger this abnormal intestinal immune reaction. In addition, inflammation is required by SE to colonize intestinal mucosa and compete with resident microflora<sup>[44]</sup>. In experimental studies, prolonged exposure to concentrated smoke leads to decreased expression and activity of the anti-inflam-

matory enzyme heme oxygenase-1<sup>[45]</sup>, and an increase in cell autophagy in the bowel<sup>[46]</sup>. It is possible that chronic smoking may cause a pro-inflammatory state, and *Salmonella* infection could be facilitated in smoking patients. *Salmonella* infection and tobacco consumption are a major public health problem in Chile and worldwide<sup>[9,13-15]</sup> ([http://www.bcn.cl/carpeta\\_temas/tema\\_as\\_portada.2006-09-25.0806013222/documentospdf-sobre-obesidad/VIGIA20.pdf](http://www.bcn.cl/carpeta_temas/tema_as_portada.2006-09-25.0806013222/documentospdf-sobre-obesidad/VIGIA20.pdf) and [http://www.redsalud.gov.cl/portal/docs/page/minsalcl/g\\_home/submenu\\_portada\\_2011/ens2010.pdf](http://www.redsalud.gov.cl/portal/docs/page/minsalcl/g_home/submenu_portada_2011/ens2010.pdf)), and there should be a greater emphasis on the importance of food safety and smoking avoidance.

Notably, we did not observe any association with a higher severity in patients exposed to SE compared to those not exposed, defined as the presence of stricturing or penetrating lesions or the need for immunosuppressants, anti-TNF therapy, hospitalization or surgery.

A limitation of our study is the relatively small sample population; therefore, future larger studies will be needed to confirm the relationship between smoking and infection with SE. However, the absence of this association in a control sample without CD supports the notion that this is a specific feature of CD patients.

In conclusion, our study found no association between exposure to SE and CD in a new well-defined population of Chilean CD patients. We observed a positive correlation between SE exposure and cigarette smoking in patients with CD, but not with disease severity. This research more precisely defines the real role of *Salmonella* exposure, an important environmental factor in CD, and how risk factors combine to trigger CD in a given patient.

## ACKNOWLEDGMENTS

We thank nurse Carolina Reyes for her important contribution to the development of this research.

## COMMENTS

### Background

Different environmental factors have been studied in Crohn's disease (CD). An important environmental factor that has been implicated as a possible trigger of CD is infectious gastroenteritis. There is a major controversy concerning the role of *Salmonella enterica* (SE) as a risk factor for CD. It is possible that there are important geographical differences; however, to date, there are still no data addressing the interactions between SE exposure and other environmental factors and the clinical implications of these interactions in CD.

### Research frontiers

Different gene-environment and gene-gene interactions have been studied in CD. However, environment-environment interaction studies and their clinical implications are scarce. There may be important ethnic variations. The focus of this research was to establish the real importance of an environmental factor as infectious gastroenteritis caused by SE in Chilean CD patients.

### Innovations and breakthroughs

Results of previous studies on the role of SE in CD have been controversial. The present study was designed to evaluate the role of SE in CD and its interactions with genetic and environmental risk factors in Chilean patients. The authors determined previous exposure to SE defined by the presence of anti-*Salmonella* IgG. Although their study showed no difference in previous exposure to *Salmonella* between CD patients and controls, they observed that smoking was

associated with exposure to SE in CD. If they analyze a key element, such as clinical implication of SE exposure, they did not observe a correlation between SE exposure and CD severity. This research more precisely defines the role of *Salmonella* infection, an important environmental factor, in CD and how risk factors combine to trigger CD in a given patient.

### Applications

The study results suggests that SE exposure is not associated with CD; however, the authors observed that smoking was associated with exposure to SE in Chilean CD patients, independent of other factors, implying a particular pattern of environment-environment interaction.

### Terminology

Gene-gene, gene-environment, or environment-environment interactions: In complex diseases, such as CD, there are different implications or consequences for the disease when two factors (gene and/or environmental) are present in the same patient.

### Peer review

This paper represents a considerable amount of good work, and it is a well-done and controlled study. It is a study in a well-defined population. This manuscript aimed to study the association between exposure to SE and CD. In addition, they also analyzed the involvement of cigarette smoking. They showed no association for the SE status and CD, but positive association between SE and smoking in CD.

### Abstract

**AIM:** To evaluate individual components of the antro-

pyloro-duodenal (APD) motor response to graded small intestinal glucose infusions in healthy humans.

**METHODS:** APD manometry was performed in 15 healthy subjects (12 male;  $40 \pm 5$  years, body mass index  $26.5 \pm 1.6$  kg/m<sup>2</sup>) during four 20-min intraduodenal infusions of glucose at 0, 0.5, 1.0 and 1.5 kcal/min, in a randomised double-blinded fashion. Glucose solutions were infused at a rate of 1 mL/min and separated by 40-min "wash-out" period. Data are mean  $\pm$  SE. Inferential analyses are repeated measure analysis of variance with Bonferroni post-hoc testing.

**RESULTS:** At 0 kcal/min frequency of pressure waves were: antrum ( $7.5 \pm 1.8$  waves/20 min) and isolated pyloric pressure waves (IPPWs) ( $8.0 \pm 2.3$  waves/20 min) with pyloric tone ( $0.0 \pm 0.9$  mmHg). Intraduodenal glucose infusion acutely increased IPPW frequency ( $P < 0.001$ ) and pyloric tone ( $P = 0.015$ ), and decreased antral wave frequency ( $P = 0.007$ ) in a dose-dependent fashion. A threshold for stimulation was observed at 1.0 kcal/min for pyloric phasic pressure waves ( $P = 0.002$ ) and 1.5 kcal/min for pyloric tone and antral contractility.

**CONCLUSION:** There is hierarchy for the activation of gastrointestinal motor responses to duodenal glucose infusion. An increase in IPPWs is the first response observed.

**Key words:** Glucose; Gastrointestinal motility; Pyloric; Antral; Duodenum; Manometry; Motor activity; Blood glucose

**Core tip:** Antro-pyloro-duodenal manometry was performed in 15 healthy subjects. Subjects were randomly given 20 min intraduodenal infusions of glucose at 0, 0.5, 1.0 and 1.5 kcal/min. Intraduodenal glucose infusion acutely increased isolated pyloric pressure wave

frequency and pyloric tone and decreased antral wave frequency in a dose-dependent fashion. A threshold for stimulation was observed at 1.0 kcal/min for pyloric phasic pressure waves and 1.5 kcal/min for pyloric tone and antral contractility. These data suggest that there is hierarchy for the activation of gastrointestinal motor responses to small intestinal glucose stimulation.

## INTRODUCTION

Gastric emptying of liquid nutrient is regulated at approximately 2-3 kcal/min by antro-pyloro-duodenal (APD) motor activity<sup>[1,2]</sup>. Nutrient in the small intestine stimulates receptors and initiates a feedback loop that affects motility of individual components of the APD area<sup>[3]</sup>. These motor changes include antral suppression<sup>[1]</sup>, and stimulation of phasic and tonic pyloric contractions<sup>[4,5]</sup>.

The precise APD motor response to nutrient probably depends in part on the macronutrient composition of the “meal”. Recent data suggest that the “doses” of lipid nutrient initiating these motor changes in health are much less than previously recognised<sup>[6]</sup>. Likewise small intestinal carbohydrate infusions at rates that are within normal gastric emptying rates have marked effects on the APD unit<sup>[7]</sup>. However, the specific threshold and/or hierarchy of the APD response to nutrient stimulation are unknown. The aim of this study was to assess the responses of the distal stomach to graded small intestinal nutrient stimulation in health.

## MATERIALS AND METHODS

### Subjects

Studies were performed in fifteen healthy volunteers [male:female, 12:4; age:  $40 \pm 5$  years; body mass index (BMI):  $26.5 \pm 1.6$  kg/m<sup>2</sup>]. Subjects were screened and excluded if they were diabetic, pregnant or breast feeding, had previous gastrointestinal surgery, a history of gastrointestinal disease or taking medications known to alter gastrointestinal motility. None of the subjects regularly smoked tobacco or drank more than 20 g of alcohol per day.

The protocol was approved by the research ethics committee of the Royal Adelaide Hospital, and each subject gave written informed consent prior to the commencement of the study.

### Measurement techniques

**Multi-lumen perfusion manometry:** APD motility

was assessed by a 100-cm multi-lumen perfusion manometric assembly (outer diameter 3.5 mm; Mui Scientific, Ontario, Canada). The assembly incorporated 15 pressure recording channels (side-holes spaced 1.5 cm apart), with a 4.5 cm sleeve-sensor, and an infusion port. Correct placement of the sleeve across the pylorus was determined using continuous measurement of the antro-duodenal transmucosal potential difference (TMPD) gradient<sup>[8]</sup>. The assembly was positioned so that five side holes (A1-A5) were located in the gastric antrum and seven in the proximal duodenum (Figure 1). The infusion port was located at the catheter tip to enable the delivery of enteral feed directly into the duodenum 9 cm distal to the pylorus. Thirteen manometric lumina were perfused with degassed water at a rate of 0.04 mL/min except for the sleeve perfused at a rate of 0.15 mL/min. To monitor TMPD two channels on either end of the sleeve were perfused with degassed 0.9% saline. Pressure and TMPD data were recorded on a computer using purpose written software program (Medical Measurement Systems, Enschede, The Netherlands)<sup>[8]</sup>.

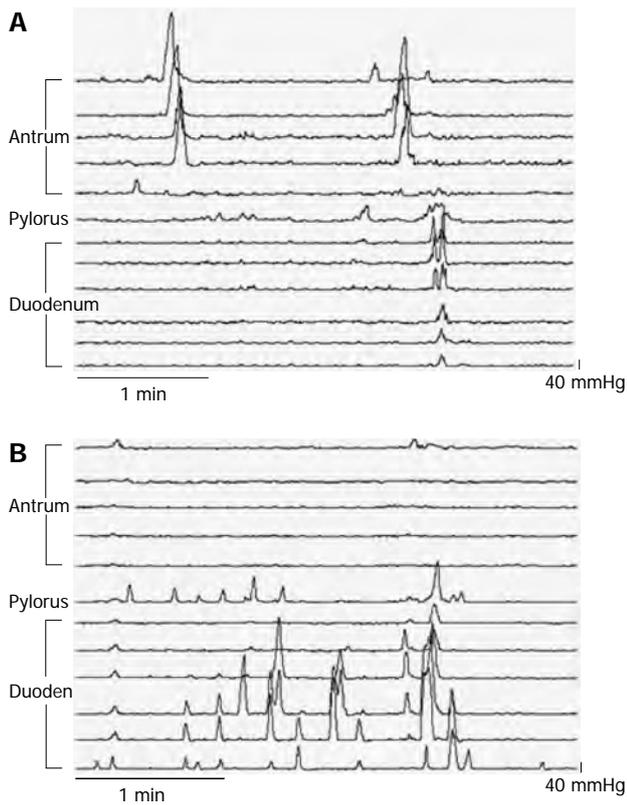

**Blood glucose concentration:** As hyperglycaemia has a major impact on gastric motility<sup>[9]</sup>, blood glucose concentrations were measured using a portable glucometer (Precision Plus, Abbott Laboratories, Bedford, United States) every 20 min throughout the study.

### Protocol

Subjects were studied in the gastrointestinal motility laboratory of the Royal Adelaide Hospital after an overnight fast. The manometric catheter was inserted into an anaesthetised nostril and passed into the stomach. The catheter passed into the duodenum assisted by spontaneous peristalsis. A cannula was inserted into an antecubital vein for blood sampling.

Each subject received intraduodenal infusions of 50% glucose solution (Pharmalab NSW Australia) diluted in water at: (1) 0.5 kcal/min; (2) 1 kcal/min; (3) 1.5 kcal; and (4) 0 kcal/min (0.9% saline only). Each solution was prepared in separate 20 mL syringes by a study investigator who was not involved in the data analysis and infused at a rate of 1 mL/min. Randomisation of glucose load was computer generated. Each syringe was then covered by the investigator preparing the syringes and labelled according to the randomisation schedule. The syringe was connected to the manometric catheter using opaque minimal volume extension tubing to ensure blinding of the research staff.

Following correct positioning of the catheter sleeve across the pylorus, a 20 min fasting period commenced. At the end of the fasting period the scheduled load was infused directly into the duodenum, *via* a volumetric syringe driver [Terumo Syringe Pump (STC-523), Medtel Australia], followed by a 40 min “washout” period of 0.9% saline (1 mL/min). A similar schedule was followed for all glucose loads. Blood samples were taken every 20 min throughout the study period to measure blood glucose

**Figure 1** Representative trace of intraluminal motility at (A) 0 kcal/min and at (B) 1.5 kcal/min. Occlusive contraction waves commence in the antrum and propagate through the duodenum. At 1.5 kcal/min isolated pyloric pressure waves occurred more frequently and a reduction in propagated antral contractility was observed.

concentrations.

### Data analysis

Manometric data were imported into Acqknowledge 3.2.7 and were analysed manually. The frequencies of APD pressure waves were determined as previously described<sup>[8]</sup>. In brief, pressure waves were included in the analysis when a rise in intraluminal pressure was greater than the minimum amplitude over the appropriate time-period and when the assembly was positioned correctly according to established TMPD criteria. Migrating motor complex (MMC) phase III activity associated pressure waves were considered to be representative of fasting motor patterns and were counted as zero for the period of phase III activity. Antral phase III MMC activity was defined as rhythmic pressure wave activity occurring at a maximum frequency (three pressure waves per minute) for at least one minute with a temporal relationship with duodenal activity. Duodenal phase III MMC was defined as a maximum frequency of 10-12 pressure waves/min for at least 2 min<sup>[8]</sup>.

A pressure wave in the antrum and pylorus was defined as a pressure rise of 10 mmHg or more from baseline and lasting between 6.1 and 20 s<sup>[10]</sup>. Isolated pyloric pressure waves (IPPWs) were defined as pressure waves at least 10 mmHg amplitude recorded only in the sleeve channel<sup>[5]</sup>. A duodenal PW was defined as a pressure rise

of 6 mmHg or more from baseline and lasting between 0.8 and 7 s<sup>[10]</sup>. Change in pyloric tone (basal pyloric pressure) was calculated as the difference in baseline pressure in the sleeve sensor from the duodenum<sup>[11]</sup> at 4-min intervals and presented as mean over 20 min.

### Statistical analysis

Data are presented as mean  $\pm$  SE. Repeated-measures analysis of variance (RM-ANOVA) were used to test for effects on pressure wave activity and pyloric tone of different caloric loads. Residuals were normally distributed and, furthermore, analyses using the equivalent non-parametric test (Friedman) remained significant. On testing there was no order effect apparent. Differences at the level of  $P < 0.05$  were considered significant and allowed post-hoc comparison between loads which were corrected according to Bonferroni adjustment.

## RESULTS

All subjects tolerated the study without adverse symptoms or effects.

### Motility

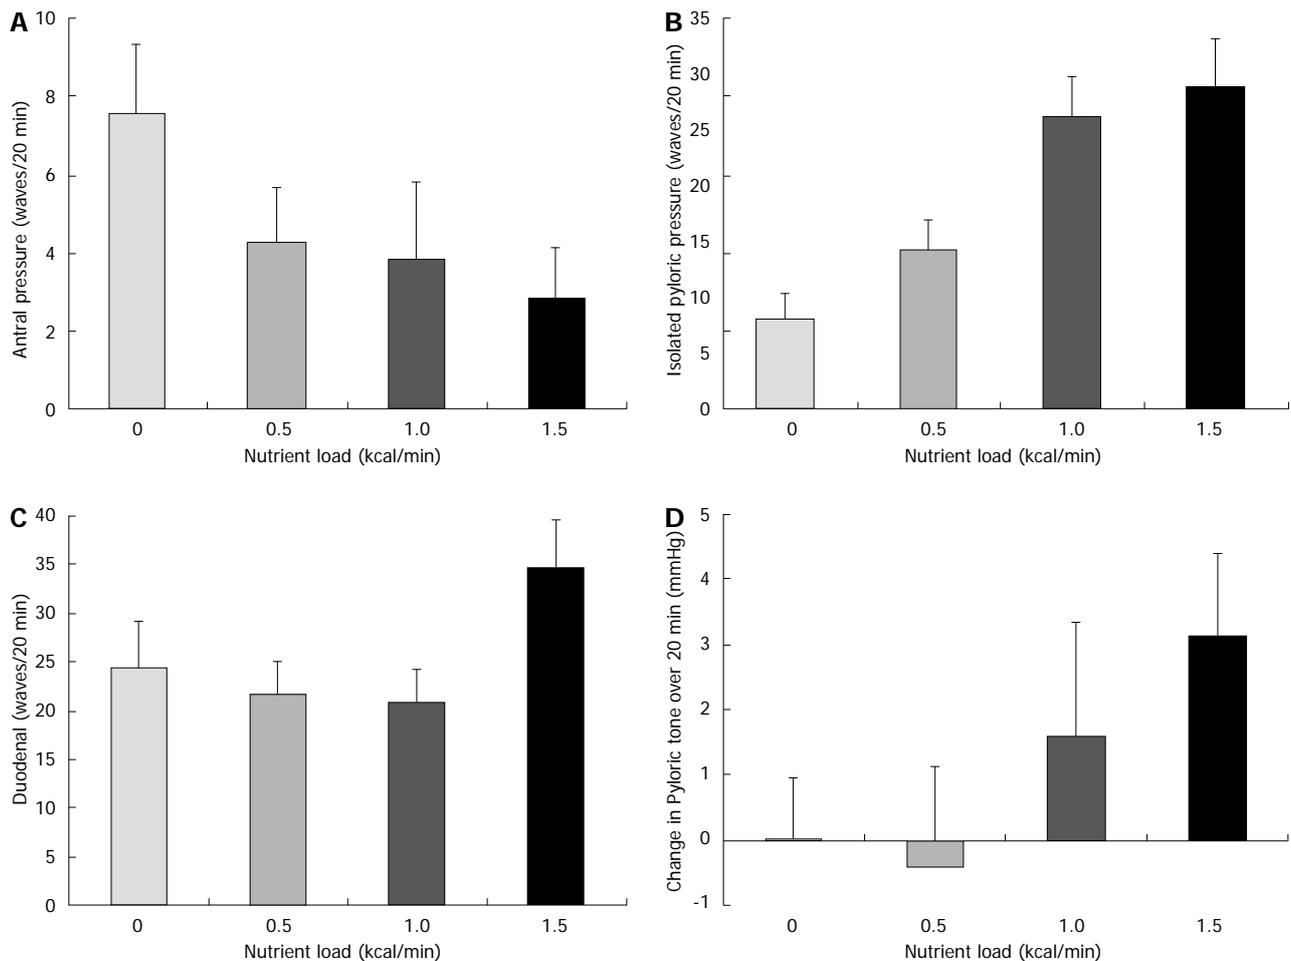

An example of a manometric trace at two different loads is shown in Figure 1.

**Antral pressure waves:** The effect of glucose loads on antral pressure wave activity is shown in Figure 2A. Increasing the caloric load had an effect on antral wave frequency ( $P = 0.007$ ) with marked attenuation of antral pressure wave activity at 1.5 kcal/min, when compared to 0 kcal/min (0 kcal/min:  $7.5 \pm 1.8$  waves/20 min *vs* 1.5 kcal:  $2.8 \pm 1.3$  waves/20 min;  $P = 0.007$ ).

**IPPWs:** The effects of glucose loads on IPPW activity are shown in Figure 2B. The frequency of IPPWs were affected by caloric load ( $P < 0.001$ ) with a substantial increase in pressure waves occurring with increasing nutrient (0 kcal/min:  $8.0 \pm 2.3$  waves/20 min *vs* 1.0 kcal:  $25.9 \pm 3.7$  waves/20 min;  $P = 0.002$ ). The increasing frequency of IPPW during glucose infusion occurred in a dose dependent fashion with 1.0 kcal/min the observed threshold to stimulate the pylorus (0 kcal/min:  $8.0 \pm 2.3$  waves/20 min *vs* 0.5 kcal/min:  $14.2 \pm 2.7$  waves/20 min;  $P = 0.294$ ; but 0.5 kcal/min  $14.2 \pm 2.7$  waves/20 min *vs* 1.0 kcal:  $25.9 \pm 3.7$  waves/20 min;  $P = 0.037$ ).

**Duodenal pressure waves:** The effects of glucose loads on duodenal wave activity are shown in Figure 2C. There was a difference between treatments over time in duodenal motor wave activity with different caloric loads ( $P = 0.012$ ). However, post-hoc testing did not reveal a difference between the individual loads (0 kcal/min:  $24.4 \pm 4.7$  waves/20 min *vs*  $34.7 \pm 4.9$  waves/20 min,  $P = 0.22$ ; and 0.5 kcal/min  $21.7 \pm 3.3$  waves/20 min *vs*  $34.7 \pm 4.9$  waves/20 min,  $P = 0.058$ ).

**Pyloric tone:** The effects of glucose loads on pyloric

**Figure 2** Antral, isolated pyloric, duodenal pressure waves and pyloric tone at differing caloric loads. A: Reduction in antral motility occurred with increasing glucose load with marked attenuation of antral pressure wave activity at 1.5 kcal/min, when compared to 0 kcal/min (0 kcal/min:  $7.5 \pm 1.8$  waves/20 min vs 1.5 kcal:  $2.8 \pm 1.3$  waves/20 min;  $P = 0.007$ ); B: The frequency of isolated pyloric pressure waves increased with increasing caloric load. The number of waves/20 min were statistically different between 0 and 1.0 kcal/min (0 kcal/min:  $8.0 \pm 2.3$  waves/20 min vs 1.0 kcal/min:  $25.9 \pm 3.7$  waves/20 min;  $P = 0.002$ ); C: The nutrient load did not effect duodenal wave frequency when comparing 0 kcal/min to 1.5 kcal/min (0 kcal/min:  $24.4 \pm 4.7$  waves/20 min vs 1.5 kcal/min:  $34.7 \pm 4.9$  waves/20 min;  $P = 0.22$ ); D: Pyloric tone increased in response to increasing caloric loads ( $P = 0.015$ ). Between 0.5 and 1.5 kcal/min the difference was significant (0.5 kcal/min:  $-0.4 \pm 1.1$  mmHg vs 1.5 kcal/min:  $3.1 \pm 1.3$  mmHg;  $P = 0.008$ ).

tone are shown in Figure 2D. There was an observed difference between treatments in pyloric tone ( $P = 0.015$ ). The difference between 0 and 1.5 kcal/min was significant prior ( $P = 0.035$ ), but not following Bonferroni adjustment ( $0.0 \pm 0.9$  vs  $3.12 \pm 1.3$ ;  $P = 0.207$ ). However, the difference remained significant between 0.5 and 1.5 kcal/min ( $-0.4 \pm 1.1$  vs  $3.1 \pm 1.3$ ;  $P = 0.008$ ).

### Blood glucose concentrations

Blood glucose concentrations were similar prior to commencing each infusion (0, 0.5, 1.0 and 1.5 kcal/min:  $6.5 \pm 0.3$  mmol/L,  $5.9 \pm 0.2$  mmol/L,  $5.8 \pm 0.3$  mmol/L vs  $5.7 \pm 0.2$  mmol/L;  $P = 0.625$ ) and at the completion of the infusion ( $5.9 \pm 0.2$ ,  $5.9 \pm 0.2$ ,  $6.4 \pm 0.3$  vs  $6.2 \pm 0.2$ ;  $P = 0.079$ ).

## DISCUSSION

The major finding of this study is that, in health, there is

a hierarchical response in the APD motor area to increasing glucose loads. The hierarchical response is graded, with initial stimulation of IPPWs and then inhibition of antral activity and an increase in pyloric tone. An increase in duodenal pressure wave frequency also occurred with a caloric load of 1.5 kcal/min.

In health, gastric emptying of nutrient liquid is regulated by the distal stomach which is affected by nutrient stimulating receptors in the small intestine<sup>[2]</sup>. Pilichiewicz *et al*<sup>[6]</sup> showed that intraduodenal infusions of as little as 0.25 kcal/min of lipid emulsion (10% intralipid) attenuated antral motility and increased pyloric phasic pressure waves. The same authors also showed that glucose at 1 kcal/min for 120 min reduced antral wave frequency but an increase in IPPWs only occurred at 4 kcal/min<sup>[7]</sup>. Pressure waves isolated to the pylorus are an integral component of the APD response to duodenal nutrient, and may be the most important mechanism to slow gastric emptying<sup>[4]</sup>. In addition, pyloric pressure waves assist

with the mixing of chyme<sup>[12]</sup> and initial stimulation of IPPWs prior to effects on other components of the APD unit should assist with trituration. Accordingly, we hypothesised that APD motor function would be affected by carbohydrate load in a hierarchical fashion and, given their substantial importance, IPPWs would occur early. It was anticipated that the magnitude of effect may be, relatively, small and the protocol was designed to detect small differences. The carbohydrate loads chosen were around 1 kcal/min<sup>[7]</sup>, which were considered physiologically relevant, the sample size was increased compared to previous studies<sup>[6,7]</sup> and the study was undertaken on a single day to minimise intrasubject variability. Lastly, the infusion periods were limited to 20 min as “adaptation” to small intestinal caloric loads has been reported during prolonged infusions<sup>[13]</sup> and if this occurred, it would have reduced the likelihood of detecting a true difference. This study shows that modulation of each component of the APD unit is hierarchical and dependent on caloric load; initially resistance to trans-pyloric flow occurs with IPPWs and, subsequently, antral propulsive force decreases. The implication of this finding is that small intestinal delivery of nutrient, even within so-called “normal” gastric emptying rates has a substantial effect on APD motor patterns.

Duodenal phasic activity is characterised by irregular motor patterns with both antegrade and retrograde pressure wave sequences<sup>[14]</sup>. These contraction wave sequences commonly propagate only over a short distance causing intermittent and bidirectional flow of chyme (to aid mixing of chyme and exposure of chyme to luminal receptors). However, more prolonged antegrade wave activity is required for aboral movement of chyme and it has been previously reported that increasing nutrient load decreases the frequency of the sequences<sup>[7,15]</sup>. In contrast, we detected a strong trend to increased duodenal activity with increasing loads. This may reflect a chance finding or the relationship between nutrient load and duodenal activity is non-linear, with initial small increments in load increasing frequency of contractions and above a certain threshold (perhaps 1.5 kcal/min) a reduction in duodenal wave frequency occurs.

The proposed mechanisms underlying modulation of the APD unit are neural and hormonal. Fone and colleagues showed that stimulation of phasic pyloric pressure waves during intraduodenal glucose at 2.4 kcal/min are mediated *via* ascending enteric nerves and ACh-stimulation of muscarinic receptors<sup>[16]</sup>. Both cholecystokinin and glucagon-like peptide-1 are secreted, albeit temporarily, in response to 1 kcal/min of intraduodenal glucose<sup>[17]</sup> and endogenous secretion of these hormones are known to have substantial effects on APD motility and, thereby, gastric emptying<sup>[18-21]</sup>.

While this study was undertaken in health, implications of these data for pathological conditions can be speculated upon. Gastric emptying is frequently slowed with healthy aging and in conditions such as diabetes and critical illness<sup>[22-24]</sup>. This slowing has been attributed

in part to “hypersensitivity” to small intestinal nutrient, which appears to be, at least in part, hormonally-mediated *via* hormones such as cholecystokinin<sup>[25]</sup>. These data in health suggest the hypothesis that the process of aging or the effects of critical illness exacerbates this hierarchical sensitivity. Further study in this area would be of interest.

The limitations of this study should be recognised. Only occlusive pressure waves are detected by manometry. Non-occlusive antral pressure waves and/or non-peristaltic flow may also have been affected<sup>[26]</sup>. However pyloric closure prevents transpyloric flow. It would be of interest to repeat this study using measurement techniques that detect non-occlusive antral pressure waves. In addition, the duodenal nutrient infusion was non-pulsatile and short term (20 min). However, the feedback mechanism is the same whether the intra-duodenal nutrient is infused in a pulsatile or non-pulsatile fashion<sup>[27]</sup>. The aim of this study was only to measure the acute response to duodenal nutrient infusion and as motor responses adapt<sup>[13]</sup>, particularly at lower loads<sup>[17]</sup>, the response during more prolonged stimulation at these loads could be different. It should also be recognized that blood glucose concentrations were not clamped and hyperglycemia, even within the physiological range, affects APD motor responses and gastric emptying<sup>[28-30]</sup>. However glucose concentrations were similar despite the differing loads, suggesting that this is unlikely to explain the adaptive response observed.

In summary, glucose loads as low as 1 kcal/min infused into the duodenum initiate APD motor responses that will slow gastric emptying. The acute APD motor response to an intra-duodenal carbohydrate load is hierarchical and “dose” dependant, with an increased frequency of IPPW, followed by a decrease in antral wave frequency.

The authors acknowledge the technical assistance of Mr Matthew Summers and Mr Antony Zaknic.

## COMMENTS

### Background

Emptying of liquid nutrient from the stomach is regulated by antro-pyloro-duodenal (APD) motor activity. Nutrient within the small intestine initiates a feedback loop that affects motility of the APD area. Recent data suggest that the “doses” of lipid nutrient initiating these motor changes in health are much less than previously recognised. Likewise small intestinal carbohydrate infusions at rates that are within normal gastric emptying rates have marked effects on the APD unit. However, the specific threshold and/or hierarchy of the APD response to nutrient stimulation are unknown. The aim of this study was to assess the responses of the distal stomach to graded small intestinal nutrient stimulation in health.

### Research frontiers

The specific threshold and/or hierarchy of the APD response to nutrient stimulation are unknown.

### Innovations and breakthroughs

This study shows that modulation of each component of the APD unit is hierarchical and dependent on caloric load; initially resistance to trans-pyloric flow oc-

curs with isolated pyloric pressure waves and, subsequently, antral propulsive force decreases.

### Applications

The implication of this finding is that small intestinal delivery of nutrient, even within so-called "normal" gastric emptying rates has a substantial effect on APD motor patterns.

### Terminology

APD manometry is a technique used to measure luminal occlusive contractions, which result in peristaltic flow.

### Peer review

This is a continuum of authors' previous works and tested a role of diet in the duodenum in the stimulation of the APD motor response. It's worth to publish on this journal as a brief report or communication.

polymorphisms and haplotypes of the *ITGA1* gene and the risk of gastric cancer.

**METHODS:** The study subjects were 477 age- and sex-matched case-control pairs. Genotyping was performed for 15 single nucleotide polymorphisms (SNPs) in *ITGA1*. The associations between gastric cancer and these SNPs and haplotypes were analyzed with multivariate conditional logistic regression models. Multiple testing corrections were carried out following methodology for controlling the false discovery rate. Gene-based association tests were performed using the versatile gene-based association study (VEGAS) method.

**RESULTS:** In the codominant model, the ORs for SNPs *rs2432143* (1.517; 95%CI: 1.144-2.011) and *rs2447867* (1.258; 95%CI: 1.051-1.505) were statistically significant. In the dominant model, polymorphisms of *rs1862610* and *rs2447867* were found to be significant risk factors, with ORs of 1.337 (95%CI: 1.029-1.737) and 1.412 (95%CI: 1.061-1.881), respectively. In the recessive model, only the *rs2432143* polymorphism was significant (OR = 1.559, 95%CI: 1.150-2.114). The C-C type of *ITGA1* haplotype block 2 was a significant protective factor against gastric cancer in the both codominant model (OR = 0.602, 95%CI: 0.212-0.709,  $P = 0.021$ ) and the dominant model (OR = 0.653, 95%CI: 0.483-0.884). The *ITGA1* gene showed a significant gene-based association with gastric cancer in the VEGAS test. In the dominant model, the A-T type of *ITGA1* haplotype block 2 was a significant risk factor (OR = 1.341, 95%CI: 1.034-1.741). SNP *rs2447867* might be related to the severity of gastric epithelial injury due to inflammation and, thus, to the risk of developing gastric cancer.

**CONCLUSION:** *ITGA1* gene SNPs *rs1862610*, *rs2432143*, and *rs2447867* and the *ITGA1* haplotype block that includes SNPs *rs1862610* and *rs2432143* were significantly associated with gastric cancer.

### Abstract

**AIM:** To evaluate the association between the genetic

## INTRODUCTION

Gastric cancer is the second most common cancer in South Korea and represents the second leading cause of cancer death for both men and women worldwide<sup>[1,2]</sup>. Approximately one million new cases of stomach cancer are estimated to have occurred (989000 cases, 7.8% of the total), currently making it the fourth most common malignancy in the world, following cancers of the lung, breast and colo-rectum<sup>[2]</sup>. Epidemiological studies have provided evidence that a high intake of salt and nitrite-rich foods and *Helicobacter pylori* (*H. pylori*) infection are associated with a high incidence of gastric cancer in South Korea<sup>[3-7]</sup>.

The risk of developing gastric cancer is estimated to be increased 2-6 fold in patients with *H. pylori* infection<sup>[8]</sup>. The risk of gastric cancer among individuals infected with *H. pylori* is influenced by bacterial virulence. The most widely studied *H. pylori* virulence factors are the *cag* (cytotoxin-associated gene) antigens<sup>[9]</sup>. Compared to individuals infected with *cagA*-negative *H. pylori* strains, those infected with *cagA*-positive *H. pylori* strains show a higher risk of developing gastric cancer<sup>[10]</sup>. To introduce *cagA* into host cells, the *cagL* protein of *H. pylori* binds to integrins on the basolateral surface of gastric epithelial cells<sup>[11,12]</sup>.

Integrins are members of a family of heterodimeric cell-surface proteins that mediate cell-matrix and cell-cell interactions. The 18 integrin  $\alpha$ -subunits and 8  $\beta$ -subunits together form at least 25 different integrins<sup>[13]</sup>. Integrins mediate signaling events that are essential for stable cell adhesion, spreading, migration, survival, proliferation and differentiation. Several integrins, including  $\alpha 1\beta 1$ , bind to extracellular matrix proteins present in the basal membrane of mature vessels<sup>[14,15]</sup>. The tumor progression and metastasis of various cancers are associated with integrins<sup>[16,17]</sup>.

The *ITGA1* gene, located on chromosome 5q11.2,

encodes the integrin  $\alpha 1$  subunit, which is involved in the adhesion of gastric cancer cells to the peritoneum. The adhesion of integrin  $\alpha 1$ -positive gastric cancer cells to the extracellular matrix is a critical process in peritoneal dissemination<sup>[18,19]</sup>. There are few studies addressing the roles of integrins in the development of gastric cancer. An association with an increased risk of gastric cancer has only been reported for the *ITGA2* C807T polymorphism in a Chinese population<sup>[20]</sup>. As the level of integrin  $\alpha 1\beta 1$  is up-regulated in association with inflammation of the gastrointestinal tract mucosa, which is the first step in gastric carcinogenesis<sup>[21]</sup>, it is possible that the integrin  $\alpha 1$  subunit plays an important role in gastric cancer development.

The purpose of this study was to evaluate the association between the genetic polymorphisms and haplotypes of the *ITGA1* gene and the risk of gastric cancer.

## MATERIALS AND METHODS

### Study subjects

This subjects included in this study consisted of 477 newly diagnosed gastric cancer patients and an equal number of age- (within 3 years) and sex-matched controls. The diagnoses of the gastric cancer patients were all histologically confirmed at Chungbuk National University Hospital and Eulji University Hospital, which are located in a geographically central region of South Korea. Controls were selected from individuals receiving routine medical examinations in these hospitals, and individuals with a previous diagnosis of any type of cancer were excluded. Trained interviewers used a structured questionnaire including questions about demographic factors, smoking habits, alcohol consumption and dietary habits to interview all subjects who provided written informed consent. Peripheral blood samples were collected from all subjects. This study was approved by the institutional review boards of Chungbuk National University Hospital, South Korea (IRB No. 2011-09-071).

### Selection of single nucleotide polymorphisms in *ITGA1*

At the International HapMap Project website (<http://hapmap.ncbi.nlm.nih.gov/>), tag SNPs were selected using a cut-off minimum minor allele frequency in the JPT population of 0.05 and pairwise tagging ( $r^2 = 1-0.8$ ). SNPs that significantly deviated from Hardy-Weinberg equilibrium were discarded.

Genomic DNA was extracted from whole blood using the QuickGene-810 nucleic acid isolation system (Fujifilm, Tokyo, Japan) and the QuickGene DNA Whole Blood Kit (Kurabo, Osaka, Japan), in accordance with the manufacturer's instructions. DNA was stored at 4 °C until use. SNP genotyping was performed using a GoldenGate Genotyping Assay with VeraCode technology (Illumina, San Diego, CA, United States). A custom GoldenGate assay was designed for the analysis of the selected SNPs in the *ITGA1* gene. Those SNPs were then assessed for suitability for the GoldenGate genotyping platform, and

**Table 1** Characteristics of the study subjects *n* (%)

Variables	Controls ( <i>n</i> = 477)	Cases ( <i>n</i> = 477)	OR (95%CI)
Age (yr)	57.8 ± 10.2	58.7 ± 9.9	
mean ± SD			
Sex			
Males	301 (63.1)	301 (63.1)	
Females	176 (36.9)	176 (36.9)	
Smoking status			
Non-smokers	225 (47.6)	194 (41.0)	1.00 (reference)
Smokers	248 (52.4)	279 (59.0)	1.64 (0.95-2.84)
Alcohol intake status			
Non-drinkers	194 (40.7)	189 (39.6)	1.00 (reference)
Drinkers	283 (59.3)	288 (60.4)	1.18 (0.71-1.76)

the analysis was carried out on the validated SNPs. The average call rate was 99.2%. Genotyping was carried out by Macrogen (Seoul, South Korea).

### Statistical analysis

The study power was calculated using the “case-control for discrete traits” mode in the Genetic Power Calculator<sup>[22]</sup>. The following parameters were applied: risk allele frequency -0.4, alpha error -0.01, and disease prevalence -0.1%. The power of a codominant model was 0.7768 when the heterozygous OR was set to 1.5. For a dominant model, when the OR for a genotype with one or 2 risk allele(s) was taken as 2, the power was 0.8821. When a value of 2 was input for the OR for a genotype with 2 risk allele(s), the power of a recessive model was 0.8182.

Testing for deviation from the HWP was performed for each SNP in both cases and in controls using Pearson's  $\chi^2$  test. *D* values were measured using Lewontin's method for all combinations of biallelic loci<sup>[23,24]</sup>, and linkage disequilibrium blocks were structured using Haploview version 4.2 (Daly Lab at the Broad Institute Cambridge, MA, United States). Haplotype blocks were constructed and statistically compared between cases and controls with SNP Analyzer version 2.0 (ISTEC Inc., Goyang, South Korea).

Student's *t* test was used to compare continuous variables between patients and control subjects. Associations between gastric cancer and the investigated SNPs and haplotypes were estimated *via* the OR and their corresponding 95%CI derived from multivariate conditional logistic regression models, after adjusting for potential confounding factors such as age, sex, smoking history, and alcohol intake. The genotypes of major homozygotes, heterozygotes and minor homozygotes were coded as 0, 1, and 2 in the codominant model, 0, 1 and 1 in the dominant model, and 0, 0 and 1 in the recessive model, respectively. Multiple testing corrections were carried out using Benjaminin and Hochberg's methods for controlling the false discovery rate (FDR)<sup>[25]</sup>. A two-sided adjusted *P* value of < 0.05 was considered statistically significant. FDR *Q* values were calculated separately for the SNPs and haplotypes based on these numbers. Gene-based association tests were performed using the versatile gene-based association study (VEGAS) method<sup>[26]</sup>. For these statistical analyses, SAS version 9.2 (SAS Institute,

Cary, NC, United States) was employed.

## RESULTS

Patient characteristics are summarized in Table 1. No significant difference was observed between the distributions of the age, sex, and smoking and drinking habits of the cases and controls.

Table 2 lists and provides the frequencies of the 15 selected SNPs in the study subjects. None of the polymorphisms were significantly deviated from Hardy-Weinberg equilibrium. All the minor allele frequencies of the cases and controls were greater than 10%.

The haplotype linkage disequilibrium blocks and haplotype frequencies for *ITGA1* are shown in Figure 1. *D* values were measured using Lewontin's method. Four block haplotypes were constructed using Haploview version 4.2. The common haplotypes (frequency > 10%) in each block accounted for 84.2%, 99.8%, 91.6% and 99.9% for the cases and 85.7%, 99.8%, 91.2% and 99.9% for the controls.

The observed associations between the genetic polymorphisms in the *ITGA1* gene and the risk of gastric cancer are shown in Table 3. In the codominant model, the OR of 1.517 obtained for SNP *rs2432143* (95%CI: 1.144-2.011; *P* = 0.003; FDR *Q* = 0.045) was statistically significant, even after controlling the FDR, and that for *rs2447867*, of 1.258 (95%CI: 1.051-1.505; *P* = 0.012; FDR *Q* = 0.090), was marginally significant. In the dominant model, the *rs1862610* and *rs2447867* polymorphisms were not statistically significant risk factors for gastric cancer, displaying ORs of 1.337 (95%CI: 1.029-1.737; *P* = 0.029; FDR *Q* = 0.217) and 1.412 (95%CI: 1.061-1.881; *P* = 0.018; FDR *Q* = 0.217), respectively. Only the *rs2432143* polymorphism was marginally significant in the recessive model, exhibiting an OR of 1.559 (95%CI: 1.150-2.114; *P* = 0.004; FDR *Q* = 0.060).

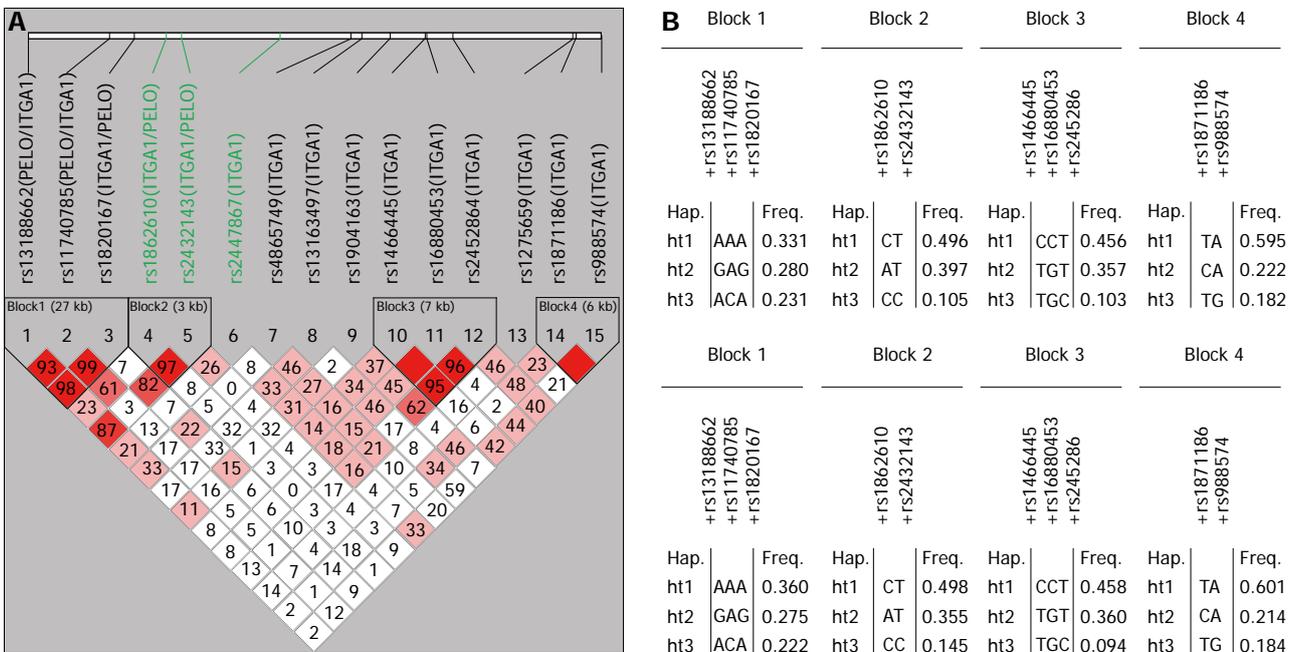

When the *P* values for the minor alleles of the codominant, dominant and recessive models were subjected to the VEGAS test, no significant gene-based associations were found. However, when the lower *P* value generated by the dominant and recessive models was input for every SNP, the value of the test statistic was 29.622, which was statistically significant (*P* = 0.037).

Four haplotype blocks were constructed using SNP Analyzer version 2.0. These blocks were evaluated for an association with the risk of gastric cancer (Table 4). The C-C type of *ITGA1* haplotype block 2 was marginally significant in the codominant model (OR = 0.602, 95%CI: 0.212-0.709; *P* = 0.021; FDR *Q* = 0.063) and was a significant protective factor against gastric cancer in the dominant model (OR = 0.653, 95%CI: 0.483-0.884; *P* = 0.006; FDR *Q* = 0.018). In the dominant model, the A-T type of *ITGA1* haplotype block 2 was a significant risk factor (OR = 1.341, 95%CI: 1.034-1.741; *P* = 0.027; FDR *Q* = 0.045). No haplotype block was found to be significant in the recessive model.

## DISCUSSION

The present study focused on the association of genetic polymorphisms and haplotypes of the *ITGA1* gene with gastric cancer risk. It has been suggested that the integrin  $\alpha 1$  subunit could be involved in gastric cancer carcinogenesis. Integrins on gastric epithelial cells have been reported to serve as a portal for the entry of *H. pylori cagA*<sup>[11]</sup>. Additionally, the integrin  $\alpha 1$  subunit is involved in the adhesion and dissemination of gastric cancer cells to the peritoneum<sup>[18]</sup>, and an *ITGA2* polymorphism has been reported to be associated with an increase in the risk of gastric cancer<sup>[20]</sup>. However, to our knowledge, no previous study has examined the association between *ITGA1* polymorphisms and the risk of gastric cancer.

The SNPs *rs1862610*, *rs2432143* and *rs2447867* were significantly associated with an increase in the risk of gastric cancer. After controlling the FDR, only SNP

*rs2432143* in the codominant model was statistically significant. In a gene-based association test, the *ITGA1* gene was found to be significantly associated with gastric cancer.

The C-C type of *ITGA1* haplotype block 2, which includes *rs1862610* and *rs2432143* in intron 1 of the *ITGA1* gene, was found to be a significant protective factor and the A-T type to be a risk factor for gastric cancer. This statistical significance was maintained after controlling the FDR. However, the precise molecular mechanism related to these SNPs is not clear. Based on SNP function prediction using computational methods, SNPs *rs1862610* and *rs2432143* are not predicted to be involved in any structural or functional changes in the integrin  $\alpha 1$  subunit. However, we cannot rule out the possibility that these SNPs are either associated with the stability of *ITGA1* mRNA, or in linkage disequilibrium with an as yet unknown functional polymorphism affecting the ex-

pression or function of the integrin  $\alpha 1$  subunit.

We used public databases of SNPs related to gastric cancer and assessed the potential functions of selected SNPs with SNP function prediction software. Among the 15 selected SNPs, only two were located in exons, and one was non-synonymous. The potential function was not predicted for any of these SNPs, except for *rs2447867*, which was predicted to be an exonic splicing enhancer (ESE). ESEs are clinically significant because synonymous point mutations in ESEs that were previously thought to be silent mutations can lead to exon skipping and the production of a non-functional protein. As loss of integrin  $\alpha 1\beta 1$  has been observed in some other malignancies<sup>[27]</sup>, non-functional integrin  $\alpha 1\beta 1$  could be associated with gastric cancer.

The increased expression of integrin molecules by epithelial cells during inflammation of the underlying lamina propria is probably an adaptive response to prevent extensive epithelial cell sloughing caused by inflammatory mediators. Loss of epithelial integrity due to a decrease in the function of integrin results in more severe injury of the epithelium<sup>[21]</sup>. At these sites of tissue injury, bone marrow-derived cells are recruited, and these cells can be a potential source of malignancy<sup>[28]</sup>. Because chronic infection with *H. pylori* also induces repopulation of the stomach with bone marrow-derived cells, there is a possibility that a non-functional integrin  $\alpha 1$  subunit and *H. pylori* infection would have a synergistic effect in increasing the risk of gastric cancer. The major limitation of the present study is that we did not test for the presence of antibodies against *H. pylori* and the *cagA* antigen in the sera of the case and control subjects.

The OR obtained for SNPs *rs1862610*, *rs2432143*, and *rs2447867* were all below 1.6, while the OR for the *ITGA2* C807T polymorphism in relation to gastric cancer in a Chinese population is 1.57<sup>[20]</sup>. These relatively small values can be explained by the promiscuity and redundancy of integrins: one integrin can bind several different ligands, and many different integrins can bind to the same ligand<sup>[29]</sup>. Therefore, if an integrin is not functioning, other integrins can compensate for at least some of its function.

In conclusion, the *ITGA1* gene SNPs *rs2432143* and *rs2447867* and the *ITGA1* haplotype block that includes SNP *rs2432143* are significantly associated with gastric cancer risk.

## COMMENTS

### Background

Integrins mediate signaling events that are essential for stable cell adhesion, cell spreading, migration, survival, proliferation and differentiation. Several integrins, including  $\alpha 1\beta 1$ , bind to extracellular matrix proteins present in the basal membranes of mature vessels. Tumor progression and the metastasis of various cancers are associated with integrins. The *ITGA1* gene, located on chromosome 5q11.2, encodes the integrin  $\alpha 1$  subunit, which is involved in the adhesion of gastric cancer cells to the peritoneum. Adhesion of integrin  $\alpha 1$ -positive gastric cancer cells to the extracellular matrix is a critical process in peritoneal dissemination. As integrin  $\alpha 1\beta 1$  is up-regulated during inflammation in the gastrointestinal tract mucosa, which is the first step in gastric carcinogenesis, it is possible that the integrin  $\alpha 1$  subunit plays an important role in the development of gastric cancer. It has been suggested that the integrin  $\alpha 1$  subunit could be involved in gastric cancer carcinogenesis. Integrins on gastric epithelial cells have been reported to serve as a portal for the entry of *Helicobacter pylori* (*H. pylori*) *cagA*. As integrin  $\alpha 1\beta 1$  is up-regulated during inflammation in the gastrointestinal tract mucosa, which is the first step in the gastric carcinogenesis, it is possible that the integrin  $\alpha 1$  subunit plays an important role in the development of gastric cancer.

genesis, it is possible that the integrin  $\alpha 1$  subunit plays an important role in the development of gastric cancer. It has been suggested that the integrin  $\alpha 1$  subunit could be involved in gastric cancer carcinogenesis. Integrins on gastric epithelial cells have been reported to serve as a portal for the entry of *Helicobacter pylori* (*H. pylori*) *cagA*. As integrin  $\alpha 1\beta 1$  is up-regulated during inflammation in the gastrointestinal tract mucosa, which is the first step in the gastric carcinogenesis, it is possible that the integrin  $\alpha 1$  subunit plays an important role in the development of gastric cancer.

### Research frontiers

There are few studies addressing the role of integrins in the development of gastric cancer. An association with an increased risk of gastric cancer has only been reported previously for the *ITGA2* C807T polymorphism in a Chinese population. No earlier study has focused on the association of *ITGA1* gene single nucleotide polymorphisms (SNPs) and haplotypes with gastric cancer risk.

### Innovations and breakthroughs

To the best of the authors' knowledge, this present study is the first to suggest a significant association of the genetic polymorphisms and haplotypes of *ITGA1* gene with an increased gastric cancer risk.

### Applications

Integrins on gastric epithelial cells have been reported to serve as a portal of entry for *H. pylori* *cagA*, and loss of epithelial integrity due to a decrease in the function of integrins results in more severe injury of the epithelium. Studies are needed addressing the interaction of non-functional integrin  $\alpha 1$  subunit and *H. pylori* infection in increasing the risk of gastric cancer.

### Peer review

This paper is focused on the *ITGA1* polymorphisms and haplotypes, and gastric cancer risk in a Korean population. The results showed the SNPs *rs1862610*, *rs2432143*, and *rs2447867*, and the *ITGA1* haplotype block which includes SNPs *rs1862610* and *rs2432143* were significantly associated with gastric cancer. It is interesting.

### Abstract

**AIM:** To find a non-invasive strategy for detecting choledocholithiasis before cholecystectomy, with an acceptable negative rate of endoscopic retrograde cholangiopancreatography.

**METHODS:** All patients with symptomatic gallstones were included in the study. Patients with abnormal liver functions and common bile duct abnormalities on ultrasound were referred for endoscopic retrograde cholangiopancreatography. Patients with normal ultrasound

were referred to magnetic resonance cholangiopancreatography. All those who had a negative magnetic resonance or endoscopic retrograde cholangiopancreatography underwent laparoscopic cholecystectomy with intraoperative cholangiography.

**RESULTS:** Seventy-eight point five percent of patients had laparoscopic cholecystectomy directly with no further investigations. Twenty-one point five percent had abnormal liver function tests, of which 52.8% had normal ultrasound results. This strategy avoided unnecessary magnetic resonance cholangiopancreatography in 47.2% of patients with abnormal liver function tests with a negative endoscopic retrograde cholangiopancreatography rate of 10%. It also avoided unnecessary endoscopic retrograde cholangiopancreatography in 35.2% of patients with abnormal liver function.

**CONCLUSION:** This strategy reduces the cost of the routine use of magnetic resonance cholangiopancreatography, in the diagnosis and treatment of common bile duct stones before laparoscopic cholecystectomy.

and abnormal liver function. *World J Gastroenterol* 2013; 19(35): 5877-5882 Available from: URL: <http://www.wjnet.com/1007-9327/full/v19/i35/5877.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5877>

## INTRODUCTION

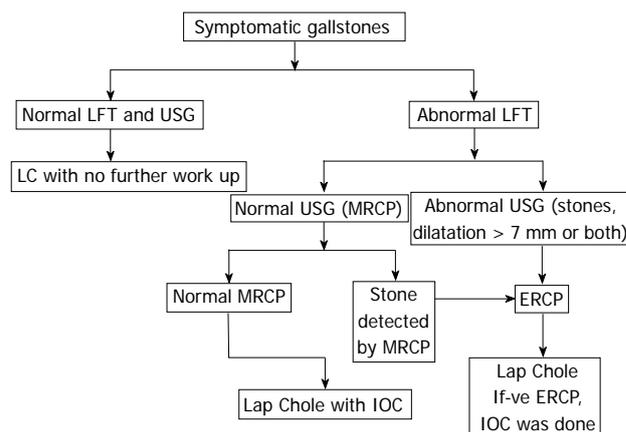

Gallstone disease is one of the most common surgical problems worldwide. Both environmental and genetic factors are known to contribute to susceptibility to the disease<sup>[1]</sup>. It has been reported that in Saudi Arabia there is an increasing incidence of gallstone disease<sup>[2]</sup>, especially in the high altitude provinces in the Asir<sup>[3]</sup> and Taif regions<sup>[4]</sup>, and similar findings have been reported for other countries that have similar environmental and nutritional factors<sup>[5,6]</sup>. Complications of gallstone disease vary from simple recurrent biliary colic to life-threatening conditions such as ascending cholangitis and pancreatitis. In addition, the disease is thought to be a risk factor for developing pancreaticobiliary cancer, particularly in patients with choledocholithiasis [common bile duct stones (CBDS)], approximately 10% of patients with symptomatic gallstones<sup>[7]</sup>.

Since symptomatic gallstone is a common indication for surgery, an accurate preoperative detection of CBDS is imperative in order to decrease operative risks and health care costs<sup>[7-9]</sup>. Better detection and treatment of CBDS before laparoscopic cholecystectomy (LC) would help deliver an appropriate, fast, and cost effective treatment<sup>[10]</sup>. Liver function tests (LFTs) and abdominal ultrasonography (USG), combined with medical history and clinical examinations are currently the standard preoperative methods used to diagnose patients with gallstones<sup>[9-14]</sup>. However, this approach is often not accurate enough to establish a firm diagnosis of CBDS<sup>[4,8,9]</sup>.

Imaging tests are routinely used to confirm a choledocholithiasis diagnosis. While abdominal USG is the most commonly used screening modality, other imaging tests used for this purpose include endoscopic and laparoscopic USG, magnetic resonance cholangiopancreatography (MRCP), intraoperative cholangiography (IOC) and endoscopic retrograde cholangiopancreatography (ERCP).

ERCP was the gold standard for diagnosing and treating CBDS; however, it is invasive, has associated morbidity and mortality, and has been shown to have a negative rate up to 75% in some studies<sup>[5]</sup>. Therefore, it was abandoned as a diagnosing method and used only for stone extraction.

MRCP is a noninvasive procedure with no associated morbidity that has become the gold standard in diagnosing CBDS; however, it should only be used when proper indications are observed<sup>[9-14]</sup> due to its high cost and limited availability<sup>[11,15,16]</sup>. Many authors have proposed its routine use<sup>[17-19]</sup> in all patients with suspected CBDS, however, in high probability patients, its cost and the need for ERCP to remove the stones makes it questionable.

**Figure 1** Algorithm followed in the management of symptomatic gallstones. LFT: Liver function test; USG: Ultrasonography; LC: laparoscopic cholecystectomy; MRCP: Magnetic resonance cholangiopancreatography; ERCP: Endoscopic retrograde cholangiopancreatography; IOC: Intraoperative cholangiography.

IOC is particularly valuable in patients with unclear anatomy and those with preoperative predictors of choledocholithiasis but negative findings on MRCP<sup>[20,21]</sup>. Many scoring indices and guidelines have been developed to determine acceptable preoperative indications for IOC, but none so far have proved satisfactory<sup>[9,22-24]</sup>. Therefore, the aim of the current study was to find a non-invasive preoperative approach, using MRCP, ERCP, and IOC, to diagnose and treat CBDS prior to performing LC.

## MATERIALS AND METHODS

We conducted a prospective study on all patients with symptomatic gallstones who presented at Al Hada Armed Forces Hospital in Taif, Saudi Arabia from April 2006 to April 2010. Patients not fit for surgery were excluded from the study. In addition, patients who presented with acute pancreatitis were excluded since we have a different protocol for them in our center. The study was approved by the local committee on human research, and all patients gave written informed consent. All patients underwent detailed preoperative evaluations consisting of clinical history, laboratory testing including LFT, (serum bilirubin, alkaline phosphatase, serum glutamic-oxaloacetic transaminase and serum glutamic pyruvic transaminase), and USG examination.

An algorithm was designed (Figure 1). Patients with normal LFT and no bile duct abnormalities were referred for LC without further work-up. Patients with abnormal LFT and USG proven CBDS and/or bile duct dilatation > 7 mm were referred for ERCP for stone removal, followed by LC. Patients with abnormal LFT and normal bile ducts (determined by USG) were referred for MRCP, and if CBDS were detected, they were referred for ERCP for stone removal, followed by LC. MRCP and ERCP negative cases underwent LC with IOC to detect false negative cases and avoid retained stones. For these patients, intraoperative discovery of CBDS would indicate

**Table 1 Demographic data n (%)**

Characteristic	Value
Total number of patients	896
Female patients	717 (80)

stone removal by ERCP in the same sitting with the LC.

**Statistical analysis**

SPSS 18.0 (SPSS, Chicago Illinois) was used for carrying out statistical analysis. Group differences were further analyzed by  $\chi^2$  and difference between means of continuous variables was tested by Student's *t* test. Multivariate logistic regression analysis was adopted to control for confounders and level of significance was determined at *P* < 0.05.

**RESULTS**

A total of 896 patients were included in the study. Table 1 shows the patient demographic information. Out of these, 703 (78.5%) patients underwent LC without any further workup. Patients who had abnormal LFTs [193 (21.5%)] were older and there were more males in this group.

Table 2 demonstrates the breakdown of all the pa-

**Table 3 Final endoscopic retrograde cholangiopancreatography findings**

Presence of stones	Patient	US abnormal	Mean T.Bili (mg/dL)	Mean Al-P (ratio to normal)
Stones	109 (56.5)	82 (90)	4.3 ± 2.1	1.9 ± 0.8
No stones	84 (43.5)	9 (10)	2.9 ± 1.3	1.3 ± 0.6
<i>P</i> value		< 0.0001	< 0.01	< 0.001
Total	193	91	3.7	1.7

Data are expressed as absolute numbers (percentage) or mean ± SD. MRCP: Magnetic resonance cholangiopancreatography; Al-P: Alkaline phosphatase; T.Bili: Total bilirubin; US: Ultrasound.

tients with abnormal LFT. CBD abnormalities were detected on USG in 91 (47.2%) patients and ERCP was used to extract stones in 90% of them. Abnormal LFT results, in which USG found dilatation but no stones were observed in 28 patients. The mean CBD diameter was 8.8 mm in these patients, with stones being extracted by ERCP in 85.7%. In 40 patients with abnormal LFT results and for whom USG detected both dilatation and stones, the mean CBD diameter was 9 mm, with stones being extracted by ERCP in 90%.

Normal bile ducts were detected by USG in 102 (52.8%) patients and ERCP was used to extract stones in 26.5% of them. IOC detected two patients with CBDS in the MRCP negative group (false negative 2.9%) and none in the ERCP negative group. There were seven patients with false positive MRCP where the ERCP did not detect any stones (false positive of 21%). This high percentage could be explained by the time between the MRCP and the ERCP that is about 2-3 d because of which the stones could have passed.

More importantly when looking at this group, 29/102 (28.4%) patients had a total bilirubin > 4 mg/dL which is counted as a high risk in recent guide lines (9); out these 17 (58.6%) patients did not have stones on IOC and ERCP was not conducted in this group of patients.

Stones were confirmed in 90% of the patients with an abnormal LFT and USG findings. ERCP detected stones in 24.5% of the patients with normal findings. This strategy avoided the use of MRCP in 47.2% of patients with abnormal LFT with a negative rate for the ERCP of 10% only. It also helped avoid unnecessary ERCP in 17 (58.6%) patients with total bilirubin > 4 mg/dL.

Statistical findings are shown in Table 3, where patients with abnormal USG, total bilirubin and alkaline phosphatase had a significant stone prediction in a univariate analysis. After controlling for confounders in multivariate Logistic regression analysis Alkaline phosphatase and USG findings were found to be significant predictors for CBDS. However, total bilirubin was found not to be a significant predictor (Table 4).

Multivariate statistical analysis found that the rise in alkaline phosphatase was a significant predictor for CBDS. It became highly significant when double the normal alkaline phosphatase value. In this case, the probability of stone detection by ERCP increased 30-fold when

Both	38 (95.0)	2 (5.0)	61	13.03-285.1

<sup>1</sup>The adjusted measure of association between risk factors and common bile duct stones was expressed as the OR with 95%CI. Adjusted or crude ORs with 95%CI that did not include 1.0 were considered significant.

this enzyme level was within the normal range.

In addition, in USG findings that detected CBD dilatation and those that detected stones were both significant predictors for the presence of CBDS found by ERCP. Detection of both dilation and stones concurrently was a highly significant predictor of the presence of CBDS, which were about 60 times more likely than when USG results were normal.

## DISCUSSION

CBDS can remain hidden for years, frequently passing undetected into the duodenum. When the symptoms become apparent, the presentation will likely include obstructive jaundice or more serious complications such as acute pancreatitis or cholangitis<sup>[7,25]</sup>. Preoperative detection and intervention to remove these stones is vital<sup>[8]</sup>. An increase in bilirubin and alkaline phosphatase levels may be the only evidence of choledocholithiasis<sup>[10-12]</sup>. USG examination may confirm the presence of CBDS but cannot definitively exclude them when not detected<sup>[10]</sup>. The gold standard for treating these stones is ERCP, which has sensitivity and specificity rates both around 95%<sup>[8,11,14,26,27]</sup>. However, if the clinical, radiological, and laboratory testing indicates a low probability of choledocholithiasis, less invasive method such as MRCP should be performed first<sup>[9]</sup>.

The sensitivity of transabdominal USG is low for detecting CBDS (22%-55%), but it is better at detecting CBD dilatation (sensitivity 77%-87%). For patients with abnormal LFT which USG detects CBDS, successful diagnosis of choledocholithiasis has been reported to be above 80%. Negative CBDS detection by ERCP in such patients may be related to the passage of these stones into the duodenum before the procedure<sup>[4,28,29]</sup>.

The diameter of a normal bile duct is 3-6 mm. it increases by one mm every 10 years after the age of 60, causing mild dilatation in the elderly<sup>[30]</sup>. CBD greater than 8 mm in patients with an intact gallbladder is usually indicative of biliary obstruction<sup>[9]</sup>. Although no single factor strongly predicts choledocholithiasis in patients

with symptomatic gallstones, many studies have shown that the probability of CBDS is higher in the presence of multiple abnormal prognostic signs. Patients with such markers are considered to be at high risk, and preoperative ERCP is indicated when there are no available facilities for performing CBD laparoscopic exploration<sup>[9-13,31-34]</sup>.

In the present study, abnormal LFT results were observed in 21.5% in patients with symptomatic gallstones, a higher incidence than previously reported in the literature (15%)<sup>[35]</sup>. This discrepancy may be related to environmental (Taif is a high-altitude province), cultural or social factors<sup>[2-4,6,7]</sup>. Our facility is a tertiary hospital serving a widespread rural area.

Therefore, the routine use of MRCP as has been recommended by others for patients with abnormal LFT<sup>[17-19]</sup> is not practical or cost effective.

Among the patients involved in the study, there were 78.5% patients with normal LFT results and no CBD abnormalities detected by USG. They were therefore referred for LC without further workup, consistent with the recommendations made by the Standards of Practice Committee of the American Society for Gastrointestinal Endoscopy (SPC-ASGE)<sup>[9]</sup>. The results of our study, which concluded before the publication of the 2010 guidelines, were similar, patients with symptomatic gallstones but normal LFT and USG are considered to be at low risk for choledocholithiasis. For these patients, they recommend, as we do, cholecystectomy, without further evaluation to avoid the cost and risks of additional preoperative biliary evaluation, which are not justified by the low probability of CBDS<sup>[9]</sup>. Whether or not to perform routine IOC or laparoscopic US during LC remains an area of controversy<sup>[20,21]</sup>.

We found (52.8%) patients with abnormal LFT but normal CBD USG results, who were sent for MRCP examination. This group of patients is considered by the SPC-ASGE to be at intermediate risk of choledocholithiasis, and their guidelines recommend further evaluation with preoperative EUS or MRC or an IOC<sup>[9]</sup>, as we do. However, they do recommend that a total bilirubin higher than 4 mg/dL, should be considered as a high probability of CBDS. In our study, we found total bilirubin to be not a significant predictor on multivariate analysis. Also, in 17 (58.6%) of the patients with high total bilirubin (> 4 mg/dL) and normal USG, CBDS was not detected by IOC in the operating room. Therefore, as per their recommendation ERCP was avoided in this group in our study.

Statistical findings revealed that a rise in bilirubin level was not a significant predictor for detecting CBDS. However, this finding should be reevaluated considering the higher incidences of hepatitis, sickle cell anemia, and secondary polycythemia (related to the high altitude) in our province. Yang *et al.*<sup>[36]</sup> found that among the components of the LFTs, alkaline phosphatase was a better indicator for choledocholithiasis than bilirubin. However, the SPC-ASGE reported modestly better CBDS positive predictive values for bilirubin. They found cholestatic

liver biochemical tests, in particular alkaline phosphatase and  $\gamma$ -glutamyl transpeptidase, increases progressively with the duration and severity of biliary obstruction.

In the present study, MRCP helped avoid unnecessary ERCP in 58.6% of patients with high total bilirubin and normal CBD USG results. It was associated with a false negative rate of 2.96% and false positive rate of 21%, similar to those reported in other studies<sup>[16,37]</sup>.

Patients with abnormal LFT and USG were classified as a high risk for CBDS. By applying this algorithm, we diagnosed and treated these patients directly with ERCP and avoided the cost of MRCP and stones were extracted in 90%, with a low negative incidence of ERCP of 10%. This led to a shorter hospital stay and was even far better when some patients had the ERCP and the LC in the same sitting.

IOC has multiple advantages, as some centers use it routinely to identify the biliary anatomy and others use it for stone detection<sup>[15,16]</sup>. Its routine use is still controversial; however, in selective cases it is widely adopted. In cases where CBDS are thought of, it can be used with less cost and in the same time as the LC where it will take few minutes. However, not many general surgeons are familiar with this use, making it a less popular procedure. Therefore, its use in selective cases has been accepted. We have recommended its use in patients with negative MRCP or ERCP since these procedures have a false negative rate and discharging these patients with retained CBDS can lead to delayed acute presentation like acute pancreatitis, cholangitis and cystic duct leak<sup>[25,38]</sup>.

In conclusion, we recommend the use of this simple algorithm to stratify patients into low risk when LFT and USG are normal. These patients can go for LC with no further work-up. Patients with abnormal LFT or US are stratified as intermediate risk regardless of the total bilirubin level and should undergo MRCP as the risk of ERCP is not justified. Patients with abnormal LFT and USG are stratified as high risk and should undergo ERCP and stone extraction with LC in the same sitting if possible, as the cost of MRCP and the time needed is not justified.

## COMMENTS

### Background

Symptomatic gallstones with abnormal liver function tests are seen in higher percentages in higher altitude areas. Choledocholithiasis is the commonest cause; however, it is a challenge to diagnose and treat these cases while maintaining a low cost and minimum hospital stay. In this study the authors tried to design a simple pathway to diagnose and treat this problem without the over use of magnetic resonance cholangiopancreatography that is costly or the use of endoscopic retrograde cholangiography that has major side effects.

### Research frontiers

In the past all patients with common bile duct stones (CBDS) were subjected to endoscopic retrograde cholangiopancreatography (ERCP). This was the best way to diagnose these patients, however, there were complications like bleeding, perforation or even death with this procedure. Then magnetic resonance cholangiopancreatography (MRCP) was developed and became widely used. However, it is very costly and after the diagnosis of CBDS an ERCP was needed to remove the stone. Recently some authors have advocated the routine use of MRCP without looking in the cost or even its availability. The authors believe that it is time to reach a balance between the uses of both procedures to get

the best of both when needed.

### Innovations and breakthroughs

The authors have developed a simple pathway for the treatment of CBDS which has the least cost and requiring a minimal hospital stay. The authors have also found that the total bilirubin level does not play a part in the pathway as mentioned by the American Endoscopy Society.

### Applications

This simple pathway can be applied in any patient care facility even if it is not very advanced. The pathway does not have any special requirements.

### Peer review

The manuscript is quite well written. The methods are adequate. The results justify the conclusions drawn.

individuals with and without erosive esophagitis. Risk factors for erosive esophagitis were evaluated by multivariate logistic regression.

**RESULTS:** Erosive esophagitis was diagnosed in 507 of 5015 subjects who were individually age and sex matched to 507 esophagitis-free control subjects. In patients with erosive esophagitis, BMI, waist circumference, blood pressure, fasting plasma glucose, triglyceride levels, aspartate aminotransferase, alanine aminotransferase, the ratio of total cholesterol to HDL-C, and the ratio of low-density lipoprotein cholesterol to HDL-C were significantly higher and HDL-C was significantly lower compared to patients without erosive esophagitis (all  $P < 0.05$ ). In a multivariate analysis, central obesity (OR = 1.38; 95%CI: 1.0-1.86), hypertension (OR = 1.35; 95%CI: 1.04-1.76), hypertriglyceridemia (OR = 1.34; 95%CI: 1.02-1.76), cardiovascular risk factors as defined by a ratio of total cholesterol to HDL-C  $> 5$  (OR = 1.45; 95%CI: 1.06-1.97), and aspartate aminotransferase (OR = 1.59; 95%CI: 1.08-2.34) were significantly associated with erosive esophagitis.

**CONCLUSION:** Metabolic syndrome, impaired liver function, and a higher ratio of total cholesterol to HDL-C were associated with erosive esophagitis.

### Abstract

**AIM:** To investigate whether erosive esophagitis is correlated with metabolic syndrome and its components, abnormal liver function, and lipoprotein profiles.

**METHODS:** We conducted a cross-sectional, case control study of subjects who underwent upper endoscopy during a health examination at the Health Management and Evaluation Center of a tertiary medical care facility located in Southern Taiwan. Metabolic syndrome components, body mass index (BMI), liver function, dyslipidemia, and cardiovascular risk factors, as defined by the ratio of total cholesterol to high-density lipoprotein cholesterol (HDL-C), and the ratio of low-density lipoprotein cholesterol to HDL-C were compared between

**Core tip:** A cross-sectional, case control study of subjects who underwent upper endoscopy during a health examination was conducted. Metabolic syndrome components, body mass index, liver function, and dyslipidemia were compared between individuals with and without erosive esophagitis. Risk factors for erosive esophagitis were evaluated. Erosive esophagitis was diagnosed in 507 of 5015 subjects who were individually age- and sex-matched to 507 esophagitis-free control

subjects. In addition to metabolic syndrome, we also found that abnormal liver function and predictors of future coronary heart disease were associated with erosive esophagitis.

Erosive esophagitis associated with metabolic syndrome, impaired liver function, and dyslipidemia. *World J Gastroenterol* 2013; 19(35): 5883-5888 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5883.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5883>

## INTRODUCTION

The prevalence of erosive esophagitis in Asian countries has dramatically increased during the last two decades<sup>[1-3]</sup>. The prevalence of erosive esophagitis in the Taiwanese adult population is estimated to be 10%-15%<sup>[1,4]</sup>. Although the mechanism underlying this increase in prevalence remains to be determined, several risk factors of erosive esophagitis have been identified, including male sex, hiatal hernia, smoking, alcohol consumption, and obesity<sup>[5-7]</sup>. Metabolic syndrome is a complex disorder comprising central obesity, high blood pressure (BP), hyperglycemia, hypertriglyceridemia, and a low concentration of high-density lipoprotein cholesterol (HDL-C). In addition to being associated with cardiovascular disease and diabetes mellitus, metabolic syndrome and its component elements have also been associated with various gastrointestinal diseases and abnormal liver function<sup>[7-12]</sup>. The correlation between erosive esophagitis and body mass index (BMI) is controversial<sup>[13,14]</sup>, as is the association between erosive esophagitis and hypertriglyceridemia or hyperglycemia<sup>[5,13-15]</sup>. This study was undertaken to characterize the correlation between erosive esophagitis and metabolic syndrome and its components, abnormal liver function and abnormal lipoprotein profiles - that have been used to predict coronary heart disease.

## MATERIALS AND METHODS

### Subjects

This study was designed as a cross-sectional, case control study. From January 2008 to December 2008, 5981 subjects visited the Health Management and Evaluation Center of a tertiary medical care facility located in Southern Taiwan for routine health examinations. Our center offers a variety of healthcare tests and procedures, including upper gastrointestinal endoscopy. The majority of subjects underwent a self-paid physical check-up; others were employees coming for their regular medical check-up. Most of the subjects were free of symptoms and were not chronic alcohol drinkers. Of the 5031 subjects who underwent upper gastrointestinal endoscopy, 507 were diagnosed with erosive esophagitis. The severity of erosive esophagitis was graded from A-D according

to the Los Angeles classification<sup>[16]</sup>. We matched each case subject, according to age and gender, with one control selected from the 4508 subjects with normal upper endoscopic findings. The study was approved by the institutional review board of the hospital in which the study was conducted.

### Definition of metabolic syndrome and obesity

In this study, metabolic syndrome was defined according to the modified National Cholesterol Education Program Adult Treatment Panel III for Asian populations. The waist circumference cutoff measurement was altered according to the criteria of the Bureau of Health Promotion, Department of Health, because the absolute risk of diabetes and cardiovascular disease is greater in Asians with a lesser degree of obesity<sup>[17,18]</sup>. Metabolic syndrome was diagnosed when at least three of the following criteria were found: (1) waist circumference  $\geq 90$  cm for men and  $\geq 80$  cm for women; (2) systolic BP  $\geq 130$  mmHg, diastolic BP  $\geq 85$  mmHg, or current use of antihypertensive drugs; (3) triglyceride (TG)  $\geq 150$  mg/dL; (4) HDL-C  $< 40$  mg/dL for men and  $< 50$  mg/dL for women; and (5) fasting plasma glucose  $\geq 110$  mg/dL or current use of antihyperglycemic drugs. Subjects with a BMI  $\geq 25$  kg/m<sup>2</sup> were defined as obese according to the Steering Committee of the World Health Organization Regional Office for the Western Pacific<sup>[19]</sup>. Subjects with elevated serum alanine aminotransferase (ALT) (ALT  $> 40$  U/L) or aspartate aminotransferase (AST) (AST  $> 37$  U/L) levels were considered to have abnormal liver function. Cardiovascular risk, which is determined by a ratio of total cholesterol (TC)/HDL-C  $> 5$  and correlates significantly with the risk for cardiovascular events<sup>[20]</sup>, was evaluated for its association with erosive esophagitis.

### Statistical analysis

Statistical analysis were performed using SPSS (Statistical Package for the Social Sciences) 15 software (SPSS, Chicago, IL, United States). Continuous variables are expressed as the mean  $\pm$  SD. Student's *t* test was used to compare continuous variables. Univariate analysis was performed using a  $\chi^2$  test for categorical variables. For each variable, the OR and 95%CI were calculated. A two-tailed *P* value of  $< 0.05$  was considered statistically significant. Multivariate analysis in the logistic regression model was conducted to examine the associations between erosive esophagitis and different risk factors.

## RESULTS

### Prevalence of erosive esophagitis

Of the 5031 subjects who underwent upper gastrointestinal endoscopy, 16 were excluded from the analysis because of prior gastric surgery, gastric cancer, or peptic ulcer. Erosive esophagitis was diagnosed in 507 of 5015 subjects. The mean age of subjects with erosive esophagitis was  $51.2 \pm 11.2$  years, and 82.6% were male.

**Table 1 Comparison between subjects with and without erosive esophagitis**

	With erosive esophagitis (n = 507)	Without erosive esophagitis (n = 507)	P value
Age (yr, mean ± SD)	51.2 ± 11.2	51.2 ± 11.2	-
Sex (M/F)	419/88	419/88	-
BMI (kg/m <sup>2</sup> )	25.6 ± 3.6	24.9 ± 3.4	< 0.001
Waist circumference (cm)	87.3 ± 12.9	84.8 ± 11.9	< 0.001
Systolic BP (mmHg)	132.3 ± 18.1	129.2 ± 17.7	0.003
Diastolic BP (mmHg)	87.2 ± 11.7	84.2 ± 10.8	< 0.001
Fasting plasma glucose (mg/dL)	105.9 ± 36.5	101 ± 29	0.009
Triglycerides (mg/dL)	165 ± 107.4	137.1 ± 99.5	< 0.001
HDL-C (mg/dL)	50.4 ± 15	52.2 ± 14.5	0.025
TC/HDL-C	4.27 ± 1.26	4.04 ± 1.13	0.001
LDL-C/HDL-C	2.56 ± 0.96	2.46 ± 0.87	0.049
AST (U/L)	31 ± 28.7	27.3 ± 13.4	0.004
ALT (U/L)	37.1 ± 26.4	31.2 ± 21.6	0.005

The P values are based on Student's *t* test. M: Male; F: Female; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BP: Blood pressure; BMI: Body mass index; HDL-C: High-density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol; TC: Total cholesterol.

### Characteristics of subjects with and without erosive esophagitis

The subject characteristics are summarized in Table 1. When compared with age- and sex-matched controls, BMI, waist circumference, systolic and diastolic BP, fasting plasma glucose, triglyceride levels, AST/glutamate-oxaloacetate transaminase (GOT) and ALT/glutamate-pyruvate transaminase (GPT) levels, the ratio of TC to HDL-C, and the ratio of low-density-lipoprotein cholesterol to HDL-C (LDL-C to HDL-C) were significantly higher and HDL-C was significantly lower in subjects with erosive esophagitis (all *P* < 0.05).

### Univariate and multivariate analyses of the associations between erosive esophagitis and risk factors

The results from the univariate and multivariate logistic regression analyses are shown in Table 2. BMI  $\geq$  25 kg/m<sup>2</sup> (OR = 1.72; 95%CI: 1.10-1.80), central obesity (OR = 1.60; 95%CI: 1.20-2.14), hypertension (OR = 1.43; 95%CI: 1.11-1.86), hyperglycemia (OR = 1.39; 95%CI: 1.07-1.80), hypertriglyceridemia (OR = 1.50; 95%CI: 1.15-1.95), and cardiovascular disease risk factors of TC/HDL-C > 5 (OR = 1.57; 95%CI: 1.17-2.12), AST > 37 U/L (OR = 1.67; 95%CI: 1.14-2.45), and ALT > 40 U/L (OR = 1.40; 95%CI: 1.04-1.90) were significantly associated with erosive esophagitis, according to the univariate analyses. Furthermore, the multivariate logistic regression analysis confirmed the associations of central obesity, hypertension, hypertriglyceridemia, the ratio of TC/HDL-C > 5, and high AST levels with erosive esophagitis (all *P* < 0.05).

### Association of erosive esophagitis with metabolic syndrome

Table 3 shows that the presence of metabolic syndrome

( $\geq$  3 metabolic criteria) was associated with a higher probability of erosive esophagitis than the presence of < 3 metabolic criteria (OR = 1.475; 95%CI: 1.149-1.895). The prevalence of metabolic syndrome was higher in subjects with erosive esophagitis than in those without (47.1% *vs* 37.7%, respectively; *P* < 0.005).

## DISCUSSION

In this study, erosive esophagitis was identified in 10.1% of subjects who underwent routine health examinations. Central obesity, hypertension, hypertriglyceridemia, a high TC/HDL-C ratio (TC/HDL-C > 5), and AST > 37 U/L were significantly associated with erosive esophagitis. Previously, Chua *et al*<sup>[13]</sup> showed that an increase in BMI was related to an increase in erosive esophagitis, but Chung *et al*<sup>[14]</sup> did not find a significant association between BMI and erosive esophagitis. Our study showed that central obesity, but not BMI, was an independent risk factor for erosive esophagitis.

A possible reason for this finding is that BMI is not a good indicator of the percentage of body fat among Asian populations<sup>[21]</sup>. Only the visceral component of abdominal fat increases the risk for erosive esophagitis because visceral adipose tissue is strongly associated with elevated serum levels of proinflammatory adipokines, which may play a role in the development of erosive esophagitis<sup>[7,14,22]</sup>. In addition, central obesity may increase intra-abdominal pressure and decrease lower esophageal sphincter pressure, resulting in esophageal sphincter relaxation with acid reflux, which may lead to esophagitis<sup>[22-24]</sup>.

Studies have also shown that hypertriglyceridemia is associated with erosive esophagitis<sup>[13-15]</sup>, but contrasting results have also been reported<sup>[5]</sup>. The present study shows that hypertriglyceridemia is a potential risk factor for erosive esophagitis. Although the underlying mechanisms still need to be fully characterized, high dietary fat intake and delay in gastric emptying may increase the risk of erosive esophagitis<sup>[25,26]</sup>.

The association of hyperglycemia and erosive esophagitis is controversial. Moki *et al*<sup>[5]</sup> demonstrated a positive relationship between erosive esophagitis and hyperglycemia. However, the majority of studies have found that hyperglycemia is not associated with erosive esophagitis<sup>[13-15,27]</sup>. Our results also indicate that hyperglycemia is not associated with erosive esophagitis. Gastric emptying can be delayed by diabetic autonomic neuropathy, which may promote erosive esophagitis. However, most individuals in our study population were in generally good health, without diabetic autonomic neuropathy, which may explain our finding that hyperglycemia is not associated with erosive esophagitis. The association of hypertension and erosive esophagitis is also controversial. Gudlaugsdottir *et al*<sup>[28]</sup> suggested that erosive esophagitis was associated with hypertension, but Wu *et al*<sup>[29]</sup> failed to establish a significant relationship between hypertension and erosive esophagitis. Our study showed that hyperten-

sion is an independent risk factor for erosive esophagitis.

Several studies have reported that abnormal liver function is related to metabolic syndrome<sup>[10-12]</sup>. In addition to metabolic syndrome, high BMI, central obesity, and hyperlipidemia are associated with hepatic steatosis<sup>[30,31]</sup>. The severity of hepatic steatosis is significantly correlated with the results of hepatic enzyme tests<sup>[32]</sup>. Several studies have reported an association between gastroesophageal reflux disease (GERD) and chronic liver disease<sup>[33-36]</sup>. Suzuki *et al*<sup>[36]</sup> showed that more than 30% of patients with chronic liver disease had GERD. Ueda *et al*<sup>[34]</sup> showed a relatively higher incidence of GERD in patients with alcoholic liver disease. We found that abnormal liver function (higher AST level) was a risk factor for erosive esophagitis. Although the underlying mechanisms are not clear, hepatic steatosis related to metabolic syndrome, a risk factor of erosive esophagitis, may provide a potential explanation. The TC/HDL-C ratio has been used to predict the risk of future coronary heart diseases. This practice is supported by several studies that have demonstrated that the TC/HDL-C ratio is the most significant predictor of future coronary heart disease, along with smoking and diabetes mellitus<sup>[37-39]</sup>. Our study showed that subjects with erosive esophagitis might have a higher cardiovascular risk than those without erosive esophagitis. The present study has several limitations. First, only the association between abnormal liver function and erosive esophagitis was analyzed, and no further evaluation was conducted to determine the relationship between erosive esophagitis and hepatic steatosis or chronic hepatitis B or C. Second, this study had a cross-sectional design, and therefore, only the associations between erosive esophagitis and metabolic syndrome, abnormal liver function, and

dyslipidemia could be determined. Further studies with a longitudinal design are required to evaluate their possible causal relationships.

In conclusion, metabolic syndrome and its components, such as central obesity, BP, and hypertriglyceridemia, are independent risk factors for erosive esophagitis. Abnormal liver function, including elevated AST, and cardiovascular risk factors were also found to be associated with erosive esophagitis. Further studies are needed to investigate the underlying mechanisms responsible for the relationship between abnormal liver function, cardiovascular risk, and erosive esophagitis.

## ACKNOWLEDGMENTS

Dr. Rue-Tsuan Liu is appreciated for his discussion and opinion.

## COMMENTS

### Background

Erosive esophagitis is becoming more prevalent in Asia, but the underlying mechanism remains unknown. Obesity has been associated with erosive esophagitis. However, the associations of metabolic syndrome, its components, and liver function with erosive esophagitis are controversial.

### Research frontiers

Several previous studies have identified the risk factors of erosive esophagitis, including male sex, hiatal hernia, smoking, alcohol consumption, and obesity. This study further determined the associations between erosive esophagitis and metabolic syndrome, its components, and liver function.

### Innovations and breakthroughs

The present study demonstrated that metabolic syndrome, impaired liver function, and dyslipidemia were associated with erosive esophagitis.

### Applications

Individuals with metabolic syndrome and high cardiovascular risk, as defined by

a higher ratio of total cholesterol to high-density lipoprotein cholesterol (HDL-C), are at higher risk for erosive esophagitis. This finding may suggest that treating metabolic disorders can prevent or reduce the risk of erosive esophagitis. However, further studies are needed to confirm this finding.

### Terminology

Metabolic syndrome is a complex disorder comprising central obesity, high blood pressure, hyperglycemia, hypertriglyceridemia, and a low concentration of HDL-C. Cardiovascular risk, which is determined by a total cholesterol/HDL-C ratio > 5, correlates with the risk of cardiovascular events.

### Peer review

Authors undertook to characterize the correlation between erosive esophagitis and metabolic syndrome and its components, abnormal liver function, and abnormal lipoprotein profiles. This case-controlled study is well organized and has enough potential for publication.

### Abstract

**AIM:** To investigate the effect of early enteral nutrition (EEN) combined with parenteral nutritional support in patients undergoing pancreaticoduodenectomy (PD).

**METHODS:** From January 2006, all patients were given EEN combined with parenteral nutrition (PN) (EEN/PN group,  $n = 107$ ), while patients prior to this date were given total parenteral nutrition (TPN) (TPN group,  $n = 67$ ). Venous blood samples were obtained for a nutrition-associated assessment and liver function tests on the day before surgery and 6 d after surgery. The assessment of clinical outcome was based on postoperative complications. Follow-up for infectious and noninfectious complications was carried out for 30 d after hospital discharge. Readmission within 30 d after

discharge was also recorded.

**RESULTS:** Compared with the TPN group, a significant decrease in prealbumin (PAB) ( $P = 0.023$ ) was seen in the EEN/PN group. Total bilirubin (TB), direct bilirubin (DB) and lactate dehydrogenase (LDH) were significantly decreased on day 6 in the EEN/PN group ( $P = 0.006$ ,  $0.004$  and  $0.032$ , respectively). The rate of grade I complications, grade II complications and the length of postoperative hospital stay in the EEN/PN group were significantly decreased ( $P = 0.036$ ,  $0.028$  and  $0.021$ , respectively), and no hospital mortality was observed in our study. Compared with the TPN group (58.2%), the rate of infectious complications in the EEN/PN group (39.3%) was significantly decreased ( $P = 0.042$ ). Eleven cases of delayed gastric emptying were noted in the TPN group, and 6 cases in the EEN/PN group. The rate of delayed gastric emptying and hyperglycemia was significantly reduced in the EEN/PN group ( $P = 0.031$  and  $P = 0.040$ , respectively).

**CONCLUSION:** Early enteral combined with PN can greatly improve liver function, reduce infectious complications and delayed gastric emptying, and shorten postoperative hospital stay in patients undergoing PD.

**Key words:** Enteral nutrition; Parenteral nutrition; Pancreaticoduodenectomy; Complications; Metabolism

**Core tip:** On the basis of our experience and the findings of previous studies, we investigated the effect of early enteral nutrition combined with parenteral nutritional support in patients undergoing pancreaticoduodenectomy enrolled in a retrospective controlled clinical trial. The results of this study showed that early enteral nutritional support combined with parenteral nutrition can greatly improve nutritional status and liver function, decrease the incidence of infectious complications and delayed gastric emptying, and shorten the length

of postoperative hospital stay.

Effect of early enteral combined with parenteral nutrition in patients undergoing pancreaticoduodenectomy. *World J Gastroenterol* 2013; 19(35): 5889-5896 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5889.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5889>

## INTRODUCTION

Pancreaticoduodenectomy (PD) is currently considered the treatment of choice for carcinoma of the periampullary region. Patients who are candidates for PD often have associated comorbidities such as diabetes, jaundice, and protein-energy malnutrition. PD results in loss of the gastric pacemaker and a partial pancreatic resection, and the physiologic consequence of this is a high incidence of postoperative malnutrition. PD is associated with a high incidence of postoperative complications, and this high rate of complications is likely to be multifactorial and may include overall nutritional debilitation<sup>[1]</sup>. Postoperative nutritional support therapy could ameliorate the clinical outcome in many types of surgical treatment, diminish the incidence of postoperative complications, and may be important in patients undergoing PD.

Recent research has shown that early postoperative enteral nutrition (EN) enhanced immunocompetence, decreased clinical infection rates, maintained gut structure and function, and can potentially attenuate catabolic stress responses in patients after surgery<sup>[2,3]</sup>. In addition, EN is believed to be safer and less expensive than parenteral nutrition (PN). However, postoperative total enteral feeding is associated with complications such as diarrhea, abdominal distention, and abdominal cramps. These symptoms worsen with increasing caloric intake and can lead to discontinuance of enteral feeding<sup>[2,4]</sup>. Gastroparesis is a frequent postoperative event following PD resection, and this often necessitates prolonged gastric decompression and enteral nutritional support<sup>[5]</sup>. Clinical data on postoperative early enteral nutrition (EEN) after PD are very limited. Therefore, on the basis of our experience and the findings of previous studies, we investigated the effect of EEN combined with parenteral nutritional support in patients undergoing PD enrolled in a retrospective controlled clinical trial.

## MATERIALS AND METHODS

### Patient selection

From January 2004 to June 2011, 196 patients underwent PD due to peri-ampullary tumors in the Department of Hepatobiliary Surgery at the Affiliated Drum Tower Hospital of Medical School of Nanjing University, China, where the authors work. Nineteen patients with manifest metabolic diseases (*e.g.*, diabetes mellitus and hyperthy-

roidism), severe hemorrhagic disease, ongoing infection, inflammatory bowel diseases or severe renal abnormality were excluded. Three patients with a history of gastric or pancreatic resection were also excluded, given the possible influence this procedure may have on the incidence of delayed gastric emptying. From January 2006, all patients were given EEN combined with PN (EEN/PN group,  $n = 107$ ), while patients prior to this date were given TPN (TPN group,  $n = 67$ ).

The primary endpoint of this study was the occurrence of major complications, and the secondary endpoint was 30 d after hospital discharge. The Nutrition Risk Screening 2002 (NRS 2002) scoring system<sup>[6]</sup> was used in this study, and the post-operative NRS 2002 score in all patients was  $\geq 3$ , indicating that all patients required nutritional support.

### Treatment

TPN was given 24 h/d for 5 d from the first day after PD. The nitrogen intake was 0.25 g/kg body weight per day, caloric intake was 125.4 kJ/kg per day and lipid intake was 1.1 g/kg per day. The nonprotein calories were given as dextrose (5.0 g/kg per day) and fat emulsion in a ratio of 2:1. The source of lipids was the standard lipid emulsion (20% emulsion, 5.5 mL/kg per day, long chain triglycerides: medium chain triglycerides 1:1, Huarui Pharmaceuticals, Jiangsu Province, China). Patients received 1.5 g amino acids/kg per day, administered as a commercially available compound amino acid solution (20% solution, Huarui Pharmaceuticals, Jiangsu Province, China). The proportion of nonprotein calories with nitrogen in both groups was 501.6 kJ/g. The PN solutions were prepared by a clinical pharmacist under aseptic conditions and adjusted to the weight of each patient. The amino acids, fat emulsion and dextrose mixture with electrolytes, vitamins and trace elements were administered *via* a central venous catheter. As soon as bowel function returned on 3-4 d after surgery, all patients were given liquid carbohydrate and cow's milk protein in equal amounts orally.

The surgical treatment was standardized, and lymph-node dissection was performed according to the definition provided by Pedrazzoli *et al*<sup>[7]</sup>. PD was performed by three groups of surgeons using the same technique. All patients received the same antibiotics postoperatively.

Patients in the EEN/PN group underwent preoperative placement of a conventional gastric tube. When gastrojejunostomy was complete, nasojejunal nutrition tubes were positioned (10 F, NUTRICIA Pharmaceutical Co., The Netherlands) from the nasal cavity to the output loops of the jejunum (approximately 20-25 cm with the help of a surgeon). The jejunum nutrition tube filar guide was then removed when the tube was in the correct position.

EN was given to patients in the EEN/PN group 24 h/d. An infusion of 100 mL of 5% glucose and sodium chloride injection (GNS) *via* a nasojejunal feeding tube was commenced within 24 h of surgery and 500 mL of 5% GNS was given on post-operative day 2 (POD2). On

	EN	7649.4 (6081.9-10282.8)	54.9 (43.65-73.8)	54.9 (43.65-73.8)	256.2 (203.7-344.4)

Data are expressed as absolute average or average (range). POD: Post-operation day; PN: Parenteral nutrition; EN: Enteral nutrition.

POD3, 250 mL of Peptisorb liquid (2092 kJ/500 mL, NUTRICIA Pharmaceutical Co., the Netherlands) and 250 mL of 5% GNS were administered. Patients received 500 mL of Peptisorb liquid on POD4, and 1000 mL on POD5. From POD3, the PN recipe was adjusted according to the amount of EN, and the total caloric intake of PN and EN was 125.4 kJ/kg per day. PN was stopped on POD6, and patients in the EEN/PN group reached a maximum volume of total caloric intake following Peptisorb liquid (30 mL/kg per day). Oral intake started on POD7 and EN was stopped when the patients tolerated an intake of over 1000 kcal/d.

The body weight of the patients in this study varied from 48.1-84.6 kg, with an average body weight of 60.3 kg. Based on the range and average body weight, the ranges and averages of the calories, protein, fat and carbohydrates in the enteral and parenteral regimens in the EEN/PN group are listed in Table 1.

### Assessment

Venous heparin blood samples were obtained on 1 d (the day before surgery), and 6 d after surgery. Three types of measurement were carried out. First, a nutrition-associated assessment was carried out, which included serum albumin, prealbumin (PAB), total protein (TP), transferrin (TF) and total lymphocyte counts (TLCs). Serum albumin, PAB, total protein and TF were determined by an automatic biochemistry analyzer (HITACHI 7600, Hitachi Co., Tokyo, Japan). TLCs were determined using an automatic blood cell analyzer (COULTER STKS). The prognostic nutritional index (PNI) was calculated as follows:  $PNI = 0.005 \times TLC (10^6/L) + \text{albumin (g/L)}$ . The normal value of PNI is more than 50, and PNI values < 40 indicated malnutrition. Nitrogen balance was calculated as follows:  $N \text{ balance (g N/d)} = [\text{protein intake (g/d)/6.25}] - [\text{urinary urea (g/24 h)/2.14} + 3 \text{ g (nitrogen lost in skin and stool per day)}]$ . Second, a liver function assessment was carried out, which included serum total bilirubin (TB), direct bilirubin (DB), alanine aminotransferase (ALT), aspartate aminotrans-

ferase (AST) and lactate dehydrogenase (LDH) measurements. Liver function was determined by an automatic biochemistry analyzer (HITACHI 7600). Finally, clinical outcome was assessed based on postoperative complications. These complications were graded according to the Clavien-Dindo classification<sup>[8]</sup>, which was validated in pancreatic surgery<sup>[9]</sup>. Complications graded as III to V were considered as major. Pancreatic fistula and delayed gastric emptying were defined according to the International Study Group of Pancreatic Surgery (ISGPS)<sup>[10,11]</sup>. Operative mortality was defined as in-hospital death or death occurring within 30 d of discharge. Follow-up for infectious and noninfectious complications was carried out for 30 d after hospital discharge. Readmission within 30 d after discharge was also recorded.

### Statistical analysis

The results are expressed as mean  $\pm$  SD. Data were analyzed using the Statistical Analysis System (SAS). Differences between means were evaluated using the Student *t* test when normal distribution was confirmed by the Shapiro-Wilks test. When the hypothesis of normal distribution was rejected, differences between groups were tested by nonparametric statistics using the Mann-Whitney test for unpaired samples and Wilcoxon criteria for paired samples. Fisher's exact test was used for analysis of categorical values when appropriate. A *P* value of < 0.05 was considered significant.

## RESULTS

A total of 174 patients were enrolled in the study, 67 patients in the TPN group and 107 patients in the EEN/PN group. The mean age of the subjects was 53.2 years (range, 37-68 years). Demographic and preoperative clinical data, including age, sex, preoperative hemoglobin, preoperative albumin and the number of patients with jaundice or preoperative endoscopic nasal biliary drainage, are summarized in Table 2. No significant differences with respect to intraoperative factors, including opera-

**Table 2** Preoperative clinical data, intraoperative factors and histopathology of the patients enrolled in the study

	TPN group	EEN/PN group
Sex (male/female)	44/23	70/37
Age (yr)	52.8 ± 11.2	53.9 ± 10.6
Intraoperative factors		
Patients with jaundice (%)	79.1	83.2
Patients with preoperative ENBD (%)	50.7	48.6

tion time, blood loss, number of patients who received blood transfusion and histopathological diagnosis, were observed between the two groups ( $P > 0.05$ ).

### Nutrition-associated assessment

No significant difference in the pre-operative nutrition-associated assessment was seen between the two groups. Compared with the results on the day before PD, a decrease in TP, PAB, TF and PNI was observed on day 6 after PD in all patients in this study, and a significant decrease in PAB in the TPN group ( $P < 0.05$ ) with no significant difference ( $P > 0.05$ ) in the EEN/PN group (Table 3).

Compared with the TPN group, a significant decrease in PAB ( $P = 0.02$ ) was seen in the EEN/PN group. However, no significant differences in TF, TP and PNI were noted between the two groups ( $P > 0.05$ ). Nitrogen balance was negative in both groups on day 6, with no significant difference between the two groups (Table 3).

### Liver function assessment

No significant differences in pre-operative liver function assessment were seen between the two groups. Compared with the results on the day before surgery, a significant decrease in ALT, AST, TB, DB and LDH was observed on 6 d in both groups ( $P < 0.05$ ), and a very significant decrease in TB and DB in the EEN/PN group ( $P < 0.01$ ).

Compared with the TPN group, a significant decrease in TB, DB and LDH was seen in the EEN/PN group ( $P < 0.05$ ). No significant differences in ALT and AST were observed between the two groups ( $P > 0.05$ ; Table 4).

### Clinical outcome

A prognostic score for major morbidity after PD has recently been proposed by Braga *et al.*<sup>[12]</sup>. The predictive risk score of major complications after PD in the two groups are listed in Table 5. There were no significant differences between the two groups in the score categorized in 4 risk

classes ( $P > 0.05$ ).

Table 6 shows the postoperative outcome in the two groups. Reoperation was necessary in 9 patients, and the causes of reoperation were early bleeding (1 case in the TPN group and 2 cases in the EEN/PN group), late bleeding (1 case in the EEN/PN group), abdominal abscess (2 cases in the TPN group and 2 cases in the EEN/PN group) and intestinal obstruction (1 case in the EEN/PN group). The causes of readmission in this study were intestinal obstruction (1 case in the TPN group and 2 cases in the EEN/PN group) and cholangitis (1 case in the TPN group and 1 case in the EEN/PN group). The rate of grade I complications, grade II complications and the length of postoperative hospital stay in the EEN/PN group were significantly reduced ( $P < 0.05$ ), and no hospital mortality was observed in this study (Table 6).

Postoperative complications are shown in detail in Table 7. There were 39 cases of infectious complications in the TPN group (8 cases of pneumonia, 7 cases of abdominal abscess, 5 cases of bile leak, 2 cases of pancreatic fistula, 4 cases of cholangitis, 8 cases of wound infection and 5 cases of urinary tract infection) and 42 cases in the EEN/PN group (6 cases of pneumonia, 6 cases of abdominal abscess, 7 cases of bile leak, 4 cases of pancreatic fistula, 3 cases of cholangitis, 10 cases of wound infection and 6 cases of urinary tract infection). Compared with the TPN group (58.2%), the rate of infectious complications in the EEN/PN group (39.3%) was significantly decreased ( $P < 0.05$ ). Eleven cases of delayed gastric emptying were observed in the TPN group, and 6 cases in the EEN/PN group. The rate of delayed gastric emptying and hyperglycemia was significantly decreased in the EEN/PN group ( $P < 0.05$ ). There were 29 cases of enteral-feeding-related complications in the EEN/PN group, including diarrhea, abdominal distention, and abdominal cramps. These symptoms were alleviated by slowing down the speed of enteral transfusion or by the administration of medications. None of the patients discontinued enteral feeding, and no enteral-feeding-related complications were noted in the TPN group.

## DISCUSSION

PD is associated with a high incidence of postoperative complications, and an overall morbidity rate of 48% can be anticipated at major centers<sup>[13]</sup>. The high rate of complications is likely to be multifactorial and may include overall nutritional debilitation, as most patients with periampullary tumors present with significant weight loss due to anorexia and malabsorption, and are expected to have a period of inadequate oral intake up to 10 d after surgery<sup>[14]</sup>. Compared with the results on the day before PD, a decrease in TP, PAB, TF, PNI and negative nitrogen balance were observed on day 6 in all patients in this study. Perioperative nutritional support can be beneficial in these patients in that it may reduce mortality and morbidity, and the length of hospital stay<sup>[15]</sup>.

Numerous studies have suggested that EN has sev-

eral advantages over TPN. Early enteral feeding was shown to reduce postoperative septic complications in a meta-analysis of 8 prospective randomized trials, and improve glucose tolerance, protein kinetics and wound healing. Furthermore, EN is safer and less expensive than PN<sup>[16,17]</sup>. However, postoperative total enteral feeding is associated with complications such as diarrhea, abdomi-

nal distention, and abdominal cramps. These symptoms worsen with increasing caloric intake and can lead to discontinuance of enteral feeding<sup>[2,3]</sup>. On the basis of these findings, we considered EEN combined with PN to be a better mode of postoperative nutritional support than total enteral feeding. On the first three days after surgery in this study, the amount of EN increased slowly to avoid severe gastrointestinal complications. Twenty-

Numbers of single types of complications do not add up to the number of patients within the 2 groups, due to the possible occurrence of more types of complications in some patients. EEN: Early enteral nutrition; PN: prognostic nutritional; TPN: Total parenteral nutrition.

nine cases in the EEN/PN group had enteral-feeding-related complications, these symptoms were alleviated by slowing down the speed of enteral transfusion or by the administration of medications, and none of the patients discontinued enteral feeding or dropped out of the study. PAB, which is more sensitive than albumin for evaluating protein synthesis in the liver due to its shorter half-life, was decreased on day 6 in all patients in this study. Compared with the TPN group, a significant decrease in PAB ( $P < 0.05$ ) was observed in the EEN/PN group.

Changes in transaminase and bilirubin are the most important indices for evaluating liver function in patients after PD. All patients in this study underwent PD to remove biliary obstruction, therefore, ALT, AST, TB, DB and LDH were significantly reduced. Lack of enteral feeding has several metabolic and endocrine consequences on intestinal and liver function. Experimental studies have shown that the fasted state reduces the secretion of several gastrointestinal hormones, such as cholecystokinin, gastrin and peptide YY. These hormones are instrumental in stimulating bile flow and gallbladder contraction, and for maintaining intestinal motility<sup>[18-20]</sup>. EN can also stimulate hepatic circulation and ameliorate liver function<sup>[21]</sup>. In the present study, a significant decrease in TB and DB in the EEN/PN group was observed compared with that in the TPN group.

EN preserved the gut flora architecture, prevented gastrointestinal mucosa atrophy, and inhibited microbial translocation from the gut to the blood stream<sup>[22,23]</sup>. Compared with the TPN group, the rate of infectious complication in the EEN/PN group was significantly decreased. The reduced length of postoperative hospital stay in the

EEN/PN group indicated that the time to complete recovery could be shortened by EEN support combined with PN. This may be explained by the lower number of complications.

Delayed gastric emptying (DGE) is also known as “gastroparesis”. DGE is not a fatal complication, but sometimes results in a significant prolongation of hospital stay and increased hospital costs. DGE has been reported to be affected by several factors including gastric dysrhythmias due to intra-abdominal complications, gastric atony after duodenal resection in response to a reduction in motilin levels, pylorospasm secondary to vagotomy, and angulation of the reconstructed alimentary tract<sup>[24-26]</sup>. Eleven cases of DGE were observed in the TPN group, and 6 cases in the EEN/PN group. EEN-support therapy significantly decreased the rate of DGE. One potential mechanism for the decreased rate of DGE due to EN may be the mechanical effects caused by the nasojejun tube or simply its presence across the anastomosis, which stimulates the motility of the stomach and jejunum, while another mechanism may be the stimulation of bowel movements by the input of nutritional liquids<sup>[27,28]</sup>.

In conclusion, we have shown that early enteral nutritional support combined with PN can greatly improve nutritional status and liver function, decrease the incidence of infectious complications and delayed gastric emptying, and shorten postoperative hospital stay in patients undergoing PD. Future randomized controlled trials are necessary to identify the correct application of PN and EN in patients receiving PD.

## COMMENTS

### Background

Pancreaticoduodenectomy (PD) is associated with a high incidence of postoperative complications. This high rate of complications is likely to be multifactorial and may include overall nutritional debilitation. Postoperative nutritional support therapy could ameliorate the clinical outcome in many types of surgical treatment and diminish the incidence of postoperative complications. The clinical data on postoperative early enteral nutrition (EEN) combined with parenteral nutrition (PN) after PD is very limited.

### Research frontiers

Recent research has shown that early postoperative enteral nutrition enhanced immunocompetence, lowered clinical infection rates, and maintained gut structure and function, and can potentially attenuate catabolic stress responses in patients after surgery. However, postoperative total enteral feeding is associated with complications such as diarrhea, abdominal distention, and abdominal cramps. These symptoms worsened with increasing caloric intake and can lead to discontinuance of enteral feeding.

### Innovations and breakthroughs

The authors investigated the effect of EEN combined with parenteral nutritional support in patients undergoing PD enrolled in a retrospective controlled clinical trial on the basis of their experience and the findings of previous studies. The results of this study show that early enteral nutritional support combined with PN can greatly improve nutritional status and liver function, decrease the incidence of infectious complications and delayed gastric emptying, and shorten postoperative hospital stay.

### Applications

The results of this study show that early enteral nutritional support combined with PN can greatly improve nutritional status and liver function, decrease

the incidence of infectious complications and delayed gastric emptying, and shorten postoperative hospital stay in patients undergoing PD. These findings are clinically relevant for guiding surgeons in the perioperative administration of medications during PD.

### Peer review

This is an interesting study which is well written and referenced. It is a non-randomized retrospective study of the effect of EEN combined with parenteral nutritional support for patients receiving PD. PD is a major surgical procedure for the treatment of periampullary tumors which will result in a high incidence of complications and postoperative malnutrition, but nutritional support can improve patient's malnutrition and diminish the incidence of postoperative complications.

and 103 females) and 200 healthy individuals who served as controls (control, 109 males and 91 females), aged between 6 and 16 years were enrolled in this study. The four non-synonymous single nucleotide polymorphisms (SNPs) in the *UCP3* gene polymorphisms of rs1726745, rs3781907, rs11235972 and rs1800849, were genotyped using MassArray. Body mass index (BMI), waist and hip circumference, blood pressure (BP), fasting blood glucose (FBG), insulin and lipid profiles were measured and B-ultrasound examination was performed in all subjects.

**RESULTS:** NAFLD patients showed risk factors for metabolic syndrome: elevated BMI, waist-to-hip ratio, BP, FBG, homeostasis model assessment-estimated insulin resistance, total triglyceride, total cholesterol and low-density lipoprotein-cholesterol, while decreased high-density lipoprotein-cholesterol level compared with the control group. The GG genotype distributions of rs11235972 in the NAFLD group differed significantly from that in the control group. We found that waist circumference between CC ( $58.76 \pm 6.45$  cm) and CT+TT ( $57.00 \pm 5.59$  cm), and hip circumference between CC ( $71.28 \pm 7.84$  cm) and CT+TT genotypes ( $69.06 \pm 7.75$  cm) were significantly different with and without rs1800849 variation ( $P < 0.05$ ).

**CONCLUSION:** A higher prevalence of rs11235972 GG genotype was observed in the NAFLD group compared with the control group. No differences were observed for the other SNPs. However, there was a significant difference in body height in addition to waist and hip circumference between the CC (mutant type group) and CT+TT group with and without rs1800849 variation.

### Abstract

**AIM:** To confirm the hypothesis that polymorphisms of the uncoupling protein 3 (*UCP3*) gene are associated with the occurrence of nonalcoholic fatty liver disease (NAFLD).

**METHODS:** A total of 250 NAFLD patients (147 males

studies of pediatric nonalcoholic fatty liver disease (NAFLD). Uncoupling protein 3 (*UCP3*) is considered to be associated with obesity, given the role for *UCP3* in the regulation of energy and lipid metabolism. This is the first study to report that there significant difference of body height, waist and hip circumference between CC (mutant type group) and CT+TT group with and without rs1800849 variation were found. This study confirmed the hypothesis that polymorphisms of the *UCP3* are associated with the occurrence of NAFLD. These variations could be useful for the diagnosis and/or prognosis of NAFLD.

## INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is a clinicopathologic condition characterized by abnormal lipid deposition in hepatocytes in the absence of excess alcohol intake. NAFLD comprises a wide spectrum of liver damage, including simple steatosis, steatohepatitis, fibrosis or even cirrhosis of the liver<sup>[1]</sup>. NAFLD does not only impact adults, but is also one of the major causes of liver diseases in children<sup>[2]</sup>. There are few population-based prevalence studies of pediatric NAFLD. Some studies have suggested a prevalence of 2.6%-9.6% for suspected NAFLD among children and adolescents in the United States<sup>[3,4]</sup> and Asia<sup>[5,6]</sup>. NAFLD has been shown to be associated with metabolic syndrome (MetS), which comprises obesity, type 2 diabetes, dyslipidemia and high blood pressure (BP) with insulin resistance being the central mechanism<sup>[7,8]</sup>. Theoretically, many variations in candidate genes related to MetS may contribute to the pathogenesis of NAFLD, such as genes related to insulin resistance and genes influencing hepatic free fatty acid metabolism. Elucidation of genetic factors that predispose an individual to NAFLD may lead to the development of non-invasive biomarkers for the early diagnosis of NAFLD and may allow early preventive and therapeutic strategies for those at the high risk.

Uncoupling protein 3 (*UCP3*) gene is located on chromosome 11q13. *UCP3* is a mitochondrial anion carrier protein with a highly selective expression in skeletal muscle, a major site of thermogenesis in humans, which makes an attractive target for studies into the regulation of body weight. Reduced expression of *UCP3* decreases energy expenditure and increased expression of *UCP3* mRNA in muscle is related to an increase in the metabolic rate and to a lower body mass index (BMI)<sup>[9,10]</sup>. Therefore, *UCP3* may be involved in obesity, given the role of *UCP3* in the regulation of energy and lipid metabolism.

Genetic variants of *UCP3* have been identified, and specifically polymorphisms of 55C/T may impact type 2 diabetes mellitus (T2DM), obesity and weight gain<sup>[11-13]</sup>. This study confirmed the hypothesis that polymorphisms of the *UCP3* are associated with the occurrence of NAFLD. These variations could be useful for the diagnosis and/or prognosis of NAFLD, although the functional significance of *UCP3* polymorphisms is not clear.

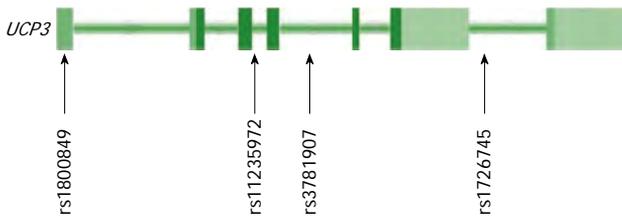

## MATERIALS AND METHODS

### Subjects

A total of 250 NAFLD children and 200 healthy individuals (controls), aged between 6 and 16 years were enrolled in this study. NAFLD children (147 males and 103 females) were referred to our endocrinology department from January 2006 to September 2011; NAFLD was defined according to the revised definition and treatment guidelines for NAFLD by the Chinese Hepatology Association in February 2006<sup>[14,15]</sup>, and was diagnosed by means of a protocol using clinical, laboratory and ultrasound examinations in combination. In this study, NAFLD was diagnosed as a diffusely echogenic change on liver B-ultrasonography (fatty infiltration in liver), with or without elevated serum aminotransferase levels, and other factors which can cause liver fatty infiltration or aminotransferase elevation, such as infectious hepatitis (hepatitis B and C, Epstein-Barr virus infection), drug-induced hepatitis, and some metabolic diseases were excluded. None of the subjects had a history of alcohol consumption. Blood samples ( $n = 200$ ) were also obtained from healthy individuals, who served as controls (109 males and 91 females) in 2011 from the Department of Child Health Care, The Affiliated Yuying Children's Hospital of Wenzhou Medical University and Ningbo Women and Children's Hospital. The protocol was approved by the Medical Ethics Committee of The Children's Hospital of Zhejiang University School of Medicine. Written informed consent were obtained from parents (or guardians) and children (where appropriate).

### Laboratory assessment

The weight and height of the subjects were measured with a calibrated scale after removing shoes and heavy clothing, if any. BMI is calculated by taking the ratio of weight in kilogram and the square of height in meter. Waist was measured at the midpoint between the lower border of the rib cage and the iliac crest. Hip circumference was determined at the widest circle of the bottom. Venous blood samples were obtained from the subjects after an overnight fasting (12 h) for the measurement of fasting blood glucose (FBG), fasting insulin (FIN), total triglyceride (TG), total cholesterol (TCHO), high-density lipoprotein-cholesterol (HDL-C) and low-density lipoprotein-cholesterol (LDL-C), alanine transaminase (ALT) and aspartate aminotransferase (AST). All laboratory biochemical parameters were measured in a conventional automated analyzer.

**Figure 1** Locus of the human *UCP3* gene in 11q13. The uncoupling protein 3 (*UCP3*) gene consists of seven exons separated by six introns. Boxes indicate exons, while lines indicate introns and intergenic regions. Mark the polymorphism locations.

**Liver ultrasound examination**

Sagittal hepatic sections that encompassed longitudinal images of the right liver lobe and the ipsilateral kidney were obtained. Liver-kidney contrast with two other well-known ultrasonographic findings of fatty liver, vascular blurring and deep attenuate, enabled us to grade fatty change semi-quantitatively<sup>[15]</sup>. Ultrasound examination was carried out and blinded to laboratory values on the same equipment (GE, LOGIC 500), using a convex 3.5-5.0 MHz probe. NAFLD and healthy individuals underwent liver ultrasound examination.

**DNA preparation and single nucleotide polymorphism genotyping**

Using information on single nucleotide polymorphism (SNP) allelic frequencies from the website of the National Center for Biotechnology Information (NCBI) and the SNP browser software 3.0 (Applied Biosystems, Branchburg, NJ, United States), SNPs on the human *UCP3* gene with minor allele frequencies > 30% were selected. SNPs with relatively high minor allele frequencies have been shown to be very useful as genetic markers for genetic association studies. We selected four non-synonymous SNPs in the *UCP3* gene: polymorphisms of rs1726745, rs3781907, rs11235972, and rs1800849 (Figure 1). Genomic DNA was extracted from blood samples collected from each subject. Polymorphisms were genotyped using an automated platform MassARRAY (Sequenom, San Diego, CA). Polymerase chain reaction for the DNA sequence containing the target SNP was performed. The products were extended one base in SNP sites using the SNP specific primer. The products were applied into the MassARRAY SpectroCHIP array and crystallized with matrix in the chip. The crystal containing chip was moved to the mass spectrometer vacuum tube and excited using an instantaneous nanosecond (10<sup>-9</sup> s) laser. The molecular of matrix absorb the radiation energy, which lead to energy accumulation causing crystal matrix sublimation, DNA molecule desorption and transformation to metastable ions.

**Statistical analysis**

Quantitative data with normal distribution were presented as mean ± SD. Categorical variables were expressed as a percentage and examined using the  $\chi^2$  test and Fisher's tests. Hardy-weinberg test was performed to

**Table 1** Demographic and biochemical features of patients with nonalcoholic fatty liver disease and normal controls

	NAFLD (n = 250)	Controls (n = 200)	P value
Gender (M/F)	147/103	109/91	0.36

FIN (mIU/L)	20.49 ± 17.25	6.98 ± 3.59	0.00
HOMA-IR	4.57 ± 3.92	1.52 ± 0.78	0.00

Data are expressed as absolute mean ± SD. Analysis was conducted using  $\chi^2$  test and *t* test. NAFLD: Nonalcoholic fatty liver disease; BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic pressure; WHR: Waist-to-hip ratio; FBG: Fasting blood glucose; TCHO: Total cholesterol; HDLc: High-density lipoprotein-cholesterol; LDLc: Low-density lipoprotein-cholesterol; TG: Total triglyceride; ALT: Alanine transaminase; AST: Aspartate aminotransferase; FIN: Fasting insulin; HOMA-IR: Homeostasis model assessment-estimated insulin resistance; M: Male; F: Female.

calculate allelic frequencies using the  $\chi^2$  test. Multivariate logistic regression analysis by using stepwise selection was constructed to determine which of the potential risk factors of NAFLD were. Given the BMI, HOMA-IR, ALT, TCHO, rs1726745, rs3781907, rs11235972, and rs1800849 risk factors relative to the potential number of variables in our model, only those variables that had the highest possibility for independent prediction of outcome in our logistic regression were included. Multivariate logistic regression analysis was performed to estimate the OR and 95%CI for the potential risk factors of NAFLD. The statistical significance of means was estimated by independent *t* test. HOMA-IR = fasting insulin (μU/mL) × fasting glucose (mmol/L)/22.5. A *P* value of < 0.05 was regarded as statistical significant. All data analysis was done using the SPSS for windows (version 13.0; SPSS, Inc., Chicago, IL, United States). Haploview software (Cambridge, MA, United States) was used to screen tag SNPs.

**RESULTS**

The clinical features of the NAFLD and control groups are shown in Table 1. There was no significant difference in age and gender (*P* > 0.05). NAFLD patients showed most of the risk factors for the MetS: elevated BMI, waist-to-height ratio (WHR), BP, FBG, HOMA-IR, TG, TCHO and LDL, while decreased HDL level compared to control group.

TCHO: Total cholesterol; ALT: Alanine transaminase; HOMA-IR: Homeostasis model assessment-estimated insulin resistance; BMI: Body mass index.

The distributions of the four SNPs (rs1726745, rs3781907, rs11235972 and rs1800849) obeyed the Hardy-Weinberg equilibrium in all subjects. The genotypic distributions of the four loci in the *UCP3* gene are shown in Figure 1 and Table 2. The genotype distributions of rs11235972 in the NAFLD group differed significantly from that in the control group.

When all variables were put into multivariate logistic regression analysis, higher BMI and HOMA-IR were risk factors for the development of NAFLD (Table 3). The clinical features in subjects with or without rs1800849 variation are shown in Table 4. There were no significant differences in anthropometric and biomedical variables with or without rs11235972 variation in the NAFLD and in the control groups, respectively. We found body height between the CC (142.93 ± 13.08 cm) and CT+TT (139.38 ± 12.10 cm), waist circumference between the CC (58.76 ± 6.45 cm) and CT+TT (57.00 ± 5.59 cm) and hip circumference between the CC (71.28 ± 7.84 cm) and CT+TT (69.06 ± 7.75 cm) genotypes were significantly different in the control group with and without rs1800849 variation (*P* < 0.05).

When all genotypes of the four loci were entered into haplotype analysis using Haploview, only two haplotypes' alleles *i.e.*, GC and AT frequencies were accepted for assessment between the NAFLD and control groups. How-

ever, this did not reach the significance as an independent risk factor for NAFLD (Table 4 and Figure 2).

## DISCUSSION

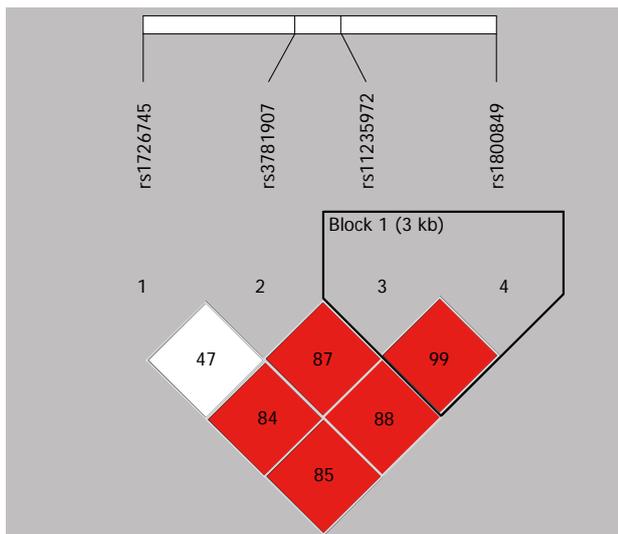

Previous reports have demonstrated that the prevalence of NAFLD increased 10%-80% in individuals with obesity, 35%-90% in individuals with T2DM, 30%-56% in individuals with hypertension, and 26%-58% in individuals with dyslipidemia<sup>[16-18]</sup>. The prevalence of the MetS among subjects with NAFLD is 17%-36%, depending on gender and criteria used<sup>[19]</sup>. In the present study, we found that an increased risk of NAFLD was significantly associated with BMI, WHR, BP, FBG, HOMA-IR, TG, TCHO and LDL, and decreased HDL level. In agreement with these studies, Iacobellis *et al.*<sup>[20]</sup> reported that a BMI evaluation may be useful in identifying those children at higher risk for disease progression. In the present study, children with NAFLD had an elevated WHR, a surrogate marker for visceral fat. Visceral fat is closely correlated with hepatic TG content, elevated ALT, liver inflammation, and fibrosis<sup>[21-23]</sup>. Central obesity is a better measure of predisposition to insulin resistance, and is more closely associated with NAFLD.

*UCP3* is considered to be associated with obesity, given the role for *UCP3* in the regulation of energy and

Analysis was conducted using *t* test. Statistically significant differences between groups are shown in bold. NAFLD: Nonalcoholic fatty liver disease; M: Male; F: Female; BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic pressure; WHR: Waist-to-hip ratio; FBG: Fasting blood glucose; HDL: High-density lipoprotein-cholesterol; LDL: Low-density lipoprotein-cholesterol; TG: Total triglyceride; ALT: Alanine transaminase; AST: Aspartate aminotransferase; FIN: Fasting insulin; HOMA-IR: Homeostasis model assessment-estimated insulin resistance.

**Figure 2** Linkage Disequilibrium mapping around the uncoupling protein 3 between nonalcoholic fatty liver disease and control groups.

lipid metabolism. However, the effect of genetic polymorphisms in *UCP3* on the pathogenesis of NAFLD has not been clearly documented. In our study, the GG genotype distribution of rs11235972 in the NAFLD group differed significantly from the control group. The results from the literature are controversial. Yoon *et al.*<sup>[24]</sup> genotyped 6 polymorphisms of *UCP3* among overweight female subjects (*n* = 458), and genetic effects on BMI and changes after a very low calorie diet were examined. They found that several polymorphisms in the *UCP2-3* gene cluster showed associations with changes in BMI and fat mass. Hamada *et al.*<sup>[25]</sup> determined whether the *UCP3*-55 C/T SNP was associated with obesity according to the criteria for Japanese (BMI ≥ 25 kg/m<sup>2</sup>) and

**Table 5** Haplotype frequencies of rs1800849, rs11235972, rs3781907, rs1726745

Block	Frequencies		χ <sup>2</sup>	P value
	NAFLD	Control		
GC	0.712	0.682	0.901	0.343
AT	0.282	0.307	0.702	0.402

NAFLD: Nonalcoholic fatty liver disease.

serum HDL-C levels in the general population. Subjects with the T/T genotype had significantly higher HDL-C levels than those with the C/C genotype or C/T genotype. Furthermore, subjects with the T/T genotype had a significantly lower BMI than those with the C/C genotype<sup>[25]</sup>. Salopuro *et al.*<sup>[26]</sup> found that the *UCP3* gene variant rs3781907 was associated with increased serum TCHO and LDL cholesterol levels. The rs1726745, rs11235972 and rs1800849 variants in the *UCP3* gene are associated with serum total and LDL-cholesterol at baseline. However, de Luis *et al.*<sup>[27]</sup> did not demonstrate an association between the -55CT polymorphism of the *UCP3* gene and fat distribution in obese patients. There might be true variability in the association among different populations, particularly different ethnic groups.

A common promoter polymorphism has also been identified in the *UCP3* gene (rs1800849), a rare allele associated with obesity in a recessive manner in several studies<sup>[10-12]</sup>. Moreover, the rs1800849 allele is associated with a higher WHR<sup>[28]</sup>, but no association between rs1800849 and WHR existed in the current study. We showed a significant difference in height, and waist and hip circumference between the CC (mutant type group) and CT+TT group with and without rs1800849 variation (Table 5).

One limitations in this study was that we used abdominal ultrasonography to diagnose NAFLD, although validation ultrasonography has a sensitivity of 91.7% and a specificity of 100%<sup>[29]</sup>. The diagnosis of NAFLD was based on ultrasound and was not confirmed by liver biopsy due to the invasive procedure usually not initially performed and ethical considerations. Thus, surrogate markers are commonly used, such as transaminases and imaging techniques. Computed tomography is more specific but is not used for screening of fatty liver in obese children. Magnetic tomography is more useful in adults and not appropriate for children due to ionizing radiation. Magnetic resonance imaging and 1H-MRS have the greatest accuracy to determine hepatic fat content, but are rarely used due to high costs. A higher prevalence of the rs11235972 GG genotype was noted in the NAFLD group compared with the control group; no differences were observed for the other SNPs. BMI and HOMA-IR increased the risk of NAFLD. Moreover, no increased risk for developing NAFLD was found to be associated with the rs1800849 variant based on multivariate analysis. A significant difference in height, and waist and hip circumference between the CC and CT+TT group with and without rs1800849 variation was demonstrated.

## ACKNOWLEDGMENTS

We sincerely thank the parents and children for participating in this study. We thank the nursing staff of our department for their dedicated care of these young patients during the collection and evaluation of blood samples. The authors thank Mr David Cushley for carefully reviewing the manuscript.

## COMMENTS

### Background

Nonalcoholic fatty liver disease (NAFLD) is a clinicopathologic condition characterized by abnormal lipid deposition in hepatocytes in the absence of excess alcohol intake. There are few population-based prevalence studies of pediatric NAFLD. Elucidation of genetic factors that predispose an individual to NAFLD may lead to development of non-invasive biomarkers for the early diagnosis of NAFLD.

### Research frontiers

Uncoupling protein 3 (*UCP3*) is considered to be associated with obesity, given the role for *UCP3* in the regulation of energy and lipid metabolism. However, the effect of genetic polymorphisms in *UCP3* on the pathogenesis of NAFLD has not been clearly documented.

### Innovations and breakthroughs

Theoretically, many variations in candidate genes related to MetS may contribute to the pathogenesis of NAFLD. This is the first study to report that there significant difference of body height, waist and hip circumference between CC (mutant type group) and CT+TT group with and without rs1800849 variation were found.

### Applications

This study confirmed the hypothesis that polymorphisms of the *UCP3* are associated with the occurrence of NAFLD. These variations could be useful for the diagnosis and/or prognosis of NAFLD.

### Terminology

*UCP3* gene is located on chromosome 11q13. *UCP3* is a mitochondrial anion carrier protein with a highly selective expression in skeletal muscle, a major site of thermogenesis in humans, which makes an attractive target for studies into

the regulation of body weight.

## Peer review

The authors examined the polymorphisms of the *UCP3* gene associated with the occurrence of NAFLD. Higher rs11235972 GG genotype prevalence has been observed in the NAFLD group compared with the control group. There significant difference of body height, waist and hip circumference between CC (mutant type group) and CT+TT group with and without rs1800849 variation were found. This is an interesting manuscript about NAFLD in children and *UCP3* polymorphisms. The manuscript has adequate methodology and is good written.

### Abstract

**AIM:** To investigate the influence of chronic hepatitis B virus (HBV) infection [based on the status of hepatitis B e antigen (HBeAg), HBV DNA, and cirrhosis] on superimposed acute hepatitis E.

**METHODS:** A total of 294 patients were recruited from the Department of Infectious Diseases of the Third Affiliated Hospital, Sun Yat-sen University, from January 2003 to January 2012. The patients were classified into two groups: an HBV + hepatitis E virus (HEV) group (a group with chronic HBV infection that was superinfected with acute hepatitis E,  $n = 118$ ) and an HEV group (a group with acute hepatitis E,  $n = 176$ ). We retrospectively analyzed and compared the clinical features of the two groups. Statistical analyses were performed using the  $\chi^2$  test or Fisher's exact test for categorical variables and the Student's  $t$  test for

continuous variables. A  $P$  value  $< 0.05$  was considered statistically significant.

**RESULTS:** The peak values of prothrombin time, serum total bilirubin, and Model for End-Stage Liver Disease scores were significantly higher in the HBV + HEV group. More patients in the HBV + HEV group had complications (39.8% vs 16.5%,  $P = 0.000$ ) and developed liver failure (35.6% vs 8.5%,  $P = 0.000$ ). Additionally, the mortality of the HBV + HEV group was significantly higher (20.3% vs 7.4%,  $P = 0.002$ ). Further analysis of the HBV + HEV group showed that there were no significant differences in complication occurrence, liver failure incidence, or mortality between patients with different HBeAg and HBV DNA statuses. However, in patients with underlying cirrhosis, complication occurrence and liver failure incidence significantly increased. In total, 12.7% of the patients in the HBV + HEV group received anti-HBV treatment, but this therapy failed to reduce mortality in patients who developed liver failure.

**CONCLUSION:** The presence of underlying cirrhosis in chronic HBV infection results in more severe clinical outcomes with superimposed acute hepatitis E. Anti-HBV treatment cannot improve the prognosis of liver failure caused by HBV-HEV superinfection.

**Key words:** Chronic hepatitis B virus infection; Acute hepatitis E; Superinfection; Clinical profile; Anti-hepatitis B virus treatment

**Core tip:** Previous studies have shown that chronic hepatitis B virus (HBV) infection has a negative impact on superimposed acute hepatitis E. However, it remains unknown whether the disease severity of acute hepatitis E correlates with the underlying HBV replication status or with liver histological lesions. Our study

showed that the disease severity of acute hepatitis E correlated not with the HBV replication status (based on the status of hepatitis B e antigen and HBV DNA), but rather with the presence of underlying cirrhosis. This finding raised the question of whether anti-HBV treatment improves the outcome of liver failure caused by HBV-hepatitis E virus superinfection. We found that anti-HBV treatment could not improve the prognosis of such liver failure.

Influence of chronic HBV infection on superimposed acute hepatitis E. *World J Gastroenterol* 2013; 19(35): 5904-5909 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5904.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5904>

## INTRODUCTION

Infection by hepatitis B virus (HBV) is a serious public health problem worldwide. Two billion people worldwide have been infected with HBV, including more than 240 million cases of chronic infection<sup>[1,2]</sup>. During the chronic course of HBV infection, there is a chance that patients may be sporadically superinfected with other viruses, such as hepatitis E virus (HEV). HEV is mainly endemic in tropical and subtropical developing countries, including China. Studies of serum epidemiology in China showed that HEV superinfection in patients with chronic hepatitis B is present in 17.6% of these patients<sup>[3]</sup>.

HEV generally causes an acute, self-limiting illness, followed by a complete recovery. Recent studies have shown that HEV can result in severe disease in patients with underlying chronic HBV infection and even liver failure<sup>[4-7]</sup>. In the chronic course of HBV infection, there are different statuses of hepatitis B e antigen (HBeAg) and HBV DNA, and certain patients have a higher probability of developing cirrhosis. No previous studies are available regarding whether these different chronic statuses have different influences on the superinfection of HBV and HEV.

Liver failure related to HBV activation remains a rapidly progressive and frequently fatal condition. Traditional treatment is generally supportive. International HBV treatment guidelines recommend initiating nucleos(t)ide analogs as early as possible in this patient population<sup>[8,9]</sup>. Studies on the efficacy of nucleoside analogs have been emerging in recent years. Recent studies have shown that anti-HBV treatment could improve the outcome of this patient population<sup>[10-13]</sup>. Superinfection with HEV is another common cause of liver failure in patients with chronic HBV infection, accounting for 20% of cases in regions endemic for HEV<sup>[4]</sup>. Importantly, such liver failure caused by HBV and HEV results in high mortality rates. However, there are still no data on anti-HBV treatment for liver failure caused by the superinfection of HBV and HEV, as previous studies did not consider

patients with superinfection.

The aim of our study was to investigate the impact of chronic HBV infection on superimposed acute hepatitis E, particularly the influence of the status of HBeAg, HBV DNA, and cirrhosis on disease severity. Furthermore, we evaluated the effect of anti-HBV treatment on HBV-HEV superinfection. The use of a single liver function index is limited in assessing liver function, but the Model for End-Stage Liver Disease (MELD) score<sup>[14]</sup>, which combines multiple indices, can play a useful role in this assessment. The MELD score system has been used extensively for the allocation of donor livers worldwide<sup>[15]</sup> and has been validated for use in chronic hepatitis B (CHB)<sup>[16]</sup>. Thus, the MELD score was applied for a comprehensive analysis of liver function.

## MATERIALS AND METHODS

### Patients

This work was approved by the local ethics committee of our university. A total of 294 patients were recruited from the Department of Infectious Diseases of the Third Affiliated Hospital, Sun Yat-sen University, from January 2003 to January 2012. Among these patients, 118 were diagnosed with acute hepatitis E and chronic HBV superinfection (HBV + HEV group), and 176 patients were diagnosed with acute hepatitis E alone (HEV group). Acute hepatitis E was diagnosed when patients were hospitalized with typical symptoms of acute viral hepatitis and the presence of anti-HEV serum IgM and IgG. The presence of HBsAg and the absence of anti-HBc IgM established a diagnosis of chronic HBV infection. The diagnosis of liver failure was based on the Guidelines for Diagnosis of Liver Failure (2006)<sup>[17]</sup> and included the presence of two or more of the following: an international normalized ratio (INR)  $\geq 1.5$ , serum total bilirubin (TBil)  $> 10$  times the upper limit of normal, ascites, hepatic encephalopathy, decreased liver size, or hepatorenal syndrome. The complications that were observed were ascites, peritonitis, hepatic encephalopathy, gastrointestinal bleeding, and hepatorenal syndrome.

### Detection

Anti-HEV serum IgM and IgG were detected with an enzyme-linked immunosorbent assay (Genelabs Technologies, Singapore). HBsAg, HBsAb, HBeAg, HBeAb, and HBcAb were detected with an automatic rapid immunoassay system (AxSYM; Abbott, United States). HBV DNA levels were determined by real-time polymerase chain reactions using commercial diagnostic kits (Da-an GeneCo., Guangzhou, China) with a lower detection limit of 500 copies/mL. Liver function tests were performed using an automatic biochemical analyzer (AU 640; Olympus, Japan). In this study, prothrombin time (PT)-INR (PT/reference PT) = international sensitivity index. The PT was measured using the detection reagent STA-Neoplastine(r) CI PLUS with an automatic coagulometer (STA-R) (Diagnostica Stago, France). A diagnosis of underlying cirrhosis was made based on clinical,

**Table 1** Demographic and clinical characteristics of the hepatitis B virus + hepatitis E virus group and hepatitis E virus group

	HBV + HEV group ( <i>n</i> = 118)	HEV group ( <i>n</i> = 176)	<i>P</i> values
Age (yr)	44.5 ± 13.8	54.1 ± 15.8	0.000 <sup>1</sup>
Sex			0.000 <sup>1</sup>
Male	109 (92.4)	140 (79.5)	
Female	9 (7.6)	36 (20.5)	
ALT (U/L)	266.0 ± 227.3	262.9 ± 212.9	0.905
AST (U/L)	228.9 ± 207.1	228.4 ± 213.1	0.986
PT (s)	22.1 ± 11.3	16.8 ± 7.9	0.000 <sup>1</sup>
PTA (%)	57.3 ± 26.6	77.2 ± 24.9	0.000 <sup>1</sup>

Death	24 (20.3)	13 (7.4)	0.002 <sup>1</sup>

<sup>1</sup>Denotes significant *P* value. Data are expressed as absolute *n* (%) or mean ± SD. HBV: Hepatitis B virus; HEV: Hepatitis E virus; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; PT: Prothrombin time; PTA: Prothrombin activity; TBil: Serum total bilirubin; MELD: Model for End-Stage Liver Disease.

biochemical, and ultrasonographic findings. Sample collection, transportation, preservation, and processing were performed according to the manufacturer's instructions.

#### Calculation of MELD scores

MELD score =  $3.8 \times \log_e$  [serum bilirubin (μmol/L) × 0.058] +  $11.2 \times \log_e$  (PT-INR) +  $9.6 \times \log_e$  [serum Cr (μmol/L) × 0.011] + 6.4 × (0 or 1) (cholestatic or alcoholic cirrhosis: 0; other liver diseases: 1)<sup>[14]</sup>.

#### Statistical analysis

Statistical analyses were performed using SPSS 19.0 software (SPSS Inc., Chicago, United States). The  $\chi^2$  test or Fisher's exact test were used for categorical variables, and the Student's *t* test was used for continuous variables. Continuous variables are expressed as the mean ± SD, and categorical variables are expressed as the percentage (number). *P* values < 0.05 were considered statistically significant.

## RESULTS

### Demographic characteristics

The demographic characteristics of the 294 patients are shown in Table 1. The males outnumbered the females in both groups. The mean ages at admission were 44.5 and 54.1 years in the HBV + HEV and HEV groups, respectively.

### Laboratory findings

Liver function tests were performed at admission and regularly after admission. We compared the most severe laboratory abnormalities in the biochemical profile between the two groups (Table 1). The mean peak values of PT (22.1 *s* *vs* 16.8 *s*, *P* = 0.000) and TBil (334.7 μmol/L *vs* 277.5 μmol/L, *P* = 0.031), as well as the mean MELD

score (20.0 *vs* 15.1, *P* = 0.000), were significantly higher in the HBV + HEV group compared with the HEV group. In contrast, the mean values of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) did not differ significantly between the two groups.

### Clinical outcomes

As shown in Table 1, the incidences of complications, liver failure, and death were compared between the two groups with respect to clinical outcomes. Complications were noted in 39.8% (47/118) and 16.5% (29/176) of the patients in the HBV + HEV and HEV groups, respectively, and the occurrence of complications in the HBV + HEV group was significantly higher than that in the HEV group (*P* = 0.000). The incidence of liver failure was significantly higher among patients with superinfection than among patients with acute hepatitis E alone (35.6% *vs* 8.5%, *P* = 0.000). The mortality rates were also significantly different between the two groups (20.3% in the HBV + HEV group and 7.4% in the HEV group).

### Influence of chronic status of HBV infection on acute hepatitis E

To evaluate the influence of chronic HBV infection (based on the status of HBeAg, HBV DNA, and cirrhosis), we performed further analysis of the HBV + HEV group (Table 2). Of the 118 patients in the HBV + HEV group, 16.9% (20/118) were HBeAg-positive, 55.1% (65/118) were HBV DNA-positive, and 14.4% (17/118) had underlying cirrhosis. The occurrence of complications, liver failure, and death did not differ significantly between the HBeAg (+/-) and HBV DNA (+/-) subgroups. Patients with underlying cirrhosis had a significantly higher incidence of complications and liver failure. The mortality rate was 23.5% in the cirrhosis subgroup and 19.8% in the non-cirrhosis subgroup, which was not a significant difference.

### Anti-HBV treatment in the HBV + HEV group

Of the 118 patients in the HBV + HEV group, only 15 (12.7%) patients took oral anti-HBV agents. Three of these patients received lamivudine, and the other 12 patients received entecavir. In the HBV + HEV group, 42 patients developed liver failure, and 28.6% received anti-HBV treatment. Only 3.9% of patients without liver failure received anti-HBV treatment.

The mean mortality rates among the 42 patients with liver failure were 66.7% and 53.3% for patients who were and were not receiving anti-HBV treatment, respectively, which were not significantly different (Table 3).

## DISCUSSION

Due to the high prevalence of both HBV and HEV infection and the lack of cross-immunity between the two viruses, HBV-HEV superinfection is common<sup>[3,18]</sup>.

In our study, patients with acute hepatitis E superimposed on chronic HBV infection had higher peak laboratory abnormalities and poorer outcomes. There was also

**Table 2** Influence of chronic hepatitis B virus infection on acute hepatitis E *n* (%)

MELD score	33.2 ± 9.4	28.3 ± 9.2	0.129
Mortality	8 (66.7)	53.3 (16/30)	0.506

Data are expressed as absolute *n* (%) or mean ± SD. HBV: Hepatitis B virus; HEV: Hepatitis E virus; MELD: Model for End-Stage Liver Disease.

a higher prevalence of liver failure among those patients. The present study confirmed the previous finding that acute HEV infection can cause severe liver injury in patients with chronic HBV infection<sup>[4,7]</sup>. This result indicates that chronic HBV infection has a negative impact on the clinical features of acute hepatitis E. However, it remains unknown whether the disease severity of acute hepatitis E correlates with the underlying HBV replication status or liver histological lesions. Our further analysis of the superinfection group showed that the disease severity of superimposed acute hepatitis E correlated not with the HBV replication status (based on the status of HBeAg and HBV DNA), but rather with the presence of underlying liver histological lesions (liver cirrhosis).

It has long been suggested that patients with chronic HBV infection are immunologically different from people without HBV infection. For instance, patients with chronic HBV infection have been reported to have impaired cell-mediated immunity<sup>[19,22]</sup>, decreased peripheral-blood T cell numbers<sup>[23,24]</sup>, impaired interferon production<sup>[25,26]</sup>, and imbalanced cytokine levels<sup>[27,28]</sup> and may have other currently unrecognized differences. The severity of acute viral hepatitis has been suggested to be dependent on host immune factors rather than on the direct toxicity of the virus. Thus, with impaired and imbalanced immunity in chronic HBV infection, HEV may trigger an excessive immunological response and then induce severe damage in hepatocytes. Alternatively, hepatocyte impairment may accumulate during the chronic course of HBV infection. Thus, with preexisting liver lesions, especially due to cirrhosis, hepatocytes may be limited in their ability to regenerate. This limitation contributes to more severe liver injury in patients with acute hepatitis E superimposed on chronic HBV infection.

According to our data, most patients in the HBV + HEV group were HBeAg-negative, and nearly 50% were HBV DNA-negative. Further analysis showed that the disease severity of acute hepatitis E did not correlate with the status of HBeAg or HBV DNA. This finding indicates that in the superinfection of HBV and HEV, chronic HBV infection is inactive, and HEV is the main trigger factor for severe disease. Thus, the finding raises the question of whether anti-HBV treatment improves the outcome of HBV-HEV superinfection, which requires further investigation.

Acute exacerbation frequently occurs in the natural course of chronic HBV infection. In the case of acute exacerbation caused by spontaneous HBV activation, anti-HBV treatment can strongly suppress HBV replication, and most patients can recover. However, certain patients may develop liver failure, which is named HBV-related acute-on-chronic liver failure (HBV-ACLF). HBV-ACLF remains a rapidly progressive and frequently fatal condition for which mortality reaches 25% to 35%. International guidelines recommend initiating nucleos(t)ide analogs as early as possible in this patient population<sup>[8,9]</sup>. Recent studies have shown that anti-HBV treatment can improve the outcome of HBV-ACLF<sup>[10-13]</sup>. Superinfection with HEV is another common cause of liver failure in chronic HBV infection and is present in 20% of cases in regions endemic for HEV<sup>[4]</sup>. Importantly, such liver failure caused by HBV and HEV results in high rates of mortality. However, for the liver failure caused by the superinfection of HBV and HEV, there are still no data on anti-HBV treatment. In our study, we evaluated the results of anti-HBV treatment administration to the HBV + HEV group. Of the 76 patients without liver failure, only 3.9% took anti-HBV drugs, but the prognosis of this patient population was good. This finding indicates that it is not necessary to administer anti-HBV treatment as soon as possible to patients with HBV-HEV superinfection in mild disease. The necessity of anti-HBV treatment for HBV infection should be re-evaluated by monitoring the HBV DNA level and liver function tests after recovery from acute hepatitis E.

As shown by our data, up to 28.6% of patients received anti-HBV treatment once superinfection caused liver failure. The mortality rate among patients receiving anti-HBV treatment was 66.7%, which was not significantly different from the mortality rate of patients not receiving anti-HBV treatment. Thus, anti-HBV treatment

was unable to improve the outcome of the liver failure caused by HBV-HEV superinfection. As mentioned previously, HEV infection plays the most important role in the disease. The infection triggers strong immunological injury in hepatocytes, which results in liver failure. Anti-HBV treatment can inhibit HBV replication but cannot stop the strong immune activity, so the therapy cannot improve the outcome of this patient population.

In conclusion, our study indicates that acute hepatitis E is associated with more severe disease in patients with chronic HBV infection and that disease severity correlates with the underlying cirrhosis in chronic HBV infection. Anti-HBV treatment cannot improve the prognosis of liver failure caused by HBV-HEV superinfection. As HBV vaccination is being aggressively pursued worldwide, HEV vaccination should also be considered in endemic areas when a vaccine becomes available<sup>[29]</sup>. Additionally, preventive measures are important to the related morbidity and mortality, such as the consumption of boiled water and well-cooked food.

The main limitation of the present study is its retrospective nature. HEV-RNA levels were not regularly checked, so we are not convinced that there is no substantial contribution of HEV load to the disease severity of HBV-HEV superinfection. Additionally, underlying cirrhosis was mainly assessed by ultrasonography. Thus, it is possible that early-stage underlying cirrhosis was missed. Despite these limitations, our study is significant because the work provides preliminary support for not administering anti-HBV treatment in HBV-HEV superinfection, as chronic HBV replication status (based on the status of HBeAg and HBV DNA) does not determine the outcome of HBV-HEV superinfection.

## COMMENTS

### Background

Hepatitis B virus (HBV)-hepatitis E virus (HEV) superinfection is common. Recent studies have shown that HEV can result in severe disease in patients with underlying chronic HBV infection and even liver failure. However, whether the disease severity of acute hepatitis E correlates with the underlying HBV replication status (based on the status of HBeAg and HBV DNA) or liver histological lesions and whether anti-HBV treatment can improve the outcome of HBV-HEV superinfection are unknown.

### Research frontiers

The present study investigated the influence of chronic HBV infection (based on the status of HBeAg, HBV DNA, and cirrhosis) on superimposed acute hepatitis E. Furthermore, the study evaluated the effect of anti-HBV treatment on HBV + HEV superinfection.

### Innovations and breakthroughs

The disease severity of superimposed acute hepatitis E correlated not with the HBV replication status (based on the status of HBeAg and HBV DNA), but rather with the presence of underlying cirrhosis. Anti-HBV treatment did not improve the prognosis of liver failure caused by HBV-HEV superinfection.

### Peer review

This study is of great interest and offers useful implications for the treatment of HBV-HEV superinfection.

### Abstract

**AIM:** To evaluate the efficacy and safety of paclitaxel-nedaplatin combination as a front-line regimen in Chinese patients with metastatic esophageal squamous cell carcinoma (ESCC).

**METHODS:** A two-center, open-label, single-arm phase II study was designed. Thirty-nine patients were enrolled and included in the intention-to-treat analysis of efficacy and adverse events. Patients received 175 mg/m<sup>2</sup> of paclitaxel over a 3 h infusion on 1 d, followed by nedaplatin 80 mg/m<sup>2</sup> in a 1 h infusion on 2 d every 3 wk until the documented disease progression, unac-

ceptable toxicity or patient's refusal.

**RESULTS:** Of the 36 patients assessable for efficacy, there were 2 patients (5.1%) with complete response and 16 patients (41.0%) with partial response, giving an overall response rate of 46.1%. The median progression-free survival and median overall survival for all patients were 7.1 mo (95%CI: 4.6-9.7) and 12.4 mo (95%CI: 9.5-15.3), respectively. Toxicities were moderate and manageable. Grade 3/4 toxicities included neutropenia (15.4%), nausea (10.3%), anemia (7.7%), thrombocytopenia (5.1%), vomiting (5.1%) and neutropenia fever (2.6%).

**CONCLUSION:** The combination of paclitaxel and nedaplatin is active and well tolerated as a first-line therapy for patients with metastatic ESCC.

**Key words:** Esophageal squamous cell cancer; Front-line chemotherapy; Paclitaxel; Nedaplatin

**Core tip:** Esophageal cancers are among the most aggressive tumors with a poor prognosis. Till now, there has been no standard chemotherapy regimen for advanced esophageal cancer. In this paper, we conducted a phase II study on combination chemotherapy consisting of paclitaxel and nedaplatin in previously untreated patients with metastatic esophageal squamous cell carcinoma (ESCC). Our results demonstrated that the combination of two drugs is active and well tolerated as a first-line therapy for patients with recurrent or metastatic ESCC.

as front-line chemotherapy in Chinese patients with metastatic esophageal squamous cell carcinoma. *World J Gastroenterol* 2013; 19(35): 5910-5916 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i35/5910.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5910>

## INTRODUCTION

China accounts for about half of the world's esophageal cancer cases, about 250000 each year, and 85% of the total global incidence occurs in the developing world, according to the World Health Organization report. Overt and incurable metastatic disease is present at diagnosis in 50% of patients. Furthermore, even after curative surgery, local recurrences and/or distant metastases are detected in more than 50% of the patients within 5 years of follow-up<sup>[1]</sup>. The median survival of patients with metastatic esophageal carcinoma is only 3-8 mo<sup>[2]</sup>. Palliative chemotherapy may lead to distant tumor and symptom control. The effect of chemotherapy on survival is unclear for lack of large randomized trials. Up till now there has been no global standard regimen for the first-line treatment of advanced disease. Of the available regimens, the regimen containing 5-fluorouracil (5-FU) and cisplatin is widely used in China, with RR ranging from 15%-45%<sup>[3-5]</sup>. However, treatment with 5-FU and cisplatin can induce severe toxicity<sup>[6]</sup>. What's more, almost all patients have to be hospitalized for this treatment. Therefore, it is imperative to develop effective and well-tolerated chemotherapeutic agents for treatment.

Recently, paclitaxel, a natural product isolated from the bark of the yew tree *Taxus brevifolia*, has demonstrated some promising responses against digestive tract cancer. As a single agent, paclitaxel has been reported to achieve a response rate of 32% in esophageal cancer and gastroesophageal junction cancer<sup>[7]</sup>. Besides, several phase I / II studies have shown that paclitaxel-based regimens have significant activity in patients with locally advanced and metastatic esophageal cancer<sup>[8-12]</sup>. However, toxicity for combination therapy was significant and included severe myelosuppression, gastrointestinal (GI) and neurologic toxicity, and a significant rate of hospitalization for treatment-related complications. So it is urgent to seek new combination treatments that could achieve similar outcome and induce relatively minimal toxicities.

Nedaplatin cis-diammine-glycolate platinum (NDP) is a new platinum derivative, selected from a series of platinum analogues based on its pronounced preclinical antitumor activity against various solid tumors with lower nephrotoxicity<sup>[13]</sup>. Preclinical studies indicate that nedaplatin has an antitumor activity comparable to cisplatin<sup>[14-16]</sup> and has been shown experimentally to overcome cisplatin resistance in a cisplatin-resistant K562 cell line<sup>[14]</sup>. Clinically, single agent nedaplatin has shown a wide spectrum of antitumor activity, producing the favorable response rates in head and neck<sup>[17]</sup>, esophagus<sup>[18]</sup>, non-small cell lung<sup>[19,20]</sup>, and cervical cancers<sup>[21]</sup>. These reports prompted us to use

a new combination of nedaplatin and paclitaxel for patients with metastatic esophageal carcinoma, because these patients have poorer tolerance, and a less toxic treatment is desirable. The current phase II study was conducted to evaluate the efficacy and safety of nedaplatin-paclitaxel combination as a front-line regimen in Chinese patients with metastatic esophageal squamous cell carcinoma.

## MATERIALS AND METHODS

### Study design

This was a two-center, open-label, single-arm phase II study evaluating the efficacy and toxicities of nedaplatin and paclitaxel in patients with metastatic esophageal squamous cell carcinoma who had no previous treatment. The primary end point was response to treatment. Secondary end points were toxicity, progression-free survival (PFS) and overall survival (OS).

### Eligibility criteria

Patients aged 18-75 years with measurable target lesion pathologically confirmed advanced or metastatic esophageal squamous cell carcinoma were eligible for the study. Prior chemotherapy for advanced disease was not permitted. However, neoadjuvant or concurrent chemotherapy was allowed, provided that the treatment was completed at least 6 mo before the start of the current study. Patients were required to have Eastern Cooperative Oncology Group (ECOG) performance status of 0-2, with a life expectancy  $\geq 3$  mo, an adequate bone marrow, liver and kidney function, as indicated by an absolute neutrophil count (ANC)  $\geq 1500/\mu\text{L}$ , a platelet count  $\geq 100000/\mu\text{L}$ , serum creatinine  $\leq 2.0$  mg/dL, serum bilirubin  $\leq 1.5$  mg/dL, and serum alanine aminotransferase  $\leq 2.5$  times higher than the upper limit of the normal (except in those cases with liver involvement when a value  $\leq 5$  times the upper limit of the normal was accepted). All patients were given written informed consents to participate in this study, which was also approved by the Ethics Committee of two centers.

### Exclusion criteria

Patients with evidence of central nervous system metastases, an inability to take oral medication were excluded. Gastroesophageal junction tumors were excluded from the study. Exclusion criteria also included pathologically confirmed adenocarcinoma, prior malignancies (other than non-melanoma skin cancer or *in situ* cervical cancer) within the previous 5 years, and uncontrolled infection or severe comorbidity such as myocardial infarction within 6 mo or symptomatic heart diseases. Pregnant or lactating women were excluded from the study; women with childbearing potential were required to agree to have adequate contraception.

### Study treatment

Patients received 175 mg/m<sup>2</sup> of paclitaxel over a 3 h infusion on 1 d, followed by nedaplatin 80 mg/m<sup>2</sup> in a 1 h

infusion on 2 d every 3 wk until the documented disease progression, unacceptable toxicity or patient's refusal. These doses were based on a phase I trial of chemotherapy using paclitaxel and nedaplatin in chemotherapy-naïve patients with unresectable squamous cell carcinoma (SCC)<sup>[22]</sup>. Paclitaxel infusions preceded the administration of nedaplatin in the current study, as the interaction of nedaplatin and paclitaxel is highly schedule-dependent<sup>[23,24]</sup>. As prophylactic agents, dexamethasone (*iv* 20 mg), promethazine (*iv* 25 mg) and cimetidine (*iv* 400 mg) were given 30 min before paclitaxel administration. All patients received adequate antiemetic therapy prior to chemotherapy. Granulocyte colony-stimulating factor was administered at physician's discretion.

### Response of treatment and adverse effects

All patients were screened for medical history and underwent a physical examination. Complete blood cell count (CBC) was performed every week, blood biochemical test and electrocardiogram were performed before every cycle. After every two cycles of treatment, response was evaluated by two independent experts using RECIST criteria. Of the lesions observed prior to treatment, a maximum of five measurable lesions from each metastasized organ up to a total of 10 lesions were selected as target lesions. In the cases of partial response (PR) or complete response (CR), a confirmative computed tomography (CT) scan was performed 4 wk later and this was followed by a CT scan after every two treatment cycles. After discontinuation of treatment, follow-up visits were done every 3 mo to document late toxic effects, disease progression and survival. Toxicity was reported using an NCI-CTC version 3.0 toxicity scale.

### Dose modification

The dose of paclitaxel was reduced to 150 mg/m<sup>2</sup> if one of the following conditions occurred: grade 3 neutropenia with infection, grade 4 neutropenia, grade 3 thrombocytopenia or > grade 3 sensory neurotoxicity. If toxicity persisted, a second dose reduction of paclitaxel to 135 mg/m<sup>2</sup> was allowed. In cases of fatigue or asthenia above grade 3, treatment was postponed for 1 wk and restarted when the patient recovered to below grade 2. Patients requiring a delay in therapy for > 2 wk or more than two dose reductions were removed from the study. A new cycle of therapy could begin if the neutrophils count were  $1.5 \times 10^9/L$ , the platelets count were  $75 \times 10^9/L$ , and all relevant nonhematological toxicities were grade 2. Once a dose had been reduced during a treatment cycle, re-escalation was not permitted during any other subsequent cycles.

### Statistical analysis

A Simon's two stage phase II design was used. The treatment program was designed to reject response rates of 20% and to provide a significance level of 0.05 with a statistical power of 80% to assess the activity of the regimen at a 40% response rate<sup>[25]</sup>. The upper limit for a first-stage treatment rejection was 4 responses among 18 evaluable patients; the upper limit of second-stage rejection was 10

responses among 33 evaluable patients. Assuming a dropout rate of 20%, a total of 39 patients were required. All enrolled patients were included in the intention-to-treat (ITT) analysis of efficacy. Analysis of PFS and overall survival analysis were performed by the Kaplan-Meier method. The PFS was calculated from the initiation of chemotherapy to the date of the disease progression, while overall survival was measured from the initiation of chemotherapy to the date of the last follow-up or death. Statistical data were obtained using an SPSS 11.0 software package (SPSS Inc., Chicago, IL, United States).

## RESULTS

### Patients' characteristics

Between June 2008 and July 2010, a total of 39 patients from 2 centers (Including Anhui Provincial Hospital affiliated to Anhui Medical University and Anhui Provincial Cancer Hospital) were enrolled. Their baseline characteristics are shown in Table 1.

### Efficacy and survival

A total of 39 patients were assessable for response (Table 2). Two patients were not evaluated because of loss to follow-up after two courses, and 1 patient withdrew consent because of toxicities after 1 course. Two patients (5.1%) achieved a CR, 16 patients (41.0%) had PR, 15 patients (38.5%) had SD and 3 patients had PD (7.7%). The median follow-up period was 13.1 mo (range 3.3-28.6 mo). The median PFS for all patients was 7.1 mo (95%CI: 4.6-9.7, Figure 1A). The median OS was 12.4 mo (95%CI: 9.5-15.3, Figure 1B), with a 1-year survival rate of 53.8%.

### Adverse events

A total of 141 courses of treatment were given and patients received a median 4 courses (range, 1-6 courses). AE frequencies in this population are listed in Table 3. The most common haematologic AE was leucopenia, which occurred with grade 3/4 in 6 patients (15.4%). Febrile neutropenia was observed in 1 patient (2.6%). Although this case was successfully treated with antibiotics and G-CSF, this patient withdrew his consent after this experience. Grade 3/4 anemia was observed in 3 patients (7.7%) and grade 3 thrombocytopenia in 2 patients (5.1%). Major nonhematologic AEs (in order of decreasing frequency) were nausea (59.0%), fatigue (56.4%), vomiting (46.2%), myalgia (43.6%), alopecia (30.8%), and diarrhea (15.4%). Grade 3/4 nausea vomiting was observed in 4 patients (10.3%) and in 2 patients (5.1%). Hepatic and renal toxicities were mild. No treatment-related death occurred during this study.

## DISCUSSION

Esophageal cancer has two main pathological forms: squamous cell carcinoma (ESCC) and adenocarcinoma. Because cardiac adenocarcinoma has been usually classified as gastric cancer, primary esophageal adenocarci-

noma represents only < 1% of esophageal cancer patients in China<sup>[26]</sup>. In view of most cases being ESCC, we focused on this type of esophageal cancer in our study. Recurrent or metastatic ESCC remains incurable disease. Systematic combined chemotherapy has been part of combined modality therapy as a palliative treatment for this patient population.

However, there is no standard chemotherapy regimen for advanced esophageal cancer, various kinds of chemotherapy regimens have been tried to prolong survival and improve quality of life. The most commonly used regimen as the first-line chemotherapy is the combination of cisplatin (100 mg/m<sup>2</sup> per day) and 5-FU (1000 mg/m<sup>2</sup> per day continuous infusion for 96-120 h) in metastatic esophageal cancer<sup>[27]</sup>. The randomized phase II study comparing cisplatin/5-FU to cisplatin alone in advanced squamous cell esophageal cancer demonstrated that the combination arm was superior to cisplatin alone arm in terms of RR (35% *vs* 19%, respectively), and OS (33 wk *vs* 28 wk, respectively)<sup>[6]</sup>. However, high rate of treatment-related deaths (16%) was not acceptable. What's more, continuous infusion of 5-FU requires an indwelling venous access, which provides a source for venous thrombosis and sepsis and makes therapy burdensome to the patient. Until recently, newer agents such as taxanes (paclitaxel and docetaxel), vinorelbine, irinotecan, capecitabine, oxaliplatin and nedaplatin have been investigated as single agent or in combination in neoadjuvant or palliative settings<sup>[28]</sup>.

In the current study, the overall RR was 46.2% (50.0% for 36 valuable patients), the disease control rate was

**Table 2** Tumor response (intention-to-treat analysis) *n* (%)

Response	<i>n</i> = 39

Progressive disease	3 (7.7)
Not assessable	3 (7.7)

84.6% with a median TTP of 7.1 mo and a median OS of 12.4 mo. This study shows that this regimen has encouraging antitumor activity. Recently, several phase II studies were published of paclitaxel and platinum based regimens for advanced or metastatic esophageal cancer<sup>[5,8,9,11,12]</sup>. Gong *et al*<sup>[5]</sup> reported that the overall RR was 43.6% and the median progression-free survival (PFS) and OS was 6 and 10 mo, respectively, in a phase II study with metastatic esophageal cancer treated with the same combination regimen. Polee *et al*<sup>[11]</sup> reported that paclitaxel and cisplatin induced a relative longer median PFS of 8 mo, but the median time of OS was only 9 mo. The highest median OS (13 mo) was reported with 7 mo of median TTP by Zhang *et al*<sup>[12]</sup>. The results of our study can be consistent with those of these published studies.

In consideration of the performance status and chemotherapy tolerance of cancer patients in metastatic setting, treatment related toxicities should be strictly limited. In the present study, the most common grade 3/4 toxicities were leucopenia (15.4%), nausea (10.3%) and anemia (7.7%), thrombocytopenia (5.1%), vomiting (5.1%), respectively. Only one patient with febrile neutropenia was discontinued from the study, who was successfully treated with antibiotics and G-CSF. There was no treatment-related death during this study. The toxicities of nedaplatin and paclitaxel regimen were similar with the paclitaxel based regimen reported by Zhang *et al*<sup>[12]</sup> and Ilson *et al*<sup>[10]</sup>, and more minimal than other studies which applied gemcitabine plus cisplatin, paclitaxel plus carboplatin, nedaplatin plus docetaxel, or irinotecan plus cisplatin/cisplatin-5-FU<sup>[9,29-33]</sup>. The combination of nedaplatin and paclitaxel was deemed safe in patients with metastatic esophageal carcinoma in spite of the observed toxicity.

So far, some drugs have been applied for advanced esophageal carcinoma, such as capecitabine and oxaliplatin. More recently, a randomized phase III trial evaluated capecitabine and oxaliplatin as alternatives to infused 5-FU and cisplatin, respectively, for untreated advanced esophagogastric carcinoma<sup>[34]</sup>. The more active regimens including epirubicin, oxaliplatin and capecitabine achieved the median PFS of 7 mo and median OS of 11.2 mo, while the relative higher treatment-related toxicities were reported. Of note, all the patients in that study were pathologically confirmed adenocarcinoma. So, the standard chemotherapy for advanced or metastatic ESCC still needs more clinical trials.

In conclusion, the results from our phase II study demonstrated that the combination of nedaplatin and

**Table 3 Adverse events assessment n (%)**

paclitaxel is active and well tolerated as a first-line therapy for patients with recurrent or metastatic ESCC. It provides recurrent or metastatic ESCC patients with an effective, safe and convenient chemotherapeutic strategy.

### ACKNOWLEDGMENTS

The authors are grateful to all the patients and all the staff at the study centers who contributed to this study.

### COMMENTS

#### Background

Esophageal cancers are among the most aggressive tumors with a poor prognosis. Till now, there has been no standard chemotherapy regimen for advanced esophageal cancer. In this paper, the author conducted a phase II study on combination chemotherapy consisting of paclitaxel and nedaplatin in previously untreated patients with metastatic esophageal squamous cell carcinoma (ESCC).

#### Research frontiers

The most commonly used regimen as the first-line chemotherapy is the combi-

nation of cisplatin (100 mg/m<sup>2</sup> per day) and 5-fluorouracil (1000 mg/m<sup>2</sup> per day continuous infusion for 96-120 h) in metastatic esophageal cancer. However, high rate of treatment-related deaths (16%) was not acceptable. So, new regimens were explored to improve the efficacy and safety in metastatic ESCC.

#### Innovations and breakthroughs

The results demonstrated that the combination of nedaplatin and paclitaxel is active and well tolerated as a first-line therapy for patients with recurrent or metastatic ESCC. It provides recurrent or metastatic ESCC patients with an effective, safe and convenient chemotherapeutic strategy.

#### Applications

The combination of paclitaxel and nedaplatin is active and well tolerated as a first-line therapy for patients with metastatic ESCC.

#### Terminology

Paclitaxel, a natural product isolated from the bark of the yew tree *Taxus brevifolia*, has demonstrated some promising responses against digestive tract cancer. And nedaplatin is a new platinum derivative, selected from a series of platinum analogues based on its pronounced preclinical antitumor activity against various solid tumors with lower nephrotoxicity.

#### Peer review

This is a good clinical study in which the authors evaluated the efficacy and safety of paclitaxel-nedaplatin combination as a front-line regimen in Chinese patients with metastatic ESCC. The results are interesting and suggest that the combination of the above two drugs is active and well tolerated as a first-line

therapy for patients with metastatic ESCC.

### Abstract

**AIM:** To evaluate the association between 25-hydroxyvitamin D [25(OH)D] and sustained virological response (SVR) in hepatitis C virus (HCV) infected individuals.

**METHODS:** Relevant studies were identified by systematically searching MEDLINE databases up to March 2012 and abstracts of the European and American Congress of Hepatology conducted in 2011. Studies must provide information on SVR and the levels of 25(OH)D<sub>3</sub> and/or 25(OH)D<sub>2</sub> [henceforth referred to as 25(OH)D] in sera samples from HCV infected individuals. The inclusion criteria were: clinical studies that included HCV infected patients aged older than 18 years regardless of HCV genotype or ethnic group; provided information on SVR rates; and were reported in the English language

as full papers. Due to the heterogeneity of studies in categorizing serum vitamin D levels, a cut-off value of 30 ng/mL of serum 25(OH)D was used. Heterogeneity was assessed using  $I^2$  statistics. The summary odds ratios with their corresponding 95%CI were calculated based on a random-effects model.

**RESULTS:** Overall, 11 studies (8 observational and 3 interventional) involving 1575 individuals were included and 1117 HCV infected individuals (71%) showed low vitamin D levels. Most of the studies included mono-infected HCV individuals with the mean age ranging from 38 to 56 years. Four studies were conducted in human immunodeficiency virus/HCV infected individuals. Regarding vitamin D measurement, most of the studies employed radioimmunoassays ( $n = 5$ ) followed by chemiluminescence ( $n = 4$ ) and just one study employed high performance/pressure liquid chromatography (HPLC). Basal vitamin D levels varied from 17 to 43 ng/mL in the studies selected, and most of the HCV infected individuals had genotype 1 (1068/1575) with mean viral load varying from log 4.5-5.9 UI/mL. With regard to HCV treatment, most of the studies ( $n = 8$ ) included HCV individuals without previous treatment, where the pooled SVR rate was 46.4%. High rates of SVR were observed in HCV individuals with vitamin D levels above 30 ng/mL (OR = 1.57; 95%CI: 1.12-2.2) and those supplemented with vitamin D (OR = 4.59; 95%CI: 1.67-12.63) regardless of genotype.

**CONCLUSION:** Our results demonstrated high prevalence of vitamin D deficiency and high SVR in individuals with higher serum vitamin D levels or receiving vitamin D supplementation.

© 2013 Baishideng. All rights reserved.

**Key words:** Vitamin D; Hepatitis C; Therapy; Meta-analysis; Sustained virological response

**Core tip:** High vitamin D levels (above 30 ng/mL) or

supplementation are associated with sustained virological response in hepatitis C virus infected individuals.

Villar LM, Del Campo JA, Ranchal I, Lampe E, Romero-Gomez M. Association between vitamin D and hepatitis C virus infection: A meta-analysis. *World J Gastroenterol* 2013; 19(35): 5917-5924 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5917.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5917>

## INTRODUCTION

Viral hepatitis C is a serious public health problem worldwide infecting more than 130 million individuals<sup>[1]</sup>. Treatment of hepatitis C virus (HCV) infection is usually carried out using pegylated interferon (PEG-IFN) and ribavirin (RBV) for 24 wk for HCV genotypes 2 or 3, or 48 wk for HCV genotype 1 and the main objective of HCV therapy is a sustained virologic response (SVR), defined as an undetectable serum HCV-RNA level at 24 wk after the end of therapy. Rates of SVR range from 60%-70% in chronic hepatitis C (CHC) patients with genotypes 2 and 3, but is less than 50% in patients with genotype 1 using conventional therapy<sup>[2]</sup>.

Recently, studies were conducted to analyze the influence of genetic and metabolic factors in antiviral response<sup>[3-5]</sup>, and a recent review showed that vitamin D levels can influence HCV treatment<sup>[6]</sup>. Vitamin D itself is considered biologically inactive and is hydroxylated to 25-hydroxyvitamin D [25(OH)D] in the liver. 25(OH)D is the main circulating vitamin D metabolite and is used for classification of the vitamin D status<sup>[7,8]</sup>. In the kidney, 25(OH)D is converted to 1,25-dihydroxyvitamin D [1,25(OH)D] by 1-alpha-hydroxylase, however, it has been demonstrated that this conversion can occur in many extra-renal tissues including the liver<sup>[7,9]</sup>. Finally, 25(OH)D or 1,25(OH)<sub>2</sub>D bind to the ubiquitously expressed vitamin D receptor (VDR), which regulates approximately 3% of the human genome<sup>[10]</sup>. In this context, vitamin D deficiency has been associated with an increased risk of cancer<sup>[7,11]</sup>, cardiovascular<sup>[12,13]</sup>, autoimmune<sup>[14,15]</sup> and infectious diseases<sup>[6,16]</sup>.

Due to these facts, there is great research interest in the role of vitamin D status in various infectious diseases. Some studies have shown that high levels of serum vitamin D level are an independent predictor of SVR following anti-viral therapy, and higher SVR is achieved with vitamin D supplementation in CHC individuals<sup>[17-22]</sup>. However, Lange *et al*<sup>[18]</sup> found that vitamin D deficiency was associated with a lower SVR rate only in CHC genotype 2/3 patients (treated with PEG-IFN and RBV for 24 wk), but not in CHC genotype 1 patients. Moreover, Jazwinski *et al*<sup>[23]</sup> found no association between vitamin D levels and SVR in 82 African American genotype 1 CHC-naïve patients, treated with PEG-IFN and RBV.

As vitamin D has an uncertain clinical value in HCV

infected individuals and taking into consideration the limitations of previous reviews, we conducted an updated systematic review and meta-analysis to comprehensively assess vitamin D deficiency regarding antiviral therapy and the influence of vitamin D supplementation on SVR.

## MATERIALS AND METHODS

### Identification of studies

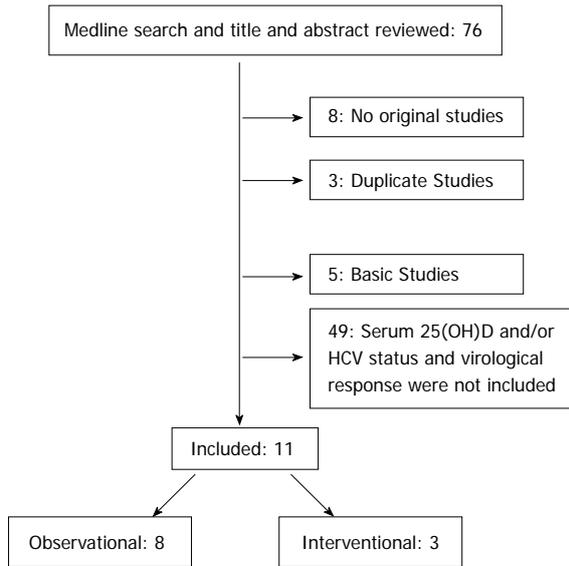

A broad search string was used in MEDLINE in order to identify relevant studies (all languages, all available years, search last completed 31.03.12) using the following search terms: [{"vitamin D"} [MeSH Terms] or {"vitamin D"} [All Fields] or {"ergocalciferols"} [MeSH Terms] or {"ergocalciferols"} [All Fields] or {"calcifediol"} [MeSH Terms] or {"calcifediol"} [All Fields] or {"calcidiol"} [All Fields] or {"25(OH)D"} [All Fields] or {"25(OH)D<sub>2</sub>"} [All Fields] or {"25(OH)D<sub>3</sub>"} [All Fields] and [{"HCV"} [MeSH Terms] or {"HCV"} [All Fields] or {"Hepacivirus"} [All Fields] or {"Hepacivirus"} [MeSH Terms]]. Abstracts from the European and American Association Congress of Hepatology (EASL 2011 and AASLD 2011) were also included in order to give more data on this theme.

Potentially relevant papers were accessed in order to review the abstract and/or full text. Only fully published articles were considered. Duplicate publications were deleted. Two researchers independently performed the literature search and data abstraction with regard to the inclusion and exclusion criteria by reading titles and abstracts. When reading titles and abstracts did not allow identification of eligible studies, articles were read in full. Only original studies conducted in humans were considered for the review. Thus, reviews and letters to the editor were excluded in the analysis, but read in full to identify potential relevant original studies. Disagreements between the two observers were resolved by discussion.

The following data were extracted: year of publication, number of patients, age, vitamin D levels, SVR percentage, method of measurement of vitamin D, HCV genotype, HCV viral load, percentage of naïve patients. When such data were not explicitly reported, they were derived from data provided in the articles or requested from the authors through personal contacts, wherever possible.

### Eligibility criteria

The study must provide information on SVR against HCV and the levels of 25(OH)D<sub>3</sub> and/or 25(OH)D<sub>2</sub> [henceforth referred to as 25(OH)D] in sera samples from HCV infected individuals. The inclusion criteria were: clinical studies that included HCV infected patients aged older than 18 years regardless of HCV genotype or ethnic group; provided information on SVR rates; and were reported in the English language as full papers. Studies were excluded if they met the following criteria: they did not provide information on 25(OH)D level, HCV status and/or SVR; basic studies; letters / case reports, or articles not reporting outcomes of interest or

**Figure 1** Prisma flowchart for the selection of publications for the systematic review and meta-analysis. HCV: Hepatitis C virus; 25(OH)D: 25-hydroxyvitamin D.

primary data (editorials, reviews).

### Statistical analysis

Data were extracted from each paper and compiled for hypovitaminosis D and HCV antiviral response. Statistical analysis was performed using the Meta-Disc software 1.4<sup>[24]</sup>, considering: (1) a summary of data from individual studies; (2) an investigation of the homogeneity of the studies both graphically and statistically; (3) calculation of clustered indices; and (4) exploration of heterogeneity. The meta-analysis was performed using the random-effect model by the Der Simonian and Laird method. Heterogeneity was tested for each planned analysis using the Cochran-Q heterogeneity test and measured using  $\chi^2$  and  $I^2$  tests, and statistical significance was considered to be present when  $P < 0.05$ .

## RESULTS

### Description of studies included in the meta-analysis

A flow diagram of the search process is shown in Figure 1. The total search yielded 61 articles and 15 abstracts, after accessing the title and abstract, 65 studies were excluded for the following reasons: 49 did not provide data on vitamin D level, HCV status and/or SVR; 5 were basic studies; 8 were reviews, letters or editorials; 3 were duplicate studies.

Eleven studies involving 1575 individuals were included in this study<sup>[17,18,20-23,25-29]</sup>. The main characteristics of these studies are shown in Tables 1 and 2. Most of the studies were conducted in Europe and only one in North America. Eight studies evaluated vitamin D levels before and after antiviral therapy<sup>[17,18,21-23,25,28,29]</sup>, while three were interventional studies where vitamin D supplementation was conducted<sup>[20,26,27]</sup>. Most of the studies included mono-infected HCV individuals with the mean age rang-

ing from 38 to 56 years. Four studies were conducted in human immunodeficiency virus/HCV infected individuals<sup>[22,25,28,29]</sup>. With regard to vitamin D measurement, most of the studies employed radioimmunoassays ( $n = 5$ ) followed by chemiluminescence ( $n = 4$ ) and just one study employed HPLC. Basal vitamin D levels varied from 17 to 43 ng/mL in the studies selected, and most of the HCV infected individuals had genotype 1 (1068/1575) with mean viral load ranging from log 4.5-5.9 UI/mL. With regard to HCV treatment, most of the studies ( $n = 8$ ) included HCV individuals without previous treatment, where the pooled SVR rate was 46.4%.

### Vitamin D levels and sustained virological response

Different cut-off values for vitamin D were employed and in order to reduce this heterogeneity, a value of 30 ng/mL was used as the cut-off value, as most of the studies used this value to define vitamin D. Among the observational studies, a total of 1411 individuals were included. Using 30 ng/mL as cut-off value, the  $\chi^2$  test of heterogeneity was high ( $P = 0.3799$ ). There was a significant difference regarding vitamin D levels and SVR, where individuals with values higher than 30 ng/mL had a higher level of SVR. Using the random effects model by the Der Simonian and Laird method, the odds ratio was 1.57 (95%CI: 1.12-2.2) regardless of genotype (Figure 2).

A total of 1117 HCV infected individuals had low vitamin D levels (cut-off value of 30 ng/mL) representing 71% of the population studied, and most of these individuals were in the interventional studies (79.3%) as compared with the observational studies (69.9%). The highest association between vitamin D levels and SVR was observed in the study by Petta *et al.*<sup>[17]</sup> as demonstrated by the OR and CI (OR = 1.96; 95%CI: 1.02-3.79).

### Vitamin D supplementation and sustained virological response

With regard to vitamin D supplementation in HCV infected individuals in the interventional studies, the pooled estimation from 3 different studies indicated that SVR rates were higher in treated HCV individuals compared with non-treated HCV individuals. In the meta-analysis of SVR in the interventional studies where the cut-off value was 30 ng/mL, the OR was 4.59 (95%CI: 1.67-12.63) regardless of genotype (Figure 3). The test of heterogeneity (Cochran-Q = 2.86;  $df = 2$ ;  $P = 0.2395$ ), inconsistency  $I^2 = 30\%$ , and  $t = 0.2454$ . Of these studies, the OR values were higher in the study where only genotype 1 HCV individuals were included<sup>[27]</sup> (8.68) compared to the other 2 studies, one study included genotypes 1 and non-1<sup>[20]</sup> (1.90) and the other study recruited genotype 2 and 3 HCV infected individuals (5.78)<sup>[26]</sup>.

### Quality of the studies

Low heterogeneity was observed in the studies included in this meta-analysis according to the  $Q$  value for the observational (7.49) and interventional studies (2.86). The possible sources of heterogeneity across the studies were

NA: Not available as mean value; HCV: Hepatitis C virus; HIV: Human immunodeficiency virus; HPLC: High performance/pressure liquid chromatography; 25(OH)D: 25-hydroxyvitamin D.

also explored using meta-regression analysis with the following co-variables as predictor variables: HCV genotype (1 and non-1); previous treatment (yes or no); Origin (Europe or America); method of vitamin D determination (HPLC, chemiluminescence or radiomunoassay). None of these variables interfered with the levels of vitamin D according SVR (data not shown). It is likely that this occurred because most of the studies were from Europe, including HCV genotype I individuals without previous treatment.

Although low heterogeneity was found, it was not possible to ensure high quality of all studies included in this meta-analysis. Some studies did not provide relevant data such as, mean age of the population included<sup>[23,28]</sup>, mean basal vitamin D measurement<sup>[20,23,28]</sup>, or mean HCV viral load<sup>[23,26-28]</sup>.

## DISCUSSION

Our review and meta-analysis summarize the results of eleven studies, which included a total of 1575 cases with hepatitis C, where basal 25(OH)D levels and 25(OH)D supplementation were associated with SVR in HCV patients. This updated review confirms and extends earlier results of a systematic review conducted by Cholangitis<sup>[6]</sup>, who reported that vitamin D deficiency is very frequent before liver transplantation and ranges between 51% and

92%, whereas, in the liver transplantation setting, the prevalence of vitamin D deficiency is also high.

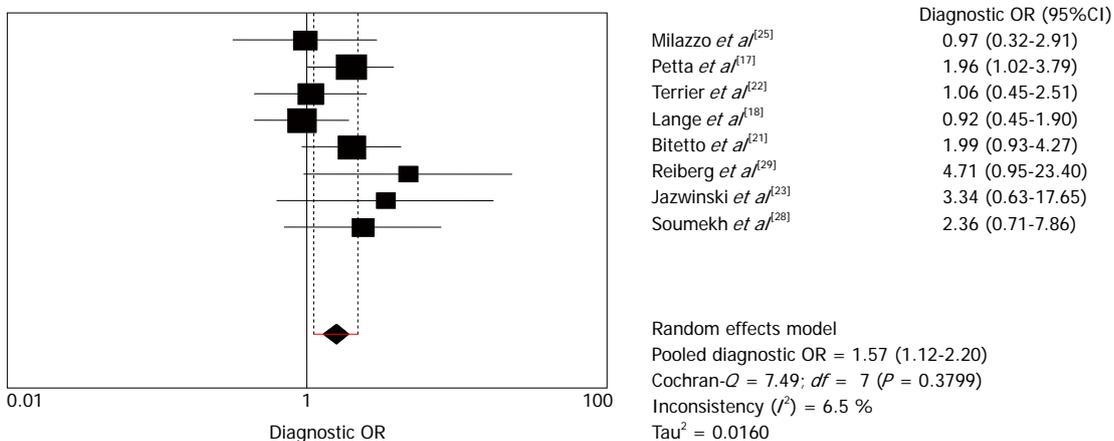

Vitamin D is metabolized by the liver and converted to 1,25-dihydroxyvitamin D<sub>3</sub>, which is the active form of the vitamin<sup>[29,30]</sup>. Individuals with chronic liver disease may have poor conversion from vitamin D<sub>3</sub> or any of its other biologically active metabolites<sup>[31]</sup>. Severe liver disease may increase the risk of vitamin D deficiency and/or there might be a relationship between vitamin D deficiency and fibrosis. Putz-Bankuti *et al*<sup>[32]</sup> and Baur *et al*<sup>[33]</sup> also showed that low levels of 25(OH)D are associated with fibrosis and suggested that low 25(OH)D levels may predict hepatic decompensation and mortality in patients with chronic liver failure. More recently, Gal-Tanamy *et al*<sup>[34]</sup> showed that vitamin D<sub>3</sub> increased the expression of the VDR and inhibited viral replication in cell culture.

Due to the observation of vitamin D deficiency in chronic liver disease patients, some studies have been conducted to evaluate vitamin D supplementation in these patients<sup>[20,26,27]</sup>. In some of these studies, it is reported that higher sunlight exposure or vitamin D supplementation should be recommended in patients with CHC<sup>[20,26,27]</sup>. In the present meta-analysis, vitamin D supplementation was related to higher SVR rates in HCV infected individuals, where the highest level was observed among genotype 1 HCV infected individuals. Although only a few studies regarding vitamin D supplementation

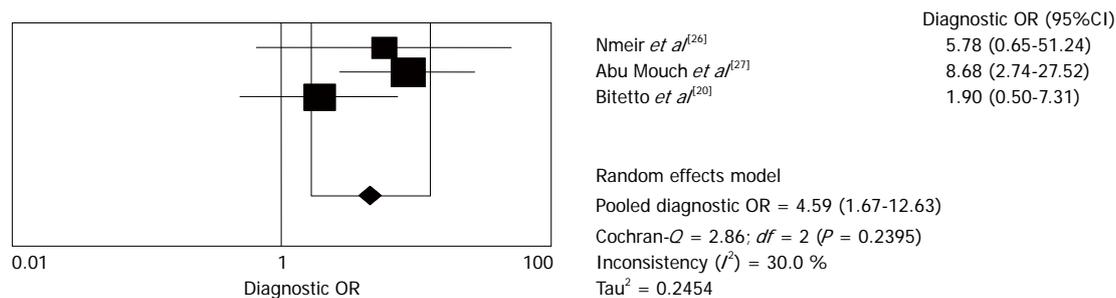

**Figure 2 Meta-analysis of 8 observational studies regarding vitamin D levels and sustained virological response against hepatitis C virus infection.**

fulfilled the eligibility criteria, different patterns were observed. The first study included only genotypes 2 and 3, the second included only genotype 1 and the third study involved genotypes 1, 2 and 3. Moreover, two of these studies were prospective and one was retrospective. Some limitations of these studies included the small number of patients, lack of vitamin D level assessment during therapy in the treatment and control groups, the design of prospective and randomized studies which were not placebo-controlled in one study<sup>[27]</sup>, and the retrospective

design of the study where immunocompromised HCV patients were supplemented with low-dose vitamin D (800 IU/d) after liver transplantation and most of the HCV patients (75%) had low vitamin D levels despite treatment<sup>[20]</sup>.

In this meta-analysis, the levels of vitamin D were also associated with SVR, although different methods of vitamin D determination were used. Lai *et al*<sup>[8]</sup> demonstrated bias and variability in 25(OH)D measurements between laboratories and between different assays [qui-

**Figure 3** Meta-analysis of 3 interventional studies regarding vitamin D levels and sustained virological response against hepatitis C virus infection.

mioluminescence and liquid chromatography-tandem mass spectrometry (LC-MS/MS)] which can significantly affect clinical decision-making. In this situation, the adoption of common standards to allow assay calibration is urgently required.

Our study is the first meta-analysis of serum 25(OH)D levels and HCV infection in observational and interventional studies. Given the very small numbers of studies available to date, additional studies, ideally from different countries and populations are needed to assess potential differences in the associations between 25(OH)D and SVR for HCV. Large differences can be observed in different populations, depending on exposure to sunlight or vitamin D supplementation, and genetic differences<sup>[23]</sup>. Moreover, patients of African and Hispanic descent are less likely to respond to standard therapy<sup>[23]</sup> probably due to polymorphisms of the interleukin (IL)-28B gene, polymorphism of the VDR or vitamin D deficiency<sup>[17,35,36]</sup>. In this meta-analysis, all the individuals were Caucasian and most lived in Europe, which could explain vitamin D deficiency in this population resulting from possible low exposure to sunlight.

Meta-analysis is an important tool for revealing trends that may not be apparent in a single study. Pooling of independent, but similar studies increases precision and therefore the confidence level of the findings. A particular strength of our study is the application of advanced statistical techniques which allowed a summary of adjusted associations across studies and over the entire range of serum 25(OH)D values, despite the very heterogeneous categorization of 25(OH)D levels in the individual studies. Our study also has important limitations. First, as data on serum 25(OH)D in individuals were not available in each study, median, midpoints and mean of the groups were used for pooling. As a result, estimates of risk may have been less accurate than if data points on each individual had been used. Second, our meta-analysis was limited by the data provided in the individual studies, and although the authors tried to obtain the raw data from the articles, not all were available. Finally, although our review searched the MEDLINE database, recent Congress of Hepatology and Gastroenterology articles, and extensive checks for completeness by cross-referencing were employed, we cannot exclude the possibility that relevant studies may have been missed.

Despite its limitations, our review and meta-analysis

support previous suggestions and provide the most comprehensive empirical evidence to date that basal serum 25(OH)D levels and vitamin D supplementation improves SVR in HCV infected individuals. However, available data are still sparse and in-depth analyses of these associations, in the context of additional longitudinal and prospective studies, are highly desirable to enable more precise estimates and a better understanding of the role of vitamin D in HCV infection.

## ACKNOWLEDGMENTS

The authors would like to thank Christian Lange, Raymond T Chung, Assy Nimer, Andrea Branch, Eric Trépo, Mattias Mandorferk, Kian Bichoupan, Markus Peck, Alison Jazwinski, Laura Milazzo, and Salvatore Petta who kindly answered questions regarding their manuscripts in order to provide more information for this meta-analysis.

## COMMENTS

### Background

Hepatitis C virus (HCV) is a serious public health problem worldwide infecting more than 130 million individuals. Recently, studies have been conducted to analyze the influence of genetic and metabolic factors on antiviral response, and a recent review showed that vitamin D levels can influence HCV treatment.

### Research frontiers

Vitamin D itself is considered biologically inactive and is hydroxylated to 25-hydroxyvitamin D [25(OH)D] in the liver. Some studies have suggested that vitamin D deficiency is associated with an increased risk of cancer, cardiovascular, autoimmune and infectious diseases. However, due to the limitations of previous reviews, the authors conducted an updated systematic review and meta-analysis to comprehensively assess vitamin D deficiency with regard to antiviral therapy and the influence of vitamin D supplementation on sustained virological response.

### Innovations and breakthroughs

Previous individual studies demonstrated that high levels of vitamin D (above 30 ng/mL) or supplementation are associated to sustained virological response (SVR) in HCV infected individuals. In the present study, a meta-analysis of observational and interventional studies was conducted which proved that high levels of vitamin D (above 30 ng/mL) or supplementation are associated with SVR in HCV infected individuals.

### Applications

By showing that basal vitamin D levels or supplementation are important for high rates of SVR in HCV patients, this study may provide a future strategy for therapeutic intervention in the treatment of HCV patients.

### Terminology

HCV is an infection caused by a virus transmitted by the parenteral route. Vitamin D itself is considered biologically inactive and is hydroxylated to 25(OH)D in the liver. In the kidney, 25(OH)D is converted to 1,25(OH)<sub>2</sub>D by 1-alpha-

hydroxylase, however, it has been demonstrated that this conversion can occur in many extra-renal tissues including the liver. Finally, 25(OH)D or 1,25(OH)<sub>2</sub>D bind to the ubiquitously expressed vitamin D receptor, which regulates approximately 3% of the human genome.

### Peer review

The authors examined the influence of vitamin D levels or supplementation among HCV infected individuals. It was observed that high levels of vitamin D or supplementation are strongly associated to SVR among HCV infected individuals. The results are interesting and may represent the role of metabolic factors in HCV infection.

### Abstract

Cholecystectomy is a common procedure. Abnormalities in the anatomy of the biliary system are common but an abnormal location of the gallbladder is much rarer. Despite frequent pre-operative imaging, the aberrant location of the gallbladder is commonly discovered at surgery. This article presents a case of a patient with the gallbladder located to the left of the falciform ligament in the absence of situs inversus totalis that presented with right upper quadrant pain. A laparoscopic cholecystectomy was performed and it was noted that the cystic duct originated from the right side. The presence of a left sided gall bladder is often associated with various biliary, portal venous and other anomalies that might lead to intra-operative injuries. The spectrum of unusual positions and anatomical gallbladder abnormalities is reviewed in order to facilitate elective and emergent cholecystectomy as well as other hepatobiliary procedures. With proper identification of the anatomy, minimally invasive approaches are still considered safe.

**Key words:** Left sided gallbladder; Laparoscopic chole-

cystectomy; Sinistroposition of the gallbladder; Situs inversus; Bile duct anomaly; Liver anomalies; Portal vein anomaly; Liver transplant

**Core tip:** In the absence of situs inversus, left sided gallbladders are rare anomalies. They are most commonly encountered during surgery as they usually present with right sided pain and routine preoperative testing fails to identify them. Various biliary, portal venous and other anomalies are associated with left sided gallbladders and their spectrum is reviewed in this article. Recognition of these associated anomalies will help achieve safety in hepatobiliary procedures and prevent injuries.

### INTRODUCTION

Located to the left side of the falciform ligament, left sided gallbladders are rare anomalies and a result of a distinct embryological process. They are seldom identified pre-operatively, and as they are associated with various biliary, portal venous, and other anomalies, the surgeon must be familiar with the potential variations that he might encounter. A left sided gallbladder was encountered during a laparoscopic cholecystectomy at our institution in a patient that presented with right sided abdominal pain. Careful dissection revealed that the cystic duct was crossing from the right side and that critical view was established with the identification of the cystic artery. The spectrum of the possible anomalies associated with left sided gallbladders is wide but does not preclude the successful performance of a minimally invasive cholecystectomy or any other hepatobiliary procedure.

## CASE REPORT

The patient is a 64-year-old female with multiple medical problems including type II diabetes mellitus, a history of deep venous thrombosis and pulmonary embolism, kidney stones and hypertension who presented to the hospital with a five day history of sharp, right-sided abdominal pain radiating to her epigastric area, chest, bilateral back, right flank and right shoulder. This was the first time patient experienced this kind of pain, and she denied history of prior cholecystitis. She had a history prior extracorporeal shockwave ureteral lithotripsy, but the admitting discomfort was different from that of prior renal colic. Three months prior to the admission, the patient had colonoscopy and esophagogastroduodenoscopy, which were normal.

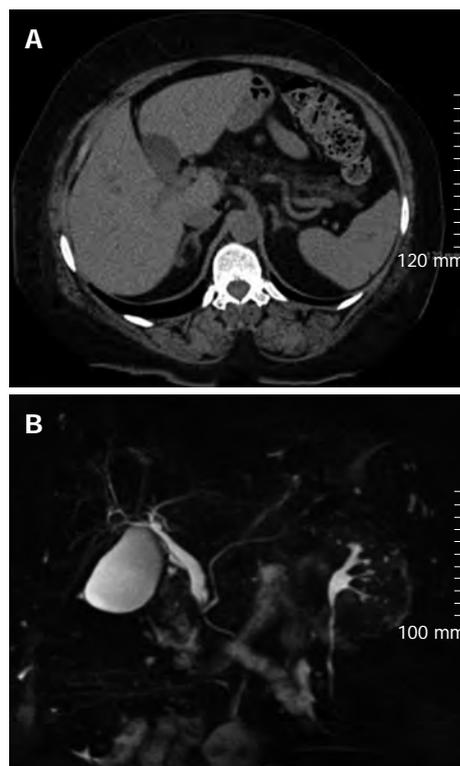

On physical examination she had stable vital signs and was afebrile. The abdomen was nondistended and nontender. Laboratory data on admission revealed a normal white cell count, normal total bilirubin, normal alkaline phosphatase, normal aspartate aminotransferase (AST) and normal alanine aminotransferase (ALT) amylase and lipase were not elevated. An abdominal ultrasound revealed gallbladder sludge with small calculi, no gallbladder wall thickening and no dilatation of the biliary tract. Computed tomography (CT) of the abdomen and pelvis showed gallstones without CT-evidence of cholecystitis, and biliary dilatation up to 9 mm. Secondary to the dilatation of the common bile duct (CBD) on the CT, magnetic resonance cholangiopancreatography (MRCP) was performed and demonstrated cholelithiasis without signs of choledocholithiasis.

During this admission, laparoscopic cholecystectomy was performed. Upon insertion of the camera into the umbilical port, the gallbladder was visualized and was located immediately to the left of the falciform ligament, and below segment III of the liver. The gallbladder wall was mildly edematous. The cystic duct and the cystic artery were identified, and it was observed that the artery was to the right of the duct. After the identification of the critical view of safety, the cystic artery and the cystic duct were clipped and divided in a standard fashion. The operation was completed without difficulties and the patient recovered and was discharged home on the second postoperative day. Pathological evaluation identified multiple small, less than 1 mm stones and the thickness of the gallbladder wall measured 3 mm, consistent with chronic cholecystitis and cholelithiasis.

The CT scan of the abdomen did not appear to demonstrate an abnormal location of the gallbladder (Figure 1A) but the finding of the gallbladder to the left of the falciform ligament was present on preoperative MRCP (Figure 1B).

## DISCUSSION

Left sided gallbladders without situs inversus are rare and have a prevalence of 0.04%-0.3%<sup>[1,2]</sup>. A distinction should be made between gallbladders that are truly left sided also

**Figure 1** Radiological images of the abdomen. A: Computed tomography scan without contrast demonstrating the gallbladder to the left of the falciform ligament; B: Magnetic resonance cholangiopancreatography showing a dilated common bile duct on coronal view.

referred to as sinistroposition and gallbladders located to the left of abnormally located right-sided round ligaments<sup>[3]</sup>. True left sided gallbladders exist because of two possible embryological etiologies. The first mechanism is due to the attachment and migration of the gallbladder to the left lobe in which case the cystic duct is in a normal anatomic position and crosses in front of the common duct from right to left, as is the case in the case reported herein<sup>[4]</sup>. The second mechanism is formation of the gallbladder by budding directly from the left side in which case the cystic duct joins the CBD or left hepatic duct from the left side<sup>[4,5]</sup>. Right-sided round ligaments on the other hand, are associated with a normal position and anatomy of the cystic duct, and with anomalous portal venous branching, which is crucial during the performance a hepatectomy, for example<sup>[3]</sup>.

Despite being truly left-sided, gallbladders with sinistroposition almost always cause right-sided symptoms when they become symptomatic making their preoperative diagnosis difficult<sup>[2]</sup>. It is believed that the visceral nerve fibers do not transpose with the gallbladder causing right-sided pain<sup>[6]</sup>. In the present case, the abnormal position of the gallbladder was only discovered at surgery, despite the patient having undergone preoperative ultrasound, CT, MRCP and endoscopic ultrasound, which is consistent with other case reports<sup>[2,3,7]</sup>. However, an intraoperative finding of a left sided gallbladder should not preclude the decision to proceed laparoscopically with minor modifications in the standard approach and port

placement. Donthi *et al*<sup>[8]</sup>, for example, placed their ports in a mirror image to a typical right-sided standard laparoscopic cholecystectomy, achieving adequate exposure and traction for dissection. Keeping in mind the possible anatomic variations associated with the condition along with careful dissection and the establishment of the critical view of safety, with or without intra-operative cystic duct cholangiography, will minimize complications. Ligation and division of the cystic duct and artery should be close to the gallbladder. The surgeon should make every effort to identify key anatomic landmarks as one would attempt to do during a standard cholecystectomy. Cases of single port cholecystectomy have even been reported in patients with situs inversus without adverse occurrences<sup>[9,10]</sup>. A more comprehensive literature review of patients with

left sided gallbladders without situs inversus undergoing surgery is summarized in Table 1.

In a conclusion, a left-sided gallbladder is an unusual anatomic variant. Patients commonly present with typical biliary colic and cholecystitis symptoms. The abnormal location might not be discovered until the start of the laparoscopic procedure. Proper anatomic identification of key landmarks will permit most or all of these procedures to be performed using minimally invasive techniques.

### Abstract

Minimal invasive techniques have allowed for major surgical advances. We report our initial experience of performing total laparoscopic left hepatectomy (segments II-IV) with the Lotus (laparoscopic operation by torsional ultrasound) Ultrasonic Scalpel. The perioperative and postoperative courses of the young female patient were uneventful and she is in a good general condition without complaints 18 mo after surgery. To the best of our knowledge, this is the first total laparoscopic hemihepatectomy to be performed in Greece, as well as the first laparoscopic liver resection using Lotus shears.

### INTRODUCTION

The development of minimally invasive hepatic resection techniques in the early 1990s established new surgical standards<sup>[1,2]</sup> and introduced highly innovative instruments such as ultrasonic dissectors, saline coagulation, and radiofrequency ablation<sup>[3-6]</sup>. We report our initial experience of performing a laparoscopic left hepatectomy with the ground-breaking Lotus (laparoscopic operation by torsional ultrasound) Ultrasonic Scalpel (S.R.A. Developments, Ashburton, Devon, United Kingdom).

### CASE REPORT

A 35-year-old asymptomatic woman with an unremarkable past medical history was referred to our department for surgical management of a liver lesion. The

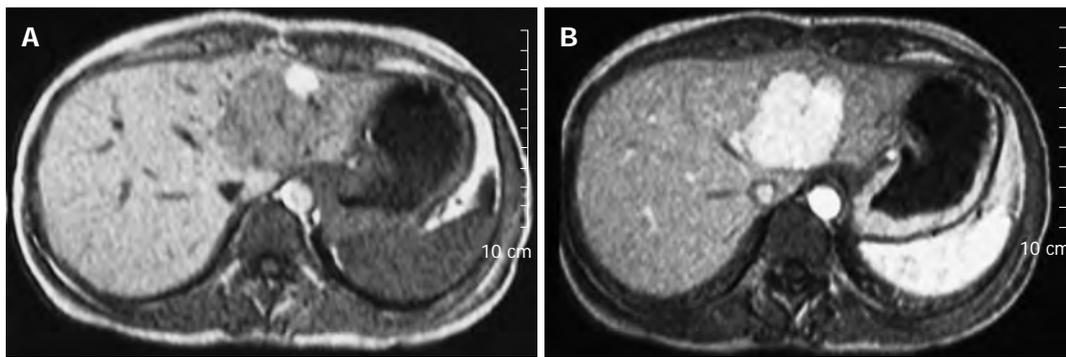

Figure 1 Magnetic resonance imaging showing the liver lesion in segments III/IV. Note the mass effect on the middle and left hepatic veins.

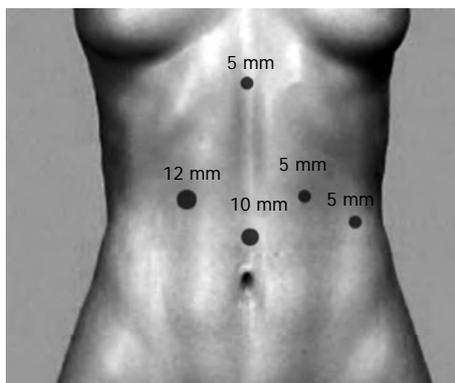

Figure 2 Patient positioning and trocar placement.

tumor had been diagnosed during work-up of elevated  $\gamma$ -glutamyltransferase (GT) (135 U/mL, normal laboratory range 7-36 U/mL) detected at premarital testing. Complete blood count, biochemical profile, liver function tests (except for  $\gamma$ GT), and tumor markers were within the normal range. There was no history of oral contraceptive use. Abdominal ultrasound showed a 5-cm isoechoic liver mass in the left hepatic lobe. Gadolinium-enhanced magnetic resonance imaging (MRI) demonstrated a 5.2-cm lesion in segments III/IV, with compression of the middle and left hepatic veins (Figure 1). A laparoscopic left hemihepatectomy was scheduled with a presumed diagnosis of liver adenoma.

### Surgical technique

With the patient in the supine position and under general anesthesia<sup>[7]</sup>, five trocar ports were placed as follows: an observation port (10 mm) 4 cm above the umbilicus; a main manipulation port (12 mm) in the midclavicular line below the right costal margin; a 5-mm port below the xiphoid process; and two 5-mm ports (for the assistant surgeon) in the left midclavicular and left anterior axillary lines, respectively (Figure 2). The operating surgeon stood between the patient's legs.

After the falciform and left triangular ligaments were transected, a replaced left hepatic artery branch was identified, clipped, and transected (Figure 3A and B). The left

branch of the portal vein was bluntly dissected (Figure 3C) and ligated with an Endopath ETS Articulating Linear Cutter (Ethicon Endo-Surgery, Blue Ash, OH, United States). The liver parenchyma was divided using the Lotus Ultrasonic Scalpel (Figure 3D and E). Non-absorbable clips were used to control the middle hepatic vein, large vessels, intrahepatic bile ducts, and the left hepatic duct. Once this had been achieved, the left hepatic vein was exposed, dissected, and divided with an Endopath ETS Articulating Linear Cutter (Ethicon Endo-Surgery) (Figure 3F). The resected specimen (segments II-IV) was removed *via* a 6-cm supraumbilical incision (Figure 4).

Total operating time was approximately 4 h. Estimated blood loss was < 400 mL. The patient had an uneventful hospital course and was discharged on post-operative day 6. Pathological evaluation of the specimen revealed focal nodular hyperplasia. The patient married 6 mo later and is currently in good health 18 mo after the procedure.

### DISCUSSION

Ultrasound-activated scalpels are safe and effective devices<sup>[8]</sup>. The Lotus Ultrasonic Scalpel introduced the concept of torsional rather than longitudinal ultrasound emissions to achieve transection and hemostasis. Its mechanism of action includes a vibratory grooved blade that generates compression forces directly into the target tissue, and a central blade that cuts as the Teflon jaw is closed. The components of the acoustic systems vibrate harmonically at 36.0 kHz. Laparoscopic torsional ultrasound shears have significant advantages over conventional cutting bipolar forceps when used to divide and coagulate pedicles in gynecological surgery. The Lotus shears are associated with shorter bisection times, less thermal damage, and more effective control of intraparenchymal blood vessels and bile ducts (a major limitation of previous devices).

To the best of our knowledge, this is the first total laparoscopic hemihepatectomy performed in Greece, as well as the first laparoscopic liver resection using Lotus shears. The effectiveness of the Lotus device further emphasizes the importance of surgical innovation in laparoscopic liver surgery.

### Abstract

Takayasu's arteritis (TA) and Crohn's disease (CD) are two rare autoimmune disorders; however some reports describe the presence of both diseases in the same patient. This finding has suggested the possibility that both diseases could share some common etiologic origin. We describe a case of a 13-year-old male affected by CD characterized by fever, diarrhea, weight loss, abdominal pain and elevation of inflammatory markers. Clinical and histological features from colonic specimens were consistent with CD. Treatment with steroids and azathioprine was started, however disease flared every time steroids were tapered. One year later, while still on treatment, he came back to our attention for dyspnea at rest and at night, tiredness and weakness. At physical examination a diastolic heart murmur was found as well as a left carotid artery bruit. A trans-thoracic echocardiography showed mild aortic valve insufficiency, left ventricular hypertrophy and a dilated ascending aorta with same findings at the aortic arch. A computed tomography scan showed abdominal aorta

thickening, dilated thoracic aorta and the presence of a thoracic aortic aneurysm. TA associated with CD was diagnosed and medical treatment with cyclophosphamide, steroids and aminosalicic acid was started, with good clinical response at 6 mo follow-up. We discuss the presence of possible common causes for the two diseases and the importance of differential diagnosis in those patients characterized for intractable disease.

**Key words:** Crohn's disease; Takayasu arteritis; Intractable inflammatory bowel disease; children; Treatment

**Core tip:** It is known that both Takayasu's arteritis (TA) and Crohn's disease (CD) can present together in the same patient although this association is considered extremely rare. We would like to underline the importance of considering an alternative diagnosis in those patients characterized by intractable diseases; in our case, in fact, an intractable CD masked TA and the patient did not achieve clinical remission until he was treated with major immunosuppressive therapy; a treatment which can not be considered a standard protocol for CD.

### INTRODUCTION

Takayasu's arteritis (TA) is a rare, chronic, relapsing large vessel vasculitis affecting the aorta and its major branches, and presenting manifestations include fatigue, weight loss, hypertension, headaches, strokes, and ischemic abdominal pain. Absence of peripheral pulses has given it the name "pulseless disease". Crohn's disease (CD)

is an idiopathic, chronic, relapsing transmural inflammation affecting primarily the gastrointestinal mucosa. The inflammatory process tends to be eccentric and segmental, often with skipped areas (normal regions of bowel between inflamed areas). Both diseases can be considered rare: in the United States, the reported incidence of pediatric CD is 4.56/100000 and the pediatric prevalence is 43/100000<sup>[1]</sup>, while the incidence of TA is almost 1 case per million. However there are some reports describing the presence of the two conditions in the same patient. It occurs usually during adulthood, while in children this association is extremely rare, but almost 1 in 10 patients with TA may develop CD or CD-like colitis.

Herein we describe the case of a child initially diagnosed as having CD who then presented with TA as well.

## CASE REPORT

A 13-year-old-boy presented with a 3 mo history of fever, diarrhea, weight loss and abdominal pain. Laboratory examination revealed elevation of inflammatory markers (erythrocyte sedimentation rate: 110 mm/h; C-reactive protein: 12.5 mg/dL) with microcytic anemia (Hb: 9.2 gr/dL; mean corpuscular volume 68 fl).

Abdominal ultrasound showed an increased terminal ileum wall thickness, while colonoscopy presented linear and aphthous ulcers with some areas of cobblestone mucosa. A biopsy showed the presence of basal plasmacytosis, an increase of lamina propria cellularity (round cells and neutrophils), basal lymphoid aggregates and epithelioid granuloma.

### *Clinical and histological features were consistent with CD*

Treatment with steroids and azathioprine was started, however disease flared every time steroids were tapered. One year later, while still on treatment, he came back to our attention for a clinical picture characterized by dyspnea at rest and at night, with extreme tiredness and weakness. At physical examination a diastolic heart murmur was found as well as a left carotid artery bruit. Transthoracic echocardiography showed mild aortic valve insufficiency, left ventricular hypertrophy and a dilated ascending aorta with same findings at the aortic arch. A computed tomography scan showed abdominal aorta thickening, a dilated thoracic aorta and the presence of a thoracic aortic aneurysm. TA associated with CD was diagnosed and medical treatment with cyclophosphamide, steroids and aminosalicic acid (ASA) was started with good clinical response at 6 mo follow-up.

## DISCUSSION

Although TA is a form of vasculitis that chiefly affects the aorta and its major branches, systemic features such as weight loss, fevers, and fatigue are found in 42%-83% of children at diagnosis of active TA<sup>[2]</sup>. At the same time musculoskeletal disease, including arthritis, arthralgia, and myalgia, is present in 12%-65% of children as well as skin manifestations, lymphadenopathy posterior reversible

encephalopathy syndrome, keratouveitis, bilateral ocular ischemic syndrome and relapsing polychondritis<sup>[2]</sup>.

TA-associated diseases also include pyoderma gangrenosum, ankylosing spondylitis, juvenile rheumatoid arthritis and inflammatory bowel disease<sup>[2]</sup>. TA in patients with CD was first described in 1970<sup>[3]</sup>, but co-existence of TA and CD has been reported in the following years<sup>[4]</sup> even if mostly in adulthood, while its presence in childhood is considered extremely rare. The expected prevalence of CD in patients with TA, if present by chance alone, is approximately 0.05%-0.2%. Thus it has been suggested that this unexpected association is more than just a coincidence<sup>[5]</sup>.

Although the pathogenesis of both diseases remains unclear some similarities have been found. Pro-inflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$ , are common in both and anti-TNF- $\alpha$  monoclonal antibody is an effective therapeutic agent for both TA and CD suggesting the presence of a common inflammatory pathway<sup>[6]</sup>. In addition, the presence of granulomatous vasculitis was found in 15 out of 25 patients affected by CD<sup>[6]</sup>; on the other hand the vasculitis of TA is characterized by granulomatous inflammation characterized by transmural inflammation of portions of the arterial wall (including the elastic laminae) and granulomas containing multinucleated histiocytic and foreign body giant cells, histiocytes, lymphocytes (which are predominantly CD4<sup>+</sup> T cells), and some plasma cells with fibroblasts<sup>[7]</sup>. Clinical details of 21 reported cases of TA associated with CD<sup>[5,8]</sup> showed that CD preceded TA in 13 reported cases as seen in the present patient. In these cases TA developed while being treated with corticosteroids, azathioprine and/or disease modifying drugs, such as 5-ASA, irrespective of the activity of CD and in one case also during infliximab treatment.

We present the interesting case of a patient affected by TA arising some months after CD. Although the exact mechanisms underlying the coexistence of the two diseases is not clear, it seems unlikely that coincidence could account for the simultaneous occurrence of these rare diseases, but the data are insufficient to allow for certainty. As explained above, it seems that a granulomatous inflammation may be considered a final method of development for many different conditions like TA and CD; however chronic granulomatous disease (CGD), Behcet disease or interleukin 17 deficiency may present with the same histological features. On this basis we could speculate that in these patients, inflammatory bowel disease could be considered an intestinal involvement of TA, rather than the coexistence of two different clinical conditions. Unfortunately there are no data on intestinal specimens in patients affected by TA and it is not clear if TA could be considered, in these cases, an extra-intestinal involvement of CD. In addition we would like to underline the importance of considering an alternative diagnosis in those patients affected by CD who do not respond to conventional treatment. In these cases, it is mandatory to rule out the presence of CGD, Behcet disease or TA.

**Key words:** Esophagus; Giant fibrovascular polyp; Esophageal polyp; Fibroepithelial polyps

**Core tip:** We report an unusual case of giant hypopharyngeal polyp in a patient with anemia by chronic oozing. Giant esophageal and hypopharyngeal polyps are benign tumors rarely encountered in clinical practice; in fact, there are approximately 250 cases reported in the literature. The interesting fact is the patient regurgitated the polyp during the extraction of the echoendoscope (photo), fortunately without experiencing respiratory distress. It is rare to diagnose these polyps and it is even rarer to perform emergency surgery due to the presence of a large, regurgitated polyp that occupies most of the oral cavity.

### Abstract

Giant esophageal and hypopharyngeal polyps are benign tumors rarely encountered in clinical practice. In most cases, they are completely asymptomatic; however, despite the rarity of these tumors, interest in giant esophageal polyps derives from their degree of growth (characterized by slow growth into the esophageal lumen) and their mobility. In fact, if regurgitation occurs, they can ascend into the oral cavity and be aspirated into the airways, with potentially lethal consequences. The removal of these giant polyps is recommended. An adequate preoperative evaluation to identify the correct origin of the stalk is mandatory for a successful endoscopic or surgical treatment. A 60-year-old man was admitted to our hospital for anemia. The patient underwent gastroscopy, contrast computed tomography and endoscopic ultrasound. At the conclusion of the procedure, during the extraction of the echoendoscope, the patient began retching and regurgitated the polyp, without experiencing respiratory distress. The patient underwent a left cervicotomy and polyp dissection *via* a pharyngotomy.

### INTRODUCTION

Giant esophageal and hypopharyngeal polyps are benign tumors rarely encountered in clinical practice; they represent approximately 0.03% of all esophageal/hypopharyngeal neoplasms<sup>[1]</sup>. The majority originate from the upper third of the esophagus, rarely from the hypopharynx, and extremely rarely from the oropharynx. They may vary greatly in size; however, they can extend along the entire length of the esophagus until reaching the gastric cavity. In most cases, they are completely asymptomatic; however, they rarely can cause anemia by chronic oozing. In addition, they can cause asphyxiation by regurgitation of the polyp into the oral cavity. The world literature contains about 110 cases of giant oropharyngeal or esopha-

geal polyps (> 5 cm); they are most often successfully treated by peroral, cervicotomic, or thoracotomy surgery; they also can be managed by endoscopy<sup>[2]</sup>.

## CASE REPORT

A 60-year-old man, with a negative medical history, was admitted to another hospital eight months ago for anemia and underwent colonoscopy (findings: negative), gastroscopy (findings: esophageal neoformation of the lower third of the esophagus), and computed tomography (CT) (findings: submucosal esophageal neoformation capturing contrast medium, extending from the cervical to the cardiac esophagus). After transfusion therapy, the patient refused any surgical treatment. He enjoyed good health until another episode of anemia occurred (hemoglobin 8.6 g/dL) and he presented at our facility. The patient underwent a gastroscopy (findings: esophageal stenosis for submucosal neoformation arising from the cervical esophagus, occupying approximately 50% of the esophageal lumen, with mucosal integrity, and protrusion of a neoformation with erosion of its apex into the gastric cavity). He also underwent a contrast CT (findings: bulky neoformation jutting into the esophageal lumen extending from the cervical to the distal esophagus with a maximum diameter of 35 mm × 46 mm, associated with increased esophageal diameter) (Figure 1). The patient then underwent an endoscopic ultrasound (EUS) (findings: thickening of the esophageal wall due to a solid, hypoechoic, neoformation, with hyperechoic areas and a vascular network, originating from the submucosa of the cervical esophagus, which affected the esophagus from cardiac portion to the upper esophageal sphincter) (Figure 2). At the conclusion of the procedure, during the extraction of the echoendoscope, the patient began retching and regurgitated the polyp, without experiencing respiratory distress (Figure 3). The patient was taken to the operating room and, under general anesthesia, a gastroscopy was repeated. It revealed that the origin of the polyp was not at the upper esophageal sphincter (UES), as previously diagnosed by CT, EUS, and the first gastroscopy; rather, it originated in the hypopharynx below the left arytenoid cartilage, with a stalk of about 3 cm in length. The patient underwent a left cervicotomy and polyp dissection *via* a pharyngotomy. The removal of the polyp was performed with a stapler (Endogia 45, Ethicon®). At the conclusion of the procedure, a dual lumen nasogastric tube was placed. On the seventh postoperative day the patient underwent a radiological evaluation with water-soluble contrast medium, which imaged good transit in the absence of extraluminal spillage. The patient began a semi-liquid diet and was discharged on the 10<sup>th</sup> postoperative day. A gastroscopic evaluation 45 d postoperatively was normal.

## DISCUSSION

Benign esophageal/hypopharyngeal tumors are rare and

Figure 1 Computed tomography (mediastinal window setting) shows bulky neoformation jutting into the esophageal lumen.

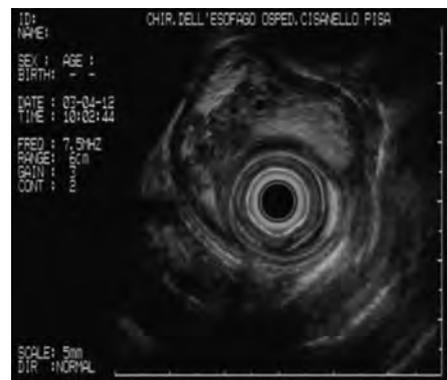

Figure 2 Endoscopic ultrasound shows a solid, hypoechoic, neoformation, with hyperechoic areas and a vascular network.

Figure 3 Giant, regurgitated hypopharyngeal polyp.

represent less than 1% of esophageal/hypopharyngeal neoplasms, *e.g.*, Moersch and Harrington<sup>[3]</sup> discovered 44 (0.59%) benign esophageal tumors in 7459 consecutive autopsies at the Mayo Clinic. Most of these tumors are intramural, represented by leiomyomas, neurofibromas, and hemangiomas; the intraluminal lesions are represented by fibrolipomas, fibromixomas, hamartomas, fibromas, and lipomas<sup>[4]</sup>. These tumors are globally ranked by the World Health Organization as fibrovascular polyps. Histologically, giant esophageal polyps are covered by

squamous epithelium with a fibrovascular axis, consisting of adipose and connective tissue to varying degrees, and a well-developed vascular network. Despite the rarity of these tumors, interest in giant esophageal polyps derives from their degree of growth (characterized by slow growth into the esophageal lumen) and their mobility. In fact, if regurgitation occurs, they can ascend into the oral cavity and be aspirated into the airways, with potentially lethal consequences. They are more frequent in males (male:female ratio = 3:1)<sup>[4]</sup>, and are usually diagnosed in the sixth or seventh decade of life; however, fibrovascular polyps have been reported in childhood<sup>[5]</sup>. About 85% are located in the upper third of the esophagus, close to the UES, and originate as small mucosal tumors, extending into the esophageal lumen due to the constant downward thrust by food ingestion and peristalsis. In the present case, the polyp was attached in an unusual site, at the level of the left anterolateral hypopharyngeal wall immediately below the ipsilateral arytenoid cartilage, with dimensions of 18 cm × 5.4 cm × 4 cm. Fibrovascular polyps usually occur as solitary lesions; however, some authors have reported synchronous polyps<sup>[6]</sup>. Due to progressive tumor growth, most patients report progressive dysphagia, initially with solid food and then with liquids. The second most frequent symptom is the regurgitation of the polyp into the hypopharynx or oral cavity with the risk of aspiration into the airways, resulting in asphyxia<sup>[7-10]</sup>. In a small percentage of patients, aspiration of the polyp may be the presenting symptom. Other symptoms include pharyngeal globus, weight loss, odynophagia, pharyngodynia, vomiting, abdominal pain, gastroesophageal reflux, hiccups, melena, and anemia<sup>[4,11]</sup>. The latter two symptoms are a result of ulceration of the apical part of the polyps due to gastric acidity or reflux of gastric contents into the esophagus. Malignant degeneration of these polyps is rare.

Fibrovascular polyps can be detected by either a barium esophagogram or gastroscopy. The former may reveal a dilated esophagus, with a gross intraluminal defect usually arising in proximity to the UES. However the examination may be entirely negative especially if the polyp remains in contact with the esophageal wall. The diagnosis, however, by gastroscopy, sometimes may be difficult or impossible because the fibrovascular polyp can completely or partially occupy the esophageal lumen, move against the esophageal wall and thus present a similar appearance to the mucosa. Diagnostic suspicion can be confirmed with a rear view, because if the terminal part of the polyp protrudes into the gastric cavity, it may image as a “clapper of a bell”; thus illustrating the circumferential space between the two walls. EUS may be useful for diagnosis because it clearly highlights the fibrovascular axis of the polyp, the echogenic aspect of adipose tissue, and the presence of anechoic areas due to its vascular network. Finally, this imaging procedure can help in a diagnosis *via* a needle aspiration. CT and magnetic resonance (MR) can be useful in confirming diagnostic suspicion and in deciding the proper surgical approach.

In particular, MR with axial coronal and sagittal scans, allows a precise identification of the stalk, an essential requirement for proper treatment. Despite a careful diagnostic process, fibrovascular polyps can be confused with intramural lesions; thus, identification of the stalk can be difficult and incorrect. In a review by Caceres *et al*<sup>[2]</sup>, 22% of barium esophagograms and 33% of gastroscopies yielded false negative results. Due to the potentially disastrous complications, removal of benign esophageal and hypopharyngeal polyps is strongly recommended. This can be achieved using a transoral, transcervical, transthoracic, or endoscopic approach, depending on the location and size of the polyp.

Two field approaches (abdominal and cervical) have also been described in patients with unusually large polyps<sup>[12]</sup>. It is clear that the correct diagnosis is essential to avoid unnecessary intervention and especially to choose the type of the intervention: surgical or endoscopic. For example, Oh *et al*<sup>[13]</sup> reported some difficulty in removing a cervical esophageal fibrovascular polyp through a right thoracotomy. Most polyps are surgically removed, especially those with a large, vascularized stalk; however, it has been performed endoscopically by dissection of the peduncle by ligature, electrocoagulation, or laser<sup>[14,15]</sup>. Generally, the removal of the polyp is curative and recurrence after resection is rare; however, some authors have reported a recurrence<sup>[16,17]</sup>.

In conclusion, giant esophageal polyps are extremely rare, benign tumors, whose removal is recommended because of the possibility of fatal consequences, bleeding and malignant transformation (rare). An adequate pre-operative evaluation to identify the correct origin of the stalk is mandatory for a successful endoscopic or surgical treatment. In addition to the removal of the giant polyp, all mucosal redundancy must be evaluated and possibly removed to avoid recurrences, which are rare but possible.

### Abstract

We report the case of a 17-year-old male admitted to our academic hospital with massive rectal bleeding. Since childhood he had reported recurrent gastrointestinal bleeding and had two exploratory laparotomies 5 and 2 years previously. An emergency abdominal computed tomography scan, gastroscopy and colonoscopy, performed after hemodynamic stabilization, were considered normal. High-dose intravenous proton pump inhibitor (PPI) therapy was initiated and bleeding stopped spontaneously. Two other massive rectal bleeds occurred 8 h after each cessation of PPI which led to a hemostatic laparotomy after negative gastroscopy and small bowel capsule endoscopy. This showed long tubular duplication of the right colon, with fresh blood in the duplicated colon. Obscure lower gastrointestinal bleeding is a difficult medical situation and potentially life-threatening. The presence of ulcerated ectopic gastric mucosa in the colonic duplication explains the partial efficacy of PPI therapy. Obscure gastrointestinal

bleeding responding to empiric anti-acid therapy should probably evoke the diagnosis of bleeding ectopic gastric mucosa such as Meckel's diverticulum or gastrointestinal duplication, and gastroenterologists should be aware of this potential medical situation.

**Key words:** Colonic duplication; Gastro-intestinal duplication; Gastrointestinal bleeding; Hemostatic colorectal surgery; Proton pump inhibitor therapy

**Core tip:** Obscure lower gastrointestinal bleeding is a difficult medical situation and potentially life threatening. The collaboration between endoscopists and radiologists usually allow location of the source of bleeding, but some rare situations, such as gastrointestinal malformations, need surgical intervention to diagnose and concomitantly treat an obscure bleeding source. In terms of medical therapy, only proton pump inhibitor therapy has efficacy in peptic ulcer disease. Obscure gastrointestinal bleeding responding to empiric anti-acid therapy should suggest the diagnosis of bleeding ectopic gastric mucosa such as Meckel's diverticulum or gastrointestinal duplication, and gastroenterologists should be aware of this potential medical situation.

### INTRODUCTION

Obscure lower gastrointestinal bleeding is a difficult medical situation which is potentially life-threatening. No

**Figure 1** Colonic duplication. A: Macroscopic analysis of the resected colonic duplication: colonic duplication with a pen showing the anastomosis with the right colon; B: Pathological analysis of the duplication: pathological analysis showing intestinal duplication with a smooth muscle coat and an ectopic gastric mucosal lining; C: Bleeding ulcer in the colonic duplication: macroscopic view of a large bleeding ulcer near the anastomosis between the duplicated and the right colon; D: Computed tomography scan coronal view of the colonic duplication: retrospective coronal reconstruction of the emergency computed tomography scan showing the duplicated right colon (arrow) which was not visible in the axial view.

medical therapy is currently available to manage these patients until endoscopic, radiologic or surgical therapy is performed after the identification of the bleeding lesion. Proton pump inhibitor (PPI) therapy is not recommended for bleeding lesions downstream of the angle of Treitz. We describe here the partial efficacy of PPI therapy in massive obscure gastrointestinal bleeding due to a bleeding ulcer in the ectopic gastric mucosa of an undiagnosed colonic duplication.

## CASE REPORT

A 17-year-old male was admitted to the emergency room of our academic hospital with massive rectal bleeding. He had reported recurrent gastrointestinal bleeding since childhood, which led to multiple hospitalizations. At 5 and 2 years before this admission he underwent exploratory laparotomies because of suspicion of a Meckel diverticulum. On admission, blood pressure was lowered to 80/55 mmHg, with a reflex tachycardia of 120 beats/min. The hemoglobin level was 5.7 g/dL. Initial resuscitation required significant volume replacement, and the transfusion of 3 blood units and 3 fresh bags of frozen plasma. High-dose intravenous PPI therapy at the dosage used in peptic ulcer bleeding (8 mg/h) was initiated.

An emergency abdominal computed tomography (CT) scan, performed after hemodynamic stabilization, was considered normal. A gastroscopy and an ileocolonosco-

py, with a water-jet device after preparation by an enema, were normal. Bleeding stopped spontaneously, and after a 24-h clinical and biological stabilization, we decided to stop the PPI therapy because of the absence of gastroduodenal ulcer disease.

Unfortunately, a further massive rectal bleed consisting of red fresh blood with melena, and hemodynamic instability occurred 8 h later. High dose intravenous PPI therapy was reintroduced and gastroscopy conducted by a French national expert in endoscopy was once again considered normal. Small bowel capsule endoscopy was then performed and his initial interpretation eliminated a bleeding lesion upstream of the angle of Treitz. PPI therapy was once again stopped and 8 h later a third massive rectal bleed occurred which led to selective mesenteric arteriography. This showed suspicious hypervascularization of the right colon. Hemostatic laparotomy was performed because of the patient's unstable condition and lack of a diagnosis. This showed long tubular duplication of the right colon, which was connected to the cecum at one end (Figure 1A), with fresh blood in the duplicated colon. Although anastomosis was not visible during the endoscopy, the capsule was seen inside the duplicated colon. Hemostatic right hemicolectomy with ileocolonic anastomosis was performed. Pathological analysis (Figure 1B) showed intestinal duplication, with intimate attachment to the mesentery, a smooth muscle coat and an ectopic gastric mucosal lining. A large ulcer with stigma of recent hem-

orrhage (Figure 1C) was present near the anastomosis. Retrospective analysis of the CT scan by a senior gastro-intestinal radiologist using coronal reconstruction agreed with our diagnosis as difficult and rare, but possible (Figure 1D, arrow). Two years after the surgery, the patient had no further gastrointestinal bleeding.

## DISCUSSION

Duplications of the gastrointestinal tract are rare congenital anomalies that can occur anywhere along its length<sup>[1,2]</sup>, and are characterized by attachment to at least one part of the tract, a layer of smooth muscle and epithelial lining resembling some part of the tract<sup>[3]</sup>. Colonic duplication is a rare abnormality, accounting for 4%-18% of all gastrointestinal duplications, and is usually located in the cecum. Tubular types are found in only 18% of cases and are most often encountered in the small and large bowel. Gastric mucosa is frequently observed in the wall of the duplications, irrespective of their site of origin in the alimentary tract<sup>[3]</sup>. Clinically, they can become a problem at any age, but the majority are discovered during the neonatal period or infancy<sup>[4,5]</sup>. They can manifest as abdominal masses<sup>[6]</sup>, bowel obstruction and gastrointestinal hemorrhage<sup>[7]</sup>. A diagnosis of intestinal duplication can be difficult and is usually performed intraoperatively.

This case highlights the diagnostic and therapeutic evaluation during massive gastrointestinal bleeding of unknown origin. First, despite all diagnostic tools available nowadays in a tertiary center, obscure gastrointestinal bleeding can sometimes be a diagnostic and therapeutic challenge. The growing efficacy of endoscopic devices (gastroscopy, colonoscopy with washing-pump, small bowel capsule endoscopy and enteroscopy) and radiologic procedures (high resolution CT scan, arteriography) tend to make the surgical procedure therapeutic only. This case highlights the unusual but still existing role of surgery in the diagnosis and treatment of massive gastrointestinal bleeds of unknown etiology<sup>[8]</sup> in challenging cases. Whereas such a role is common in cases of obscure bleeding during childhood, the usefulness of surgical exploration must not be ignored in adults. Gastrointestinal congenital malformations such as colonic duplication are a rare cause of obscure gastrointestinal bleeding. Coronal and sagittal reconstruction of CT scans can be very useful and must always be made in cases where there is an absence of diagnosis.

In terms of medical therapy, PPI therapy represents

the treatment of choice in non-portal hypertensive gastrointestinal bleeding of the upper gastrointestinal tract<sup>[9]</sup>. No drugs are approved nowadays for the management of lower gastrointestinal hemorrhage<sup>[8]</sup>. In this case, the discrepancy in the efficacy of PPI therapy and no sign of a gastroduodenal ulcer is explained by the pathology result. High dose PPI therapy probably acted on the bleeding ulcer existing in the ectopic gastric mucosa in the duplicated right colon. Rare cases have already been reported on the hemostatic efficacy of anti-acid therapy (H<sub>2</sub>-receptor antagonist or PPI) in bleeding Meckel's diverticula whose histological analysis reveals ectopic gastric mucosa in more than half of the cases<sup>[10]</sup>. Obscure gastrointestinal bleeding responding to empiric anti-acid therapy should probably suggest the diagnosis of bleeding ectopic gastric mucosa such as Meckel's diverticulum or gastrointestinal duplication.

**Key words:** Capsule endoscopy; Odometer; Localisation; Hardware; Software

**Core tip:** In order to improve localisation, capsule endoscopy developers proposed the use of an applied external magnetic field. However, this affords only a rough estimate of capsule - hence lesion - localization. Therefore, a modified capsule design was proposed in 2010. It consists of a capsule fitted with protruding wheels attached to a spring-mechanism. This allows the wheels to retract or expand to fit the lumen, whilst the capsule passes through the intestine, acting as a miniature odometer. Using three-dimensional printing technology, we built a conceptual capsule prototype and miniature wheels; with the latter, we perform *in vitro* and *ex vivo* proof-of-concept experiments.

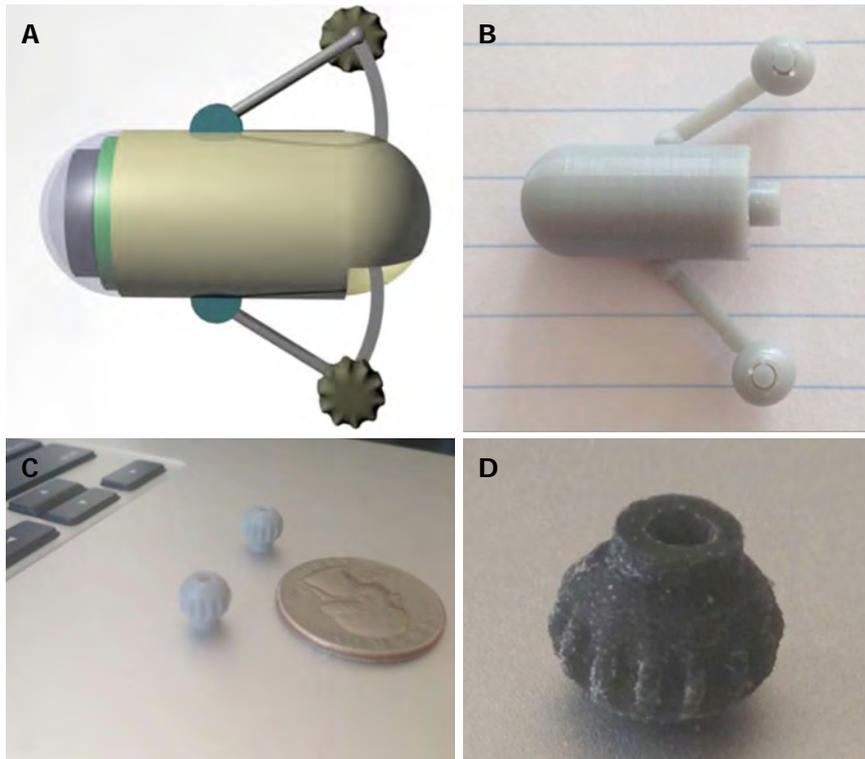

### Abstract

In order to improve lesion localisation in small-bowel capsule endoscopy, a modified capsule design has been proposed incorporating localisation and - in theory - stabilization capabilities. The proposed design consists of a capsule fitted with protruding wheels attached to a spring-mechanism. This would act as a miniature odometer, leading to more accurate lesion localization information in relation to the onset of the investigation (spring expansion *e.g.*, pyloric opening). Furthermore, this capsule could allow stabilization of the recorded video as any erratic, non-forward movement through the gut is minimised. Three-dimensional (3-D) printing technology was used to build a capsule prototype. Thereafter, miniature wheels were also 3-D printed and mounted on a spring which was attached to conventional capsule endoscopes for the purpose of this proof-

Karargyris A, Koulaouzidis A. Capsule-odometer: A concept to improve accurate lesion localisation. *World J Gastroenterol* 2013; 19(35): 5943-5946 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i35/5943.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i35.5943>

### TO THE EDITOR

Since its commercialization in the early 2000s, wireless capsule endoscopy (CE) has become a mainstream investigation for the small-bowel<sup>[1]</sup>. However, as with any technological advancement, there are performance limitations. In CE, the two main issues are low video resolution and reduced image capture rate<sup>[2]</sup>. Additionally, current systems offer somewhat crude localisation software - of

**Figure 1** Capsule odometer, conceptual design and its three-dimensional printing realisation. A: Conceptual design<sup>[10]</sup> of a capsule endoscope (herein called ODOcaps) with protruding wheels attached to a spring-mechanism; B: Three-dimensional printing technology used to build a capsule prototype; C: Wheels were initially produced with UV Curable Acrylic Plastic; D: Wheels later made of a synthetic resilient, textile-like material (TPU 92A-1).

questionable help - in mapping the imaged small-bowel. To address these issues, “smarter” CE designs have been proposed using enhanced digital circuits<sup>[2]</sup> with more efficient antennae<sup>[2-7]</sup>, and on-board video-compression<sup>[8]</sup> to conserve battery energy and increase video resolution and image capture frame rate.

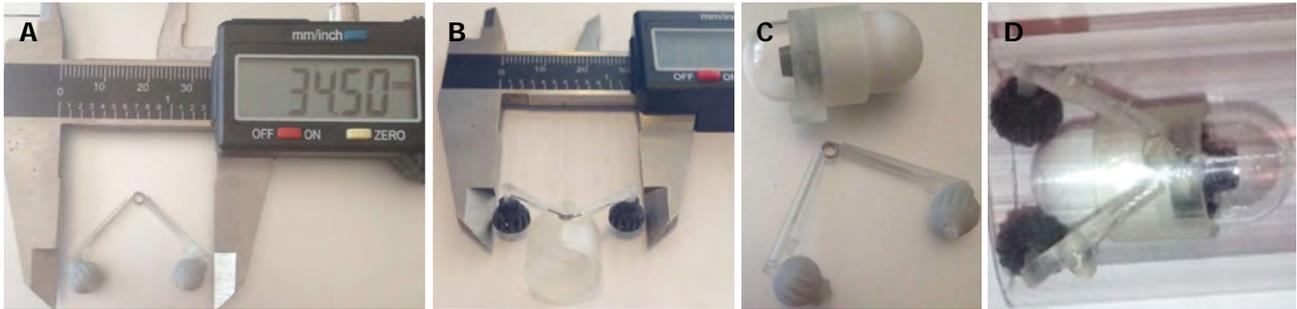

In order to improve capsule localisation, capsule endoscope developers have proposed the use of an applied external magnetic field powerful enough to manoeuvre a capsule<sup>[9]</sup>. In addition, by using geometric algorithms and applying magnetic forces, measurement of the location of the capsule as a vector in the coordinate’s space is achievable<sup>[9]</sup>. However, this method affords only a rough estimate of capsule position due to: (1) constant changes in the anatomy of the human intestine; and (2) all measurements are taken relative to the externally applied magnetic field.

In 2010<sup>[10]</sup>, we proposed a modified capsule design incorporating localisation and stabilization capabilities. The proposed design consists of a capsule fitted with protruding wheels attached to a spring-mechanism (Figure 1A). These springs allow the wheels to retract or expand to fit the lumen whilst the capsule passes through the intestine. This would then lead to more accurate location information, hence accurate lesion localisation, in relation to the onset (pyloric opening) of the investigation. Furthermore, this capsule could theoretically allow stabilization of the recorded video as any erratic, non-forward movement through the gut is minimised.

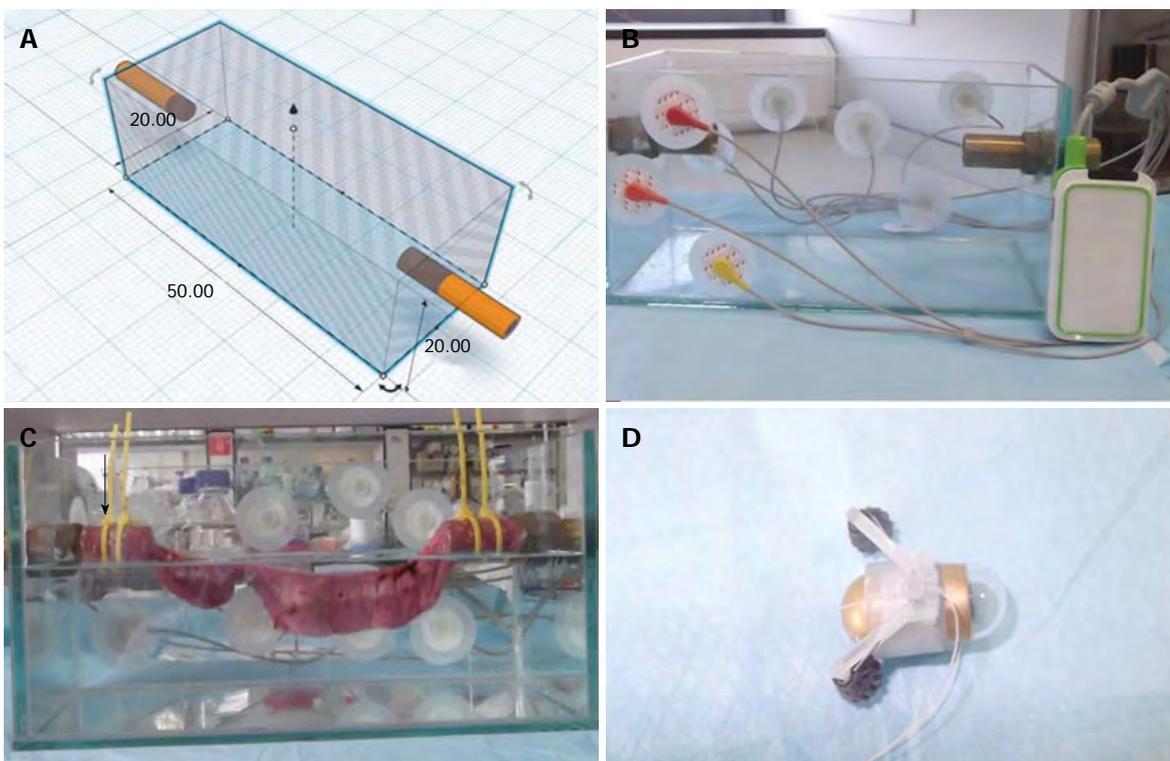

Therefore, we aim to test the feasibility of the pro-

posed design *in vitro* and *ex vivo*. Three-dimensional (3-D) printing technology<sup>[11,12]</sup> was used to build a conceptual capsule prototype (herein called ODOcaps) (Figure 1B). Furthermore, miniature wheels were initially produced with UV Curable Acrylic Plastic (Figure 1C). They were later re-designed and made of a synthetic resilient, textile-like material (TPU 92A-1) (Figure 1D). This material is produced *via* laser sintering, a process similar to stereo-lithography that uses temperature-sensitive powder (instead of UV-sensitive liquid), causing the powder to become a coherent mass without melting<sup>[13]</sup>. For the tread area of the wheels, two designs were considered: smooth or tractor-tread and tested on various types of surfaces. The tractor-tread design of the wheels was selected because it could - theoretically - achieve better traction and full rotation of the wheels when in contact with the intestinal mucosa.

Thereafter, the wheels were inserted in 3-D printed, L-shaped miniature tubes (UV Curable Acrylic Plastic; Figure 2A) allowing almost frictionless rotation. The tubes along with the wheels were attached to a spring (stainless steel torsion spring<sup>[14]</sup> with 90° deflection and 0.093 inch pounds torque from Associated Spring Raymond) to allow extension/retraction of the wheels, Figure 2B. Thereafter, spring with wheels was clipped onto a 3-D printed ring (11.5 mm in diameter made of UV Curable Acrylic Plastic; Figure 2B and C). The ring has two (1 mm) holes, diametrically opposite to each other. The ring was designed to tightly fit on conventional CE

**Figure 2** *In vitro* experiment. A: Wheels inserted in three-dimensional printed, L-shaped miniature tubes. Tubes along with the wheels attached to a spring; B: stainless steel torsion spring with 90° deflection and 0.093 inch pounds torque from Associated Spring Raymond allows extension/retraction of the wheels; C: Three-dimensional printed ring (11.5 mm in diameter made of UV Curable Acrylic Plastic on a demo PillCam® SB2); D: Inserted into one end of a translucent tube and pulled through by a silk string.

**Figure 3** *In vivo* experiment. A and B: Glass tank (50 cm × 20 cm × 20 cm) with fix points for the intestine (metal tubes) and entry points for the capsule device, C: Standard simulated intestinal environment created by mounting 32 cm long, freshly harvested porcine small-intestine to both ends of a fluid-filled tank (arrow); D: Capsule device (assembled ring with wheels on spring on a MiroCam®) was inserted into the suspended bowel *via* one of the metal tubes.

systems (PillCam® SB2, Given® Imaging Ltd., Israel; MiroCam®, IntroMedic Ltd., South Korea) and the holes were used for the insertion of a 0.5 mm silk string.

For the *in vitro* experiment, a translucent polycarbonate tube (internal diameter 22 mm and 50 cm long; Figure 2D) was used. The tube characteristics mimic the diameter and slippery surface of an adult small-bowel. The assembled ring with wheels on spring was fitted on a demo PillCam® SB2 and was inserted into one end of the tube; thereafter, it was pulled through by the string (Figure 2D). While the capsule was pulled along the tube, the wheels were observed rotating constantly without any skidding effect. A video that demonstrates this experiment is available at: <http://dl.dropbox.com/u/7591304/Capsule.mov>.

For the *ex vivo* experiment; a glass tank (50 cm × 20 cm × 20 cm) with fix points for the intestine (metal tubes) and entry points for the assembled device was constructed (Figure 3A and B)<sup>[15]</sup>. A standard simulated intestinal environment (Figure 3C) was created by mounting a 32 cm long, freshly harvested porcine (Large White x Landrace 15-mo-old female sow) small-intestine to both ends of a fluid-filled tank<sup>[15]</sup>. The tank was filled with Normal Tyrode's Solution - Base1 (NTS-1) and Base2 (NTS-2), (Dr. Lohmann Diaclean GmbH, Germany), diluted with 9l of sterile water. Thereafter, the assembled ring with wheels on spring fitted on a MiroCam®) was inserted into the suspended bowel *via* one of the metal tubes (Figure 3D). Consistency of wheels' rotation was

validated by utilising an all-purpose endoscope, Findoo MircoCam (dnt® GmbH, Germany). The latter was introduced from the same end as the capsule and recorded the wheels movement while following the moving capsule. A video is available at: <http://dl.dropboxusercontent.com/u/7591304/1035301R.AVI>

In conclusion, *in vitro* and *ex vivo*, “proof of concept” experimentation based on a conceptual CE design (Figure 1A and B) - that at least in theory offers enhanced localisation capabilities - showed promising preliminary results. Further elaborate experiments (*i.e.*, at first stage, force measurements and construction of a functional prototype)<sup>[16]</sup> and *in vivo* experiments with this prototype are essential and currently under way.

## ACKNOWLEDGMENTS

We feel truly indebted to Dr Adrian Thompson, as without his invaluable help this work would not have been possible. We also like to help Dr Dimitrios Sigounas for his help with the *ex vivo* experiment.

**AIMS AND SCOPE** *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup>, and 28<sup>th</sup> each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

**INDEXING/ABSTRACTING** *World Journal of Gastroenterology* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2012 Impact Factor: 2.547 (34/74); Total Cites: 19145 (6/74); Current Articles: 944 (1/74); and Eigenfactor® Score: 0.06035 (6/74).

Gravante G, Yahia S. Medical influences, surgical outcomes: Role of common medications on the risk of perforation from untreated diverticular disease. *World J Gastroenterol* 2013; 19(36): 5947-5952 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/5947.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.5947>

### Abstract

Numerous drugs, largely used in the wards or at home, have a significant influence on patients with untreated diverticular disease. The consequences can be disastrous, may require an emergency operation, postoperative intensive care, and overall influence the patient's length of stay and the final outcomes. Bearing these considerations in mind the routine or chronic administration of pain-killers, steroids and non-steroidal anti-inflammatory should be balanced in patients with known diverticular disease as it normally happens with other conditions potentially affected by these drugs (*i.e.*, peptic ulcer disease or chronic obstructive pulmonary disease). This is even more important in the old and frail patient where an eventual surgical treatment may not always be possible.

**Key words:** Perforation; Diverticular disease; Medications; Drugs; Risk factor

**Core tip:** Numerous drugs have an influence on patients with untreated diverticular disease. This is even more

### INTRODUCTION

Colonic diverticular disease is a common disease with a prevalence that increases with aging (65% by 80 years)<sup>[1]</sup>. A minority of patients (15%) experience severe complications. Pseudodiverticula are the most common and usually composed of the mucosal and submucosal layers. Therefore, they act as locus minoris resistentiae on the bowel wall and increase the predisposition towards perforation. Abscess formation, purulent or fecal peritonitis are the most common consequences of perforation and are associated with a high morbidity, intensive care requirements, prolonged hospital admissions and increased mortality (12%-36%)<sup>[1,2]</sup>. Conditions that predispose to an increased intraluminal pressure or reduced resistance of the diverticular mucosa can lead to perforation<sup>[1]</sup>. In this view, excessive colonic segmentation may increase intracolonic pressures and the stress forces acting on the diverticular mucosa<sup>[3]</sup>, while impairment of the mucosal barrier of the diverticulum may lead to mucosal weakening through modifications of the secretion of protective mucus<sup>[3]</sup>. Numerous drugs have such effects on patients and therefore increase the risk of perforation from colonic diverticula. The association of perforated diverticular disease with these drugs has been described in various studies. The diverticular disease is usually untreated at the

time of perforation and sometimes even undiagnosed as some patients are unaware of its presence until the perforation manifests.

## NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are one of the most commonly used classes of medications. On large surveys 17% of the general population assumes NSAIDs as chronic anti-inflammatory medications or for long-term pain control, and prescriptions for generic ibuprofen, naproxen and selective inhibitors of the cyclooxygenase 2 enzyme exceed every year the cost of billions<sup>[4]</sup>. A description of the pathophysiological and clinical effects of NSAIDs on the normal colonic mucosa is essential for a proper understanding of their influence on segments affected by diverticular disease. NSAIDs manifest their harmful action on the mucosa through the inhibition of the COX enzymes<sup>[5,6]</sup>. Cyclooxygenase (COX)-1 normally synthesizes protective prostaglandins while COX-2 is pro-inflammatory. In the first case, the lack of protective prostaglandins weakens the diverticular mucosa to noxious agents, in the second the inflammatory reaction in cases of microperforation of the diverticula is diminished and therefore the ability to contain the extracolonic contamination<sup>[5,6]</sup>.

NSAIDs have long been associated with complications in the upper gastrointestinal tract. More recently, adverse effects upon the small and large intestine have become more recognized and reported. Individuals who regularly take NSAIDs have a significantly higher incidence of lower intestinal lesions when compared with non-NSAID takers, and such risk increases with the duration of NSAIDs ingestion. NSAIDs have been associated with a particular form of colitis<sup>[7]</sup> that present with diarrhoea, anemia and non specific abdominal pain<sup>[8]</sup>. Endoscopy revealed flat ulcers in the entire colon similar to ulcerations and erosions found in the small bowel<sup>[8,9]</sup>. The median time from onset of symptoms to diagnosis was 1.8 years (range, 0.0-11.5 years)<sup>[8]</sup> and prolonged use of NSAIDs increased the risk of mucosal damage more than the short use<sup>[7]</sup>. In portions of large bowel not affected by underlying diseases numerous cases of strictures were also reported<sup>[10-15]</sup>. Such lesions appeared on endoscopy as concentric “diaphragm-like” strictures similarly to those described in the small bowel<sup>[8,9]</sup>. Finally, NSAIDs-induced perforations have been described especially in the cecum<sup>[16-19]</sup>, usually caused by more distal strictures<sup>[10,11]</sup>.

NSAIDs are frequently used to treat concomitant arthritic or cardiovascular diseases and not necessarily prescribed to alleviate symptoms in patients with diverticular disease<sup>[20]</sup>. Most patients are even unaware of the presence of diverticular disease until the perforation occurred<sup>[20]</sup>. In segments of the colon affected by diverticular disease NSAIDs increased the risk of bleeding<sup>[21-24]</sup> and perforation of diverticula. Six retrospective case-

controls studies have analysed the association between perforated diverticular disease and NSAIDs, making it the most studied class of drugs with regards to such association (Table 1)<sup>[20,25-29]</sup>. The incidence of NSAIDs in patients with perforated diverticular disease was compared with healthy controls<sup>[20,25,27]</sup> or with patients having simple non-perforated diverticular disease<sup>[20,26,28]</sup>. Overall, NSAIDs were present in 10% of patients with perforated diverticular disease (118/1182) and 3.8% of controls (391/10385), sub-classified in 3.4% in healthy people (341/9950) and 11.5% in non-perforated diverticular disease (50/435). When compared with healthy controls, OR for the use of NSAIDs in patients with perforations was 1.5 (95%CI: 1.01-2.3) for Humes *et al*<sup>[27]</sup>, 1.8 (95%CI: 0.96-3.4) for Mpofo *et al*<sup>[25]</sup>, 2.1 (95%CI: 1.3-3.4) for Goh *et al*<sup>[20]</sup>. When compared to simple diverticular disease OR were higher: 3.6 (95%CI: 1.5-8.4) for Piekarek *et al*<sup>[28]</sup>, 4.6 (95%CI: 1.7-12.5) for Goh *et al*<sup>[20]</sup>, 4.8 (95%CI: 1.6-14.8) for Corder<sup>[26]</sup>. ORs results are consistent among studies and indicate a higher presence of NSAIDs in patients experiencing perforation compared to both control groups. Interesting, higher ORs are present when perforated patients are compared to non-perforated ones as if the presence of diverticula increase the predisposition to perforation from NSAIDs compared to healthy subjects.

## CORTICOSTEROIDS

Corticosteroids are potent anti-inflammatory and immunosuppressive drugs used for a number of common and rare diseases. It is estimated that up to 0.9% of the general population receives oral administrations of corticosteroids, and 22% of these patients continue the treatment for longer than 6 mo. The most frequent indications are respiratory diseases (80%) followed by pathologies of the musculoskeletal system (12%) and the skin (10%)<sup>[30]</sup>. Arthropathies are most likely to require a chronic treatment compared to the other indications<sup>[30]</sup>.

The relationship between chronic rheumatic diseases, long-term use of corticosteroids and complications from diverticular disease has long been investigated from different perspectives. In a large study on patients with rheumatoid arthritis corticosteroids were associated with perforations of the lower gastrointestinal tract and death<sup>[31]</sup>. At the same time, patients with chronic rheumatic conditions experienced a six-fold increase of death from complicated diverticular disease than the general population<sup>[32]</sup>. The long-term use of corticosteroids has been described in chronic rheumatic patients suffering from perforated diverticular disease<sup>[33-37]</sup>. Sporadic cases of diverticular perforation have also been reported in patients following neurosurgery operations<sup>[38]</sup>, transplants<sup>[39-43]</sup> or under steroidal treatment for asthma and cancer<sup>[44]</sup>. In some patients the diverticular disease was even unsuspected until the fatal event happened<sup>[34,38]</sup>.

Corticosteroids may increase the likelihood of clinically-manifested diverticular perforations by both etiologic and contributing mechanisms. Steroidal use inhibits

NSAIDs: Non-steroidal anti-inflammatory drugs; Ca<sup>2+</sup>: Calcium-channels blockers; HC: Healthy control; DD: Non-perforated diverticular disease.

the cyclo-oxygenase enzyme in the gut that normally produces prostaglandins with local protecting effects<sup>[1]</sup>. Prostaglandins enhance the gut mucosal barrier by stimulating the secretion of mucin and bicarbonate and increasing the local blood flow<sup>[45]</sup>. Their absence predisposes the mucosa to the effects of noxious agents such as bacteria and toxins<sup>[45]</sup>. Additionally, corticosteroids are potent immunosuppressant that masks the immune response to local inflammations and small perforations. The ability of the body to contain small perforations is therefore impaired, their local effects are therefore increased and even the classic clinical symptoms may be masked until advanced contaminations eventually become evident<sup>[46]</sup>.

Four case-controls studies have investigated so far the association of perforated diverticular disease and corticosteroids (Table 1)<sup>[25-28]</sup>. In two studies controls were healthy people<sup>[25,27]</sup> and in the rest non-perforated diverticular disease<sup>[26,28]</sup>. Overall, corticosteroids were present in 4.4% of patients with perforated diverticular disease (49/1112) and 0.7% of controls (71/9560), sub-classified in 0.7% in healthy people (68/9300) and 1.2% in non-perforated diverticular disease (3/260). All studies confirmed an increased risk of perforation with their use that was 2.7 (OR = 1.604.6) according to Humes *et al*<sup>[27]</sup>, 13.2 (RR, 95%CI: 1.81-96.5) for Corder<sup>[26]</sup>, 28.3 (OR, 4.8-165.7) for Piekarek *et al*<sup>[28]</sup>, and 31.9 (OR, 95%CI: 6.4-159.2) for Mpofu *et al*<sup>[25]</sup>. However, a more careful analysis shows that the risk increase presented by Humes *et al*<sup>[27]</sup> is markedly lower than those reported by the other authors<sup>[25,26,28]</sup>. No direct comparison of the corticosteroids incidences is possible for the control groups because of the above-mentioned heterogeneity among studies (two analyse healthy people and two non-perforated diverticular diseases). Still, case groups present similar patients with perforated diverticular disease in all four studies and therefore incidences can be directly compared. In the study of Humes *et al*<sup>[27]</sup> only 2.2% (20/899) of perforated patients use corticosteroids compared to 10%-17%

reported by the others (10/64 = 16%, 10/95 = 10.5%, and 9/54 = 17%)<sup>[25-28]</sup>. This could explain the lower increase in the risk conferred by corticosteroids reported by Humes *et al*<sup>[27]</sup> compared to the others. The main difference noted among these studies is that the report of Humes is based on a nationwide database prospectively-maintained by local general practitioners (General Practice Research Database, United Kingdom). This database has provided a larger number of patients than any other local-based study, possibly giving more reliable epidemiological figures ( $n = 8980$  controls,  $n = 890$  cases).

## OPIOIDS

Opioids are common analgesics used to control pain in acute (*i.e.*, postoperative pain) and chronic conditions (*e.g.*, oncological pain, arthritis and headaches). Although they are not the first choice according to the World Health Organization analgesic ladder, it is still estimated that up to 90% of the population use them at least once in the lifetime while 0.56% are chronic users (greater than 6 mo assumption), especially elderly women<sup>[47]</sup>. The overall gastrointestinal effects consist in depression of the peristalsis with clinical manifestations of nausea, vomiting and constipation<sup>[48]</sup>. Opioids act on gut motility by decreasing the autonomic activity of the central nervous system and by binding to the mu- and kappa-receptors of the myenteric and submucosal plexuses in the gut<sup>[49,50]</sup>. The pathophysiological effects consist in an increase in the frequency of non-propulsive phasic contractions of the colon and decreased to absent propulsive migrating contractions<sup>[51]</sup>. The increase of non-propulsive contractions accounts for the higher intraluminal pressures. In fact, the administration of morphine produces high intraluminal sigmoid pressures in segments with colonic diverticula through the production of peristaltic segmentations<sup>[52-54]</sup>. These higher pressures may contribute either to the production of new diverticula or, in an already diseased segment, to

the perforation of some of them. On the other side the absence of propulsive complexes is responsible for the constipation and increased frequency of ileus. The reduction in the transit time may therefore prolong the exposure of the diverticular wall to potential pathogens<sup>[1]</sup>.

Due to all these premises, the safety of administering opioids in patients with diverticular disease was questioned early in the medical literature<sup>[52]</sup>. However, the association between opioids and perforated diverticular disease is one of the least examined compared to the other classes of drugs. The first study that report the frequency of opioids use in patients with perforation from diverticular disease is based on a large cross-sectional study in the Norwich area (United Kingdom) that found opioids were used by 26% of the population presenting with diverticular perforation<sup>[2]</sup>. More recently, both case reports<sup>[55]</sup> and case-control studies<sup>[27,28]</sup> have further reported on the association among opioids and perforation from diverticular disease. In case-controls studies data were collectively presented for drugs used as required or regularly with no differentiation according to the duration or regularity of the assumption (Table 1)<sup>[27,28]</sup>. In the study of Piekarek *et al.*<sup>[28]</sup>, patients with diverticular disease were retrospectively examined and divided in two groups according to the perforation status. In the perforated group (case group) the use of opioids was present in 20.4% of patients ( $n = 11/54$ ) while in the non-perforated group (control group) it was 6.0% (11/183). This corresponded to an OR for perforation with opioids of 4.5 (95%CI: 1.7-12.2). Differently from Piekarek *et al.*<sup>[28]</sup>, Humes *et al.*<sup>[27]</sup> conducted a larger population-based study gathering data from the General Practice Research Database. In their study controls were healthy people not affected by the diverticular disease. Current opioids use was present in 6.3% (57/899) of perforated cases (case group) *vs* 2.4% (218/8980) of healthy patients (control group) with a lower OR than that reported by Piekarek *et al.*<sup>[28]</sup> (2.2, 95%CI: 1.6-3.0)<sup>[27]</sup>. Both studies confirm that the current use of opioids increases the possibility of diverticular perforation. The different ORs observed can have different explanations. First, it is possible that differences not reported in the regularity or duration of opioids have significant influences on the occurrence of perforation. Second, the different control groups (healthy controls *vs* non-perforated diverticular disease) may provide a different baseline level for the calculation of the added risk towards perforation derived from the use of opioids, similar for the data reported on NSAIDs.

## CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are a common class of drugs frequently prescribed in elderly people to treat hypertension and ischemic heart disease. They act by blocking the calcium channels in smooth muscle cells and therefore relaxing the contraction of non-voluntary musculature. Although this effect is desirable on peripheral circulation, to an extent it influences also the gastrointestinal motility

and has been used to treat pathologic contractions of the gastrointestinal tract (*i.e.*, anal fissures from increased anal sphincter tone). The muscle-relaxant properties of these medications could have a beneficial effects in reducing intracolonic luminal pressures<sup>[56]</sup>. At the same time, some of them also increase the mucosal vascular flow therefore acting on the second main risk factor for diverticular perforation (weakened mucosal barrier)<sup>[57,58]</sup>.

So far, three case control studies have analyzed the effects of Calcium channel blockers on the likelihood of perforation from diverticular disease (Table 1)<sup>[3,27,28]</sup>. In all studies the use of such medications was more frequent in controls than in patients that experienced perforated diverticular disease: 15% (72/150) in healthy controls *vs* 6.7% (8/120) in perforated patients for Morris *et al.*<sup>[3]</sup>, 1.2% (104/8980) in healthy controls *vs* 0.7% (6/899) in perforated patients for Humes *et al.*<sup>[27]</sup>, and 11.5% (21/183) in patients with simple diverticular disease *vs* 3.7% (2/54) in perforated patients according to<sup>[28]</sup>. These data corresponded to ORs of 0.4 (95%CI: 0.2-0.9)<sup>[3]</sup>, 0.54 (95%CI: 0.24-1.24)<sup>[27]</sup>, 0.14 (95%CI: 0.02-0.95)<sup>[28]</sup>. Among the three reports the only one in which the association was not statistically significant was the one of Humes *et al.*<sup>[27]</sup> although the authors still suggested “a potentially protective role”. The differences among this study (large population-based) and the others have already been outlined.

## OTHER DRUGS

Few other classes of drugs have been sporadically investigated. Antimuscarinic drugs are commonly prescribed for depression, psychoses, but also as muscle relaxants for overactive bladder. Their characteristics could also influence the gastrointestinal musculature and prevent excessive contractions and therefore perforations from diverticular disease. However, the only study that compared healthy controls *vs* patients with perforated diverticular disease failed to provide a significant association<sup>[3]</sup>. Statins also were investigated in one study<sup>[27]</sup> for their potential anti-inflammatory qualities that could protect the diverticular mucosa<sup>[59]</sup>. Current use of a statin was associated with a lower risk of perforation (OR = 0.44, 95%CI: 0.20-0.95)<sup>[27]</sup>.

## CONCLUSION

Numerous drugs, largely used in the wards or at home, have an influence on patients with untreated diverticular disease. The consequences elicited can be disastrous, would ideally require an emergency operation with post-operative intensive care monitoring for definitive treatment, and influence the overall length of stay and final outcomes. Bearing these considerations in mind, the routine or chronic administration of pain-killers, steroids and non-steroidal anti-inflammatory should be balanced in patients with known diverticular disease as it normally happens with other associated conditions that could be affected by these drugs (*i.e.*, peptic ulcer disease or chron-

ic obstructive pulmonary disease). This is even more important in old and frail patients in which an eventual surgical treatment may not always be a possibility.

### Abstract

Alcoholic cirrhosis remains the second most common indication for liver transplantation. A comprehensive medical and psychosocial evaluation is needed when making a decision to place such patients on the transplant list. Most transplant centers worldwide need a minimum of 6 mo of alcohol abstinence for listing these patients. Patients with alcohol dependence are at high risk for relapse to alcohol use after transplantation (recidivism). These patients need to be identified and require alcohol rehabilitation treatment before transplantation. Recidivism to the level of harmful drinking is reported in about 15%-20% cases. Although, recurrent cirrhosis and graft loss from recidivism is rare, occurring in less than 5% of all alcoholic cirrhosis-related transplants, harmful drinking in the post-transplant pe-

riod does impact the long-term outcome. The development of metabolic syndrome with cardiovascular events and *de novo* malignancy are important contributors to non liver-related mortality amongst transplants for alcoholic liver disease. Surveillance protocols for earlier detection of *de novo* malignancy are needed to improve the long-term outcome. The need for a minimum of 6 mo of abstinence before listing makes transplant a nonviable option for patients with severe alcoholic hepatitis who do not respond to corticosteroids. Emerging data from retrospective and prospective studies has challenged the 6 mo rule, and beneficial effects of liver transplantation have been reported in select patients with a first episode of severe alcoholic hepatitis who are unresponsive to steroids.

**Key words:** Alcoholic liver disease; Liver transplantation; Transplant evaluation; Recidivism; Six months rule; Alcoholic hepatitis

**Core tip:** Alcoholic cirrhosis remains the second most common indication for liver transplantation. Due to effective immune suppression regimens, graft loss and recurrent alcoholic liver disease rarely leads to mortality. However, the development of non-hepatic disorders such as malignancy and metabolic syndrome contributes to long-term morbidity and mortality. Although recidivism does impact long-term survival, data on the accuracy of 6 mo rule in predicting recidivism are scanty and controversial. Emerging data on the beneficial role of liver transplant provides a ray of hope for select patients with alcoholic hepatitis.

## INTRODUCTION

In the United States, about 60% of the general population admits to alcohol use, and about 8%-10% report heavy drinking (2 or more drinks per day)<sup>[1]</sup>. One drink is equivalent to 12 oz. of beer (4%-5% weight by volume or w/v), 6 oz. of wine (8%-10% w/v), and 2 oz. of hard liquor or whiskey (45% w/v). Of the various factors responsible for liver disease, the most important are the duration and amount of alcohol consumed. Pooled data from several epidemiological studies report a minimum intake of 30 g/d of alcohol in women and 50 g/d in men, consumed over at least 5 years is required to cause liver cirrhosis<sup>[2]</sup>. The prevalence of and the mortality rates from cirrhosis parallel the prevalence rates of alcohol consumption in the population globally. Several host and environmental factors increase the risk of development of liver disease, such as gender (women are more prone), hard liquor compared to wine, binge drinking (5 or more drinks at one time), drinking on an empty stomach, genetic factors such as *PNPLA3* gene polymorphisms, concomitant hepatitis C virus (HCV) infection, and obesity<sup>[3,4]</sup>.

Alcohol remains the third most common preventable cause of death after smoking and hypertension. Alcohol-related mortality affects the young and middle-aged population, with loss of the most productive life years. Although cirrhosis is the fourth leading cause of death in the US in people aged between 45 and 54 years of age, the mortality rate rises with increasing age reaching as high as 31 per 100000 amongst people in the age group of 75-84 years. Liver-related complications from alcohol contributes to 4% in mortality and 5% in disability adjusted life years (DALY) globally with the highest impact in Europe where similar figures are 7% and 12% respectively<sup>[5]</sup>. This huge disease burden has an economic impact of about 125 billion Euros annually in Europe, accounting for 1.3% of the gross domestic product. In 2006, the estimated total economic cost of excessive alcohol consumption in the US amounted to \$223.5 billion. Of the \$223.5 billion, 72.3% (\$161.3 billion) represented the costs related to lost productivity, secondary to impaired productivity at work (45.9%) and lost productivity due to alcohol-related deaths (83180; 40.3%). In addition, another 11% (\$24.6 billion) is lost due to increased healthcare costs, the largest expenditures coming from specialty treatment for alcohol abuse and dependence (43.4%), and hospitalizations due to medical conditions related to excessive drinking (20.8%). The remainder of the expenditure was due to the costs associated with the criminal justice system (\$21 billion) and motor vehicle crashes (\$14 billion)<sup>[6]</sup>. These figures are probably underestimates due to inaccuracies in death certificate reports, since the mention of alcohol as contributing cause of death may have social and legal implications.

Alcohol abstinence remains the cornerstone in the management of patients with alcoholic liver disease with the potential for improvement in liver histology, com-

plications, and survival. However, complete reversibility of liver function usually does not occur once cirrhosis sets in. The use of corticosteroids and/or pentoxifylline in patients with severe alcoholic hepatitis provides about 50% survival benefit; nearly 20%-25% of such patients succumb to their illness despite treatment with these drugs. Thus, the curative management options for patients who are non-responsive to drugs and/or abstinence are limited, with the exception of liver transplantation (LT), a definitive treatment option for patients with cirrhosis and end-stage liver disease. In this article, we review the current status and special considerations on the use of LT for alcoholic cirrhosis and controversies and emerging data on liver transplantation for patients with severe alcoholic hepatitis that is non-responsive to pharmacological therapies.

## LIVER TRANSPLANTATION FOR ALCOHOLIC CIRRHOSIS

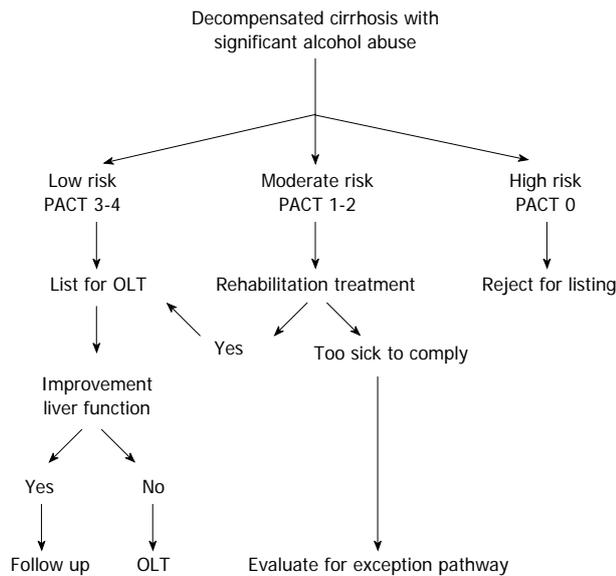

LT is a definitive treatment option for patients with cirrhosis and ESLD. Over the last two decades, advances in technical aspects of the operative procedure, intraoperative and postoperative care, and immunosuppression protocols have led to graft and patient survivals of over 90% at one year after LT<sup>[7,8]</sup>. Currently, LT is an accepted treatment modality for ESLD patients who have an estimated 1 year survival of less than 10%<sup>[9]</sup>. The excellent graft and patient outcomes of patients transplanted for alcoholic cirrhosis have encouraged physicians and the transplant communities to more readily refer these patients for liver transplant evaluation<sup>[8-10]</sup>. Alcoholic liver disease remains the second most common indication for LT, accounting for approximately 40% of all primary transplants in Europe and about 25% in the United States<sup>[8,11]</sup>. However, in spite of the encouraging data, disparities remain on the referral pattern of patients with alcoholic cirrhosis. In one study, only 21% patients were found to qualify for LT based on the current American Association for Study of Liver Diseases (AASLD) guidelines<sup>[12]</sup>.

### *Evaluation of alcoholic cirrhosis patients for liver transplantation*

Evaluation for LT of a patient with alcoholic liver disease requires a multidisciplinary approach, with important contributions from psychiatrists and addiction specialists. However, the overall evaluation process of a patient with alcoholic cirrhosis for LT is similar to that of a patient with non-alcoholic cirrhosis, including the indications and contraindications for LT. However, there are certain specific issues that need to be addressed during the evaluation process, which will be briefly discussed.

### *Evaluation for alcohol use*

The first step is to obtain a detailed and accurate history from the patient and the relatives and friends, of alcohol use to ascertain that the patient meets the criteria

**Figure 1** Psychosocial evaluation of patients with alcoholic cirrhosis awaiting listing for liver transplantation. OLT: Optical line terminal; PACT: Psychosocial Assessment of Candidacy for Transplantation.

for the diagnosis of alcohol-related cirrhosis<sup>[13]</sup>. Patients with alcohol dependence (tolerance to alcohol with use of increasing amounts, withdrawal symptoms, failed abstinence attempts, craving, and eye opener to avoid a hangover) should be identified, as these patients would often require rehabilitation treatment to maintain abstinence. As noted above, the history of alcohol use should be confirmed with relatives or friends since self-reported use of alcohol is often inaccurate. In one study, 18 of 82 alcoholic cirrhotic with a Department of Motor Vehicle record of driving under the influence (DUI) were not discovered on patient self-report<sup>[14]</sup>. Apart from the amount of alcohol use, it is mandatory to determine the date of the last drink in order to assess the duration of abstinence. A consensus conference in 1997 stated the need for minimum abstinence duration of 6 mo prior to listing a patient for LT (6 mo rule)<sup>[15]</sup>. The concept behind this rule was to allow the full benefit of abstinence on the liver functions, as studies have shown that the maximum benefit of abstinence is observed within the first 3-6 mo<sup>[16]</sup>. AASLD recommends that patients who continue to have significant liver disease despite 6 mo of abstinence should be considered and evaluated for LT<sup>[17]</sup>.

### Medical evaluation

A careful assessment should be made of the effects of alcohol on other organs including the presence of cardiomyopathy, chronic pancreatitis, Wernicke's encephalopathy, alcohol-related dementia, peripheral neuropathy, and upper aero-digestive malignancies as these can affect LT candidacy<sup>[18]</sup>. For example, patients with memory loss or confusion may be misdiagnosed as hepatic encephalopathy, instead of Wernicke's encephalopathy or alcohol dementia. Similarly, patients may have narcotic dependent due to chronic pancreatitis or may have poor

performance status due to peripheral neuropathy that is unrelated to the liver disease. These issues need to be addressed as they have a negative impact on LT outcome. Therefore, detailed cardiac and neurological assessment should be done in alcoholic cirrhotic to assure their LT candidacy. Although, malnutrition does not impact outcome after LT, malnourished patients are known to have greater length of hospital stay and consume more hospital resources compared to well-nourished patients<sup>[19]</sup>. Therefore, nutritional status should be assessed and malnourished patients should receive supplementation for optimizing their nutritional status.

### Psychosocial evaluation

Although psychosocial evaluation is mandatory for all transplant candidates, it is more important in alcoholic cirrhotic. Psychosocial Assessment of Candidacy for Transplantation (PACT) scale is a common tool used at most centers for evaluating candidates for all types of transplants<sup>[20]</sup>. This scale is used to assess social support, psychological health, life style factors, and patients' understanding of the transplant process including the follow up process after transplantation. Alcohol and substance abuse are only one part of this scale. Patients with intermediate risk for recidivism are recommended to undergo rehabilitation treatment before being considered for LT (Figure 1).

The data on the impact of rehabilitation treatment in maintaining abstinence are scanty, especially with respect to whether this treatment needs to be administered as out-patient sessions or as an in-patient intensive treatment for 2-3 wk followed by outpatient sessions. In a randomized study, motivational enhancement therapy (MET,  $n = 46$ ) was beneficial compared to treatment as usual (TAU,  $n = 45$ ) in reducing the amount and frequency of drinking prior to transplantation<sup>[21]</sup>. In this study, MET consisted of intensive 50-min sessions every month for 7 sessions along with Alcoholic Anonymous (AA) attendance. By contrast, TAU comprised of intensive outpatient treatment and community AA referral. However, compliance with the treatment was an issue since the average number of sessions in the MET group was only 3.8 instead of 7 as was proposed initially<sup>[21]</sup>. There are many reasons for failed adherence to rehabilitation treatment, the most important being inability to attend these sessions due to sickness from liver disease. These patients could be considered for exceptional pathway after multidisciplinary assessment and discussion (Figure 1). A randomized controlled trial on 84 alcoholic cirrhotic on the use of baclofen in maintaining abstinence and reducing hospital readmission rates has provided encouraging results<sup>[22]</sup>. It was observed that a higher proportion of patients maintained abstinence with baclofen compared to placebo (71% vs 29%,  $P = 0.0001$ ) and had a longer mean duration of abstinence (62 d vs 31 d,  $P = 0.001$ ). Further, there was improvement in liver function in patients treated with baclofen as compared to patients receiving placebo<sup>[23]</sup>.

**Detection of relapse to alcohol use (recidivism)**

While awaiting LT, patients should be followed regularly and closely to confirm abstinence as patients not complying with this recommendation should lose their listing status. At each visit, physicians should perform detailed history, urine drug screening, serum nicotine in recent or current smokers, and blood ethanol or other markers of alcohol use. In one study, random blood alcohol screens reduced recidivism by 37%<sup>[24]</sup>. Methanol testing is more sensitive and detects recent alcohol use when blood ethanol levels are normal<sup>[25]</sup>. Gamma glutamyltransferase (GGT) is a more sensitive test (70%) than aminotransferase for chronic heavy alcohol use. However, it is not specific in the pre-transplant setting as it may be elevated in cirrhotic patients<sup>[5]</sup>. Carbohydrate-deficient transferrin (CDT) is an FDA approved marker for alcohol abuse. Moderate to heavy alcohol use reduces the carbohydrate content of transferrin molecule synthesized by the liver<sup>[26]</sup>. Its performance in detecting alcohol use is better when combined with GGT, with sensitivity of 90% and 75% in males and females respectively<sup>[26]</sup>. However, since CDT levels are impacted by the severity of liver disease, its use is limited in the pre-transplant setting. Further, CDT levels are affected by smoking and need to be adjusted for total transferrin levels in females<sup>[27]</sup>. New biomarkers using metabolites of alcohol such as ethyl glucuronide (eTG) are under investigation. Urine eTG is extremely sensitive and can detect alcohol level as low as 10 ng/mL and may become falsely positive with the use of alcohol-containing medications and hand sanitizers. In one study, a cut-off level of 0.5 mg/L, as detected by liquid chromatography-mass spectroscopy (LC-MS), is 89% sensitive and 99% specific with a negative predictive value of 99% and positive predictive value of 89%. Increasing the cut-off level to 1 mg/L did not improve the specificity but decreased the sensitivity to 75%<sup>[28]</sup>. In this study, combining UeTG with CDT could accurately diagnose 93% of patients with recidivism. UeTG may be falsely negative in patients with urine infection especially with *E. coli* as this metabolite of alcohol may be degraded by the bacterium<sup>[29]</sup>. Ethyl sulfate (EtS) another metabolite of alcohol is not affected by bacterial degradation and its simultaneous measurement in the urine can overcome this limitation<sup>[30]</sup>. However, the short-term window for positivity limits the use of these markers in routine clinical practice after the last heavy alcohol use: a few hours for BAL and methanol, and 4-5 d for UeTG and EtS<sup>[28]</sup>. In this regard, hair analysis for ethyl glucuronide is useful since the metabolite remains in hairs for one month<sup>[31]</sup>. A cut off level of 7 pg/mg of hair sample is a strong indicator of regular alcohol use, and a cut off level of 30 pg/mg can be accurately diagnose heavy drinking<sup>[32]</sup>. Other markers such as phosphatidyl ethanol, acetaldehyde, Cytochrome P-450 (CYP) E, mono amino oxidase-B, 5-tryptophol, and fatty acid ethyl ester are experimental and unavailable for clinical application at the present time<sup>[33]</sup>.

**Recidivism after liver transplantation for alcoholic cirrhosis**

Recidivism is reported in 10%-60% of transplant recipients for alcoholic liver disease<sup>[34-37]</sup>. The large variation in prevalence rates of recidivism is perhaps due to different definitions used, with some defining recidivism as any alcohol use while others only include harmful drinking, defined as 2 or more drinks per day, which is reported in 15%-20% patients. Recidivism rates across different studies are also affected by the duration of follow up. In a pooled analysis from 50 studies evaluating recidivism after liver transplantation, the rates of any alcohol use after LT were 5.7% per 100 person years, and 2.5% per 100 person years risk for harmful drinking<sup>[38]</sup>. DiMartini *et al.*<sup>[39]</sup> reported on the patterns of alcohol use after LT. Nearly 45% patients reporting some alcohol use (26% rare slips and 19% harmful drinking). Of those with harmful drinking, about 1/3<sup>rd</sup> each reported early start (within 2-3 years after LT) with subsequent decline, continued harmful drinking throughout, and late start (after the first 3 years and then persisting with alcohol use).

Data on the accuracy of 6-mo pre-transplant abstinence in predicting recidivism are scanty and controversial. In a systematic review of 22 studies reporting predictors of recidivism, only 2 of the 11 studies evaluating this variable reported it to be an accurate predictor of recidivism<sup>[40]</sup>. Social and family support, preexisting psychiatric comorbidities, polysubstance use, unsuccessful attempts at rehabilitation, younger age at LT, and family history of alcoholism emerged as the strongest predictors for recidivism<sup>[40]</sup>. In another study based on the duration of drinking, the number of daily drinks consumed, and the number of previous alcoholism treatments, the high-risk alcoholism relapse (HRAR) score (ranging from 0-6) was calculated and compared with 6-mo abstinence in predicting recidivism. HRAR emerged as a stronger predictor of abstinence with 79%, 69%, and 54% agreement between HRAR and 6 mo abstinence for low, moderate, and high HRAR groups respectively<sup>[41]</sup>. The impact of pre-transplant motivational enhancement therapy on recidivism could not be assessed in a randomized study due to the small sample size<sup>[21]</sup>.

**Outcomes of patients transplanted for alcoholic cirrhosis**

The patient survival rates after LT for alcoholic cirrhosis based on data from different parts of the world have been reported to be 81%-92%, 78%-86%, and 73%-86% at 1, 3, and 5 years respectively<sup>[8,11,42]</sup>. There is improvement in the quality of life, mood status and cognitive functioning, with no difference compared to patients transplanted for non-alcoholic cirrhosis<sup>[43,44]</sup>. Patients were able to return to society and lead active and prolific lives, irrespective of the indication for transplantation<sup>[34,45]</sup>.

Concomitant alcohol abuse and HCV infection is observed in about 14% of individual with chronic liver disease<sup>[3]</sup>. The data on outcomes in HCV positive drink-

<sup>1</sup>Any use of alcohol in this study was reported as recidivism. Other studies defined recidivism as heavy drinking defined with variable amount of alcohol use across different studies. LRD: Liver related death.

ers are scanty and conflicting. Studies using transplant registries from the United States and Europe, suggest worse survival outcomes compared to HCV negative alcoholic cirrhosis<sup>[11,46,47]</sup>, although a study from a single European center reported similar outcomes<sup>[48]</sup>. It should be noted that in the latter study, patients received antiviral therapy more often compared to patients with HCV cirrhosis alone, which may explain the difference in the outcome<sup>[48]</sup>. Unfortunately, such information is lacking in data collected from registries. Further, HCV positive drinkers may have been misclassified in the registry databases due to lack of information on the amount of alcohol use. Further studies using data from single or multiple centers with detailed information on these variables are needed to examine post-transplant outcomes of alcoholic cirrhosis and concomitant HCV infection.

Relapse to harmful drinking affects long-term patient survival. Compared to abstinent patients transplanted for non-alcoholic liver diseases, the survival rates in patients with recidivism to harmful drinking are similar initially but become worse after 5-10 years (45%-68% *vs* 75%-86%)<sup>[49-52]</sup>. The proportion of patients dying from liver-related cause in patients transplanted for alcoholic cirrhosis varies from 6%-88% in various series (Table 1). Graft loss from recurrent disease related to alcohol use is rare<sup>[53,54]</sup>. Rates of graft loss due to recidivism are 0%-6% in most series except two studies from the same institution which reported 38% and 50% graft loss related to alcohol use (Table 1)<sup>[55,55]</sup>. Harmful drinking in the early phase of post-transplant period is more significant in terms of the impact on liver graft. In one study, graft loss and liver-related mortality occurred in 72% and 45% respectively in patients with early onset harmful drinking compared to 45% and 0% amongst those who were abstinent, had rare slips, or later use of harmful drinking<sup>[56]</sup>. Recurrent cirrhosis and graft loss accounts for about 3% of the original cohort of transplant recipients for alcoholic cirrhosis<sup>[57]</sup>. It is unclear whether certain genetic factors in the donor liver play a protective role despite recidivism to harmful drinking in these patients who were originally genetically predisposed to alcohol-related liver injury. However, once recurrent cirrhosis sets in, the outcome is worse compared to patients with a functional graft (30%  $\pm$  17% *vs* 75%  $\pm$  6% survival at 10 years,  $P = 0.045$ )<sup>[57]</sup>.

With the introduction of effective immune suppression regimens, which protect the liver graft, non-hepatic disorders including metabolic syndrome and malignancies have become more important causes of patient mortality after LT for alcoholic liver disease. Registry analyses from Europe and United States have shown that cardiovascular causes and *de novo* malignancies were significantly over-represented in patients who had undergone transplantation for ALD *vs* recipients without ALD<sup>[11,47]</sup>. Although, the metabolic syndrome is seen frequently on long term follow up after LT, patients transplanted for alcoholic cirrhosis are particularly prone to this complication followed by patients transplanted for non-alcoholic steatohepatitis-related ESLD<sup>[58,59]</sup>. The development of the metabolic syndrome is a risk factor for cardiovascular death in patients who survive the first year after LT<sup>[60]</sup>.

The development of *de novo* malignancy in LT recipients was recognized as early as 1972<sup>[61]</sup>. About 5%-15% of patients receiving liver transplantation develop *de novo* extrahepatic malignancy. Skin cancer accounts for 30%-50% followed by post-transplant lymphoproliferative disorders (PTLD) and solid organ cancers<sup>[62,63]</sup>. The risk is higher compared to the general population for skin as well as solid organ cancers with standardized incidence ratio of about 15 and 2-2.5 respectively<sup>[64,65]</sup>. The risk increases with time to as high as 19% and 34% at 10 and 15 years post-transplant respectively<sup>[64]</sup>. The risk for *de novo* malignancy is 1.5-2 folds higher in transplant recipients for alcoholic liver disease compared to transplants for non-alcohol-related etiologies<sup>[66-69]</sup>. Patients transplanted for alcoholic cirrhosis are at a unique risk for the development of upper aero-digestive cancers with about 10-fold higher risk compared to transplants for other indications<sup>[68-70]</sup>. Intensive screening for head and neck cancers prior to transplant does not seem to be cost effective, with only 0.17% prevalence of this cancer in one study that evaluated 581 patients with alcohol-related cirrhosis<sup>[71]</sup>.

The use of immune suppression post-transplantation is believed to be the major mechanism for the development of *de novo* malignancy<sup>[62,63]</sup>. Other risk factors are older age, male gender, and Epstein Barr virus reactivation or infection for lymphoproliferative malignancy, and exposure to sun for non-melanoma skin cancer<sup>[63,72,73]</sup>. The mechanisms involved in predisposing alcohol-related

transplant patients to malignancy are poorly understood. Oncogenic properties of acetaldehyde, a metabolite of alcohol, and the inhibition of DNA methylation have been blamed<sup>[74]</sup>. Smoking both pre and post-transplant increases the risk for upper aerodigestive cancers in patients transplanted for alcoholic cirrhosis<sup>[62,63]</sup>. In one study, 60% of the 202 LT recipients analyzed reported a life time history of smoking, with 54% using both alcohol and tobacco in the pre-transplant period. Of those who quit, 20% patients had a relapse to smoking in the post-LT period<sup>[75]</sup>. In another study, a higher proportion of transplanted patients had a positive smoking history compared to transplants for non-alcoholic diseases (82% *vs* 45%,  $P = 0.001$ ), with a higher mean number of cigarettes smoked by alcoholics (25 *vs* 16 cigarettes per day,  $P = 0.001$ )<sup>[76]</sup>.

The development of malignancy has a significant impact on patient survival, with about 38% and 53% risk of death at 1 and 5 years after diagnosis<sup>[68]</sup>. *De novo* malignancy accounts for 30%-40% of all deaths in LT recipients who survive the first year after transplantation<sup>[77,78]</sup>. Implementation of intensive surveillance protocols in the post-transplant period has been shown to improve survival by detection of these cancers at an early stage<sup>[79,80]</sup>. Patients should be instructed to use sun screens when exposed to sun, come for annual physical checkup including skin and ENT examinations, and avoid use of nicotine and alcohol. Intensive protocols have included annual chest X-ray, urine examination, CT chest, abdomen and pelvis, mammography, PAP smear, in addition to standard guidelines for colonoscopy screening. With such a protocol, the overall survival in the surveillance group showed significant improvement (11.3 years *vs* 3.1 years,  $P = 0.001$ )<sup>[79]</sup>. However, clear guidelines for other cancers including the frequency of work-up have not been developed.

A higher occurrence of neurological complications has been reported in patients transplanted for alcoholic liver disease, resulting in greater resource utilization<sup>[81,82]</sup>. These include profound confusion in the early postoperative period, and structural injury from prolonged alcohol use which remained unrecognized before transplant<sup>[83,84]</sup>. Therefore, detailed and accurate pre-transplant assessment for neurological issues is needed in patients with alcoholic-related cirrhosis, as alluded to earlier in the pre-transplant evaluation section.

## LIVER TRANSPLANTATION FOR ALCOHOLIC HEPATITIS

Alcoholic hepatitis is a distinct clinical syndrome seen in patients with chronic and active alcohol use with a potential for mortality of 40%-50% in patients with untreated severe disease. Alcoholic hepatitis occurs in 35%-40% of patients with chronic excessive alcohol use, and represents about 0.2% (20 of every 1000) hospital admissions in the United States<sup>[85,86]</sup>. The true prevalence is difficult to assess as many patients remain undiagnosed and only

10%-35% of alcohol-related cirrhotic may have changes consistent with alcoholic hepatitis on liver biopsy<sup>[87]</sup>. The incidence rates of ALD-related deaths decreased from 6.9/100000 persons in 1980 to 4.4/100000 persons in 2003. The age- and sex-adjusted alcoholic liver disease related mortality (per 100000 persons) decreased from 6.3 to 4.5 in Caucasians, 11.6 to 4.1 in African Americans, and 8.0 to 3.7 in the "other" race groups<sup>[88]</sup>. Overall, the incidence of alcoholic hepatitis is about 7%-10% in mild illness and 40%-50% with severe disease<sup>[85-89]</sup>. Although, mortality from alcoholic hepatitis has decreased over the last decade as with alcoholic cirrhosis, patients with alcoholic hepatitis and concomitant HCV infection remain at a higher risk of death with 20%-25% higher mortality as compared to alcoholic hepatitis patients without HCV infection<sup>[86]</sup>. One of the possible reasons may be fear of physicians and gastroenterologists in using corticosteroids for the treatment of alcoholic hepatitis in the presence of HCV infection<sup>[90]</sup>. More studies are needed aimed at generating guidelines for managing alcoholic hepatitis patients who also have HCV infection.

The available treatment options that include the use of corticosteroids and/or pentoxifylline achieve about 50% survival benefit, with the likelihood of mortality in about 20%-25% patients<sup>[85,89]</sup>. With the current lack of available pharmacological options for patients with non-response to steroids, there remains an unmet need for the development of newer and more effective drugs. These patients generally do not qualify for LT because of the requirement of 6 mo of abstinence demanded by most transplant centers worldwide. This requirement cannot be met by alcoholic hepatitis patients who do not respond to steroids since by definition they were drinking up until at least 3 wk prior to getting sick. Further, there are other ethical concerns and controversies involved in the use of LT for these patients such as: (1) public opinion that this disease is self-inflicted; (2) shortage of donor livers and the view that they should be allocated to more deserving patients; and (3) the risk of recidivism after LT<sup>[91]</sup>. The other side of the argument is that pre-transplant abstinence of 6 mo is not a strong predictor of recidivism. Further, patients transplanted for alcoholic cirrhosis with histological changes consistent with alcoholic hepatitis on explants have been shown to have similar post-LT survival compared to patients without such histological changes<sup>[87]</sup>. An obvious ethical question is whether severe alcoholic hepatitis patients who do not respond to treatment should be left to their fate to die or should be considered for LT as suggested by the French consensus group<sup>[91]</sup>.

The same group took the lead and challenged the 6 mo abstinence rule in a prospective case control study. In this study, 26 patients (mean age 47 years, 58% males) with a first episode of severe alcoholic hepatitis (median MELD 30<sup>[22-47]</sup>) who did not respond to steroids were recruited from four different centers in Europe (2006-2010) and received LT as a life-saving option. The patients underwent detailed and rigorous psychosocial evalua-

tion by the resident team, hepatologist, anesthesiologist, and surgeon and LT was approved only if all four teams cleared the patient. The median duration between declaring a patient as non-responder to steroids (Lille score  $\geq 0.45$ ) and receipt of LT was 9 (1-13) d<sup>[92]</sup>. Compared to the 26 matched patients who did not receive LT (control group), patients receiving LT had a significantly better outcome at 1 mo (77%  $\pm$  9% *vs* 25%  $\pm$  8%,  $P < 0.001$ ) and at 2 years (73%  $\pm$  8% *vs* 23%  $\pm$  8%,  $P < 0.001$ ). Patients receiving LT had survival similar to patients responding to steroid treatment (78%  $\pm$  8% *vs* 83%  $\pm$  4%,  $P = 0.33$ )<sup>[92]</sup>. As can be seen, the majority of deaths in the control group occurred within the first month, indicating the importance of transplanting these patients early without waiting for the 6 mo abstinence requirement. Three patients resumed alcohol intake at 720, 740, and 1145 d after LT. The first two patients reported harmful drinking of 30 g/d and  $> 50$  g/d of alcohol respectively, while the 3<sup>rd</sup> patient was consuming a lower amount, about 10 g/wk. However, recidivism in this study was self-reported which is known to be frequently inaccurate<sup>[92]</sup>. None of the patients lost the graft due to alcohol use. However, three of the 6 deaths in this study were due to invasive fungal infections. This is unlikely to be due to pre-existing infections as all these patients were undergoing daily rigorous infection work-up prior to LT. Prospective studies are required to evaluate strategies of immune suppression for preventing fungal infections. The authors concluded that LT should be considered as a salvage option in select patients with severe alcoholic hepatitis who do not respond to steroids. With the strict selection of patients, only about 2%-3% of the original cohort with alcoholic hepatitis was amenable to this treatment modality<sup>[92]</sup>. In the United States, nearly 50000 patients with alcoholic hepatitis are admitted annually. Considering that about 20% of these patients have severe disease, which translates to about 200-300 patients who may qualify for LT as a therapeutic option. However, any amendment in the guidelines for liver transplantation in patients with alcoholism may have an adverse impact on public preferences for liver-transplant allotment and may decrease willingness to donate. However, this has not occurred in response to transplantation being offered to patients with fulminant hepatic failure due to self-inflicted acetaminophen poisoning, or in intravenous-drug users with acute hepatitis B virus infection. Before implementing this in routine practice, with the potential of adversely affecting the liver donor pool, more data are needed on larger patient populations. Until then, there is a ray of hope for patients with a first episode of alcoholic hepatitis who do not respond to steroids and have excellent psychosocial support systems.

Similar findings were reported in a retrospective study using the UNOS database. In this study, 55 patients (mean age 51 years, 76% males) received LT (2004-2010) for a listing diagnosis of alcoholic hepatitis (median MELD 24<sup>[16-34]</sup>). The results were compared with 165 patients (matched for age, gender, UNOS region, MELD score,

and donor risk index), transplanted for alcoholic cirrhosis. There was no difference in the respective outcomes at 1, 3, and 5 years for liver graft survival (87% *vs* 84%,  $P = 0.58$ , 82% *vs* 77%,  $P = 0.47$ , and 75% *vs* 73%,  $P = 0.97$ ) and patient survival (93% *vs* 88%;  $P = 0.33$ , 87% *vs* 81%,  $P = 0.33$ , and 80% *vs* 78%,  $P = 0.91$ )<sup>[93]</sup>. A higher proportion of alcoholic hepatitis patients had concomitant HCV infection compared to the alcoholic cirrhosis controls (27% *vs* 7%,  $P = 0.02$ ). After controlling for HCV and other recipient and donor factors, the graft and patient survival was not different, with OR (95%CI) of 0.82 (0.41-1.63) and 0.7 (0.33-1.54) respectively<sup>[93]</sup>. Since patients with alcoholic hepatitis have underlying alcoholic cirrhosis in about 60%-70% cases, the outcomes were also compared based on the explant diagnosis. A total of 46 patients with an explant diagnosis of alcoholic hepatitis were compared with 138 patients with an explant diagnosis of alcoholic cirrhosis, again the outcomes were similar. Moreover, 11 patients with a listing as well as explant diagnosis of alcoholic hepatitis compared to 33 patients with a listing and explant diagnosis of alcoholic cirrhosis had equivalent outcomes<sup>[93]</sup>. None of the patients died or lost their graft secondary to alcohol use. However, in addition to the drawbacks of a retrospective study, this study was limited by the lack of information on alcohol drinking history.

## SUMMARY AND FUTURE PERSPECTIVES

In conclusion, alcoholic cirrhosis remains the second most common indication for LT. Although, outcomes are excellent in general, recidivism does impact long-term survival. Graft loss and recurrent alcoholic liver disease rarely leads to mortality. However, the development of metabolic syndrome and *de novo* malignancy contribute to the majority of deaths in the long term. The emerging data on the beneficial role of LT provides a ray of hope for select patients with alcoholic hepatitis with the following characteristics: (1) first episode of severe alcoholic hepatitis; (2) failure to respond to pharmacological approach; and (3) excellent psychosocial support. However, certain unsettled issues need to be resolved. These include: (1) The current discrimination for transplant evaluation and transplant listing of patients with alcoholic cirrhosis; (2) physician and center based barriers to liver transplant evaluation and listing; (3) accurate predictors independent of pre-transplant sobriety duration for post-transplant relapse to heavy drinking; (4) genetic factors in the donor graft that may protect the recipient from recurrent disease despite relapse to heavy drinking; (5) simple and accurate biomarkers for use in clinical practice to detect recidivism with a long window period; (6) cost-effective surveillance protocols for early detection of *de novo* malignancy after liver transplantation; (7) creation of a prospective database on the outcome of LT in patients with a first episode of acute alcoholic hepatitis; and (8) development of better immune suppression regimens in these patients, especially

in reducing invasive fungal infections.

60% in most studies, both for rectal wall invasion and for lymph nodes involvement. In particular the ability to predict complete pathological response, in order to tailor the surgical approach, remains low. Due to the radio-induced tissue modifications, combined with imaging technical aspects, low rate accuracy is achieved, making modern imaging techniques still unreliable in restaging rectal cancer after chemo-radiotherapy.

**Key words:** Rectal cancer; Restaging; Neoadjuvant therapies; Diagnostic accuracy; Complete pathological response

### Abstract

In patients with advanced rectal cancer, neoadjuvant chemo radiotherapy provides tumor downstaging and downsizing and complete pathological response in up to 30% of cases. After proctectomy complete pathological response is associated with low rates of local recurrence and excellent long term survival. Several authors claim a less invasive surgery or a non operative policy in patients with partial or clinical complete response respectively, however to identify patients with true complete pathological response before surgical resection remains a challenge. Current imaging techniques have been reported to be highly accurate in the primary staging of rectal cancer, however neoadjuvant therapy course produces deep modifications on cancer tissue and on surrounding structures such as overgrowth fibrosis, deep stroma alteration, wall thickness, muscle disarrangement, tumor necrosis, calcification, and inflammatory infiltration. As a result, the same imaging techniques, when used for restaging, are far less accurate. Local tumor extent may be overestimated or underestimated. The diagnostic accuracy of clinical examination, rectal ultrasound, computed tomography, magnetic resonance imaging, and positron emission tomography using 18F-fluoro-2'-deoxy-D-glucose ranges between 25% and 75% being less than

**Core tip:** Neoadjuvant chemoradiotherapy has become the standard treatment for patients with advanced rectal cancer allowing reduction of local recurrences and increased sphincters' preservation. New trends have proposed the possibility to change the planned surgical resection after neoadjuvant treatment, in case of extensive tumor response, and several Authors claim limited resection or non operative "wait and see" policy. In this setting restaging plays a crucial role in identifying patients with complete response. The diagnostic accuracy in predicting tumor response of the currently available imaging techniques is extensively reviewed in order to determine the reliability.

### INTRODUCTION

In the last two decades the treatment of rectal cancer has been modified by virtue of the introduction of neoadju-

vant treatment<sup>[1]</sup>, better imaging techniques and improvement of surgery with total mesorectal excision (TME). The crucial goals reached by upgrading diagnostic techniques and therapeutic strategies accounts for reduction of local recurrence rate and increase of sphincter preserving surgeries.

Preoperative chemoradiation therapy (CRT) has become the standard treatment in the last decade<sup>[1-3]</sup>. Advantage of neoadjuvant treatment is the downsizing/downstaging of the tumor thus allowing the preservation of the sphincter, in case of extremely distal rectal lesions, and, often, avoiding multiorgan resection in case of responding tumor that had involved other organs before the neoadjuvant regimen. The overall benefits of this therapeutic regimen are, eventually, the reduction rates of local recurrence and the improvement in survival<sup>[4-7]</sup>.

Reduction of local recurrence after surgery was first achieved with the introduction of complete excision of the visceral rectal mesentery, bringing up the concept that mesorectum harbors positive lymph nodes and tumor residues<sup>[8]</sup>. Moreover, it has been highlighted that surgical local radicality has to be carried out by improving the control on radial margins tumor-spread other than distal and proximal ones<sup>[9,10]</sup>. These findings have been demonstrated by pathological analysis of circumferential resection margin (CRM).

The key of neoadjuvant treatment and restaging of the tumor is, finally, the possibility of changing the planned surgical treatment and, in particular, the chance of providing a sphincter preserving procedure. In a more experimental way, new trends have proposed local resection in case of extensive tumor response<sup>[11]</sup> or a non-surgical “wait-and-see course” in case of complete tumor regression<sup>[12-15]</sup>. On the contrary, for non-responding or poor responding rectal tumors, more aggressive, traditional surgery, after restaging, is indicated. This decision depends mostly on the reliability of the imaging techniques provided by modern technology and the synergy between the radiologist and surgeon.

The main issue of re-staging after CRT with imaging techniques, is to discriminate cancerous mass from non malignant tissue because of the radio induced overgrowth fibrosis<sup>[16]</sup>. Tumor tissue changes, during and within 6-8 wk after chemo-radiotherapy, account for deep stroma alteration. Fibrosis compresses the colon tissue and ends up in causing wall thickness and muscle disarrangement. Other variation are tumor necrosis, calcification, and inflammatory infiltration of lymphocytes and macrophages<sup>[17]</sup>.

The tumor regression grade (TRG) exactly reflects the ratio between residual tumor percentage and overgrowing fibrosis percentage. Thus the more reliable restaging technique has, eventually, the goal to predict TRG because it positively correlates with disease free and overall survival<sup>[18]</sup>. Ideally, precise staging of rectal cancer has to define the tumor depth of invasion through the rectal wall, detect positive lymphnodes, and establish the resectability of locally advanced tumors.

Several techniques have been described to restage rectal carcinoma after CRT, the most predominantly used being computer tomography (CT) scan, rectal ultrasounds (RUS), and magnetic resonance imaging (MRI).

In the present study we revise the accuracy and reliability of current techniques, used to re-stage rectal cancer after neoadjuvant therapy, in terms of sensitivity, specificity, and diagnostic accuracy, compared with pathological findings after surgical resection. Special attention will be paid to the ability to predict complete response (cPR).

## CLINICAL EXAMINATION

There is no doubt that clinical examination, comprising digital rectal examination (DRE) and proctoscopy, is the first and essential approach to patients with rectal cancer. Moreover, clinical assessment of response to CRT may provide important information regarding the surgical strategy. Nevertheless few studies evaluated the accuracy of clinical assessment in predicting tumor response after completion of CRT, and the majority of these studies were retrospective. Clinical assessment may underestimate<sup>[19,20]</sup> or overestimate<sup>[21]</sup> pathological response therefore most authors claim that clinical examination is inaccurate and should not be used as the unique mean to define the efficacy of neoadjuvant therapy.

Only 2 studies tried to answer the question whether clinical parameters are able to predict cPR. In the study by Perez *et al*<sup>[22]</sup>, 99 patients were prospectively examined, by the same experienced colorectal surgeon, after 12 wk from completion of CRT; 16 patients had a complete clinical response (cCR), 3 underwent local excision of a residual scar, and a cPR was confirmed; 13 patients were enrolled in a strict follow-up without radical surgery, only one patients subsequently developed a local recurrence after a mean follow-up of 42 months; moreover the cCR positively correlated with the PET results<sup>[22]</sup>. On the contrary Hiotis *et al*<sup>[23]</sup> retrospectively analyzed 448 patients and found that 75% of patients with cCR had residual cancer in the resected specimens: 60% having T2 or T3 disease, and 18% node-positive disease. In addition, in the group of patients with no residual primary tumor at histology (T0), the percentage of node positivity was 15%.

Habr-Gama *et al*<sup>[24]</sup>, in an effort to standardize the clinical findings, clearly defined clinical and endoscopic sign to define complete response as: whitening of the mucosa, with or without telangiectasia, or loss of pliability of the rectal mucosa, absence of deep or superficial ulceration, or palpable nodule or stenosis located in previously tumor bearing area. Nevertheless the likelihood of detecting occult nodal disease in patients with no residual primary tumor is highly unlikely.

In conclusion even if clinical parameters may predict tumor response, they are unable to distinguish cPR and to predict which patient does not require surgical excision following CRT.

## RECTAL ULTRASOUNDS

The assessment of rectal tumor by means of ultrasonography is based on the evaluation of depth of invasion through the 5 layers of the bowel wall. With high resolution probes T1-2 tumors can be correctly diagnosed and even SM1, SM2 and SM3 tumors can be recognized<sup>[25]</sup>. On the other hand the mesorectum and peritoneum cannot be visualized by endorectal probe thus limiting the use of ultrasound for the evaluation of CRM.

Endorectal ultrasound can visualize perirectal lymph nodes and nodes located in the mesorectum while lymph nodes along the mesentery or the upper pelvis are generally unreachable. Normal lymph nodes are usually not seen sonographically. Enlarged lymph nodes are considered benign if oval shaped, and thought to be inflammatory if hyper echoic with well defined margins. There is no agreement as when to consider a lymph node as pathological. Dimensional, morphologic, and echographic pattern are to be considered. Nodes greater than 5 mm, round shaped and with echogenicity similar to the primary tumor (hypoechoic), are usually considered as predictors of metastatic involvement by most, but not all authors, who may choose only one of the aforementioned parameters, in particular size is considered the most reliable feature.

Different probes are employed for imaging rectal cancer including transrectal rigid, rotating or non rotating probe, either two-dimensional or with three-dimensional reconstruction, flexible endoscope either radial or linear, miniprobes able to pass through the biopsy channel<sup>[26]</sup>, with frequency ranging between 5 and 10 MHz. No comparison of the performance of different instruments has been made up to now. Unlike other imaging modalities, the endorectal ultrasound in the different settings is performed by a radiologist, a gastroenterologist or a colorectal surgeon, and this could be a further confounding factor when examining the accuracy of the examination.

There is no consensus regarding the time that must elapse between CRT and evaluation. The majority of the authors re-examined the patients after 4 to 6 wk. However a better diagnostic accuracy for N staging has been reported by Huh when the patients are re-evaluated after 7 wk<sup>[27]</sup> from completion of CRT.

Accuracy in T restaging ranges between 27% to 72%, with overstaging between 16% and 53%. In the majority of the studies T1-2 stage are more misdiagnosed than T3<sup>[8,9,11-13,16,18,28-30]</sup>. When examining the accuracy to correctly diagnose T0 the figure drop to 0% to 60%<sup>[31-33]</sup>. Gavioli *et al*<sup>[29]</sup> studied the modification of morphology induced by radiotherapy in 29 patients. They found that fibrosis replacing tumor corresponded to hypoechoic pattern at ultrasound that was difficult to differentiate from the pattern related to the tumor itself, thus inducing overstaging. In some cases of complete pathological response the fibrosis caused persistent interruption of the 5 layers leading to misinterpretation of the examination.

The accuracy in restaging lymph nodal involvement is somehow higher than accuracy for primary tumor, ranging between 39% and 83% and being around 70% in most studies. For this parameter overstaging was only slightly more common than understaging (8%-39% *vs* 11%-28%). Correct identification of N0 varies between 70% and 80%<sup>[8,9,11-13,16,18,28-30,34]</sup>. Moreover 13%-55% of patients with lymph nodal involvement were recognized as N0<sup>[30,34,35]</sup>.

When compared with other imaging techniques, namely CT and standard MRI, ultrasound resulted the most accurate in determining rectal wall infiltration and lymph node involvement in some studies<sup>[31]</sup>, while performed worse in others<sup>[27]</sup>.

It is of note that in the majority of the studies diagnostic accuracy is reported separately for T and N stage, thus preventing accuracy for complete pathological response (ypT0N0) to be determined. Kahn examined 25 patients with T0N0 tumors after preoperative radiotherapy and reported that endorectal ultrasound failed to detect the absence of disease in 83% of patients, with overstaging of T0 lesions diagnosed as T1 in 67% of cases and T2 in 16%. In the 25 patients' series of Maor, ultrasound correctly predicted postchemoradiation T0N0 stage in only 50% of cases. Radovanovic reported only one correct diagnosis out of 5 patients (20%) with cPR<sup>[36]</sup>. While complete remission was not correctly predicted in any of the 11 patients by Huh *et al*<sup>[27]</sup>.

The occurrence of uT0 harboring microscopic foci of tumor at histology is also reported<sup>[35]</sup>.

In conclusion endorectal ultrasound is insufficient in detecting which tumors become T0N0 after neoadjuvant treatment to possibly undergo limited resection or non-operative treatment.

## COMPUTER TOMOGRAPHY

CT is one of the preferred tools to evaluate tumor response, in relation to the tumor size modification, because of its high reproducibility and availability. Compared with the other commonly used techniques, CT scan is more largely accessible, faster, inexpensive and less operator-dependent. Also the unique advantage of CT is that a single scan provides staging for local tumor and distant metastasis. Therefore every re-staging techniques pattern usually includes a total body CT scanning.

Accuracy of CT scan in predicting T stage after neoadjuvant course is still debated in the literature and the results are often inconsistent or discordant<sup>[17,27,37]</sup>.

In a recent study, 90 patients with locally advanced rectal cancer were prospectively analyzed before and after neoadjuvant regimen. Accuracy of CT in predicting pathological T after radiotherapy was low (37%). However CT was reported to be accurate in the identification of involved CRM (71%)<sup>[37]</sup>. Conversely, Lee *et al*<sup>[17]</sup> have demonstrated, in a series of 91 patients undergoing CT restaging after neoadjuvant course, that T status positively correlated with pathological examination with an accu-

cy of 61%. Moreover they found a statistically significant correlation with CT downstaging assessment and TRG at pathology. However over staging was frequently found in patients with fibrosis and alteration in muscle disarrangement<sup>[17]</sup>. In the study conducted by Huh *et al*<sup>[27]</sup> on 80 patients, CT accuracy in restaging the depth of rectal wall invasion was poor (46.3%). CT was also found to more likely overstage T3 tumor and understage T2 ones<sup>[27]</sup>.

Finally CT scan is commonly considered an unreliable restaging technique to assess cPR<sup>[17,38]</sup>. In none of patients retrospectively analyzed by Huh CT scan was able to predict cPR<sup>[27]</sup>.

Nodal involvement detection plays a crucial role in those selected cases which are candidates to receive a local excision after extensive tumor response. In a local excision setting, it is compulsory to be aware of any residual nodal disease risk. Moreover the size of lymph nodes “per se” is considered not satisfactory for the determination of presence of disease. It has been shown that also texture arrangement and nodes profile are prognostic factors for malignancy<sup>[39,40]</sup>. However restaging lymph nodes after neoadjuvant course could also be more complex since radiotherapy has the ability to reshape and modify the size and the texture of the nodes.

In terms of nodal involvement CT has an accuracy of 82% by using a cut off of 10 mm<sup>[37]</sup>. On the contrary, in a 5mm cut-off setting, accuracy has been reported to be 62%<sup>[38]</sup>. In Huh series, with respect to nodal involvement, CT demonstrated a sensitivity of 56% and a specificity of 74%.

## MAGNETIC RESONANCE IMAGING

MRI currently plays a crucial role in the primary staging of rectal cancer by leading the therapeutic management. MRI shows high accuracy in the assessment of CRM and sphincter invasion assessment<sup>[3,4,41-43]</sup>, and high resolution T2 weighted images are considered the standard sequences to evaluate rectal cancer<sup>[44,45]</sup>.

However, when it comes to restage rectal cancer, MRI utility remains debatable. Several Authors have reported a reduction of its accuracy after neoadjuvant regimen<sup>[46,47]</sup>. Accuracy in predicting rectal wall invasion is 50% (sensitivity, 100%; specificity 35%) and nodal involvement is 65%<sup>[48]</sup>. Prediction of CRM is reported to be 66%-85%<sup>[37,43]</sup>.

The disappointing accuracy of MRI imaging in restaging rectal cancer is due both to overstaging and understaging<sup>[48]</sup>. Typically, overstaging, in the assessment of rectal wall invasion, occurs because after radiotherapy the responding tumors can be replaced by fibrosis, inflammatory and vascular proliferation<sup>[7,48]</sup>. This often results in overstaging T1 or T2 tumors<sup>[46,47]</sup> because tumors are surrounded by diffuse hypointense tissue infiltration<sup>[48]</sup> and the thickness caused by fibrosis is overestimated by MRI. Another common cause of overstaging is radio-induced ulceration or proctitis<sup>[48]</sup>. Understaging is usually due to the inability to detect a small residual tumor overwhelmed

by fibrotic tissue<sup>[46,47]</sup>. To overcome this issue, Kim *et al*<sup>[48]</sup> suggested that comparison of both pre- and post neoadjuvant course should be mandatory to improve the accuracy of MRI restaging. Position, extension, and signal intensity of the tumor are to be considered the key points to compare MRI images before and after neoadjuvant course<sup>[48]</sup>. Measurement of tumor size by three dimensional MR volumetry can be effective to establish tumor downsizing and it has shown good correlation with ypT stage after neoadjuvant regimen<sup>[49,50]</sup>. Perfusion MRI imaging is able to determine tumor vascularization which reflects aggressiveness of the tumor. The microcirculation enhancement could suggest an increased tumor angiogenicity. Thus this technique is reported to be effective in predict tumor response to neoadjuvant course<sup>[51-53]</sup>. Moreover, in diffusion weighted MRI, apparent diffusion coefficient (ADC) could be a useful parameter to predict responsiveness of tumor to neoadjuvant treatment. ADC reduction has been associated to cell apoptosis and increased response to radiotherapy<sup>[54,55]</sup>. It is crucial also to consider that some histological types of adenocarcinoma have different behavior under CRT and different appearance at MRI. For instance, mucinous adenocarcinoma is more aggressive than usual adenocarcinoma and its typical feature is the production of mucin. This histological type is considered poor responder to neoadjuvant and, noteworthy, the great amount of mucin leads to misinterpretation of MRI imaging<sup>[56]</sup> because of its high signal intensity on T2 weighted images<sup>[48,57]</sup>.

Nodal staging by MRI usually relies on size criteria. Typically a lymph node is considered malignant when its short axis measure over 0.5 cm<sup>[58,59]</sup>. It has been reported that also the examination of imaging features such as undefined edges, dissimilar signal enhancement within the node could increase the accuracy of MRI<sup>[39,60]</sup>. Nonetheless, due to fibrosis, undefined borders might be detected after chemoradiotherapy in negative nodes<sup>[48]</sup>. Therefore lymph nodes restaging often results in overstaging because, usually, alteration of nodes structure after radiotherapy is associated with tumor invasion<sup>[46,47]</sup>. New promising strategies using lymph node specific paramagnetic nanoparticles have been reported to increase the accuracy in detecting micro metastasis<sup>[61-63]</sup>.

## PET

Positron emission tomography using <sup>18</sup>F-fluoro-2'-deoxy-D-glucose (FDG-PET) is a diagnostic modality that visualizes the cellular glucose metabolism; it exploits the enhanced glycolysis in tumor cells to distinguish cancer from surrounding tissue with normal metabolic activity. Nowadays functional PET images are coupled with anatomical computed tomography scan so that PET/CT is normally employed for better tumor localization and improvement of diagnostic accuracy<sup>[64,65]</sup>.

PET/CT has been used as noninvasive tool in rectal cancer patients, after neoadjuvant CRT, to detect metabolic activity in the residual tumor and to assess change induced by the treatment<sup>[66,67]</sup>. There is however lack of

uniformly regarding several issues: time interval between end of treatment and examination, parameters used to evaluate tumor response, and criteria to define and measure response.

Radiotherapy and chemotherapy cause tissue inflammation with accumulation of FDG uptake<sup>[68,69]</sup>, since this reaction may last up to several months from the end of treatment, the choice of the time interval to perform the examination is of crucial importance. In addition radiotherapy and chemotherapy can produce a confounding effects called “stunning” a reversible phenomenon characterized by temporarily decrease of glucose metabolisms in viable tumor cells, lasting several weeks. Although the optimal time for the acquisition of PET images has not been established, the control is performed by most authors after 4-6 wk from the end of CRT; it seems that earlier restaging could underestimate tumor response<sup>[70]</sup>.

Different parameters can be used to evaluate tumor response: maximum standardized uptake value (SUV<sub>max</sub>), absolute difference ( $\Delta$ SUV<sub>max</sub>), mean standardized uptake value (SUV<sub>mean</sub>), percent SUV max difference (response index RI), and change in total lesion glycolysis ( $\gamma$ TLG). Depending on the adopted criteria sensitivity and specificity may vary widely. Moreover different cut off value are reported for each parameter producing different diagnostic accuracy. In the majority of the studies the evaluated end point is response to treatment, in relation to regression in T stage or TRG (tumor regression grade). It is important to underline that, for the reasons previously mentioned, and for the limited spatial resolution of PET, that ranges between a 0.4- and 1.0-cm<sup>[71-74]</sup>, it is almost impossible to distinguish major to complete pathological response and therefore to find out  $\gamma$ T0N0 tumors. Sensitivity and specificity of FDG-Pet in predicting response, irrespectively from criteria and cut off value, range between 45%-84.5% and 79%-81%<sup>[73,75-79]</sup>. Few authors evaluated the relation between PET and complete pathological response. In the series of Cho *et al*<sup>[64]</sup> 18F-FDG PET/CT correctly predicted three of the four patients with a pathologic complete response after preoperative CRT. While the only patient with complete response at histopathology was correctly detected by visual FDG-PET analysis by Denecke *et al*<sup>[80]</sup>.

In conclusion although FDG-PET can be considered a promising tool to assess metabolic response after neoadjuvant treatment and to recognize patients more prone to respond to radio chemotherapy from non responders, its role in defining complete response to tailor the therapy is far to be reached.

## CONCLUSION

Neoadjuvant course is effective in producing downstaging and downsizing of locally advanced rectal tumor. Tumor response to such treatment has been significantly associated with improved outcome after surgical resection<sup>[81,82]</sup>.

Enthusiasm about these findings has drove inves-

tigators to sphincter preserving and organ sparing surgery<sup>[83,84]</sup>. In this setting, trans-anal resection of partial responder tumor with negative lymph node assessment by pelvic imaging could be considered as paradigm organ sparing resection.

Moreover the effects of cytoreduction, provided by multimodality treatment, can produce complete clinical response (absence of clinically detectable tumor) or complete pathological response (absence of viable tumor cells at pathology examination after cancer resection) in up to 30% of patients<sup>[5,23,85-87]</sup>. Given that rectal resection is related to significant morbidity, several authors have recommended careful “wait and see strategy” in clinical complete response cases<sup>[13,88-90]</sup>. In this setting rectal cancer restaging after multimodality treatment has been claimed to provide adjustment of the surgical conduct.

Current imaging techniques have been reported to be highly accurate in the primary staging of rectal cancer. On the other hand, radiotherapy and chemotherapy course produce deep modifications on cancer tissue and on surrounding structures. As a result, when used to restage rectal cancer after CRT, the same imaging techniques produce inconstant results. Indeed pathological T stage and lymph nodes status prediction has been shown to be far less inaccurate when compared to primary staging.

Overstaging is a basic issue of current imaging modality. The overstaging is commonly due to the inability of distinguish residual tumor from radio-induced desmoplastic reaction and overgrowth fibrosis in the surrounding tissue. False positive diagnosis can clearly lead to over treat patients that indeed could take advantage of organ sparing surgery such as local excision for  $\gamma$ T1 N0 tumors. Moreover this possibility could be considered for high surgical risk patients thus avoiding morbidity and mortality of rectal resection.

On the contrary, understaging could lead to consider local excision in patients with occult mesorectal positive lymph node, thus producing a non-oncological resection with consequent reduction of survival. Furthermore it has been reported that, after radiotherapy, local recurrence could be more aggressive than native tumor and the situation could be more concerning when leaving untreated patients with complete response without surgically removing the site of the tumor<sup>[91]</sup>.

However, Habr-Gama *et al*<sup>[13]</sup> found no significant difference in terms of survival and disease free rate when comparing patients with complete clinical response undergoing “wait and see policy” and patients with histologically proven complete response after surgery. Interestingly this group, when assessing complete pathological response, mainly relies on direct endoscopic visualization of rectal mucosa and uses additional radiological studies only in case of recurrence suspicion<sup>[24]</sup>.

Although currently available imaging techniques display an overall low accuracy in restaging rectal cancer, CT scan and MRI are efficient in excluding tumor extent to adjacent organs (T4 tumor) and CRM invasion<sup>[57]</sup>.

Clear assessment of lymph node status should be provided when considering local tumor excision due to the risk of leaving positive mesorectal nodes. Prediction of lymph node positivity is reported to be still poor. Moreover there is no consensus about the standard criteria to define lymph nodes positivity. It is clear that the size measurement only is not reliable and analysis of nodal contour, shape and structure has to be considered to improve the accuracy of restaging.

In conclusion modern imaging techniques are unreliable in restaging rectal cancer after CRT given the low correspondence between pathological status prediction and actual pathological assessment. In our opinion imaging evaluation patterns are to be reexamined to reduce the false positive and false negative percentage and to broaden diagnostic accuracy.

### Abstract

Irritable bowel syndrome (IBS) is common gastrointestinal problems. It is characterized by abdominal pain or discomfort, and is associated with changes in stool frequency and/or consistency. The etiopathogenesis of IBS may be multifactorial, as is the pathophysiology, which is attributed to alterations in gastrointestinal motility, visceral hypersensitivity, intestinal microbiota, gut epithelium and immune function, dysfunction of the brain-gut axis or certain psychosocial factors. Current therapeutic strategies are often unsatisfactory. There is now increasing evidence linking alterations in the gastrointestinal microbiota and IBS. Probiotics are living organisms which, when ingested in certain numbers, exert health benefits beyond inherent basic nutrition. Probiotics have numerous positive effects in the gastrointestinal tract. Recently, many studies have suggested that probiotics are effective in the treatment of IBS.

The mechanisms of probiotics in IBS are very complex. The purpose of this review is to summarize the evidence and mechanisms for the use of probiotics in the treatment of IBS.

**Key words:** Probiotics; Irritable bowel syndrome; Visceral hypersensitivity; Brain-gut axis; Immune function

**Core tip:** Irritable bowel syndrome (IBS) is a common gastrointestinal problem and its etiopathogenesis is not fully understood. So the treatments of IBS are based on the predominant symptom. But these treatments are often unsatisfactory. Probiotics have numerous positive effects in the gastrointestinal tract. Many studies have shown that probiotics are effective in the treatment of IBS. In this review, we have summarized the efficacy, the safety and the mechanisms of probiotics in IBS.

### INTRODUCTION

Irritable bowel syndrome (IBS) is one of the most frequent gastrointestinal problems. IBS has a prevalence of 12%-20% of the population worldwide and 18%-23% in China, and it is 2-3 times more common in women than men<sup>[1]</sup>. About 20%-38% of IBS patients will consult their doctor, accounting for 12% of visits to general practitioners, 28% of visits to specialists, and a significant percentage of visits to outpatient departments of tertiary level hospitals<sup>[2]</sup>.

IBS is characterized by abdominal pain or discomfort, which is relieved by defecation or the passage of gas,

and is associated with changes in stool frequency and/or consistency, without physical, radiological or endoscopic abnormalities or laboratory findings indicating organic disease<sup>[3]</sup>. Abdominal bloating or distension affects 15%-30% of the general population, but is increased to 75%-90% in female IBS patients and constipation-predominant IBS<sup>[4]</sup>. In all, 28% of IBS patients suffer from abdominal bloating all the time, which is slightly less than abdominal pain (33%)<sup>[5,6]</sup>. Many IBS patients state that abdominal discomfort is greater than abdominal pain. It is worse in the afternoon and evening, but better at night; it becomes worse when standing and is relieved when in a supine position. There is no correlation with defecation or retaining flatus, although it is worsened by eating and menstruation. Other gastrointestinal symptoms are also common: incomplete defecation, burning pain on defecation, urgency to defecate, rectal tenesmus, esophageal balloon, heartburn, chest pain, early satiety, abdominal bloating or distension, flatulence; and extragastrointestinal symptoms: asthenia, adynamia, headache, dizziness, sleep disorders, pollakiuria, neck pain, back pain, dysmenorrhea, dyspareunia, fibromyalgia. IBS patients have more psychosocial or mental complaints, and they are absent from work due to acute common diseases. This comorbidity has a significant influence on the patient's clinical and diagnostic management, and therapeutic plan. Although the symptoms of IBS are used to establish the suspected diagnosis, individually they are not sufficiently sensitive or specific. Predictive value increases when patients are aged < 50 years and an absence of warning symptoms or signs are considered, which is not the case with another common functional digestive disorder, functional dyspepsia.

Diagnosis is fundamentally through clinical symptoms, and is based on the Rome III criteria of 2006, with the isolated exclusion of metabolic or organic diseases (benign or malignant) according to the patient's personal or family history. If there is abdominal bloating or distension, it is advisable to rule out lactose, fructose or trehalose intolerance, an excessive intake of insoluble fiber, and small intestinal bacterial overgrowth. According to Rome III there are several types of IBS: (1) diarrhea-predominant IBS; (2) constipation-predominant IBS; (3) alternating IBS (sometimes diarrhea, sometimes constipation); and (4) undefined IBS. In any of these types there may be psychological, psychosocial or psychiatric alterations, or an exaggerated intestinal response to everyday stress. It seriously affects the quality of life of those who suffer from it, and accounts for the use of large amounts of healthcare resources.

IBS patients are known to self-medicate very often. A review of the use of OTC drugs and medicines shows that they take antacids, proton pump inhibitors, fiber and laxatives, antidiarrhea agents, antispasmodics, antidepressants, sedative-hypnotics, and analgesics more frequently<sup>[7]</sup>. Treatment of IBS has been based on the predominant symptom. It must be individualized, emphasizing the absence of a serious or worrying condition,

and straightforwardly explaining the nature and cause of the symptoms. But the therapies available at present (spasmolytics or antidepressants at low doses for the pain, anti-diarrhea agents or 5HT<sub>3</sub> antagonists for diarrhea, lubiprostone, linaclotide, bulk-forming laxatives or 5HT<sub>4</sub> agonists for constipation) have only proven slightly more effective in comparison with placebo, and none have been capable of altering its natural course, as the effect disappears as soon as treatment is stopped<sup>[8-11]</sup>. At the same time IBS patients often resort to alternatives such as medicinal herbs, homeopathy, acupuncture, antibiotics, hypnosis or psychotherapy, but randomized controlled studies with these types of therapy are compromised by their low methodological quality, and in general these treatments are not recommended<sup>[12,13]</sup>.

Now there is a tendency to return to an etiopathogenesis-based or pathophysiology-based therapeutic approach, attempting to influence the possible existence of intestinal dysbacteriosis, altered intestinal fermentation and intestinal microbiota, excess production or alteration in the management of intestinal gas, but also subclinical mucosal inflammation, especially in patients in whom the onset of IBS followed an episode of acute bacterial gastroenteritis, antibiotics or immunosuppressants, because these can affect the normal balance of intestinal microflora<sup>[14,15]</sup>. Thus, one therapeutic approach in IBS patients could be to modulate intestinal microflora to correct an imbalance such as probiotics.

## MECHANISMS OF IBS

The etiopathogenesis, which is not fully understood, may be multifactorial, as is the pathophysiology, which is attributed to alterations in gastrointestinal motility, visceral hypersensitivity, intestinal microbiota, gut epithelium and immune function, dysfunction of the brain-gut axis or certain psychosocial factors. Some studies have demonstrated that there may be some autonomic dysfunction with an increased or sustained response to normal psychophysical stress in IBS patients; and further studies have found that salivary chromogranin, a derivative of catecholamines that is released in response to acute stress, is high in IBS patients and may be reduced using muscle relaxation techniques<sup>[16]</sup>. At the same time the management of intestinal gas is different in IBS patients and control subjects; whilst the latter expel the gas infused into the jejunum rapidly, the former retain it, causing them symptoms, regardless of whether or not intestinal gas production is increased<sup>[17]</sup>. Although genetic factors play a minor role compared to learned behavior, they do influence symptomatic expression and especially therapeutic response<sup>[18,19]</sup>. The specific mechanisms have been reported as follows.

### Visceral hypersensitivity

There is visceral hypersensitivity in IBS patients, expressed by: (1) increased ileocolonic response to bile acid perfusion; (2) reduced rectal adaptation to distension; and

(3) reduced pain threshold to rectal distension. Hypervigilance to digestive events would contribute to visceral hypersensitivity, perhaps due to inadequate processing of afferent information in certain areas of the central nervous system, such as the anterior cingulate cortex, the amygdala, and the dorsomedial frontal cortex, as shown by dynamic magnetic resonance imaging studies, which indicate an increase in the vascularization of these areas in response to colon stimulation that does not occur in controls<sup>[20,21]</sup>. IBS patients are more prone to take surgical interventions such as appendectomy, cholecystectomy and hysterectomy to relieve symptoms; this is because these symptoms can be mistaken for other diseases. Now it was pointed out that patients who have undergone cholecystectomy with follow-up as a cohort for 10-15 years have twice as high a risk of suffering from IBS<sup>[22]</sup>. It is assumed that the continued presence of bile salts in the colon may give rise to symptoms of IBS, as these patients are known to have a hyper response to these substances.

### Immune activation

Despite being considered a non-organic disease, it has certain organic components problems, especially in post-infectious IBS (PI-IBS)<sup>[23]</sup>. Although PI-IBS explains only 23%-35% of IBS cases, it shows the relationship between exposure to the infectious agent → mucosal and systemic inflammation → clinical expression of IBS. Increased levels of peripheral cytokines, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-1, IL-6, intraepithelial lymphocytes and CD3 and CD25 cells in the lamina propria, were found in IBS patients<sup>[24,25]</sup>. At the same time, a nonspecific microscopic inflammation with increased mast cells and neutrophils were found in mucosal biopsies. There is speculation that IBS symptoms may result from cytokine or mediator secretion by these inflammatory cells. Increased production of proinflammatory and decreased production of anti-inflammatory cytokines was in fact demonstrated<sup>[26]</sup>. In addition, a low-grade inflammatory infiltration and activation of mast cells in proximity to nerves in the colonic mucosa were found and may be involved in the pathogenesis of pain episodes. These results suggested that immune activation plays an important role in IBS patients.

### Intestinal hormone secretion

Although little is known about intestinal hormone secretion in IBS patients, high levels of cholecystokinin and vasoactive intestinal polypeptide were found in the plasma and rectosigmoid mucosa, whilst substance P (SP) and somatostatin were normal<sup>[27]</sup>. However, neuropeptide Y levels in the plasma and rectosigmoid mucosa are lower in diarrhea-predominant IBS, but not in constipation-predominant IBS.

### Intestinal microflora

Host intestinal microflora interactions lead to immune tolerance, sustain the function and integrity of the epithelial barrier and its vascularization, promote the devel-

opment and maintenance of gut-associated lymphoid tissue (GALT), and are essential for the development of jeuno-colonic motility under physiological conditions. Some studies have found that a dysregulated interaction between the intestinal bacteria, the gut barrier, the intestinal immune system and GALT play a fundamental role in IBS. Patients have a different composition of intestinal bacteria such as *Bacteroides* spp., *Bifidobacterium* spp., *Lactobacilli* spp. and others compared to healthy controls. When ribosomal RNA-based microbiological technologies were used with cloning and sequencing of genes, these differences were even more significant. These new views in the pathogenesis of IBS changed the treatment approach to influence the composition of the gut microbiota and to stop the inflammatory process and to interfere in the dysregulated intestinal immune system. Among several treatment options, the use of probiotics seemed to be promising.

## PROBIOTICS

Since Elie Metchnikoff first published “The prolongation of life: optimistic studies” in 1907, the concept of probiotics is 100-year-old now. In 1998 Guarner *et al* defined probiotics as living microorganisms that have benefits for the gastrointestinal tract and its immune function after being ingested. In 2003 the concept of “immune function of probiotics” was introduced, including the fact that probiotics modulate the immune response throughout the mucosa associated lymphoid tissue system; this idea maintains the concept that intestinal mucosa and intestinal microflora constitute an anatomical-functional unit that regulates both the cell-mediated and humoral immune responses and the local production of cytokines. In 2008, a review defined probiotics as living microorganisms, which when ingested in certain numbers, exerted health benefits beyond inherent basic nutrition.

Now probiotics are becoming an increasingly important part in the diet of everyday life, as their general and gastrointestinal beneficial effects are being gradually proven. It has become necessary to harmonize marketing criteria, evaluate the efficacy of probiotics, and correctly define what is a probiotic, what the effective doses are, and whether they are completely safe. Probiotics are defined at three levels: genus, species and strain; it is essential to understand that their properties depend on all three and cannot be assigned to other similar ones, even if they share the same genus and species. The therapeutic benefits of a strain of probiotics cannot be extended to other strains, and their efficacy has to have been proven individually. Therefore, we shall now examine evidence available to date. Usually probiotics are certain types of Streptococcus, Lactobacilli, and Bifidobacteria, but also other non-pathogenic bacilli such as *E. coli*-Nis1917 and yeasts such as *Saccharomyces boulardii*. The best known and most widely used probiotics are *Lactobacillus plantarum* 299v, *Lactobacillus rhamnosus* LGG, *Lactobacillus reuteri*, *Lactobacillus acidophilus*, *Lactobacillus casei* and *Bifidobacterium*

*infantis*, *lactis* or *brevis*. Probiotics can be administered not only as functional foods, but also in pharmaceutical forms similar to medicines. For a probiotic to be effective, five conditions must be fulfilled: (1) it must not be toxic or pathogenic; (2) it must have a proven beneficial effect on the host; (3) it must contain a sufficiently large number of viable microorganisms per unit; (4) it must be capable of surviving in the intestine, reproducing, maintaining itself, and having intraluminal metabolic activity; and (5) it must remain viable during storage and use.

## EFFICACY AND SAFETY OF PROBIOTICS IN IBS

The evidence about probiotics in the treatment of IBS is type II (grade B). It is because not all probiotics have been shown to be equally effective, and there are still relatively few studies, some of which are not randomized controlled trials (RCTs), some with a single probiotic, others with multiple species, and even some combined with prebiotics. The Clinical Practice Guideline about IBS in the Treatment section concluded that probiotics could improve the global symptoms of IBS patients based on some RCTs. In recent years there have been numerous publications, which have confirmed the effect<sup>[28-32]</sup>. Many good clinical studies using mainly lactobacilli and bifidobacteria alone or in combination have been published<sup>[33-37]</sup>. In general, it appears that probiotics are effective in IBS patients. However, looking at single trials, it seems that probiotics are more effective on single symptoms than on the entire IBS. It is difficult to compare because of variations in the study design, probiotics strains used, doses administered and formulation. There is still a need for further studies to determine the most effective species and strain, the right doses and to clarify whether a combination is better than a single strain.

The safe use of probiotics is an absolutely crucial matter. Conventional toxicology and safety evaluation has limitations for the safety assessment of probiotics. Vigorous debate continues on what constitutes appropriate safety testing for novel probiotic strains proposed for human use. In recent years several organizations have formulated approaches to assess the safety of probiotics. The Joint FAO/WHO working group on drafting guidelines for the Evaluation of Probiotics in Food proposed a framework consisting of strain identification and functional characterization, followed by safety assessment and Phase 1, 2 and 3 human trials. These studies have shown that the use of probiotics in IBS patients and healthy subjects involves a very low risk of bacterial complications, although over 80 cases of bacteremia have been reported in Finland, associated with severe prior comorbidities or surgery, and always with *Lactobacillus*<sup>[38]</sup>. Lactobacilli, Bifidobacteria and other commensal microorganisms are generally regarded as safe, although certain doubts have been raised regarding their use at massive doses in immunodepressed patients or in those who undergo intestinal resection due to benign or malignant disease<sup>[39]</sup>. Other

microorganisms such as *Enterococcus* may be opportunistic pathogens depending on host conditions.

In conclusion, the concept of using probiotics in IBS patients is interesting and it appears that certain probiotics strains are efficacious on several symptoms and very safe.

## MECHANISMS OF PROBIOTICS IN IBS

It is well known that probiotic strains have numerous positive effects in the gastrointestinal tract. The beneficial effects of probiotics in IBS could be explained by increasing the mass of beneficial bacteria in the digestive tract, decreasing bacterial overgrowth in the small bowel and reversing the imbalance between the pro- and anti-inflammatory cytokines. Probiotics can also reinforce the intestinal mucosal barrier and normalize the motility of the digestive tract and its visceral sensitivity. Recently it was also demonstrated that some lactobacilli strains may modulate intestinal pain attacks by inducing the expression of  $\mu$ -opioid and cannabinoid receptors in the intestinal epithelial cells. In conclusion, probiotics have various actions: (1) physical barrier effect; (2) competition for nutrients; (3) metabolic interactions; (4) bacteriocin production; (5) reinforcement of the intestinal mucosal barrier; (6) reduction of intestinal permeability and bacterial translocation; and (7) regulation of the intestinal inflammatory response by modulating the secretion of cytokines and the immune response. The specific mechanisms of probiotics have been reported as follows.

### *Inhibition of pathogen binding*

Bacteria in the gut compete for nutrients and space. Probiotics have been demonstrated to adhere to a range of human intestinal cell lines and commonly found in mucosal biopsies of healthy individuals<sup>[40]</sup>. Probiotics reduce the adherence of pathogenic bacteria on the epithelial cells and thus the ability of pathogenic bacterial translocations. Probiotics can control the growth of pathogenic bacteria and regulate intraluminal fermentation by stimulating the secretion of bacteriocins and defensins, modulate signal transduction (*e.g.*, NF- $\kappa$ B) and influence the innate/adaptive immune system (*e.g.*, IgA secretion).

### *Enhanced barrier function*

Probiotics have been demonstrated to enhance barrier function. The probiotic VSL#3 can protect cultured T84 monolayers from invasion by *Salmonella* by enhancing barrier function<sup>[41,42]</sup>. Our studies have also found that VSL#3 protected the epithelial barrier and increased the tight junction protein expression in vivo and in vitro by activating the p38 and extracellular regulated protein kinases (ERK) signaling pathways<sup>[43]</sup>.

### *Immune function*

Some studies have demonstrated that probiotics have an anti-inflammatory effect. In a study from Cork, assessing individual bacterial species, improvement in symptoms

with Bifidobacteria was associated with changes in the relative production of anti-inflammatory (IL-10) to pro-inflammatory (IL-12) cytokines<sup>[44]</sup>. Animal model and human studies have evaluated immunologic modulation with specific probiotics. The potential anti-inflammatory effect of *Lactobacillus reuteri* in an experimental rodent study demonstrated an inhibition of TNF- $\alpha$ -induced production of IL-8<sup>[45]</sup>. *Lactobacillus casei* can also significantly decrease TNF- $\alpha$  release in ileal tissues from an experimental rodent study<sup>[46]</sup>. Other studies also evaluated the anti-inflammatory effects of probiotics and demonstrated activity against cytokines, including interferons.

The main action on the immune function of probiotics is carried out by dendritic cells (DCs), antigen presenting cells for T lymphocytes that are found in mucosae, lymphoid tissues, lymph, lymph nodes, spleen and peripheral blood. DC phenotype and cytokine production is modulated by the intestinal microflora; furthermore, these cells are involved in the local immune response to B lymphocyte activation and IgA synthesis by plasmacytes.

### Colonic transit and motility

Effects of probiotics on colonic transit have been reported in IBS patients with predominant bloating. In IBS patients with predominant bloating, the colonic transit was significantly retarded with probiotic VSL#3 relative to placebo. The effect on transit was not associated with the worsening of bowel function. Bazzocchi *et al* showed that the colon's reflex motor responses to balloon distension were reduced during an open-label study with VSL#3. Further studies are indicated to explore the mechanism of the retarded transit of stools and potential effects on colonic sensation and fermentation of nutrients reaching the colon.

### Effect on intraluminal milieu

Effects of probiotics on intraluminal milieu have been reported as follows: (1) reduction of intracolonic gas of bacterial origin due to an increase in Lactobacilli and Bifidobacteria, and a consequent decrease in the proportion of Clostridia and Veillonella; (2) normally metabolize nutrient substrates reaching the colon with the formation of gas and increase in the production of intracolonic short chain fatty acids (SCFA) and a consequent improvement in colonic propulsion. The SCFA may induce propulsive contractions and accelerate transit or enhance fluid and sodium absorption in the colon<sup>[47]</sup>. Thus, alteration in the resident colonic flora with administration of probiotics may modify the colonic metabolism of nutrient substrates to alter colonic transit and fluid fluxes; and (3) reduced malabsorption of bile acids in diarrhea predominant IBS, because Lactobacilli and Bifidobacteria are capable of deconjugation and absorbing bile acids, thus reducing luminal bile salt load to the colon, which reduces colonic secretion and mucosal permeability changes.

### Alterations in visceral hypersensitivity

Some studies have shown that *E. coli* Nissle 1917 inhibits

the visceral hypersensitivity associated with trinitrobenzene sulphonic acid (TNBS) colitis and *L. paracasei* inhibits the visceral hypersensitivity associated with inflammation in healthy mice in whom the bacterial microbiota have been disturbed by antibiotics<sup>[48]</sup>. This latter study showed a clear anti-inflammatory effect and also an inhibition of SP staining, a marker of afferent pain pathways, which was increased after the antibiotic treatment<sup>[49]</sup>. This effect on neuropeptides is of particular interest given the key role visceral hypersensitivity is believed to play in IBS and the recent demonstration of increased SP and transient receptor potential vanilloid 1 receptor (TRPV1) positive fibres in IBS mucosal biopsies<sup>[50]</sup>. Probiotics can regulate the action of mastocytes in the vicinity of nerve endings within the intestinal lamina propria. An entirely novel mode of action of probiotics has recently been demonstrated in which *L. acidophilus* increased the expression of l-opioid and cannabinoid receptors in normal animals, a phenomenon which was associated with an inhibition of visceral sensitivity equivalent to that of morphine 0.1 mg/kg<sup>[51]</sup>.

## FECAL MICROBIOTA TRANSPLANTATION AND IBS

Fecal microbiota transplantation (FMT), or infusion of a fecal suspension from a healthy individual into the gastrointestinal tract of another person to cure a specific disease, is best known as a treatment for recurrent *Clostridium difficile* infection. The earliest and most frequently quoted report of FMT is that by Eiseman *et al*<sup>[52]</sup>, who successfully treated patients using fecal enemas in the 1950s.

FMT also has been used successfully for IBS. Recent studies have shown that the intestinal microbiota play an important role in immunity and energy metabolism and that an imbalance in our commensal intestinal bacteria can predispose to disease development<sup>[53-56]</sup>. Re-establishment of the wide diversity of intestinal microbiota *via* infusion of donor feces into the colon is the proposed mechanism by which FMT results in clinical improvement in patients with IBS.

FMT is by no means a new therapeutic modality, however, it did not receive public attention until recently, after several studies were published showing that stool is a biologically active, complex mixture of living organisms with great therapeutic potential for *Clostridium difficile* infection<sup>[57-59]</sup> and other gastrointestinal diseases<sup>[60-63]</sup>.

Unlike the concept of probiotics, which alter the metabolic or immunological activity of the native gut microbiota, the premise of FMT has always been to introduce a complete, stable community of gut microorganisms, which are aimed at repairing or replacing the disrupted native microbiota. Engraftment of donor microbiota was accompanied by normalization of the patient's bowel function. In addition, other mechanisms could be involved that might explain how FMT works. The metabolic activities of gut bacterial species can have

consequences both locally, on the gut mucosa, and systemically. Disruption of these bacterial species can result in potentially harmful metabolic alterations, leading to the partitioning of toxic substances across the gastrointestinal mucosa where these substances are absorbed into systemic circulation. Gustafsson *et al*<sup>[64]</sup> analyzed gut microbiota metabolism pre-FMT and post-FMT in patients with antibiotic-associated diarrhea and found marked disturbances in the majority of microflora-associated characteristics in patients with antibiotic-associated diarrhea. Administration of a human fecal enema corrected these alterations and relieved diarrhea.

## CONCLUSION

Probiotics are used regularly in most populations regardless of medical indications. There is reasonable evidence of a modest benefit in IBS patients. Selection of those who will respond requires a better understanding of exactly what the mode of action is in IBS. Like most therapies in IBS probiotics are unlikely to be beneficial for all patients. However, given their impressive safety profile, a trial of probiotics is certainly worth considering. Care must be taken to recommend the exact strain or species that has shown benefit in treating IBS, and not to extrapolate success of one probiotic species to another. In addition, further large good quality trials are needed to predict which patient groups are most likely to respond to probiotics, perhaps through fecal microbial profiling.

### Abstract

The liver has particular tolerogenic properties that allow its spontaneous acceptance in some animal species. Liver structure is considered to favor a tolerogenic environment. The peripheral tolerance mechanisms also play a role in spontaneous tolerance to liver graft. In a clinical setting, the main challenge nowadays facing liver transplantation is minimization of immunosuppression with the goal of donor-specific tolerance. Mechanisms involved in tolerance to transplanted organs are complex and partly unknown. A significant mechanism in tolerance induction is chimerism. Chimerism can be induced through transplantation of allogeneic donor bone marrow/stem cells under appropriate host conditioning. This review focuses on the tolerance mechanisms in liver transplantation and highlights the role of chimerism and allogeneic bone marrow/stem cell transplantation in tolerance development.

**Key words:** Immunotolerance; Chimerism; Bone marrow transplantation; Stem cell transplantation; Liver transplantation

**Core tip:** The liver is considered an immune privileged organ. The main challenge facing liver transplantation

is to induce donor-specific tolerance. Numerous reports have documented the phenomenon of microchimerism in liver transplant recipients. Most have demonstrated that higher levels of chimerism in liver transplantation are associated with reduced incidence of acute rejection and better initial graft acceptance. Mechanisms involved in chimerism-induced tolerance have only been partly elucidated. Chimerism can be induced through transplantation of allogeneic donor bone marrow cells under appropriate host conditioning and represents a clinically feasible approach for the induction of durable liver transplantation tolerance.

### INTRODUCTION

The availability of non-specific immunosuppressive agents has allowed liver transplantation to become an established treatment of end-stage liver disease. With the introduction of new immunosuppressants the incidence of acute rejection has considerably decreased, and transplanted patient survival is now 83% and 70% after 1 and 5 years, respectively<sup>[1]</sup>. However, immunosuppressive drugs broadly suppress the immune system, and their use is associated with an increased risk of neoplasms, opportunistic infections, and end-organ toxicity<sup>[2,3]</sup>. Thus, the main challenge nowadays facing liver transplantation is minimization of immunosuppression with the goal of donor-specific tolerance. Tolerance is defined as a state of donor-specific hyporesponsiveness in the recipient in the absence of immunosuppression<sup>[4]</sup>. Mechanisms involved in tolerance to transplanted organs are complex and partly unknown. This review focuses on the tolerance mechanisms in liver transplantation and to highlight

the role of chimerism and allogeneic bone marrow/stem cell transplantation in tolerance development.

## LIVER AS A PRIVILEGED IMMUNE ORGAN

It is generally recognized that after clinical liver transplantation, the incidence of chronic rejection is lower than after transplantation of other organ grafts. Among animal species such as pigs, and selected rat and mouse combinations, liver transplants may be performed with no immunosuppression<sup>[5-7]</sup>. In selected patients with liver transplantation, immunosuppressive therapy can be withdrawn without occurrence of graft rejection<sup>[8-10]</sup>. Furthermore, co-transplantation of a liver allograft can prevent rejection of other organ grafts from the same donor<sup>[11,12]</sup>. The transplanted liver may even behave as an immunosuppressor when transplanted to animals suffering rejection after pancreas transplantation<sup>[13]</sup>. Liver allografting also reverses ongoing rejection of the heart<sup>[14]</sup>. All of these facts had led people to consider the liver to be an immunologically privileged organ that may be tolerated with less immunosuppression after transplantation, and immunosuppressants can sometimes even be completely withdrawn<sup>[15]</sup>.

## TOLERANCE MECHANISMS IN LIVER TRANSPLANTATION

The mechanisms responsible for this relative tolerogenicity of the liver have only been partially elucidated, and liver structure is considered to have major implications for hepatic immune function. The liver is a place where gastrointestinal tract antigens and alloantigens in transplanted liver are presented to lymphocytes through a complex network of sinusoidal cells and antigen presenting cells (APCs)<sup>[16]</sup>. The context in which liver-resident antigens are presented to T cells favors a tolerogenic environment. Liver sinusoidal endothelial cells (LSECs) have a unique phenotype expressing myeloid cell markers (CD1, CD4 and CD11c), similar to immature dendritic cells (DCs). LSEC-activated CD4<sup>+</sup> lymphocytes cannot differentiate into T helper (Th)1 [interleukin (IL)-2-producing] cells, and express high immunosuppressive IL-10 levels<sup>[17]</sup>. Besides, LSEC-stimulated CD8<sup>+</sup> lymphocytes cannot respond to new antigenic stimuli<sup>[18]</sup>.

A recent study demonstrated that the liver capacity to induce tolerance partly results from *in situ* T-cell activation. It is well known that hepatocytes, as non-professional APCs, may play key roles in regulating immune responses and facilitating tolerance induction<sup>[19]</sup>. Warren *et al.*<sup>[20]</sup> showed intrahepatic lymphocytes and circulating naïve CD8<sup>+</sup> cells could interact with hepatocytes by means of cytoplasmic extensions capable of going through LSEC fenestrations. This local activation of T cells by hepatocytes provides the latter with a significant role as APCs and induces tolerance development in the liver<sup>[21]</sup>.

A number of observations indicate that a high per-

centage of non-conventional lymphocytes-which only rarely are found in peripheral blood-in the liver graft may also play a relevant role in the induction of tolerance<sup>[22]</sup>. Natural killer (NK) cells represent up to 30%-40% of liver lymphocytes, but only 10%-15% of peripheral mononuclear cells. Liver NK cells contain perforin and granzymes, exert stronger cytotoxicity against K562 target cells when compared with blood NK cells, and secrete interferon (IFN)- $\gamma$ , but no IL-10 or Th2 cytokines, upon stimulation with monokines. Liver NK cells seem to emit negative signals to the host T cells upon their migration into the liver following liver transplantation, thus contributing to liver graft tolerance<sup>[23]</sup>.

The peripheral tolerance mechanisms also play a role in liver graft spontaneous tolerance. Bishop *et al.*<sup>[24]</sup> demonstrated after liver transplantation that a large number of donor leukocytes rapidly migrate to secondary lymphoid organs and stimulate production of IL-2 and IFN- $\gamma$  by host CD4<sup>+</sup> cells, which then become depleted and subsequently undergo apoptosis.

A distinct subset of T cells that play an important role in peripheral regulation is natural T regulatory cells (Tregs). They constitutively express CD25, and constitute 5%-10% of peripheral CD4<sup>+</sup> T cells in healthy mice and humans. The CD4<sup>+</sup>/CD25<sup>high</sup> Tregs are best recognized by expression of the transcriptional regulator forkhead box (Fox)P3<sup>[25]</sup>. Dieckmann *et al.*<sup>[26]</sup> showed that human peripheral blood CD4<sup>+</sup>CD25<sup>+</sup> Tregs can suppress allogeneic responses through soluble mediators such as IL-10 and/or transforming growth factor- $\beta$ . It was recently found that peripheral blood CD4<sup>+</sup>CD25<sup>+</sup>Foxp3<sup>+</sup> cells increased in patients with liver grafts and might contribute to spontaneous tolerance<sup>[27]</sup>.

Compared with peripheral tolerance, central tolerance phenomena occur primarily in the thymus. So far, two experimental approaches exist in murine models that may generate highly stable central tolerance to allogeneic thymus transplantation or bone marrow transplantation (BMT). Induction of mixed chimerism through transplantation of allogeneic donor bone marrow/stem cells under appropriate host conditioning, is one of the most reliable strategies to induce transplantation tolerance and has been used in clinical practice<sup>[28]</sup>. Next, we focus on the mechanisms and applications of chimerism induced by allogeneic bone marrow/stem cell transplantation in tolerance introduction in liver transplantation.

## CHIMERISM

Chimerism can be defined as a phenomenon in which cells from one individual are present in another individual. Two types of chimerism have been described: microchimerism and macrochimerism. Microchimerism usually occurs when bone marrow/stem cells are transplanted in a conditioned recipient and the donor pluripotent hematopoietic stem cells (HSCs) engraft in the recipient and produce all its lineages, including the donor immune system. Microchimerism arises as a result of migration of passenger leukocytes from a transplanted allograft into an

unconditioned recipient and donor pluripotent HSCs do not engraft, but alternatively hematopoietic-derived cells from the donor organ are produced and migrate systemically. Consequently, not all stem-cell-derived lineages are produced and low levels of donor cells are found in the recipient's blood<sup>[29]</sup>.

## CHIMERISM AND TOLERANCE IN LIVER TRANSPLANTATION

Tolerance induction with live donor leukocytes became the bedrock of modern transplantation after its first description in mice<sup>[30]</sup>. Numerous reports have documented that mononuclear cells of donor type migrate out of the graft after transplantation of solid organs and these cells can persist in the recipient over several years, thus leading to allogeneic microchimerism<sup>[31]</sup>. Jonsson *et al*<sup>[32]</sup> prospectively investigated the peak levels and kinetics of donor leukocyte chimerism in human recipients following liver transplantation. The peak levels of chimerism were observed within the first 48 h following transplantation and ranged from 0.15% to 20% of total peripheral blood mononuclear cells. In almost all patients, there was an early peak level of chimerism that declined over time such that donor leukocytes were only intermittently detectable after 3-4 wk. In another study, Verdonk *et al*<sup>[33]</sup> prospectively collected blood samples of 21 liver transplant recipients up to 3 mo after transplantation. They found donor chimerism in 71% of their liver transplant recipients and chimerism was most frequently found in the first month after transplantation. However, by polymerase chain reaction (PCR) for donor type DNA sequences, microchimerism has been described to be present in patients > 10 years after liver transplantation. Some of these patients were off immunosuppressive treatment for various periods of time and all had good graft functions<sup>[34]</sup>. Stable levels of donor chimerism, in the absence of other major clinical events, may be a marker of transplantation tolerance, and may help to tailor immunosuppressive treatment in liver transplantation<sup>[35]</sup>. As low as 1% donor chimerism is sufficient to induce robust tolerance to donor-specific organs, cells, and tissues<sup>[36]</sup>.

So far, the mechanisms of induction of tolerance by microchimerism are still a matter of speculation. It has been suggested that donor leukocytes of bone marrow origin present in organ grafts represent a functional part of the donor immune system that is incorporated into the recipient's immune system, and a new hybrid immune system is thus established in the recipient and reciprocal bidirectional donor:host tolerance results<sup>[37]</sup>. Starzl *et al*<sup>[38]</sup> make a strong argument that allogeneic microchimerism, in which the donor passenger leukocytes migrate widely into the recipient's lymphoid tissues, is essential for the maintenance of clonal exhaustion-deletion that is induced by the initial flood of passenger leukocytes during the first few weeks after transplantation, and the survival of passenger leukocytes is associated with long-term acceptance of the graft. It is not known what determines the release of donor leukocytes from the graft. These

cells may be stimulated to migrate from the allograft by high local concentrations of tumor necrosis factor- $\alpha$  and IL-1 secreted early after transplantation. Alternatively, they may be mobilized or released by the organ procurement and reperfusion process. Cold preservation of liver allografts may result in injury to adhesion molecules of sinusoidal-lining cells, with the resultant sloughing of viable cells into the sinusoidal lumen<sup>[39]</sup>. Once donor stem cells have engrafted, they coexist and develop together with those of recipient origin giving rise to all hematopoietic cell types. Consequently, not only self-reactive but also donor-reactive thymocytes are intrathymic ally eliminated through negative selection, leading to a robust state of tolerance. Billingham *et al*<sup>[30]</sup> have shown that the induced tolerance is T cell mediated, and thymectomy of recipient mice before establishment of mixed chimerism results in failure to induce tolerance.

According to the concept of the two-way paradigm proposed by Starzl *et al*<sup>[40]</sup>, clinical organ transplantation under immunosuppression involves a double-immune reaction that has host-versus-graft as well as graft-versus-host arms<sup>[41]</sup>. After transplantation, except for the migration of donor hematopoietic cells into host tissues, protecting the allograft, the host's own hematopoietic cells also repopulate the allograft, protecting it from autologous alloreactive T cells<sup>[42]</sup>. Chimeric cells can either be circulating or they can be integrated into the parenchyma, which was first described in transplanted organs in 1969<sup>[43]</sup>. Okabayashi *et al*<sup>[44]</sup> termed it reverse chimerism. In their model, reduced-size livers of the DA rat strain were transplanted into the allogeneic green fluorescence protein (GFP) + Lewis recipients. In this strain combination, a combination of tacrolimus and plerixafor led to indefinite graft survival. Histological examination of the grafts showed a surprisingly high percentage of the liver parenchyma expressing GFP. This unexpected finding suggests that the host's HSCs were mobilized, repopulating the liver and converting to hepatocytes. In other studies, chimeric endothelium and duct epithelium were also found in transplanted livers<sup>[45,46]</sup>. Chimerism was also reported in other transplanted organs: recipient-derived endothelial cells were found in kidney grafts<sup>[47]</sup>; chimeric cardiomyocytes and smooth muscle cells were found in transplanted hearts<sup>[48]</sup>; and chimeric bronchial epithelium and type II pneumocytes were found in transplanted lungs<sup>[49]</sup>. These results are of interest because of their potential clinical application in organ transplantation. It may be conceivable to perfuse a deceased donor allograft with recipient stem cells pretransplantation, thus reversing chimerism and inducing transplantation tolerance.

## ALLOGENEIC BONE MARROW/STEM CELL TRANSPLANTATION IN TOLERANCE INDUCTION IN LIVER TRANSPLANTATION

Many studies suggest that chimerism is essential for tolerance induction in transplantation, therefore, the logical

next step is to augment it. Chimerism can be induced through transplantation of allogeneic donor bone marrow/stem cells under appropriate host conditioning. To surmount physiological and immunological barriers for successful bone marrow cell (BMC) engraftment, various myeloablative or nonmyeloablative conditioning protocols have been developed involving the global elimination of recipient T cells<sup>[50]</sup>. Myeloablative irradiation leads to complete destruction of the hematopoietic repertoire of the host, which is then reconstituted by donor BMCs. Apart from the toxicity of this approach, full donor chimerism is associated with a higher incidence and severity of graft-versus-host disease and some degree of immunoincompetence for primary immune responses, and is therefore clinically undesirable<sup>[51]</sup>. Mixed chimerism can be achieved by nonmyeloablative doses of total body irradiation (TBI) combined with different medication protocols to overcome pre-existing alloreactive T cells in the periphery. Rahhal *et al.*<sup>[52]</sup> prepared mixed chimeras by transplanting  $10^8$  T-cell-depleted allogeneic BMCs into Wistar Furth rats recipients conditioned with 300-600 cGy TBI. An 11-d course of tacrolimus and one dose of antilymphocyte serum were administered postoperatively. Mixed chimerism was initially achieved in almost all recipients and induced long-term acceptance of composite tissue allotransplants. Co-stimulation blockade, consisting of an anti-CD154 monoclonal antibody and the fusion protein cytotoxic T-lymphocyte antigen (CTLA)4-Ig inhibits CD40-CD40L and CD28-CD80/86 interactions between T cells and (allo)antigen-presenting cells<sup>[53]</sup>. Pree *et al.*<sup>[28]</sup> outlined a nonmyeloablative murine BMT protocol including 3 Gy TBI on day 1, a conventional dose of fully mismatched BMCs on day 0, plus a single dose injection of anti-CD154 on day 0 and administration of CTLA4-Ig on day 2. With this protocol, high levels of mixed chimerism (20%-90%) in all tested lineages is induced and maintained for the length of follow-up, and donor skin is accepted permanently in the majority of chimeras, whereas third party skin is rejected promptly.

In humans, BMT-induced mixed chimerism has been shown to confer acceptance of donor-specific skin<sup>[54]</sup> and kidney allografts<sup>[55]</sup> without long-term immunosuppression. Similar results were also observed in the field of liver transplantation. In a pilot study in 1997, donor peripheral blood stem cell (DPBSC) infusions were performed in three recipients of living-related liver transplantation (LRLT). The results, at 20 wk post-transplant, suggested that the levels of donor cells detected in LRLT recipients treated with DPBSC infusions may be higher than that in recipients of cadaver donor liver allografts, indicating that administration of DPBSCs to recipients of liver transplants is a feasible procedure<sup>[56]</sup>. Since then, many human trials of HSC infusion before or after liver transplantation have been performed and tolerance induction observed in the patients<sup>[57-59]</sup>. Tryphonopoulos *et al.*<sup>[60]</sup> perioperatively administered to liver transplant recipients unmodified cadaveric donor bone marrow infusions (DBMIs) ( $5 \times 10^8$ /kg) in order to enhance chimerism. They

found that patients who had DBMI tolerated withdrawal of tacrolimus or cyclosporine-based immunosuppression more often and had 5-6-fold more chimerism. Donckier *et al.*<sup>[61]</sup> reported three patients prospectively enrolled in an original protocol designed to promote graft acceptance in living donor liver transplantation. The protocol relies on the use of donor stem cells administered after liver transplantation as tolerogenic/suppressive cells<sup>[62]</sup>. Post-transplant immunosuppression and conditioning included steroids, rapamycin and antithymocyte globulin. Donor CD34<sup>+</sup> stem cells were infused 7 d post-transplant. The clinical observations demonstrated that donor stem cell infusion combined with recipient conditioning may allow early immunosuppression withdrawal or minimization after liver transplantation.

All of these studies provide hope for liver transplant recipients to be off drugs for the rest of their lives. However, researchers have cautioned that only the healthiest patients will be able to withstand the conditioning regimens that allow donor stem cells to engraft, and for the comprehensive application of bone marrow/stem cell transplantation in solid organ transplantation, there is still a long way to go<sup>[63-66]</sup>.

Establishment of chimerism in donor liver with recipient-type BMCs prior to liver transplantation is another strategy to induce tolerance to the liver graft. Sanada *et al.*<sup>[14]</sup> established chimerism in rat donor liver by intraportal injection of recipient-type BMCs, followed by intramuscular administration of FK506 for 5 d. At 1-2 mo later, livers were harvested and transplanted. No immunosuppressants were used. They found that with livers from rats pretreated with recipient-type BMCs, survival of liver allografts was significantly extended. However, the significance of reverse microchimerism in liver transplantation is still controversial. In a recent study, Aini *et al.*<sup>[67]</sup> compared the proportions of recipient-derived hepatocytes in long-term stable liver allografts and late dysfunctional allografts caused by chronic rejection. They found that hepatocyte chimerism was a constant event. However, the extent of engraftment of recipient-derived hepatocytes does not seem to correlate with the degree of hepatic injury in long-term liver allografts. More importantly, this protocol cannot itself be applicable to clinical allotransplantation because it needs donor preparation long before liver transplantation.

## SUMMARY AND CONCLUSION

The liver has particular tolerogenic properties that allow its being spontaneously accepted in some animal species. Liver structure is considered to favor a tolerogenic environment. The peripheral tolerance mechanisms also play a role in liver graft spontaneous tolerance. A most significant mechanism in tolerance induction is chimerism. The mechanisms of induction of tolerance by microchimerism are still a matter of speculation. Chimerism can be induced through transplantation of allogeneic donor bone marrow/stem cell under appropriate host

conditioning. In humans, BMT-induced mixed chimerism has been shown to confer acceptance of donor liver allografts without long-term immunosuppression. However, recipients must be able to withstand the conditioning regimens that allow donor stem cells to engraft.

### Abstract

**AIM:** To investigate whether electroacupuncture (EA) at Zusanli (ST36) prevents intestinal barrier and remote organ dysfunction following prolonged hemorrhagic shock through a vagus anti-inflammatory mechanism.

**METHODS:** Sprague-Dawley rats were subjected to about 45% of total blood volume loss followed by delayed fluid replacement (DFR) with Ringer lactate 3h after hemorrhage. In a first study, rats were randomly divided into six groups: (1) EAN: EA at non-channel acupoints followed by DFR; (2) EA: EA at ST36 after hemorrhage followed by DFR; (3) VGX/EA: vagotomy (VGX) before EA at ST36 and DFR; (4) VGX/EAN: VGX before EAN and DFR; (5)  $\alpha$ -bungarotoxin ( $\alpha$ -BGT)/EA:

intraperitoneal injection of  $\alpha$ -BGT before hemorrhage, followed by EA at ST36 and DFR; and (6)  $\alpha$ -BGT/EAN group:  $\alpha$ -BGT injection before hemorrhage followed by EAN and DFR. Survival and mean arterial pressure (MAP) were monitored over the next 12 h. In a second study, with the same grouping and treatment, cytokine levels in plasma and intestine, organ parameters, gut injury score, gut permeability to 4 kDa FITC-dextran, and expression and distribution of tight junction protein ZO-1 were evaluated.

**RESULTS:** MAP was significantly lowered after blood loss; EA at ST36 improved the blood pressure at corresponding time points 3 and 12 h after hemorrhage. EA at ST36 reduced tumor necrosis factor- $\alpha$  and interleukin (IL)-6 levels in both plasma and intestine homogenates after blood loss and DFR, while vagotomy or intraperitoneal injection of  $\alpha$ -BGT before EA at ST36 reversed its anti-inflammatory effects, and EA at ST36 did not influence IL-10 levels in plasma and intestine. EA at ST36 alleviated the injury of intestinal villus, the gut injury score being significantly lower than that of EAN group ( $1.85 \pm 0.33$  vs  $3.78 \pm 0.59$ ,  $P < 0.05$ ). EA at ST36 decreased intestinal permeability to FITC-dextran compared with EAN group ( $856.95$  ng/mL  $\pm$   $90.65$  ng/mL vs  $2305.62$  ng/mL  $\pm$   $278.32$  ng/mL,  $P < 0.05$ ). EA at ST36 significantly preserved ZO-1 protein expression and localization at 12 h after hemorrhage. However, EA at non-channel acupoints had no such effect, and abdominal vagotomy and  $\alpha$ -BGT treatment could weaken or eliminate the effects of EA at ST36. Besides, EA at ST36 decreased blood aminotransferase, MB isoenzyme of creatine kinase and creatinine vs EAN group at corresponding time points. At the end of 12-h experiment, the survival rate of the EA group was significantly higher than that of the other groups.

**CONCLUSION:** EA at ST36 attenuates the systemic inflammatory response, protects intestinal barrier integrity, improves organ function and survival rate after

hemorrhagic shock *via* activating the cholinergic anti-inflammatory mechanism.

**Key words:** Hemorrhagic shock; Zusanli; Electro-acupuncture; Intestinal permeability; Tight junction

**Core tip:** The most important novel findings from this study are that when delayed resuscitation is inevitable during emergency situations such as hemorrhagic shock occurring in war without sufficient fluids, electroacupuncture at ST36 can be performed and it can successfully attenuate systemic inflammation, decrease gut injury and permeability and improve blood pressure and outcomes, which is consistent with preserved intestinal barrier function after hemorrhage and delayed fluid resuscitation.

Electroacupuncture improves gut barrier dysfunction in prolonged hemorrhagic shock rats through vagus anti-inflammatory mechanism. *World J Gastroenterol* 2013; 19(36): 5988-5999 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/5988.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.5988>

## INTRODUCTION

The current treatment for hypovolemic shock focuses on maintaining sufficient tissue perfusion and vital organ function with early and adequate fluid replenishment. Delayed fluid resuscitation for hemorrhagic shock usually occurs when mass casualties happen in austere environments such as battlefield, earthquake, or accidents, where intravenous fluid resuscitation is often difficult or even impossible. Subsequent to delayed resuscitation of hypovolemic shock, a high mortality and an increase in incidence of serious complications such as systemic inflammatory response syndrome (SIRS) and the multiple organ dysfunction syndrome (MODS) may thus befall to these victims<sup>[1]</sup>. Although delayed resuscitation have been demonstrated to result in a more profound shock insult than early resuscitation<sup>[2,3]</sup>, its pathological mechanisms remain poorly understood. One potential pathogenic mechanism appears to be associated with proinflammatory cytokine response<sup>[4,5]</sup> and, gut plays a key role in the development of intestinal and systemic inflammatory response following hemorrhagic shock and severe burn<sup>[6]</sup>. Gut becomes a source of proinflammatory mediators resulting from impairment of intestinal mucosal barrier that may amplify SIRS, produce a systemic response state and distant organ failure, and lead to MODS or even death<sup>[7-9]</sup>. Thus, interventions to prevent intestinal barrier breakdown, excessive inflammation and subsequent organ dysfunction when hemorrhagic shock prolonged due to delayed resuscitation are crucial in controlling hemorrhagic shock without sufficient fluid infusion, especially during evacuation and transportation.

The cholinergic anti-inflammatory pathway is a neural mechanism that inhibits the expression of pro-inflammatory cytokines through the interaction of the principle vagus nerve neurotransmitter, acetylcholine, and the cholinergic  $\alpha 7$  nicotinic acetylcholine receptor ( $\alpha 7nAChR$ ) subunit located on cytokine-expressing cells by stimulating the vagus nerve by either electrical or pharmacological methods<sup>[10,11]</sup>. Activation of the cholinergic anti-inflammatory pathway by vagus nerve stimulation can prevent cytokine release and tissue injury<sup>[12]</sup>, prolong survival and protect against the development of hypotension in rats during lethal hemorrhagic shock<sup>[13]</sup>. Recently, researchers have demonstrated an expanded role for vagus nerve stimulation and the cholinergic anti-inflammatory mechanism that provides a protective effect on the gut against epithelial barrier dysfunction and alleviates inflammatory injury in intestine and remote organs<sup>[14-16]</sup>. However, due to complicated manipulation and untoward side effects, including serious tissue injury, it is still difficult to apply electrical stimulation to the vagus nerve in clinical practice. Therefore, a more clinically desirable alternative therapy needs to be established during the resuscitative phase of trauma care.

Acupuncture as one of the therapeutic maneuvers in traditional Chinese medicine (TCM) has been applied in clinics for thousands of years, and it has been found to have a bidirectional neuron-endocrine-immune system regulating effect, and antagonize systemic inflammatory response without side effects. We have demonstrated that electroacupuncture (EA) at ST36 had a significantly positive effect on hemorrhagic shock<sup>[2]</sup> in rats with delayed fluid resuscitation, however, its mechanism remains unknown. We have recently furthermore proved that EA alleviated intestinal barrier insult and system inflammation in a rat ischemia model through activating the cholinergic anti-inflammatory pathway<sup>[17]</sup>. Therefore, we investigated whether EA at ST36 protected intestinal barrier function, thus preventing remote organ injury after prolonged hemorrhagic shock in rats with delayed fluid replacement (DFR) through activating the cholinergic anti-inflammatory-dependent mechanism.

## MATERIALS AND METHODS

### Animals

Male Sprague-Dawley rats (8-10 wk, 240-260 g) were purchased from Experimental Animal Center of Military Medical Sciences of the Chinese PLA. Rats were acclimatized for a while in mesh cages in a temperature-controlled room with a 12-h light-dark cycle in the animal quarter of our laboratory and fasted overnight, but allowed free access to water until 4 h before surgery. The research protocols were approved by the Committee of Scientific Research of the First Hospital Affiliated to General Hospital of PLA, China. The experiment was conducted in compliance with the Guide for Care and Use of Laboratory Animals of National Research Council, China.

### Surgical procedures

Rats were anesthetized and instrumented with 3% isoflurane inhalation (Yeeran Technology Limited, Beijing, China). Ketamine 10 mg/kg was hypodermically injected for local anesthesia. Isoflurane (0.7%) was used to maintain anesthesia during the experiments. Animals were allowed to breath spontaneously under a nose cone scavenging system using a veterinary anesthesia delivery system (Kent Scientific TOPO, Torrington, CT, United States). With aseptic technique, poly-ethylene (PE50) catheters were placed in the right carotid artery for continuous artery blood pressure monitoring, in the left femoral artery for blood withdrawal, and in the right femoral vein for fluid infusion. A 2-cm upper-midline laparotomy incision was made to identify gastroesophageal junction and expose the dorsal and ventral vagus nerve on the distal esophagus with a Phenix XLT165-LB stereomicroscope (Phenix Optical Instrument Group Company, Jiangxi Province, China). Rectal temperature was maintained at 37 °C with a heating pad and a heating lamp.

### Hemorrhagic shock protocol

Each animal's estimated blood volume was calculated using the formula<sup>[18]</sup>: Total blood volume (TBV) (mL) = body weight (g) × 0.06 (mL/g) × 0.77. Hemorrhagic shock was induced by withdrawing 45% of the calculated TBV within 20 min (30% was withdrawn over the first 3 min and suspended for 7 min, and the rest 15% was withdrawn over another 10 min), using an infusion or a withdrawal pump (Kelifeng Apparatus, Beijing, China). The completion of the hemorrhagic shock model concluded the preparation phase, and the time was metered 0. Mean arterial pressure (MAP) was monitored using a PICCO-PLUS cardio-pulmonary volume monitor (PULSION, Feldkirchen, Germany) after exsanguinations were initiated, and recorded 0.5 h before bleeding, immediately upon completion of the hemorrhagic shock (0), 3 h and 12 h after blood loss. The early survival rate was recorded at 12 h after bleeding. Fluid resuscitation was initiated 3 h after exsanguinations.

### Animal grouping and treatment

All the animals underwent the same surgical procedure and hemorrhagic shock protocol, and the experimental rats were randomly assigned to six groups: (1) EAN group: Rats underwent EA at non-channel acupoints located 0.5 cm lateral and distal from ST36 points<sup>[19]</sup>, followed by DFR similar to EA group; EA parameters and delayed rehydration were the same as the EA group; (2) EA group: Animals underwent EA at ST36 points, which were located at posterior and lateral side of the knee joint, 5 mm below capitulum fibulae<sup>[19]</sup>, immediately after the blood loss followed by DFR 3 h after hemorrhage. EA at ST36 with an electro-acupuncture apparatus (HANS, LH202H) was performed as described before<sup>[17]</sup>. Briefly, both hind limbs were shaved and the skin was disinfected. ST36 acupuncture point was punctured with a depth of 7 mm, and then the needle was connected

with an electro-acupuncture apparatus. The electric current with the intensity of 2 mA and 2-100Hz was continued for 1.5 h immediately after hemorrhage. Three hours after blood loss, rats were given a femoral vein infusion with Ringer lactate (2 times the amount of blood loss); (3) VGX/EA group: Animals underwent vagotomy of the dorsal and ventral vagus nerve on the distal esophagus prior to EA at ST36 immediately after blood loss followed by DFR; EA parameters and delayed rehydration were the same as the EA group; (4) VGX/EAN group: Animals underwent vagotomy similar to VGX/EA group before EA at non-channel acupoints similar to EAN group immediately after blood loss followed by DFR. EA parameters and delayed rehydration were the same as the EA group; (5)  $\alpha$ -BGT/EA group:  $\alpha$ -bungarotoxin ( $\alpha$ -BGT 1  $\mu$ g/kg, an antagonist of  $\alpha$ 7 subunit of cholinergic nicotinic receptor, which inhibits the  $\alpha$ 7 subunit of acetylcholine receptors by blocking a pivotal communication pathway between the efferent vagus and intestinal immune cells<sup>[20,21]</sup>) was injected intraperitoneally prior to hemorrhage and followed by EA at ST36 and DFR similar to EA group. EA parameters and delayed rehydration were the same as the EA group; and (6)  $\alpha$ -BGT/EAN group:  $\alpha$ -BGT was injected intraperitoneally prior to hemorrhage and followed by EA at non-channel acupoints and DFR similar to EAN group.

Each group was then randomly divided into two subgroups: one subgroup ( $n = 12$ ) for investigation of survival rate and MAP; the other one ( $n = 18$ ) for cytokine levels, organ parameters, gut injury score, ZO1 detection and intestinal permeability to FITC-dextran test; blood and intestine for cytokine levels were harvested at 0, 3 and 12 h after blood loss (3-5 animals per group); blood for organ parameters test, and intestine for gut injury score, ZO1 detection and intestinal permeability to FITC-dextran test were harvested at 12 h after blood loss (3-5 animals per group).

The scheme for whole experiment is as follows in Figure 1.

### Samples of blood and intestine

Rats were anesthetized with 3% isoflurane inhalation. Blood was drawn through left femoral artery at 0, 3 and 12 h after blood loss, and then the animals were sacrificed for distal small intestine harvest. Plasma was obtained by centrifuging the blood at  $10000 \times g$  for 10 min at 4 °C. Organ functions were assessed by measuring blood aminotransferase (ALT), MB isoenzyme of creatine kinase (CK-MB) and creatinine (Cr) using a Cobas 6000 automatic biochemical analyzer (Roche Diagnostics, Basel, Switzerland). Segments of distal small intestine were harvested and immediately homogenized on ice with 1 mL denaturing lysis buffer or nondenaturing lysis buffer for Western blotting or ELISA. The homogenate was then centrifuged at  $10000 \times g$  for 10 min at 4 °C. Aliquots of the supernatants of plasma and tissue were stored at -80 °C until use. Segments of intestine were also harvested and fixed in 4% paraformaldehyde for histologic

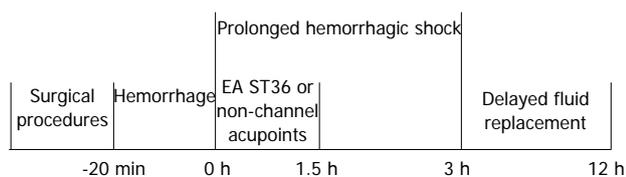

Figure 1 The scheme for whole experiment. EA: Electroacupuncture; ST36: Zusanli.

evaluation and immunofluorescence.

### Detection of TNF- $\alpha$ , IL-6 and IL-10 levels in plasma and intestine

TNF- $\alpha$ , IL-6 and IL-10 levels in the plasma and intestine were assessed using commercially available ELISA kit according to the protocol provided by the manufacturer (Nanjing Jiancheng Corp., Nanjing, China). Supernatants were transferred into fresh tubes for the evaluation. Briefly, after adding 50  $\mu$ L assay buffer, 50  $\mu$ L samples or standard concentration for TNF- $\alpha$ , IL-6 or IL-10 were incubated with 50  $\mu$ L diluted Biotin-Conjugate for 2 h at room temperature. After 3 washes, the plates were incubated with Streptavidin-HRP for 1 h at room temperature. After 3 washes, 3,3',5,5'-Tetramethylbenzidine (TMB) substrate solution was added to the plates for 15 min and the reaction was stopped with stop solution. The absorbance rate was read at 450 nm. The concentrations of the samples were calculated according to the standard curve. The plasma TNF- $\alpha$ , IL-6 and IL-10 levels were expressed as pg/mL. Intestine TNF- $\alpha$ , IL-6 and IL-10 levels were expressed as picograms per milligram of protein.

### Histopathologic score

The paraformaldehyde-fixed intestine was embedded in paraffin, and cut into 2- $\mu$ m sections. Hematoxylin and eosin staining of the intestine was performed by the Pathology Department of the First Hospital Affiliated to the People's Liberation Army General Hospital. Then the sections were viewed under a light microscope and evaluated by a pathologist blinded to the experimental groups. The injury to the intestinal mucosa was scored using the grading system as previously described<sup>[22]</sup>.

### Intestinal epithelial permeability

An *in vivo* intestinal permeability assay was performed to assess gut barrier function as described by Kao *et al.*<sup>[23]</sup>. Briefly, 30 min before sacrifice, animals were anesthetized with inhaled isoflurane. A midline laparotomy incision was made and a 10-cm segment of distal ileum was isolated between silk ties. A solution of 1.0 mL phosphate-buffered saline (PBS, pH 7.2) containing 25 mg 4-kDa fluorescein isothiocyanate (FITC)-dextran (Sigma-Aldrich, St. Louis, MO, United States) was injected into the lumen of the isolated segment of intestine. The bowel was returned to the abdominal cavity and the abdomen was closed. Animals were maintained lightly under general anesthesia for 30 min, and systemic blood was drawn by left femoral artery puncture and placed in heparinized

Eppendorf tubes on ice. Plasma was obtained by centrifuging the blood at  $10000 \times g$  for 10 min at  $-4^\circ\text{C}$ . Plasma fluorescence was measured by a fluorescence spectrophotometer (Synergy2; BioTek Multi-Detection Microplate reader, United States) and compared with a standard curve of known concentrations of FITC-dextran diluted in rat plasma.

### Immunofluorescence

After deparaffinization, the intestine sections were rehydrated and incubated in citrate buffer (Zhongshan Jinqiao Biotechnology Co., Ltd., Beijing, China) for heat-induced antigen retrieval. After three washes with PBS, sections were incubated with 3% bovine serum albumin (BSA) (Zhongshan Jinqiao Biotechnology Co., Ltd., Beijing, China) for 30 min to block nonspecific binding sites. The sections were then incubated in the ZO-1 antibody (1:100; Life Technologies, Gaithersburg, MD, United States) at  $4^\circ\text{C}$  overnight. The following day, after washing with PBS three times, they were treated with Alexa Fluor 488 secondary goat anti-rabbit antibody in 1% BSA for 1 h at room temperature. Prolong Fade (Antifade Mounting Medium, Beyotime Institute of Biotechnology, Beijing, China) was added on placement of cover slips. Images were viewed using the Olympus fluorescence microscope (BX51-DP71) with exposure-matched settings.

### ZO-1 expression

The harvested gut tissues were placed in 1 mL lysis buffer (50 mmol/L Tris-HCl, pH 7.4; 150 mmol/L NaCl; 1% NP-40; 0.1% sodium dodecyl sulphate), then homogenized and centrifuged at  $12000 \times g$  for 10 min. Following centrifugation, the supernatant was collected and analyzed for protein concentration. Protein concentrations were determined using a protein assay kit (Applygen Technologies Inc, Beijing, China). Total protein (100  $\mu$ g) was loaded onto a sodium dodecyl sulfate-polyacrylamide (SDS-PAGE) gel and run at 120 volts for 2 h. After electrophoresis, the protein was transferred to a polyvinylidene difluoride membrane (PVDF; Applygen Technologies Inc, Beijing, China) and blocked for 2 h in TBST (50 mmol/L Tris; 150 mmol/L NaCl; 0.05% Tween 20) containing 5% milk (Applygen Technologies Inc, Beijing, China). The membrane was then incubated with the primary antibodies against glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (1:5000; Zhongshan Jinqiao Biotechnology Co., Ltd., Beijing, China), and ZO-1 (1:500; Life Technologies, Gaithersburg, MD, United States) at  $4^\circ\text{C}$  overnight. After 3 washes in TBST, the membrane was incubated with corresponding secondary antibodies conjugated to horseradish peroxidase at room temperature for 30 min and chemiluminescence was detected using SuperECL Plus (Applygen Technologies Inc, Beijing, China). Films were developed using a standard photographic procedure. Quantitative analysis of detected bands was carried out by densitometer scanning (ImageJ).

### Statistical analysis

Data were analyzed using a commercial statistical soft-

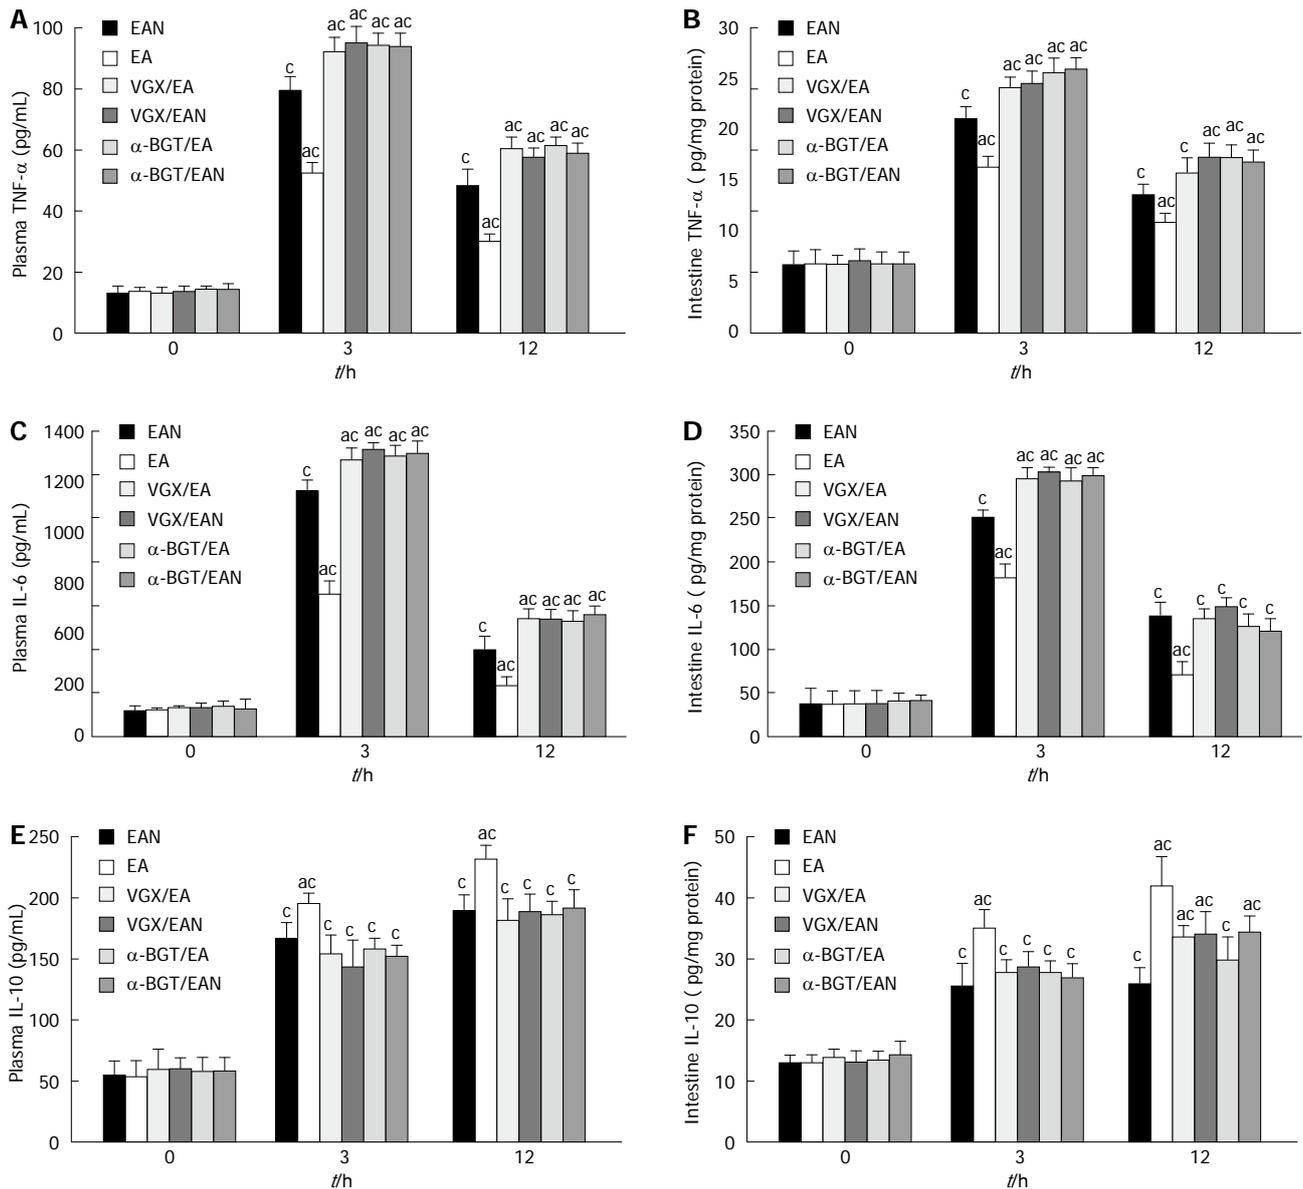

Figure 2 Tumor necrosis factor- $\alpha$ , interleukin-6 and interleukin-10 levels in plasma and intestine at 0, 3 and 12 h after blood loss. Blood samples and intestine were obtained at 0, 3 and 12 h after blood loss. Data are expressed as mean  $\pm$  SD (3-5 animals per group at each time point). <sup>a</sup> $P < 0.05$  vs EAN group; <sup>c</sup> $P < 0.05$  vs 0 h in the same group. EA: Electroacupuncture; VGX: Vagotomy;  $\alpha$ -BGT:  $\alpha$ -bungarotoxin; TNF: Tumor necrosis factor; IL: Interleukin.

ware package (SPSS statistics 17.0). Continuous variables were expressed as mean  $\pm$  SEM. Statistical significance of differences between groups was determined using one way analysis of variance (ANOVA) followed by Dunnett's test and SNK-q for multiple comparisons. If some variables were abnormally distributed, the Kruskal-Wallis H test was used. Significance was declared for  $P$  values  $< 0.05$ .

## RESULTS

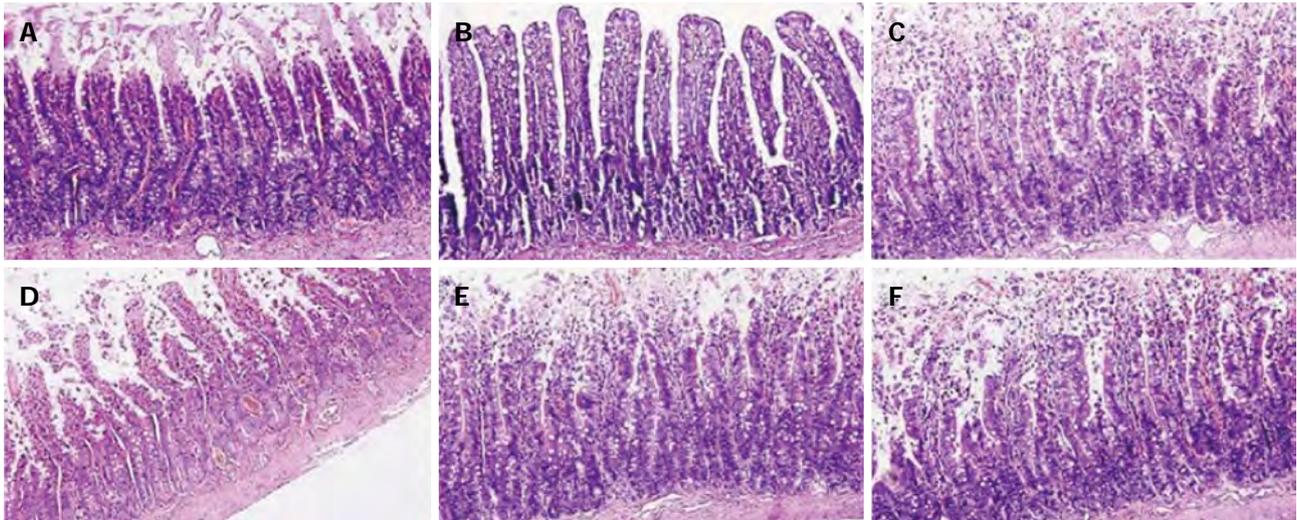

### Effect of EA ST36 on plasma and intestinal cytokine levels

Figure 2 illustrates the effect of EA ST36 on TNF- $\alpha$  (Figure 2A, B), IL-6 (Figure 2C, D) and IL-10 (Figure 2E, F) levels in plasma and intestine in rats with DFR after

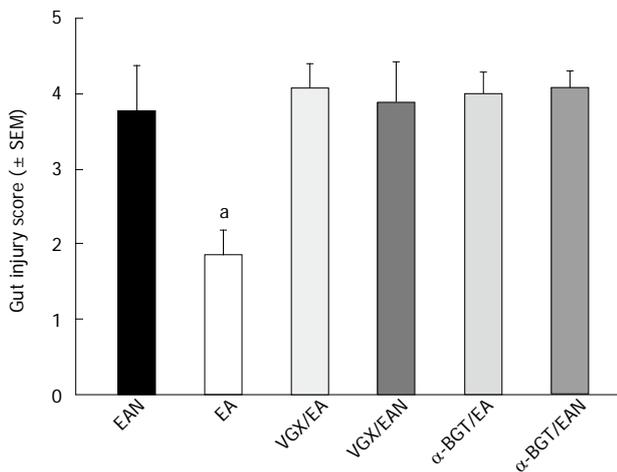

fatal hemorrhagic shock. Hemorrhage and DFR induced pronounced rises in the concentrations of TNF- $\alpha$ , IL-6 and IL-10 in plasma and intestine homogenates. EA at ST36 reduced TNF- $\alpha$  and IL-6 levels in both plasma and intestine homogenates after blood loss and DFR, while vagotomy or intraperitoneal injection of  $\alpha$ -BGT before EA at ST36 reversed its anti-inflammatory effects. In contrast, EA at ST36 did not influence the increases in plasma and intestinal IL-10 during hemorrhagic shock and DFR. These evidences suggested that EA at ST36 attenuated the release of TNF- $\alpha$  and IL-6, but did not suppress IL-10 level in plasma and intestine.

### EA ST36 decreased intestinal injury

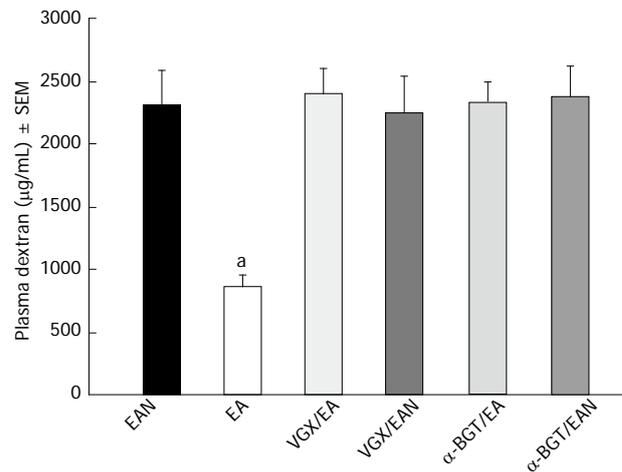

Histological evaluation of intestinal injury was performed at 12 h after blood loss. Sections of distal ileum from ani-

**Figure 3** Intestinal histology at 12 h after blood loss. Electroacupuncture (EA) at ST36 protected against intestinal injury after hemorrhagic shock and delayed fluid replacement, whereas EA at ST36 after vagotomy or injection of  $\alpha$ -bungarotoxin eliminated such protection. Sections of distal ileum were harvested at 12 h after blood loss and stained with hematoxylin and eosin. All images are taken at  $\times 200$  magnification with black bar = 5  $\mu$ m (3-5 animals per group at 12 h after blood loss).

**Figure 4** Gut injury scores at 12 h after blood loss. Gut injury was scored by a pathologist blinded to the experimental groups on a scale of 0-4, (as described in Materials and Methods). <sup>a</sup> $P < 0.05$  vs EAN group, (3-5 animals per group at 12 h after blood loss). EA: Electroacupuncture; VGX: Vagotomy;  $\alpha$ -BGT:  $\alpha$ -bungarotoxin.

**Figure 5** Intestinal permeability to 4-kDa fluorescein isothiocyanate-dextran at 12 h after blood loss. Electroacupuncture (EA) at ST36 protected the intestine from an increase in permeability after hemorrhagic shock and delayed fluid replacement, whereas EA at ST36 after vagotomy or injection of  $\alpha$ -bungarotoxin eliminated such protection. <sup>a</sup> $P < 0.05$  vs EAN group, (3-5 animals per group at 12 h after blood loss). EA: Electroacupuncture; VGX: Vagotomy;  $\alpha$ -BGT:  $\alpha$ -bungarotoxin

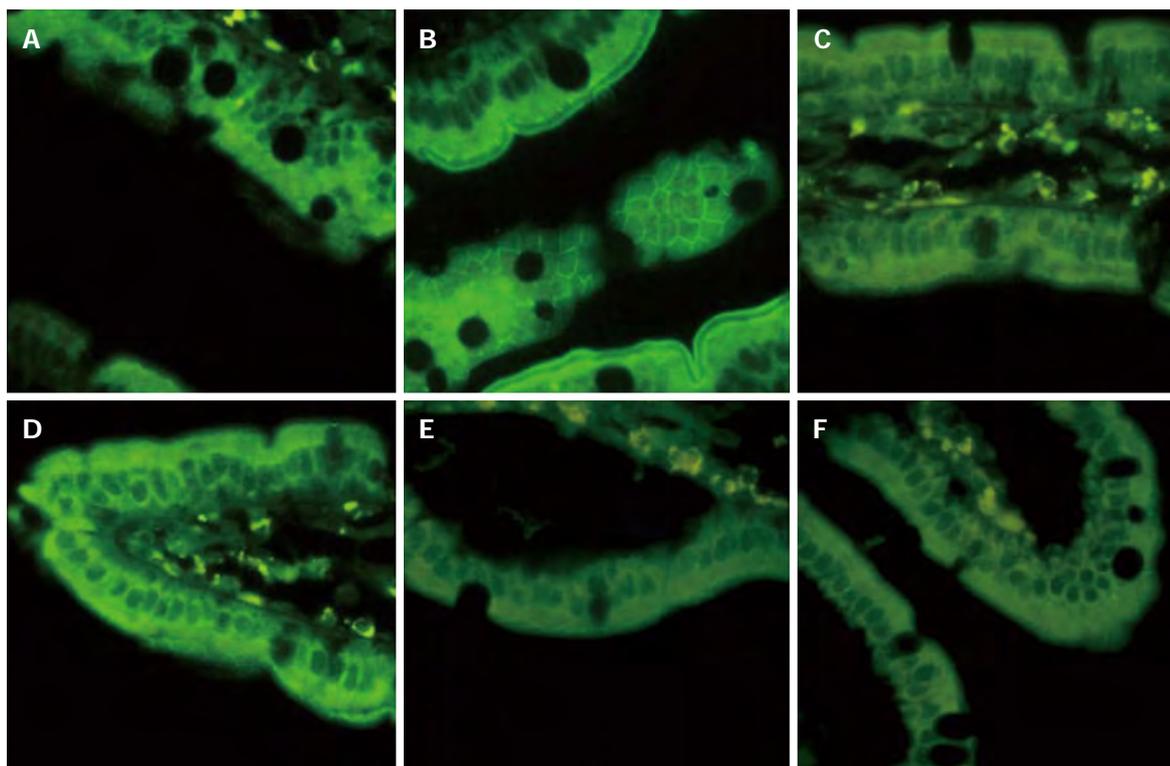

mals in EAN group showed villous tip necrosis, blunting, and sloughing of villi (Figure 3A). EA at ST36, which was applied immediately after blood loss, significantly attenuated the mucosal damage (Figure 3B). In contrast, when abdominal vagotomy or intraperitoneal injection of  $\alpha$ -BGT was performed and as such the intact neuroenteric axis was interrupted, EA at both ST36 and non-channel acupoints failed to prevent the histologic changes induced by hemorrhagic shock in the gut (Figure 3C-F). These data demonstrated that an intact vagus nerve is required for the biological effect of EA at ST36 in protecting against gut injury.

Gut injury scores were measured in all 6 groups (Figure 4). Animals in EAN group had an average injury score that was significantly higher than in EA group (3.78  $\pm$  0.59 *vs* 1.85  $\pm$  0.33,  $P < 0.05$ ). Abdominal vagotomy

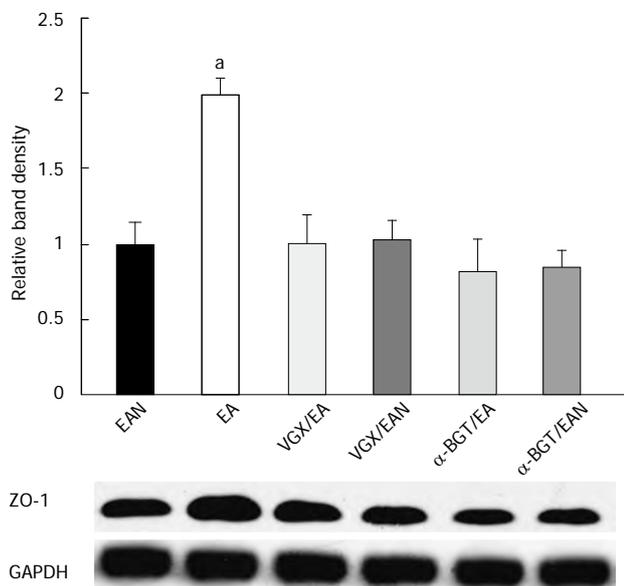

or intraperitoneal injection of  $\alpha$ -BGT before EA at ST36 eliminated the protective effects of EA at ST36 and resulted in similar scores as animals in VGX/EAN,  $\alpha$ -BGT/EAN and EAN groups (3.9  $\pm$  0.53, 4.1  $\pm$  0.29 *vs* 3.78  $\pm$  0.59;  $P > 0.05$ , respectively).

#### EA at ST36 lowered intestinal permeability

The intestinal permeability was evaluated in an *in vivo* assay using FITC-Dextran (Figure 5). Animals in EA group had a significantly lower level of plasma FITC-Dextran when compared with EAN group (856.95  $\pm$  90.65 ng/mL *vs* 2305.62  $\pm$  278.32 ng/mL,  $P < 0.05$ ). However, when abdominal vagotomy or  $\alpha$ -BGT injection was performed before EA at ST36, the intestinal permeability

**Figure 6** Intestinal ZO-1 immunofluorescent staining at 12 h after blood loss. Animals in EAN group showed a low fluorescent intensity at the cell periphery after hemorrhagic shock, and electroacupuncture (EA) at ST36 showed preservation of the robust structure of ZO-1 staining, whereas after vagotomy or injection of  $\alpha$ -bungarotoxin, it eliminated such protection. All images are taken at  $\times 400$  magnification with black bar = 5  $\mu\text{m}$ . (3-5 animals per group at 12 h after blood loss, size bar = 2  $\mu\text{m}$ ).

**Figure 7** Intestinal ZO-1 protein expression at 12 h after blood loss. Intestinal extracts were obtained from animals at 12 h after blood loss for measurement of ZO-1 protein expression using Western blotting. Representative Western blotting for the ZO-1 protein is shown with its corresponding glyceraldehyde 3-phosphate dehydrogenase loading control to demonstrate equal protein load in all lanes. Electroacupuncture at ST36 resulted in preservation of protein expression. Significant reduction in ZO-1 expression was seen in all the other groups.  $^aP < 0.05$  vs EAN group, (3-5 animals per group at 12h after blood loss). EA: Electroacupuncture; VGX: Vagotomy;  $\alpha$ -BGT:  $\alpha$ -bungarotoxin; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

was indistinguishable from animals in EAN group, and animals in VGX/EAN or  $\alpha$ -BGT/EAN group also showed no protection in reducing intestinal permeability compared with animals in EAN group ( $2249.87 \pm 294.17$  ng/mL and  $2400.15 \pm 203.15$  ng/mL vs  $2305.62 \pm 278.32$  ng/mL).

**EA ST36 prevented loss and redistribution of ZO-1**

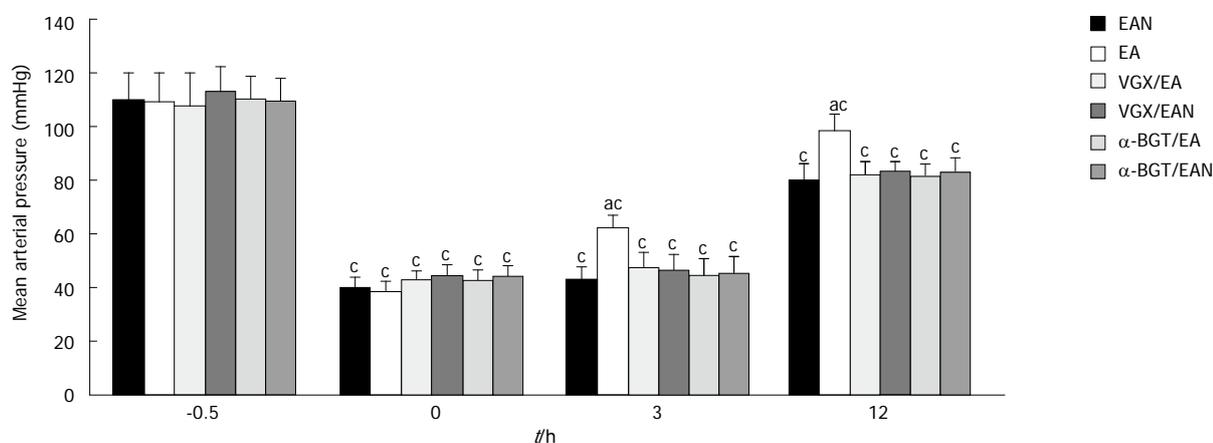

The tight junction protein, ZO-1, undergoes protein expression alterations in response to hemorrhagic shock. Exposure-matched fluorescent intensity correlated to the amount of ZO-1 protein expression after immunostaining (Figure 6). After blood loss, animals in EAN group showed a loss and redistribution in ZO-1 expression evidenced by a low fluorescent intensity at the cell periphery (Figure 6A). Animals in EA group (Figure 6B) showed preservation of the robust structure of ZO-1. In contrast, animals treated with EA at ST36 or non-channel acupoints after abdominal vagotomy, no protection was afforded to the intestinal mucosa, evidenced by the easy interruption and partial disappearance of ZO-1 staining in the periphery of villous epithelial cells (Figure 6C, D). And EA at ST36 or non-channel acupoints after  $\alpha$ -BGT injection also offered no protection against ZO-1 disruption (Figure 6E, F).

These results were confirmed by Western blotting for the ZO-1 protein in intestinal tissue lysates (Figure 7). When compared with the average relative band density of

animals in EAN group, animals treated with EA at ST36 had significantly higher ZO-1 expression ( $P < 0.05$ ). In contrast, intestinal ZO-1 protein levels were significantly decreased in animals receiving abdominal vagotomy or  $\alpha$ -BGT injection before EA at ST36. ZO-1 protein levels in VGX/EAN or  $\alpha$ -BGT/EAN group receiving EA at non-channel acupoints after vagotomy or  $\alpha$ -BGT injection were not significantly different from that in EAN group.

#### EA ST36 lowered plasma ALT, CK-MB and Cr

There was a significant decrease in ALT, CK-MB and Cr in the EA group compared with EAN group ( $P < 0.05$ ; Table 1). However, there was no significant difference of ALT, CK-MB, BUN and Cr among the EAN, VGX/EA, VGX/EAN,  $\alpha$ -BGT/EA and  $\alpha$ -BGT/EAN groups.

#### EA at ST36 improved the blood pressure and raised the survival rate

MAP in each group was significantly lowered after blood loss. MAP at time 0 was only 35%-45% of that before blood loss; after 3 h, MAP in each group increased to dif-

ferent degrees. At 3 h and 12 h after hemorrhage, the EA group displayed higher MAP levels than the EAN group ( $P < 0.05$ ) (Figure 8) while the VGX/EA, VGX/EAN,  $\alpha$ -BGT/EA and  $\alpha$ -BGT/EAN groups had low MAP levels similar to the EAN group.

As shown in our previous study<sup>[2]</sup>, at 12 h after blood loss, the survival rate of the EA group was significantly higher than that of the other groups ( $P < 0.05$ ). Ten (83.3%) of 12 rats in the EA group were alive 12 h after blood loss. In contrast, only 5 (41.7%) of 12 rats in the EAN group survived after being subjected to hemorrhagic shock treated with EA at non-channel acupoints and DFR. When rats subjected to hemorrhagic shock were treated with EA at ST36 after abdominal vagotomy or  $\alpha$ -BGT injection, 6 (50%) of 12 rats in VGX/EA group, 5 (41.7%) in  $\alpha$ -BGT/EA group, 5 (41.7%) in VGX/EAN group and 5 (41.7%) in  $\alpha$ -BGT/EAN group survived 12 h after blood loss.

## DISCUSSION

The most important novel findings from this study

are that when delayed resuscitation is inevitable during emergency situations such as hemorrhagic shock in war without sufficient fluids, EA at ST36 can be performed and it can successfully attenuate systemic inflammation, decrease gut injury and permeability and improve blood pressure and outcomes, which is consistent with preserved intestinal barrier function after hemorrhage and delayed fluid resuscitation. Based on our previous studies from this lab<sup>[2,24]</sup>, these results have provided further evidence for a role of acupuncture in an emergency treatment after shock and trauma.

It is regarded that the intestinal tract is one of the earlier organs involved in ischemia-reperfusion injury after hemorrhagic shock. In order to maintain the blood supply of the vital organs during hemorrhagic shock, the intestinal blood flow sharply reduced, and dysfunction of the intestinal mucosal barrier occurs. The ischemia of the small intestine leads rapidly to an impairment of mucosa barrier function, and thus the earliest restitution of the mesenteric blood flow is essential. However, in a very harsh environment with a lack of decent medical support, such as accident and war, immediate resuscitation is sometimes unavailable, the delayed fluid resuscitation occurs, threatening the life of those with extensive injury or hemorrhagic shock. It has also been recognized that a delay in such replenishment could sometimes be fatal due to complications subsequent to delayed resuscitation of hypovolemic shock. One strategy for reducing such a hazard is to try to supplement liquid with sufficient electrolytes by mouth until intravenous infusion fluids are available<sup>[25]</sup>. In recent years, we have been working on the alternative methods to treat the complications caused by delayed fluid resuscitation. We have found that oral resuscitation is an effective way to partly replace immediate resuscitation when the intravenous infusion is not available<sup>[1]</sup>. More recently, we have demonstrated that EA at ST36 can significantly improve the survival rate and blood pressure after fatal hemorrhagic shock in rats<sup>[2]</sup>.

The gut barrier has been found to be seriously damaged at the early phase of hemorrhagic shock<sup>[26]</sup>. The protective effect of traditional Chinese medicine against intestinal and gastric mucosal injury after hemorrhagic shock in rats has been investigated<sup>[27,28]</sup>. Increasing evidences suggest that the effect of EA at ST36 for gastrointestinal disorders may involve vagal reflex. The dorsal vagal complex (DVC) consists of the nucleus of the solitary tract (NTS), which receives primary visceral afferent information, and the dorsal motor nucleus of the vagus (DMV), which contains the efferent vagal neurons innervating visceral organs. Therefore, DVC plays an important role in regulating visceral functions. A previous study has demonstrated that there is a commonality of central nervous system (CNS) cell groups in brain controlling ST36 point, including DMV and NTS<sup>[29]</sup>. EA at ST36 generated an increased c-Fos expression in the neurons of DMV<sup>[30]</sup> and promoted the gastric myoelectric activity, which was regulated by the vagus, and substance P (SP) which is widely present in DVC and involved in the excit-

atory effects<sup>[31]</sup>. It has been proved that EA at ST36 can increase the efferent activity of the vagal nerve<sup>[32]</sup>. Taken together, these data suggest that EA at ST36 is relevant to vagus nerve and it has beneficial effects in intestinal barrier function. In this set of experiments, we stimulated ST36 points after hemorrhagic shock, established its efficacy, and compared its effects with EA at ST36 or non-channel acupoints after abdominal vagotomy or  $\alpha$ -BGT injection. We demonstrated that EA at ST36 is effective in preventing intestinal barrier breakdown after hemorrhagic shock with delayed resuscitation. We also showed, as a proof of concept, that its biological effect is dependent on an intact vagus nerve.

Increasing evidence points to extensive cross-talk between intestinal barrier breakdown and cytokine overproduction. The gut has been shown to be a source of inflammatory cytokine with capability of priming neutrophils after ischemia injury or hemorrhagic shock<sup>[6,33]</sup>. These cytokines originating from the gut may then exacerbate the systemic inflammatory response and potentially lead to a further damage to gut permeability<sup>[7,34]</sup>. It has also been demonstrated that IL-6 is essential for the development of gut barrier dysfunction after hemorrhagic shock<sup>[35]</sup>. IL-10 has also been proved to play a pivotal role in regulating proinflammatory cytokine release following trauma-hemorrhage<sup>[36]</sup>. In our previous studies, we demonstrated that EA at ST36 can alleviate intestinal pro-inflammatory factors, tissue edema and insult of intestinal mucosa<sup>[37]</sup>, significantly protect against tumor necrosis factor- $\alpha$  induced-multiple organ dysfunction in rats with sepsis<sup>[38]</sup>, and promote gastric emptying in rats with a 40% blood volume loss<sup>[39]</sup>. EA at ST36 has been shown to have a regulatory effect on TNF- $\alpha$  level in rats<sup>[40]</sup>. This study also demonstrated that acupuncture at ST36 significantly attenuated the expression of pro-inflammatory cytokine TNF- $\alpha$  and IL-6 levels in plasma and intestinal homogenate, but failed to suppress the anti-inflammatory cytokine IL-10 levels in plasma and intestine. These data suggests the anti-inflammatory potential of the use of ST36 acupuncture against hemorrhagic shock. Non-channel acupoints acupuncturing, vagotomy or  $\alpha$ -BGT injection before EA at ST36 showed no effects in reducing the production of TNF- $\alpha$  and IL-6, which suggested that anti-inflammatory effect of EA at ST36 may be exerted through the vagal nerves, and their integrity is essential.

In our previous study, we demonstrated that EA at ST36 can effectively protect organ function<sup>[24]</sup>, improve the early survival rate, increase the intestinal tissue diamine oxidase activity and alleviate intestinal ischemia in rats with DFR after hemorrhagic shock<sup>[2]</sup>, but its mechanism is unknown. This study demonstrated that this protective effect of EA at ST36 may be related to its protection of intestinal barrier function. In this study, EA at ST36 effectively prevented histologic injury of the gut mucosa, reduced permeability of the distal ileum to 4-kDa FITC-dextran and maintained intestinal tight junction protein expression and function. We also proved that this biologi-

cal effect is dependent on an intact vagus nerve. Disrupting the neurenteric axis *via* surgical abdominal vagotomy would abolish the protective effect of EA at ST36.

It has been found that tight junction proteins are critical structural proteins to maintain the mucosal barrier function<sup>[41,42]</sup>, and loss of gut barrier function is a major contributor to the systemic inflammatory response that ultimately leads to multiple organ failure<sup>[43]</sup>. Modulation of tight junction proteins can be effective in protecting the remote organ function in burned mice<sup>[44]</sup>, but its mechanism is also unclear. In this study, EA at ST36 can also significantly improve blood pressure, parameters of organ function and survival rate, which is in accordance with decreased intestinal permeability and improved intestinal tight junction protein distribution and expression.

There are several limitations in this study. All of our measures were evaluated with the rats under anesthesia, which might be different between human and animals. We did not monitor the change of vagal nerve activity before and after EA at ST36. The experimental duration is short. Meanwhile, more *in vitro* researches are needed to clarify the mechanism of ZO1 protein affected by EA at ST36. Besides, the model we used in this study is subjected to withdraw about 45% of the calculated TBV and such a large volume may be lethal and cause severe damage to the animals.

In summary, this study showed that EA at ST36 attenuated the release of TNF- $\alpha$  and IL-6 in plasma and intestine, alleviated the impairment of intestinal barrier function, and improved parameters of organ function and the early survival rate of hemorrhagic shock rats with DFR. The protective role of EA at ST36 is possibly related to an intact vagus nerve and it might exert its effects *via* cholinergic  $\alpha 7$  nicotinic acetylcholine receptor.

The authors thank Drs. Jiang-Yang Lu, Yi-Duo Jin, Xiu-Li Ma, Hui-Zhen Ding, Na Feng, Wen-Xia Yang, Yi Yang, Ming-Feng Jia and Dong-Mei Yang from Department of Pathology, First Hospital Affiliated to the PLA General Hospital, for their technical assistance concerning pathology in this project.

## COMMENTS

### Background

Fluid resuscitation for hemorrhagic/burn shock is often challenging when mass casualties occurring in austere circumstances such as in the battlefield or site of an unexpected accident or a disaster, where intravenous fluid resuscitation is difficult or even impossible. Subsequent to delayed resuscitation of hypovolemic shock, a high mortality and an increase in incidence of serious complications such as systemic inflammatory response syndrome (SIRS) and the multiple organ dysfunction syndrome (MODS) may thus befall to these victims. Thus, interventions such as drug or acupuncture to prevent excessive inflammation and subsequent organ dysfunction when hemorrhagic shock prolonged due to delayed resuscitation are of great significance in controlling hemorrhagic shock without sufficient fluid infusion, especially during evacuation and transportation.

### Research frontiers

The current treatment for hypovolemic shock focuses on maintaining sufficient tissue perfusion and vital organ function with early and adequate fluid

replenishment. It is of great importance to seek clinically alternative therapies when delayed fluid replenishment is inevitable. Activation of the cholinergic anti-inflammatory pathway by vagus nerve stimulation has been demonstrated to inhibit inflammatory response, prolong survival and protect against the development of hypotension during lethal hemorrhagic shock. Gut, especially the intestinal barrier function, plays a key role in the development of intestinal and systemic inflammatory response and protection of organ function following hemorrhagic shock. Recently, researchers have demonstrated an expanded role for vagus nerve stimulation and the cholinergic anti-inflammatory mechanism that provides a protective effect on the gut against epithelial barrier dysfunction and alleviates inflammatory injury in intestine and remote organs. However, due to complicated manipulation and untoward side effects, including serious tissue injury, it is still difficult to apply electrical stimulation to the vagus nerve in clinical practice. Therefore, a more clinically desirable alternative therapy is needed during the resuscitative phase of trauma care. Acupuncture as one of the therapeutic maneuvers in traditional Chinese medicine (TCM) has been applied in clinics for thousands of years, and it has been found to have a bidirectional neuron-endocrine-immune system regulating effect, and antagonize the systemic inflammatory response without side effects. The authors demonstrated that electroacupuncture (EA) at Zusanli had a significant positive therapeutic effect in hemorrhagic shock rats with delayed fluid resuscitation, however, its mechanism remains unknown. The authors had also proved that EA can alleviate intestinal barrier insult and system inflammation in a rat ischemia model through activating the cholinergic anti-inflammatory pathway.

### Innovations and breakthroughs

The most important novel findings from this study are that when delayed resuscitation is inevitable during emergency situations such as hemorrhagic shock occurring in the battlefield or site of an unexpected accident or a disaster without sufficient fluids, EA at ST36 can be performed and it can successfully attenuate systemic inflammation, decrease gut injury and permeability and improve blood pressure and outcomes, which is consistent with preserved intestinal barrier function after hemorrhage and delayed fluid resuscitation.

### Applications

The study results provide evidences for acupuncture as an emergency intervention of anti-shock and protection of gut barrier function after severe hemorrhage and trauma.

### Terminology

Cholinergic anti-inflammatory pathway: The cholinergic anti-inflammatory pathway is a neural mechanism that inhibits the expression of cytokine through the interaction of the principle vagus nerve neurotransmitter, acetylcholine, and the  $\alpha 7nAChR$  subunit located on cytokine expressing cells by stimulating the vagus nerve by either electrical or pharmacological methods. EA: EA is a modification of conventional acupuncture that stimulates acupoints with electrical current instead of manual manipulations and appears to have more consistently reproducible results in both clinical and research settings.

### Peer review

The study is somewhat interesting, well designed and results seem to be very congruent among the different aspects of systemic inflammation and intestinal barrier function investigated.

### Abstract

**AIM:** To provide long-term survival results of operable duodenal gastrointestinal stromal tumors (DGISTs) in a tertiary center in China.

**METHODS:** In this retrospective study, the pathological data of 28 patients with DGISTs who had been treated surgically at the Second Department of General Surgery, Sir Run Run Shaw Hospital (SRRSH) from June 1998 to December 2006 were reviewed. All pathological slides were examined by a single pathologist to confirm the diagnosis. In patients whose diagnosis was not confirmed by immunohistochemistry at the time of resection, representative paraffin blocks were reassembled, and sections were studied using antibodies against CD117 (c-kit), CD34, smooth muscle actin (SMA), vimentin, S-100, actin (HHF35), and desmin. Operative procedures were classified as wedge resection (WR), local resection with pure closure, without duodenal transection or anastomosis), segmental resection [SR,

duodenal transection with Roux-Y or Billroth II gastrojejunostomy (G-J), end-to-end duodenoduodenostomy (D-D), end-to-end or end-to-side duodenojejunostomy (D-J)], and pancreaticoduodenectomy (PD, Whipple operation with pancreatojejunostomy). R0 resection was pursued in all cases, and at least R1 resection was achieved. Regional lymphadenectomy was not performed. Clinical manifestations, surgery, medical treatment and follow-up data were retrospectively analyzed. Related studies in the literature were reviewed.

**RESULTS:** There were 12 males and 16 females patients, with a median age of 53 years (20-76 years). Their major complaints were "gastrointestinal bleeding" (57.2%) and "nonspecific discomfort" (32.1%). About 14.3%, 60.7%, 17.9%, and 7.1% of the tumors originated in the first to fourth portion, respectively, with a median size of 5.8 cm (1.6-20 cm). Treatment was by WR in 5 cases (17.9%), SR in 13 cases (46.4%), and by PD in 10 cases (35.7%). The morbidity and mortality rates were 35.7% and 3.6%, respectively. The median post-operative stay was 14.5 d (5-47 d). During a follow-up of 61 (23-164) mo, the 2-year and 5-year relapse-free survival was 83.3% and 50%, respectively. Eighty-four related articles were reviewed.

**CONCLUSION:** Surgeons can choose to perform limited resection or PD for operable DGISTs if clear surgical margins are achieved. Comprehensive treatment is necessary.

© 2013 Baishideng. All rights reserved.

**Key words:** Gastrointestinal stromal tumors; Duodenum; Limited resection; Pancreaticoduodenectomy; Survival

**Core tip:** Duodenal gastrointestinal stromal tumors (DGISTs) represent a subset of small bowel gastrointestinal stromal tumors that require special consideration given their clinical manifestations, particularly difficult surgical

decisions and poor prognosis. Surgeons can choose to perform limited resection or pancreaticoduodenectomy for operable DGISTs according to the tumor size, location, proximity to the duodenal papilla, and their technical feasibility, and both these two approaches lead to a similar oncological prognosis if clear surgical margins are achieved. The prognosis of a DGIST is poor, thus comprehensive treatment is necessary.

Gastrointestinal stromal tumors of the duodenum: Surgical management and survival results. *World J Gastroenterol* 2013; 19(36): 6000-6010 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/6000.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.6000>

## INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasms of the gastrointestinal tract, although the annual incidence rates reported worldwide are less than 20 per million, and only about 5000 new cases are diagnosed annually in the United States<sup>[1-3]</sup>. GIST is a primary gastrointestinal disease that can arise anywhere along the digestive tract in adults. The stomach (60%) and jejunioileum (30%) are the most common primary sites, and only a small number of cases have been reported in the colorectum (< 5%), esophagus and appendix (< 1%)<sup>[4,5]</sup>. In addition, duodenal lesions represent approximately 5% of GISTs.

All GISTs harbor some malignant potential, although only 10%-30% are clinically malignant. In the past decade following Fletcher's report<sup>[6]</sup>, primary GISTs are not classified as "benign" or "malignant", but are stratified by the probability of recurrence after complete resection into very low, low, intermediate, and high risk on the basis of their size and mitotic rate. Subsequently, Miettinen *et al.*<sup>[7]</sup> suggested that the anatomical origin may be another independent factor for risk stratification, indicating that DGISTs share maximal risks with rectal GISTs compared with those of the stomach and jejunioileum.

Although DGISTs are relatively rare, they account for nearly 30% of all primary tumors of the duodenum, and the vast majority of patients present with gastrointestinal bleeding<sup>[4]</sup>. With regard to treatment, DGISTs often pose difficult surgical problems, due to the complex anatomical relationship around the duodenum, *i.e.*, unlike the stomach or other intestinal segments where complete excision with wide margins are relatively straightforward procedures, wide resection of DGISTs will almost always entail a pancreaticoduodenectomy (PD), which is massively invasive and technically challenging<sup>[8,9]</sup>.

In recent years, a limited resection (LR) of DGISTs demonstrated a comparable effect to PD in selected cases<sup>[10]</sup>. However, the optimal surgical approach (LR or PD) for DGISTs is largely unknown, as all the available evidence has been derived from small retrospective

series<sup>[11]</sup>. In addition, scholars have gradually recognized the complexities of DGISTs, and these tumors have been classified separately from other small intestine GISTs into an independent category<sup>[12]</sup>. Also, a number of papers on DGISTs have been released<sup>[8-10,13-16]</sup>. Nevertheless, more experience with long-term oncological observations is required, especially for surgeons. This article aims to provide a single center experience of operable DGIST cases in China, and an update on the clinical management of DGISTs.

## MATERIALS AND METHODS

### Data collection

In this retrospective study, the pathological data of 28 patients with DGISTs who had been treated surgically at the Second Department of General Surgery, Sir Run Run Shaw Hospital (SRRSH) from June 1998 to December 2006 were reviewed. All data were collected once a definite diagnosis had been made. The author (Xiu-Jun Cai) managed his first case of DGIST as an independent attending and maintained his interests. During this review period, the patients of five attending surgeons in our department were included, and the priority of these data was approved by the patients while in hospital and by the surgeons. In addition, the patients were confirmed as cases by an inverse retrieve from the inpatient system of our hospital. This study was approved by the Institutional Review Board of SRRS.

All pathological slides were reviewed by a single pathologist to confirm the diagnosis. In patients whose diagnosis was not confirmed by immunohistochemistry at the time of resection, representative paraffin blocks were reassembled, and sections were studied using antibodies against CD117 (c-kit), CD34, smooth muscle actin (SMA), vimentin, S-100, actin (HHF35), and desmin. Tumors were classified as GISTs only if tumor cells were characterized by the typical morphology with positive staining for CD117 and/or CD34. Patient age, gender, presentation, medical history, laboratory and radiology examinations, surgery, medical treatment and follow-up data were obtained from patient records, including operative notes, pathology reports, and outpatient data. None of the patients were lost to follow-up due to good communication between the authors, patients and their primary care providers.

Operative procedures were classified as wedge resection (WR, local resection with pure closure, without duodenal transection or anastomosis), segmental resection [SR, duodenal transection with Roux-Y or Billroth II gastrojejunostomy (G-J), end-to-end duodenoduodenostomy (D-D), end-to-end or end-to-side duodenojejunostomy (D-J)], and pancreaticoduodenectomy (PD, Whipple operation with pancreatojejunostomy). R0 resection was pursued in all cases, and at least R1 resection was achieved. Regional lymphadenectomy was not performed.

### Statistical analysis

The overall survival (OS), disease-related survival (DRS), and relapse-free survival (RFS) were conventionally de-

fined. Survival was determined using the Kaplan-Meier method, and Cox regression was employed for multivariate analysis. A Pearson's, Spearman Rank, or Kendall's tau-b correlation was evaluated between variables if appropriate, and differences were analyzed using the Mann-Whitney *U* or unpaired Student's *t* test. All tests were two-sided and *P* values less than 0.05 were considered statistically significant. Software including Prism v5.04 (GraphPad Software Inc., La Jolla, CA, United States), SAS 9.2 for Windows (SAS Institute Inc., Cary, NC, United States), and the Thomson Data Analyzer (Thomson Reuters Corp., New York, NY, United States) were used

for statistics and literature reviews.

## RESULTS

### Patients

There were 12 males and 16 females patients, aged  $54.3 \pm 2.4$  years (mean  $\pm$  SEM if Gaussian distributed, median: 53, range: 20-76 years), and male patients ( $50.3 \pm 3.6$  years) were younger than female patients ( $59.6 \pm 2.5$  years,  $P = 0.0595$ ). The chief complaint (lead symptom) was summarized as "gastrointestinal bleeding" (57.2%), "nonspecific discomfort" (32.1%), and "incidentally

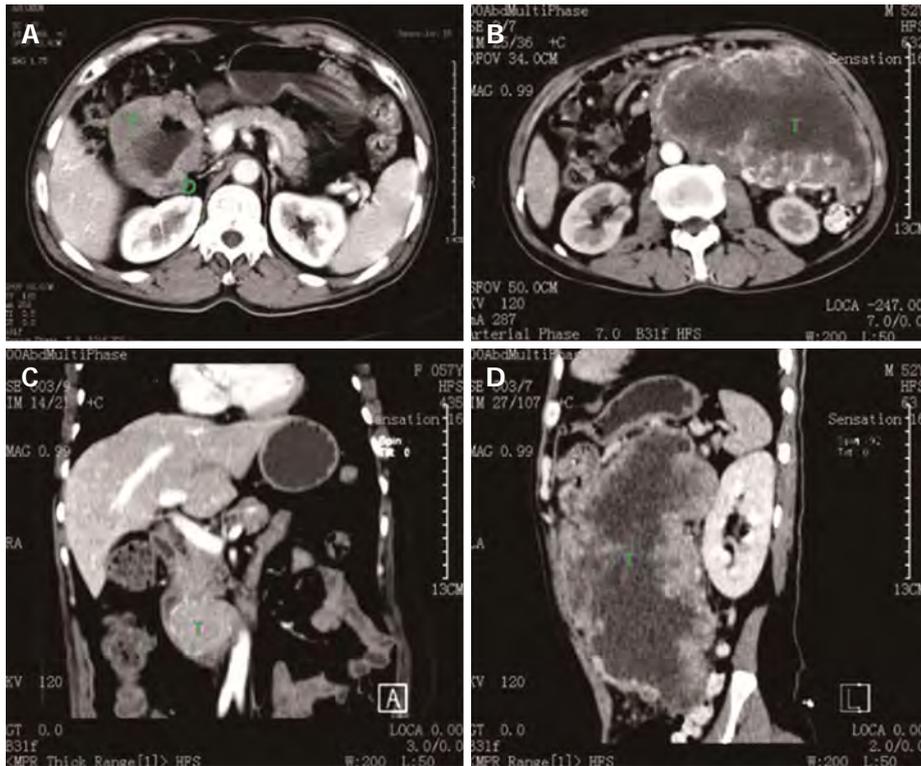

Figure 1 Respective computed tomography images. A: For case 28; B, D: For case 20; C: For case 18. (T: Tumor; D: Duodenum).

found" (10.7%); the symptoms were not correlated with tumor size or site ( $P > 0.05$ ). Four patients (14.3%) had comorbid gallbladder diseases. Seven patients (25.0%) had undergone one or two previous operations, two of which were for malignancy, and another two patients had essential hypertension or schistosomiasis. None of the patients had diabetes or neurofibromatosis (Table 1).

The hemoglobin in all patients was  $92.8 \pm 6.3$  g/L, which was highly correlated with the symptoms: the hemoglobin in patients with "gastrointestinal bleeding" was  $70.5 \pm 4.4$  g/L, whereas that of "non-gastrointestinal bleeding" patients ( $n = 12$ ) was  $122.4 \pm 7.3$  g/L ( $P < 0.0001$ ).

Each patient underwent abdominal ultrasonography (US), with 100% clinical availability, and only eight patients had positive results for DGISTs or duodenal tumors (vague reports of abdominal tumors were defined as negative), giving a sensitivity of 28.6% (8/28). The clinical availability of computed tomography (CT), magnetic resonance imaging (MRI), upper gastrointestinal barium examination (GI), gastroduodenoscopy (ES), endoscopic ultrasonography (EUS), digital subtraction angiography (DSA), and preoperative biopsy guided by CT, ES or EUS were 96.4%, 14.3%, 39.3%, 67.9%, 17.9%, 3.6%, and 53.6%, respectively. The sensitivities in sequence were 74.1%, 100%, 90.9%, 68.4%, 100%, 100%, and 26.7%. Collectively, twenty patients (71.4%) were diagnosed with duodenal tumors preoperatively, including ten (35.7%) with DGISTs; four patients (14.3%) were diagnosed with abdominal tumors of uncertain origin; minor diagnoses were retroperitoneal tumors (7.1%),

tumors of the pancreas head (3.6%) and acute abdomen (3.6%). Representative images are shown in Figures 1-3.

### Surgery

All surgical techniques were performed under general anesthesia. Intraoperatively, all tumors were single, solid, encapsulated but fragile, part of which had an irregular thick-walled necrotic core or multiple necrotic loculi. Four tumors originated in the bulb (D1, 14.3%), seventeen in the descending section (D2, 60.7%), five in the horizontal section (D3, 17.9%), and two in the ascending section (D4, 7.1%). The tumor size varied from 1.6 cm to 20 cm with a median of 5.8 cm (95%CI: 5.3-8.6), and was independent of the tumor site ( $P > 0.05$ ) (Table 2).

Five patients (17.9%) underwent a WR, 13 (46.4%) a SR, and 10 (35.7%) a PD. When SR patients were subdivided, four G-J (30.8%), four D-D (30.8%), and five D-J (38.4%) reconstructions were carried out. In addition, six concomitant operations were performed, *i.e.*, four cholecystectomies for gallbladder comorbidities and two intestinal resections for iatrogenic vessel injuries in the mesocolon transversum or the root of the small bowel mesentery.

Perioperative blood transfusions were common (78.6%) in this cohort, and eleven patients (39.3%) required intensive care as a postoperative transition, staying for 1-5 d (median: 2 d; 95%CI: 1.2-3.4 d). Eight (28.6%) major early complications occurred, including leakage of the choledochoenterostomy/duodenojejunostomy (7.1%) and delayed gastric emptying (DGE, 21.4%). Consequently, due to the intraoperative and early postop-

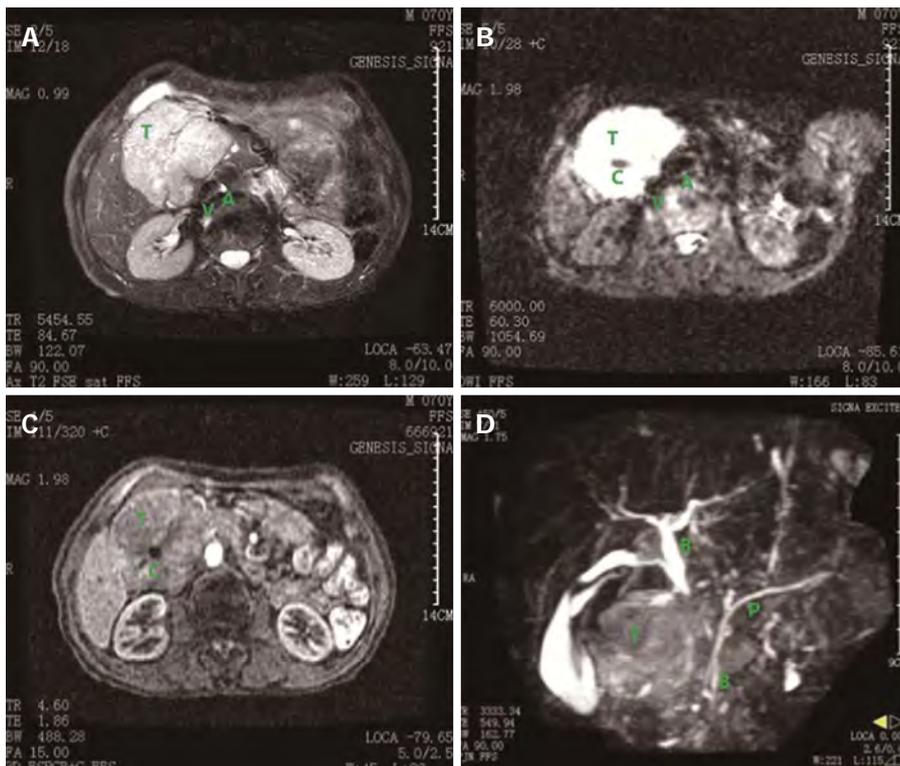

Figure 2 Respective magnetic resonance imaging images. A-C: For case 4; D: For case 22. T: Tumor; C: Necrotic core; A: Abdominal aorta; V: Inferior vena cava; B: Common bile duct; P: Main pancreatic duct.

erative morbidities, the following three reoperations were performed: a total enterectomy for the mesenteric root injury; an abdominal irrigation and drainage for the choledochoenterostomy failure; and a gastrojejunostomy for DGE.

The overall post-operative stay was 5-47 d (median: 14.5 d; 95%CI: 14.2-24.1 d), and was closely correlated with the surgical approaches; the intervals from the WR, PD, and SR to discharge were  $10.6 \pm 1.3$ ,  $14.6 \pm 2.5$  ( $P > 0.05$  for WR), and  $25.9 \pm 4.1$  d ( $P = 0.0412$  for PD,  $P = 0.0393$  for WR), respectively.

### Pathology and risk classifications

The positive rates of the four principal immunohisto-

chemistry markers, CD117, CD34, SMA, and S-100 were 96.4%, 64.3%, 60.7%, and 42.9%, respectively. Moreover, another three markers were introduced in certain patients: vimentin (13/13, total/positive), actin (18/8), and desmin (9/0). According to Fletcher's criterion 6, there were two patients (7.1%) with very low risk, nine patients (32.1%) with low risk, six patients (21.4%) with intermediate risk, and 11 patients (39.3%) with high risk, however, by applying Miettinen's criterion 7, 11 patients (39.3%) showed low risk and the other 17 (60.7%) possessed high risk (Table 3).

### Survival analysis

The median OS was 64.5 mo, including three elderly pa-

tients who died of lung cancer, pneumonia, and stroke, respectively. The median RFS and DRS in the whole patient group and subgroups are listed in Table 4, and the results of multivariate analysis are shown in Table 5. Moreover, a nomogram developed by Gold *et al*<sup>[17]</sup> to predict the probability of 2- and 5-year RFS was used, and the predicted values were compared to the actual values (Table 4 and Figure 4).

## DISCUSSION

GISTs are a family of tumors thought to arise from the interstitial cells of Cajal in the gastrointestinal tract. Recently, the putative stem and progenitor cells for GISTs have been identified<sup>[1]</sup>. Most GISTs have oncogenic mutations in either KIT or platelet-derived growth factor receptor- $\alpha$  (PDGFRA), and there is substantial evidence that these mutations are pathogenetic for the initiation of GISTs. Histopathologically, GISTs are usually well circumscribed and surrounded by a pseudocapsule, ranging in size from millimeters to 40 cm, with a median size between 5 cm and 8 cm, while large GISTs often show

cystic degeneration or central necrosis<sup>[18]</sup>. Microscopically, GISTs are defined as morphologically spindle cell, epithelioid, or occasionally pleomorphic, mesenchymal tumors, usually (approximately 95%) express the KIT protein and often (up to 90%) harbor mutations of a gene that encodes for a type III receptor tyrosine kinase (either KIT or PDGFRA)<sup>[19]</sup>.

Surgery is the mainstay of treatment for localized, resectable GISTs. The tumor should be removed *en-bloc* with its pseudocapsule to yield an adequate resection margin. The optimal width of the tumor-free margin has not been defined, and it is unclear if re-resection is beneficial for positive microscopic surgical margins (R1), especially as the free radial margin is the one that is positive in most instances and there is no additional tissue to be removed<sup>[20]</sup>. Lymphadenectomy is not warranted unless there is gross nodal involvement. In cases of unresectable or marginally resectable disease, adjuvant tyrosine kinase inhibitor (TKI) therapy should be considered. Following surgical resection, GISTs often recur locally, spread diffusely throughout the serosal surfaces of the abdomen and/or metastasize to the liver. Advanced disease is associated with

metastases to distant sites, including the lung and bone. Prior to the advent of TKI therapeutics, the prognosis for advanced GISTs was poor owing to their inherent resistance to both chemotherapy and radiation therapy<sup>[1]</sup>.

DGISTs share the above-mentioned factors, but have individuality. DGISTs are unique entities, not only due to their anatomical location, but also their clinical manifestations, particularly difficult surgical decisions and poor prognosis. This is why DGISTs have attracted the authors' interests as well as the attention of the French Sarcoma Group (GSF-GETO). In the 47<sup>th</sup> Annual Meet-

ing of the American Society of Clinical Oncology held in Chicago in June 2011, Duffaud *et al*<sup>[12]</sup> at GSF-GETO12 retrospectively analyzed 66 resectable DGIST patients with a median tumor size of 6 cm (1.5-31 cm), 29 of whom underwent WR, 23 SR, and 14 PD. During a median follow-up of 36 (1-168) mo, their 4-year OS and RFS rates were 89% and 58%, respectively. Duffaud's report is the largest cohort study in the surgical rather than pathological field, thus has current significance.

The clinical presentations of DGISTs are highly variable according to their size and the existence of mucosal

ulceration, but not tumor site<sup>[8,9]</sup>. The most common clinical presentation is reported to be gastrointestinal bleeding or abdominal pain. Interestingly in this series, the authors found that large tumors (> 5 cm) caused less gastrointestinal bleeding ( $P < 0.05$ ); this can be rationalized by the different phenotype of DGISTs, “submucosal/ulcerous type” or “serosal/massive type”, most small tumors were the former type and the majority of large tumors were the latter type<sup>[21]</sup>. More than 60% of DGISTs are located in the descending section, however, the reason for this is unclear.

Preoperatively, a variety of alternative examinations can be adopted, among which CT and MRI seem to be the best imaging modalities for assessment of the primary lesion and detection of metastases, whereas EUS is the optimum non-invasive tool for the clinical diagnosis<sup>[22,23]</sup>. Furthermore, EUS-guided biopsy has been established for the pathological diagnosis, although the sensitivity of DGIST samples obtained by EUS-guided biopsy is unsatisfactory compared with stomach GISTs (37.5% *vs* 84.4%)<sup>[24]</sup>. Recently, CT- or US-guided biopsy has been abandoned for resectable GISTs, due to the risk of pseudocapsule rupture and tumor spillage in the peritoneal cavity<sup>[4]</sup>. By integrating all the diagnostics, 71.4% of patients were accurately or probably diagnosed as having a DGIST. Moreover, the sensibility of preoperative diagnosis was correlated to Fletcher's or Miettinen's risk ( $P < 0.01$ ) and initial hemoglobin levels ( $P < 0.05$ ); that is, the tumor with malignant behavior has a tendency to be diagnosed as an abdominal/retroperitoneal tumor or a pancreatic cancer rather than a DGIST, whereas decreased hemoglobin potentially raises suspicion of gastrointestinal diseases, and possibly DGISTs.

The optimal surgical approach (LR or PD) for DGISTs is controversial. Goh *et al*<sup>[10]</sup> suggested that LR is associated with a shorter operation time, a similar complication rate, and a comparable disease-specific survival; Duffaud *et al*<sup>[12]</sup> concluded that LR rather than PD should be pursued to preserve optimal pancreas function for a better quality of life. According to the relatively few patients with long-term follow-up in this report, the findings support the views above. Although the DRS fol-

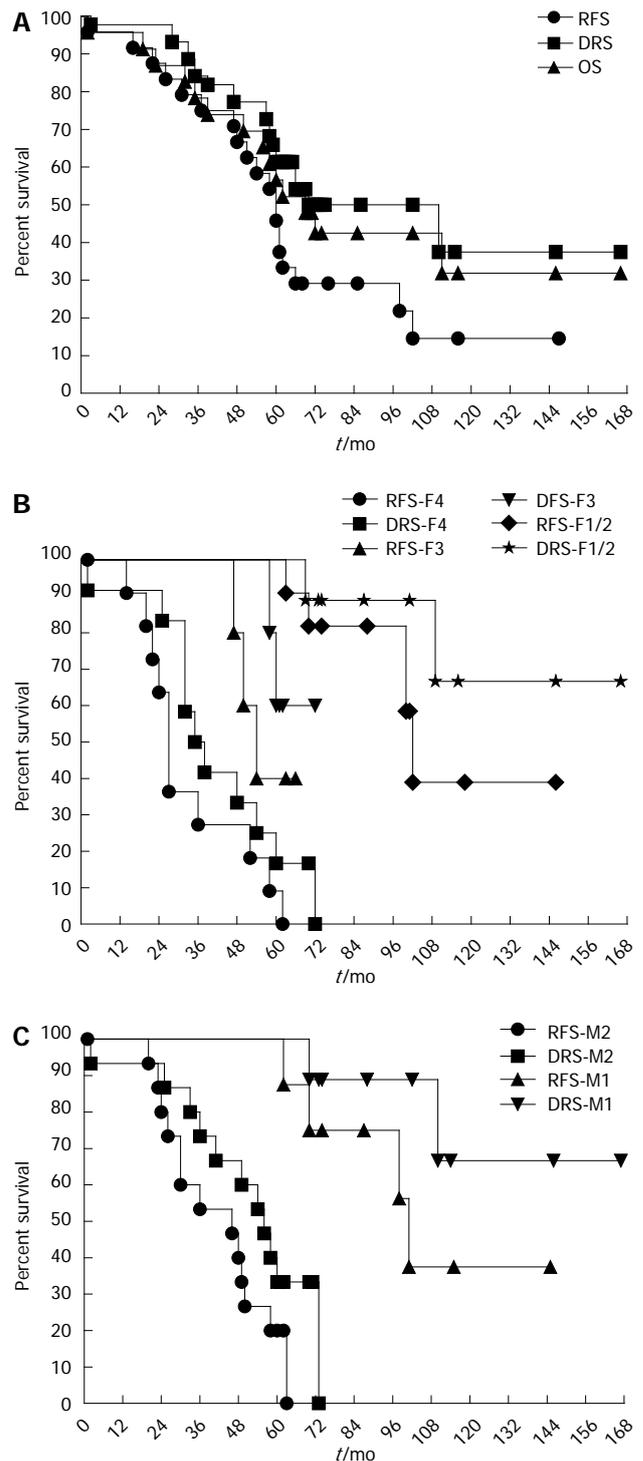

Figure 4 Survival curves. DRS: Disease-related survival; RFS: Relapse-free survival; OR: Overall survival; DFS: Disease free survival.

lowing PD seemed poor ( $P < 0.05$ ), after adjusting the covariates, PD tended to be performed in patients with high risk ( $P < 0.05$ ), and the results proved that LR and PD had a similar impact on RFS and DRS ( $P > 0.05$ ), thus, both surgical approach lead to a similar oncological prognosis if clear surgical margins are achieved<sup>[4,14]</sup>. Patients undergoing LR and PD showed similar overall morbidities (44.4% *vs* 20.0%;  $P > 0.05$ ) with the excep-

tion of DGE which was more frequent in the SR group (46.2%), and prolonged postoperative stay ( $P > 0.05$ ).

Regardless of the pros and cons outlined above, essential factors which influence whether LR or PD is chosen are tumor size, location, proximity to the duodenal papilla, and technical feasibility<sup>[25-28]</sup>. In general, WR with primary closure can be performed for small lesions if the resulting lumen is adequate and the Vater ampulla can be preserved, even by laparoscopy or combined laparoscopic surgery<sup>[29,30]</sup>. Occasionally, the antimesenteric defect after WR can be closed by Roux-en-Y duodenojejunostomy, whereas the mesenteric defect inside the “C” loop of the pancreas head can be repaired by translocation of the distal common bile duct as a patch<sup>[31,32]</sup>. SR with gastrojejunostomy or end-to-side/-end duodenojejunostomy may be performed for larger tumors located in the D1, D3 and D4. The side[D]-to-end[J] duodenojejunostomy is not recommended due to possible duodenal leakage and stump stasis (stump syndrome)<sup>[33]</sup>. Some scholars advocate resection and anastomosis even for lesions close to the papilla by performing the anastomosis just below the ampulla, which has been achieved by performing a lateromedial anastomosis opposite the papilla or by performing papilloplasty with a temporary stent catheter inserted into the papilla to avoid possible postoperative stenosis<sup>[34,35]</sup>. PD is only indicated when the tumor is located in the D2 and involves the papilla, pancreas, or if the tumor is large with high malignant potential and has involved the adjoining organs<sup>[8]</sup>. PD combined with major hepatectomy for a DGIST with localized liver metastases has also been reported<sup>[36]</sup>. PD can provide a wider tumor clearance, but reconstruction is difficult and there is an increased risk of long-term anastomotic stenosis, as both the pancreatic and common bile ducts are likely to be smaller in diameter<sup>[37]</sup>. In this context, the author introduced the binding pancreaticojejunostomy, which resolved these problems, improved the anastomotic operability, and decreased postoperative complications<sup>[38,39]</sup>. In addition, for ES-accessible mini tumors (less than 1.2 cm) in the D1, D2, and proximal D3, EUS-assisted band ligation is also feasible, although the necessity is debated<sup>[40]</sup>.

Beside complete resection, pharmacological treatments are necessary<sup>[41]</sup>. Glivec® (imatinib), a TKI, is now widely prescribed in the United States and Western countries for high-risk local GIST patients as adjuvant therapy after surgery and in metastatic GIST patients as first-line treatment<sup>[2,20,42]</sup>. However, in China, only 8.1% of urban patients (Table 3, 7.1% of present cases) take imatinib, although the Glivec® International Patient Assistance Program (GIPAP) was officially started in September 2003 by the China Charity Foundation, the Tumor Drug Department of Novartis, and the Max Foundation, with the objective of providing free medicines to patients who needed treatment. GIPAP has relatively strict eligibility criteria, and the annual Glivec® cost is far beyond the economic realities in China, therefore only a few urban patients benefit from this donation program, let alone

rural populations. Accordingly, neoadjuvant imatinib therapy is impractical in China, despite the fact that it is believed to allow LR in patients with locally advanced DGISTs<sup>[12]</sup>.

In terms of the survival analyses, Duffaud *et al*<sup>[12]</sup> indicated that only mitotic rate predicted RFS; whereas the present study showed that not only mitotic rate, but also tumor size and various combinations of these two parameters in addition to Gold's point, Fletcher's risk and Miettinen's risk predict RFS with similar statistical powers ( $P < 0.001$ ). Moreover, preoperative diagnosis of a duodenal tumor is also a positive factor for better patient survival, however, it is not an independent parameter. Gold *et al*<sup>[17]</sup> of the Memorial Sloan-Kettering Cancer Center have developed a nomogram to predict the probability of 2- and 5-year RFS for resected GISTs patients, and tested it in patients from the Spanish Group for Research on Sarcomas and the Mayo Clinic. With regard to the present cohort, Table 4 shows that the actual 2-year RFS rate was similar to the predicted value (83.3% *vs* 83%), but the actual 5-year RFS rate was lower than the predicted value (50% *vs* 70%), this may be due to the more malignant behavior of DGISTs compared with other small intestinal GISTs.

The limitations of this study include its retrospective design, small sample size, single center experience, and lack of adjuvant therapy. As analyses with small numbers of patients sometimes give misleading results, readers should be careful in evaluating these findings. However, based on a comprehensive literature review, it is necessary to strengthen these results. Future prospective studies enrolling larger numbers of patients and/or multiple medical centers are required.

## COMMENTS

### Background

Duodenal gastrointestinal stromal tumors (DGISTs) are a rare entity of gastrointestinal stromal tumors (GISTs), with characteristic clinical manifestations. Few cohorts with the exception of case studies have been reported. The purpose of this report is to provide long-term survival results of operable DGISTs in a tertiary center in China.

### Research frontiers

Although DGISTs are relatively rare, they account for nearly 30% of all primary tumors of the duodenum, and the vast majority present with gastrointestinal bleeding. With regard to treatment, DGISTs often pose difficult surgical problems, due to their complex anatomical relationship around the duodenum, *i.e.*, unlike the stomach or other intestinal segments where complete excision with wide margins are relatively straightforward procedures, wide resection of DGISTs will almost always entail a pancreaticoduodenectomy (PD), which is massively invasive and technically challenging.

### Innovations and breakthroughs

In recent years, a limited resection (LR) of DGISTs demonstrated a comparable outcome to PD in selected cases. However, the optimal surgical approach (LR or PD) for DGISTs is largely unknown, as all the available evidence has been derived from small retrospective series. In addition, scholars have gradually recognized the complexities of DGISTs, and these tumors have been classified separately from other small intestine GISTs into an independent category. Also, a number of papers on DGISTs have been released. Nevertheless, more experiences with long-term oncological observations are required, especially for surgeons.

### Applications

This article provides a single center experience of operable cases in China, and

an update on the clinical management of DGISTs.

### Terminology

GIST is the most common mesenchymal neoplasm of the gastrointestinal tract. GIST is a primary gastrointestinal disease that can arise anywhere along the digestive tract in adults.

### Peer review

DGIST represents a subset of small bowel GISTs that requires special consideration given its clinical manifestations, especially for the difficult surgical decisions and poor prognoses. Surgeons can choose the limited resection or pancreaticoduodenectomy for operable DGISTs according to the tumor size, location, proximity to the duodenal papilla, and their technical feasibility, and either of the two approaches leads to an indistinctive oncological prognosis as long as clear surgical margins are achieved. The prognoses of DGISTs are poor, thus a comprehensive treatment is necessary. The authors provided a single center experience of operable cases in China, and reviewed update on the clinical management of DGISTs.

### Abstract

**AIM:** To report outcomes on patients undergoing radiofrequency ablation (RFA) for early oesophageal squamous neoplasia from a National Registry.

**METHODS:** A Prospective cohort study from 8 tertiary referral centres in the United Kingdom. Patients with squamous high grade dysplasia (HGD) and early squamous cell carcinoma (ESCC) confined to the mucosa were treated. Visible lesions were removed by endoscopic mucosal resection (EMR) before RFA. Following initial RFA treatment, patients were followed up 3 monthly. Residual flat dysplasia was treated with RFA until complete reversal dysplasia (CR-D) was achieved or progression to invasive Squamous cell cancer defined as infiltration into the submucosa layer or beyond. The main outcome measures were CR-D at 12 mo from start of treatment, long term durability, progression to cancer and adverse events.

**RESULTS:** Twenty patients with squamous HGD/ESCC completed treatment protocol. Five patients (25%) had EMR before starting RFA treatment. CR-D was 50% at 12 mo with a median of 1 RFA treatment, mean 1.5 (range 1-3). Two further patients achieved CR-D with repeat RFA after this time. Eighty per cent with CR-D remain dysplasia free at latest biopsy, with median follow up 24 mo (IQR 17-54). Six of 20 patients (30%) progressed to invasive cancer at 1 year. Four patients (20%) required endoscopic dilatations for symptomatic structuring after treatment. Two of these patients have required serial dilatations thereafter for symptomatic dysphagia with a median of 4 dilatations per patient. The other 2 patients required only a single dilatation to achieve an adequate symptomatic response. One patient developed cancer during follow up after end of treatment protocol.

**CONCLUSION:** The role of RFA in these patients re-

mains unclear. In our series 50% patients responded at 12 mo. These figures are lower than limited published data.

**Key words:** Squamous neoplasia; Oesophageal cancer; Endoscopic mucosal resection; High-grade dysplasia; Radiofrequency ablation

**Core tip:** Squamous cell cancer of the esophagus is an aggressive pathology with a poor prognosis and therefore early intervention is paramount to improve survival. Minimally invasive endoscopic therapy with endoscopic resection and radiofrequency ablation in patients with early squamous neoplasia of the esophagus has the potential to treat selected patients. Early response to RFA is prognostically important. Further studies with more patient numbers are required to explore the long and short term efficacy of this intervention in these complex patients.

## INTRODUCTION

Squamous cell cancer (SCC) comprises nearly 90% of all esophageal cancers worldwide<sup>[1]</sup>. The incidence of esophageal SCC has fallen in the western world in the past 3 decades but still remains between 4 and 16 per 100000 population. This is strongly dependent on geographical location worldwide with figures far higher in Asia<sup>[2]</sup>. In the western world factors such as alcohol and tobacco play an important role in the development of oesophageal SCC<sup>[3]</sup>. This condition carries a poor prognosis with an overall five year survival rate of 10%-15%<sup>[4]</sup>. Those treated with surgery following neo-adjuvant therapy still carry a poor prognosis with a 5 year overall survival of about 33%. Surgery carries a significant mortality of 5% and postoperative morbidity of up to 47%<sup>[5]</sup>. The precursor lesion to SCC is known as squamous dysplasia. The World Health Organization (WHO) refers to squamous dysplasia as squamous intra-epithelial neoplasia and has further categorized the condition depending on the grade of dysplasia as low grade intra-epithelial neoplasia (LGIN) through to high grade intra-epithelial neoplasia (HGIN)<sup>[6]</sup>. Non invasive SCC is often referred to as ESCC.

Squamous high-grade dysplasia and ESCC carry a risk of progression to invasive SCC of up to 65% at 3.5 years and as high as 74% at 13.5 years<sup>[7]</sup>. The chance of lymph

node metastasis is dependent upon the penetration and depth of the lesion. Lesions restricted to the epithelial layer (mL) or the lamina propria (m<sup>2</sup>) have a low rate of lymph node metastases (< 5%); lesions that penetrate into the muscularis mucosae (m3) or the first third of the submucosa (sm1) have a higher risk (5%-15%)<sup>[8-12]</sup>. Once there is deeper submucosal (sm2 and sm3) involvement the risk of lymph node spread can be in the region of 24%<sup>[13,14]</sup> and surgical or oncological interventions are the treatments of choice. Traditional treatment for squamous neoplasia has been surgery or chemo-radiotherapy. However with disease limited to the mucosa the risk of lymph node involvement is low and minimally invasive endoscopic therapy is an alternative.

With the advances in minimally invasive esophageal endotherapy over the past decade there are now additional treatment options for patients with squamous HGD and ESCC confined to the lamina propria. Centers in Asia and the Western countries have shown that the use of EMR is effective and curative for these patients<sup>[15,16]</sup>. However this form of endotherapy is associated with significant oesophageal stenosis<sup>[17]</sup> and therefore alternative treatments have been desirable. The use of photodynamic therapy in this cohort of patients has again shown promising results<sup>[18]</sup> but is not widely available and again is associated with significant stenosis post treatment.

Endoscopic submucosal dissection (ESD) has been developed in Asia as one of the standard endoscopic resection techniques for early squamous neoplasia of the oesophagus. ESD enables oesophageal lesions, regardless of their size, to be removed en bloc and thus has a lower local recurrence rate than EMR. The *en bloc* resection rate is greater than 90% (90.6%-100%)<sup>[19-25]</sup>. *En bloc* resection, meaning resection in a single piece, facilitates an accurate histological assessment and reduces the risk of recurrence. In fact, the local recurrence rate after oesophageal ESD is extremely low (0%-3.1%)<sup>[21-25]</sup>. ESD is yet to become established in the united kingdom as this techniques is not widely available and is confined to specialist center's only.

RFA using the HALO system (BÂRRX Medical, Sunnyvale, California, United States) is a novel minimally invasive field ablation technique which has established efficacy for treating HGD and early adenocarcinoma arising in Barrett's esophagus (BE)<sup>[26]</sup>. The HALO System uses ultra short pulsed radiofrequency that ablates the mucosa whilst preserving the submucosa. Emerging evidence suggests that RFA is safe and efficacious in the management of squamous HGD<sup>[26-29]</sup>. We report the United Kingdom HALO registry experience of the first 20 patients with squamous HGD and ESCC who have completed treatment protocol.

The UK HALO RFA registry was created to audit outcomes of patients undergoing RFA for HGD/early neoplasia in BE and patients with squamous esophageal HGD/ESCC. It is a prospective multicenter registry which holds patient data from 20 centers nationwide.

## MATERIALS AND METHODS

### Ethical approval

Ethical approval was granted by the Joint UCL/UCLH Committee on the ethics of Human research (REC REF 08/H0714/27). The HALO ablation system has already been approved by the US Food and Drug Administration (FDA). In addition it is a European Cleared (CE) device as well as having been approved by the National Institute of Clinical Excellence (NICE) in the United Kingdom for treatment of HGD in BE.

### Inclusion criteria

All patients referred for consideration for endotherapy for squamous HGD and early SCC were invited to enter at collaborating centers. Patients had an endoscopic and histological diagnosis of squamous HGD or ESCC confirmed by two independent expert gastrointestinal histopathologist prior to embarking on endotherapy.

### Enrolment

Between January 2008 and March 2013 a total of 670 patients were enrolled to the registry from a total of 20 centers nationwide in the United Kingdom. Amongst these, 27 patients from 8 centers had squamous HGD or ESCC. Twenty of these have completed treatment protocol.

### Pre-enrolment staging

All patients were referred by the cancer center specialist multidisciplinary team (sMDT). All had endoscopic assessment with multiple biopsies to exclude invasive disease. All investigators used the Paris Classification to classify macroscopic lesions<sup>[30]</sup>. Enhanced endoscopic techniques including chromoendoscopy with Lugol's iodine, narrow band imaging (Olympus, Hamburg, Germany) and I-scan (Pentax, Hoya Corporation, Japan) were used to target areas of suspected squamous dysplasia (see Figure 1) depending on which technology was present in the respective hospitals. Endoscopic ultrasound (EUS) and CT scanning was performed according to sMDT requirements. Endoscopic ultrasound was used if there were visible lesions seen to ensure that the neoplasia was confined to the mucosa. Endoscopic mucosal resection (EMR) was performed for any raised visible lesions and assessed by two expert gastrointestinal histopathologists at each center. Four quadrant biopsies were then obtained every 2 cm through the oesophagus to map for any further neoplasia. If invasive cancer was detected, the patient was referred back to the sMDT for alternative therapy. Invasive cancer was defined as neoplasia invading into the submucosa such that it was no longer amenable to endoscopic therapy with EMR or RFA.

### Registry endoscopy protocol

Once consented patients had their first ablation as described below. At 3 mo all patients returned for follow up endoscopy where mapping biopsies were taken using chromoendoscopy with Lugol's iodine and enhanced endoscopic imaging. As well as targeted biopsies of USLs

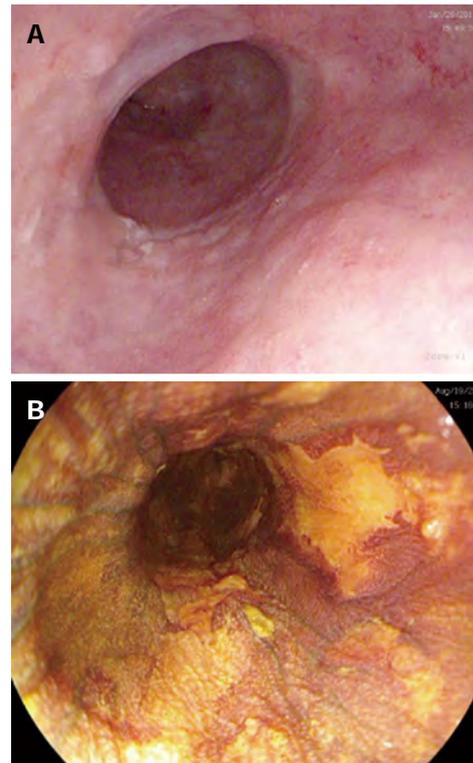

Figure 1 Endoscopic views of a segment of squamous high grade dysplasia with macroscopic lesions suggestive of dysplasia with (A) high definition white light endoscopy and confirmation of areas of dysplasia with (B) Lugol's iodine dye spray representing unstained lesions.

seen after Lugol's staining, systematic 4 quadrant biopsies every 2 cm were taken through the squamous esophagus to map any residual dysplasia. Any new raised visible lesions were treated with EMR. A decision to repeat RFA treatment was based on histology rather than visual clearance of disease. At 12 mo after the first ablation, biopsies were again taken to assess for eradication of dysplasia (CR-D) and this was defined as the primary end point. Patients with residual disease at this point were considered for ongoing endotherapy at the clinicians' discretion after consultation with the patient and discussion at the sMDT. Development of invasive cancer at any time was defined as treatment failure and data were censored at this point. An overview of the study protocol is shown in Figure 2.

### Radiofrequency ablation procedures and follow up procedures

RFA was delivered circumferentially (HALO 360) or focally (HALO 90) at 12 J/cm<sup>2</sup>. As opposed to the 2 ablations delivered for RFA in BE at each treatment session, only a single ablation was delivered in the registry protocol for squamous HGD. In patients with multifocal dysplasia circumferential RFA was applied and focal RFA administered in patients with unifocal well defined areas of dysplasia. These areas were reported in centimeters from the incisors so that follow up procedures could use this reference to interrogate treated segments of esophagus for success or failure.

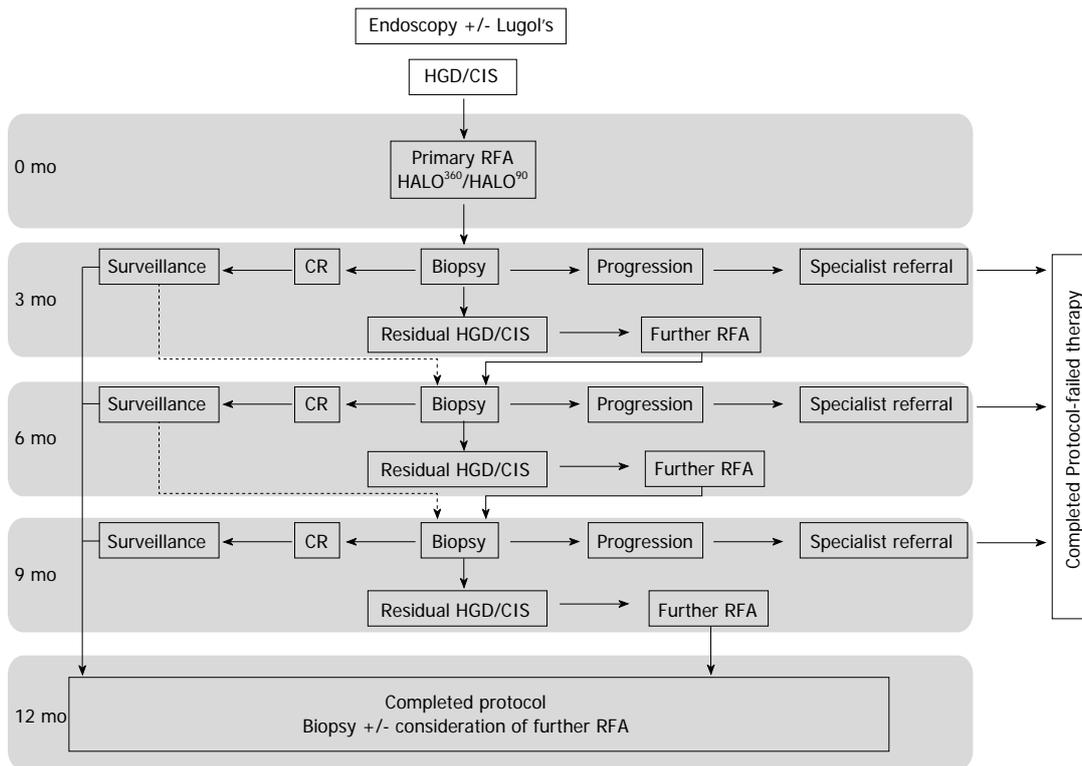

Figure 2 HALO radiofrequency ablation protocol for ablation of Squamous high grade dysplasia and carcinoma *in situ*. Endoscopic mucosal resection (EMR) was carried out at any stage for new visible lesions. RFA: Radiofrequency ablation; HGD: High grade dysplasia; CIS: Carcinoma in situ; CR: Complete reversal.

Chromoendoscopy with magnifying endoscopy and enhanced imaging were used at follow up procedures to examine the previously treated areas referenced at the previous endoscopy. Again all histology was reviewed by two expert gastrointestinal histopathologists.

**Post procedure care/follow up**

All patients were maintained on a twice-daily regimen of a proton pump inhibitor. Soluble co-codamol was prescribed for discomfort post procedure. All patients were discharged home the same day after review by the endoscopist. Follow up endoscopies were carried out at 3 monthly intervals as per protocol with enhanced endoscopic imaging and lugol’s chromoendoscopy (Figure 2).

**Primary and secondary end points and long term outcomes**

The primary end points were complete reversal of squamous dysplasia (CR-D) at 12 mo and development of invasive cancer at any stage. Secondary end points include long-term durability, number of RFA procedures and adverse events. We also followed up all patients who progressed to cancer so that we could determine their long-term outcomes.

**Statistical analysis**

Endpoints such as CR-D at end of protocol were compared to the patient’s baseline status using log rank test and long term outcomes predicted with Kaplan-Meier survival analysis.

**RESULTS**

Twenty seven patients were treated at 8 different centers nationwide. Twenty of these have completed the treatment protocol and we report the outcomes of these patients.

Pre treatment parameters are given in Table 1. Four patients (20%) had disease limited to 1cm (focal disease) and the remaining 16 patients had definable lengths of dysplasia (multi-focal disease) with a median length of 5cm (IQR 1-10). Five patients (25%) had EMR before starting RFA treatment. All patients gave informed written consent. Median follow up for those who had successful ablation and are still in follow up (*n* = 10) is 24 mo (IQR 17-54).

Patients had a median of 1 RFA session and mean of 1.5 RFA treatments during the protocol period. A total of 6 rescue EMRs have been carried out in 6 patients after their first RFA. Two of these patients had already undergone EMR prior to initiating RFA treatment.

**Reversal of dysplasia at end of protocol**

Ten patients (50%) had reversal of dysplasia/CIS (CR-D) at end of protocol after a median of 1 treatment. Eight of these patients (80%) remain free of dysplasia on their latest follow up (median follow up from first treatment 24 mo, range 19-54 mo, see Figure 3). Of the 2 patients who had a recurrence after initial successful RFA, one progressed to invasive disease. The other had multifocal low grade dysplasia (LGD) 4 mo after completing treatment and at latest follow up (41 mo after protocol end) has had 3 further circumferential ablations and one focal

**Table 1** Demographic data of all patients in squamous high grade dysplasia, carcinoma in situ United Kingdom radiofrequency ablation registry *n* (%)

<sup>1</sup>Focal dysplasia refers to single plaques of dysplasia 1 cm or less in length;

<sup>2</sup>Multi-focal dysplasia refers to multiple plaques of dysplasia > 1 cm in length. ESCC: Early squamous cell carcinoma.

ablation. This patient still has LGD at latest follow up. The clinician and patient have, nonetheless, agreed to perform a further RFA treatment.

Four patients (20%) had residual dysplasia at 12 mo. One patient was referred for surgery to remove the dysplasia. One patient left the country and has been lost to follow up. The other 2 have opted to have further RFA and after a mean of 2 RFA treatments over 10 mo are free of disease at present (Figure 3). Figure 4 shows the predicted rate of dysplasia reversal in all 20 patients who have undergone treatment and completed protocol using Kaplan Meier outcome statistics.

#### Previous endoscopic resection and baseline histology

Although our numbers are too small to draw firm conclusions, there is a trend towards baseline histological grade (HGD or ESCC) having an influence on eventual outcome with HGD having a better outcome (66% *vs* 33%, HR = 0.535, *P* = 0.0308, 95%CI: 0.141-1.505, Log rank test). Larger numbers are however needed to confirm this trend. Our data do not suggest that EMR before commencing RFA influences dysplasia reversal rates and long term outcomes (33% *vs* 66%, HR = 0.229, *P* = 0.778, 95%CI: 0.3264-3.642, *P* = 0.8882, Log Rank test). Dysplasia reversal was also the same whether EMR was required during the RFA protocol (3/6 - 50%) or whether patients underwent RFA alone (7/14 - 50%).

#### Early cancer progression and overall cumulative risk of progression

Four of the 20 (20%) patients had progressed to invasive SCC at their first follow up and therefore no further RFA was performed. Two further patients who were treated with an initial circumferential RFA followed by an EMR at follow up endoscopy progressed to invasive cancer

at protocol end. All progressors were referred for consideration of chemoradiotherapy. Using Kaplan Meier analysis, the risk of progression to invasive disease in all 20 patients who completed the protocol is 26% at 18 mo (Figure 5).

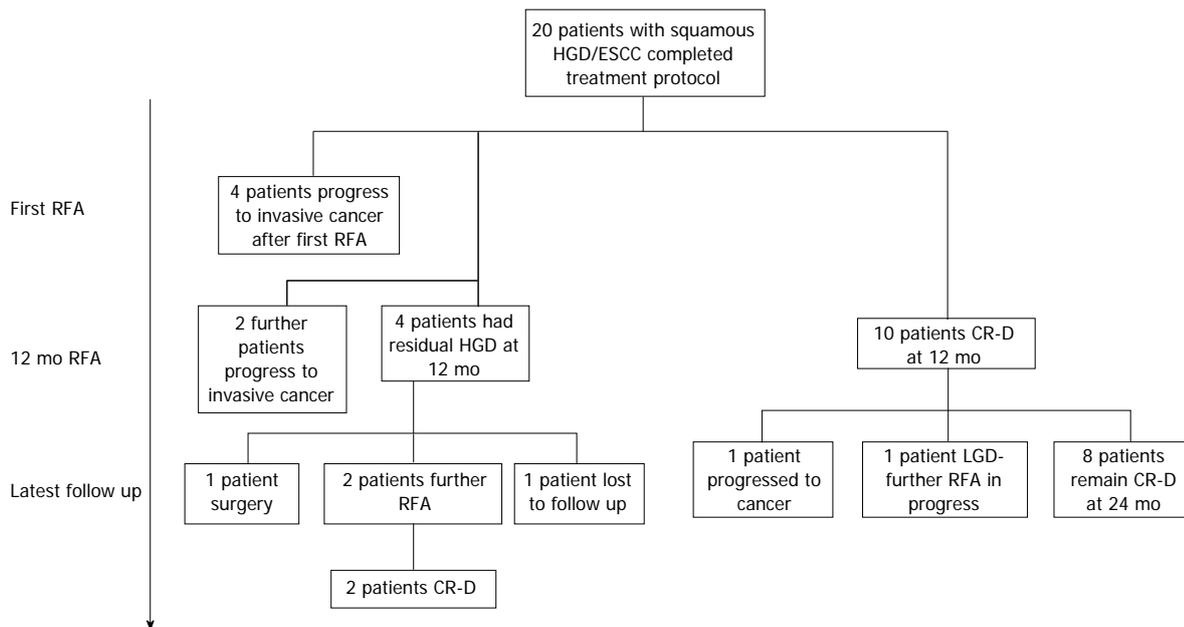

#### Adverse events

One patient suffered a superficial esophageal tear following sizing prior to attempted circumferential ablation. The procedure was discontinued and focal ablation was used at the same procedure. The patient was discharged home without any complications. Four patients (20%) required dilatations for moderate esophageal structuring after their first circumferential treatment. Only one had been treated by EMR prior to RFA. Two of these patients have required serial dilatations thereafter for symptomatic dysphagia with a median of 4 dilatations per patient. The other 2 patients required only a single dilatation to achieve an adequate symptomatic response. Three serious adverse events have been reported to date. Two patients had bleeding at their follow up endoscopy after biopsies and required adrenaline injection. Both occurred following Lugol's iodine application. Although they were admitted overnight in hospital for observation they were discharged the following day without blood transfusion.

## DISCUSSION

The role for endotherapy such as RFA as a first line intervention for patients with squamous HGD and ESCC *in situ* is yet to be established as standard practice. Squamous dysplasia is a very aggressive pathology and early diagnosis and intervention are paramount as disease progression often precludes curative therapy. However the high surgical mortality rate of up to 2%-5% and subsequent morbidity of 20%-50% means that alternative minimally invasive and novel techniques must be investigated<sup>[5,11,12,31]</sup>.

Early literature into the use of RFA in squamous dysplasia emerged in 2008, following on from its recognized potential in early Barrett's neoplasia. Pouw *et al*<sup>[32]</sup> described the case of a 66-year-old patient with a unifocal lesion within the esophagus. This lesion had arisen after the patient had previously undergone chemoradiotherapy for a T2N1M0 squamous cell cancer of the hypopharynx. Following pre-treatment staging to ensure the lesion was confined to the mucosal surface only, the patient received a single balloon based ablation and had no recurrent disease at 4 mo follow up. Subsequent to this report, data regarding the efficacy of RFA in squamous dysplasia have been limited. One of the largest series to date examined the success of RFA in 13 patients within two tertiary centers<sup>[28]</sup>. Nine of the study cohort (69%) required EMR at baseline for visible nodules prior to commencing RFA. Dysplasia reversal was excellent in these patients with 100% achieving CR-D with a median of 2 treatments and remaining disease free with a follow up period of 17 mo from first treatment. In this study patients received 2 ablations at each treatment endoscopy with 12 J/cm<sup>2</sup> for the circumferential ablation and 15 J/cm<sup>2</sup> for focal

**Figure 3** Outcomes for all 20 patients who have completed treatment protocol with radiofrequency ablation for squamous high grade dysplasia/early squamous cell carcinoma. RFA: Radiofrequency ablation; HGD: High grade dysplasia; ESCC: Early squamous cell carcinoma; CR-D: Complete reversal dysplasia; LGD: Low grade dysplasia.

ablation. Stenosis and stricturing was confined to just 2 of the 13 patients in this series. This same group has recently gone on to investigate the efficacy of RFA in a larger cohort of 29 patients in a prospective study<sup>[33]</sup>. This study was conducted in a single Chinese center. All patients underwent an index circumferential ablation of all unstained lesions (USLs) with Lugol’s chromoendoscopy. All patients were followed up at 3 monthly intervals with chromoendoscopy with biopsies followed by focal ablation of any USLs. Using the Chinese classification of squamous neoplasia<sup>[34]</sup>, 18 patients had moderate intraepithelial neoplasia (MGIN), 10 had high grade intraepithelial neoplasia (HGIN), and a single patient had early ESCC. At 12 mo 97% (28/29) had a complete reversal of neoplasia and furthermore there was no progression to invasive cancer within the treated group. The single patient with residual disease at 12 mo had EMR for unifocal disease with clear resection margins.

In our study examining outcomes from the UK RFA registry of patients with squamous dysplasia undergoing RFA, CR-D was 50% at protocol completion, although dysplasia was later reversed in two further patients following more RFA sessions. These figures are lower than the limited published data from other centers worldwide<sup>[28]</sup>. We designed our study with a protocol end at 12 mo so that this study could be directly compared with those previously published. It may be that future studies should consider alternative end points to allow for a longer duration of treatment.

In our series 20% of patients progressed to invasive disease after only one session of RFA and were then offered chemo-radiotherapy. These patients represent most of those who eventually developed cancer. This suggests that a single RFA treatment might even be considered as

a staging procedure. Early failure would identify patients who should be treated with more conventional modalities. Indeed, 80% of those who achieved successful reversal of dysplasia at the end of the RFA treatment protocol remain in remission at most recent follow up.

The 20% rate of progression after a single treatment may also point to the fact that these patients may have been under staged and may in some cases harbor more aggressive neoplasia at baseline that was not sampled. Whereas with other dysplastic conditions of the esophagus such as BE where there are often distinct areas of abnormality within the macroscopically visible columnar lined mucosa, with squamous dysplasia these areas are subtle. Detection relies on adjuncts such as chromoendoscopy with Lugol’s iodine solution, optical endoscopic enhancements and the experience and expertise of the endoscopists to spot anomalies. Even with Lugol’s solution the accuracy of detecting lesions varies greatly. In a recently published series the positive predictive value for Lugol’s detecting squamous neoplasia in unstained lesions after RFA was only 14%<sup>[33]</sup>.

It appears that the use of EMR in our cohort of patients is somewhat limited compared to similar published studies<sup>[15,35,36]</sup>. Only 5 patients (25%) underwent EMR before starting HALO RFA and there were a total of only 6 resections in 4 patients after their index treatment. This may account for the lower rates of dysplasia clearance and progression after the index treatment. Visible nodular lesions before or after RFA treatment may harbor submucosal disease and unless resected early may represent recurrence and progressive invasive disease.

The published data on the success of RFA in BE is robust and plentiful whilst there is limited data on its use in squamous HGD. The AIM dysplasia trial<sup>[26]</sup> demon-

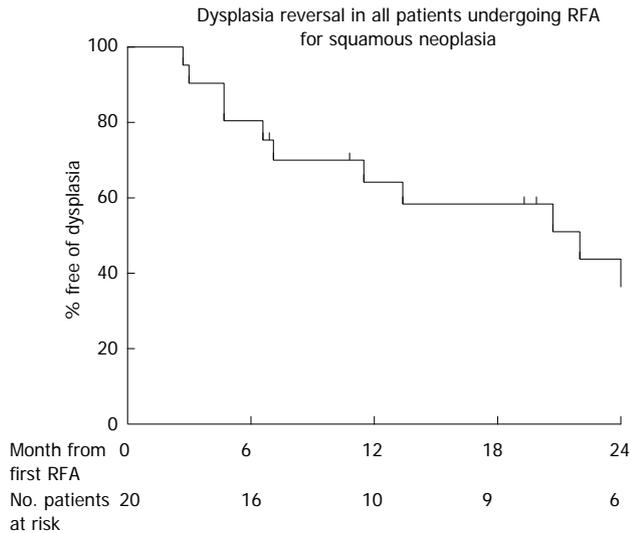

Figure 4 Kaplan Meier outcome statistics predicting the risk of recurrent dysplasia and durability of radiofrequency ablation treatment in all 20 patients treated with radiofrequency ablation. RFA: Radiofrequency ablation.

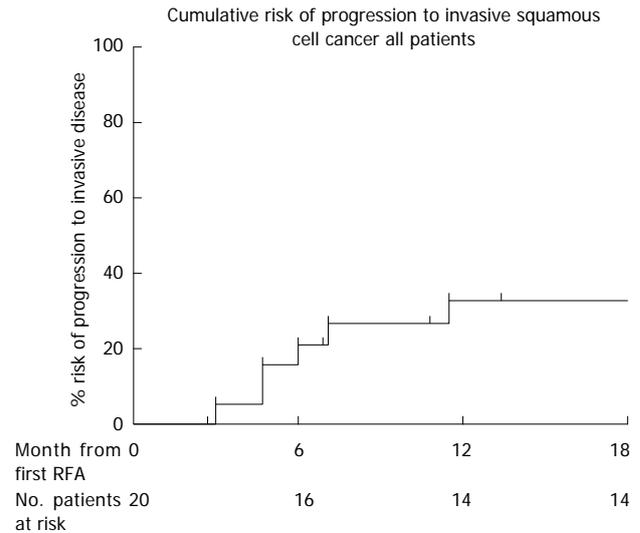

Figure 5 Cumulative risk of cancer progression in all 20 patients who completed treatment with radiofrequency ablation for high grade dysplasia/early squamous cell carcinoma in the United Kingdom radiofrequency ablation registry. RFA: Radiofrequency ablation.

strated impressive outcomes with reversal of HGD in patients with BE as high as 81% with a structured ablation protocol over 12 mo. In this protocol all patients were ablated twice at each treatment with 12 J/cm<sup>2</sup> for both circumferential and focal ablation. Mean treatments per patient was 3.5 ablations and stricturing occurred in 5% requiring dilatations. Subsequent published literature and our own outcomes from the RFA United Kingdom national registry have reproduced similar outcomes in patients with BE<sup>[37]</sup>. In 335 patients with Barrett’s related neoplasia, HGD was cleared from 86% of patients, all dysplasia from 81%, and BE from 62%, at the 12-mo time point, following a mean 2.5 RFA procedures.

There is still debate about the number of ablations patients with squamous dysplasia should undergo. It is also not clear whether these should be performed at successive treatment encounters or whether these patients should undergo staging with chromoendoscopy after successive treatments. In our series, the median number of ablations was only one (range 1-3) for the 10 patients who achieved CR-D at 12 mo. These were all circumferential balloon ablations. This compares to a median of 3 ablations administered in patients with BE during a similar treatment protocol in published series. This may account for the lower eradication rates but the protocol was designed to provide an extremely cautious approach to restaging these patients after every treatment in view of the aggressive nature of the disease.

The rate of stricturing in our series was 20%. All 4 patients who developed strictures had undergone circumferential balloon ablation with the HALO 360 device. This rate is higher than noted in trials of ablation for Barrett’s oesophagus<sup>[27,28]</sup>. Nonetheless they were all overcome with straightforward dilatations. In a recent series of patients treated with RFA for squamous dysplasia the rate of stricturing was 14% after circumferential ablation<sup>[33]</sup>. Other than a self-limiting bleed from biopsies

and not from a RFA procedure our study confirms that RFA is a safe procedure with few other reported adverse events.

A criticism of the protocol in the United Kingdom registry is that there may be too long an interval between treatments due to the requirement of a mapping endoscopy every 3 mo after RFA. With the aggressive nature of this disease it is very important to restage these patients early after treatment and perhaps shortening the intervals between treatment and follow up may help improve outcomes. Current United Kingdom practice is to only ablate once at each treatment session for patients with squamous neoplasia compared to the double ablation carried out in BE with mucosal cleaning of the coagulum between treatments. Recent publications have used 2 ablations per session safely in patients with squamous dysplasia and our practice may have to change to improve outcomes. Delivering 2 ablations at a single treatment session is standard practice for patients undergoing RFA for BE. Bergman and colleagues<sup>[33]</sup> explored various ablation energy settings in patients with squamous dysplasia. These included 2 ablations at a single treatment session with and without coagulum clearance between ablations. In 16 cases where they employed a 12 J/cm<sup>2</sup> - clean - 12 J/cm<sup>2</sup> protocol CR-D at 12 mo was 100% with a stricture rate of 19% compared to a CR-D of 86% and stricture rate of 14% with a 12 J/cm<sup>2</sup> - no clean - 12 J/cm<sup>2</sup> ablation protocol. By using lower energy settings of 10 J/cm<sup>2</sup> for the second ablation or using 10 J/cm<sup>2</sup> for delivering both ablations they did not compromise CR-D (100%) but interestingly had no strictures. The numbers in each of these treatment groups were however low (4 and 2 cases respectively).

Another short coming of our study is the small size of the cohort. These lesions are rarely diagnosed at an early stage. With the availability of high definition en-

doscopy and growing experience of minimally invasive endotherapy as an alternative to surgical and oncological interventions, these numbers will undoubtedly grow in the coming years.

This study examines data from 8 different centers nationwide. Despite standardized protocols, the expertise and experience of each endoscopist will be very different and individual preference and clinical practice will differ from one center to another. These patients have all undergone endotherapy within the confines of demanding endoscopy service provision. These data represent real life outcomes of integrating novel and ground breaking endotherapy to existing practice.

## ACKNOWLEDGMENTS

This work was undertaken at UCLH/UCL who received a proportion of funding from the Department of Health's NIHR Biomedical Research Centres funding scheme. The views expressed in this publication are those of the authors and not necessarily those of the Department of Health.

## COMMENTS

### Background

Oesophageal cancer carries a poor prognosis as it is often diagnosed at a stage where curative therapy is no longer possible. Squamous cell cancer (SCC) of the oesophagus carries a 5-year survival of 10%-15%. The precursor lesion to SCC is squamous dysplasia. Treatment of these early lesions with endoluminal therapy may help to improve outcomes in these high risk patients.

### Research frontiers

Radiofrequency ablation (RFA) is a novel and minimally invasive field ablation technique that has shown good safety and efficacy for treating patients with Barrett's related neoplasia in the oesophagus. By combining endoscopic mucosal resection for visible lesions and RFA, patients with early squamous neoplasia of the oesophagus may be treated at an early stage of the disease.

### Innovations and breakthroughs

There are only limited series reporting the use of RFA in patients with early squamous neoplasia to date. These data better inform us on patients that are likely to succeed with endoscopic therapy but also the importance of careful staging in these patients before treatment.

### Applications

This prospective study may better inform clinicians about minimally invasive endoscopic therapy in these patients where perhaps more radical treatments are not an option for patients.

### Peer review

The authors present a good study to evaluate the role of radiofrequency ablation in early squamous cell cancer and high grade squamous dysplasia. They provide a new finding of early response to RFA is prognostically important. This could be clinically relevant for physicians to perform RFA in the management of squamous high-grade dysplasia.

### Abstract

**AIM:** To investigate the metabolic enzymatic capacity of the colon mucosa to detoxify noxious carcinogenic compounds.

**METHODS:** We investigated the activity of 2 conjugating enzymes-the microsomal uridine glucuronosyltransferase (UGT) and the cytosomal glutathione S-transferase (GST) in the uninjured mucosa of the colon transversum and sigmoideum in patients with adenomatous polyps and colorectal cancer. Biopsies were taken from the mucosa during colonoscopies which were done for clinical (diagnostic) reasons. After storage, the biopsy material was homogenized and after differential centrifugation the enzyme assays were performed with 4-nitrophenol (UGT) and 1-chloro 2,4-dinitrobenzene (GST) as substrates.

**RESULTS:** About 48 patients were included of which

28 had adenomas and 20 had colorectal carcinomas confirmed by histopathology. Enzyme activities were expressed as nmol/mg per minute protein for the GST and as pmol/mg per minute protein for the UGT. Analysis of variance (*F*-test) indicated that both enzymes were more widely distributed in adenoma than in cancer patients. The means  $\pm$  SD were smaller for cancer patients: GST for adenomas  $268 \pm 152$  vs  $241 \pm 69$  for carcinomas and UGT for adenomas  $197 \pm 200$  vs  $150 \pm 86$  for carcinomas.

**CONCLUSION:** Compared to patients with adenomatous colon polyps those with colorectal carcinoma exhibited a lower capacity of detoxifying enzyme metabolism and their activities clustered over a smaller range.

© 2013 Baishideng. All rights reserved.

**Key words:** Glutathione S-transferase; UDP-glucuronosyltransferase; Detoxification; Colon adenoma; Colon carcinoma

**Core tip:** Protective enzymes can conjugate carcinogenic chemicals. The functional capacity of these enzymes is diminished in patients with colorectal cancer and in some patients with colon adenomas.

### INTRODUCTION

Colorectal cancer is an important cause of cancer death in Western countries. In Europe, colorectal cancer (CRC) is the second cause of death from malignant disease

after lung cancer<sup>[1]</sup>. It is estimated that up to 10% of CRC cases can be attributed to hereditary factors leaving approximately 90% of so called sporadic colorectal cancer cases, which may be attributed to diet and lifestyle factors<sup>[2]</sup>. Epidemiological studies have shown the importance of dietary habits in the risk for CRC. Diets low in fruit and vegetables, and high in red meat and fat are associated with an increased risk of CRC<sup>[3,4]</sup>. Humans may be daily exposed to a large variety of toxic or even carcinogenic compounds, present in food<sup>[5]</sup> or as a result of lifestyle habits such as smoking or use of alcohol<sup>[6,7]</sup>. However, humans possess a highly efficient system of defense against such harmful compounds. Detoxification enzymes such as UDP-glucuronosyltransferases (UGTs)<sup>[8]</sup> and glutathione S-transferases (GSTs)<sup>[9]</sup> are responsible for the efficient modification and detoxification of harmful molecules. These enzymes are present in many tissues and also in the gastrointestinal tract in esophagus, stomach, small intestine, large intestine and in the liver<sup>[8-11]</sup>. UDP-glucuronosyltransferases catalyze the conjugation with glucuronic acid of a wide variety of exogenous compounds (*e.g.*, drugs, pesticides, tobacco smoke components such as benzo(a)pyrene) as well as endogenous compounds (*e.g.*, bilirubin, bile acids, steroid hormones)<sup>[8]</sup>. Glutathione S-transferases catalyze the reaction of glutathione with mainly exogenous electrophiles (*e.g.*, polycyclic aromatic hydrocarbons, heterocyclic amines) and endogenous products of oxidative stress<sup>[9]</sup>. The conjugates formed by these enzyme reactions are generally less toxic than their precursors and are more water-soluble, which facilitates their biliary and renal excretion. The gastrointestinal tract is in direct contact with potentially toxic or (pre) carcinogenic agents, ingested by food, medication, drugs, *etc.* and the intestinal mucosa acts as a first-line barrier<sup>[12]</sup>. Tissue-specific expression of the different isoforms of GSTs and UGTs in colon and liver was demonstrated to result in the differences in enzyme activities as measured in these tissues<sup>[10,11,13,14]</sup>.

Earlier, we demonstrated an inverse relationship between GST enzyme activity and cancer risk in several organs of the gastrointestinal tract<sup>[15]</sup>, suggesting that the levels of phase II detoxification enzymes could be pivotal in cancer prevention. After comparison of detoxification levels in small intestine (a site of low cancer risk) and large intestine (high cancer risk), we even postulated that the levels of detoxification enzymes in the colon could be critically low<sup>[16]</sup>.

We now investigated mucosal GST and UGT detoxification activities in normal mucosa of patients with colorectal adenomas, which are at risk to develop colorectal cancer, and in patients who already did develop colorectal cancer. Individual susceptibility to CRC could be partly due to low levels of detoxification enzymes.

## MATERIALS AND METHODS

### Patients

Fifty-one patients gave their written informed consent to use additional biopsy material for this study, the protocol

of which was approved by the Ethics Committee of the university of Dresden/Germany. Colonoscopies were performed exclusively for clinical (diagnostic) reasons in all patients and colorectal cancer or adenomas were confirmed in  $n = 48$  patients. Figure 1 shows the characteristics of the 48 patients included in the statistical analyses of the study. Endoscopic findings were confirmed by histopathology using a standard protocol. Information on the clinical variables was taken from the patients' clinical files. Consecutive patients with adenomatous polyps or colorectal cancers were included regardless of localization, size, stage and histological grading. All patients with neoplasia of the colon were included if there was pathologically proven neoplasia. We excluded patients with insufficient clinical data and those without biopsies of the uninvolved mucosa.

### Methods

Forceps biopsies of the colon mucosa were taken from the uninvolved mucosa of the transversum and the sigmoid colon. Biopsy material was shock-frozen and stored in liquid nitrogen until analysis. Biopsies were weighed and homogenized by 15 strokes in a plastic/plastic potter in 5 volumes of a buffer solution (pH = 7.4) containing 0.25 mol/L saccharose, 20 mmol/L Tris/HCl and 1 mmol/L dithiothreitol (all chemicals were from Sigma, Zwijndrecht, The Netherlands). Half of the total homogenate was frozen at  $-80^{\circ}\text{C}$  in small aliquots and used for the UGT assay. The other half of the homogenate was used for preparation of cytosol by centrifugation for 60 min at 150000  $g$  and at  $4^{\circ}\text{C}$  in a 42.2Ti rotor (Beckman Optima L-70K). The supernatant (cytosol) was frozen at  $-80^{\circ}\text{C}$  in small aliquots and used for the GST assay. Protein content was determined in cytosol ( $2 \times 5 \mu\text{L}$ ) and homogenate ( $2 \times 5 \mu\text{L}$ ) and GST enzyme activity in the cytosolic fractions ( $2 \times 10 \mu\text{L}$ ) was determined with 1-chloro-2,4-dinitrobenzene as substrate as described before<sup>[17]</sup>. UGT enzyme activity in the homogenates ( $1 \times 20 \mu\text{L}$ ) was measured with 4-nitrophenol as substrate according to Strassburg *et al.*<sup>[18]</sup> Usually, 2-3 biopsy particles per patient were taken from each site (uninvolved colon transversum and colon sigmoideum). For some patients not enough biopsy material was obtained to perform the complete set of enzyme assays (Figure 1). Combined activity was calculated as the mean of the activity of sigmoid and transversum when both locations were biopsied per patient, otherwise as the activity of one of the two locations only.

### Statistical analysis

Patient characteristics were analyzed using descriptive statistical methods. Enzyme activities in the different groups analyzed were described using means and standard deviations and compared using the  $t$ -test. An  $F$ -test was used to compare the variances in the two groups. The correlation between GST and UGT was described numerically using the Spearman correlation coefficient and graphically using linear regression exhibiting both confidence intervals (for the means) and prediction intervals for the

actual values. SAS/STAT software, Version 9.3 was used for all statistical analyses. *P*-values  $\geq 0.05$  were identified as not significant (NS) throughout this paper.

## RESULTS

We investigated whether patients with adenomas or CRC differed in their colon capacity to metabolize noxious chemical compounds using the activities of detoxifying conjugating phase II enzymes as biomarkers. Table 1 shows the patients' demographic characteristics: 20 patients had colorectal carcinomas with stage 2 and 3 and 28 patients had adenomatous polyps of various location, size and histological types. In 3 patients the

Enzyme activities	Adenomas ( <i>n</i> = 28)	Carcinomas ( <i>n</i> = 20)	<i>P</i> -value ( <i>F</i> -test)
GST (nmol/mg per minute)			
Transversum	225 $\pm$ 104 (19)	237 $\pm$ 72 (18)	0.1342
Sigmoid	265 $\pm$ 152 (27)	232 $\pm$ 78 (19)	0.0046
Combined	268 $\pm$ 152 (28)	241 $\pm$ 69 (20)	0.0007
UGT (pmol mg per minute)			
Transversum	231 $\pm$ 269 (17)	159 $\pm$ 122 (16)	0.0015
Sigmoid	170 $\pm$ 158 (23)	144 $\pm$ 96 (17)	0.0456
Combined	197 $\pm$ 200 (27)	150 $\pm$ 86 (19)	0.0005

Number of enzyme assays given in brackets. GST: Glutathione S-transferase; UGT: Uridine glucuronosyltransferase.

diagnosis remained unclear as to the type of neoplasia. The means for GST enzyme activity were lower in the cancer patients than in adenoma patients (except for the transversum), but this difference did not reach statistical significance (Table 2). The UGT means were also lower in cancer patients even when distinguishing between the transversal and sigmoidal location. While the means of enzyme activities were not significantly different when using a t-test it was obvious that the ranges and the standard deviations were much wider for the adenoma patients. Adenoma patients had a wider distribution and cancer patients aggregated at a lower level and over a smaller range. This difference, indicated by the size of the standard deviations could be manifested by using the *F*-test which showed a statistically significant difference for UGT both in the transversum and sigmoid and for GST in the sigmoid. Figure 2 shows the individual distribution of the UGT and GST enzyme activity in the colon transversum of adenoma patients (left panel) and CRC patients (right panel) in the form of a regression analysis with the 95% CIs (for the means) and prediction intervals (for the actual values). The range was narrower for the cancer patients. No statistically significant differ-

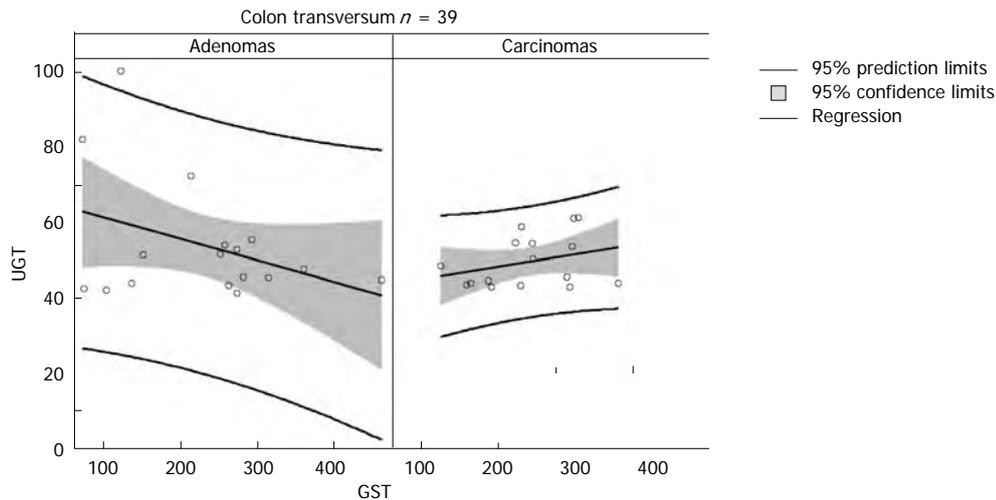

Figure 2 Distribution of enzyme values of uridine glucuronosyltransferase and glutathione S-transferase in the colon mucosa of the transversum of adenoma and carcinoma patients. The correlation between uridine glucuronosyltransferase (UGT) and glutathione S-transferase (GST) over the range of enzyme activities is illustrated in the colon transversum of 39 patients.

**Table 3 Gender differences between glutathione s-transferase and uridine glucuronosyltransferase activities in the colon of patients with colon-neoplasia**

	Male	Female	t-test	F-test
GST (combined)	258 ± 139 (36)	235 ± 68 (15)	0.54	0.006
Transversum	218 ± 94 (26)	251 ± 71 (13)	0.28	0.310
Sigmoid	267 ± 137 (34)	202 ± 75 (14)	0.10	0.020
UGT (combined)	198 ± 180 (34)	146 ± 99 (15)	0.30	0.020
Transversum	231 ± 238 (23)	153 ± 108 (12)	0.29	0.009
Sigmoid	168 ± 142 (29)	141 ± 110 (13)	0.54	0.360

Number of enzyme assays in brackets. For the *t*-test and the *F*-test *P*-values are indicated. GST: Glutathione S-transferase; UGT: Uridine glucuronosyltransferase.

ences of enzyme levels were found between the transversum and sigma, both, for UGT and GST. For this reason the means from the transversum and the sigma were also pooled for the analysis of the combined enzyme levels.

The enzyme activities could be influenced by a variety of clinical factors. Using the clinical charts we examined the major clinical variables to find out if these were affecting the enzyme levels. Both enzymes activities were not influenced by age, alcohol and nicotin consumption, use of aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) and body mass index (BMI). Female patients had lower enzyme levels and less variability than males (Table 3). There were more males than females among the polyp patients (24 *vs* 4) than among the cancer patients (9 *vs* 11). Also, alcohol consumption was more prevalent in the polyp patients (15 *vs* 13) than in the cancer patients (3 *vs* 17). No differences were detected between both groups for nicotin use, aspirin or other NSAID medications and body weight.

## DISCUSSION

We measured the kinetic detoxifying enzyme activity in

the uninvolved normal appearing mucosa of patients with benign and malign neoplasia of the colon. Usually enzyme values can be expressed using mRNA and protein levels, but these parameters do not reflect the functional activity within the epithelial cells of the mucosa. Using kinetic data we could obtain direct information on the metabolic capacity of the tissue. Both UGT and GST had a significantly different distribution between patients with benign neoplasia (adenomas) and those with cancerous neoplasia (CRC). The type of neoplasia was associated with the enzyme levels and an increased variance was found in the polyp patients. On the other hand the enzyme levels could inform on the degree of neoplasia and its evolution. Cancer patients had a smaller range at a lower level. This could mean that cancer patients had lost some of the mucosal detoxifying potential, predisposing them to develop cancer. The wide range of enzyme values could indicate that some patients with adenomas who were in the lower range might be at risk to develop cancer. It is possible that adenoma patients who are in the higher range are protected from cancer development since they possess a higher protective enzyme capacity. This hypothesis needs to be validated by longitudinal follow-up studies of enzyme values in polyp patients over long periods of time. Previously, we found in the rectum of healthy controls GST-levels of  $321 \pm 29$  nmol/mg per minute protein ( $n = 10$ )<sup>[19]</sup> which were higher than those reported in this paper.

The UGT enzyme system is located in the endoplasmic reticulum of the mucosal intestinal cells and these enzymes can detoxify hazardous chemical compounds - mostly lipophilic - which penetrate deep into the interior of the cells. The GST enzymes are located within the cytoplasm of the cells and use intracellular glutathione to protect the cells from electrophilic chemicals. Both enzymes perform conjugation reactions and thereby render xenobiotics water-soluble (phase II metabolism). The conjugated metabolites can be readily excreted by

the liver or the kidney. Phase II enzymes can be induced by their substrates and are influenced by environmental chemicals and clinical factors in the human body<sup>[20]</sup>. In contrast to our previous publication<sup>[21]</sup> there were no significant differences of enzyme levels relating to the location between the upper and the lower segments. However, this might be due to the different patient population (mainly normal and inflammatory findings) investigated previously. Female gender was associated with a higher prevalence of carcinomas and lower enzyme activities. This might have contributed to the observed enzyme disparities. One limitation of this study was the small number of patients in the 2 groups. Furthermore due to the small sample size enzyme values at the m-RNA level could not be studied. Further studies should include enzyme measurements at the protein and mRNA level. More patients and addition of a control group with non-neoplastic diseases of the colon should be included.

Our results suggest that protective enzymes could be diminished in the colon mucosa of cancer patients. Reduced activities of protective enzymes could lead to increased susceptibility to develop colorectal cancer.

## ACKNOWLEDGMENTS

We want to thank Sascha Mack for helping us to collect the patient data.

## COMMENTS

### Background

It is still controversial which factors determine the development of colorectal neoplasia. Exogenous dietary agents can be broken down by protective enzymes in the colon mucosa.

### Research frontiers

The cellular mutations of the tumor tissue in colorectal cancer (CRC) are thoroughly investigated but preneoplastic aberrations in the mucosa of the colon that lead to development of neoplasia are rarely investigated. The authors studied the properties of the uninvolved mucosa in patients with colon neoplasia by investigating the activities of protective enzymes.

### Innovations and breakthroughs

The direct comparison of activities of conjugating protective enzymes in carcinoma and adenoma patients has not been reported so far. It is highly informative to find out whether 2 types of neoplasia with different degree of malignant potential exhibit variances in the distribution of enzyme activities. We found that lower enzyme activities were associated with CRC but adenoma patients still retained sufficient activities. Susceptibility to develop CRC could depend on the enzyme levels expressed by the preneoplastic mucosa. Low enzyme levels could be a risk factor for adenoma patients to develop CRC.

### Applications

By inducing protective enzymes with dietary agents it might be feasible to prevent neoplasia in the colon.

### Terminology

Conjugating enzymes represent Phase 2 of drug metabolism. They mainly break down lipophilic carcinogenic compounds.

### Peer review

This paper makes good efforts in trying to understand that, protective enzymes could be diminished in the colon mucosa of cancer patient and reduced activities of these enzymes could lead to increased susceptibility to develop colon cancer.

### Abstract

**AIM:** To examine whether rendezvous endoscopic retrograde cholangiopancreatography (ERCP) is associated with less pancreatic damage, measured as leakage of proenzymes, than conventional ERCP.

**METHODS:** Patients ( $n = 122$ ) with symptomatic gallstone disease, intact papilla and no ongoing inflammation, were prospectively enrolled in this case-control

designed study. Eighty-one patients were subjected to laparoscopic cholecystectomy and if intraoperative cholangiography suggested common bile duct stones (CBDS), rendezvous ERCP was performed intraoperatively ( $n = 40$ ). Patients with a negative cholangiogram constituted the control group ( $n = 41$ ). Another 41 patients with CBDS, not subjected to surgery, underwent conventional ERCP. Pancreatic proenzymes, procarboxypeptidase B and trypsinogen-2 levels in plasma, were analysed at 0, 4, 8 and 24 h. The proenzymes were determined in-house with a double-antibody enzyme linked immunosorbent assay. Pancreatic amylase was measured by an enzymatic colourimetric modular analyser with the manufacturer's reagents. All samples were blinded at analysis.

**RESULTS:** Post ERCP pancreatitis (PEP) occurred in 3/41 (7%) of the patients cannulated with conventional ERCP and none in the rendezvous group. Increased serum levels indicating pancreatic leakage were significantly higher in the conventional ERCP group compared with the rendezvous ERCP group regarding pancreatic amylase levels in the 4- and 8-h samples ( $P = 0.0015$ ;  $P = 0.03$ ), procarboxypeptidase B in the 4- and 8-h samples ( $P < 0.0001$ ;  $P < 0.0001$ ) and trypsinogen-2 in the 24-hour samples ( $P = 0.03$ ). No differences in these markers were observed in patients treated with rendezvous cannulation technique compared with patients that underwent cholecystectomy alone (control group). Post procedural concentrations of pancreatic amylase and procarboxypeptidase B were significantly correlated with pancreatic duct cannulation and opacification.

**CONCLUSION:** Rendezvous ERCP reduces pancreatic enzyme leakage compared with conventional ERCP cannulation technique. Thus, laparo-endoscopic technique can be recommended with the ambition to minimise the risk for post ERCP pancreatitis.

## INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy and stone extraction is considered a standard procedure in the management of common bile duct stones (CBDS). Currently ERCP is often performed before the cholecystectomy (preoperative ERCP) or after it (postoperative ERCP). An alternative and increasingly appealing strategy is to carry out ERCP during the cholecystectomy (intraoperative ERCP) as a one-step procedure.

Many authors caution against using ERCP to aid surgical intervention in the management of CBDS owing to the risks of procedure-induced pancreatitis and postoperative failure to cannulate the bile duct. Despite more than three decades of efforts to reduce complication rates, post-ERCP pancreatitis (PEP) remains the most frequent, feared and unpredictable complication with an overall incidence ranging from 3% to 15%<sup>[1-5]</sup> whereas failure to achieve deep biliary cannulation varies between 1.5% and 20%<sup>[6,7]</sup>. The most serious of the several known procedure-related risk factors of PEP are closely associated with prolonged and repeated attempts at cannulation and inadvertent contrast filling of the pancreatic duct<sup>[2,8]</sup>.

Rendezvous cannulation involves a combined laparo-endoscopic approach and can be used in conjunction with intraoperative ERCP. The concept was described for the first time in 1993<sup>[9]</sup>. Approaches for and definitions of rendezvous cannulation have varied over the years, but the basic principle remains an antegrade biliary cannulation over the papilla of Vater. If conducted correctly, the rendezvous procedure offers immediate biliary cannulation and avoids inadvertent cannulation of the pancreatic duct<sup>[10]</sup>.

The question underlying our study is whether combining rendezvous cannulation with ERCP might reduce the incidence of PEP. Considering the incidence of PEP,

large study groups are needed to investigate the impact of different ERCP techniques. On the other hand, pancreatic enzyme leakage is a sensitive marker of pancreatic damage related to development of acute pancreatitis and has been used as such in numerous previous studies<sup>[11]</sup>. In the clinical laboratory, pancreatic amylase is the most frequently used early sign of acute pancreatitis<sup>[12-15]</sup>. Procarboxypeptidase B (proCAPB) has been suggested as an even more sensitive marker for acute pancreatitis, while the proenzyme trypsinogen-2 may be a useful indicator for acute pancreatitis as well as revealing the severity of pancreatitis<sup>[16-19]</sup>.

The aim of our prospective case-control study was to investigate whether use of rendezvous cannulation technique could prevent post-ERCP pancreatic damage in patients treated for gallbladder and common bile duct stones. The primary end point was estimated as leakage of pancreatic pro-enzymes (pancreatic amylase, proCAPB and trypsinogen-2) after ERCP.

## MATERIALS AND METHODS

### *Patients and controls*

Between April 2005 and November 2010 patients who fulfilled the inclusion criteria (Table 1) were recruited as they presented at the Department of Surgical Gastroenterology, Karolinska University Hospital. All patients had a physical examination, were screened for baseline serum markers and were examined with abdominal ultrasonography, CT-scan or MRCP to confirm cholecysto- and/or choledocholithiasis and to rule out ongoing pancreatitis and/or cholecystitis. Among these patients we identified three study groups. Regardless of suspicion of CBDS, patients with cholecystolithiasis who were fit for surgery, were prepared for a standard laparoscopic cholecystectomy. According to the results of the intraoperative cholangiography, patients were allocated to one of two groups: rendezvous ERCP group (positive finding of CBDS) or laparoscopic cholecystectomy only (negative finding of CBDS). The third group, which received conventional ERCP, included patients with high suspicion of choledocholithiasis who had already had a cholecystectomy and patients with cholecystolithiasis and CBDS who were unsuitable for surgery. All patients were hospitalised for a minimum of 24 h, had a clinical examination at 4, 8 and 24 h postoperatively, and had a 30-d follow-up interview by telephone. Post ERCP pancreatitis was defined as post-procedural onset of upper abdominal pain lasting more than 24 h and combined with pancreatic amylase concentration in serum of at least three times the upper reference limit<sup>[20]</sup>.

Demographic and procedure-related data were collected prospectively before and after the procedure and follow-up data were noted at 4, 8 and 24 h postoperatively and at 30 d follow-up. All patients gave oral and written informed consent before they entered the study, which was approved by the Regional Research Ethics Committee of Stockholm.

**Table 1** Inclusion and exclusion criteria

Inclusion criteria	
Clinical and radiological findings fulfilling indication for cholecystectomy due to gallstone	
Clinical and radiological findings fulfilling indication for ERCP due to CBDS	
Adult, $\geq 18$ yr	
Informed consent	
Exclusion criteria	
Acute or chronic pancreatitis	
Acute cholangitis	
Acute cholecystitis	
Antiinflammatory medication	
Failure to perform cholangiography	
Pancreatic or biliary cancer	
Prior ERCP with sphincterotomy	
Conversion from laparoscopic to open cholecystectomy	

ERCP: Endoscopic retrograde cholangiopancreatography; CBDS: Common bile duct stones.

### Laparoscopic cholecystectomy

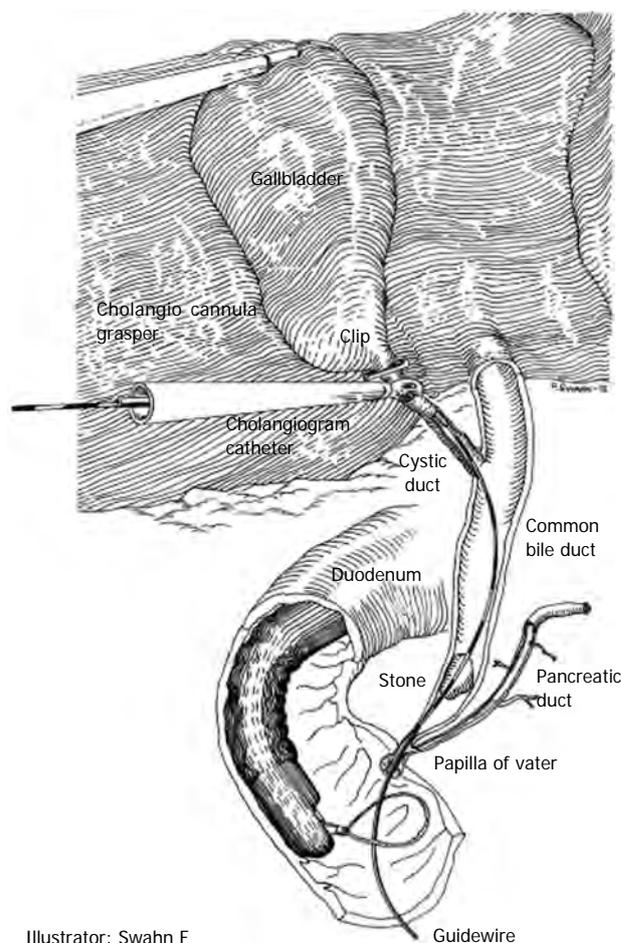

Laparoscopic cholecystectomy was performed according to standard laparoscopic technique with pneumoperitoneum, introduction of four troachars and isolation of the cystic duct. All procedures included intraoperative cholangiography through a small incision of the cystic duct to check for CBDS and to delineate bile duct anatomy.

### Rendezvous ERCP

When cholangiography during laparoscopic cholecystectomy reveals CBDS, the endoscopist is called to the operating room. While waiting for the endoscopist to arrive, the surgeon inserts a transcystic guide wire (Jag-wire™ 450 cm  $\times$  0.0635 cm or 450 cm  $\times$  0.0889 cm, Boston Scientific Corporation, Natick, MA, United States) through the existing cholangiography catheter and advances the guide wire through the choledochus, papilla of Vater into the duodenum. The pneumoperitoneum is deflated to facilitate transoral introduction and positioning of the duodenoscope. For rendezvous cannulation, the guide wire is captured with a polypectomy snare and pulled gently through the working channel of the duodenoscope (Figure 1). When the guide wire is in place, a sphincterotome is introduced over it and the rendezvous cannulation can be completed when the sphincterotome enters the common bile duct. After sphincterotomy, any stones are extracted with retrieval balloons or baskets. The first sweeping is done in choledochus along the transcystic guide wire. Then the guide wire is extracted (with the balloon catheter positioned in choledochus) and repositioned in the intrahepatic ducts to allow clearance of possible remaining supracholedochal stones. If there is any suspicion that stone clearance may be incomplete, a biliary stent is inserted.

### Conventional ERCP

Conventional ERCP was performed with Olympus TJF-160R or TJF-160VR (Olympus Optical, Tokyo, Japan)

Illustrator: Swahn F

**Figure 1** Laparo-endoscopic cannulation technique employing a transcystic guidewire, inserted by the surgeon through a cholangiocannula grasper and captured by the endoscopist with a polypectomy snare in the duodenum.

and wire-guided cannulation (WGC) technique through a sphincterotome (Autotome™ RX 44 Cannulating Sphincterotome, Boston Scientific Corporation, Natick, MA, United States). The complexity of cannulation was rated subjectively by the endoscopist, based particularly on the difficulty of cannulation, the number of inadvertent pancreatic duct cannulations and contrast injections with pancreatic duct filling. If the cannulation required more than six attempts or precut technique, it was considered a difficult cannulation.

All procedures were performed by one of three senior endoscopists with 7-15 years' experience of ERCP and with a present procedure rate of approximately 150-300 ERCP investigations per year. All patients were investigated under general anesthesia. Prophylactic antibiotics were administered as a single intravenous dose of 4 g piperacillin and 0.5 g tazobactam (Tazocin®, Wyeth AB, Solna, Sweden) prior to all procedures. Cholangiography was performed by using Iohexol (Omnipaque®, GE Healthcare, Stockholm, Sweden) monomeric non-ionic contrast medium. Sphincterotomy was carried out with pulsating cutting and coagulation diathermy system (ERBE, Elektromedizin, Tübingen, Germany).

Data are expressed as mean ± SD or *n* (%). <sup>1</sup>Conventional endoscopic retrograde cholangiopancreatography (CV ERCP) *vs* rendezvous ERCP (RV ERCP); <sup>2</sup>Laparoscopic cholecystectomy (LC) without ERCP. ASA: American Society of Anesthesiologists.

### Laboratory analysis

Blood samples were collected in ice-cold EDTA (ethylenediaminetetraacetic acid) tubes immediately prior to surgery or endoscopy (0-sample) and sampling repeated at 4 ± 1 h, 8 ± 2 h and 24 ± 4 h after laparoscopic cholecystectomy or ERCP. Plasma was obtained after centrifugation at 2200 r/min for 10 min and then frozen and stored at -70 °C until further analysis.

ProCAPB B and trypsinogen-2 levels in plasma were determined in-house with a double-antibody enzyme linked immunosorbent assay developed at the Department of Surgery, Clinical Sciences, Skåne University Hospital, Malmö<sup>[17,19]</sup>. Pancreatic amylase was measured by an enzymatic colourimetric modular analyser with the manufacturer's reagents (Roche, Diagnostics GmbH, Mannheim, Germany) at the Department of Clinical Chemistry at Karolinska University Hospital in Huddinge, accredited by the Swedish Board for Accreditation and Conformity Assessment. All samples were blinded at analysis.

### Ethics approval

This study was conducted with the approval of the Regional Research Ethics Committee of Stockholm, Sweden.

### Statistical analysis

Power calculations assumed a pancreatic enzyme reaction rate of 14% with the use of the conventional ERCP cannulation technique. Assuming a reduction in pancreatic reaction rate to 1% in the rendezvous group and 1% in the control group, 40 patients in each study arm were required to determine this difference with a 95% probability and with a 75% power ( $\chi^2$  test of equal proportions). The variables pancreatic amylase, proCAPB and trypsinogen-2 were analysed using a mixed linear model with one between-group factor *i.e.*, conventional ERCP, rendezvous ERCP and control group and one within-group factor, time (0, 4, 8 and 24 h) and the subsequent interaction between the factors. In case of significant

interactions, simple main effect tests were performed, *i.e.*, effects of one factor when the level of the other factor was fixed. Results are presented as mean, SD and 95% CIs. The distribution of some variables (*e.g.*, proCAPB, trypsinogen-2, pancreatic amylase) was positively skewed and in these cases the variables were log-transformed before the formal analyses. The binomial response was subsequently analysed by fitting a generalised estimating equations model with the Genmod procedure in SAS<sup>®</sup> System 9.1, SAS Institute Inc., Cary, NC, United States. These latter parameters are presented as OR and 95%CI. *P*-values less than 0.05 were considered statistically significant.

## RESULTS

### Patient characteristics

A total of 139 patients (41 men and 98 women) with a median age of 54 years were enrolled into the study. During the inclusion period 17 patients were excluded due to: acute pancreatitis immediately prior to ERCP (*n* = 3), conversion of the operation from laparoscopic to open cholecystectomy (*n* = 6), tumour (*n* = 4), and retraction of informed consent (*n* = 4), leaving 122 participants for further analyses. Relevant preoperative demographic characteristics (Table 2) did not differ between the three study groups in terms of gender, BMI, physical status according to ASA-classification, baseline laboratory values for CRP, pancreatic amylase, proCAPB and trypsinogen-2. However, there was a difference in age, with the conventional ERCP group being somewhat older. In addition, there was an expected difference between the control group and the other two groups regarding bile duct width, alkaline phosphatase and bilirubin levels but no significant difference between the rendezvous and conventional ERCP group.

### Clinical outcomes

PEP emerged in three (7%) of the 41 patients cannulated with conventional ERCP, *vs* none of those cannulated

**Table 3** Clinical outcome and biometric results at 4-, 8- and 24 h after conventional endoscopic retrograde cholangiopancreatography, rendezvous endoscopic retrograde cholangiopancreatography and laparoscopic cholecystectomy alone (*n* = 122)

Data are expressed as mean ± SD or *n* (%). *P*-value indicate differences between conventional endoscopic retrograde cholangiopancreatography (CV ERCP) vs rendezvous ERCP (RV ERCP) and <sup>a</sup>*P* < 0.05. <sup>1</sup>Laparoscopic cholecystectomy (LC) without ERCP. NA: Not applicable.

by use of rendezvous technique (*P* = 0.24) (Table 3). According to the Cotton criteria<sup>[20]</sup>, one of these cases was classified as moderate and two as mild. Cannulation of the biliary duct was scored as difficult in nine (22%) cases where conventional ERCP was used, and precut sphincterotomy was performed in six of these (15%). There were three (7%) cases of unsuccessful cannulation and these failures were not associated with juxtapancreatic diverticula or other duodenal abnormalities. Contrast medium was inadvertently infused into the main pancreatic duct in 11 (27%) of the patients in the conventional ERCP group. In the rendezvous ERCP group, transcystic antegrade biliary rendezvous cannulation was successful in all 40 cases and no unintentional cannulation or opacification of the pancreatic duct occurred.

Complete CBDS clearance at the index procedure was achieved in 38 (95%) of the rendezvous ERCP procedures vs 29 (71%) patients in the conventional ERCP group (*P* = 0.01), even though there was no significant difference in stone size (*P* = 0.40) or procedure time (*P* = 0.11) between the two study groups. After an additional ERCP, all patients, including the three whose initial cannulation failed, had their bile ducts cleared of stones.

In the 41 control patients, no case of pancreatic duct opacification during cholangiography was noted, nor was acute pancreatitis or hyperamylasemia observed. Two major postoperative complications were recorded: one patient had postoperative intra-abdominal bleeding which did not need surgical intervention and one had postoperative bile leakage from the cystic duct, which was successfully treated by endoscopic placement of a temporary stent.

#### Laboratory markers

The post-procedural time course of pancreatic amylase showed no difference between the controls and the ren-

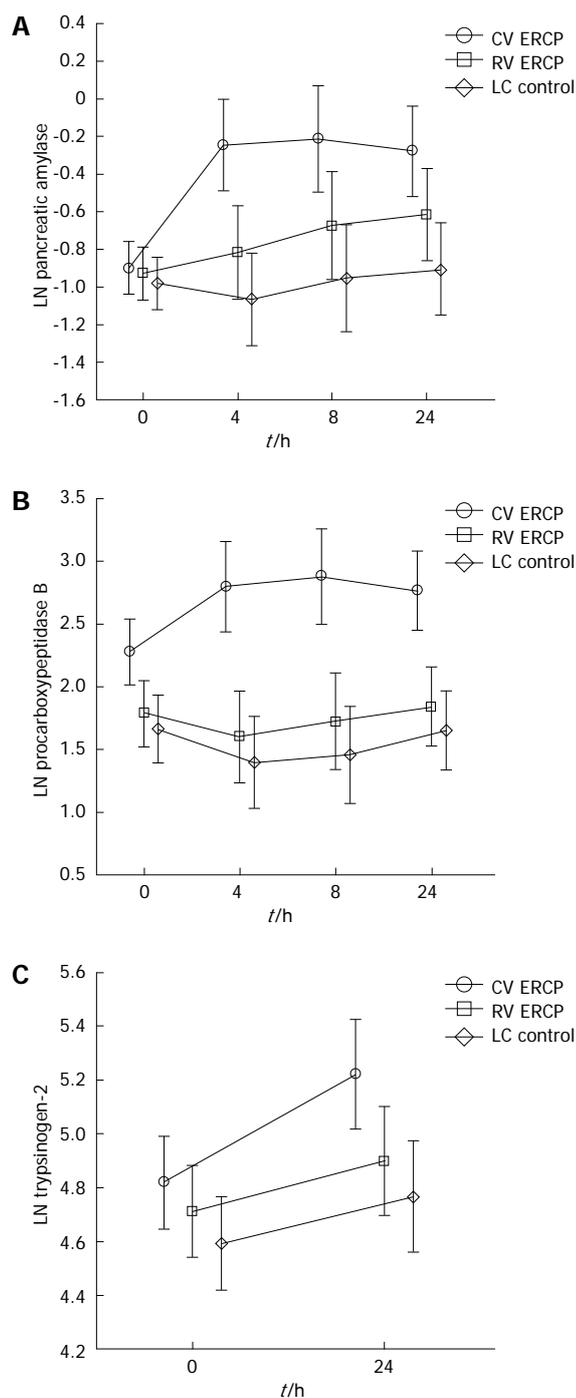

dezvous ERCP group (Figure 2A). In those subjected to a conventional ERCP, amylase levels had already increased significantly at 4 h and remained elevated throughout the 24-h monitoring time. Virtually the same picture emerged concerning the plasma levels of proCAPB (Figure 2B). Plasma concentrations of trypsinogen-2 were also significantly increased at 24 h in patients subjected to a conventional ERCP (Figure 2C). CRP values rose as expected in the groups subjected to surgery (rendezvous and control group) at 24 h after the completion of the procedure.

We explored other possible confounders but were unable to demonstrate any relationship between these laboratory variables and procedure time, the number of cannulation attempts, age, gender, comorbidity, degree of CBD dilatation, number or size of CBDS or the need for precut cannulation techniques. However, if side branches of the pancreatic duct side had been filled with contrast medium, this was significantly associated with the plasma level of proCAPB (*P* = 0.009) and most likely pancreatic amylase (*P* = 0.051).

## DISCUSSION

This study shows that transcystic guide wire assisted rendezvous cannulation at ERCP can be done in conjunction with bile duct stone clearance without increasing post-procedural leakage of pancreatic enzymes. This observation supports the hypothesis that rendezvous cannulation can prevent the risk of PEP. In fact, inadvertent contrast injection into the pancreatic duct during conventional ERCP was the factor most clearly associated with leakage of pancreatic enzymes into the systemic circulation, which we interpret as indicating risk of developing PEP.

The correlation between ERCP and PEP can be difficult to study, owing to the large number of patients required to ensure sufficient statistical power. In order to

**Figure 2** Approximate analysis and figure based on serum values at all times (0, 4, 8 and 24 h) using a mixed linear model. A: Pancreatic amylase before (0) and at 4, 8 and 24 h after the procedure; B: Procarboxypeptidase B before (0) and at 4, 8 and 24 h after the procedure; C: Trypsinogen-2 before (0) and at 4, 8 and 24 h after the procedure. y-axis values are logarithmically transformed. Vertical bars denote 95% confidence intervals. Circles: Conventional endoscopic retrograde cholangiopancreatography (ERCP); Squares: Rendezvous ERCP; Diamonds: Laparoscopic cholecystectomy control.

overcome these methodological difficulties, we utilised two biochemical markers, proCAPB and trypsinogen-2, as surrogate variables of pancreatic inflammatory response. These have both been shown to be superior to lipase and pancreatic amylase as diagnostic markers of acute pancreatitis, especially if the objective is to distin-

guish mild from severe pancreatitis<sup>[21,22]</sup>. ProCAPB and trypsinogen-2 have also been shown to discriminate pancreatitis from non-pancreatic disorders with an accuracy of 95% to 99%<sup>[19,21]</sup>. This distinction is essential, since two of our three study groups were subjected to additional surgical trauma in the form of laparoscopic cholecystectomy, which might increase unspecific inflammatory responses.

A potential weakness of the study is the lack of randomisation. Indeed, our original intention was to perform a randomised controlled trial. However, based on the promising results of our previous attempts with rendezvous ERCP<sup>[23]</sup>, we considered it ethically indefensible to perform conventional ERCP intraoperatively. First, the operating theatre during ongoing surgery is poorly suited for conventional ERCP and endoscopy under suboptimal circumstances would expose the patient to an unnecessary risk of pancreatic injury. Second, a study design where patients are randomised to postoperative ERCP could increase the risk of cannulation failures that would necessitate additional surgical exploration of the common bile duct. Therefore we considered this alternative study design more appropriate to address our research question. The present case-control design opens for selection bias, *e.g.*, in that patients selected for laparoscopic cholecystectomy with or without rendezvous ERCP were younger than those selected for conventional ERCP, of whom most had already their gallbladder removed, in some cases years earlier. However, this is to some degree counterbalanced by the fact that young age has repeatedly been found to be an independent risk factor for PEP<sup>[3,4,24,25]</sup> whereas older patients may be protected, *e.g.*, by age-related pancreatic atrophy<sup>[26]</sup>. These factors would be more likely to underestimate than overestimate the associations we found.

We observed only three cases of the clinically relevant outcome, PEP, all in the group subjected to conventional ERCP and none in the rendezvous group. This difference did not reach statistical significance, most likely due to low statistical power. Previous trials have proposed a relationship between rendezvous cannulation and a decreased risk of PEP but to date these studies have been either too small or not adequately designed to address this pertinent question. A recent systematic review by La Greca *et al.*<sup>[10]</sup> concluded that intraoperative ERCP and bile duct clearance during laparoscopic cholecystectomy was associated with low risk of PEP and could be recommended. Scrutiny of the cited papers reveals that in cases involving complete transcystic bile duct cannulation, where the guide wire was brought into the duodenal lumen, the incidence of PEP was even lower, ranging from 1.7% to 2.2%<sup>[27,28]</sup>. This contrasts to studies in which cannulation was not complete, where the corresponding incidence of PEP ranged from 3% to 7.6%<sup>[29-32]</sup>. Our data confirm to these previous findings and highlight the relevance of completing the rendezvous guide wire based cannulation to minimise PEP.

In most conventional ERCP procedures, biliary cannulation is easy, completely uneventful and antegrade

cannulation can be regarded as redundant. Our definition of difficult cannulation is arbitrary and subjective; however, even the most experienced endoscopist cannot predict whether a cannulation is going to be difficult or not until an attempt has been made, and each attempt at cannulation is potentially harmful. This is one of several arguments in favour of making rendezvous cannulation routine during laparoscopic cholecystectomy: regardless of the appearance of the papilla, the success rate of single-pass biliary cannulation approaches 100%. Repeat interventions, use of precut incision and so on should be kept to a minimum to diminish the risk of a variety of procedure-related complications.

Opacification of the pancreatic duct is another significant sign associated with difficult cannulation and the development of pancreatitis<sup>[3,8,24,25,33]</sup>. In our series, we found a significant correlation between elevated levels of amylase ( $P < 0.001$ ) or proCASP ( $P = 0.002$ ) and inadvertent cannulation and injection of contrast material into the pancreatic duct. Moreover, all three of our patients who developed PEP had had contrast medium injected into the pancreatic duct. Clearly, many of the risks associated with difficult cannulation, inadvertent pancreatic duct cannulation and contrast injection can be circumvented with rendezvous cannulation.

Current clinical evidence suggests that the risk of pancreatitis can be reduced, at least among high-risk patients, by temporary placement of a pancreatic stent that dislodges spontaneously<sup>[34,35]</sup>. At the time we began our study there was no routine of using prophylactic pancreatic stents at our institution and we have therefore not offered this option during the study. Such stenting could clearly have affected the outcome for patients who were allocated to the conventional ERCP group and had a guidewire or minimal contrast injection into the pancreatic duct. Nonetheless, we firmly believe that it is preferable to use a technique that completely avoids cannulation of the pancreatic duct.

Transient asymptomatic hyperamylasemia has very little clinical significance and is usually not recognised as a complication. In the present study the levels of amylase after conventional ERCP were increased at 4, 8 and 24 h compared with levels in the rendezvous and the control group. These results are in line with other reports<sup>[36]</sup>, where a majority of the ERCP procedures involving cannulations that were characterised as difficult were associated with hyperamylasemia and PEP.

A few prospective studies<sup>[16,18,37]</sup> demonstrate that patients affected by PEP have significantly elevated concentrations of trypsinogen-2 in urine six and 24 h after the index procedure, even in if the pancreatitis is mild. Our study confirms these findings: we found higher concentrations of trypsinogen-2 in plasma at 24 h in the conventional ERCP group than in the rendezvous and control groups. Taken together the surrogate markers we have used to detect early signs of PEP appear to be of high clinical relevance.

An additional advantage of the rendezvous approach, one of utmost clinical relevance, appeared when we ana-

lysed the CBDS clearance rate. Even though all stones were eventually cleared in both study groups, there was a significant advantage for the rendezvous technique during the index procedure. This finding is in line with the compilation of 21 reports by La Greca *et al*<sup>[10]</sup> which demonstrated an overall success rate of 92.3% for rendezvous ERCP.

In conclusion, combined laparo-endoscopic trans-cystic guidewire rendezvous cannulation of the CBD minimizes the risk of unintentional pancreatic duct engagement and subsequent inflammatory damage to the gland. In addition, more complete CBDS removal can be offered. Thus, intraoperative ERCP with rendezvous cannulation technique shall be recommended to manage CBDS in conjunction with cholecystectomy.

## ACKNOWLEDGMENTS

The authors wish to express their gratitude to deceased professor Anders Borgström for taking part of the initial planning of the study and Mrs. Anne-Marie Rohrstock for skilful laboratory technical assistance, both at the Department of Surgery, Malmö University Hospital. We also thank Mrs. Elisabeth Berg, LIME Karolinska Institutet, for the statistical analysis and to professor Margery K Herrington for linguistic support. Preliminary data has been presented in abstract form during poster session at the 19<sup>th</sup> United European Gastroenterology Week meeting (Endoscopy Suppl I, 2011; 43: P1140).

## COMMENTS

### Background

Endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy and stone extraction is a standard procedure in the management of common bile duct stones (CBDS). The method is, however, marred by complications like pancreatitis, bleeding and perforation. Intraoperative rendezvous ERCP during cholecystectomy with cannulation over a guidewire represents an alternative method to remove CBDS that theoretically may, due to a significantly reduced risk to cannulate the pancreatic duct, decrease the risk of procedural induced pancreatitis.

### Research frontiers

The concept of rendezvous cannulation involving a combined laparo-endoscopic approach and used in conjunction with intraoperative ERCP has been described previously. The question whether intraoperative rendezvous ERCP reduces the risk of post ERCP pancreatitis (PEP) rate or not is, however, not known mainly due to the fact that the incidence of PEP is rather low and large study groups are therefore needed in order to reach enough statistical power to investigate the impact of different ERCP techniques.

### Innovations and breakthroughs

To overcome the methodological difficulties in studying the effects of intraoperative rendezvous ERCP on PEP the authors utilised two highly sensitive and specific biochemical markers, procarboxypeptidase B and trypsinogen-2, as surrogate variables of pancreatic inflammatory response. These have both been shown to be superior to lipase and pancreatic amylase as diagnostic markers of acute pancreatitis, especially if the objective is to distinguish mild from severe pancreatitis.

### Applications

The study results have helped to obtain an increased knowledge of the beneficial effects that intraoperative rendezvous ERCP may have in reducing PEP. The proposed mechanism for this is that, due to cannulation over the guidewire, the risk of cannulating the pancreatic duct and thus injecting contrast in the duct is minimal.

## Terminology

ERCP: An endoscopic method to examine the bile- and pancreatic ducts as well as to, by intervention, remove, common bile duct stones or relieve bile duct obstruction. Pancreatic amylase, procarboxypeptidase B and trypsinogen-2: Biochemical markers that serve as surrogate variables of pancreatic inflammatory response.

## Peer review

The authors of this paper report that intraoperative rendezvous ERCP reduces the release of the pancreatic markers (pancreatic amylase, procarboxypeptidase B and trypsinogen-2) compared with conventional ERCP. As only a few papers have been published in this topic, this paper can provide additional data for the accumulation of the knowledge in this field. The case control design of the study, however, opens for selection bias which weakens the power of the conclusion.

### Abstract

**AIM:** To evaluate weight loss and surgical outcomes of Roux-en-Y gastric bypass (RYGB) and laparoscopic adjustable gastric band (LAGB).

**METHODS:** Data relating to changes in body mass index (BMI) and procedural complications after RYGB (1995-2009;  $n = 609$ ; 116M: 493F;  $42.4 \pm 0.4$  years) or LAGB (2004-2009;  $n = 686$ ; 131M: 555F;  $37.2 \pm 0.4$

years) were extracted from prospective databases.

**RESULTS:** Pre-operative BMI was higher in RYGB than LAGB patients ( $46.8 \pm 7.1$  kg/m<sup>2</sup> vs  $40.4 \pm 4.2$  kg/m<sup>2</sup>,  $P < 0.001$ ); more patients with BMI  $< 35$  kg/m<sup>2</sup> underwent LAGB than RYGB (17.1% vs 4.1%,  $P < 0.0001$ ). BMI decrease was greater after RYGB. There were direct relationships between weight loss and pre-operative BMI ( $P < 0.001$ ). Although there was no difference in weight loss between genders during the first 3-year post-surgery, male LAGB patients had greater BMI reduction than females ( $-8.2 \pm 4.3$  kg/m<sup>2</sup> vs  $-3.9 \pm 1.9$  kg/m<sup>2</sup>,  $P = 0.02$ ). Peri-operative complications occurred more frequently following RYGB than LAGB (8.0% vs 0.5%,  $P < 0.001$ ); majority related to wound infection. LAGB had more long-term complications requiring corrective procedures than RYGB (8.9% vs 2.1%,  $P < 0.001$ ). Conversion to RYGB resulted in greater BMI reduction ( $-9.5 \pm 3.8$  kg/m<sup>2</sup>) compared to removal and replacement of the band ( $-6.0 \pm 3.0$  kg/m<sup>2</sup>). Twelve months post-surgery, fasting glucose, total cholesterol and low density lipoprotein levels were significantly lower with the magnitude of reduction greater in RYGB patients.

**CONCLUSION:** RYGB produces substantially greater weight loss than LAGB. Whilst peri-operative complications are greater after RYGB, long-term complication rate is higher following LAGB.

**Key words:** Bariatric surgery; Gastric bypass; Gastric banding; Weight loss; Complications; Co-morbidity; Outcomes

**Core tip:** Roux-en-Y gastric bypass (RYGB) produces substantially greater weight loss and resolution of co-morbidities than laparoscopic adjustable gastric band (LAGB) in a community setting, in both the short-

and long-term. Although peri-operative complications are higher with RYGB than LAGB, which are non-fatal and mostly related to wound infection, the long-term complication rate is higher after LAGB. Where LAGB fails to induce or maintain weight loss, RYGB appears to be the superior salvage procedure. The better outcomes for LAGB in males compared to females after 3 years post-surgery are intriguing and needs further confirmation.

## INTRODUCTION

Obesity is increasing in prevalence in the Western world and affects approximately 30% of the population<sup>[1,2]</sup>. It is associated with significant co-morbidities including diabetes, cardiovascular disease and obstructive sleep apnoea<sup>[1,3]</sup>. Unfortunately, medical treatment with lifestyle modification or pharmacotherapy is only modestly effective with a high relapse rate<sup>[4,5]</sup>. Bariatric surgery is recommended for patients with a body mass index (BMI) > 40 kg/m<sup>2</sup> or BMI > 35 kg/m<sup>2</sup> with significant co-morbidities<sup>[2,3]</sup>. Two commonly performed bariatric procedures are Roux-en-Y gastric bypass (RYGB) and laparoscopic gastric banding (LAGB)<sup>[2,3]</sup>.

Currently, the choice between these bariatric procedures is based mainly on patient and surgeon preference, and varies significantly between regions of the world. In contrast to the United States and Europe, LAGB is the most common procedure in Australia (90%; with -10% RYGB)<sup>[6,7]</sup>, perhaps because LAGB is perceived as a safer, minimally invasive, fully reversible and adjustable procedure<sup>[6,7]</sup>. In Australia, the number of LAGB procedures increased by 10 times over the last decade, as compared to the stable rate of RYGB procedures (Figure 1). This is despite the majority of available data, including the recent systematic and network meta-analysis of randomised trials on weight loss outcome at 1 year, indicating that RYGB produces greater weight loss with more frequent resolution of type 2 diabetes, hypertension, dyslipidemia and sleep apnoea (OSA)<sup>[3,8-10]</sup>.

For LAGB, meticulous follow up has been suggested to play an important role in achieving and maintaining the weight loss, and this may be responsible for some of the impressive weight loss reported by Australian LAGB centers<sup>[7,11-13]</sup>. Alternatively drop-outs or “treatment failures” may be under-reported. Thus, the aim of the current study was to compare weight loss and surgical outcomes of RYGB and LAGB from two large, prospectively maintained surgical databases.

## MATERIALS AND METHODS

Data from two clinical databases of obese patients who underwent primary RYGB or LAGB were reviewed. The data have been collected prospectively and maintained by two experienced bariatric surgeons performing predominantly either RYGB (PG) or LAGB (JB) in Adelaide, South Australia. The RYGB cohort included all patients who had surgery from 1995 to 2009, by either open or laparoscopic techniques. The LAGB group included all patients who underwent the procedure from 2004 to 2009 (Figure 2). The RYGB cohort included both public and private patients, whereas all patients in the LAGB group were treated in private hospitals.

### Patient selection

For both RYGB and LAGB cohorts, the patients were assessed individually by the respective surgeon and a dietician as well as, in most cases, a multi-disciplinary team (physician, exercise physiologist, psychologist) prior to surgery. In general, the decision to undertake bariatric surgery followed the recommendations of the American Society for Metabolic and Bariatric Surgery Clinical Issues Committee<sup>[1]</sup>.

### Data collection

Both databases were kept electronically (Microsoft Office Access<sup>®</sup> for RYGB cohort and Filemaker Pro V8 for LAGB cohort) and maintained by the surgeon and the practices. For all patients, information on demographics, pre-operative and post-operative body mass index, and pre-operative co-morbidities were recorded. Details on the peri-operative and long-term complications were also recorded for the affected cases. Scanned copies of serial laboratory measurements (fasting glucose, lipid profile and liver function test) were available in approximately 50% of cases.

Data on patient demographics, date and type of procedure and changes in BMI over the period of follow up were exported to excel files from Microsoft Office Access<sup>®</sup>. Data regarding obesity related co-morbidities, medications, resolution of co-morbidities, and serial laboratory measurements were collected by reviewing each patient’s files (both paper and electronic). Complete serial data on blood glucose, lipid profiles and changes on co-morbidities over the first 12 mo after surgery were available for 301 RYGB and 545 LAGB patients.

### Surgical techniques

**Open RYGB procedure:** After midline incision, a gastric pouch of approximately 25 mL was created by stapling off the proximal stomach with a TA 90B four-row stapler (Autosuture<sup>®</sup>, Covidien<sup>®</sup>), or the stomach was divided using a linear stapler (GIATM, Covidien<sup>®</sup> or TLCTM, Ethicon<sup>®</sup>) stapler. The pouch volume was not measured using upper gastrointestinal endoscopy or a balloon device. A retrocolic and retrogastric 100-cm Roux limb was

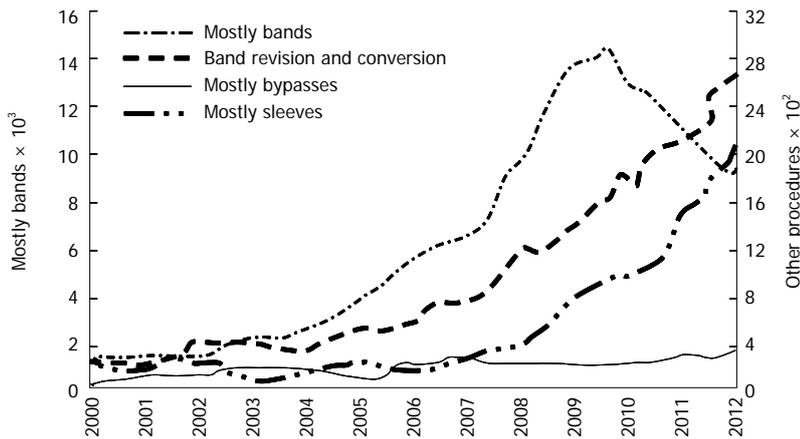

Figure 1 Comparison of changes in the performance of different type of bariatric procedures over a 10-year period in Australia based on medical benefit schedule item number.

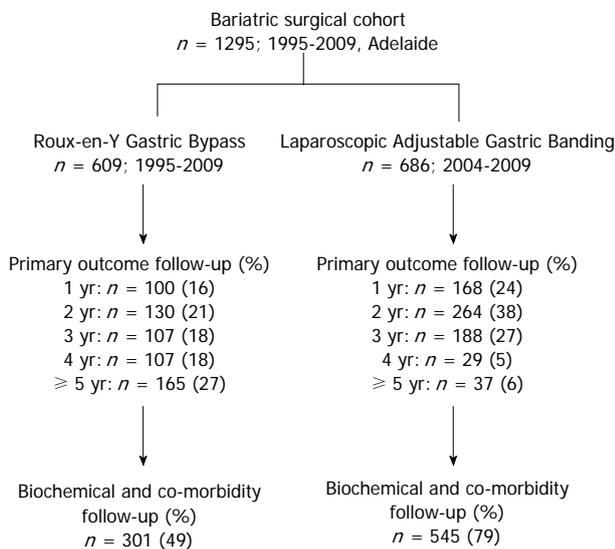

Figure 2 Flow chart of studied cohort in relation to clinical outcomes.

anastomosed to the gastric pouch using a two-layered hand-sewn technique, with an outer 3/0 polypropylene non-absorbable continuous layer and an inner 3/0 PDS absorbable continuous suture. A hand-sewn side-to-side jejuno-jejunal anastomosis was performed. The integrity of the gastro-jejunosomy was tested with methylene blue.

**Laparoscopic RYGB procedure:** A five-port technique was used. The stomach was transected with a laparoscopic linear stapler (Endo-GIATM, Covidien® or EndopathTM, Ethicon®). The two anastomoses were either performed with a hand-sewn technique or with stapling devices (EEATM OrViITM XL circular stapler, Endo-GIATM, Covidien®). Again, the integrity of the gastro-jejunosomy was tested with methylene blue.

**Laparoscopic adjustable gastric banding procedure:** Commercially available laparoscopic adjustable gastric

bands from Allergan Inc (Lap Band; Allergan, Inc, Irvine, California) were used. The size of the gastric band system used was at the discretion of the surgeon. The band was inserted using the pars flaccida technique, which involved adequate exposure of the angle of His by retracting the gastric fundus inferiorly. Dissection was continued until the left crus of the diaphragm was completely exposed. A small incision in the avascular aspect of the gastro-hepatic ligament was created, and care was taken to identify and preserve the hepatic branch of the vagus nerve. Blunt dissection was used to create a space between the base of the right crus and its overlying peritoneum. A long grasper was then gently passed above the right crus, underneath the gastroesophageal junction, toward the angle of His. The lap-band was passed around the gastroesophageal junction and snapped in place and secured with 3 gastrogastic sutures. The band reservoir was filled with 3 mL of normal saline for APS bands, and 4 mL of normal saline for APL bands.

**Post-operative care and follow up**

Patients from either centre followed a strict post-operative protocol. For both procedures, clear liquids were provided on the first post-operative day and a full-liquid diet on the second.

Patients undergoing RYGB were seen in the clinic 2 wk post-operatively, every 3 mo for the first year, and then annually thereafter. After LAGB, patients were asked to continue seeing a dietician, psychologist, exercise physiologist and a general practitioner with an interest in obesity and bariatric surgery. Most patients returned every 3 mo for the first year, and 6-monthly thereafter for patients who progressed well. Some patients may have seen the bariatric GP more frequently depending on progress and problems experienced. Band adjustments were most commonly performed at week 2 and 6 postoperatively, then every 3 mo for the first year (total of 5 visits). Adjustments to the band were performed according to manufacturer’s guidelines.

**Table 1** Characteristics of patients with Roux-en-Y gastric bypass and laparoscopic adjustable gastric band *n* (%)

	<b>RYGB (<i>n</i> = 609)</b>	<b>LAGB (<i>n</i> = 686)</b>
Gender (M:F)	116: 493	131: 555
Age (yr)	42.4 ± 10.5 <sup>b</sup>	37.2 ± 9.4
Initial BMI (kg/m <sup>2</sup> )	46.8 ± 7.1 <sup>b</sup>	40.4 ± 4.2
Co-morbidities (sub-group analysis)	( <i>n</i> = 301)	( <i>n</i> = 545)
Total co-morbidities	216 (71.0)	363 (66.6)
Type 2 diabetes mellitus ( <i>n</i> )	82	95
Hypertension ( <i>n</i> )	51	157
Hyperlipidemia ( <i>n</i> )	116	117

Duration of follow-Median (yr)	2.0 (1.0-5.0)	1.6 (1.0-2.2)

<sup>b</sup>*P* < 0.01 vs LAGB. BMI: Body mass index; RYGB: Roux-en-Y gastric bypass; LAGB: Laparoscopic adjustable gastric band; M: Male; F: Female.

For both surgeries, most patients were advised to take supplementary vitamins (including vitamin D) and calcium.

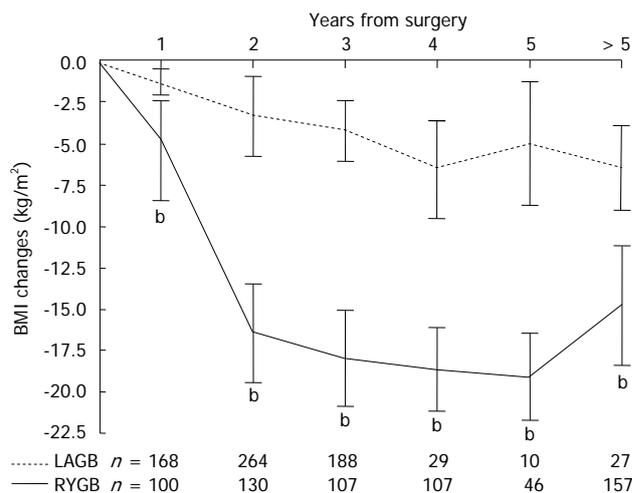

**Definitions of outcome measures**

**Primary outcome measures:** (1) Weight loss. This was expressed as change in BMI from baseline over the study duration; and (2) Complications and need for re-operation. Acute (< 30 d) and long-term (≥ 30 d) complications included use of unexpected drug therapy or imaging, total parenteral nutrition, a bedside procedure, blood transfusion, a hospital stay longer than twice the median stay, diagnostic or therapeutic endoscopy, re-operation (with or without organ resection or anastomotic revision), or death.

**Secondary outcome measures:** (1) Diabetes mellitus and hyperlipidemia. As data regarding the need for anti-diabetic or anti-cholesterol medications were incomplete, only improvement rather than “resolution” of diabetes mellitus or hyperlipidemia could be assessed, and the change from baseline to 12 mo was compared between the procedures. Improvement in diabetes mellitus was defined as a fasting blood glucose < 5.5 mmol/L. Improvement in hyperlipidemia was expressed as a percentage of patients who had normalization of plasma total cholesterol (level < 5.5 mmol/L) or plasma triglycerides (level < 2.0 mmol/L); and (2) Obstructive sleep apnoea. Resolution of obstructive sleep apnea was defined as the absence of requirement for continuous positive airway pressure after surgery.

**Statistical analysis**

Data were expressed as mean ± SD, unless stated otherwise. Comparison of variables between the two surgical groups was undertaken using  $\chi^2$  tests for categorical data and independent t-test for continuous data sets. The differences in changes in weight loss outcome over time between the groups were compared using Kaplan Meier analysis. All analyses were performed using GraphPad Prism statistical software, version 6 (GraphPad Software

**Figure 3** Changes in body mass index in patients who underwent Roux-en-Y gastric bypass and laparoscopic adjustable gastric band up to 5 years post-surgery. <sup>b</sup>*P* < 0.001 vs laparoscopic adjustable gastric band (LAGB). RYGB: Roux-en-Y gastric bypass.

Inc., La Jolla, CA, United States).

**RESULTS**

A total of 1295 patients was included in the study; 609 underwent RYGB (116M:493F; age: 42.4 ± 10.5 years) and 686 underwent LAGB (131M:555F; age: 37.2 ± 9.4 years). For the RYGB cohort, 13% (78) of procedures were performed laparoscopically. The initial BMI was significantly higher in patients who underwent RYGB than LAGB (46.8 ± 7.1 kg/m<sup>2</sup> vs 40.4 ± 4.2 kg/m<sup>2</sup>, *P* < 0.01). Overall, 161/1295 (12%) patients underwent bariatric surgery with an initial BMI between 30 and 35 kg/m<sup>2</sup>, and it was more prevalent in patients who underwent LAGB (128/686 vs 33/609, *P* < 0.0001). The median number of follow up visits after surgery was 6 in both groups, with 63% of RYGB patients and 38% of LAGB patients had follow-up duration of greater than 3 years (Table 1 and Figure 2).

**Body mass index**

Overall, RYGB resulted in a significantly greater decrease in BMI than LAGB (-14.8 ± 3.4 kg/m<sup>2</sup> vs -2.9 ± 1.2 kg/m<sup>2</sup>, *P* < 0.0001). The greater reduction in BMI after RYGB over LAGB was observed at all time points, and the peak weight loss was observed at year 4 for both procedures (Figure 3). Irrespective of pre-operative BMI, weight reduction was greater after RYGB than LAGB (*P* < 0.001, Figure 4). For both surgical groups, there was a direct relationship between weight loss and the pre-operative BMI (*P* < 0.001) (Figure 4).

**Complication and re-operation rates**

Peri-operative complications were higher with RYGB than LAGB (8.0% vs 0.5%, *P* < 0.001). The majority of the acute complications in the RYGB group were minor and did not require any surgical intervention (Table 2). Long-

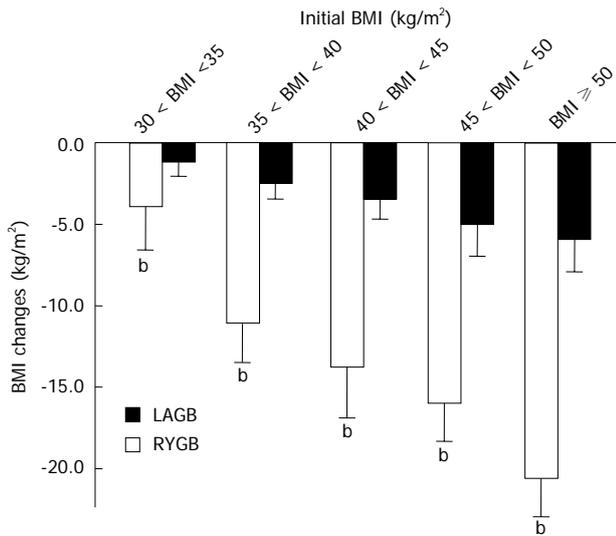

Figure 4 Relationship between the degree of weight loss and presenting body mass index induce by Roux-en-Y gastric bypass and laparoscopic adjustable gastric band procedure. <sup>b</sup>*P* < 0.001 vs laparoscopic adjustable gastric band (LAGB). DVT and PE (2)	
Endoscopy for stomal obstruction (4)	
Mechanical failure (3)	
Long-term complications (n)	
n = 13 (2.1%)	n = 61 (8.9%) ( <i>P</i> < 0.0001 vs RYGB)
Reversal of RYGB (n = 1)	Removed and replaced LB (19)
Incisional hernia (n = 7)	Replacement of port (16)
Bowel obstruction (n = 5)	Removed LB (13)
	Converted to RYGB (7)
	Stomal obstruction required dilation (3)
	Mechanical failure (3)

RYGB: Roux-en-Y gastric bypass; LAGB: Laparoscopic adjustable gastric band; LB: Lap-band.

term complications necessitating corrective procedures were higher following LAGB than RYGB (8.9% vs 2.1%, *P* < 0.001). Conversion to RYGB resulted in a greater BMI reduction ( $-9.5 \pm 3.8 \text{ kg/m}^2$ ) as compared to removal and replacement of the band ( $-6.0 \pm 3.0 \text{ kg/m}^2$ ) (Figure 5).

**Impact of gender on outcomes of RYGB and LAGB**

Pre-operative BMI was similar in males and females undergoing LAGB ( $41.1 \pm 4.5$  vs  $40.3 \pm 4.3 \text{ kg/m}^2$ ), but greater in males than females undergoing RYGB ( $47.9 \pm 4.9$  vs  $44.9 \pm 3.8 \text{ kg/m}^2$ , *P* < 0.01). RYGB induced greater weight loss than LAGB in both genders (male:

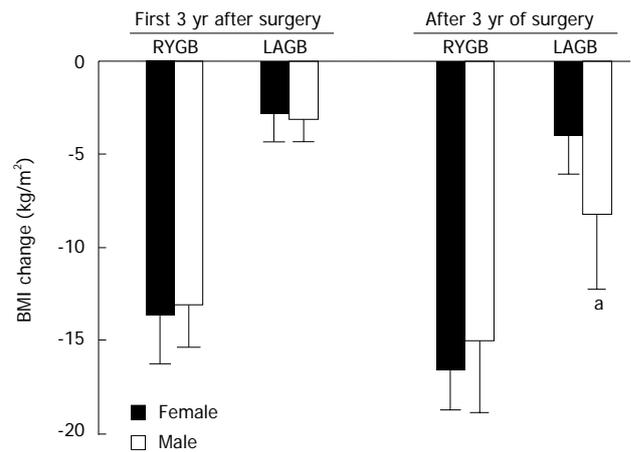

Figure 6 Body mass index changes after Roux-en-Y gastric bypass and laparoscopic adjustable gastric band in male and female 3 years post-surgery. <sup>a</sup>*P* = 0.02 vs female. RYGB: Roux-en-Y gastric bypass; LAGB: Laparoscopic adjustable gastric band.

$-13.8 \pm 3.1$  vs  $-3.5 \pm 1.9 \text{ kg/m}^2$ ; *P* < 0.0001; female:  $-15.0 \pm 3.8$  vs  $-2.9 \pm 1.3 \text{ kg/m}^2$ , *P* < 0.0001), with no differences in weight loss between genders during the first 3 years of surgery. Thereafter LAGB males had a greater reduction in BMI than females ( $-8.2 \pm 4.3$  vs  $-3.9 \pm 1.9 \text{ kg/m}^2$ , *P* = 0.02, Figure 6).

The rates of acute (male: 9/116 vs female: 40/493) or long-term complications (male: 2/116 vs female: 11/493) were similar in males and females after RYGB. In the LAGB cohort, however, longer term complications requiring corrective procedures, were less likely to occur in males than females (male: 2/131 vs female: 59/555, *P* < 0.001). The rate of acute complication for both genders was similar after LAGB (male: 0/131 vs female: 4/555).

**Blood sugar, lipid profiles and co morbidities**

There were no differences in age, gender, initial BMI and magnitude of weight loss between those patients for whom biochemical/co-morbidity data was, or was not, available (Table 3). Before surgery, there were no differences in the proportion of patients with diabetes mellitus, hyperlipidemia or hypertension (Table 1). The presence of significant co-morbidities (diabetes mellitus, hypertension, sleep apnoea) in patients who had initial BMI between 30-35 kg/m<sup>2</sup> was 45% in both RYGB and LAGB groups.

Fasting blood glucose (33% vs 17%, P = 0.02), total cholesterol (54% vs 4%, P < 0.001), and plasma triglyceride (81% vs 27%, P < 0.0001) normalised more frequently after RYGB than after LAGB, respectively (Table 4). Fasting blood glucose, total cholesterol and triglyceride levels were significantly reduced 12 mo after both types of procedures, however the magnitude of improvement was greater and the onset of improvement was earlier after RYGB (Table 5). Both procedures resulted in a similar increase of plasma high-density lipoprotein.

Patients who underwent RYGB were more likely to have obstructive sleep apnea (OSA: 32% vs 20%, P < 0.001; Table 3). The proportion of patients who had resolution of OSA were significantly higher after RYGB than after LAGB (10% vs 3%, P = 0.03; Table 4).

**DISCUSSION**

For patients who underwent bariatric surgery for morbid obesity this data shows that, while both procedures are safe, RYGB was associated with: (1) substantially greater weight loss; (2) lower fasting blood glucose, total cholesterol and triglyceride levels; (3) greater risk of acute non-fatal complications; and (4) lower rate of re-operation rate in long-term. Following band failure, conversion to RYGB resulted in a greater reduction in BMI, than band replacement, and may therefore be a preferable rescue procedure. This may be particularly relevant for patients with inadequate resolution of co-morbidities after LAGB. Furthermore, the current study demonstrates the differential impact of gender on weight loss and complications in patients who underwent LAGB but not RYGB. The greater weight loss observed in males 3

years post lap band insertion was associated with a significantly lower rate of long-term band related complications.

The findings of this study are consistent with the available data from both randomized and non-randomized clinical trials<sup>[3,8-10,14-18]</sup>. Currently, only 2 prospective randomized comparisons of RYGB against LAGB have been performed and both have methodological weaknesses<sup>[8,17]</sup>. Although the first study found better short-term weight loss and a lower number of weight loss failures after RYGB, the sample size was small (24 RYGB *vs* 27 LAGB) limiting the capacity to make definitive conclusions, particularly about uncommon adverse events<sup>[17]</sup>. The larger, second trial (111 RYGB *vs* 86 LAGB) confirmed the superior weight loss after RYGB as compared to LAGB, but was criticized for significant differences in baseline BMI between the groups and an unusual high rate of gastro-jejunostomy stricture<sup>[8]</sup>. Both studies showed a higher rate of peri-operative but lower incidence of later complications and need for re-operation after RYGB than LAGB<sup>[8,17]</sup>. Similar outcomes have been reported from pair-matched studies, as well as systematic and network meta-analyses<sup>[3,8-10,14-18]</sup>.

The marked improvement or normalization of fasting blood glucose and lipid profile after both RYGB and LAGB in this current study are in keeping with previous studies<sup>[3,8-10,14-18]</sup>. The observation that, of the two procedures, RYGB has a much greater benefit for these co-morbidities, is consistent with previously reported data<sup>[3,9]</sup>. The greater proportion of patients with OSA in the RYGB group is most likely related to the greater initial BMI, which is a known risk factor for OSA. Similar, the greater resolution of OSA after RYGB, as compared to LAGB, is most likely related to the greater reduction in BMI, and the finding is consistent with the current literature<sup>[3]</sup>.

The differences in acute and long-term complications in the current study are also in keeping with the current literature<sup>[3,8-10,14-18]</sup>. Given RYGB is a more complex operation with a longer operative time, it is not surprising that the prevalence of acute post-operative complications was higher after RYGB than LAGB. It is, however, important to note that none of the complications were fatal and most were related to wound infection and managed successfully with medical therapy. Compared to the 1% mortality reported internationally, there were no surgical deaths amongst our RYGB cohort. The reasons for the absence of mortality may relate to the meticulous patient assessment and selection, pre-operative preparation, and anaesthetist with a special interest and expertise in dealing with complex bariatric patients. The impressively low rate of acute complications after LAGB in this report should be highlighted and is consistent with the current literature<sup>[3,8-10,14-18]</sup>, suggesting that LAGB is an extremely safe bariatric procedure.

Except for the study of Nguyen *et al*<sup>[8]</sup>, which was criticized for the unusually high rate of gastro-jejunos-

tomy stricture after RYGB, our and other long-term follow-up studies have consistently shown a higher rate of long-term complication and the need for re-operation after LAGB as compared to RYGB<sup>[3,8-9]</sup>.

The superior weight loss at 3 years after LAGB in males as compared with females may relate, at least in part, to a lower number of postoperative long-term complications. Other studies have either shown similar<sup>[14,19,20]</sup> or worse outcomes<sup>[8,21]</sup> for males than females after LAGB. One reason for this is the poor adherence of men to post-band advice and follow-up<sup>[22,23]</sup>. On the other hand, men are less likely to have over-eating disorders, are more willing to exercise if feeling well<sup>[22,23]</sup>, and generally have better outcomes in most studies of diet induced weight loss<sup>[24]</sup>. In the most recent large study of LAGB procedures ( $n = 3000$ ), the occurrence of proximal gastric pouch dilatation, a known risk factor for poor weight loss, was significantly more common in women than men (5.1% *vs* 1.3%), and was highest in younger women<sup>[23]</sup>. The possibility of selection biases by selectively chosen highly motivated males cannot be excluded. Regardless, better outcomes for LAGB in males than females indicates that gender may be an important consideration in procedure choice and needs further confirmation.

It is notable that about 12% of patients with BMI between 30 and 35 kg/m<sup>2</sup> underwent bariatric surgery, particularly in the LAGB group (18% *vs* 5% in RYGB group). This may reflect patient pressure in the private system, concomitant co-morbidities or pre-operative weight loss prior to the initial consultation, together with the perception that LAGB is reversible and safe. Weight loss in this group of patients was particularly poor (RYGB:  $-3.9 \pm 0.3$  kg/m<sup>2</sup>, and LAGB:  $-1.5 \pm 0.3$  kg/m<sup>2</sup>), highlighting the rigorous protocols for patient selection in order to optimise outcomes.

There are strengths and weaknesses in this current study. The large sample size, a well maintained prospective database and an extended follow-up are the strengths of the current study. To our knowledge, our study is the largest comparative study on RYGB versus LAGB with follow up over 5 years. On the other hand, the weaknesses are potential selection biases by 2 independent surgeons who only performed either RYGB or LAGB, incomplete data relating to plasma biochemistry, and the lack of details on medications for co-morbidities.

In a community setting, RYGB produces substantially greater weight loss and resolution of co-morbidities than LAGB in both the short- and long-term, at a cost of higher peri-operative complications, which are non-fatal and mostly related to wound infection. The long-term complication rate is higher after LAGB. Where band failure occurs, RYGB is the superior salvage procedure. The better outcomes for LAGB in males compared to females after 3 years post-surgery needs further confirmation. Gender, like extent of co-morbidities and

BMI, may be an important consideration in procedure choice.

## COMMENTS

### Background

Currently, the choice between these bariatric procedures is based mainly on patient and surgeon preference, and varies significantly between regions of the world. In contrast to the United States and Europe, laparoscopic adjustable gastric band (LAGB) is the most common procedure in Australia and the number of procedures increased by 10 times over the last decade. This is despite the majority of available data indicating that LAGB produces smaller weight loss and less frequent resolution of comorbidities than Roux-en-Y gastric bypass (RYGB).

### Research frontiers

This study aimed to compare the "real-life" weight loss and surgical outcomes of RYGB and LAGB from two large referral bariatric centres in South Australia, in which the databases were prospectively maintained over 10 years.

### Innovations and breakthroughs

In contrast to the impressive weight loss reported by a single Australian LAGB center, the results of the current study are consistent with the available literature on the outcomes of bariatric surgery. The main findings are: (1) RYGB produces substantially greater weight loss and resolution of co-morbidities than LAGB in a community setting, in both the short- and long-term; (2) although peri-operative complications are higher with RYGB than LAGB, which are non-fatal and mostly related to wound infection, the long-term complication rate is higher after LAGB; (3) fasting glucose, total cholesterol and low density lipoprotein levels were significantly lower 12 mo after RYGB than LAGB; and (4) where LAGB fails to induce or maintain weight loss, RYGB appears to be the superior salvage procedure.

### Applications

This study suggests that, in a community setting, RYGB is safe and produces superior short- and long-term weight loss outcomes than LAGB. These data need to be acknowledged and disseminated in the Australian community to allow both surgeons and patients to make an appropriate decision on the choice of bariatric procedure.

### Terminology

LAGB is a weight loss surgical procedure which involves placement of an inflatable band at the top of the stomach to restrict over-eating. In contrast, RYGB involves surgical reconstruction of both the stomach and the small intestine into a small stomach pouch and a bypass of food through the small intestinal. RYGB not only restricts eating but also leads to malabsorption of food.

### Peer review

This is one of the largest trials that compared the "real-life" weight loss and surgical outcomes of the two most commonly performed bariatric procedures in the world, RYGB and LAGB. The results are interesting and suggest that RYGB is safe in a tertiary centre and is superior to LAGB in term of both short- and long-term weight loss outcomes. The data, therefore, enhance the current knowledge in the area of bariatric surgery and allow appropriate decision making in the management of the epidemic obesity.

### Abstract

**AIM:** To evaluate the *in vitro* effect of amoxicillin and clarithromycin on the *cag* pathogenicity island (*cag* PAI).

**METHODS:** One hundred and forty-nine clinical isolates of *Helicobacter pylori* (*H. pylori*) cultured from gastric biopsies from 206 Colombian patients with dyspeptic symptoms from a high-risk area for gastric cancer were included as study material. Antimicrobial susceptibility was determined by the agar dilution method. Resistant isolates at baseline and in amoxicillin and clarithromycin serial dilutions were subjected to genotyping (*cagA*, *vacA* alleles *s* and *m*), Glu-Pro-Ile-

Tyr-Ala (EPIYA) polymerase chain reaction and random amplified polymorphic DNA (RAPD). Images of the RAPD amplicons were analyzed by Gel-Pro Analyzer 4.5 program. Cluster analyses was done using SPSS 15.0 statistical package, where each of the fingerprint bands were denoted as variables. Dendrograms were designed by following Ward's clustering method and the estimation of distances between each pair of *H. pylori* isolates was calculated with the squared Euclidean distance.

**RESULTS:** Resistance rates were 4% for amoxicillin and 2.7% for clarithromycin with 2% double resistances. Genotyping evidenced a high prevalence of the genotype *cagA*-positive/*vacA s1m1*. The 3' region of *cagA* gene was successfully amplified in 92.3% (12/13) of the baseline resistant isolates and in 60% (36/60) of the resistant isolates growing in antibiotic dilutions. Upon observing the distribution of the number of EPIYA repetitions in each dilution with respect to baseline isolates, it was found that in 61.5% (8/13) of the baseline isolates, a change in the number of EPIYA repetitions lowered antibiotic pressure. The gain and loss of EPIYA motifs resulted in a diversity of *H. pylori* subclones after bacterial adjustment to changing conditions product of antibiotic pressure. RAPD PCR evidenced the close clonal relationship between baseline isolates and isolates growing in antibiotic dilutions.

**CONCLUSION:** Antibiotic pressure does not induce loss of the *cag* pathogenicity island, but it can lead - in most cases - to genetic rearrangements within the 3' region *cagA* of the founding bacteria that can affect the level of tyrosine phosphorylation impacting on its cellular effects and lead to divergence of *cagA*-positive subclones.

**Key words:** *Helicobacter pylori*; Antimicrobial susceptibility; *cag* pathogenicity island; *cagA* 3' region; Random

amplified polymorphic DNA-polymerase chain reaction

**Core tip:** This study evaluated the *in vitro* effect of amoxicillin and clarithromycin on the *cag* pathogenicity island (*cag* PAI). It was found that the effect of antibiotic pressure does not induce loss of *cag* PAI, but it can lead - in most cases - to genetic rearrangements (loss or gain of Glu-Pro-Ile-Tyr-Ala motif) within the 3' region of *cagA* gene of the founding bacteria that can affect the level of tyrosine phosphorylation impacting on its cellular effects and lead to divergence of *cagA*-positive subclones, which as a set could alter the pathogenic process of *Helicobacter pylori* in cases with treatment failure.

## INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is a Gram-negative bacteria in spiral form and microaerophilic that infect the gastric mucosa of approximately 50% of the world's population<sup>[1-4]</sup>. It is usually acquired during childhood<sup>[5]</sup> and when not treated it persists for decades causing clinically asymptomatic chronic gastritis<sup>[6-8]</sup>, although histologically apparent. In a subset of infected individuals, the presence of the bacteria is associated to peptic ulcer, adenocarcinoma, and gastric lymphoma<sup>[3,6]</sup>. Clinical results of the infection are related to the host's immunological defense mechanisms, environmental factors like cigarette smoking and excessive salt intake, diet low in antioxidants, phylogeographic origin<sup>[9]</sup>, and the bacteria's virulence capacity<sup>[8]</sup>. *H. pylori* uses many modalities to colonize the gastric epithelium and some of these adaptation strategies contribute to the progression of the disease<sup>[10]</sup>, among them gene products encoded by *cagA* and *vacA*.

The *cagA* gene is a marker of the *cag* pathogenicity island, present in over 50% of the *H. pylori* strains<sup>[7]</sup>, encodes for the CagA protein one of the main determinants of pathogenicity associated to infection by *H. pylori*<sup>[2,11,12]</sup>, followed by *H. pylori* adhesion to the gastric epithelium, CagA is translocated within the cytoplasm of the epithelial cell via the type IV secretion system, where kinases from the Src and Ab1 family phosphorylate it into specific tyrosine residues inside the Glu-Pro-Ile-Tyr-Ala (EPIYA) repetition motifs<sup>[1,2]</sup>. These EPIYA motifs can be repeated within the protein's variable region<sup>[1]</sup>, and are defined as EPIYA-A, -B, -C, and -D according to the amino acids surrounding them<sup>[2]</sup>. Species of nearby CagA proteins almost always contain EPIYA-A and EPIYA-B sites, followed by one to three repetitions of EPIYA-C in the *H. pylori* Western-type isolates (ABC, ABCC, and ABCCC) or one EPIYA-D site in East Asian-type iso-

lates (ABD). CagA variability with respect to the EPIYA motifs can play an important role in *H. pylori* pathogenesis<sup>[2]</sup>. CagA-positive clinical isolates with increased number of EPIYA motifs obtained from Eastern populations have been associated to higher severity of active chronic gastritis and atrophy. Likewise, an increased number of EPIYA motifs within the Western-type CagA protein has been related to increased levels of phosphorylation, high secretion of interleukin-8, cell elongation, and formation of "hummingbird" phenotype<sup>[1,11]</sup>. Hence, determination of the number of EPIYA motifs within the *cagA* variable region in clinical *H. pylori* isolates is more important than the mere detection of the *cagA*<sup>[1]</sup> and can be useful in predicting the bacteria's pathogenic activity<sup>[11]</sup>.

The *vacA* gene is present in all *H. pylori* strains, although it is only expressed in 50%-65% of them<sup>[5,12]</sup>, it encodes a vacuolating toxin of 88-kDa (VacA) that affects the gastric epithelial cells and is important in the pathogenesis of peptic ulcers and gastric adenocarcinoma<sup>[7]</sup>. Two regions of marked sequence diversity are distinguishable within the *vacA* gene. The *s* region (encodes the signal peptide) is present as *s1* or *s2* allele, while the *m* region (mid region) can be *m1* or *m2*. The combination of the allele mosaic from the *s* and *m* region determines the production of vacuolating cytotoxin and is associated to the bacteria's pathogenicity. The strains harbored *vacA s1m1* have been strongly associated to increased virulence and greater epithelial gastric damage and ulceration than *s2m2* strains<sup>[7,12]</sup>. Thus, *cagA*-positive and *vacA s1m1* genotypes are associated to high risk of gastric cancer<sup>[7]</sup>.

*H. pylori* has extraordinary allelic diversity and genetic variability<sup>[7,13]</sup>, generated through an elevated rate of point mutations, intragenomic and intergenomic recombination<sup>[13]</sup>, phenomena facilitated by the presence of reactive oxygen species (ROS) and reactive nitrogen species (RNS) produced from inflammatory lesions induced by the *H. pylori* infection. This complex environment propitiates a second-order selection that implies variation in mutator genes, creating a non-linear diversification system<sup>[14]</sup>. The fact that virulence factors in *H. pylori* are linked to disease implies that they are a fixed characteristic, but this is not the case and genotype variations can occur through genetic rearrangements<sup>[14]</sup> that eliminates particular immune-stimulating genetic regions (*cag* PAI) or causes variations in potential immune-stimulating molecules (number of EPIYA repetitions in CagA)<sup>[5,13]</sup>, probably reflecting the local selection of *H. pylori* particular phenotypes<sup>[14]</sup> as an escape recourse to the immune response of the host induced by environmental pressures.

This variety of strategies and gene products permit *H. pylori* to persistently colonize its host and cause disease. Within this context, its eradication can contribute to the treatment and prevention of gastric pathologies associated to the infection. Substantial improvements have been accomplished in the efficacy of treatment regimes; nevertheless, all still present faults to completely eradicate the infection<sup>[15]</sup>. This study evaluated the *in vitro* effect of the antibiotics used in standard triple therapy over

specific virulence factors like *cag* PAI, in *H. pylori* isolates from Colombian patients from a high risk region for gastric cancer, to understand the course of the infection in unsuccessful treatments.

## MATERIALS AND METHODS

### Subjects

During 2009, 206 volunteer subjects were recruited with symptoms of dyspepsia, 44.2% (91/206) men ranging in age from 18-68 years, in a population from Túquerres in the high Andes mountains of Colombia, characterized by a high prevalence of *H. pylori* and preneoplastic lesions<sup>[8,16]</sup>. Exclusion criteria included prior gastrectomy, chronic disease, intake of H<sub>2</sub>-receptor antagonists, proton pump inhibitors, or antibiotic intake during the last four weeks prior to endoscopy. During upper gastrointestinal tract endoscopy, biopsies were obtained of gastric antral and body and embedded in paraffin for histopathological evaluation. Additional biopsies, two antral (greater and lesser curvature) and one gastric body (greater curvature) were taken for *H. pylori* culture and immediately frozen in thioglycolate with glycerol. The samples were delivered in liquid nitrogen to the Department of Pathology at Universidad del Valle (Cali, Colombia) for analysis. This research was approved by the Ethics Committee at Universidad del Valle. All the participants provided informed consent.

### Histopathology

Histopathological diagnosis for each participant was independently evaluated by expert pathologists in antral and body gastric sections stained with hematoxylin and eosin, according to the Sydney classification system<sup>[17]</sup>. The categories were non-atrophic gastritis (NAG), multifocal atrophic gastritis without intestinal metaplasia (MAG), intestinal metaplasia (IM), and dysplasia. Cases with discordant diagnosis were again revised and consensus was reached.

### Culture and phenotypic and microscopic identification of *H. pylori*

Fragments of antral and body gastric mucosa were homogenized under sterile conditions in 200 µL of saline solution 0.89% using a homogenizer (Kimble-Kontes, Vineland, NJ, United States). The homogenized was placed on Columbia agar plates (Oxoid, Basingstoke, Hampshire, England) with defibrinated sheep blood at 7% plus selective supplement for *H. pylori* (Dent) containing Vancomycin (10 mg/L), Sodium cefsulodin (5 mg/L), Trimethoprim lactate (5 mg/L), and Amphotericin B (5 mg/L) (Oxoid, Basingstoke, Hampshire, England). The agar plates were incubated under microaerophilic conditions (6% O<sub>2</sub>, 6% CO<sub>2</sub>, 88% N<sub>2</sub>, using CampyPak Plus envelope, BBL, Nashville, TN, United States) at 37 °C from four to eight days until observing small gray translucent colonies. The typical colonies were sub-cultured and later identified as *H. pylori* through their morphology, Gram-

stain, and biochemical analyses for oxidase, catalase, and urease activity.

### Antimicrobial susceptibility in *H. pylori* isolates

Antimicrobial resistance was evaluated by agar dilution method according to guidelines from the Clinical and Laboratory Standards Institute<sup>[18]</sup> using Mueller-Hinton (MHA) agar (Merck KGaA, Darmstadt, Germany) supplemented with defibrinated sheep blood at 7%. Double serial clarithromycin and amoxicillin dilutions (Genfar laboratories, Bogotá, Cundinamarca, Colombia) of 0.25, 0.5, 1.0, 2.0, and 4.0 µg/mL were added to MHA plates. Bacterial isolates sub-cultured in Columbia agar for no more than 72 h were re-suspended in saline solution and turbidity was adjusted at a concentration equivalent to a McFarland 2 standard (containing  $1 \times 10^7$  or  $1 \times 10^8$  CFU/mL), 1 µL of the adjusted inoculum was placed directly onto each MHA agar plate with dilutions of the antibiotic. The minimum inhibitory concentration (MIC) of clarithromycin and amoxicillin was determined after 72 h of incubating the isolates under microaerophilic conditions at 37 °C, and it was recorded as the lowest concentration of the antibiotic that inhibits visible growth of the colonies<sup>[12]</sup>. An isolate was considered resistant to clarithromycin or amoxicillin when its MIC was  $\geq 1.0$  µg/mL. The *H. pylori* reference strain ATTC<sup>®</sup> 43504 was used as quality control strain to monitor MIC precision when using the agar dilution method, considering MIC cutoff points  $< 0.015$  µg/mL as sensitive and  $> 0.12$  µg/mL as resistant to clarithromycin and amoxicillin.

### DNA extraction from *H. pylori* isolates

Bacterial DNA was extracted from pure *H. pylori* cultures that showed resistance to clarithromycin and/or amoxicillin in each of the serial dilutions and from the isolates themselves in baseline (without antibiotic pressure). In all cases, single colonies were taken with swabs and washed in a 1.5 mL tube with 200 µL of sterile saline solution (0.89%). Tube contents were homogenized in vortex for 10 s and centrifuged in a 320R universal micro-centrifuge (Hettich Inc, Tuttlingen, Germany) at 13000 rpm for 2 min at 4 °C. Thereafter, the supernatant was discarded and the bacterial pellet was re-suspended in 300 µL of Lysis buffer (3 µL of Tris HCl 1 mol/L, pH 8.0 (Promega, Madison, WI, United States), 3 µL of EDTA 0.5 mol/L (Calbiochem, Gibbstown, NJ, United States), 15 µL of SDS 10% (Calbiochem, Gibbstown, NJ, United States), 3 µL of proteinase K (10 mg/mL) (Invitrogen, Carlsbad, CA, United States), and 276 µL of distilled water) and incubated in dry well (Labnet, Edison, NJ, United States) at 56 °C for 18 h. Then, the proteinase K was inactivated by heating at 70 °C for 10 min and 120 µL of NaCl 5 mol/L (Calbiochem, Gibbstown, NJ, United States) was added, homogenized by vortex and centrifuged for 5 min at 13000 rpm; the supernatant was transferred to another tube in which two volumes of absolute alcohol were added (Mallinckrodt, St.Louis, Mo, United States), again centrifuged at 13000 rpm for

20 min, then discarding the supernatant and adding 200  $\mu$ L of ethanol at 70%. Once more, it was centrifuged for 5 min at 10000 rpm and then the supernatant was discarded; each tube was dried by inversion at room temperature. Finally, 50  $\mu$ L of TE buffer were added (Tris-HCl 10 mmol/L, pH 8.0 (Promega, Madison, WI, United States), EDTA 1 mmol/L, pH 8.0 (Calbiochem, Gibbstown, NJ, United States) and the DNA was stored at -20 °C. The yield and purity of the DNA was determined by optical density at 260/280 nm in Gene Quant II<sup>®</sup> spectrophotometer (Pharmacia Biotech, Piscataway, NJ, United States) according to manufacturer's instructions.

### Virulence markers for *H. pylori*

To genotype the virulence of *H. pylori* isolates resistant in baseline to clarithromycin and amoxicillin, separate PCR reactions were carried out in a thermocycler (Swift Mini-Pro<sup>™</sup>, Esco Technologies, Hatboro, PA, United States) for *vacA-s* and *vacA-m*, *cagA*, *cag* empty-site. Four sets of primers were initially used in this study. To amplify the *s* region of the *vacA* gene, VA1F and VA1R primers were used, which amplify a fragment of 259 bp (allele *s1*) and 286 bp (allele *s2*). To detect the *m* region of the *vacA* gene, HPMGF and HPMGR primers were employed, which resulted in the amplification of a fragment of 401 bp (allele *m1*) and 476 bp (allele *m2*). The *cagA* gene was amplified to validate the ability of the EPIYA polymerase chain reaction (PCR) to detect the presence of the *cag* PAI, using *cagAF* and *cagAR* primers that amplify a fragment of 183 bp from the 5' end of the *cagA* gene<sup>[19]</sup>. The negative isolates for the *cagA* gene were in all cases confirmed by *cag* empty-site PCR employing ES-F and Rnew-1R primers<sup>[7]</sup>, upon detecting a fragment of 106 bp that indicated the loss of the *cag* PAI. Each experiment included a positive and negative reaction control.

### Amplification of the 3' *cagA* variable region

To detect the presence of the *cag* PAI and characterize the number of EPIYA motifs present in the 3' *cagA* variable region in resistant isolates at each of the antibiotic dilutions (with antibiotic pressure) and in same isolates in baseline (without antibiotic pressure), a PCR reaction was carried out using *cagA2530S* and *cagA3000AS* primers<sup>[11]</sup>. The size of the amplicons expected varied in the range of 370 bp (2 EPIYA motifs), 470 bp (3 EPIYA motifs), 570 bp (4 EPIYA motifs), 670 bp (5 EPIYA motifs)  $\pm$  25 bp and were approximately 100 bp equidistant, indicating the presence of multiple repeated sequences. In cases where a clear band was not evidenced or the presence of amplified, a second PCR was carried out under the same conditions, employing 1  $\mu$ L of the initial amplified, along with the respective controls to detect possible cross contamination. During the development of the trials, *H. pylori* strain 26695 (ATCC 700392) were used (number of access AE000511.1) as size control of the nucleotide sequence encoding for three EPIYA motifs-ABC (470 bp  $\pm$  25 bp), and *H. pylori* strain ATCC 43504 that presents

an EPIYA-ABCCC motif (670  $\pm$  25 bp); thus, predicting the number of repetitions of the EPIYA motifs was possible by direct comparison of the sizes corresponding to PCR amplified.

### RAPD PCR

The genomic differences between *H. pylori* isolates found before and after antibiotic pressure were evaluated by using random primers: 1254 (5'-CCGCAGCCAA-3') and 1281 (5'-AACGCGCAAC-3')<sup>[20]</sup>. These oligonucleotides were amplified in a final 12.5  $\mu$ L reaction volume composed of 2.5  $\mu$ L of PCR buffer (10 mmol/L of Tris-HCl pH 8.0 and 50 mmol/L of KCl-Promega, Madison, WI, United States), 3 mmol/L MgCl<sub>2</sub>, 1 U of Go *taq* polymerase (Promega, Madison, WI, United States), 250  $\mu$ mol/L of dNTPs (Promega, Madison, WI, United States), 25 pmol of each primer, and 1  $\mu$ L of bacterial DNA. The amplification was carried out in a thermocycler (Swift MiniPro<sup>™</sup>, Esco Technologies, Hatboro, PA, United States), prior denaturalization for 5 min at 94 °C, followed by 45 cycles of: 94 °C for 1 min, 36 °C for 1.30 min, 72 °C for 2 min, followed by a final incubation at 72 °C during 10 min. Band size was estimated by using a 100 bp DNA Ladder (Fermentas International Inc., Vilnius, Lithuania). Each isolate was tested with the primers described under the same conditions at least twice and only evident and reproducible bands were evaluated.

### Electrophoresis of amplicons

All the amplicons obtained in each of the previously described PCR reactions were run on agarose gel (SeaKim, FMC Bioloabs) at 2%, stained with ethidium bromide (Invitrogen, Carlsbad, CA, United States) at 0.5  $\mu$ g/mL, in an electrophoresis chamber (Fotodyne Inc., Hartland, WI, United States) at 75 V for 40 min provided by a EC-105 Compact Power Supply (Thermo Fisher Scientific Inc, Asheville, NC, United States).

### Statistical analysis

Initially, univariate and bivariate analyses were conducted; the categorical variables were described as proportions. To determine the statistical significance of the differences in the proportions of *cag* PAI detection *via* *cagA* PCR and EPIYA PCR among baseline resistant isolates and in amoxicillin and clarithromycin dilutions, the McNemar test was employed for data related to the SPSS 15.0 statistical package (SPSS Inc., Chicago, IL, United States). Images of the amplicons obtained *via* RAPD PCR were analyzed through the Gel-Pro Analyzer 4.5 program for Windows (Media Cybernetics, Inc, Rockville, MD, United States). Molecular weights of the well-defined, single-pattern bands were analyzed with this program and a matrix of binary data was constructed based on the presence (1) and absence (0) of the bands observed (polymorphic) among the isolates. Ratios among isolates were established through cluster analysis carried out with the SPSS 15.0 statistical package (SPSS Inc., Chicago, IL, United States), where each of the fingerprint bands were

**Table 1** Minimum inhibitory concentration of the antibiotics and percentages of resistance among strains

Antibiotic	MIC ( $\mu\text{g/mL}$ )			Resistance ( $n = 149$ )
	MIC <sub>50</sub>	MIC <sub>90</sub>	Range	$n$ (%)
Amoxicillin	2	4	0.25-4.0	6 (4)
Clarithromycin	2	4	0.25-4.0	4 (2.7)

2% (3/149) of the isolates showed double resistance. MIC: Minimum inhibitory concentration.

denoted as variables. The dendrograms were designed by following Ward's clustering method and the estimation of distances between each pair of *H. pylori* isolates was calculated with the squared Euclidean distance. In the clusters, fingerprints with distances less than or equal to five were considered related and distances above five were unrelated. The cluster analysis and the association to antimicrobial susceptibility were evaluated by using the  $\chi^2$  exact. The statistical significance was accepted with a  $P$  value  $\leq 0.05$ .

## RESULTS

Global prevalence of infection by *H. pylori* was 85.4% (176/206) and 72.3% (149/206) by histology and culture, respectively. Isolates positive for *H. pylori* were characterized by antimicrobial susceptibility.

### Histopathology

Among the 176 participants diagnosed through histopathology, 140 (79.5%) presented non-atrophic chronic gastritis, four (2.3%) multifocal atrophic gastritis without intestinal metaplasia, and 32 (18.2%) were diagnosed with multifocal atrophic gastritis with intestinal metaplasia (data not shown).

### Antimicrobial susceptibility

The antimicrobial susceptibility of the 149 isolates is shown in Table 1; MIC<sub>50</sub> and MIC<sub>90</sub> values are indicated. A total of 136 (91.3%) of the bacterial isolates were sensitive to clarithromycin and amoxicillin, while six (4%) of the isolates were AmxR, and four (2.7%) were ClaR. Only three (2%) of the isolates were resistant to both antibiotics. Global resistance was at 8.7% (13/149). The histopathological diagnosis of the participants with isolates that showed resistance was as follows: nine (69.2%) presented non-atrophic chronic gastritis, two (15.4%) had multifocal atrophic gastritis without metaplasia and two (15.4%) had multifocal atrophic gastritis with intestinal metaplasia. It is interesting to find that 50% (2/4) participants diagnosed through histopathology with multifocal atrophic gastritis presented AmxR/ClaR double-resistant isolates (SV323 and SV399) (Table 2).

### Genotyping of virulence genes

The genotyping results of *H. pylori* isolates resistant to amoxicillin and clarithromycin are shown in Table 2. In

23% (3/13) of the participants with isolates resistant to the antibiotics evaluated, colonization was documented with multiple *H. pylori* strains; in one of the cases (SV438) it was impossible to determine the infecting bacterial genotype. It was observed that in all isolates the *cagA*-positive genotype predominated. *vacA s1m1* alleles were predominant, present in 84.6% (11/13), while *s2m2* alleles were only observed in 7.7% (1/13) of the isolates. None of the resistant isolates obtained in this study presented genotypes *s1m2* or *s2m1*.

### Detection of the 3' variable region of the *cagA* gene

Successful amplification took place of the 3' variable region of the *cagA* encoding for EPIYA phosphorylation motifs of the CagA protein in 92.3% (12/13) of the baseline resistant isolates (without antibiotic pressure) and in 60% (36/60) of the resistant isolates growing at each of the serial amoxicillin and clarithromycin dilutions (with antibiotic pressure) (Table 2). This permitted confirming the presence of the *cag* PAI previously detected by *cagA*-specific PCR, as well as characterizing the number of EPIYA motifs present. Amplicon size was in the range of 470-670 bp ( $\pm 25$  bp), according to that suggested by Panayotopoulou *et al.*<sup>11</sup> except for some cases where strong bands were obtained -reproducible with unexpected molecular weights close to 170 and 270 bp ( $\pm 25$  bp) (Figure 1A and Table 2). A single PCR product was observed in 49.3% (36/73) of the isolates obtained between baseline resistant samples and antibiotic dilutions and more than one PCR product with sizes corresponding to different numbers of EPIYA repetitions in 16.43% (12/73) of the isolates. All isolates negative for EPIYA PCR ( $n = 25$ ) were confirmed by *cag* empty-site PCR, finding only four isolates as true *cagA*-negative. When comparing amplification proportions of EPIYA PCR *vs cagA* PCR in detecting *cag* PAI in isolates growing in the amoxicillin and clarithromycin serial dilutions, significant differences were found (McNemar test  $P = 0.006$  and  $P = 0.031$ , respectively), contrasting with the baseline resistant isolates where no significant differences were found between both PCR methods ( $P > 0.05$ ) (Table 3).

### Analysis of RAPD profiles

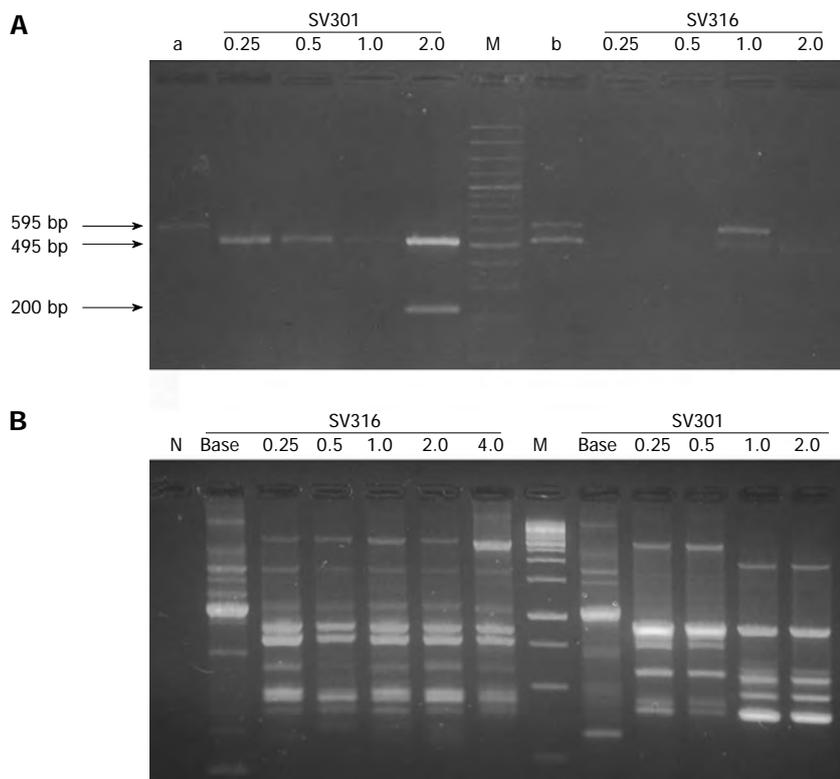

Primers 1281 and 1254 generated a reproducible RAPD fingerprints; they were capable of discriminating 73 different profiles. The number and size of the bands obtained with primer 1281 varied from 3 to 20 and from 76 to 1111 bp, respectively. It was determined if antibiotic pressure was associated to RAPD clusters. Most of the baseline resistant isolates (12/13; 92.3%) and under antibiotic pressure of amoxicillin (18/32; 56.3%) and clarithromycin (18/28; 64.3%) were included in cluster I in comparison to the distribution of these isolates in clusters II and III ( $P = 0.003$ ).

With primer 1254, well-defined patterns were generated of two to 19 fragments in a range from 49 to 1950 bp (Figure 1B). The dendrogram based on RAPD profiles obtained with this primer includes the antimicrobial susceptibility

**Table 2** Distribution of *cagA* genotypes (Glu-Pro-Ile-Tyr-Ala motifs) and *vacA* *s* and *m* among *Helicobacter pylori* isolates obtained from patients with chronic gastritis coming from a region of high risk for gastric cancer, according to profile of *in vitro* antibiotic resistance

### Effect of antibiotic pressure on the number of EPIYA repetitions

Upon observing the distribution of the number of EPIYA repetitions in each of the serial dilutions of the antibiotics with respect to the baseline isolates, change at the number of EPIYA repetitions was found in 61.5% (8/13) of the baseline isolates under antibiotic pressure. In six of these isolates (SV301, SV328, SV440, SV323, SV399 y SV433), the change consisted in loss of EPIYA repetitions evidenced by the low molecular weight of the amplified bands. In contrast, two isolates (SV316 and SV333) revealed gain of EPIYA repetitions. The gain and loss of EPIYA motifs resulted in a diversity of *H. pylori* subclones after bacterial adjustment to changing conditions product of antibiotic pressure. In all cases, the genotyping results and the presence of a single band in the EPIYA PCR for the baseline isolate permitted discarding the presence of more than one infecting *cagA*-positive isolate, except for isolate SV328 that presented in baseline three CagA species that differed in the number of EPIYA repetitions; after antibiotic pressure, alteration of the number of EPIYA repetitions was evidenced in two of the CagA species present (MIC 0.25 µg/mL) and its subsequent loss with increased concentration of the antimicrobial (MIC 0.5 µg/mL). Also, in three isolates no change was noted in the 3' variable region of the *cagA* and in the two remaining cases (SV338 and SV438) change could not be documented due to absence of EPIYA PCR amplification. We used RAPD PCR to evaluate the clonal relationship of the isolates and verify that these strains had the same origin. Specifically, the RAPD fingerprints generated by both primers reflected a close clonal relationship between baseline isolates (without pressure) and isolates growing in antibiotic dilutions (under pressure).

## DISCUSSION

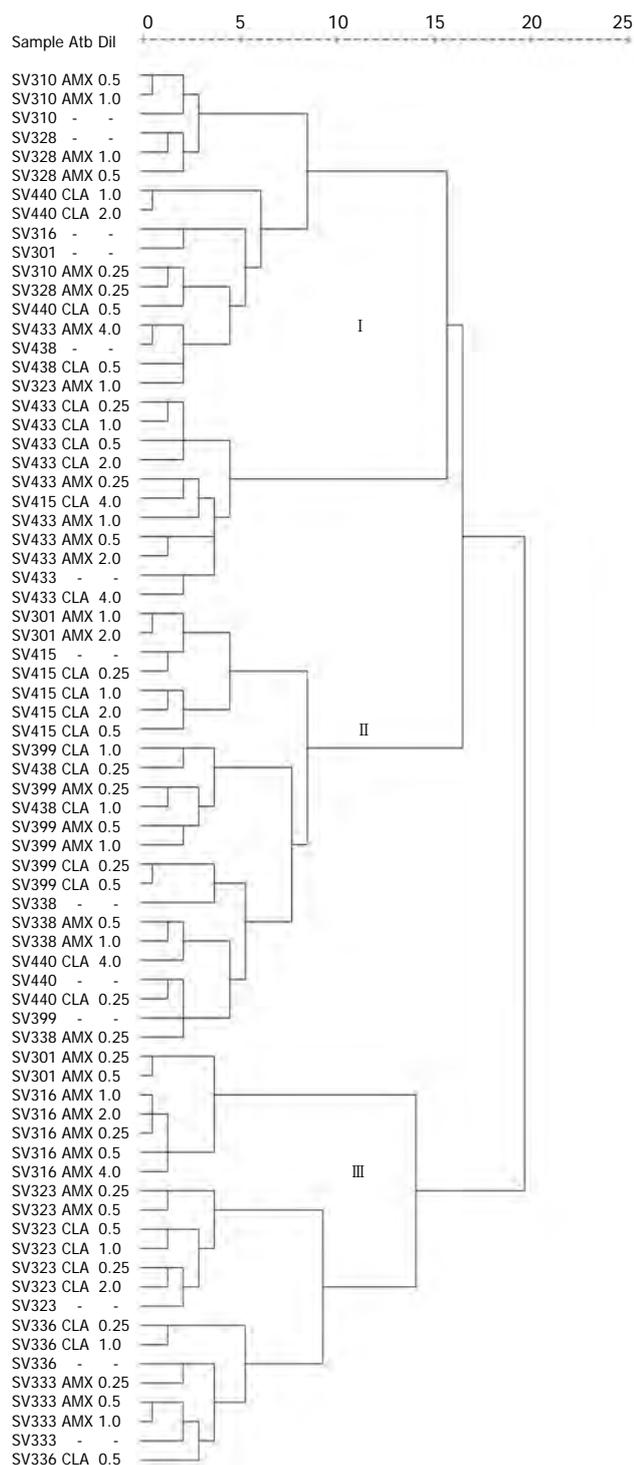

Gastric infection by *H. pylori* is a prominent risk factor for gastric cancer; the outcome of the infection is determined by the pathogen's characteristics in combination with environmental and host factors. It has been demonstrated that the precursor lesions that lead to the development of intestinal-type gastric adenocarcinoma have a series of sequential changes in the gastric mucosa<sup>[21]</sup>. The

prolonged process of these precancerous lesions provides an opportunity to prevent the progression to more advanced stages; hence, efforts must be aimed at primary prevention. Anti-*H. pylori* treatment regimes combine two or more antibiotics with a proton pump inhibitor; however, they are not 100% effective in infection resolution<sup>[12]</sup>. The purpose of this research was to evaluate the *in vitro* effect of amoxicillin and clarithromycin on *cag* PAI and the 3' variable region of the *cagA* of *H. pylori*, to understand the course of the infection in unsuccessful treatments.

We found *H. pylori* prevalence of 85.4% and 72.3% through histology and culture, respectively. Differences between the results could be due to the unequal distribution of *H. pylori* in the stomach. These results also coincide with the prevalence of the infection (73.8%) previously reported by Bravo *et al.*<sup>[16]</sup> using histology within the same community. Differences observed through histology between both studies can be due to participant age and sex. Some 79.5% of the subjects diagnosed via histopathology presented non-atrophic chronic gastritis and the proportion observed of gastric cancer precursor lesions was low; findings unexpected in a population at high risk for gastric cancer. This could be due to sample bias; over half (55.8%) of the subjects recruited were women and the intestinal-type gastric adenocarcinoma is predominant in men<sup>[5]</sup>.

Also, a low resistance rate to clarithromycin was noted in this population (2.7%), which agrees with the resistance rate reported in another Colombian region with similar geographic conditions, Pereira (2.2%)<sup>[22]</sup>, and other regions in Latin America<sup>[23,24]</sup>, but differing from the rates reported in Ecuador (9.5%)<sup>[25]</sup>, Brazil (9.8%), the metropolitan region in Chile (20%)<sup>[26]</sup>, Mexico (25%)<sup>[27]</sup>, and Argentina (27.7%)<sup>[12]</sup>. A relatively high resistance rate was also noted for amoxicillin (4%), similar to rates documented within the country by other authors in patients with dyspepsia symptoms in Bogotá (3.8%)<sup>[28]</sup> and (7%)<sup>[29]</sup>, although contrasting with the results obtained by Álvarez *et al.*<sup>[22]</sup> who found no isolates resistant to amoxicillin in Pereira, agreeing with that described in other parts of the world, where resistance rates to this antibiotic are null or below 2%<sup>[12,23,30,31]</sup>, implying an added difficulty to manage infection by *H. pylori* in our environment. In general, increased resistance to these two antibiotics could be a risk factor to consider for unsuccessful treatment within this population; thus, inasmuch as treatment is based on tests to antibiotic susceptibility, it may be more efficient in achieving high eradication rates. Additionally, studies conducted by our group have found that cases where treatment was not successful was associated to increased prevalence of less virulent strains<sup>[15,32]</sup>; it is not clearly known if this phenomenon is because of the effect of positive selection of certain genotypes (*cagA*-negative/*vacA* *s2m2*) in cases of multiple infection or because of loss of specific virulence factors (*cag* PAI) induced by antibiotic pressure, and this is the question we seek to respond.

The combination of different *cagA* genotypes and

**Figure 2** Dendrogram of the profile of random amplified polymorphic DNAs generated with primer 1254 in *Helicobacter pylori* isolates resistant in baseline and resistant isolates growing at each of the serial dilutions of amoxicillin and clarithromycin. Three separate clusters (I, II and III) are indicated. In none of the clusters was segregation of sensitive and resistant isolates significant ( $P = 0.704$ ). Cluster analyses were designed by following Ward's hierarchical clustering method and estimation of distances between each pair of *Helicobacter pylori* (*H. pylori*) isolates were calculated with the squared Euclidean distance. Distances between isolates are given in a 25-point standardized scale that reflects with sufficient precision the existing proportionality between the original distances. The fusions produced near the origin of the scale (left) indicate that the cluster formed is quite homogeneous. Conversely, fusions produced on the final zone of the scale (right) indicate the cluster formed is quite heterogeneous. Atb: Antibiotic, Dil: Dilution.

*vacA s* and *m* alleles illustrate the genomic variability of *H. pylori*<sup>[12]</sup>. This study found high prevalence of the *cagA* gene and *vacA s1m1* alleles in baseline amoxicillin and clarithromycin resistant isolates; these observations agree with previous findings reported by Sicinski *et al*<sup>[7]</sup> who genotyped gastric biopsies embedded in paraffin of two Colombian populations with contrast in the risk of gastric cancer, finding that the most virulent *cagA*-positive/*vacA s1m1* strains are more prevalent in the high-risk area. In 23% of these resistant isolates, genotyping of *cagA* and *vacA* permitted our documenting infection by multiple strains of *H. pylori*. Mixed infection with two or more *H. pylori* strains colonizing the same patient possibly represent a stable association during long-term colonization.

Also, although no theoretical bases exist to predict an association between antibiotic resistance and virulence markers, several studies have been carried out to find an association. Most studies have shown no significant correlation<sup>[33]</sup>; however, studies conducted in northern Wales<sup>[34]</sup>, central Italy<sup>[35]</sup> and western Argentina<sup>[12,36]</sup> found a clear association between virulent genotypes and antibiotic resistance. The correlation between virulence factors and antimicrobial resistance varies in different countries and although we did not evaluate this possible relationship, we found that the *cagA*-positive/*vacA s1m1* genotype predominated in resistant isolates; nevertheless, this could be a product of the high prevalence of circulating virulent strains in this region<sup>[2,7,16]</sup> and not a reflection of a possible association between virulence factors and resistance.

Over 98% of the *cagA*-positive isolates harbored a CagA protein with three (495 bp) or four (595 bp) EPIYA motifs located quite probably on the ABC or ABCC combination, respectively. Although in none of the cases were PCR products sequenced, with this methodology we can certainly predict the presence of these combinations, as demonstrated by that reported by Panayotopoulou *et al*<sup>[11]</sup>. Nonetheless, in amplicons with unexpected sizes of 170 and 270 bp (+25 bp) and over four EPIYA repetitions (695 bp), sequencing is indispensable to establish the exact type of EPIYA motif combinations; although in the last case, predicting the correct number of EPIYA motifs was possible, being one of the limitations in our study. In no case do we expect to find East Asian-type strains with EPIYA-D motif circulating in the population, although the primers used were also designed for its detection, these predictions are supported by a prior study performed by our group with 41 individuals from the same location, which evaluated through sequencing the variations in the *cagA* carboxyl-terminal end, which varied considerably in size, number, and structure of EPIYA motifs (ABC, ABCC, ABCBC, ABCC, or ABCCC) and no *H. pylori* strain contained an EPIYA-D motif<sup>[2]</sup>.

A total of 25 cases were EPIYA PCR negative and were then confirmed by *cagA*-specific PCR and *cag* empty-site PCR, finding only four of them as true *cagA*-negative,

which evidences: (1) the low sensitivity of EPIYA PCR compared to *cagA* PCR, which contrasts with the observations by Panayotopoulou *et al.*<sup>[11]</sup> who suggest that the lack of amplification of the EPIYA PCR can precisely identify the *cagA*-negative cases. Perhaps, the differences observed in our case can be the effect of the random degradation of the bacterial DNA extracted from some samples -hindering amplification of large-size fragments (> 200 bp); in any case, it is wise to validate the detection of the *cagA* gene by *cagA*-specific PCR; and (2) the inefficiency of the DNA extraction method used in those cases where amplification was not obtained<sup>[37]</sup>. However, EPIYA PCR is a simple strategy to detect the *cagA* status and for precise prediction of the number and type of EPIYA motifs, involving a single amplification step<sup>[11]</sup> and permitting rapid screening of multiple isolates. Additionally, the EPIYA PCR facilitated the identification of *cagA*-positive *H. pylori* subclones closely related within the same isolate, harbored different number of EPIYA repetitions, indistinguishable in genotyping.

Because of the methodological approach employed in this study, it was possible to document *in vitro* that the effect of antibiotic pressure does not induce loss of *cag* PAI, but it can lead - in most cases - to genetic rearrangements within the 3' region of *cagA* gene of the founding bacteria that produces a non-directed alteration (loss or gain) of EPIYA motifs. *H. pylori* has shown a unique genetic variability and these genetic changes could hypothetically be guided by intra-specific homologous recombination<sup>[11,14]</sup> and favored by their panmictic population structure<sup>[3,6]</sup>, permitting the bacteria to quickly adapt to changing conditions, being able to: (1) eliminate particular immune-stimulating genetic regions (EPIYA motifs) that would result in the production of a non-phosphorylatable form of CagA that does not induce profound morphological changes in the host cell<sup>[38]</sup> supported by amplicons of unexpected molecular weights (170 and 270 bp) obtained in this study; and (2) induce variations within the 3' terminal of the *cagA* encoding sequence that lead to differentiation in subclones with different numbers of EPIYA repetitions that can act as potential reservoirs of genetic elements for their cohabitants, with dominant clones favored by natural selection and additionally serve as escape recourse to the host's immune response; thus, increasing their possibilities to adapt, evolve, and persist. In cases in which the 3' variable region of the *cagA* remained intact following antibiotic pressure, suggests the presence of unknown extrinsic factors that can be influencing the phenomenon.

In most cases, the RAPD fingerprints confirmed the close clonal relationship existing among the isolates growing under antibiotic pressure and their corresponding baseline isolate, gathering them within the same cluster; for this reason, the cluster analysis for primer 1254 did not show differences in the segregation of isolates without pressure (baseline) and with pressure (AmxR and/or ClaR) among the three clusters formed, and although the cluster analysis based on the profile generated by the

other primer (1281) did reveal significant differences ( $P = 0.003$ ) among the three clusters, the differences observed are attributed to gathering most of the isolates within cluster I, without discriminating between isolates without pressure and those under pressure, likewise, always gathering the isolates under antibiotic pressure along with the baseline isolate. Some isolates under specific antibiotic concentration were not grouped along with their other clones at different antibiotic concentrations within the same cluster, probably due to the presence of more than one subclone within that isolate that induced a distortion in the RAPD pattern with this being a technique that generates a profile based on the complete DNA. Even though these observations agree with that expected, no differences should exist between isolates growing in each of the antibiotic dilutions and the baseline isolate because they are the same isolate.

These findings are specially important because of their possible implications for the treatment and evolution of gastro-duodenal diseases caused by *H. pylori*, suggesting that acquisition or deletion of EPIYA motifs product of the antibiotic effect can affect the phosphorylation level of tyrosine, impacting on its cellular effects<sup>[11]</sup> and leading to the divergence of *cagA*-positive *H. pylori* subclones, which as a set could alter the pathogenic process of *H. pylori* in cases with treatment failure. Such pool of *H. pylori* clones may exist in dynamic equilibrium within any potential host<sup>[11]</sup>, cooperating through quorum sensing and recombination, which can lead to down-regulation of interaction with the host<sup>[14]</sup> to induce lesser damage, even when some damage is inevitable, given that in these subclones the divergent CagA species would be normally expressed by inducing several degrees of "hummingbird" phenotype upon the infected epithelial cells<sup>[11]</sup>. This hypothesis could explain - in part - the observations registered by Mera *et al.*<sup>[39]</sup> who during a follow up of a cohort for 12 years found that those subjects receiving anti-*H. pylori* treatment but remaining infected showed decreased histopathological score -0.19 over the average histopathology score at baseline. Additional *in vitro* studies including a higher number of resistant isolates are necessary to determine the direct effect of clarithromycin and amoxicillin upon the *cagA* gene and evaluate their effect on the *vacA* gene, which was not considered in this study, even though it is a gene susceptible to genetic modifications according to that reported by Argent *et al.*<sup>[40]</sup>. Likewise, new studies are needed aimed at evaluating the *in vivo* effect of anti-*H. pylori* treatment upon virulence factors previously described in *H. pylori* isolates from patients with treatment failure and deciphering the complex molecular mechanisms through which these genomic alterations are produced. Upon proving its effect on *cagA*, this methodological approach could constitute a useful prognosis tool in clinical practice, when detecting the presence of multiple subclones and determining the number and type of EPIYA motifs, permitting the prediction of pathogenic activity of the bacteria in unsuccessful treatments.

Finally, given the generalized use of antibiotics in our environment to combat diverse infectious agents, it is tempting to speculate that inadequate treatments (not *H. pylori*-targeted) can, likewise, significantly impact upon *H. pylori* strains co-existing along with their host.

appropriate, results are clearly presented and conclusions are corroborated by the results.

We are very grateful to Professor Francis Mégraud, INSERM - U853, Université Bordeaux Segalen, France, for comments on the manuscript.

## COMMENTS

### Background

*Helicobacter pylori* (*H. pylori*) is a prominent risk factor for gastric cancer, higher risk in individuals infected with *cagA*-positive strains. Its eradication with antibiotics constitutes a chemoprevention strategy; however, treatments are not completely effective and seem to contribute to increasing the prevalence of less virulent strains.

### Research frontiers

Virulence-associate genotypes of *H. pylori* are increasingly recognized as determinants of the clinical outcome of the infection. The fact that virulence factors are linked to disease implies that they are a fixed characteristic, but this is not the case and genotype variations can occur through genetic rearrangements that either eliminates particular immunostimulatory genetic regions (*cag* pathogenicity island) or causes variations in potential immunostimulatory molecules (number of Glu-Pro-Ile-Tyr-Ala motifs in *CagA*) probably reflecting the local selection of *H. pylori* particular phenotypes as an escape resource to the immune response of the host induced by environmental pressures.

### Innovations and breakthroughs

Some studies indicate that failure to eradicate *H. pylori* from the stomach may result in an increase in the prevalence of less virulent genotypes. It is unknown if this phenomenon is due to the positive selection of certain genotypes (*cagA*-negative/*vacA s2m2*) in cases of multiple infection or loss of specific virulence factors (*cag* PAI) induced by antibiotic pressure. This study shows that antibiotic pressure does not induce loss of the *cag* PAI, but it can lead to genetic rearrangements within of the *cagA* variable region that can affect the level of tyrosine phosphorylation impacting on its cellular effects and lead to divergence of *cagA*-positive subclones, which as a set could alter the pathogenic process of *H. pylori* in cases with treatment failure.

### Applications

These *in vitro* findings are specially important because of their possible implications for the treatment and evolution of gastro-duodenal diseases caused by *H. pylori*, suggesting that acquisition or deletion of EPIYA motifs product of the antibiotic effect can affect the phosphorylation level of tyrosine and leading to the divergence of *cagA*-positive *H. pylori* subclones. Further studies are needed aimed at evaluating the effect of anti-*H. pylori* treatment on the *cagA* variable region in *H. pylori* isolates from patients with treatment failure and deciphering the complex molecular mechanisms through which these genomic alterations are produced. Upon proving its effect on *cagA*, this methodological approach could constitute a useful prognosis tool in clinical practice, when detecting the presence of multiple subclones and determining the number and type of EPIYA motifs, permitting the prediction of pathogenic activity of the bacteria in unsuccessful treatments.

### Terminology

The *cag* pathogenicity island is a genomic fragment of approximately 40 kb that contains 30 genes that encode a type IV secretion apparatus, which export proteins from bacterial cytoplasm to host epithelial cells. The terminal gene in the island, *cagA*, is commonly used as a marker for the entire *cag* locus.

### Peer review

This manuscript deals with the evaluation of the *in vitro* effect of amoxicillin and clarithromycin on the *cag* PAI. The authors found that antibiotic pressure does not induce loss of the *cag* PAI and leads in most cases to genetic rearrangements within the 3' region of *cagA* of the bacteria that lead to divergence of *cagA*-positive subclones. This study is interesting and original. Methods are

### Abstract

**AIM:** To investigate differences between common gastric cancer and  $\alpha$ -fetoprotein (AFP)-producing gastric cancer according to the presence or absence of liver metastasis.

**METHODS:** Between 1997 and 2011, 1299 patients underwent gastrectomy for gastric cancer (GC) at our institute and their hospital records were reviewed retrospectively. Patients were immunohistochemically divided into two groups: 23 patients (1.8%) with AFP-producing GC and 1276 patients (98.2%) without it.

**RESULTS:** AFP-producing GC patients had a significantly higher incidence of deeper tumors, venous invasion, lymphatic invasion, lymph node metastasis, and liver metastasis and a poorer prognosis ( $P < 0.005$ ) than those without AFP-producing GC. However, multi-

variate analysis revealed that AFP-positivity was not an independent prognostic factor. The prognosis of AFP-producing GC was similar to that of AFP-non producing GC according to the presence or absence of liver metastasis. Concerning recurrence, 47.8% of patients (11/23) with AFP-producing GC and 20.0% of patients (256/1276) without AFP-producing GC exhibited recurrence. Liver metastasis [90.9% (10/11)] was the most prevalent in AFP-producing GC patients. Multivariate analysis revealed that liver metastasis was the only independent prognostic factor in AFP-producing GC (HR = 17.6, 95%CI: 2.1-147.1;  $P = 0.0081$ ).

**CONCLUSION:** AFP-producing GC is similar to common GC without liver metastasis, which should be specifically targeted in an effort to improve the prognosis of AFP-producing GC patients.

**Key words:**  $\alpha$ -fetoprotein; Gastric cancer; Liver metastasis; Poor prognosis; Immunostaining

**Core tip:** In the present study, we re-evaluated the clinicopathological characteristics and clinical outcomes of consecutive patients with  $\alpha$ -fetoprotein (AFP)-producing gastric cancer (GC). The results obtained clearly demonstrated that clinical behaviors were different between patients with and without AFP-producing GC. However, the prognosis according to the presence or absence of liver metastasis was similar between patients with and without AFP-producing GC. Our results show that liver metastasis should be specifically targeted in an effort to improve the prognosis of AFP-producing GC.

## INTRODUCTION

$\alpha$ -fetoprotein (AFP) was initially found in the human fetus in 1956 and is normally produced in the fetal liver and yolk sac<sup>[1]</sup>. AFP is considered to be a useful tumor marker in screening or monitoring patients with hepatocellular carcinomas or yolk sac tumors. Previous studies have shown that AFP may be produced in other cancers including primary gastric cancer (GC)<sup>[2-6]</sup>.

The incidence of AFP-producing GC is low and has been reported to be 1.3%-15% in GC<sup>[7-11]</sup>. Since AFP-producing GC was first described in 1970 by Bourrille *et al.*<sup>[12]</sup>, several cases of early and advanced AFP-producing GC have since been reported. Most of them exhibited a poor prognosis with a high incidence of lymphatic invasion, venous invasion, and synchronous and metachronous liver metastasis. Therefore, AFP-producing GC has been associated with a poorer prognosis than AFP-non producing GC<sup>[12-16]</sup>. However, most of these studies were restricted to the overall prognosis, and few studies conducted subgroup analyses with special reference to the presence or absence of liver metastasis.

In the present study, we re-evaluated the clinicopathological characteristics and clinical outcomes of consecutive patients with AFP-producing GC. The results obtained clearly demonstrated that clinical behaviors were different between patients with and without AFP-producing GC. However, the prognosis according to the presence or absence of liver metastasis was similar between patients with and without AFP-producing GC. It is important to note that the overall poorer prognosis of AFP-producing GC is not related to difficulties in treating it, but from the lack of effective and recommended treatments for liver metastasis of common GC. Our results show that liver metastasis should be specifically targeted in an effort to improve the prognosis of AFP-producing GC.

## MATERIALS AND METHODS

### Patients

Between 1997 and 2011, 1375 patients with histologically confirmed primary gastric adenocarcinoma underwent gastrectomy at the Department of Digestive Surgery, Kyoto Prefectural University of Medicine. A total of 76 GC patients with active or chronic hepatitis, fatty liver, and hepatocellular carcinoma were excluded from this analysis, and 1299 patients were enrolled in this study and their hospital records were reviewed retrospectively.

Resected specimens were examined by pathologists based on classifications of the 14th Japanese Classification of Gastric Carcinomas (JCGC)<sup>[17]</sup> and 7<sup>th</sup> tumor-node-metastasis (TNM)<sup>[18]</sup>. The clinicopathological find-

ings of these patients were determined retrospectively on the basis of their hospital records. Histological types were classified as differentiated (papillary, moderately, and well-differentiated adenocarcinoma) and undifferentiated (poorly, undifferentiated, signet-ring cell carcinoma, and mucinous adenocarcinoma) based on the 14<sup>th</sup> JCGC.

In this study, specimens were fixed in a 10% neutral buffered formaldehyde solution and embedded in paraffin. They were then stained with hematoxylin and eosin and examined histologically. They were also examined immunohistochemically to determine the presence of the tumor-associated antigen AFP. Immunohistochemical analyses were performed using the streptavidin-biotin method. Sections were dewaxed in xylene, passed through ethanol, and incubated with 3% hydrogen peroxide in methanol for 4 min to block endogenous peroxidase activity. Sections were washed in phosphate-buffered saline (PBS) and 10% normal rabbit serum was applied for 20 min to reduce nonspecific antibody binding. AFP, a rabbit polyclonal antibody purchased from the DAKO Corporation, was diluted 1:100 and reacted with tissue specimens at room temperature for 2 h. Specimens were washed three times with PBS. Sections were incubated with biotinylated rabbit antimouse immunoglobulin G at a dilution of 1:100 for 30 min followed by three washes. Slides were reacted with a streptavidin-biotin peroxidase reagent for 30 min at a dilution of 1:100 and washed with PBS three times. Hepatocellular carcinoma cell tissues containing AFP were used as positive controls. The first antibody was replaced with a sodium phosphate buffer for negative controls. Consequently, the immunoreactivity of AFP was demonstrated in 23 primary lesions of GC patients.

The follow-up program schedule for all patients comprised a regular physical examination and laboratory blood tests including tumor markers such as CEA and CA19-9, chest X-rays every 3 mo in the first postoperative year, every 6 mo in the second post-operative year, and annually thereafter for at least 5 years. Computer tomography (CT) was performed annually in patients with pathological stage I - II tumors and every 6 mo in patients with more than pathological stage III tumors for the first 5 years. Otherwise, CT was performed within one month when elevations in tumor markers and/or symptoms were detected in follow-up laboratory blood tests and regular physical examinations. Endoscopy was performed in all patients annually to screen for cancer in the gastric remnant.

### Statistical analysis

The  $\chi^2$  test and Fisher's exact probability test were performed to compare clinicopathological characteristics between each group. Cause-specific death was recorded when the cause of death was specified as recurrent gastric cancer. Post-recurrence survival from recurrence to death, and overall survival from curative gastrectomy to death were estimated using the Kaplan-Meier method, and the log-rank test was used to assess differences be-

tween clinical factors. A *P*-value less than 0.05 was considered significant.

## RESULTS

### Clinicopathological characteristics of patients with primary AFP-producing GC in GC

The mean patient age was 64.5 (range 27-94) years, and

**Figure 1** Survival curves between  $\alpha$ -fetoprotein-producing gastric cancer and  $\alpha$ -fetoprotein non producing gastric cancer. The postoperative cause-specific 5-year survival rate of patients with  $\alpha$ -fetoprotein (AFP)-producing gastric cancer (GC) was significantly poorer than that of patients without AFP-producing GC (5-year survival rate: 50.3% and 76.5%, *P* = 0.002).

the male: female ratio was 2.1:1. Clinicopathological characteristics were compared between AFP-producing GC and AFP-non producing GC groups (Table 1). Patients with AFP-producing GC had a significantly higher incidence of venous invasion (*P* < 0.0001), lymphatic invasion (*P* = 0.0071), larger tumor size (*P* = 0.0073), lymph node metastasis (*P* = 0.0007), liver metastasis (*P* < 0.0001), and advanced stage (*P* = 0.0002) than those with AFP-non producing GC. The postoperative cause-specific 5-year survival rate of patients with AFP-producing GC was significantly poorer than that of patients without AFP-producing GC (5-year survival rate: 50.3% and 76.5%, *P* = 0.002) (Figure 1).

### Univariate and multivariate survival analyses in 1299 GC patients

Of all 1299 GC patients analyzed, univariate analysis showed that age, location, macroscopic type, tumor size, histological type, venous invasion, lymphatic invasion, pT categories, pN categories, the presence of AFP-producing GC, and liver metastasis were prognostic factors (Table 2). Furthermore, multivariate analysis using stepwise Cox regression procedures demonstrated that macroscopic type, tumor size, venous invasion, lymphatic invasion, pN categories, and liver metastasis were independent prognostic factors. However, the presence of AFP-producing GC was not an independent prognostic factor (Table 2).

### Comparison of recurrence patterns between patients with and without AFP-producing GC

To develop surveillance programs and treatment strategies, we compared recurrence patterns between patients with and without AFP-producing GC. Distant metastasis and recurrence developed in 47.8% of patients (11/23) with AFP-producing GC and 20.0% of patients (256/1276) without AFP-producing GC. Of these, liver metastasis [90.9% (10/11)] was the most prevalent in AFP-producing GC patients, while peritoneal recurrence

[44.1% (113/256)] was the most common in patients without AFP-producing GC (Table 3).

**Comparison of clinicopathological factors and prognosis between AFP-producing GC patients with and without liver metastasis**

We investigated prognostic factors affecting prognosis in AFP-producing GC. Univariate and multivariate analyses using stepwise Cox regression procedures revealed that the presence of liver metastasis was the only independent prognostic factor (HR = 17.6, 95%CI: 2.1-147.1; P = 0.0081) (Table 4). However, no significantly different prognostic factor was observed between patients with or without liver metastasis in AFP-producing GC (Table 5).

**Comparison of survival curves between patients with and without AFP-producing GC according to the presence or absence of liver metastasis**

To confirm that the presence of AFP-producing GC was not an independent prognostic factor in GC, we performed subgroup analysis according to the presence or absence of liver metastasis between patients with and without AFP-producing GC. The results obtained showed that the prognosis of AFP-producing GC was similar to that of AFP-non producing GC according to the presence (Figure 2A, P = 0.3778) or absence (Figure 2B, P = 0.5024) of liver metastasis.

**Table 3** Comparison of recurrence patterns between patients with and without α-fetoprotein -producing gastric cancer n (%)

Site	GC patients with recurrence	
	AFP-producing GC (n = 11)	AFP-non producing GC (n = 256)
Peritoneum	1 (9.1)	113 (44.1)
Liver	10 (90.9)	44 (17.2)
Lung	1 (9.1)	3 (1.2)
Bone	0 (0.0)	13 (5.1)
Lymph nodes	0 (0.0)	48 (18.8)
Others	0 (0.0)	46 (18.0)

The incidence of recurrence was 47.8% in the α-fetoprotein (AFP)-producing group and 20.0% in the AFP-non producing group. The most likely recurrence pattern was liver metastasis and peritoneal metastasis in the AFP-producing group and AFP-non producing group, respectively. GC: Gastric cancer.

**DISCUSSION**

AFP-producing GC has been shown to exhibit more aggressive behavior and a poorer prognosis than common GC because of its high incidence of liver metastasis. Liu and his colleagues reported that the 1-, 3- and 5-year survival rates of AFP-producing gastric cancer were 53%, 35%, and 28%, respectively<sup>[10]</sup>. Chang and his colleagues examined 24 patients with AFP-producing gastric cancer and showed that the prognosis was poor due to the high incidence of synchronous and metachronous liver metastasis<sup>[8]</sup>. In Japan, one study reported that the 5-year

Significantly different values are highlighted using boldface type. <sup>1</sup>*P* values are from  $\chi^2$  or Fisher's exact test and were significant at < 0.05. No significantly different prognostic factor was observed between patients with or without liver metastasis in  $\alpha$ -fetoprotein-producing gastric cancer. TNM: Tumor, nodes, metastasis.

survival rate of AFP-producing GC was 28.4%<sup>[7]</sup>. However, most of these studies have been restricted to overall prognosis in AFP-producing GC. To date, few subgroup analyses have been performed with special reference to liver metastasis and its related prognosis in AFP-producing GC.

In this study, we clearly demonstrated that the clinical behaviors of patients with and without AFP-producing GC were different (Table 1), and also that prognoses between patients with and without AFP-producing GC regarding the presence or absence of liver metastasis

**Figure 2** Survival curves between patients with and without  $\alpha$ -fetoprotein-producing gastric cancer according to the presence (A) or absence (B) of liver metastasis. The prognosis of  $\alpha$ -fetoprotein (AFP)-producing gastric cancer (GC) was similar to that of AFP-non producing GC according to the presence (A, *P* = 0.3778) or absence (B, *P* = 0.5024) of liver metastasis.

were similar in subgroup analyses (Figure 2). At first, we hypothesized that the presence of AFP-producing GC was an independent prognostic factor in GC because the prognosis of AFP-producing GC is known to be poorer than that of common GC. Indeed, the 5-year survival rate of patients with AFP-producing GC was significantly poorer than that of patients without AFP-producing GC. Patients with AFP-producing GC also had a significantly higher incidence of lymph-venous invasion, larger tumor size, lymph node metastasis, liver metastasis, and advanced stage. However, multivariate analysis using step-wise Cox regression procedures demonstrated that the presence of AFP-producing GC was not an independent prognostic factor. These findings suggested that AFP-producing GC is not different from common gastric cancer. AFP-producing GC without liver metastasis does not necessarily have a poor prognosis.

The reason why the prognosis of AFP-producing GC is still poor is that there are currently no standard or recommended treatments for liver metastasis of GC. Even in recent prospective randomized control trials, such as JCOG9912, SPIRITS, TOGA, and START studies using S-1 based regimens, a survival benefit was found particularly in non-measurable tumor recurrences such as peritoneal recurrence<sup>[19-22]</sup>. Therefore, it is important to note that the poorer prognosis of AFP-producing GC

is not related to difficulties in treating it, but from the lack of effective and recommended treatments for liver metastasis of common GC. If a treatment strategy for liver metastasis of GC was established similar to that for colorectal cancer, the prognosis of AFP-producing GC may be markedly improved because of its distinct metastatic pattern.

Concerning patterns of recurrences, distant metastasis and recurrence developed in 47.8% of patients (11/23) with AFP-producing GC and 20.0% of patients (256/1276) without AFP-producing GC. In AFP-producing GC patients, 90.9% of patients (10/11) developed liver metastasis, while peritoneal recurrence occurred in only 9.1% (1/11). In contrast, peritoneal recurrence [44.1% (113/256)] was the most prevalent in patients without AFP-producing GC, with liver metastasis accounting for 17.2% (44/256) (Table 3). Regarding the prognoses of 23 patients with AFP-producing GC, 5-year survival rates between patients with and without liver metastasis were 0% and 90.0%, respectively (data not shown). Moreover, univariate and multivariate analyses in AFP-producing GC revealed that liver metastasis was the only independent prognostic factor (Table 4).

Our results show that liver metastasis should be specifically targeted in an effort to improve the prognosis of AFP-producing GC. However, our study included a small number of patients with AFP-producing GC. Therefore, a larger sample size is needed to confirm these clinical features of AFP-producing gastric cancer.

In the present study, we demonstrated that liver metastasis was the only independent prognostic factor in AFP-producing GC. The absence of standard or recommended treatments for liver metastasis of GC also means that there is no effective treatment strategy for AFP-producing GC. Considering other rarely developing recurrences excluding liver metastasis in AFP-producing GC, the use of hepatic infusion chemotherapy or systemic chemotherapy following resection of hepatic metastasis may be a more efficient treatment than that for liver metastasis of common GC<sup>[23-25]</sup>. In conclusion, clinical behaviors between patients with and without AFP-producing GC were different. However, prognoses were similar according to the presence or absence of liver metastasis. Liver metastasis should be specifically targeted in an effort to improve the prognosis of AFP-producing GC.

## COMMENTS

### Background

$\alpha$ -fetoprotein (AFP)-producing gastric cancer (GC) is generally known to exhibit more aggressive behavior and a poorer prognosis than common GC because of its high incidence of liver metastasis. However, little is known about the clinical behavior of AFP-producing GC with regard to the presence or absence of liver metastasis.

### Research frontiers

The authors re-evaluated the clinicopathological characteristics and clinical outcomes of patients with AFP-producing GC. The results obtained clearly demonstrated that clinical behaviors were different between patients with and without AFP-producing GC. Concerning recurrence, while the incidence of peritoneal recurrence was the highest in AFP-producing GC, liver metastasis was the

most prevalent in AFP-non producing GC. Moreover, the prognosis according to the presence or absence of liver metastasis was similar between patients with and without AFP-producing GC.

### Innovations and breakthroughs

Multivariate analysis revealed that AFP-positivity was not an independent prognostic factor and also that liver metastasis was the only independent prognostic factor in AFP-producing GC. It is important to note that the overall poorer prognosis of AFP-producing GC is not related to difficulties in treating it, but from the lack of effective and recommended treatments for liver metastasis of common GC.

### Applications

The prognosis according to the presence or absence of liver metastasis was similar between patients with and without AFP-producing GC. The results show that liver metastasis should be specifically targeted in an effort to improve the prognosis of AFP-producing GC.

### Terminology

AFP was initially found in the human fetus and is normally produced in the fetal liver and yolk sac. AFP is considered to be a useful tumor marker in screening or monitoring patients with hepatocellular carcinomas or yolk sac tumors. Some studies showed that AFP could be produced in other cancers including primary GC. Liver metastasis refers to cancerous tumors that have spread to the liver from somewhere else in the body. The risk of cancer spreading to the liver depends on the site of the original cancer. Liver metastasis may be present when the original (primary) cancer is diagnosed, or it may occur months or years after the primary tumor is removed.

### Peer review

This is an interesting manuscript from a group that has done excellent work on gastric cancer. The authors evaluated the effect of AFP-producing gastric carcinoma on survival. Their conclusion that AFP production was not an independent predictor of poor survival is in contradistinction to other reports.

### Abstract

**AIM:** To evaluate the clinical outcomes of radiation therapy (RT) for early-stage gastric mucosa-associated lymphoid tissue lymphoma (MALToma).

**METHODS:** The records of 64 patients treated between 1998 and 2011 were analyzed retrospectively. For *Helicobacter pylori* (*H. pylori*)-positive patients ( $n = 31$ ), chemotherapy or *H. pylori* eradication therapy was the initial treatment. In patients with failure after *H. pylori* eradication, RT was performed. For *H. pylori*-negative patients ( $n = 33$ ), chemotherapy or RT was the first-line treatment. The median RT dose was 36 Gy. The target volume included the entire stomach and

the perigastric lymph node area.

**RESULTS:** All of the patients completed RT without interruption and showed complete remission on endoscopic biopsy after treatment. Over a median follow-up period of 39 mo, the 5-year local control rate was 89%. Salvage therapy was successful in all relapsed patients. Secondary malignancies developed in three patients. The 5-year overall survival rate was 94%. No patient presented symptoms of moderate-to-severe treatment-related toxicities during or after RT.

**CONCLUSION:** Radiotherapy results in favorable clinical outcomes in patients with early-stage gastric MALToma who experience failure of *H. pylori* eradication therapy and those who are *H. pylori* negative.

© 2013 Baishideng. All rights reserved.

**Key words:** Gastric mucosa-associated lymphoid tissue lymphoma; Radiation therapy; Treatment response

**Core tip:** Radiation therapy is an effective salvage treatment for patients with gastric mucosa-associated lymphoid tissue lymphoma (MALToma) who experience failure of *Helicobacter pylori* (*H. pylori*) eradication therapy. For patients with *H. pylori*-negative gastric MALToma, radiation therapy is recommended as the initial treatment. The risk of treatment-related toxicities and secondary malignancies is acceptable.

Clinical outcomes of radiation therapy for early-stage gastric mucosa-associated lymphoid tissue lymphoma. *World J Gastroenterol* 2013; 19(36): 6062-6068 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/6062.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.6062>

## INTRODUCTION

Mucosa-associated lymphoid tissue lymphoma (MALToma) was first described by Isaacson in 1983<sup>[1]</sup>. The World Health Organization (WHO) and the Revised European American Lymphoma Classification (REAL) later categorized it as an independent entity<sup>[2,3]</sup>.

The stomach is the most common extranodal site of MALToma (50%-70% of all cases), and *Helicobacter pylori* (*H. pylori*) infection is the most important risk factor<sup>[4]</sup>. In numerous studies, *H. pylori* eradication therapy had excellent outcomes for gastric MALToma with a reported complete remission (CR) rate of 70%-80%<sup>[4-6]</sup>. As a result, *H. pylori* eradication therapy is now employed as the sole first-line treatment<sup>[7]</sup>. For *H. pylori*-negative patients, radiation therapy (RT) has recently been accepted as a preferred treatment modality. The role of surgery has declined gradually because of the high incidence of post-operative morbidity and mortality<sup>[8]</sup>.

MALToma is characteristically a localized disease<sup>[9-11]</sup>, and it is very sensitive to radiation. Accordingly, MALToma at extranodal sites, such as the orbital adnexa and the parotid and thyroid glands, has been treated with a moderate dose (25-40 Gy) of RT as an initial treatment<sup>[12-17]</sup>. Retrospective studies have largely confirmed the effectiveness of RT for gastric MALToma<sup>[18-27]</sup>. However, the low case numbers of previous studies render the evidence of the effectiveness of RT insufficient.

In this study, we investigated the clinical outcomes and associated adverse effects of RT in patients with early-stage gastric MALToma who were unresponsive to *H. pylori* eradication therapy and in *H. pylori*-negative patients.

## MATERIALS AND METHODS

Between November 1998 and March 2011, 71 patients who were diagnosed with localized gastric MALToma received RT at Samsung Medical Center. Among them, 7 patients were excluded from this study; 5 patients were excluded because they also had small foci of diffuse large B-cell lymphoma. Two patients were immediately lost to follow up after the completion of RT. We retrospectively analyzed the remaining 64 patients. These patients had stage I or II<sub>1</sub> MALToma according to the Lugano staging system<sup>[28]</sup>. All of the patients were histologically diagnosed with gastric MALToma by endoscopic biopsy. Subsequently, patients underwent a systemic staging work-up, including laboratory tests, such as blood cell counts, biochemical profile and lactate dehydrogenase, computed tomography (CT), positron-emission tomography (PET) or bone marrow biopsy.

### Treatment before RT

Of the 64 patients, 40 patients received treatment related to gastric MALToma before RT. *H. pylori* eradication therapy consisting of a 1-2 wk course of amoxicillin (1000 mg twice daily), clarithromycin (500 mg twice daily) and

a proton pump inhibitor (omeprazole or esomeprazole) followed by maintenance of the proton pump inhibitor was performed in 31 patients. Among the patients treated with *H. pylori* eradication therapy, 3 had no evidence of *H. pylori* infection.

Chemotherapy consisting of either a combination of cyclophosphamide, doxorubicin, vincristine and prednisolone (CHOP) every 3 wk or cyclophosphamide, vincristine and prednisolone (CVP) every 3 wk was performed in 15 patients until 2002. Among them, 6 patients received both *H. pylori* eradication therapy and chemotherapy (Figure 1).

Twenty-four patients without *H. pylori* infection did not receive any treatment before RT.

### Radiation therapy

All patients underwent simulation using fluoroscopy or a CT simulator. Before simulation, the patients were trained to breathe in a regular and shallow cycle to maintain a constant stomach motion.

The clinical target volume (CTV) was the entire stomach plus the perigastric lymph nodes for stage I gastric MALToma. The CTV for stage II<sub>1</sub> patients was determined as the CTV for stage I gastric MALToma plus a generous margin extending from the involved lymph nodes. To cover the perigastric lymph nodes, we included a 2-cm margin from the outline of stomach wall, which was observed on fluoroscopy after the ingestion of a barium suspension. The planned target volume (PTV) was individualized, considering setup error and stomach movement. CT planning was conducted for 39 patients following the introduction of the CT simulator. The entire stomach was defined at every respiratory stage in 4-dimensional CT slices. After the internal target volume (ITV) was defined, the CTV was set as the ITV plus a 1-cm margin to cover the perigastric lymph nodes. The PTV was the CTV plus 1 cm, and the planning geometry consisted of 2 to 4 coplanar or non-coplanar beams using high-photon energy (10-15 MV).

The daily fraction size was either 1.8 Gy or 2.0 Gy. The total radiation dose ranged from 30 Gy to 44 Gy, with a median of 36 Gy.

### Treatment response

We assessed the treatment response histologically using endoscopic biopsy after the completion of RT. The first post-RT endoscopic examination was typically performed 1-2 mo after RT. The next endoscopic biopsies were performed every 3 to 6 mo in the first two or three years and annually thereafter. CT findings were not considered to evaluate the treatment response. The response criteria were based on the GELA (Groupe d'Etude des Lymphomes de l'Adulte) histologic grading system<sup>[29]</sup>.

### Statistical analysis

The end points were overall survival (OS) and local control (LC). Time was calculated from the initiation of RT to the event of interest. LC was defined as the time in-

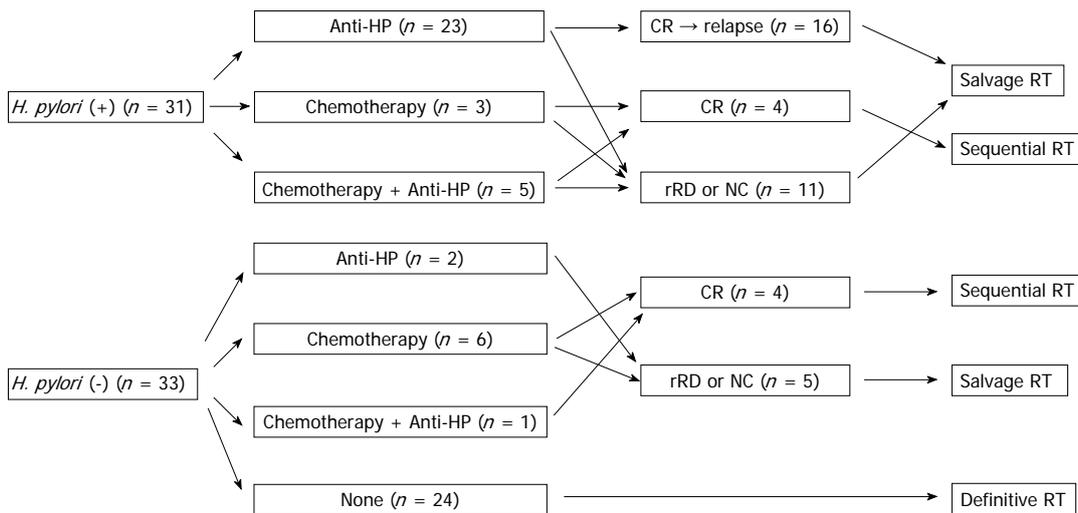

Figure 1 Initial treatment before radiation therapy. *H. pylori*: *Helicobacter pylori*; Anti-HP: anti-*Helicobacter pylori* therapy; CR: Complete remission; rRD: Residual responding disease; NC: No change; RT: Radiation therapy.

terval to relapse, which was confirmed by biopsy. OS was defined as the period from diagnosis to the date of last

follow up or death. We calculated the LC and OS rates using the Kaplan-Meier method. All analyses were performed using IBM SPSS Statics version 19.0 (SPSS Inc., Chicago, IL).

## RESULTS

### Patient characteristics

Patient characteristics are summarized in Table 1. The median age was 49 years, and 53 patients (83%) were stage I. The gastric body was the site most commonly involved, and *H. pylori* infection was detected in 31 patients (48%). As an initial therapy, 31 patients (48%) received *H. pylori* eradication therapy, and 24 patients (38%) received RT.

Seventeen of 40 patients (43%) achieved CR with prior treatment before RT. Nine patients who achieved CR with *H. pylori* eradication therapy relapsed after a median disease-free interval of 19 mo (range: 9 to 56 mo). CR after chemotherapy was achieved in 5 of 9 patients. The combination of *H. pylori* eradication therapy and chemotherapy was successful in 3 patients. Those who achieved CR after chemotherapy received RT as sequential therapy. The remaining 23 patients had persistent disease at the time of referral for salvage RT (Figure 1).

The median interval between the initiation of first treatment and the initiation of RT was 8 mo (range, 1 to 40 mo).

### RT response

All patients showed a histological CR at the post-treatment endoscopic biopsy. Three patients had not achieved CR at the first post-treatment endoscopic biopsy, but they had achieved a histological CR at a subsequent evaluation 4 to 5 mo after RT without any further treatment.

### Survival

Over a median follow-up period of 39 mo (range, 9-131

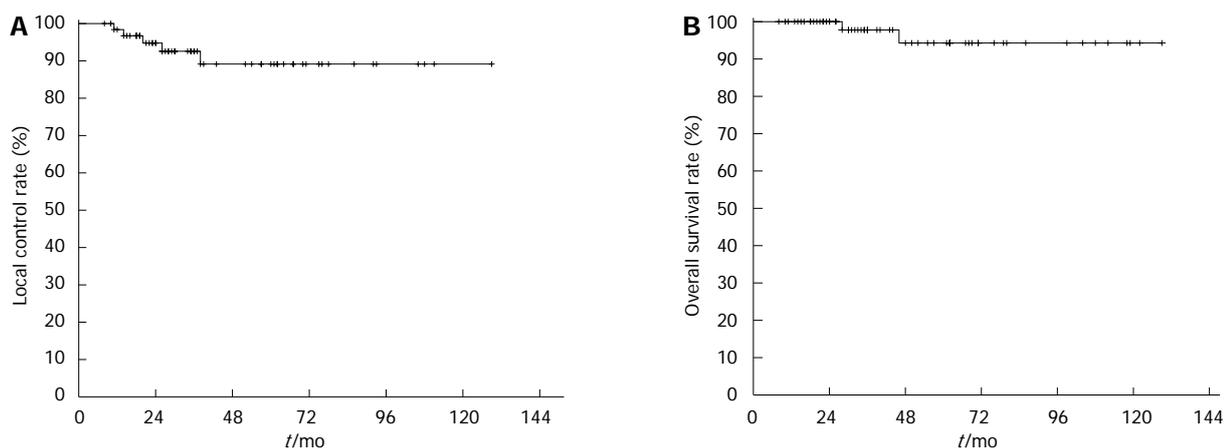

Figure 2 Local control rate (A) and overall survival rate (B) for all patients.

mo), MALToMa relapsed in 5 patients (Table 2), and the 5-year LC of all patients was 89% (Figure 2A). Two patients (cases 4 and 5 in Table 2) received *H. pylori* eradication therapy due to positive conversion of *H. pylori* at relapse and finally gained secondary CR. The other three patients (cases 1, 2 and 3) who were not *H. pylori* infected at relapse did not receive any treatment, and MALToMa was not detected on subsequent endoscopy.

At the study end point, 62 patients remained alive. One patient died due to relapse following the development of malignant lymphoma involving the mesenteric lymph nodes and bone marrow at 29 mo after RT. Another patient died of intercurrent disease 47 mo after RT. The 5-year overall survival rate was 94% (Figure 2B).

#### Treatment-related toxicities and secondary malignancies

All patients completed RT without interruptions due to treatment-related toxicities. Some patients experienced mild nausea and epigastric soreness, but these symptoms were managed with anti-emetics or antacids. None of the patients complained of gastrointestinal bleeding or perforations. Neither renal nor hepatic toxicities developed.

One patient with *H. pylori* infection was diagnosed with metachronous gastric cancer 21 mo after RT. He underwent subtotal gastrectomy with Billroth type I reconstruction. On pathologic examination, tubular adenocarcinoma was confined to the mucosa, and metastasis to the regional lymph nodes was not found.

Transformation into malignant lymphoma occurred in two patients at intervals of 26 and 31 mo following

the initiation of RT. The sites involved were the mesenteric lymph node and the supraclavicular lymph node, respectively. These patients received 6 cycles of salvage chemotherapy with the CHOP regimen. One patient died of rapid disease progression 6 mo later. The other patient survived in a cured state.

## DISCUSSION

Currently, *H. pylori* eradication therapy is the only established treatment for low-grade gastric MALToMa in *H. pylori*-positive patients<sup>[7]</sup>. The treatment modality that should be selected for patients who do not respond to *H. pylori* eradication therapy is currently controversial. Recently, many small retrospective studies and a pooled-data analysis<sup>[19,21,22,26,30]</sup> have demonstrated that RT has excellent clinical outcomes and feasibility. As a result, RT has become a preferred non-invasive local treatment modality. The results of our present study also support the effectiveness of RT for these patients.

The application of salvage RT in this setting depends to a high degree on defining the time at which *H. pylori* eradication failed. Most studies with salvage RT for gastric MALToMa have not defined the time to *H. pylori* eradication therapy failure. Our institution also did not have consensus regarding the failure of *H. pylori* eradication therapy. The range of the interval between the initiation of prior treatment and the timing of RT initiation was variable and not homogeneous. Previous studies have demonstrated that 80%-90% of patients may achieve a

histological CR within one year after *H. pylori* eradication therapy<sup>[6,20]</sup>. The European Society of Medical Oncology has proposed that at least 12 mo be allowed before initiating another treatment in patients who achieve clinical and endoscopic remission in addition to *H. pylori* eradication, albeit with persistent lymphoma at the histological level<sup>[7]</sup>.

In addition, reference data for the evaluation of RT response are lacking. In this study, 3 patients did not show CR at the first post-treatment endoscopy, which was performed 1 to 2 mo after RT, but they had achieved CR at the next endoscopy, which was performed 4 to 5 mo later. We therefore suggest that a minimum follow-up period of 6 mo is needed to evaluate the effects of RT.

For *H. pylori*-negative patients, *H. pylori* eradication therapy can be attempted as an initial treatment because of the possibility of a false-negative test or low bacteria counts. However, the response rate has been reported to vary (0%-83%)<sup>[21,27,31]</sup>. In contrast, several small retrospective studies reported a response rate of 100% for RT as the initial treatment for *H. pylori*-negative patients with MALToma<sup>[18,21,25,27]</sup>. In these previous studies, CR was confirmed in all patients at the post-treatment endoscopic biopsy after RT. In the absence of randomized trial data due to the rarity of disease, we cannot directly compare *H. pylori* eradication therapy with RT as an initial treatment for *H. pylori*-negative patients. However, a survey of the literature suggests that RT shows superior performance compared to *H. pylori* eradication therapy in the initial treatment of *H. pylori*-negative patients. Recent evidence indicates that the t(11;18)(q21;q21) translocation in gastric MALToma predicts resistance to *H. pylori* eradication therapy<sup>[32]</sup>. This same translocation has been detected in nearly half of patients with *H. pylori*-negative gastric MALToma<sup>[33]</sup>. Therefore, in these subgroups, RT may be an appropriate treatment. As additional data become available, routine testing for the t(11;18)(q21;q21) translocation at the time of MALToma diagnosis may become a useful guide for selecting the initial treatment.

The 5-year LC rate in this study was 89%, which is comparable to those reported by previous studies<sup>[13,17,18]</sup>. Until 6 mo after the completion of RT, all patients showed histological CR on follow-up endoscopic biopsy. However, 5 patients developed relapse at disease-free intervals of 11 to 38 mo. Three patients achieved histological CR on the subsequent evaluation without any further treatment, which could be due to false-positive results at the initial examinations. The other two patients, who were initially *H. pylori* negative, developed recurrence coincident with *H. pylori* infection, and they were successfully treated with *H. pylori* eradication therapy as a salvage treatment. This example may indicate an important role for *H. pylori* infection in the mechanism of the local recurrence of gastric MALToma.

The major concern regarding stomach irradiation is the risk of perforation and bleeding. A collective review places this risk at 4% or less<sup>[34]</sup>. Additionally, the risk may be much lower in early-stage and low-grade disease, given

the lower radiation doses and target volumes. Another concern is renal toxicity. In the past, the irradiated target volume was the entire abdomen followed by an additional dose to the entire stomach and the perigastric lymph nodes<sup>[24]</sup>. With increasing knowledge of the spread pattern of low-grade gastric MALToma, the target volume has been reduced to the stomach plus the regional lymphatics<sup>[11]</sup>. Local RT with the use of three-dimensional conformal or intensity-modulated techniques has the particular advantage of reducing the radiation dose to the kidneys, particularly on the left side<sup>[19,35]</sup>. Our study, in agreement with numerous other studies, demonstrated no gastric perforation or bleeding and no renal toxicity attributable to RT.

Whether secondary malignancies such as gastric cancer develop years after irradiation is still controversial. Reports of secondary malignancies within the RT field in the treatment of gastric MALToma appear to be rare<sup>[13,21,23]</sup>. In this study, secondary gastric cancer occurred in one case. For secondary gastric cancer, gastric MALToma itself could be an additional risk factor because of the common pathogenesis, *i.e.*, *H. pylori* infection, irrespective of the treatment modality<sup>[34,36-38]</sup>. However, the effects of irradiation cannot be neglected. Because the latent period from irradiation to the development of secondary malignancies can reach a few decades and nearly all patients with gastric MALToma are expected to be long-term survivors in a cured state, close, long-term follow up is required to observe the development of radiation-induced secondary cancer.

Malignant transformation in MALToma is uncommon. The transformation rates reported in some studies ranged from 3% to 19% and did not apparently depend on the site involved<sup>[10,14,17]</sup>. In the present study, transformation developed in 2 patients (3.1%) with a disease-free interval of 26 to 31 mo, which is consistent with other published reports (ranging from 6 to 116 mo)<sup>[14,17]</sup>. Following malignant transformation, the mortality rate is higher than that for MALT lymphoma.

In conclusion, the results of the present study further support the use of RT for patients with MALToma who experience failure of *H. pylori* eradication therapy and for *H. pylori*-negative patients. The rationale of treating such patients with RT can be summarized as follows. First, gastric MALToma tends to be a localized disease. Second, MALToma is a radio-sensitive tumor. Third, RT has the advantage of stomach preservation. Lastly, RT has low treatment-related morbidity. Although local relapse developed in some cases, all cases were salvaged successfully. Ongoing risks for secondary malignancy or malignant transformation warrant regular long-term follow-up with systemic evaluation and testing for *H. pylori* infection.

## COMMENTS

### Background

Gastric mucosa-associated lymphoid tissue lymphoma (MALToma) is highly associated with *Helicobacter pylori* (*H. pylori*) infection. Therefore, *H. pylori* eradication therapy is the standard treatment. However, in clinical practice,

persistent disease or recurrence after *H. pylori* eradication therapy are often found. Additionally, a substantial number of gastric MALToma patients are not *H. pylori* positive. Radiation therapy (RT) has been shown to have good clinical outcomes and feasibility for the treatment of gastric MALToma in these patients in many small retrospective studies.

### Research frontiers

Some reports from single institutions have shown that RT is effective for patients with gastric MALToma that is resistant to *H. pylori* eradication therapy or that recurs following an initial clinical response. Additionally, in other small reports, patients with *H. pylori*-negative gastric MALToma and low response rates to *H. pylori* eradication therapy were treated successfully with RT.

### Innovations and breakthroughs

This study is one of the largest single-institution experiences to report the clinical outcomes of gastric MALToma treated with RT. RT has an excellent role as either a salvage or definitive treatment for gastric MALToma. In particular, for *H. pylori*-negative gastric MALToma patients, in whom the t(11;18)(q21;q21) translocation is frequently found, RT should be applied as the initial treatment because this translocation tends to be resistant to *H. pylori* eradication therapy. With aid of the three-dimensional conformal technique, fatal toxicities related to radiation can be minimized.

### Applications

RT is the preferred salvage treatment modality for *H. pylori* infection-associated gastric MALToma patients who are unresponsive to *H. pylori* eradication therapy. Additionally, it can be an effective initial treatment for gastric MALToma patients without *H. pylori* infection.

### Terminology

MALToma is a B cell-originating cancer in the marginal zone of the MALT, which is the diffuse system of small areas of lymphoid tissue found in various sites of the body.

### Peer review

This paper is well written. It is acceptable for publication.

### Abstract

**AIM:** To investigate the effects of diammonium glycyrrhizinate (Gly) on portal hypertension (PHT) in isolated portal perfused rat liver (IPPL) with carbon tetrachloride (CCl<sub>4</sub>)-induced chronic hepatitis.

**METHODS:** PHT model was replicated with CCl<sub>4</sub> in rats for 84 d. Model was identified by measuring the ascetic amounts, hepatic function, portal pressure *in vivo*, splenic index, and pathological alterations. Inducible nitric oxide synthase (iNOS) in liver was assessed by immunohistochemistry. IPPLs were performed at d<sub>0</sub>, d<sub>28</sub>, d<sub>56</sub>, and d<sub>84</sub>. After phenylephrine-induced constriction, Gly was geometrically used to reduce PHT.

Gly action was expressed as median effective concentration (EC<sub>50</sub>) and area under the curve (AUC). Underlying mechanism was exploited by linear correlation between AUC values of Gly and existed iNOS in portal triads.

**RESULTS:** PHT model was confirmed with ascites, splenomegaly, serum biomarkers of hepatic injury, and elevated portal pressure. Pathological findings had shown normal hepatic structure at d<sub>0</sub>, degenerations at d<sub>28</sub>, fibrosis at d<sub>56</sub>, cirrhosis at d<sub>84</sub> in PHT rats. Pseudo lobule ratios decreased and collagen ratios increased progressively along with PHT development. Gly does dose-dependently reduce PHT in IPPLs with CCl<sub>4</sub>-induced chronic hepatitis. Gly potencies were increased gradually along with PHT development, characterized with its EC<sub>50</sub> at  $2.80 \times 10^{-10}$ ,  $3.03 \times 10^{-11}$ ,  $3.77 \times 10^{-11}$  and  $4.65 \times 10^{-11}$  mol/L at d<sub>0</sub>, d<sub>28</sub>, d<sub>56</sub> and d<sub>84</sub>, respectively. Existed iNOS was located at hepatocyte at d<sub>0</sub>, stellate cells at d<sub>28</sub>, stellate cells and macrophages at d<sub>56</sub>, and macrophages in portal triads at d<sub>84</sub>. Macrophages infiltrated more into portal triads and expressed more iNOS along with PHT development. AUC values of Gly were positively correlated with existed iNOS levels in portal triads.

**CONCLUSION:** Gly reduces indirectly PHT in IPPL with CCl<sub>4</sub>-induced chronic hepatitis. The underlying mechanisms may relate to rescue NO bioavailability from macrophage-derived peroxynitrite in portal triads.

## INTRODUCTION

Portal hypertension (PHT) is a fetal complication in patients with advanced chronic hepatitis<sup>[1]</sup>. Some changes are reversible in PHT pathogenesis, such as an increase of hepatic vascular resistance and an elevation of portal hyperemia<sup>[2]</sup>. Therefore, it is possible to develop drugs for PHT therapy.

Insufficient intrahepatic nitric oxide (NO) bioavailability is involved in PHT development<sup>[3]</sup>. Macrophages in portal triads generate peroxynitrite *via* inducible nitric oxide synthase (iNOS)<sup>[4]</sup> and superoxide *via* NADPH oxidases<sup>[5]</sup>. Under chronic hepatitis, macrophages infiltrated more into portal triads and expressed more iNOS<sup>[6,7]</sup>. Peroxynitrite was derived from NO and superoxide, to reduce NO bioavailability<sup>[3,4]</sup>. The decreased NO availability leads to an increase in intrahepatic portal resistance, resulting in PHT<sup>[3,4]</sup>.

Diammonium glycyrrhizinate (Gly), a molecule derived from a medical plant of *Radix glycyrrhizae*, is effective in treatment of PHT patients<sup>[8]</sup> and animals<sup>[9,10]</sup>, but the underlying mechanisms are still unclear<sup>[9-11]</sup>. In our previous studies, we demonstrated that Gly lower PHT in isolated portal perfused rat livers (IPPRLs) at physiological status<sup>[12]</sup>.

Suitable perfuse velocities were designated as anatomic preloads in IPPRLs with CCl<sub>4</sub>-induced chronic hepatitis at four stages<sup>[13]</sup>. A pharmacodynamic model of PHT had been developed in IPPRLs with chronic hepatitis, as median effective concentration (EC<sub>50</sub>) values of phenylephrine and acetylcholine<sup>[14]</sup>. This model makes it possible to evaluate candidates for PHT therapy. Furthermore, several studies have shown that Gly enhances NO generation from inflammatory macrophages<sup>[15,16]</sup>, limits superoxide release and increases NO bioavailability<sup>[16]</sup>.

In this study, we investigated the effects of Gly on PHT in the IPPRLs with CCl<sub>4</sub>-induced chronic hepatitis, and on NO bioavailability from the macrophages in portal triads.

## MATERIALS AND METHODS

### Animals and materials

Male Wistar rats (200 ± 13 g) were obtained from Animal Centre of Chinese Academy of Medical Sciences. Rats were maintained in a Special Pathogen Free laboratory, with a 25.0 ± 0.2 °C, a 12-h/12-h light/dark photoperiod and 45% ± 2% humidity. All rats were fed standard rodent pellets and allowed free access to filtered water. All experiment procedures were performed in accordance with the Guidelines of Animal Experiments from the Committee of Medical Ethics, National Health Department of China.

Carbon tetrachloride (CCl<sub>4</sub>, CAS 56-23-5), olive oil (CAS 8001-25-0) and heparin sodium (MW 12000, CAS 9041-08-1) were obtained from Sinopharm Chemical Reagent Company; Acetylcholine chloride (CAS 60-31-1) and phenylephrine hydrochloride (CAS 61-76-7) were from Sigma (United States); Diammonium Gly (CAS 79165-06-3) were from Shanghai Institute of Materia Medica, Chinese Academy of Sciences.

### Portal hypertensive model

As described previously<sup>[13,14,17]</sup>, PHT model was replicated by subcutaneous injection with 3 mL/kg mixture of 40% (v/v) CCl<sub>4</sub> in olive oil, twice weekly for 0, 4, 8 and 12 wk; age-matched animals did with olive oil along as vehicle control (Figure 1). Forty-eight hours after last injection, rat was weighted (W<sub>b</sub>) and anesthetized with pentobarbital sodium (50 mg/kg) subcutaneously, a midline incision was made to open abdominal cavity, soak up ascitic samples, expose liver vessels, measure portal pressure, collect blood sample, and canalize hepatic artery, portal vein, hepatic vein. The remained blood in the isolated livers was eliminated with perfusate containing 20.0 µg/mL of heparin sodium through hepatic artery.

### Isolated perfused liver system

As described previously<sup>[13,14,17]</sup>, the velocity in each IPPRL was finely controlled by a quantified roller pump. The perfuse pressure was continuously recorded with the Powerlab linked to a computer with a pressure transducer immediately ahead of the portal inlet cannula. The global viability of portal perfused livers was assessed with gross appearance, a stable perfusate pH (7.40 ± 0.10), a stable perfuse pressure, and active response to acetylcholine.

### Ascitic quantification

As described previously<sup>[13,14,17]</sup>, exudative liquid was soaked up by dried soft paper in a tube (W<sub>0</sub>). Before (W<sub>1</sub>) and after (W<sub>2</sub>) the wet paper with exudation was dried enough, the paper with tube was weighed exactly. Basing on the body weight (W<sub>b</sub>), exuded water (EWR) and dried mass ratios (EDMR) were calculated as  $EWR = (W_1 - W_2)/W_b \times 1000$  and  $EDMR = (W_2 - W_0)/W_b \times 1000$ , expressed as exudative weight (g) per kilogram body weight (g/kg).

### Hepatic function

Sera were separated by centrifugation at 300 g for 5 min and were stored at -80 °C. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), total protein (TP) and albumin (Alb) were determined by an autoanalyzer (Hitachi 7060; Hitachi, Japan) with commercial kits (Biosino Biotechnology and Science, China) according to the manufacturer's instructions.

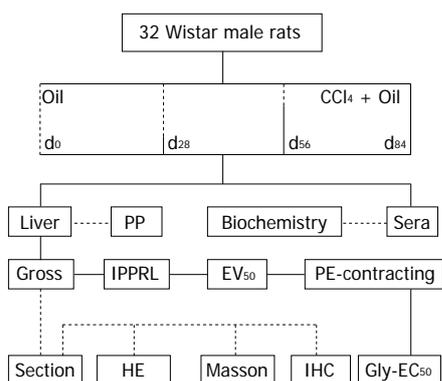

### Pathological changes

**Organ indexes:** Liver, spleen and kidneys were weighed (W<sub>i</sub>) and the organ indexes (OI) were calculated for each

**Table 1 Exudations and organ indexes (mean ± SE, n = 8)**

Groups	Exudations [g/(100g)]		Organ indexes [g/(100g)]		
	Water	Dried mass	Liver	Spleen	Kidneys
d <sub>00</sub>	0.223 ± 0.091	0.490 ± 0.260	2.801 ± 0.347	0.163 ± 0.040	0.731 ± 0.096
d <sub>28</sub>	0.372 ± 0.127 <sup>b</sup>	1.250 ± 0.210 <sup>b</sup>	5.936 ± 1.081 <sup>b</sup>	0.236 ± 0.037 <sup>b</sup>	0.854 ± 0.095 <sup>a</sup>
d <sub>56</sub>	0.791 ± 0.134 <sup>bd</sup>	1.540 ± 0.150 <sup>bd</sup>	4.472 ± 0.909 <sup>bd</sup>	0.292 ± 0.103 <sup>b</sup>	0.861 ± 0.117 <sup>a</sup>
d <sub>84</sub>	2.267 ± 0.732 <sup>bdf</sup>	3.590 ± 1.610 <sup>bdf</sup>	3.037 ± 0.349 <sup>df</sup>	0.409 ± 0.095 <sup>bde</sup>	1.071 ± 0.117 <sup>bdf</sup>

<sup>a</sup>P < 0.05, <sup>b</sup>P < 0.01 vs d<sub>00</sub>; <sup>d</sup>P < 0.01 vs d<sub>28</sub>; <sup>e</sup>P < 0.05, <sup>f</sup>P < 0.01 vs d<sub>56</sub>.

**Figure 1 Experimental design of glycyrrhizinate on portal hypertension.** Rat model of portal hypertension was replicated with CCl<sub>4</sub> in olive oil (full line), age-matched rats did with olive oil (dotted line). PP: Portal pressure in vivo; IPPRL: Isolated portal perfused rat liver; EV<sub>50</sub>: Median effective velocity; PE: Phenylephrine; HE: Haematoxylin-eosin stain; Masson: Masson's trichrome stain; IHC: Immunohistochemistry; Gly: Diammonium glycyrrhizinate; EC<sub>50</sub>: Median effective concentration of Gly relaxation.

rat (OI<sub>i</sub> = W<sub>i</sub>/W<sub>b</sub> × 100).

**Histological morphometry:** After perfusion as described previously<sup>[13,14]</sup>, a portion of left lobe from each liver was fixed in 10% buffered formaldehyde, embedded in paraffin, cut as 6 μm sections, and stained with haematoxylin-eosin (HE) and Masson's trichrome (Masson). Images were acquired with a Digital Pathology system (Hamamatsu, Japan). Ten fields from each liver were randomly selected, the percentage of lobules (ratio of lobule area per total analyzed field area × 100, under × 10, in HE) and one-ten thousandth of collagen (ratio of collagen area per total analyzed field area × 10000, under × 40, in Masson) were measured using Image Pro Plus analysis system 7.0.1 (No41N70000-60555, Media cybernetics, United States); the average of values from ten random fields generated a datum.

**Immunohistochemical morphometry:** Formalin-fixed, paraffin-embedded, 6 μm sections were used. Rat iNOS was stained with a rabbit polyclonal antibody (1:200, Santa Cruz Biotechnology) and an avidin-biotin peroxidase immunostaining kit with diaminobenzidine (Boster, Wuhan, China). One set of sections was counterstained with hematoxylin for observing cellular location; the other set did not for quantifying existed levels. Microscopic images under × 40 were acquired with Digital Pathology System.

Mean optical density (OD), positive staining area (A<sub>P</sub>) and total observed area (A<sub>T</sub>) were measured using Image Pro Plus Analysis System. Levels of existed iNOS were represented as diaminobenzidine-OD average per volume [OD × (A<sub>P</sub>/A<sub>T</sub>)<sup>3/2</sup>]; the average of values from ten random fields generated a datum.

**Pharmacodynamic actions**

As described previously<sup>[13,14]</sup>, pharmacodynamical model in IPPRLs with chronic hepatitis was modified delicately with structural and functional preloads at d<sub>0</sub>, d<sub>28</sub>, d<sub>56</sub> or d<sub>84</sub> in PHT development. Perfused velocity as structural preload was defined as 3935.50, 4720.63, 4753.35, or 5164.16 μL/min<sup>[13]</sup>; Concentration of phenylephrine as functional preloads was designated as 1.69 × 10<sup>-10</sup>, 2.64 × 10<sup>-10</sup>, 5.82 × 10<sup>-10</sup> or 8.24 × 10<sup>-10</sup> mol/L<sup>[14]</sup>.

Portal pressure in each IPPRL was initially maintained at defined velocity for 30 min<sup>[13]</sup>. Maintained pressure was near to portal pressure *in vivo*. Elevated pressure was stabilized for 10 min after phenylephrine-induced constriction at designated concentration<sup>[14]</sup>. Elevated pressure was considered as the baseline for analyzing Gly to relax hepatic portal venules. Cumulative geometric concentrations of Gly (10<sup>-12</sup>-10<sup>-6</sup> mol/L, k = 0.10) were finally used in recirculating perfusate to reduce elevated portal pressure. Gly concentration-response curve was regressed from the cumulative concentrations and the changed percentage of perfused pressure from the baseline of phenylephrine constriction.

**Statistical analysis**

Data are expressed as mean ± SD in each stage. Unpaired *t* test was used, P < 0.05 was considered significance. Equation, EC<sub>50</sub> with its 95%CI and area under the curve (AUC) of Gly were calculated by regression analysis using Graph-Pad Prism 4 (Graph-Pad Software) in non-linear fit and various slopes. EC<sub>50</sub> values of Gly were regressed linearly with the duration (0, 4, 8 and 12 wk) in chronic hepatitis; AUC values of Gly did with the levels of existed iNOS in portal triads.

**RESULTS**

**General feature**

**Ascites:** As one of PHT consequences, exuded watery and dried mass ratios increased progressively along with PHT development (P < 0.01, Table 1).

**Table 2** Changed levels of serum biomarkers (mean ± SE, n = 8)

Groups	ALT (IU/L)	AST (IU/L)	ALP (IU/L)	TP (g/L)	Alb (g/L)
d <sub>0</sub>	49.63 ± 14.03	124.13 ± 20.20	72.88 ± 14.58	63.63 ± 4.26	33.12 ± 1.97
d <sub>28</sub>	237.13 ± 107.91 <sup>b</sup>	503.25 ± 235.12 <sup>b</sup>	318.75 ± 147.81 <sup>b</sup>	56.84 ± 5.43 <sup>b</sup>	25.93 ± 3.16 <sup>b</sup>

<sup>b</sup>P < 0.01 vs d<sub>0</sub>; <sup>d</sup>P < 0.01 vs d<sub>28</sub>; <sup>f</sup>P < 0.01 vs d<sub>56</sub>. PP: Portal pressure; iNOS: Inducible nitric oxide synthase.

**Organ indexes:** Hepatic indexes were the lowest at d<sub>0</sub>, the highest at d<sub>28</sub>, higher at d<sub>56</sub> and lower at d<sub>84</sub>. Splenic or renal indexes increased gradually from d<sub>0</sub> to d<sub>84</sub> (P < 0.01, Table 1).

**Hepatic function:** ALT and AST activities in sera at d<sub>28</sub> increased from that at d<sub>0</sub>, then relieved at d<sub>56</sub> and d<sub>84</sub>. ALP activities at d<sub>28</sub> and d<sub>56</sub> increased from that at d<sub>0</sub>, then relieved at d<sub>84</sub>; TP and Alb levels at d<sub>28</sub> and d<sub>56</sub> decreased from that at d<sub>0</sub>, then relieved at d<sub>84</sub> (P < 0.05, Table 2).

**Portal hypertensive feature**

**PHT:** The portal pressures in vivo increased progressively from d<sub>0</sub> to d<sub>84</sub> in PHT development. Elevated portal pressures (> 20 mmHg) at d<sub>56</sub> and d<sub>84</sub> reached to the diagnostic criteria of clinic PHT (P < 0.01, Table 3).

**Pathologic changes:** At d<sub>0</sub>, histological observation showed normal hepatic structure; some droplet steatosis appeared in hepatocytes, collagen located only at portal triads (Figure 2A). At d<sub>28</sub>, hepatic steatosis and cellular swellings were observed pathologically; hepatic sinusoids were severely narrowed by enlarged hepatic cords (Figure 2B). At d<sub>56</sub>, hepatic fibrosis had been demonstrated with more deposited collagen, relieved enlarged hepatic cords, and widened hepatic sinusoids. Deposited collagen had extended into lobules from portal triads, separated lobules incompletely; therefore circulative directions had not changed in hepatic sinusoids (Figure 2C). At d<sub>84</sub>, hepatic cirrhosis had been demonstrated with deposited collagen separated through the lobules, pseudo lobules formed all over, circulative directions had completely deranged in hepatic sinusoids (Figure 2D).

**Pseudo lobule ratio:** Pseudo lobule ratios decreased progressively from d<sub>0</sub> to d<sub>84</sub> in PHT development (P < 0.01, Table 3).

**Collagen ratio:** Collagen ratios increased progressively from d<sub>0</sub> to d<sub>84</sub> in PHT development (P < 0.01, Table 3).

**iNOS distribution**

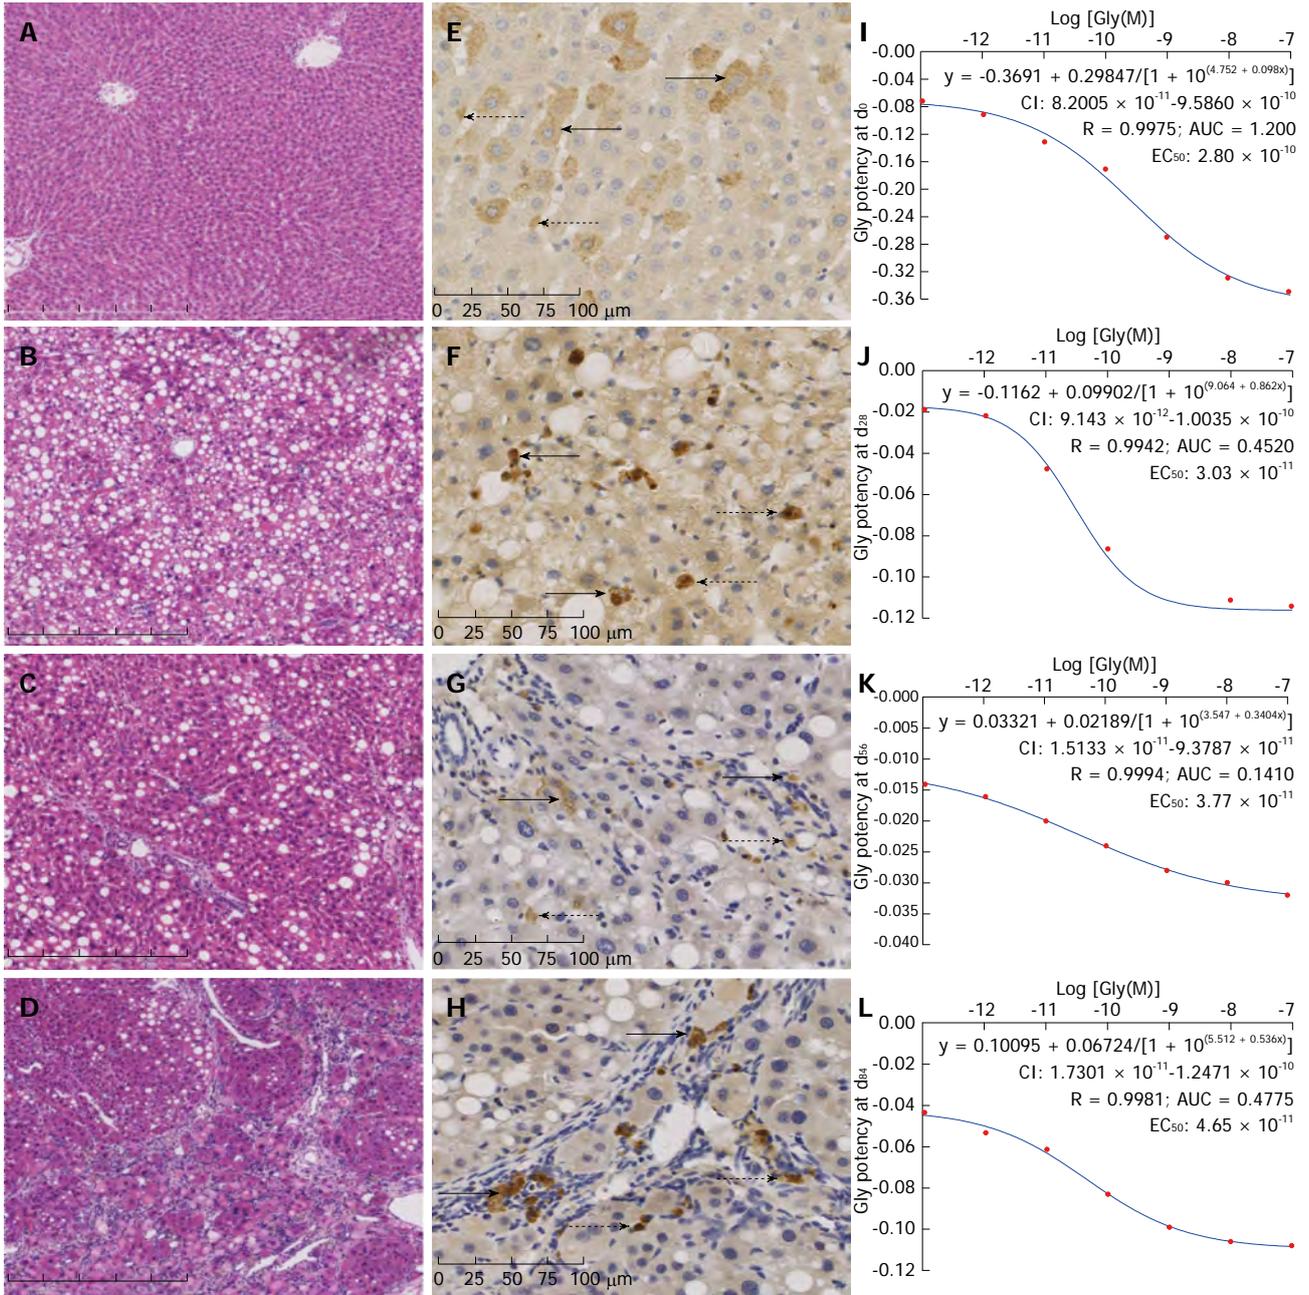

**Localization:** At d<sub>0</sub>, iNOS was mainly located in hepatocytes and scattered stellate cells of lobules (Figure 2E). At d<sub>28</sub>, positive granules were thinner in scattered hepatocytes, thicker in the stellate cells in lobules (Figure 2F). At d<sub>56</sub>, granules in hepatocytes were completely quenched; positive granules limited within macrophages in portal triads and stellate cells in lobules (Figure 2G). At d<sub>84</sub>, thick positive granules located in macrophages in portal triads and stellate cells in pseudo lobules (Figure 2H).

**Quantification:** Levels of existed iNOS per volume in portal triads at d<sub>28</sub>, d<sub>56</sub> and d<sub>84</sub> were significantly increased by 19.39%, -20.00%, and 43.03% from that at d<sub>0</sub> (P < 0.01, Table 3); these at d<sub>56</sub> and d<sub>84</sub> were decreased by 32.99% and increased by 19.80% from that at d<sub>28</sub>, respectively (P < 0.01). So did it increased by 78.79% at d<sub>84</sub> from that at d<sub>56</sub> (P < 0.01).

**Gly reducing PHT**

**Dose-effective relation:** Gly had the same shape of dose-effective curves at d<sub>0</sub> (Figure 2I), d<sub>28</sub> (Figure 2J), d<sub>56</sub> (Figure 2K), d<sub>84</sub> (Figure 2L), respectively, in PHT development. The equations of effective potency to reduce PHT were  $y = -0.3691 + 0.29847/[1 + 10^{(4.75212 + 0.09841x)}]$  (R = 0.9975, P < 0.01),  $y = -0.1162 + 0.09902/[1 + 10^{(9.064 + 0.8616x)}]$  (R = 0.9942, P < 0.01),  $y = -0.03321 + 0.02189/[1 + 10^{(3.547 + 0.3404x)}]$  (R = 0.9994, P < 0.01), and  $y = 0.10095 + 0.06724/[1 + 10^{(5.5121 + 0.5336x)}]$  (R = 0.9981, P < 0.01); EC<sub>50</sub> values with their 95% CIs were  $2.80 \times 10^{-10}$  ( $8.20 \times 10^{-11} - 9.59 \times 10^{-10}$ ),  $3.03 \times 10^{-11}$  ( $9.14 \times 10^{-12} - 1.00 \times 10^{-10}$ ),  $3.77 \times 10^{-11}$  ( $1.51 \times 10^{-11} - 9.38 \times 10^{-11}$ ), and  $4.65 \times 10^{-11}$  ( $1.73 \times 10^{-11} - 1.25 \times 10^{-10}$ ) mol/L, respectively.

**Time-effective relation:** Pathological development af-

**Figure 2** Glycyrrhizinate reduced portal hypertension in isolated portal perfuse rat liver with chronic hepatitis. A: Normal hepatic structure at d<sub>0</sub> (× 100); B: Hepatic degeneration at d<sub>28</sub> (× 100); C: Hepatic fibrosis at d<sub>56</sub> (× 100); D: Hepatic cirrhosis at d<sub>84</sub> (× 100); E: Inducible nitric oxide synthase (iNOS) were located at the hepatocyte (solid arrow) and scattered stellates (dashed arrow) at d<sub>0</sub> (× 400); F: iNOS were located at hepatocytes (solid arrow) and stellates (dashed arrow) in the lobules at d<sub>28</sub> (× 400); G: iNOS were located at stellates (dashed arrow) in the lobules and macrophages (solid arrow) outside of lobules at d<sub>56</sub> (× 400); H: iNOS were located at macrophages (solid arrow) outside of lobules and stellates (dashed arrow) at d<sub>84</sub> (× 400); I: Diammonium glycyrrhizinate (Gly) reducing portal hypertension at d<sub>0</sub>; J: Gly reducing portal hypertension at d<sub>28</sub>; K: Gly reducing portal hypertension at d<sub>56</sub>; L: Gly reducing portal hypertension at d<sub>84</sub>.

ected on Gly potency to reduce PHT. Therefore, EC<sub>50</sub> values of Gly ( $Y \times 10^{-11}$  mol/L) related linearly with durations of PHT ( $y = 0.0289x + 2.1967$ ,  $R = 0.9985$ ,  $P < 0.05$ ).

**Mechanic connection:** Existed iNOS was involved in Gly potency to reduce PHT. Therefore, AUC values of Gly regressed linearly with existed iNOS levels in portal triads at d<sub>28</sub>, d<sub>56</sub>, d<sub>84</sub> in PHT development ( $y = 0.2669x + 0.0931$ ,  $R = 0.9517$ ,  $P < 0.05$ ).

## DISCUSSION

PHT is a common complication in patients with advanced chronic hepatitis<sup>[1]</sup>. It is possible to develop therapeutic candidates against reversible mechanisms in PHT pathogenesis<sup>[1,2]</sup>. In this study, we use PHT model in IPPRL with CCl<sub>4</sub>-induced chronic hepatitis to investigate the potential effects of Gly on PHT, and to explore further the possible underlying mechanisms. NO does directly decrease PHT<sup>[2,18]</sup>. However, eNOS-derived NO

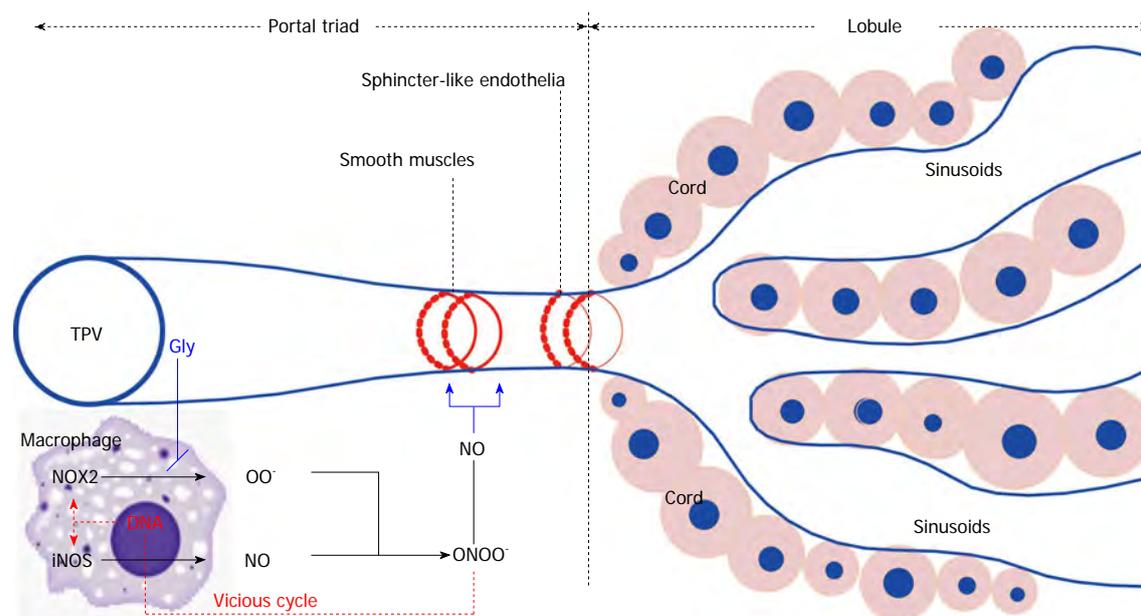

Figure 3 Glycyrrhizinate indirectly reduced portal hypertension. Gly: Diammonium glycyrrhizinate; TPV: Terminal portal venule; NOX: Nicotinamide adenine dinucleotide oxidase; OO·: Superoxide; iNOS: Inducible nitric oxide synthase; NO: Nitric oxide; ONOO·: Peroxynitrite; Gly: Glycyrrhizinate.

precedes systemic hyperemia<sup>[19]</sup>, and iNOS-derived NO reduces itself bioavailability *via* peroxynitrite<sup>[4]</sup>. Extracellular superoxide dismutase in cirrhosis inhibits peroxynitrite generation, increases NO bioavailability, and reduces PHT degree<sup>[3]</sup>. In this regard, local NO bioavailability could be drug targets for PHT. Intrahepatic resistance is mainly originated from terminal portal venules<sup>[5]</sup>. Macrophage-derived iNOS in portal triads contributed to more this resistance. Gly is a molecular from a medical plant<sup>[6]</sup> used for treating PHT<sup>[7-12]</sup>, it can increase NO bioavailability<sup>[12,16]</sup>.

Three findings were obtained in this study. (1) A rat model of PHT with chronic hepatitis was confirmed by ascites, portal pressure, splenic index, serum biomarkers and pathological changes. Four stages of CCl<sub>4</sub>-induced chronic hepatitis were hepatic degenerations, fibrosis, cirrhosis only, cirrhosis with PHT<sup>[13,14,17]</sup>. CCl<sub>4</sub> is transformed into trichloromethyl *via* cytochrome P450 2E1<sup>[17,20]</sup>, trichloromethyl initiated lipid peroxidation consequently. Therefore, free radicals injury is the major mechanism involved in CCl<sub>4</sub>-induced chronic hepatitis, which is associated with the pathogenesis of human disease; (2) As a drug candidate for PHT, Gly had the similar S shapes of dose-effective curves to reduce PHT in IPPRLs with chronic hepatitis at various stages. EC<sub>50</sub> value of Gly at d<sub>0</sub> was nearly 10 times higher than these at d<sub>28</sub>, d<sub>56</sub>, and d<sub>84</sub>, indicating that Gly may be more effective on PHT than on physiological portal pressure. EC<sub>50</sub> values of Gly were geometrically increased at d<sub>28</sub>, d<sub>56</sub>, and d<sub>84</sub>, suggesting that the portal responsibility in pathological status may be gradually decreased along with PHT development; and (3) Existed iNOS disappeared gradually in lobules, and strengthened continuously in portal triads in PHT development. AUC values of Gly were positively correlated

with levels of existed iNOS in portal triads.

Gly had been shown to cause renal and central systemic hypertension *via* inhibiting type 2 11β-hydroxysteroid dehydrogenase<sup>[21]</sup>. Possible mechanisms of Gly to relax directly portal vein included inhibiting gap junction intercellular communications<sup>[22]</sup> and activating peroxisome proliferator-activated receptor<sup>[23]</sup>. As hepatic artery being ligated in this study, IPPRL was made to evaluate the effects of Gly on portal venules alone. Under this condition, portal resistance is mainly originated from both of smooth muscle cells in terminal portal venules and sphincter-like endothelia at hepatic sinusoid inlets<sup>[24]</sup>. Different from extrahepatic vasodilators<sup>[25]</sup>, Gly relaxes indirectly portal vein *via* improving intrahepatic NO bioavailability<sup>[26]</sup>. In this study, AUC values of Gly depend on macrophage-derived iNOS in portal triads. Macrophages infiltrated in portal triads expressed more iNOS and oxidative enzymes, consequently generated more peroxynitrite to decrease NO bioavailability<sup>[15]</sup>. Gly reduces superoxide<sup>[27]</sup>, decreases peroxynitrite, increases NO bioavailability<sup>[4]</sup>, and relieves PHT (Figure 3)<sup>[24]</sup>.

Our results suggested that Gly reduces PHT, which might explain therapeutic effectiveness of Gly-contained prescriptions for patients with PHT ascites. It is also a clue to find more effective candidates related to macrophage-generated iNOS or NADPH oxidase, which partially contributes to the effects of Gly to reduce PHT. Gly or its more effective derivatives should be exploited as candidates to maintain NO bioavailability in terminal portal venules, especially against free radical injury.

## COMMENTS

### Background

Portal hypertension (PHT) is a common complication of chronic hepatitis, with

significant morbidity and mortality in clinic. It is important to develop new drugs for this disease. A sensitive pharmacological model has been established for PHT in the isolated perfused rat livers, which supplies suitable methods for evaluating candidates for PHT.

### Research frontiers

Diammonium glycyrrhizinate (Gly) is one of the representative candidates for PHT in experiment and clinic. It relaxes portal veins in isolated portal perfused rat livers at physiological status. It is also believed that the inducible nitric oxide synthase (iNOS) expressed from infiltrated macrophages in portal triads is important to increase portal resistance. The sensitive pharmacological model was used here to investigate the effect of Gly on PHT, and to exploit further the possible mechanisms of its actions.

### Innovations and breakthroughs

The intrahepatic portal resistance of PHT originates mainly from the smooth muscle cells in terminal portal venules and the sphincter-like endothelia at hepatic sinusoid inlets. Gly is effective for reducing PHT in isolated portal perfused rat livers with chronic hepatitis, with the similar S shape and different potency from its dose-effective curves. As PHT advanced, it was found that more macrophages infiltrated in portal triads and expressed more iNOS. Therefore, macrophage iNOS in portal triads involves in the pathogenesis, on which with Gly acted. The mechanisms of Gly for PHT in isolated portal perfused rat liver with chronic hepatitis are related to increase of nitric oxide (NO) bioavailability.

### Applications

Gly reducing PHT might explain the actions of medical plants in Chinese prescriptions. More effective derivate might be generated from Gly molecule structure. NO bioavailability is a candidate target for PHT.

### Terminology

Peroxyntirite is the anion with the formula ONOO<sup>-</sup>, an unstable structural isomer of nitrate. It derives from both of NO and O<sub>2</sub> in activated macrophages at portal triads with chronic hepatitis. It damages all biomolecules in cells, such as DNA and proteins. Peroxyntirite could let NO availability decrease severely.

### Peer review

The authors investigated the effect of Gly on PHT. They found that Gly reduce PHT in isolated portal perfuse rat livers with chronic hepatitis. Such action may explain Chinese medical herbs for PHT. It also suggests that NO availability involve in the pathogenesis of PHT.

### Abstract

**AIM:** To detect whether the up-to-seven should be used as inclusion criteria for liver transplantation for hepatocellular carcinoma.

**METHODS:** Between April 2002 and July 2008, 220 hepatocellular carcinoma (HCC) patients who were diagnosed with HCC and underwent liver transplantation (LT) at our liver transplantation center were included. These patients were divided into three groups according to the characteristics of their tumors (tumor diameter, tumor number): the Milan criteria group (Group 1), the in up-to-seven group (Group 2) and the out up-to-seven group (Group 3). Then, we compared long-term survival and tumor recurrence of these three groups.

**RESULTS:** The baseline characteristics of transplant recipients were comparable among these three groups, except for the type of liver graft (deceased donor liver transplant or live donor liver transplantation). There were also no significant differences in the pre-operative  $\alpha$ -fetoprotein level. The 1-, 3-, and 5-year overall survival and tumor-free survival rate for the Milan criteria

group were 94.8%, 91.4%, 89.7% and 91.4%, 86.2%, and 86.2% respectively; in the up-to-seven criteria group, these rates were 87.8%, 77.8%, and 76.6% and 85.6%, 75.6%, and 75.6% respectively ( $P < 0.05$ ). However, the advanced HCC patients' (in the group out of up-to-seven criteria) overall and tumor-free survival rates were much lower, at 75%, 53.3%, and 50% and 65.8%, 42.5%, and 41.7%, respectively ( $P < 0.01$ ).

**CONCLUSION:** Considering that patients in the up-to-seven criteria group exhibited a considerable but lower survival rate compared with the Milan criteria group, the up-to-seven criteria should be used carefully and selectively.

© 2013 Baishideng. All rights reserved.

**Key words:** Up-to-seven criteria; Liver transplantation; Outcome; Hepatocellular carcinoma; Recurrence

**Core tip:** The up-to-seven criteria were introduced several years ago, but there is still no consensus about their effectiveness. Two hundred and twenty patients were divided into three groups according to the characteristics of their tumors: the 1-, 3-, and 5-year overall survival and tumor-free survival rate for the Milan criteria group were higher than that in the up-to-seven criteria group. However, the advanced hepatocellular carcinoma patients' overall and tumor-free survival rates were much lower. So considering that patients in the up-to-seven criteria group exhibited a considerable but lower survival rate compared with the Milan criteria group, the up-to-seven criteria should be used carefully and selectively.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is a major health problem worldwide and is the sixth most common cancer and the third most common cause of cancer death<sup>[1]</sup>. This disease is especially problematic for Asian countries, which have a high prevalence of hepatitis B virus (HBV) and hepatitis C virus infection<sup>[2]</sup>. Effective management of early HCC includes resection, radiofrequency ablation and liver transplantation (LT). Liver transplantation remains the best treatment for small HCC resulting from chronic liver disease, as it both removes the neoplastic lesion and eliminates the underlying disease in a single procedure. However, post-operative recurrence is still a major problem related to HCC LT. Stringent inclusion criteria have been adopted to ensure tumor free survival after LT. The first criteria for HCC LT were introduced by Mazzaferro *et al.*<sup>[3]</sup> and were named the Milan criteria: a solitary lesion of < 5 cm, or 2 to 3 nodules all < 3 cm and without microscopic vascular invasion or extrahepatic disease. Due to the favorable results that have been achieved, *i.e.*, a 5-year post-transplant survival exceeding 70% and a rate of tumor recurrence below 15%, the Milan criteria have been used as the standard selection criteria for HCC LT all over the world<sup>[4,5]</sup>. Several years later, based on greater experience, some groups argued that the Milan criteria should be expanded, as a substantial number of patients with HCC exceeding these criteria could also greatly benefit from transplantation<sup>[6-10]</sup>. The most representative set of new criteria were the University of California San Francisco criteria proposed by Yao *et al.*<sup>[6]</sup>: 1 lesion  $\leq$  6.5 cm in diameter or 2 to 3 lesions, each  $\leq$  4.5 cm in diameter, with a total diameter of  $\leq$  8 cm. Several groups argued the Milan criteria were too strict and excluded some HCC patients from LT, despite the possibility of benefit, and that the criteria should be expanded. Therefore, the Milan group (Mazzaferro *et al.*<sup>[11]</sup>) attempted to expand the Milan criteria and create a new set called the up-to-seven criteria (new Milan criteria): hepatocellular carcinomas with seven as the sum of the size of the largest tumor (in cm) and the number of tumors. In Milan group's study, the up-to-seven groups achieved a 5-year an overall survival rate of 71.2%. Following this study, several other studies demonstrated that the up-to-seven criteria could be useful as a model for evaluating potential candidates for liver transplantation to treat HCC<sup>[12-15]</sup>. Although the up-to-seven criteria have been analyzed all over the world, they have not been as widely accepted as the Milan criteria, even 4 years after their conception. Meanwhile, there is still no research on these criteria in China, where most HBC infections and nearly 55% of worldwide HCC occurs<sup>[16]</sup>. Therefore, in our study, we compared the outcomes of Milan criteria patients with those of up-to-seven criteria patients, and then we evaluated the effectiveness of the up-to-seven criteria as inclusion criteria for HCC LT.

## MATERIALS AND METHODS

From April 2002 to July 2008, 220 HCC patients underwent LT in our liver transplantation center and were included in

our study. All of these patients were diagnosed with HCC based on pre-operative imaging studies, and the diagnoses were confirmed by pathology. Patients with cholangio-hepatocellular cancer or other liver diseases were excluded from this study. All of the tumor characteristics were evaluated by histological examination. Of these 220 cases, 58 patients met the Milan criteria (Group 1), 90 patients met the up-to-seven criteria (Group 2) and 130 patients did not meet either the Milan criteria or up-to-seven criteria (Group 3). We retrospectively collected the data of these three groups and then compared their baseline characteristics, intraoperative data, post-operative recovery and long-term survival, including the overall survival, tumor-free survival and recurrence rate. All of the data were collected from the Chinese Liver Transplant Registry (<http://www.cltr.org>).

In our study, the grafts for liver transplantation were from living right lobe donors and deceased donors. No prisoners were included as donors, and all of the whole liver grafts were donations after cardiac death. All of these donations were volunteered by the donor or the family. For grafts that came from living donors, the donor was required to be within three degrees of consanguinity with the recipient, as verified by a DNA test, and all of the living donor liver transplantations were performed after obtaining approval from the Ethics Committee of the West China Hospital and local authorities. All of the donations were voluntary and altruistic. We informed the donors and their families of the possible risks of donor hepatectomy. Written consent was provided by the donors for the storage of their information in the hospital database and its use for research.

The surgical procedures performed on the donor and the recipients are described in our previous reports<sup>[17-19]</sup>. Routine post-LT triple-immunosuppressive treatment in our center includes tacrolimus or cyclosporin, mycophenolate mofetil, and steroids. For patients with HBV infection, the anti-HBV protocol after LT included lamivudine combined with low-dose hepatitis B immunoglobulin therapy<sup>[20]</sup>. The doses of tacrolimus and cyclosporine were adjusted based on the measured serum level.

### Statistical analysis

All of the data were managed and analyzed using SPSS 17.0 statistical software. Descriptive variables such as age, MELD score, and tumor diameter were expressed as the mean  $\pm$  SE. Categorical data such as gender and graft type were computed using the Pearson  $\chi^2$  test or Fisher's exact test. The overall survival and tumor-free survival rates were calculated and compared using Kaplan-Meier analysis. Only tumor-related deaths were included in the recurrence-free survival analysis. The log-rank test was performed to compare survival curves. Two-sided *P* values were computed and a difference of *P* < 0.05 was adopted as the threshold for statistical significance.

## RESULTS

### Baseline characteristics

Over six years, 220 HCC patients underwent LT at our

BMI: Body mass index; LD: Liver disease; HBV-DNA: Hepatitis B virus DNA; DDLT: Deceased donor liver transplantation; LDLT: Living donor liver transplantation; AFP:  $\alpha$ -fetoprotein; HCV: Hepatitis C virus.

transplantation center, and all of them were followed up for at least 5 years. The baseline characteristics of the donors and recipients are summarized in Table 1. There were no significant differences among three groups with respect to recipient gender, age, or body mass index (BMI). The most common etiology of cirrhosis was hepatitis B infection. There were only 2 cases of hepatitis C infection. No differences were observed in either underlying liver disease (hepatitis virus) or HBV-DNA level. However, fewer patients underwent LDLT in the out up-to-seven group: 19.2% (23 cases) of patients in the out up-to-seven group, 37.9% (22 cases) patients in the Milan group, and 31.3% (28 cases) patients in the in up-to-seven criteria group ( $P < 0.05$ ) underwent LDLT. The pre-LT liver function, determined by the Meld score and Child score, were also not different among the three groups. There were also no differences among the three groups with respect to donor characteristics, including donor age, BMI and donor risk index.

### Tumor characteristics

There was no difference in the total diameter of the tumors between the Milan criteria and the up-to-seven criteria groups ( $P = 0.307$ ). However, the diameter in the Out up-to-seven criteria group was much larger than that in the other two groups ( $P = 0.000$ ). The out up-to-seven criteria group had the highest tumor number, followed

by the up-to-seven criteria group. There were no diffused targets in either the Milan group or the up-to-seven criteria group. However, there were 34 cases with diffused targets in the out up-to-seven criteria group. Seventy-on cases were diagnosed with macrovascular invasion by pre-LT imaging scans, and the diagnoses were confirmed by histological examination. However, there was no significant difference in the AFP level among the three groups ( $P > 0.05$ , shown in Table 1). One new target was found in the explanted liver of a patient in the Milan group, and 3 new targets were found in the up-to-seven group. The diameters of these new targets ranged from 0.8 to 3.0 cm.

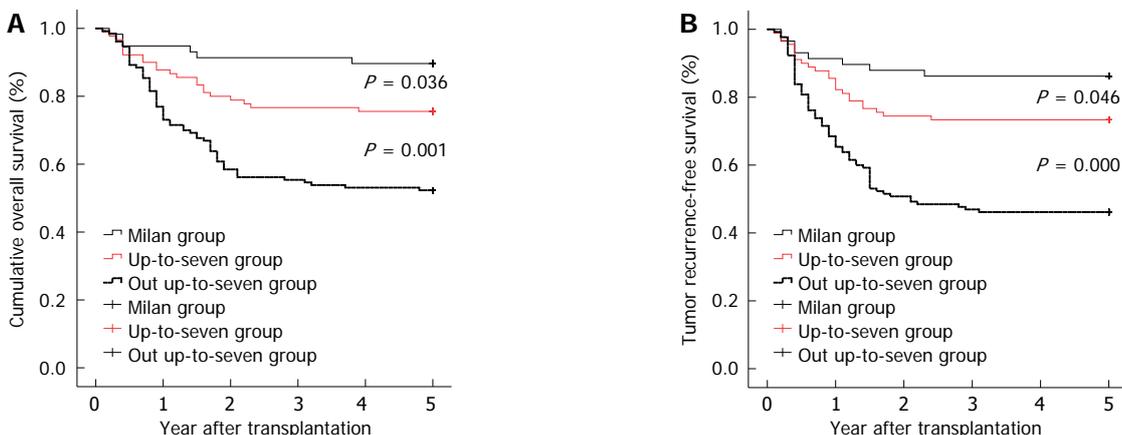

### Survival and tumor recurrence

The length of follow-up for all the patients in our study was at least 5 years, and no significant differences were observed among the groups. The 1-, 3-, and 5-year overall and tumor-free survival rates of Milan criteria group were superior to those of the up-to-seven patients [94.8% vs 87.8%, 91.4% vs 77.8%, and 89.7% vs 76.6%, respectively ( $P = 0.036$ ) and 91.4% vs 85.6%, 86.2% vs 75.6%, and 86.2% vs 75.6%, respectively ( $P = 0.046$ )]. The 1-, 3-, and 5-year overall survival rates (75%, 53.3%, and 50%, respectively) and tumor-free survival rates (65.8%, 42.5%, and 41.7%, respectively) in the patients whose HCCs did not meet the up-to-seven criteria were much

**Table 2 Site of hepatocellular carcinoma recurrence or metastasis after liver transplantation**

	Liver	Lung	Bone	Liver + lung	Lung + bone	Intra-abdominal	Other
Milan group	3	1	0	1	0	0	0
In up-to-seven group	8	3	1	4	0	0	0
Out up-to-seven group	16	21	1	9	10	4	3

Other: Lung and brain (1 case), lung and spine liver, lung and bone.

**Figure 1 Survival and tumor recurrence.** A: Overall survival rates of two groups ( $P = 0.498$ ); B: Tumor recurrence-free rates of two groups ( $P = 0.838$ ).

lower than those of the other patients ( $P < 0.01$ , Table 1). The most common reason for mortality within 1 year was complications, and not tumor recurrence, for the Milan criteria group and up-to-seven criteria group (none of the patients in the Milan criteria group and 2 patients (18.2%) in the up-to-seven group died from tumor recurrence within 1 year). However, most of the 26 (86.7%) deaths within 1 year in the out up-to-seven criteria group were due to tumor recurrence. However, 1 year after LT, the most common cause of mortality for all three groups was tumor recurrence.

The most common site of recurrence was the liver graft for all three groups, and lung metastasis was the second common site of recurrence. Additionally, some patients were diagnosed with combined organ recurrence or metastasis to the liver, lung or bone (Table 2). Although more patients were diagnosed with recurrence or metastasis in the out up-to-seven group than in the other groups, the site of recurrence or metastasis was not significantly different among the three groups. In the 71 cases who were diagnosed with macrovascular invasion, 54 (71.6%) tumors recurred or metastasized after LT (Figure 1).

## DISCUSSION

All of the baseline characteristics were comparable among the three groups, except for the source of the liver graft, as there were many fewer living donor liver transplantations in the up-to-seven group compared with the Milan criteria group. The main reason for this selective bias was the absence of a national organ allocation

system such as the United Network for Organ Sharing in China; the lack of such a system means that the criteria for HCC living donor liver transplantation are much stricter than deceased donor liver transplantation because living donor liver graft harvest involves potential risks to donors, including death<sup>[18,21]</sup>. However, this bias was assumed to have no impact on our analyses, as the results of another of our studies indicated that there were no significant differences in postoperative complications, tumor recurrence rate, survival rate, and HBV recurrence between deceased donor liver transplant (DDLT) and live donor liver transplantation (LDLT) patients<sup>[22]</sup>. Many other reports<sup>[23,24]</sup> have also indicated that there is no difference in long-term outcomes between DDLT and LDLT. Some published papers<sup>[25]</sup> have even indicated that early graft regeneration and features specific to living-donor liver transplantation (LDLT) may adversely influence the recurrence of HCC. Our data indicated that LDLT was performed more frequently in the Milan criteria group, so this selective bias did not affect the long-term survival rate.

Since the Milan criteria for HCC LT were proposed in 1996, dozens of models from all over the world have been developed to expand the indications for LT for patients with HCC without compromising overall or tumor-free survival compared with patients who underwent LT based on the Milan criteria. The main aim of expanding the Milan criteria was to include more HCC patients but maintain comparable outcomes. Although few reports have suggested that tumor involvement in the portal branches is a contraindication for LT<sup>[26,27]</sup>, there is general agreement among various researchers

that patients presenting macrovascular invasion or extrahepatic spread should be excluded from LT given the unacceptable rate of recurrence<sup>[10]</sup>; this presumption was confirmed by our analysis, which showed a very high recurrence rate (71.6%) in these cases. However, the proposed expanded criteria appear to be vague: the upper diameter of a single tumor ranges from 5 to 9 cm<sup>[6,28-30]</sup>, and the highest number of tumors ranges from 3 to unlimited<sup>[6,28,29,31]</sup>. Some published studies did not even impose upper limits on the tumor number or diameter<sup>[32,33]</sup>. Thirteen years after the Milan criteria were developed, the Mazzaferro group proposed an expanded set of criteria called the up-to-seven criteria (new Milan criteria). In their study, the 5-year overall survival rate for Milan group patients was 73.3%; this finding is comparable to our results, which showed a 5-year overall survival of 75%. However, for the up-to-seven criteria patients, the overall survival rate in our study was 53.3%, which was much lower than the 71.2% reported in the Mazzaferro *et al*<sup>[11]</sup>. Several studies have evaluated the effectiveness of using the up-to-seven criteria as inclusion criteria for HCC LT<sup>[14,15]</sup>. de Ataide *et al*<sup>[12]</sup> directly compared the long-term outcomes of a Milan criteria group and an up-to-seven criteria group. Their results showed that the post liver transplantation survival rates were 87.7%, 74.5% and 65.3% at 1, 3, and 5 years among patients who met the up-to-seven criteria, and these rates were similar to those in patients meeting the Milan criteria. However, there is still some disagreement regarding the up-to-seven criteria. In a letter to Mazzaferro and his colleagues, Sotiropoulos *et al*<sup>[13]</sup> stated that although the up-to-seven criteria are based on objective tumor characteristics such as tumor size, tumor number, and microvascular invasion, these characteristics represent pathology findings and not preoperative objective tumor characteristics, and therefore, the up-to-seven criteria are illusive and not applicable in clinical practice. In the present study, 71 patients (59.1%) in the out up-to-seven criteria group showed macrovascular invasion, which was an independent risk factor for HCC recurrence after LT. Our data on the tumor characteristics for this analysis all come from pre-operative imaging data and were confirmed by the histological examination. Only a few targets (4 cases) were found in the explanted liver. We did not evaluate the new targets in the out up-to-seven group because there were some cases with diffused tumors, so finding and calculating new tumor targets would have been very difficult in these patients.

Our Milan criteria patients exhibited a 89.7% 5-year overall survival rate, and this rate is higher than that in some reports<sup>[10]</sup> but comparable with those in many other reports<sup>[29,34,35]</sup>. Although the up-to-seven criteria group included 90 patients, which was much higher than the number of patients in the Milan criteria group (53 cases), the main aim of expanding the Milan criteria was to include more HCC patients without compromising outcomes; this, in our study, long-term (5-year) survival was much lower in the up-to-seven group. The concept of the

“metro ticket” has been used to demonstrate this point, that is, expanding the criteria to allow both increased size and increased number of nodules resulted in an increased risk of recurrence. The further the criteria are expanded, the higher the risk in terms of survival<sup>[4]</sup>. However, although the survival rate in the up-to-seven criteria group was lower than that in the Milan criteria group, the 5-year overall survival rate was still considerable at 76.6%, which was comparable with the Milan criteria 5-year survival rate in many other reports<sup>[10]</sup>. Meanwhile, the overall survival rate of patients who met the up-to-seven criteria was much higher than those who did not meet up-to-seven criteria (5-year survival rate: 76.6% *vs* 50%). These comparisons suggest that the up-to-seven criteria may be accepted.

The limitations of this study include the fact that these data were retrospectively collected and analyzed. A future randomized study would be the best way to evaluate the effectiveness of the up-to-seven criteria as inclusion criteria for HCC LT. However, this ideal design would be very difficult to implement due to logistical challenges. In addition, a large multicenter study comparing a larger number of patients with HCC LT would be ideal for future analyses.

In conclusion, considering the differences in long-term outcome, care should be taken when using the up-to-seven criteria rather than the Milan criteria to include HCC patients in LT.

Thanks for the data from the Chinese Liver Transplant Registry (<http://www.cltr.org>).

## COMMENTS

### Background

Liver transplantation remains the best treatment for small hepatocellular carcinoma (HCC) resulting from chronic liver disease. However, post-operative recurrence is still a major problem related to HCC liver transplantation (LT). Stringent inclusion criteria have been adopted to ensure tumor free survival after LT. The first criteria for HCC LT were introduced in 1996 and were named the Milan criteria. Several years later, based on greater experience, some groups argued that the Milan criteria should be expanded. Therefore, the Milan group attempted to expand the Milan criteria and create a new set called the up-to-seven criteria (new Milan criteria): HCCs with seven as the sum of the size of the largest tumor and the number of tumors.

### Research frontiers

Although the up-to-seven criteria have been analyzed all over the world, they have not been as widely accepted as the Milan criteria, even 4 years after their conception. Meanwhile, there is still no research on these criteria in China, where most hepatitis B virus and hepatitis C virus infections and nearly 55% of worldwide HCC occurs.

### Innovations and breakthroughs

The up-to-seven criteria were introduced several years ago, but there is still no consensus about their effectiveness. Two hundred and twenty patients were divided into three groups according to the characteristics of their tumors in the authors' center. Considering that patients in the up-to-seven criteria group exhibited a considerable but lower survival rate compared with the Milan criteria group, the up-to-seven criteria should be used carefully and selectively.

### Applications

Considering the differences in long-term outcome, care should be taken when

using the up-to-seven criteria rather than the Milan criteria to include HCC patients in LT.

**Peer review**

This is an interesting study comparing liver transplant outcomes in 3 groups of patients with different stage of HCC.

### Abstract

**AIM:** To investigate the dynamic features of insulin-like growth factor- I receptor (IGF- I R) expression in rat hepatocarcinogenesis, and the relationship between IGF- I R and hepatocytes malignant transformation at mRNA or protein level.

**METHODS:** Hepatoma models were made by inducing with 2-fluorenylacetylamide (2-FAA) on male Sprague-Dawley rats. Morphological changes of hepatocytes were observed by pathological Hematoxylin and eosin staining, the dynamic expressions of liver and serum IGF- I R were quantitatively analyzed by an enzyme-linked immunosorbent assay. The distribution of hepatic IGF- I R was located by immunohistochemistry. The fragments of *IGF- I R* gene were amplified by reverse transcription-polymerase chain reaction, and confirmed by sequencing.

**RESULTS:** Rat hepatocytes after induced by 2-FAA were changed dynamically from granule-like degeneration, precancerous to hepatoma formation with the progressing increasing of hepatic mRNA or IGF- I R expression. The incidences of liver IGF- I R, IGF- I R mRNA, specific IGF- I R concentration (ng/mg wet liver), and serum IGF- I R level (ng/mL) were 0.0%, 0.0%,  $0.63 \pm 0.17$ , and  $1.33 \pm 0.47$  in the control; 50.0%, 61.1%,  $0.65 \pm 0.2$ , and  $1.51 \pm 0.46$  in the degeneration; 88.9%, 100%,  $0.66 \pm 0.14$ , and  $1.92 \pm 0.29$  in the precancerosis; and 100%, 100%,  $0.96 \pm 0.09$ , and  $2.43 \pm 0.57$  in the cancerous group, respectively. IGF- I R expression in the cancerous group was significantly higher ( $P < 0.01$ ) than that in any of other groups at mRNA or protein level. The closely positive IGF- I R relationship was found between livers and sera ( $r = 0.91$ ,  $t = 14.222$ ,  $P < 0.01$ ), respectively.

**CONCLUSION:** IGF- I R expression may participate in rat hepatocarcinogenesis and its abnormality should be an early marker for hepatocytes malignant transformation.

**Key words:** Hepatoma; Insulin-like growth factor- I re-

ceptor; Immunohistochemistry; Gene amplification; Sequencing; Rat hepatoma model

**Core tip:** The abnormality of insulin-like growth factor- I receptor (IGF- I R) expression was progressively increased in hepatocarcinogenesis at mRNA or protein level, and there was a positive correlation between circulating blood and liver IGF- I R, suggesting that the over-expression of liver IGF- I R release into blood, and serum IGF- I R should be an early useful marker for monitoring malignant transformation of rat hepatocytes.

Overexpression of insulin-like growth factor- I receptor as a pertinent biomarker for hepatocytes malignant transformation. *World J Gastroenterol* 2013; 19(36): 6084-6092 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/6084.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.6084>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death, especially in the inshore area of the Yangtze River<sup>[1-3]</sup>. Multiple pathogenic factors, including infection with hepatitis B virus or hepatitis C virus, chronic hepatitis and cirrhosis with the subsequent multistage pathogenesis, have been extensively studied<sup>[4-6]</sup>. Recent advances in molecular genetics have identified a large number of activated or suppressed genes may play significant roles in HCC<sup>[7-9]</sup>. Insulin-like growth factor (IGF) signaling is specifically required for hepatoma progression<sup>[10]</sup>, especially in IGF- II and IGF- I receptor (IGF- I R) which are the very important signaling contributors. Surgical liver transplantation or resection remains the mainstay of curative therapy for patients in the early stage of HCC<sup>[11,12]</sup>.

Carcinoembryonic IGF- II was reported to be over-expressed at different stages of HCC development<sup>[12]</sup>. Integrative genomic analysis showed enrichment of IGF activation in the proliferation subclass of HCC. Effective blockage of IGF signaling with A12 provides the rationale for testing this therapy in clinical trials<sup>[13]</sup> and confirmed that it plays the biologic role primarily through IGF- I R<sup>[14]</sup>. Although the IGF- I R expression is distributed widely in multiple tissues, it is high in fetal liver but not in adult liver<sup>[10]</sup>. IGF- I R is an important regulatory factor necessary for cell growth and differentiation, provides mitogenic signal for tumor growth<sup>[15]</sup>, exhibits a very potent anti-apoptotic activity<sup>[16]</sup>, induces vascular endothelial growth factor expression, and able to maintain the cell phenotype transformation in carcinogenesis<sup>[17,18]</sup>. However, the features of IGF- I R expression during hepatocytes malignant transformation have not yet been reported. Thus, the objectives of the present study were to investigate the dynamic expression features of IGF- I R

in rat hepatocarcinogenesis, and the relationship between IGF- I R expression and hepatocyte malignant transformation at mRNA or protein level.

## MATERIALS AND METHODS

### *Hepatoma model and pathological analysis*

Rat hepatoma models were made as described previously<sup>[13]</sup>. Briefly, 54 male Sprague-Dawley rats (4-wk-old, body weight 120-130 g) from the Experimental Center of Medical Animals, Nantong University, China were used to induce HCC development by fed foods with 0.05% 2-fluorenylacetylacetamide (2-FAA, Sigma). Rats were monitored daily for survival and weight loss, recorded their clinical signs and sacrificed at different days. All procedures performed on the animals were conducted in accordance with the guidelines for experimental animals approved by the Animal Care and Use Committee of Nantong University, China. According to the plan, 5 mL of blood was drawn from rat hearts and serum was separated for IGF- I R test, and livers were used for pathology, immunohistochemistry, total RNA extraction, and quantitative analysis of IGF- I R expression. Rat liver tissues were fixed in 10% formaldehyde solution, sectioned after dehydration, and paraffin embedding and then performed with HE staining to observe morphological changes under microscope.

### *Total RNA extraction*

Liver tissue (20 mg) was homogenized on ice after adding 1.0 mL of TRIzol reagent in a glass homogenizer which was made RNase-free by 0.1% DEPC water. One milliliter slurry was transferred into the tubes and centrifuged at 15000 rpm for 10 min at 4 °C. 0.8 mL of the supernatant was put into another tube, and then 0.2 mL of chloroform was added into the tube, mixed by vortexing 2 min, centrifuged at 10000 rpm for 10 min at 4 °C, 0.3 mL of the supernatant was collected into another RNase-free tube, equivalent 100% isopropanol and then another 0.5 mL of 50% isopropanol were added, mixed gently for 30 s, centrifuged at 15000 rpm for 5 min at 4 °C. The supernatant was removed, the RNA pellets were washed with 1.0 mL of 75% ethanol, mixed, and centrifuged at 15000 rpm for 5 min at 4 °C. The RNA pellets were air dried 3 min at room temperature, reconstituted in 20 µL of 0.1% lithium chloride, and incubated at 50 °C for 5 min. The purity and concentration of total RNA was estimated, and the ratio was calculated according to absorbance (*A*) readings at *A*<sub>260</sub>/*A*<sub>280</sub> nm.

### *IGF- I R cDNA synthesis*

In a 0.2 mL tube, 2 µg of RNA was combined with 1 µL of random primer (Oligo-dT<sub>18</sub>, 0.5 µg/µL) and adjusted volume to 12 µL with dH<sub>2</sub>O, centrifuged for 5 s. Denature RNA and primer were incubated at 70 °C for 5 min and placed on ice for 30 s, then centrifuged for 5 s, placed on ice and added the reagents as follows: 4 µL of 5 X cDNA Synthesis Buffer, 1 µL of RNase OUT (20 U/µL), 2 µL dNTP Mix (10 mmol/L), centrifuged for 5 s,

incubated at 37 °C for 5 min, placed on ice for 30 s, then added 1 µL of RevertAid M-MuLV Reverse Transcriptase (20 U/µL). Lastly, the reaction was terminated by heating at 70 °C for 5 min after incubating for 60 min at 37 °C.

#### **Primers and nested polymerase chain reaction**

According to rat IGF- I R mRNA full-length sequence (NM052807), and the primers were designed by Premier Primer 5.0 software. External primer P<sub>1</sub>: 5'-CTGCGGCGA TGAAGAAAAGA-3'(nt 1038-1057) and P<sub>2</sub>: 5'-TG-GAGGTGAAACGGAGAAC A-3' (nt 1521-1540), 503 bp; Internal primer P<sub>3</sub>: 5'-ATGCCCTGGTCTCCCTTGTC CT T-3' (nt 1229-1250) and P<sub>4</sub>: 5'-TTTGCTCTGCC-GTCCCTTTGTT-3' (nt 1449-1470), 242 bp. IGF- I R cDNA was amplified by a nested Polymerase chain reaction (PCR), with the 1<sup>st</sup> stage was performed in 2 µL of cDNA (0.1 µg/µL), 2.0 µL of the mix primers (P<sub>1</sub>, P<sub>2</sub>), 12.5 µL of Priemix Taq, and adjusted volume to 25 µL with dH<sub>2</sub>O under the following conditions: 94 °C for 5 min followed by 35 cycles of 94 °C for 10 s, 55 °C for 30 s, 72 °C for 1 min and a final extension step of 10 min at 72 °C; the 2<sup>nd</sup> stage was performed according to above same condition except for 1 µL of the 1<sup>st</sup> PCR solution, and 2 µL of the mix primers (P<sub>3</sub>, P<sub>4</sub>), and finally, the PCR product was stored at 4 °C for analysis.

#### **Electrophoresis and sequencing**

Agarose (0.375 g) was added to 25 mL of TAE buffer, superheated for 3 times. When the agarose cooled to about 50 °C, 1.5 µL of ethidium bromide (10 mg/mL) was added, poured into taped gel tray, placed the combs. 300 mL of TAE buffer was poured into the electrophoresis box. Mixed 8 µL of PCR product with 1 µL of loading dye and put into a well, DNA ladder into another gel well, than electrophoresized on 1.5% agarose gel at 100 V for 30 min, observed with UV Transilluminator at 320 nm, Cut and purified the DNA fragments from the gels for sequencing in MegaBACE DNA sequencer, and the alignment of nucleotide sequences was compared with the original IGF- I R gene sequence.

#### **Immunohistochemistry**

Rat livers were fixed in 10% neutral formalin, embedded in paraffin and 4 µm of section was cut, dewaxed, hydrated, and treated with 3% H<sub>2</sub>O<sub>2</sub> to quench endogenous peroxidase; tissue antigens were retrieved with microwave; and then the sections were blocked by normal animal serum. The first antigen of IGF- I R was dropped on tissue section overnight at 4 °C and thoroughly washed by PBS. Subsequently, the slides were washed in PBS again after adding biotinylated secondary antibody and incubating for 10 min, then added drops of streptomycin avidin-peroxidase (S-P), incubated for 10 min at room temperature, rinsed by dH<sub>2</sub>O and added DAB. After immunostaining, the slides were restrained with hematoxylin, dehydrated in a series of ethanol solutions, covered with neutral gum,

and observed under the microscope (Olympus BX 50). The negative control included 0.01 mol/L PBS instead of the primary and secondary antibodies and S-P agent. Breast-cancerous tissues with positive IGF- I R expression served as positive control. Sensitive gamma-glutamyl-transferase (GGT) is used as a control at the same stage<sup>[19]</sup>. As IGF- I R-positive expression was evident as brown particles in tissues. IGF- I R expression in livers was divided in weakly positive (+, 10%-25% positive cells); moderately positive (++, 26%-75%); and strongly positive (+++, > 75%).

#### **Extraction and measurement of total protein**

Liver tissue (50 mg) was homogenized for 3 min after the addition of 1.0 mL of PBS. The slurry was transferred into tubes (1.5 mL) and centrifuged at 5000 rpm for 4 min at 4 °C. The supernatant was put into another tube and stored at 4 °C. The concentration of total protein was determined by BCA protein measuring kit. Working Reagent was prepared by mixing BCA Reagents (50:1, Reagent A:B), 10 µL of each protein standard was pipetted into a 96-well plate and diluted to 100 µL with 0.9% normal saline. Besides, the standards were added into the 96-well plate as follows: 0, 1, 2, 4, 8, 12 and 20 µL, and each well was added up to 20 µL with diluent. Then 5 µL of tissue proteins were pipetted into the wells and adjusted volume to 20 µL with 0.9% normal saline. In the end, added 200 µL BCA Working Reagent, incubated at 37 °C for 30 min and the absorbance was measured at 562 nm on a plate reader.

#### **Detection of serum and liver IGF- I R levels**

The levels of liver IGF- I R were detected using a rat IGF- I R enzyme-linked immunosorbent assay (ELISA) kit according to the manufacturer's instructions. For the study, 100 µL of standard or tissue protein were separately put into each well of a 96-well ELISA plate, mixed gently for 30 s, incubated for 120 min at 37 °C. 100 µL of biotinylated anti-rat-IGF- I R was added, and incubated for 60 min at 37 °C. And then 100 µL of HRP-conjugate was added to the wells, and incubated for 60 min at 37 °C. Next, 100 µL of enzyme substrate working fluid was added to each well in dark for 5-10 min at 37 °C. Then, 100 µL of stop solution was put into each well, and absorbance was read at 492 nm. During the procedure, washing the plate was according to the ELISA kit. The levels of serum IGF- I R were detected in the same way.

#### **Statistical analysis**

Data were expressed as mean ± SD and subjected to analysis of variance. Differences between groups were assessed by using Newman-Keuls test, the Fisher's exact test or Rank-Sum test. Statistical significance was accepted at the level of *P* value less than 0.05 by using the Stata 7.0 software.

HCC: Hepatocellular carcinoma.

## RESULTS

### Pathological morphological alteration of livers

The morphological changes of rat livers in hepatocarcinogenesis induced with 2-FAA are shown in Table 1 and Figure 1. The morphological alteration of liver in rat hepatocarcinogenesis (Figure 1A-C) was confirmed by

HE staining (Table 1; Figure 1D-F), and the model rats were divided into 4 groups: the control group ( $n = 12$ ), the degeneration group ( $n = 18$  Figure 1D), the precancerous group ( $n = 9$ , Figure 1E), and the HCC group ( $n = 9$ , Figure 1F). The granule-like degeneration appeared in the cytoplasm and a large heterogeneous nucleus was seen occasional (the degeneration group, Figure 1A and D) at an early stage. At the intermediate stage, some areas had the trend to form nodules, hepatic plate cell layers increased, focal cell layers surpassed three, the nuclear chromatin was denser, and the ratio of nucleus to cytoplasm increased (the precancerous group, Figure 1B and E). The nodular hyperplasia at the later stage was observed in many areas, the structure of hepatic tissue disappeared, the hepatic cells arranged into nest or funicular form, the medium large and the nuclear chromatin was more dense, and the ratio of nucleus to cytoplasm increased, and all were confirmed as well differentiated HCC (the HCC group, Figure 1C and F), indicated that histological changes in hepatocytes from granule-like degeneration to precancerous and HCC, and confirmed by the immunohistochemistry of corresponding stage hepatic GGT

**Figure 2** Gene amplification, sequencing and homological analysis of liver insulin-like growth factor I receptor. A: The amplified fragments of rat insulin-like growth factor I receptor (IGF- I R) mRNA by reverse transcription-nested polymerase chain reaction 1, no positive fragments from control rat liver 2, the positive fragments from degeneration rat (Deg) liver; 3, the positive fragments from precancerous rat (Pre-C) liver, and 4, the positive fragments from hepatocellular carcinoma (HCC) rat liver; B: The amplified fragment of rat IGF- I R mRNA was confirmed by sequencing and alignment of nucleotide sequences from rat liver.

**Table 2** Total RNA and insulin-like growth factor- I receptor mRNA expression in hepatocarcinogenesis *n* (%)

Group	<i>n</i>	Total RNA level			IGF- I R mRNA	
		( $\mu\text{g}/\text{mg}$ wet liver)	<i>q</i>	<i>P</i> value	Positive	<i>P</i> value
Control	12	1.58 $\pm$ 0.94			0 (0.0)	
Degeneration	18	1.91 $\pm$ 0.60 <sup>1</sup>	1.177	0.249	11 (61.1) <sup>1</sup>	< 0.001
Precancerosis	9	2.00 $\pm$ 0.21 <sup>1</sup>	1.308	0.206	9 (100) <sup>1</sup>	< 0.001
HCC	9	2.86 $\pm$ 0.60 <sup>1</sup>	3.843	0.001	9 (100) <sup>1</sup>	< 0.001

<sup>1</sup>Compared with the control group. IGF- I R: Insulin-like growth factor- I receptor; HCC: Hepatocellular carcinoma.

(Figure 1G-I).

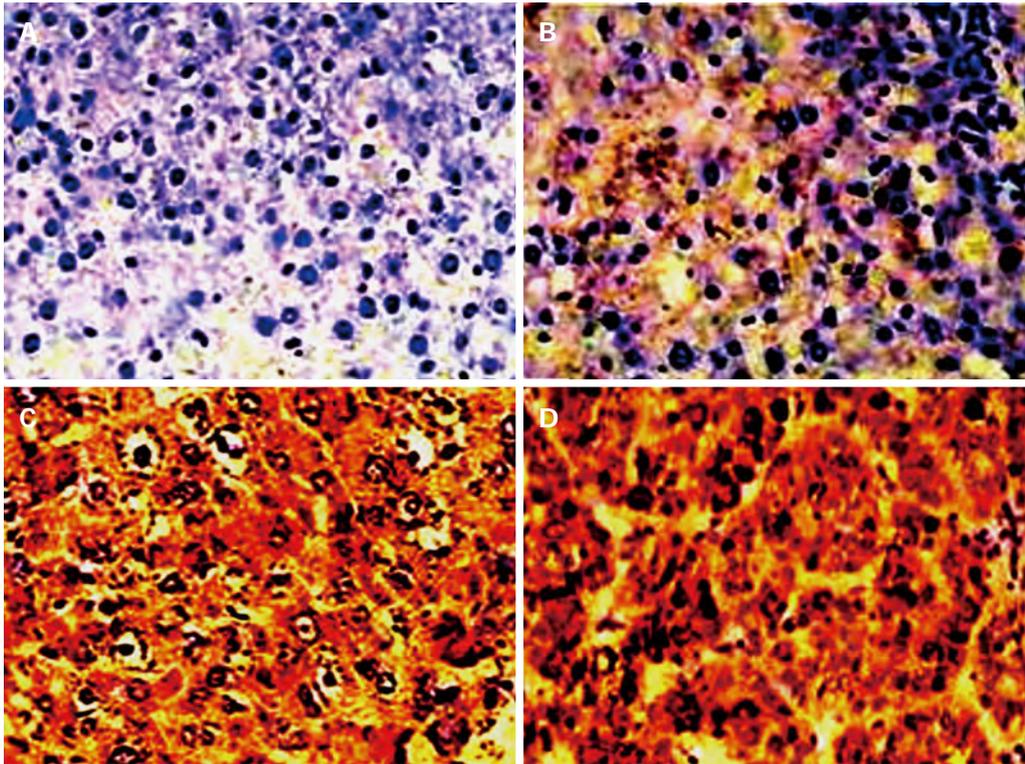

**Expression of hepatic IGF- I R mRNA**

The quantitative analysis of total liver RNA from the different stages and the positive fragments of liver IGF- I R mRNA amplification in hepatocarcinogenesis are shown in Table 2 and Figure 2. The metabolic levels of hepatic nucleic acid were vigorous and the expression of hepatic total RNA was progressively increased from the control to HCC. The specific concentration of total RNA ( $\mu\text{g}/\text{mg}$  wet liver) was significantly higher in the HCC group than that in the control group ( $F = 6.840, P < 0.001$ , Table 2). The amplified fragments of hepatic IGF- I R mRNA could be detected clearly in the HCC, precancerous, or part of degeneration group (Figure 2A) and the IGF- I R gene fragments were confirmed by sequencing (Figure 2B). The expression of IGF- I R mRNA was

progressively increased in hepatocarcinogenesis and the incidence was 0% in the control, 61.1% in the degeneration, 100% in the precancerous, and 100% in the HCC group (Table 2), respectively.

**Dynamic expression of hepatic IGF- I R**

The positive with brown particles and cellular distribution of liver IGF- I R expression analyzed by immunohistochemistry is shown in Figure 3 and the result is summarized in Table 3. The immunohistochemistry evidences indicated the positive IGF- I R expression and hepatocyte distribution of IGF- I R positive expression increased gradually along with the occurrence (Figure 3) of hepatocyte malignant transformation. The nucleus was stained in some atypical hyperplasia areas; while near the area of necrosis, the cells were mainly stained in cytoplasm and nucleus, and the positive cells were always

**Figure 3** Immunohistochemical analysis of rat liver insulin-like growth factor I receptor at the different stage of rat hepatocyte malignant transformation ( $\times 200$ ). A: No positive staining in the liver from control rat; B: The weaker insulin-like growth factor I receptor (IGF- I R) expression in the liver from degeneration rat; C: The significantly IGF- I R expression in the liver from precancerous rat; D: The over-expression of liver IGF- I R in hepatoma rats.

located in the edge of the portal area or central vein area (Figure 3C or D), and the IGF- I R levels in the precancerous or HCC group were significantly higher than that in the control group (Table 3,  $P < 0.001$ ). Of the 18 cases with degeneration, the IGF- I R-expression was detected in 9 cases and 5 of them showed moderately or strongly positive; of the 9 cases with HCC, IGF- I R over-expression was detected in 9 cases and 8 of them showed moderately or strongly positive expression (Table 3).

#### Quantitative analysis of circulating and liver IGF- I R

The levels of circulating or liver IGF- I R expression during hepatocyte malignant transformation are shown in Table 4. There was a rising tendency of serum or liver IGF- I R along with the morphological changes in hepatocarcinogenesis with HCC > precancerous > degeneration > control. The average serum IGF- I R level in the precancerous group was significantly higher than that in the control or degeneration group ( $P < 0.01$ ); and the level in the HCC group was significantly higher than that in the control or degeneration group ( $F = 11.850$ ,  $P < 0.001$ ); The IGF- I R level in the livers in the HCC group was obviously higher than that in the control, degeneration or precancerous groups ( $F = 8.720$ ,  $P < 0.001$ ). Moreover, there was a positive correlation ( $r = 0.91$ ,  $t = 14.222$ ,  $P < 0.001$ ) found between serum and liver IGF- I R, suggesting that the over-expression of liver IGF- I R release into blood and circulating IGF- I R monitor hepatocyte malignant transformation.

## DISCUSSION

HCC is one of the most common cancers and causes of mortality<sup>[20,21]</sup>. A great deal of progress in understanding the mechanism(s) of hepatocarcinogenesis has been achieved in recent years<sup>[16,22]</sup>. IGFs imbalance affect the malignant transformation of hepatocytes, and the over-expressions of IGF- II and IGF- I R promote mitosis and cellular transformation and inhibiting apoptosis<sup>[10]</sup>. IGF- I R is a trans-membrane tyrosine kinase receptor located on chromosome 15q26.3 composed of two  $\alpha$  and two  $\beta$  subunits linked by disulfide bonds. The extracellular  $\alpha$  subunit is responsible for ligand binding, whereas the  $\beta$  subunit consists of a trans-membrane domain and a cytoplasmic tyrosine kinase domain. It is always expressed efficiently in rat nonparenchymal cells including Kupffer cells, stellate cells and increases the sensitivity of the hepatocytes to IGFs mitogenic effect. In this study, the dynamic models of HCC were applied to investigate the features of IGF- I R expression in hepatocarcinogenesis, the relationship between IGF- I R expression and hepatocytes malignant transformation, and explore the multistage pathogenesis of HCC.

Hepatoma models were successfully induced in male SD rats for investigating the dynamic expression and alteration features of IGF- I R and IGF- I R-mRNA during hepatocytes malignant transformation (Table 1). At an early stage, the morphological changes of hepatocytes showed the granule-like degeneration appeared in the

**Table 4 Insulin-like growth factor- I level in rat livers or sera during malignant transformation of hepatocytes**

Group	<i>n</i>	Serum IGF- I R			Liver IGF- I R		
		nmol/mL	<i>q</i>	<i>P</i> value	nmol/mg wet liver	<i>q</i>	<i>P</i> value
Control	12	1.03 ± 0.47			0.43 ± 0.17		
Degeneration	18	1.51 ± 0.46 <sup>1</sup>	1.486	0.318	0.55 ± 0.20 <sup>1</sup>	0.456	0.812
Precancerosis	9	1.92 ± 0.29 <sup>1</sup>	4.116	0.003	0.66 ± 0.14 <sup>1</sup>	0.578	0.748
HCC	9	2.43 ± 0.57 <sup>1</sup>	7.674	< 0.001	0.96 ± 0.09 <sup>1</sup>	6.357	< 0.001

<sup>1</sup>Compared with the control group. IGF- I R: Insulin-like growth factor- I receptor; HCC: Hepatocellular carcinoma.

cytoplasm and a large heterogeneous nucleus occasionally. At the intermediate stage, the nuclear chromatin was denser and the ratio of nucleus to cytoplasm increased. And at the later stage, the structure of hepatic tissue disappeared, the medium large and the nuclear chromatin was denser, and the ratio of nucleus to cytoplasm increased (Figure 1). Hepatocytes were transformed into malignant cells with a large synthesis of nucleic acid. Moreover, at the stage of precancerous to hepatoma formation with the progressing increasing of liver total RNA and IGF- I R mRNA were significantly higher than those in the control or degeneration group (Table 2 and Figure 2), indicated that the activation and transcription of hepatoma related genes be closely connected with nucleic acid synthesis and IGF- I R participate in hepatocarcinogenesis<sup>[23,24]</sup>.

Significant abnormalities of IGF- I R gene transcription and expression could be detected during the process of hepatocytes malignant transformation. Recent researches showed that HCC include the over-expression of IGF- II<sup>[13]</sup>, which have close relationship with the degree of differentiation<sup>[25]</sup>. It exerts its actions mainly *via* IGF- I R. The combination then leads to activation of the phosphatidylinositol3-kinase and the Ras/mitogen activated protein kinase pathways and contributes to mitosis, proliferation, transformation and anti-apoptosis. IGF- II mRNA is over-expressed at early stage of HCC formation<sup>[13]</sup>. Immunohistochemistry of dynamic models revealed that the expression levels of IGF- I R in rat hepatic tissues and sera assumed a rising tendency during the development of HCC (Table 3, Figure 3). The average level of IGF- I R from the precancerous groups was higher than that in the normal and degeneration groups.

The over-expression of liver IGF- I R release into the blood and circulating IGF- I R could be detected (Table 4), suggesting that HCC is a high-IGF- I R expressing tumor along with the malignant transformation of hepatocytes and its abnormality should be a potential molecular marker for HCC development<sup>[26,27]</sup>.

HCC has exhibit numerous genetic abnormalities as well as epigenetic alterations including modulation of DNA methylation. Molecular factors are involved in the process of HCC development and metastasis. Several laboratories have implicated constitutive activation of miRNA as one of the early key events involving in neoplastic progression of the liver. Recent studies *in vivo* revealed that interfering with signaling *via* IGF- I R has an antitumor effect by inducing apoptosis and inhibiting cell growth<sup>[13,28]</sup>. Further studies will permit us to analyze mechanism of human hepatocarcinogenesis and pay attention to these areas. However, the combination of pathological features and some biomarkers with high sensitivity and specificity for early diagnosis of HCC seems to be more practical up to present.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death, especially in the inshore area of the Yangtze River. Insulin-like growth factor (IGF) signaling is specifically required for HCC progression, especially in IGF- II and IGF- I receptor (IGF- I R) which are the very important signaling contributors.

### Research frontiers

IGF- I R is an important regulatory factor necessary for cell growth and differentiation, provides mitogenic signal for tumor growth, exhibits a very potent anti-apoptotic activity, induces vascular endothelial growth factor expression, and able to maintain the cell phenotype transformation in carcinogenesis. However,

the features of IGF- I R expression during hepatocytes malignant transformation have not yet been reported.

### Innovations and breakthroughs

The dynamic models of rat hepatoma were applied to investigate the features of IGF- I R expression in hepatocarcinogenesis for the first time. The IGF- I R expression was progressively increased during hepatocyte malignant transformation at mRNA or protein level, and there was a positive correlation between sera and liver IGF- I R, indicating that the IGF- I R over-expression in liver tissues release into blood and circulating IGF- I R monitor occurrence of rat hepatoma.

### Applications

Overexpression of IGF- I R might participate in rat hepatocarcinogenesis and its abnormality should be an early molecular marker for hepatocyte malignant transformation.

### Peer review

This paper was aimed at investigating the expression of IGF- I R during hepatocarcinogenesis induced by 2-fluorenylacetylacetamide in Sprague-Dawley rats. Increase in IGF- I R mRNA and protein incidence and expression are reported in preneoplastic and neoplastic tissue. It is an interesting animal model study for the pathway of the IGF- I R in the HCC.

### Abstract

**AIM:** To explore the feasibility and safety of endoscopic retrograde cholangiopancreatography and laparoscopic cholecystectomy (LC) performed during the same session.

**METHODS:** Between July 2010 and May 2013, 156 patients with gallstones and common bile duct (CBD) stones were enrolled in this retrospective study. According to the sequence of endoscopic procedures and LC, patients were classified into two groups: in group 1, patients underwent endoscopic stone extraction and LC during the same session, and in group 2, patients underwent LC at least 3 d after endoscopic stone extraction. Outcomes of the endoscopic procedures and LC were compared between the two groups, respectively.

**RESULTS:** There were 91 patients in group 1 and 65 patients in group 2. The characteristics of the two groups were similar. The mean duration of the endoscopic procedures was 34.9 min in group 1 and 35.3

min in group 2. There were no significant differences in the success rate of the endoscopic procedures (97.8% for group 1 vs 98.5% for group 2), the total rate of endoscopic complications (4.40% for group 1 vs 4.62% for group 2) and CBD stone clearance rate (96.7% for group 1 vs 96.9% for group 2). Duration of LC was 53.6 min in group 1 and 52.8 min in group 2. There were no significant differences in the overall LC-related morbidity and postoperative hospital stay.

**CONCLUSION:** Endoscopic stone extraction and LC performed during the same session was feasible and safe in patients with gallstones and concomitant CBD stones.

**Key words:** Cholecystectomy; Laparoscopic; Endoscopic; Therapy

**Core tip:** There is still controversy regarding the optimal therapeutic algorithm for patients with gallstones and concomitant common bile duct stones. Endoscopic retrograde cholangiopancreatography combined with laparoscopic cholecystectomy is an alternative technique. This study originated from a surgical team adept in the techniques of laparoscopy, duodenoscopy and choledochoscopy. The sample size in this study was larger than most current studies. We are confident that the outcomes from this study are more objective and helpful to the surgeons who manage gallstones and common bile duct stones during the same session.

Endoscopic retrograde cholangiopancreatography and laparoscopic cholecystectomy during the same session: Feasibility and safety. *World J Gastroenterol* 2013; 19(36): 6093-6097 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/6093.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.6093>

## INTRODUCTION

Approximately 5% to 15% of patients with gallstones have concomitant common bile duct (CBD) stones<sup>[1]</sup>. As the debate on the optimal choice for these patients is ongoing, surgeons are often bewildered by the variety of therapies which have emerged in the minimally invasive era. Laparoscopic cholecystectomy (LC) combined with endoscopic clearance of CBD stones is an appropriate option. Early LC after endoscopic CBD stone extraction is currently considered a good algorithm<sup>[2-5]</sup>. Reports of endoscopic stone extraction and LC being performed during the same session have continued to rise since LC became the standard procedure for cholecystectomy<sup>[6,7]</sup>. Many efforts have been made to develop this type of combination and the results are encouraging<sup>[8-15]</sup>.

If endoscopic stone extraction and LC are to be performed during the same session as routine practice, the feasibility and safety should be investigated objectively. In the present study, we compared this method with the current practice where LC is performed after endoscopic stone extraction. Our surgical team is adept in the techniques of laparoscopy duodenoscopy and choledochoscopy, and the indications for the use of these minimally invasive procedures were stricter and more objective. In addition, this study provided more details on the combination of laparoscopic and duodenoscopic therapy during the same session.

## MATERIALS AND METHODS

In this retrospective study, 156 patients with gallstones and CBD stones underwent endoscopic stone extraction and LC performed by the same surgical team at Taizhou People's Hospital (Taizhou, Jiangsu Province, China) between July 2010 and May 2013. The study was approved by our ethics committee, and written consent was obtained from each patient. After being informed about the related therapeutic maneuver, the patients chose the sequence of endoscopic procedure and LC. According to this sequence, the patients were classified into two groups: in group 1, patients underwent endoscopic stone extraction and LC during the same session, and in group 2, patients underwent LC at least 3 d after endoscopic stone extraction<sup>[5]</sup>. Dr. Zang JF, who has significant experience in manipulation of the duodenoscope, laparoscope and choledochoscope, performed all main endoscopic and laparoscopic procedures in this study.

In group 1, general anesthesia with intubation from mouth was chosen in all patients. The endoscopic retrograde cholangiopancreatography (ERCP) procedure was performed with the patients in the prone position. A duodenoscope (TJF160R, Olympus, Japan) was inserted into the duodenal second segment *via* the mouth. A cholangiogram was carried out using C-arm X-ray (BV-Libra, Philips) and an endoscopic sphincterotomy (EST) was performed to extract the CBD stones. The stones were removed by basket or balloon catheter. Stones larger than 10 mm were removed using a mechanical lithotripter. A

**Table 1 Characteristics of the patients**

Characteristic	Group 1 (n = 91)	Group 2 (n = 65)
Age (yr)	53.6 ± 8.7	55.3 ± 9.4
Sex (male/female)	32/59	17/48
ASA (I / II / III)	63/23/5	12/4/19/49
Diameter of CBD (mm)	10.5 ± 2.6	11.2 ± 2.7
Maximal diameter of CBD stone (mm)	6.4 ± 1.4	6.7 ± 1.3
Bilirubin (μmol/L)	37.3 ± 8.6	39.1 ± 9.2
Alanine aminotransferase (U/L)	127.2 ± 43.5	119.5 ± 47.8
Aspartate aminotransferase (U/L)	105.9 ± 32.7	109.8 ± 35.0
Gamma glutamyl transpeptidase (U/L)	224.3 ± 63.3	233.1 ± 65.1

CBD: Common bile duct; ASA: American Society of Anesthesiologists.

nasobiliary drain was inserted if there was a possibility of retained stones. This allowed sequential cholangiography and irrigation. Following ERCP, care was taken to remove all the gas from the stomach to facilitate LC. The patients were then placed in the reverse Trendelenburg position. LC was performed using the three trocar technique. A subhepatic drain was positioned if there was concern about the anatomy of the cystic duct and a danger of bleeding.

In group 2, patients underwent endoscopic stone extraction with general anesthesia by intubation. If there were no complications related to ERCP, LC was performed three d later. Otherwise, LC was delayed until the ERCP-related complications were successfully treated.

### Statistical analysis

Medical records, endoscopic and operative reports were reviewed. The statistical data were analyzed using *t* test, Pearson's  $\chi^2$  or Fisher's exact test. The results were analyzed using a statistical analysis program (SPSS 16.0). *P* < 0.05 was considered statistically significant.

## RESULTS

### Patients' characteristics

The characteristics of the two treatment groups, including main pre-operative biochemical data, are shown in Table 1. No significant differences were identified with respect to age, gender and other medical conditions.

### Outcomes of endoscopic procedures

During the same period, two patients undergoing ERCP in group 1 and one patient in group 2 converted to laparoscopic common bile duct exploration (LCBDE) due to unsuccessful bile duct cannulation. There was no significant difference in the success rate of endoscopic procedures (97.8% for group 1 *vs* 98.5% for group 2; Fisher's exact test *P* = 1.000). The mean duration of endoscopic procedures was 34.9 min in group 1 and 35.3 min in group 2. Pancreatitis was observed in 2 patients in each group. EST-related hemorrhage occurred in one patient in group 1 and one patient in group 2. One patient in group 1 experienced cholangitis. The total rates of endoscopic complications were 4.40% in group 1 and 4.62% in group

**Table 2** Outcomes of endoscopic procedures, laparoscopic cholecystectomy

	Group 1 (n = 91)	Group 2 (n = 65)
Endoscopic procedures		
Success rate	97.80%	98.50%
Time (min)	34.9 ± 10.9	35.3 ± 9.7
Complications	4.40%	4.62%
Pancreatitis (n)	2	2
Hemorrhage (n)	1	1
Cholangitis (n)	1	0
Nasobiliary drainage (n)	11	8
CBD stone clearance	96.70%	96.90%
Laparoscopic cholecystectomy		
Operation duration (min)	53.6 ± 12.1	52.8 ± 13.4
Subhepatic drainage (n)	6	5
Time to flatus (h)	17.5 ± 6.7	18.3 ± 7.1
Complications (n)

Total (P < 0.01)	5.32 ± 1.26	9.27 ± 1.31

CBD: Common bile duct.

2 (Fisher's exact test,  $P = 1.000$ ). CBD stone clearance rates (96.7% for group 1 *vs* 96.9% for group 2; Fisher's exact test  $P = 1.000$ ) were not significantly different. Complications of ERCP were treated conservatively. Outcomes of endoscopic procedures are shown in Table 2.

### Outcomes of laparoscopic cholecystectomy

Mortality was not observed in the treatment groups. Duration of surgery was 53.6 min in group 1 and 52.8 min in group 2 ( $P = 0.70$ ). The overall LC-related morbidity (including conversion) was 3/91 in group 1 and 2/65 in group 2 (Fisher's exact test,  $P = 1.000$ ). Bile duct injury was not observed in this study. The median time to flatus was 17.5 h in group 1 and 18.3 h in group 2 ( $P = 0.47$ ). There was no significant difference in postoperative hospital stay between the groups ( $P = 0.27$ ). The total length of hospital stay in group 1 was shorter than that in group 2 (5.32 ± 1.26 d in group 1 *vs* 9.27 ± 1.31 d in group 2,  $P < 0.001$ ). The outcomes of LC are shown in Table 2.

## DISCUSSION

As therapies for patients with gallstones and CBD stones are discussed in the current era of minimal invasion, biliary surgeons are required to master more techniques than ever before. Following the development of endoscopic techniques over the last three decades, these techniques have been confirmed as efficient and safe in the treatment of CBD stones. However, the diagnostic value of these methods in biliary diseases, especially benign diseases, has decreased markedly due to inherent invasion. Magnetic resonance cholangio pancreatography has gradually become an alternative and is considered to be a noninvasive diagnostic technique in biliary diseases<sup>[16-18]</sup>. ERCP combined with LC is widely used to treat gallstones with con-

comitant CBD stones. However, ERCP and LC are often performed by two separate surgical teams, which results in difficulties when these two procedures are carried out during the same session. In this study, ERCP and LC were performed by the same surgical team as a routine procedure. Therefore, the outcomes are more convincing and objective than many other reports<sup>[9,10]</sup>.

The feasibility of endoscopic CBD stone extraction and LC during the same session is a problem for surgeons. Although this protocol was proposed twenty years ago, only a few medical faculties have carried out this procedure. A likely reason for this is that there is no specific standard process to refer to. In addition, the technique is difficult, especially when choosing the patient's position in ERCP and managing distension of the intestine due to air insufflation. Initially, patients were placed in the supine position. However, three problems forced us to change this: difficulty in locating the endoscopic tip in the second portion of the duodenum, trouble with positioning the papilla correctly and repeated interference due to liquid in the duodenal cavity. In our view and that of ElGeidie<sup>[13]</sup>, the disadvantages of the supine position advocated by Terruzzi *et al*<sup>[19]</sup> may not be easily resolved due to the inherent anatomy of the papilla, which is located in the posterior medial duodenal wall. In comparison with the supine position, the prone position is our favored position which is optimal for cannulation of the papilla and obtaining good-quality radiographic images. Furthermore, the prone position provides a natural pressure due to the weight of the abdomen, restricting distension of the intestine. General anesthesia with tracheal intubation can reduce patients' discomfort and make airway management easier. The only problem with the prone position was that it took operators a few minutes to change the patient's position twice. In addition, we insufflated the least amount of air during ERCP and suctioned the duodenal and gastric cavity thoroughly at the end of ERCP. It is also important that endoscopists control the time of ERCP by prudent preoperative evaluation and exact intraoperative judgment, including optimal timing of conversion therapy. We selected patients in whom the maximal diameter of stones was less than 15 mm. Thus, the average duration of our endoscopic procedure was approximately 35 min. Using this protocol, ERCP was not an obstacle to subsequent LC if more attention was paid to the choice of patients and manipulation of ERCP.

The safety of the combination of laparoscopic and endoscopic techniques during the same session is also a focus of concern for surgeons. Currently, morbidity and mortality in endoscopic and laparoscopic procedures are very low with skilled operators. There are no disputes when LC and endoscopic CBD stone extraction are discussed. In the present study, there were no differences in complication rates and patients' recovery between the two treatment groups, which demonstrated that this combination was safe. In order to reduce ERCP-related complications, many authors have used the laparo-endo-

scopic rendezvous technique which was considered helpful in cannulation of the bile duct and preventing post-ERCP pancreatitis<sup>[10,11,15]</sup>. However, this technique failed as the endoscopist performed ERCP with the patient in the supine position and the guidewire was unable to pass through the cystic duct. As proficient endoscopists, we regard the rendezvous technique as a transitional method and not the ultimate method. With the help of a guidewire and needle-knife, the overall success of bile duct cannulation was 97% and the mean time to bile duct access was 10 min according to our records. The rate of post-ERCP pancreatitis, which was mild in most patients, was 4% in our hospital. Direct ERCP during surgery is more likely to become the mainstream maneuver rather than the rendezvous technique. LC with endoscopic stone extraction during the same session could be considered a safe procedure as the rate of LC-related complications, including bile duct injury and conversion, was low in our hospital. This was consistent with our previous results which showed that the earlier LC is performed after the endoscopic procedure, the better the outcome will be<sup>[5]</sup>.

With regard to same-session surgery for patients with concomitant gallstones and choledocholithiasis, laparoscopic common bile duct exploration (LCBDE) is another good choice rather than the combination of duodenoscopy and laparoscopy. These techniques have similar primary ductal clearance rates and morbidity<sup>[20,21]</sup>. Some studies have shown that LCBDE is more cost-effective<sup>[21,22]</sup> and more beneficial in the preservation of papillary function than ERCP, although suffering due to T-tube placement is a major disadvantage. Difficulties in LCBDE include extraction of the CBD stone and suturing of the CBD incision. With regard to the indications for LCBDE and endoscopic stone extraction, a clear consensus has emerged although different surgeons have different opinions. A CBD with a diameter smaller than 8 mm is regarded as a contraindication to LCBDE. Similarly, large stones may be a barrier to duodenoscopy. Although endoscopic extraction of large stones (even 25 mm) has been reported, we prefer to perform LCBDE in these cases (stone diameter  $\geq$  15 mm). Laser lithotripsy by choledochoscope in LCBDE may be more direct and easier for the management of large stones. For patients who were fit for both procedures, the final choice involved many aspects: patients' desire, hospital resources, and surgeons' technique. The long-term effects of endoscopic sphincterotomy include recurrent stones, cholangitis, and cholangiocarcinoma, however, current evidence may partly dispel these associations<sup>[23,24]</sup>.

In conclusion, endoscopic stone extraction and LC performed during the same session is feasible and safe in patients with gallstones and concomitant CBD stones. We propose that surgeons mastering endoscopic and laparoscopic techniques may attempt this procedure. More objective studies including a comparison of this modality and LCBDE, especially the long-term effects, are urgently needed.

## COMMENTS

### Background

Approximately 5% to 15% of patients with gallstones have concomitant common bile duct stones. The debate on the optimal treatment choice for these patients is ongoing, and surgeons are often bewildered by the variety of therapies emerging in the minimally invasive era. Endoscopic retrograde cholangiopancreatography (ERCP) and laparoscopic cholecystectomy (LC) performed during the same session have been reported in many studies with encouraging results. However, most available data have come from surgeons who have usually mastered one technique either ERCP or LC. Available studies on this combined therapeutic modality included small sample sizes.

### Research frontiers

Reports on endoscopic stone extraction and LC performed during the same session have continued to increase since LC became the standard procedure for cholecystectomy. If endoscopic stone extraction and LC are to be performed during the same session as routine practice, the feasibility and safety should be investigated. Although this protocol was proposed twenty years ago, no specific standard practice has been established. Morbidity and mortality in both endoscopic and laparoscopic procedures are very low with skilled operators. The safety of combining laparoscopic and endoscopic techniques during the same session should be evaluated before it becomes a routine procedure.

### Innovations and breakthroughs

This method was compared with the method used in current practice, laparoscopic cholecystectomy after endoscopic stone extraction. Their surgical team is adept in the techniques of laparoscopy, duodenoscopy and choledochoscopy, and the indications for use of these minimally invasive procedures are stricter and more objective. In addition, this study provided more details on the combination of laparoscopic and duodenoscopic therapy during the same session.

### Applications

The outcomes of this study are more objective for evaluating the effect of ERCP/LC on gallstones and concomitant common bile duct (CBD) stones. Also, it offers surgeons more choice when they want to manage gallstones and CBD stones during the same session.

### Peer review

ERCP and LC performed during the same session is a good choice for patients with gallstones and concomitant CBD stones. This study originated from a surgical team, which is adept in the techniques of laparoscopy, duodenoscopy and choledochoscopy. It is helpful for surgeons to manage gallstones and common bile duct stones during the same session.

### Abstract

**AIM:** To clarify the association between *Helicobacter pylori* (*H. pylori*) infection and the risk of esophageal carcinoma through a meta-analysis of published data.

**METHODS:** Studies which reported the association between *H. pylori* infection and esophageal cancer published up to June 2013 were included. The odds ratios (ORs) and corresponding 95%CIs of *H. pylori*

infection on esophageal cancer with respect to health control groups were evaluated. Data were extracted independently by two investigators and discrepancies were resolved by discussion with a third investigator. The statistical software, STATA (version 12.0), was applied to investigate heterogeneity among individual studies and to summarize the studies. A meta-analysis was performed using a fixed-effect or random-effect method, depending on the absence or presence of significant heterogeneity.

**RESULTS:** No significant association between *H. pylori* infection and esophageal squamous cell carcinoma (ESCC) risk was found in the pooled overall population (OR = 0.97, 95%CI: 0.76-1.24). However, significant associations between *H. pylori* infection and ESCC risk were found in Eastern subjects (OR = 0.66, 95%CI: 0.43-0.89). Similarly, cytotoxin-associated gene-A (CagA) positive strains of infection may decrease the risk of ESCC in Eastern subjects (OR = 0.77, 95%CI: 0.65-0.92), however, these associations were not statistically significant in Western subjects (OR = 1.26, 95%CI: 0.97-1.63). For esophageal adenocarcinoma (EAC) the summary OR for *H. pylori* infection and CagA positive strains of infection were 0.59 (95%CI: 0.51-0.68) and 0.56 (95%CI: 0.45-0.70), respectively.

**CONCLUSION:** *H. pylori* infection is associated with a decreased risk of ESCC in Eastern populations and a decreased risk of EAC in the overall population.

**Key words:** *Helicobacter pylori*; Esophageal carcinoma; Cancer risk; Meta-analysis

**Core tip:** Based on this meta-analysis, we found that *Helicobacter pylori* infection may have a protective effect against esophageal squamous cell carcinoma in

Eastern populations and against esophageal adenocarcinoma in the overall population.

## INTRODUCTION

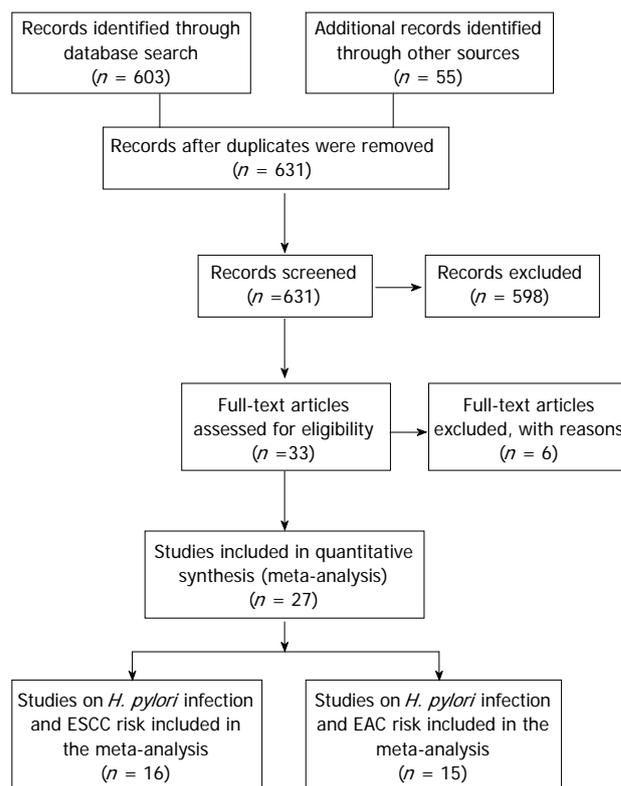

Esophageal cancer (EC), which mainly consists of esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC), is the eighth most common cancer worldwide, with 481645 new cases in 2008, and is the sixth leading cause of cancer death, with 406533 deaths<sup>[1]</sup>. Despite advances in the molecular mechanism of carcinogenesis, the etiology of this malignancy remains unclear. A better understanding of the influencing factors and underlying mechanisms involved in EC development and progression will provide appropriate targets for the development of effective strategies for the prevention of this prevalent malignancy.

*Helicobacter pylori* (*H. pylori*) is a helical-shaped Gram-negative bacterium and has been identified as the major causative agent of various benign and malignant gastrointestinal tract diseases<sup>[2]</sup>. A study showed that cytotoxin-associated gene-A (CagA)-positive strains conferred a greater risk than CagA-negative strains<sup>[3]</sup>. Islami *et al*<sup>[4]</sup> carried out an excellent meta-analysis and reported an inverse association between CagA-positive *H. pylori* colonization and the risk of EAC, but not ESCC. However, recent studies reported inconclusive results, and some showed the reverse relationship between *H. pylori* and ESCC<sup>[5,6]</sup>. Therefore, an updated meta-analysis was performed which included all eligible studies to evaluate the association between *H. pylori* infection and EC risk.

## MATERIALS AND METHODS

### Search strategy

To identify all articles that examined the association between *H. pylori* infection and esophageal carcinoma, we conducted a literature search in the PubMed databases up to April 2013 using the following MeSH terms and keywords: “*Helicobacter pylori*” [MeSH] OR (*Campylobacter pylori*) OR (*H. pylori*) OR (*H. pylori*) AND (“Esophageal Neoplasms” [MeSH] OR (Cancer of Esophagus) OR (Cancer of the Esophagus) OR (Esophageal Cancer) OR (Esophagus Cancer) OR (Esophagus Neoplasm) OR (Neoplasms, Esophageal)). Additional studies were identified by a hand search from references of original studies or review articles on this topic. Two authors reviewed the search results to reduce the possibility of missing relevant published papers. Where data were missing, we contacted the authors for the

**Figure 1** Flow diagram of study identification. ESCC: Esophageal squamous cell carcinoma; EAC: Esophageal adenocarcinoma; *H. pylori*: *Helicobacter pylori*.

relevant information. Eligible studies included in this meta-analysis had to meet the following criteria: (1) Articles should clearly describe studies on the association between *H. pylori* infection and esophageal cancer risk; and (2) The esophageal cancer diagnoses and the sources of cases and controls should be stated. The literature excluded in this study was mainly due to the following reasons: lacking a normal control group, reviews, the research design being not scientific and reasonable, and including repeated data. A total of 27 publications met the eligibility criteria and were included in the present study<sup>[5-31]</sup>.

### Data extraction

The following data from each article were extracted: authors, year of publication, country of participants, study design, source of controls, number of controls and of cases, *H. pylori* detection method, and *H. pylori* infection status. The data were extracted and registered in two databases independently by two investigators (Zheng QQ and Wang FL) who were blind to journal names, institutions and funding grants. Any discrepancy between these two investigators was resolved by a third investigator (Xie FJ), who participated in the discussion and made the ultimate decision. Equivocal or missed data were excluded in order to unify the formation of the information<sup>[11,23]</sup>. One article was used as a partial adjusted value, due to crude data<sup>[10]</sup>, and 2 articles that were included totally or partially in another article<sup>[32,33]</sup>.

<sup>1</sup>*Helicobacter pylori* (*H. pylori*) positivity definition; <sup>2</sup>Because the article showed that there was no difference in age and gender between cases and health controls, this study was analyzed as a matched population study; <sup>3</sup>Individual-matching of controls to cases for age and gender/reporting adjusted ORs for the association between *H. pylori* and cancer. Clin: Clinical based; Pop: Population based; NR: Not reported; Hp Dm: Hp detection method; S: Serology; H: Histology; U: Rapid urease test; His<sup>+</sup>: Positive histological examination of tissue samples; HpSe<sup>+</sup>: Sero-positivity for antibodies to whole-cell; VacA<sup>+</sup>: Sero-positivity for antibodies to VacA; CagA<sup>+</sup>: Sero-positivity for antibodies to cytotoxin-associated gene-A; U<sup>+</sup>: Positive rapid urease test; GERD: Gastroesophageal reflux disease; ESCC: Esophageal squamous cell carcinoma; EAC: Esophageal adenocarcinoma; GI: Gastrointestinal.

### Statistical analysis

The dichotomous data on *H. pylori* positive results in the EC group and control group were summarized. OR and 95%CI of OR were calculated to assess the association between *H. pylori* infection and EC risk. If the *H. pylori* data were not shown in the article, the OR and 95%CI: value were extracted. An analysis of the heterogeneity of the studies was performed using the  $\chi^2$ -based *Q* test. A *P* value less than 0.05 was considered significant for heterogeneity. If the studies were shown to be homogeneous with *P* > 0.05 for the *Q*-statistics, the summary of OR was calculated by a fixed-effects model (the Mantel-Haenszel method), otherwise, the random-effects model (the DerSimonian and Laird method) was used. The potential publication bias was assessed graphically using Begg's test and funnel plots. All analyses were performed with STATA software (version 12.0; Stata Corp LP, College Station, TX, United States), using two-sided *P* values.

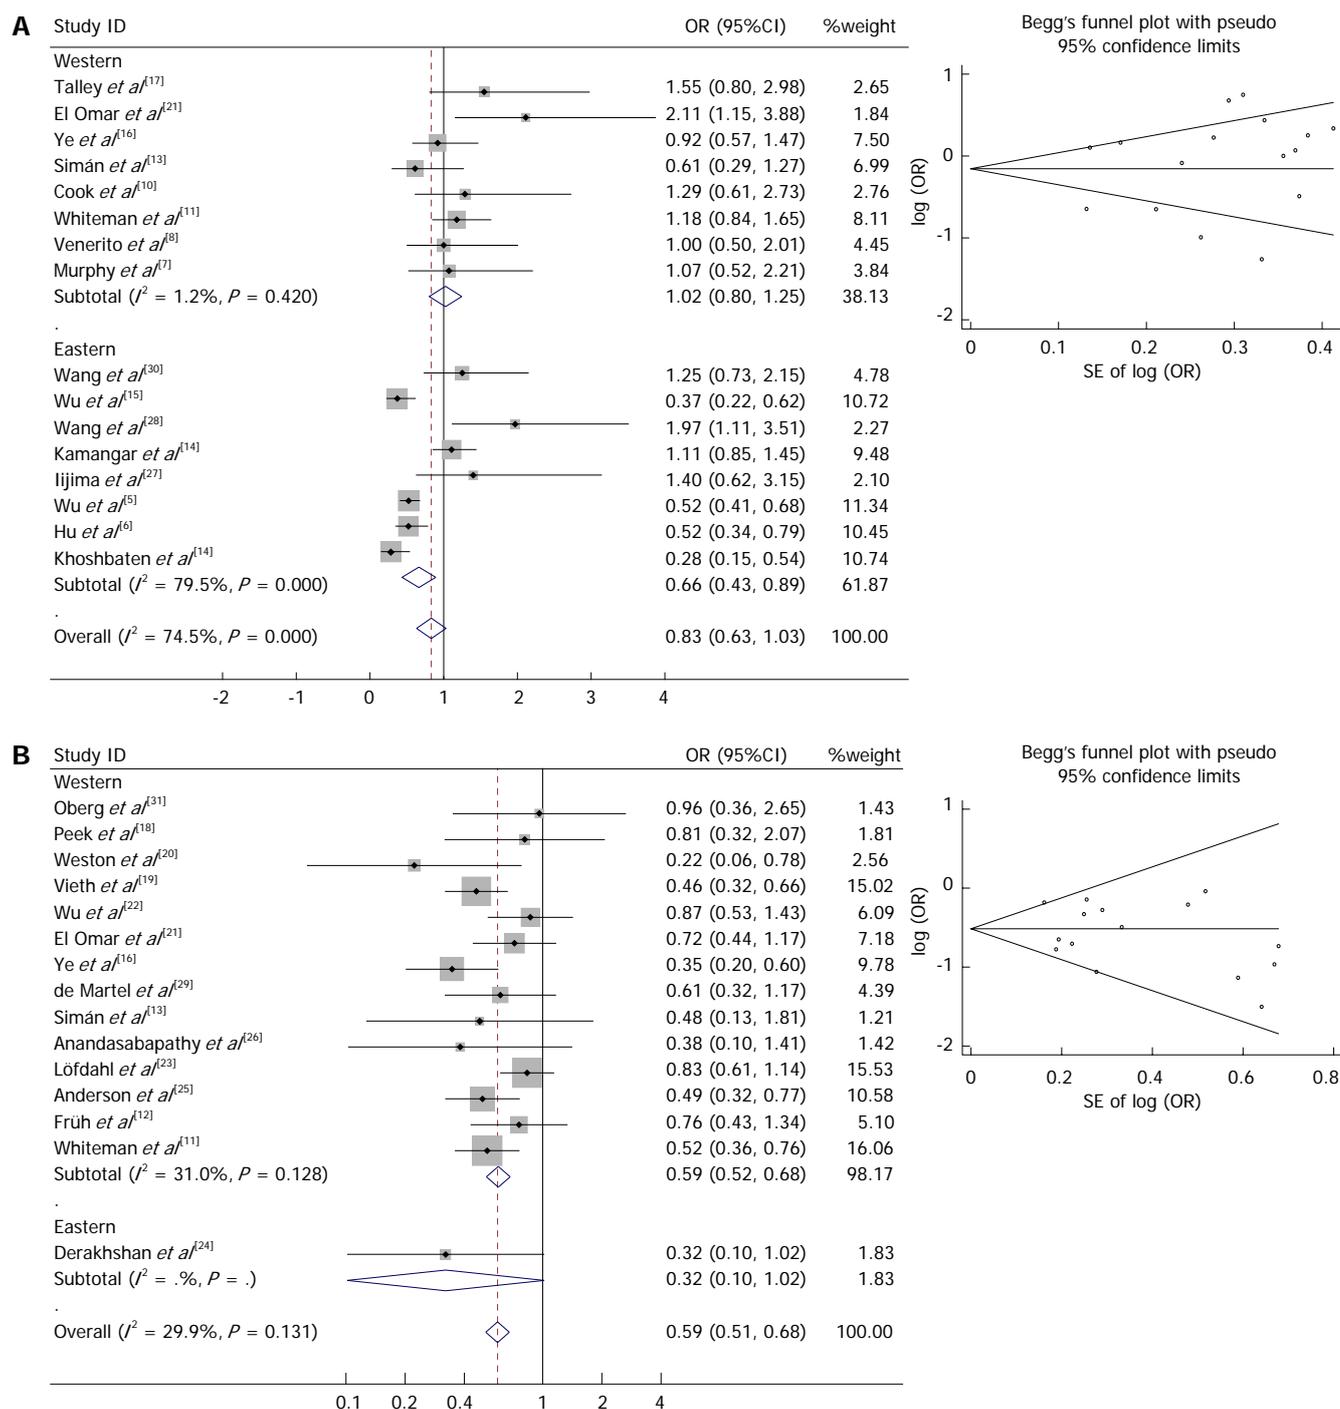

## RESULTS

### Eligible studies

Twenty-seven eligible studies on *H. pylori* infection and esophageal cancer were identified through the literature search and selection based on the inclusion and exclusion criteria (Figure 1). The year of publication for these studies ranged from 1991 to 2012. There were 18 studies on Western (Finland, Germany and Ireland) populations and 9 studies on Eastern (Iran and China) populations. With respect to study type, 17 studies were population-based, 10 studies were hospital-based and one study did not specify. Adjusted ORs with corresponding 95%CIs were reported in 17 studies. The selected study characteristics are summarized in Table 1.

### Test of heterogeneity

We analyzed the heterogeneity of all 16 studies on ESCC and the fifteen studies on EAC, respectively. For *H. pylori* infection in the ESCC risk study, the *Q* statistic was significant (*P* < 0.01) and the *I*<sup>2</sup> statistic showed a high variation (*I*<sup>2</sup> = 74.5%) among the study results, thus a random-effect model was used for further analysis (Figure 2A and Table 2). In the EAC study, no significant heterogeneity was observed in the overall comparison (*I*<sup>2</sup> = 29.9%, *P*<sub>heterogeneity</sub> = 0.131), and a fixed-effect model was used to calculate the overall ORs (Figure 2B and Table 2).

**Figure 2** Forest plot and Begg's funnel plot of the association between *Helicobacter pylori* infection and esophageal carcinoma. Studies are sorted in order of publication year. A: Esophageal squamous cell carcinoma (random-effect model); B: Esophageal adenocarcinoma (fixed-effect model).

***H. pylori* infection and ESCC risk**

The association between *H. pylori* infection and ESCC risk is shown in Figure 2A and Table 2. With the exception of the clinical-based Western studies, CagA<sup>+</sup> strains in the Eastern and Western studies did not show obvious heterogeneity calculated using the fixed-effect model. The remaining results were significantly heterogeneous ( $P < 0.01$ ) calculated using the random-effect model.

In the random-effects model, no statistically significant factor influenced the risk of ESCC in the presence

of *H. pylori* infection (OR = 0.83, 95%CI: 0.63-1.03). When population-based studies were analyzed alone, the combined OR for the association between *H. pylori* infection and ESCC risk was 2.86 (95%CI: 1.60-5.11). When clinical-based studies were analyzed alone, the combined OR for *H. pylori* infection was 1.49 (95%CI: 0.66-2.31). When stratified by study location, there was a statistically significant decrease in ESCC risk in the Eastern population (OR = 0.66, 95%CI: 0.43-0.89), however, we did not find a significant association in the Western popula-

**Table 2** Meta-analysis of the *Helicobacter pylori* infection on the risk of esophageal squamous cell carcinoma and esophageal adenocarcinoma

	Studies	<i>P</i> <sup>1</sup>	<i>I</i> <sup>2,2</sup>	Overall OR (95%CI)
Esophageal squamous cell carcinoma				
Case/control (1961/5704)				
All studies	16	< 0.01	74.50%	0.83 (0.63, 1.03)
Population-based studies	14	< 0.01	76.00%	0.79 (0.59, 1.00)
Clinical-based studies	2	0.86	< 0.01	1.49 (0.66, 2.31)
Eastern studies	8	< 0.01	79.50%	0.66 (0.43, 0.89)

Western studies	6	0.39	3.60%	1.26 (0.97, 1.63) <sup>3</sup>
Esophageal adenocarcinoma				
Case/control (1330/4705)				
All studies	15	0.131	29.9	0.59 (0.51, 0.68)
Population-based studies	8	0.106	40.9	0.62 (0.52, 0.73)
Clinical-based studies	7	0.319	14.5	0.53 (0.40, 0.68)
Eastern study	1	-	-	-
Western studies	14	0.128	31	0.60 (0.52, 0.68)
Studies with matched controls	10	0.139	33.6	0.62 (0.53, 0.72)
Studies without matched controls	5	0.333	12.7	0.49 (0.36, 0.66)
<i>Hp</i> <sup>+</sup> definition as <i>HpSe</i> <sup>+</sup>	8	0.299	16.6	0.55 (0.45, 0.66)
<i>Hp</i> <sup>+</sup> definition as <i>His</i> <sup>+</sup>	4	0.334	11.7	0.46 (0.33, 0.64)
Adjusted results	8	0.200	28.6	0.51 (0.40, 0.61)
<i>CagA</i> <sup>+</sup> vs <i>Hp</i> <sup>-</sup>	8	0.11	39.9	0.56 (0.45, 0.70)
Eastern study	0	-	-	-
Western studies	8	0.11	39.9	0.56 (0.45, 0.70)

<sup>1</sup>*P* value for *Q* statistical in random effects model; <sup>2</sup>Higgins *I*<sup>2</sup> statistic for heterogeneity in random effects model; <sup>3</sup>The overall value synthesized by fixed effects model. *HpSe*<sup>+</sup>: Sero-positivity for antibodies to whole-cell; *CagA*<sup>+</sup>: Sero-positivity for antibodies to cytotoxin-associated gene-A.

tion (OR = 1.02, 95%CI: 0.80-1.24). In the sub-group analyses of “*Hp*<sup>+</sup> only definition as *HpSe*<sup>+</sup>”, “studies with matched controls”, “studies without matched controls” no significant correlation between *H. pylori* infection and ESCC risk was found.

As studies have indicated that individuals infected with *CagA*-positive *H. pylori* strains have a higher risk of developing peptic ulcers and gastric cancer compared to those harboring *CagA*-negative *H. pylori* strains<sup>[34,35]</sup>, the association between *CagA*<sup>+</sup> stains and ESCC was also evaluated (Figure 3A). The overall OR was 0.97 (95%CI: 0.76-1.24) and showed high heterogeneity among the studies (*I*<sup>2</sup> = 52.0%, *P*<sub>heterogeneity</sub> = 0.03). This high heterogeneity may be caused partly by regional or ethnic differences, as heterogeneity values may weaken during location subgroup analysis. Similarly, *CagA*<sup>+</sup> strains of infection may decrease the risk of ESCC in Eastern subjects (OR = 0.77, 95%CI: 0.65-0.92), but not in Western subjects (OR = 1.26, 95%CI: 0.97-1.63) or the overall population (OR = 0.90, 95%CI: 0.78-1.05).

### *H. pylori* infection reduced the risk of EAC

Forest plot analyses are shown in Figure 2B. The overall positive rate of *H. pylori* infection in EAC was 35.96% (479/1332), which was significantly lower than that in normal controls 44.00% (2070/4705; OR = 0.71,

95%CI: 0.63-0.81). Quantitative meta-analyses showed that, compared with the control group, the combined OR of EAC in the presence of *H. pylori* infection was 0.59 (95%CI: 0.51-0.68). Table 2 also shows the results of subgroup analyses. The summary OR (95%CI) for clinical-based and population-based studies were 0.62 (95%CI: 0.52-0.73) and 0.53 (95%CI: 0.40-0.68), respectively. In the sub-group analyses of “Western studies”, “studies with matched controls”, “studies without matched controls”, “*Hp*<sup>+</sup> definition as *HpSe*<sup>+</sup>” and “adjusted results”, *H. pylori* infection was also inversely associated with EAC risk. Furthermore, compared with the *Hp*-population, *CagA*<sup>+</sup> strains of *H. pylori* also played a protective role in EAC carcinogenesis (OR = 0.56, 95%CI: 0.45-0.70, Figure 3B). However, only one study focused on the Eastern population and the OR was 0.32 (95%CI: 0.10-1.02).

### Sensitivity analysis and publication bias

Sensitivity analysis was performed to assess the influence of each individual study on the pooled ORs by omitting a single study each time, and no substantial change in the corresponding pooled OR (data not shown) was observed. Begg's funnel plot and Egger's test were performed to assess publication bias. Begg's funnel plots were symmetrical (Figure 2), and the *P* values for ESCC

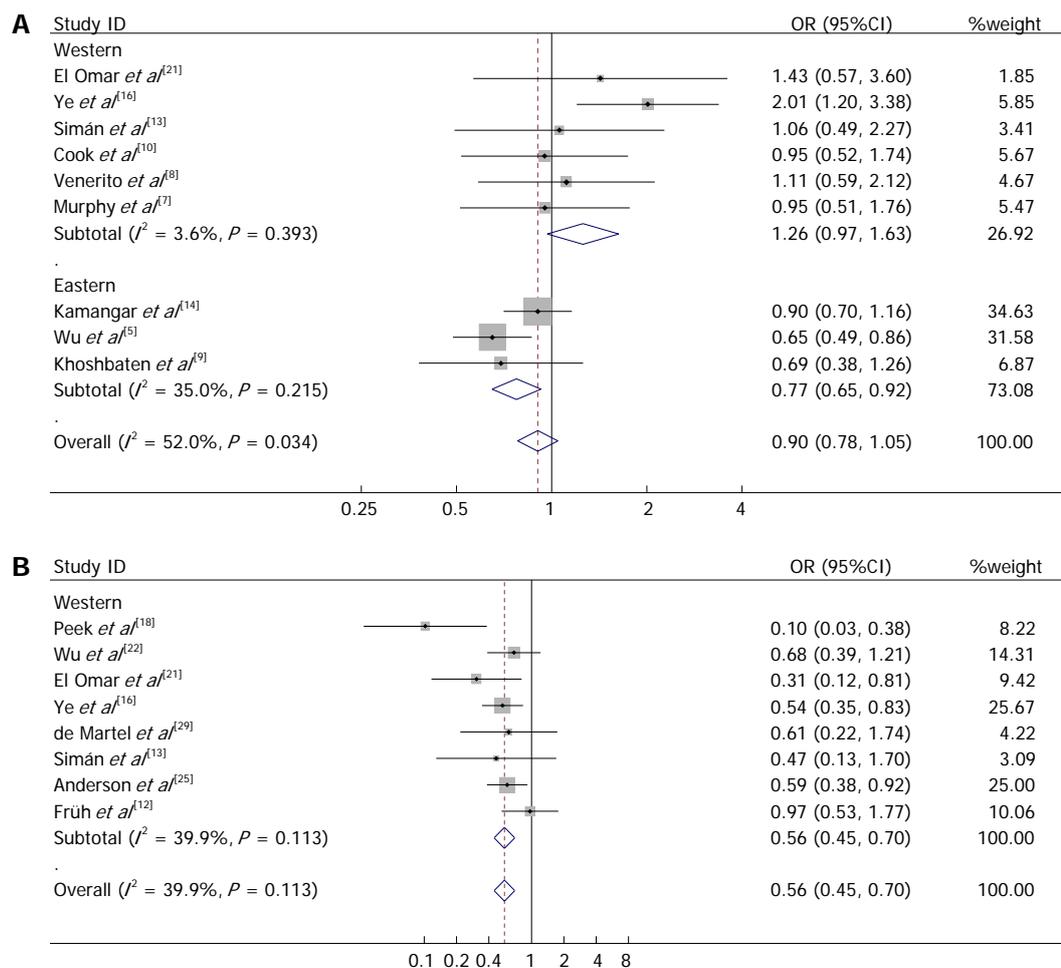

Figure 3 Meta-analysis with a fixed-effect model for the association between cytotoxin-associated gene-A-positive *Helicobacter pylori* infection and esophageal cancer. A: Esophageal squamous cell carcinoma (random-effect model); B: Esophageal adenocarcinoma (fixed-effect model).

and EAC were 0.753 and 0.621, respectively. The statistical results still did not show publication bias using Egger's test, and the *P* values for ESCC and EAC were 0.424 and 0.371, respectively. Therefore, there was no significant publication bias in the eligible studies.

## DISCUSSION

In the present study, we collected all available, published studies and performed a meta-analysis to examine the association between *H. pylori* infection and the risk of esophageal cancer. Twenty-seven studies were critically reviewed to clarify the controversial results from previous reports. Our meta-analysis showed that *H. pylori* infection significantly decreased the risk of EAC in Western populations. In terms of ESCC risk, no significant association was found when the Eastern and Western populations were pooled. In the stratified analysis of study location, no significant association between *H. pylori* infection and ESCC risk in Western subjects was found. However, we observed a significant association between *H. pylori* infection and decreased risk of ESCC in East Asian populations.

There are several explanations for this phenomenon.

There are fundamental differences in the carcinogenesis pathways between ESCC and EAC. Possible risk factors for ESCC include cigarette smoking, alcohol consumption, hot-temperature food, low intake of vegetables, salty food, pickled vegetables, nutrient deficiency, chronic mucosal irritation and a family history of cancer<sup>[36,37]</sup>, while EAC is closely related to Barrett's esophagus<sup>[38,39]</sup>. Genetic differences between ethnic groups may also induce diverse effects. For example, Umar *et al*<sup>[40]</sup> conducted a meta-analysis which showed that the PLCE1 polymorphism conferred significant risk for gastric and esophageal tumors in Asians (Chinese), but not in Caucasians. In Eastern populations, the incidence rates of EAC are generally higher in urban areas, where diet and lifestyle are similar to those in Western counties. Therefore, nutritional intake and lifestyle combined with *H. pylori* infection may have parallel effects in Eastern and Western populations<sup>[41,42]</sup>. In contrast, ESCC patients were mainly found in areas of Eastern developing countries, where nutrient absence and hot beverage intake are more universal than in Western populations. These different factors may influence the protective effect of *H. pylori* infection. Genetic factors, tumor biological characteristics and their complicated interactions with environmental factors may modulate risk

in ESCC.

Our study also showed that *H. pylori* infection is a strong protective factor against EAC, which is highly consistent with previous reports<sup>[4,43]</sup>. The underlying mechanism whereby *H. pylori* infection protects the esophagus has not been fully elucidated. *H. pylori* infection-related gastritis may result in lower gastric acid secretion<sup>[44]</sup>. Hypoacidity induced by atrophic gastritis has been proffered as one reason for this inverse association with EC. *H. pylori* infection reduced ghrelin synthesis in infected persons, which induced early satiety thereby preventing obesity and rapid gastric emptying, thus reducing the likelihood of gastroesophageal reflux, which may explain this protective effect<sup>[45]</sup>.

Two other meta-analyses have summarized the relationship between *H. pylori* infection and EC risk<sup>[4,43]</sup>. The advantages of our meta-analysis are as follows: Compared with the previous two meta-analyses, the present study was much larger, with more than twice as many cancer cases as the earlier studies. In addition, several subgroup analyses were conducted to identify potential sources of heterogeneity. Secondly, according to our selection criteria, all the studies in our meta-analysis had acceptable quality and the cases and controls were collated from all included studies, which significantly increased the statistical power. Thirdly, our study suggested that *H. pylori* infection decreased the risk of ESCC. This study should be repeated which could be beneficial in detecting novel mechanisms to reduce the risk of EC. We also found that our study had several limitations. Heterogeneity for the ORs in ESCC was observed among the studies. This heterogeneity may be due to various factors, such as diversity in the population characteristics, differences in the number of cases and controls, *H. pylori* detection methods and study design. However, heterogeneity was eliminated in the Western population after stratifying by ethnicity. The variables used to adjust these values were not consistent across the studies, which may limit the reliability of the data. Too few studies were identified to allow for subgroup analysis by covariates. Subgroup analyses regarding other confounding factors such as age and gender were conducted in the present study, but did not reduce the heterogeneity in the Eastern population. Only one study focused on the relationship between *H. pylori* infection and EAC risk in Eastern subjects (OR = 0.32, 95%CI: 0.10-1.02) which was not statistically significant ( $P = 0.05$ ). Further studies are required to confirm the protective role of *H. pylori*.

In conclusion, despite these limitations, our meta-analysis indicated that *H. pylori* infection may contribute to the decreased risk of EAC in the overall population and of ESCC in the Eastern population. To confirm our findings, further well-designed studies with large sample size and standardized laboratory methods in diverse ethnic populations should be performed to validate this association. The potential molecular mechanism of these protective effects should also be clarified to reduce the high morbidity caused by this malignancy.

## COMMENTS

### Background

Esophageal cancer is one of the most deadly malignancies. Many studies have explored the association between *Helicobacter pylori* (*H. pylori*) infection and esophageal cancer risk. However, the results were inconclusive and even controversial. Therefore, it is necessary to perform a meta-analysis in order to obtain a more precise evaluation of the relationship between *H. pylori* infection and esophageal cancer risk.

### Research frontiers

*H. pylori* has been identified as a pathogen in gastric cancers. To date, there have been many case-control studies on the association between *H. pylori* infection and esophageal cancer risk, but few meta-analyses have been conducted on this topic.

### Innovations and breakthroughs

This meta-analysis indicated that *H. pylori* infection might play a protective in esophageal squamous cell carcinoma (ESCC) risk in Eastern populations and in esophageal adenocarcinoma (EAC) risk in the overall population. Further studies are required to confirm these findings.

### Applications

*H. pylori* infection is inversely associated with ESCC risk in Eastern populations and with EAC risk in the overall population. This meta-analysis provided a structured and systematic integration of information on the etiology of esophageal cancer, and the results may provide valuable information for researchers and clinicians.

### Terminology

In cytotoxin-associated gene-A (CagA) positive strains of *H. pylori* the genome contains the cag pathogenicity island. This island includes approximately 31 putative genes, including CagA the gene that encodes the CagA protein strains that translocate the CagA protein into host cells and are significantly more likely to cause gastric cancer and other gastric diseases than CagA-negative strains.

### Peer review

These researchers performed a meta-analysis to clarify the association between *H. pylori* infection and development of esophageal carcinoma. The results are very important and create other questions in mind that lead to further studies.

metal stent; Endoscopic retrograde cholangiopancreatography; Biliary stricture; Jaundice

**Core tip:** Inability to retrieve a fully covered biliary self-expanding metal stent (SEMS) due to potential fixation of the stent to the duct wall can be addressed by the insertion of a second SEMS within the existing one, which facilitates the release of the initial SEMS.

Menon S. Removal of an embedded "covered" biliary stent by the "stent-in-stent" technique. *World J Gastroenterol* 2013; 19(36): 6108-6109 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/6108.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.6108>

### Abstract

A 46-year-old man was admitted with obstructive jaundice and cross-sectional imaging with computed tomography suggested distal biliary obstruction. A distal common bile duct stricture was found at endoscopic retrograde cholangiopancreatography (ERCP) and cytology was benign. A 6 cm fully covered self-expanding metal stent (SEMS) was inserted across the stricture to optimize biliary drainage. However, the SEMS could not be removed at repeat ERCP a few months later. A further fully covered SEMS was inserted within the existing stent to enable extraction and both stents were retrieved successfully a few weeks later. Fully covered biliary (SEMS) are used to treat benign biliary strictures. This is the first reported case of inability to remove a fully-covered biliary SEMS. Possible reasons for this include tissue hyperplasia and consequent overgrowth into the stent proximally, or chemical or mechanical damage to the polymer covering of the stent. Application of the stent-in-stent technique allowed successful retrieval of the initial stent.

**Key words:** Self-expanding metal stent; Self expanding

### INTRODUCTION

The endoscopic management of benign biliary strictures has been transformed by the advent of removable fully covered metal stents. We report a case in which a fully covered biliary stent could not be removed endoscopically initially.

### CASE REPORT

A 46-year-old man was admitted with abdominal pain and obstructive jaundice [Bilirubin 14 mg/dL, Alanine aminotransferase (ALT) 123 IU/L, Alkaline phosphatase (ALP) 640 IU/L and a raised Amylase 350 U/L]. Cross-sectional imaging with computed tomography confirmed an enlarged and markedly calcified head of pancreas (Figure 1). Endoscopic retrograde cholangiopancreatography (ERCP) revealed a 2.5 cm distal common bile duct (CBD) stricture with proximal biliary dilatation. A 6 cm fully covered self-expanding metal stent (SEMS) (Wallflex, Boston Scientific, Boston, MA, United States) was inserted across the stricture. Cytology from the stricture was

Figure 1 Cholangiogram outlining a distal biliary stricture (arrow).

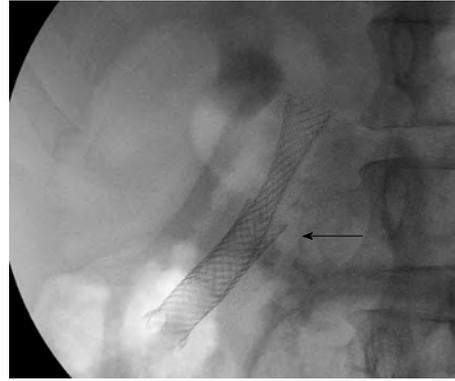

Figure 2 Second covered stent deployed over existing stent (arrow).

benign. At repeat ERCP 5 mo later, the SEMS could not be removed endoscopically with suggestion of the stent having embedded into the bile duct wall. Mild residual stricturing was noted at the apex of the SEMS. Further dilatation of the stricture was carried out to 10 mm and an in-stent dilatation was carried out to 12 mm to release the stent from the duct wall without success. At further ERCP in the next few weeks, a second 6 cm fully covered SEMS was inserted across the existing stent (Figure 2). Six weeks later, both stents were removed easily. Cholangiography suggested complete resolution of the original stricture. Examination of the initially inserted stent suggested possible damage to the silicone polymer stent covering (Figure 3) and is subject to further investigation.

## DISCUSSION

Embedded SEMS in the esophagus can be removed by inserting a fully covered SEMS within the SEMS, which causes pressure necrosis of tissue across the uncovered portion of the embedded SEMS, thereby facilitating its removal<sup>[1]</sup>. This technique has been used previously for removing uncovered biliary SEMS<sup>[2,3]</sup>.

Fully covered biliary (SEMS) are used widely to treat benign biliary strictures. This is the first reported case of inability to remove a fully-covered biliary SEMS. Possible reasons for this include tissue hyperplasia and consequent overgrowth into the stent proximally, or chemical or mechanical damage to the polymer covering of the stent. Application of the stent-in-stent technique allowed successful retrieval of the initial stent.

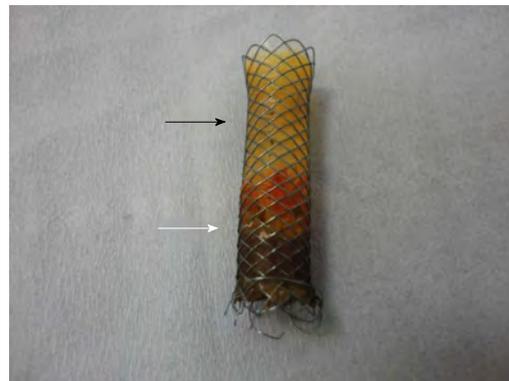

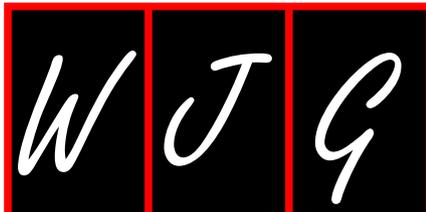

Figure 3 Covered stent after extraction. The white arrow indicates its duodenal end. There is evidence of damage to the polymer covering of the stent (black arrow).

### Abstract

Hepatic vein stenosis is a rare but serious complication following liver transplantation. Multiple modalities can be utilized to image the hepatic vasculature. Magnetic resonance venography (MRV) provides certain advantages over ultrasound, computed tomography angiography and digital subtraction venography. MRV utilizes the same imaging principles of magnetic resonance angiography in order to image the venous system. Blood pool contrast agents, specifically gadofosveset trisodium, allow for steady state imaging up to 1 h following injection, with improved visualisation of vital venous structures by utilising delayed steady state imaging. Additionally, the inherent physics properties of magnetic resonance imaging also provide excellent soft tissue detail and thus help define the extent of complications that often plague the post-liver transplant patient. This case report describes the use of gadofosveset trisodium

### INTRODUCTION

The inherent physics principles of magnetic resonance imaging (MRI) make it extremely sensitive to blood flow. MRI investigations of blood flow have been targeted at investigation of the arterial system; the same principles can be applied to the venous system for the diagnosis and planning of therapy targeted at improving, re-establishing or decreasing venous flow, depending on the underlying diagnosis. Digital subtraction venography (DSV) is regarded as the most accurate method for diagnosis of venous thrombosis as well as venous stenosis<sup>[1]</sup>. However, DSV has associated morbidity related to radiation dose, intravenous contrast injection and venous puncture.

Magnetic resonance angiography (MRA) uses specific acquisition sequences to highlight blood flow and is widely used to assist in the management of patients with vascular disease<sup>[2]</sup>.

Magnetic resonance venography (MRV) utilizes the

same imaging principles as MRA in order to image the venous system. Blood pool contrast agents such as gadofosveset trisodium (Ablavar, Lantheus, N Bellerica, Mass, United States) allow improved first pass imaging due to the increased relaxivity of the contrast agent<sup>[3]</sup>. The important clinical property that makes it ideal for venous imaging is the longer intravascular dwell time, allowing for steady state acquisitions up to 1 h following injection. Delayed, steady state imaging facilitates improved visualization of vital venous structures with a small decay in signal.

This case report presents a novel application of a blood pool contrast agent in planning an intervention in a liver transplant patient with perianastomotic hepatic vein stenosis.

## CASE REPORT

A 47-year-old female was referred to the interventional radiology department with refractory ascites following a live donor liver transplant 10 mo previously for papillary cholangiocarcinoma.

A transjugular cavogram demonstrated an inferior vena cava (IVC) stenosis, however we were unable to reflux contrast into the transplant hepatic veins (Figure 1). A decision was made to abandon the procedure and perform further imaging in order to demonstrate and delineate the hepatic venous anastomosis. An US study was originally performed but the result was deemed insufficient to delineate the anatomy prior to further intervention.

A contrast enhanced MR venogram (GE Healthcare 1.5T, Giles, United Kingdom) was performed using Gadofosveset Trisodium (Ablavar, Lantheus, N Bellerica, Mass, United States). Spoiled gradient echo sequences were obtained using first pass imaging (Coronal acquisition, Flip angle: 30°, FoV: 40 cm, section thickness 2.8 mm, frequency coding: 320, phase coding: 192, NEX: 0.75, K-space filling: centric, spatial resolution: 1.25/2.1) at 25 s and steady state imaging (Coronal acquisition, Flip angle: 20°, FoV: 40 cm, section thickness 2.8 mm, frequency coding: 320, phase coding: 320, NEX: 1, K-space filling: centric, spatial resolution: 1.25/1.25) at 2 min and 5 min after injection of 10 mL Gadofosveset Trisodium (1 mL/s) followed by a 30 mL saline flush (1 mL/s).

The first pass images demonstrated a patent hepatic arterial anastomosis, with no focal arterial pathology seen. The 5-min steady state imaging demonstrated a patent hepatic venous stenosis with a significant perianastomotic stenosis (Figure 2A) and an IVC stenosis (Figure 2B). No hepatic or portal venous thrombosis was seen.

A combined transhepatic and transjugular hepatic venoplasty was performed following review of the imaging. Initially, an ultrasound guided transhepatic puncture of the right hepatic vein was performed and a guidewire inserted across the perianastomotic stenosis into the right atrium (Figure 3). In order to obtain through and through access to the hepatic venous and IVC stenosis, a

Figure 1 Digital subtraction venogram *via* a pigtail catheter placed in the infrahepatic inferior vena cava demonstrating inferior vena cava stenosis (arrow) and no reflux of contrast into the transplant hepatic veins.

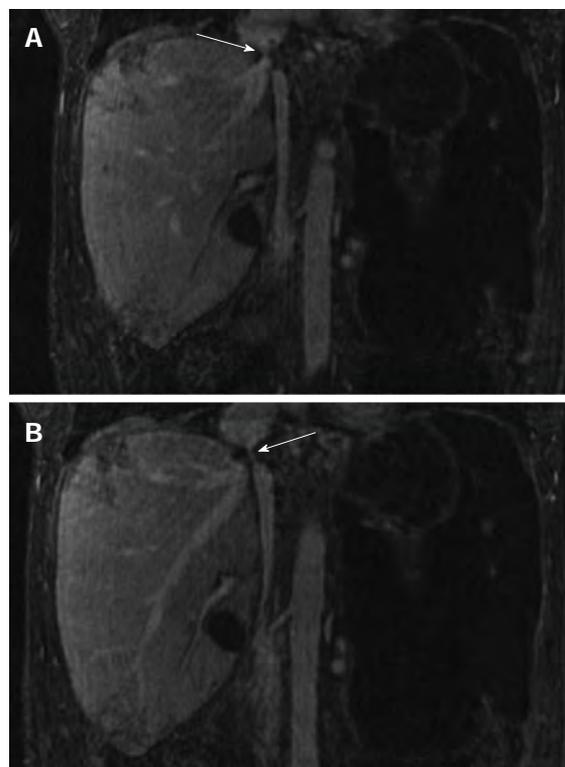

Figure 2 Five-minute steady state imaging. A: Coronal T1 weighted ultrafast gradient echo steady state magnetic resonance imaging image obtained 5 min following administration of Gadofosveset trisodium demonstrates inferior vena cava stenosis (white arrow); B: Coronal T1 weighted ultrafast gradient echo steady state magnetic resonance imaging image obtained 5 min following administration of gadofosveset trisodium demonstrating patent, but stenosed transplant hepatic vein (white arrow).

loop snare was introduced from a jugular venous access site and the guidewire was snared and retracted through the jugular venous access site (Figure 4). The stenoses were dilated using a high-pressure balloon (Atlas, Bard Medical, Tempe, AZ, United States), with satisfactory angiographic appearances post venoplasty (Figure 5). Both stenoses were treated concurrently due to their close proximity. The hepatic venous/right atrial gradient decreased from 15 to 8 mmHg following the procedure;

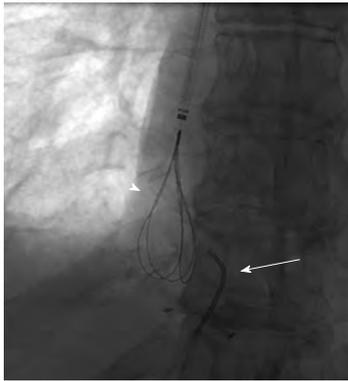

Figure 3 Fluoroscopic image demonstrating a loop snare inserted through the internal jugular vein access (arrowhead), and an angled catheter (arrow) through the right hepatic vein. Access to the right hepatic vein was achieved *via* percutaneous ultrasound guided puncture.

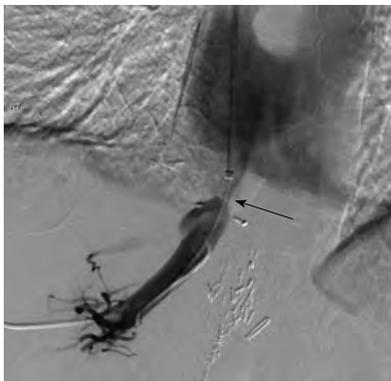

Figure 4 Digital subtraction venogram demonstrating through and through access across the hepatic venous stenosis (arrow).

due to the close proximity of the hepatic venous and IVC stenoses, a separate gradient across the IVC stenosis was not felt to be practical given a second catheter would need to be placed in the infra-hepatic IVC, in order to maintain the hepatic venous access. The patient was monitored post-procedure for four hours as per departmental protocol and discharged with no peri-procedural complications.

The patient was reviewed three months post treatment at our transplant clinic, where the ascites had completely resolved and she had resumed her normal daily activities. Doppler ultrasound demonstrated normal flow in the hepatic vein with no evidence of recurrent stenosis. A follow-up MRI was performed 1-year post venoplasty as part of annual surveillance to exclude tumor recurrence. The MRI demonstrated no evidence of ascites (Figure 6), which together with the patient's normal liver function parameters and clinical examination, confirmed a satisfactory result. Follow-up venography was not felt to be necessary given the clinical response.

## DISCUSSION

This technical report demonstrates the benefit of steady-

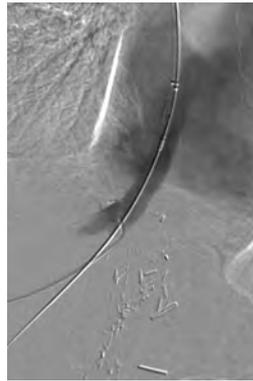

Figure 5 Completion venoplasty demonstrating satisfactory post-venoplasty appearances of the hepatic vein.

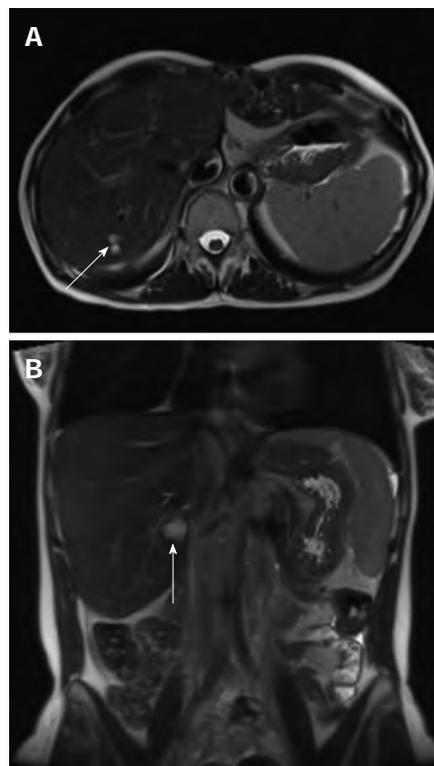

Figure 6 Follow up magnetic resonance imaging axial (A) and coronal (B) balanced gradient echo sequences (True FISP; Siemens Medical, Erlangen, Germany) through the liver performed as part of routine annual tumor surveillance at 1 year following venoplasty of the hepatic vein and inferior vena cava stenosis demonstrated normal appearance of the liver apart from simple parenchymal cysts (arrow). No ascites was seen.

state imaging using a blood pool contrast agent, Gadofosveset Trisodium. MRI provides exquisite soft tissue contrast and allows for the delineation of liver transplant anatomy either prior to embarking on a therapeutic intervention or if conventional angiography is unsuccessful as in this case. Cannulation of the stenosed hepatic vein proved technically challenging and without adequate reflux of contrast into the hepatic veins, cross-sectional imaging was required in order to plan a safe combined transhepatic and transjugular approach.

Hepatic vein stenosis is a rare but serious complication after liver transplantation<sup>[4]</sup>. It has been reported to occur from 1% to 6% of the cases. It can occur both acutely or in a delayed fashion. Acute hepatic vein stenosis is thought to be due to surgical technique whereas delayed stenosis is caused by intimal hyperplasia or perianastomotic fibrosis<sup>[4]</sup>. Clinical signs of hepatic vein stenosis include hepatic dysfunction, liver engorgement, ascites, and occasionally variceal bleeding. If the stenosis occurs at the level of the suprahepatic IVC as in this case, renal dysfunction and lower extremity edema may occur.

Gadofosveset Trisodium (Ablavar, Lantheus, N Bellerica, Mass, United States) reversibly binds to serum albumin, providing significantly higher relaxivity and prolonged intravascular enhancement compared to existing extracellular MR contrast agents<sup>[2]</sup>. The optimal dose is 0.03 mmol/kg, however in our experience greater than 10mL of contrast is not required in the majority of patients. The safety and efficacy of the contrast medium has been studied using a variety of clinical scenarios including aorto-iliac occlusive disease and pedal arterial disease which demonstrated the contrast agent to improve the rate of interpretability and improved diagnostic confidence<sup>[2]</sup>.

The significantly longer intravascular time allows equilibrium imaging due to a prolongation of the T1 relaxivity, despite the inevitable dilution of the injected contrast medium after first pass imaging<sup>[5]</sup>. Prolonged T1 reduction thus allows diagnostic imaging of the vascular tree 45-60 min after injection of contrast. The increased imaging window can be used to acquire images with much higher spatial resolution without a significant loss of vessel to background contrast.

A rapid injection rate is not required. A saline chaser of at least 30 mL at a rate similar to the injection rate of the contrast medium ensures the full dose of contrast medium enters the central circulation without affecting the signal to noise ratio (SNR)<sup>[6]</sup>.

The use of Gadofosveset Trisodium for problem solving in liver transplant patients, to our knowledge has not been described. The same parameters utilized for our traditional abdominal first pass and steady state imaging were utilized for image acquisition and provided the interventional radiology team with the anatomical detail

required to perform the necessary venoplasty.

The favourable safety profile and the low dose required to obtain diagnostic images (0.03 mmol/kg) makes this agent preferable as to date, there have been no reported cases of NSF associated with gadofosveset trisodium<sup>[2,7]</sup>.

In conclusion, MRV of transplant livers using a blood pool contrast agent is an accurate, noninvasive method of evaluating the vascular anastomoses (arterial, hepatic and portal venous systems). The longer intravascular dwell time of Gadofosveset Trisodium allows imaging with little loss of SNR. MRV with a blood pool contrast agent is a robust MRI technique, which eliminates contrast bolus timing, provides good temporal and spatial resolution and allows for dynamic image acquisition whilst compensating for differences in patient blood flow dynamics.

### Abstract

Gastric diverticula are rare and uncommon conditions. Most gastric diverticula are asymptomatic. When symptoms arise, they are most commonly upper abdominal pain, nausea and emesis, while dyspepsia and vomiting are less common. Occasionally, patients with gastric diverticula can have dramatic presentations related to massive bleeding or perforation. The diagnosis may be difficult, as symptoms can be caused by more common gastrointestinal pathologies and only aggravated by diverticula. The appropriate management of diverticula depends mainly on the symptom pattern and as well as diverticulum size. There is no specific therapeutic strategy for an asymptomatic diverticulum. Although some authors support conservative therapy with antacids, this provides only temporary symptom relief since it is

not able to resolve the underlying pathology. Surgical resection is the mainstay of treatment when the diverticulum is large, symptomatic or complicated by bleeding, perforation or malignancy, with over two-thirds of patients remaining symptom-free after surgery, while laparoscopic resection, combined with intraoperative endoscopy, is a safe and feasible approach with excellent outcomes. Here, we present two cases of uncommon large symptomatic gastric diverticula with a discussion of the cornerstones in management and report a minimally invasive solution, with a brief review of the literature.

**Key words:** Gastric diverticulum; Laparoscopic gastric diverticulectomy; Abdominal pain; Dysphagia; Gastric; Diverticulum

**Core tip:** Gastric diverticula are infrequent anatomic abnormalities and are usually asymptomatic. They present with variable symptoms. Although most symptomatic patients are diagnosed during evaluation of vague epigastric discomfort, severe complications, including perforation and hemorrhage, may occur. We report a successful laparoscopic approach as a minimally invasive solution to a symptomatic gastric diverticula with a brief literature review on this rare condition. Knowledge of the pitfalls in diagnosis and treatment of a gastric diverticulum are essential for successful and complete relief of symptoms.

Large symptomatic gastric diverticula: Two case reports and a brief review of literature. *World J Gastroenterol* 2013; 19(36): 6114-6117 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i36/6114.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i36.6114>

## INTRODUCTION

A gastric diverticulum is a pouch protruding from the gastric wall and has similar characteristics to duodenal, jejunal and colonic diverticula<sup>[1]</sup>. Generally it is a very rare and uncommon condition with a prevalence of 0.04% in contrast radiographs and 0.01%-0.11% in upper gastrointestinal endoscopies<sup>[2,3]</sup>. It occurs equally in men and women, typically in the fifth and sixth decades. Although most patients are asymptomatic, occasionally abdominal symptoms occur, including vague pain, epigastric fullness, bleeding or perforation<sup>[4-6]</sup>. Gastric diverticula are usually 1-3 cm in diameter and can be divided into true diverticula comprising all gastrointestinal layers and pseudodiverticula which are often found in the antrum<sup>[7,8]</sup>. We present two cases of uncommon large symptomatic gastric diverticula with discussion of the cornerstones in management, and report a minimally invasive solution, with a brief review of literature.

## CASE REPORT

Two 51-year-old and 49-year-old women were referred to our Department for evaluation of symptoms of epigastralgia and upper abdomen tenderness, respectively. They denied weight loss, hematemesis and melena. The patients did not complain of vomiting or any abnormal bowel function. Abdominal examinations revealed no masses or other abnormalities. A barium esophagogastric study was performed, which showed an image of a protruding pouch in the upper gastric region (Figure 1). To confirm the diagnosis, an upper endoscopy was conducted, demonstrating diverticula directed posteriorly off the fundus of the stomach that measured 5 cm and 8 cm in diameter, respectively (Figure 2). The diverticula had a narrow neck but no ulcer was identified. Functional examination with esophageal stationary manometry and 24-h esophagogastric pH-multichannel intraluminal impedance monitoring showed normal values. The electrogastrography monitoring showed an increase in bradyarrhythmic gastric activity in both patients. Patients were presented for surgery and the operations were performed laparoscopically. The interventions were substantially the same for both patients. Because inspection of the stomach did not show a diverticulum at the anterior surface, the bursa omentalis was opened by dividing the gastrocolic omentum. Under endoscopic control, the diverticula were resected at the neck with EndoGIA (Universal, US Surgical Corporation, Norwalk, CO, United States) and then successfully retrieved with a laparoscopic pouch (Figure 3). Then, the staple lines were carefully examined and tested by submerging insufflated stomach under sterile irrigation to observe bubbles and there was no evidence of a leak. Histology confirmed a gastric diverticula of 5 cm and 8 cm, respectively, with normal mucosa in both cases. The procedures were uneventful. Patients were placed on a regular diet on postoperative day 3 and discharged 5 d later. Patients did not show any complications after surgery. On their first 6-mo follow-up visit, neither patient complained of any

symptoms, while normal radiographic and endoscopic examinations, and regular values of esophageal manometry and 24-h esophagogastric pH-multichannel intraluminal impedance were found.

## DISCUSSION

Moebius in 1661 and later Roax in 1774 first described gastric diverticula<sup>[9]</sup>. The literature suggests that most symptomatic diverticula are found in patients between 20 and 60 years of age<sup>[10-12]</sup>, while a unique study showed that only 4% of gastric diverticula occurred in patients younger than 20 years<sup>[11]</sup> and no differences in incidence between sexes have been described<sup>[4]</sup>. Two types of gastric diverticula are recognized according to Akerlund<sup>[13]</sup> and Schmidt *et al.*<sup>[14]</sup>: congenital (true) and acquired (false) diverticula, with congenital types being more common<sup>[2,15-17]</sup>. True diverticula have all layers of the gastric wall, and it is believed that these congenital diverticula occur as a result of splitting of the longitudinal muscular fibers at the cardia level, leaving only circular muscle fibers in the gastric wall and creating a weakening to allow a diverticulum to form during the fetal period. This hypothesis is supported by Reich<sup>[18]</sup> who reported fetal gastric diverticula and by Lewis, which described gastrointestinal diverticula in embryos in 1908<sup>[19]</sup>. False diverticula, also classified as pulsation and traction diverticula, do not car-

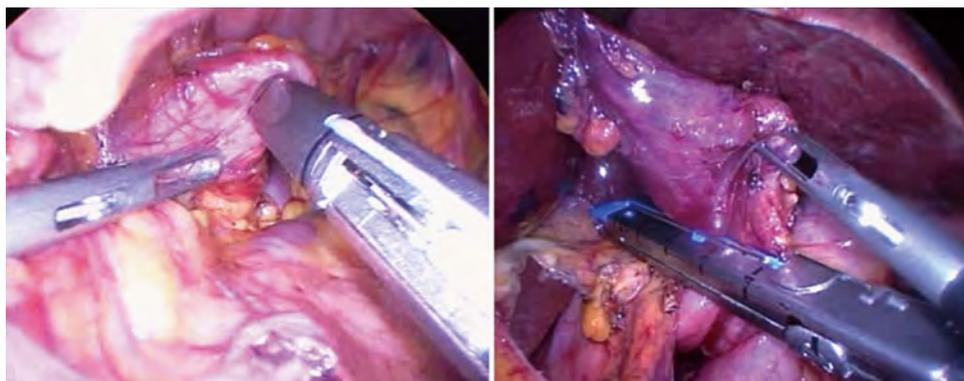

Figure 3 Exposure of the neck of the diverticulum for preparation of diverticulectomy and resection at the neck with a linear stapler.

ry all layers of the gastric wall<sup>[20]</sup>. Pulsation diverticula are those arising from increased intraluminal pressure, such as chronic coughing, obesity and pregnancy. Traction diverticula arise from perigastric adhesions from concurrent diseases, such as peptic ulcer disease, pancreatitis, malignancy, gastroesophageal reflux and cholecystitis<sup>[11,12]</sup>. Gastric traction diverticula have been reported after surgical procedures on the stomach, including Roux-en-Y gastric bypass<sup>[12,21,22]</sup>. Even if gastric diverticula can arise virtually anywhere along stomach, most congenital diverticula (70%) are typically located on the posterior wall of the stomach just below the gastroesophageal junction<sup>[2]</sup>, while acquired diverticula are usually situated near the gastric antrum. Typical diverticula are 1-3 cm in diameter but large diverticula as demonstrated above can occur<sup>[2,15]</sup>.

Most gastric diverticula are asymptomatic<sup>[22]</sup>, however when symptoms arise, depending on the size of the diverticular neck, they are most commonly upper abdominal pain, nausea, and emesis, and are described in 18%-30% of cases<sup>[2,21]</sup>. Wide-neck diverticula often go unnoticed perhaps because food and digestive juices are less likely to become trapped. It has been suggested that food retention with subsequent distension of the gastric diverticulum may cause pain<sup>[23,24]</sup>. Dyspepsia and vomiting are less common<sup>[21,25]</sup>. Occasionally, patients with gastric diverticula can have dramatic presentations related to massive bleeding or perforation<sup>[26]</sup> due to food retention with subsequent release of gastric juices within the mucosal sac, causing diverticulitis and possibly ulceration or hemorrhage. There are two reports of invasion with adenocarcinoma<sup>[27,28]</sup>. The diagnosis may be difficult, as complaints can be caused by more common gastrointestinal pathologies and only be aggravated by diverticula. Methods of detection can fail, therefore, a combined approach should be used<sup>[8]</sup>. The presence of a mucosal sac can be confirmed with upper gastrointestinal contrast studies and endoscopies. These are the most reliable diagnostic tests but reports in the literature confirm that they can still miss the lesion if it has a narrow neck that precludes entry of the contrast or scope, giving false negative results<sup>[2,11,29]</sup>. In a large review, Palmer<sup>[11]</sup> reported that 5% of gastric diverticula are missed during upper gastrointestinal investigation. Other reports recommend the use of upper endoscopy<sup>[22,30]</sup> for diagnosis,

as this modality easily confirms the location and size of the diverticulum and provides the opportunity to biopsy any concurrent pathology. This diagnostic tool can rule out associated pathology and may be able to reproduce symptoms with distention of the diverticulum, indicating which patients would benefit from resection<sup>[15,22]</sup>. Computerized tomography scans are also used to diagnose diverticula; however, these have also mistaken diverticula for adrenal masses<sup>[31]</sup>.

Appropriate management of a diverticulum depends mainly on the symptoms as well as on the diverticulum size. There is no specific therapeutic strategy for an asymptomatic diverticulum<sup>[5,18]</sup>. However, routine surveillance with a periodic physical examination is recommended, given the potential onset of complications<sup>[20]</sup>. Diverticula exceeding 4 cm are more prone to produce complications and tend to respond less favorably to medications. Although some authors support conservative therapy with antacids, this provides only temporary symptom relief and is not able to resolve the underlying pathology<sup>[20]</sup>. A necessity for successful treatment with complete relief of symptoms is the association of the symptoms with the diverticulum. Palmer<sup>[11]</sup> found that in 30 of 49 symptomatic patients with a gastric diverticulum, symptoms were attributable to other gastrointestinal diseases, and 6 of 9 patients with symptoms caused by a gastric diverticulum who underwent open surgery showed excellent outcomes. Resection of gastric diverticula in all patients will lead to unsatisfactory results<sup>[22]</sup>. Surgical resection is the mainstay of treatment when the diverticulum is large, symptomatic or complicated by bleeding, perforation or malignancy, with over two-thirds of patients remaining symptom-free after surgery<sup>[11]</sup>. Several surgical approaches have been described including invagination of the diverticulum as well as partial gastrectomy<sup>[32,33]</sup>, however, since the first successful laparoscopic resection of a gastric diverticulum in the late 1990s, this approach is now considered safe and feasible<sup>[34]</sup>. The most favorable approach providing better exposure is by placing a, right upper quadrant port, and 2 left upper quadrant ports. Laparoscopic dissection has been performed by either releasing the gastrocolic ligament, thus allowing exposure of the superior posterior wall of the stomach<sup>[5,34-36]</sup>. Simple diverticulum resection

with a laparoscopic cutting stapler has been reported to be successful<sup>[37]</sup>. In some cases the surgical approach can be challenging because the diverticulum is often collapsed and hidden in the splenic bed. Sometimes, a resection of the wrong part of the stomach has also been described<sup>[22]</sup>. For this reason the surgical procedure should be combined with intraoperative endoscopy to find an elusive diverticula by stretching the diverticular sac<sup>[4,34-36]</sup>.

In conclusion, laparoscopic resection is a safe and feasible surgical approach with excellent outcomes and is strongly indicated for symptomatic gastric diverticula.

### Abstract

Anatomic variations of the right biliary system are one of the most common risk factors for sectoral bile duct injury (BDI) during cholecystectomy. Isolated right posterior BDI may in particular be a challenge for both diagnosis and management. Herein we describe two cases of isolated right posterior sectoral BDI that took place during laparoscopic cholecystectomy. Despite effective external biliary drainage from the liver hilum in both cases, there was a persistent biliary leak observed which was not visible on endoscopic retrograde

cholangiogram. Careful evaluation of images from both endoscopic and magnetic resonance cholangiograms revealed the diagnosis of an isolated right posterior sectoral BDI. These were treated with a delayed bisegmental (segments 6 and 7) liver resection and a Roux-en-Y hepaticojejunostomy respectively with good outcomes at 24 and 4 mo of follow-up. This paper discusses strategies for prevention of such injuries along with the diagnostic and therapeutic challenges it offers.

**Key words:** Cholecystectomy; Bile duct injury; Sectoral bile duct; Hepaticojejunostomy; Liver resection

**Core tip:** Anatomic variations of the right biliary system are common but the low insertion of the right sectoral bile duct into the common hepatic duct (or the cystic duct) is rare. This is clinically important as places the patient at particular risk for its injury during cholecystectomy. Moreover, it can be very difficult to be diagnosed and managed properly. It often presents with a persistent biliary leak which is not visible on endoscopic retrograde cholangiogram. We describe two such cases, present the diagnostic imaging with two different treatment options and discuss preventive and management strategies. This can be of clinical value for both surgeons, gastroenterologists and endoscopists.

## INTRODUCTION

Bile duct injury (BDI) is one of the most serious complications of both open and laparoscopic cholecystectomy. They often result from misidentification of anatomy by the operating surgeons and anatomic variations within the biliary tree<sup>[1]</sup>. Variations in biliary tree anatomy occur in about 25% of patients with aberrant right hepatic ducts being the most common. The low insertion of a right sectoral hepatic duct into the common hepatic duct or the cystic duct (Figure 1) increases the risk of injury during both open<sup>[2,3]</sup> and laparoscopic cholecystectomy<sup>[4,5]</sup>. Therefore, a detailed knowledge and awareness of all possible anatomical variants is crucial for surgeons to avoid complications.

Herein we describe the diagnosis and treatment of an isolated right posterior sectoral BDI sustained during laparoscopic cholecystectomy in two patients. We emphasize the preventive measures to be taken at surgery and discuss the diagnostic and therapeutic options.

## CASE REPORT

### Case 1

A 15-year-old female patient with a symptomatic gallstone disease underwent a laparoscopic cholecystectomy converted to an open procedure in November 2010 in a regional institution. The patient was discharged home on the 6<sup>th</sup> day post operation. She presented 5 d following discharge with abdominal pain and was found to have a subhepatic fluid collection on ultrasound scanning. At relaparotomy drainage of a biloma and abdominal lavage was performed. The patient was discharged home again 16 d following cholecystectomy with an abdominal drain left in place as it still produced around 150-200 mL of bile daily. Due to persistence of a biliary leak, endoscopic retrograde cholangiography (ERC) was performed 20 d after initial surgery. This showed no evidence of a leak and a consult of a hepatobiliary surgeon was requested. During careful evaluation of all the ERC images it became obvious that the right posterior (segments 6 and 7) sectoral bile duct was clearly missing (Figure 2). The diagnosis of an isolated Strasberg type C bile duct injury<sup>[6]</sup> was further confirmed by magnetic resonance cholangiography with maximum-intensity-projection using the slice-stacking technique and T2-weighted sequences. This showed a leak from the right posterior sectoral duct that was isolated from the remaining biliary system (Figure 3). Continued external drainage for a period of several weeks was recommended allowing time for the local inflammation to settle and for possible spontaneous closure of the leak or to serve as a bridge for a definitive repair. The leak persisted at around 150-250 mL/d at which stage definitive surgery was opted for. A Roux-en-Y hepaticojejunostomy to the damaged posterior sectoral duct was initially planned. However, an attempt to identify the damaged duct during surgery was unsuccessful. Therefore, a bisegmental (segments 6 and 7) hepatic resection

was performed in order to remove the affected parenchyma of the liver. The postoperative course was uneventful and the patient was discharged home 10 d after surgery. She remains well at present at 27 mo post cholecystectomy and 24 mo after definitive surgical treatment.

### Case 2

A 21-year-old female patient underwent cholecystectomy for acute cholecystitis in a regional hospital in September 2012. The procedure started laparoscopically but was converted to open surgery because of difficulties localizing anatomical structures. The patient was discharged 6 d following surgery. She was readmitted one week later with fever, abdominal pain and vomiting. Abdominal ultrasound confirmed a subhepatic fluid collection, which proved to be bilious in origin at percutaneous drainage. A drain was left in the subhepatic space and the biliary leak continued (200-300 mL/d) despite its absence on ERC performed. At this stage, 56 d post cholecystectomy, the patient was referred to the authors institute for further management. Following admission the patient was found to be in reasonably good health other than for the persistent biliary leak. A magnetic resonance cholangiogram was performed and this revealed a leak from a right posterior sectoral duct that had no communication with the remaining biliary tree (Strasberg type C injury)<sup>[6]</sup>. The ERC was performed once again and confirmed an intact intra and extrahepatic biliary tree with an absent right posterior duct. The patient was then offered surgical repair. During surgery, an open stump of the right posterior sectoral duct (confirmed by intraoperative cholangiography) measuring around 3 mm in diameter was identified. A Roux-en-Y hepaticojejunostomy was performed. The postoperative course was uneventful and the patient was discharged home 11 d after surgery. She remains well and asymptomatic at 4 mo of follow-up with undilated biliary tree on ultrasonography and normal values of serum bilirubin, alkaline phosphatase and transaminase levels.

## DISCUSSION

Dangerous anatomy, pathology and surgery are three main risk factors which may be responsible for BDI during open and laparoscopic cholecystectomy<sup>[7]</sup>. Incorrect interpretation of anatomy appears to be the most common cause of injury, particularly in isolated right sectoral BDI<sup>[4,5]</sup>. The most dangerous scenario includes the cystic duct located close to or joining the sectoral duct or the sectoral duct draining into the cystic duct or the gallbladder neck (Figure 1)<sup>[7,8]</sup>. This should be always kept in mind during surgery and anticipated until proven otherwise. In order to prevent the injury and identify any variant anatomy early, complete circumferential dissection of the gall bladder neck and the cystic duct should be performed before clip placement.

Anomalous drainage of the right posterior sectoral bile duct into the cystic duct or the common hepatic duct is seen in around 2%-5% of patients<sup>[4,5,9-11]</sup>. Its injury does

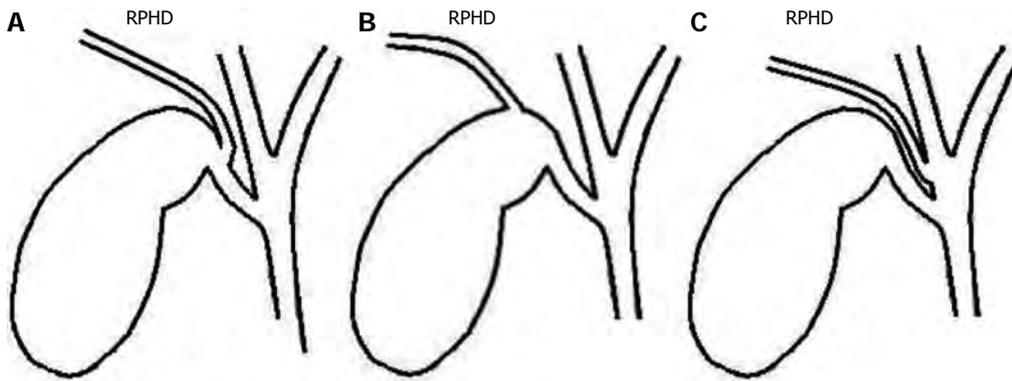

Figure 1 Dangerous anatomical variants of right posterior hepatic duct draining into the cystic duct (A), gall bladder neck (B) or the common hepatic duct (C). RPHD: Right posterior hepatic duct.

Figure 2 Endoscopic retrograde cholangiogram showing seemingly “normal” biliary tree with no evidence of a biliary leak. However, only the left hepatic duct (long arrow) and the right anterior hepatic duct (short arrow) are visible.

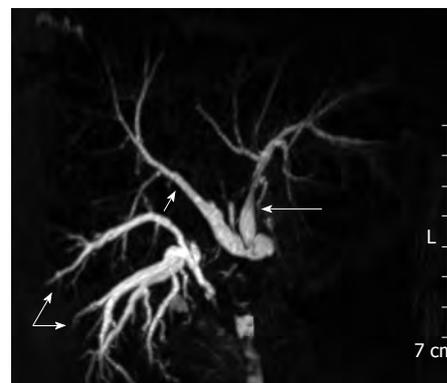

Figure 3 Magnetic resonance cholangiography with the use of T2-weighted sequences and maximum-intensity-projection imaging. The fluid-containing bile ducts as high signal-intensity structures; the right posterior hepatic ducts of segments 6 and 7 are shown (double arrow) with no connection to the right anterior duct (single short arrow) and the left hepatic duct (single long arrow); the abdominal drain placed in the subhepatic area and draining the bile externally is also visible in between the right anterior and posterior hepatic ducts.

not belong to the original classification of BDI described by Bismuth *et al*<sup>[12]</sup>. It is recognized though by Strasberg classification as the occlusion (type B) or a leak (type C) from a duct not in communication with the common bile duct<sup>[6]</sup>. The true incidence of Strasberg type B injury may be underestimated since some of them are likely to be asymptomatic and pass unnoticed leading to atrophy or segmental cirrhosis of part of the liver. While occlusion of the duct usually leads to cholestasis or recurrent episodes of cholangitis<sup>[3,13]</sup>, its transection presents mainly with signs of biliary peritonitis or external biliary leak *via* the abdominal drain<sup>[4,14-16]</sup>, which was the case in our patients.

Proper diagnosis and management of right sectoral BDI remains difficult. The results of ERC may be interpreted as “normal” with no biliary leaks visible (Figure 2). The leak may then be erroneously attributed to injury to a minor biliary radical in the gall bladder fossa (the ducts of Luschka) and delay the diagnosis. However, careful evaluation of the obtained ERC images may reveal that only the right anterior sector of the liver (segments 5 and 8) is visualized and the posterior (segments 6 and 7) missing<sup>[3,4]</sup> (Figure 2). Magnetic resonance cholangiography can further confirm the lack of communication between the injured duct and the common bile duct (Figure 3).

This makes endoscopic treatment impossible in such cases and is essential for treatment planning.

The treatment depends on the timing of recognition of the type of injury. External biliary drainage should allow prompt control of the leak, eliminate the risk of sepsis and serve as a bridge for definitive repair<sup>[4]</sup>. Total nonoperative management has recently been advocated as a way to obviate the need for surgery in up to 50% of patients<sup>[16]</sup>. If the leak persists beyond approximately 8 wk, treatment with Roux-en-Y hepaticojejunostomy is usually indicated<sup>[12,16,17]</sup>. However, the risk of late stricture at the anastomosis may be as high as 33%<sup>[4]</sup> making the resection of the affected liver sector an attractive alternative<sup>[4,18]</sup>. As we were not able to find and locate the injured duct during surgery in the first case, this was the only treatment option for our patient. Placement of a percutaneous, transhepatic catheter into the injured duct prior to surgery may help the surgeon identify the site of injury facilitating dissection of the hepatic hilum prior to reconstruction<sup>[4]</sup>. However, application of this technique on an undilated biliary system may be a challenge even

for an experienced hepatobiliary radiologist<sup>[16]</sup>. For this reason we did not decide to attempt this approach in our patient. While surgery remains the mainstay treatment in most centers, management of such injuries using the interventional radiology approach has also been reported. This includes the application of minimally invasive and percutaneous techniques of ablation of the affected duct by ethanol or acetic acid injection<sup>[19,20]</sup>.

In summary, proper diagnosis and management of right sectoral BDI remains difficult. It should always be suspected and looked for if a biliary leak following cholecystectomy persists despite its absence on endoscopic cholangiogram. In addition to a bilioenteric reconstruction with the Roux limb of jejunum, resection of the affected part of the liver is another treatment option.

### Abstract

Biliary ascariasis is a common problem in rural areas in China. The common presentations include biliary colic, acute cholangitis, obstructive jaundice, choledocholithiasis and acute cholecystitis. Here, we describe a case with biliary ascariasis two days after endoscopic sphincterotomy for choledocholithiasis. A living ascaris was successfully removed by endoscopic retrograde cholangiopancreatography. This case indicated that biliary ascariasis is not an uncommon complication of endoscopic sphincterotomy in some regions where ascariasis is epidemic.

### INTRODUCTION

Biliary ascariasis is a common problem in rural areas in China, especially in the Northwest region. Common presentations include biliary colic, acute cholangitis, obstructive jaundice, choledocholithiasis and acute cholecystitis<sup>[1]</sup>. In this report we describe a case with biliary ascariasis after endoscopic sphincterotomy for choledocholithiasis.

### CASE REPORT

An 18-year-old Chinese woman presented with complaints of abdominal pain, fever and jaundice. Magnetic resonance cholangiopancreatography (MRCP) showed multiple common bile duct (CBD) stones (Figure 1). Routine endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy were performed and several CBD stones were retrieved successfully. The recovery was uneventful until the onset of progressively intolerable abdominal pain two days later. Abdominal ultrasonography revealed a dilated common bile duct (10 mm) with an ill-defined linear echogenic shadow inside

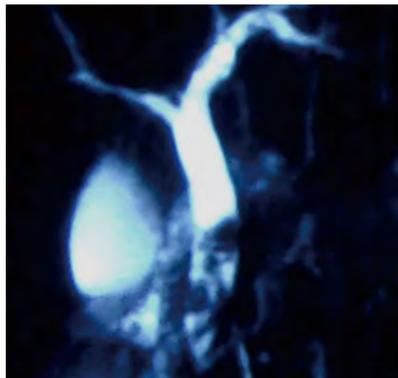

Figure 1 Magnetic resonance cholangiopancreatography showing multiple common bile duct stones.

Figure 2 Abdominal ultrasonography revealed a dilated common bile duct with an ill-defined linear echogenic shadow inside (arrow). CBD: Common bile duct.

(Figure 2). The gallbladder was normal. Biliary ascariasis was suspected and ERCP was repeated. The head of a worm was at the sphincterotomy-performed papilla (Figure 3). One living ascaris of about 25 cm in length was removed using a dormia basket (Figure 4).

## DISCUSSION

Endoscopic sphincterotomy is the treatment of choice for patients with choledocholithiasis. Its main complications include bleeding, pancreatitis, perforation and infection<sup>[2]</sup>. Biliary ascariasis, one of contributing factors of biliary stones, does not figure in the list. However, biliary ascariasis is a common complication of endoscopic sphincterotomy in some regions where ascariasis is epidemic. For example, Gupta *et al*<sup>[3]</sup> reported four cases of biliary ascariasis among 273 cases with post-endoscopic sphincterotomy for choledocholithiasis in Kashmir, India. Biliary ascariasis occurred only two days after sphincterotomy in the present study, which contrasts with the interval period of 2-24 wk in Gupta's report<sup>[3]</sup>.

Abdominal ultrasonography can facilitate the diagnosis of biliary ascariasis in most of cases. The characteristic sonographic feature of worms in the common bile duct is a long, linear, parallel echogenic strip, usually without acoustic shadowing<sup>[4]</sup>. ERCP, considered the gold standard for the diagnosis of biliary ascariasis, should be reserved for therapeutic rather than diagnostic use, because papillotomy may lead to reentry of the worm into the common bile duct<sup>[5]</sup>. In addition, sphincterotomy is not recommended unless a basket cannot be introduced inside the common bile duct to hold the ascaris<sup>[6]</sup>. Dead ascaris and stones in the same patients have been reported to be pulled out simultaneously through the CBD<sup>[6]</sup>. In this patient, CBD stones were removed successfully by the first ERCP and no signs of either living or dead biliary ascaris were found. The living ascaris found by the second ERCP was thought to have resulted from the entry of the worm into the common bile duct through the open papilla; therefore, anthelmintics were used to prevent reentry of any other ascaris residing in the small bowel. Six months of follow-up were uneventful.

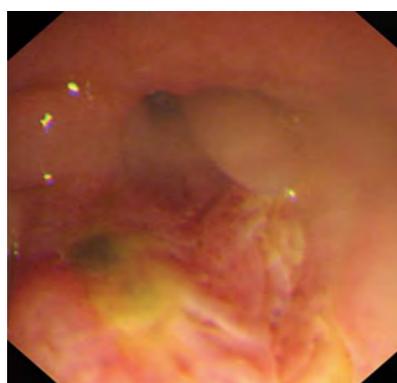

Figure 3 The head of a worm observed in the sphincterotomy-performed papilla.

Figure 4 A living ascaris of about 25 cm in length was removed using a dormia basket.

Previously, Zargar *et al*<sup>[7]</sup> described the endoscopic management of postoperative biliary ascariasis in 19 consecutive patients who underwent cholecystectomy and choledocholithotomy. ERCP was performed 4 to 16 d after biliary tract surgery and roundworms in the CBD were extracted from 10 patients, from the hepatic ducts of patients, or from both ducts in seven patients. Taken together, we suggest that endoscopic management is an effective and safe approach for extracting ascarids from

the biliary tree of postoperative patients.

lesions within the lumen of the biliary tree including the gallbladder, papilla of Vater, and pancreatic duct have been proposed collectively as a preinvasive neoplastic lesion. The patient reported here was an interesting case of intraluminal papillary neoplasm involving the gallbladder and metachronously the extrahepatic bile duct. This letter to the editor encourages clinicians to detect more of such neoplastic lesions.

### Abstract

A 77-year-old woman complained of epigastralgia, and a tumor (5 cm in diameter) of the gallbladder neck was detected by image analysis. Following cholecystectomy, the tumor was pathologically diagnosed as intraductal papillary neoplasm (IPN), gastric type, with associated invasive carcinoma. About 10 mo later, intraluminal multiple masses (3 foci, up to 1.8 cm) were noted in the extrahepatic bile duct, and the resected specimen showed that all tumors had similar gross and microscopic features as seen in gallbladder IPN without invasion, and they were synchronous multiple lesions. This case showed a papillary tumor of the gallbladder of gastric phenotype, and confirmed that the gallbladder is a target of IPN in addition to the bile ducts.

### TO THE EDITOR

The World Health Organization (WHO) Classification of Tumours of the Digestive System (2010) recognizes intraductal papillary neoplasms of the bile duct (IPNBs) as a precancerous entity of cholangiocarcinoma<sup>[1,2]</sup>. Before the recognition by WHO, this entity was called by various and many different names, such as biliary papilloma and papillomatosis, and papillary adenocarcinoma<sup>[2-4]</sup>. IPNBs are occasionally multicentric along the intrahepatic and extrahepatic bile duct, synchronously and metachronously.

Interestingly, IPNB shares many features with intraductal papillary mucinous neoplasms of the pancreas (IPMN-Ps). For example, four phenotypes of epithelium are recognized in IPNB as well as IPMN-P<sup>[1,5,6]</sup>: pancreatobiliary, intestinal, oncocytic, and gastric types. Intracystic papillary neoplasm (IPN) of the gallbladder was newly described in addition to papillary adenomas in the 2010 WHO classification.

We have recently experienced a case of IPN of the gallbladder followed by metachronous IPNBs of the extrahepatic bile duct. A 77-year old woman complained of epigastralgia, and a tumor of the gallbladder neck was

**Figure 1** Cauliflower tumor of the gallbladder shows papillary neoplasm composed of columnar epithelium with fine fibrovascular core, resembling gastric foveola (hematoxylin and eosin, x 100).

**Figure 2** Intraluminal masses of the extrahepatic bile ducts and dilatation of extrahepatic bile duct shown by endoscopic retrograde cholangiography.

detected by computed tomography (CT) and magnetic resonance imaging (MRI). By cholecystectomy, a papillary, cauliflower-like tumor (5 cm × 4.8 cm) growing intraluminally was found at the gallbladder neck, and the remaining gallbladder was distended. Most of the tumor showed a well-differentiated papillary neoplasm composed of columnar epithelium with supranuclear mucin, resembling gastric mucosa, particularly gastric foveola, covering fine vasculo-fibrous cores (Figure 1), and showed moderate- to high-grade intraepithelial neoplasia. There was focal invasion of moderately differentiated tubular adenocarcinoma in the gallbladder wall. There was no metastasis, and the gallbladder mucosa, except for the tumor, did not show dysplastic or metaplastic changes. The tumor was diagnosed as IPN of the gallbladder with associated invasive carcinoma.

About 10 mo later, intraluminal multiple masses of the extrahepatic bile duct and secondary dilatation of the intra/extrahepatic bile ducts were demonstrated by CT, MRI and endoscopic retrograde cholangiography (Figure 2). The affected extrahepatic bile duct was surgically resected. The resected bile duct was dilated and filled with three separate brown papillary masses (1.8 cm × 1.4 cm, 1.5 cm × 1.5 cm, and 1.2 cm × 1.1 cm). There was no mucin within the resected bile ducts. These extrahepatic tumors commonly showed similar gross and microscopic features as seen in gallbladder IPN, but no invasion. There were no significant pathological changes in the background of the extrahepatic bile ducts. There was no continuity between the three lesions and they were regarded as synchronous multiple lesions.

Immunohistochemically, MUC5AC and MUC6 were diffusely positive, whereas MUC2-positive cells were scattered in these IPNs, and MUC1 was not observed in any of the four IPNs of the gallbladder and bile ducts. These IPNs were regarded as gastric type.

Similar to IPNB, IPN of the gallbladder may present with a pancreatobiliary or intestinal phenotype<sup>[2,3]</sup>. Distin-

guishing IPN from papillary adenomas of the gallbladder may be controversial. The vast majority of IPNs of the gallbladder have a biliary phenotype, whereas papillary adenomas exhibit an intestinal or gastric phenotype. This case showed a papillary tumor of the gallbladder of gastric phenotype, and confirmed that the gallbladder is a target of IPN in addition to the bile ducts.

### Abstract

Hepatocellular carcinoma (HCC) is the sixth most common cancer and the third leading cause of cancer-related death in the world. With advances in imaging diagnostics, accompanied by better understanding of high-risk patients, HCC is now frequently detected at an early stage; however, the prognosis remains poor. The recurrence rate after treatment of HCC is higher than that associated with cancers of other organs. This may be because of the high incidence of intrahepatic distant recurrence and multicentric recurrence, especially with hepatitis C virus (HCV)-related hepatocellular carcinoma. The Barcelona Clinic Liver Cancer (BCLC) classification has recently emerged as the standard classification system for the clinical management of patients with HCC. According to the BCLC staging system, curative therapies (resection, transplantation, transcatheter arterial chemoembolization, percutaneous ethanol injection therapy, percutaneous microwave coagulation therapy and percutaneous radiofrequency ablation) can improve survival in HCC patients diagnosed at an early stage and offer a potential long-term cure. However, treatment strategies for recurrent disease are not mentioned in the BCLC classification. The strategy for recurrence may differ according to the recurrence pattern, *i.e.*, intrahepatic distant recurrence *vs* multicentric

recurrence. In this article, we review recurrent HCC and the therapeutic strategies for reducing recurrent HCC, especially HCV-related HCC.

**Key words:** Hepatocellular carcinoma; Intrahepatic distant recurrence; Multicentric recurrence; Hepatitis C virus; Interferon; Arterial chemotherapy

**Core tip:** Recent advances in treatment modalities have improved the survival rate of patients with hepatocellular carcinoma (HCC). However, long-term outcomes of patients with HCC remain unsatisfactory because of the high incidence of distant intrahepatic recurrence, multicentric recurrence and low survival rates. In particular, hepatitis C virus-related hepatocellular carcinoma has a much higher recurrence rate than other cancers. In this article, we describe the prognosis of recurrent HCC and the therapeutic strategies for reducing recurrent HCC.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common causes of cancer mortality in the world<sup>[1,2]</sup>. It is estimated that HCC is responsible for more than 600000 deaths annually worldwide<sup>[3]</sup>.

Recent advances in treatment modalities have improved the survival rate of patients with HCC<sup>[4,5]</sup>. However, long-term outcomes for patients with HCC remain unsatisfactory because of the high incidence of intrahepatic distant recurrence, multicentric recurrence and low

survival rates.

In many cases, surgical options for HCC are limited because of complicating hepatic cirrhosis; furthermore, HCC is associated with a 5-year recurrence rate of approximately 80% after radical treatment, which is much higher than that of other gastrointestinal carcinomas, resulting from its tendency to multicentric carcinogenesis secondary to chronic liver disease, or intrahepatic distant recurrence<sup>[6,7]</sup>.

Typically, recurrence rates in HCC follow a 2-peak distribution. Early recurrence usually occurs within 2 years after resection, and is most closely related to cancer metastasis, while late recurrence mainly results from *de novo* tumors as a consequence of the carcinogenic cirrhotic environment<sup>[7]</sup>. Therefore, a treatment strategy with a focus on recurrence is necessary.

In recent years, the Barcelona Clinic Liver Cancer (BCLC) classification has emerged as the standard classification system for the clinical management of patients with HCC<sup>[8]</sup>. However, in the recommendations regarding topical therapy for the treatment of early stage HCC, the BCLC guidelines do not mention a strategy for reducing recurrence. Togo *et al*<sup>[9]</sup> recommended a strategy based on the differentiation between recurrence types, *i.e.*, intrahepatic distant recurrences *vs* multicentric recurrence. Transcatheter arterial infusion (TAI) with platinum agents may be effective as adjuvant therapy for the prevention of residual liver recurrence after hepatectomy, probably by suppression of the development of intrahepatic micrometastasis, rather than multicentric carcinogenesis. Furthermore, antiviral treatment, including interferon (IFN), is recommended for preventing multicentric recurrence. We discuss a possible strategy for reducing the recurrence of hepatitis C virus (HCV)-related HCC in terms of our clinical data.

---

## PREVENTIVE TREATMENT STRATEGY PRIOR TO DEVELOPMENT OF RECURRENT MULTIPLE HEPATOCELLULAR CARCINOMA TO MAINTAIN RESIDUAL HEPATIC FUNCTION

---

IFN therapy may be useful in the prevention of recurrence of HCC secondary to chronic viral hepatitis after radical treatment by inhibiting multicentric carcinogenesis, while chemotherapy based on TAI is recommended to inhibit intrahepatic metastasis.

It is widely recognized that HCV infection is a major cause of liver cirrhosis and HCC in Japan and other countries. According to the Liver Cancer Study Group of Japan, 67.7% of Japanese patients with HCC are HCV antibody-positive<sup>[10]</sup>.

We evaluated the treatment response and functional hepatic reserve in patients who received combination

therapy with PEG-IFN  $\alpha$ -2b and ribavirin (RBV) after radical treatment of HCV-related HCC<sup>[11]</sup>.

This study comprised 54 patients with primary HCV-related HCC (stage I / II) whose survival rate, meta-chronous recurrence rate and hepatic functional reserve were assessed. Among these patients, 29 received combination therapy with PEG-IFN  $\alpha$ -2b and RBV after treatment of HCC (secondary IFN treatment group), and the other 25 did not receive IFN, including PEG-IFN  $\alpha$ -2b and RBV (non-secondary treatment group). The 1- and 3-year cumulative survival rates were 100.0% and 90.2% in the secondary IFN treatment group, and 96.0% and 61.2% in the non-secondary treatment group, respectively, showing a significant difference between the groups. Multivariate analysis identified secondary IFN treatment as a significant factor related to prognosis. In the PEG-IFN  $\alpha$ -2b/RBV group, serum albumin levels decreased transiently but increased thereafter, indicating improvement in hepatic functional reserve. These results show that combination therapy with IFN, including PEG-IFN  $\alpha$ -2b and RBV, following treatment of HCC, contributes to improvement in hepatic functional reserve and increases treatment options in the case of recurrence.

---

## TREATMENT STRATEGIES FOR INTRAHEPATIC METASTASIS

---

For intrahepatic metastasis, on the other hand, it is essential to select treatment not only for overt lesions, but also for micrometastasis. Hence, combination therapy, including intra-arterial treatment, such as transcatheter arterial chemoembolization (TACE), is required for initial treatment or treatment of recurrence.

### ***Efficacy of platinum-containing drugs in transhepatic arterial infusion***

After treatment of HCC, the remaining liver is still in a state of precarcinogenesis. The protective effect of chemotherapy against recurrence in the remaining liver is demonstrated by its efficacy in patients with a high probability of intrahepatic metastasis, and thus, a high recurrence rate.

Although it is well-established that more effective chemotherapy, performed preoperatively in patients with intrahepatic micrometastasis or with the possibility of intraoperative tumor spread, may prevent tumor recurrence in the residual liver and further improve prognosis, few reports have described such cases. Systemic chemotherapy is generally not effective in most cases of HCC. Further, chemotherapy often impairs liver function in cases complicated by cirrhosis. At present, systemic chemotherapy with cytotoxic anticancer agents is only used infrequently in the treatment of HCC. Compared with systemic chemotherapy, hepatic arterial infusion (HAI) chemotherapy has the advantages of increasing the local concentration of chemotherapeutic agents to levels that are adequate to kill cancer cells without damaging healthy

liver tissue, and of reducing systemic side effects.

### **Treatment strategy and problems with TACE**

In Japan, TACE, which is recommended for inoperable patients in whom local puncture therapy is not indicated according to the guidelines for the management of liver cancer, plays a central role in the treatment of recurrent advanced multiple HCC<sup>[12,13]</sup>.

TACE is primarily performed as chemolipiodolization, using anticancer drugs mixed with lipiodol<sup>[14,15]</sup>. There have also been several retrospective reports of TACE with anthracyclines *vs* platinum compounds, suggesting the utility of platinum compounds<sup>[16,17]</sup>. However, no single effective drug has been identified, because no prospective comparative studies have been performed, and various anticancer drugs, including epirubicin, cisplatin, mitomycin C and doxorubicin, have been used with intercenter variance.

Kaibori *et al*<sup>[18]</sup> previously recommended that preoperative whole-liver chemolipiodolization reduces postoperative recurrence and prolongs survival in patients undergoing resection of hepatocellular carcinoma.

However, they subsequently performed a randomized controlled trial to evaluate the influence of preoperative TACE on survival after the resection of HCC, following which they concluded that preoperative selective TACE and whole-liver chemolipiodolization plus TACE do not reduce the incidence of postoperative recurrence or prolong survival in patients with resectable HCC<sup>[19]</sup>.

While intra-arterial chemotherapy is not highly appreciated in the West, HAI resulting in high local drug concentrations, is expected to improve the prognosis and prevent disease recurrence, because lesions are often localized to the liver even in advanced stages of HCC. However, various therapeutic regimens have been tried, without reaching a consensus regarding the administration method or dose level.

We previously reported that platinum agents, such as cisplatin, which are widely used for the treatment of a variety of malignancies, may be effective for HCC treatment.

In Japan, a fine powder formulation of cisplatin (cisplatin powder) (DDPH, IA call; Nippon Kayaku, Tokyo, Japan) was developed in 2004 and approved for the treatment of HCC *via* a transarterial approach, without lipiodol or embolic material. Cisplatin powder is readily soluble and more suitable for the preparation of high-concentration (about three times) aqueous solutions (1.4 mg/mL) than conventional cisplatin formulations (0.5 mg/mL). Therefore, a single session of TAI therapy with cisplatin powder has the benefit of increasing drug concentration locally in the HCC, and is expected to have a high therapeutic efficacy.

We evaluated the effectiveness of additional chemotherapy with the platinum-containing drugs carboplatin (CBDCA) and DDPH in preventing intrahepatic distant tumor recurrence<sup>[20]</sup>.

Seventy-eight patients with a diagnosis of primary stage I / II HCC who underwent TACE and RFA after

whole liver arterial infusion of CBDCA (25 patients) or DDPH (53 patients) for local control and recurrence prevention were followed up on a long-term basis. The clinical background factors, intrahepatic distant tumor recurrence rate, and intrahepatic distant tumor recurrence factors were compared between the CBDCA and DDPH groups. While no significant differences in background clinical characteristics were observed between the two groups, the intrahepatic distant tumor recurrence rate was significantly lower in the DDPH group<sup>[20]</sup>. In multivariate analysis using Cox's proportional hazard model, whole liver arterial infusion of DDPH was identified as an independent factor for the prevention of recurrence, *i.e.*, whole liver arterial infusion of DDPH significantly prevented intrahepatic distant tumor recurrence. Significant prevention of recurrence by a single infusion of DDPH compared with CBDCA suggests the utility of DDPH-based treatment strategies in patients with intrahepatic metastasis.

However, no evidence of its contribution to patient survival has been found, and TAI is not mentioned in any Western guidelines<sup>[21]</sup>. Nevertheless, it has been shown that some patients with TACE-refractory HCC were responsive to repeated TAI, with survival being prolonged in these responsive patients. According to the 18<sup>th</sup> nationwide follow-up survey of primary liver cancer, 85.8% of 1862 Japanese HCC patients treated with chemotherapy underwent TAI<sup>[10]</sup>. TAI is relatively often selected as the final choice for advanced HCC, including recurrent HCC; therefore, it is important to improve the response rate to TAI.

Thus, treatment strategies with DDPH-based TAI need to be established by conducting prospective randomized control trials<sup>[22,23]</sup>.

## **CONCLUSION**

Currently, the efficacy of tertiary prevention of HCC with any agent, including chemotherapy, HCV therapy, or IFN, has yet to be proven, and safe and effective chemotherapy for HCC-recurrence has yet to be established.

In this article, we reviewed our strategy for improving survival and reducing the recurrence of HCV-related HCC.

When deciding on treatment strategies for recurrence of HCV-related HCC, it is very important to select appropriate treatment according to the degree of disease progression, and to determine the patient's functional hepatic reserve. The type of recurrence and previous treatments also should be taken into consideration. It is also imperative to establish preventive strategies against precarcinogenesis associated with multicentric carcinogenesis and residual intrahepatic metastasis as early as possible, thereby improving prognosis.

### Abstract

Acute variceal hemorrhage, a life-threatening condition that requires a multidisciplinary approach for effective therapy, is defined as visible bleeding from an esophageal or gastric varix at the time of endoscopy, the presence of large esophageal varices with recent stigmata of bleeding, or fresh blood visible in the stomach with no other source of bleeding identified. Transfusion of blood products, pharmacological treatments and early endoscopic therapy are often effective; however, if primary hemostasis cannot be obtained or if uncontrollable early rebleeding occurs, transjugular intrahepatic portosystemic shunt (TIPS) is recommended as rescue treatment. The TIPS represents a major advance in

the treatment of complications of portal hypertension. Acute variceal hemorrhage that is poorly controlled with endoscopic therapy is generally well controlled with TIPS, which has a 90% to 100% success rate. However, TIPS is associated with a mortality of 30% to 50% in such a setting. Emergency TIPS should be considered early in patients with refractory variceal bleeding once medical treatment and endoscopic sclerotherapy failure, before the clinical condition worsens. Furthermore, admission to specialized centers is mandatory in such a setting and regional protocols are essential to be organized effectively. This review article discusses initial management and then focuses on the specific role of TIPS as a primary therapy to control acute variceal hemorrhage, particularly as a rescue therapy following failure of endoscopic approaches.

**Key words:** Cirrhosis; Portal hypertension; Transjugular intrahepatic portosystemic shunt; Variceal hemorrhage

**Core tip:** The transjugular intrahepatic portosystemic shunts (TIPS) is a highly effective treatment for bleeding esophageal and gastric varices with control of the bleeding in over 90% of the patients. Many papers have been published in the last decade that led to technical improvements and definition of the best indications for this promising treatment of complications of portal hypertension. The purpose of this article is to describe the different treatment options for patients with refractory esophageal and gastric varices bleeding and the role of TIPS as a rescue therapy. Technical aspects of this procedure and the current indications are also discussed.

Cercueil JP. Transjugular intrahepatic portosystemic shunt for the management of acute variceal hemorrhage. *World J Gastroenterol* 2013; 19(37): 6131-6143 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i37/6131.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i37.6131>

## INTRODUCTION

Acute variceal hemorrhage is a common clinical emergency and most often is caused by cirrhosis-related portal hypertension<sup>[1]</sup>. Less common causes include splenic vein thrombosis, hepatic veno-occlusive disease, and primary biliary cirrhosis<sup>[1]</sup>. It is defined as visible bleeding from an esophageal or gastric varix at the time of endoscopy, the presence of large esophageal varices with recent stigmata of bleeding or fresh blood visible in the stomach with no other source of bleeding identified<sup>[1]</sup>. The frequency of gastroesophageal varices in cirrhosis varies from 30% to 70% with bleeding occurring in approximately one-third of patients<sup>[2]</sup>. Twenty percent of cirrhotics with acute variceal hemorrhage die within 6 wk<sup>[3]</sup>. The rebleeding rates range from 30% to 40% at 6 wk and the mortality from rebleeding reaches 30%<sup>[4]</sup>. Gastroesophageal varices account for approximately 80% of all cases of variceal hemorrhage<sup>[2,5]</sup>. The precipitating cause for hemorrhage, presumably an acute rise in portal pressure and subsequent variceal rupture, remains uncertain. However, several factors have been implicated including raised intra-abdominal pressure, bacterial infection, continued excess alcohol consumption and postprandial increase in splanchnic blood flow<sup>[4,5]</sup>. Predictive factors for variceal hemorrhage include a hepatic venous pressure gradient (HVPG) of > 20 mmHg<sup>[6,7]</sup>, the presence of large varices with red signs<sup>[8]</sup> and underlying severe liver disease (Child-Pugh grade C)<sup>[2]</sup>.

Optimal management of variceal hemorrhage requires a multidisciplinary approach involving a team of gastroenterologists, hepatologists, critical care physicians, surgeons, and interventional radiologists. The principal components of therapy include airway maintenance, hemodynamic stabilization, control of the variceal hemorrhage, and alteration of the hemodynamic effects of portal hypertension. Treatment options for the management of acute variceal hemorrhage include endoscopic therapy, use of vasoactive drugs, balloon tamponade and esophageal transaction. These various methods, either alone or in combination, are effective in controlling acute variceal hemorrhage in 80% to 90% of patients<sup>[3]</sup>. Patients who do not respond to these measures are referred for rescue therapies, which include transjugular intrahepatic portosystemic shunt (TIPS) and surgical portosystemic shunts with or without splenectomy. Because of the higher mortality of surgery in the acute setting, TIPS is the favored rescue procedure for uncontrolled variceal hemorrhage<sup>[6]</sup>.

The purpose of this review is to describe the different therapeutic options available to control acute variceal hemorrhage and then to focus on the potential role of

TIPS as a primary therapy to control acute variceal hemorrhage, particularly as a rescue therapy following failure of endoscopic approaches.

## INDICATIONS-GASTROINTESTINAL BLEEDING

TIPS has been used to treat many complications related to portal hypertension. The relative efficacy of TIPS has been tested with randomized controlled trials (variceal bleeding, refractory ascites), whereas other indications have been evaluated in uncontrolled case series.

The causes of gastrointestinal hemorrhage in a patient with portal hypertension may be variceal rupture, portal hypertension gastropathy, postsclerotherapy ulcers, peptic ulcer disease, hemorrhagic gastritis, and Mallory-Weiss tear. TIPS is generally accepted as a second-line therapy after failure of endoscopic and medical therapy of bleeding from gastroesophageal varices<sup>[9]</sup>.

### Primary prophylaxis of variceal bleeding

Bleeding from esophageal varices is a common and severe complication of portal hypertension. Prevention of the initial bleeding can be achieved in a number of cases by endoscopic variceal ligation or  $\beta$ -blocker treatment. However, TIPS has never been tested in this situation as the use of surgical portacaval shunts has demonstrated that this approach is associated with higher morbidity and mortality rates<sup>[10]</sup>.

Bleeding from gastric varices is often severe and difficult to control, particularly when fundal varices are involved. The first-line treatment is endoscopic sclerotherapy with cyanoacrylate<sup>[11]</sup>. TIPS has been used in a number of uncontrolled trials in patients in whom endoscopic therapy failed<sup>[12,13]</sup>. A recent controlled trial has shown that TIPS is more efficient than cyanoacrylate in prevention of rebleeding (secondary prophylaxis) from large gastric varices<sup>[14]</sup>. This finding, although interesting, must be confirmed by after a long-term follow-up. Importantly, due to the large size of fundal varices, the risk of rupture is still present even at a low portacaval gradient (< 12 mmHg) after TIPS<sup>[15]</sup>. This is probably best explained by the relationship between the variceal tension (and therefore the risk of rupture) and the variceal size. For this reason, it is recommended to embolize gastric varices at the time of TIPS placement<sup>[10,16]</sup>.

### Acute variceal bleeding

When initial bleeding occurs, it is usually controlled with less invasive endoscopic treatment and/or pharmacological therapy. In the rare instance when bleeding remains uncontrollable, TIPS has been used as a rescue treatment with good results. However, prognosis relies on the general condition of the patient, the value of the liver function reserve, and the associated comorbidities<sup>[17-20]</sup>. However, a recent randomized controlled trial evaluated the use of emergent TIPS as compared to standard medical therapy in patients with severe portal hypertension and a

**Table 1** Transjugular intrahepatic portosystemic shunt *vs* endoscopic therapy in the prevention of rebleeding: Results from meta-analyses *n* (%)

Study finding	Reference, value

All-cause mortality		
TIPS	130 (27.5)	111 (25.2)
Endoscopic therapy	118 (24.8)	98 (22.1)
OR (95%CI) for TIPS	1.14 (0.85-1.54)	1.17 (0.85-1.61)

TIPS: Transjugular intrahepatic portosystemic shunt.

Child-Pugh score of 7-13<sup>[21]</sup>. Treatment failure was more frequent in the medical group (50% *vs* 12%) and the survival rate was better in the TIPS group (11% *vs* 38%)<sup>[21]</sup>. This approach could justify the use of TIPS early after bleeding in patients with moderate or severe liver failure and severe portal hypertension. Current evidence supports the use of TIPS not as a primary form of treatment, but rather as a rescue treatment for patients with bleeding esophageal varices who failed pharmacological and endoscopic treatments.

### Secondary prophylaxis of variceal bleeding

The strongest evidence in favor of performing a TIPS procedure exists for the secondary prevention of variceal bleeding. Twelve randomized controlled trials have been published on this topic, describing results for 948 patients, 472 of whom received a TIPS<sup>[22-33]</sup>. Recent meta-analyses found a more than threefold decrease in the risk of recurrent bleeding after insertion of a TIPS compared with various forms of endoscopic therapy (Table 1)<sup>[34,35]</sup>. Rates of rebleeding after insertion of TIPS ranged from 9.0% to 40.6%. Conversely, continued endoscopic therapy resulted in a 20.5% to 60.6% rate of rebleeding. All-cause mortality rates were similar between the TIPS and endoscopic therapy groups. However, there was a more than twofold increase in the rate of development of hepatic encephalopathy after a TIPS procedure<sup>[22-33]</sup>.

### Ectopic varices

Varices may develop anywhere along the digestive tract in patients with portal hypertension (duodenum, jejunum, colon, rectum) and may bleed. Local treatments are either impossible or associated with a high rate of rebleeding. The best approach is the TIPS procedure, which can be combined with embolization of the varices<sup>[36,37]</sup>.

**Table 2** Contraindications to placement of a transjugular intrahepatic portosystemic shunt

Absolute	Relative
Congestive heart failure	Portal vein thrombosis
Severe pulmonary hypertension	Hepatocellular carcinoma
Severe systemic sepsis	Severe coagulopathy
Unrelieved biliary obstruction	Hepatic encephalopathy
Severe tricuspid regurgitation	Obstruction of all hepatic veins

### Portal hypertensive gastropathy

These gastric lesions rarely induce problematic bleeding. Nonetheless, anecdotal case reports have suggested that TIPS may control bleeding in these patients<sup>[38]</sup>.

### Gastric antral vascular ectasia

Chronic bleeding from gastric antral vascular ectasia may be difficult to manage. However, TIPS does not help to control this type of hemorrhage, probably because these vascular lesions are related to liver disease and not to portal hypertension<sup>[38,39]</sup>.

### Other indications

Despite limited evidence, TIPS has found wider clinical use than just secondary prevention of variceal bleeding, treatment of refractory acute variceal bleeding and management of refractory ascites. These clinical indications include Budd-Chiari syndrome<sup>[40,41]</sup>, hepatic veno-occlusive<sup>[42]</sup>, hepatic hydrothorax<sup>[43-46]</sup>, hepatorenal syndrome<sup>[47,48]</sup>, and hepatopulmonary syndrome<sup>[49]</sup>.

## CONTRAINDICATIONS

Absolute contraindications to TIPS include right heart failure and pulmonary arterial hypertension. The TIPS survival benefit in patients with severe liver failure (Child-Pugh class C cirrhosis, model for end-stage liver disease score > 22, serum bilirubin > 3 mg/dL) also remains unclear. Relative contraindications include hepatic encephalopathy (which may worsen following TIPS creation), polycystic liver disease (technically challenging with a high incidence of hemorrhagic complications), active sepsis (poor outcomes), and chronic organized portal vein thrombosis (technically challenging for successful TIPS creation). Acute portal vein thrombus is not a contraindication for TIPS, but it necessitates extensive stenting to prevent shunt occlusion<sup>[50]</sup>. The contraindications are summarized in Table 2.

## PRE-TIPS TREATMENT OPTIONS FOR ACUTE VARICEAL BLEEDING

### Initial management

As with all acutely unwell patients, the basic resuscitation pathway (airway, breathing, circulation) should be instigated. Initially, the airway and breathing should be

assessed. Endotracheal intubation should be considered early, especially in patients who are deemed at high risk for aspiration, that is, those demonstrating signs of encephalopathy or ongoing severe uncontrolled hemorrhage. The adequacy of filling of the circulation should then be assessed and two large bore intravenous canula inserted before placement of a central line. Plasma expanders and packed red blood cells should be used to replace volume loss and any underlying coagulopathy corrected with platelets and fresh-frozen plasma. Despite portal pressure correlating directly with plasma volume, all cirrhotic patients with variceal hemorrhage should be maintained at a normal central venous pressure, while avoiding under filling the circulation in order to “keep the portal pressure low”<sup>[51]</sup>. Ideally, these patients should be admitted to an intensive care or high dependency unit where cardiac monitoring and high intensity nursing are readily available. All patients with cirrhosis and gastrointestinal bleeding are at an increased risk of bacterial infection and thus prophylactic antibiotics should be administered<sup>[52,53]</sup>. Several meta-analyses have demonstrated a reduction in bacterial infections and improved survival attributed to the use of short-term prophylactic antibiotics<sup>[54]</sup>. No consensus exists as to which antibiotic should be given but intravenous quinolones are generally recommended for 5-7 d followed by oral quinolones<sup>[55-57]</sup>.

### Endoscopic therapy

Sclerotherapy and variceal band ligation are the two endoscopic interventions currently used. Endoscopic sclerotherapy involves a sclerosant such as ethanolamine injected directly into the bleeding varix. Variceal band ligation is associated with fewer side effects than sclerotherapy. Banding devices that allow multiple bands to be applied without repeated reintroduction of the endoscope should be used. Variceal band ligation is the preferred endoscopic therapy for the secondary prevention of esophageal variceal hemorrhage and most centers now also use band ligation to control acute bleeding<sup>[58]</sup>.

### Pharmacological treatment

Various pharmacological agents, including vasopressin, somatostatin, octreotide and terlipressin, are of benefit in acute variceal bleeding<sup>[59-61]</sup>. These drugs cause splanchnic vasoconstriction and thus reduce portal flow. They are particularly useful when an out-of-hours endoscopy service is unavailable. Temporary cessation of bleeding and reduction in treatment failure has been reported with early administration of these drugs<sup>[62]</sup>. An ongoing debate does continue about the efficacy of these agents, particularly vasopressin analogues, as they are not without significant side effects such as increased risk of mesenteric ischemia and myocardial infarction. These agents should therefore be used with caution in patients with known atheromatous disease. Vasopressin is no longer used alone and rarely with nitrates, with terlipressin being the current agent of choice. Because a significant proportion

of patients suspected of variceal hemorrhage will actually be bleeding from nonvariceal sources, widespread use of vasoactive drugs before endoscopy should be discouraged, as is diagnostic endoscopy attempted by someone who is unable to perform band ligation or sclerotherapy. Combination therapy of these vasoactive agents and endoscopic therapy is becoming common but a meta-analysis of several studies, although demonstrating initial improvement in hemostasis, did not reveal a reduction in mortality with combination therapy<sup>[63]</sup>.

### Balloon tamponade

Balloon tamponade is invaluable in cases of uncontrolled hemorrhage when an endoscopy service is unavailable or when control cannot be achieved endoscopically. Balloon tamponade, however, is not without complications that include gross esophageal ulceration and esophageal perforation. To minimize complication rates, this procedure should be performed only by experienced staff and in the majority of cases, lone inflation of the gastric balloon should be sufficient. In the rare cases that the esophageal balloon requires inflation, inflation pressure should be closely monitored and regular deflation should also be performed. Nursing protocols should be produced and should include regular checks of the gastric balloon position and regular aspiration from both the gastric and esophageal ports. Medical staff should be alerted if blood aspiration volumes are increasing at either port. Panés *et al.*<sup>[64]</sup> examined the use of esophageal tamponade in 151 cases and reported that although balloon tamponade achieved hemostasis, 50% of patients experienced rebleeding on removal of the Stenstaken-Blackmore tube. It is essential therefore that balloon tamponade is considered only as a holding measure until a definitive procedure can be performed.

---

## TIPS PROCEDURE

---

### Timing of salvage therapy

Although the above studies illustrate the efficacy and applicability of TIPS in the setting of uncontrolled variceal bleeding, there remains a debate about the best time to perform the procedure. Although a convenient definition of uncontrolled variceal bleeding can be taken as failure of two endoscopic treatments, this does not necessarily indicate criteria for TIPS insertion. Patients with a Child-Pugh A score and whose bleeding does not appear life threatening may be managed by balloon tamponade followed by further sessions of endoscopic band ligation and generally do not require TIPS. Conversely, patients with advanced liver disease who have had a single massive bleed and unsuccessful endoscopic treatment on one occasion and require balloon tamponade, may be better treated by TIPS early rather than undergoing a second endoscopic therapy session. Monescillo *et al.*<sup>[65]</sup> showed that early insertion of TIPS might confer extra benefit. The basis of this is probably due to reducing the duration

or risk of hypotension that is likely to be detrimental for patients with decompensated liver disease.

### **Pre-procedural imaging**

Any prior imaging studies (ultrasound, computed tomography, magnetic resonance imaging), should be reviewed to confirm portal vein patency and to assess the presence of gastroesophageal varices and other porto-systemic shunts that may compete with the TIPS. The location of the portal vein bifurcation should be determined based on prior imaging, as an extrahepatic portal vein bifurcation occurs in 25% of patients and accessing an extrahepatic portal vein during TIPS carries a high mortality<sup>[10,66]</sup>. Imaging may also demonstrate the presence of splenic vein thrombosis, for which TIPS is not the treatment of choice, ascites, and general hepatic morphology. If there is large-volume ascites, pre-procedural paracentesis should be performed. If no imaging is available, Doppler ultrasound assessment of the portal vein is recommended before initiating the TIPS procedure<sup>[66]</sup>. The procedure is performed under general anesthesia and thus an emergency consultation with anesthesia is initiated as soon as TIPS is considered.

### **Equipment specifications**

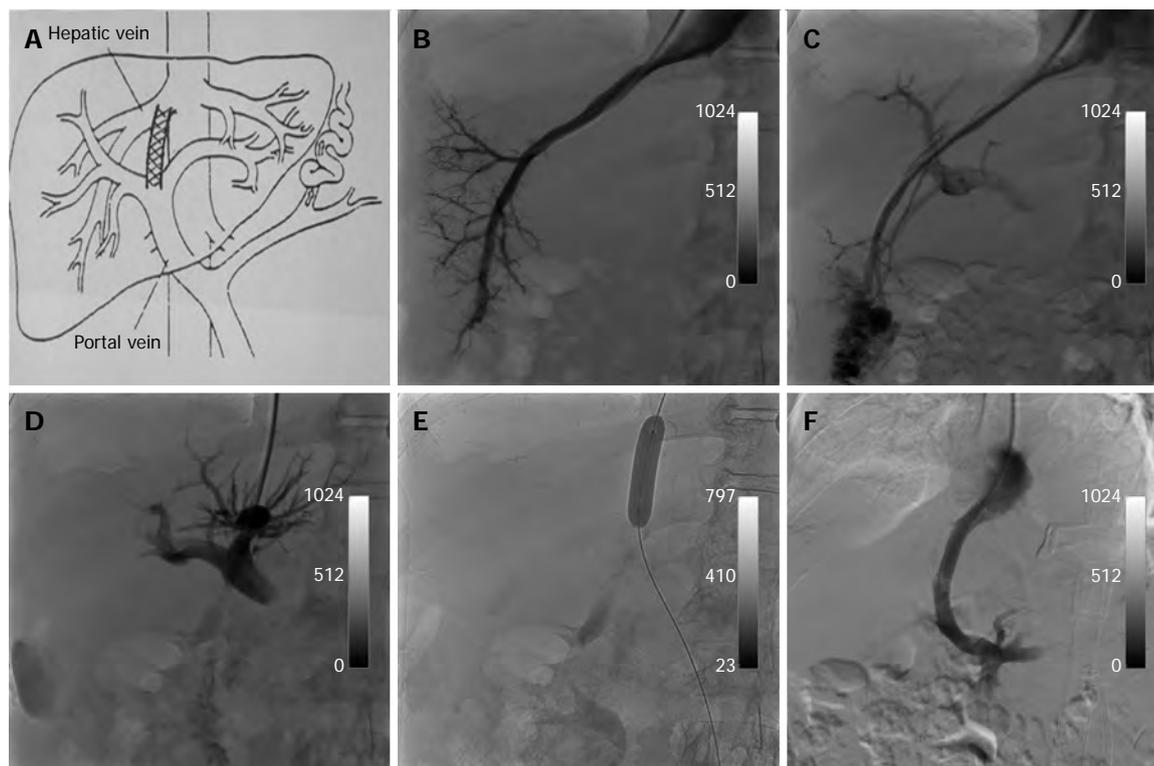

The procedure room should have the necessary equipment for continuous hemodynamic monitoring as well as for anesthesia, with access to oxygen, anesthetic gases, and suction. The angiographic equipment should allow for high-resolution fluoroscopy, digital subtraction angiography (DSA), and operator-definable protocols for performing CO<sub>2</sub> DSA, low-frame-rate fluoroscopy, and road map imaging. A trained radiologic technologist who is familiar with the necessary catheters, guidewires, balloons, stents, and imaging equipment should be present. Anesthesia or nursing personnel are essential for patient monitoring and assistance with hemodynamic measurements. The physician operator should be an interventional radiologist who is trained in performing TIPS procedures, as these require a high level of technical expertise and knowledge of the equipment, materials, anatomy, physiology, pathology, appropriate technique, and potential complications. The operator must be able to cope with the difficulties that are often associated with emergency TIPS<sup>[6,9,50,66]</sup>.

### **Shunt technique**

**Sets:** Three types of TIPS sets are commercially available. Two sets, made by Cook Medical (Bloomington, IN, United States), include the “RingTIPS set” and the “Rosch-Uchida TIPS set”. The RingTIPS set has a 16-G curved Colapinto needle, while the Rosch-Uchida set has a 16-G curved blunt cannula through which a 5-Fr catheter with an inner needle is advanced to access the portal vein. After using the needle to advance the catheter, the needle is removed and the catheter is slowly withdrawn while maintaining suction in the catheter. There is also a cope version of the ring set, which uses a 20- to 21-G-

long needle. Another set is made by AngioDynamics (Queensbury, NY, United States) and has a hollow 21-G needle that is passed through a hollow, curved cannula.

**Steps:** After entry into the internal jugular vein, a catheter is introduced and guided through the superior vena cava, right atrium, and inferior vena cava into a hepatic vein. The use of the proximal portion of the hepatic vein has two purposes. The first is to utilize, for shunt creation, the largest diameter of the hepatic vein to potentially prevent or delay any outflow shunt stenosis. The second is to be sure that one begins cephalad to the desired portal vein entry site. A needle inserted through the catheter is then used to puncture the liver from a central portion of the hepatic vein and enter the main portal branch, usually the right portal vein. In the right hepatic vein, the cannula is rotated approximately 90° anteriorly and then advanced and maintained with continual caudal pressure, so that it is wedged against the wall of the hepatic vein. When in the middle hepatic vein, the cannula is rotated posteriorly in the same way. Carbon dioxide wedged hepatic venography is used to identify the portal vein<sup>[67]</sup>. Iodinated contrast medium can also be used. The puncture can be also navigated with ultrasonography. Depending on the anatomy, it might be possible to use a tract from the right hepatic vein to the left portal branch, and vice versa. The needle tract is then dilated by a balloon catheter, establishing a connection between the portal and systemic circulation directly inside the liver parenchyma. The parenchymal tract is kept open by insertion of an expandable metallic stent. A dedicated TIPS stent graft was designed to extend the covered portion to the orifice of the hepatic vein at the inferior vena cava<sup>[41]</sup>. The only uncovered part of the stent graft, which is 2 cm long, is the section that protrudes into the portal vein. This both anchors the device and allows blood to flow through the interstices of the uncovered portion to the peripheral (parenchymal) portal vein branches. The alternative to the dedicated stent graft has been a self-expandable stent used for bridging portal and hepatic veins in a similar way. The bare stents are used for patients at high risk of hepatic encephalopathy or for recanalization of the portal vein. The shunt diameter is finalized by balloon dilatation of the deployed stent graft or stent. Depending on the diameter of the expandable stent or stent graft used for TIPS creation, various amounts of portal blood are diverted into the systemic circulation, resulting in the decompression of portal hypertension. The size of the balloon catheter is usually 8 mm. Depending on the pressure gradient measured between the portal vein and right atrium after stent or stent graft placement, a larger angioplasty balloon catheter is an option to achieve adequate stepwise decompression. For liver transplant candidates, precise positioning of both ends of the stent or stent graft is critical<sup>[6,50]</sup>. The needle may exit the liver and lacerate the liver capsule or enter the hepatic artery. Embolization of the parenchymal tract is the first-line

**Figure 1** Conventional transjugular intrahepatic portosystemic shunt creation technique. A: Schematic diagram shows transjugular intrahepatic portosystemic shunt (TIPS) connecting the right hepatic vein to the right portal vein. The shunt extends from main portal vein to confluence of right hepatic vein and inferior vena cava; B: Right hepatic venogram shows course of hepatic vein; C: Transhepatic portogram using iodinated contrast material shows course of portal veins; D: Injection of contrast medium through Colapinto needle confirms needle position within portal vein before passage of guidewire; E: Dilatation of a tract through the hepatic parenchyma that is interposed between the hepatic and portal veins; F: Portal venogram obtained after TIPS insertion shows flow through the FLUENCY polytetrafluoroethylene-covered stent. Peripheral portal vein branches are no longer opacified because of reversal of flow.

treatment to prevent hemoperitoneum. The TIPS tract must be intraparenchymal, or dilatation of the extrahepatic portion of the portal vein results in fast exsanguination, a complication that occurs in approximately 1% of procedures. Entry into the right or left portal vein branch should be at least 1 to 2 cm from the portal vein bifurcation. The direct injection into the dilated tract should be done as soon as possible to reveal potential extravasation. If it is positive, the balloon is again inflated and the stent graft placed to tamponade the extrahepatic leak. According to the patient's blood pressure, fluid volume resuscitation is immediately initiated and the anesthesiologist is called<sup>[6,9,50,66]</sup>. The final step of the TIPS procedure is placement of pigtail catheter over the portal vein guide wire for follow-up portography and blood pressure measurement within the main portal vein. Once the value is stabilized and recorded, the tip of the sheath or pigtail catheter is moved to the hepatic vein or the suprahepatic inferior vena cava, and the blood pressure is again recorded. Thus, at the completion of the TIPS procedure, at least four pressure values will have been obtained: those in the portal vein and hepatic vein (or inferior vena cava) before and after shunt placement. The different steps are summarized in Figure 1.

### Embolization of varices

Embolization of the esophageal varices at the time of

the TIPS is easily accomplished but its routine application has been also controversial. While embolization after TIPS occurs in 24% to 48% of patients<sup>[68,69]</sup>, it is not clear whether the combination of TIPS and variceal embolization is more effective than TIPS alone. Some authors recommend transjugular embolization of the varices to increase the effect of the shunt with respect to acute hemostasis<sup>[68,70]</sup>, and other authors do not perform embolization<sup>[71]</sup>. In our clinical practice, we perform embolization of varices only if we observe persistent contrast flow into the varices in the control portography after TIPS. Variceal embolization is also indicated for patients with recurrent esophageal bleeding despite a patent shunt<sup>[68]</sup>. Embolization of esophageal varices is most commonly performed with the use of metallic coils, but the use of liquid agents such as opacified enbucrilate and ethanol have also been described<sup>[17]</sup>. The use of absolute ethanol is not recommended due to the possible adverse effects including cardiovascular collapse due to the possible venous channels between the portal system and the pericardium, mainly from the pericardiophrenic vein.

### Post-procedural follow-up

Recurrence or worsening of the portal hypertension symptoms should prompt an ultrasound with Doppler to exclude TIPS stenosis. Shunt velocities between 50 and 250 cm/s are associated with high (> 90%) sensitiv-

**Table 3** Acute and chronic complications after transjugular intrahepatic portosystemic shunt placement

Acute complications	Acute complications	Chronic complications
Minor or moderate Stent displacement	Life-threatening Hemobilia	Portal vein thrombosis

Arrhythmia	Cardiac failure	Progressive liver failure
Shunt thrombosis	Liver ischemia	Chronic recurrent encephalopathy
Hepatic vein obstruction	Sepsis	Stent dysfunction

ity and specificity for shunt dysfunction<sup>[72]</sup>. In addition, most hepatologists order routine TIPS surveillance tests at regular intervals using ultrasound with Doppler in asymptomatic patients. Patients with a suspected TIPS dysfunction should undergo TIPS venography. If the original TIPS was created using a bare-metal stent, placement of a covered stent is likely to improve long-term shunt patency<sup>[73]</sup>. Other commonly used measures include balloon angioplasty within the stents and the placement of additional stents in patients to extend cranial or caudal length of the stent. Hepatic encephalopathy refractory to medical management or progressive hepatic dysfunction after TIPS placement might require endovascular shunt reduction. A commonly used technique involves shunt catheterization by two parallel guidewires followed by simultaneous deployment of two stents within the shunt. One of the stents is a covered endograft through which blood flow will be conducted, whereas the second device is a balloon-expandable bare-metal stent, the diameter of which determines the ultimate shunt diameter. Usually, the bare-metal stent is placed along the cephalic aspect of the covered stent. This allows continued access to the balloon expandable stent if further reduction is necessary<sup>[74,75]</sup>.

## OUTCOMES

### Complications

The TIPS procedure may lead to a number of adverse events (Table 3). Technical complications sustained at the time of TIPS placement can include transcapsular puncture, which may occur in as many as 33% of cases<sup>[10]</sup>. The capsular perforation leads to significant intraperitoneal hemorrhage 1% to 2% of the time<sup>[10]</sup>. Clinically significant hemobilia is also rarely observed after the procedure. The stent can be placed too far into the inferior vena cava or even into the right atrium at the cranial end or far into the main portal vein at the caudal end of the shunt in up to 20% of patients<sup>[10]</sup>. On occasion, stents may migrate because of catheter and balloon manipulation<sup>[76]</sup>. Diversion of portal venous flow through the shunt diminishes the metabolic filtering effect of the hepatic parenchyma, leading to new or worsened encephalopathy in 30% to 46% of patients<sup>[34,35]</sup>. Chronic recurrent disabling hepatic encephalopathy can occur in 5% to 10% of patients and may lead to a complete loss of the patient's autonomy<sup>[10,66]</sup>. Several pre-TIPS parameters have been tested to

predict post-TIPS hepatic encephalopathy (Table 4)<sup>[10,34,35]</sup>. Deterioration of hepatic function in approximately 10% of patients<sup>[35]</sup>, and hepatorenal syndrome is occasionally observed<sup>[77]</sup>. TIPS stenosis and occlusion was the method of choice before wide acceptance of PTFE-covered stents (Viatorr; W.L. Gore and Associates, Flagstaff, AZ, United States). The most common site of shunt stenosis is at the hepatic venous end. The culprit of midstent stenosis is thought to be intimal hyperplasia within the bare-metal stent due to contact between traversed biliary radicles and stent lumen<sup>[76]</sup>. The incidence of stenosis due to hyperplasia within the stent ranged from 18% to 78%<sup>[76]</sup> for bare-metal stents, which led to recurrence of portal hypertension complications and required frequent invasive procedures for reconstitution of flow. The introduction of PTFE-covered stent grafts led to dramatic improvement in long-term TIPS patency. A randomized controlled trial published in 2007 established a PTFE-covered stent as the preferred device for TIPS<sup>[78]</sup>. In that study, 80 patients were randomized to receive either a covered ( $n = 39$ ) or a bare ( $n = 41$ ) metal stent and were followed for two years after TIPS placement. Compared with patients treated with a bare-metal stent, patients with a PTFE-covered stent had a significantly lower rate of TIPS dysfunction (15% *vs* 44%), a higher rate of primary patency (76% *vs* 36%), a lower rate of clinical relapse (10% *vs* 29%), and were less likely to develop encephalopathy (33% *vs* 49%)<sup>[78]</sup>. On the basis of these data, a PTFE-covered stent became the standard of care device for de novo TIPS. Patients who have a bare metal stent TIPS should undergo shunt revision with a PTFE-covered stent in the event of shunt dysfunction<sup>[76]</sup>.

### Mortality

Acute variceal hemorrhage that is poorly controlled with endoscopic therapy is generally well controlled with TIPS, which has a success rate of 90% to 100%. However, TIPS also has a mortality rate of 27% to 50%<sup>[19,66,79,80]</sup>. Increased mortality is related to a Child-Pugh C clinical status, hemodynamic instability at the time of the TIPS procedure, and the presence of other comorbidities. In general, early TIPS intervention allows for better control of hemorrhage with decreased mortality. Patients with a

high HVP ( $> 20$  mmHg) and acute variceal bleeding have a better survival with TIPS than with endoscopic therapy<sup>[65]</sup>. Most of the deaths of patients after emergency TIPS are related to hepatic failure, multiorgan failure, and sepsis, often accompanied by variceal and nonvariceal bleeding, while only a minority are related to recurrent variceal bleeding<sup>[13,69,81]</sup>. Death occurring within 30 d of the procedure is most commonly caused by multiorgan failure, and death more than 30 d following the procedure is most commonly related to liver failure<sup>[81]</sup>. Many studies reporting on emergency TIPS for the rescue treatment of acute esophageal varices bleeding have shown low survival rates and significantly higher mortality rates than patients undergoing elective TIPS<sup>[6,12,17,19,21,65]</sup>. In one study, 42 of 123 (34.1%) of patients died within 30 d of TIPS for acute bleeding, while only 16.5% died following elective TIPS creation<sup>[82]</sup>. As an independent predictor of mortality, patients bleeding at the time of TIPS creation were 2.9 times more likely to die than those associated with elective TIPS placement. Similar findings have been reported by Helton *et al.*<sup>[83]</sup> who reported a 56% in-hospital mortality rate for patients who were actively bleeding or hemodynamically unstable at the time of the TIPS *vs* 5.5% following nonemergency procedures. The reported mortality associated with TIPS varies widely because the inclusion criteria, timing of the TIPS, and the severity of liver disease. Many reports combine the results of patients actively bleeding during TIPS with those of the patients who were stable during the procedure. Several reports describing different prognostic factors associated with mortality after TIPS have been published<sup>[68,69,82]</sup>. Prognostic factors are not intended to predict outcome or management on individual basis or to deny a patient a potentially lifesaving intervention, but are useful as guidelines to develop appropriate expectations and to weigh different therapeutic options. Final decisions are based on the individual patient needs and overall clinical condition<sup>[65,84]</sup>. Many of these prognostic factors correlate with the mortality of patients undergoing elective TIPS. In patients with acute variceal bleeding, however, these predictors may fail because the hepatic reserve and renal function are difficult to evaluate in the acute setting<sup>[65]</sup>. Events such as bleeding, infection, and high-dose diuretic therapy may affect the renal and liver function in a transient way. No single prognostic criterion is available to accurately select patients with a very high risk of death<sup>[85]</sup>. However, several selection criteria have been described due to an increased amount of experience within the field with relation to TIPS<sup>[86]</sup>.

### **Effect on liver and spleen stiffness**

Variceal bleeding still remains the major cause of death in patients with cirrhosis, with increasing numbers of inpatient cases with advanced liver disease and portal hypertension. For those patients, TIPS has become the rescue treatment of choice, preferred over liver transplantation. Therefore, it is crucial to ensure that the inserted TIPS effectively decreases portal vein pressure to prevent

variceal bleeding. Non-invasively assessing the pressure of the portal vein as a function of the TIPS has been a challenge. Color Doppler sonography can measure flow velocities in the TIPS, but it cannot reflect the pressure of the portal vein and its pitfalls and inaccuracies lead to a lack in necessary sensitivity<sup>[87]</sup>. More recently, a novel ultrasound-based acoustic radiation force impulse (ARFI) elastography has been developed that can provide information on the local mechanical property of a tissue<sup>[88]</sup>. An acoustic push pulse transmitted by the transducer toward the tissue produces an elastic shear wave that propagates through the tissue. The propagation of the shear wave is followed by detection pulses that are used to measure the velocity of the shear wave propagation, which is directly related to tissue elasticity. In other words, the speed of shear wave is dependent on the elasticity of the tissue<sup>[88]</sup>.

Gao *et al.*<sup>[89]</sup> prospectively assessed the stiffness of the liver and spleen with ARFI imaging pre- and post-TIPS placement. The investigators measured stiffness of the liver and spleen with mean shear wave velocity (MSV, m/s) on ARFI imaging for 10 healthy volunteers and 10 patients who underwent TIPS placement for treatment of portal hypertension. The portal vein pressure was measured during TIPS placement. A significant difference in portal vein pressure was found for the pre- ( $27.67 \pm 5.86$  mmHg) and post- ( $18.00 \pm 6.93$  mmHg) TIPS insertion. Significant differences were also found in MSV of the liver and spleen between healthy subjects and patients with portal hypertension. There was no significant difference found in MSV of the liver pre- and post-TIPS placement. However, a statistically significant difference in MSV of the spleen pre- and post-TIPS placement was demonstrated. In addition, the authors reported a significant difference in spleen index between healthy subjects and patients with portal hypertension, as well as between pre- and post-TIPS placement. The MSV of the spleen measured with ARFI correlated well with portal vein pressure. Hence, the authors concluded that spleen stiffness determined by means of MSV on ARFI imaging could be used as a quantitative marker for monitoring the portal vein pressure as the function of the TIPS.

In this study, as well, the authors had prospectively shown a close correlation between the stiffness of the spleen and portal vein pressure. Based on these data, one can clearly note that the stiffness of the spleen measured with MSV changes as the portal vein pressure changes following TIPS placement. This is the first quantitative demonstration of the effectiveness of TIPS on the stiffness of the spleen measured with MSV value on ARFI imaging. One parameter that was not significantly affected by TIPS placement was the MSV value of the liver. The most plausible explanation for this finding is that TIPS can have a direct impact on the pressure of the portal vein but have no effect on the stiffness of a fibrotic liver. The tissue mechanical property of a cirrhotic liver is very hard due to the severe fibrosis developed in the liver parenchyma, which has poor elasticity. In addition, MSV of the spleen has potential to serve as an indicating

marker with which to assess portal vein pressure. Finally, it may be used as a non-invasive predictor in screening for recurrent portal hypertension when TIPS malfunction develops.

### Economic benefit

Early insertion of TIPS in high-risk patients with acute variceal hemorrhage reduces rebleeding and mortality. However, the economic benefit of utilizing this approach remains unclear. Harman *et al*<sup>[90]</sup> retrospectively carried out a cost-effectiveness analysis of patients who may benefit from early TIPS insertion. The costs were calculated in a 12-mo follow-up from index bleeding admission and compared to a theoretical 12-mo follow-up cost related to early TIPS insertion. Over one year, 78 patients were admitted with variceal hemorrhage; 27 patients (35%) were eligible for early TIPS insertion. The actual cost for the 12-mo follow-up was £138473.50. The authors estimated early TIPS insertion would save £534.70 per patient per year ( $P < 0.0001$ ). According to sensitivity analysis, early TIPS was the dominant treatment modality up to a theoretical rebleeding rate of 6%, and the economic threshold of £15000 per bleeding episode saved was achieved at a 12% yearly rebleeding rate, suggesting it would be financially viable to adopt early TIPS as an intervention up to a 12% yearly rebleeding rate. This study indicates strict patient selection is vital to reduce the rebleeding rate when utilizing early TIPS insertion. There is an important balance between selecting patients at high risk of rebleeding, who are likely to benefit from early TIPS insertion to prevent rebleeding, but also to exclude patients with the most severe hepatic dysfunction where early TIPS insertion is unlikely to alter the natural history of their disease. Strict patient selection reduces rebleeding-related admissions, thus reducing follow-up costs; this is a key concept for centers to focus on before introducing early TIPS as routine practice. Finally, Harman *et al*<sup>[90]</sup> found 35% of their bleeding cohort were eligible for early TIPS insertion, further establishing early TIPS insertion as a cost-effective intervention. This has important implications for the future provision and organization of interventional radiology services. Future prospective studies evaluating early TIPS insertion are warranted, and including similar economic modeling will help to confirm the financial viability of introducing early TIPS insertion into routine clinical practice.

### CONCLUSION

The TIPS procedure is now a well-established treatment for complications of portal hypertension. Technical advances and well-designed clinical studies provide a scientific basis to define the best indications. Patients with acute variceal bleeding with a Child-Pugh score  $> 12$ , APACHE score II  $> 18$  points, hemodynamically unstable, receiving vasopressors and coagulopathy, and/or bilirubin  $> 6$  mg/dL have a high risk of early death after TIPS. In specific, in some individual clinical situations

it may be wise to withhold the TIPS because the mortality rate will be very high regardless of the therapy given. Every effort should be taken to stabilize the patient before TIPS, including the use of tamponade tubes and aggressive correction of coagulopathy. Once medical treatment and sclerotherapy fail, emergency TIPS should be considered early before the clinical condition worsens. Patients at high risk for early mortality after TIPS should be considered for expedited liver transplantation if available. Cost analysis must be performed in the future taking into account recent developments including technical improvements, better patient selection, and better post-TIPS management.

### Abstract

Hepatocellular carcinoma (HCC) is one of the most frequent tumors worldwide. The majority of HCC cases occur in patients with chronic liver disease. Despite regular surveillance to detect small HCC in these patients, HCC is often diagnosed at an advanced stage. Because HCC is highly resistant to conventional systemic therapies, the prognosis for advanced HCC patients remains poor. The introduction of sorafenib as the standard systemic therapy has unveiled a new direction for future research regarding HCC treatment. However, given the limited efficacy of the drug, a need exists to look beyond sorafenib. Many molecular targeted agents that inhibit different pathways involved in hepatocarcinogenesis are under various phases of clinical development, and novel targets are being assessed in HCC. This review aims to summarize the efforts to target molecular components of the signaling pathways that are responsible for the development and progression of HCC and to discuss perspectives on the future direction of research.

**Key words:** Hepatocellular carcinoma; Targeted therapy; Molecular agents; Sorafenib

**Core tip:** Sorafenib is the first drug to prolong survival of patients with advanced hepatocellular carcinoma (HCC). This advance has shifted the paradigm of systemic treatment for HCC toward molecular targeted therapy. This review aims to summarize the efforts to target molecular components of the signaling pathways that are responsible for the development and progression of HCC and to discuss perspectives on the future direction of research.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is a common solid cancer and the third most frequent cause of cancer-related mortality worldwide. The 5-year relative survival rate for patients with HCC is only 7%, and very few patients with symptomatic disease survive for > 1 year<sup>[1]</sup>. One of the primary reasons for the poor prognosis of patients with HCC is the lack of effective treatment options, especially for those with advanced disease. Although surgery and percutaneous ablation can achieve long-term control in some patients with early HCC, fewer than 40% of patients are diagnosed at early stages; hence, only a minority of HCC patients are eligible for potentially curative therapies, such as resection, transplantation, or percutaneous ablation<sup>[2]</sup>. Furthermore, systemic therapies (such as stan-

dard chemotherapeutic agents) do not provide significant efficacy in HCC based on randomized trials<sup>[3]</sup>.

In recent years, improved knowledge of the oncogenic processes and signaling pathways that regulate tumor cell proliferation, differentiation, angiogenesis, invasion and metastasis has led to the identification of several potential therapeutic targets, which has driven the development of molecularly targeted therapies. An ideal cancer target meets the following criteria: (1) the target is relatively specific for cancer cells (not expressed or expressed at very low levels in normal cells but overexpressed in cancer cells). Meanwhile, overexpression of the target is associated with malignant biological phenotypes and/or poor prognosis; (2) inhibition of the target is efficacious (the target plays an essential role in cancer initiation and progression, and inhibition of expression or activity of the target induces growth suppression and/or apoptosis in cancer cells); and (3) the target is “drugable” as an enzyme (*e.g.*, a kinase) or a cell surface molecule (*e.g.*, a membrane-bound receptor) that can be easily screened for small-molecule inhibitors or targeted by a specific antibody<sup>[4]</sup>.

The aim of this article is to review the efforts to target molecular components of the signaling pathways that are responsible for the development and progression of HCC and to summarize the evidence for the clinical activity of these agents in patients with HCC.

## HCC DEVELOPMENT AND SIGNALING PATHWAYS

Hepatocarcinogenesis is a multistep process initiated by external stimuli that lead to genetic changes in hepatocytes or stem cells, resulting in proliferation, apoptosis, dysplasia and neoplasia. The majority of HCC cases are related to chronic viral infections. However, the mechanisms by which hepatitis B virus (HBV) or hepatitis C virus (HCV) induce malignant transformation seem to differ. HBV DNA integrates into the host genome, inducing chromosome instability and insertional mutations that may activate various oncogenes, such as cyclin A<sup>[5-7]</sup>. Viral proteins, in particular X protein (HBx), act as transactivators to upregulate several oncogenes (such as *c-myc* and *c-jun*) and transcriptional factors [(such as nuclear factor- $\kappa$ B)]<sup>[8-10]</sup>. Additionally, HBx activates promoters of genes encoding IL-8, tumor necrosis factor (TNF), transforming growth factor (TGF)- $\beta$  and epidermal growth factor receptor (EGFR)<sup>[11]</sup>. HBx can also stimulate several signal transduction pathways, including the JAK/STAT, RAS/RAF/MAPK, and Wnt/ $\beta$ -catenin pathways<sup>[12-14]</sup>.

The contributions of HCV to hepatocarcinogenesis are mediated by viral proteins, including core, NS3 and NS5A proteins. HCV core protein can promote apoptosis or cell proliferation through interaction with p53 or upregulation of Wnt-1 at the transcriptional level<sup>[15,16]</sup>. NS4A and NS4B proteins mediate translational inhibition and degradation of various cellular proteins<sup>[17]</sup>. Cirrhosis

is present in approximately 80%-90% of HCC patients and constitutes the largest single risk factor. In cirrhotic liver, changes in fat metabolism associated with the activation of adipocyte-like pathways are thought to be involved in neoplastic transformation<sup>[18]</sup>.

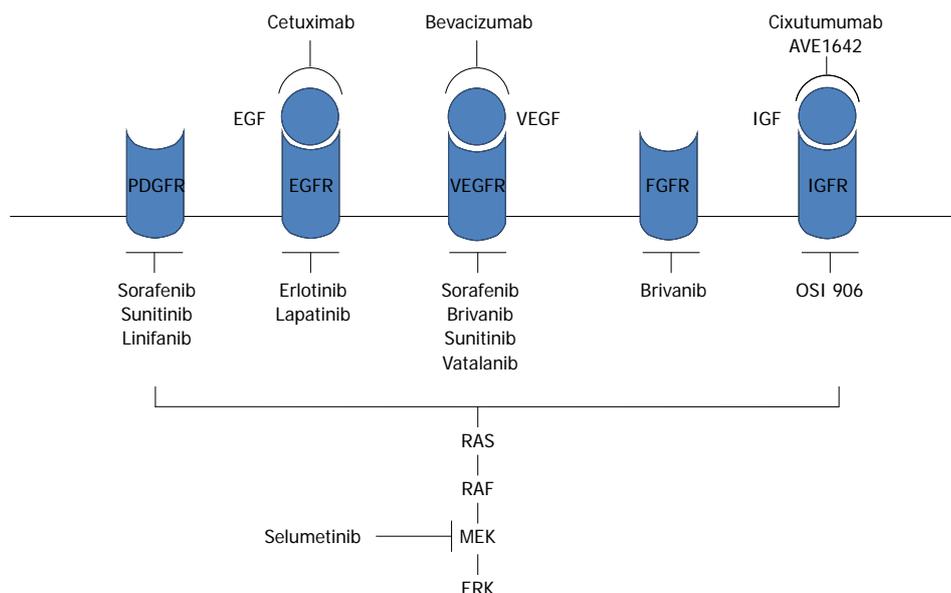

## MAPK PATHWAY (RAS/RAF/MEK/ERK)

The Raf/MAPK/extracellular-signal-regulated kinase (ERK) pathway is an important pro-survival signaling pathway that is primarily involved in cell growth and survival and regulates cell differentiation. This pathway transduces extracellular signals from membrane-bound tyrosine kinase receptors, such as EGFR, insulin-like growth factor receptor (IGFR), vascular endothelial growth factor receptor (VEGFR), *c-Met* and platelet-derived growth factor receptor (PDGFR), to the nucleus. Growth factor binding results in receptor phosphorylation, which activates an adapter molecule complex known as GRB2/SHC/SOS. This sequence in turn activates the RAF/mitogen/extracellular protein kinase (MEK)/ERK pathway, which triggers a cascade of specific phosphorylation events<sup>[19]</sup>. Within this pathway, the small GTPase RAS and the serine/threonine kinase Raf are the key signal regulators<sup>[20]</sup>. Intermediate signaling is regulated by MEK1 and MEK2, which are responsible for phosphorylating and activating the final downstream signaling molecules extracellular-regulated protein kinases (ERK)1 and ERK2<sup>[21]</sup>. ERK1/2 regulates cellular activity by acting on more than 100 substrates in the cytoplasm and nucleus. RAS also regulates the phosphatidylinositol 3-kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) pathway, the phospholipase C/protein kinase C pathway and the *ral* guanine nucleotide dissociation stimulator pathway<sup>[22,23]</sup>.

Up-regulated activation of the Raf/MAPK/ERK signaling pathway has been well documented in HCC and correlates with advanced stage<sup>[24,25]</sup>. Mechanisms for the increased activity of the Raf/MAPK/ERK signaling pathway in HCC include down-regulation of Raf kinase inhibitor protein (a suppressor of the Raf/MAPK/ERK pathway) and induction by hepatitis viral proteins (such as the hepatitis B X protein and the hepatitis C core protein)<sup>[26-28]</sup>.

Targeting Raf kinase is one of the most promising targeted approaches for the treatment of HCC. Sorafenib has strong inhibitory activity against Raf-1 (C-Raf) kinase and B-Raf (wild-type B-Raf and mutant V600E B-Raf) and has been shown to inhibit other serine/threonine kinases, the pro-angiogenic receptor tyrosine kinases VEGFR, PDGFR and FGFR1, and tyrosine kinases such as *c-kit*, Flt-3 and RET, which are involved in tumor progression and overall prognosis (Figure 1)<sup>[29]</sup>.

Selumetinib (AZD6244) is an oral non-ATP-competitive small-molecule inhibitor of the mitogen-activated protein kinase MEK1/2. A recent study has shown that selumetinib plus rapamycin exerts antitumor and antiangiogenic effects in preclinical models of human HCC<sup>[30]</sup>. In a phase I / II study of selumetinib in combination with

**Figure 1** Ras/Raf/MEK/ERK signaling pathways and molecular targeted agents which is currently available or in development for hepatocellular carcinoma. EGF: Epidermal growth factor; EGFR: EGF receptor; ERK: Extracellular signal-regulated kinase; FGFR: Fibroblast growth factor receptor; IGF1R: Insulin-like growth factor receptor; PDGFR: Platelet-derived growth factor receptor; VEGF: Vascular endothelial growth factor; VEGFR: VEGF receptor; MEK: Mitogen/extracellular protein kinase.

sorafenib in advanced HCC, the objective responses were 3 partial response (PR), 6 stable disease (SD) and 2 progressive disease (PD) among 11 patients, and the common toxicities were diarrhea, rash, fatigue, and hypertension<sup>[31]</sup>.

Another phase I / II study has evaluated the combination of the MEK inhibitor RDEA119 and sorafenib in patients with advanced cancer (NCT00785226).

### PI3K/AKT/MTOR PATHWAY

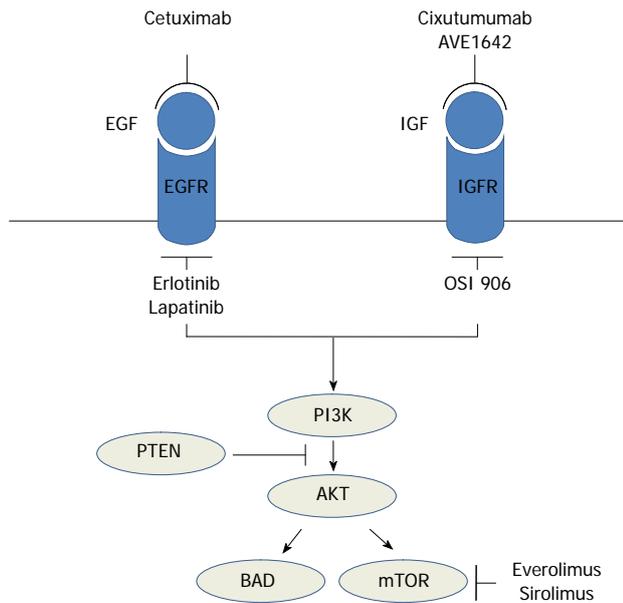

The PI3K/Akt/mTOR pathway also plays an important role in cell growth, survival regulation, metabolism and anti-apoptosis<sup>[32]</sup>. The binding of growth factors (such as IGF and EGF) to their receptors activates PI3K<sup>[19]</sup>. PI3K subsequently produces the lipid second messenger PIP3b (phospho-inositol triphosphate), which in turn activates the serine/threonine kinase AKT. Activated AKT also phosphorylates several cytoplasmic proteins, most notably mTOR and BCL-2-associated death promoter<sup>[19]</sup>. The activation of mTOR increases cellular proliferation, and inactivation of BAD decreases apoptosis and increases cell survival<sup>[21]</sup>. In normal tissue, this pathway is negatively regulated by the tumor suppressor phosphatase on chromosome 10 [phosphatase and tensin homolog (PTEN)], which targets the lipid products of PI3K for dephosphorylation<sup>[21]</sup>.

Expression of both IGF and the IGF receptor is up-regulated in HCC and cirrhotic liver, resulting in stimulation of the PI3K/AKT/mTOR signaling pathway in addition to activation of the RAF/MEK/ERK and WNT/ $\beta$ -catenin pathways<sup>[33,34]</sup>. Anomalies in PTEN function may lead to overactivation of the PI3K/AKT/mTOR pathway in HCC. PTEN expression is reduced in nearly half of all HCC tumors, resulting in constitutive

activation of the PI3K/AKT/mTOR pathway<sup>[35]</sup>. Decreased PTEN expression has been shown to correlate with increased tumor grade, advanced disease stage and reduced overall survival (OS) in patients with HCC<sup>[35]</sup>. In a mutation analysis of HCC samples, activation of the IGF pathway, upregulation of EGF, dysregulation of PTEN, and aberrant mTOR signaling were present in half of the samples; inhibition of mTOR activity with a rapamycin analog (everolimus) was effective in improving survival and suppressing recurrence<sup>[36]</sup>. These results suggest that mTOR pathway activation plays a crucial role in the pathogenesis of HCC (Figure 2).

The PI3K inhibitor RG7321 and the Akt inhibitor perifosine target the PI3K/Akt/mTOR pathway and are in early stages of clinical development. The mTOR inhibitors everolimus (RAD001), sirolimus (Rapamune) and temsirolimus (CCI-779) have been studied for efficacy and safety in patients with advanced HCC. Everolimus has produced a median progression-free survival (PFS) of 3.8 mo and OS of 8.4 mo in phase I / II testing in patients with advanced HCC<sup>[37]</sup>. A phase III study to compare everolimus and placebo and a phase I / randomized phase II study (sorafenib + everolimus *vs* sorafenib alone) to test the efficacy and tolerance of sorafenib in combination with everolimus are underway (NCT01035229). In a phase II study of sirolimus in patients with advanced HCC, sirolimus exhibited some antitumor activity in patients with advanced HCC<sup>[38]</sup>. However, larger studies are required to determine the value of this agent.

Temsirolimus, an mTOR inhibitor, has been approved for the treatment of advanced renal cell carcinoma. The efficacy and potential utility of this agent in HCC is currently under investigation (NCT01079767).

**Figure 2** PI3K/Akt/mTOR pathway and the molecular agents targeting this pathway. BAD: BCL-2-associated death promoter; EGF: Epidermal growth factor; EGFR: EGF receptor; IGFR: Insulin-like growth factor (IGF) receptor; mTOR: Mammalian target of rapamycin; PTEN: Phosphatase and tensin homolog; PI3K: Phosphatidylinositol-3-kinase.

## VEGF/VEGFR, PDGFR, AND FGFR

Normal angiogenesis is maintained by a balance between proangiogenic and anti-angiogenic factors<sup>[39]</sup>. The angiogenic balance is disturbed in HCC. Angiogenesis is important for HCC growth and metastasis and occurs as a result of complex alterations that involve promoting factors [such as VEGF, angiopoietin and fibroblast growth factor (FGF), inhibitory factors, including thrombospondin (TSP) and angiostatin], and the surrounding tissue. A number of angiogenic growth factors, including VEGF-A, angiopoietin-2 and PDGF, have been shown to be upregulated in HCC tumors at the gene expression level and plasma protein level in patients with HCC compared with cirrhotic patients<sup>[40]</sup>. The principal angiogenic factors involved are VEGFs, PDGFs, TGF- $\alpha$  and - $\beta$ , basic FGF, EGF, hepatocyte growth factor (HGF), angiopoietins and interleukin-4 and -8<sup>[39,41]</sup>. These growth factors and cytokines induce angiogenic signaling through a variety of mechanisms, including activation of the RAF/MEK/ERK, PI3K/AKT/mTOR and JAK/signal transducer and activator pathways.

Increased VEGF expression has been reported in cirrhotic and dysplastic liver tissue, suggesting a possible role for VEGF-mediated angiogenesis in hepatocarcinogenesis<sup>[42]</sup>. VEGF clearly plays an important regulatory role in HCC; high levels of VEGF expression have been linked with HCC tumor grade, poor outcome after resection, disease recurrence, poor disease-free survival (DFS) and OS, vascular invasion and portal vein emboli<sup>[43-46]</sup>. Expression of FGF-2 is also elevated in patients with HCC, and FGF-2 expression in HCC correlates with

tumor microvessel density and postoperative recurrence rate<sup>[47-49]</sup>. Tumor angiogenic expression correlates with microvascular density in patients with HCC, and high serum angiogenic levels are associated with decreased survival at 5 years<sup>[50]</sup>.

The VEGF pathway can be targeted through two approaches: anti-VEGF monoclonal antibodies or inhibitors of the receptor tyrosine kinase associated with VEGFR. The anti-VEGF monoclonal antibody bevacizumab was the first angiogenesis inhibitor to be approved as an antineoplastic agent. Bevacizumab has shown encouraging early evidence of efficacy in patients with advanced HCC<sup>[51,52]</sup>. The combination of bevacizumab with either cytotoxic agents (gemcitabine, oxaliplatin, and capecitabine) or erlotinib has also shown encouraging results in four phase II trials in patients with advanced HCC<sup>[53-56]</sup>.

Sorafenib is an orally available multikinase inhibitor that was originally designed to target VEGFR-1, -2, -3, PDGFR and c-kit. In a phase II study of patients with advanced inoperable HCC, sorafenib induced a PR in 2% of the patients. The median time to progression (TTP) was 4.2 mo and median OS was 9.2 mo<sup>[57]</sup>. In the phase III SHARP (Sorafenib HCC Assessment Randomized Protocol) trial, sorafenib (400 mg twice daily) significantly prolonged OS compared with placebo in patients with advanced HCC (10.7 mo in the sorafenib group *vs* 7.9 mo in the placebo group)<sup>[58]</sup>. The median time to radiological progression was significantly longer in the sorafenib group (5.5 mo *vs* 2.8 mo). In another randomized phase III study performed in the Asia-Pacific region, the OS was 6.5 mo in the sorafenib group compared with 4.2 mo in the placebo group (the hazard ratio in the sorafenib group was 0.68,  $P = 0.014$ )<sup>[59]</sup>. Sorafenib is the only targeted therapy to have been approved for clinical use in several countries, including the United States and in Europe. Although sorafenib improved OS in patients with HCC, the associated toxicities may significantly affect patients' quality of life. High rates of dermatologic side effects have commonly been reported with sorafenib, the most clinically significant of which is hand-foot skin reaction<sup>[60]</sup>. Despite initial responses to sorafenib, most HCC patients experience a loss of efficacy. No effective second-line treatment options currently exist for patients who are resistant or refractory to and/or intolerant of sorafenib.

Beyond sorafenib, sunitinib is the most studied multikinase inhibitor targeting VEGFR-1 and VEGFR-2. Sunitinib also displays inhibitory activities against other receptor tyrosine kinases, including PDGFR-a/b, c-KIT, FLT3, and RET kinases. Sunitinib is currently indicated for the treatment of renal cell carcinoma and gastrointestinal stromal tumors<sup>[61-63]</sup>. Two phase II studies of sunitinib in patients with advanced HCC have been performed. In the first study, the PR rate was 2.9%, and 50% of the patients achieved stable disease<sup>[64]</sup>. In a second phase II study, one (2.7%) patient experienced a confirmed PR and 13 (35%) of 37 patients achieved stable

disease<sup>[65]</sup>. A phase III study comparing sunitinib with sorafenib (NCT00699374) was discontinued due to a greater incidence of adverse events in the sunitinib group and because sunitinib failed to demonstrate superiority or non-inferiority to sorafenib in extending the survival of patients with advanced HCC.

Brivanib is a dual inhibitor of VEGFR and fibroblast growth factor receptor signaling pathways. Because FGF signaling may contribute to acquired “resistance” or compensatory signaling during anti-VEGFR therapy, the simultaneous inhibition of these 2 pathways by brivanib may both delay initial progression in response to antiangiogenic therapy (as first-line treatment) and successfully treat tumors that have already progressed during the course of anti-VEGFR therapy (as second-line treatment)<sup>[66,67]</sup>. Brivanib has demonstrated a disease control rate of 51% and an OS of 10 mo as first-line monotherapy in a phase II trial of predominantly Asian patients with HCC<sup>[68]</sup>. In another phase II trial of brivanib in patients with HCC who had been treated with sorafenib, brivanib caused a tumor response rate of 4.3% and disease control rate of 45.7%<sup>[69]</sup>.

Large randomized phase III Brivanib Study in Patients at Risk (BRISK) HCC program trials have been conducted to evaluate the role of brivanib in advanced HCC (BRISK-FL, BRISK-PS and BRISK-APS). The BRISK-PS trial evaluated brivanib *vs* placebo in patients who had failed or were intolerant to sorafenib therapy (NCT00825955). This study did not meet its primary end point of improving OS, but treatment with brivanib showed improvements in the response rate<sup>[70]</sup>. The BRISK-FL trial (NCT00858871) directly compared the clinical outcomes of brivanib *vs* sorafenib in patients with advanced HCC who received no prior systemic therapy. The median OS was 9.5 mo in the brivanib arm compared with 9.9 mo in the sorafenib arm, which was not a statistically significant difference. No significant survival differences were observed between subgroups based on geographic regions, cause of HCC or disease severity. The study did not meet its primary OS objective based upon a non-inferiority statistical design<sup>[71]</sup>.

Vatalanib (PTK787) is a potent tyrosine kinase inhibitor that binds directly to the ATP-binding sites of VEGF receptors. Vatalanib inhibits both Flt-1 and Flk-1/KDR and other class III receptor tyrosine kinases, such as PDGFR- $\beta$ , Flt-4, c-kit, and c-fms<sup>[72]</sup>. In a phase I / II study of vatalanib combined with doxorubicin in patients with advanced HCC, the overall response rate was 26.0%, with all of the responding patients achieving PR. Another 20% of the patients achieved SD for at least 12 wk<sup>[73]</sup>.

Linifanib (ABT-869) is a novel receptor tyrosine kinase inhibitor with potent activity against members of the VEGFR and PDGFR families<sup>[74]</sup>. In a phase II study of linifanib in advanced HCC, the estimated objective response rate was 9.1%, the median time to disease progression was 3.7 mo, and the median OS was 9.7 mo<sup>[75]</sup>. An open-label, randomized phase III study of the efficacy

and tolerability of linifanib *vs* sorafenib in advanced HCC (NCT01009593) was conducted. The OS of linifanib given as monotherapy once daily was similar to sorafenib given twice daily per standard of care<sup>[76]</sup>.

TSU-68 is an oral tyrosine kinase inhibitor of FGFRs, VEGFRs and PDGFR and has demonstrated some clinical efficacy in a phase I / II trial of heavily pretreated patients with advanced HCC. Treatment of patients with unresectable or metastatic HCC with TSU-68 was associated with disease stabilization or improvement in 51% of the patients<sup>[77]</sup>. A randomized placebo-controlled phase III trial in Japan, South Korea and Taiwan is currently recruiting patients with unresectable HCC and will evaluate transcatheter arterial chemoembolization (TACE) in combination with either TSU-68 or placebo.

Cediranib (AZD2171) is another selective inhibitor of VEGFR-1, -2 and -3. Cediranib also exhibits activity against c-kit, PDGFR- $\beta$ , and FLT4 at nanomolar concentrations. In a phase II clinical study of advanced HCC, the median OS was 5.8 mo. No patients experienced confirmed response. The median time to progression was 2.8 mo<sup>[78]</sup>.

## EGFR, IGF AND HGF/c-MET SIGNALING

EGFR, a member of the human epidermal growth factor receptor (HER) family, contains an intracellular tyrosine kinase domain which can trigger signal transduction through the MAPK and PI3K/Akt/mTOR pathways. Thus, these receptors contribute to cell growth, differentiation, survival and adhesion<sup>[79]</sup>. EGFR overexpression has been reported in HCC. Immunohistochemical analysis by Buckley *et al*<sup>[80]</sup> revealed that EGFR was overexpressed in 50 (66%) of 76 HCCs, and fluorescence *in situ* hybridization (FISH) showed additional *EGFR* gene copies in 17 (45%) of 38 HCCs. EGFR-targeting drugs include anti-EGFR antibodies (such as cetuximab and panitumumab) and inhibitors of EGFR tyrosine kinases (such as erlotinib, lapatinib and gefitinib); these drugs have been used widely for the treatment of HCC.

Cetuximab is a recombinant chimeric monoclonal antibody that targets the extracellular domain of EGFR. In a phase II clinical trial of cetuximab in patients with advanced HCC, the median OS was 9.6 mo and the median PFS was 1.4 mo. The treatment was generally well tolerated. No treatment-related grade 4-5 toxicities occurred. Grade 3 aspartate aminotransferase, hypomagnesemia, and fever without neutropenia were each noted in 1 patient<sup>[81]</sup>. A randomized trial comparing gemcitabine-oxaliplatin (GEMOX) alone with a GEMOX-cetuximab combination is ongoing to define the real contribution of anti-EGFR therapy.

Erlotinib is a potent and reversible inhibitor of EGFR tyrosine kinase. In an *in vitro* study, erlotinib potentially suppressed the growth of human EGFR-expressing HCC cell lines. Erlotinib has been shown to inhibit the RAF/MEK/ERK signaling pathway and block signal

transducer and activator of transcription-mediated signaling<sup>[82]</sup>. A phase III placebo-controlled, double-blind SEARCH (Sorafenib and Erlotinib, a Randomized Trial Protocol for the Treatment of Patients with HCC) trial has been conducted in patients with advanced HCC. Three hundred sixty-two patients received sorafenib plus erlotinib and 358 received sorafenib plus placebo. No significant differences were observed in OS or TTP between the arms. Erlotinib, when added to sorafenib as the standard of care in advanced HCC, did not prolong overall survival<sup>[83]</sup>.

Lapatinib is a dual inhibitor of EGFR and HER-2/NEU that acts by docking into the ATP binding site of the two receptors<sup>[84]</sup>. Phase II results have indicated that lapatinib is well tolerated and have shown preliminary evidence of antitumor activity in HCC<sup>[85]</sup>. Among 40 patients with advanced HCC, the response rate was 5%, median PFS was 2.3 mo and median OS was 6.2 mo.

The IGF/IGFR signaling pathway regulates several cellular processes, including proliferation, motility and inhibition of apoptosis<sup>[86]</sup>. Ligand binding to IGF-1R triggers rapid receptor autophosphorylation, which in turn initiates downstream cellular effectors, ultimately leading to activation of PI3K, protein kinase B and the RAF/MEK/ERK pathway<sup>[87]</sup>. In HCC, dysregulation of IGF signaling occurs predominantly at the level of IGF-2. IGF-2 is overexpressed in 16%-40% of human HCCs, and IGF-2R (an alternative receptor for IGF-2) is underexpressed in approximately 80% of HCCs<sup>[88,89]</sup>. Associations have been reported between disease stage, metastasis and survival and the functions of IGF and IGFR in HCC<sup>[90,91]</sup>. Several strategies to target this system, including monoclonal antibodies against the IGF-1 receptor (IGF-1R) and small molecule inhibitors of the tyrosine kinase function of IGF-1R, are under active investigation.

Pre-clinical evidence obtained from HCC cells has shown that IMC-A12 (cituxumumab), a human monoclonal antibody that blocks IGF-1R. A phase I study of IMC-A12 yielded a partial response in HCC<sup>[92]</sup>. However, a subsequent phase II study in patients with advanced HCC showed that IMC-A12 is inactive as a monotherapy<sup>[93]</sup>. Up to 46% of the patients developed grade 3-4 hyperglycemia in this study. Hyperglycemia may be the dose limiting toxicity of IGF-1R monoclonal antibodies.

BIIB022 is an anti-IGF-1R monoclonal antibody that blocks binding of both IGF-1 and IGF-2 to IGF-1R. This agent does not appear to cause hyperglycemia, which is a common side effect of receptor-specific antibodies. A planned phase I / II study comparing sorafenib with or without BIIB022 in patients with advanced HCC was terminated due to a business decision by the sponsor company.

AVE1642 is another monoclonal antibody that specifically blocks IGF-1R signaling. This agent has been evaluated in combination with sorafenib in a phase I study in advanced HCC patients<sup>[94]</sup>. Long-lasting disease stabilization was observed in most patients with PD.

OSI-906 is a novel potent dual tyrosine kinase inhibitor of both IGF-1R and insulin receptor. The unique advantage of OSI-906 over the previous class of anti-IGF drugs is its ability to minimize IGF-2 activity in situations in which IGF-1R inhibition alone is not sufficient. The phase II study of second-line treatment for advanced HCC patients who failed first-line treatment with sorafenib (NCT01101906) was terminated because the sponsor decided not to pursue the development of this drug.

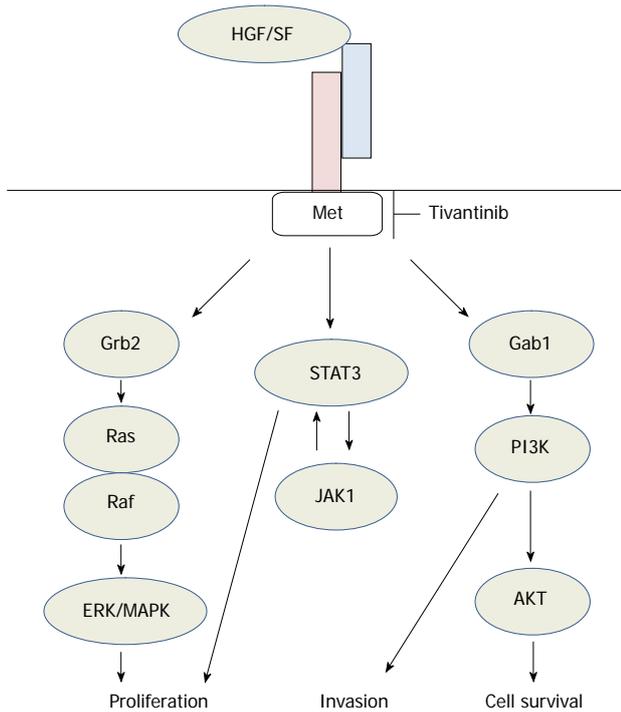

The HGF/Met pathway is involved in tumor growth, invasion and angiogenesis in various types of cancer<sup>[95]</sup>. c-Met is a tyrosine kinase receptor for the HGF ligand. HGF-induced activation of c-MET ultimately leads to the activation of downstream effector molecules, including phospholipase C, PI3K and ERK<sup>[96]</sup>. c-MET overexpression has been observed in 20%-48% of HCC, and overexpression has been linked with decreased 5-year survival in patients with HCC (Figure 3)<sup>[97-99]</sup>.

Tivantinib (ARQ 197) is a selective, oral MET receptor tyrosine kinase inhibitor with broad-spectrum antitumor activity as single agent. MET overexpression has been shown to be a negative prognostic factor in HCC after sorafenib failure. Tivantinib demonstrated a nearly doubling of PFS and OS in the MET high group compared to placebo in a phase II study as second-line treatment in patients with advanced HCC<sup>[100]</sup>. The activity of tivantinib in combination with sorafenib is also promising. Adverse events include hematological toxicity, asthenia and loss of appetite. The initially high incidence of neutropenia in patients with HCC led to dose reduction from 360 mg *bid* to 240 mg *bid*. Currently, a pivotal phase III study in advanced, MET-high HCC after sorafenib failure is planned.

## WNT-BETA-CATENIN PATHWAY

A major and early carcinogenic event in the development of HCC seems to be the abnormal regulation of the transcription factor  $\beta$ -catenin, a key component of the WNT signaling pathway.

During normal cell homeostasis, Wnt proteins are absent. Initiation of Wnt signaling leads to a series of events that cause loss of  $\beta$ -catenin phosphorylation, which prevents its degradation.  $\beta$ -catenin then accumulates in the cytoplasm and translocates into the nucleus. Hepatocytes with nuclear translocation of  $\beta$ -catenin display abnormal cellular proliferation and express membrane proteins involved in HCC, metastatic behavior, and cancer stem cells<sup>[101]</sup>. A high incidence of  $\beta$ -catenin mutations (nearly 40%) has been observed in HCC cases that occur in patients with HCV. HCC cases that occur in HBV patients display  $\beta$ -catenin activation that is induced in a mutation-dependent manner by the expression of HBx protein<sup>[102,103]</sup>. Agents targeting Wnt- $\beta$ -catenin are under development. Preliminary studies targeting the Wnt- $\beta$ -catenin pathway have demonstrated a potential space for new novel therapies to treat HCC.

**Figure 3** The c-Met signaling pathway suggested in hepatocellular carcinoma. Gab1: GRB2-associated binding protein 1; Grb2: Growth factor receptor-bound protein 2; HGF/SF: Hepatocyte growth factor/scatter factor; JAK1: Janus kinase 1; Met: Met proto-oncogene; PI3K: Phosphatidylinositol-3-kinase; STAT3: Signal transducer and activator of transcription 3; ERK: Extracellular signal-regulated kinase.

### JAK/STAT PATHWAY

The Jak/Stat pathway is activated by more than 40 cytokines and growth factors and is involved in multiple cell functions, including differentiation, proliferation, and apoptosis<sup>[104]</sup>. In this pathway, cytokines induce phosphorylation of the Janus tyrosine kinases (Jak1, 2 and 3 and Tyk2), which is followed by activation of Stat1-6<sup>[105]</sup>. The phosphorylation of Jak1, Jak2, and Tyk2 tyrosine kinases is not detected in normal livers but increases significantly between surrounding non-neoplastic liver and HCCs<sup>[106]</sup>. Activation of Stat1, Stat3, and Stat5 has been shown to be significantly higher in tumors than in the respective surrounding livers; pStat3 is higher in HCC with poor prognosis than in HCC with better prognosis<sup>[106]</sup>. The levels of Jak/Stat targets, including Bcl-xl, Mcl-1, cyclin D1, and c-Myc, are markedly elevated in the majority of HCCs. A phase I study of the JAK2 inhibitor AZD1480 in advanced solid malignancy (including HCC) is planned (NCT01219543).

### FUTURE PERSPECTIVES

Molecular targeted agents that have been introduced into clinical use in recent years have been approved for the treatment of a specific cancer and then frequently used to treat various other types of cancer (Table 1). Genetic alterations clearly play a major role in hepatocarcinogenesis, and abnormalities in several critical molecular

**Table 1** Molecular targets and therapeutic agents

signaling pathways have been identified as contributing to tumor development and progression<sup>[107,108]</sup>.

Currently, sorafenib is the only effective systemic treatment option for advanced HCC. While the drug is effective for patients with advanced HCC, sorafenib prolongs life expectancy for only approximately three mo. To move beyond sorafenib monotherapy, a potential role for this agent in the adjuvant setting following surgical resection, radiofrequency ablation, or TACE or in combination with other targeted agents or chemotherapy is under investigation.

Several new promising multi-targeted molecules have been developed and are currently under investigation for the treatment of HCC (Table 2). Unfortunately, HCCs are refractory to many targeted therapies. Therefore, resistance to treatment remains the major challenge for targeted therapy. Many resistance mechanisms have been identified, including epigenetic changes, alternative splicing, target inactivation, upregulation of alternative pathways (by cellular adaptation to the pathway being targeted), and a range of mutations. A combination of different agents or a single “unspecific” inhibitor of several pathways may offer advantages to overcome resistance. Combinations of targeted agents with chemotherapy regimens also remain to be further explored. Molecular targeted therapy blocking angiogenesis has demonstrated somewhat promising results, but the efficacy of these agents is limited by survival pathways induced by hypoxia. Thus, the inhibition of hypoxia-induced survival signals

**Table 2** Efficacy results of targeted therapies for advanced hepatocellular carcinoma

Molecular targets/agents	Phase	Efficacy	Ref.
VEGF/VEGFR Sorafenib	Phase III SHARP Sorafenib <i>vs</i> placebo	Median OS: 10.7 mo <i>vs</i> 7.9 mo	[58]

ITT: Intent to treat; OS: Overall survival; PD: Progressive disease; PFS: Progression-free survival; PR: Partial response; RR: Response rate; SD: Stable disease; TTP: Time to progression; VEGF: Vascular endothelial growth factor; VEGFR: Vascular endothelial growth factor receptor; mTOR: Mammalian target of rapamycin; PI3K: Phosphatidylinositol-3-kinase; Met: Met proto-oncogene; EGFR: Epidermal growth factor (EGF) receptor.

might be required for targeted agents to block angiogenesis as an adjuvant therapy following TACE. Additionally, exploring potential markers that can help in identifying the patients who are most likely to respond (or to at least identify those who will not respond) to treatment is critical. Future development of genomic analysis of HCC will aid in the identification of specific biomarkers for patient selection for either single agent or combination molecular targeted therapies.

### Abstract

Chronic pancreatitis (CP) is a progressive disease with irreversible changes in the pancreas. Patients commonly present with pain and with exocrine or endocrine insufficiency. All therapeutic efforts in CP are directed towards relief of pain as well as the management of associated complications. Endoscopic therapy offers many advantages in patients with CP who present with ductal calculi, strictures, ductal leaks, pseudocyst or associated biliary strictures. Endotherapy offers a high rate of success with low morbidity in properly selected patients. The procedure can be repeated and failed endotherapy is not a hindrance to subsequent surgery. Endoscopic pancreatic sphincterotomy is helpful in patients with CP with minimal ductal changes while minor papilla sphincterotomy provides relief in patients with pancreas divisum and chronic pancreatitis. Extracorporeal shock wave lithotripsy is the standard of care in patients with large pancreatic ductal calculi. Long term follow up has shown pain relief in over 60% of patients. A transpapillary stent placed across the disruption provides relief in over 90% of patients with ductal leaks. Pancreatic ductal strictures are managed by single large bore stents. Multiple stents are placed for refractory

strictures. CP associated benign biliary strictures (BBS) are best treated with multiple plastic stents, as the response to a single plastic stent is poor. Covered self expanding metal stents are increasingly being used in the management of BBS though further long term studies are needed. Pseudocysts are best drained endoscopically with a success rate of 80%-95% at most centers. Endosonography (EUS) has added to the therapeutic armamentarium in the management of patients with CP. Drainage of pseudocysts, cannulation of inaccessible pancreatic ducts and celiac ganglion block in patients with intractable pain are all performed using EUS. Endotherapy should be offered as the first line of therapy in properly selected patients with CP who have failed to respond to medical therapy and require intervention.

**Key words:** Chronic pancreatitis; Endoscopic retrograde cholangiopancreatography; Pancreatic sphincterotomy; Extracorporeal shockwave lithotripsy; Endosonography

**Core tip:** Chronic pancreatitis is a challenge to the therapeutic endoscopist. A patient with chronic pancreatitis can present with ductal calculi, leaks, pseudocysts, strictures, pancreatic malignancy or a biliary obstruction. Endoscopic therapy offers a high rate of success in properly selected patients. It offers many advantages over surgery, which for a long time was considered the gold standard in the treatment of chronic pancreatitis. This chapter deals with the management of chronic pancreatitis associated strictures, calculi, leaks and pseudocysts. The role of endosonography in management of pseudocysts, cannulation of inaccessible ducts and pain relief has also been discussed.

## INTRODUCTION

Chronic pancreatitis (CP) is a disease of varied etiology and characterized by progressive and irreversible damage to the pancreas with resultant loss of both endocrine and exocrine functions. Alcohol, smoking, genetic factors and metabolic disorders are common etiological causes<sup>[1]</sup>. In our country the non alcoholic type of CP is more prevalent<sup>[2,3]</sup>. Irrespective of the etiology, the majority of patients with CP present with pain as the dominant symptom.

As the disease is irreversible, almost all therapeutic efforts are directed towards control of pain and management of complications associated with CP. For the therapeutic endoscopist, CP is a challenge as patients can present with ductal strictures, calculi, ductal disruption, pseudocysts, biliary strictures, duodenal narrowing or a pancreatic malignancy. Endotherapy is performed in patients with CP who are unlikely to respond or have failed medical therapy as well as to manage the above mentioned complications. Surgery has often been considered the best therapeutic option for patients with CP<sup>[4]</sup>. However with advances in technology and techniques, endotherapy is offered as first line management in many patients with CP. Endotherapy offers many distinct advantages over surgery. It has a high success rate and low morbidity in properly selected patients. The procedure can be repeated with no extra risk, unlike the morbidity and difficulty associated with repeat surgery. The results are comparable to surgery and failed endotherapy does not hinder subsequent surgery<sup>[5-8]</sup>. The endoscopic approach can also predict the response to surgical therapy<sup>[9]</sup>. The endoscopic techniques used are endoscopic retrograde cholangiopancreatography (ERCP) and endosonography (EUS). Extracorporeal shockwave lithotripsy (ESWL) is a part of the endoscopic armamentarium. Advances in EUS have improved therapeutic options, including pseudocyst drainage and cannulation of inaccessible main pancreatic duct (MPD).

In this review, we will discuss the role of endotherapy in diagnosis and management of CP related pancreatic ductal strictures, stones, common bile duct (CBD) strictures and pseudocyst.

## ROLE OF ENDOSCOPY IN THE DIAGNOSIS OF CP

ERCP was earlier used both for diagnosis and management of patients with CP. It has sensitivity of 73%-94% and specificity of 90%-100% in visualizing duct related changes in CP<sup>[10]</sup>. The emergence of magnetic resonance cholangiopancreatography (MRCP) with secretin stimulation, as well as EUS, has minimized the role of ERCP in diagnosing CP. EUS is a better diagnostic modality, especially in early and less advanced CP, as it identifies both ductal and parenchymal changes<sup>[11]</sup>. EUS has a sensitivity of close to 100% as compared to 80% with ERCP in patients with early CP<sup>[12]</sup>. MRCP being non-invasive offers a better alternative to ERCP for visualizing ductal changes.

## CP WITH MINIMAL DUCTAL CHANGES

Painful CP can occasionally present with minimal or no ductal change in absence of ductal strictures or stones. This is classified as type I CP according to Cremer classification or mild CP of Cambridge classification<sup>[13,14]</sup>. Endoscopic pancreatic sphincterotomy (EPS) is a documented mode of therapy and offers symptomatic relief in some of these patients. Both the standard pull type and the needle knife sphincterotomy over a stent can be performed. A 64% relief in pain on follow up of 6.5 years has been reported following EPS<sup>[15]</sup>. High success rates of 98% and low complication rates of around 4% have been reported on retrospective analysis<sup>[16]</sup>. Randomized studies have shown a higher incidence of pancreatitis in high risk patients following pull type sphincterotomy as compared to the needle knife technique<sup>[17]</sup>. Most workers report an incidence of around 12% for post EPS pancreatitis. Placement of a nasopancreatic tube (NPT) or pancreatic stent can reduce this incidence significantly<sup>[18]</sup>. Restenosis is reported in around 14% of patients on long term follow up<sup>[19]</sup>. It is believed that restenosis is less common following the longer incision with the pull type as compared to needle knife technique<sup>[20]</sup>. The presence of periductal fibrosis seen in patients with CP may lower the incidence of post procedure pancreatitis. An additional biliary sphincterotomy is only indicated in the following conditions<sup>[21]</sup>: (1) presence of cholangitis; (2) CBD > 12 mm diameter; (3) serum alkaline phosphates > 2 times upper limit of normal; and (4) difficult access to MPD.

### Minor papilla sphincterotomy

Minor papilla sphincterotomy (MiES) was first performed by Cotton<sup>[22]</sup>. It is indicated in those patients with CP with minimal ductal changes who have a pancreas divisum or a dominant dorsal duct. Both the pull type and needle knife technique can be used. The evidence of any definite benefit from MiES is debatable as studies include small numbers of heterogeneous patients and are not conclusive. Significant pain relief on a 2-year follow up has been reported following MiES and stenting of patients with CP<sup>[23]</sup>. Relief of pain is also seen in 41% of patients with CP following MiES as compared to 77% with acute recurrent pancreatitis or 33% of patients with CP with no pain<sup>[24]</sup>. Post ERCP pancreatitis has been reported in up to 15% of patients<sup>[25]</sup> and restenosis was seen in 20%-24% on a 6-year follow up<sup>[26]</sup>.

## ENDOSCOPIC MANAGEMENT OF PANCREATIC DUCTAL STRICTURES

Strictures of MPD are frequently seen as a consequence of CP and could be due to inflammation or fibrosis. In our experience of 1000 patients who underwent ESWL, the incidence of strictures was 18%<sup>[2]</sup>. MPD strictures are defined as a high grade narrowing of MPD with one of the following<sup>[19,27]</sup>: (1) MPD dilatation > 6 mm beyond

the stricture; (2) failure of contrast to flow alongside the stricture or 6 Fr NPT; and (3) presence of pain during continuous perfusion of the NPT with normal saline for 24 h.

Endotherapy is ideal for single strictures in the head while isolated strictures in the tail or multiple strictures with a chain of lake appearance are not amenable to endotherapy<sup>[9]</sup>. Prior to stent placement tight strictures need to be dilated with Teflon bougies, Sohendra stent retriever or a balloon dilator<sup>[9,27]</sup>. Large bore stents 7-10 Fr should be deployed as they have longer patency<sup>[27]</sup>. Delhaye *et al*<sup>[27]</sup> followed a protocol where a single stent was placed across a stricture and exchanged every 6 mo or when the patient was symptomatic. Stents were placed for 24 mo. Patients were restented if symptoms recurred. Surgery was considered if patients responded to stent placement but needed frequent or repeated stenting. Cumulative data from several workers revealed pain relief between 70%-94% for a single pancreatic stent on follow up of 14-69 mo<sup>[9]</sup>. Recurrence of strictures was reported in 38% of patients after 2 years follow up<sup>[28]</sup>. The concept of multiple plastic stenting for MPD strictures not responding to a single stent placement was advocated by Costamagna *et al*<sup>[29]</sup>. In their study, after removal of a single stent, the stricture was dilated and multiple plastic stents 8.5-11.5 Fr diameter were placed. A mean of 3 stents were used. The stents were removed 12 mo later. Stricture resolution was seen in 95% and pain relief in 84% on a 38 mo follow up.
