### Abstract

Pseudocysts and biliary obstructions will affect approximately one third of patients with chronic pancreatitis (CP). For CP-related, uncomplicated, pancreatic pseudocysts (PPC), endoscopy is the first-choice therapeutic option. Recent advances have focused on endosonography-guided PPC transmural drainage, which tends to replace the conventional, duodenoscope-based coma immediately approach. Ancillary material is being tested to facilitate the endosonography-guided procedure. In this review, the most adequate techniques depending on PPC characteristics are presented along with supporting evidence. For CP-related biliary obstructions, endoscopy and surgery are valid therapeutic options. Patient co-morbidities (*e.g.*, portal cavernoma) and expected patient compliance to repeat endoscopic procedures are important factors when selecting the most adapted option. Malignancy should be reasonably ruled out before embarking on the endoscopic treatment of presumed CP-related biliary strictures. In endoscopy,

the gold standard technique consists of placing simultaneous, multiple, side-by-side, plastic stents for a one-year period. Fully covered self-expandable metal stents are challenging this method and have provided 50% mid-term success.

**Key words:** Biliary stricture; Chronic pancreatitis; Pseudocyst; Endoscopic retrograde cholangio-pancreatography; Endoscopic ultrasonography; Stent

**Core tip:** Endoscopy is the first-choice treatment of pancreatic pseudocysts. The transduodenal route may be preferable over the transgastric route. Two transmural double pigtail stents should be left for at least 2 mo. In the case of a disconnected pancreatic tail, secretin-enhanced magnetic resonance pancreatography should be obtained to decide about stent removal. Biliary strictures should be thoroughly investigated to rule out malignancy. To this aim, improved methods of biliary sampling have become available. Even with multiple biliary stents, potentially fatal cholangitis is frequent in the absence of regular stent revision. Fully covered self-expandable metal stents have provided 50% mid-term success.

### INTRODUCTION

Common local complications of chronic pancreatitis (CP) include pancreatic pseudocysts (PPCs) and bili-

ary obstructions. These two complications develop in patients during the course of CP at a rate of 20%-40% for PPCs and 3%-23% for biliary obstructions<sup>[1,2]</sup>. PPCs consist of a collection of pancreatic juice enclosed by a wall of fibrous granulation tissue, which may arise as a consequence of acute pancreatitis, pancreatic trauma or CP<sup>[3]</sup>. Biliary obstruction may be caused by fibrosis, compression by a PPC or cancer. The present review covers the full spectrum of endoscopic management of local complications of CP; it is not an analysis of specific studies and it does not encompass the management of uncomplicated CP, which has recently been reviewed elsewhere<sup>[4]</sup>.

## SEARCHES

Searches for relevant articles were conducted in Medline through PubMed on May 2013, without time limits, using the following search terms: “pancreatitis, chronic”[MeSH Terms] OR (“pancreatitis”[All Fields] AND “chronic”[All Fields]) OR “chronic pancreatitis”[All Fields] OR (“chronic”[All Fields] AND “pancreatitis”[All Fields]) AND pseudocyst[All Fields] AND (“endoscopy”[MeSH Terms] OR “endoscopy”[All Fields]) OR “pancreatitis, chronic”[MeSH Terms] OR (“pancreatitis”[All Fields] AND “chronic”[All Fields]) OR “chronic pancreatitis”[All Fields] OR (“chronic”[All Fields] AND “pancreatitis”[All Fields]) AND pseudocysts[All Fields] AND (“surgery”[Subheading] OR “surgery”[All Fields] OR “surgical procedures, operative”[MeSH Terms] OR (“surgical”[All Fields] AND “procedures”[All Fields] AND “operative”[All Fields]) OR “operative surgical procedures”[All Fields] OR “surgery”[All Fields] OR “general surgery”[MeSH Terms] OR (“general”[All Fields] AND “surgery”[All Fields]) OR “general surgery”[All Fields]); “pancreatitis, chronic”[MeSH Terms] OR (“pancreatitis”[All Fields] AND “chronic”[All Fields]) OR “chronic pancreatitis”[All Fields] OR (“chronic”[All Fields] AND “pancreatitis”[All Fields]) AND biliary[All Fields] AND (“endoscopy”[MeSH Terms] OR “endoscopy”[All Fields]). Articles written in English were selected for complete review on the basis of the abstract. Additional papers were identified by manually checking the reference lists of the articles selected for review.

## PANCREATIC PSEUDOCYSTS

### *Differential diagnosis of pseudocyst-cystic neoplasm*

Pseudocysts are the most frequent pancreatic fluid collections. The differential diagnosis between PPCs and cystic neoplasms or, less frequently, necrotized tumors, may be difficult in patients who present for the first time with a pancreatic fluid collection. Amongst the various cystic neoplasms that may affect the pancreas, mucinous cystic neoplasms and intraductal papillary mucinous neoplasms harbor a malignant potential-many of which require surgical resection<sup>[5]</sup>. As only a few of the available tests provide a high degree of certainty, a diagnosis is usually

made by analyzing a set of data, including demographic data and clinical history<sup>[6]</sup>, cross-sectional imaging<sup>[7]</sup>, and endosonography-guided sampling of the fluid content and of the wall of the lesion<sup>[8,9]</sup>. Research has recently focused on the identification of new biomarkers and on *in vivo* confocal microscopic examination of the cyst wall through a needle inserted under endosonographic guidance<sup>[10,11]</sup>.

### *Indications for treatment*

Widely accepted indications for PPC treatment include the presence of symptoms such as abdominal pain, gastric outlet obstruction, early satiety, weight loss, jaundice, and infected or enlarging PPC<sup>[12]</sup>. Some authors also recommend treating PPCs in asymptomatic patients to prevent potential PPC-related complications, although these occur only in a minority of patients<sup>[13,14]</sup>. Other such debated indications include compression of major vessels, intracystic hemorrhage, pancreaticopleural fistula, and PPCs with a diameter greater than 5 cm without any regression after more than 6 wk and a cyst wall thickness larger than 5 mm<sup>[15]</sup>. In patients with CP, PPCs rarely resolve spontaneously, particularly if their diameter is greater than 4 cm or if they have developed outside of the pancreas<sup>[16]</sup>.

### *Results: Choosing endoscopic vs surgical treatment*

Endoscopic drainage is recommended as a first-line treatment of accessible uncomplicated PPCs because it provides significantly better results compared to surgery in terms of cost, duration of hospital stay and quality of life up to three months post-procedure, as demonstrated in a small randomized controlled trial (RCT)<sup>[17]</sup>. Reviews of non-comparative historical series of endoscopic and of surgical treatments of PPCs have reported similar results for both modalities in terms of morbidity, with 13% for endoscopic treatments and 16% for surgical treatments. A PPC recurrence rate during long-term follow-up has also been reported of 11% *vs* 10%, respectively, for endoscopic and surgical treatments. An advantage was found in favor of the endoscopic method in terms of mortality (0.2% *vs* 2.5%)<sup>[15,18]</sup>.

Some, but not all, authors have reported that endoscopic PPC drainage yielded higher success rates in the setting of CP *vs* acute pancreatitis. For example, Baron *et al*<sup>[19]</sup> reported resolution of 92% of chronic pseudocysts *vs* 74% of acute pseudocysts in a series of 138 patients while Hookey *et al*<sup>[20]</sup> reported resolution of 94% of chronic pseudocysts *vs* 92% of acute pseudocysts in a series of 116 patients.

A first-line surgical approach is usually adopted if necrosis has not yet liquefied and if treatment cannot be delayed. Endoscopy carries a lower success rate and higher morbidity rate in such instances; the reader is referred to a recent review for the comparison of currently available techniques in this particular indication<sup>[21]</sup>. Pancreatic necrosectomy requires expert endoscopic skill, dedication and adequate patient selection.

### Endoscopic technique

Access route: A direct communication between the PPC and the main pancreatic duct (MPD) may be demonstrated in 40%-66% of all PPCs<sup>[22]</sup>. Such a communication allows drainage of the PPC *via* a stent inserted into the PPC through the papilla ("transpapillary drainage") as opposed to a stent being inserted into the PPC through the digestive wall ("transmural drainage").

No RCT has compared the transpapillary *vs* the transmural drainage route but, in nonrandomized comparative studies, procedure-related morbidity was lower with the transpapillary route (2% *vs* 15%) and long-term success was similar<sup>[20,22,23]</sup>. The transpapillary route is usually reserved for relatively small (diameter < 5 cm) PPCs located in the head or the body of the pancreas.

### "Conventional" endoscopic-guided vs endosonography-guided technique

Endosonography-guided PPC drainage tends to replace the "conventional" endoscopic approach that uses a duodenoscope or, in some cases, a gastroscope. A recent meta-analysis found that the single demonstrated advantage of the endosonography-guided technique is the possibility to drain non-bulging PPCs<sup>[24]</sup>, which represent approximately half of all PPCs<sup>[22]</sup>. The most important limitations of the endosonography-guided technique reside in the thinner diameter of the working channel of the echoendoscope and in the lower maneuverability of the elevator. While the "conventional" approach is relatively standardized, new material is constantly being tested to make endosonography-guided PPC drainage a single-step, reliable procedure. One of the most recent devices allows puncturing, dilating the puncture tract and inserting two guidewires into the PPC without any device exchange. The device is made of a catheter with two balloons, one to anchor it to inside the PPC and the other one to dilate the puncture tract<sup>[25]</sup>.

### Transgastric vs transduodenal transmural route

Some PPCs may be accessed through either the gastric or the duodenal wall. In such cases, the transduodenal route may be preferable as long-term success has been reported more frequently with the transduodenal *vs* the transgastric route (83% *vs* 64%); procedure-related morbidity was 10% with both routes<sup>[26]</sup>. The difference in long-term success may be related to the longer durability of cystoduodenal compared with cystogastric fistulas (the latter ones typically close a few days after stent removal).

### Number and type of stents

Two double pigtail stents are usually inserted for transmural drainage; a naso-cystic catheter may be left in place to rinse the PPC cavity with saline if debris is present. In a large retrospective series, the insertion of a single *vs* multiple stent was independently associated with the failure of endoscopic PPC drainage, defined as severe procedure-related complication or need for another treatment modality<sup>[27]</sup>. In that series, straight stents were used

and they were associated with frequent bleeding (7% of patients, with surgery required in two thirds of them) and stent migration.

### Stenting duration

Enterocystic transmural stents should not be retrieved before PPC resolution and not before at least 2 mo of stenting. This recommendation is mostly based on a RCT that allocated 28 patients (including 15 with CP) who had PPC resolution after transmural drainage to either stent maintenance or early stent retrieval; in the latter allocation group, stent retrieval was performed at a median of 2 mo post stent insertion<sup>[28]</sup>. PPC recurrence was more frequent in the early stent retrieval group (38% *vs* 0%) and, in another, retrospective, series, a stenting duration of 6 wk or less was independently associated with the failure of endoscopic PPC drainage<sup>[27]</sup>.

### Procedure-related complications

Reported figures largely vary from center to center with average morbidity rates of 13% and average mortality rates of 0.3%<sup>[15,29]</sup>. Major complications include hemorrhage, perforation and infection. Most of these can be managed by non-operative means, including endoscopic coagulation, arterial embolization, repeat endoscopic drainage in the case of secondary infection and antibiotics in the case of retroperitoneal perforation. The following measures may help in preventing procedure-related complications:

**Secondary infection:** Although no data on the efficacy of antibiotic prophylaxis for endoscopic PPC drainage are available, antibiotic administration has been recommended immediately before transmural or transpapillary PPC drainage<sup>[30]</sup>. The decision whether to continue antibiotics or not after the procedure should be based on drainage adequacy and on the presence or absence of necrosis<sup>[12]</sup>.

**Bleeding:** Severe bleeding usually arises from dilated arteries or veins. Pseudoaneurysms of the splenic artery may develop in the vicinity of PPCs. Imaging preceding the endoscopic drainage of PPCs should look for pseudoaneurysms and, in the case that one is discovered, have its prophylactic embolization discussed if the transmural route is elected. Extrahepatic portal hypertension develops during the course of CP in 15% or more of patients. It is frequently associated with PPC as well as leading to higher morbidity in patients who undergo pancreatic surgery<sup>[31]</sup>. The endosonography-guided technique of PPC drainage has been recommended in such patients although it has not been demonstrated to decrease the risk of bleeding<sup>[32]</sup>.

### In the case of infected PPC, should the strategy be different?

Primary infection is a rare complication of CP-related PPCs; secondary infection following stent occlusion or

endoscopic attempt at draining pancreatic necrosis is more frequent<sup>[33]</sup>.

Infected PPCs present a thick content that may not drain adequately through one or two thin plastic stents. Traditionally, in such cases, more large-bore stents are inserted together with a nasocystic catheter that is used for PPC irrigation. These additional interventions have resulted in similarly high success rates in patients with infected PPCs as compared with those who present uncomplicated PPC<sup>[20,34]</sup>. As inserting multiple stents plus a nasocystic catheter requires time and may be technically challenging, fully covered self-expandable metal stents (FCSEMSs) seem to be a promising alternative for draining PPCs with a thick content. In a series of 20 patients with an infected PPC that was drained by endosonography-guided FCSEMS transmural insertion alone, clinical success was achieved in 17 patients<sup>[35]</sup>. The authors suggested that using FCSEMSs rather than plastic stents plus nasocystic drains in patients with infected PPCs may decrease the number of endoscopic procedures, increase the final success rate, and reduce the time required for PPC resolution. FCSEMSs specifically designed for PPC drainage have become available from various manufacturers; they present a short length, a large lumen, and a diabolo shape aimed at preventing stent migration<sup>[25,36]</sup>.

#### ***In the case of complete MPD rupture, should the strategy be different?***

If complete MPD rupture occurs, the disconnected pancreatic tail may keep secreting pancreatic juice that, in the absence of effective drainage, will lead to prolonged fluid accumulation. Bridging of complete MPD ruptures should be attempted and a combination of transmural PPC drainage plus a transpapillary stent bridging the MPD rupture should be considered<sup>[37,38]</sup>. The stent should be left in place for a long duration, at least as long as secretin-enhanced magnetic resonance pancreatography demonstrates juice outflow from the disconnected pancreatic tail<sup>[39]</sup>.

## **BILIARY STRICTURES**

### ***Differential diagnosis***

It is of paramount importance to reasonably rule out malignancy before embarking on the endoscopic treatment of presumed CP-related biliary strictures, as such a treatment usually lasts for one year and the course of pancreatic cancer is rapid. Particular attention should be paid to patients who present risk factors for pancreatic cancer; these include patients over 50 years of age, female gender, white race, or an absence of pancreatic calcifications and presence of exocrine insufficiency<sup>[40,41]</sup>. Patients with hereditary pancreatitis present a very high risk of pancreatic cancer.

The accuracy of standard CT scanning and of endosonography for disclosing pancreatic cancer is limited in patients with CP<sup>[42,43]</sup>. Endosonography, supplemented by fine needle aspiration (FNA) plus biliary endoluminal

sampling and assessment of malignancy biomarkers, is part of the standard work-up of a biliary stricture detected in the setting of CP. Other examination modalities such as probe-based endoluminal real-time microscopy are investigational. It should be kept in mind that endosonography-guided FNA is less accurate in the presence than in the absence of CP<sup>[41,44]</sup>, although this decrease in accuracy has been suggested to be confined to a subset of patients who present with obstructive jaundice and a biliary stent<sup>[45]</sup>. Furthermore, in the community, the accuracy of endosonography-guided FNA for diagnosing pancreatic cancer is likely to be much lower than the 90% figure that is widely reported in the literature (latter reports originate from tertiary centers and use per-protocol analysis)<sup>[46,47]</sup>. The technical details of the sampling procedure and of the sample processing are extremely important to reach a high diagnostic accuracy; they have recently been reviewed elsewhere for endosonography-guided FNA and for endoluminal biliary sampling<sup>[48-50]</sup>. Recent improvements in the field of endoluminal biliary sampling include the development of more effective sampling devices and the use of rapid on-site examination for smears as well as for tissue biopsies<sup>[48,51,52]</sup>.

### ***Indications for treatment***

Generally accepted indications for the treatment of CP-related biliary strictures include symptoms such as secondary biliary cirrhosis, biliary stones, progression of biliary stricture, and asymptomatic elevation of serum alkaline phosphatase (greater than 2 or 3 times the upper limit of normal values) or of serum bilirubin or both for longer than one month.

### ***Results: Choosing endoscopic vs surgical treatment***

Guidelines recently issued by the European Society of Gastrointestinal Endoscopy propose that the choice between endoscopic and surgical treatment should rely on local expertise, loco-regional or systemic patient comorbidities and expected patient compliance with repeat endoscopic procedures<sup>[53]</sup>. No strong recommendation could be made about the choice between the endoscopic and the surgical approach to CP-related biliary strictures due to the lack of comparative studies. In conditions different from CP, two comparative nonrandomized studies that included 143 patients with biliary strictures related to a traumatism have found that long-term success was similar (77%-83%) with the endoscopic and the surgical approaches<sup>[54,55]</sup>. However, the endoscopic techniques used in these studies are not current anymore and the endoscopic treatment is more effective in post-traumatic compared with CP-related biliary strictures<sup>[29]</sup>. Another study has compared the endoscopic *vs* the surgical drainage of CP-related biliary strictures; however, surgery was performed in only 6 patients, of whom five also had a pancreatic resection<sup>[56]</sup>.

Patient complications such as portal cavernoma or cirrhosis are often decisive factors in the selection of the endoscopic *vs* the surgical modality. Other factors that

may influence this selection include the expected patient compliance with endoscopic stent exchanges and, less importantly, the presence or absence of pancreatic calcifications. In a retrospective series of 14 patients, only two patients presented for elective stent exchanges scheduled at 3-mo intervals<sup>[57]</sup>. Most patients were admitted with biliary infection due to stent occlusion after the scheduled stent exchange date. Another series that included 29 patients treated with multiple, side-by-side, plastic biliary stents reported the occurrence of at least 20 episodes of cholangitis (in this latter series, stents were exchanged when symptoms of clogging developed). The mean interval between stent exchanges was 6 mo in patients who were alive at the end of follow-up as compared to 22 mo ( $P < 0.05$ ) in the three patients who died during follow-up (two of them from cholangitis)<sup>[58]</sup>. The presence of pancreatic calcifications has been associated with long-term failure of single plastic biliary stenting<sup>[59]</sup> but this factor may be less relevant if simultaneous multiple, side-by-side, plastic stents are used<sup>[60]</sup>.

### Endoscopic technique

**Plastic stents:** If the endoscopic treatment modality is selected, temporary placement of simultaneous multiple, side-by-side, plastic stents is the gold standard amongst the various techniques available. A single nonrandomized series has compared long-term results after temporary placement of single *vs* multiple simultaneous plastic stents; clinical success was reported in 24% *vs* 92% of patients, respectively<sup>[60]</sup>.

From a practical point of view, amongst plastic biliary stents, polyethylene models are recommended because they allow obstruction relief more frequently than Teflon models<sup>[61]</sup>, and the exchange of plastic stents with an increasing number of stents is usually scheduled at 3-mo intervals for a total stenting duration of 12 mo<sup>[58,60,62]</sup>. It has recently been suggested that with multiple, side-by-side, plastic stents, the interval between stent exchanges could be extended<sup>[63]</sup>. However, as mentioned above, special care should be taken regarding the generally poor compliance and poor physical status of patients with alcoholic CP. It is recommended to implement a recall system to care for patients who do not turn up for stent exchanges at scheduled dates.

**Self-expandable metal stents:** “Definitive” insertion of self-expandable metal stents (SEMSs) (*i.e.*, with no intended SEMS removal) for benign biliary strictures has almost been abandoned due to the development of biliary epithelial hyperplasia that leads to late biliary obstruction<sup>[64]</sup>. Recent studies of the endoscopic treatment of CP-related biliary strictures have focused on the temporary placement of covered SEMS with a shift of interest from partially covered to fully covered SEMS designs<sup>[65,66]</sup>. Spontaneous SEMS migration has been the main drawback with FCSEMSs; new stent designs aiming to prevent migration include the adjunction of anchoring fins, the positioning of the stent covering on the internal

side of the SEMS and a flared-ends design. Such SEMSs remain investigational for the treatment of benign biliary strictures.

If FCSEMSs are used to treat benign biliary strictures, a stenting duration  $> 90$  d is recommended as this was independently associated with stricture resolution in a multicenter trial that included 133 patients with benign biliary strictures, 44 of these being CP-related<sup>[67]</sup>. In this trial, stricture resolution at the time of stent removal was reported in 26 (59%, intention-to-treat analysis) patients with CP. Other studies that included more than 10 patients followed up for at least one year after FCSEMS removal showed a success rate of approximately 50%: (1) Perri *et al*<sup>[66]</sup> inserted a Niti-S stent with either a straight or a flared-ends design in 17 patients who had previously received a single plastic stent. Two years following FCSEMS removal, 56% of patients had presented no stricture relapse and had normal liver function tests. The flared-ends design partially prevented FCSEMS migration while all straight FCSEMSs migrated; and (2) Poley *et al*<sup>[68]</sup> inserted a Hanaro prototype FCSEMS in 13 patients who had previously received a single plastic stent; success was reported in 6 (43%) of them.

FCSEMSs currently are the most promising alternative to multiple, side-by-side, plastic biliary stents. Despite their main advantages, *i.e.*, a reduced number of endoscopy procedures and a lower incidence of stent obstruction, FCSEMSs need improvements in their design as well as additional large multicenter trials before they can possibly be recommended as a first-line option for the endoscopic treatment of CP-related biliary strictures.

## OTHER COMPLICATIONS

Other complications of CP include splenic vein thrombosis, pancreatic adenocarcinoma, pancreatic ascites and pleural effusion.

Splenic vein thrombosis is present in approximately 12% of patients with CP and it is usually asymptomatic but may cause bleeding in 7% of patients<sup>[69]</sup>. In the case of bleeding, endoscopic variceal obturation using *N*-butylcyanoacrylate is effective in achieving hemostasis, and a splenectomy is an effective way to prevent recurrent bleeding<sup>[70]</sup>.

For the treatment of pancreatic adenocarcinoma, the endosonography-guided delivery of various cytotoxic agents is a rapidly evolving field that remains investigational<sup>[71]</sup>.

Pancreatic ascites and pleural effusion are rare complications of CP; they may or may not be associated with PPC and they present a high morbidity. The aim of endoscopic therapy in such patients is to insert a stent to bridge the MPD rupture that is responsible for pancreatic juice leakage; high success rates have been reported<sup>[72]</sup>.

## CONCLUSION

Progress has recently been made in the field of the endo-

scopic treatment of CP-related complications.

With regard to uncomplicated PPCs, endoscopic drainage has been shown to be feasible in almost all cases and to be superior to surgical drainage. Techniques associated with the best clinical outcome have been identified. With regard to CP-related biliary obstructions, improvements in the design of FCSEMSs are challenging the standard technique and have the potential to improve patient acceptability.

## Multimodal treatment of hepatocellular carcinoma on cirrhosis: An update

Marco Vivarelli, Roberto Montalti, Andrea Risaliti

Marco Vivarelli, Roberto Montalti, Hepatobiliary and Abdominal Transplantation Surgery, Department of Gastroenterology and Transplantation, Polytechnic University of Marche, 60129 Ancona, Italy

Andrea Risaliti, Department of Surgery and Transplantation, University of Udine, 33100 Udine, Italy

Author contributions: Vivarelli M conceived and designed the study; Montalti R drafted the article and acquired, analyzed and interpreted the data; Risaliti A revised the manuscript.

### Abstract

Hepatocellular carcinoma (HCC) is the most frequent primary liver tumor, and overall, it is one of the most frequent cancers. The association of HCC with chronic liver disease, and cirrhosis in particular, is well known, making treatment complex and challenging. The treatment of HCC must take into account the presence and stage of chronic liver disease, with the aim of preserving hepatic function that is often already impaired, the stage of HCC and the clinical condition of the patient. The different treatment options include surgical resection, transplantation, local ablation, chemoembolization, radioembolization and molecular targeted therapies; these treatments can be combined in various ways to achieve different goals. Ideally, liver transplantation is best treatment for early stage HCC on cirrhosis because it removes both the tumor and the chronic disease that produced it; however, the application of this powerful tool is limited by the scarcity of donors. Downstaging and bridging are different strategies for the management of HCC patients who will undergo liver transplantation. Several professionals, including

gastroenterologists, radiologists and surgeons, are involved in the choice of the most appropriate treatment for a single case, and a multidisciplinary approach is necessary to optimize the outcome. The purpose of this review is to provide a comprehensive description of the current treatment options for patients with HCC by analyzing the advantages, disadvantages and rationale for their use.

### INTRODUCTION

Hepatocellular carcinoma (HCC) accounts for nearly

90% of the primary liver tumors and is currently the third leading cause of cancer death worldwide. Approximately 500000 new cases of HCC are diagnosed worldwide each year, with a peak incidence observed in countries in which the hepatitis B virus (HBV) is endemic, such as Southeast Asia and sub-Saharan Africa<sup>[1]</sup>. As the number of carriers of chronic liver disease increases, HCC has become a major public health issue.

The main risk factor for HCC is the presence of chronic liver disease, particularly when the disease has already resulted in liver cirrhosis. The constant process of destruction and repair within the parenchyma that is associated with cirrhosis increases hepatocyte metabolism and amplifies the risk of mutations in a multistep progression from hyperplastic nodule to early HCC and finally to moderately/poorly differentiated HCC.

Hepatitis B and C viruses (HBV and HCV) are known to have oncogenic potential, and the risk of HCC in HBV and HCV carriers is increased independently of the presence of cirrhosis<sup>[2,3]</sup>. Malignant transformation of hepatocytes in the infected liver could be caused by chronic inflammation and the oxidative DNA damage that leads to genetic and epigenetic changes. There is also evidence that proteins encoded by HBV and HCV may have a direct role in hepatocarcinogenesis; in fact, proteins encoded in the genome of each of these viruses have been linked to alterations in hepatocyte physiology and hepatocellular signal transduction<sup>[4]</sup>. Other causes of chronic liver diseases, such as alcohol abuse, non-alcoholic steatohepatitis (NASH), hemochromatosis,  $\alpha$ 1-antitrypsin deficiency, autoimmune disease and Wilson disease are associated with a higher risk of developing HCC and require close patient monitoring. In Western countries, obesity and metabolic syndromes associated with type II diabetes, which are strictly related with NASH, are now emerging as new potential predisposing factors for HCC<sup>[1]</sup>.

Among patients with cirrhosis, the cumulative 5-year risk of developing HCC ranges from 5% to 30%, depending on the presence and stage of underlying liver disease, ethnicity, age, sex and duration of the exposure to primary hepatotropic viruses<sup>[1,5]</sup>.

The main peculiarity of HCC is that the treatment of the tumor must take into account the presence and stage of chronic liver disease, with the aim of preserving hepatic function that is often already impaired. A key step in the choice of therapy is therefore the correct assessment of the functional reserve of the liver, which is often more important than the staging of the tumor itself.

Several options are available for the treatment of HCC, and these can often be combined; the choice of treatment and the timing of its administration therefore must be balanced accurately.

The aim of the present review is to provide an update than can be useful in clinical practice for determining the most appropriate treatment for HCC patients.

## HCC SCREENING

The achievement of a curative treatment for HCC de-

pends on the detection of the tumor at an early stage. Once the population at risk is identified, screening of HCC is based on ultrasonography and measurement of serum alpha-fetoprotein (s-AFP) levels.

It is recommended that patients with advanced liver fibrosis (F3) or established cirrhosis undergo a liver ultrasound (US) and serum measurements every 6 mo<sup>[6]</sup>. In these patients, ultrasound has a sensitivity between 58% and 89% and a specificity of 90%<sup>[7]</sup>. The sensitivity of s-AFP measurements is lower and ranges between 25% and 65% when values above 20 ng/mL are considered positive<sup>[1]</sup>. The sensitivity and specificity of s-AFP measurement for the detection of HCC increase proportionally with higher blood s-AFP levels, particularly when the level is above 400 ng/mL.

Once the presence of HCC is confirmed, the s-AFP level can be correlated with tumor stage, particularly with the size and multifocality of the tumor and the presence of microvascular invasion. Overall, a screening strategy that combines abdominal ultrasonography and measurement of s-AFP every 6 mo in patients with cirrhosis can reduce HCC mortality by approximately 40%<sup>[8,9]</sup>.

## HCC DIAGNOSIS

The cirrhotic liver often displays multiple non-neoplastic nodules (regenerative nodules) that result from the chronic inflammatory process. These nodules must be differentiated from HCC, and the diagnostic strategy varies depending on the size of the nodule detected on ultrasound. At present, the most widely used diagnostic algorithm for the diagnosis of HCC is that proposed by the American Association for the Study of Liver Diseases (AASLD)<sup>[10]</sup> (Figure 1, modified by Forner *et al.*<sup>[11]</sup>).

The nature of nodules with a diameter of less than 1 cm cannot be precisely defined during ultrasound, and a follow-up control after 3-4 mo is required. Nodules detected at US with a diameter greater than 10 mm must be further investigated with contrast-enhanced triphasic or quadriphasic computed tomography (CT) imaging or magnetic resonance (MR) imaging. The diagnosis of HCC is based on an arterial hypervascular phase (wash-in) followed by disappearance of the contrast in the venous phase (wash-out)<sup>[12]</sup>.

Recent reports have demonstrated that MR has a higher sensitivity compared with CT<sup>[13]</sup>; however, if the data from the first imaging procedure are not conclusive, confirmation using a different technique is recommended. In cases in which the diagnosis is uncertain, a s-AFP level > 400 ng/mL has a high positive predictive value<sup>[1]</sup>. Histological confirmation through percutaneous liver biopsy should be restricted to those nodules with features on MR or CT that are not typical enough to allow a diagnosis<sup>[14]</sup>. In fact, the histological diagnosis of HCC is complex, requires a great degree of expertise and relies on the assumption that the core of the nodule has been effectively sampled by the small needle that is used for the percutaneous biopsy. The sensitivity and specificity reported for nodules less than 20 mm in diameter is

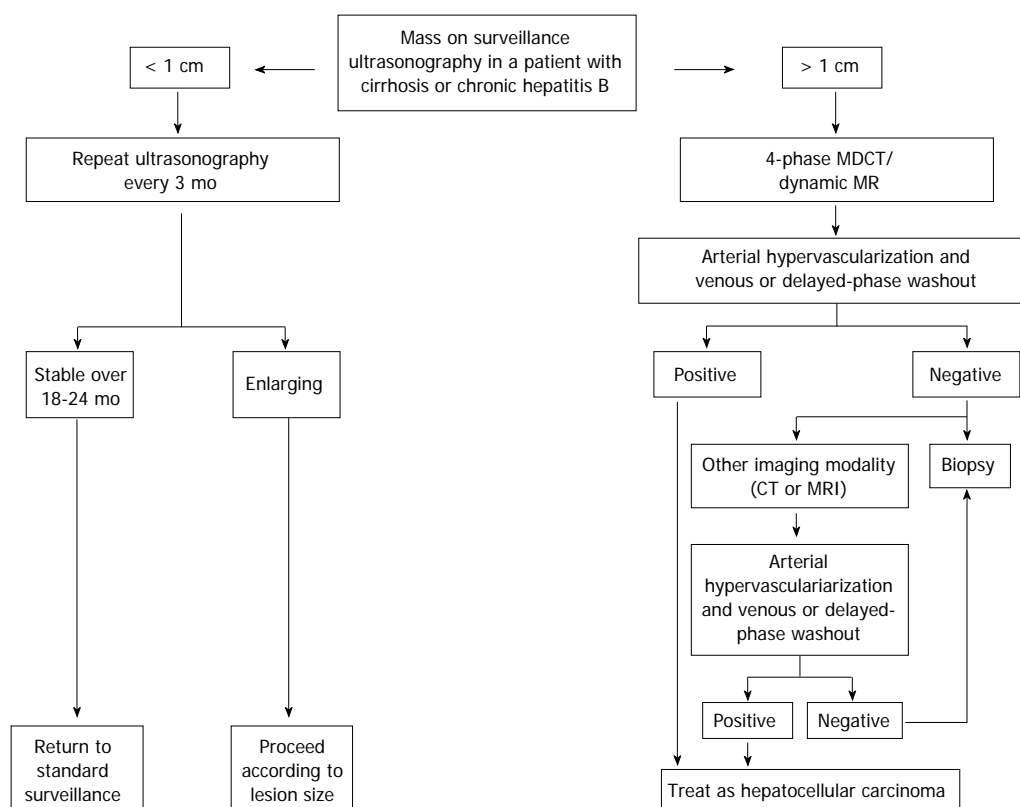

Figure 1 Diagnostic algorithm for hepatocellular carcinoma. Modified by Forner *et al*<sup>[11]</sup>. MDCT: Multidetector computed tomography; MR: Magnetic resonance; CT: Computed tomography; MRI: Magnetic resonance imaging.

60%<sup>[15]</sup>. A risk of tumor seeding in the path of the puncture has been reported in approximately 2.5% of the cases with a median time of development of 17 mo<sup>[16]</sup>.

### HCC staging

The severity of chronic liver disease is usually classified according to the Child-Pugh and model for end-stage liver disease (MELD) scores, and the tumor is staged with the TNM system; in the setting of liver transplantation, the indication for liver replacement is based mainly on the Milan criteria<sup>[17]</sup>. Another staging system that has gained acceptance is the Barcelona Clinic Liver Cancer (BCLC) score, the advantage of which is that it takes into account the characteristics of the tumor as well as the liver function and the general conditions of the patient<sup>[8]</sup> (Figure 2). The BCLC system was developed after a retrospective analysis of several cohort studies on patients with HCC at different stages. This system identifies patients with early HCC who may benefit from curative therapies (stage 0 and A), those at intermediate (stage B) or advanced (stage C) stages who may benefit from palliative treatments and those with a very poor life expectancy (stage D). BCLC is the most commonly used staging system in Europe, and it has been approved by the European Association for the Study of the Liver (EASL) and the AASLD.

### Multidisciplinary management of HCC

Given the complexity of the clinical scenario, the deci-

sion on the most appropriate treatment for a patient with HCC should be made by a multidisciplinary team that includes a hepatologist, hepatobiliary surgeon, transplant surgeon, radiologist and pathologist<sup>[18]</sup>. No single treatment strategy can be applied to all patients, and treatment should be individualized.

In the management of HCC, attention must be focused on the presence and degree of the underlying chronic liver disease at first observation, which will influence the choice of the treatment<sup>[19]</sup>.

Liver resection can be offered to patients with well-preserved liver function; however, the amount of parenchyma that can be removed in carriers of chronic liver disease is inferior to that which is considered as the safety limit in a normal liver (a “future remnant liver” that is  $\geq 30\%$  of the hepatic volume is generally considered acceptable)<sup>[19]</sup>. Despite a normal liver function, the regenerative potential of a liver that harbors a chronic disease can be surprisingly low.

In cases of impaired liver function, non-surgical procedures or liver transplantation (LT) can be offered; in this setting, the number, size and location of the nodules determine the choice of treatment.

Surgical resection, transplantation and ablation are the treatments that offer the highest rates of complete response and are therefore considered as curative<sup>[10]</sup>. There are no randomized trials comparing the efficacy of these three approaches, and all evidence is based on the rate of cure reported in different series.

Transarterial chemoembolization (TACE) is the least invasive approach; however, it cannot be considered curative.

Ideally, LT is best treatment for early stage HCC on cirrhosis because it removes both the tumor and the chronic disease that has produced it. However, the application of this powerful tool is limited by the scarcity of donors, which results in strict patient selection criteria to optimize the results.

Candidates for LT for whom a long waiting time (> 6 mo) is predicted may be offered resection, local ablation or transarterial chemoembolization as a 'bridge' to transplantation to minimize the risk of tumor progression while they are on the waiting list<sup>[20]</sup>. The same procedures can also be utilized in attempts downstage tumors that are beyond the eligibility criteria for LT at the time of diagnosis.

Yu *et al*<sup>[21]</sup> performed a study on HCC patients who exceeded the University of California San Francisco (UCSF) criteria for LT; these patients were downstaged to fit the UCSF criteria using locoregional therapy and finally underwent LT. Patients who were successfully downstaged prior to transplantation had tumor-free and overall survival rates similar to those observed in patients who met the criteria from the beginning.

A 5-year survival comparable to that of "within criteria" HCC patients can be achieved using LT after successful downstaging. Successful downstaging should include tumor size, number of viable tumors and s-αFP

concentrations before and after downstaging. Then, a minimum observation period of 3 mo is recommended before considering LT<sup>[22]</sup>.

If a patient's hepatic function allows it, liver resection can be offered prior to future transplantation by pursuing two different strategies: first, resection can be used as the primary therapy with LT offered as a rescue therapy should the patient develop tumor recurrence or postoperative liver failure (salvage transplantation); second, resection can be performed on patients with a high risk of tumor progression while awaiting transplantation (bridge to transplantation)<sup>[23,24]</sup>.

## SURGICAL RESECTION

When performed in specialized centers, hepatic resection (HR) can be highly effective, with 5-year overall survival rates well above 50% in the major series<sup>[25]</sup>. Resection is the recommended treatment for patients without advanced fibrosis as long as an R0 resection can be performed with a low risk of postoperative liver failure<sup>[14]</sup>.

The elements that must be taken into account when considering resection of the cirrhotic liver are the Child-Pugh and MELD scores of the underlying liver disease, the degree of portal hypertension and the extension of the parenchymal excision required to obtain a free resection margin.

The aim of HR is to obtain radical resection with

limited surgical morbidity; to achieve this goal, patient selection is crucial. For the last several decades, the selection of candidates for resection has been based on Child-Pugh classification. However, Child-Pugh classification is far from accurate for predicting postoperative liver failure; in fact, some Child-Pugh A patients already have liver functional impairment with an increased bilirubin concentration, clinically significant portal hypertension or even minor fluid retention necessitating diuretic treatment<sup>[26]</sup>. The further investigation of hepatic functional reserve tests, such as the aminopyrine breath test or clearance of indocyanine green (ICG), has been proposed; however, their predictive value remains poorly validated. In Japan, the ICG retention rate is utilized to identify the best candidates for resection<sup>[27]</sup>, whereas portal pressure and bilirubin are the variables used in Europe and the United States<sup>[10]</sup>. Recently, a preoperative MELD score  $\geq 10$  was associated with a higher incidence (40%) of postoperative liver failure<sup>[28]</sup>.

Markers of portal hypertension including a porto-caval gradient  $> 10$  mmHg, the presence of esophageal varices, splenomegaly and a platelet count lower than  $1 \times 10^{11}/L$  are predictors of postoperative morbidity and mortality<sup>[29]</sup>. In patients without relevant portal hypertension and normal concentrations of bilirubin, the 5-year survival is 70%, whereas this value is 50% for individuals with portal hypertension and is even lower when both these risk factors are present<sup>[30,31]</sup>.

By integrating all of these factors, HR can be safely performed on patients with Child-Pugh class A chronic liver disease, a MELD score  $\leq 10$ , a platelet count  $> 100,000/mm^3$  and a porto-caval gradient  $< 10$  mmHg. These factors dramatically limit the potential number of candidates, and overall, less than 30% of patients are candidates for HR<sup>[29]</sup>.

After HR, the 5-year survival for cirrhotic patients with HCC ranges from 30% to 50%, whereas the operative mortality ranges from 3% to 8%<sup>[29]</sup>. The severity of cirrhosis, size of the tumor, number of tumors, presence of vascular tumor invasion and presence of satellite nodules are well-established prognostic factors for recurrence and survival<sup>[27,32,33]</sup>. Late recurrence is mainly due to the carcinogenic effect of underlying chronic liver disease<sup>[34]</sup>.

Absolute contraindications to HR are the presence of extrahepatic metastases or neoplastic invasion of the main portal trunk. Neoplastic portal vein thrombosis is a poor prognostic factor; however, in highly selected cases, hemi-hepatectomy can be feasible, particularly when thrombosis of a main branch of the portal vein has led to hypertrophy of the contralateral hemiliver.

When compared with open surgery, laparoscopy in cirrhotic patients could have the advantage of avoiding the interruption of collateral abdominal veins that are present as a result of portal hypertension. Several studies have indeed demonstrated the benefits of the laparoscopic approach in terms reduced bleeding and lower postoperative morbidity and mortality<sup>[35,36]</sup>.

## LIVER TRANSPLANTATION

HCC is the only solid cancer that can be treated with transplantation. Transplantation is the best curative option for patients with decompensated (Child-Pugh B or C) cirrhosis; however, due to the shortage of donors, it can only be offered to a limited number of patients. Candidates for LT are patients with tumors that have favorable pathological features and therefore a low likelihood of recurrence.

The most widely adopted criteria for selecting HCC carriers for transplantation are the Milan criteria. According to these criteria, LT can be considered only for patients with a single tumor  $< 5$  cm in diameter or for patients with up to 3 tumors  $< 3$  cm without macrovascular invasion<sup>[17]</sup>. A recent systematic review of 90 studies that followed 17780 patients over a 15-year period identified the Milan criteria as an independent prognostic factor of outcome after LT<sup>[37]</sup>.

Despite recent discussions concerning the restrictive nature of the Milan criteria, these criteria have been adopted by the vast majority of transplant centers. The results of LT in HCC within the Milan criteria are outstanding, with 5-year survival approaching 80%, which is similar to that observed in patients transplanted for benign diseases<sup>[30,38,39]</sup>. Outside the Milan criteria, survival is significantly reduced, which is likely due to an increased prevalence of variables associated with risk of recurrence, such as microvascular invasion, in tumors at more advanced stages<sup>[40]</sup>.

Neoadjuvant therapy through TACE can occasionally downstage tumors that were outside the Milan criteria at the time of diagnosis; in these cases, the results of LT are similar to those achieved when the criteria were met at first observation<sup>[41]</sup>.

The time spent on the waiting list is a key factor that must be considered when assessing the results of LT in HCC patients; it depends on the availability of donors in a given area and on the system used to prioritize organ allocation. It was demonstrated that 15%-20% of patients with HCC initially within the Milan criteria experience tumor progression until they dropped out from the waiting list; this highlights the need to analyze the results of LT using an intention to treat approach<sup>[42]</sup>. Although treatments aimed at delaying tumor progression, such as ablation and transarterial chemoembolization, are widely used, their efficacy is unproven<sup>[43]</sup>. Live donation is a valid strategy for extending the donor pool; however, its applicability is reduced because of societal constraints, scarcity of appropriate donors and the possible morbidity and mortality of donors<sup>[44]</sup>.

Currently, organs are allocated worldwide based on MELD score; however, HCC patients with low MELD scores are given extra points to shorten their waiting time and avoid tumor progression. This policy is questioned by some authors because it might be disadvantageous for patients without HCC<sup>[45]</sup>.

## LOCOREGIONAL TREATMENTS

Local ablation techniques have been developed for patients with surgical contraindications and can be performed either through a percutaneous approach or, less commonly, through laparoscopy. These maneuvers include percutaneous ethanol injection (PEI), radiofrequency ablation (RFA), microwave ablation, cryoablation, laser-induced thermotherapy, high-intensity focused ultrasound and irreversible electroporation<sup>[46]</sup>.

The first percutaneous treatment was PEI, which induces coagulative necrosis of the lesion as a result of cellular dehydration, protein denaturation and chemical occlusion of small tumor vessels due to the effects of the injected absolute alcohol. Ablation techniques such as RFA, microwave ablation, and laser ablation utilize high temperatures; conversely, cryoablation causes direct tumor freezing<sup>[47]</sup>.

The evaluation of responses to locoregional treatments and molecular-targeted therapies of HCC is currently based on modified RECIST (mRECIST) criteria, which measure the diameter of the viable tumor component of target lesions<sup>[48]</sup>.

### Radiofrequency ablation

RFA is the technique of choice for local destruction of liver tumors. RFA induces coagulative necrosis of the tumor with safety margins around the lesion and is the most commonly used local ablative technique. RFA has largely replaced PEI because it produces better results in terms of recurrence-free survival and requires fewer treatment sessions<sup>[49]</sup>. RFA can be performed percutaneously under imaging guidance (ultrasound, CT or MRI) or during surgery guided by intraoperative US. The advantage of RF in the treatment of HCC in cirrhotic patients is that it allows selective destruction of the tumor, sparing the surrounding parenchyma, and can be easily repeated in case of recurrence. Complete ablation of lesions smaller than 2 cm is possible in more than 90% of cases<sup>[50]</sup>.

There are several major limits to the use of RF: (1) complete necrosis is rarely observed when the tumor diameter is > 3 cm or when the tumor is adjacent to a major blood vessel due to the cooling effect of the blood flow; (2) it is difficult to reach some areas of the liver parenchyma percutaneously (*e.g.*, segment 1); (3) subcapsular lesions can undergo rupture in the peritoneum; (4) bladder injury can occur when lesions in segments IVb-5 are treated; and (5) targeting the lesion can be difficult under ultrasound guidance in livers with multinodular cirrhosis.

Taking these limitations into account, the benefit of RF in the treatment of HCC has been well demonstrated, with overall 5-year survival rates between 33% and 55% in selected series<sup>[51]</sup>. The effectiveness of RFA has led to the proposal of this technique as an alternative to HR.

In the only randomized prospective trial with balanced groups of patients comparing HR to RFA for HCC < 3 cm in patients with cirrhosis, no difference was

observed in terms of overall and disease-free survival, whereas RF was associated with lower perioperative morbidity (4.2% *vs* 55.5%,  $P < 0.05$ ) and mortality (0% *vs* 1.1%)<sup>[52]</sup>. However, in a retrospective comparative study of Child-Pugh class A patients, surgery was significantly more effective for patients with single tumors > 3 cm in diameter, with an overall 3-year survival of 66% after surgery (*vs* 37% after RFA,  $P = 0.004$ ) and a 3-year disease-free survival of 44% (*vs* 19%,  $P = 0.001$ )<sup>[53]</sup>. This observation was confirmed by subsequent studies performed by different groups<sup>[54-56]</sup>. A recent systematic review and meta-analysis of 12 controlled trials showed a not notable difference in the short-term effectiveness of RFA and HR in the treatment of early-stage hepatocellular carcinoma meeting Milan criteria, but the long-term efficacy of HR was better than that of RFA<sup>[57]</sup>. However, HR was associated with more complications and a longer hospital stay.

Rather than competing techniques, RFA and HR are effective therapeutic options that can be chosen based on the severity of chronic liver disease as well as the size and location of the tumor.

### Transarterial chemoembolization

Transarterial chemoembolization (TACE) is the most commonly used initial treatment for unresectable HCC<sup>[58]</sup> and is also the first-line therapy for downstaging tumors that exceed the criteria for transplantation or to avoid tumor progression in patients awaiting LT. TACE may also be considered as a neoadjuvant treatment that can be utilized before HR or RF ablation to reduce tumor volume and possibly target satellite micrometastases<sup>[59]</sup>.

The rationale behind TACE use is the well-characterized angiogenic activity of HCC that results in hypervascular arterial feeding. This technique depends on the intra-arterial infusion of a cytotoxic chemotherapeutic agent emulsified with Lipiodol followed by embolization of the feeding vessels through a trans-arterial catheter<sup>[60]</sup>. TACE is a well-established treatment for HCC in cirrhotic patients, and its efficacy for improving survival compared with the other supporting treatments has been demonstrated<sup>[61]</sup>.

The maximum and sustained retention of the chemotherapeutic agent is used as a measure of the success of TACE; thus, embolic microspheres are employed that have the ability to sequester chemotherapeutic agents. The concentration of these microspheres is increased within the tumor, and their contents are subsequently released in a controlled manner over a 1-wk period, which reduces the systemic toxicity to a minimum<sup>[62]</sup>.

Doxorubicin-eluting beads (DEB) are another trans-arterial liver-directed therapy. The use of an eluting bead can be considered an improvement over conventional TACE. DEB are preformed, deformable microspheres that are loaded with doxorubicin (up to 150 mg per treatment). The pharmacokinetic profile of DEB significantly differs from that of conventional TACE; in particular, the peak drug concentration in the serum is lower for DEB-

TACE compared with conventional TACE. An objective response rate of 70% to 80% according to the EASL criteria has been achieved<sup>[63]</sup>. One- and 3-year survival rates of 89.9% and 66.3%, respectively, have been reported in a heterogeneous cohort of patients with BCLC (stages A to C) treated with DEB-TACE<sup>[64]</sup>.

Absolute contraindications for TACE are decompensated cirrhosis (Child-Pugh B  $\geq$  8, including jaundice, clinical encephalopathy and refractory ascites), extensive tumor with massive replacement of both lobes in their entirety, severely reduced portal vein flow (portal vein occlusion or hepatofugal blood flow), and a creatinine clearance  $< 30$  mL/min<sup>[65]</sup>.

### Microwave ablation

Microwave ablation (MWA) is a potentially curative ablation procedure that has been proven to be safe in both percutaneous and intraoperative settings<sup>[66]</sup>. MWA can be utilized in patients with advanced liver disease and HCC, provides a more predictable ablation compared with RFA and requires fewer treatment sessions<sup>[21,67,68]</sup>.

Microwave ablation creates an electromagnetic field in the tissues surrounding the ablation antenna with an extension of several centimeter, without flow of electrical current. Tissue within the MWA field heats rapidly to temperatures over 100 °C without the detrimental effects of tissue impedance, allowing a more rapid and consistent ablation<sup>[10]</sup>. Microwave ablation carries the risk of more severe injury to adjacent structures due to differences in energy delivery when compared with RFA; therefore, the operative approach is preferred over the percutaneous approach because it allows liver mobilization and protection of adjacent organs<sup>[66,69,70]</sup>.

### Radioembolization

Radioembolization is a newer hepatic transarterial technique that employs radioactive substances such as Iodine-131-labeled Lipiodol<sup>[71]</sup> or microspheres containing Yttrium-90<sup>[72]</sup>. This technique has been shown to be feasible and safe for the treatment of HCC in cirrhotic patients<sup>[73,74]</sup>. Microspheres are delivered to the tumor area for selective production of high energy and low penetration radiation. Radioembolization can be safely performed in patients with portal vein thrombosis due to the minimally embolic effect of 90Y microspheres<sup>[75]</sup>. The reported rate of complete tumor necrosis is 90% for patients with HCC  $< 3$  cm<sup>[76]</sup>, whereas the rate of complete necrosis after TACE varies widely in the literature, from 15% to 70%<sup>[77]</sup>.

### Radiation therapy

Radiation therapy is generally not considered an option in HCC consensus documents or national guidelines, primarily because of the lack of level 1 evidence<sup>[78]</sup>. However, experience with conformal radiation therapy (RT), intensity modulated RT, stereotactic body RT and particle therapy is rapidly increasing. RT should be considered as a treatment option in patients unsuitable for other established local therapies<sup>[78]</sup>. RT has also been used as

a bridge to liver transplant and can be safely combined with locoregional therapies such as TACE<sup>[78,79]</sup>.

## SYSTEMIC TREATMENTS

Systemic treatment of HCC in cirrhotic patients is not effective due to the poor chemosensitivity of the tumor, and the impairment of hepatic function significantly increases the toxicity of chemotherapy.

Because the demonstrated benefits of systemic chemotherapy and hormonal treatments are lacking<sup>[80,81]</sup>, molecular targeted therapies have recently been developed. Sorafenib, an inhibitor of multi-kinase, has antiproliferative and antiangiogenic activity, delays tumor progression and is currently the only agent with proven efficacy for the treatment of patients with advanced HCC<sup>[11,82-84]</sup>. This multitargeted tyrosine kinase inhibitor is a small molecule that inhibits vascular endothelial growth factor receptor, platelet-derived growth factor receptor, B-Raf, Fms-related tyrosine kinase and c-kit<sup>[85,86]</sup>.

The use of sorafenib is currently recommended for patients with preserved liver function and advanced HCC who are not suitable for HR or LT and have failed to respond to locoregional treatments<sup>[87]</sup>. It is recommended that the treatment be continued until progression of the tumor is demonstrated. The main side effects associated with the use of sorafenib are diarrhea and hand-foot skin reaction; other possible side effects include anorexia, nausea, vomiting, weight loss, hoarseness of voice, asthenia and hypertension<sup>[52,88]</sup>. These effects can occasionally require dose reduction or treatment discontinuation. The potential benefit of sorafenib as adjuvant treatment after LT has not been demonstrated.

On the basis of a large randomized phase III study, the Sorafenib HCC Assessment Randomized Protocol<sup>[83]</sup>, Sorafenib has been approved by the United States Food and Drug Administration for the treatment of patients with advanced HCC.

Studies are ongoing that aim to identify the best responders to Sorafenib; c-Jun N-terminal kinase (JNK) activity was positively correlated with the CD133 expression level and inversely correlated with the therapeutic response to Sorafenib. Accordingly, JNK activity may be considered as a new predictive biomarker for response to Sorafenib treatment<sup>[89]</sup>.

To date, there is no second-line treatment for patients who are intolerant to Sorafenib or experience tumor progression while undergoing treatment.

## COMBINED TREATMENTS

A combination of the different therapeutic approaches mentioned thus far is often required to address the different clinical peculiarities of HCC patients. For example, chemoembolization or RFA can be performed before radical surgery with curative intent (HR or LT) to allow effective tumor downstaging or reduce tumor growth. Different authors have proposed HR as a first-line ther-

apy in patients who are candidates for LT<sup>[90]</sup>; however, the possible effect of previous surgery on the technical complexity of the liver transplantation procedure is a matter of debate<sup>[90,91]</sup>. One argument in favor of hepatic resection prior to LT is that histological analysis of the tumor can provide useful information regarding its oncological behavior: features such as the presence of a tumor capsule, the degree of differentiation or the presence of micro-vascular invasion can be precisely assessed in the surgical specimen and are well-known prognostic factors. However, there is no consensus among different authors regarding the influence that histological parameters should have on the therapeutic strategy; some authors suggest that LT should be contraindicated for patients with tumors that display poor prognostic histological criteria, whereas others recommend transplant priority in the presence of the same risk factors<sup>[23,92]</sup>.

## CONCLUSION

The treatment of HCC in cirrhotic patients has changed significantly over the past several decades and has become a major clinical issue. Patients with HCC on cirrhosis can benefit from several effective treatments that will improve their survival; however, the choice of the most appropriate options depends on several factors, namely: (1) severity of the underlying chronic liver disease; (2) stage of the tumor assessed *via* imaging; (3) histological features of the tumor (when available); (4) availability of an active transplant program; (5) availability of a hepatobiliary surgical unit; and (6) availability of an experienced interventional radiology service.

Some of these variables may account for the different attitudes that are often observed. To ensure that the most effective treatment can be offered for a given case, a multidisciplinary approach is warranted, and professionals skilled in the administration of the different treatment types should be available. The increase in the incidence of HCC justifies the development of services related to the management of this tumor.

### Abstract

Abnormal liver biochemical tests are present in up to 30% of patients with inflammatory bowel disease (IBD), and therefore become a diagnostic challenge. Liver and biliary tract diseases are common extraintestinal manifestations for both Crohn's disease and ulcerative colitis (UC), and typically do not correlate with intestinal activity. Primary sclerosing cholangitis (PSC) is the most common hepatobiliary manifestation of IBD, and is more prevalent in UC. Approximately 5% of patients with UC develop PSC, with the prevalence reaching up to 90%. Cholangiocarcinoma and colon cancer risks are increased in these patients. Less common disorders include autoimmune hepatitis/PSC overlap syndrome, IgG4-associated cholangiopathy, primary biliary cirrhosis, hepatic amyloidosis, granulomatous hepatitis, cholelithiasis, portal vein thrombosis, liver abscess, and non-alcoholic fatty liver disease. Hepatitis B reactivation during immunosuppressive therapy is a major concern, with screening and vaccination being recommended in

serologically negative cases for patients with IBD. Re-activation prophylaxis with entecavir or tenofovir for 6 to 12 mo after the end of immunosuppressive therapy is mandatory in patients showing as hepatitis B surface antigen (HBsAg) positive, independently from viral load. HBsAg negative and anti-HBc positive patients, with or without anti-HBs, should be closely monitored, measuring alanine aminotransferase and hepatitis B virus DNA within 12 mo after the end of therapy, and should be treated if the viral load increases. On the other hand, immunosuppressive therapy does not seem to promote reactivation of hepatitis C, and hepatitis C antiviral treatment does not influence IBD natural history either. Most of the drugs used for IBD treatment may induce hepatotoxicity, although the incidence of serious adverse events is low. Abnormalities in liver biochemical tests associated with aminosalicylates are uncommon and are usually not clinically relevant. Methotrexate-related hepatotoxicity has been described in 14% of patients with IBD, in a dose-dependent manner. Liver biopsy is not routinely recommended. Biologics-related hepatotoxicity is rare, but has been shown most frequently in patients treated with infliximab. Thiopurines have been associated with veno-occlusive disease, regenerative nodular hyperplasia, and liver peliosis. Routine liver biochemical tests are recommended, especially during the first month of treatment. All these conditions should be considered in IBD patients with clinical or biochemical features suggestive of hepatobiliary involvement. Diagnosis and management of these disorders usually involve hepatologists and gastroenterologists due to its complexity.

**Key words:** Inflammatory bowel disease; Hepatobiliary disorders; Extraintestinal manifestations; Primary sclerosing cholangitis; Drug-induced liver injury; Hepatotoxicity; Hepatitis B; Hepatitis C

**Core tip:** Hepatobiliary disorders are common extraintestinal

testinal manifestations of inflammatory bowel disease (IBD) that become a diagnostic challenge for the gastroenterologist. In this review, we have summarized the main diseases involving the hepatobiliary system in IBD and secondary liver toxicity to IBD treatment. This review also highlights the impact of immunosuppressive and anti-tumor necrosis factor treatment in hepatitis B and C, as well as its prophylaxis and treatment, according to current clinical practice guidelines.

Hepatobiliary manifestations in inflammatory bowel disease: The gut, the drugs and the liver. *World J Gastroenterol* 2013; 19(42): 7327-7340 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7327.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7327>

## INTRODUCTION

Hepatobiliary diseases are relatively common in inflammatory bowel disease (IBD) and therefore become a diagnostic challenge. Liver and biliary tract disorders are typical extraintestinal manifestations in both Crohn's disease (CD) and ulcerative colitis (UC). In patients receiving immunosuppressive therapy, including biologics, the risk of hepatitis B reactivation is high, so patients undergoing this therapy should be screened for hepatitis B surface antigen (HBsAg) and anti-HBc prior to starting the treatment. Most of the drugs used for IBD treatment have also been associated with hepatotoxicity. All these conditions should be ruled out in IBD patients with clinical or biochemical features suggestive of liver involvement, as summarized in this review.

Bibliographic searches were performed in the MEDLINE electronic database up to February 2013 using the Medical Subject Headings terms: ("inflammatory bowel disease" OR "Crohn's disease" OR "ulcerative colitis") AND ("liver" OR "biliary tract" OR "primary sclerosing cholangitis" OR "hepatobiliary disorders" OR "small-duct PSC" OR "PSC/AIH overlap syndrome" OR "IgG4-associated cholangitis" OR "primary biliary cirrhosis" OR "hepatic amyloidosis" OR "granulomatous hepatitis" OR "cholelithiasis" OR "portal vein thrombosis" OR "liver abscess" OR "non-alcoholic fatty liver disease" OR "viral hepatitis" OR "hepatitis B" OR "hepatitis C" OR "drug-induced liver injury" OR "drug-induced hepatitis" OR "hepatotoxicity").

## HEPATOBIILIARY DISORDERS ASSOCIATED WITH INFLAMMATORY BOWEL DISEASE

Hepatobiliary manifestations constitute some of the most common extraintestinal manifestations of IBD. They typically adopt an independent course irrespective of intestinal activity and are present in both UC and CD.

### Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic fibro-sclerotic disorder of the intrahepatic and extrahepatic biliary tree, and is the most common hepatobiliary manifestation of IBD. The association of PSC and IBD was described for first time in 1965<sup>[1]</sup>.

**Epidemiology:** Approximately 70%-80% of patients with PSC have concomitant IBD and about 1.4%-7.5% of patients with IBD will develop PSC<sup>[2]</sup>; however the course of IBD is not related to PSC. It is more prevalent in males, in UC, and in young and middle-aged patients<sup>[3]</sup>. UC has been reported in 25 to 90 percent of patients with PSC<sup>[4]</sup>. In a Spanish multicenter study, based on a survey, UC was present in 44%<sup>[5]</sup>. Nevertheless, the real prevalence of UC in PSC is up to 90% when rectal and sigmoid biopsies are routinely obtained<sup>[6]</sup>.

PSC is typically characterized by progressive inflammation, obliterative fibrosis, and destruction of intra- and extrahepatic bile ducts, leading to end-stage liver disease and portal hypertension<sup>[7]</sup>. Patients with PSC may also develop complications such as cholestasis-associated manifestations, biliary stricture, cholangitis, cholelithiasis, cholangiocarcinoma, and colon cancer. The diagnosis of PSC is usually previous to IBD, but PSC may be diagnosed over time, after a proctocolectomy in UC patients<sup>[8]</sup>.

**Etiology:** The etiology of PSC remains unclear. Genetic, immunological, and environmental factors seem to contribute to its pathogenesis. First-degree relatives of patients with PSC show an increased risk of PSC and UC, supporting a genetic predisposition to these conditions<sup>[9]</sup>. Multiple genetic factors associated with susceptibility have been described, like HLA-B8, HLA-DRB1\*0301 (DR3), HLADRB3\*0101 (DRw52a), and HLA-DRB1\*0401 (DR4)<sup>[10,11]</sup>. In addition, three UC susceptibility loci have been associated with PSC, harboring the presumed candidate genes REL, IL2, and CARD9<sup>[12]</sup>. An autoimmune mechanism has been suggested, since both are immune-mediated disorders, and are also associated with other autoimmune diseases. Several autoantibodies may be present, such as antinuclear antibodies (ANA) in 24%-53%, smooth muscle antibodies (SMA) in 13%-20%, and anti-perinuclear cytoplasmic antibodies (pANCA) in 65%-88% of patients<sup>[13-15]</sup>. Other autoantibodies, including anticardiolipin, thyroperoxidase, and rheumatoid factor may be present, but show uncertain clinical significance. In one study, 97% of cases with PSC were positive for, at least, one autoantibody, while 81% were positive for three or more<sup>[16]</sup>. An inflammatory response to chronic or recurrent bacterial infection into the portal circulation or ischemic damage to the bile ducts has also been postulated<sup>[17]</sup>. Therefore, the most plausible theory involves the exposure of genetically predisposed individuals to an environmental agent that provokes an anomalous immune response, leading to disease development.

IBD in PSC patients has a distinct behavior, as it shows a higher incidence of rectal sparing, backwash

ileitis, extensive colitis, pouchitis after ileal pouch anal anastomosis, colon dysplasia, colon cancer, and poorer prognosis<sup>[18-21]</sup>. Patients with UC and PSC usually have a lower grade of colon inflammation and a milder course, compared to patients without PSC<sup>[22]</sup>. In addition, severe progressive PSC requiring liver transplantation appears to reduce histological activity and the need for colectomy in UC<sup>[23,24]</sup>.

**Diagnosis:** Most patients with PSC are asymptomatic at diagnosis. This disease should be considered in patients with IBD and abnormal liver biochemical tests, where a marked elevation of serum alkaline phosphatase is commonly found<sup>[25]</sup>. In symptomatic patients, fatigue and pruritus are common. Other features include abdominal pain, jaundice, and weight loss. Cholangitis occurs in 10%-15% of patients during the course of the disease. Biochemical tests usually show a cholestatic pattern. Aminotransferases levels are typically lower than 300 IU/L. Additional biochemical parameters are hypergamma-globulinemia (30% of cases), increased serum IgM levels (40%-50%), and p-ANCA (30%-80%). Serum albumin levels later decrease during the course of the disease, and the presence of hypoalbuminemia earlier may indicate active IBD.

Diagnosis is established by the demonstration of diffuse, multifocal strictures and dilations in the intra- and extrahepatic bile ducts. In 41% of cases, the gallbladder and cystic duct may also be involved<sup>[26]</sup>. In the early stages of the disease, superficial ulcerations of the bile ducts may be the only manifestation found. Endoscopic retrograde cholangiopancreatography (ERCP) is considered the gold standard technique for PSC diagnosis. It can be both diagnostic and therapeutic, and also may be useful in the early diagnosis of cholangiocarcinoma. Magnetic resonance cholangiography (MRCP) is a non-invasive alternative with high sensitivity and specificity, and without the risks related to the technique<sup>[27]</sup>. Liver biopsy is only recommended in cases of clinical suspicion of small-duct PSC, as it is rarely diagnostic of PSC<sup>[28]</sup>. The most specific histologic finding in PSC is fibrous obliteration of small bile ducts, with periductal concentric fibrosis in an "onion skin" pattern. Other abnormalities are non-specific and similar to those in primary biliary cirrhosis. Liver biopsy is helpful for staging the disease and determining prognosis. Ludwig described 4 stages of PSC based on morphologic features<sup>[29]</sup>.

**Prognosis:** PSC is a progressive disease that, ultimately, results in portal hypertension, cirrhosis, and hepatic failure. The median survival time without liver transplantation is approximately 12 years. Survival is significantly worse in symptomatic patients at the time of diagnosis<sup>[30]</sup>. Coexisting IBD may also be related to a poorer prognosis, as it has been associated with a younger age at diagnosis, the development of malignant complications, dysplasia and/or colon cancer<sup>[31,32]</sup>. Patients with PSC usually develop complications of end-stage liver disease

with portal hypertension, such as varices, ascites, and hepatic encephalopathy. The Mayo Risk Score based on age, serum bilirubin, albumin, aspartate aminotransferase, and the presence of variceal bleeding, has been used to assess disease progression and prognosis<sup>[33]</sup>. Other complications include steatorrhea and fat-soluble vitamin deficiency, secondary to chronic cholestasis, amyloidosis secondary to amyloid A protein deposition in tissues due to a progressive inflammatory process<sup>[34]</sup>, dominant biliary strictures, cholangiocarcinoma, and colon cancer. The risk for cholangiocarcinoma is significantly increased in PSC and its development remains unpredictable. The annual incidence has been estimated as 1.5%<sup>[35]</sup>. Risk factors include the presence of IBD, cirrhosis, variceal bleeding, a dominant stricture in the bile duct, and alcohol intake<sup>[36]</sup>. Worsening jaundice, weight loss, and abdominal discomfort are suspicion symptoms. Diagnosis may be difficult, as imaging techniques and brush cytology show a lack of sensitivity for early detection. However, ERCP and cytology of bile duct strictures is highly specific<sup>[37]</sup>. Prognosis is devastating, with a survival rate of 10% two years after diagnosis<sup>[38]</sup> and a recurrence rate in the transplanted liver of about 20%-25%<sup>[39]</sup>. Patients with PSC have an increased risk for gallbladder cancer, pancreatic cancer and, in cirrhotic patients, hepatocellular carcinoma. A higher risk of colorectal dysplasia/cancer has also been described among UC patients with PSC<sup>[21]</sup>, even after liver transplantation<sup>[40]</sup>. The severity and the duration of PSC have not been significantly associated with the risk of colon cancer<sup>[41]</sup>. In patients with ileal pouch-anal anastomosis, the risk for dysplasia persists after colectomy<sup>[42]</sup>. Therefore, surveillance for colorectal cancer should be strongly recommended in PSC patients with UC<sup>[43]</sup>.

**Treatment:** Treatment of PSC associated with UC does not differ from PSC without IBD. As no pharmacologic therapy has proven effective for PSC, treatment goals are the control of symptoms and the management of complications. Ursodeoxycholic acid (UDCA) has been shown as effective in liver function improvement based on biochemical tests but it had no effect on liver histology, liver transplant-free survival, requirements for liver transplantation, development of cholangiocarcinoma, or incidence of death<sup>[44,45]</sup>. In a meta-analysis, UDCA does not appear to decrease either the risk of adenomas or colon cancer<sup>[46]</sup>. Immunosuppressants, chelators, and steroids have been used without any benefit.

Liver transplantation is the only therapy that can change the inevitable outcome. The appropriate moment for liver transplantation can be difficult to determine, as patients with advanced disease may not show signs of liver failure. Survival rates after hepatic transplant at 5 and 10 years are 85% and 70%, respectively<sup>[47]</sup>. However, in 20%-25% of cases, PSC recurs in the transplanted liver<sup>[39]</sup>.

Endoscopic management of PSC is indicated in cases of cholangitis, exacerbate jaundice, or suspicion of cholangiocarcinoma. Endoscopic dilation of dominant

strictures, with or without stenting, has been shown to alleviate cholestasis and to improve laboratory test results, although it does not prevent disease progression<sup>[48]</sup>.

### **Small-duct PSC**

Small-duct PSC is characterized by laboratory and histological findings similar to PSC but with normal cholangiogram. The presence of coexisting IBD is required for the diagnosis of this entity<sup>[49]</sup>. In a large multicenter study, 80% of patients with small-duct PSC had concurrent IBD (78% UC and 21% CD)<sup>[50]</sup>. Progression of small-duct PSC to PSC was observed in 12%-23% of cases. Small-duct PSC has been associated with a better long-term prognosis as compared with large-duct PSC. Cholangiocarcinoma has not been previously described. Some patients may require liver transplantation for end-stage liver disease, and the disease may recur after liver transplantation. In IBD patients with cholestatic liver function tests altered and a normal cholangiogram by ERCP/MRCP, a biopsy is recommended to rule out small-duct PSC, after excluding other hepatobiliary disorders.

**AIH/PSC overlap syndrome:** AIH/PSC overlap syndrome has been described in patients with IBD, especially UC<sup>[51]</sup>. The diagnosis is suspected when features of AIH and PSC are present in the same patient, requiring a definitive diagnosis of AIH based on the International Autoimmune Hepatitis Group Criteria, which includes demographic, histologic, and laboratory markers<sup>[52]</sup>. Diagnosis, treatment, and prognosis of the overlap syndrome are controversial and so standardized diagnostic criteria are needed<sup>[53,54]</sup>. Previous studies have reported cases that initially presented with laboratory markers and histologic features of either AIH or both diseases with a normal cholangiography, only to develop pathologic characteristics of PSC during the follow-up<sup>[52,55,56]</sup>. Intrahepatic and extrahepatic bile ducts may be affected. Conventional corticosteroid therapy, alone or in conjunction with UDCA (13-15 mg/kg daily), has been variably effective, and cyclosporine, mycophenolate mofetil, and budesonide have been beneficial in selected patients. The cholestatic features that influence the prognosis of autoimmune hepatitis must be defined and incorporated into the definition of the syndrome<sup>[57]</sup>.

### **IgG4-associated cholangiopathy**

IgG4-associated cholangiopathy (IAC) is a biliary disease of unknown immunopathogenesis. Indistinguishable from PSC according to cholangiographic characteristics, it shows distinct histological findings. It is one of a variety of IgG4-related systemic disease and has been described in patients with concurrent UC<sup>[58]</sup>. Clinical diagnostic criteria for IgG4-related disease require systemic organ involvement, elevated serum IgG4 levels ( $\geq 135$  mg/dL), and histopathological findings<sup>[59]</sup>. IgG4 levels have also been reported in 9%-36% of patients with PSC, although these levels are usually lower than in patients with IAC<sup>[60,61]</sup>. The identification of IgG4 plasma

cell infiltrating the bile duct and other organs is decisive in reaching the diagnosis<sup>[58,59]</sup>. Clinically, patients with IAC are older at diagnosis compared to patients with PSC. Obstructive jaundice can be the first symptom, whereas it is rarely present in PSC<sup>[62]</sup>. Steroids are the first-choice therapy of IAC, as they result in the resolution of jaundice, improve liver laboratory parameters, and reduce serum IgG4 levels and the reversal of strictures on cholangiogram<sup>[63]</sup>. Azathioprine (AZA) should be considered alongside those with proximal and intrahepatic stenosis, and those that relapse during and/or after corticosteroid therapy<sup>[64]</sup>.

### **Primary biliary cirrhosis**

Primary biliary cirrhosis (PBC) frequently accompanies various autoimmune diseases including Sjögren syndrome, chronic thyroiditis, and rheumatoid arthritis, but rarely IBD<sup>[65]</sup>. There are a few reported cases of both diseases in the literature<sup>[66,67]</sup>. The clinical presentation varies from typical PBC; affecting males more frequently, being diagnosed at younger age and at earlier stages of PBC, and usually associated with previously diagnosed mild left-side UC. Although the pathogenesis of this disease has not yet been clarified, environmental and genetic factors are considered important in the susceptibility to both diseases.

### **Hepatic amyloidosis**

Secondary amyloidosis is an unusual complication of IBD, more frequent in CD than in UC (0.9% *vs* 0.07%)<sup>[68]</sup>. Chronic activity in the bowel contributes to amyloid deposition in the vasculatures and sinusoids of almost any organ, including the liver. It may present as asymptomatic hepatomegaly and is more common in men with colonic diseases. Treatment is based on controlling gut inflammation, thereby decreasing the release of the acute phase reactant serum amyloid A<sup>[69]</sup>. In some cases, colchicine can be effective.

### **Granulomatous hepatitis**

Granulomatous hepatitis is another rare complication of CD, which is characterized by granulomas on the liver biopsy. The main manifestation is an increase in cholestatic enzymes such as alkaline phosphatase. Granulomatous hepatitis is often secondary to different medications, including sulfasalazine<sup>[70]</sup>. Other causes are malignancies, infections, or CD metastasis<sup>[71]</sup>. Corticosteroids and immunosuppressive drugs have been used in its treatment.

### **Cholelithiasis**

It has been estimated that patients with CD have a doubled risk for gallstones comparing to IBD-free controls, while UC is not associated with an increased risk<sup>[72]</sup>. The incidence of gallstones is raised in patients with Crohn's ileitis or ileal resection, ranging from 13% to 34%<sup>[73]</sup>. Risk factors associated with its development are CD location at diagnosis, surgery, and extent of ileal resection. Other factors include the age of the patient, frequency

of clinical recurrences, length of hospital stay, and the use of total parenteral nutrition. The pathophysiology of cholelithiasis in CD is not well defined. Abnormal malabsorption of bile acids that interfere with enterohepatic circulation has been proposed. Moreover, reduced gallbladder motility has been described in CD and increased gallstone cholesterol concentrations have been identified in patients with ileoanal anastomosis<sup>[74]</sup>.

### Portal vein thrombosis

IBD is associated with an increased risk of vascular complications, such as arterial and venous thromboembolisms, which are considered extraintestinal manifestations. Portal vein thrombosis is a rare but potentially life-threatening complication, with an incidence in IBD patients higher than that of the general population. In a Mayo Clinic study, portal/mesenteric vein thrombosis was reported in 1.3% of IBD cases, with a mortality of 50%<sup>[75]</sup>. Recent abdominal surgery, younger age, and female gender are associated with a higher incidence of portal vein thrombosis<sup>[76]</sup>. The factors involved in this pathogenesis are diverse. Acquired prothrombotic factors can be identified, such as inflammation, immobilization, extent of colon disease, surgery, central catheters, corticosteroids, and smoking<sup>[77,78]</sup>. Furthermore, patients with IBD have increased platelet counts, factor V and VIII levels, and fibrinogen, along with decreased antithrombin III levels. Anticoagulants, such as low-molecular-weight heparin and warfarin, are mainstays of therapy, even in the setting of gastrointestinal bleeding<sup>[73]</sup>. In the presence of a congenital hypercoagulable state, lifelong systemic anticoagulation should be considered, although in other prothrombotic conditions, a six-month course provides adequate coverage<sup>[79]</sup>.

### Liver abscess

The association between liver abscesses and IBD is uncommon<sup>[80,81]</sup>, but hepatic abscesses can be an initial manifestation of CD<sup>[82]</sup>. The mechanism of abscess development may be related to direct extension of intra-abdominal abscesses or due to portal pyemia, secondary to an increase in intestinal mucosa permeability. Among associated risk factors, intra-abdominal abscesses, fistulizing disease, malnutrition, and treatment with steroids and metronidazole have been reported.

### Non-alcoholic fatty liver disease

Non-alcoholic fatty liver disease (NAFLD) is a clinicopathological syndrome with a histologic spectrum ranging from benign steatosis to non-alcoholic steatohepatitis (NASH)<sup>[83]</sup>. Steatosis is described in up to 50% of abnormal liver biopsies in IBD patients and has been related to colitis severity. It was presumed secondary to severe illness, with malnutrition, hypoproteinemia, and corticosteroids primarily responsible<sup>[84]</sup>. On the other hand, NAFLD occurs in 8.2% of the IBD population, which is much lower than the frequency reported in the United States general population (33.6%). Those patients who

developed NAFLD tended to be older, and developing IBD at an older age normally requires small bowel surgery<sup>[85]</sup>. It has been reported that IBD patients develop NAFLD with fewer metabolic risk factors than non-IBD NAFLD patients. In multivariate analysis, hypertension (OR = 3.5), obesity (OR = 2.1), small bowel surgeries (OR = 3.7), and use of steroids at the time of imaging (OR = 3.7) were independent factors associated with NAFLD. NAFLD is also less common among patients who received antibodies against tumor necrosis factor alpha (anti-TNF- $\alpha$ ) therapy.

## VIRAL HEPATITIS AND IBD

Chronic hepatitis B and C are two common diseases. The WHO estimates that 350 million people in the world suffer from chronic hepatitis B, and more than 200 million from hepatitis C<sup>[86,87]</sup>. Hepatitis B infection is transmitted during delivery or early childhood. Hepatitis C is a blood-borne disease spread mainly *via* blood product transfusion and misuse of illegal drugs. Around 20% of patients with chronic hepatitis B show cirrhosis progression and 5% are at risk of developing hepatocellular carcinoma.

Chronic hepatitis B infection is a dynamic process, owing to the interaction between the hepatitis B virus and the host immune system. Its natural history is covered by five different phases<sup>[88]</sup> (Table 1): (1) Immunotolerant phase: characterized by positive hepatitis B e antigen (HBeAg), higher HBVDNA titre, and normal or near normal ALT levels. Liver biopsy at this phase shows mild or no inflammatory lesions and scarce non-progressive fibrosis; (2) Immunoclearance phase: positive HBeAg, lower HBVDNA, and raised aminotransferase levels. Liver histology shows necroinflammatory activity together with fibrosis progression. Spontaneous HBeAg clearance and anti-HBe seroconversion could occur at this phase; (3) HBsAg inactive carrier: characterized by negative HBeAg, positive anti-HBe, residual viremia (HBVDNA lower than 2000 IU/mL), and ALT levels under the normal limit. Liver histology shows minimal or no lesions; (4) Chronic hepatitis B: HBeAg negative could appear after unsuccessful seroconversion. HBVDNA remains quantifiable and ALT levels are fluctuant. Fibrosis progression is common; and (5) Resolved infection: characterized by loss of HBsAg and could be a stable phase, with negative HBsAg and non-detectable HBVDNA with normal ALT levels and excellent prognosis.

Chronic hepatitis C is a progressive liver disease that could evolve to cirrhosis. Risk factors associated with fibrosis progression are alcohol consumption, HIV co-infection, and adult age at infection.

Chronic hepatitis B patients showing HBVDNA > 2000 IU/mL and at least moderate necroinflammatory activity or fibrosis in a liver biopsy should be treated with entecavir or tenofovir and, in selected cases, with peginterferon  $\alpha$ -2a. In patients with chronic hepatitis C and positive HCV RNA, antiviral treatment should be started. In genotype 1, protease inhibitor-based triple therapy is

**Table 1** Phases of chronic hepatitis B infection

Phase	Characteristics	HBVDNA	ALT	Liver histology
Immune tolerant	HBeAg positive	> 2000000 UI/mL	Normal	Normal or mild inflammation
Immune active	HBeAg positive	> 200000 UI/mL	Elevated	Chronic hepatitis Active cirrhosis
Inactive carrier	HBeAg negative Anti-HBe positive	< 2000 UI/mL	Normal	Normal or mild inflammation Mild fibrosis Inactive cirrhosis
HBeAg negative chronic hepatitis	HBeAg negative Anti-HBe positive	> 20000 UI/mL	Elevated (fluctuating)	Chronic hepatitis Active cirrhosis
Remission	HBsAg negative Anti-HBe positive	Indetectable in serum and detectable in liver	Normal	Normal Mild fibrosis Inactive cirrhosis

HBV: Hepatitis B virus; ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen.

the first choice and, in non-1 genotype, standard peginterferon plus ribavirin.

Viral reactivation during immunosuppressive therapy is a major concern in viral hepatitis B and C. Viral reactivation is defined by an increase of 1 log in viral load or re-appearance of the virus after previous clearance. A flare of ALT is common and in some cases may develop into acute liver failure.

Hepatitis B reactivation depends on two main factors: (1) type of immunosuppressive drug used, and (2) hepatitis B phase prior to treatment. In a recent meta-analysis including 14 studies and 485 HBsAg-positive patients undergoing chemotherapy, one in three patients developed hepatitis and the mortality rate reached 7%. Positive HBeAg and detectable HBVDNA, together with steroids or rituximab in hematologic neoplasms, were independent factors associated with the risk of developing reactivation<sup>[89]</sup>. In patients with HBsAg loss, reactivation risk was around 3%-10% and mainly associated with the combination of steroids and rituximab in hematologic neoplasms<sup>[90]</sup>.

Hepatitis B reactivation prophylaxis is recommended from one week before chemotherapy to 12 mo after cessation of this therapy. Lamivudine has shown to decrease mortality rate<sup>[89]</sup>. However, it has been associated with an increased risk of developing resistant variants, so drugs with a higher genetic barrier, like entecavir or tenofovir<sup>[91]</sup>, are recommended if immunosuppressors need to be used for more than one year.

Hepatitis C reactivation management is controversial, due to both its frequency and clinical manifestations remaining unclear. Hepatitis has been reported in 11% of cases and reactivation in 36% of the few patients with HCV RNA evaluated before and after chemotherapy, mainly in those treated with rituximab for hematologic neoplasms<sup>[92]</sup>. Interferon-based therapy is not recommended for hepatitis C reactivation prophylaxis. Further combination of direct antiviral drugs could be useful in avoiding hepatitis C reactivation in this setting.

As immunosuppressive drugs, like AZA, methotrexate (MTX), and anti-tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), are being used more frequently in IBD, concerns about viral reactivation are increasing.

### Hepatitis B and IBD

At the beginning of this century, hepatitis B infection prevalence was slightly higher in patients with IBD than in the general population, which was mainly related to increased surgical procedures and blood transfusions<sup>[93,94]</sup>. However, recent studies in France and Spain did not confirm these data. Prevalence of hepatitis B in IBD has been estimated to be similar to the general population as a consequence of several health system measures, like overall vaccination, safe transfusions, and surgical procedures. Prevalence of anti-HBc was 7.1% in CD and 8% in UC in a Spanish population<sup>[95,96]</sup>.

Hepatitis B reactivation is a major health problem. Patients undergoing immunosuppressive therapy are at risk of developing hepatitis B reactivation. Acute liver failure requiring orthotopic liver transplantation has been reported in a patient under AZA and steroid treatment<sup>[97]</sup>. TNF $\alpha$  plays a role in hepatitis B virus replication, so anti-TNF $\alpha$  drugs could promote hepatitis B reactivation<sup>[98]</sup>. Infliximab, together with AZA or steroids, have been implicated in hepatitis B reactivation in seven cases from several series<sup>[94,99-102]</sup>. No cases have been reported in patients receiving adalimumab or certolizumab pegol. Nevertheless, hepatitis B reactivation seems to be a class-effect, so more cases should be expected with the continuing use of these new drugs. In patients with HBsAg loss reactivation is infrequent, but one case treated with infliximab has been reported<sup>[103]</sup>. A collaborative multicenter and retrospective Spanish study (REPENTINA) showed a reactivation rate of 36% (9/25) in patients with positive HBsAg; six out of nine developed liver failure, three underwent liver transplantation, and one died. No HBsAg-negative patients developed hepatitis B virus reactivation. In this study, the key factor for reactivation was the combination of two or more immunosuppressive drugs, independently of agent type. The absence of reactivation was associated with the use of only one drug for a short period of time<sup>[104]</sup>.

Clinical practice guidelines from AEEH, EASL, and ECCO revised this topic and recommended prophylaxis of hepatitis B reactivation in patients with IBD receiving immunosuppressive agents<sup>[104-106]</sup>. HBsAg, anti-HBc, and anti-HBs should be tested before immunosuppressive

therapy with two goals: avoid possible fatal complications and use antiviral drugs to control hepatitis B virus replication: (1) HBV serologically-negative patients should receive vaccination. Vaccination rates in IBD are variable. In Spain, only 56% of young people showed anti-HBs antibodies<sup>[95]</sup>. Vaccine response was around 46% using double doses in patients with IBD receiving anti-TNF drugs. However, AZA seems not to influence vaccine response. In non-responders a new complete vaccination course should be recommended. Hepatitis B screening is highly recommended immediately after the diagnosis of IBD, and vaccination is indicated in serologically-negative patients<sup>[107]</sup>; (2) Patients showing HBsAg positive and HBVDNA > 2000 IU/mL should be treated with tenofovir or entecavir as chronic hepatitis B patients; (3) Patients showing HBsAg positive and HBVDNA < 2000 IU/mL or undetectable levels, and patients with HBsAg negative and HBVDNA positive should be treated with tenofovir or entecavir for 6 to 12 mo after the end of immunosuppressive therapy. ALT levels and HBVDNA titre should be monitored every three months during treatment; and (4) Patients showing HBsAg negative and anti-HBc positive with or without anti-HBs should be closely monitored every 1 to 3 mo, measuring ALT and HBVDNA until 6 to 12 mo after the end of therapy. For patients with an increase in viral load, entecavir or tenofovir therapy should be immediately started.

### Hepatitis C and IBD

The prevalence of hepatitis C infection was increased in IBD patients younger than 50-year-old in comparison with the general population in studies of the last decade of the twentieth century<sup>[94]</sup>. However, recent studies have demonstrated a similar prevalence to the general population both in Spain (2.3% in CD and 1.3% in UC) and France (0.79% in CD and 1.59% in UC)<sup>[96,97]</sup>.

The impact of immunosuppressive therapy for IBD on hepatitis C remains controversial. Steroids could promote viral replication, as demonstrated after liver transplantation. However, steroids have been used to treat hepatitis C without success or adverse events. ALT flares have been reported after stopping steroid therapy in patients with IBD<sup>[108]</sup>. Steroid therapy should be avoided in patients with hepatitis C, and patients should be closely monitored after any withdrawal or tapering process. Immunosuppressive drugs like AZA, MTX, cyclosporine, and mycophenolate mofetil have been largely used in the liver transplantation setting, showing a slight antiviral activity against hepatitis C<sup>[109-111]</sup>. MTX did not affect hepatitis C disease in patients with arthritis<sup>[112]</sup>. Therefore, immunosuppressive therapy with these drugs seems to be safe. Indeed, in a Spanish study, 16% (8/51) of patients with chronic hepatitis C and IBD receiving immunosuppressive therapy developed non-severe liver dysfunction, seven related to steroids, and one case with AZA<sup>[104]</sup>.

TNF $\alpha$  plays a major role in the pathogenesis of chronic hepatitis C and associated metabolic abnormalities. TNF $\alpha$  is crucial in hepatitis C-induced insulin resistance, but could also modulate interferon response.

Increased TNF $\alpha$  levels have been associated with impaired sustained virological response (SVR)<sup>[113]</sup>. Thus, TNF $\alpha$  inhibition could be more beneficial than harmful in the management of chronic hepatitis C. Etanercept improved SVR in patients with chronic hepatitis C receiving peginterferon plus ribavirin<sup>[114]</sup>. Patients suffering from rheumatoid arthritis and hepatitis C treated with etanercept or infliximab did not show any changes in transaminases level or viral load<sup>[115]</sup>. Although etanercept is not effective on IBD, a class-effect should be expected, and the use of anti-TNF $\alpha$  could be safe in hepatitis C associated with IBD.

CD is characterized by a Th1 response. Interferon seems to play an immunomodulatory activity-enhancing Th1 response, and can cause outbreak of CD<sup>[116]</sup>. On the other hand, some authors have suggested that interferon could be safely used in patients with IBD, due to a lack of negative impact on the gut<sup>[117,118]</sup>. In a prospective study including 11 patients with IBD and hepatitis C, peginterferon plus ribavirin achieved SVR in a similar way to non-IBD patients. During treatment six patients developed gastrointestinal symptoms that required optimization of immunosuppressive agents without impacting antiviral treatment<sup>[119]</sup>. Several case reports showed a beneficial effect of interferon-alpha and beta on patients with UC<sup>[120,121]</sup>. A systematic review, including three prospective studies, demonstrated no effect of interferon-alpha on UC<sup>[122]</sup>, although new cases or exacerbation of UC have been seen in patients treated with interferon-alpha<sup>[123,124]</sup>. Higher doses of interferon used in hepatitis C, in comparison with lower doses in UC trials, could partially explain this discrepancy. Finally, 10 patients with CD and 10 with UC in remission or showing mild bowel activity underwent antiviral therapy for hepatitis C. No patient developed reactivation of IBD during treatment or the 12 mo of follow-up<sup>[125]</sup>, confirming data from a recent review concluding that interferon does not impair IBD course<sup>[126]</sup>.

In summary, hepatitis C antiviral treatment has no influence on IBD natural history, and immunosuppressive therapy for IBD does not promote reactivation of hepatitis C. Currently, no therapeutic option for reactivation prophylaxis nor vaccination are available for hepatitis C, but in the near future interferon-free regimen combining protease, polymerase, and NS5A inhibitors could be useful in the management of hepatitis C in IBD.

## DRUG-INDUCED LIVER INJURY IN IBD

Approximately 30% of patients with IBD show abnormalities in liver biochemical tests during the course of the disease. Most of the drugs used in IBD have potential hepatotoxicity<sup>[127]</sup> (Table 2).

### Aminosalicylates: Sulfasalazine and mesalazine

Sulfasalazine, an association between sulfapyridine and 5-aminosalicylate (5-ASA), was the first aminosalicylate used in the treatment of IBD. This drug has been replaced in the last two decades by mesalazine or 5-ASA,

**Table 2 Drug induced hepatobiliary manifestations in inflammatory bowel disease**

Manifestation	Drug
Drug induced hepatitis	Azathioprine
	6-mercaptopurine
	Methotrexate
	Cyclosporine
	Infliximab
Reactivation of hepatitis B	Anti-TNF therapy
	Corticosteroids
Drug induced pancreatitis	Azathioprine
	6-mercaptopurine
	Methotrexate
Hepatosplenic T-cell lymphoma	Combination of anti-TNF and immunosuppressive therapy

TNF: Tumor necrosis factor.

due to its adverse effects. Mesalazine is indicated for the induction and maintenance of the clinical remission in patients with UC with mild-moderate activity. The efficacy of this drug in CD remains controversial.

The anti-inflammatory effect of aminosalicylates is unclear. Synthesis inhibition of prostaglandins and leukotrienes (which show antioxidant and immunomodulatory activity) are well known. Aminosalicylates are safe drugs, and rarely lead to severe adverse effects such as bone marrow aplasia, pancreatitis, nephropathy, or hepatotoxicity. Altered liver function tests (cytolysis or cholestasis) may be detected during treatment with them. These abnormalities usually have no clinical relevance, although hepatotoxicity induced by acute hypersensitivity and acute liver failure has been described. In clinical trials, abnormalities in liver biochemical tests have been observed in 2% of UC patients treated with mesalazine<sup>[128]</sup>. The United Kingdom's Committee on Safety of Medicines observed that, between 1991 and 1998, the incidence of toxic hepatitis was 3.2 and 6 cases per million of prescriptions for mesalazine and sulfasalazine, respectively, and the presence of rheumatoid arthritis was a stronger risk factor than IBD<sup>[129]</sup>. Therefore, given the low risk of hepatotoxicity, a close monitoring of liver biochemical tests is not necessary in patients treated with aminosalicylates.

### Methotrexate

Methotrexate (MTX) has both anti-proliferative and immunosuppressive activities, impairing DNA synthesis (*via* inhibition of dihydrofolate reductase) as well as decreasing the production of proinflammatory cytokines and inducing lymphocyte apoptosis, respectively. The main indication in IBD is maintenance of clinical remission in steroid-dependent CD patients, after adverse effects or lack of efficacy of thiopurines. MTX efficacy in UC is controversial. On the other hand, MTX is contraindicated in pregnancy. Regarding adverse effects, myelosuppression and hepatotoxicity are dose-dependent. These effects were documented in up to 25% of patients with rheumatoid psoriatic arthritis, highlighting the association

with obesity, alcoholism, diabetes, previous abnormalities in biochemical liver tests and, especially, an accumulated dose higher than 15 g, as risk factors. Currently, liver fibrosis and cirrhosis are less frequent, probably due to close monitoring of liver parameters, proper selection of patients, and simultaneous treatment with folic acid, which decreases MTX-related adverse effects. Sabeni *et al.*<sup>[130]</sup>, in Italy, detected hepatotoxicity in 14.3% of patients with IBD treated with MTX during a mean follow-up of 26 mo. Te *et al.*<sup>[131]</sup>, in the United States, carried out a study in 20 IBD-patients treated with MTX with a mean follow-up of 131 mo and accumulated doses of 2.6 g. Liver fibrosis in biopsies was detected in one patient; the rest of the patients showed mild histological changes only. No association between abnormalities in liver biochemical tests and liver histology was found<sup>[131]</sup>. Regular liver laboratory studies are recommended in patients treated with MTX<sup>[132]</sup>. Nowadays, liver biopsy is not recommended routinely during MTX treatment<sup>[133]</sup>. However, it should be performed in cases of persistent alteration of transaminases (especially if they do not decrease after reducing the drug dose) and in patients with high accumulated doses, together with other risk factors. On the other hand, transient elastography (Fibroscan®) is emerging as diagnostic method of liver fibrosis in these patients. Treatment needs to be discontinued in cases of liver fibrosis or cirrhosis<sup>[134]</sup>.

### Anti-TNFα: Infliximab and adalimumab

Infliximab and adalimumab are monoclonal antibodies against TNFα, indicated in several rheumatologic, dermatologic, and gastrointestinal diseases. The main indication is the induction and maintenance of clinical remission in steroid-resistant or steroid-dependent CD and UC patients without response to immunosuppressive therapy. Early on, they are recommended in CD associated with risk factors or in the presence of severe perianal disease. Biological agents inhibit TNFα, preventing the release of proinflammatory cytokines, leukocyte migration, expression of endothelial molecules, fibroblast proliferation, and prostaglandin synthesis.

The main adverse effects of these drugs are opportunistic infections, hepatitis B virus reactivation, lymphoproliferative diseases, neurological diseases, and autoimmune diseases, such as lupus-like syndromes. Severe hepatotoxicity is a very rare condition in biological therapy, being most frequent in patients treated with infliximab. It is difficult to determine cause-effect associations between liver damage and these drugs in some cases due to confounding factors, like the presence of other drugs and other concomitant diseases. The drug label of infliximab (Remicade®) showed that, in clinical trials, ALT raised more than three times in 4.9% of patients with CD and in 2.5% of patients with UC, without clinical relevance. In contrast, serum ALT levels were less altered in the placebo group. On the other hand, the drug label of adalimumab (Humira®) indicates that serum ALT levels were similar in patients with IBD and a placebo.

According to infliximab indications, jaundice has been an uncommon finding, as well as infectious hepatitis, with liver failure being a very rare condition<sup>[135]</sup>. The Food and Drug Administration considers infliximab a hepatotoxic drug<sup>[136]</sup>. Recently, hepatotoxicity by these drugs has been evaluated in the United States (2003-2011), where only 34 cases were found, confirming the peculiarity of this adverse effect. Most cases (76%) were related to infliximab, showing a hepatocellular or cholestatic pattern with autoimmune characteristics, and improving after discontinuation of the drug<sup>[137]</sup>. Cross hepatotoxicity has not been documented in anti-TNF agents. In fact, in cases of infliximab-induced hepatotoxicity, adalimumab has been shown to be safe<sup>[138]</sup>.

### Thiopurines (azathioprine and 6-mercaptopurine)

AZA and its metabolite, 6-mercaptopurine (MP), are the immunosuppressive agents most commonly used in IBD. They are purine analogues, which interfere in nucleic acid synthesis and inhibit the proliferation of B and T lymphocytes, although the most relevant action is the apoptotic activation of T lymphocytes. The main indication of these drugs in CD and UC is the maintenance of clinical remission, preventing the use of steroids.

The active metabolites of AZA and MP are the 6-thioguanine nucleotides. In the liver, AZA is modified to MP, which is metabolized by xanthine oxidase and thiopurine methyltransferase (TPMT) in 6-thiouric acid and 6-methylmercaptopurine, resulting ultimately in 6-thioguanine nucleotides by hypoxanthine phosphoribosyltransferase. The decreased activity of TPMT facilitates the increasing in 6-thioguanine nucleotide levels, which are related to adverse effects. In fact, the efficacy of AZA and MP is limited owing to their adverse effects, which are responsible for treatment discontinuations in up to 15% of patients. Adverse effects are classified as dose-independent, dose-dependent, or idiosyncratic (which appears during the first two weeks of treatment). Regarding dose-independent adverse effects, the most common are allergic reactions (fever, exanthema, myalgias, and arthralgias) and acute pancreatitis. Among dose-dependent adverse effects, gastrointestinal intolerance and myelotoxicity are present in 2%-5% of patients. In retrospective studies, hepatotoxicity affected 3% of patients with an annual incidence of 1.4%, while these results are higher in prospective studies (10%)<sup>[139]</sup>. AZA and MP are able to damage the vascular endothelium, especially sinusoids and terminal veins, promoting veno-occlusive disease, regenerative nodular hyperplasia, and liver peliosis. These complications could be detected between 3 mo and 3 years after the beginning of treatment, and generate portal hypertension<sup>[140,141]</sup>. In general, mechanisms for AZA and MP hepatotoxicity remain unclear. It is thought that the main reason is the intracellular accumulation of 6-thioguanine nucleotides due to the decreased activity of TPMT.

It is recommended to determine levels of TPMT before the beginning of treatment with AZA or MP and

routinely perform liver biochemical tests, especially during the first months of treatment, to detect myelotoxicity and/or hepatotoxicity. Mild abnormalities in liver parameters, without clinical relevance, allow the continuation of treatment at a lower dose. However, jaundice or persistent alterations in spite of reduced dose require an immediate stop to treatment<sup>[142]</sup>.

## CONCLUSION

Hepatobiliary disorders are common extraintestinal manifestations of IBD, and PSC represents the most prevalent disease among them. Abnormal liver biochemical tests are present in up to 30 percent of patients with IBD and emerge as a diagnostic challenge. Drug-induced hepatotoxicity should always be rule out, as most IBD treatments have been associated with liver toxicity, although the incidence of serious complications is low. Hepatitis B screening and vaccination is recommended in patients with IBD. Reactivation prophylaxis with entecavir or tenofovir is mandatory in patients under immunosuppressive therapy showing HBsAg positive, independently from viral load. HBsAg negative and anti-HBc positive patients, with or without anti-HBs, should be closely monitored, and treated if the viral load increase. Diagnosis complexity often requires a joint gastroenterologist and hepatologist approach.

### Abstract

This review considers the physiological and molecular biochemical mechanisms of bile formation. The composition of bile and structure of a bile canaliculus, biosynthesis and conjugation of bile acids, bile phospholipids, formation of bile micellar structures, and enterohepatic circulation of bile acids are described. In general, the review focuses on the molecular physiology of the transporting systems of the hepatocyte sinusoidal and apical membranes. Knowledge of physiological and biochemical basis of bile formation has implications for understanding the mechanisms of development of pathological processes, associated with diseases of the liver and biliary tract.

**Key words:** Bile acids; Bile phospholipids; Bile micelle structures; Bile salt transporters

**Core tip:** Over the past 50 years, significant progress has been made in understanding the mechanisms of bile formation and secretion. This became possible due to the advances of fundamental investigations in cell

### INTRODUCTION

Bile is a lipid-rich hepatic secretion that is necessary for elimination of cholesterol and xenobiotics from the body and for dispersion and efficient absorption of digested dietary lipid in the upper small intestine<sup>[1]</sup>. Biliary function is a vital function of the liver, which results from the sequential vectorial transport of endogenous and exogenous substrates through three compartments: the vascular space, cellular space and biliary space. Canalicular bile is produced by polarized hepatocytes that hold transporters in their basolateral (sinusoidal) and apical (canalicular) plasma membrane<sup>[2]</sup>. The biliary function is responsible for the homeostasis of lipid metabolism, in particular cholesterol metabolism, elimination of toxic endo- and xenobiotics such as bilirubin, lipid bacteria products (endotoxin), and several inflammatory mediators<sup>[3]</sup>. Bile coming into the canaliculi is modified by cholangiocytes through secretion and absorption. The main determinant of bile formation is an osmotic filtration process resulting from active transport of bile acids and other osmotic solutes<sup>[3]</sup>. Pavlov *et al*<sup>[4]</sup> established the basic mechanisms of bile secretion, its entry into the duodenum, and the role of bile in digestion. Bile is essential for the intestinal digestion and absorption of nutrients. Almost half a century had passed before the

experimentally founded ideas on the mechanisms of bile formation appeared. Later, they were clarified and in the late 1970s took shape as a number of hypotheses of the mechanisms of bile formation. Recent insights into the cellular and molecular mechanisms that control the function and regulation of hepatobiliary transport have led to a greater understanding of the physiological significance of bile secretion. Individual carriers for bile acids and other organic anions in the liver and intestine have now been obtained from several species. In addition, complex networks of signals that regulate key enzymes and membrane transporters located in cells that participate in the metabolism or transport of biliary constituents are being unraveled<sup>[5]</sup>. Most of the membrane transporters ensuring bile formation have now been identified. The expression of these membrane transporters is regulated through transcriptional and post-transductional mechanisms. Transcriptional regulation is under the control of nuclear receptors activated by ligands such as bile acids, which act as endogenous steroids synthesized from cholesterol in hepatocytes<sup>[3]</sup>.

Bile is an iso-osmotic electrolytic fluid that is formed in the liver and is a product of its secretory function. Bile is primarily secreted by hepatocytes (*i.e.*, canalicular bile) and subsequently delivered to the intrahepatic bile ducts, where it is modified by cholangiocytes (*i.e.*, ductal bile). Bile secretion by liver parenchymal cells is the result of vectorial transcellular transport of solutes and involves the coordinated action of transport proteins at the basolateral (sinusoidal) and apical (canalicular) membranes of the hepatocyte. A complex network of signals controls uptake and efflux transporters on a long- and short-term timescale, including regulation at the level of gene transcription, protein translation and maturation, covalent modification, and dynamic localization of transporter proteins, as well as substrate availability<sup>[6]</sup>.

## COMPOSITION OF BILE AND STRUCTURE OF A BILE CANALICULUS

Bile contains almost all body components: proteins, lipids, carbohydrates, vitamins, mineral salts, and trace elements. The greater part of the bile proteins consists of globulins, and the lesser part comprises albumins. Phospholipids, cholesterol and its esters, neutral fats, and fatty acids rank high among bile lipids. Lecithins (phosphatidylcholines, PCs) are the major representatives of bile phospholipids. They are synthesized in the liver from the same components as plasma PCs; however, they differ from the latter in the higher content of palmitic acid<sup>[7]</sup>. The human bile concentration of free fatty acids and  $\alpha$ -monoglycerides is small. Human cystic bile shows small quantities of diglycerides and is virtually free of triglycerides.

The electrolyte content of bile is similar to that of plasma. The major cations are sodium, potassium, and calcium; the anions are chloride and bicarbonate. The bile content of sodium is about 10 times higher than that of

Figure 1 The bile content of anions, cations and taurocholic acid.

potassium. Excretion of sodium, potassium, and calcium into the bile is closely related to the rate of metabolic processes in the liver and depends on its functional state and on the content of salts in the body. The bile concentration of anions is 5-15 times smaller than that of cations.

A deficit of anions is compensated for by taurocholate (Figure 1). Bile contains a considerable quantity of phosphorus, magnesium, iodine, iron, and copper. The relative proportions of the major bile components are distributed in the following order: bile acids (67%), phospholipids (22%), proteins (4.5%), cholesterol (4%), and bilirubin (0.3%). Among the bile acids, the primary bile acids, cholic and chenodeoxycholic acids in a ratio of 1:1, account for about 50%. These are followed by the secondary bile acids, deoxycholic and lithocholic acids, as well as ursodeoxycholic and sulfolithocholic acids in the decreasing order.

The use of color cathode-luminescence scanning electron microscopy (CCL SEM) has made it possible to study the qualitative composition of dehydrated human bile and its components in the native state. CCL SEM provides video information about the structural pattern of bile and its chemical composition. Loginov *et al*<sup>[8]</sup> were the first to show the earlier unknown phenomenon of cathode autoluminescence of non-conjugated bilirubin, unesterified cholesterol, high-molecular-weight protein, and other organic compounds. The pictures (Figure 2) show that the amorphous powder mass of bilirubin is red-emitting (Figure 2A), crystal cholesterol luminesces blue (Figure 2B), and the green coloration tinged with red is predominant in the sample of protein (Figure 2C). Graphically, all three samples have chromaticity histograms in the form close to the Gaussian curve.

Examination of the dehydrated samples of normal bile by CCL SEM has ascertained the tree-type structure of precipitates (Figure 2D). The qualitative assessment of the samples suggests their balanced content of three ma-

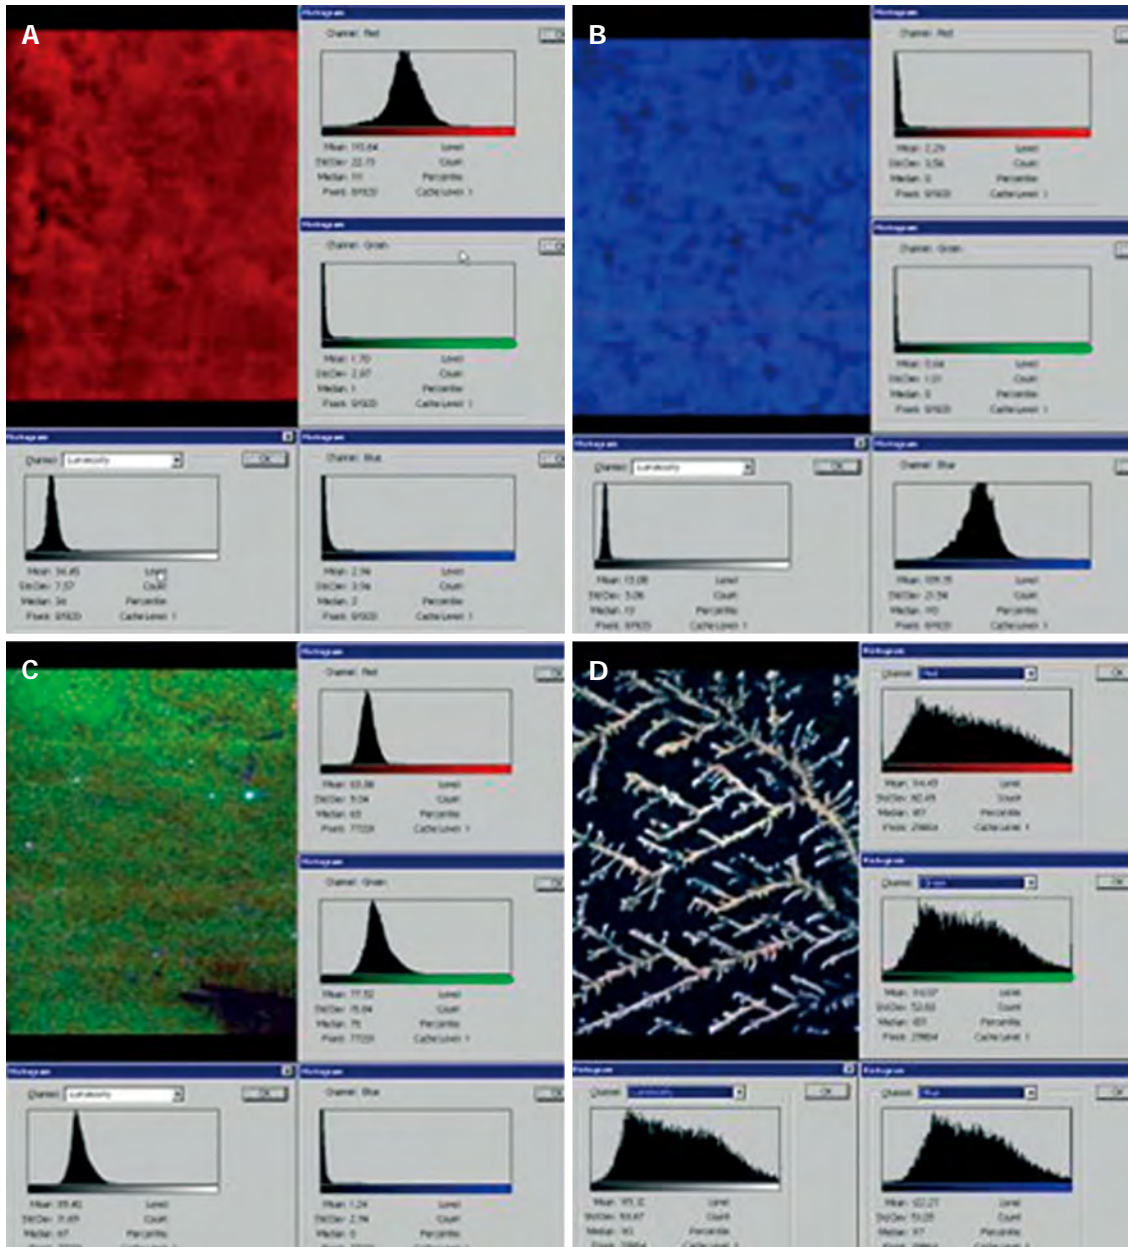

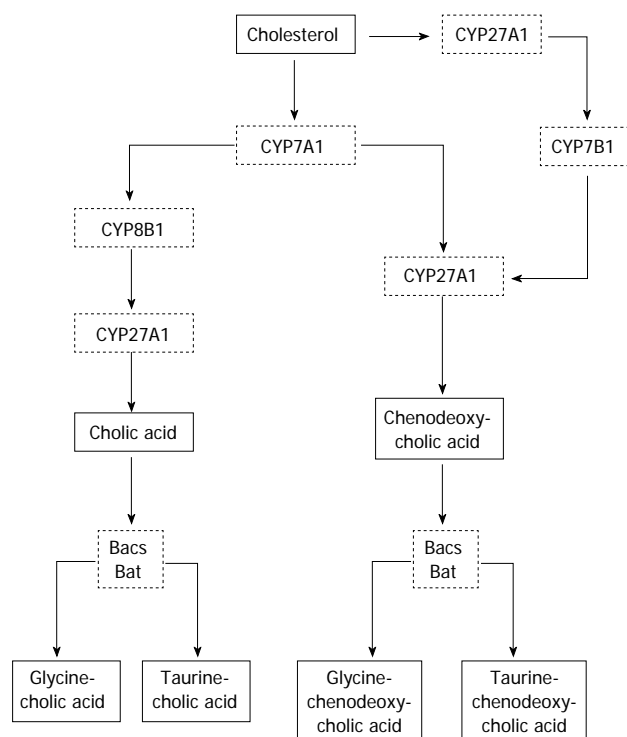

Figure 2 Color cathode-luminescence scanning electron microscopy images. for bile components: bilirubin, cholesterol, and protein. Hepatocytes are the major epithelial cells in the liver, and are polarized. The polarized surfaces of hepatocytes consist of a basolateral domain facing the circulation and an apical domain that forms the bile canaliculus; the smallest branch of the biliary tree<sup>[9]</sup>. A major function of the liver is biliary secretion, which requires hepatocyte polarization. The mechanisms controlling hepatocyte polarization are only partially understood<sup>[10]</sup>. Structurally, they include cytoskeletal, tight junction and intracellular trafficking components. Recently, it was discovered that the major mammalian bile acid, taurocholate, accelerated polarity in primary rat hepatocytes. Taurocholate increases cellular cAMP and signals through an exchange protein activated by cAMP (EPAC)-Rap1-MEK-liver kinase B1 (LKB1)-AMP-activated protein kinase (AMPK) pathway for its

polarity effect. Fu *et al*<sup>[9]</sup> have discussed possible mechanisms for how taurocholate affects different cell polarity factors, particularly AMPK, and thereby regulates events that generate polarity.

Bile production starts in the intercellular bile canaliculi. The bile canaliculus lumen is formed by the external hemileaflet of the apical part of the plasma membrane of the adjacent hepatocytes and the tight junctions located at the point of contact of the hepatocytes. The hepatocyte tight junctions separate the bile canaliculus lumen from the hepatic blood system<sup>[11]</sup>. Tight junctions contain proteins, including occludin, claudin and zona occludens (ZO)-1 protein. The integrity of tight junctions depends on the presence of protein ZO-1 on the inner surface of the plasma membrane. The impaired integrity of the tight junctions is accompanied by regurgitation of

canalicular bile into the sinusoids. Three individual domains, such as sinusoidal, lateral, and canalicular parts of the membrane, are arbitrarily identified in the hepatocyte plasma membrane. The differences in the lipid and protein composition of the three domains of the hepatocyte plasma membrane determine its functional polarity. The sinusoidal membrane is enriched with receptors, enzymes, and transport proteins. The lateral membrane of the hepatocyte is involved in intercellular interaction, but it contains no transport systems. Transport systems for bile acids, organic anions and cations, as well as the enzymes  $\gamma$ -glutamyltransferase,  $Mg^{2+}$ -ATPase, and alkaline phosphatase are located on the canalicular membrane.  $Cl/HCO_3^-$  exchangers and selective  $Cl$  channels are also identified<sup>[12]</sup>. Whether there are transport systems for glutathione and its conjugates in the apical membrane is still debated<sup>[13]</sup>. The release of glutathione S-conjugates from cells is an ATP-dependent process mediated by integral membrane glycoproteins<sup>[14]</sup>.

The hepatocyte cytoplasm around the bile canaliculus contains cytoskeletal structures: microtubules, microfilaments, and intermediate filaments<sup>[15]</sup>. The microtubules take part in the mediated vesicular transport, secretion of lipids. The microfilaments determine canalicular contractility and motor activity. The intermediate filaments form a network between the plasma membranes, nucleus, intracellular organelles, and other cytoskeletal structures. The canaliculus is the least branch of a biliary tree and has a diameter of approximately 1  $\mu m$ .

## BIOSYNTHESIS OF BILE ACIDS

In 1848 Strecker discovered bile acids<sup>[16,17]</sup>. In chemical structure, they belong to a group of steroids and are cholan acid derivatives. Bile acids are the end metabolic product of cholesterol and one of the most important routes of its elimination from the body<sup>[18-20]</sup>. Bile acid synthesis occurs through two pathways: the classic (neutral) pathway or the alternative (acidic) pathway<sup>[21,22]</sup>. The liver is the only organ that has all 14 enzymes required for *de novo* synthesis of two primary bile acids in humans, cholic acid (CA; 3 $\alpha$ , 7 $\alpha$ , 12 $\alpha$ -trihydroxy-cholan acid) and chenodeoxycholic acid (CDCA; 3 $\alpha$ , 7 $\alpha$ -dihydroxy-cholan acid)<sup>[23]</sup>.

The biosynthetic pathway includes a number of successive enzymatic conversions associated with the oxidation of cholesterol in the smooth endoplasmic reticulum and the shortening of its side chain in mitochondria. The production of bile acids involves restoration of a double bond in cholesterol, C-3 inversion to give rise to a 3 $\alpha$ -OH-group, further  $\alpha$ -hydroxylation of either only a 7-carbon atom or 7- and 12-carbon atoms, as well as  $\beta$ -oxidation of the side chain of cholesterol. Cytochrome P450 is involved in all oxidative reactions. The classic bile acid biosynthetic pathway is initiated by enzyme cholesterol-7 $\alpha$ -hydroxylase (CYP7A1) (Figure 3)<sup>[20]</sup>. The enzyme CYP7A1 of smooth endoplasmic reticulum is a limiting link in the synthesis of bile acids<sup>[20]</sup>. The activity of this enzyme is regulated by the quantity of intestinally absorbed bile acids, other than cholesterol<sup>[20,24]</sup>. Numerous studies have demonstrated that bile acids, steroid hormones, inflammatory cytokines, insulin, and growth factors inhibit CYP7A1 transcription through the 5'-upstream region of the promoter<sup>[25-30]</sup>. Sterol 12  $\alpha$ -hydroxylase (CYP8B1) is required for synthesis of CA. Mitochondrial sterol 27 hydroxylase (CYP27A1) catalyzes sterol side chain oxidation, after which cleavage of a three-carbon unit in the peroxisomes leads to formation of a C24 bile acid. Cholesterol is converted to two primary bile acids in human liver, CA and CDCA. Key regulated enzymes, CYP7A1, CYP8B1, CYP27A1, and 7 $\alpha$ -hydroxylase (CYP7B1) expressed, in the pathways are indicated. CYP7A1 initiates the classic (neutral) bile acid biosynthetic pathway in the liver. CYP27A1 initiates the alternative (acidic) pathway in the liver and macrophages. CA and CDCA are conjugated to glycine (G) and taurine (T). Bile acid: CoA synthase (BACS) and bile acid: amino acid transferase (BAT) are two key enzymes involved in amino conjugation of bile acids<sup>[20]</sup>.

An alternative (acidic) pathway is initiated by CYP27A1, which in addition to the liver is expressed in macrophages and most other tissues, and may contribute significantly to total bile acid synthesis (Figure 3). Other minor pathways initiated by 25-hydroxylase in the liver and 24-hydroxylase in the brain also may contribute to bile acid synthesis. A nonspecific CYP7B1 expressed in all tissues is involved in the generation of oxidized metabolites (oxysterols), which may be transported to the

liver and converted to CDCA<sup>[20]</sup>. Farnesoid X receptor (FXR) plays a central role in the regulation of bile acid synthesis, excretion, and transport<sup>[31,32]</sup>. FXR inhibits *CYP7A1*<sup>[33]</sup>, *CYP8B1*<sup>[34]</sup>, and *CYP27A1*<sup>[35]</sup> transcription. It has been reported that peroxisome proliferator activated receptor (PPAR) $\alpha$  plays a role in the regulation of bile acid synthesis<sup>[36]</sup>. Bile acids induce *PPAR $\alpha$*  transcription *via* induction of FXR<sup>[37]</sup>.

Di- and tri-hydroxycholanolic primary bile acids are produced from cholesterol during biosynthesis of bile acids in humans. Under normal conditions, 200-600 mg primary bile acids is formed daily<sup>[20,38]</sup>. Bile acid synthesis increases in the morning regardless of food intake<sup>[39]</sup>. In humans, bile acid synthesis exhibits a diurnal rhythm with two peaks around 15:00 and 21:00 h<sup>[20]</sup>. Bile acids lost in the feces (0.2-0.6 g/d) are replenished by *de novo* synthesis in the liver to maintain a constant bile acid pool. Hepatic conversion of cholesterol to bile acid balances fecal bile acid excretion and this process represents a major route for elimination of cholesterol from the body<sup>[40,41]</sup>.

Bile acids are physiological detergents that generate bile flow and facilitate intestinal absorption and transport of lipids, nutrients and vitamins<sup>[20]</sup>. Bile acids, end products of the pathway for cholesterol elimination, are required for dietary lipid and fat-soluble vitamin absorption and maintain the balance between cholesterol synthesis in the liver and cholesterol excretion<sup>[21]</sup>.

## CONJUGATION OF BILE ACIDS

Under physiological conditions, free bile acids are not frequently found in bile. Newly synthesized bile acids conjugate with glycine or taurine, by giving rise to bile salts: (chenodeoxy-)cholyglycine or (chenodeoxy-)cholytaurine (Figure 3). The physiological significance of bile acids conjugation is that their salts are more polar compounds than free bile acids. Conjugation of bile acids to glycine or taurine decreases bile acid toxicity and increases their solubility that benefits secretion into bile. Conjugated bile acids have a smaller critical concentration for micellar formation<sup>[42]</sup>. The taurine conjugates of bile acids are more polar compounds than their glycine conjugates<sup>[43]</sup>. Taurine (2-aminoethanesulfonic acid) is the most abundant free amino acid in humans and plays an important role in several essential biological processes such as bile acid conjugation, maintenance of calcium homeostasis, osmoregulation and membrane stabilization<sup>[44]</sup>. Taurine is efficient at reducing plasma and liver cholesterol concentrations. The cholesterol-lowering effect of taurine is involved in the regulatory mechanism of cholesterol and bile acid homeostasis that is mediated by *CYP7A1*, which has become a biomarker for cholesterol metabolism and is itself also regulated by several factors and nuclear receptors<sup>[45]</sup>.

The C-24 conjugation of free cholanolic acids with glycine or taurine is accomplished by hepatocyte acyl-transferases. The reaction proceeds in two steps with the participation of ATP and in the presence of  $Mg^{2+}$ . BACS and BAT are involved in amino acid conjugation of bile

acids<sup>[20]</sup>. FXR stimulates bile acid conjugation by inducing expression of genes encoding BACS and BAT, which also are induced by hepatocyte nuclear factor (HNF) 4 $\alpha$ <sup>[46]</sup>. Thus, FXR and HNF4 $\alpha$  may coordinately regulate bile acid synthesis and conjugation.

The normal human ratio of the glycine to taurine conjugates of bile acids is 3:1. The ratio of the glycine/taurine conjugates may be altered under the influence of alimentary and hormonal factors, in some liver diseases. The presence of unconjugated bile acids in the bile most frequently is a result of hepatic disease.

In the intestine, glyco- and tauro-conjugated CA and CDCA are deconjugated, and 7 $\alpha$ -dehydroxylase activity in bacterial flora removes a 7 $\alpha$ -hydroxy group to form secondary bile acids deoxycholic acid (DCA; 3 $\alpha$ ,12 $\alpha$ -dihydroxy) and lithocholic acid (LCA; 3 $\alpha$ -monohydroxy), respectively<sup>[20]</sup>.

Bile acids may be also exposed to glucuronidation or sulfation, which results in a reduction of their toxic properties and promotes their urinary and fecal excretion<sup>[43,47-49]</sup>. A small amount of bile acids circulated to the liver is sulfoconjugation at the 3-hydroxy position by sulfotransferase (SULT2A1) and rapidly secreted into bile. Sulfation is the major pathway for detoxification of extremely hydrophobic bile acids in humans<sup>[50]</sup>. Details of bile acid chemistry, biology, physiology, and synthesis have been reviewed recently<sup>[51,52]</sup>.

## BILE PHOSPHOLIPIDS

Phospholipids are a heterogeneous group of substances. They contain fatty acids with a varying length of carbon chain. Phospholipids are an important component of cell membranes, plasma, and bile. In all mammalian species, including humans, bile phospholipids are represented solely by a mixture of PC (lecithin) molecules. The fatty acids of bile PC molecules greatly differ from those of lecithin of plasma and liver tissue. Depending on fatty acid residues at C1 and C2 of the glycerine molecule that is part of PC, there are a variety of lecithins. Human bile predominantly contains 1-palmitoyl, 2-linoleyl, and 1-palmitoyl, 2-oleoyl PCs. This lecithin subpool represents nearly 5% of the total pool of hepatic PCs. The lecithins destined for bile secretion have been shown to be apparently completely synthesized *de novo*<sup>[53]</sup>. Selection of certain types of PC seems to occur during bile formation<sup>[7]</sup>. Bile salts and primarily PC are the main organic solutes in bile, and play a crucial role in cholesterol and dietary lipid solubilization. Bile salts and phospholipids in concert increase the biliary solubility of cholesterol by > 1 million-fold, thereby permitting entry of hepatocellular cholesterol into bile<sup>[54]</sup>. Hepatic PC biosynthesis is likely to be regulated by bile salts. Biliary lipid secretion is driven by bile salts, the primary metabolites of cholesterol. There are multiple data showing that the biliary secretion of PC (as cholesterol secretion) depends on that of bile acids<sup>[55,56]</sup>. It has also been shown that the secretion of bile phospholipids is not only associated with that of bile acids, but is regulated by the amount and type of bile

Figure 4 Proposed model for lipid secretion into bile<sup>[58]</sup>. BSEP: Bile salt export pump; MDR3: Multidrug-resistance protein 3; MRP2: Multidrug-resistance-associated protein 2; ATP: Adenosine triphosphate; ADP: Adenosine diphosphate; Pi: Inorganic phosphate.

salts passing through the hepatocytes<sup>[7,57]</sup>.

The use of electron microscopy has demonstrated that phospholipids are secreted as vesicles into bile, and that vesicle secretion is almost wholly dependent upon MDR3 P-glycoprotein function<sup>[58]</sup>. Biliary-specific PC molecules are recruited initially from intracellular sources, predominantly the endoplasmic reticulum<sup>[59]</sup>. A proposed mechanism for PC delivery to the canalicular plasma membrane involves monomeric transfer *via* binding to the cytosolic PC transfer protein (PC-TP)<sup>[60]</sup>; a process that is stimulated by low concentrations of bile salts typical of the hepatocytic cytosol. Alternatively, biliary lipid may arrive at the canalicular membrane *via* intracellular vesicle transport<sup>[1]</sup>.

Biliary PC molecules are translocated from the endoplasmic to the exoplasmic hemileaflet by the action of a transmembrane translocator<sup>[61]</sup>.

MDR3 P-glycoprotein is thought to translocate PCs from the internal to the external hemileaflet of the hepatocyte canalicular plasma membrane; possibly generating microdomains of the more fluid biliary-type PCs. Luminal bile salts, secreted as monomers through the action of bile salt transporters (cBATs), interact preferentially with these microdomains to promote vesiculation of the membrane external hemileaflet; possibly involving non-lamellar phase transitions. Cholesterol, which can freely flip between the internal and external hemileaflets, may be released into bile either by diffusing laterally into nascent vesicles, or by bile-salt-mediated transfer through the aqueous phase. The model is based on data from the study<sup>[59]</sup> and published work<sup>[1,62,63]</sup>.

Crawford *et al*<sup>[58]</sup> proposed the concept that biliary PC

molecules are flipped from the internal to the external hemileaflet of the hepatocyte canalicular membrane by the action of MDR3 P-glycoprotein, followed by release of PC vesicles from the external hemileaflet into bile (Figure 4). Formation and detachment of unilamellar vesicles from the canalicular membrane is presumably mediated by the detergent action of luminal bile salts.

Vesiculation of the external hemileaflet provides an explanation of how luminal bile salts can extract large quantities of phospholipid on the basis of their detergent action, without disrupting the integrity of the detergent-resistant canalicular plasma membrane. This remarkable mechanism for selective secretion of membrane phospholipids appears to be uniquely adapted to the detergent environment of the bile canaliculus.

## BILE MICELLES

Bile lecithins, bile acid salts, and cholesterol are amphiphilic molecules (Figure 5). In this connection, in the water medium, such as bile, these compounds cannot exist in the monomolecular form and they generate micellar or lamellar structures.

According to the inclusions into the lipid complex, simple micelles (PC + cholesterol), up to 3 nm in size, mixed (PC + cholesterol + bile acids), 3-6 nm in diameter, and vesicles (PC + cholesterol + bile acids), 25-130 nm in diameter, are identified (Figure 6).

They can all contain amphiphilic proteins on their surface. Lipid molecular inclusions in the micelles of bile acids and the formation of mixed micelles are the main form of interaction of bile acids and lipids in the bile.

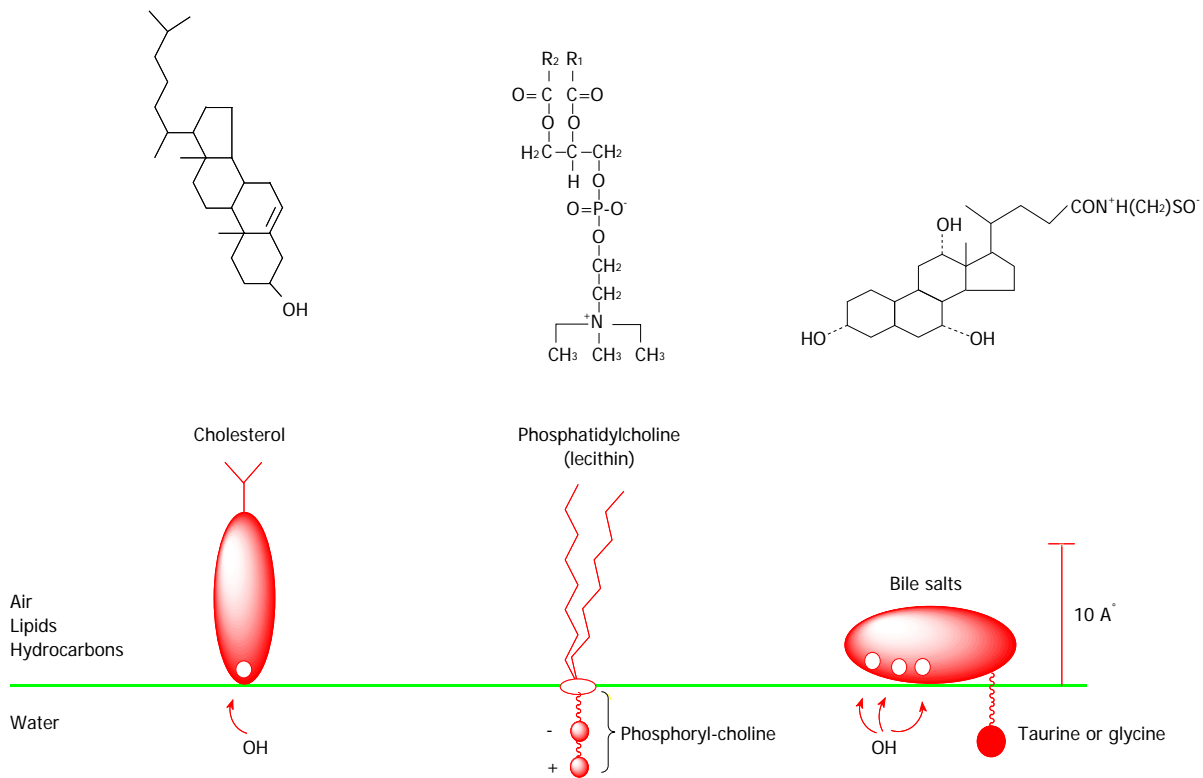

Figure 5 Chemical formulas and simple images of cholesterol, lecithins, and bile salts on a boundary of two phases-water: lipids (air, hydrocarbons).

Figure 6 Formation of micelles structures in the system containing bile acids, lecithin, and cholesterol. BA: Bile acids; Ch: Cholesterol; L: Lecithin.

By forming mixed micelles, bile acids along with lecithin provide cholesterol solubilization. Bile salts as detergents form micelles when the critical concentration of micellar formation (CCM) is achieved. CCM depends on the type of bile salts and their hydrophobicity. Based on their hydrophobic properties, bile acids may be arranged in the following order: deoxycholate > chenodeoxycholate > cholate > ursodeoxycholate<sup>[64]</sup>. Hydrophobic, but not hydrophilic, bile acids are efficacious endogenous ligands of the nuclear receptors FXR (NR1H4), pregnane X receptor (PXR; NR1I2), and vitamin D receptor (VDR; NR1I1) that play critical roles in the regulation of bile acid synthesis and metabolism<sup>[20]</sup>.

A mixture of bile acids, lecithin, and cholesterol at certain molecular ratios is able to form lamellar liquid-crystalline structures<sup>[64]</sup>. Vesicles are monolamellar glob-

ules that consist of phospholipids and bile acids. At a certain concentration (about 0.1 mmol/L), phospholipids as amphiphiles have been found to produce enclosed globules, in which the polar heads are directed outward, and the nonpolar "tails" are inside. This particle is capable of forming many substances, including protein, and cholesterol, by providing solubilization of the latter by bile acids. Vesiculation is largely determined by the hydrophilic-hydrophobic balance of bile acids and the content of cholesterol<sup>[65]</sup>. The proportion of bile-mixed micelles and vesicles depends on the concentration and composition of bile acids. The most important feature of phospholipid masses is their ability to change their consistency from crystalline gel to liquid-crystalline state depending on environmental conditions. The liquid-crystalline states are typified by the structural order peculiar to true crystals

with the preserved mobility of the molecules observed in solutions. The fusion of monolamellar vesicles may give rise to multilamellar vesicles. The vesicles are a rather stable formation and together with micelles play a pivotal role in the solubilization and transport of cholesterol into the bile<sup>[24]</sup>.

Lipid vesicles 60-80 nm in diameter have been documented repeatedly by electron microscopy and quasielastic light scattering of freshly secreted hepatic bile<sup>[1,58]</sup>. Microscope laser light scattering of bile canaliculi in isolated rat hepatocyte couplets also detects intraluminal vesicles of similar size; the numbers of which increase upon cellular incubation with bile salts<sup>[66]</sup>.

Acid-dependent and acid-independent bile fractions are identified<sup>[67]</sup>. The former is associated with the synthesis and active transport of bile acids in the hepatocytes. The volume of the resultant bile is linear with the concentration of bile acids, caused by the osmotic effect of bile acid anions, and Sperbet<sup>[68]</sup> first argued it in 1959. The bile composition greatly varies in the bile canaliculi due to the increased constant volume of water and bicarbonates irrespective of the secretion of bile acids. This acid-independent bile fraction is regulated by an active  $\text{Na}^+$  transport. Its physiological role is to dilute and excrete an acid-dependent fraction<sup>[69]</sup>. Further bile formation occurs in the bile ducts because a fluid enriched with bicarbonates and chlorides is produced in the latter. This process is under the control of secretin (80%) and other gastrointestinal hormones. The volume of the water secreted in the ducts depends to greater degree on the active transport of bicarbonates<sup>[70]</sup>.

## ENTEROHEPATIC CIRCULATION OF BILE ACIDS

The bile acids synthesized in the hepatocyte participate in the human body, in the so-called enterohepatic circulation. Conjugated bile acids are secreted from the hepatocytes into the bile canaliculus by canalicular bile salt export pump (BSEP, ABCB11). Some bile acids secreted in the bile duct are reabsorbed in the cholangiocytes and recycled back to hepatocytes (the cholangiohepatic shunt)<sup>[20]</sup>. The bulk of bile acids secreted are stored in the gallbladder. After each meal, gallbladder contraction empties bile acids into the intestinal tract. Bile acids are mixed up with food masses (together with other digestive secretions), and take an active part in the processes of fat and fat-soluble vitamins metabolism and absorption.

Fatty acids and monoglycerides formed from neutral fats with participation of bile acids and of lipases in the upper parts of the small intestine are absorbed by enterocytes as lipid-biliary complexes. These complexes disintegrate in the enterocytes. Released monoglycerides and fatty acids are used by the cells as energy and building materials or are transported to the basolateral membrane of the enterocytes and enter the portal venous system. Bile acids may return to the intestine and continue to participate in metabolism and absorption of fat and fat-

soluble vitamins. As bile acids are moving through the intestine they may participate 4-6 times in the transportation of monoglycerides and fatty acids in enterocytes.

In the small intestine, bile acids are absorbed by both passive and active mechanisms<sup>[71]</sup>. Although passive absorption occurs down the length of the intestine, active absorption of bile acids is restricted to the ileum<sup>[72,73]</sup>. Passing through the intestinal tract, some bile acids are reabsorbed in the upper intestine by passive diffusion, but most bile acids (95%) are reabsorbed in the distal ileum by apical sodium-dependent bile acid transporter (ASBT) located in the brush border membrane<sup>[71]</sup>. In humans and all other vertebrates examined to date, the ileal epithelium has developed an efficient transport system for the active reclamation of bile acids<sup>[51]</sup>. Approximately 95% of the bile acids secreted into bile are derived from the recirculating pool<sup>[71]</sup>. Bile acids are transdiffused across the enterocytes to the basolateral membrane where the organic solute transporter and heterodimer (OST/OST) effluxes bile acids into the portal blood circulation<sup>[74,75]</sup>, transports them to the sinusoids, where they are taken up by  $\text{Na}^+$ -dependent taurocholate cotransport peptide (NTCP) into hepatocytes<sup>[20]</sup>. The bulk of bile acids are absorbed by hepatocytes into the liver, and again excreted into the bile. Later, this enterohepatic cycle recurs. Hepatocytes are known to secrete as much as 90% of the bile acids that have returned into the cells during enterohepatic circulation, and about 10% of the newly synthesized bile acids<sup>[20]</sup>. A bile acid pool of about 3 g is recycled 4-12 times a day<sup>[71]</sup>. At a fundamental level, the bile acid enterohepatic circulation can be viewed as a series of storage chambers (gallbladder and small intestine), valves (sphincter of Oddi and ileocecal valve), mechanical pumps (canaliculi, biliary tract, and small intestine), and chemical pumps (hepatocyte and enterocyte transporters)<sup>[71]</sup>.

The enterohepatic circulation of bile acids serves as an important physiological route for recycling bile acids and absorption of nutrients, as well as regulation of whole-body lipid metabolism<sup>[20]</sup>. Enterohepatic circulation ensures a continuous supply of bile acids to be used repeatedly for lipid absorption during the digestion of a single meal or multiple meals throughout the day<sup>[76]</sup>. Efficient intestinal reabsorption and hepatic extraction of bile acids also enables effective recycling and conservation that largely restricts these potentially cytotoxic detergents to the intestinal and hepatobiliary compartments.

FXR plays a key role in the control of enterohepatic circulation of bile acids. FXR induces the expression of BSEP in the canalicular membrane, which is the driving force for bile formation. FXR inhibits *Ntcp* transcription by SHP-dependent inhibition of retinoid X receptor/retinoic acid receptor induction of *Ntcp*<sup>[77]</sup>. Thus, FXR plays a critical role in the coordination of bile acid synthesis, biliary bile acid secretion, intestinal bile acid reabsorption and secretion, and bile acid uptake into hepatocytes.

Hepatocytes hold a central position in the enterohepatic circulation of bile acids, with which their highest (as compared to other cells) content of cholanics acids is as-

sociated.

### **Molecular mechanisms of hepatocyte bile secretion**

Hepatocyte secretion of bile is the passive transhepato-cellular filtration of water and electrolytes ( $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$ ) from blood into the bile canalicular cavity, which is caused by the osmotic gradient between the bile and blood, which results from active transport of organic and inorganic anions from blood and hepatocytes to the bile canaliculi. The ionic transport systems that govern ionic and electrical gradients onto the membrane surface ( $\text{Na}^+/\text{K}^+$ ,  $\text{Na}^+/\text{H}^+$ ,  $\text{Na}^+/\text{HCO}_3^-$ ,  $\text{Cl}^-/\text{HCO}_3^-$ , and  $\text{Na}^+/\text{Ca}^{2+}$ ) are the basis for the mechanism of targeted bile secretion<sup>[78]</sup>. The transport of bile salts, organic anions and cations, bilirubin and other substances from the portal blood into the biliary system is accomplished through the action of an array of transporter proteins in the hepatocytes<sup>[79]</sup>.

The hepatocytes are polar cells in which the transport of osmotically active bile components has a strict direction from the sinusoidal (basal) surface to its canalicular (apical) part. There is evidence on the importance of taurocholic acid in the directed transport of substances in the liver cells<sup>[44]</sup>. This vectorial trans-hepatocellular movement of bile acids is a remarkably concentrative transport process that is driven by a distinct set of primary (ATP-dependent), secondary ( $\text{Na}^+$  gradient-dependent), and tertiary ( $\text{OH}^-$  or  $\text{HCO}_3^-$ -dependent anion exchange) transport systems at the sinusoidal and canalicular plasma membranes<sup>[80,81]</sup>. Bile secretion is a highly regulated process. To maintain this process, liver cells must transport bile acids efficiently from the portal blood into bile. ATP binding cassette (ABC) transporters<sup>[57]</sup> mediate transport of bile salts. Expression of these transporters is regulated in a coordinate fashion by a set of nuclear hormone receptors explaining the old observation of coupling between bile salt secretion and biliary lipid secretion. Over the past two decades, there has been significant progress toward identifying the individual membrane transporters and unraveling their complex regulation<sup>[74]</sup>. The hepatocytes are polarized cells that express differential transport systems in their plasma membrane domains. Molecular cloning has identified most of these transport proteins, and their transport properties characterized by functional studies. The NTCP, the bile salt export pump (BSEP), the ASBT, and the organic solute transporter OST $\alpha$ -OST $\beta$ , the major bile acid transporters that control the fate of bile acids, through either absorption and enterohepatic cycling or excretion and elimination from the body.

These transporters play a key role in the vectorial transfer of solutes and water from sinusoidal blood into the bile, thus contributing to bile formation and the biliary excretion of various xenobiotics. In the liver and intestine, transporters play a critical role in maintaining the enterohepatic circulation and bile acid homeostasis<sup>[71,82]</sup>.

Bile acids determine the secretion of an acid-dependent bile fraction. The transport of bile acids from the sinusoidal space to the bile canaliculus comprises their penetration across the sinusoidal and canalicular

membranes and movement inside the hepatocytes. The molecular and metabolic processes occurring on the hepatocyte sinusoidal membrane involve: (1) hepatocyte absorption of bile acids and proteins from blood; and (2) transmembrane transfer of inorganic ions. The principal intracellular molecular and metabolic processes determining the mechanisms of hepatocyte bile secretion are: (1) biosynthesis and conjugation of bile acids; (2) hydroxylation and conjugation of bile acids entering the hepatocytes from the blood; and (3) transfer of bile acids and proteins from the perisinusoidal to pericanalicular area of the hepatocytes.

The molecular mechanisms of hepatocyte canalicular membrane function ensure the transmembrane transfer of bile acids, proteins, inorganic and organic cations and anions into the bile canalicular cavity.

**Molecular physiology of the transporting systems of the hepatocytic sinusoidal membrane:** The specific feature of transport of bile acids from blood to the hepatocyte across the sinusoidal membrane is to overcome the high gradient of their concentration and electrical potential. Hepatocytes absorb bile acids from the blood by the bile acid carriers, which are integral hepatocyte sinusoidal membrane proteins<sup>[78]</sup> (Figure 7).

Liver sinusoids possess a specific architecture that allows passage of organic compounds bound to albumin through endothelial fenestrae into the space of Disse, from where they can be taken up by the sinusoidal transport systems of the hepatocytes<sup>[83,84]</sup>.

The bulk (about 85%) of the bile acids are present in plasma as a complex of plasma proteins (mainly, albumin)-bile acid, therefore, it has been shown that albumin performs its inherent transport function and contributes to the interaction of bile acids with specific sinusoidal membrane receptors in the mechanisms of hepatocyte absorption of bile acids. The bile acids in sinusoidal blood are efficiently taken up by hepatocytes from Disse's space despite being highly albumin bound, due to the existence in the basolateral membrane of transporters<sup>[85,86]</sup>. The powerful techniques of molecular biology have enabled gene cloning of the transporters involved in biliary secretion and the enterohepatic circulation of bile acids. This has permitted elucidation of their function as well as their regulation by nuclear receptors<sup>[87]</sup>. The enterohepatic circulation results from efficient ileal absorption, and is highly regulated at two sites. In the hepatocytes, biosynthesis of bile acids is regulated by negative feedback by the nuclear receptor FXR as well as by cytokines and by a peptide (FGF-19) liberated by bile acids from the ileal enterocytes. In the ileal enterocytes, bile acid reclamation is regulated by negative feedback by FXR and other nuclear receptors. BSEP mediates uphill canalicular bile acid secretion<sup>[87]</sup>. The plasma membranes of hepatocytes have been found to contain the proteins that selectively bind bile acids<sup>[87]</sup>. This uptake is carried out against an electrochemical gradient, is saturable<sup>[88]</sup>, and depends on the structure of the bile acids. It is more

**Figure 7** Mechanisms of the transport of bile acids, water, and electrolytes through the hepatocyte (transcellular pathway) and intercellular space (paracellular pathway). Localization and function of sinusoidal and canalicular hepatocellular transporters. The  $\text{Na}^+$ -dependent sinusoidal uptake of bile salts (BS) is mediated by  $\text{Na}^+$ -dependent taurocholate cotransport peptide. The  $\text{Na}^+$ -independent hepatic uptake of organic anions (OA), BSs and type II organic cations (OC) is mediated by members of the OATP family. Sinusoidal uptake of type I OC is mediated by OCT1. Transport across the canalicular membrane is driven mainly by ATP-dependent export pumps. MDR1 mediates canalicular excretion of amphiphilic type II OC and other hydrophobic compounds. MDR3 functions as a PC flippase. BSEP mediates apical excretion of BSs. MRP2 transports non-bile-salt organic anions, such as bilirubin glucuronides (BGs), GSH, and sulfated/glucuronated bile salts. Canalicular transport of  $\text{HCO}_3^-$  is mediated by the  $\text{Cl}^-/\text{HCO}_3^-$  exchanger AE2. AQP9 and AQP8 are involved in the transport of water across the sinusoidal and the canalicular membrane, respectively. The nature of the water channels in human liver has been characterized<sup>[84]</sup>. GC: Golgi apparatus (complex); ER: Endoplasmic reticulum; N: Nucleus.

efficient for trihydroxy- than for dihydroxy-bile acids and for conjugated more than for unconjugated bile acids<sup>[89]</sup>. Transporters on the basolateral membrane, which faces the space of Disse, are responsible for the uptake of bile salts and organic anions<sup>[79]</sup>. The liver cells have an active transport system to transfer bile acids from the blood to the hepatocytes. Basolateral uptake transporters can be divided into  $\text{Na}^+$ -dependent and  $\text{Na}^+$ -independent systems. The NTCP, the main  $\text{Na}^+$ -dependent bile acids transporter<sup>[90-92]</sup> is only expressed in the basolateral membrane<sup>[93]</sup>. NTCP, (gene name SLC10A1) is the founding member of the SLC10 family of solute carrier proteins, which includes two bile acid carriers (SLC10A1/NTCP and SLC10A2/ASBT), one steroid sulfate transporter (SLC10A6/SOAT), and four orphan carriers (SLC10A3, SLC10A4, SLC10A5, SLC10A7)<sup>[94-96]</sup>.  $\text{Na}^+$ -dependent uptake involves co-transport of solutes with  $\text{Na}^+$ . Moreover, the driving force is the energy of ATP generated by  $\text{Na}^+, \text{K}^+$ -ATPase. This enzyme is located on the sinusoidal and lateral membranes of hepatocytes<sup>[97,98]</sup> and undetectable on the canalicular (apical) part<sup>[99,100]</sup>. The active transport of bile acids ensures their continuous hepatocyte pumping from blood to bile, thus causing their low level in the blood flowing from the liver and in plasma as a whole. The properties of NTCP satisfy all the functional criteria for hepatocyte  $\text{Na}^+$ -coupled bile acid uptake<sup>[71,94]</sup>. The major physiological substrates of NTCP include all the major glycine- and taurine-conjugated bile ac-

ids<sup>[93,101-104]</sup>. Depending on the structure of the bile acid and NTCP, unconjugated bile acids are moderate or weak substrates<sup>[102,105,106]</sup> and sulfated bile acids appear to be only weakly transported<sup>[107]</sup>. The high level of NTCP expression at the sinusoidal membrane of hepatocytes and high affinity of NTCP for conjugated bile acids promote efficient extraction of bile acids from portal blood. Thus, NTCP functions to maintain the enterohepatic circulation of bile acids and maintain plasma concentrations at a minimum.

The uptake of bile acids by  $\text{Na}^+$ -independent mechanisms seems to be mediated by less-specific transporters, known as organic anion-transporting polypeptides (OATPs), which exchange these molecules for other anions, such as  $\text{HCO}_3^-$ , glutathione (GSH) or even other bile acids<sup>[89,90,108]</sup>.

Four OATPs have been cloned and characterized from human liver: OATP1A2 (SLC10A2/SLC21A3; formerly, OATP-A), OATP1B1 (SLC21A6; formerly, OATP-C or LST-1), OATP1B3 (SLC21A8; formerly, OATP-8) and OATP2B1 (SLC21A9; formerly, OATP-B). These transporters may take up bile acids (mainly unconjugated forms), endogenous OA- (thyroid hormones, monoconjugated bilirubin) and xenobiotic compounds (e.g., toxins, drugs and food components)<sup>[109]</sup>. In contrast to NTCP, members of the OATP family expressed on the hepatocyte sinusoidal membrane, such as Oatp1a1 (Slc10a1), efficiently transport unconjugated or sulfated

bile acids, suggesting that these carriers participate in the hepatic uptake of those bile acid species *in vivo*<sup>[89,102,110]</sup>. The heterodimeric protein OST $\alpha$ /OST $\beta$  is expressed at the basal membrane of hepatocytes and cholangiocytes<sup>[111]</sup>. This is a sodium-independent bile acid transporter that may play a role in bile acid efflux from hepatocytes toward blood when these compounds are accumulated under cholestatic conditions. Moreover, in cholangiocytes, in addition to playing a similar role, this transporter may also be involved in the cholehepatic shunting of bile acids.

Hepatocellular uptake of organic cations is mediated by two separate transport systems, which depends on the substrate molecular size<sup>[112]</sup>. Thus, small (type I) organic cations are taken up by the organic cation transporter, OCT1/Oct1 (SLC22A1/Slc22a1), which is electrogenic in nature. In contrast, human OATP-A mediates the uptake of bulky (type II) organic cations. In addition to conjugated and unconjugated bile salts, Oatps/OATPs accept other cholephilic compounds, including glucuronidated (and maybe unconjugated) bilirubin, exogenous organic anions (*e.g.*, sulfobromophthalein), leukotrienes, estrogen-conjugates (*e.g.*, estrone-3-sulfate or estradiol-17- $\beta$ -d-glucuronide), thyroid hormones, mycotoxins, and numerous xenobiotics<sup>[92,113-115]</sup>.

**Molecular physiology of the intracellular processes underlying the hepatocyte secretion of bile:** In order to explain the transit of bile acids from the sinusoidal membrane to the pericanalicular region, two different, not mutually exclusive, mechanisms have been proposed: (1) simple diffusion of bile acids bound to intracellular proteins<sup>[116]</sup>; and (2) vesicular transport of bile acids driven by cytoskeleton contractile activity<sup>[117,118]</sup>. Two arguments have been raised against the role of the second mechanism. One is that hepatic transit of labeled bile acids is too fast<sup>[118]</sup>. The second is that the baseline secretion of bile acids is not modified by microtubular disruption<sup>[117]</sup>. However, the overload of bile acids intensifies the vesicular trafficking from the Golgi complex to the pericanalicular zone<sup>[119]</sup>, and under these circumstances the alteration in the functional integrity of the cytoskeleton results in impaired bile acid secretion<sup>[120]</sup> and subsequent cholestasis<sup>[121]</sup>.

The quantity of ABC transporters in the apical membrane is regulated by the amount of biliary components available for secretion<sup>[122,123]</sup>. The regulated intracellular vesicular traffic of canalicular ABC transporters<sup>[123,124]</sup> is crucial for normal bile secretion. BSEP (formerly SPGE, a sister of P-glycoprotein) is the main, if not the only, canalicular bile acid transporter<sup>[125]</sup>, and it is also located in subcanalicular vesicles that may act as an intracellular pool. It is therefore probable that the impaired secretion of bile acids observed in overloaded conditions is an indirect result of the distortion of the increased vesicular traffic of transporters to the canalicular membrane<sup>[120]</sup>. These and other studies<sup>[126,127]</sup> have established the actual role of vesicular trafficking in hepatocytes, and have

demonstrated that specific vesicle trafficking machinery is required for membrane polarity. The overall functions based on hepatocyte polarity are not attributable to the mere presence of transporters in both poles of these cells<sup>[128]</sup> but also to their intracellular trafficking and temporary anchorage to the different hepatocyte membranes (Figure 7).

**Molecular physiology of the transporting systems of the hepatocyte canalicular membrane:** After traversing the cell by Fick's diffusion, cholephilic compounds mostly bound to high-affinity cytosolic proteins are excreted into the bile mainly by ATP-dependent pumps of the superfamily of ABC transporters; in particular those belonging to the family of multidrug-resistance proteins, MDR/Mdr, or to the family of multidrug-resistance-associated proteins, MRP/Mrp<sup>[57,71]</sup>.

MDRs/Mdrs are members of the ABC superfamily that were originally described in cancer cell lines, where they confer resistance to therapeutic agents. Three gene products were identified in rodents, Mdr1a (Abcb1a), Mdr1b (Abcb1b) and Mdr2 (Abcb4), and two in humans, MDR1 (ABCB1) and MDR 3 (ABCB4). MDR1/Mdr1 functions as an efflux pump for a wide range of amphiphilic, bulky type II cationic drugs, together with other hydrophobic compounds, such as endogenous and exogenous metabolites or toxins, steroid hormones, hydrophobic peptides and even glycolipids<sup>[113]</sup>. Two closely related but functionally distinct Mdr1 isoforms, mdr1a and mdr1b, are present in the murine but not human phenotype<sup>[129]</sup>. MDR3/Mdr2 functions as a flippase, which translocates PC from the inner to the outer hemileaflet of the canalicular membrane, followed by release of PC-containing vesicles from the outer hemileaflet into bile; a process facilitated by the detergent properties of luminal bile salts<sup>[58]</sup>.

Monoanionic bile salts are excreted in the canalicular pole by the bile salt export pump (BSEP/Bsep; ABCB11/abcb11); another member of the MDR family<sup>[130]</sup>. In contrast, canalicular efflux of divalent, bipolar sulfated or glucuronidated bile salts is mediated by the multidrug-resistance-associated protein 2 (MRP2/Mrp2; ABCC2/Abcc2)<sup>[131,132]</sup>. This carrier is also engaged in the biliary excretion of many other organic anions, including glutathione-S-conjugates (*e.g.*, leukotriene C4 or sulfobromophthalein, among others), glucuronides (*e.g.*, bilirubin and estrogens), and reduced (GSH) and oxidized glutathione (GSSG) - the former with low affinity<sup>[133,134]</sup>. Both GSSG and GSH are major determinants of the so-called "canalicular bile-salt-independent bile flow"<sup>[135]</sup>.

The canalicular membrane domain also contains the electroneutral anion exchanger 2 (AE2/Ae2; SLC4A2/slca4a2), which extrudes HCO<sub>3</sub><sup>-</sup> by exchanging the anion for biliary Cl<sup>-</sup><sup>[136]</sup>. It functions to regulate intracellular pH when hepatocytes are exposed to an alkaline load<sup>[136]</sup>. In addition, AE2/Ae2 plays a role in bile flow generation, because HCO<sub>3</sub><sup>-</sup> excretion is thought to be an additional primary driving force of the canalicular bile-salt-inde-

**Figure 8**  $^{31}\text{P}$ -NMR spectroscopy hepatic (left part of figure) and gallbladder (right part of figure) bile. Signals: 12,31 (standard); inorganic phosphate (Pi); phosphatidylcholine (PCh). PCh signal of gallbladder bile is increased with respect to such signals from hepatic bile. Signal of standard and inorganic phosphate of gallbladder bile are decreased with respect to such signals of hepatic bile. The concentration of lipids is increased by water absorption by gallbladder mucosa.

pendent bile flow<sup>[136,137]</sup>. Both in humans and rats, three transcript variants of AE2/Ae2 have been described: the full-length transcript AE2a/Ae2a, expressed from the upstream promoter in most tissues, and the alternative transcripts AE2b<sub>1</sub>/Ae2b<sub>1</sub> and AE2b<sub>2</sub>/Ae2b<sub>2</sub>, expressed in a more tissue-restricted fashion (mainly in liver and kidney). AE2b<sub>1/2</sub>/Ae2b<sub>1/2</sub> transcription is driven from overlapping promoter sequences within intron 2, which results in AE2/Ae2 protein isoforms with short N-terminal differences<sup>[138,139]</sup>.

In water transporters, for a solute to drive blood-to-bile vectorial water transport primarily, resultant osmotic forces need to be associated with aquaporin (AQP)-mediated transcellular movement of water molecules from plasma to the bile canaliculus<sup>[140]</sup>. Both immunochemical and functional studies have demonstrated the constitutive expression of the water channel AQP9 at the basolateral membrane of rat hepatocytes, and the regulated expression of the water channel AQP8 at the hepatocellular canalicular membrane domain<sup>[140-142]</sup>. AQP8 is suggested to play a role in bile formation, facilitating the osmotic movement of water under choleretic stimulus<sup>[140,142]</sup>. AQP isoforms that mediate polarized water transport in human hepatocytes, if any, remain to be identified.

### Gallbladder

The bile formed outside the digestive periods enters the gallbladder that performs two important functions: concentration of bile and its storage up to the evacuation into the duodenum. Minor quantities of bile acids (about 1.3%) are absorbed in the gallbladder walls. Micelles and vesicles enter the gallbladder where the concentration of lipids is increased by water absorption, which causes some physicochemical changes in the bile (Figure 8).

If the gallbladder functions well due to its contraction, all agglomerated vesicles and micelles with bile flow reach the duodenum. The gallbladder mucosa actively absorbs amino acids (this has been established by  $^{35}\text{S}$ -

labelled methionine) and an albumin bile protein fraction<sup>[143]</sup>.

Thus, the gallbladder takes an active part in changing the composition of bile *via* reabsorption of its components into the blood and making the bile components circulate along the small circuit: liver-gallbladder-blood-liver.

The flow of bile is lowest during fasting, and a majority of that is diverted into the gallbladder for concentration. When chyme from an ingested meal enters the small intestine, acid and partially digested fats and proteins stimulate secretion of cholecystokinin and secretin. These enteric hormones have important effects on pancreatic exocrine secretion. They both are also important for secretion and flow of bile.

**Cholecystokinin:** The name of this hormone describes its effect on the biliary system-cholecysto = gallbladder and kinin = movement. The most potent stimulus for release of cholecystokinin is the presence of fat in the duodenum. Once released, it stimulates contractions of the gallbladder and common bile duct, resulting in delivery of bile into the gut.

**Secretin:** This hormone is secreted in response to acid in the duodenum. Its effect on the biliary system is similar to that seen in the pancreas: it stimulates biliary duct cells to secrete  $\text{HCO}_3^-$  and water, which expands the volume of bile and increases its flow into the intestine.

### Sphincter of Oddi

The sphincter of Oddi is located at the interface of the common bile duct and the main pancreatic duct at their confluence into the duodenum. Anatomical and immunohistochemical studies have indicated that the sphincter of Oddi is richly innervated with cholinergic, adrenergic, and peptidergic neurons.

The location of the sphincter of Oddi determines its function: to regulate the entry of bile and pancreatic juice into the duodenum and to prevent reflux of duodenal contents into the common bile duct and the main pancreatic duct. The sphincter coordinates the time and rate of secretion of about 3 L/d of bile and pancreatic juice into the duodenum<sup>[144]</sup>. Normally, the sphincter is characterized by considerable phase contractions throughout the interdigestive period.

### Transport of bile acids along the portal venous system

Bile acid salts come from the intestine into the portal venous system. Bile acids with venous blood enter the liver where they are apparently completely (99%) absorbed by hepatocytes. And only a small quantity (about 1%) of bile acids enters the peripheral blood. In this connection, in healthy individuals the blood concentration of circulating bile acid salts is small.

In the hepatocytes, the secondary bile acids, deoxycholic and lithocholic, are subject to hydroxylation and they conjugate with glycine or taurine. Bile acids come as

Figure 9 Formation of IX $\alpha$  bilirubin from heme.

conjugates from the liver into the bile again. The normal enterohepatic circulation of bile acids occurs 2-6 times daily depending upon the dietary regimen.

It has been shown that the normal kidneys are not involved in the excretion of bile acids from the body. Portal venous blood bile acids are bound by plasma proteins, mainly albumins<sup>[145]</sup> and, to a lesser extent, by  $\alpha$ - and  $\beta$ -globulins. The data available suggest binding of blood bile salts to lipoproteins<sup>[146,147]</sup>. The bile acids are loosely bound to lipoproteins. In healthy individuals, bile acids are detectable in all classes of lipoproteins<sup>[147]</sup>.

## METABOLISM OF BILE PIGMENTS

Bilirubin is a principal bile pigment. Bilirubin is formed in the cells of the reticuloendothelial system. Unconjugated bilirubin is a product of heme catabolism (Figure 9). Degradation of heme involves its conversion to biliverdin followed by reduction of biliverdin to bilirubin<sup>[148,149]</sup>. Two different enzyme systems are involved in the production of bilirubin from heme: (1) microsomal heme oxygenase<sup>[150-152]</sup>, and (2) cytosolic biliverdin reductase<sup>[153,154]</sup>.

The heme oxygenase activity is detectable in all body

tissues. However, the highest activity of this enzyme is found in the spleen<sup>[150]</sup>. Heme oxygenase has an evident stereospecificity for the  $\alpha$ -meso-bridge of a heme molecule, resulting in the formation of primarily IX- $\alpha$  isomers of biliverdin in man.

Cytosolic biliverdin reductase is also present in all body tissues; its activity is most pronounced in the spleen, liver, and kidney.

A gram of hemoglobin produces 36.2 mg of bilirubin<sup>[151]</sup>. In an adult, the daily bilirubin production determined by different methods is  $3.9 \pm 0.7$  mg/kg (or 250-350 mg/d) - when determined with labeled bilirubin; and  $4.4 \pm 0.7$  mg/kg established from CO<sub>2</sub> formation when heme is converted to bilirubin<sup>[149,154]</sup>. Normally, a human being generates bilirubin IX- $\alpha$  and a minor quantity of its structural isomers: bilirubins IX- $\beta$ , IX- $\gamma$  or IX- $\delta$ .

Bilirubin is liberated from the endothelial tissue cells to plasma, binds to albumin, and is delivered to the hepatocytes and taken up by liver cells in a form dissociated from albumin. Bilirubin transport across the basolateral part of a membrane within the hepatocyte is accomplished by transport systems such as organic anions

transport protein<sup>[155]</sup>, *via* the flip-flop mechanism<sup>[156]</sup>, or by simple diffusion due to chemical concentration gradient. The uptake of bilirubin is highly effective because of its rapid hepatic metabolism and excretion into the bile and of the presence of cytosolic binding proteins, such as glutathione-*S*-transferase. Unconjugated bilirubin is a nonpolar (fat-soluble) substance. In the endoplasmic reticulum of hepatocytes, bilirubin is converted by microsomal UDP-glucuronyl transferase to a polar conjugate with glucuronic acid. Mono- and diglucuronide bilirubin is formed. Water-soluble conjugate of bilirubin is easily excreted into bile. Much smaller fractions of bilirubin are conjugated to sulfates, glucose, or xylose<sup>[157]</sup>.

The physiological significance of conjugation of bilirubin to sugars or glucuronic acid is diminishing its toxic properties through increasing molecular hydrophilicity, which improves bilirubin transport across the membrane structures and ensures secretion into the bile. However, IX $\beta$ , IX $\gamma$ , and IX $\delta$  isomers of bilirubin require no conjugation for bile secretion because they have no rigid structure as compared to the molecule of bilirubin IX $\alpha$ . The latter has a rigid structure due to intramolecular hydrogen bonds. Interestingly, the destruction of the bonds can improve the biliary secretion of bilirubin IX $\alpha$ . It has been demonstrated that UV blood irradiation results in destruction of intramolecular hydrogen bonds in bilirubin. This facilitates the diffusion of bilirubin IX $\alpha$  molecules across the membrane structures without conjugation with glucuronic acid or sugars.

A greater proportion of conjugated bilirubin in the bile is present in the mixed micelles containing cholesterol, phospholipids, and bile acids. Conjugated bilirubin is hydrolyzed by bacterial glucuronidases under urobilinogens. Having a nonpolar molecule, urobilinogen is well absorbed in the small intestine, and in minimal quantities in the colon. The liver and kidneys re-excrete small quantities of absorbed urobilinogen. In hepatocyte dysfunction, hepatic urobilinogen re-excretion is impaired and renal excretion is increased<sup>[151,153,154]</sup>.

## SECRETION OF WATER AND ELECTROLYTES INTO BILE

Formation of bile and generation of bile flow are driven by the active secretion of bile salts, lipids and electrolytes into the canalicular and bile duct lumens followed by the osmotic movement of water<sup>[158]</sup>. Thus, water has to cross rapidly into and out of the cell interior driven by osmotic forces. Bile as a fluid, results from complicated interplay of hepatocyte and cholangiocyte uptake, secretion and concentration that involves various transporters of lipids, anions, cations, and water. Considering bile is composed of > 95% water, the molecular basis and regulatory mechanisms of water transport in hepatocytes during bile formation are still under evaluation<sup>[159]</sup>.

Theoretically, water can flow through the hepatocyte epithelial barrier either across tight junctions between adjacent hepatocytes (paracellular route) or across he-

patocyte plasma membranes (transcellular route). The paracellular route was traditionally proposed as the major pathway for water movement.

The tight junctions play an important role in the paracellular secretion of water and the dissolved low-molecular-weight compounds of the latter. Water and electrolytes are assumed to pass from the intercellular space through the tight junctions into the bile canalicular lumen<sup>[99]</sup>. Moreover, the selectivity of electrolyte excretion is considered to be caused by the presence of a negative charge at the site of a tight junction. This charge serves also as a barrier to regurgitation of substances from the bile canaliculus into the sinusoidal space. The molecular mechanisms of paracellular permeability are currently associated with the functioning of the specific tight junction protein ZO-1. ZO-1 is phosphorylated with protein kinases, which is of importance in the molecular mechanisms responsible for the regulation of paracellular permeability<sup>[160]</sup>. Tight junctions exhibit low water permeability but allow electrolyte permeation that enables canalicular spaces to shrink below the van't Hoff equilibrium during the osmotic maneuver<sup>[161]</sup>. Nonetheless, the experimental data supporting this view remain limited and largely indirect<sup>[162]</sup>.

The cloning and functional characterization of a family of proteins that works as membrane water channels, named AQP<sup>s</sup><sup>[163]</sup>, challenged the former concepts of water transport and contributed to the better understanding of bile physiology. The discovery of the AQP water channels has clarified the mechanisms by which water, the major component of bile, moves across the hepatobiliary epithelia<sup>[164]</sup>.

Direct osmotic water permeability assessment by stopped-flow spectrophotometry in canalicular and sinusoidal plasma membrane vesicles revealed the presence of both lipid (non-channel) and AQP-mediated pathways for sinusoidal and canalicular water movement<sup>[165]</sup>. The study demonstrated that the canalicular plasma membrane domain has lower water permeability than the sinusoidal membrane, and thus it is rate limiting for transcellular water transport in hepatocytes<sup>[159]</sup>. However, upon cAMP stimulus the intracellular AQP8 inserts to the canalicular domain and so this membrane becomes highly water permeable. Therefore, the transcellular pathway *via* water channels seems to account for most of the water entering the bile canaliculus. Hepatocytes express AQPs, a family of membrane channel proteins that facilitate the osmotically driven movement of water molecules. AQP8 is localized to canalicular membranes and modulates membrane water permeability, providing a molecular mechanism for the osmotically coupled transport of solute and water during bile formation.

There is experimental evidence suggesting that defective hepatocyte AQP8 expression leads to alterations in normal bile physiology. Thus, AQP8 protein is down-regulated (and canalicular water permeability decreased), in established rat models of cholestasis, such as sepsis-associated cholestasis, estrogen-induced cholestasis, and

extrahepatic obstructive cholestasis<sup>[166]</sup>.

The entry of inorganic cations and anions into the hepatocytes is effected with the participation of specific ion channels and carriers, which include  $\text{Na}^+/\text{K}^+$ -ATPase,  $\text{Na}^+/\text{H}^+$ -exchanger,  $\text{Na}^+/\text{HCO}_3^-$  cotransporter, and  $\text{Na}^+$ -independent carrier of  $\text{SO}_4^{2-}$ <sup>[153]</sup>. It is suggested<sup>[167]</sup> that by analogy with the mechanisms of water reabsorption from the bile in the gallbladder, water is reabsorbed by the bile duct epithelial cells as a result of  $\text{Na}^+$ -coupled cotransport of  $\text{Cl}^-$ . Enhanced reabsorption after removal of the gallbladder is regarded as an adaptive mechanism that provides bile concentration.

The primary mechanism of biliary copper excretion involves ATP7B-mediated vesicular sequestration of copper rather than direct copper translocation across the canalicular membrane<sup>[168]</sup>.

The microfilament system is of no small importance in the canalicular secretion of bile. Bile is transported to the ducts *via* contraction of a canaliculus, which is associated with the activity of microfilaments. The latter play a great role in the regulation of permeability of a tight junction for water and electrolytes.

## SECRETION OF PROTEINS INTO BILE

Proteins, as bile acids, are referred to as the osmotically active components of bile, which determine the rate of its secretion<sup>[99]</sup>. Albumin and the other proteins that are close to its molecular weight make a major contribution to the creation of an osmotic gradient.

Tens of different proteins with a molecular weight of 6-220 kDa are detectable in the bile<sup>[99]</sup>. The greater part of them are blood proteins; the lesser are the proteins entering the bile directly from the hepatocytes and epithelial cells of bile ducts. The experimental data<sup>[99]</sup> suggest that many plasma proteins interact with the specific receptors available on the sinusoidal membrane of hepatocytes and form a plasma protein-receptor complex that enters the liver cells *via* endocytosis.

The intracellular transfer of proteins from the perisinusoidal area of a hepatocyte to its pericanalicular one is mainly accomplished by targeted vesicular transport. The large proportion of proteins entering the hepatocyte from blood as a receptor-plasma protein complex generate a receptosome (endosome) and are transported in such a form to the Golgi apparatus, then to the canalicular membrane<sup>[99]</sup>. The newly synthesized proteins entering the bile canaliculi are also transported just from the hepatocytes by targeted vesicular transport. It is presumed that apolipoproteins perform in the bile the same function as lipoproteins in the serum, that is, ensure lipid transport<sup>[169]</sup>.

Apoproteins are taken up from the sinusoidal space by endocytosis, transported in the hepatocytes as vesicles and released into the bile across the canalicular membrane by exocytosis<sup>[170]</sup>.

In conclusion, the cholesterol that is newly synthesized in the hepatocytes serves as a substrate for the

synthesis of bile acids. The synthesis of bile acids is a key point in the formation of bile. Acid-dependent and acid-independent bile fractions are identified. The structure of a hepatocyte provides a targeted transport of bile constituents from the basolateral to apical membrane of a liver cell. The transport of bile acids across the sinusoidal membrane is associated with the overcoming of a high concentration gradient and an electrical potential and it is accomplished by an active transport with the participation of carrier proteins. The vesicles are the basic form of the transport of lipids in and out of the cell itself. Bile lipids are secreted into the bile canaliculi as monolamellar vesicles. Bile acids pass across the apical part of a hepatocytic membrane independently, by ABC transporters, solubilize the phospholipids and cholesterol from the membrane surface in the bile canalicular lumen.

There is a constant transformation of vesicles to and from micelles in the bile canaliculi and ducts as a result of absorptive and secretory processes with the participation of bile acids. All the aforesaid suggests considerable progress made in the understanding of the mechanisms of bile formation and excretion, which has made possible due to the advances of fundamental investigations in cell biology, molecular biology and biochemistry.

### Abstract

Although the incidence of gastric cancer has been declining in recent decades, it remains a major public health issue as the second leading cause of cancer death worldwide. In China, gastric cancer is still the main cause of death in patients with malignant tumors. Most patients are diagnosed at an advanced stage and mortality is high. Cyclooxygenase-2 (COX-2) is a rate-limiting enzyme in prostanoid synthesis and plays an important role in the development and progression of gastric cancer. The expression of COX-2 in gastric cancer is upregulated and its molecular mechanisms have been investigated. *Helicobacter pylori* infection, tumor suppressor gene mutation and the activation of nuclear factor-kappa B may be responsible for the elevated expression of COX-2 in gastric cancer. The mechanisms of COX-2 in the development and progression of gastric cancer are probably through promoting the proliferation of gastric cancer cells, while inhibiting apoptosis, assisting angiogenesis and lymphatic metastasis, and participating in cancer invasion and immunosuppression. This review is intended to discuss, comment and summarize recent research progress on the role of COX-2 in gastric cancer development and progression, and elucidate the

molecular mechanisms which might be involved in the carcinogenesis.

**Key words:** Cyclooxygenase-2; Gastric cancer; Prostaglandin; Carcinogenesis; Molecular mechanism

**Core tip:** Cyclooxygenase-2 (COX-2) plays an important role in gastric cancer development and progression. The present review aims to determine the molecular mechanism of COX-2 overexpression in gastric cancer and focus on the detailed information on COX-2 involved in carcinogenesis. By reviewing research progress, this may be helpful in clarifying the internal relationship of the afore-mentioned aspects.

### INTRODUCTION

Gastric cancer is one of the most common malignant tumors worldwide, and the morbidity and mortality associated with this disease are ranked second highest of all malignant neoplasms<sup>[1-3]</sup>. In China, the incidence of gastric cancer has been declining in recent years<sup>[4]</sup>. Since 75% of gastric cancer patients are diagnosed at an advanced stage and cannot be cured merely by surgery, chemotherapy combined with surgery is often the primary treatment. There are many factors that affect the prognosis of gastric cancer, and of these factors invasion and metastasis are leading causes of death. The role of cyclooxygenase-2 (COX-2) in gastric cancer development and progression

has been extensively studied. The expression of COX-2 is elevated in gastric cancer tissues, therefore, inhibition of COX-2 expression may prevent or reverse gastric carcinogenesis. This review focuses on the crucial role of COX-2 in gastric cancer development and progression. In addition, its mechanisms of action are illustrated.

## COX

COX, also known as prostaglandin synthase, is the rate-limiting enzyme responsible for the conversion of arachidonic acid (AA) into the various prostaglandins (PGs), a family of lipid mediators that have widespread and diverse biological functions<sup>[5]</sup>. This enzyme possesses both peroxidase activity in catalyzing prostaglandin G<sub>2</sub> (PGG<sub>2</sub>) to prostaglandin H<sub>2</sub> (PGH<sub>2</sub>) and COX catalytic activity in the conversion of PGG<sub>2</sub> from AA<sup>[6]</sup>. Members of the PGs family including PGD<sub>2</sub>, PGE<sub>2</sub>, PGF<sub>2</sub>, PGG<sub>2</sub>, and PGH<sub>2</sub> are widely distributed in organic bodies and play different roles in metabolism<sup>[7-11]</sup>. It is reported that PGE<sub>2</sub> was overexpressed in tumor tissues and was involved in carcinogenesis<sup>[12-14]</sup>.

COX, with a relative molecular mass of 71000, is a type of glycoprotein which is located on the surface of the nuclear membrane and microsomal membrane. Two COX isoforms have been found: COX-1 and COX-2. Although COX-1 and COX-2 share a high level of homology (65%), the activity and expression of these enzymes are different, and they can function independently within the same cell type<sup>[15]</sup>.

The *COX-1* gene, comprised of 11 exons and 10 introns, is a type of housekeeping gene, which is located at chromosome 9 q<sup>32-33.3</sup>. The full length of the *COX-1* gene is about 22.5 kb, and no hogness box and promoter elements are found. In most tissues, COX-1 is composed of 599-600 amino acid residues and expressed constitutively and continuously<sup>[16]</sup>. The basic functions of COX-1 are not only promoting the synthesis of PGs, but also maintaining the homeostasis of an organism such as regulating the clotting mechanism, stabilizing renal blood flow and protecting gastric mucosa<sup>[17-19]</sup>. COX-1 is expressed negatively or weakly in tumor tissues and is not involved in carcinogenesis<sup>[20]</sup>.

The *COX-2* gene, located at chromosome 1q<sup>25.2-25.3</sup>, is composed of 10 exons and 9 introns. With hogness box, CAAT/enhancer binding protein (C/EBP) and cAMP response elements in the 5'-terminal nucleotide sequence, the gene is approximately 8.3 kb in size<sup>[21]</sup>. There are also some binding sites in the gene sequence such as the activator protein-2 (AP-2) binding site and the nuclear factor-kappa B (NF-κB) binding site<sup>[22]</sup>. COX-2 is composed of 604 amino acid residues and is expressed negatively in normal tissues and organs under physiological conditions, except the constitutive expression in kidney and brain. It is inducible in response to certain stimuli such as growth factors and cytokines. COX-2 is involved in many pathological processes such as inflammation and carcinogenesis<sup>[23,24]</sup>. It was reported that more than 15% of

malignant tumors are correlated with infection<sup>[25]</sup>. Various inflammation networks have been confirmed to play crucial roles in the microenvironment of carcinogenesis<sup>[26]</sup>, and the most important network is the COX-2/PGE<sub>2</sub> pathway<sup>[27]</sup>. In addition, it has been well established that COX-2 is up-regulated in a variety of cancers and promotes their growth<sup>[28-30]</sup>.

## EXPRESSION OF COX-2 IN GASTRIC CANCER

The first report on the expression of COX-2 in gastric cancer was from Ristimaki *et al.*<sup>[23]</sup>. Their study showed that human gastric adenocarcinoma tissues contained significantly higher levels of COX-2 mRNA when compared with paired gastric mucosal specimens devoid of cancer cells. Immunohistochemical staining detected COX-2 protein expression in the cytoplasm of gastric carcinoma cells, but not in the surrounding stroma. Ue-fuji confirmed the overexpression of COX-2 protein in human gastric adenocarcinomas by immunoblotting, and reported that overexpression of COX-2 protein was independent of the histologic type of gastric cancer<sup>[31]</sup>. A study further confirmed the significant difference in COX-2 protein expression between normal tissues and gastric cancer tissues<sup>[32]</sup>. Researchers found that the overexpression of COX-2 protein was not related to the clinicopathological characteristics of gastric cancer patients<sup>[33]</sup>, but related to tumor node metastasis clinical stage, depth of invasion and metastasis<sup>[33,34]</sup>. A series of studies showed that COX-2 protein expression was associated with intestinal histological subtype, proximal location, tumor size and advanced clinical stage and lymph node involvement<sup>[35-39]</sup>. Importantly, the expression of COX-2 protein and mRNA was already detected in noninvasive gastric dysplasia<sup>[40,41]</sup>. Thus, it seems likely that COX-2 plays a role in early gastric carcinogenesis.

There are controversial results in the association between COX-2 and survival rate. Although COX-2 played a crucial role in gastric carcinogenesis and was relevant to the degree of tumor differentiation, the expression of COX-2 protein was not correlated with survival rate. In addition, it made little sense in predicting gastric cancer prognosis<sup>[42]</sup>. In contrast, other research results suggested that COX-2 was an independent prognostic factor for gastric cancer as the 5-year survival rate of COX-2 protein positively expressed patients was lower than that of negatively expressed patients<sup>[43]</sup>. In addition, early-stage gastric cancer patients with high expression of COX-2 protein were at a higher risk for cancer-related death than those with a low level of COX-2 expression<sup>[35]</sup>. Another study<sup>[44]</sup> assessed the correlation between tumor progression and epithelial mesenchymal transition using multivariate analysis, and showed that COX-2 protein overexpression was an independent prognostic factor for poor survival, due to angiogenesis, cancer invasion and metastasis. Recently, scientists also found that COX-2 protein and *p53* expression were independent prognostic

factors for poor survival, in addition to late-stage disease and non-curative surgery<sup>[45]</sup>. Most of the findings illustrated above share the similar points, while the controversial points need to be further investigated to reach a consensus.

## MECHANISM OF ELEVATED COX-2 EXPRESSION IN GASTRIC CANCER

### *Helicobacter pylori* infection

Some studies suggested that *Helicobacter pylori* (*H. pylori*) infection was significantly related to COX-2 expression<sup>[46-48]</sup>. *H. pylori* infection can lead to a local inflammatory response, phenotypic change of epithelial cells, promotion of cell proliferation and inhibition of cell apoptosis, and ultimately an increased risk of gastric cancer<sup>[49]</sup>.

*H. pylori* is classified as a class I carcinogen by the International Agency for Research on Cancer. Over-expression of COX-2 was detected in *H. pylori* positive gastritis compared with *H. pylori* negative gastritis<sup>[50]</sup>. COX-2 over-expression was found in 50%-80% of gastric cancer patients. Another study showed that 24 h after *H. pylori* infection of epithelial cells in mice, the expression of COX-2 and PGE<sub>2</sub> were significantly elevated<sup>[51]</sup>. An *in vitro* study also obtained similar results<sup>[48]</sup>. After the co-culture of MKN 28 cell lines with *H. pylori* for 24 h, the COX-2 mRNA transcription level increased five-fold and the expression of PGE<sub>2</sub> increased three-fold, suggesting that synthesis of COX-2 and PGE<sub>2</sub> was one of the factors for *H. pylori* associated gastric cancer<sup>[52]</sup>.

The mechanism of COX-2 over-expression caused by *H. pylori* infection is not entirely clear. In an *in vitro* study, *H. pylori* induced the expression of COX-2 and inducible nitric oxide synthase by activating AP-1 of AGS cells<sup>[53]</sup>. Cytokines from the *H. pylori* associated inflammatory response also promoted the upregulation of COX-2<sup>[54]</sup>. In an *in vivo* study, *H. pylori* infection influenced the expression of 385 genes, and 160 of these genes were related to COX-2, including the inflammation genes (*Icam1*), the apoptosis genes (*Cln*), the proliferation genes (*Gdf3*, *Igf2*), the gastric physiology genes (*Galr-1*) and the epithelial barrier function genes (*Tjp1*, *Aqp5*). After treatment with NS398, a COX-2 inhibitor, the expression of 140 genes changed, which indicated that COX-2 was correlated with the occurrence of gastritis<sup>[55]</sup>. Another study indicated that *H. pylori* could lead to the phosphorylation of p38 mitogen-activated protein kinase (p38 MAPK) and its downstream transcription factor ATF-2, and the expression of COX-2 could be inhibited by a p38 MAPK inhibitor. These results indicated that the p38/ATF-2 signal transduction pathway induced by *H. pylori* was the crucial mechanism involved in COX-2 expression<sup>[56]</sup>. Infection with *H. pylori* stimulated the secretion of gastrin which promoted the expression of COX-2 and extended the half-life of COX-2 mRNA<sup>[57]</sup>. In addition, the inhibitor of gastrin-releasing peptide decreased the expression of COX-2, which indicated that gastrin may be involved

in COX-2 expression induced by *H. pylori*<sup>[58]</sup>.

### Suppressor gene mutation

An imbalance of oncogenes and suppressor genes is responsible for carcinogenesis. The mutation of a suppressor gene can lead to the occurrence of cancer. A study revealed that COX-2 expression in patients with *P53* mutation was higher than in those without *P53* mutation. This indicated that *P53* mutation might be related to COX-2 over-expression<sup>[59]</sup>. The protein of wild-type *P53* could inhibit the formation of a complex composed of TATA box binding proteins and promoters located upstream of the gene sequences, and eventually inhibited the expression of COX-2. In contrast, the product of mutant type *P53* could elevate COX-2 expression by the Ras/Raf/MAPK signal pathway. Moreover, COX-2 could reversibly induce mutation of *P53*, and both were co-expressed in gastric cancer tissues<sup>[60]</sup>.

*P16* is a tumor suppressor gene located at chromosome 9p<sup>21</sup>. It can inhibit the function of cyclinD1/CDK4 and CDK6 complex, and cause *p53*-independent G1 arrest through the phosphorylation of pRb<sup>[61,62]</sup>. This gene is usually inactivated in human gastric cancers for different reasons. A study indicated that *p16* was found to harbor promoter methylation associated with the loss of protein expression in cancer cells, suggesting that *p16* inactivation due to promoter methylation may be important for gastric tumorigenesis<sup>[63]</sup>. Other mechanisms such as mutation and homozygous deletion, are also responsible for the inactivation of *p16*, which lead to the development and progression of tumors<sup>[64]</sup>. Researchers explored the expression of COX-2 protein and *p16* protein in gastric cancer mucosa, and found that COX-2 protein expression was negatively related to *p16* protein expression. There may be a relationship between the expression of COX-2 and *p16*. However, the mechanism involved needs to be clarified in further research<sup>[65,66]</sup>.

### NF-κB

NF-κB is a protein which has the ability to combine with the nucleotide sequence in the promoter region and enhancer region of some genes, and consequently activate or enhance the transcription of these genes. NF-κB is usually distributed in the cytoplasm in the inactive form under physiological conditions. It is then activated and enters the nucleus in response to outside stimuli. The NF-κB signal pathway is involved in many processes such as the inflammatory response, cell proliferation, apoptosis and carcinogenesis. Some inflammatory cytokines, such as tumor necrosis factor (TNF)-α, can activate NF-κB, and this activated transcription factor can induce over-expression of inflammatory factors including COX-2 and TNF-α itself, forming the inflammatory network in the tumor microenvironment<sup>[67]</sup>. The COX-2 promoter region contains several elements, with the presence of two NF-κB consensus sites<sup>[68]</sup>. COX-2 expression decreased significantly when NF-κB was blocked by chondroitin sulfate<sup>[69,70]</sup>. Expression of COX-2 and NF-κB increased

simultaneously during the process from chronic atrophic gastritis, dysplasia to gastric cancer. The co-expression of COX-2 and NF- $\kappa$ B played an important role in the angiogenesis of stomach tissues. In addition, NF- $\kappa$ B up-regulated the expression of vascular endothelial growth factor (VEGF), which is an important promoter of angiogenesis<sup>[71]</sup>.

## MECHANISM OF COX-2 IN GASTRIC CARCINOGENESIS

### Cell proliferation and apoptosis

Accumulating evidence indicates that inflammation plays an important role in the development of cancers<sup>[72,73]</sup>. TNF- $\alpha$ , which is a mediator of PGE<sub>2</sub>, plays a crucial role in mediating the inflammatory process through activation of NF- $\kappa$ B. It has been found that stromal NF- $\kappa$ B can enhance proliferation of epithelial cells by inducing cytokines, chemokines, and growth factors, such as IL-6, IL-1 $\beta$ , macrophage inflammatory protein-2 and TNF- $\alpha$ , while epithelial NF- $\kappa$ B can suppress apoptosis by inducing anti-apoptotic proteins, such as GADD45 $\beta$ , A1/Bfl1, and cIAP1<sup>[74,75]</sup>. As a product of AA catalyzed by COX-2, PGE<sub>2</sub> is involved in gene mutation and cancer cell proliferation<sup>[76]</sup>. Protein encoded by COX-2 genes is a type of oncogenic protein, which could promote the high expression of PGE<sub>2</sub>. PGE<sub>2</sub> can stimulate the growth of blood vessels, inhibit local immune function and regulate a variety of signal transduction pathways which ultimately influence the proliferation of cells and the growth of tumors<sup>[77]</sup>. It has also been confirmed that over-expression of COX-2 promoted cell proliferation by weakening the anti-proliferative effect of transforming growth factor- $\beta$  (TGF- $\beta$ )<sup>[78]</sup>.

An *in vitro* study showed that cell proliferation was suppressed when gastric cells were treated with COX-2 small interfering RNA (siRNA)<sup>[79]</sup>. In MKN-45 cells, inhibition of COX-2 with NS-398 led to reduced proliferation and induction of apoptosis, connected with downregulation of *Bcl-2* (an anti-apoptotic gene) and upregulation of *Bax* (an apoptotic gene)<sup>[80]</sup>. COX-2 was a regulatory factor in the *Bcl-2* upstream sequences, which upregulated the expression of *Mcl-1*, a member of the *Bcl-2* family, through the phosphatidylinositol 3-kinase (PI3K) signal pathway, and eventually inhibited the apoptosis of cancer cells<sup>[81]</sup>. Some studies confirmed that COX-2 could inhibit the apoptosis of cancer cells by inducing the mutation of *P53*<sup>[82]</sup>. Other researchers indicated that COX-2 weakened the apoptotic signal mediated by *Fas* protein. After adding the COX-2 inhibitor, they detected the elevated expression of caspase, a key enzyme of death receptor signaling and apoptotic signaling pathways<sup>[83]</sup>.

### Angiogenesis and lymphatic metastasis

The growth and metastasis of tumors depend on the formation of new blood vessels. PGE<sub>2</sub> and PGF<sub>2</sub> can promote vessel formation directly or indirectly<sup>[84]</sup>. Research

has found that COX-2 over-expression was associated with increased PGE<sub>2</sub> biosynthesis and angiogenesis in gastric cancer<sup>[85]</sup>. Furthermore, COX-2 can induce cells to produce VEGF and TGF- $\beta$ , which could promote endothelial cell migration and tubular morphogenesis. In addition, VEGF was an independent prognostic factor for gastric cancer prognosis<sup>[86]</sup>. After being transfected with COX-2 siRNA, the expression of VEGF was down-regulated and the growth of gastric cancer cells was significantly inhibited<sup>[22]</sup>. Other studies indicated that COX-2 upregulated the expression of *Bcl-2* and *Akt*, which can inhibit the apoptosis of endothelial cells and promote vessel formation<sup>[87,88]</sup>.

VEGF-C has been identified as a new member of the VEGF family and is considered a specific lymphangiogenic factor. It can promote the formation and dilation of lymphatic vessels, enhance the permeability of lymphatic vessels and facilitate lymphatic metastasis. A recent study confirmed a positive correlation between the expression of COX-2 and VEGF-C in gastric cancer patients, and both were related to gastric cancer prognosis<sup>[89]</sup>.

### Invasion and metastasis

Invasion is the premise of cancer metastasis which involves a variety of cytokines. Adhesion molecule is a type of cell surface glycoprotein that mediates cell adhesion. E-cadherin adhesion which inhibits the separation of cancer cells from tissue can prevent cancer cell invasion. COX-2 can lower the activity of E-cadherin, thus the invasiveness of cancer cells is enhanced for further metastasis. The activity of E-cadherin was enhanced after inhibition of COX-2<sup>[90]</sup>. It has been confirmed that the over-expression of matrix metalloproteinase (MMP) accelerated the decomposition of collagen in local tissues, which was beneficial to the spread of cancer cells. A correlation between COX-2 and MMP upregulation was also found<sup>[91]</sup>. COX-2 inhibitors reduce the expression of MMP<sup>[92]</sup>. CD44, which acts as the membrane receptor of hyaluronic acid and is expressed in cancer stem-like cells, played an important role in cancer metastasis. A large number of CD44(+) gastric glands was found in human adenocarcinomas and adjacent metaplasias, but not in normal gastric epithelium. In addition, CD44(+) tumor cell expansion is triggered by the cooperative actions of PGE<sub>2</sub> and Wnt in gastric tumorigenesis<sup>[93]</sup>. Studies also confirmed that PGE<sub>2</sub> could upregulate the expression of CD44<sup>[94]</sup>, while COX-2 inhibitor could inhibit CD44 expression<sup>[95]</sup>. A study demonstrated that CD44v, a variant form of CD44, could protect tumor cells from oxidative stress in a mouse gastric cancer model, thus it plays an important role in tumor development<sup>[96]</sup>. Other possible mechanisms include the upregulation of urokinase-type plasminogen activator (uPA) in promoting the metastasis of cancer cells<sup>[97]</sup> and more potential pathways need to be further clarified.

### Immunosuppression

It has been found that COX-2 was involved in the im-

munosuppression in gastric cancer, where effector T cells were suppressed by regulatory T cells. In Treg cells, expression of COX-2 was correlated with that of forkhead box p3. By using a COX-2 inhibitor, the immunosuppression of effector T cells was reversed<sup>[98]</sup>. The possible mechanisms involved may be as follows: PGE<sub>2</sub> disabled the function of dendritic cells in the tumor microenvironment and the cells could not present the tumor antigen effectively, and eventually the T cells did not recognize or kill the cancer cells<sup>[99]</sup>. In addition, PGE<sub>2</sub> may also reduce the immunosurveillance of the immune system on mutant cells by inhibiting the expression of human leucocyte antigen I and II, and by reducing the production of lymphokine. The immunosurveillance effect could be enhanced by using a COX-2 inhibitor and stimulating the activity of natural killer cells<sup>[100]</sup>.

## CONCLUSION

The COX-2/PGE<sub>2</sub> pathway involved in the inflammatory response plays a critical role in the microenvironment of gastric tumorigenesis. Expression of COX-2 is elevated in gastric cancer and its over-expression is associated with *H. pylori* infection, mutation of suppressor genes and NF- $\kappa$ B. Over-expressed COX-2 participates in gastric carcinogenesis by promoting cell proliferation, inhibiting cell apoptosis, inducing vessel formation, and enhancing metastasis and immunosuppression. Although progress has been made in exploring the mechanism of gastric cancer development, some issues remain to be explored in further studies. As research continues, interventions in gastric cancer using COX-2 as a target might eventually become a specific treatment of choice.

### Abstract

The intestinal mucosa is characterized by a high complexity in terms of structure and functions and allows for a controlled demarcation towards the gut lumen. On the one hand it is responsible for pulping and selective absorption of alimentary substances ensuring the immunological tolerance, on the other hand it prevents the penetration of micro-organisms as well as bacterial outgrowth. The continuous regeneration of surface epithelia along the crypt-villus-axis in the small intestine is crucial to assuring these various functions. The core phenomena of intestinal epithelia regeneration comprise cell proliferation, migration, differentiation, and apoptosis. These partly contrarily oriented processes are molecularly balanced through numerous interacting signaling pathways like Wnt/ $\beta$ -catenin, Notch and Hedgehog, and regulated by various modifying factors. One of these modifiers is acyl-CoA synthetase 5 (ACSL5). It plays a key role in *de novo* lipid synthesis, fatty acid degradation and membrane modifications, and regulates several intestinal processes, primarily through different variants of protein lipidation, *e.g.*, palmitoylation. ACSL5 was shown to interact with proapoptotic molecules, and besides seems to inhibit proliferation along the crypt-villus-axis. Because of its proapoptotic and antiproliferative characteristics it could

be of significant relevance for intestinal homeostasis, cellular disorder and tumor development.

**Key words:** Acyl-CoA synthetase; Apoptosis; Carcinogenesis; Colorectal cancer; Intestinal homeostasis

**Core tip:** Acyl-CoA synthetase 5 (ACSL5) activates long-chain fatty acids by coenzyme A linkage and plays a key role in fatty acid metabolism. On the basis of its mitochondrial localization, ACSL5 forms an exceptional member among the acyl-CoA synthetase family. Although its various functions are not yet fully understood, ACSL5 seems to represent a modifier of cellular vitality along the crypt-villus-axis.

Intestinal acyl-CoA synthetase 5: Activation of long chain fatty acids and behind. *World J Gastroenterol* 2013; 19(42): 7369-7373 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7369.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7369>

### INTRODUCTION

Acyl-CoA synthetase 5 (ACSL5) is part of the acyl-CoA synthetase family who plays a key role in *de novo* lipid synthesis, fatty acid degradation and subsequently membrane modifications. Their main function is the activation of long-chain fatty acids by coenzyme A linkage, these conjugates are primarily utilized for triglyceride synthesis, packed into chylomicrons and secreted through the basolateral membrane<sup>[1-3]</sup>. Along the intestinal crypt-villus-axis (CVA) they either cause cell proliferation or cell apoptosis<sup>[4]</sup>. The fatty acid activation requires a two-step reaction, catalysed through these enzymes. The first step results in an acyl-AMP intermediate of ATP. AMP

is then replaced with CoA and the activated acyl-CoA is generated. Except for the resulting acyl-CoA, free fatty acids (the substrates of these enzymes) are able to pass through membranes. The ACSL-derived esterification prevents it from leaving the cell. The length of the carbon chain (12–20 C atoms) of the fatty acids defines the substrate specificities of the different acyl-CoA synthetases. On this basis, five different subfamilies were identified<sup>[5]</sup>. Their sequences differ at N-terminus, which is presumably the reason for their diversity in sub-cellular localisation. ACSL1 and 6 are associated with the plasma membrane. They might play a role in the cellular fatty acid assimilation<sup>[6,7]</sup>. ACSL4 was mainly found in ER and peroxisomes<sup>[8]</sup>. The gene *ACSL5* lies on chromosome 10q25.1–q25.2<sup>[9,10]</sup>. The functional protein is localized on the inner mitochondrial membrane<sup>[11,12]</sup> and has a significant regulatory function in the mitochondrial energy metabolism. The pH-dependence of this molecule is especially important. It shows a high functional activity under alkaline conditions. This observation is of special interest in the case of mitochondria: In contrast to the enclosing cytoplasm their pH is more basic by one point and they show a more alkaline pH with beginning apoptosis<sup>[13]</sup>. In this context the pH conditions of tumor genesis and a differing functionality of ACSL5 should be considered as well<sup>[14]</sup>.

Analysing the role of ACSL5 in differentiation and senescence of enterocytes, a sensitization to TRAIL-dependent apoptosis was found<sup>[4]</sup>, whilst the Triacsin C-induced apoptosis induction in glioma cells was inhibited. Mashima *et al.*<sup>[9]</sup> postulated an ACSL5-dependent survival of tumor cells. There is evidence to suggest a cell regulatory involvement of ACSL5 in addition to its lipid modifying function<sup>[15]</sup>.

Triacsin C [1-hydroxy-3-(E,E,E-2',4',7'-undecatrienylidene) triazene] was identified as a potent competitive inhibitor of acyl-CoA synthetase activity<sup>[16]</sup>. Its inhibitory effects depend on the N-hydroxytriazene moiety of the molecule, resulting in a dramatic reduction in cholesterol as well as triglyceride synthesis with non-transition of macrophages to foam cells or enhanced eicosanoid release in leucocytes<sup>[17,18]</sup>. Kaemmerer *et al.*<sup>[18]</sup> showed that human ACSL5 is, unlike rat ACSL5, sensitive to the competitive inhibition by triacsin C and does not compensate for other triacsin C sensitive ACSL isoforms.

This mini review outlines the modifying role of ACSL5 in different cellular processes at the interface between proliferation and apoptosis.

## ACSL5 AS A REGULATOR OF THE CELLULAR RENEWAL ALONG THE CVA IN HUMAN SMALL INTESTINE

The CVA in adult human small intestine is important for maintaining intestinal homeostasis and this process is controlled by regulatory signaling pathways such as Wnt/ $\beta$ -catenin, Notch, Hedgehog, and apoptosis. Canonical

Wnt signaling plays a key role in regulating intestinal cell proliferation<sup>[19]</sup>. A mutation-derived activation of the cascade initiates the adenocarcinoma sequence. Blocking canonical Wnt signals leads to a proliferative arrest of epithelial cells in the crypts of Lieberkuhn. The cell sorting receptors EphB2 and B3 are also target molecules of the pathway, as they control the positioning of Paneth cells towards the crypt bottom, whereas all other differentiated epithelial cells migrate along the CVA<sup>[20]</sup>.

The highest amount of Notch activity is found in intestinal stem cells<sup>[21,22]</sup>. The transcription factors Hes-1 and Math-1 conduct the differentiation of progenitor cells into enteroendocrine, goblet and Paneth cells<sup>[23,24]</sup>. Blocking of Notch signaling with the  $\gamma$ -secretase inhibitor dibenzazepine results in a rapid conversion of proliferative crypt cells into post-mitotic goblet cells<sup>[25,26]</sup>.

The Hedgehog pathway with its main epithelial proteins Sonic (Shh) and Indian (Ihh) Hedgehog is of central relevance in villus formation and stem cell homeostasis<sup>[27,28]</sup>.

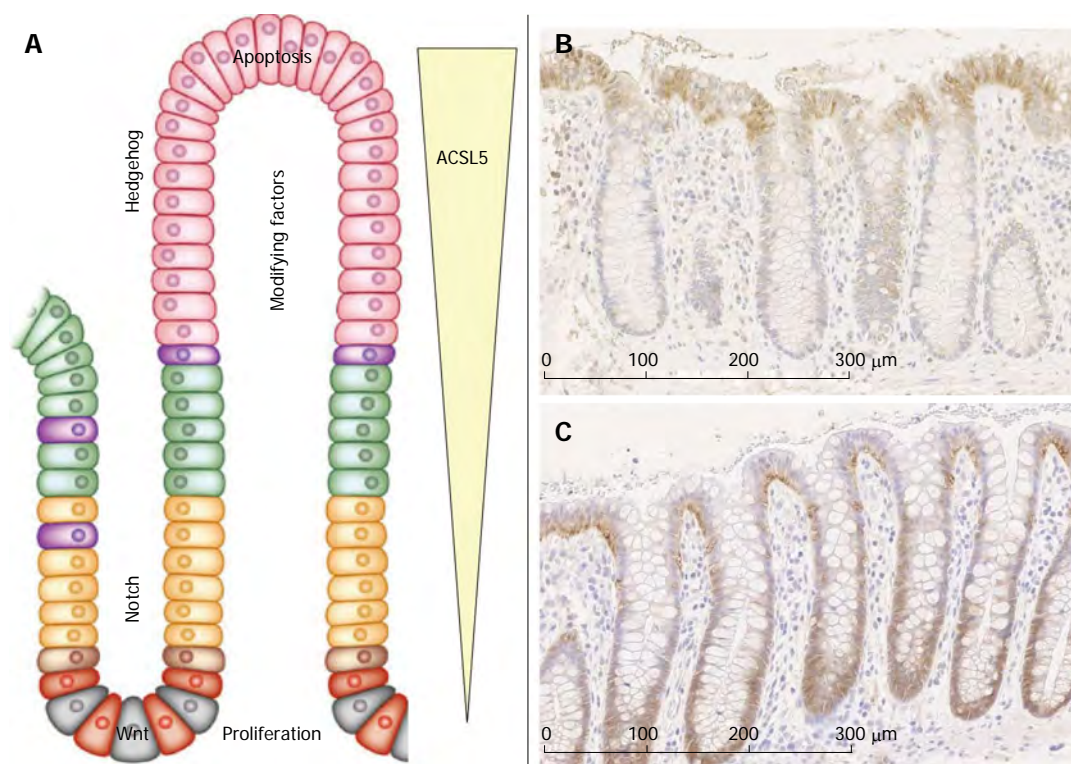

ACSL5 is expressed in an ascending gradient along the CVA with the highest expression level in enterocytes at the villus tip (Figure 1). It is assumed that ACSL5 sensitizes these enterocytes towards TRAIL-derived apoptosis susceptibility by down-regulation of the anti-apoptotic FLIP and up-regulation of TRAIL-R1 on the cell surface. TRAIL shows a corresponding gradient expression pattern<sup>[4]</sup>. Gassler *et al.*<sup>[4]</sup> suggested an ACSL5-dependent link to TRAIL-induced apoptosis by the ceramide neosynthesis, which is known to play a key role in TRAIL-induced apoptosis<sup>[29]</sup>, occurring mainly at mitochondrial membranes<sup>[30]</sup>.

Adenocarcinomas with an invasive phenotype and enhanced proliferation showed decreased levels of ACSL5<sup>[4]</sup>. A functional correlation between ACSL5-derived apoptosis susceptibility of enterocytes and increased tumor development is assumed<sup>[31]</sup>.

## LIPID MODIFICATIONS CONTROL INTESTINAL SIGNALING PATHWAYS OF CENTRAL RELEVANCE

Long-chain polyunsaturated fatty acids show significant modifying functions in the cell cycle, resulting in inflammation and cancer development<sup>[32,33]</sup>. They enter into cells by means of concentration gradients or transport proteins. The retention in the cell depends on its further metabolic function and intracellular modification. The different ACSL isoforms activate a broad range of long-chain fatty acids and channel them into specific downstream pathways that can vary in a tissue-specific manner<sup>[34]</sup>. An over-expression of ACSL5 increases the fatty acid incorporation into diacylglycerol and triacylglycerol but does not affect FA used for  $\beta$ -oxidation<sup>[35]</sup>.

A lipid modification of central relevance in several intestinal pathways is palmitoylation. Palmitate, a 16-carbon saturated fatty acid, is covalently bound to more than 100

**Figure 1** Expression of acyl-CoA synthetase 5 and  $\beta$ -catenin in normal human intestinal mucosa. Schematic overview of signaling pathways in intestinal mucosa (A) immunostaining of acyl-CoA synthetase 5 (ACSL5) (B) and  $\beta$ -catenin (C).

cellular and viral proteins. In most cases, the fatty acid is thioester (S-acyl) posttranslationally linked to cysteine. The reaction is catalysed by palmitoyl-acyltransferases, where palmitoyl-CoA serves as the donor. The palmitoylation is a dynamic process by means of its reversible linkage<sup>[36-38]</sup>. Palmitoylation has several effects on molecule functionality and is especially relevant for signaling cascades<sup>[39,40]</sup>. Protein hydrophobicity and membrane association are increased and protein/protein or protein/lipid interactions are augmented<sup>[41]</sup>. Modifications derived from fatty acids are described for the proteins associated with Wnt signaling, which are very important for secretion and activity. A fatty acid modification at serine promotes cysteine palmitoylation<sup>[42,43]</sup>. Without this fatty acid attachment at the Wnt ligand, N-glycosylation and secretion were still possible. In contrast, the absence of N-glycosylation resulted in a decreased secretion rate.

One example for an apoptosis-associated ligand that is regulated by palmitoylation is the human Fas ligand (FasL), responsible for correct signal transduction finally resulting in cell death. Palmitoylation regulates its transmembrane domain and is critical for efficient FasL-mediated killing and FasL processing<sup>[44,45]</sup>.

Another molecule regulated by S-palmitoylation is  $\gamma$ -secretase. Its diverse substrates originate from several pathways with a focus on type I integral membrane proteins, including Notch1 homologues, Notch ligands, Delta and Jagged, cell adhesion receptors N- and E-cadherins, low density lipoprotein receptor-related protein, ErbB-4, netrin receptor DCC<sup>[46,47]</sup>. Cheng *et al.*<sup>[46]</sup> identified S-pal-

mitoylation of  $\gamma$ -secretase subunits nicastrin and APH-1, and characterized its role on DRM association, protein stability, and  $\gamma$ -secretase enzyme activities.

Palmitoylation of Hedgehog proteins is important for effective signaling. Protein fatty acylation is not only found to be a regulator for membrane association of intracellular proteins, but also for the signaling activity and efficacy of secreted proteins<sup>[48,49]</sup>. Palmitoylation thus controls mechanisms leading to an altered reaction of the cells towards external signaling.

ACSL5 may play a role in channelling fatty acids towards palmitoylation and other lipid functions with high relevance for cellular behaviour<sup>[18]</sup>. An over-expression of ACSL5 in HepG2 showed an increased palmitate oxidation<sup>[50]</sup>. An ACSL5-mediated lipid modification of proliferation- and apoptosis-associated molecules might be an interface in the intestinal CVA.

## CONCLUSION

The intestinal epithelium is subject to continuous self-renewal along the CVA, and progress has been made towards understanding the task of the various signal transduction pathways in proliferation, differentiation, migration and apoptosis of epithelial enterocytes. ACSL5 is a protein localized in mitochondria that plays a key role in fatty acid metabolism and apoptosis. Although its various functions are not yet fully understood, ACSL5 seems to represent a modifier of cellular vitality along the CVA, providing fatty acids for several molecular events.

### Abstract

**AIM:** To study the mechanism of 5-fluorouracil (5-FU) resistance in colon cancer cells and to develop strategies for overcoming such resistance by combination treatment.

**METHODS:** We established and characterized a 5-FU resistance (5-FU-R) cell line derived from continuous exposure (25  $\mu\text{mol/L}$ ) to 5-FU for 20 wk in 5-FU sensitive HCT-116 cells. The proliferation and expression of different representative apoptosis and anti-apoptosis markers in 5-FU sensitive and 5-FU resistance cells were measured by the MTT assay and by Western blotting, respectively, after treatment with Resveratrol (Res) and/or 1,3-Bis(2-chloroethyl)-1-nitrosourea (BCNU). Apoptosis and cell cycle arrest was measured by 4',6'-diamidino-2-phenylindole hydrochloride staining and fluorescence-activated cell sorting analysis, respectively. The extent of DNA damage was measured by

the Comet assay. We measured the visible changes in the DNA damage/repair cascade by Western blotting.

**RESULTS:** The widely used chemotherapeutic agents BCNU and Res decreased the growth of 5-FU sensitive HCT-116 cells in a dose dependent manner. Combined application of BCNU and Res caused more apoptosis in 5-FU sensitive cells in comparison to individual treatment. In addition, the combined application of BCNU and Res caused a significant decrease of major DNA base excision repair components in 5-FU sensitive cells. We established a 5-FU resistance cell line (5-FU-R) from 5-FU-sensitive HCT-116 (mismatch repair deficient) cells that was not resistant to other chemotherapeutic agents (*e.g.*, BCNU, Res) except 5-FU. The 5-FU resistance of 5-FU-R cells was assessed by exposure to increasing concentrations of 5-FU followed by the MTT assay. There was no significant cell death noted in 5-FU-R cells in comparison to 5-FU sensitive cells after 5-FU treatment. This resistant cell line overexpressed anti-apoptotic [*e.g.*, AKT, nuclear factor  $\kappa\text{B}$ , FLICE-like inhibitory protein], DNA repair (*e.g.*, DNA polymerase beta (POL- $\beta$ ), DNA polymerase eta (POLH), protein Flap endonuclease 1 (FEN1), DNA damage-binding protein 2 (DDB2)] and 5-FU-resistance proteins (thymidylate synthase) but under expressed pro-apoptotic proteins (*e.g.*, DAB2, CK1) in comparison to the parental cells. Increased genotoxicity and apoptosis were observed in resistant cells after combined application of BCNU and Res in comparison to untreated or parental cells. BCNU increased the sensitivity to Res of 5-FU resistant cells compared with parental cells. Fifty per cent cell death were noted in parental cells when 18  $\mu\text{mol/L}$  of Res was associated with fixed concentration (20  $\mu\text{mol/L}$ ) of BCNU, but a much lower concentration of Res (8  $\mu\text{mol/L}$ ) was needed to achieve the same effect in 5-FU resistant cells. Interestingly, increased levels of adenomatous polyposis coli and decreased levels POL- $\beta$ , POLH, FEN1 and DDB2 were noted after the same combined treatment in resistant cells.

**CONCLUSION:** BCNU combined with Res exerts a synergistic effect that may prove useful for the treatment of colon cancer and to overcome drug resistance.

**Key words:** 5-fluorouracil; 1,3-Bis(2-chloroethyl)-1-nitrosourea; Resveratrol; Colon cancer; Combination therapy

**Core tip:** 5-fluorouracil (5-FU) resistance in colon cancer patients is a common phenomenon that requires immediate resolution. In this paper, we used two commonly administered clinical drugs, 1,3-Bis(2-chloroethyl)-1-nitrosourea (BCNU) and Resveratrol (Res), and studied their effects on 5-FU sensitive and resistance colon cancer cells. The drug combination was more effective in 5-FU resistant cells than in 5-FU sensitive cells and was more effective than the individual treatments. The BCNU-Res combination mediated its action by compromising the base excision repair cascade. This combination might be useful for treatment of 5-FU resistant colon cancer patients.

## INTRODUCTION

Colon cancer ranks as second in cancer related deaths in Western countries, and accounts for approximately 10%-15% of all cancers; half of these patients eventually metastasize<sup>[1]</sup>. The prognosis for patients who develop metastatic tumors is very poor, although several chemotherapeutic methods have been used to improve their survival and quality of life<sup>[2]</sup>. The antimetabolite 5-fluorouracil (5-FU) has been used as a first line therapy in colon cancer; however, in the clinical setting, more than 40% of cases are resistant. Combinations of 5-FU with Leucovorin (LV), Cisplatin, and Oxaloplatin, or with plant derived compounds including Curcumin, Resveratrol, and Quinacrine have increased the response rate up to 25%-30%<sup>[3-8]</sup>. 5-FU exerts anti-proliferative and cytotoxic effects on cells by inhibiting thymidylate synthase (TS) or by misincorporation into DNA and RNA<sup>[9]</sup>.

The misincorporation of 5-fluorodeoxyribosyl residues in DNA is generally repaired by mismatch repair (MMR)<sup>[10-12]</sup> and cells grow continuously. However, any disturbance of the repair system will cause incomplete removal of 5-FU, leading to cell death. Thus, resistance to 5-FU in certain cancers may be the result of highly efficient DNA repair in the 5-FU resistant cells. Several

investigators have used multiple combinations of drugs to increase the sensitivity of 5-FU resistant-cancer cells, but these studies showed very poor clinical responses<sup>[4-6,8]</sup>.

The well-known natural product Resveratrol (Res) has demonstrated high antitumoral efficiency without harmful side effects of conventional chemotherapies. Res (3,4,5-trihydroxy-trans-stilbene) is a polyphenolic phytoalexin widely present in plants and enriched in red grapes, peanuts and other sources<sup>[13]</sup>. This compound demonstrates beneficial functions in normal cells both in *in vitro* and *in vivo* model systems<sup>[13]</sup>. On the other hand, this compound exhibits cytotoxic effects on the majority of malignant cells, blocking the three major stages of carcinogenesis (*i.e.*, initiation, promotion and progression)<sup>[13]</sup> in several cancer cell types, such as breast, colon, melanoma, uterine, lung and leukemia cells<sup>[13-21]</sup>. Recently, using HCT-116 colon cancer cells, we demonstrated that 5-FU increases the sensitivity to resveratrol by inducing DNA damage and the MAPK pathway<sup>[7]</sup>. A significant inhibition of cell proliferation, migration, and increased apoptosis were observed when moderate concentration of Res (15  $\mu\text{mol/L}$ ) were combined with very low concentration of 5-FU (0.5  $\mu\text{mol/L}$ )<sup>[7]</sup>.

1,3-Bis(2-chloroethyl)-1-nitrosourea (BCNU or carmustine) belongs to the family of haloethylnitrosoureas. It is a common synthetic alkylating chemotherapeutic agent used for treating various types of cancers, including brain tumors, Hodgkins and non-Hodgkins lymphoma and multiple myeloma<sup>[22]</sup>. It is highly lipophilic, capable of readily crossing the blood-brain barrier. It reacts with DNA and forms several exocyclic DNA adducts, which includes the saturated ethanol adducts of adenine, cytosine, and guanine (1,N6-ethanol-A, 3,N4-ethanol-C, N2,3-ethanol-G, and 1,O6-ethanol-G) and produces intra strand cross-links in DNA<sup>[23-26]</sup>. It can also produce mono substituted purine bases in DNA<sup>[23]</sup>. BCNU is classified as an animal carcinogen<sup>[27]</sup>, and has been demonstrated as genotoxic both *in vivo* and *in vitro*<sup>[27]</sup>. This limits the use of this drug at higher doses, unless the drug is combined with some natural anticancer compounds that will not only decrease the toxic effect, but also synergistically increase its effectiveness. Several combinations of BCNU have been tried, such as with  $\text{As}_2\text{O}_3$ <sup>[28]</sup>,  $\text{O}^6\text{BG}$ <sup>[29]</sup> and TMZ<sup>[30]</sup>, to increase the sensitivity in cancer cells, but without success.

Recently, researchers attempted to target DNA damage/repair and cell cycle checkpoint signaling pathways as a means of cancer treatment<sup>[31-33]</sup>. This is relevant for 5-FU therapy, as TS inhibition and incorporation of the fluorinated base into DNA occurs during S-phase. The PI3K-like kinases, ataxia telangiectasia-mutated (ATM) and ATM-related (ATR), are central mediators in the response to DNA damage during S-phase<sup>[34]</sup>. Evidence suggests the involvement of S-phase checkpoint pathways in response to 5-FU treatment and TS inhibition<sup>[35]</sup>. A recent report suggested that ATR and CHK1 status influence cellular sensitivity to 5-FU in a MMR- or BER-mediated response-dependent manner, dictated by the

drug dose and exposure period<sup>[36]</sup>. It was also reported that 5-FU-mediated apoptosis also involved modulation of the major long patch base excision repair (LP-BER) protein Flap endonuclease 1 (FEN1)<sup>[10,37]</sup>. We have already reported that activation of adenomatous polyposis coli (APC) blocks the base excision repair pathway by interaction with DNA polymerase beta (POL-β) and FEN1<sup>[38-41]</sup>. Thus, one strategy for killing 5-FU resistant cells includes combining multiple drugs that will damage DNA, inhibit the DNA repair system and hamper cell cycle regulation in cancer cells.

In the present study, we developed a novel chemotherapeutic combination to increase the sensitivity of 5-FU resistant colon cancer cells using a synthetic DNA damaging agent, BCNU, and a plant derived anti-cancer agent, Res, and investigated the mechanism of anti cancer potentiality against 5-FU resistance. We first measured the anti-cancer potentiality of this combination in 5-FU sensitive human colon cancer cells. A 5-FU resistant cell line was derived from HCT-116 colon cancer cells after prolonged treatment with 5-FU, which was sensitive to other chemotherapeutic agents. These cells were treated with the BCNU and Res combination and drug efficacy was measured. The BCNU and Res combination increased apoptosis of the 5-FU resistant cell lines by inducing DNA damage and inhibiting the base excision repair pathway. We also used isobologram analysis to evaluate whether the drug combination has a synergistic, additive or antagonist effect on human colon cancer.

## MATERIALS AND METHODS

### Cell culture and treatment

The HCT-116 colon cancer cell line (obtained from American Type Culture Collection, VA, United States, Cat # CCL-247) was cultured in RPMI-1640 with 1% antibiotic (100 units of penicillin and 1 mg streptomycin per milliliter in 0.9% normal saline) and supplemented with 10% fetal bovine serum (HIMEDIA, Mumbai, India) in a humidified CO<sub>2</sub> incubator in 5% CO<sub>2</sub> at 37 °C. Drugs like Res, 5-FU, LV, BCNU were purchased from Sigma Chemical Ltd. (St. Louis, MO, United States). DNA polymerase eta (POLH) and DNA damage-binding protein 2 (DDB2) antibodies were procured from Abcam (MA, United States). Apurinic/aprimidinic (AP) endonuclease 1 (APE) and POL-β antibodies were purchased from Novus Biologicals (CO, United States). The anti-APC antibody was purchased from Calbiochem (CA, United States). All the other antibodies used in the experiments were procured from Cell Signaling Technology (Danvers, MA, United States). A 1 mmol/L stock of Res, 5-FU, BCNU and LV was prepared in absolute ethanol, DMSO, 50% ethanol and distilled water, respectively, and was stored at -20 °C. During treatment, Res, 5-FU and BCNU were diluted in RPMI and then added to the cultures to achieve the desired final concentration. LV (1 μmol/L) was added in combination with 5-FU in each treatment. When they reached 60%-70% confluency, the cells were treated with 5-FU, Res, BCNU and the combination of

BCNU and Res (in each case of the combination treatment, the cells were pre-treated with BCNU (20 μmol/L) for 24 h and then exposed to Res for another 48 h).

### Establishment of 5-FU resistant cell line

In our earlier report, we demonstrated that the minimum concentrations needed for causing fifty percent cell death in culture (LC<sub>50</sub>) in HCT-116 cells by 5-FU was 10 μmol/L<sup>[7]</sup>. To make stable 5-FU resistant cell lines, HCT-116 cells were exposed to 25 μmol/L for more than 20 wk. Every 48 h the media was replaced with fresh media and cells were treated with fresh 5-FU of same concentration. Initially, more than 80% of the cells died within a few days; the remaining 20% cells survived and developed 5-FU resistance. At the end of the exposure, 5-FU resistance was checked by a cell survival assay (MTT) in the presence of 5-FU and the transformed characteristic was confirmed by measuring several biomarkers. No significant cell death was noted after 5-FU treatment allowing the cells to be designated as 5-FU-R cells.

### MTT assay

The anchorage dependent cell viability of normal HCT-116 and 5-FU-R cells was measured after treatment with various drugs using a reliable and sensitive colorimetric assay: the MTT [3-(4,5-Dimethylthiazol-2yl)-2,5-diphenyl tetrazolium bromide] cell proliferation assay, as described previously<sup>[7,42]</sup>. Approximately, 10000-12000 cells were plated in a 96 well tissue culture plate in triplicate and incubated for 24 h, after which they were exposed to various concentrations of the indicated compounds for 48 h. At the end of the treatment, the cells were washed with 1 × phosphate buffered saline (PBS) and then 100 μL of 0.05% MTT reagent (Sigma) was added to each well and kept for 6 h in incubation at 37 °C to allow the formation of purple formazan crystals. 100 μL of detergent solution (10% NP-40 with 4 mmol/L HCl) was added to each well of the 96 well tissue culture plate and the reaction mixture was incubated for 1 hr at room temperature. The color intensity was measured spectrophotometrically using a microplate reader (Berthold, Germany) at 570 nm. The data were calculated as percentages of the control. All assays were performed at least three times.

### Nuclear staining with 4',6-diamidino-2-phenylindole

To determine the apoptosis of HCT-116 and 5-FU-R cells after treatment with the indicated drug, 4',6-diamidino-2-phenylindole (DAPI) nuclear staining was carried out. Cells at 70%-80% confluency were treated with the desired drug for indicated time, as mentioned in the figure legend. The cells were then washed with PBS and fixed with acetone: methanol (1:1) for 15 min at -20 °C in the dark. Fixed cells were washed once with PBS and then DAPI solution was added and incubation was continued for 1 h at 37 °C in the dark. Excess DAPI was removed by washing with PBS and the stained cells were visualized under a fluorescence microscope (Nikon, Japan) at × 40 magnification.

### Cell cycle

Regulation of cell cycle and apoptosis were measured using fluorescence-activated cell sorter (FACS) analysis. HCT-116 and 5-FU-R cells were cultured in 60 mm tissue culture discs until they reached 60%-70% confluency. They were then treated with the indicated drug. After treatment, cells were trypsinized and washed with PBS containing RNase-A and fixed with 70% ethanol. The cells were incubated at -20 °C overnight and then re-suspended in 0.1 mL of Propidium Iodide (PI, 50 µg/mL) and incubated for 1 h in the dark at room temperature. Finally, FACS was used to sort the cells (Becton and Dickinson, CA). Cell Quest Software was used to determine the DNA content of the cells at various phases of the cell cycle (Becton and Dickinson, CA).

### Single cell gel electrophoresis or comet assay

After drug treatment, DNA damage in HCT-116 and 5-FU-R cells was determined by performing a single cell gel electrophoresis assay following the method of Tice *et al.*<sup>[43]</sup>. Cells were suspended in PBS and about 5000-6000 cells were mixed with low melting agarose at 37 °C and spread on a microscopic slide. After solidifying, the slides were dipped in chilled lysis solution (10 mmol/L Tris, 100 mmol/L EDTA, 2.5 mol/L NaCl, 1% Triton × 100, 10% DMSO and pH 10.0) for 1 h. After lysis the slides were put in freshly prepared alkaline electrophoresis buffer and electrophoresis was performed at 20 V for 20 min. Slides were then dipped in neutralization buffer (0.4 mol/L Tris-HCl and pH 7.5) and washed with distilled water, followed by 70% ethanol, and allowed to dry. Later, 40 µL of SYBR green dye was added to each slide, which was incubated in the dark for 30 min at room temperature. A fluorescence microscope (Nikon, Japan) at a magnification of × 10 was used to visualize DNA migration. TriTek CometScore™ software was used to analyze the comet lengths.

### Western blotting

Cells were plated on 100 mm tissue culture discs and were treated with the indicated drug when they reached 70% confluence. After treatment, the cells were washed with PBS and were lysed using the RIPA lysis buffer (50 mmol/L Tris, 150 mmol/L NaCl, 0.5 mmol/L Deoxycholate, 1% NP-40, 0.1% SDS, 1 mmol/L NaVO<sub>4</sub>, 5 mmol/L EDTA, 1 mmol/L PMSF, 2 mmol/L DTT, 10 mmol/L β-glycerophosphate, 50 mmol/L NaF, 0.5% Triton × 100, protease inhibitor cocktail) for 45 min at 4 °C. The lysates were centrifuged at 14000 rpm for 10 min to remove the cell debris. The supernatant was collected in a separate tube and protein quantification was performed by Bradford method using BSA as a standard. Approximately 100 µg of protein were loaded in each well and separated using 10% SDS-PAGE. After separation, the proteins were transferred to a PVDF membrane. The membrane was blocked and then probed with specific antibody, according to the manufacturer's protocol.

### Analysis of combined drug effect

Synergistic, additive or antagonist drug effects were de-

termined by isobologram analysis<sup>[28]</sup>. Isobologram plots were drawn by plotting the individual LC<sub>50</sub> values of the drugs in their respective X- and Y-axis. The LC<sub>50</sub> values were obtained from the individual drugs effect of MTT assays. Then, a line was used to join both the data points and the LC<sub>50</sub> value of the combined drug was spotted on the same plot. In principle, if the spotted point (LC<sub>50</sub> value of combined drugs) falls on the line then it considered as additive, whereas if it falls below or above the line, then it considered as a synergistic or antagonist drug effect, respectively.

## RESULTS

### Cytotoxic effect of 5-FU, BCNU and Res in HCT-116 colon cancer cells

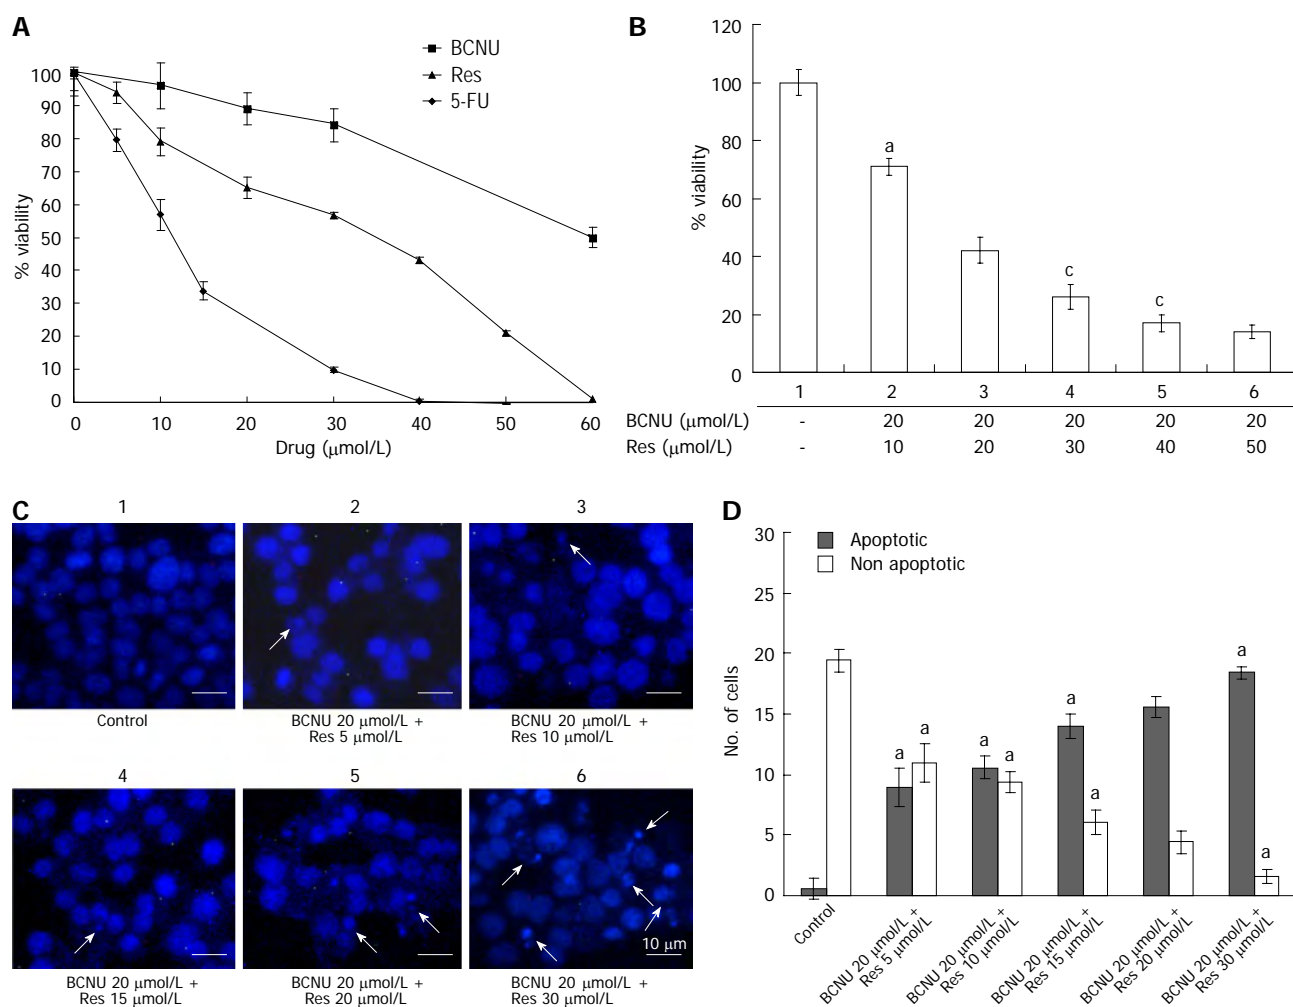

To determine the LC<sub>50</sub> (concentrations needed for fifty percent cell death in culture) and to understand the cytotoxic effect of each drug on HCT-116 cells, the MTT assay was carried out. Three known chemotherapeutic agents (5-FU, BCNU and Res) were chosen for experimentation (Figure 1A). The cells were treated for 48 h before the MTT assay. Figure 1A shows that increasing the concentrations of each drug increased cell death. 5-FU was the most effective among the three drugs and BCNU was the least effective. LC<sub>50</sub> was noted at 10 µmol/L 5-FU while 35 µmol/L Res and 60 µmol/L BCNU were needed to achieve the same amount of cell death (Figure 1A). Although 5-FU offered maximum cytotoxic effects on colon cancer cells, more than 50% of cells exhibited resistance<sup>[44]</sup>. To overcome such resistance and to increase the efficacy of Res, a combined treatment was employed comprising BCNU and Res. The BCNU concentration was kept constant at 20 µmol/L and varied concentrations of Res were added. The combination of BCNU with Res increased the sensitivity of HCT-116 cells. Fifty percent cell death was observed when 18 µmol/L Res was combined with 20 µmol/L BCNU (Figure 1B) ( $P < 0.05$ ).

### Detection of apoptosis in HCT-116 cells by DAPI staining

5-FU, BCNU and Res killed colon cancer cells, but to confirm whether the killing effect of the drugs was through apoptosis or necrosis, DAPI nuclear staining was performed. Figure 1C shows that the number of apoptotic nuclei increased with increasing concentrations of Res when combined with 20 µmol/L BCNU as compared with untreated cells. More than fifty percent apoptotic nuclei were observed when 20 µmol/L BCNU was associated with 15 µmol/L of Res. Figure 1D shows a graphical representation of the number of apoptotic and non-apoptotic nuclei ( $P < 0.05$ ).

### Combined effect of BCNU and Res caused DNA damage in HCT-116 cells

To determine whether a combination of BCNU and Res caused apoptosis through DNA damage or by another mechanism, we measured the DNA damaging efficiency of this combination in HCT-116 cells by DNA damage

**Figure 1** Anti-proliferative and apoptotic effect of 1,3-Bis(2-chloroethyl)-1-nitrosourea and/or resveratrol on HCT-116 colon cancer cells. **A:** Anchorage-dependent cell survival of HCT-116 cells after treatment with Res, 5-FU and BCNU; **B:** Bar diagram representing the % viability of HCT-116 after BCNU+ Res exposure. HCT-116 cells were cultured in 96 well plates and grown to 60%-70% confluence. The cells were then treated with different compounds according to the materials and methods. Data are the mean  $\pm$  SD of three different experiments. <sup>a</sup> $P < 0.05$  vs 20 μmol/L BCNU + 20 μmol/L Res; <sup>c</sup> $P < 0.05$  vs 20 μmol/L BCNU + 50 μmol/L Res; **C:** Apoptotic nuclei after 4',6'-diamidino-2-phenylindole hydrochloride staining. Images were taken using a fluorescent microscope (Nikon-Eclipse, Japan) at  $\times 40$  magnification. Arrows indicate the apoptotic nuclei. Data are the representation of one of the replicates of three different experiments; **D:** A graphical representation of apoptotic nuclei. <sup>a</sup> $P < 0.05$  vs 20 μmol/L BCNU + 20 μmol/L Res. 5-FU: 5-fluorouracil; Res: Resveratrol; BCNU: 1,3-Bis(2-chloroethyl)-1-nitrosourea.

assays (single cell gel electrophoresis or comet assay). The cells were pre-treated with 20 μmol/L BCNU for 24 h prior to exposure with various concentrations of Res for another 48 h. The comet formation and average comet length increased with increasing concentrations of Res (Figure 2A). Figure 2B shows the average comet length of combined treatment. Compared with untreated cells, the average comet length increased when Res was combined with BCNU (Figure 2B) ( $P < 0.05$ ). Thus, the data suggests that the DNA damaging effect of Res was magnified in presence of BCNU.

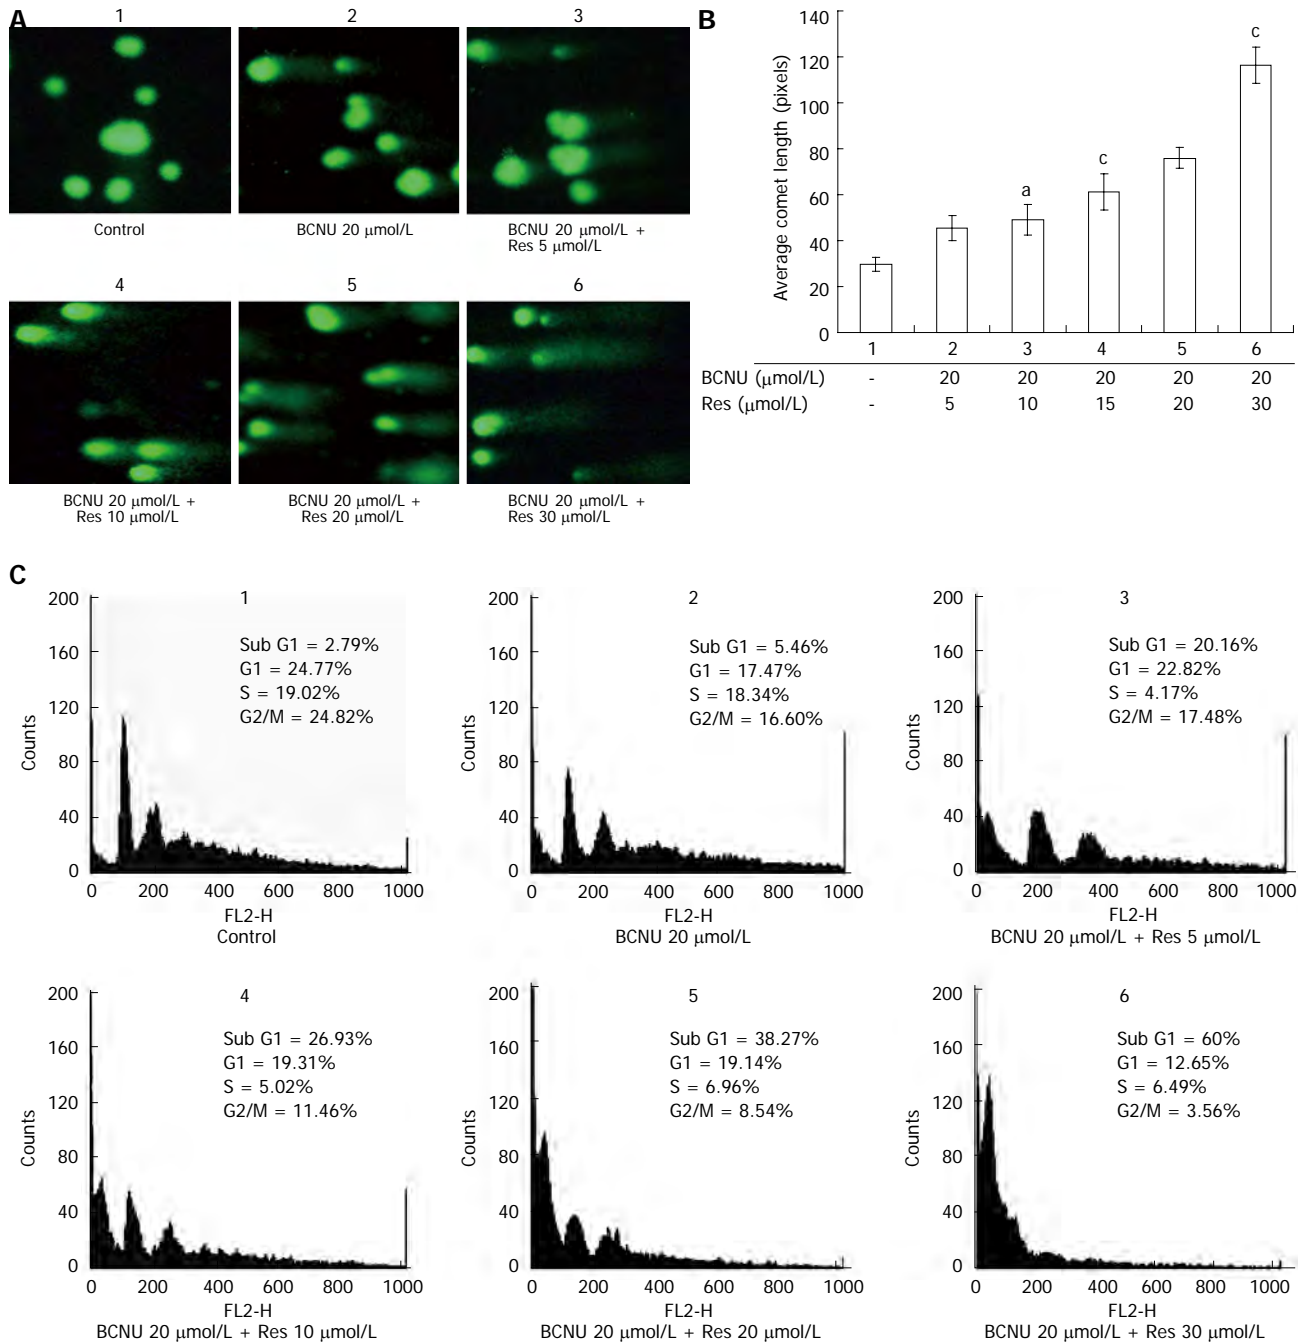

#### Effects of BCNU and Res on the cell cycle regulation and apoptosis of HCT-116

It was reported that Res halts the cell cycle at S phase in various cancer cells, such as breast, colon and pancreas<sup>[45-49]</sup>. Similarly, it was also reported that BCNU arrests the cell cycle in the G2/M phase transition<sup>[50]</sup>. To determine the regulation of cell cycle profile by BCNU

+ Res combination, we treated the cells with the above-mentioned drugs and performed FACS analysis at the end of the exposure. The percentages of G2/M population of cells decreased with increasing concentrations of Res combined with BCNU in comparison with the control (Figure 2C). The percentages of apoptotic cells (sub G1) population increased in a dose dependent manner with Res combined with a fixed concentration of BCNU. Interestingly, approximately 60% apoptosis was noted when 30 μmol/L Res was combined with 20 μmol/L of BCNU (Figure 2C).

#### Effects of BCNU and Res on the expression level of apoptotic markers in HCT-116 cells

The combined effect of BCNU and Res on apoptosis, cell cycle regulation and DNA damage repair proteins in HCT-116 cells was studied by measuring the protein expression levels of well known markers, such as Bcl-2-associated X protein (BAX), B-cell lymphoma-extra large

**Figure 2** Regulation of cell cycle and genotoxicity of HCT-116 cells after 1,3-Bis(2-chloroethyl)-1-nitrosourea and/or resveratrol treatments. **A:** Comet assay showing the DNA damaging effect of the drugs in HCT-116 cells. Images were taken using a fluorescent microscope (Nikon-Eclipse, Japan) at  $\times 20$  magnification. Data are the representation of one of the replicates of three different experiments; **B:** Bar diagram represents the average comet - length in pixels as obtained from TriTek CometScore™ software. After treatment as mentioned in the materials and method fluorescence-activated cell sorting analysis was performed and the DNA content of the cell was measured by Cell Quest Software (Becton and Dickinson, CA). Data are the representation of one of the replicates of three different experiments. 5-FU: 5-fluorouracil; Res: Resveratrol; BCNU: 1,3-Bis(2-chloroethyl)-1-nitrosourea.

(BCL-XL), Poly (ADP-ribose) polymerase (PARP), p21, proliferating cell nuclear antigen (PCNA), APE, phosphatase and tensin homolog (PTEN), FEN1 and human homolog of cyclin dependent kinase-2 (CDC-2) (Figure 3). The level of BAX increased compared with treatment with BCNU alone, whereas the level of BCL-XL decreased (Figure 3). The levels of CASPASE-3 and cleaved product of PARP also increased compared with BCNU alone (Figure 3). Thus, the data indicated that treatment

with the BCNU and Res combination results in apoptosis in HCT-116 cells, as reflected by the elevated BAX/BCL-XL ratio, PARP cleavage and CASPASE-3 expression (Figure 3).

#### Effects of BCNU and Res on the expression level of cell cycle regulatory and DNA repair proteins in HCT-116 cells

DNA damage repair proteins, such as FEN1, APE, and

**Figure 3** Combined effects of 1,3-Bis(2-chloroethyl)-1-nitrosourea and resveratrol on various cellular markers in HCT-116 colon cancer cells. Expression pattern of apoptotic, DNA damage/repair and cell cycle regulatory proteins after drug treatment. Data are the representation of one of the replicates of three different experiments. Glyceraldehyde phosphate dehydrogenase (GAPDH) served as a loading control. BAX: Bcl-2-associated X protein; BCL-XL: B-cell lymphoma-extra large; PARP: Poly (ADP-ribose) polymerase; PCNA: Proliferating cell nuclear antigen; PTEN: Phosphatase and tensin homolog; FEN1: Flap endonuclease 1; CDC-2: Cyclin dependent kinase-1; Res: Resveratrol; BCNU: 1,3-Bis(2-chloroethyl)-1-nitrosourea; APE: Apurinic/aprimidinic (AP) endonuclease.

PCNA, were assayed to determine the effects on DNA damage/repair in HCT-116 cells after BCNU and Res combination treatment (Figure 3). FEN1 and PCNA levels decreased when the dose of Res increased, whereas the level of APE remained almost constant during combination treatment (Figure 3). The cell cycle regulatory protein p21 and PTEN increased, while CDC-2 decreased, after combined treatment for 48 h. PTEN is considered to be a cell cycle regulatory tumor suppressor protein, and an increase in PTEN expression indicates the anti-tumor property of the combined drug. Increased p21 expression during the combination treatment indicated negative cell cycle regulation. A decrease in CDC-2 expression also indicated negative regulation of the cell cycle. Thus, these experiments demonstrated that treatment with a combination of BCNU and Res induced apoptosis in colon cancer cells by affecting cell cycle regulation and DNA damage/repair. Therefore, this novel drug combination can be used for treating 5-FU resistant cells.

#### **Establishment of a 5-FU-resistant stable cell line**

The 5-FU-R cell line was further characterized by measuring the expression pattern of anti-apoptotic, cell cycle and DNA damage repair proteins, such as nuclear factor kappa-light-chain-enhancer of nuclear factor  $\kappa\text{B}$  (NF $\kappa\text{B}$ ), FLICE-like inhibitory protein (FLIP), casein kinase 1 (CK1), disabled homolog 2 (DAB2), glycogen synthase kinase 3 beta (GSK-3 $\beta$ ), AKT, POLH, TS, POL- $\beta$ ,

DDB2, and FEN1, which were altered in stable cell line compared to normal HCT-116 cells (Figure 4). The expression levels of AKT, NF $\kappa\text{B}$ , FLIP, POLH, GSK-3 $\beta$ , POL- $\beta$ , DDB2, and FEN1 were increased in comparison with HCT-116 cells. However, the levels of CK1 and DAB2 expressions decreased compared with HCT-116 cells (Figure 4). Interestingly, widely established 5-FU resistance protein thymidylate synthase also increased in 5-FU-R cells compared with HCT-116 cells (Figure 4).

#### **Cytotoxicity of the BCNU and Res combination in 5-FU-R cells**

The experiments discussed above indicated that BCNU and Res combination significantly increased the sensitivity of HCT-116 colon cancer cells. To determine the optimum concentration of the BCNU and Res combination for cytotoxicity of 5-FU-R cells, an MTT assay was carried out. BCNU showed similar cytotoxic profile in 5-FU-R cells compared with HCT-116 cells (LC<sub>50</sub> 55  $\mu\text{mol/L}$ ) (Figure 5A); however, it was noted that 5-FU resistant cells were more sensitive to Res compared with HCT-116 parental cells. The LC<sub>50</sub> of Res in 5-FU-R cells was 18  $\mu\text{mol/L}$ , but was 35  $\mu\text{mol/L}$  in HCT-116 cells (Figure 1A *vs* Figure 5A). Interestingly, it was noted that there was little or no effect of 5-FU on 5-FU-R cells, even after treatment with 100  $\mu\text{mol/L}$  for 48 h (Figure 5A). This data suggests that 5-FU-R cells are resistant to 5-FU, but sensitive to other chemotherapeutic drug, such

**Figure 4 Characterization of 5-fluorouracil-resistant cells.** The cell lysates of HCT-116 and 5-FU-R cells were immunoblotted using specific antibody. The lower panel shows the expression of  $\beta$ -actin, which was the loading control (to ensure the same amount of protein loaded in each lane). Data are the representation of one of the replicates of three different experiments. CK1: Casein kinase 1; FLIP: FLICE-like inhibitory protein; NF $\kappa$ B: nuclear factor  $\kappa$ B; POL- $\beta$ : DNA polymerase beta; POLH: DNA polymerase eta; protein Flap FEN1: Endonuclease 1; DDB2: DNA damage-binding protein 2; 5-FU: 5-fluorouracil; Res: Resveratrol; BCNU: 1,3-Bis(2-chloroethyl)-1-nitrosourea; TS: Thymidylate synthase.

as Res.

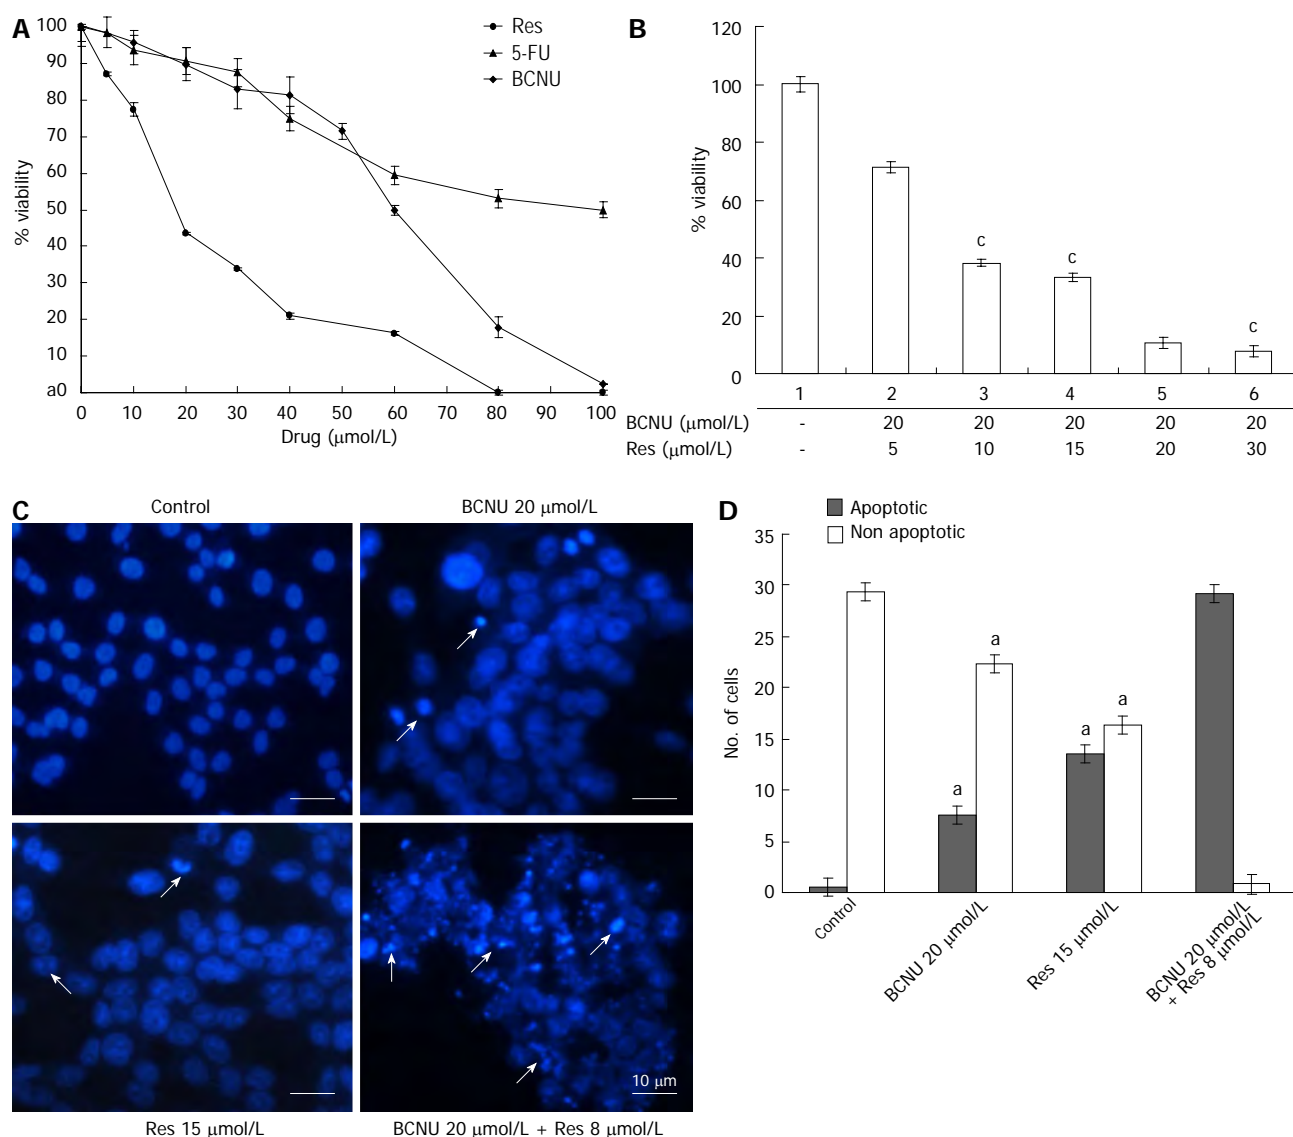

A dose dependent decrease in cell viability was observed when increasing concentrations of Res were added to the 20  $\mu$ mol/L BCNU pre-treated 5-FU-R cells (Figure 5B). Fifty percent cell death ( $LC_{50}$ ) was noticed when 8  $\mu$ mol/L of Res was combined with 20  $\mu$ mol/L of BCNU (Figure 5B) ( $P < 0.05$ ). Interestingly, it was noted that lower concentrations of Res were needed to cause fifty percent cell death in 5-FU-R cells compared with HCT-116 cells ( $LC_{50}$  for HCT-116 cells was 18  $\mu$ mol/L vs  $LC_{50}$  for 5-FU-R cells was 8  $\mu$ mol/L). Thus, it appeared that 5-FU-R resistant cells (Figure 5B) were more susceptible than HCT-116 cells (Figure 2B) to the BCNU and Res combination.

Apoptosis of 5-FU-R cells was measured by DAPI nuclear staining after exposure to the optimum formulation (BCNU 20  $\mu$ mol/L + Res 8  $\mu$ mol/L), BCNU and

Res. Although treatment with BCNU and Res alone caused cell death, increased cell death was observed by treatment with the combination compared with BCNU and Res alone (Figure 5C). However, Res alone caused more apoptosis than BCNU alone (Figure 5C). Figure 5D shows the graphical representation of the number of apoptotic and non-apoptotic nuclei ( $P < 0.05$ ).

#### **Combined effect of BCNU and Res caused increased DNA damage, and decreased cell cycle regulatory protein expression and apoptosis in 5-FU-R cells**

To elucidate the underlying mechanism of the sensitivity 5-FU-R cells to the BCNU and Res combination, a series of experiments were carried out. To determine whether the BCNU and Res combination caused DNA damage, a comet assay was performed after treatment with BCNU 20  $\mu$ mol/L + Res 8  $\mu$ mol/L for 48 h. The average comet length and number of comets increased with the combination treatment compared with BCNU and Res alone or untreated cells (Figure 6A). Figure 6B shows the average comet length, in pixels, of 5-FU-R cells treated with BCNU and Res alone and in combination [BCNU (20  $\mu$ mol/L) + Res (8  $\mu$ mol/L)] ( $P < 0.05$ ). The average comet length almost doubled when 8  $\mu$ mol/L of Res was combined with BCNU compared with BCNU alone. The percentage of apoptosis and cell cycle profile cells were also measured by FACS analysis after treatment with the combined drugs (Figure 6C). Increased accumulation of the G<sub>2</sub>/M (24%) population was noted after the BCNU treatment in comparison to Res (19.33%) and untreated cells (10%). Interestingly, the increase in G<sub>2</sub>/M population decreased when Res was combined with BCNU; however, the observed percentage of apoptosis (sub G<sub>1</sub>) was as high as 70%. To further confirm the apoptosis and to determine the status of various protein biomarkers, Western blotting was carried out. Figure 6D shows the expression patterns of apoptotic markers, such as cleaved product of PARP, BAX, CASPASE-3 and BCL-XL. The cleaved product of PARP and the BAX/BCL-XL ratio increased with increasing concentration of the combined drug. Cell cycle regulatory proteins, such as p21 and PTEN increased, while CDC-2 decreased after combined treatment for 48 h, indicating that this drug combination has adverse effect on cell cycle regulation in the 5-FU-R cells. Figure 6E represents the expression pattern of DNA repair proteins when treated with the combined drug and Res and BCNU alone. The levels of FEN1, POLH, DDB2 and POL- $\beta$  were decreased in cells that were treated with BCNU and Res alone compared with the control, but the combination treatment showed a radical decrease in the levels of these proteins compare with the control and treatment with each drug alone (Figure 6E). Interestingly, the level of tumor suppressor and DNA repair protein APC was completely abolished after individual (BCNU and Res) treatment, but increased after combined drug exposure compared with untreated cells. This result clearly indicates that the BCNU and Res works additively or synergistically and their mode of ac-

**Figure 5** Anti-proliferative and apoptotic effect of 3-Bis(2-chloroethyl)-1-nitrosourea and/or resveratrol on 5-fluorouracil-R cells. tion was to modulate DNA damage/repair pathway.

### BCNU and Res synergistically increase the sensitivity in human colon cancer cells

The above data showed that the BCNU and Res combination increased the sensitivity of colon cancer cells. To determine whether these two drug work additively or synergistically, we performed isobologram analysis. Figure 6F shows the occurrence of a synergistic interaction of Res and BCNU in both the HCT-116 and 5-FU-R cell lines. The  $\text{LC}_{50}$  value of the Res and BCNU in HCT-116 cells were 30 and 60  $\mu\text{mol/L}$ , respectively, but for the combination, fifty percent cell death occurred at 20  $\mu\text{mol/L}$  BCNU and 18  $\mu\text{mol/L}$  Res (Figure 2B), which were much lower than dose of each individual drug (point Q). Point Q appeared below the lines, which suggested a

synergistic interaction of these drugs. To further investigate the synergistic interaction of these drugs against the 5-FU-R cells, the same isobologram was plotted using the  $\text{LC}_{50}$  value of MTT data from Figure 5B. Interestingly, the fifty percent cell death (point P) with the combined drug appeared below the line, clearly indicating synergistic activity of BCNU and Res in 5-FU-R cells (Figure 6F).

## DISCUSSION

5-FU is widely used for the treatment of many types of cancers, including colorectal, breast, and cancers of the aerodigestive tract. Notably, 5-FU is routinely employed in the management of colorectal cancer *via* one of the two FDA-approved first line combinatorial chemothera-

The point P and Q represent the 50% cell death of the combined drug in case of 5-FU-R and HCT-116 cells, respectively. 5-FU: 5-fluorouracil; Res: Resveratrol; BCNU: 1,3-Bis(2-chloroethyl)-1-nitrosourea.

py regimes, which involve intravenous administration of the fluorinated base analog<sup>[10,11]</sup>. One problem with 5-FU treatment is that more than 50% of tumors demonstrate resistance to 5-FU in the clinical setting. Thus, novel treatments are needed to treat these resistant tumors. Novel biological agents, such as the monoclonal antibodies Cetuximab (an epidermal growth factor receptor inhibitor) and Bevacizumab (a vascular endothelial growth factor inhibitor), have recently been shown to provide additional clinical benefit for patients with metastatic colorectal cancer. However, these agents have demonstrated marginal results when treating resistant tumors<sup>[51,52]</sup>.

During the past few decades, investigators have attempted to elucidate the mechanism underlying 5-FU resistance<sup>[10-12]</sup>. Some investigators developed 5-FU resistant cell lines and studied their sensitivity to multiple chemotherapeutic agents by activation and inhibition of several signaling pathways<sup>[53,54]</sup>. Unfortunately, none of these agents showed promising results.

In the present report, we developed a new strategy for overcoming 5-FU resistance by establishing 5-FU-R cell lines and studying their sensitivity to a combination treatment with BCNU and Res. BCNU and Res display anti-cancer properties by inducing DNA damage, arresting cell cycle progression, inhibiting anti-apoptotic makers and autophagy<sup>[13,28]</sup>. We have shown recently that moderately low concentration of 5-FU (0.5  $\mu\text{mol/L}$ ) increased chemoprevention potential of Res in colon cancer cells<sup>[7]</sup>. However, in that report we could not eliminate the probability of 5-FU resistance because of presence of 5-FU. Thus, that cocktail will not be appropriate for the treatment of 5-FU resistance patients. In the present study, we treated the cells with BCNU and Res to increase the sensitivity of 5-FU resistant cell lines. Initially, we

checked whether BCNU and Res combination increase the sensitivity of 5-FU sensitive HCT-116 cells. LC<sub>50</sub> was observed at 60  $\mu\text{mol/L}$  BCNU and 35  $\mu\text{mol/L}$  Res; however, the same amount of cell death was observed when 18  $\mu\text{mol/L}$  Res was combined with 20  $\mu\text{mol/L}$  BCNU. Reduction of both BCNU and Res concentration for fifty percent cell death revealed that BCNU and Res killed HCT-116 colon cancer cells synergistically (Figure 1B). The isobologram data (Figure 6F) also support the synergistic action of BCNU and Res to kill colon cancer cells.

Cell death associated with the synergistic effects of treating cells with a combination of BCNU and Res was further confirmed by multiple parameters, such as DAPI nuclear staining, comet assay, FACS analysis and measuring the expression patterns of several DNA damage/repair, cell cycle regulatory and apoptosis related protein biomarkers. Increased numbers of apoptotic nuclei after DAPI stain, average comet formation and comet length, percentage of sub G<sub>1</sub> population were observed after combined treatment (BCNU + Res) in HCT-116 cells. An increased ratio of BAX/BCL-XL, cleaved product of PARP, tumor suppressor PTEN, cell cycle regulatory protein p21, and CASPASE-3 were also noted in BCNU and Res combination. Thus, the data suggests that the BCNU and Res combination represents a potential treatment option for 5-FU resistant colon cancer.

We have developed a 5-FU resistant cell line from 5-FU sensitive HCT-116 cells by continuous treatment with 5-FU. These cells were resistant to 5-FU, but sensitive to other chemotherapeutic agents, such as Res. The cell death effects of the BCNU and Res combination in the resistant cell lines were measured. MTT cell survival, DAPI nuclear staining and comet assays showed that the

BCNU + Res combination was highly effective to sensitize the 5-FU-R cells in comparison to individual compounds. They caused cell death synergistically. The FACS analysis showed approximately 70% cell death when 20  $\mu\text{mol/L}$  BCNU combined with 8  $\mu\text{mol/L}$  Res (Figure 6C). By contrast, approximately 60% cell death was observed when 20  $\mu\text{mol/L}$  of BCNU combined with 30  $\mu\text{mol/L}$  Res in HCT-116 sensitive cells. Increased percentages (70% *vs* 60%) of apoptosis even at lower concentration of Res (8  $\mu\text{mol/L}$  *vs* 30  $\mu\text{mol/L}$ ) indicated that Res was more effective to sensitize the 5-FU-R than HCT-116 cells when combined with BCNU. The expression of PARP cleaved product and BAX/BCL-XL ratio increased with the combined treatment (BCNU + Res) in 5-FU-R cells compared with Res and BCNU alone (Figure 6D). Isobologram analysis also indicated that BCNU and Res also killed the 5-FU-R cells synergistically.

To study the mechanism of action of the BCNU and Res combination, we have first analyzed whether the DNA damage/repair pathway was involved. Comet assays showed that the average comet length and comet formation increased in both 5-FU sensitive and resistant cell lines after treatment with the BCNU + Res combination. Interestingly, a much lower concentration of Res (8  $\mu\text{mol/L}$ ) was needed to cause the same comet length in 5-FU-R cells compared with 5-FU sensitive cells (Res 30  $\mu\text{mol/L}$ ) (Figure 2B *vs* Figure 6B). This observation suggests that Res was more effective in causing DNA damage in 5-FU-R cells than in 5-FU sensitive cells when associated with the same amount of BCNU. This data prompted us to check the level of DNA damage/repair related proteins after treatment with BCNU + Res in 5-FU-R cells. Interestingly, the major DNA repair proteins, such as FEN1, POLH, DDB2 and POL- $\beta$  decreased in case of combination treatment while the level of APC increased in comparison to the individual drug as well as untreated cells (Figure 6E).

Multiple pieces of evidence indicate that the repair of apurinic/apyrimidinic (AP)-sites in DNA occurs through two sub-pathways of BER, which differ on the basis of repair gap size and the enzymes involved in these repair pathways<sup>[55]</sup>. These sub-pathways are designated as “single-nucleotide BER” or “short patch (SP)-BER” and “multinucleotide BER” or “long patch (LP)-BER”. In both pathways, repair is started by removal of a damaged base by a DNA glycosylase leaving an abasic (AP-site) DNA. The resulting AP sites are subsequently acted upon by an APE to generate a 3' hydroxyl group and a 5'-deoxyribosephosphate (dRP) terminus. In SP-BER, Pol- $\beta$  extends the 3' terminus by a single nucleotide and removes the dRP moiety with its dRP lyase activity. Finally, the nick is sealed by DNA ligases<sup>[56]</sup>. However, the oxidized or reduced AP sites become resistant to  $\beta$ -elimination and cannot be excised by the dRP lyase activity of Pol- $\beta$ . Then the modified AP-site is repaired *via* the LP-BER pathway, in which Pol- $\beta$ ,  $\delta$  or  $\epsilon$  incorporates 2-15 nucleotides, displacing the strand containing the modified AP-site. Then, the DNA flap structure is

cleaved by FEN1, and the nick is sealed by a DNA ligase<sup>[57,58]</sup>. APC expression is induced in cancer cell lines upon exposure to DNA-damaging agents<sup>[39,40,59,60]</sup>, suggesting an interaction between APC and the DNA repair machinery. We have already shown that APC physically interacts with Pol- $\beta$ , FEN1 and blocks BER by blocking strand-displacement synthesis and then DNA repair<sup>[39-42]</sup>. Increased levels of APC and decreased levels of Pol- $\beta$  and FEN1 after combined treatment with BCNU + Res revealed that this cocktail kills cancer cells by inhibiting the BER pathway. Thus, the above result indicates that BCNU + Res in combination caused cell death through reduction of BER repair pathway. The possible cause of this effect might be activation of APC by the combination but not the individual treatments.

A new and emerging concept is to sensitize cancer cells to DNA-damaging agents by inhibiting various proteins in DNA repair pathways. Molecular docking or NMR studies identified small molecular weight inhibitors (SMIs) that target the BER pathway by inhibiting APE1 and Pol- $\beta$  activities<sup>[61]</sup>. Although a number of Pol- $\beta$  inhibitors have been reported in recent years<sup>[61,62]</sup>, more potent and selective inhibitors are still needed. Since abasic DNA damage (which may also be caused by BCNU) can also be repaired by LP-BER, there is a need for agents that can block the LP-BER pathway as well, in which 5'-flap endonuclease 1 (FEN1) plays a major role<sup>[63]</sup>. FEN1 recognizes and removes the 5'-flap structure generated by Pol- $\beta$  during the strand-displacement synthesis. The removal of this flap is essential for the joining of the newly synthesized DNA strand with the parent strand by DNA ligase to complete the repair. Interestingly, the FEN1 level decreased after BCNU and Res combination in both cell lines, indicating that the BCNU + Res combination inhibited the removal of flap from the newly synthesized step in LP-BER. BCNU + Res might cause more DNA damage that could not be repaired by the cells because of a lack of sufficient FEN1. This would result in mutations accumulating within the cells, eventually leading to apoptosis instead of survival. However, more study will be needed to understand the molecular mechanism involving the BER pathway triggered by the BCNU + Res combination.

In conclusion, this study showed that a combination of BCNU and Res could be useful to overcome 5-FU resistance in colon cancer patients. BCNU and Res caused apoptosis in both the HCT-116 cells and 5-FU-R cells by inhibiting the base excision repair, especially *via* the FEN1 protein of the LP-BER pathway. These findings represent a novel concept for overcoming 5-FU resistance in colon cancer patients.

## COMMENTS

### Background

Colon cancer is one of the most common causes of cancer-related death worldwide. 5-fluorouracil (5-FU) is a widely used chemotherapeutic drug for the treatment of colon cancer, but resistance to this drug is a barrier to successful chemotherapy.

## Research frontiers

1,3-Bis(2-chloroethyl)-1-nitrosourea (BCNU) is a synthetic drug commonly used to treat brain tumors as it can pass through the blood-brain barrier. BCNU is highly effective against cancer, but causes toxicity at very high concentrations. Resveratrol is a plant-derived compound used to treat various forms of cancer. Res has low toxicity and efficacy. Combining BCNU with resveratrol (Res) increases the efficacy of Res and reduces the toxicity of BCNU, making the combination an good tool to inhibit HCT-116 cells and overcome 5-FU resistance. Moreover, these drugs are DNA damage specific, resembling similar mechanism of action to that of 5-FU by reducing DNA repair components. Hence, these drugs were chosen for the combination therapy.

## Innovations and breakthroughs

This report highlighted the importance of combination therapy, which surpassed the monotherapy involving BCNU and Res to inhibit the growth of HCT-116 cells and overcome 5-FU resistance. This is the first study to report a combination of BCNU and Res for the treatment of colon cancer and to overcome 5-FU resistance effectively. The authors reported the mechanism of action of the combined drug, *i.e.*, inhibition of the DNA damage/repair pathway and arresting the cell cycle, thereby leading to apoptosis. The authors also reported that the drug to be more effective in the resistant cells than the normal cancer cells.

## Applications

This study highlights the action of BCNU combined with Res, which could prove to be a major tool for the treatment of 5-FU sensitive/resistant colon cancer patients and could also be tested for its ability to overcome resistance to other drugs, as this cocktail had specificity towards drug resistant cells.

## Terminology

BCNU is a common synthetic alkylating chemotherapeutic agent belonging to the family of haloethylnitrosoureas. Resveratrol is a polyphenolic phytoalexin widely available in plants, such as red grapes.

## Peer review

The research work in this manuscript is about the tumor suppression action of BCNU in combination with resveratrol on 5-fluorouracil HCT-116 cell lines, which were made resistant to 5-FU on constant exposure of 5-FU. The study is interesting and well executed. The point is clearly made.

### Abstract

**AIM:** To investigate whether an ablative margin (AM)  $> 1.0$  cm might reduce chance of recurrence for patients with hepatocellular carcinoma (HCC) tumors 3.1 to 5.0 cm in size, compared with an AM of 0.5-1.0 cm.

**METHODS:** From October 2005 to December 2012, 936 consecutive patients with HCC who received radiofrequency ablation were screened. Of these, 281 patients, each with a single primary HCC tumor of 3.1 to 5.0 cm in size on its greatest diameter, were included in the study. Based on the AM width, we categorized patients into the 0.5-1.0 cm group and the  $> 1.0$  cm

group. Local tumor progression (LTP)-free survival, intrahepatic distant recurrence (IDR)-free survival and overall survival (OS) rates were obtained using the Kaplan-Meier method.

**RESULTS:** The 1-, 2-, 3-, 4-, and 5-year LTP-free survival rates and IDR-free survival rates were significantly higher in the  $> 1.0$  cm group compared with the 0.5-1.0 cm group (97.5%, 86.3%, 73.6%, 49.5% and 26.4% vs 91.3%, 78.4%, 49.5%, 27.8%, and 12.8%; 95.1%, 90.3%, 77.0%, 61.0% and 48.3% vs 95.2%, 85.9%, 62.6%, 47.2% and 28.5%;  $P < 0.05$ ). The 1-, 2-, 3-, 4-, and 5-year OS rates were 98.6%, 91.5%, 69.2%, 56.0% and 42.2%, respectively, in the 0.5-1.0 cm group and 100%, 98.9%, 90.1%, 68.7% and 57.4%, respectively, in the  $> 1.0$  cm group ( $P = 0.010$ ). There were no significant differences in complication rates between the two groups. Both univariate and multivariate analyses identified AM as an independent prognostic factor linked to LTP, IDR, and OS.

**CONCLUSION:** For HCC tumors  $> 3.0$  cm and  $\leq 5.0$  cm, AM  $> 1.0$  cm could reduce chances of recurrence compared with AM of 0.5-1.0 cm, emphasizing the need for a more defensive strategy using AMs  $> 1.0$  cm for ablating HCC tumors of 3.1 to 5.0 cm.

**Key words:** Hepatocellular carcinoma; Radiofrequency ablation; Ablative margin; Recurrence; Survival

**Core tip:** Recurrence is the most important factor for prognosis of hepatocellular carcinoma (HCC) after radiofrequency ablation. Although a sufficient ablative margin (AM) is an essential way to minimize recurrence risk, the optimal AM for HCC tumors 3.1 to 5.0 cm remains controversial. This study provides evidence

that, for HCC tumors 3.1 to 5.0 cm, AMs > 1.0 cm could reduce chance of recurrence compared to AMs of 0.5-1.0 cm, which emphasizes the need for more strategic AMs that are > 1.0 cm for ablation of HCC tumors of 3.1 to 5.0 cm.

Radiofrequency ablation of hepatocellular carcinoma sized > 3 and  $\leq$  5 cm: Is ablative margin of more than 1 cm justified? *World J Gastroenterol* 2013; 19(42): 7389-7398 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7389.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7389>

## INTRODUCTION

Radiofrequency (RF) ablation is accepted as a potentially curative treatment modality for hepatocellular carcinoma (HCC) at an early stage when transplantation and resection are precluded<sup>[1,2]</sup>. Local tumor progression (LTP) and intrahepatic distant recurrence (IDR) have been repeatedly found to be the most important prognostic factors, with the incidence rates of 2%-53% and 43%-53%, respectively<sup>[1,3-5]</sup>. LTP that occurs after complete RF ablation is widely considered to result from residual tumor cells in the peritumoral area, which contains microvascular invasion and satellite micronodules due to an insufficient ablative margin (AM), although there is a possibility of *de novo* occurrence at the site. Pathogenesis of IDR is thought to result from intrahepatic metastasis of the primary tumor, viable residual tumor or an HCC of multicentric origin<sup>[6,7]</sup>. Therefore, a sufficient AM that encompasses both the main tumor and the area of adjacent parenchyma containing microvascular invasion or satellite micronodules, should theoretically ensure pathologically complete ablation, and would thus be an essential way to minimize risk of LTP and IDR<sup>[8,9]</sup>.

The optimal safe AM for HCC is controversial<sup>[3,10-12]</sup>. Accumulating data have demonstrated that recurrence rates, such as LTP rates, differ greatly for tumors of various sizes but similar AMs<sup>[3,13]</sup>. For HCCs  $\leq$  3.0 cm, the 3-year LTP rates for patients treated by RF ablation with AMs of 0.5-1.0 cm are reportedly 10%-20%<sup>[3,14-17]</sup>. However, for HCC tumors 3.1 to 5.0 cm treated with AMs of 0.5-1.0 cm, the 3-year LTP rates were as high as 39%<sup>[18]</sup>. This can be well explained by the data from histopathological investigations on both the scope of peritumoral microvascular invasion and satellite micronodules and the incidence rate between HCCs  $\leq$  3.0 cm and those > 3.0 cm<sup>[19,20]</sup>. Only 14.5%-19% of single small HCC ( $\leq$  3.0 cm) reportedly have satellite micronodules, located within 1.0 cm from the main tumor<sup>[21]</sup>. In contrast, for HCC tumors 3.1 to 5.0 cm, 26.3%-36.9% had peritumoral satellite micronodules, located more than 1.0 cm from the main tumor in most cases<sup>[9]</sup>. These data indicate that for HCCs  $\leq$  3.0 cm, AMs of 0.5-1.0 cm are likely to remove most peritumoral lesions. However, for HCC tumors 3.1

to 5.0 cm, AMs of  $\leq$  1.0 cm seem insufficient to ensure pathological complete tumor clearance in most cases.

Although the idea that AMs > 1.0 cm would be more likely to completely delete tumor tissues seems intuitively logical, no study to date has been conducted to determine the optimal AM for HCC tumors 3.1 to 5.0 cm. Based on the experience of the surgical requirement of a tumor-free margin  $\geq$  1.0 cm wide<sup>[9]</sup>, we supposed that for HCC tumors 3.1 to 5.0 cm, AMs > 1.0 cm might reduce chance of recurrence compared with AMs of 0.5-1.0 cm. Therefore, the purpose of this study was to elucidate the survival benefit of AMs wider than 1.0 cm for HCC tumors 3.1 to 5.0 cm.

## MATERIALS AND METHODS

### Patients

To determine whether AMs > 1.0 cm in RF ablation for HCC tumors 3.1 to 5.0 cm might greatly reduce chance of recurrence compared with AMs of 0.5-1.0 cm, a prospective cohort study was performed. From October 2005 to December 2012, 936 consecutive patients with HCC received RF ablation at the Department of Hepatobiliary Surgery, Beijing Chao-yang Hospital Affiliated to Capital Medical University, China. Among them, 327 patients suffered from a single primary HCC tumor each, 3.1 to 5.0 cm in diameter. Written informed consent was obtained from all patients. The study was approved by the investigation and ethics committee of Beijing Chao-yang Hospital, Capital Medical University according to the standards of the Declaration of Helsinki.

Among the 327 HCC patients, 291 who met the inclusion criteria were enrolled in this study. The inclusion criteria were (1) a single primary HCC tumor 3.1 to 5.0 cm at its greatest diameter on preoperative investigations; (2) no other therapy prior to RF ablation except for trans-arterial chemoembolization (TACE); (3) getting imaging-complete ablation with AM  $\geq$  0.5 cm after RF ablation; (4) no other therapy in the period of follow-up except for RF ablation or TACE for LTP or IDR; and (5) complete follow-up data. The exclusion criteria were (1) extrahepatic metastasis before LTP or IDR; and (2) follow-up period less than 6 mo. A total of 10 patients were excluded from the study for developing extrahepatic metastasis before LTP or IDR ( $n = 7$ ), or follow-up period less than 6 mo ( $n = 3$ ). The remaining 281 patients were included in this study (Table 1). There were 195 men and 86 women. Their median age was 52 years (range, 24-88 years). Of these, 231 (82.2%) were positive for serum hepatitis B virus surface antigen, 18 (6.4%) positive for serum HCV antibody, and 2 (0.7%) positive for both. Liver cirrhosis was observed in 92 patients (32.4%). In 126 of the 281 patients, preoperative diagnosis of HCC was histologically confirmed by needle biopsy under CT guidance. In the remaining 155 patients, HCC was established on the basis of compatible radiological features in contrast-enhanced multiphase helical CT scan and dynamic contrast-enhanced MRI. The median diameter of

the HCC nodules was 4.1 cm (range: 3.1-5.0 cm). Tumor location was described according to Couinaud segmental anatomic classification. Liver function was classified according to the Child-Pugh classification. In all, 136 (48.4%) and 145 (51.6%) showed Child-Pugh classes A and B, respectively. Randomization was not performed in this study. The aim of this study was explained to all of the approved patients in advance, and safe AMs > 1.0 cm were tried in all patients, although AMs of  $\geq$  0.5 cm are routinely considered adequate. On the basis of their AMs, we categorized patients into 2 groups: the 0.5-1.0 cm group and the > 1.0 cm group. Their demographic characteristics are shown in Table 1. The treatment algorithm of the present study is depicted in Figure 1.

### TACE

In the study, TACE was performed in all patients, both for radiological assessment of AMs, and for oncological purposes, 2-3 wk before RF ablation by two interven-

**Figure 1** Flow diagram of the enrollment and follow-up. A total of 281 patients met the inclusion criteria. HCC: Hepatocellular carcinoma; RF: Radiofrequency; TACE: transcatheter arterial chemoembolization; AM: Ablative margin.

tional radiologists (YM Zhou and K Gao) with a standard regimen. TACE was performed through the femoral artery using the technique of Seldinger under local anesthesia<sup>[22]</sup> by injecting 6-10 mL of an emulsion of iodized oil (Lipiodol; Aulnay-Sous-Bois, France) and 20-40 mg of epirubicin hydrochloride (Zhejiang Haizheng, China) into the tumor feeding arteries. The selected doses of iodized oil and anticancer drug were individually based on the patient's liver function and tumor size. Injection was discontinued upon full accumulation of iodized oil into the tumor vessels. No gelatin sponge was used after TACE.

### RF ablation

A percutaneous approach was most commonly preferred in this study. Laparoscopic RF ablation was considered in the presence of the following: (1) tumors on the liver edge or surface, protruding out of the liver; (2) tumors located in the left lobe, under the bottom of the heart, for which percutaneous RF ablation might cause heart injury; or (3) tumors close to visceral organs, such as the gallbladder, small and large bowels, and stomach. If other intra-abdominal procedures were planned, then open RF ablation was used.

Percutaneous RF ablation was performed under CT guidance (GE Yokogawa Medical Systems Ltd, Tokyo, Japan). To ensure the safety and tolerance of patients, each patient had respiratory control with a tracheal tube or a laryngeal mask airway under intravenous anesthesia during RF ablation procedure. This relatively more invasive protocol also helped improve targeting accuracy by providing a transient stop of respiration at end expiratory status during the procedures of planning and

**Figure 2** Three-dimensional computed tomography for radiofrequency ablation imaging in a patient with hepatocellular carcinoma. A: The computed tomography (CT) images prior to the second radiofrequency (RF) ablation; B: The CT images after the second RF ablation. 1: Axial plane; 2: Coronal plane; 3: Sagittal plane. The ablative margin is  $< 0.5$  cm prior to the second RF ablation, and it has been ablated to  $\geq 0.5$  cm after the second RF ablation. Black arrow indicates the shortest width of the area of low density outside the iodine stained tumor.

targeting. Laparoscopic RF ablation and open RF ablation were performed with laparoscopic and open surgery techniques as usual with laparoscopic and intraoperative ultrasonographic assistance. All RF procedures in this study were performed using either a 15-gauge multitined electrode (Starburst XL; RITA Medical Systems, Manchester, GA, United States) or Cool-tip ACTC2025 or ACTC1525 electrodes, and an RF generator (RITA 1500; RITA Medical Systems Inc, Manchester, GA, United States or Covidien Healthcare, Ireland), according to their respective manufacturers' protocols. For patients treated with multitined expandable electrodes, when needle arrays are introduced into the tumor and positioned satisfactorily, the RF generator produces RF energy and maintains an average temperature of  $105^{\circ}\text{C}$ . A series of arrays, radiating from the central hollow probe, are pushed forward and unfolded gradually to 3, 4, or 5 cm until they reach the borders of the tumor. RF energy is delivered at 5-min intervals until the output power drops below 30 W in the final step of the procedure. For patients treated with Cool-tip electrodes, the RF generator (Covidien Healthcare, Ireland) was used. Unlike the RITA electrode, the Cool-tip electrode is straight, without arrays. With a 2.5 cm exposed tip, the Cool-tip electrodes can produce ablation zones of 4.5 cm with a single placement of electrodes and a maximum power of 200 W. Also, the Cool-tip RF generator continuously monitors tissue impedance throughout the procedure

and adjusts the output accordingly. For this application, the ablation protocol was preset to the automatic mode, and ablation usually was carried out for 15 to 20 min, which was a little bit longer than that suggested in the manufacturer's protocol, with the intent of attaining a satisfactory degree of tumor collapse. Cold saline continuous irrigation of the needle was provided with an external pump. In the clinical settings, we selected the type of electrode depending on the size, geometry and location of the index tumor. A multiple-overlapping ablation technique was adopted for pursuing AMs  $\geq 0.5$  cm. Electrode track ablation technique was also performed to minimize post-procedural bleeding and tumor seeding.

#### Post-treatment assessment

For post-treatment evaluation, contrast-enhanced CT scans were performed 1 mo after the procedure in all cases. The initial unenhanced CT acquisition was followed by enhanced acquisitions obtained at 30 and 70 s after the bolus administration of intravenous contrast material. The contrast agent used was 100 mL iopamidol (Iopromide Injection, Bayer Schering Pharma, Guangzhou, China). Any contrast-enhancing areas beyond the margin of the ablation zone on post-ablation CT indicated incomplete tumor ablation. Additional sessions were scheduled for ablation of residual tumors. The diagnosis and treatment procedures were repeated until imaging

**Table 2** Comparison of the recurrence pattern between the 0.5-1.0 cm group and > 1.0 cm group *n* (%)

Recurrence pattern	0.5-1.0 cm group ( <i>n</i> = 158)	> 1.0 cm group ( <i>n</i> = 123)	<i>P</i> value <sup>1</sup>
LTP only	74 (46.8)	39 (31.7)	0.01
IDR only	34 (21.5)	22 (17.9)	0.45
LTP + IDR	38 (24.1)	16 (13.0)	0.02
Total LTP	112 (70.9)	55 (44.7)	< 0.001

<sup>1</sup>Fisher's exact test. IDR: Intrahepatic distant recurrence; LTP: Local tumor progression.

complete ablation was achieved (Figure 1).

### Evaluation of ablative margin

Three-dimensional reconstructions of CT images were made before and after RF ablation (Figure 2). To define the AM as accurate as possible, we performed qualitative side-by-side comparison of CT scans obtained before and after RF ablation. Two radiologists (Cao BX and Qian XJ) who were blind to the results of quantitative analysis assessed in consensus whether an AM of 0.5-1.0 cm or > 1.0 cm was achieved in each case. For this analysis, the adjacent hepatic vessels or the hepatic capsule were used to facilitate comparison. The variation between the two radiologists' findings was < 5%. In the evaluation, the AM was defined as the narrowest width of the area of low density outside the iodine stain (Figure 2). When the iodine stain in the tumor was not uniform, measuring AM was more difficult. In such instances, when the radiologists did not concur (*n* = 11), we compared carefully the imaging data before and after RF ablation, outlined the contours of the tumor in this area and measured AM according to the tumor contour rather than the edge of the iodine stain.

### Follow-up

The follow-up protocol mainly included routine physical examination, laboratory tests, and measurement of AFP levels every month, as well as dynamic CT studies every 2 or 3 mo. Definitions are based on the standardization by the International Working Group on Image-Guided Tumor Ablation<sup>[23]</sup>. LTP was defined by the presence of a nodular lesion that was enhanced during the hepatic arterial phase and washed out by the delayed phase, and was found along the peripheral margin of the low-attenuated ablative zone. IDR was defined by a lesion with similar characteristics but not in contact with the original ablation zone in the liver. Overall survival (OS), defined as the interval between date of initial therapy and date of death or the last follow-up examination for living patients, was also evaluated.

In cases of LTP or IDR, other supplemental examinations like hepatic DSA, Lipiodol CT of the liver, CT of the chest and lower abdomen, and bone scintigraphy were performed for other potential tumor nodules.

When LTP or IDR was confirmed, patients were hospitalized as soon as possible. Basically, repeat RF ablation treatment cycles were administered for LTP and IDR of ≤ 4 nodules. Five or more IDR nodules, or nodules in unsuitable locations for RF ablation, were treated with TACE. TACE was performed through the femoral artery using the aforementioned technique.

### Complications

Major complications were assessed on the basis of the previously described guideline for image-guided tumor ablation<sup>[23]</sup>. Complication rates were evaluated for the total number of ablation sessions. We defined a major complication as an event that led to substantial morbidity and disability, increased the level of care required, resulted in hospital admission, or substantially lengthened the hospital stay. All other complications were considered minor.

### Statistical analysis

Continuous data are expressed as median and range. Comparisons were made with the Mann-Whitney *U* test. Categorical data were compared using the Fisher's exact test. Rates of LTP-free survival, IDR-free survival and OS rates were calculated by the Kaplan-Meier method and compared using the log-rank test. Risk factors for LTP, IDR and overall survival were evaluated by univariate analyses using Cox regression tests. If multiple risk factors were shown to be significant by this test, we performed multivariate analysis using Cox regression tests to identify independent prognostic factors for LTP, IDR and OS. All statistical analyses were performed using the SPSS 15.0 statistical software (SPSS Inc., Chicago, Illinois, United States). All reported *P* values were 2-sided. *P* < 0.05 was considered statistically significant.

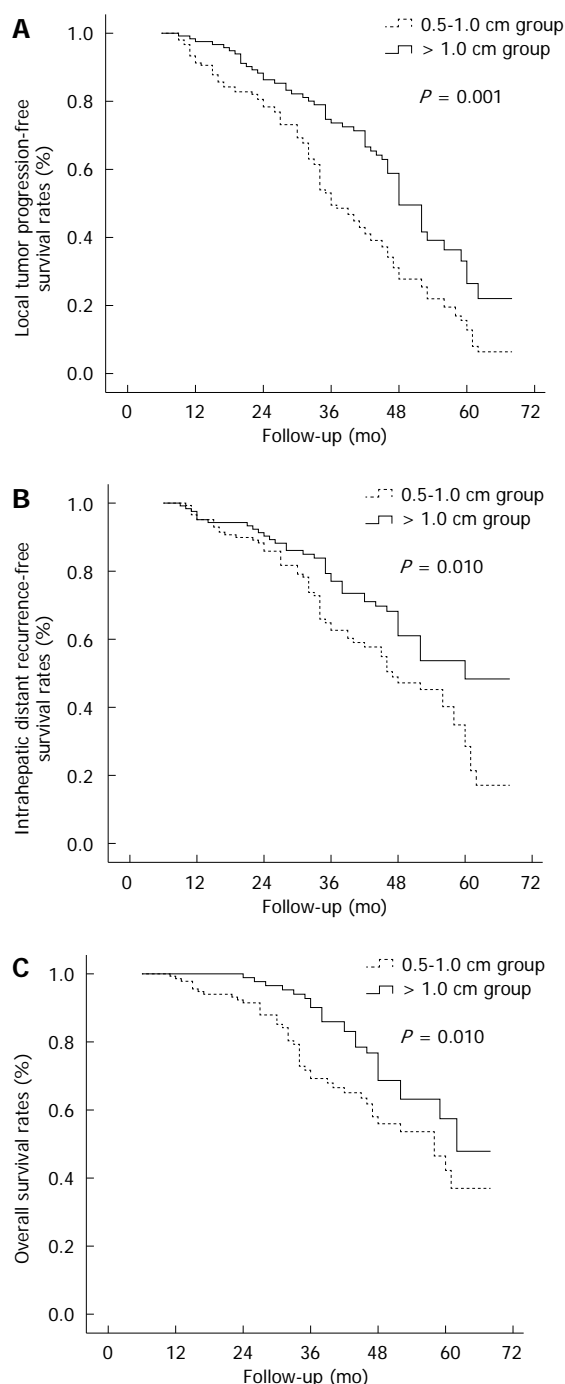

## RESULTS

### LTP-free survival

During the follow-up, LTP was found in 112 (70.9%) of 158 patients in the 0.5-1.0 cm group and in 55 (44.7%) of 123 patients in the > 1.0 cm group (*P* < 0.001) (Table 2). The rates of LTP-only and total LTP in the 0.5-1.0 cm group (46.8% and 70.9%, respectively) were significantly higher than those in the > 1.0 cm group (31.7% and 44.7%, respectively, *P* = 0.010 and < 0.001, respectively). The 1-, 2-, 3-, 4-, and 5-year LTP-free survival rates were 91.3%, 78.4%, 49.5%, 27.8% and 12.8%, respectively, in the 0.5-1.0 cm group and 97.5%, 86.3%, 73.6%, 49.5% and 26.4%, respectively, in the > 1.0 cm group (Figure 3A), and differed significantly between the two groups (*P* = 0.001).

### IDR-free survival

During the follow-up, IDR was found in 72 (45.6%) of 158 patients in the 0.5-1.0 cm group and 38 (30.9%) of 123 patients in the > 1.0 cm group (Table 2). There

**Figure 3** Kaplan-Meier analysis between the 0.5-1.0 cm group and the > 1.0 cm group. A: The local tumor progression-free survival rates; B: The intrahepatic distant recurrence-free survival rates; C: The overall survival rates.

was no significant difference in the rates of IDR-only between the 0.5-1.0 cm group and the > 1.0 cm group (21.5% *vs* 17.9%,  $P = 0.450$ ). However, the rates of total IDR in the 0.5-1.0 cm group was significantly higher than those in the > 1.0 cm group (45.6% *vs* 30.9%,  $P = 0.012$ ). The 1-, 2-, 3-, 4-, and 5-year IDR-free survival rates were 95.2%, 85.9%, 62.6%, 47.2% and 28.5%, respectively, in the 0.5-1.0 cm group and 95.1%, 90.3%, 77.0%, 61.0% and 48.3%, respectively, in the > 1.0 cm group (Figure 3B); the two groups differed statistically ( $P$

$= 0.010$ ).

### OS rates

As of December 2012 (with a median follow-up of 38.2 mo), 203 patients (72.2%) remained alive, and 78 (27.8%) had died, including 55 patients in the 0.5-1.0 cm group and 23 patients in the > 1.0 cm group. The cause of death was HCC in 58 patients (74.4%), liver failure in 7 (9.0%), upper gastrointestinal bleeding in 3 (3.8%), causes unrelated to liver disease in 4 (including 3 patients who died of cardiovascular disease and 1 of cerebral hemorrhage; 5.1%), and undetermined causes in 6 patients (who died in emergency situations at other hospitals without definite diagnoses related to death; 7.7%). The 1-, 2-, 3-, 4-, and 5-year OS rates were 98.6%, 91.5%, 69.2%, 56.0% and 42.2%, respectively, in the 0.5-1.0 cm group and 100%, 98.9%, 90.1%, 68.7% and 57.4%, respectively, in the > 1.0 cm group (Figure 3C); the two groups differed significantly ( $P = 0.010$ , log-rank test).

### Safety (complications)

No procedure-related death was observed. Major complications were observed in 5 (1.8%) of 281 patients. Of these, 2 patients in the 0.5-1.0 cm group and 1 patient in the > 1.0 cm group developed pneumothorax when laparoscopic RF ablation was performed. During the laparoscopic surgery, the presence of pneumothorax was confirmed immediately after the puncture of the RF probe. All of the pneumothorax was successfully treated by chest tube placement at the end of the operation. One patient in the 0.5-1.0 cm group suffered an intra-abdominal hemorrhage. He responded to transfusion of 2 units of packed red blood cells and required no other intervention. Two patients in the > 1.0 cm group developed hemopneumothorax and recovered from chest tightness and chest tube placement. Minor complications, including asymptomatic right pleural effusion, were noted within 3 d of the procedures in 13 patients of the 0.5-1.0 cm group and 15 patients of the > 1.0 cm group (0.5-1.0 cm group *vs* > 1.0 cm group,  $P = 0.271$ ); however, none of these patients required interventional-drainage procedures.

### Factors associated with LTP, IDR, and OS

Using univariate analysis, the tumor size (4.1-5.0 cm,  $P = 0.005$ ), AM (> 1.0 cm,  $P = 0.003$ ), AFP (> 200 ng/mL,  $P = 0.028$ ), and number of ablation sessions for imaging complete ablation (CA, 2 sessions,  $P = 0.031$ ) were found to be significant factors for predicting LTP, IDR, and OS (Table 3). In multivariate analyses of the 4 factors that were found to be significant in univariate analysis, the hazard ratios (HRs) for tumor size, AM, AFP, and number of ablation sessions for imaging CA are detailed in Table 4. Only the AM was found to be a significant independent factor linked to LTP, IDR, and OS.

<sup>1</sup>Cox regression analysis. LTP: Local tumor progression; IDR: Intrahepatic distant recurrence; OS: Overall survival; AFP:  $\alpha$ -fetoprotein; AM: Ablative margin.

## DISCUSSION

Over the past years, the rapid development and refinement of RF ablation technology has led to increasing use of this treatment modality in HCC patients<sup>[24]</sup>. Extensive clinical studies support RF ablation as a preferred treatment for very early HCC<sup>[25]</sup>. However, tumor recurrence, including LTP and IDR, frequently occurs, affecting the prognosis. Furthermore, rapid tumor progression after RF ablation, which may mostly be associated with the progression of residual HCC, has been gaining increasing attention<sup>[26-29]</sup>. These experimental data indicated that any residual tumors might be a disaster for individual HCC patients who received RF ablation. Thus, we should try to remove microvascular invasions and satellite micronodules around the main tumor of HCC to decrease the likelihood of residual tumor, the incidence rates of LTP, IDR and the rapid tumor progression.

From perspective of pathological clearance of the tumor tissue, AMs should be as wide as possible. How-

ever, correctly obtaining a sufficient AM around all sides of a tumor of medium size is not easy. Specifically, to get a 1.0-cm AM for lesions sized 3.0, 4.0 and 5.0 cm in diameters, the volumes of peritumoral tissue to ablate are 3.6, 2.4 and 1.7 times, respectively, the volume of the main tumor<sup>[30]</sup>. A little increase of the dimension of the ablation zone means a tremendous increase of the amount of ablation tissue. For example, if we increase the AM from 1.0 to 1.5 cm for a lesion of 4.0 or 5.0 cm in diameter, respectively, the amounts of tissue to ablate will be theoretically increased by as much as 58.8% and 49.3% respectively, and this does not take into account the increased difficulty and time to accomplish it. So we should balance the perfect AM standard against its feasibility in clinical practice. As a compromise settlement, we take an AM of more than 1.0 cm as a minimum requirement for HCC nodules of 3.1 to 5.0 cm.

Although an AM > 1.0 cm cannot guarantee that all peritumoral tumor tissues are ablated in all cases, 2 ways can be used to compensate for the conservativeness

of this standard. First, there may be some decrease in the size of the ablation zone due to tissue healing and scar formation when measured 1 mo after ablation and the real AM might be underestimated in some extent. Second, in our performance of RF ablation treatment, we took an AM of more than 1 cm thick as the least requirement and tried to make it as wide as possible.

The precise evaluation of AM after RF ablation is rather difficult, especially for HCC lesions of medium size or larger which did not get TACE/trans-arterial embolization (TAE) pretreatment<sup>[3]</sup>. First, AM area is not clearly visualized on images because both the ablated tumor and AM appear as areas that lack contrast enhancement. Second, AMs around tumors are usually not symmetrical and the measurement of AM by subtracting the diameter of the index tumor from that of ablation zone is not as precise as expected. So in the present study, all enrolled patients received TACE pretreatment, aiming to facilitate the evaluation of AM as precise as possible.

We demonstrated that tumor size, AM, AFP, and number of ablation sessions before getting an AM > 1.0 cm were significant risk factors for LTP, IDR, and OS of HCC after RF ablation, using univariate analysis. Our results were in line with those of previous studies on risk factors related to recurrence of HCC after RF ablation<sup>[11,31]</sup>. However, only AM was found to be a significant independent factor linked to LTP, IDR, and OS of HCC after RF ablation using multivariate analysis. These findings confirmed that AMs > 1.0 cm are an important predictive factor for recurrence of HCC tumors 3.1 to 5.0 cm after RF ablation. It is easy to understand that an AM > 1.0 cm can reduce rates of LTP and IDR and eventually increase OS rate. An AM > 1.0 cm can lead to a further clearance of possible residues of microvascular invasion and satellite micronodules by ablating more viable tumor containing liver parenchyma and decrease probability of metastasis of the residual tumor cell by intrahepatic portal vein.

We are aware of the limitations of this analysis. This study was not randomized. Moreover, the AM standard of 1.0 cm referred only to the safety margin for liver resection advocated by most surgeons. Also, the biological nature of HCC as a commonly accepted important risk factor was not demonstrated in this study due to the limited number of cases with pathological examination. One further limitation is the fact that this was a single-center study; these results might not be reproducible consistently in other settings. The results may be influenced by the physicians' expertise and the institution's volume of care. Nevertheless, our data may be helpful for clinicians who treat HCC with RF ablation and may also be useful as a basis for the design of future trials. Again, more prospective, large randomized studies are needed to assess the benefit of AMs > 1.0 cm for medium-sized HCC lesions in patients who receive RF ablation.

Notwithstanding its preliminary character, this study

does provide evidence that, for HCC tumors 3.1 to 5.0 cm, AMs > 1.0 cm could reduce chance of recurrence compared with AMs of 0.5-1.0 cm, which emphasizes the need for more defensive strategies in using AMs wider than 1.0 cm for ablation of HCC tumors 3.1 to 5.0 cm. However, confirmation in a prospective multicenter randomized trial is required.

## COMMENTS

### Background

Radiofrequency (RF) ablation is becoming accepted as a promising technique for treatment of patients with hepatocellular carcinoma (HCC). Recurrence of HCC after RF ablation occurs frequently and is associated with poor prognosis. A sufficient ablative margin (AM) is an essential way to minimize the risk of recurrence. However, the optimal AM for HCC tumors 3.1 to 5.0 cm in size is unclear.

### Research frontiers

Theoretically, AMs that encompass both the main tumor and an area of adjacent parenchyma that contains microvascular invasion or satellite micronodules, ensuring a pathological complete ablation, will minimize risk of tumor recurrence. A current research hotspot is to affirm that, for HCC tumors 3.1 to 5.0 cm, AMs > 1.0 cm reduce recurrence risk compared with AMs of 0.5-1.0 cm.

### Innovations and breakthroughs

Accumulating data show that the recurrence rates after RF ablation, such as local tumor progression (LTP) or intrahepatic distant recurrence (IDR) rate, are quite different in varied-sized tumors with similar AMs. For HCC tumors ≤ 3.0 cm, an AM of 0.5-1.0 cm may remove most peritumoral lesions. However, for HCC tumors 3.1 to 5.0 cm, AMs ≤ 1.0 cm seem insufficient to ensure pathological complete tumor clearance in most cases. In this study, we confirmed that AMs > 1.0 cm are an important predictor for recurrence of HCC tumors 3.1 to 5.0 cm after RF ablation.

### Applications

The study results provide evidence that, for HCC tumors 3.1 to 5.0 cm, AMs > 1.0 cm could reduce chances of recurrence compared with AMs of 0.5-1.0 cm, emphasizing the need for a more defensive strategy that used AMs > 1.0 cm for ablation of HCC tumors 3.1 to 5.0 cm.

### Terminology

LTP was defined by the presence of a nodular lesion that was enhanced during the hepatic arterial phase and washed out by the delayed phase and was found along the peripheral margin of the low-attenuated ablative zone. IDR was defined by a lesion with similar characteristics that did not contact the original ablation zone in the liver. Overall survival was defined as the interval between date of initial therapy and date of death, or the last follow-up examination for living patients.

### Peer review

This is a good prospective cohort study in which the authors analyzed the survival benefit of radiofrequency AMs > 1.0 cm for HCC tumors 3.1 to 5.0 cm. The results are interesting and suggest that for HCC tumors 3.1 to 5.0 cm, AMs > 1.0 cm could reduce chance of recurrence compared with narrower AMs of 0.5-1.0 cm, emphasizing the need for a more defensive strategy, using wider AMs > 1.0 cm for ablation of HCC tumors 3.1 to 5.0 cm.

### Abstract

**AIM:** To analyze the role of *rs12979860* and *rs8099917* polymorphisms in hepatitis C virus (HCV) genotype 1 infection of Brazilians.

**METHODS:** A total of 145 adult patients diagnosed with genotype 1 chronic hepatitis C (CHC) who had completed a 48-wk regimen of pegylated-interferon  $\alpha$ -2a or -2b plus ribavirin combination therapy were recruited from six large urban healthcare centers and 199 healthy blood donors (controls) from a single site between January 2010 and January 2012. Data on the patients' response to treatment was collected. Polymerase chain reaction-restriction fragment length polymorphism genotyping of the interleukin (*IL*)*28B* gene fragment encompassing the single nucleotide polymorphisms (SNPs) *rs12979860* (C/T) and *rs8099917* (T/G) was carried out for 79 of the CHC patients and 199 of the controls. Bi-directional amplicon sequencing of the two SNPs was carried out for the remaining 66 CHC patients.

**RESULTS:** SNP *rs12979860* genotyping was successful in 99.5% of the controls and 97.2% of the CHC patients, whereas the SNP *rs8099917* genotyping was successful in 95.5% of the controls and 100% of the

CHC patients. The genotype and allele distributions for both rs12979860 and rs8099917 were significantly different between the control and CHC patient groups, with significantly higher genotype frequencies of CC and TT in the controls ( $P = 0.037$  and  $0.046$ , respectively) and of TT and GG in the CHC patients ( $P = 0.0009$  and  $0.0001$ , respectively). Analysis of the CHC patients who achieved sustained virological response (SVR) to treatment ( $n = 55$ ) indicated that the rs12979860 C allele and CC genotype were predictors of SVR ( $P = 0.02$ ). No significant correlation was found between rs8099917 genotypes and treatment response, but carriers of the T allele showed significantly higher rates of SVR ( $P = 0.02$ ). Linkage disequilibrium analysis of the group that achieved SVR showed a significant association between rs12979860 and rs8099917 ( $P = 0.07$ ).

**CONCLUSION:** The higher allele frequency of rs12979860 C and rs8099917 T observed in non-HCV-infected individuals may indicate a potential protective role for these *IL28B*-related polymorphisms.

**Key words:** Hepatitis C; Interleukin 28B; Single nucleotide polymorphisms; Sustained virological response; Brazil

**Core tip:** This study investigated the differential distribution of interleukin 28B genetic variants between patients with chronic hepatitis C genotype 1 infection and non-infected healthy controls, and evaluated the association of these polymorphisms with patient response to standard antiviral therapeutic regimens. Genotype and allele frequencies of rs12979860 and rs8099917 were significantly different between the patients and controls, and the patterns suggested a potential protective role against hepatitis C virus infection. Finally, the rs12979860 CC genotype showed correlation to achievement of sustained virological response following pegylated-interferon/ribavirin-based therapy.

## INTRODUCTION

Hepatitis C virus (HCV) infection results in a broad spectrum of clinical outcomes and symptoms, ranging from spontaneous viral elimination to chronic infection and from jaundice to end-stage liver failure. Despite the

introduction of highly efficacious antiviral drugs based on viral protease inhibition, most countries continue to rely on the established combination therapy based on an immune-modulator plus an antiviral [most frequently pegylated-interferon  $\alpha$ -2a or -2b (PegIFN- $\alpha$ -2a/2b) and ribavirin (RBV)] even though this strategy is associated with high failure rates<sup>[1]</sup>. Studies to uncover the mechanisms underlying non-/low- or unsustained response to treatment have identified a number of contributing factors, related to both the virus itself (*i.e.*, genotype and viral load) and the host (*i.e.*, age, sex, ethnicity, concomitant liver fibrosis, and metabolic abnormalities<sup>[2,3]</sup>); thus, it is theorized that interaction between the virus and host genetics may be an important determinant of the natural history of HCV infection and may be predictive of therapy outcome.

A recent genome-wide association study (GWAS) of > 600000 polymorphisms in a cohort of HCV-infected patients found a single nucleotide polymorphism (SNP) on chromosome 19 associated with therapy response<sup>[4]</sup>. Subsequent GWAS studies implicated the rs8099917 (TG) polymorphism in the genetic region of this chromosome related to the interleukin (*IL*)28B gene and showed direct associations of the SNP to spontaneous clearance of HCV and treatment outcome<sup>[5,6]</sup>. Subsequent related studies have identified an additional *IL28B*-related SNP, rs12979860, and confirmed these two polymorphisms as strong predictors of therapy response and contributors to the epidemiological and ethnical distribution of HCV infection<sup>[7-9]</sup>. In addition, comparative analysis has identified significant differential prevalence profiles of these SNPs for HCV-infected patients and healthy controls<sup>[4]</sup>, suggesting potential roles for each in disease susceptibility and/or resistance.

The prevalence rate of HCV remains high in Brazil, particularly when compared to the other Latin American countries<sup>[10]</sup>, yet little data is available on the genetic variation profile of this disease in Brazilians. This study was designed to analyze the differential genotypic and allelic distributions of the *IL28B*-related SNPs, rs12979860 and rs8099917, in a cohort of Brazilian patients infected with HCV genotype 1 and healthy controls, as well as to investigate the potential association of these polymorphisms with treatment outcome.

## MATERIALS AND METHODS

### Patients

Between January 2010 and January 2012, adult patients who had undergone combination therapy for chronic infection with HCV genotype 1 [48-wk combination of PegIFN- $\alpha$ -2a/2b and RBV (15 mg/kg)] were recruited from the following six large urban healthcare centers: Hospital Municipal São José, Joinville/SC ( $n = 25$ ); Hospital Universitário Gaffrée Guinle ( $n = 26$ ) and Hospital Universitário Clementino Fraga Filho ( $n = 66$ ), Rio de Janeiro/RJ; Hospital da Universidade Federal de Pelotas ( $n = 12$ ), Pelotas/RS; Santa Casa de Misericórdia ( $n = 2$ ),

**Table 1** Demographic characteristics of the study participants

Characteristic	HCV ( <i>n</i> = 145)	Control ( <i>n</i> = 198)
Age (yr), mean $\pm$ SD	55.5 $\pm$ 10.0	32.2 $\pm$ 10.0
Sex, M/F	52%/48%	66%/34%
Skin color		
White	75.70%	88.00%
Black	19.20%	5.00%
Brown	5.10%	7.00%

HCV: Hepatitis C virus.

Porto Alegre/RS; and Hospital da Universidade Federal do Maranhão (*n* = 14), São Luis/MA. Patients with co-infection of hepatitis B virus or human immunodeficiency virus, or with any other concomitant chronic liver disease, were denied study enrollment. Blood sample and data on treatment outcome was collected for each enrolled patient. The treatment outcome of sustained virological response (SVR) was defined by a negative result for detection of serum HCV RNA at month six post-treatment. Patients who did not achieve SVR (including those who relapsed) were collectively categorized as non-responders (NR).

### Healthy controls

Healthy individuals presenting for blood donation at HE-MOSC Joinville/SC in 2010 were recruited for the study. Study enrollment was offered to individuals with no clinical or laboratory evidence of liver disease or other major pathological conditions. All enrolled controls were > 18 years old and lacked familial relationship.

### Racial classification

To phenotypically classify each study participant by race, we employed the criteria published by the Brazilian Institute of Geography and Statistics<sup>[11]</sup>; the skin color categories (white, brown, black, yellow, and Indian) were self-reported by each participant.

### Ethics statement

The study was approved by each of the participating healthcare center's Institutional Committees, which required adherence to the Brazilian normative for ethics in research. Informed consent was obtained from each participant before blood sampling.

### Genotyping methods

The HCV patients' blood samples were collected by finger puncture and stored as blots on FTA Elute Micro Cards<sup>®</sup> (Whatman, Kent, United Kingdom) for subsequent genomic DNA extraction according to the manufacturer's protocol. The controls' blood samples were collected by venipuncture and stored in EDTA for subsequent genomic DNA extraction *via* the QIAamp DNA Miniprep Kit (Qiagen, Chatsworth, CA, United States).

The genotyping of SNPs rs12979860 and rs8099917 was performed at the Universidade da Região de Joinville and the Instituto de Biofísica Carlos Chagas Filho.

For all 199 control samples and 79 of the HCV-infected samples, genotyping was performed *via* PCR-restriction fragment length polymorphism analysis<sup>[12]</sup> on an LGC XP thermocycler (BIOER Technology Co., Tokyo, Japan) and results were documented by the Mini-Bis Pro Gel Imaging System (DNR Bio-Image Systems Ltd., Jerusalem, Israel). The remaining 66 HCV-infected samples were genotyped by bi-directional amplicon sequencing using the DYEnamic<sup>™</sup> ET Dye Terminator Cycle Sequencing Kit and the MegaBACE 1000 DNA Sequencer (GE Healthcare, Pittsburgh, PA, United States). The HCV treatment responses and *IL28B* genotyping results of this subgroup of patients were previously reported<sup>[13]</sup>.

### Statistical analysis

Data analysis was performed by the SPSS statistical software (v13.0; SPSS Inc., Chicago, IL, United States). Continuous variables were compared by Student's *t*-test for parametric variables, or by Mann-Whitney *U* test for non-parametric distributions. All *P*-values are two-tailed and values < 0.05 were considered statistically significant. The  $\chi^2$  G test for "Goodness of Fit" was used to verify whether the proportions of the polymorphisms were unequally distributed between controls and patients or in Hardy-Weinberg equilibrium (HWE). Differences in allele and genotype frequencies between different groups were assessed by Pearson's  $\chi^2$  test (with  $\chi^2$  test for linear trend when appropriate).

## RESULTS

The demographic characteristics of the HCV-infected patients and healthy controls are summarized in Table 1. SNP rs12979860 genotyping was successful in 142 (97.2%) of the patients and 198 (99.5%) of the controls, and SNP rs8099917 genotyping was successful in all 145 (100%) of the patients and 190 (95.5%) of the controls.

### Genotype and allele distributions among the HCV-infected patients and healthy controls

Analysis of rs12979860 showed that the HCV-infected group had a significantly lower prevalence of the CC genotype (30.3% *vs* control group: 47.4%, *P* = 0.037) and the C allele (0.53 *vs* 0.69, *P* = 0.0073) and T allele (0.47 *vs* 0.31, *P* = 0.0073), but a significantly higher prevalence of the TT genotype (24.8% *vs* 8.9%, *P* = 0.0009). Analysis of rs8099917 showed that the HCV-infected group had a significantly lower prevalence of the TT genotype (46.2% *vs* control group: 67.4%, *P* = 0.043) and of the T allele (0.63 *vs* 0.83, *P* = 0.0009), but a significantly higher prevalence of the GG genotype (20.0% *vs* 1.5%, *P* = 0.0001) and of the G allele (0.37 *vs* 0.17, *P* = 0.0008).

Both of the *IL28B* SNPs were in HWE among individuals belonging to the control group (rs12979860, *P* = 0.7; rs8099917, *P* = 0.1), but only the rs12979860 SNP was in HWE for the HCV group (*P* = 0.21). Linkage disequilibrium analysis showed that both SNPs were associated with the controls as well as the HCV-infected patients (*P* = 0.0001).

**Table 2** Demographic characteristics and clinical parameters of hepatitis c virus-infected patients stratified by response to treatment

Feature	SVR (n = 55)	NR (n = 89)	P value
Sex, M/F	54%/46%	51%/49%	0.072
Skin color			
White	89%	70%	0.032
Black	11%	26%	0.009
Brown	-	4%	ND
ALT in UI/mL, mean (IQR)	97 (54)	77 (64)	0.1
Baseline viral load in UI/mL <sup>1</sup>			
< 600000	47.80%	49.30%	0.760
≥ 600000	52.20%	50.70%	0.890
Fibrosis score <sup>2</sup>			
0-2	63.30%	49.40%	0.125
3-4	36.70%	50.60%	0.126

<sup>1</sup>This parameter was only available for 115 patients [46 of sustained virological response (SVR), and 69 of non-responders (NR)]; <sup>2</sup>According to histopathological analysis of liver biopsy tissues; this parameter was only available for 128 patients (49 of SVR, and 79 of NR). ND: Not done due to small numbers of cases; ALT: Alanine aminotransferase.

### Correlation between the *IL28B* polymorphisms and treatment outcomes

Fifty-five (39%) of the patients achieved SVR following the combination therapy. Stratification analysis of the SVR patients by race showed that the rate was significantly lower in the self-declared black individuals ( $P = 0.009$ ). None of the clinical parameters were significantly different between the SVR and NR groups (Table 2). However, the SVR group did have significantly higher prevalences of the rs12979860 CC genotype (45.5% *vs* NR: 21.0%,  $P = 0.02$ ) and C allele (0.64 *vs* 0.46,  $P = 0.019$ ). Conversely, the prevalences of the rs12979860 TT genotype and T allele were significantly higher in the NR group (30.0% *vs* SVR: 18.2%,  $P = 0.03$  and 0.54 *vs* 0.36,  $P = 0.019$ ).

There were no significant differences in the distributions of the SNP rs8099917 genotypes between the SVR and NR groups. However, the SVR group showed a significantly higher frequency of the T allele (0.74 *vs* NR: 0.57,  $P = 0.024$ ) but a significantly lower frequency of the G allele (0.26 *vs* 0.43,  $P = 0.024$ ). Linkage disequilibrium analysis of the SVR group only showed a significant association between rs12979860 and rs8099917 ( $P = 0.07$ ), similar analysis of the NR group only found no significant associations.

## DISCUSSION

Polymorphisms in the genomic sequence related to the *IL28B* gene have been implicated in the natural history of HCV infection and suggested as putative biomarkers for predicting an individual's therapy response<sup>[14-17]</sup>. In particular, the CC genotype of rs12979860 (*vs* CT) was associated with a two-fold difference in response to HCV treatment, both in Caucasians and African-Americans. Thomas *et al.*<sup>[18]</sup> reported the allele frequencies of rs12979860 in 2371 individuals from 51 populations

worldwide, and showed that the C allele occurred at a high frequency in East Asia, an intermediate frequency in Europe and North America, and a relatively low frequency in Africa. In a subsequent study, Fabris *et al.*<sup>[19]</sup> genotyped the rs12979860 polymorphism in 412 patients with end-stage liver disease due to hepatitis B or C, alcohol abuse, or other causes, and in 344 healthy controls. The patients with viral cirrhosis were found to have a significantly higher frequency of the T allele and of the TT/CT genotypes than the controls; ultimately, the authors theorized that the TT genotype may be associated with severe liver disease while the CC genotype may exert a protective effect. In an Australian-European cohort study of the rs12979860 polymorphism related to SVR, the TT, TG and GG genotypes were found to be associated<sup>[7]</sup>. Finally, a Swiss study yielded similar results, with a lower G allele frequency being associated to persistent infection and failure to respond to therapy<sup>[6]</sup>.

Among the few studies that have assessed the role of *IL28B* polymorphisms in a Brazilian population, the SNPs have shown various associations to disease outcome and treatment response. For example, Cavalcante *et al.*<sup>[20]</sup> analyzed rs12979860 in 222 patients infected with admixture HCV genotype 1, 2 and 3 who were treated with standard therapy and found that genotypes CC (rs12979860) and TT (rs8099917) were strongly associated with SVR, while CT/TT (rs12979860) and TG/GG (rs8099917) were associated to treatment failure. In addition, Lunge *et al.*<sup>[21]</sup> analyzed the association between CT (rs12979860) and spontaneous clearance of HCV infection in HIV-co-infected individuals and showed that the CT/TT genotypes conferred nearly 3-fold higher rates for developing CHC, compared to the CC genotype. The current study of *IL28B* polymorphisms' relationship to therapy response, presented herein, confirmed the predictive value of the C allele and CC genotype (rs12979860) that was previously suggested by Cavalcante *et al.*<sup>[20]</sup>. Even though the current study's cohort did not show a statistically significant association of rs8099917 to therapy response, the T allele distribution was related to treatment outcome. This finding may be explained by the lack of HWE in the sample.

Another intriguing finding from the current study is the significant differences in allele and genotype distributions between the healthy controls and HCV-infected patients, which was observed for both SNPs (rs12979860 and rs8099917), with higher C and T alleles as well as CC and TT genotypes in the healthy controls. These data are in accordance with a previous study that demonstrated significant associations for reduced frequencies of the C allele and the CC genotype with chronically-infected hepatitis patients compared to ethnically-matched healthy controls<sup>[4]</sup>. Together, these findings suggest a strong association between the C allele and higher rates of natural clearance of HCV and support the predicted role of this SNP as a protective factor against HCV infection or persistence.

The full array of biological pathways that are influ-

enced by the *IL28B* gene product and its polymorphisms has yet to be elucidated. Certainly, a gene variant has the ability to affect rates of protein production and it is interesting to consider that Shi *et al.*<sup>[22]</sup> demonstrated that patients with chronic HCV infection have significantly lower mRNA and serum levels of IL28B than either healthy controls or patients who have spontaneously cleared the virus, whereas individuals carrying the rs12979860 CC genotype showed a tendency towards higher levels compared to those carrying the CT or TT genotypes. The SNPs rs12979860 and rs8099917 are located respectively at 3 and 8 kb upstream from the *IL28B* locus, in a region that encodes IFN- $\lambda$ 3, a type 3 interferon with antiviral activity that is mediated through the JAK-STAT pathway upon induction of IFN-stimulated genes. IL28A (IFN- $\lambda$ 2) and IL29 (IFN- $\lambda$ 1) are genomically located adjacent to the *IL28B* gene, and it is possible that the rs12979860 and rs8099917 SNPs may also affect the function of these genes. Indeed, Langhans *et al.*<sup>[23]</sup> showed that IL29 levels were substantially lower in CHC patients and in patients that spontaneously resolved hepatitis, compared to healthy controls; moreover, the levels of *IL29* and *IL28A/B* were shown to be significantly higher in rs12979860 C allele heterozygous patients than in the TT homozygous patients.

The results from the current study of an HCV-infected Brazilian population indicate that the role of *IL28B* SNPs in patients' response to therapy is similar to that of other international populations. Furthermore, the data presented herein on the differential distribution of rs12979860 and rs8099917 polymorphisms between HCV-infected patients and a healthy population may contribute to a better understanding of the natural history of this complex disease.

## COMMENTS

### Background

Most countries continue to rely on drug therapies based on an immune-modulator plus an antiviral (most frequently pegylated-interferon  $\alpha$ -2a or -2b and ribavirin), even though this strategy is associated with high failure rates and significant side effects. Therefore, identification of predictive biomarkers of an individual's response to therapy is clinically relevant.

### Research frontiers

Since 2009, several genome-wide association studies have yielded data to support the association of two single nucleotide polymorphisms, rs12979860 and rs8099917, located near the interleukin (*IL*)28B gene with achievement of sustained virological response to treatment in patients infected with hepatitis C virus (HCV) genotype 1.

### Innovations and breakthroughs

This study represents the largest analysis of a Brazilian cohort conducted to date to investigate the potential association of the two most relevant *IL28B* single nucleotide polymorphisms (rs12979860 and rs8099917) in healthy individuals and chronic hepatitis C patients (CHC) treated with the pegylated-interferon  $\alpha$ -2a or -2b plus ribavirin combination therapy. The study's findings reveal significant differential distributions of the genotype and allele frequencies for both rs12979860 and rs8099917 between the healthy controls and CHC patients. In addition, the CC genotype of rs12979860 was shown to be associated with the CHC patients' ability to achieve sustained virological response to the standard therapeutic regimens.

### Applications

This study's findings support the predicted roles of rs12979860 C allele and

rs8099917 T allele as protective factors against HCV infection or persistence and suggest their potential for development as clinical biomarkers of HCV infection and therapeutic management. In general, the results indicate that genotyping *IL28B* polymorphisms in HCV-infected patients is likely to help improve the current standard of care, and may provide an opportunity for clinicians to improve patient outcome by individualizing treatment regimens.

### Peer review

The authors investigated the differential distribution of *IL28B* genetic variants between healthy Brazilians in the general population and HCV-infected patients undergoing standard drug therapy based on an immune-modulator plus an antiviral to demonstrate the associations of particular genotypes and alleles with infection and treatment response. This is a well-written and -discussed paper, of particular interest to the Brazil population.

### Abstract

**AIM:** To investigate the impact of laparoscopic colectomy on short and long-term outcomes in obese patients with colorectal diseases.

**METHODS:** A total of 98 obese (body mass index > 30 kg/m<sup>2</sup>) patients who underwent laparoscopic (LPS) right or left colectomy over a 10 year period were identified from a prospective institutionally approved database and manually matched to obese patients who underwent open colectomy. Controls were selected to match for body mass index, site of primary disease, American Society of Anesthesiologists score, and year of surgery ( $\pm$  3 year). The parameters analyzed included age, gender, comorbid conditions, American Society of Anaesthesiologists class, diagnosis, procedure, and duration of operation, operative blood loss, and amount of homologous blood transfused. Conversion rate, intra and postoperative complications as were as reoperation rate, 30 d and long-term morbidity rate were also analyzed. For continuous variables, the Student's *t* test was used for normally distributed data the Mann-Whitney *U* test for non-normally distributed data. The Pearson's  $\chi^2$  tests, or the

Fisher exact test as appropriate, were used for proportions.

**RESULTS:** Conversion to open surgery was necessary in 13 of 98 patients (13.3%). In the LPS group, operative time was 29 min longer and blood loss was 78 mL lower when compared to open colectomy ( $P = 0.03$ ,  $P = 0.0001$ , respectively). Overall morbidity, anastomotic leak and readmission rate did not significantly differ between the two groups. A trend toward a reduction of wound complications was observed in the LPS when compared to open group ( $P = 0.09$ ). In the LPS group, an earlier recovery of bowel function ( $P = 0.001$ ) and a shorter length of stay ( $P = 0.03$ ) were observed. After a median follow-up of 62 (range 12-132) mo 23 patients in the LPS group and 38 in the open group experienced long-term complications (LPS vs open,  $P = 0.03$ ). Incisional hernia resulted to be the most frequent long-term complication with a significantly higher occurrence in the open group when compared to the laparoscopic one ( $P = 0.03$ ).

**CONCLUSION:** Laparoscopic colectomy in obese patients is safe, does not jeopardize postoperative complications and resulted in lower incidence of long-term complications when compared with open cases.

## INTRODUCTION

The role of laparoscopic surgery in obese patient with colorectal diseases is still object of debate, according to several papers published in the last decade, laparoscopy is feasible and safe<sup>[1-5]</sup>. However, controversial results have been reported in term of conversion rate, overall morbidity and reoperation rate, when obese patients are compared to their non-obese counterparts<sup>[1-8]</sup>.

These controversial results could be partially explained based on the relative inexperience of the surgical team possibly due to an on-going learning curve, on the small sample size of the various studies, on the specific definition of obesity and on surgical heterogeneity<sup>[3-5,9]</sup>. In order to clarify this issue while avoiding some of the aforementioned biases, we have conducted a case-matched study comparing short and long-term outcomes of standardized right or left colectomy performed by laparoscopy or by open surgery in patients with a body mass index (BMI) > 30 kg/m<sup>2</sup>. Data were extracted from a prospective collected database.

Main goal of the present study is to assess if the documented benefits of minimally invasive approach could be translated even in a high-risk patients such obese patients.

## MATERIALS AND METHODS

Adult obese patients of both sexes candidate to a standardized right or left colectomy and who were consecutively admitted to our department from January 2002 to January 2012 were considered. Patients were identified from a prospective institutionally approved database currently recording demographics, biochemistry values, nutritional status, operative variables, and co-morbidity factors on admission, postoperative outcome and histopathologic findings of patients undergoing colon resection. The case group was selected from 118 obese patients who underwent laparoscopic colectomy identified from the Institutional Colon database. Patients were excluded if they underwent an emergency procedure ( $n = 13$ ) or non-standardized colon operations ( $n = 7$ ). Overall, the case group consisted of 98 patients. The control patients were selected from the same institutional database from January 2011, backward until we had identified one control subject for each case. Each case was manually matched with a control that had undergone open resection. The same exclusion criteria used for laparoscopic (LPS) patients were applied to the control patients' selection. The identification of control patients was done by a statistician (GR) who was unaware of postoperative outcomes. Control patients were selected to match for site of primary disease, American Society of Anesthesi-

ologists (ASA) score, and year of surgery ( $\pm 3$  year). Data collected from the hospital database, medical records and telephone calls were analyzed retrospectively.

Preoperative assessment included clinical examination, serologic evaluation, total colonoscopy and body CT scan. A virtual CT colonoscopy was additionally performed in case of incomplete colonoscopy examination. Co-morbidities on admission, as well as operative risk assessed by ASA score, were analyzed in both groups. The following details of the surgical procedure were recorded in all patients: duration of operation (min), operative blood loss (mL), and amount of homologous blood transfused (mL). Three surgeons (Staudacher C, Di Palo S, Vignali A) with extensive experience in open and laparoscopic colorectal surgery performed all the interventions<sup>[10,11]</sup>. For all the surgeons, the learning curve for laparoscopic colorectal surgery was completed before starting the present trial<sup>[12]</sup>. Patients underwent laparoscopic or open resection depending on surgeon's or patient's preference.

A mechanical anastomosis was intracorporeally fashioned in case of left colectomy, while in right colectomy, the specimen was divided extra corporeally (in laparoscopic operations) and an isoperistaltic side-to-side anastomosis was manually fashioned. Conversion to open surgery was defined when an abdominal incision longer than 7 cm was performed or when an abdominal incision was made earlier or differently from what planned at the beginning of the intervention.

All patients were treated according to the same intra and postoperative protocol: epidural analgesia maintenance for 3 d, nasogastric tube removal at the end of surgery, and bladder catheter removal on postoperative 2 d. Clear liquid diet was started on postoperative 1 d as tolerated by the patient. Postoperative infusion of fluids and electrolytes was given to all patients according to clinical requirements.

Tumor classification was done according to the 7<sup>th</sup> TNM edition<sup>[13]</sup>. Microbiological analysis and positive cultures proved all infectious complications. Patients were discharged after meeting the following conditions: bowel movement and full recovery of both ambulation ability and oral feeding. Registration of complications and need for an unexpected re-admission were recorded for the first 30 d following operation. The follow-up protocol consisted in outpatient clinic visits at 3 mo intervals for the first 2 years, then at 6 mo intervals for the next 3 years, then once a year. In patients with more than five years follow-up or with a benign disease, a systematic review of chart, office records as well as patient interview were done.

### Statistical analysis

Descriptive data were reported as mean, median, standard deviation (SD), number of patients and percentage. For continuous variables, differences between groups were tested with the Student's *t* test for normally distributed data (based on Kolmogorov-Smirnov test) or the Mann-

Whitney *U* test for non-normally distributed data. The Pearson's  $\chi^2$  test, or the Fisher exact test as appropriate, was used for proportions. A two-sided significance level less than 0.05 were used to indicate statistical significance. Confidence intervals (95%CI) were reported when appropriate. The SPSS™ software package, version 18. For Windows (SPSS Inc, Chicago, IL) was used for all the statistical analyses.

## RESULTS

### Study population

Ninety-eight obese patients with colorectal diseases, identified from a prospectively maintained database, who underwent laparoscopic right or left colectomy over a 10 year period, were matched with 98 obese patients who underwent open resection.

The two groups were adequately matched for BMI, type of surgery, and operative risk as assessed by their ASA classification (Table 1). Moreover, a similar incidence of co-morbidities on admission was observed between the two groups (Table 2). The mean  $\pm$  SD (range) BMI ( $\text{kg}/\text{m}^2$ ) was  $31.9 \pm 1.6$  (range 30-35.5) in the LPS group, and  $32.3 \pm 2.1$  (range 30.1-36.4) in the open colectomy group. No significant differences were observed between the two groups with respect to demographics, indication for surgery (benign *vs* cancer), tumor stage (among cancer patients) as well as for the incidence of previous operations (Table 1).

### Technical feasibility

Conversion to open surgery was necessary in 13 of 98 patients (13.3%). Reasons for conversion were as follows: obesity-hindering vision ( $n = 5$ ), large tumour infiltrating adjacent organ/s ( $n = 2$ ), bleeding from the ileocolic pedicle ( $n = 2$ ), dense adhesions ( $n = 2$ ), urgent splenectomy ( $n = 1$ ) and ureteral damage ( $n = 1$ ). Converted patients remained in the LPS group for an intention to treat analysis. In the converted patients, mean  $\pm$  SD (range) time from beginning of the conversion procedure to open surgery was  $22.5 \pm 38.1$  (15-80) min.

Table 2 reports the surgical characteristics of the two groups. The operation time was averagely 29 min (95%CI: 24.3-49.3) longer in LPS than open group ( $P = 0.03$ ). Operative blood loss was 78 mL lower in the LPS group when compared to open surgery ( $P = 0.0001$ ; 95%CI: 47.1-108.9). No significant differences were observed with respect to perioperative blood transfusion rate between the two groups. Moreover, among cancer patients a similar mean  $\pm$  SD number of lymph nodes was retrieved in the operative specimen in the two groups ( $16.6 \pm 10.1$  in the open group *vs*  $17.7 \pm 11.5$  in the LPS group,  $P = 0.57$ ).

### Postoperative outcomes

In the LPS group, a death occurred as a sequelae of an anastomotic leakage on postoperative day 5. No significant differences between the two groups were observed with respect to overall morbidity rate as well as for tech-

**Table 1** Demographics and clinical characteristics of the two groups *n* (%)

Variable	LPS ( <i>n</i> = 98)	Open ( <i>n</i> = 98)	<i>P</i> value
Age (yr)	66.9 $\pm$ 12.2	68.7 $\pm$ 15	0.31
Male/female	52/46	47/51	0.34
ASA score	2.3 $\pm$ 0.7	2.4 $\pm$ 0.9	0.57
BMI ( $\text{kg}/\text{m}^2$ )	31.9 $\pm$ 2.1	32.3 $\pm$ 2.5	0.13
Cancer/benign/disease	85/13	79/19	0.34
Previous surgery (%) <sup>1</sup>	8 (8.1)	10 (10.2)	0.30
Type of operation			
Right colectomy	57	57	
Left colectomy	41	41	
Tumour stage	<i>n</i> = 85	<i>n</i> = 79	0.77
Stage 0	13 (15.2)	9 (11.3)	
Stage 1	14 (16.5)	13 (16.3)	
Stage 2	29 (34.2)	32 (40.6)	
Stage 3	25 (29.4)	20 (25.4)	
Stage 4	4 (4.7)	5 (6.4)	

<sup>1</sup>Only abdominal surgeries were included; Values are reported as mean  $\pm$  SD or *n* (%). BMI: Body mass index; LPS: Laparoscopic; ASA: American Society of Anesthesiologists.

nical complications such as anastomotic leakage. Moreover, a similar incidence of hospital re-admission within 30 d and of reoperation rate was observed in the two groups (Table 2). Conversely, in the open group, the occurrence of wound complications was more than double when compared to the LPS group and the difference showed a trend toward a statistical significance ( $P = 0.09$ ). In both groups, more than 30% of the postoperative infections occurred after discharge. A similar incidence of respiratory and cardiac complications was observed in the two groups (Table 3). When the converted cases were compared to the laparoscopically completed ones, a trend toward a longer duration of surgery ( $P = 0.07$ ) and a longer length of stay was observed ( $P = 0.002$ ). Converted patients experienced a higher complications rate when compared to patients who completed the operation laparoscopically; however the difference failed to reach statistical significance (22.8 *vs* 32.4,  $P = 0.62$ ). Similar results in term of length of stay and overall complication rate were observed when converted and open surgery patients were compared (Table 4). Mean  $\pm$  SD recovery of oral food intake occurred after 2.1 (1) d in the LPS and after  $3.5 \pm 1.5$  d in the open surgery group ( $P = 0.001$ ). Mean (median, SD) length of stay was 8.6 (8; 3.1) d in the LPS group and 10.4 (10; 4.9) d in the open surgery group ( $P = 0.03$ ).

### Long-term outcomes

At a median follow-up of 62 (range 12-132) mo, 23 patients in the LPS group and 38 in the open surgery group experienced long-term complications (LPS *vs* open,  $P = 0.03$ ; Table 2). Incisional hernia was the most common complication in both groups and its occurrence was more frequent in the open surgery group when compared to the laparoscopic one ( $P = 0.03$ ). Among the converted patients, a 30.8% (4/13 pts) incisional hernia rate was observed.

## DISCUSSION

The global prevalence of obesity means that surgeons are increasingly faced with these high-risk patients. The choice of optimal operative approach and technique becomes extremely actual and crucial. The vast majority of the studies available in the literature addressing the issue of mini-invasive approach and obesity compares obese patients to their non-obese counterparts<sup>[2-6]</sup>. In our opinion, in order to better evaluate the effective impact of mini-invasive approach in obese patients, it is important to compare open and laparoscopic colectomy outcomes in the specific population of obese patients only. A definitive answer whether laparoscopic surgery would be preferable in the obese to the open approach can only be

obtained by a randomized controlled trial. To the best of our knowledge, there are no RCTs in the literature specifically addressing this issue. To limit the biases related to the design of the study and in an attempt to minimize surgical heterogeneity<sup>[14]</sup>, a single center case-matched study was performed including only well standardized surgical procedures.

In previous studies, obesity has been identified as one of the factors associated with a higher conversion rate<sup>[15-19]</sup>. In the present trial, a conversion rate of 13.3% has been obtained, which is within the range (0%-39%) previously reported by other studies dealing with this issue<sup>[1-6]</sup>. This rate is however higher when compared to the 2.6% conversion rate after laparoscopic right colectomy or the 5.2% conversion rate in left LPS colectomies reported in studies performed by our Institution in the non-obese population<sup>[20,21]</sup>. These findings are in accordance with results from Tekkis and co-workers who identified obesity as an independent predictor of conversion to open surgery at multivariate analysis with an odd-ratio of 2.2 for patients with a BMI > 28.5 kg/m<sup>2</sup> derived from a large series 1253 subjects<sup>[22]</sup>. Moreover an increasing BMI was associated with a proportionally higher conversion rates in data extracted from the laparoscopic colorectal surgery study group (LCSSG)<sup>23</sup> on 5853 recruited patients<sup>[23]</sup>.

A possible argument against the adoption of the mini-invasive approach in obese patients is that converted patients resulted in poor short and long-term outcomes when compared to patients who successfully completed the operation laparoscopically<sup>[24,25]</sup>. In our experience,

**Table 4 Outcomes of laparoscopically completed, converted and open cases**

Variable	LPS completed ( <i>n</i> = 85)	Converted ( <i>n</i> = 13)	Open ( <i>n</i> = 98)	<i>P</i> value
Operative time (min)	175 (61)	210 (86)	164 (111)	0.07 <sup>1</sup> 0.08 <sup>2</sup>
Morbidity rate	22.8%	32.4%	33.7%	0.55 <sup>1</sup> 0.91 <sup>2</sup>
Length of stay (d)	7.2 (2.5)	9.6 (3.2)	10.4 (4.9)	0.002 <sup>1</sup> 0.52 <sup>2</sup>

<sup>1</sup>Laparoscopic (LPS) completed *vs* converted; <sup>2</sup>Converted *vs* open. Values are expressed as mean (SD) or percentages.

in the converted patients, no significant difference was observed in term of postoperative morbidity when compared to laparoscopically completed cases. Similar results were reported by other authors<sup>[26,27]</sup>. Possible explanation may include the wide experience of the surgical team, in the appropriate patients' selection, or to the rapid decision to convert thus minimizing potentially adverse outcomes<sup>[1,4,10,22]</sup>.

In the present series, the overall morbidity rates did not differ between the two groups. Similarly, despite the incidence of infectious complications was about twice higher in patients in the open surgery group when compared to laparoscopic (23.6% *vs* 11%), the difference failed to reach statistical significance.

Only with respect to wound complications, a trend toward a lower rate was observed in the LPS group. These latter findings are consistent with the data recently reported by Wick *et al*<sup>[28]</sup> and Mustain *et al*<sup>[29]</sup>, who identified open surgery as an independent risk factors for surgical site infections in a large series of obese patients undergoing laparoscopic and open colorectal surgery<sup>[28,29]</sup>.

In the present series, the incidence of anastomotic leakage was similar in the two groups. Delaney and co-workers reported similar results in the only other, to the best of our knowledge, case-matched study comparing laparoscopic to open colectomy in obese patients. These authors reported an absence of statistical difference, both for the overall complications as well as for anastomotic leakage rate<sup>[27]</sup>. The absence of an adverse impact of laparoscopic colectomy on anastomotic leakage rate in the obese patients undergone laparoscopic colectomy has been recently supported by a review paper by Martin and Stocchi<sup>[9]</sup> reporting data from high volume institutions.

Moreover, patients in the LPS group experienced a shorter recovery of bowel function and a shorter length of stay when compared to their open surgery counterparts. These findings are consistent with the results reported by a large meta-analyses analyzing the outcomes of 2512 procedures from 12 RCT trials comparing LPS and the open approach for colorectal diseases in the non-obese population<sup>[30]</sup>. In our series, the earlier recovery of bowel function, the shorter length of stay as well as the lower intraoperative blood loss and a trend toward a reduction of wound complications observed in the LPS

group, deserve major consideration, as these findings indicate that some of the wide-reported short-term benefits of the mini-invasive approach are maintained even in high-risk patients, also suggesting that paradoxically, these are the patients who stands to benefit the most laparoscopic surgery.

With respect to long-term complications, patients in the LPS group experienced a significantly lower incidence of overall complications when compared to their open surgery counterparts. In particular a higher incisional hernia rate was observed in the open surgery group. Few data are available in the literature on this subject reporting controversial results. No difference in term of incisional hernias between laparoscopic or open approach has been reported or, conversely the mini-invasive approach was preferred when obese *vs* non obese patients are compared<sup>[31,32]</sup>. To the best of our knowledge, no study has reported data on long-term complications in obese patients treated with mini-invasive or with conventional approach. The mechanisms for incisional hernia occurrence have not been yet clarified. Potential risk factors have been identified and categorized into patient-related (advanced age, obesity, nutritional status,) disease and surgery-related such as emergency operation, post-operative wound infections, reoperations and others<sup>[33-35]</sup>. Moreover, an association was recently reported by Rullier *et al*<sup>[36]</sup> between the rate of hernia and the length of incision. These authors found an incisional hernia rate of 33.0% at median follow-up period of 51 mo in open group compared to 13.5% in the LPS group of patients who underwent rectal resection.

In conclusions, although there are some limitations to the study resulting from the non-randomized design, to the possible bias in patient selection for laparoscopic surgery, and to the fact that patients were treated in a single institution, our findings indicate that laparoscopic surgery can be safely performed in obese patients with colorectal disease. Moreover, minimally invasive approach has no adverse impact on postoperative complications, resulting in reduced length of stay and lower incidence of long-term incisional hernia when compared to conventional colectomy.

We thank Giovanni Radaelli MD, PHD for performing the statistical analysis of the data.

## COMMENTS

### Background

The safety and the benefits of laparoscopic colon resection, including less post-operative pain, faster recovery of bowel function, earlier mobilization, less morbidity, reduction of hospital stay, and smaller scars, have been underlined by several studies, making it now the preferred approach in the surgical management of many colorectal diseases. Obese patients are considered to be at high perioperative risks. Therefore laparoscopic surgery may be particularly advantageous in obese patients. On the other hand a colorectal resection is more difficult in obese subjects due to obesity hindering visualization and dissection of tissue planes that lead to longer operative time and increase blood transfu-

sion requirement, thus possibly impair the benefits of laparoscopic colectomy.

### Research frontiers

The study performed a single center study in which patients were matched for body mass index, site of primary disease, American Society of Anesthesiologists score, and year of surgery. Moreover only well standardized surgical procedures (left and right colectomy) were included. However, in order to better evaluate the real impact of minimally-invasive approach in obese patients, a randomized controlled trial should be conducted.

### Innovations and breakthroughs

The vast majority of previous studies, focusing on laparoscopic colectomies in obese patients, compared obese to non-obese subjects. No randomized study has been conducted. Only one case matched study compared open and laparoscopic approach in obese patients. This is the first study that analyses long-term outcomes. The principals finding of this study is that the documented benefits of laparoscopic colon resection could be translated even in a high-risk group, such obese patients, since this approach did not impair postoperative outcomes and resulted in lower incidence of long-term complications when matched with open surgery cases.

### Applications

Providing that experienced surgeons are involved, laparoscopic colorectal resection should be offered to obese patients considering its benefits when compared to conventional open surgery.

### Peer review

The authors analyze the feasibility of laparoscopic colectomy in obese patients. There are not randomized trials comparing the outcome of colectomy in obese and non-obese patients. The results confirm previous studies on the efficacy and safety of laparoscopic left and right colectomy in obese subjects. The literature on this topic is scarce, and, although another case-match study was previously published, this is the only one that analyses long term results.

**RESULTS:** Patients with NASH had higher RDW values compared with simple steatosis and healthy control groups [ $14.28\% \pm 0.25\%$  vs  $13.37\% \pm 0.12\%$ ,  $12.96\% \pm 0.14\%$  ( $P < 0.01$ ), respectively]. Patients with advanced fibrosis had higher RDW values than the mild fibrosis group ( $15.86\% \pm 0.4\%$  vs  $13.63\% \pm 0.67\%$ ,  $P < 0.01$ , respectively). RDW also correlated with fibrotic scores ( $r = 0.579$  and  $P < 0.01$ ). The variables that were significant in the univariate analysis were evaluated in multivariate logistic regression analysis, and RDW was an independent predicting factor of NASH (OR = 1.75, 95%CI: 1.129-2.711,  $P < 0.05$ ).

**CONCLUSION:** RDW a new non-invasive marker that can be used to demonstrate the presence of NASH and indicate advanced fibrotic scores.

### Abstract

**AIM:** To evaluate the red cell distribution width (RDW) as an indicator of the presence of non-alcoholic steatohepatitis (NASH) and its association with fibrotic scores.

**METHODS:** A retrospective study was carried out that included sixty-two biopsy proven NASH, 32 simple steatosis patients and 30 healthy controls. The correlation between the clinical and histopathological features of NASH patients and RDW values was evaluated. Liver fibrosis scores were measured using a 0 to 4 point scale and were divided in to two groups; fibrosis scores 0-1 were termed mild and fibrosis scores 2-4 were termed advanced fibrosis. RDW values were compared between NASH, simple steatosis and healthy controls. Univariate and multivariate analyses were performed to evaluate the independent predicting factors for the presence of liver fibrosis caused by NASH.

**Core tip:** We evaluated the role of red cell distribution width (RDW) as an indication of nonalcoholic steatohepatitis by comparing the values of biopsy proven non-alcoholic steatohepatitis (NASH) patients with simple steatosis and healthy controls. Independent predictors of the presence of NASH and advanced liver fibrosis were evaluated by using multivariate logistic regression analyses and RDW was a statistically significant independent predictor.

Is increased red cell distribution width an indicating marker of nonalcoholic steatohepatitis and fibrotic stage? *World J Gastroenterol* 2013; 19(42): 7412-7418 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7412.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7412>

## INTRODUCTION

Nonalcoholic steatohepatitis (NASH) is part of the spectrum of non-alcoholic fatty liver disease (NAFLD), which comprises simple fatty liver, NASH, associated advanced fibrosis and cirrhosis<sup>[1]</sup>. NAFLD has become one of the most common forms of chronic liver diseases in the United States and worldwide, with a prevalence of 10%-24%<sup>[2-5]</sup>. NASH is characterized by ballooning, degeneration, and lobular inflammation with various stages of fibrosis. Lobular inflammation is a hallmark of NASH, which is characterized by infiltration of lymphocytes, mononuclear cells and polymorphonuclear neutrophils. Steatosis is present in all cases and affects the hepatic lobules<sup>[6]</sup>. Simple steatosis is a benign condition with minimum progression, despite a high rate of progression to cirrhosis in 15%-25% of patients with NASH<sup>[7]</sup>. Liver fibrosis is a result of chronic injury<sup>[8]</sup>. In the absence of approved treatment modalities for NASH, care should be taken on the detection of advanced fibrosis. A liver biopsy is the only method for distinguishing NASH from other diagnoses and permits the evaluation of the damage and fibrosis of the liver. However a biopsy is an invasive and expensive procedure with important complications, such as bleeding and perforation. Therefore, there has been a search for noninvasive methods of detecting the presence of NASH and liver fibrosis to avoid these procedure-related complications.

Chronic inflammation plays a significant role in disease progression to NASH<sup>[9]</sup>. In addition, some studies have shown that certain inflammatory cytokines were higher in patients with NASH<sup>[10,11]</sup>.

Red cell distribution width (RDW) is a parameter of the variation of circulating red cells. This parameter demonstrates the heterogeneity of red cell volume and is a component of the complete blood count (CBC). The RDW is also a widely available, inexpensive and easily repeatable marker that measures red blood cell (RBC) volume variability. Recent reports have demonstrated that elevated RDW values were related to negative outcomes in cardiovascular and metabolic disorders, colon cancer and stroke independent of hemoglobin (HGB) values<sup>[12-16]</sup>. The association between RDW values and the severity of liver diseases has been also reported in two recent studies<sup>[17,18]</sup>.

In this study, we aimed to investigate the clinical utility of RDW for indicating the presence of NASH in comparison with simple steatosis and healthy controls. We also evaluated whether there is an association between RDW values, fibrotic stages and histological features of NASH.

## MATERIALS AND METHODS

### Patients

This retrospective study was performed in Gazi University Department of Gastroenterology, a tertiary reference center (Ankara, Turkey), between January 2010 and May 2013. All the patients who had persistently elevated liver enzymes and hepatosteatosis on ultrasonography, in the absence of any causes of elevated aminotransferases,

were evaluated in the study. Among them, patients who had histopathology consistent with NASH and simple steatosis were included in the study. The control group was created among individuals who had normal aminotransferase levels and normal abdominal ultrasonography. Patients who were diagnosed with viral hepatitis, sclerosing cholangitis, primary biliary cirrhosis, autoimmune hepatitis, hemochromatosis, Wilson's disease, alpha-1-antitrypsin deficiency, malignancy and drug-induced liver disease were excluded. Other exclusion criteria were alcohol consumption of > 20 g/d for men and > 10 g/d for women, presence of infectious diseases on admission, chronic renal diseases, collagen vascular diseases, malignancies, hematological diseases that might impair red cell production (such as iron deficiency, B12 or folate deficiency), increased red cell destruction, hemoglobinopathies, blood transfusions, bone marrow depression, usage of anticoagulant drugs, non-steroid anti-inflammatory drugs and hepatotoxic drugs. Patients who had diabetes mellitus were on oral antidiabetics and/or insulin therapy. Patients who had hypertension were all using angiotensin-converting enzyme inhibitors and were under control in terms of hypertension.

### Clinical and laboratory assessment

Demographical, clinical and laboratory data were collected and registered in a database by an uninformed clinician to prevent bias. Body mass index was calculated by dividing weight in kilograms (kg) by the square of height in meter (m) as (kg/m<sup>2</sup>).

Before the liver biopsy, venous blood samples were obtained from the antecubital vein from all patients between 8.30 and 10.00 am, after fasting for at least 8-12 h. A CBC containing RDW, hemoglobin (HB), white blood cell (WBC), neutrophils, lymphocytes, platelets and mean platelet volume (MPV) was performed with a Beckman Coulter Gen-S automated analyzer (High Wycombe, United Kingdom) within 2 h after obtaining the blood samples. RDW was calculated by the Beckman Coulter automated analyzer as  $RDW = SD/MCV \times 100\%$ . (The standard deviation of the volume of red blood cell (SD)/[(mean corpuscle volume) (MCV)]  $\times 100\%$ . RDW was calculated by dividing the SD by the MCV and then multiplying that result by 100. The SD represented the volume of erythrocytes or RBCs that were in the blood smear.

A Roche Modular System auto analyzer (Roche COBAS INTEGRA 800 (Indianapolis, United States) determined the Albumin, creatinine, blood urine nitrogen (BUN), alanine aminotransferase (ALT), aspartate aminotransferase (AST),  $\gamma$  glutamyl aminotransferase (GGT) and alkaline phosphatase (ALP) levels. All the laboratory analyses were performed in our hospital's hematology laboratory.

### Histopathological evaluation of the liver

Percutaneous liver biopsy was performed using a 16-G disposable needle by a skilled clinician. All liver biopsy specimens included 12 or more complete portal tracts

**Figure 1** Mild perivenular-perisinusoidal fibrosis (A) and advanced perivenular-perisinusoidal, and periportal fibrosis (B) in non-alcoholic steatohepatitis. A, B: Trichrome stain, x 400.

and were longer than 20-25 mm. All liver tissue samples were evaluated by the same experienced hepatopathologist who was blinded to the patients' clinical and laboratory data. Hematoxylin and eosin (HE) and Masson trichrome stains were used for histopathological diagnoses of formalin-fixed paraffin-embedded liver tissues. The diagnosis of NASH was evaluated on Brunt's Criteria<sup>[19]</sup>. Histological characteristics were graded according to the NAFLD scoring system recommended by the National Institute of Diabetes and Digestive and Kidney Diseases NASH Clinical Research Network<sup>[20]</sup>. Steatosis was graded as 0  $\leq$  5%; 1  $\geq$  33%-66%; 3  $\geq$  66% lobular inflammation was graded as 0 = no foci; 1  $\leq$  2 foci; 2 = 2-4 foci; 3  $\geq$  4 foci; and ballooning was graded as 0 = none; 1 = few ballooning cells; 2 = many ballooning cells, respectively.

Depending on the recommendations of Brunt's criteria steatosis (0-3), lobular inflammation (0-3) and ballooning (0-2) were then combined to establish the NAFLD activity score (0-8). Fibrosis was also scored as 0 = no fibrosis; 1 = periportal or perisinusoidal fibrosis; 2 = perisinusoidal and portal/periportal fibrosis; 3 = bridging fibrosis; and 4 = cirrhosis. While mild fibrosis was defined with fibrotic score  $\leq$  1 advanced fibrosis was defined with fibrotic score  $>$  1. Mild fibrosis caused by NASH is shown in Figure 1A and advanced fibrosis in Figure 1B.

### Ethics

The study was in accordance with the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the institutional review board.

### Statistical analysis

Statistical analyses were performed using the SPSS software version 17 and MedCalc version 12. The variables were investigated by using visual (histograms, probability plots) and analytical methods (Kolmogorov-Smirnov/Shapiro-Wilk's test) to determine whether or not they were normally distributed. Non-normally distributed and non-parametric variables were compared between groups using the Mann-Whitney *U* test where appropriate. The  $\chi^2$  test, where appropriate, was used to compare

the propositions in different groups. As the RDW was not normally distributed, the Kruskal-Wallis test was used for comparisons among NASH, simple steatosis and healthy control groups. The Mann-Whitney *U* test was used to test the significance of pairwise differences, using Bonferroni correction to adjust for multiple comparisons. For the multivariate analysis, the possible factors identified with univariate analyses were further entered into the logistic regression analysis to determine independent predictors of NASH. To assess model fit, we used Hosmer-Lemeshow goodness of fit statistics. Spearman rank correlation coefficients (*r*) were calculated to assess the correlation between RDW and liver histopathological features (inflammation, NAS score, the degree of steatosis and degree of fibrosis) and clinical characteristics of NASH patients. Receiver operating characteristics (ROC) analysis was used to evaluate the role of RDW in distinguishing subjects with NASH and fibrosis. ROC analysis was also used to distinguish advanced and mild fibrotic stage groups. Cutoff values that maximized both sensitivity and specificity were chosen for the NASH group. *P* < 0.05 was considered statistically significant.

## RESULTS

### Patient characteristics and liver histology

Sixty-two biopsy proven NASH patients, 32 biopsy proven simple steatosis patients and 30 healthy controls were recruited. The median ages of patients with NASH, simple steatosis and healthy controls were 49.5 years (22-77 years), 48 years (24-71 years) and 48 years (24-72 years), respectively. There was no statistically significant difference between the ages of participants. The mean BMI ( $\text{kg}/\text{m}^2$ ) of NASH, simple steatosis and healthy controls were  $27.13 \pm 0.37$ ,  $25.97 \pm 0.67$  and  $24.22 \pm 0.45 \text{ kg}/\text{m}^2$ , respectively (*P* < 0.01). The platelet counts among NASH, simple steatosis and healthy controls were  $245.5 \pm 34.73$ ,  $244.5 \pm 13.8$  and  $260 \pm 4.47 \times 10^3/\text{mL}$ , respectively (*P* > 0.05). However, there was an inversely significant correlation between platelet counts and fibrotic scores (*r* = -0.335 and *P* < 0.01). Among the NASH group 30/62 (48.3%), steatosis group 18/32 (56.2%) and

Hypertension	22 (35.4)	7 (21.8)	0 (0)	NS

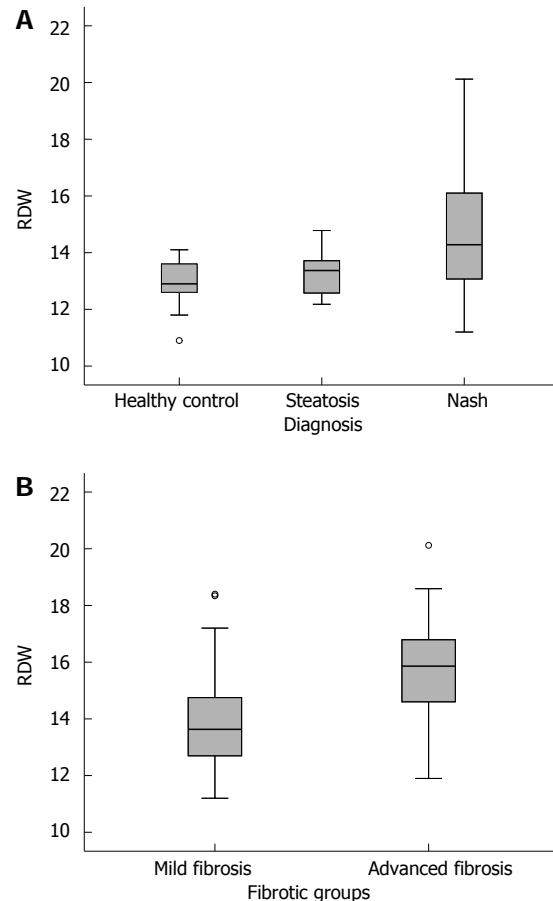

Values are presented as *n* (%) frequencies, median  $\pm$  SE for skewed distributed variables. BMI: Body-mass index; RDW: Red cell distribution width; MPV: Mean platelet volume; NS: Not significant; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT:  $\gamma$  glutamyl transferase; WBC: White blood cell; MCV: Mean corpuscle volume; BUN: Blood urine nitrogen.

healthy controls 18 (60%) were men ( $P > 0.05$ ). The median RDW values were  $14.28\% \pm 0.25\%$ ,  $13.37\% \pm 0.12\%$  and  $12.96\% \pm 0.14\%$ , respectively ( $P < 0.01$ ). The clinical and laboratory data of patients with NASH, simple steatosis and healthy control groups are summarized in Table 1. The comparison of RDW values among NASH, simple steatosis and healthy control groups is also shown in Figure 2A.

#### Relationship between RDW and the presence of NASH and fibrosis

The ROC analysis suggested that a cutoff value of 13.56 has the highest sensitivity (61.3%) and specificity (72.6%) for detecting patients with NASH with an area under the curve (AUC) of 0.70 (95%CI: 0.600-0.805), ( $P < 0.01$ ), as shown in Figure 3A.

According to the liver histopathological features, while the mild fibrosis group consisted of 40 patients, there were 22 patients in advanced fibrosis group. We compared RDW values between the mild and advanced fibrosis subgroups of NASH and found a statistically significant difference ( $13.95\% \pm 1.74\%$  and  $15.85\% \pm 1.89\%$ , respectively,  $P < 0.01$ ), as seen in Figure 2B. The ROC curve of RDW for the identification of advanced fibrosis in NASH was statistically significant (AUC = 0.78, 95%CI: 0.660-0.903,  $P < 0.01$ ), as shown in Figure 3B.

**Figure 2** Red cell distribution width values of healthy controls, simple steatosis and non-alcoholic steatohepatitis groups (A), and fibrotic subgroups of non-alcoholic steatohepatitis (B). RDW: Red cell distribution width.

#### Correlation between RDW and clinical/histopathological features of patients with NASH

In Spearman correlation analysis, there were statistically significant correlations between RDW values and fibrotic scores, age and gender, as seen in Table 2. The correlation between fibrotic scores and RDW values reached statistically significance, such that Spearman's correlation coefficients were  $r = 0.42$ , and  $P < 0.001$ , as shown in Figure 4.

Univariate analysis for the presence of NASH indicated that age, gender, platelet counts, ALT, AST, ALP, GGT, albumin, BMI and RDW were statistically significant predictor factors of the presence of the NASH. The results of univariate analysis are shown in Table 3.

Those variables that were statistically significant in univariate logistic regression analyses were furthered subjected to multivariate logistic regression analysis, and RDW continued to be statistically significant and an independent predictor of fibrosis (OR = 1.75, 95%CI: 1.129-2.711,  $P < 0.001$ ), as seen in Table 4.

## DISCUSSION

In the present study, we concluded that patients with biopsy proven NASH have higher RDW values compared

**Figure 3** Receiver operating characteristics curve of red cell distribution width values for the identification of patients with non-alcoholic steatohepatitis (A), and the identification of fibrosis in non-alcoholic steatohepatitis (B).

with simple steatosis patients and healthy controls. The increase in RDW values correlated with disease progression because the patients with advanced fibrosis had higher RDW values than the mild fibrosis group. There was a positive correlation between RDW values and fibrotic scores. As a result of multivariate logistic regression analysis RDW was identified as an independent predictor of NASH and advanced liver fibrosis.

The search for a noninvasive diagnostic marker indicating the histological changes and fibrotic stages observed in NASH is very important. The absence of approved treatment methods for NASH means that care must be taken on the detection of advanced fibrosis. The risk stratification requires an adequate evaluation of fibrosis, which only currently possible by performing a liver biopsy. Biopsy is an invasive method with natural risks, costs, and is disturbing for the patients; therefore, considerable efforts have been made in the development of noninvasive alternatives of determining the degree of liver fibrosis.

Lou *et al*<sup>[21]</sup> found that RDW values were significantly increased in patients with hepatitis B and that high RDW values were associated with disease severity. Similarly Chen *et al*<sup>[22]</sup> concluded that RDW to platelet index is a

routinely available and easily calculated index that could predict significant liver fibrosis caused by chronic hepatitis B with a high accuracy. They also estimated that this index may reduce the requirement of liver biopsy in patients infected with chronic hepatitis B. High RDW values are associated with poor outcomes in patients with cardiovascular diseases<sup>[23,24]</sup>. Although the main mechanism that causes elevation of RDW levels in these different conditions is unknown, it is speculated that inflammation may play an important role<sup>[25]</sup>. Some pathways may explain the increase in RDW values, such as impaired iron metabolism, suppressed erythropoietin gene expression, inhibition of proliferation of erythroid progenitor cells, downregulation of erythropoietin receptor expression and reduced erythrocyte circulatory half-life<sup>[26]</sup>.

Alkhouri *et al*<sup>[27]</sup> found that the neutrophil to lymphocyte ratio was higher in patients with NASH and advanced fibrosis. They hypothesized that this ratio could be used as a novel noninvasive marker to predict advanced liver fibrosis caused by NASH. Tonelli *et al*<sup>[28]</sup> reported that higher RDW values might reflect an underlying chronic inflammation, which could result in an increased risk of cardiovascular disease.

These results suggest that inflammation may be a

potential underlying biological mechanism for increased RDW values. Chronic inflammation may play a role in disease progression of NASH and fibrosis. Indeed, multiple inflammatory cytokines have been assessed in different studies as noninvasive markers for the presence of NASH and fibrosis<sup>[29]</sup>. Thus, increased RDW values may be considered as a chronic inflammatory process in the pathogenic basis of NASH. Moreover our findings revealed that RDW could discriminate fibrotic scores of NASH, making it a potentially useful marker for predicting the progression and fibrotic stages of NASH.

We hypothesized that the relationship between RDW and NASH may be a result of an effect of an inflammatory process that suppresses mature erythrocytes and secretes young erythrocytes into the circulation, leading to anisocytosis and high RDW values. To the best of our knowledge, this is the first study to evaluate an association between high RDW values and high fibrotic scores in a well-designed, specifically organized patient group of biopsy proven NASH.

There are some limitations to our study that: RDW was assessed on a single situation instead of multiple consecutive measurements, therefore we could not evaluate any biological variabilities and measurement errors that could be a result of this. Also erythropoietin, reticulocyte count, inflammatory markers such as interleukin (IL)-1, IL-6, tumor necrosis factor- $\alpha$  were not provided; they might provide some important information on the pathophysiology of underlying high RDW physiology. A lack of a marked fall in the platelet count of NASH patients may reflect the small sample size and small number of cirrhotic patients. This must be evaluated in large population based prospective studies.

In summary, our study showed that in patients with biopsy proven NASH, RDW is associated with histological severity and could be used to identify patients with advanced liver fibrosis. Unlike many other noninvasive markers of NAFLD, RDW is inexpensive, widely available and easily repeatable. Although the accuracy of RDW for detecting NASH and significant fibrosis is sufficient, RDW in combination with other markers may help to identify patients at increased risk of having

advanced disease. Perhaps independently of anemia and other factors, RDW could be used to estimate the fibrotic process of different diseases. It may become one of the cornerstones of inflammation and fibrosis if confirmed in large population based studies in the future.

## COMMENTS

### Background

Non-alcoholic steatohepatitis (NASH) is one of the most common causes of chronic liver diseases. Liver biopsy is the only method for distinguishing NASH from other diagnoses and evaluating the damage and fibrosis of liver, but it may have procedure-related clinical complications.

### Research frontiers

Therefore, there has been an attempt to find noninvasive methods for detecting the presence of NASH, liver fibrosis and avoiding procedure-related complications. In this study, the authors demonstrated that red cell distribution width (RDW) may indicate the presence of NASH and advanced liver fibrosis.

### Innovations and breakthroughs

Recent reports have demonstrated that elevated RDW values were related to negative outcomes in cardiovascular and metabolic disorders, colon cancer and stroke independent of hemoglobin values. The association between RDW values and the severity of liver diseases has also been reported in two recent studies. This is the first study to demonstrate the importance of RDW in the diagnosis of NASH and predicting advanced liver fibrosis.

### Applications

By understanding that high RDW values can be seen in the presence of NASH and advanced liver fibrosis, this study may represent a future strategy for non-invasive diagnostic method of patients with NASH.

### Terminology

RDW is a widely available, inexpensive and easily repeatable parameter of variation of circulating red cells, reflecting the heterogeneity of red cell volume, a component of the complete blood count. Chronic inflammation plays a significant role in disease progression to NASH. Liver fibrosis is a result of chronic injury and can only be diagnosed invasively by liver biopsy.

### Peer review

The results present a new laboratorial and non-invasive marker of NASH and fibrotic stage. The authors concluded that in patients with biopsy proven NASH, RDW is associated with histological severity and could be used to identify patients with advanced liver fibrosis disease. This result is interesting and RDW may be used as a non-invasive marker of indicating the presence of NASH and advanced liver fibrosis.

**Key words:** Biliary and pancreatic disease; Computed tomography-multiplanar reconstruction image; Navigation; Real-time ultrasound image; Real-time virtual sonography

### Abstract

**AIM:** To evaluate the usefulness of real-time virtual sonography (RVS) in biliary and pancreatic diseases.

**METHODS:** This study included 15 patients with biliary and pancreatic diseases. RVS can be used to observe an ultrasound image in real time by merging the ultrasound image with a multiplanar reconstruction computed tomography (CT) image, using pre-scanned CT volume data. The ultrasound used was EUB-8500 with a convex probe EUP-C514. The RVS images were evaluated based on 3 levels, namely, excellent, good and poor, by the displacement in position.

**RESULTS:** By combining the objectivity of CT with free scanning using RVS, it was possible to easily interpret the relationship between lesions and the surrounding organs as well as the position of vascular structures. The resulting evaluation levels of the RVS images were 12 excellent (pancreatic cancer, bile duct cancer, cholecystolithiasis and cholangiocellular carcinoma) and

**Core tip:** The real-time virtual sonography (RVS) system combined with ultrasonography (US) and computed tomography (CT) compensates for each of the deficiencies of US and CT. The visualization in biliary and pancreatic diseases using RVS added objectivity and detailed imaging for diagnosis lacking in conventional B-mode US and CT, and it becomes possible to make a more precise diagnosis. Moreover, it is possible to consider this system as providing images of detailed processes conveniently and in real time. RVS has potential usefulness in objective visualization and diagnosis in the field of biliary and pancreatic diseases.

Real-time virtual sonography visualization and its clinical application in biliopancreatic disease. *World J Gastroenterol* 2013; 19(42): 7419-7425 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7419.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7419>

## INTRODUCTION

Recent advancements in technology have expanded the role of diagnosis by ultrasonography (US) in biliopancreatic diseases. Ultrasonography is useful because it is non-invasive and images can be obtained in real time. However, visualization is sometimes difficult in the presence of bone, gas and air, and thus has the problem of diminished objectivity. Real-time virtual sonography (RVS) (Hitachi-Aloka Medical Ltd., Tokyo, Japan) is a technological system that was developed in an attempt to resolve such problems.

This method merges ultrasound images with information from computed tomography (CT) images to produce the displayed image. In other words, the CT volume data is pre-stored into the device and the real-time ultrasound image is displayed simultaneously while the virtual view is reconstructed as a CT-multiplanar reconstruction (MPR) image from the stored volume data<sup>[1]</sup>. This is one method of compensating for the decreased objectivity in ultrasound diagnosis. This method is used during navigation in ultrasound-guided treatment and its usefulness has been reported in the field of liver disease<sup>[2-13]</sup>; however, no data has been presented in the field of biliopancreatic disease.

## MATERIALS AND METHODS

### Aim

The RVS system was applied on patients with biliopancreatic disease to investigate its usefulness and potential. The aim of the evaluation was to assess how the target lesion was correlated with the surrounding organs and blood vessels.

### Materials

RVS was performed on 15 biliopancreatic patients at our department. Among the patients, 6 had pancreatic cancer, 1 had pancreatic endocrine tumor, 2 had gall bladder cancer, 4 had bile duct cancer, 1 had cholangiocellular carcinoma, and 1 had cholecystolithiasis.

### Device

The RVS system (Figure 1) is made up of an ultrasound diagnostic device EUB-8500 (Hitachi-Aloka Medical Ltd., Tokyo, Japan), the EUP-C514 probe (Hitachi-Aloka Medical Ltd., Tokyo, Japan), which is a convex type, a personal computer (PC) and a magnetic position sensor unit to detect the position of the probe. Pre-scanned CT volume data is stored in a medium such as a compact disc read-only memory or PC using digital imaging and communication in medicine specifications *via* a local area network. The PC can display the images at a high speed of approximately 11 frames/s, with each frame being 256 × 256 pixels of virtual sonography. The PC is equipped with a magnetic position sensor unit to obtain information on the position of the probe. The magnetic position sensor unit consists of the main unit, a magnetism

generator and a magnetic sensor. When the magnetism generator is placed close to the patient, the magnetic sensor attaches to the probe. On CT, by performing imaging of very thin slices (approximately 1 mm) by multidetector CT (MDCT) of at least 16 rows, the minimum volume data required to reconstruct MPR images can be collected. In our department, 32-row MDCT is used to collect volume data by 3-planar contrast imaging.

### Obtaining information on probe position and its calibration

Information of the ultrasound probe position is obtained by the magnetic position sensor connected to the PC. The information obtained by this sensor is on its relative position to the magnetic sensor. Therefore, to prepare an MPR image that fits the ultrasound plane, it is necessary to decide on the pre-stored CT volume data and the position (reference point) of the ultrasound image. Ensiform cartilage that is palpable from the body surface is the ideal reference point. This is used to adjust the position (calibration). Apart from ensiform cartilage, calibration can also be performed using metal markers placed in the vasculature, kidneys, umbilical cord or body surface. In our department, calibration is mainly performed using ensiform cartilage. After the calibration, the ultrasound image obtained from the ultrasound scanning is displayed simultaneously. The virtual sonography-processing program in the PC detects the probe position and angle, reconstructs the corresponding planar image from the CT volume data, and displays it as an MPR image (Figure 2).

### Definitions

The respective RVS images are evaluated based on 3 levels, namely, Excellent: hardly any displacement in position, Good: midway between Excellent and Poor, and Poor: major displacement in position. The RVS images were stored in video form and were evaluated by 3 gastroenterologists (Sofuni A, Itoi T, Itokawa F) with at least 8 years of experience in abdominal sonography evaluation.

## RESULTS

The results were based on the decisions of the majority, and the result of an actual case is shown in Table 1. The resulting evaluation levels of the RVS images were 12 excellent (pancreatic cancer, bile duct cancer, cholecystolithiasis and cholangiocellular carcinoma) and 3 good (pancreatic cancer and gallbladder cancer). The evaluation of the RVS image in the patient with pancreatic endocrine tumor was excellent (Figure 3). The diagnosis by endoscopic ultrasound-guided fine needle aspiration was poorly differentiated neuroendocrine carcinoma. The relationship between the tumor and the celiac artery posed a problem in terms of choice of treatment. With the RVS image, the ultrasound showed no vascular irregularity, and the boundary between the tumor, celiac artery (CA) and splenic artery (SPA) remained intact, thus surgery was performed. Even when surgery was performed, there was

Figure 1 Real-time virtual sonography system. Pre-scanned computed tomography volume data are processed in the main body of the ultrasound machine.

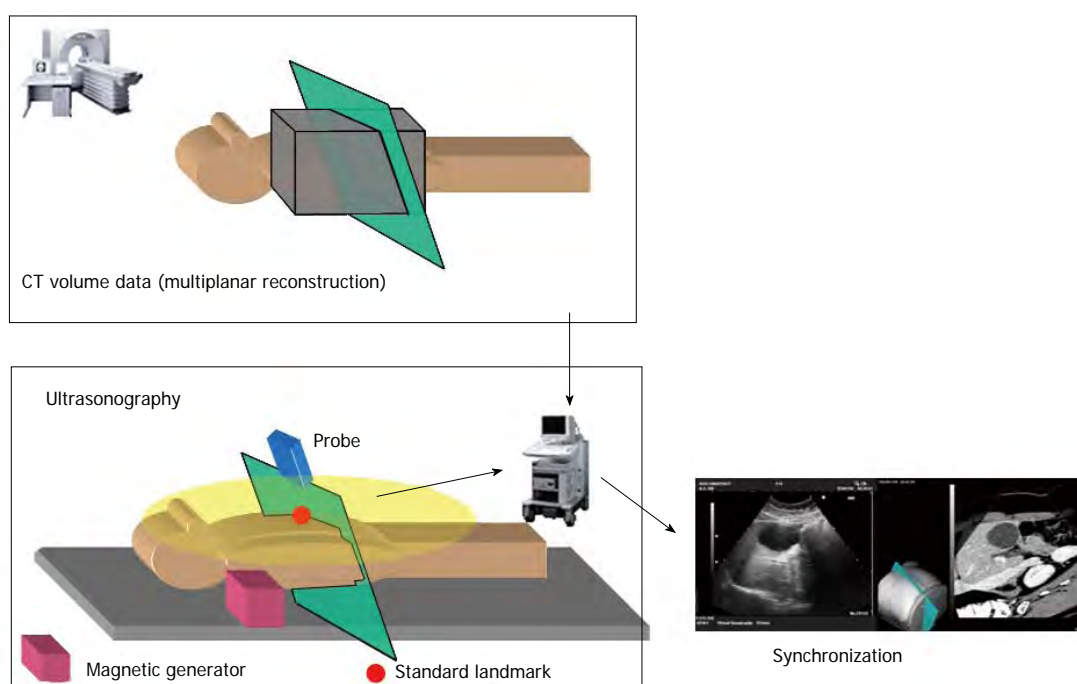

Figure 2 Calibration process. Transfer of the obtained computed tomography (CT) volume data; configuration of the settings for the standard landmark (ensiform cartilage/aorta/portal vein/other); and positional information of the probe is sensed. According to the probe sensor, the multiplanar reconstruction image is shown as an optimal angled plane.

no invasion into the arteries. With RVS, the positional relationship between the CA and the tumor could be evaluated objectively and was useful in judging whether or not surgery should be performed. Similarly, the positional relationship between the tumor mass and the vasculature could be assessed objectively, even in the cases where images of pancreatic cancer (Figure 4A, B) and bile duct cancer (Figure 4C-F) were judged as excellent. It was also useful in understanding the stage of progression and anatomical relationship. A good case (gall bladder cancer) is shown in Figure 4G.

## DISCUSSION

US is a generally subjective examination and is considered to lack objectivity, particularly in the staging of malignant tumors. By combining the objectivity of CT with the obscurity in the free scanning of US, it was possible to easily interpret the relationship between the lesions and the surrounding organs, as well as the position of vascular structures. Based on the results, incorporation of the objectivity of CT into voluntary scanning with an ultrasound probe facilitated understanding of the positional

relationships among the lesion, the surrounding organs and vasculature, and the structure of the lesion itself. According to the study, this RVS system, combined with US and CT, also confirmed the comparatively precise diagnosis in US imaging. Moreover, this system compensates for each of the deficiencies of US and CT, and it becomes possible to provide more detailed information and make a more precise diagnosis.

US is usually more useful than CT in judging detailed imaging and the relationships with surrounding structures, and moreover, it is possible to consider the RVS system as providing images of detailed processes conveniently and in real time. For example, in Figure 3, it seems that the tumor invaded the blood vessel on CT imaging, but the RVS system showed that the tumor had not invaded the blood vessel. Therefore, RVS can aid in making a precise diagnosis when CT is unable to make judgments on the staging.

Compared with conventional B-mode US and CT, RVS images achieved a rate of 80% superior visualization and 20% better visualization, according to the statistics.

The RVS visualization of lesions and the surrounding organs of all patients provided the objectivity and detailed imaging information for diagnosis lacking in conventional B-mode US and CT. It is also suggested to be useful when applied to making a diagnosis on the existence and stage of progression of malignant tumors, and the evaluation of infiltration into major blood vessels. Further studies in more patients are required to examine the applicability of this method to the diagnosis of malignant diseases and the extent of disease progression, including assessment of infiltration into major blood vessels. This needs to be investigated further in a larger number of patients.

Considering the investigations we have performed using RVS on patients in our department to date, the advantages and disadvantages of RVS are as outlined below. Five advantages are recognized at present: (1) CT objectivity in real-time sonographic images makes it easy to understand the structure and positional relationship between the lesion and the surrounding organs and vasculature; (2) it provides supportive education for surgeons and physicians that lack experience; (3) MPR images obtained by multi-slicing using the familiar operations of the ultrasound probe can be visualized instantly; (4) the display screen can be switched between the arterial phase, portal vein phase, and equilibrium phase (applies to the hemodynamics of the lesion and evaluation of the vasculature) by a simple operation; and (5) the common bile duct and pancreas are not affected by variations in breathing as much as the liver. There are 5 disadvantages: (1) the positions of the images during CT scanning and those of the US images are easily displaced due to breathing variations (liver > biliopancreatic area); (2) with only 1 reference point, synchronization of the position tends to be inadequate; (3) progression, infiltration and vascular evaluation are time-consuming and may put a strain on patients; (4) the focus is mainly on CT, thus US evaluation tends to be poor; and (5) the calibration is time-consuming. It is preferable to perform RVS after considering these advantages and disadvantages.

The main problem in the present RVS system is that when the position is displaced, calibration becomes time-

**Figure 4** The resulting evaluation levels of the real-time virtual sonography images were 12 excellent (pancreatic cancer, bile duct cancer, cholecystolithiasis and cholangiocellular carcinoma) and 3 good (pancreatic cancer and gallbladder cancer). A: Pancreatic cancer (excellent case); the positional relationships among the tumor and vessels [superior mesenteric artery (SMA) and superior mesenteric vein, (SMV)] were well evaluated; B: Pancreatic cancer (excellent case); the positional relationships among the tumor, vessels [portal vein (PV)], common bile dilatation (CBD), and main pancreatic duct (MPD) were well evaluated; C: Bile duct cancer (excellent case); the positional relationships among the tumor and vessels (SMA, SMV and PV) were well evaluated; D: Bile duct cancer (excellent case); the positional relationship between the tumor and CBD was well evaluated; E: Bile duct cancer (excellent case); the positional relationships among the tumor and vessels [proper hepatic artery (PHA), right hepatic artery (RHA), PV] were well evaluated; F: Bile duct cancer (excellent case); the positional relationships among the tumor and vessels [RHA, PV and inferior vena cava (IVC)] were well evaluated; G: Gallbladder cancer (good case); there was a gap in the positional relationships among the tumor and vessels.

consuming. At Hitachi-Aloka Medical Ltd., an ultrasound phantom was prepared to examine the precision, and RVS was performed using simulated CT. As a result, displacement of the position of the slicing plane tended to depend on the distance between the magnetism generator and the magnetic sensor. However, the distance was reported to be approximately  $\pm 5$  mm within a range of 70 cm with the magnetism generator as the center. In addition, with only 1-point calibration, there is displacement of the position. Therefore, multiple-point calibration is important. Precision for calibration needs to be improved by taking these factors into consideration. Moreover, in actual clinical settings, the position of organs may also vary according to the posture and depth of respiration of the subject. Errors can also arise due to these factors; therefore, a corrective function for positional displacement as in the synchronization of breathing needs to be installed in the device. In addition, recent advances in computer and laser technologies have enabled the construction of MPR images of MDCT to be performed easily even with a notebook PC. Taking these points into consideration, one can say that the superiority of RVS is its potential in the areas of therapy and education.

Apart from diagnosis, RVS is now commonly used

to assist treatment under ultrasound guidance in liver disease. Even in the biliopancreatic area, particularly with pancreatic cancer, focused ultrasound treatment and high intensity focused ultrasound (HIFU) treatment are now being performed<sup>[14]</sup>. In the current HIFU, treatment progresses while looking at the 2D ultrasound image. The application of this method allows easy understanding of the range of treatment, and safe treatment can be performed objectively.

This study suggests that RVS is useful when applied to making a diagnosis on the existence and stage of progression of malignant tumors, and making evaluations of infiltration into major blood vessels, in spite of some disadvantages. Further improvement and progress of RVS is expected in the field of therapy.

## COMMENTS

### Background

Ultrasonography (US) is non-invasive, and images can be obtained in real time. However, visualization is sometimes difficult with the presence of bone, gas and air, and thus has the problem of diminished objectivity. Real-time virtual sonography (RVS) is a technological system that was developed in an attempt to resolve such problems. This is one method of compensating for the decreased objectivity in ultrasound diagnosis. This method is used during navigation in

ultrasound-guided treatment and its usefulness has been reported in the field of liver disease; however, no data has been presented in the field of biliopancreatic disease.

### Research frontiers

The frontiers of research are in the fields of diagnosis and therapy for biliopancreatic disease.

### Innovations and breakthroughs

The usefulness of the RVS system has been reported in the field of liver disease; however, no data has been presented in the field of biliopancreatic disease. RVS is useful when applied to making a precise diagnosis on the existence and stage of progression of malignant tumors, and making evaluations of infiltration into major blood vessels. Recently, therapies using ultrasound for biliopancreatic disease have been developed. Further improvement and progress of RVS is expected in the field of therapy.

### Applications

The RVS system combined with US and computed tomography (CT) compensates for each of the deficiencies of US and CT, and it becomes possible to provide more detailed information and make a more precise diagnosis. Moreover, it is possible to consider the RVS system as providing images of detailed processes conveniently and in real time. Therefore, this system is useful in the case in which the detailed information and positional relationships among the lesions are needed for a precise diagnosis.

### Terminology

RVS can be used to observe an ultrasound image in real time by merging the ultrasound image with a multiplanar reconstruction CT image, using pre-scanned CT volume data. The RVS system combined with US and CT compensates for each of the deficiencies of US and CT.

### Peer review

This is a good study of the usefulness of RVS in biliary and pancreatic diseases. Twelve patients with biliary and pancreatic diseases in whom the combination of the objectivity of CT with free scanning using RVS was observed. This study showed that the visualization in biliary and pancreatic diseases using RVS had the objectivity and the detailed imaging for diagnosis lacking in conventional B-mode US and CT. This new technique has potential usefulness in visualizing and diagnosing biliary and pancreatic diseases in the future. Even though the patient numbers were small, the paper has the potential data to be used at the clinic for appropriate diagnosis.

### Abstract

**AIM:** To elucidate the characteristics of hemorrhagic gastric/duodenal ulcers in a post-earthquake period within one medical district.

**METHODS:** Hemorrhagic gastric/duodenal ulcers in the Iwate Prefectural Kamaishi Hospital during the 6-mo period after the Great East Japan Earthquake Disaster were reviewed retrospectively. The subjects were 27 patients who visited our hospital with a chief complaint of hematemesis or hemorrhagic stool and were diagnosed as having hemorrhagic gastric/duodenal ulcers by upper gastrointestinal endoscopy during a 6-mo period starting on March 11, 2011. This period was divided into two phases: the acute stress phase, comprising the first month after the earthquake disaster, and the chronic stress phase, from the second through the sixth month.

The following items were analyzed according to these phases: age, sex, sites and number of ulcers, peptic ulcer history, status of *Helicobacter pylori* (*H. pylori*) infection, intake of non-steroidal anti-inflammatory drugs, and degree of impact of the earthquake disaster.

**RESULTS:** In the acute stress phase from 10 d to 1 mo after the disaster, the number of patients increased rapidly, with a nearly equal male-to-female ratio, and the rate of multiple ulcers was significantly higher than in the previous year (88.9% vs 25%,  $P < 0.005$ ). In the chronic stress phase starting 1 mo after the earthquake disaster, the number of patients decreased to a level similar to that of the previous year. There were more male patients during this period, and many patients tended to have a solitary ulcer. All patients with duodenal ulcers found in the acute stress phase were negative for serum *H. pylori* antibodies, and this was significantly different from the previous year's positive rate of 75% ( $P < 0.05$ ).

**CONCLUSION:** Severe stress caused by an earthquake disaster may have affected the characteristics of hemorrhagic gastric/duodenal ulcers.

© 2013 Baishideng Publishing Group Co., Limited. All rights reserved.

**Key words:** Great East Japan Earthquake Disaster; Hemorrhagic gastric; Duodenal ulcer; *Helicobacter pylori* infection; Stress

**Core tip:** We determined the characteristics of hemorrhagic gastric/duodenal ulcers in the post-earthquake period within one medical district. We divided hemorrhagic gastric/duodenal ulcers into two groups, the acute stress phase group, consisting of the first month after the earthquake disaster, and the chronic stress phase group, from the second through the sixth month. We concluded that severe stress caused by this

earthquake disaster exacerbated the characteristics of hemorrhagic gastric/duodenal ulcers.

Hemorrhagic gastric and duodenal ulcers after the Great East Japan Earthquake Disaster. *World J Gastroenterol* 2013; 19(42): 7426-7432 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7426.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7426>

## INTRODUCTION

Iwate Prefectural Kamaishi Hospital is located in the southern coastal area of Iwate Prefecture and is a regional core hospital with 15 departments and 272 beds in the Kamaishi medical district (Figure 1). This hospital is a core disaster hospital in the medical district, which has a population of approximately 55000. In the Great East Japan Earthquake Disaster that occurred on March 11, 2011, the Pacific coastal regions of East Japan suffered devastating damage from the earthquake itself and the consequent tsunami. Our hospital remained functional enough to accept all patients transported by ambulance from within the medical district, even after the disaster. The East Japan Earthquake Disaster significantly increased the occurrences of cardiovascular disease, respiratory disease, and cerebrovascular disease<sup>[1-9]</sup>. Since the number of patients visiting our hospital with hemorrhagic gastric/duodenal ulcers increased after this disaster, we compared those patients with the analogous patient population in 2010, the pre-earthquake period. This study aimed to elucidate the characteristics of ulcers in the post-earthquake period within our medical district.

## MATERIALS AND METHODS

This study included 27 patients who visited our hospital with a chief complaint of hematemesis or hemorrhagic stool and were diagnosed as having hemorrhagic gastric/duodenal ulcers by upper gastrointestinal endoscopy during a 6-mo period starting on March 11, the day of the earthquake disaster, until September 10, 2011. This period was divided into 2 phases: the acute stress phase, comprising the first month after the earthquake disaster, and the chronic stress phase, from the second through the sixth month. The following items were analyzed according to these phases: age, sex, sites and number of ulcers, peptic ulcer history, status of *Helicobacter pylori* (*H. pylori*) infection, intake of non-steroidal anti-inflammatory drugs (NSAIDs), and degrees of impact of the earthquake disaster. Moreover, these data were compared with those obtained from 27 consecutive patients who visited our hospital with a chief complaint of hematemesis or hemorrhagic stool and were diagnosed as having hemorrhagic gastric/duodenal ulcers by upper gastrointestinal

endoscopy during the same period of the previous year (March 11 to September 10, 2010). Rates of hemorrhagic gastric/duodenal ulcers reportedly increased after the earthquake disaster<sup>[10]</sup>. We performed endoscopy only on patients who presented with a chief complaint of hematemesis or hemorrhagic stool during the first few months after the earthquake disaster, so only patients with confirmed hemorrhagic gastric/duodenal ulcers were included in this study. The status of *H. pylori* infection was determined by serum antibody titer. If the antibody titer was more than 10 U/mL, the patient was considered *H. pylori* positive. The titers of two patients were not examined because they were immediately transferred to other hospitals.

## RESULTS

### Hemorrhagic gastric ulcer

No patients with hemorrhagic gastric ulcers visited our hospital during the first 10 d after the earthquake disaster (Table 1, Figure 2A).

Acute stress phase (the first month after the earthquake disaster): There were 9 patients with ulcers. Compared to the mean number of patients in the previous year (3.3 patients/mo in 2010), this number represented a marked increase of approximately 3-fold after the earthquake disaster, but the difference was not statistically significant (Table 2). The mean patient age was 68.3 years, similar to that of the previous year (69.2 years). The male-to-female ratio was 6:3. Although it was not significantly different from that of the previous year (15:5), the percentage of women was higher in the study period. Regarding ulcer morphology, multiple ulcers were observed in 8 patients (88.9%), and the incidence of this form was significantly higher than in the previous year (25%) ( $P < 0.005$ ). The most common ulcer site was the gastric corpus, seen in 7 patients (77.8%), and the rate for this site was similar to that of the previous year (85%). Four patients had an ulcer history (44.4%), and the proportion of these patients was similar to that of the previous year (35%). Five patients were positive for serum *H. pylori* antibodies (55.6%), which was slightly lower than the previous year (64%) (not statistically significant).

Chronic stress phase (the second to the sixth month after the earthquake disaster): There were 11 patients with ulcers, with the mean number being 2.2 patients/mo, indicating a significant decrease compared to the number in the acute stress phase ( $P < 0.05$ ). Moreover, the number in the chronic stress phase was smaller than that of the previous year (3.3 patients/mo) (not statistically significant). The mean patient age was 65.8 years, again similar to that of the previous year (69.2 years). The male-to-female ratio was 8:3, which was also similar to that of the previous year (15:5). Regarding ulcer morphology, multiple ulcers were observed in 5 patients (45.5%), which was a significantly lower rate than in the acute stress phase ( $P < 0.05$ ). Moreover, the incidence

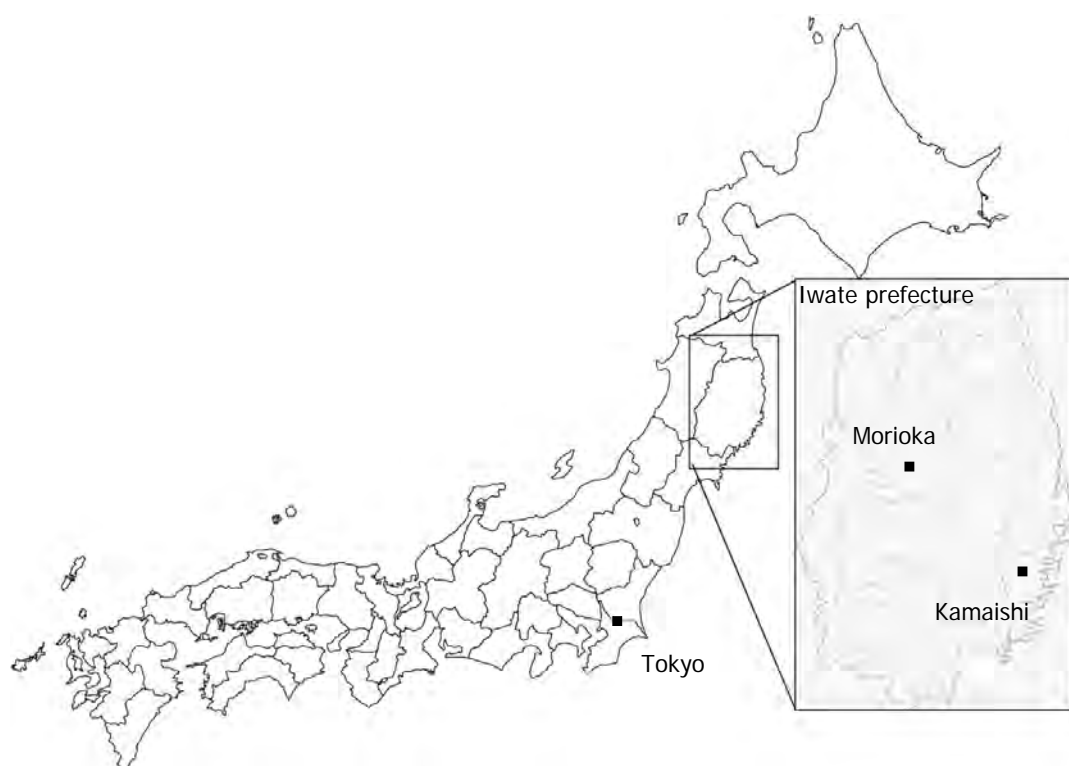

Figure 1 Location of Kamaishi city in Iwate prefecture in Japan.

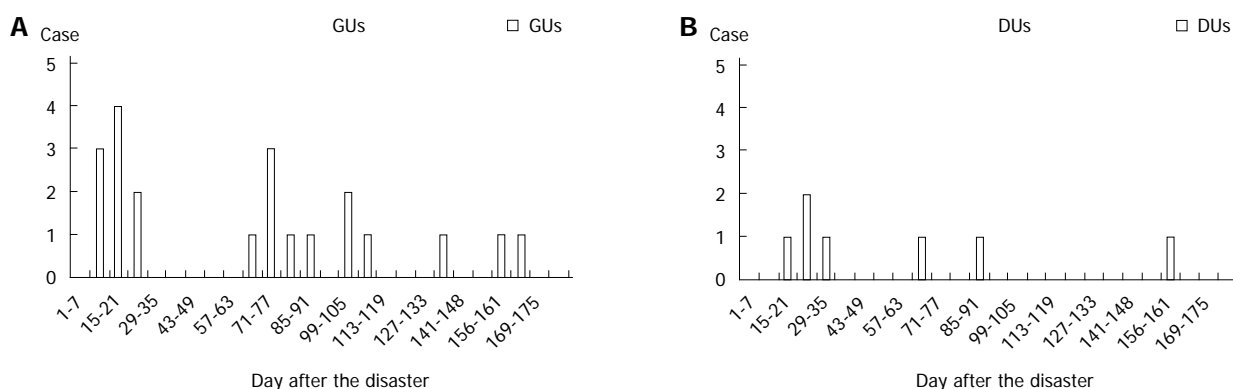

Figure 2 Incidence of hemorrhagic gastric (A) and duodenal (B) ulcers. GUs: Gastric ulcers; DUs: Duodenal ulcers.

in the chronic stress phase was nearly the same as that of the previous year (25%). Regarding ulcer site, ulcers were observed in the gastric corpus in 8 patients (72.7%), a rate that was similar to that of the previous year (85%). Three patients had an ulcer history (27.2%), and the proportion of these patients was nearly the same as that of the previous year (35%). Eight patients were positive for serum *H. pylori* antibodies (72.7%), and the proportion was similar to that of the previous year (64%).

Four of 6 patients who were negative for serum *H. pylori* antibodies used neither oral NSAIDs nor steroids at any time during the study period.

#### Hemorrhagic duodenal ulcer

No patients with hemorrhagic duodenal ulcers visited our hospital during the first 19 d after the earthquake

disaster (Table 3, Figure 2B).

Acute stress phase (the first month after the earthquake disaster): Three patients had ulcers. Compared to the mean number of patients in the previous year (1.2 patients/mo), this number was higher after the earthquake disaster, though it was not statistically significant (Table 2). The mean patient age was 68.6 years, similar to that of the previous year (57.3 years). The male-to-female ratio was 2:1, which was almost the same as that of the previous year (5:2). All patients showed multiple ulcers on the posterior wall. None of the patients had an ulcer history, which was lower than the previous year (75%), though not significantly. All patients were negative for serum *H. pylori* antibodies, and this was significantly different from the previous year (positive rate: 75%) ( $P < 0.05$ ).

GUs: Gastric ulcers; DUs: Duodenal ulcers. <sup>a</sup>*P* < 0.05 between 2011 acute stage vs 2011 chronic stage; <sup>c</sup>*P* < 0.05, <sup>d</sup>*P* < 0.01 between 2011 acute stage vs 2010.

Chronic stress phase (the second to the sixth month after the earthquake disaster): Four patients had ulcers, and the mean number of 0.8 patient/mo was similar to that of the previous year (1.2 patients/mo). The mean patient age was 56.3 years, again similar to that of the previous year (57.3 years). The male-to-female ratio was 3:1, which was also quite similar to that of the previous year (5:2). Although 4 patients (100%) had an ulcer history, there was no significant difference from the previous year (43%). Three patients were positive for serum *H. pylori* antibodies (75%), and this proportion was similar to that of the previous year (67%).

## DISCUSSION

Both *H. pylori* infection and NSAIDs have major roles

in the pathogenesis of peptic ulcers<sup>[11-16]</sup>. Stress is also considered an important causal factor in peptic ulcer disease<sup>[17]</sup>, and there are studies on the involvement of *H. pylori* infection and stress in the incidence of peptic ulcers after the Great Hanshin-Awaji Earthquake Disaster in 1995<sup>[18-20]</sup>.

In the Great East Japan Earthquake Disaster that occurred on March 11, 2011, the Kamaishi medical district (population of approximately 55000), where our hospital is located, also suffered serious damage due to the tsunami, and the combined number of dead and missing persons was approximately 2300. Many disaster victims also lost their homes. They were forced to stay at shelters or to live without adequate infrastructure, such as gas, water, and electricity supplies. These disaster victims experienced severe and unprecedented stress,

**Table 3** Details of patients with duodenal ulcers in 2011

Day	Age (yr)	Sex	Location	Number	p.h.	<i>Helicobacter pylori</i> antibody titer	Property damage	Dead family
Acute stage

p.h.: Past history of peptic ulcer; AW: Anterior wall; PW: Posterior wall.

which persisted for a considerable period of time. In this study, the acute stress phase was defined as the first month, when numerous aftershocks occurred and when the disaster victims lived under extremely severe stress due to poor living conditions. The chronic stress phase was defined as the period from the second through sixth month after the earthquake disaster. We analyzed the clinical and demographic data of ulcer patients for each period.

Because the emergency transport routes were restored the day after the earthquake, many patients were transported to our hospital immediately after this disaster. Nevertheless, the day when the first patient visited our hospital with a chief complaint of hematemesis or hemorrhagic stool after the earthquake was March 22, 11 d after the disaster. Subsequently, the number of patients visiting our hospital with one of these chief complaints gradually increased, and 12 patients (mean: 3 patients/wk) with hemorrhagic gastric/duodenal ulcer visited in the first month. Because the mean number of patients with hemorrhagic gastric/duodenal ulcers for a period of 6 mo starting March 11, 2010, had been 1.13 patients/wk, there was an apparent increase after the March 11, 2011 earthquake disaster. However, the number rapidly decreased after the first month, and the subsequent mean number was 0.75 patient/wk, which was slightly lower than that of the previous year.

Matsuura *et al.*<sup>[21]</sup> studied upper gastrointestinal bleeding after the Great East Japan Earthquake Disaster and found that there were few patients immediately after the earthquake disaster but that the number increased from a few days to 1 mo after the disaster. According to a study conducted in 1998 on peptic ulcers occurring after the Great Hanshin-Awaji Earthquake Disaster<sup>[18]</sup>, Aoyama *et al.*<sup>[18]</sup> also reported that the number of patients decreased during the first 2 wk after the earthquake disaster as compared to the previous year, then increased during the third through fourth weeks, and returned to a similar level to that of the previous year from the fifth through sixth weeks. Takakura *et al.*<sup>[22]</sup> also reported that the number of patients with gastric ulcers increased by 4-fold 2 wk after the Great Hanshin-Awaji Earthquake Disaster, gradually decreased thereafter, and it had returned to near the level of the previous year 2.5 mo later. Our data show a

similar trend to these reports. The increase in the number of patients during the acute stress phase strongly suggests that severe stress due to the violent earthquake and consequent tsunami contributed to the ulcer incidence. We have no clear explanation why the incidence of hemorrhagic gastric/duodenal ulcers was low during the first 10 d after the earthquake disaster, a time when the disaster victims were under extremely severe stresses concerning matters of life and death. It was assumed that stressful conditions might need to persist for a certain period of time before the breakdown of biological defense mechanisms.

The male-to-female ratio of gastric ulcer patients was 6:3. However, the ratio in the chronic stress phase was 8:3, a higher percentage of men. The examination of the data obtained during the same period in 2010 at our hospital also shows that the male-to-female ratio was 15:5, indicating a trend for a much higher percentage of men. Moreover, a study conducted in Japan found that the male-to-female ratio among peptic ulcer patients was 71:29, indicating that this disease occurs approximately 2.4 times more frequently in men than in women<sup>[23]</sup>. Based on a comparison of these data, an approximately equal incidence between men and women might be one of the characteristics of gastric ulcer presumably caused by acute stress after an earthquake disaster. Meanwhile, the male-to-female ratios for duodenal ulcer were 2:1 in the acute stress phase and 3:1 even in the chronic stress phase. These ratios were essentially consistent with the trends observed in most studies, and we assume that there are gender differences in the incidence of gastric and duodenal ulcers caused by acute stress.

The mean age of patients with gastric ulcers was 68.3 or 65.5 years old in the acute stress phase or chronic stress phase, respectively, which were not significantly different. The mean ages of those with duodenal ulcers were 68.6 and 56.3 years, respectively, indicating that the patients tended to be older in the acute stress phase.

Regarding the number of gastric ulcer lesions, multiple ulcers were observed in 8 (88.9%) of 9 patients in the acute stress phase. On the other hand, multiple ulcers were observed in 5 (45.5%) of 11 patients in the chronic stress phase, and an increase in the number of patients with a solitary ulcer was documented. Regarding

the number of duodenal ulcer lesions, multiple ulcers were observed in 2 (66.7%) of 3 patients in the acute stress phase. In the chronic stress phase, only 1 (25%) of 4 patients had multiple ulcers. According to the data on patients at our hospital during the same period in 2010, 5 (25%) of 20 patients had multiple gastric ulcers, and 3 (42.9%) of 7 patients had multiple duodenal ulcers. Thus, both hemorrhagic gastric and duodenal ulcers in the acute stress phase were often multiple. Kanno *et al.*<sup>[24]</sup> reported that post-disaster hemorrhagic ulcers were frequently observed in the stomach as multiple ulcers at the same time.

Five (55.6%) of 9 patients in the acute stress phase and 8 (72.7%) of 11 patients in the chronic stress phase were positive for *H. pylori* antibodies. All patients of hemorrhagic gastric/duodenal ulcers had no history of eradication therapy of *H. pylori*. During the same period in 2010 (excluding unknown cases), 7 (63.6%) of 11 patients were *H. pylori* positive, a number similar to that after the earthquake disaster. In contrast, none of the 3 patients with duodenal ulcers was positive for *H. pylori* antibodies in the acute stress phase, and this incidence was significantly lower than that of the chronic stress phase, in which 4 (100%) of 4 patients were positive. During the same period in 2010, 4 (66.7%) of 6 patients with duodenal ulcers were positive for *H. pylori* antibodies. The rate of peptic ulcer not associated with the use of drugs, such as NSAIDs, in Japanese patients negative for *H. pylori* infection was reported by Aoyama *et al.*<sup>[25]</sup> to be 1.9% to 5.1% and by Nishikawa *et al.*<sup>[26]</sup> to be 1.3%. However, Kanno *et al.*<sup>[10]</sup> reported that patients with non-*H. pylori* and non-NSAID gastroduodenal ulcers accounted for as many as 24% of cases after the Great East Japan Earthquake Disaster, and their analysis showed that there were many cases with ulceration attributable to stress. In this study, 8 (29.6%) of 27 patients, including those with gastric/duodenal ulcers, were negative for *H. pylori* antibodies and had not taken oral NSAIDs. The incidence of such cases was extremely high. All 8 patients were experiencing overwhelming stress. For example, they had dead or missing family members or were forced to stay at shelters due to the complete destruction of their homes. This raises the possibility that hemorrhagic gastric/duodenal ulcers can be caused by stress alone.

We did not encounter patients with hemorrhagic acute gastric mucosal lesion that might have been induced by primary infection by *H. pylori*. There is a minor possibility that those patients got acutely infected by *H. pylori* and were not yet serologically positive. However, no incident of waterborne infection was reported in this area during the period, and the quality of most sources of drinking water was maintained in a hygienic state. We do not think that a majority of them got infected by *H. pylori* during the study period.

As to the location of hemorrhagic duodenal ulcers, all patients had ulcers in the posterior wall of the bulb in the acute stress phase. The proportion of these patients was higher than in the chronic stress phase and the previous year. Although the difference between

these proportions was not statistically significant, stress-induced duodenal ulcers without *H. pylori* infection may tend to occur in the posterior wall of the bulb.

Our study has some limitations. This was an observational analysis that was performed on a limited closed lesion with a small sample size. Under the confused and extraordinary circumstances in the aftermath of the great disaster, detailed examinations were difficult to perform. Endoscopic examinations were mainly performed for hemorrhagic gastric/duodenal ulcers. Therefore, the pathophysiology and incidence of non-hemorrhagic and asymptomatic peptic ulcers are unknown. However, we expect that this study has some useful information for the care of hemorrhagic gastro/duodenal injury at times of great disasters.

In conclusion, severe stress caused by an earthquake disaster may have affected the characteristics of hemorrhagic gastric/duodenal ulcers.

## COMMENTS

### Background

Under severe stress, the incidence of hemorrhagic gastric/duodenal ulcers increases. However, there are few reports on the incidence and characteristics of hemorrhagic gastric/duodenal ulcers after a great earthquake disaster. Since the number of patients visiting our hospital with hemorrhagic gastric/duodenal ulcers increased after the Great East Japan Earthquake Disaster, the authors compared those patients with hemorrhagic gastric/duodenal ulcer patients in 2010, the pre-earthquake period. This study aimed to elucidate the characteristics of ulcers in the post-earthquake period within one medical district.

### Research frontiers

It is not well known whether severe stress independently causes hemorrhagic gastric/duodenal ulcers without *Helicobacter pylori* (*H. pylori*) infection and non-steroidal anti-inflammatory drug (NSAID) use.

### Innovations and breakthrough

In this medical district, all patients who developed gastric/duodenal ulcers were admitted to one hospital. Therefore, interesting differences in the characteristics of hemorrhagic ulcers before and after the earthquake disaster were observed. Moreover, it is presumed that severe stress caused by this earthquake disaster may have affected the characteristics of hemorrhagic gastric/duodenal ulcers without *H. pylori* infection and NSAIDs.

### Applications

This study will provide some useful information for the care of hemorrhagic gastro/duodenal injuries at the time of a great disaster.

### Terminology

The Great East Japan Earthquake Disaster occurred on March 11, 2011. The Pacific coastal regions of East Japan suffered devastating damage by the earthquake itself and the consequent tsunami.

### Peer review

This is an important study in which dynamic changes in the characteristics of complicated peptic ulcer patients is depicted. Taking care of patients and performing such an analysis in a devastating circumstance is encouraging to all.

### Abstract

**AIM:** To elucidate the variety of ways early-stage hepatocellular carcinoma (HCC) can appear on magnetic resonance (MR) imaging by analyzing T1-weighted, T2-weighted, and gadolinium-enhanced dynamic studies.

**METHODS:** Seventy-three patients with well-differentiated HCC (wHCC) or dysplastic nodules were retrospectively identified from medical records, and new histological sections were prepared and reviewed. The tumor nodules were categorized into three groups: dysplastic nodule (DN), wHCC compatible with Edmondson-Steiner grade I HCC (w1-HCC), and wHCC compatible with

Edmondson-Steiner grade II HCC (w2-HCC). The signal intensity on pre-contrast MR imaging and the enhancing pattern for each tumor were recorded and compared between the three tumor groups.

**RESULTS:** Among the 73 patients, 14 were diagnosed as having DN, 40 were diagnosed as having w1-HCC, and 19 were diagnosed as having w2-HCC. Hyperintensity measurements on T2-weighted axial images (T2WI) were statistically significant between DNs and wHCC ( $P = 0.006$ ) and between DN and w1-HCC ( $P = 0.02$ ). The other imaging features revealed no significant differences between DN and wHCC or between DN and w1-HCC. Hyperintensity on both T1W out-phase imaging ( $P = 0.007$ ) and arterial enhancement on dynamic study ( $P = 0.005$ ) showed statistically significant differences between w1-HCC and w2-HCC. The other imaging features revealed no significant differences between w1-HCC and w2-HCC.

**CONCLUSION:** In the follow-up for a cirrhotic nodule, increased signal intensity on T2WI may be a sign of malignant transformation. Furthermore, a noted loss of hyperintensity on T1WI and the detection of arterial enhancement might indicate further progression of the histological grade.

**Key words:** Dysplastic nodule; Hepatocellular carcinoma; Histological grading; Magnetic resonance imaging; Well-differentiated hepatocellular carcinoma

**Core tip:** The aim of this article was to differentiate between early-stage hepatocellular carcinoma (HCC) and dysplastic nodules using conventional magnetic resonance (MR) imaging. We found that conventional MR imaging could provide additional information to dif-

ferentiate between early-stage HCC and dysplastic nodules in equivocal lesions. During follow-up for a cirrhotic nodules, increased signal intensity on T2-weighted axial images may be a sign of malignant transformation. Loss of hyperintensity on T1WI and the detection of arterial enhancement may indicate further progression of the histological grade.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most commonly diagnosed malignant tumors in the world. HCC occurs primarily in patients with chronic liver disease such as hepatitis B and C infections<sup>[1,2]</sup>. HCC develops by means of a multi-step dedifferentiation process that progresses from regenerative nodule to dysplastic nodule (DN) and then to HCC<sup>[3]</sup>. Early detection of HCC in cirrhotic livers is important to improve patient outcomes and decision-making to determine optimum therapeutic strategies<sup>[4]</sup>. A follow-up system for high-risk HCC populations has been established. Additionally, research and technology have enabled increasing numbers of small nodular lesions to be detected. According to the practice guidelines of the American Association for the Study of Liver Diseases (AASLD), HCC can be diagnosed noninvasively in at-risk patients, who typically demonstrate arterial-phase enhancement and venous- or delayed-phase washout on dynamic computed tomography (CT) or magnetic resonance imaging (MRI)<sup>[5]</sup>. However, most of these nodules with characteristic CT or MR patterns are overt HCC. The percentage of well-differentiated HCCs showing typical hypervascularity in the arterial-phase followed by washout in the delayed-phase on a dynamic study ranges from 13% to 50%<sup>[6,7]</sup>. Therefore, well-differentiated HCCs are increasingly detected in our daily practice, yet many represent diagnostic difficulties.

Gadoxetic acid (Gd-EOB-DTPA)-enhanced MRI has been demonstrated to be useful in differentiating between early HCC and dysplastic nodules in several recent studies<sup>[8,9]</sup>. However, the overlap between dysplastic nodules and HCC on gadoxetic acid-enhanced MR presentations has also been mentioned in the literature<sup>[10,11]</sup>. Due to the facts that gadoxetic acid is not available in every country and is costly, conventional MRI remains an important tool in differentiating between cirrhotic nodules and early HCC. Conventional MR imaging protocols rely on T1-weighted and T2-weighted imaging and multiphase dynamic gadolinium-enhanced imaging to depict and characterize tumors<sup>[12,13]</sup>. To the best of our knowledge,

the role of conventional MR sequences in differentiating between early-stage HCC and dysplastic nodule in cirrhotic liver has not yet been established. The purpose of our study was to elucidate the variety ways of early-stage HCC can appear on MR imaging by analyzing T1-weighted, T2-weighted, and gadolinium-enhanced dynamic studies.

## MATERIALS AND METHODS

### Patient population

Approval for this retrospective study was obtained from the institutional review board of our hospital. A flow-chart for the patient selection process is shown in Figure 1. Ultimately, 73 patients (51 men and 22 women; mean age, 61 years old; range, 26-82 years) were enrolled in this study. Among them, 70 patients underwent liver biopsy, and 3 patients underwent hepatectomy. All 73 patients had liver cirrhosis: 29 patients had hepatitis B virus; 28 patients had hepatitis C virus; 9 patients had hepatitis B and C co-infections; and 7 patients had alcoholic cirrhosis. Among the 73 patients, 49 patients had Child-Pugh class A cirrhosis, and 24 patients had Child-Pugh class B cirrhosis. The diagnoses of liver cirrhosis were all based on histopathological examination.

### Histopathological diagnosis

New histological sections from the original paraffin blocks of all 73 patients' liver tumors were prepared using hematoxylin and eosin stain. The diagnostic features for HCC included the following: (1) increased cell density >2 times the density of the surrounding tissue, with an increased nuclear:cytoplasmic ratio; (2) thickened liver cell plates (2 cells or more); (3) pseudoglandular structure formations; (4) unpaired arteries; (5) sinusoidal capillarization; and (6) stromal invasion without ductular reaction at the periphery of the nodules<sup>[14,15]</sup>. Immunohistochemical stains for CD10 (Biocare Medical, Concord, CA, United States), CD34 (DAKO, Glostrup, Denmark) and cytokeratin 7 (DAKO, Glostrup, Denmark) were also performed to facilitate interpretation. The tumor nodules were categorized into three groups: DN, well-differentiated HCC compatible with Edmondson-Steiner grade I HCC (w1-HCC)<sup>[16]</sup>, and well-differentiated HCC compatible with Edmondson-Steiner grade II HCC [which also included well-differentiated HCC in the World Health Organization system (w2-HCC)]<sup>[17]</sup>.

Two pathologists with more than 10 years of experience in hepatic pathology reviewed all the histological sections independently. Differences between the two reviewers were resolved by a third pathologist to reach a final consensus. All three of the pathologists were blinded to the original pathology diagnoses and the clinical information.

The presence of high cellularity, diffuse capillarization, abnormal biliary canaliculi and stromal invasion were considered features of w1-HCC. The additional presence of nuclear pleomorphism and thicker trabecular growth further upgraded a lesion to, w2-HCC.

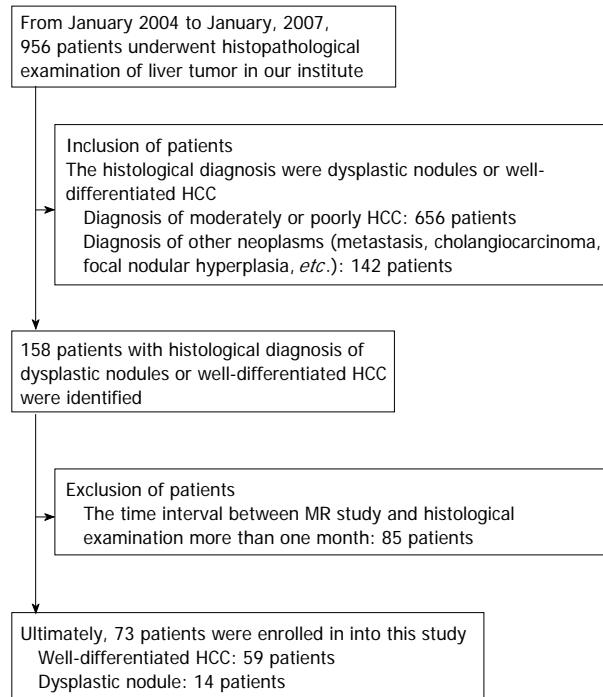

Figure 1 Flowchart of the patient selection process. HCC: Hepatocellular carcinoma; MR: Magnetic resonance.

### MR imaging

MR imaging of livers was performed using a 1.5-T MR scanner (Philips Gyroscan ACS-NT Powertrak 6000, release version 6.7.2, Best, the Netherlands) and a phased-array body coil. Turbo spin-echo (TSE) T2-weighted axial images [T2WI, TR/TE: 2500/90 ms, slice thickness/gap: 8/0.8 mm, matrix:  $192 \times 256$ , number of average (NEX): 2, TSE factor: 23, field of view (FOV): 38-40 cm, typical scanning time: 2 min 20 s] with and without fat saturation (FS, spectral fat saturation inversion recovery) and coronal T2-weighted images were obtained under respiratory trigger. Dual-echo T1-weighted imaging (TR/TE: 210/2.3 ms and 4.6 ms, slice thickness/gap: 8/0.8 mm, matrix:  $192 \times 256$ , NEX: 1, FOV: 38-40 cm, typical scanning time: 24 s) was also performed during one breath hold. Automatic shimming was applied for fat-suppression imaging to maximize magnetic field homogeneity, and flow compensation was also used.

For contrast-enhanced MR imaging, gadodiamide (Omniscan, GE Healthcare, Oslo, Norway) was administered by bolus injection (approximate rate of 2 mL/s) through a peripheral vein at a dosage of 0.1 mmol/kg. Dynamic T1-weighted fast field echo imaging (175-210/1.3-2.1, flip angle:  $80^\circ$ , matrix:  $192 \times 256$ , NEX: 1, FOV: 38-40 cm) was performed just before, 18-20 s after and 50-55 s after the contrast agent was injected. An equilibrium phase FS-T1W (TR/TE 241-344/2.7 ms, flip angle:  $70^\circ$ , slices thickness/gap: 8/0.8 mm) imaging was performed 180 s after the contrast agent injection.

### Imaging analysis

The imaging analysis was performed at a dual-screen

diagnostic workstation (GE Healthcare, Milwaukee, WI, United States). In each image assessment, liver maps were completed by drawing each individual liver lesion on a respective map according to the Couinaud system of liver anatomy. These drawings were made as accurately as possible by one investigator. All the imaging results were analyzed using visual assessment by two radiologists who each had more than 10 years of experience in abdominal MR imaging. The two observers were blinded to the clinical information and final diagnoses, and they recorded the lesion signal intensities on pre-contrast T1WI and T2WI, post-contrast T1WI and the enhancement pattern during dynamic study. The signal intensity of the focal liver nodule on dual-echo T1WI and T2WI was classified as hypointense, isointense, or hyperintense compared with adjacent liver parenchyma. The enhancement pattern of the HCC was visually classified into one of the following patterns: hypovascular, isovascular or hypervascular enhancement compared with the adjacent liver parenchyma. Any disagreements between the two reviewers were resolved by consensus with a third radiologist who was also blinded to the clinical information and final diagnoses.

### Statistical analysis

The interobserver agreement was evaluated using the kappa statistic<sup>[18]</sup>. Continuous variables such as age, tumor size, and alpha-fetoprotein were analyzed using the Kruskal-Wallis test. Categorical variables such as signal intensity and enhancement pattern were analyzed using Pearson's  $\chi^2$  test. The diagnostic performance of the HCC diagnostic criteria was evaluated along with a receiver operating characteristic analysis. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

Among the 73 patients in our study, 14 were diagnosed with a DN, 40 were diagnosed with w1-HCC, and 19 were diagnosed with w2-HCC. The clinicopathological characteristics of the growths are shown in Table 1, which shows no significant differences between the three patient groups. The interobserver agreement for the imaging analysis between the two radiologists was either good or excellent (Table 2).

Univariate analyses of MR findings for patients with DNs and wHCC are shown in Table 3. Only a hyperintense signal on T2WI was a statistically significant predictor of wHCC ( $P = 0.006$ ), whereas the other imaging features revealed no significant associations with DN and wHCC. Therefore, well-differentiated HCCs were divided into w1-HCC and w2-HCC, and the differences between DN *vs* w1-HCC and w1-HCC *vs* w2-HCC were analyzed. Only hyperintensity on T2WI was a statistically significant differentiator of DN from w1-HCC ( $P = 0.02$ ). The other imaging features revealed no significant differences between DN and w1-HCC. Hyperintensity on T1W out-phase imaging ( $P = 0.007$ ) and arterial enhancement on dynamic study ( $P = 0.005$ ) showed statistically significant

**Table 1** Clinical characteristics of the 73 cirrhotic patients with liver nodules

	Histopathological diagnosis			P value
	DN (n = 14)	w1-HCC (n = 40)	w2-HCC (n = 19)	
Age (mean ± SD, yr)	54.9 ± 12.9	62.4 ± 12.2	63.4 ± 10.8	0.129
Sex				0.629
Male	11	27	12

HBV: Hepatitis B virus; HCV: Hepatitis C virus; AFP: Alpha-fetal protein; DN: Dysplastic nodule; w1-HCC: Well-differentiated hepatocellular carcinoma compatible with Edmondson-Steiner grade I; w2-HCC Well-differentiated hepatocellular carcinoma compatible with Edmondson-Steiner grade II.

differences between w1-HCC and w2-HCC. However, T2WI and other imaging sequences showed no significant differences between w1-HCC and w2-HCC.

Using hyperintensity on T2WI as the sole criteria in differentiating wHCC from a dysplastic nodule, 25 of 59 wHCCs could be correctly diagnosed. The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were 42%, 93%, 96% and 28%, respectively. Solely using the AASLD criteria (arterial enhancement followed by washout on dynamic imaging) to differentiate between wHCC and dysplastic nodules, only 9 of 59 wHCCs (w1-HCC: 2, w2-HCC: 7) were correctly diagnosed. The sensitivity, specificity, PPV and NPV were 15%, 93%, 90% and 21%, respectively. If the diagnostic criteria were changed to either a hyperintense nodule on T2WI or a lesion that demonstrated arterial enhancement followed by washout on dynamic imaging, 27 of 59 wHCCs were correctly diagnosed. The sensitivity, specificity, PPV, and NPV were 46%, 86%, 93%, and 27%, respectively. Eighteen wHCCs were further detected by the additional hyperintense-on-T2WI criterion according to the AASLD criteria. The diagnostic performance of the AASLD criteria with additional hyperintense findings on T2WI was superior to the AASLD criteria alone in the characterization of early-stage HCC ( $P = 0.013$ ).

## DISCUSSION

The development of HCC in the cirrhotic liver is de-

**Table 2** Interobserver agreement for magnetic resonance features

scribed as either *de novo* hepatocarcinogenesis or as the result of a multistep progression. The stages of the multistep progression originate from a dysplastic nodule, which progresses to a dysplastic nodule with HCC foci, followed by a small HCC, and finally to an overt carcinoma<sup>[19,20]</sup>. In our study, typical arterial enhancing features were only detected in 12 (12/40) w1-HCCs, and there were no significant differences between DN and w1-HCC. In contrast, the arterial enhancing feature was demonstrated in 13 (13/19) w2-HCCs and showed a statistically significant difference between w1-HCC and w2-HCC ( $P = 0.005$ ). Our results might explain why the percentage of well-differentiated HCCs with arterial enhancement ranges from 43% to 66% in the current literature<sup>[21-23]</sup>. These figures may have resulted from the varied compositions of w1-HCC and w2-HCC within the studies.

The arterial enhancement during dynamic study showed a statistically significant difference between w1-HCC and w2-HCC in our study. This finding might be due to the insufficient development of non-triadal arteries in early-stage HCCs<sup>[14,24]</sup>. Kojiro<sup>[25]</sup> also reported that early HCCs tended to demonstrate histological hypovascularity. Kim *et al*<sup>[26]</sup> reported that the histological grade of HCC was an important factor influencing therapeutic results. They further suggested that treatment could be more effective after radiofrequency ablation in patients with histologically low-grade HCC. According to our results, wHCC demonstrated arterial enhancement during dynamic study, and the histological differentiation tended to be of a higher grade, so it should be treated aggressively.

In our results, only 9 wHCCs (15%) satisfied the AASLD HCC diagnostic criteria. In contrast, T2WI hyperintensity was the only imaging feature that allowed differentiation between wHCC and DN or w1-HCC and DN. The diagnostic performance of the AASLD criteria with additional hyperintensity on T2WI was superior to the AASLD criteria alone in the characterization of early-stage HCCs ( $P = 0.013$ ). Ouedraogo *et al*<sup>[27]</sup> also reported that adding T2W hyperintensity to the AASLD criteria increased the detection of HCC, especially in nodules smaller than 20 mm. According to our results, hyperintensity on T2WI alone could offer additional information in dynamic studies to differentiate between wHCC and DN, and a cirrhotic nodule that is hyperintense on

**Table 3** Comparison of magnetic resonance features between dysplastic nodule and well-differentiated hepatocellular carcinoma

	DN (n = 14)	wHCC		P value

T2WI should be aggressively biopsied.

In our study, hyperintensity on T1W out-phase imaging showed a significant difference between w1-HCC and w2-HCC. A hyperintense HCC on unenhanced T1W images tended to be lower grade histologically. This finding might be because borderline lesions and some early HCCs/wHCCs are occasionally hyperintense on unenhanced T1W images<sup>[28,29]</sup>. Matsui *et al.*<sup>[30]</sup> correlated MR signal intensity with tumor histology, and considered cell crowding, fatty accumulation and possibly copper deposition to be responsible for the hyperintensity on T1W imaging. However, the exact histological composition responsible for the signal intensity characteristics of w1-HCC and w2-HCC remains elusive.

According to the step-wise carcinogenesis model, HCC changes in appearance through the course of its development. These changes include a steadily increasing signal intensity on T2WI with gradually increasing neovascularity in most lesions. Van den Bos *et al.*<sup>[31]</sup> suggested that the increased signal on T2W images lags behind the developing neovascularity. Our results supported the proposition that an increased signal on T2W images occurs early in the developing arterial enhancement. These discrepancies in enhancement patterns and signal intensities might be due to the different patient populations being examined and the different underlying liver diseases. However, more studies are needed for a better understanding of developing HCC using MR imaging.

Recent progress in CT angiography, Gd-EOB-DTPA-enhanced MRI, diffusion-weighted imaging (DWI), contrast-enhanced ultrasound (CEUS) has made these modalities useful in differentiating HCC from dysplastic

nodules. Lee *et al.*<sup>[11]</sup> reported that hypointensity on Gd-EOB-DTPA-enhanced hepatobiliary-phase images and hyperintensity on high-b-value DWI in the surrounding liver parenchyma were useful in differentiating wHCC from benign nodules. Kudo<sup>[3]</sup> reported that CT during hepatic angiography and CT during arterial portography were the most sensitive tools in differentiating between premalignant/borderline lesions and early HCC. Real-time CEUS has the ability to detect slowly enhancing HCCs, which on CT could be interpreted as hypovascular lesions<sup>[32]</sup>. Giorgio *et al.*<sup>[33]</sup> reported that DN, early HCC and progressed HCC could be accurately differentiated using CEUS on the basis of the vascularization pattern during the arterial phase. Kudo<sup>[34]</sup> reported that Sonazoid-enhanced US could generate both hemodynamic-phase and Kupper-phase images and offer improved diagnostic performance for focal liver lesions. CEUS with Sonazoid may play an important role in the characterization of focal hepatic lesions in the future.

This study had two main limitations. First, the study was retrospective. If we had used the original pathological reports in the medical records as a standard of reference, inaccuracies due to differing standards of pathological interpretation at that time might have led to different results. To ensure accurate histological diagnoses, new histological slides were prepared from paraffin-embedded blocks, all of which were read by two experienced pathologists independently. A third pathologist was involved as needed to reach a final consensus when disagreements arose. The second limitation was that the histological diagnoses of 70 of the nodules (70/73) were based on needle biopsies. Potential sampling errors and

sampling variation are inherent in this type of examination, and they are recognized shortcomings in most comparative studies.

In conclusion, conventional MR imaging could provide additional information to differentiate between wHCC and DN in equivocal lesions. The variable presentation of wHCC in the current literature may be due to the differing cellular compositions of w1-HCC and w2-HCC. Consequently, during follow-up of a cirrhotic nodule, increased signal intensity on T2WI may be a sign of malignant transformation. Loss of hyperintensity in T1WI and the detection of arterial enhancement may indicate further progression of the histological grade.

## COMMENTS

### Background

Most well-differentiated hepatocellular carcinomas (HCCs) at an early stage do not demonstrate hypervascularity upon dynamic computed tomography/magnetic resonance (CT/MR) study, thereby making their diagnosis difficult. Some well-differentiated HCCs are fed by the portal vein instead of the hepatic artery and may look like benign nodules with "benign-appearing" patterns of vasculature. Gadoteric acid-enhanced magnetic resonance imaging (MRI) and contrast-enhanced ultrasound have been demonstrated to be useful in differentiating between early-stage HCC and dysplastic nodules in several recent studies. Due to the facts that gadoteric acid and contrast medium for ultrasound are not available in every country and are costly, conventional MRI remains an important tool in differentiating between cirrhotic nodules and early HCCs. The authors used a retrospective analysis to show the utility of MR imaging features to differentiate between dysplastic nodules and early stage HCC.

### Research frontiers

The authors compared conventional MR imaging results with histological results to evaluate the effectiveness of conventional MR imaging in the diagnosis of early-stage HCC.

### Innovations and breakthroughs

Increased signal intensity on T2-weighted axial images (T2WI) may be a sign of malignant transformation. Loss of hyperintensity on T1-weighted axial images (T1WI) and the detection of arterial enhancement may indicate further progression of the histological grade.

### Applications

The authors believe that conventional MR imaging could provide additional information in differentiating between early-stage HCC and dysplastic nodule in equivocal lesions. During follow-up for a cirrhotic nodule, increased signal intensity on T2WI may be a sign of malignant transformation and should be biopsied. Loss of hyperintensity on T1WI and the detection of arterial enhancement may indicate further progression of the histological grade and should be treated aggressively.

### Peer review

The authors describe a retrospective analysis of 73 patients with well-differentiated HCC or dysplastic nodules. The authors address the question whether MR imaging is helpful to differentiate between a dysplastic nodules and well-differentiated HCC in high-risk patients with cirrhosis. The question addressed by the authors is of high impact in the field of liver cirrhosis. Despite the limitations of the study (retrospective analysis, 73 patients), the authors have thoroughly analyzed the data and have made new histological classifications of all the specimens. The data show that increased signal intensity on T2WI may be a sign of malignant transformation.

### Abstract

**AIM:** To explore the effects of curcumin (CMN) on hepatic injury induced by acetaminophen (APAP) *in vivo*.

**METHODS:** Male mice were randomly divided into three groups: group I (control) mice received the equivalent volumes of phosphate-buffered saline (PBS) intraperitoneally (*ip*); Group II [APAP + carboxymethylcellulose (CMC)] mice received 1% CMC (vehicle) 2 h before APAP injection; Group III (APAP + CMN) mice received curcumin (10 or 20 mg/kg, *ip*) 2 h before or after APAP challenge. In Groups II and III, APAP was dissolved in pyrogen-free PBS and injected at a single dose of 300 mg/kg. CMN was dissolved in 1% CMC. Mice were sacrificed 16 h after the APAP injection to determine alanine aminotransferase (ALT) levels in serum and malondialdehyde (MDA) accumulation, superoxide dismutase (SOD) activity and hepatocyte apoptosis in liver tissues.

**RESULTS:** Both pre- and post-treatment with curcumin resulted in a significant decrease in serum ALT compared with APAP treatment group (10 mg/kg:  $801.46 \pm 661.34$  U/L; 20 mg/kg:  $99.68 \pm 86.48$  U/L vs  $5406.80 \pm 1785.75$  U/L,  $P < 0.001$ , respectively). The incidence of liver necrosis was significantly lowered in CMN treated animals. MDA contents were significantly reduced in 20 mg/kg CMN pretreatment group, but increased in APAP treated group ( $10.96 \pm 0.87$  nmol/mg protein vs  $16.03 \pm 2.58$  nmol/mg protein,  $P < 0.05$ ). The decrease of SOD activity in APAP treatment group and the increase of SOD in 20 mg/kg CMN pretreatment group were also detected ( $24.54 \pm 4.95$  U/mg protein vs  $50.21 \pm 1.93$  U/mg protein,  $P < 0.05$ ). Furthermore, CMN treatment efficiently protected against APAP-induced apoptosis *via* increasing Bcl-2/Bax ratio.

**CONCLUSION:** CMN has significant therapeutic potential in both APAP-induced hepatotoxicity and other types of liver diseases.

Curcumin protects against acetaminophen-induced apoptosis in hepatic injury. *World J Gastroenterol* 2013; 19(42): 7440-7446 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7440.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7440>

## INTRODUCTION

Acetaminophen (APAP) is a widely used analgesic and antipyretic drug that is safe and effective when taken at therapeutic dose<sup>[1]</sup>. However, it can cause severe liver damage or even acute liver failure that can be fatal in experimental animals and humans when administered in an acute or cumulative overdose<sup>[2,3]</sup>. APAP overdose is the leading cause for calls to Poison Control Centers (> 100000/year) and accounts for more than 56000 emergency visits, 2600 hospitalizations, and an estimated 458 deaths each year in the United States<sup>[3]</sup>.

APAP is metabolized by cytochrome P450 to *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI can react rapidly with glutathione (GSH), so large doses of APAP may result in a profound depletion of hepatocellular GSH<sup>[1,4]</sup>. Once GSH is exhausted, any remaining NAPQI will covalently bind to cellular proteins and induce mitochondrial dysfunction, lipid peroxidation, oxidative stress, and DNA fragmentation, eventually leads to massive hepatocyte necrosis, liver damage or death<sup>[5]</sup>. *N*-acetyl cysteine has been currently used in the treatment of APAP-induced liver toxicity<sup>[6]</sup>. In addition to its adverse reaction, a major concern when using *N*-acetyl cysteine is its relatively narrow therapeutic windows and drug toxicity<sup>[7,8]</sup>. Therefore, new and safe preventive measures against APAP toxicity are eagerly needed.

In recent years, natural products from plants have received considerable attention as a rich resource for drug development. Curcumin (CMN) is a yellow pigment purified from the root tubers of *Curcuma longa* Linn (commonly known as turmeric), which has long been used as a food colorant and preservative<sup>[9]</sup>. CMN also has a variety of biological and pharmacological activities, such as anti-inflammatory, anti-oxidant, antifungal, antibacterial and anticancer activities<sup>[10]</sup>. It was reported that CMN attenuates liver injury induced by ethanol<sup>[11]</sup>, iron overdose<sup>[12]</sup> and carbon tetrachloride intoxication<sup>[13]</sup>.

The aim of this study was to explore the effect of CMN on the prevention of APAP-induced hepatic toxicity *in vivo* and investigate whether CMN affects the production of lipid peroxidation, oxidative stress or hepatocyte apoptosis to attenuate liver damage.

## MATERIALS AND METHODS

### Materials

APAP and CMN were purchased from Sigma Aldrich (Saint Louis, MO, United States). Detection kits for superoxide dismutase (SOD) and malondialdehyde (MDA) were purchased from Nanjing Jiancheng Bioengineer Institute (Nanjing, China). Transferase-mediated dUTP-biotin nick end labeling (TUNEL) detection kit was purchased from Boster Biological Technology Co., Ltd (Wuhan, China).

### Animals and treatment

Male BALB/c mice (6-8 wk of age) were purchased from the Center for Animal Experiment of Wuhan

University (Wuhan, China). The mice were raised at an animal facility under special pathogen-free conditions with a 12-h light/dark cycle and free access to food and water at least 1 wk prior to treatment. All animal experiments were approved by the institutional animal care and use committee at the Yangtze University, and all efforts were made to minimize the number of animals used and their sufferings. Mice were randomly divided into three groups: group I (control) mice received the equivalent volumes of PBS intraperitoneally (*ip*); Group II (APAP + CMC) mice received 1% CMC (vehicle) 2 h before APAP injection; and Group III (APAP + CMN) mice received CMN (10 or 20 mg/kg, *ip*) 2 h before or after APAP challenge. In Group II and Group III, APAP was dissolved in pyrogen-free PBS and injected at a single dose of 300 mg/kg; the dose was selected on the basis of a previous related study<sup>[14]</sup>. CMN was dissolved in 1% CMC. Serum and livers were collected at 16 h after APAP treatment.

### Biochemical analysis

Alanine amino-transaminase (ALT) activity was determined using a diagnostic assay kit (Sichuan Maker Science and Technology Co., Ltd., Chengdu, China) by an automated chemistry analyzer (Olympus AU1000, Japan) by Central Laboratory of the Affiliated Jingzhou Hospital of Yangtze University.

Livers were quickly removed, washed with ice-cold PBS, blotted and weighed, and then a tissue homogenate (1% or 10%, w/v) was prepared in normal saline. The homogenates were then centrifuged at 4000 rpm (4 °C) for 20 min to collect supernatants for determination of SOD and MDA contents at 550 nm and 532 nm, respectively.

Lipid peroxidation was assessed by estimation of MDA in the liver tissues according to the method of Wills (1966). MDA was determined by the thiobarbituric acid assay using a MDA assay kit, according to the manufacturers' instructions. Liver tissue protein was measured using Coomassie Brilliant Blue protein reagent, and MDA content was expressed as nmol/mg protein. SOD activity was determined by measuring the inhibition of formation of NADPH-phenazine methosulphate nitroblue tetrazolium.

### Histochemistry

Liver tissues fixed in 10% formalin were embedded in paraffin, sectioned at 4 µm and stained with hematoxylin-eosin.

### TUNEL staining

Paraffin-embedded liver tissues were assayed for DNA fragmentation using a terminal deoxynucleotidyl TUNEL reaction, according to the manufacturer's instructions. Slides were developed with diaminobenzidine substrate, counterstained with HE, and then examined for evidence of apoptosis. The number of brown apoptotic cells was normalized to total cells as detected by HE. Four fields

of each image were counted.

### Reverse transcriptase polymerase chain reaction

RNA was extracted from the livers using TRIzol® Reagent (Invitrogen) according to the manufacturer's instruction. cDNA was synthesized from 2 µg of total RNA using PrimeScript™ 1<sup>st</sup> Strand cDNA Synthesis Kit (Takara Biotechnology, Co., Ltd., Da Lian, LiaoNing, China). PCR amplifications were performed by standard methods using following specific primers: for Bcl-2: Sense: 5'-GGC ATC TTC TCC TTC CAG-3', Anti-sense: 5'-CTA CCC AGC CTC CGT TAT-3'; for Bax: Sense: 5'-TTT CAT CCA GGA TCG AGC AGG-3', Antisense: 5'-GCA AAG TAG AAG AGG GCA ACC AC-3'<sup>[15]</sup>.

### Statistical analysis

A computer program (SPSS 13.0) was used for statistical analysis. Data were presented as mean ± SE. Student's *t* test (two groups) or one way ANOVA (multiple groups) were used. *P* < 0.05 indicated statistical significance.

## RESULTS

### CMN treatment attenuates APAP-induced liver injury

To explore the protective effect of CMN on APAP-induced hepatic toxicity, the animals were injected intraperitoneally with CMN (10 or 20 mg/kg body weight) 2 h before APAP (300 mg/kg body weight), and serum ALT was analyzed after 16 h of administration. Compared with PBS control (41.70 ± 2.82 U/L), APAP treatment significantly increased serum ALT levels (5406.80 ± 1785.75 U/L, 126.9-fold of the control, Figure 1A, *P* < 0.001 *vs* control). As expected, CMN pretreatment significantly suppressed the plasma ALT activity in a dose-dependent manner (10 mg/kg: 801.46 ± 661.34 U/L; 20 mg/kg: 99.68 ± 86.48 U/L, Figure 1A, *P* < 0.001 *vs* the model group). This protective effect was further confirmed by analysis of histological findings, as shown in Figure 1B, severe sinusoidal congestion and hemorrhage, inflammatory cell infiltration and gross necrosis were observed in the liver of mice treated with APAP. However, these pathological changes were dramatically suppressed by CMN treatment. To evaluate its potential therapeutic role, CMN was administrated after 2 h of APAP injection, and a marked reduction of serum ALT was also observed (395.40 ± 133.52 U/L, Figure 1A). Of note, CMN alone did not influence serum transaminase (Figure 1A) and urea, creatinine (data not shown) in normal control mice.

### CMN pretreatment inhibits production of MDA

As lipid peroxidation has been reported to be closely related to APAP-induced toxicity, the content of malondialdehyde, the end product of lipid peroxidation, in the liver tissues was detected at 16 h after APAP treatment. Only low levels of MDA were observed in the control mice (10.81 ± 1.46 nmol/mg protein), but a significant

increase was found in APAP-treated mice (16.03 ± 2.58 nmol/mg protein). As expected, MDA contents were significantly inhibited by 20 mg/kg CMN pretreatment (10.96 ± 0.87 nmol/mg protein, Figure 2).

### CMN pretreatment enhances activity of SOD

In addition to lipid peroxidation, oxidative stress is an early events related to radicals generated during the hepatic metabolism of APAP. SOD is an enzyme that neutralizes free radicals<sup>[16]</sup>. So the activity of SOD was investigated at 16 h after APAP treatment in the liver tissues. A significant decrease in SOD activity was observed in the mice treated with APAP compared with control group (24.54 ± 4.95 U/mg protein *vs* 45.64 ± 5.96 U/mg protein). However, pretreatment of mice with CMN induced a significant increase in the activity of SOD (50.21 ± 1.93 U/mg protein, Figure 3).

### CMN pretreatment prevents hepatocyte apoptosis

Based on the above observations, we further explored the possible mechanisms by which CMN attenuates liver injury induced by APAP. Given the importance of apoptosis in APAP-induced liver injury, the extent of hepatocyte apoptosis was determined by TUNEL assay. As shown in Figure 4A, massive hepatocyte apoptosis was detected in the livers of mice treated with APAP. CMN pretreatment markedly prevented the apoptosis induced by APAP. Furthermore, we examined the mRNA expression of anti-apoptotic protein Bcl-2 and pro-apoptotic protein Bax in the livers. As shown in Figure 4B, CMN pretreatment down-regulated the mRNA expression of Bax and up-regulated the mRNA expression of Bcl-2 compared with APAP-treated group. These data suggest that CMN inhibits hepatocyte apoptosis *via* regulating the gene expression of Bcl-2 family and then protects the mice from APAP-induced hepatic injury.

## DISCUSSION

In the present study, for the first time, we examined the effect of CMN on liver injury induced by APAP and the possible mechanisms in mice. Our data demonstrated that CMN pretreatment dose-dependently alleviated APAP-induced acute liver injury. CMN pretreatment markedly decreased ALT levels in plasma and inhibited the necrosis of hepatocytes in Con A-treated mice. Furthermore, CMN could be also considered as a rescue therapy, for it significantly decreased APAP-induced hepatotoxicity when administered 2 h after APAP overdose.

NAPQI is the reactive metabolite product generated from APAP-induced hepatic toxicity, and it was found to be formed by cytochrome P-450 by a direct two electron oxidation of APAP. At low doses, the metabolite was efficiently detoxified by GSH. However, at high doses, NAPQI leads to GSH depletion and subsequently covalently binds to cysteine residues on proteins, which results in lipid peroxidation reaction<sup>[14,17]</sup>. As a metabolite of free radical, MDA is generally considered as an impor-

**Figure 1** Curcumin treatment protects against acetaminophen-induced hepatic injury in mice. **A:** Serum alanine aminotransferase (ALT) levels were determined 16 h after acetaminophen injection. Data are expressed as mean  $\pm$  SE;  $n = 10$  mice per group. <sup>b</sup> $P < 0.01$  vs control; <sup>d</sup> $P < 0.001$  vs acetaminophen (APAP) + carboxymethylcellulose (CMC); **B:** Hematoxylin-eosin stained liver sections from animals treated with PBS, APAP + CMC and APAP + CMN (original magnification:  $\times 100$  and  $\times 400$ ). CMN: Curcumin.

tant indicator of lipid peroxidation. In this study, in line with previous reports, we found that MDA in liver tissues was increased significantly 16 h after APAP administration. As expected, our results demonstrated that CMN treatment could inhibit the increase of MDA induced by APAP, suggesting that CMN has potent beneficial effects on lipid peroxidation.

Our organism has a function to neutralize and scavenge the free radical in order to prevent oxidative damage to cells. Such endogenous mechanisms are mainly provided by a set of antioxidant enzymes such as SOD, glutathione peroxidase, and catalase. SOD represents the first line of defense against free radicals, it converts superoxide anion into hydrogen peroxide, and then hy-

drogen peroxide is converted into oxygen and water by glutathione peroxidase, making reduced GSH as its substrate<sup>[18]</sup>. As a antioxidant, CMN has been demonstrated to effectively prevent the decrease in SOD activity in a variety of experimental models, including inflammation, cardiotoxicity and carbon tetrachloride-induced liver injury models<sup>[19]</sup>. In line with these concepts, we found that the major scavenger enzyme SOD activity was significantly decreased in the liver of APAP-treated mice. As expected, pretreatment with CMN restored SOD activity. Therefore, it is suggested that the protective effect of CMN on APAP-induced injury is associated with its inhibition of oxidative stress.

Accumulating evidence suggests that hepatocyte

**Figure 2** Curcumin pretreatment inhibits malondialdehyde production after acetaminophen induction. apoptosis plays a critical role in APAP-induced hepatic injury, although the mode of cell death inflicted by APAP is still controversial<sup>[20,21]</sup>. APAP-induced apoptosis is observed not only in primary hepatocytes<sup>[22]</sup>, but also in livers of mice treated with toxic doses of APAP<sup>[23]</sup>. Also, a recent report showed that hepatic caspase-3 and caspase-9 are activated in both wild type and CXCR2 knock out mice within one hour of APAP treatment<sup>[21]</sup>. Moreover, inhibiting apoptosis prevents the development of acute liver failure<sup>[23]</sup>. Based on these concepts, we found

that apoptotic hepatocytes were significantly increased in the liver of mice 16 h after APAP treatment and the hepatocyte apoptosis was significantly reduced by CMN pretreatment. Bcl-2 protein is commonly recognized as an anti-apoptotic factor, it inhibits cell apoptosis by preventing mitochondrial membrane depolarization. As a member of the Bcl-2 family, Bax inactivates Bcl-2 by interacting with it to form a heterodimer<sup>[24]</sup>. In this study, we found that CMN pretreatment down-regulated the mRNA expression of Bax and up-regulated the mRNA

expression of Bcl-2 compared with APAP-treated group, suggesting that CMN can increase Bcl-2/Bax ratio, thus reducing APAP-induced apoptosis. The mechanisms of CMN-mediated anti-apoptotic effect remained unclear. A recent study showed that CMN exerts a potent anti-apoptotic effect *via* inhibition of TGF- $\beta$  as inducer of caspase-3 mediated apoptosis in kidney and lung tissues<sup>[25]</sup>, however, the precise mechanisms by which CMN modulates cell apoptosis in APAP-induced liver injury need to be further investigated.

In summary, our study revealed that CMN has a protective effect on the acute hepatic injury induced by APAP. Both pre- and post-treatment with CMN resulted in a significant reduction in serum ALT and hepatocyte necrosis. The protection of CMN may be related to its inhibition of lipid peroxidation and oxidative stress. Moreover, we found that CMN restored Bcl-2/Bax ratio, thus reducing the APAP-induced hepatocyte apoptosis.

## COMMENTS

### Background

Acetaminophen (APAP) can cause severe liver damage or even acute liver failure when administered in an acute or cumulative overdose. *N*-acetyl-*p*-benzoquinone imine (NAPQI) is the metabolite of APAP by cytochrome P450. Accumulation of NAPQI could induce lipid peroxidation, oxidative stress, mitochondrial dysfunction and DNA fragmentation, even liver failure or death. Thus, new and safe preventive measures against APAP-induced hepatic damage are eagerly needed.

### Research frontiers

Previous studies have shown that curcumin (CMN) exerts anti-inflammatory, anti-oxidant and anticancer pharmacological activities. APAP lead to liver injury through increasing oxidative stress, lipid peroxidation and pro-apoptosis. In this study, the authors showed that CMN improved hepatic injury through inhibiting oxidative stress, lipid peroxidation and hepatic apoptosis in APAP induced liver damage model.

### Innovations and breakthroughs

This study investigated the effect of CMN on the prevention of APAP-induced hepatic toxicity *in vivo* and examined whether CMN affects the production of lipid peroxidation, oxidative stress or hepatocyte apoptosis to attenuate liver damage. The results indicated that CMN could protect mice from APAP-induced liver injury.

### Applications

CMN was abundant in the root tubers of *Curcuma longa* Linn and can be purified by modern technology. It has a broad application prospect.

### Peer review

It is an interesting study investigating the protection effect of CMN on APAP-caused hepatitis. The experimental evidences presented that APAP induced hepatic injury, with elevated alanine aminotransferase, lipid peroxidation, oxidative stress and apoptosis were improved by CMN.

### Abstract

**AIM:** To evaluate the outcome of non-malignant and non-cirrhotic patients with portal cavernoma and to determine the predictors for survival.

**METHODS:** Between July 2002 and June 2010, we retrospectively enrolled all consecutive patients admitted to our department with a diagnosis of portal cavernoma without abdominal malignancy or liver cirrhosis. The primary endpoint of this observational study was death and cause of death. Independent predictors of survival were identified using the Cox regression model.

**RESULTS:** A total of 64 patients were enrolled in the study. During a mean follow-up period of  $18 \pm 2.41$  mo, 7 patients died. Causes of death were pulmonary

embolism ( $n = 1$ ), acute leukemia ( $n = 1$ ), massive esophageal variceal hemorrhage ( $n = 1$ ), progressive liver failure ( $n = 2$ ), severe systemic infection secondary to multiple liver abscesses ( $n = 1$ ) and accident ( $n = 1$ ). The cumulative 6-, 12- and 36-mo survival rates were 94.9%, 86% and 86%, respectively. Multivariate Cox regression analysis demonstrated that the presence of ascites (HR = 10.729, 95%CI: 1.209-95.183,  $P = 0.033$ ) and elevated white blood cell count (HR = 1.072, 95%CI: 1.014-1.133,  $P = 0.015$ ) were independent prognostic factors of non-malignant and non-cirrhotic patients with portal cavernoma. The cumulative 6-, 12- and 36-mo survival rates were significantly different between patients with and without ascites (90%, 61.5% and 61.5% vs 97.3%, 97.3% and 97.3%, respectively,  $P = 0.0008$ ).

**CONCLUSION:** The presence of ascites and elevated white blood cell count were significantly associated with poor prognosis in non-malignant and non-cirrhotic patients with portal cavernoma.

**Key words:** Extrahepatic portal vein obstruction; Portal cavernoma; Survival; Prognostic factors; Ascites

**Core tip:** Little is known regarding the prognostic factors of non-malignant and non-cirrhotic patients with portal cavernoma. We conducted a retrospective single-center study of 64 patients admitted to our department between July 2002 and June 2010 to evaluate this issue. Multivariate Cox regression analysis demonstrated that the presence of ascites was an independent prognostic factor of non-malignant and non-cirrhotic patients with portal cavernoma.

## INTRODUCTION

Portal cavernoma, also known as cavernous transformation of the portal vein, is a rare entity, which is characterized by a tangle of tortuous hepatopetal collateral veins in the hilum<sup>[1]</sup>. It is traditionally considered a sequela of extrahepatic portal vein obstruction (EHPVO) to compensate for the interrupted portal blood flow<sup>[2,3]</sup>. Current treatment strategies for portal cavernoma focus on the prevention and treatment of variceal hemorrhage, prevention of recurrent thrombosis, and treatment of symptomatic portal biliopathy<sup>[4-6]</sup>. Given the rarity of portal cavernoma, controlled studies are unavailable, and therapeutic options vary in different centers. Previous studies, in which malignancy and cirrhosis were not excluded, have revealed that the increased mortality in EHPVO patients is closely associated with advanced age, presence of malignancy and cirrhosis, high bilirubin and deterioration of liver function<sup>[7-9]</sup>. However, little information is known regarding the prognostic factors in non-malignant and non-cirrhotic patients with portal cavernoma due to its low morbidity and mortality.

We conducted a retrospective study to determine the predictors for survival of non-malignant and non-cirrhotic patients with portal cavernoma managed by a uniform therapeutic strategy at our center.

## MATERIALS AND METHODS

### Study design

Between July 2002 and June 2010, all consecutive patients with a diagnosis of portal cavernoma without abdominal malignancy or liver cirrhosis who were admitted to our department were enrolled in this observational study<sup>[10-12]</sup>, regardless of age. Baseline data were collected upon admission or referral. Regular blood tests, hepatic and renal function tests, prothrombin time, internationalized normalized ratio (INR), color Doppler ultrasound (CDUS), computed tomography (CT) and endoscopy were performed in all patients. Thrombotic risk factors of EHPVO, including *JAK2 V617F* mutation, CD55 and CD59 deficiencies, anti-cardiolipin IgG antibodies, and factor V Leiden or prothrombin gene G20210A mutation, were detected at our department after September 2009<sup>[13,14]</sup>. Additionally, we recorded the date of diagnosis of portal cavernoma at our own hospital or an outside facility. Follow-up data were obtained every six months through outpatient or phone conversations with the patient or his or her family members. The primary endpoint was death. Follow-up continued either until death or July 2010. The study protocol was approved by the ethics committee of our hospital.

### Diagnosis and definitions

Portal cavernoma was characterized by a tangle of tortuous hepatopetal collateral veins in the hilum. An acute thrombotic episode was defined as fulfillment of both of the following criteria: (1) recent onset of abdominal pain; and (2) a high intraluminal density within the portal vein on non-enhanced CT scans, while contrast-enhanced CT scans displayed cavernous vessels around the obstructed portal vein<sup>[15,16]</sup>.

As previously described, the degree of portal venous obstruction was classified as partial obstruction, complete obstruction and fibrotic cord instead of original main portal vein<sup>[12,17,18]</sup>. The extent of obstruction within the portal venous system was also evaluated.

Liver cirrhosis and hepatocellular carcinoma were excluded on the basis of a history of chronic liver disease, clinical presentation, liver function, alpha-fetoprotein and positive findings on imaging (*i.e.*, ultrasound and CT scans)<sup>[18]</sup>. A liver biopsy was obtained, if a diagnosis of cirrhosis was inconclusive or if hepatocellular carcinoma was suspected. Other abdominal malignancy was excluded by imaging.

The degree of variceal size was based on the general rules established by the Japanese Research Society for Portal Hypertension (low-risk varices: F1 or F2 with negative red color sign; high-risk: F1 or F2 with positive red color sign, or F3 irrespective of red color sign)<sup>[19]</sup>. The presence of ascites was diagnosed by physical examination, ultrasound and CT scans. The grade of ascites was based on the definitions of the International Ascites Club (grade I: mild ascites only detectable by ultrasound; grade II: moderate symmetrical abdominal distension; grade III: marked abdominal distension)<sup>[20]</sup>.

### Therapeutic strategy

Our therapeutic strategy was aimed at minimal invasiveness and maximal beneficial effects through symptom resolution.

After diagnosis of an acute thrombotic episode, the patients received a continuous intravenous infusion of unfractionated heparin followed by oral warfarin. Initially, heparin was regularly administered intravenously at a starting dose of 1000-1400 U/h for 5 d. Subsequently, oral warfarin was prescribed at the dosage of 2.5-5 mg/d for at least 6 mo and was adjusted to maintain the INR at a target of 2.5 (range 2.0-3.0)<sup>[21]</sup>. A three-day overlap between intravenous and oral anticoagulation was required. Life-long oral anticoagulants were prescribed to patients with thrombophilia. If abdominal pain was progressive, we either indirectly infused thrombolytic agents into the superior mesenteric artery or performed direct thrombolysis in the portal vein by a percutaneous transhepatic approach. If ischemic intestinal infarction was diagnosed, emergency bowel resection was performed.

Once acute variceal bleeding was diagnosed, medical or endoscopic therapy was adopted as the first-line treatment option. If active bleeding was uncontrolled or if repeated hospitalizations were necessary to control recur-

rent variceal bleeding, a transjugular intrahepatic porto-systemic shunt (TIPS) insertion was performed through a transjugular approach alone or in combination with a transhepatic or transsplenic approach, as previously described<sup>[12,18,22]</sup>. If a TIPS procedure failed or was refused, splenectomy and devascularization were considered.

Other symptomatic treatments included anticoagulation for prevention of recurrent thrombosis, diuretics and/or paracentesis plus albumin for grade II and III ascites, splenectomy for hypersplenism and massive splenomegaly and prophylactic endoscopic therapy for high-risk varices. Additionally, if patients presented with a long history of repeated gastrointestinal syndromes unresponsive to conservative therapies, the TIPS procedure was considered.

### Statistical analysis

Quantitative data were reported as mean  $\pm$  SE and were compared with the independent sample *t* test or one-way analysis of variance; qualitative data were reported as frequencies and were compared with the  $\chi^2$  test or the Fisher exact test, as appropriate. Cumulative survival rates were assessed by the Kaplan-Meier curves and were compared with a log-rank test. Independent predictors of survival were identified using the Cox regression model. The covariates incorporated into the multivariate analysis were the variables that reached statistical significance ( $P < 0.05$ ) in univariate analysis. Two-tailed  $P$  values  $< 0.05$  were considered statistically significant. All statistical calculations were performed with SPSS 12.0 (Chicago, IL, United States).

## RESULTS

### Characteristics of patients

A total of 64 patients diagnosed with portal cavernoma without liver cirrhosis or abdominal malignancy were enrolled in the study. Notably, 5 patients presented with cavernous collateral veins around a patent main portal vein<sup>[10]</sup>. Baseline patient characteristics are summarized in Table 1.

### Possible risk factors

Thrombotic risk factors of EHPVO were detected in 33 patients. Among them, 11 had positive *JAK2 V617F* mutation, none had both CD55 and CD59 deficiencies, two had weakly positive anti-cardiolipin IgG antibodies, and none had positive factor V Leiden or prothrombin gene *G20210A* mutation. Previous history of infection before admission included colitis ( $n = 1$ ), pelvic infection ( $n = 1$ ), appendicitis ( $n = 1$ ), intra-abdominal infection secondary to duodenal ulcer perforation ( $n = 1$ ), umbilical cord infection ( $n = 2$ ), megacolon disease of newborn ( $n = 1$ ), bacterial dysentery ( $n = 1$ ), and pancreatitis ( $n = 4$ ). Previous history of abdominal surgery before admission included splenectomy and devascularization for variceal bleeding ( $n = 11$ ), splenectomy for hypersplenism and/or splenomegaly ( $n = 8$ ), splenectomy for traumatic spleen

serum sodium were significantly lower in patients with ascites than in those without (Table 3). A higher Child-Pugh score was also present in patients with ascites than in those without (6.85 ± 0.26 *vs* 5.18 ± 0.07, *P* < 0.001). Additionally, superior mesenteric vein obstruction was more frequently observed in patients with ascites than in those without (15/20 *vs* 19/44, *P* = 0.027).

### Treatment

Ten patients were diagnosed with acute thrombotic episodes. None presented with variceal bleeding, but four had high-risk varices detected by endoscopy. Mild ascites was found by CDUS in three patients. The main portal

vein was completely ( $n = 9$ ) or partially ( $n = 1$ ) obstructed. After intravenous anticoagulation was administered for 2-5 d, abdominal pain was alleviated in 5 patients and aggravated in another 5 patients. For the 5 patients with improved abdominal pain, oral anticoagulation was continued. During follow-up, partial recanalization of the main portal vein was found in 1 patient, while the main portal vein became unidentifiable and was replaced by cavernous collateral vessels in the remaining 4 patients. One patient with high-risk varices experienced melena 2 wk after anticoagulation. Anticoagulants were discontinued in this patient and were not resumed. For the 5 patients with increased abdominal pain, thrombolytics were indirectly infused *via* the superior mesenteric artery in 3 patients and directly *via* the portal vein in two patients. Of the 3 patients who received indirect thrombolysis, one became asymptomatic, while the other 2 patients underwent intestinal resection for ischemic intestinal infarction. One of the 2 patients died of pulmonary embolism 5 d after surgery. Of the 2 patients receiving direct thrombolysis for 3-5 d, abdominal pain completely resolved. During follow-up, partial recanalization of the main portal vein was found in 2 patients, while the main portal vein was replaced by cavernous collateral vessels in the remaining 3 patients. No adverse events were recorded.

Twenty-nine patients presented with acute ( $n = 7$ ) and recurrent variceal bleeding ( $n = 22$ ). Of the patients with acute variceal bleeding, 5 received pharmacological treatment, 1 had emergency endoscopic sclerotherapy and one underwent embolization of the gastric varices *via* a percutaneous trans-splenic approach. Active bleeding was controlled in these patients. One patient died of massive variceal rebleeding 49 d after discharge. Of the patients with recurrent variceal bleeding, TIPS placement was attempted after admission and was technically successful in eight patients. Of the remaining 14 patients with TIPS failure, 13 experienced at least one episode of rebleeding within 6 mo, and 1 was lost to follow-up. Three of these 13 patients underwent splenectomy and devascularization, and 10 had repeated endoscopic treatments.

Additionally, TIPS procedures were attempted in 4 patients who presented with repeated episodes of abdominal distension over more than 4 years, and these were technically successful in three patients. After successful TIPS insertions, two patients with SMV thrombosis developed shunt occlusions, and one of them presented with variceal hemorrhage that was controlled by endoscopic sclerotherapy. The shunt was patent in another patient. Preoperatively, his spleen was palpably enlarged 10 cm below the left costal margin. The size of the spleen was reduced, but the spleen remained clinically palpable at 20 mo after surgery. After TIPS failure, one patient underwent splenectomy for splenomegaly (6 cm below the left costal margin) and hypersplenism (a low WBC count of  $1520 \text{ cells/mm}^3$  and a low platelet count of  $32000/\text{mm}^3$ ).

### Overall survival

After a mean follow-up of  $18 \pm 2.41$  mo, a total of seven

Figure 1 Overall survival in all patients (A), patients with and without variceal bleeding (B) and patients with and without ascites (C).

patients had died. Causes of death were pulmonary embolism ( $n = 1$ ), acute leukemia ( $n = 1$ ), massive esophageal variceal hemorrhage ( $n = 1$ ), progressive liver failure ( $n = 2$ ), multiple liver abscesses ( $n = 1$ ) and accident ( $n = 1$ ). Overall, 6-, 12- and 36-mo cumulative survival rates were 94.9%, 86% and 86%, respectively (Figure 1A). Cumulative 6-, 12- and 36-mo survival rates were similar between patients with and without variceal bleeding (92.8%, 80.2% and 80.2% *vs* 97.1%, 92.5% and 92.5%, respectively,  $P = 0.269$ , Log-rank test) (Figure 1B). Cumulative 6-, 12- and 36-mo survival rates were significantly different between patients with and without ascites (90%, 61.5% and 61.5% *vs* 97.3%, 97.3% and 97.3%, respectively,  $P = 0.0008$ , Log-rank test, Figure 1C).

Given that the risk factors of EHPVO were detected in only half of the patients, they were not included in the prognostic analysis. In the univariate analysis, variables that were significantly associated with reduced survival included the presence of ascites and hydrothorax, a low level of serum sodium, an elevated WBC count and a high Child-Pugh class (Table 4). Multivariate backward stepwise Cox regression analysis demonstrated that the presence of ascites (HR = 10.729, 95%CI: 1.209-95.183,  $P$  = 0.033) and an elevated WBC count (HR = 1.072, 95%CI: 1.014-1.133,  $P$  = 0.015) were independent pre-

dictors of increased mortality in non-malignant and non-cirrhotic patients with portal cavernoma.

## DISCUSSION

This study was primarily designed to evaluate the outcome of non-malignant and non-cirrhotic patients with portal cavernoma and to determine prognostic factors. Our study demonstrated that most patients with portal cavernoma in the absence of cirrhosis or malignancy had a relatively benign course (overall cumulative survival rate was 86% at 60 mo), which is similar to the excellent outcomes of non-cirrhotic patients with portal vein or splanchnic vein thrombosis reported by previous studies<sup>[23-25]</sup>. However, it should be noted that all deaths occurred within the first year after admission, which is explained by the following points. First, a long history of portal cavernoma was recorded in some patients. It is possible that the underlying disease or liver dysfunction had already become severe in these patients, warranting referral to our highly specialized center. Second, as shown previously, the overall mortality of splanchnic vein thrombosis patients with intestinal infarction is high<sup>[23]</sup>. As a primary cause of death, intestinal infarction and its secondary severe complications often occur at the early stage. In our study, one of two patients who underwent bowel resection for intestinal infarction died 5 d after surgery.

Despite the high prevalence of variceal bleeding in our patients, the incidence of death was not significant (only one patient died of massive variceal bleeding), mainly due to advances in treatment modalities for controlling bleeding and well-preserved liver function in these patients. More importantly, we found that the presence of ascites might act as the most important prognostic factor for death. This finding could be explained by the higher incidence of liver dysfunction in patients with ascites. Indeed, the deterioration of liver function is caused not only by the presence of ascites itself, but also by a higher prothrombin time and INR and a lower level of serum albumin and sodium, which are closely correlated with the presence of ascites. Based on the prognostic significance of ascites in non-malignant and non-cirrhotic patients with portal cavernoma, therapeutic decision making needs to be further altered. Once ascites is detected, we should pay more attention to early diagnosis and treatment of underlying comorbidities and liver dysfunction. Accordingly, we hypothesize that the prevention and treatment of liver dysfunction should be incorporated into the treatment strategy for portal cavernoma<sup>[4]</sup>.

We also found that an elevated WBC count was an independent predictor of survival. This might be explained by the fact that comorbidities, such as acute leukemia ( $n$  = 1) and multiple liver abscesses ( $n$  = 1) could be more common in patients with an elevated WBC count. However, it should be noted that the effect size was very small (hazard ratio was very close to 1). Therefore, the significance of WBC count on patient survival might be clinically slight.

Our study has several limitations. First, only patients diagnosed with portal cavernoma were included in this study. The inclusion criteria may influence the application of prognostic factors in patients with acute EHPVO. However, we believe that it was important to differentiate between the outcomes of acute EHPVO and portal cavernoma, because of their dissimilar clinical presentations and natural history. Second, the prevalence and significance of underlying etiological factors in patients with EHPVO are discussed elsewhere<sup>[13,14,26,27]</sup>, but not in this study. Therefore, we can not demonstrate the association between survival and prothrombotic factors, including acquired and inherited factors. Further work is warranted to explore the effect of etiological factors on survival. Third, given the excellent outcome of non-malignant and non-cirrhotic patients with portal cavernoma, mean follow-up time was relatively short and a low proportion of patients met the endpoints in our study. This bias might miss other potential prognostic factors. An extended follow-up should be carried out in future studies. Fourth, the laboratory analysis of ascitic fluids was not performed. We could not exclude the possibility of spontaneous bacterial peritonitis, especially in cases with an elevated WBC. Finally, given that the number of deaths was only 7, the multivariate Cox regression analysis might be inappropriate. Indeed, the number of variables included in the multivariate analysis might introduce the risk of overfitting the data, thereby leading to a high risk of false positive results. Therefore, the conclusions of this analysis should be taken with caution and further confirmed in larger studies.

In conclusion, our study suggests that the presence of ascites and an elevated WBC count are significantly associated with increased mortality in non-malignant and non-cirrhotic patients with portal cavernoma. Further studies are needed to confirm the prognostic significance of ascites in these patients and to establish a new therapeutic strategy based on the presence of ascites.

## COMMENTS

### Background

Portal cavernoma is traditionally considered a sequela of extrahepatic portal vein obstruction (EHPVO) to compensate for the interrupted portal blood flow. Due to its low morbidity and mortality in non-malignant and non-cirrhotic patients, little information is known regarding the prognostic factors of portal cavernoma.

### Research frontiers

Previous studies, in which malignancy and cirrhosis were not excluded, have revealed that the increased mortality in EHPVO patients is closely associated with advanced age, presence of malignancy and cirrhosis, high bilirubin and deterioration of liver function.

### Innovations and breakthroughs

The authors conducted an 8-year retrospective single-center study to determine the predictors for survival of non-malignant and non-cirrhotic patients with portal cavernoma managed by a uniform therapeutic strategy at our center.

### Applications

The authors found that the presence of ascites might act as the most important prognostic factor for death in non-malignant and non-cirrhotic patients with portal cavernoma. Based on the prognostic significance of ascites in non-malignant and non-cirrhotic patients with portal cavernoma, therapeutic decision making

needs to be further altered.

### Terminology

Portal cavernoma, also known as cavernous transformation of the portal vein, is a rare entity, which is characterized by a tangle of tortuous hepatopetal collateral veins in the hilum.

### Peer review

It is an interesting review of portal cavernoma evolution. In this study, the authors investigated the prognostic factors for portal cavernoma in non-malignant and non-cirrhotic patients. They were able to show that the presence of ascites and an elevated white blood cell count were strongly associated with poor prognosis in non-cirrhotic patients with portal cavernoma.

### Abstract

**AIM:** To compare the efficacy and side effects of low-dose amitriptyline (AMT) with proton pump inhibitor treatment in patients with globus pharyngeus.

**METHODS:** Thirty-four patients who fulfilled the Rome III criteria for functional esophageal disorders were included in this study. Patients were randomly assigned to receive either 25 mg AMT before bedtime (AMT group) or 40 mg Pantoprazole once daily for 4 wk (conventional group). The main efficacy endpoint was assessed using the Glasgow Edinburgh Throat Scale (GETS). The secondary efficacy endpoints included the Medical Outcomes Study 36-item short form health survey [social functioning (SF)-36] and the Pittsburgh Sleep Quality Index. Treatment response was defined as a > 50% reduction in GETS scores. All patients entering this study recorded side effects at days 1, 8, 15, 22 and 29 using a visual analogue scale.

**RESULTS:** Thirty patients completed the study. After 4

wk of treatment, the AMT group had a greater response than the conventional group (75% vs 35.7%,  $P = 0.004$ ). At day 3, the AMT group showed significantly more improvement than the Conventional group in GETS score ( $3.69 \pm 1.14$  vs  $5.64 \pm 1.28$ ,  $P = 0.000$ ). After 4 wk of treatment, the AMT group showed significantly greater improvement in GETS score and sleep quality than the Conventional group ( $1.25 \pm 1.84$  vs  $3.79 \pm 2.33$ ,  $4.19 \pm 2.07$  vs  $8.5 \pm 4.97$ ;  $P < 0.01$  for both). Additionally, the AMT group was more likely than the Conventional group to experience improvement in the SF-36, including general health, vitality, social functioning and mental health ( $P = 0.044$ ,  $0.024$ ,  $0.049$  and  $0.005$ ). Dry mouth, sleepiness, dizziness and constipation were the most common side effects.

**CONCLUSION:** Low-dose AMT is well tolerated and can significantly improve patient symptoms, sleep and quality of life. Thus, low-dose AMT may be an effective treatment for globus pharyngeus.

**Key words:** Amitriptyline; Globus pharyngeus; Side effect; Pantoprazole; Treatment response

**Core tip:** A literature review reveals that there is no single effective treatment for patients with globus pharyngeus. Low-dose amitriptyline (AMT) is extensively used to treat functional gastrointestinal disorders, especially in cases with prolonged severe symptoms and disorders that affect daily function. However, no data regarding the possible effects of AMT in patients with globus pharyngeus are available. In this study, we conclude that low-dose AMT is well tolerated and can significantly improve patient symptoms. Thus, we recommend the use of low-dose AMT for globus pharyngeus.

## INTRODUCTION

Globus pharyngeus is a condition characterized by a non-painful sensation of a lump in the throat in the absence of true dysphagia or odynophagia; the sensation frequently improves with eating<sup>[1]</sup>. It is a common condition that accounts for approximately 4% of otolaryngological referrals<sup>[2]</sup>, and it is usually long-lasting, difficult to treat, recurrent and associated with a significant impairment in quality of life. Furthermore, due to the uncertain etiology of globus, it remains difficult to establish standard investigation and treatment strategies for affected patients.

Amitriptyline (AMT) is a tricyclic antidepressant with limited application due to the side effects caused by high doses (100 mg/d). In recent years, low-dose AMT has been shown to be well tolerated and significantly effective in improving the functional gastrointestinal disorders<sup>[3-5]</sup>. In 1994, Deary *et al*<sup>[6]</sup> were the first to attempt a prospective, randomized, double-blinded, placebo-controlled trial investigating the effectiveness of AMT in patients with globus pharyngeus. Most patients could not tolerate the side effects of AMT at doses of 50 mg/d to 150 mg/d, resulting in treatment failure. To the best of our knowledge, evidence supporting the possible effects of low-dose AMT in patients with globus pharyngeus has not been reported.

Therefore, the aim of this study was to investigate the response rate, onset time, side effects and clinical predictors of symptom response to low-dose AMT treatment in patients with globus pharyngeus.

## MATERIALS AND METHODS

### Patients

In this prospective study, we enrolled 34 patients who complained of globus symptoms between September 2011 and January 2013. All patients were between 12 and 65 years of age and were newly diagnosed as having functional esophageal disorders based on the following Rome III criteria<sup>[7]</sup>: (1) persistent or intermittent, nonpainful sensation of a lump or foreign body in the throat; (2) occurrence of the sensation between meals; (3) absence of dysphagia or odynophagia; (4) absence of evidence that gastroesophageal reflux is the cause of the symptom; and (5) absence of histopathology-based diagnosis of esophageal motility disorders. All included patients fulfilled the criteria for the last 3 mo, with symptom onset at least 6 mo before diagnosis. All patients underwent otolaryngological assessment with neck/thyroid palpation and gastroscopy or laryngoscopy, and none had any organic abnormality on assessment. The following exclusion criteria were adopted: hepatic or renal disease; prostatic disease; pregnancy or breast feeding; known glaucoma;

history of seizures; history of thyroid or liver dysfunction; recent use of monoamine oxidase inhibitors; use of any proton pump inhibitor (PPI) or histamine type 2 receptor antagonist during the last 2 mo; use of tranquilizers or antidepressants that may affect esophageal motor function; and moderate to severe anxiety or depression (14-item Hamilton Anxiety Rating Scale assessed from 0 to 13 points and 17-item Hamilton Depression Rating Scale assessed from 0 to 17 points).

### Study design and procedures

This study was a prospective, randomized controlled trial in globus pharyngeus patients and was approved by the hospital ethics committee (Clinical trial registration number: ChiCTR-TRC-12001968). Written informed consent was obtained from the patients according to the Declaration of Helsinki.

Thirty-four eligible patients were randomized to receive either 25 mg AMT once daily before bedtime or 40 mg Pantoprazole once daily for 4 wk. Treatment was allocated by a simple randomization method using a computer-generated randomization schedule. Ultimately, 17 patients received AMT, and 17 patients received Pantoprazole. The primary endpoint was assessed using the Glasgow Edinburgh Throat Scale (GETS) questionnaire<sup>[8]</sup>. We observed the onset time and the treatment efficiency on days 3 and 10 and week 4, and evaluated the social functioning (SF)-36 and Pittsburgh sleep quality index (PSQI) scores at baseline and at week 4 as secondary endpoints<sup>[9,10]</sup>.

All patients entering this study recorded side effects. The severity of side effects was evaluated using a visual analogue scale (VAS) administered on days 1, 8, 15, 22 and 29 after medication.

### GETS

The GETS questionnaire provided both the primary and secondary outcomes. It is a validated questionnaire used to rate globus pharyngeus symptoms. The globus symptom score component is based on 10 questions assessing various throat symptoms. Patients subjectively grade their symptoms for each question on a 7-point Likert scale, with 0 being "none" and 7 being "unbearable". These compiled questions yield a score that represents the severity of the patient's globus symptoms, with a maximum possible score of 70. The secondary outcome is the somatic distress score, which represents the psychological impact of the patient's symptoms. This component of the questionnaire is also graded on a 7-point Likert scale, with 0 being "never" and 7 being "all of the time". This yields a maximum total score of 14. Both the overall symptom score and the somatic distress score can be used over time to assess the severity of the disease.

### Medical outcomes study 36-item short form health survey

The SF-36 is the most commonly used scale for assessing patient quality of life, and it includes eight dimensions:

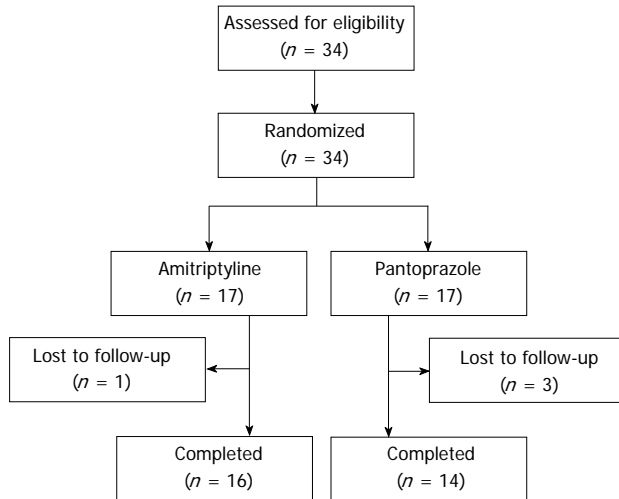

Figure 1 Consort diagram.

**Table 1 Demographic and baseline characteristics of the study patients**

Variable	AMT group n = 16	Conventional group n = 14	P value
Age (yr)	43.19 ± 10.96	42.93 ± 13.1	0.953
Gender (male/female)	6/10	5/9	1.000
BMI	21.54 ± 2.09	23.01 ± 3.49	0.166
Smoking habit	4 (18.75%)	3 (21.42%)	1.000
Alcohol consumption	6 (37.5%)	5 (35.71%)	1.000
Symptom duration (yr)	1.44 ± 0.66	1.54 ± 0.89	0.731
GETS	5.44 ± 1.63	5.71 ± 1.38	0.623
PSQI	8.75 ± 4.68	8.71 ± 5.27	0.984

Values are represented as the mean ± SD. AMT: Amitriptyline; BMI: Body mass index; GETS: Glasgow Edinburgh Throat Scale; PSQI: Pittsburgh sleep quality index.

physical functioning, role-physical (RP), bodily pain, general health (GH), vitality (VT), SF, role-emotional (RE), and mental health (MH). A higher score indicates a better quality of life.

### PSQI

Prepared by psychiatrist Buysse *et al*<sup>[9]</sup>, the PSQI assesses seven areas, including sleep quality, the time to fall asleep, sleep time, sleep efficiency, sleep disturbance, use of sleep medication and daytime dysfunction. In total, 18 items were used for the calculation of the PSQI score. Higher scores represent worse sleep quality, and a score > 7 points indicates the presence of a sleep disorder.

### Treatment response

Treatment response was defined as a > 50% reduction in the GETS score. The response was calculated as: [(score at treatment - score at baseline)/score at baseline] × 100. The treatment responses of the two groups were calculated separately.

### Statistical analysis

Data analysis was performed using SPSS 13.0 software

**Table 2 Change in glasgow edinburgh throat scale score and Pittsburgh sleep quality index in patients treated with amitriptyline vs pantoprazole and incidence of side effects n (%)**

Variable	AMT group n = 16	Conventional group n = 14	P value
GETS score			
Baseline	5.44 ± 1.63	5.71 ± 1.38	0.623
3 d	3.69 ± 1.14 <sup>1</sup>	5.64 ± 1.28	0.000

Dizziness	4 (25)	1 (7.1)	0.336
Constipation	3 (18.8)	1 (7.1)	0.602
Palpitations	1 (6.3)	0 (0)	1.000
Malaise	1 (6.3)	0 (0)	1.000

<sup>1</sup>Statistically significant difference from baseline,  $P < 0.05$  between the two groups. AMT: Amitriptyline; GETS: Glasgow Edinburgh Throat Scale; PSQI: Pittsburgh sleep quality index.

(SPSS Inc., Chicago IL, United States), and the measurement data are reported as the mean ± SD; baseline parameters and differences between the two treatments were compared using Student's *t* test. The scores at baseline and after AMT or Pantoprazole treatment were compared by paired *t* test. The VAS scores of side effects were analyzed using the  $\chi^2$  test or Fisher's exact test.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Study participants

A total of 34 patients with globus symptom were enrolled in the study. All patients were randomized to receive either AMT or Pantoprazole. Of these patients, four were lost to follow-up. A total of 30 patients (AMT 16, Pantoprazole 14) completed the study (Figure 1). The baseline characteristics of the patients are shown in Table 1. No differences were observed between the two groups in age, gender, body mass index, smoking habit, alcohol consumption, symptom duration, GETS score or PSQI score.

### Primary efficacy endpoint

The rate of effectiveness was calculated in the two groups after 4 wk of treatment, the response rate of the AMT group was significantly higher than that of the Conventional group (75% *vs* 35.7%,  $P = 0.004$ , Table 2). Compared with the Conventional group, the GETS scores of the AMT group were significantly improved at days 3 and 10, and week 4 (all  $P < 0.01$ , Table 2). Compared with baseline, the GETS scores of the AMT group were significantly reduced at days 3 and 10 and week 4 (all  $P < 0.05$ ). However, the GETS scores of the Conventional group were significantly reduced only after 4 wk of treatment. The onset time in the AMT group was significantly earlier than that in the Conventional group.

**Table 3** Changes in social functioning-36 subscale scores in patients treated with amitriptyline *vs* Pantoprazole

Variable		Baseline	Week 4	P value
PF	AMT	95 ± 11.4	95.94 ± 11.14	0.945
	Conventional	93.93 ± 7.12	95.71 ± 4.75	
RP	AMT	64.06 ± 37.6	81.25 ± 26.61 <sup>1</sup>	0.929
	Conventional	66.07 ± 37.48	80.36 ± 28.04 <sup>1</sup>	
BP	AMT	89.38 ± 16.52	90.63 ± 14.55	0.498
	Conventional	85.57 ± 20.68	86.29 ± 19.96	
GH	AMT	56.75 ± 20.92	73 ± 17.57 <sup>1</sup>	0.044
	Conventional	49.86 ± 22.49	58.71 ± 19.57 <sup>1</sup>	
VT	AMT	70.63 ± 18.15	88.44 ± 7.01 <sup>1</sup>	0.024
	Conventional	71.79 ± 24.7	73.21 ± 24.39	
SF	AMT	75 ± 18.25	92.97 ± 13.67 <sup>1</sup>	0.049
	Conventional	77.68 ± 18.46	81.25 ± 17.51 <sup>1</sup>	
RE	AMT	68.76 ± 35.42	79.18 ± 23.96 <sup>1</sup>	0.384
	Conventional	61.91 ± 41.05	69.05 ± 38.04	
MH	AMT	68.75 ± 15.68	83.5 ± 10 <sup>1</sup>	0.005
	Conventional	65.43 ± 19.32	69.14 ± 15.72	

<sup>1</sup>Statistically significant difference compared with baseline,  $P < 0.05$  between the two groups. AMT: Amitriptyline; PF: Physical functioning; RP: Role-physical; BP: Bodily pain; GH: General health; VT: Vitality; SF: Social functioning; RE: Role-emotional; MH: Mental health.

### Secondary efficacy endpoints

Compared with the Conventional group, the AMT group exhibited significant improvements in the GH, VT, SF, MH scales of the SF-36 (all  $P < 0.05$ , Table 3). Compared with baseline, the AMT group exhibited significant improvements in RP, GH, VT, SF, RE and MH (all  $P < 0.05$ ). The Conventional group experienced significant improvements in only RP, GH and SF (all  $P < 0.05$ , Table 3).

The AMT group also showed a significant improvement in PSQI compared with the Conventional group ( $4.19 \pm 2.07$  *vs*  $8.5 \pm 4.97$ ,  $P = 0.008$ , Table 2). Compared with baseline, the AMT group exhibited significant improvement. However, there were no significant differences in PSQI at baseline and after pantoprazole treatment ( $P > 0.05$ ).

### Adverse effects

The various adverse events reported in the two treatment groups are shown in Table 2. The incidence rates of dry mouth and sleepiness in the AMT group were significantly higher than in the Conventional group ( $P = 0.026$ ,  $P = 0.004$ , Table 2). The incidence rates of dizziness and constipation were also somewhat higher in the AMT group than in the Conventional group, although the difference was not statistically significant ( $P = 0.336$ ,  $P = 0.602$ , Table 2).

As shown in Figure 2, sleepiness and dizziness almost disappeared within 1 wk. Patients who had dry mouth and constipation symptoms experienced significant relief after receiving AMT for 2 wk. No serious adverse events occurred in either group.

## DISCUSSION

There is no consistent evidence attributing globus to any

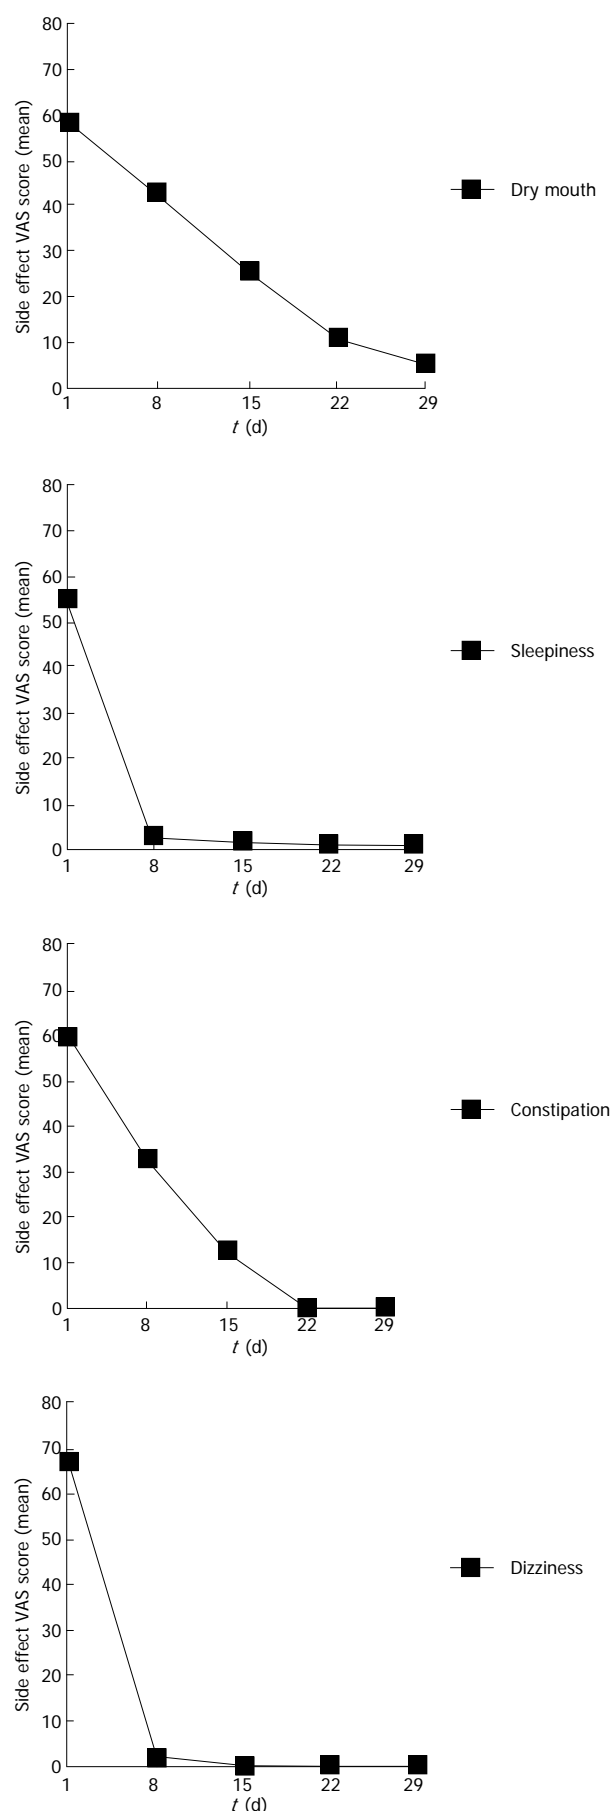

Figure 2 Side effect diagrams. VAS: Visual analogue scale.

specific anatomic abnormality, including the cricopharyngeal bar. Although it has been long since it was first described, the etiology of globus pharyngeus is poorly understood. Abnormal upper esophageal sphincter function, esophageal motility disorders, psychological factors, stress, and *Helicobacter pylori* infection of the cervical heterotopic gastric mucosa have all been suggested as potential causes of globus<sup>[11-15]</sup>. There is much controversy about the true etiology of globus pharyngeus, and it has been difficult to establish a causal relationship between globus and these other disorders<sup>[16]</sup>. In addition, esophageal balloon distention can simulate the sensation of globus at low distending thresholds, suggesting some degree of esophageal hypersensitivity<sup>[11]</sup>. Because there are few controlled studies on the treatment of globus, evidence-based treatment for this disorder is currently not available. Some studies have suggested that gastroesophageal reflux disease (GERD) is a major cause of globus<sup>[16,17-19]</sup>. Therefore, it seems practical to use anti-reflux methods as the first-line treatment for managing patients with globus<sup>[11]</sup>, although this protocol remains under considerable debate. Other established treatment options include speech and language therapy, anti-depressants, and cognitive-behavioral therapy<sup>[11,20-22]</sup>.

Low-dose AMT has been used widely in gastroenterologic practice. Morgan *et al*<sup>[23]</sup> demonstrated that the doses for the analgesic and neuromodulatory effects of AMT were below the effective doses of the antidepressant. Huang *et al*<sup>[24]</sup> observed that low-dose AMT could reduce visceral sensitivity using the noninvasive drinking-ultrasonography test in healthy volunteers. However, our understanding of the mechanism of action of this agent is limited. A commonly held hypothesis is that AMT, which indirectly stimulates norepinephrine and serotonin receptors by blocking the reuptake of norepinephrine and serotonin, works as a neuromodulator, affecting the brain-gut axis by altering neurotransmitter systems within the limbic system and other pain centers of the brain<sup>[25]</sup>. In addition, one study showed that AMT can alter sleep patterns<sup>[25]</sup>. Our study also confirmed that the AMT group showed significantly greater improvement in sleep than the Conventional group. We hypothesize that the overall effects of amitriptyline in patients with globus arise from its central nervous system activity, as altering sleep patterns modulates the regulation of the noradrenergic system of the locus coeruleus (a brain center inhibited during sleep), which alters nociception.

In our study, 5 of 14 (35.7%) patients with globus pharyngeus receiving PPI treatment as a conventional therapy were classified as responders. Dumper *et al*<sup>[26]</sup> demonstrated that there was no clinically or statistically significant difference between lansoprazole and placebo at any time point during a 3-mo treatment period. Therefore, it is important to note that although GERD is a condition that is sometimes associated with globus, this does not mean that all globus is GERD-related or that all GERD patients have globus. Thus, PPI treatment in patients with globus may not achieve satisfactory results.

To our knowledge, this is the first prospective, randomized controlled trial investigating the effectiveness of a therapeutic low dose of AMT in globus patients. The treatment efficiency of the AMT group was 75%, significantly greater than that of the Conventional group (35.7%). After 3 d of treatment, the symptoms, sleep, and quality of life of the AMT group improved more than those of the Conventional group. During treatment, average cost in the AMT group was also significantly lower than that in the Conventional group.

There are several limitations of this study. First, although many patients with globus symptoms and normal examinations were seen in our clinic, this study included only a small sample of patients with globus. A number of patients had recently started on PPI or were diagnosed with moderate to severe anxiety or depression, and excluding these patients resulted in a decreased number of cases in this study. Second, it is possible that the course of medication in our study was too short; the standard duration of AMT administration in the clinic is 4-12 wk<sup>[27]</sup>. We also evaluated only the response to short-term PPI treatment and did not investigate the response to long-term PPI treatment (3 or more months).

In conclusion, low-dose AMT is well tolerated and may be effective in reducing the symptoms of patients with globus pharyngeus while also significantly improving sleep and quality of life. However, further studies with larger sample sizes and longer follow-up periods are needed to verify our results.

## ACKNOWLEDGMENTS

We would like to thank Ming-Zhi Xu, Professor of the Guangdong Mental Disorder Research Institute, for his guidance in the use of SF-36 and the anxiety and depression scale. We also express our appreciation to Dr. Su of ENT for his assistance in diagnosing globus pharyngeus.

## COMMENTS

### Background

Low-dose amitriptyline (AMT) is extensively used for treating functional gastrointestinal disorders, although its precise mechanism of action is still not fully understood. In 1994, Deary *et al* performed the first study investigating the effectiveness of high-dose AMT (50-150 mg/d) in patients with globus pharyngeus. However, most patients could not tolerate the side effects of high doses of AMT, resulting in treatment failure. The effect of low-dose AMT in patients with globus pharyngeus has not been reported.

### Research frontiers

There is currently a lack of highly effective pharmacotherapy for globus pharyngeus. Low-dose AMT may be a good choice of treatment for patients with globus pharyngeus.

### Innovations and breakthroughs

This is the first prospective, randomized controlled trial evaluating the effectiveness of a therapeutic low dose of AMT in globus patients. The results revealed that low-dose AMT is well tolerated and can significantly improve patient symptoms, sleep and quality of life.

### Applications

Low-dose AMT can be significantly effective in improving the symptoms and quality of life of the patients, thereby supporting its clinical applicability for gastrointestinal disorders.

# Terminology

Globus pharyngeus is a physical sensation of a lump in the throat that causes difficulty or discomfort in swallowing. The sensation may also be choking or feeling as though there is a mass lodged in the esophagus. AMT is a tricyclic antidepressant that is extensively used to treat functional gastrointestinal diseases, especially in cases with prolonged severe symptoms and daily functional disorders.

# Peer review

This is an interesting paper evaluating the effect of low-dose AMT on globus pharyngeus. The study is reasonably well done, and the design and outcome assessment are standardized.

### Abstract

**AIM:** To compare the long-term clinical efficacy of chemotherapy plus radiotherapy (CRT) with that of radiotherapy alone (RT) or chemotherapy alone (CT) for locally advanced pancreatic carcinoma (LAPC).

**METHODS:** Using manual and computer-aided methods, we searched the data through the databases, including PubMed/EmBase/CNKI/CQVIP/China Journals Full Text Database and websites and proceedings of major annual meetings such as ASCO and CSCO. The methodological quality of the included studies was assessed using the Jadad scoring system. Both English and Chinese publications were searched. We collected data from controlled clinical trials on CRT vs RT or CT for LAPC, and conducted a meta-analysis of 15 included

studies. Meta-analysis was performed using RevMan4.2 Software according to the method recommended by Cochrane Collaboration.

**RESULTS:** Fifteen eligible randomized controlled trials including a total of 1128 patients were screened. Jadad score was 2 in only one article, and 3-4 in the remaining 14 studies. The meta-analysis showed that CRT was superior in the 6- and 12-mo survivals to the RT alone group or CT alone group ( $P = 0.0001$  and  $P = 0.02$ , respectively), whereas the 18-mo survival showed no significant difference ( $P = 0.23$ ). Subgroup analysis showed that the 6-, 12-, and 18-mo survivals were not significantly different between the CRT group and CT group ( $P = 0.07$ ,  $P = 0.23$ , and  $P = 0.91$ , respectively). Notably, the CRT group had significantly better 6-, 12-, and 18-mo survivals than the RT group (all  $P < 0.01$ ). CRT group had significantly more grade 3-4 treatment-related hematologic and non-hematologic toxicities than the CT group or RT group (all  $P < 0.01$ ).

**CONCLUSION:** Compared with CT or RT, CRT can benefit the long-term survival of LAPC patients, although it may also increase treatment-related toxicities.

**Key words:** Pancreatic cancer; Chemotherapy; Radiotherapy; Meta-analysis; Survival

**Core tip:** To compare the long-term clinical efficacy of chemotherapy plus radiotherapy (CRT) with that of radiotherapy alone (RT) or chemotherapy alone (CT) for locally advanced pancreatic carcinoma (LAPC), the authors analyzed the potential impact of CRT, CT or RT on the survival of the patients using meta-analysis methodologies. Meta-analysis showed that compared with CT or RT, CRT can benefit the long-term survival of LAPC patients, although it may also increase treatment-related toxicities.

Combined radiochemotherapy in patients with locally advanced pancreatic cancer: A meta-analysis. *World J Gastroenterol* 2013; 19(42): 7461-7471 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7461.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7461>

## INTRODUCTION

Pancreatic cancer is the fourth leading cause of cancer-related death in the United States<sup>[1]</sup>. Over the past decades, the standard treatment for patients with inoperable locally advanced pancreatic cancer (LAPC) was chemotherapy alone (CT) or chemo-radiation therapy (CRT)<sup>[2-4]</sup>; however, the median survival time was only 6-9 mo, and less than 10% of patients survived for 2 years<sup>[5]</sup>. Definitive results of the 2000-01 FFCD/SFRO study, in which patients randomly received CRT (60 Gy + 5-fluorouracil + cisplatin + gemcitabine) or CT, showed that the progression free survival (PFS) and overall survival (OS) were not significantly different between these two groups<sup>[6]</sup>. On the contrary, the Eastern Cooperative Oncology Group (ECOG) study, which randomly divided the LAPC patients into a gemcitabine chemotherapy group and a gemcitabine + radiotherapy group, showed that the CRT group had significantly superior OS over the CT group; meanwhile, treatment-related toxicity in the CRT group was acceptable. In the present study, we analyzed the potential impact of CRT or CT or radiotherapy alone (RT) on the survival using meta-analysis methodologies in an attempt to obtain more robust evidence.

## MATERIALS AND METHODS

### Literature collection

The search strategy was: exp pancreas/(pancreas.tw.exp); pancreatic neoplasms/(pancreas adj neoplasms, pancreas adj cancers, pancreas adj carcinomas); 30-38 exp drug therapy/exp chemotherapy adjuvant/chemotherapy; chemoradiotherapy (combin adj chemotherapy, concurrent adj chemoradiotherapy; 49-50 exp radiotherapy/exp radiotherapy adjuvant/radiotherapy.

The literature search was conducted in both English and Chinese publications. The data sources included PubMed (1964-2012), EmBase (1964-2012), CNKI (1979-2012), CQVIP(1979-2012), China Journals Full Text Database (1979-2012), websites (*e.g.*, Web of Science) and proceedings of major annual meetings such as ASCO (1995-2012) and CSCO (1995-2012). Internet searches were carried out and bibliographies of included articles were searched. Finally, the Chinese references in the selected articles were reviewed for other relevant studies. The latest updates of serial clinical studies were used. Date of last search was October 15, 2012.

### Inclusion and exclusion criteria

**Inclusion criteria:** (1) Patients were pathologically con-

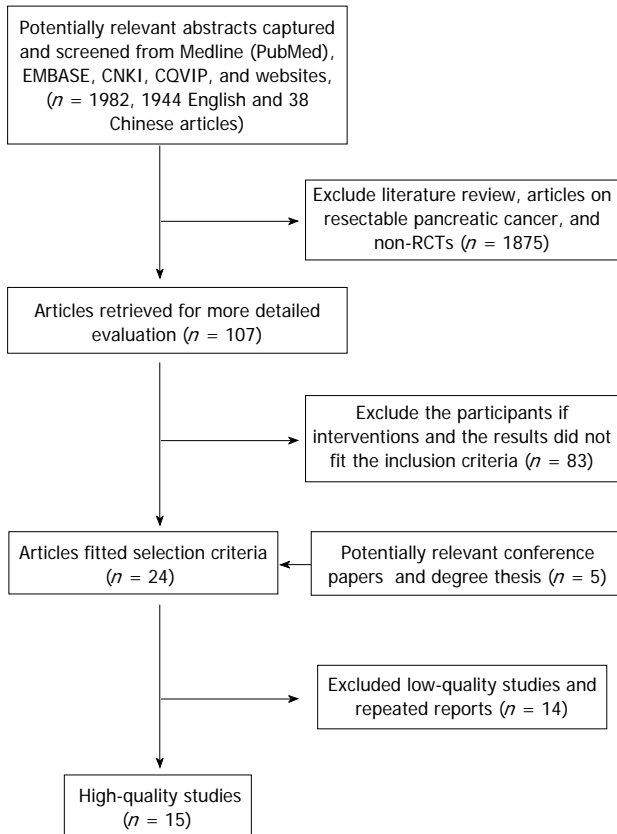

firmed to have locally advanced pancreatic malignant tumors (Tumors were judged as nonresectable due to extension to regional lymph nodes and/or vascular structures such as the superior mesenteric artery or the celiac trunk or the existence of a portal or superior mesenteric-portal venous confluent thrombosis), which were naive to surgical treatment or other anti-tumor therapies before enrollment; (2) the study was a prospective randomized controlled trial; (3) the interventions only included radiotherapy and/or chemotherapy; (4) the main endpoint was survival, and the observation lasted at least 6 mo, along with survival records; and (5) except for the treatment methods, the treatment group was parallel with the control group.

**Exclusion criteria:** (1) Patients with metastatic pancreatic cancer; individuals who suffered from relapse after anti-tumor treatment; patients who had previously received surgical treatment; patients with non-LAPC; (2) non-prospective and non-randomized/non-controlled studies; (3) other interventions were applied in addition to radiotherapy and chemotherapy; (4) only local efficacy was evaluated and no data on survival was available; and (5) low-quality studies that had a Jadad score of less than 2.

### Quality assessment

**Assessment of the included literature:** Two reviewers independently conducted methodological quality assessment and data retrieval. Cross-checking was then performed; any disagreements were resolved by discussion and, if necessary, a third reviewer. The methodological quality of the included studies was assessed using the Jadad scoring system: (1) Was the study described as randomized? Were the patients actually randomized into the treatment group or control group, and both the observers and patients did not know which group would be allocated? (2 = the appropriate randomization method was described; 1 = the author claimed the use of a randomization method); (2) Except for the targeted intervention(s), were the other procedures consistent between these two groups? (3) Was the study described as blinded (2 = both the patients and observers were blinded, and the blinding method was described; 1 = the author claimed that a double-blinding method was applied; 0 = not blinded); and (4) Was there a description of exclusion bias (*i.e.*, systematical difference of the withdrawals and drop-outs between these two groups; scored 0 or 1 for any reason of drop-outs). The final score ranged from 1 to 5. Studies scored 3 or higher were judged as "high-quality", and those scored 1 or 2 as "poor-quality". The criteria for methodological quality analysis were developed: (1) randomization; (2) blinding; (3) withdrawal or drop-outs; (4) allocation concealment; and (5) adoption of intentional analysis. The quality of the included literature was presented as weightings in a forest plot.

**Assessment of the result quality:** Using evidence-based medicine principles, we conducted a quality assessment

**Figure 1** Flow diagram depicting the process of identification and inclusion of selected studies. RCT: Randomized controlled trials.

on the design of evidence sources and finally obtained the quality of the meta-analysis results.

### Statistical analysis

Meta-analysis was performed using RevMan4.2 Software. For clinical trials reporting the summary measures or Kaplan-Meier curves, we applied the published statistical methods to analyze the risk ratio and the variance of the temporal data that cause the events<sup>[7,8]</sup>. The statistical heterogeneity of the clinical trials was analyzed using  $\chi^2$  test and  $I^2$  test;  $P > 0.05$  during  $\chi^2$  test indicates low heterogeneity. The primary analysis was completed using a fixed-effects model. If there was a significant statistical heterogeneity, a secondary confirmatory analysis was performed using a random-effects model. Meanwhile, subgroup analysis was performed to determine whether the results were affected by different interventions. By analyzing the difference between combination therapy and CT/RT, we tried to understand their different impacts on the prognosis.

## RESULTS

### Search results

The flow chart of this study is shown in Figure 1. Reviews, articles about resectable pancreatic cancer, non-randomized controlled trials (RCTs), low-quality studies and repeated reports were excluded. Finally, both review-

ers agreed to include 15 RCTs involving 1128 patients in the meta-analysis.

All of them were published in peer-reviewed international and domestic journals. The cases had been followed up for 6-36 mo. All the studies were prospective, randomized, and controlled trials. One article was claimed to be randomized, with a Jadad score of only 2, and therefore the quality was low. The remaining 14 studies scored 3-4, and belonged to high-quality literature, among which two articles used the blinding method. The meta-analysis results are listed in Table 1. There were no duplicates or mis-citations.

### Statistical analysis

**Meta-analysis on radiochemotherapy and CT/RT for LAPC:** Of these 15 RCTs ( $n = 1128$ ), 12 ( $n = 964$ ) reported the 6-mo survival; 14 ( $n = 1098$ ) reported the 12-mo survival; 9 ( $n = 805$ ) reported the 18-mo survival; the 6-, 12-, and 18-mo survival was 419, 261, and 119 cases, respectively, in the CRT group, and 238, 127, and 43 cases, respectively, in the CT group/RT group.  $P$  value was larger than 0.05 in the meta-analysis on the heterogeneity of the 6-mo survival, and a fixed-effects model was used to merge the data.  $P$  values were lower than 0.05 in the meta-analysis on the heterogeneity of the 12- and 18-mo survivals, and a random-effects model was used to merge the data. The CRT group had superior survival over the CT/RT group, while the 18-mo survival showed no such significant difference (OR = 1.78, 1.77, and 1.74; 95%CI: 1.33-2.38, 1.08-2.88, and 0.71-4.27,  $P = 0.0001$ , 0.02, and 0.23) (Table 2, Figure 2A).

**Subgroup analysis on the efficacy of radiochemotherapy and CT/RT for LAPC:** Seven RCTs ( $n = 371$ ) reported the 6-mo survival of patients after combination treatment or CT, 7 ( $n = 479$ ) reported the 12-mo survival, and 5 ( $n = 354$ ) reported the 18-mo survival. The 6-, 12-, and 18-mo survivals were reported in 129, 95, and 32 cases, respectively, in the CRT group, and 119, 91, and 37 cases, respectively, in the CT group.  $P$  value was larger than 0.05 in the meta-analysis on the heterogeneity of 6-mo survival, and a fixed-effects model was used to merge the data.  $P$  values were lower than 0.05 in the meta-analysis on the heterogeneity of the 12- and 18-mo survivals, and a random-effects model was used to merge the data. The 6-, 12-, and 18-mo survivals were not significantly different between the CRT group and the CT group (OR = 1.52, 1.49, and 1.07; 95%CI: 0.97-2.36, 0.77-2.88, and 0.33-3.45,  $P = 0.07$ , 0.23, and 0.91) (Figure 2B).

Five RCTs ( $n = 476$ ) reported the 6-mo survival after combination treatment or RT, 7 ( $n = 610$ ) reported the 12-mo survival, 4 ( $n = 451$ ) reported the 18-mo survival. The 6-, 12-, and 18-mo survivals were 246, 166, and 87 cases, respectively, in the CRT group, and 70, 36, and 37 cases, respectively, in the RT group. Meta-analysis on the heterogeneity of the 6-, 12-, and 18-mo survivals showed that the  $P$  values were larger than 0.05, and a

W: Well differentiated; M: Moderately differentiated; P: Poorly differentiated; SMF: Streptozocin, mitomycin, and 5-fluorouracil (5FU); NR: No report; GEM: Gemcitabine; RT: radiotherapy alone; MMC: Mitomycin C.

fixed-effects model was used to merge the data. The 6-, 12-, and 18-mo survivals were significantly higher in the CRT group than in the RT group (OR = 2.49, 2.42, and 3.86; 95%CI: 1.62-3.82, 1.57-3.74, 1.66-8.99, all  $P < 0.01$ ), (Figure 2C).

**Subgroup analysis on the efficacy of CRT > 50Gy and RT for LAPC:** Due to the limited number of patients and RCTs, this subgroup analysis only covered the 12-mo survival rate. Five RCTs ( $n = 409$ ) reported the 12-mo survival of patients after CRT at a dose larger than 50Gy or RT, including 32 cases in the CRT group and 98 cases in the RT group.  $P$  value was larger than 0.05 in the meta-analysis on the heterogeneity of the 12-mo survival, and a fixed-effects model was used to pool the data. The CRT group had superior 12-mo survival over the RT group (OR = 2.32; 95%CI: 1.44-3.73,  $P = 0.0005$ ) (Figure 2D).

**Subgroup analysis on the efficacy of CRT < 50 Gy and RT for LAPC:** Due to the limited number of patients and RCTs, this subgroup analysis was only made on the 6- and 12-mo survival rates. Four RCTs ( $n = 254$ ) reported the 6-mo survival and 4 ( $n = 254$ ) reported the

12-mo survival. The 6- and 12-mo survival was reported in 108 and 68 cases in the CRT group, and 42 and 12 cases in the RT group, respectively.  $P$  value was larger than 0.05 in the meta-analysis on the heterogeneity of 6- and 12-mo survival, and a fixed-effects model was used to pool the data. The CRT group had superior 6- and 12-mo survival over the RT group (OR = 2.5 and 4.12; 95%CI: 1.45-4.30 and 2.04-8.35,  $P = 0.0009$  and  $< 0.0001$ ) (Figure 2E).

Due to the limited number of cases and RCTs included, subgroup analysis was not performed on the efficacy of different doses of CRT and CT for LAPC.

**Meta-analysis on grade 3-4 treatment-related toxicity:** In total, 12 RCTs ( $n = 874$ ) reported grade 3-4 treatment-related hematologic toxicities, and 10 ( $n = 713$ ) reported grade 3-4 treatment-related non-hematologic toxicities. Meta-analysis on the heterogeneity showed that the  $P$  value was larger than 0.05, and a fixed-effects model was used to merge the data. The CRT group had significantly more grade 3-4 treatment-related hematologic and non-hematologic toxicities than the CT group or RT group (OR = 3.74 and 1.71; 95%CI: 2.56-5.47 and 1.16-2.53, both  $P < 0.01$ ) (Figure 2F).

### Sensitivity analysis

By re-analyzing the results, the sensitivity analysis was designed to re-combine the available studies to explore the effect of a certain factor on the effect, so as to understand the influences of uncertain factors and study design on the aggregate results. To avoid the effect of different chemotherapy or radiotherapy in the different randomized controlled trials on the overall results, subgroup analyses were performed to re-analyze the above studies, and the results were generally consistent with the meta-analysis findings. As shown in the sensitivity analysis, our current meta-analysis neither increased or decreased the efficacy nor exaggerated the efficacy; after the strength of the articles was changed, the results did not become negative or reversed. Therefore, our results were relatively stable and reliable.

### DISCUSSION

Pancreatic adenocarcinoma is among the most challenging solid malignancies to treat on account of its propensity for late presentation with inoperable disease, aggressive tumor biology and resistance to chemotherapy<sup>[23]</sup>. About a third of all pancreatic cancers is found to be locally advanced at the time of diagnosis, LAPC refers to local

tumors that have invaded the surrounding normal tissues and can not be surgically resected while no distant metastasis occurs<sup>[24]</sup>. As shown in early clinical practice, conventional radiotherapy for LAPC often can not improve the efficacy. The availability of three-dimensional conformal radiotherapy and intensity-modulated radiotherapy improves the therapeutic effectiveness, although controversies persist. Using the meta-analysis methodologies, we rigorously screened eligible randomized controlled trials for analysis. As shown in our current meta-analysis: (1) the CRT group had higher 6- and 12-mo survival rates than the RT alone and CT alone group; (2) subgroup analysis showed that the CRT group had higher 6-, 12-, and 18-mo survival rates than CT alone group; (3) subgroup analysis showed that the CRT group had higher 6-, 12-, and 18-mo survival rates than the RT alone group; and (4) CRT group had significantly more grade 3-4 treatment-related hematologic and non-hematologic toxicities than the CT group or RT group. By analyzing the results of 2000 FFCD/SFRO<sup>[6]</sup>, we found that concurrent three-dimensional conformal radiotherapy (total dosage: 60 Gy) with chemotherapy (DDP + 5FU), followed by GMZ chemotherapy achieved a median survival of 8.6 mo and a 1-year survival rate of 32%; the GMZ CT group had a survival of 13 mo and 1-year survival rate of 53%, sug-

Review: Radiotherapy plus chemotherapy in patients with locally advanced pancreatic cancer

Comparison: 01 CRT vs RT or CT

Outcome: 11 3-4 grade treatment related non-hematologica toxicity

**Figure 2 Meta-analysis.** A: On chemotherapy plus radiotherapy (CRT) vs chemotherapy alone (CT)/radiotherapy alone (RT) for locally advanced pancreatic carcinoma (LAPC) in the 6-, 12-, and 18-mo survivals; B: On CRT vs CT for LAPC in the 6-, 12-, and 18-mo survivals; C: On CRT vs RT for LAPC in the 6-, 12-, and 18-mo survivals; D: On CRT > 50 Gy vs RT for LAPC in the 12-mo survivals; E: On CRT < 50 Gy vs RT for LAPC in the 6- and 12-mo survivals; F: On CRT vs CT/RT for LAPC in grade 3-4 treatment-related toxicities.

gesting that the combination therapy did not change the efficacy. Meanwhile, the 60 Gy dosage induced more complications and therefore increased the mortality and

decreased the survival. The CRT protocol applied in this trial used high radiotherapy and chemotherapy dosages; furthermore, the radiation fields included not only the

cancer foci but also the peripancreatic, hilar and celiac trunk lymph nodes that had high metastatic potential (but not confirmed), which not only remarkably increased the radiotherapy-related toxic reactions but also shortened the survival. Similarly, radiochemotherapy was applied in the ECOG4201 trial, although the radiotherapy dose was lowered to 50.4 Gy. Compared with CT, concurrent radio-chemotherapy prolonged the survival (11 mo *vs* 9.2 mo) and yielded a higher 1-year survival rate (50% *vs* 32%)<sup>[25]</sup>. During concurrent radiochemotherapy, the sequencing of radiotherapy and chemotherapy can also affect the clinical efficacy. In the GERCOR study, 181 patients received 4 cycles of chemotherapy initially, among whom 53 experienced disease progression; the remaining 128 patients without disease progression were divided into a concurrent CRT group ( $n = 72$ ) and a CT group ( $n = 56$ ). The results showed that the PFS and OS were improved in the concurrent CRT group (10.8 mo and 15 mo, respectively), and these were significantly longer than those in the CT group (7.4 mo and 11.7 mo, respectively) ( $P = 0.005$ ,  $P = 0.0009$ , respectively), indicating that radiotherapy combined with chemotherapy can remarkably improve the survival<sup>[26]</sup>.

In summary, as shown in this study, the combination of chemotherapy and radiotherapy can prolong the long-term survival although it may also increase the treatment-related toxicity. More reasonably designed randomized controlled trials should be conducted to further elucidate the optimal radiotherapy dosage, the use of gemcitabine or 5-FU, and more specific chemotherapy protocols. Chemotherapy may be started for several cycles; if no disease progression occurs, concurrent radiochemotherapy may be used. By doing so, we may rule out patients with rapid disease progression to avoid the “double whammy” from chemotherapy. Along with the improvement of radiotherapy technology, the optimization of the sequencing of radiochemotherapy, and the definition of target population, the efficacy of radiochemotherapy for pancreatic cancer will be further improved, and multidisciplinary and individualized radiochemotherapy for LAPC will play a more important role.

## COMMENTS

### Background

Pancreatic cancer is the fourth leading cause of cancer-related death in the United States. Over the past decades, the standard treatment for patients with locally advanced pancreatic carcinoma (LAPC) was chemotherapy alone or chemo-radiation therapy. However, the efficacy of the combined radiotherapy and chemotherapy is currently unclear.

### Research frontiers

Over the past decades, many studies have been performed to understand the role of chemotherapy or radiation therapy alone and chemo-radiation therapy in LAPC. Some trials showed no improvement in local progression or progression-free or overall survival with the addition of radiation therapy to chemotherapy in patients with LAPC; however, some trials demonstrated improved overall survival, with acceptable toxicity. Moreover, several systematic reviews were recently published to investigate the role of chemo-radiation therapy in LAPC. However, these reviews were methodologically insufficient and thus could not achieve a comprehensive conclusion.

### Innovations and breakthroughs

Based on this meta-analysis, chemo-radiation therapy was superior in the 6- and 12-mo survivals to the radiation therapy group or chemotherapy group alone. Similar results were indicated in the subgroup analyses. The radiation therapy group had significantly more grade 3-4 treatment-related hematologic and non-hematologic toxicities than the radiation therapy group or chemotherapy group alone. These findings were not presented clearly in previous systematic reviews.

### Applications

The combination of chemotherapy and radiotherapy can prolong the long-term survival of the patients with LAPC although it may also increase the treatment-related toxicity. Chemotherapy may be started for several cycles; if no disease progression occurs, concurrent radiochemotherapy may be used.

### Terminology

Locally advanced pancreatic malignant tumors were judged as nonresectable due to extension to regional lymph nodes and/or vascular structures such as the superior mesenteric artery or the celiac trunk or the existence of a portal or superior mesenteric-portal venous confluent thrombosis. Over the past decades, the standard treatment for patients with inoperable locally advanced pancreatic cancer was chemotherapy alone or chemo-radiation therapy.

### Peer review

This is a well written manuscript analyzing therapeutic management of pancreatic cancer. In this manuscript, the authors compared the long-term clinical efficacy of chemotherapy plus radiotherapy with that of radiotherapy alone or chemotherapy alone for locally advanced pancreatic carcinoma. The data were well collected, and analyzed.

**Key words:** Hepatocellular carcinoma; Hepatogastric fistula; Fistula; Upper gastrointestinal bleeding

**Core tip:** Gastrointestinal bleeding is a common complication of hepatocellular carcinoma (HCC). However, HCC leading to Hepatogastric fistula presenting as massive upper gastrointestinal bleeding is uncommon. Here we report a case of HCC with direct invasion of the stomach leading to massive gastrointestinal bleeding. Patient was managed with selective arterial angiogram and coil embolization to control bleeding. HCC with local metastasis to adjacent structures such as gastrointestinal tract carries poor prognosis. With increasing incidence of HCC and recent improvements in the treatment of advanced HCC, this condition may become more common and awareness among clinicians should help consider this condition in the differential diagnosis and prompt management.

### Abstract

A 36-year-old male Asian immigrant with a history of hepatitis B and hepatitis C related unresectable hepatocellular carcinoma in the left lobe of the liver presented with hematemesis and severe anemia. He was diagnosed with a liver mass that was resected 8 years ago described as a benign tumor in his home country. He had received trans-arterial chemoembolization (TACE) four months ago after subsequent diagnosis of unresectable hepatoma, and currently was receiving chemotherapy with Sorafenib. After resuscitation, a contrast enhanced computerized tomography was performed which showed fistulization of hepatocellular carcinoma into adjacent stomach. This finding was confirmed during endoscopy with direct visualization of the fistulous opening. Hepatocellular carcinoma (HCC) invading the gastrointestinal (GI) tract is rare. We present a case and literature review of HCC with local invasion of the stomach causing massive upper GI bleeding after receiving TACE.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is an aggressive primary malignancy of the liver with 5-year survival rates as low as 5%<sup>[1]</sup>. It is the third leading causes of cancer deaths across the world and ninth leading cause of cancer deaths in United States<sup>[2]</sup>. While the incidence of other common cancers is decreasing in the United States, HCC is on the rise with an average annual percentage change of incidence rate of 3.5%<sup>[2]</sup>. The majority of cases of HCC are caused by chronic liver disease from hepatitis B and C (78%)<sup>[2]</sup>. Extra-hepatic metastasis is found at the time of diagnosis in up to 15% of patients

with HCC<sup>[3]</sup>. Lung is the most common site of metastasis followed by intra-abdominal lymph nodes, and bone and adrenal glands<sup>[3]</sup>. Median survival of patients with extra-hepatic manifestations is less than 6 mo<sup>[4]</sup>. Metastasis to the gastrointestinal (GI) tract is rare with rates of 0.4%-2% of cases<sup>[5]</sup> and in up to 12% of cases in autopsy series<sup>[6]</sup>. Here we report a case of HCC with direct invasion of the stomach leading to massive GI bleeding.

## CASE REPORT

A 36-year-old Asian male with hepatitis B and hepatitis C associated HCC presented with chronic melena and massive acute upper GI bleeding with large volume hematemesis. He had undergone trans-arterial chemo-embolization (TACE) four months ago for a large, diffuse, unresectable, biopsy proven HCC in the left lobe of the liver. Due to side effects from the procedure, patient declined to undergo further TACE. He had been on Sorafenib for the preceding two and one-half months prior to this presentation. Apparently, the patient had a liver mass that was resected in his home country eight years ago, described verbally to him as “a benign” tumor. Vital signs on presentation included BP 131/75 mmHg, pulse 123, RR 32, temperature 96.0 F, and oxygen saturation was 88% on 4 L *via* nasal cannula. On physical exam, he was tachycardic, chest was clear to auscultation; mucus membranes were pale, abdominal exam showed tender hepatomegaly (10 cm below right costal margin in the mid-clavicular line) and mid-epigastric tenderness. Alpha fetoprotein level was 8.3 ng/mL. Laboratory data revealed hemoglobin of 2.5 g/dL (hematocrit, 10%; mean corpuscular volume 94), leukocytosis (with white blood cell count 16.7), and platelet count of 539. Coagulation profile showed a mildly prolonged INR of 1.6 and activated partial thromboplastin time of 21. Hemoglobin from prior hospitalization 4 mo ago was 13.3 g/dL. The patient was transfused with packed red cells (7 units) and intravenous fluids were administered. Tumor marker studies including  $\alpha$ -fetoprotein (7.6 ng/mL), CEA (3.3 ng/mL), and CA 19.9 (< 0.1 U/mL), all of which were normal. Hepatitis B quantitative polymerase chain reaction was 41048 U/mL, hepatitis Be antigen was negative and hepatitis Be antibody was positive. Hepatitis C quantitative PCR was 65 IU/mL.

Abdominal computed tomography with intravenous and oral contrast noted a large left hepatic lobe mass which was increased in size (19 cm × 13 cm) compared to prior mass (16 cm × 10 cm) noted two months earlier. An EGD was performed and revealed a 1.4 cm fistula in the posterior wall of the distal gastric body with stigmata of recent bleeding *via* the fistula (Figure 1). A large amount of air was seen centrally within the mass, which appeared to communicate with the gastric lumen through a 7 mm defect along the lesser curvature near the gastric fundus (Figure 2). Subsequently, a visceral (celiac, superior mesenteric artery, and left gastric artery) arteriogram demonstrated no evidence of active

**Figure 1** Esophagogastroduodenoscopy image showing the fistulous opening of the hepatocellular carcinoma on the lesser curvature of the stomach.

bleeding. However, selective left gastric artery angiogram showed hypervascular blush within the tumor and it was selectively embolized to achieve decreased flow, utilizing a total of three, 6 mm × 10 cm long Azur detachable coils. His hemoglobin stabilized and he was discharged with plans to start second line palliative chemotherapy. He subsequently presented a month later with recurrent GI bleeding for which he had to undergo further selective embolization of celiac artery branches, which showed signs of neovascularization. The patient opted for hospice care 10 mo after diagnosis of HCC and 6 mo after treatment of acute GI bleed from hepato-gastric fistula.

## DISCUSSION

GI bleeding is a common complication in patients with HCC. Common etiologies include peptic ulcer disease, variceal bleeding due to portal hypertension from underlying cirrhosis and/or tumor invasion of portal vein causing thrombosis, and portal hypertensive gastropathy. Yeo *et al*<sup>[5]</sup> prospectively looked at 55 HCC patients who presented with GI bleeding over a period of 11 mo and found that majority had a non-variceal source of bleeding (53%) and the remainder variceal bleeding. Among patients with a non-variceal source, three patients (0.05%) bled secondary to direct invasion of tumor to gut. GI bleeding secondary to direct invasion by HCC is rare (0.05%-2%)<sup>[5,7-9]</sup>. Metastatic spread can be due to hematogenous, lymphatic or by direct invasion of the tumor into adjacent organs. The most common site of direct tumor invasion of the GI tract is stomach followed by duodenum and colon. Predisposing factors for GI tract invasion include large liver lesions (> 5 cm in size), subcapsular location and exophytic growth pattern. Suspected predisposing features include prior TACE and/or radiation therapy which can lead to ischemia and inflammatory reactions in the tumor and adjoining bowel wall. These changes can potentially lead to adhesion and local tumor invasion with subsequent fistulization<sup>[10,11]</sup>. We hypothesize a similar process in our case. Park *et al*<sup>[6]</sup> found GI tract involvement at the time of diagnosis of HCC

**Figure 2** Computerized tomography images of the abdomen. A: Showing large mass in the left lobe of the liver and oral contrast traced into liver (arrow) through fistulous opening in stomach; B: Showing large mass in the left lobe of the liver and fistulous communication between the liver mass and the stomach; C: Showing large mass in the left lobe of the liver and fistulous communication between the liver mass and the stomach. A: Anterior R: Right; L: Left; P: Posterior.

in 7/12 patients without any prior treatment. In our patient, we suspect an exophytic tumor growth pattern causing direct GI tract invasion and pressure necrosis on adjacent organs. This process was likely worsened by TACE/radiation related inflammatory reactions contributing to erosion and fistulization, with subsequent bleeding into the GI tract. Sources of gastrointestinal bleeding noted in the literature have included rupture of hepatoma into the GI tract, bleeding from the intrahepatic portion of the tumor, or bleeding from an involved vessel in the wall of the GI tract. In our case, we endoscopically documented oozing from the hypervascular edges of the gastro-hepatic fistula within the stomach.

The prognosis of patients with HCC and GI involvement is poor because of massive bleeding and/or hepatic failure. In one series, the median survival was 4 wk<sup>[7]</sup> and in a second study none survived beyond 9 mo<sup>[8]</sup>. Our patient survived 6 mo. Non-surgical techniques to achieve hemostasis include trans-arterial embolization, endoscopic injection of ethanol or adrenalin, and radiotherapy ablation. Korkolis *et al.*<sup>[12]</sup> reported a case of HCC invading the stomach and upper surface of the pancreas who underwent *en bloc* resection of left lobe of liver with liver mass (15 cm × 12 cm × 9.5 cm), total gastrectomy, distal pancreatectomy, splenectomy, cholecystectomy, radical excision of adjacent lymph node and survival of 16 mo with no local recurrence. Curative surgery is a potential option especially in good surgical candidates with reasonable functional reserve. Surgical intervention has showed prolonged survival with median survival rates of 9.7 mo as opposed to 3.0 mo in non-surgical therapy as reported in other case series<sup>[13,14]</sup>.

In conclusion, due to improvements in chemotherapy and advanced interventional radiologic chemoembolization techniques with improved short term survival in patients with unresectable HCC<sup>[15,16]</sup>, GI tract fistulization and associated upper GI bleeding are likely to become more frequent in the future. This complication may be managed *via* palliative surgical resection, or by angiographic embolization, as was performed in our patient.

### Abstract

*Helicobacter pylori* (*H. pylori*) is one of the most common chronic bacterial infections in humans, affecting half of world's population. Therapy for *H. pylori* infection has proven to be both effective and safe. The one-week triple therapy including proton pump inhibitor, clarithromycin, and amoxicillin or metronidazole is still recommended as a first-line treatment to eradicate *H. pylori* infection in countries with low clarithromycin resistance. Generally, this therapy is well-tolerated, with only a few and usually minor side effects. However, rare but severe adverse effects such as pseudomembranous colitis have been reported, *Clostridium difficile* (*C. difficile*) infection being the main causative factor in all cases. We report the cases of two women who developed pseudomembranous colitis after a 1-wk triple

therapy consisting of pantoprazole 20 mg *bid*, clarithromycin 500 mg *bid*, and amoxicillin 1 g *bid* to eradicate *H. pylori* infection. A limited colonoscopy showed typical appearance of pseudomembranous colitis, and the stool test for *C. difficile* toxins was positive. Rapid resolution of symptoms and negative *C. difficile* toxins were obtained in both patients with oral vancomycin. No relapse occurred during a four and eleven-month, respectively, follow up. These cases suggest that physicians should have a high index of suspicion for pseudomembranous colitis when evaluate patients with diarrhea following *H. pylori* eradication therapy.

**Key words:** *Helicobacter pylori* eradication; Triple therapy; *Clostridium difficile*; Pseudomembranous colitis; Vancomycin

**Core tip:** Herein are described the cases of two elderly women who developed pseudomembranous colitis after one-week triple therapy consisting of pantoprazole (20 mg *bid*), clarithromycin (500 mg *bid*), and amoxicillin (1 g *bid*) to eradicate *Helicobacter pylori* (*H. pylori*) infection. After a 10-d treatment with oral vancomycin (125 mg every 6 h) both patients had complete resolution of symptoms and negative stool test for *Clostridium difficile* toxins. Clinicians should have a high index of suspicion of pseudomembranous colitis as a rare, but severe complication of *H. pylori* therapy.

Trifan A, Girleanu I, Cojocariu C, Sfarti C, Singeap AM, Dorobat C, Grigore L, Stanciu C. Pseudomembranous colitis associated with a triple therapy for *Helicobacter pylori* eradication. *World J Gastroenterol* 2013; 19(42): 7476-7479 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i42/7476.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i42.7476>

## INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is one of the most common chronic bacterial infections in humans, affecting half of the world's population. Its prevalence is high in developing countries and low in the developed ones<sup>[1]</sup>. *H. pylori* eradication therapy is supported by numerous consensus groups around the world, and the treatment of millions of infected subjects has demonstrated that such strategy is both effective and safe. The spectrum of indications for *H. pylori* eradication therapy has steadily extended over the last decade<sup>[2]</sup> with a resultant increase in its use. The one-week triple therapy including proton pump inhibitor (PPI), clarithromycin and amoxicillin or metronidazole proposed at the first Maastricht conference<sup>[3]</sup> to eradicate *H. pylori* is still recommended as the first-line treatment by the recent Maastricht IV consensus conference<sup>[2]</sup> in countries with clarithromycin resistance rate under 15%-20% (e.g., Northern European countries)<sup>[4]</sup>. Eradication rates with standard triple therapy have fallen to 70%-80% over the past few years, mainly due to increasing resistance to clarithromycin<sup>[5]</sup>. Generally, this therapy is well-tolerated, with only a few and usually minor side effects (e.g., nausea, metallic taste). However, severe adverse effects such as pseudomembranous colitis have been reported<sup>[6-13]</sup>, *Clostridium difficile* (*C. difficile*) being the main causative agent in all cases.

We report the cases of two elderly women who developed pseudomembranous colitis after one-week triple therapy with pantoprazole, clarithromycin, and amoxicillin for *H. pylori* infection.

## CASE REPORT

The first case is a 70-year-old woman who was referred to our department with a 10-d history of watery diarrhea (6-12 stools per day) and crampy abdominal pain. Her medical history included hypertension, chronic gastritis *H. pylori* positive, and colonic diverticulosis (previously diagnosed on colonoscopy). Three weeks before admission she completed a one-week triple therapy (pantoprazole 20 mg *bid*, clarithromycin 500 mg *bid* and amoxicillin 1 g *bid*) for *H. pylori* infection. On physical examination, she looked unwell, and her abdomen was mildly tender, with no masses. Temperature and vital signs were normal. Laboratory investigations revealed leukocytosis (14800/mm<sup>3</sup>) with neutrophilia, high C-reactive protein (11.5 mg/dL), and low levels of serum albumin (2.4 mg/dL), sodium (133 mEq/L), and potassium (2.7 mEq/L). Two days before admission, stool samples examination excluded enteric bacterial pathogens (*Shigella*, *Salmonella*, *Yersinia* spp.) as well as *C. difficile* toxins. Without any prior preparation, the patient underwent a limited colonoscopy, which showed diffusely scattered off-white pseudomembranes attached to the hyperemic underlying mucosa and multiple diverticula (Figure 1). Repeated stool sample examination was positive for *C. difficile* toxins A and B. Treatment with oral metronidazole 500 mg every 8 h was initiated, replaced 72 h later with oral vancomycin 125

**Figure 1** Pre-treatment endoscopic examination. Colonoscopy revealed scattered off-white pseudomembranes, some of them around a diverticulum.

mg every 6 h due to unfavorable response. After a 10-d treatment with vancomycin, the patient had a complete resolution of the symptoms and was discharged from hospital with negative results for *C. difficile* toxins and one stool per day. During a four-month follow-up, patient remained asymptomatic.

The second case concerns a 71-year-old woman who was admitted with profuse watery diarrhea (up to 10 stools daily) and abdominal pain. Her prior medical history was unremarkable. Symptoms occurred 5 d after a one-week triple therapy (pantoprazole 20 mg *bid*, clarithromycin 500 mg *bid* and amoxicillin 1 g *bid*) for *H. pylori* eradication. Physical examination was normal, except for signs of dehydration. Microbiological examination of stools was negative for *Salmonella*, *Shigella* and *Yersinia* spp., and did not reveal any parasites. The patient had leukocytosis (12400/mm<sup>3</sup>), hypokalemia (2.8 mEq/L), and mild inflammatory syndrome. Sigmoidoscopy showed typical signs of pseudomembranous colitis, while a stool test for *C. difficile* toxins A and B proved positive. The patient received 10-d treatment with oral vancomycin 125 mg every 6 h, followed by prompt improvement in symptoms and negative test for *C. difficile* toxins. No relapse occurred during an 11-mo follow-up.

## DISCUSSION

Eradication therapy for *H. pylori* provides enormous benefits and has proved to be both effective and safe. Except from the rare and mild side-effects, eradication therapy is generally well-tolerated. Severe adverse effects such as pseudomembranous colitis following eradication therapy have very rarely been reported<sup>[6-13]</sup> which is quite surprising, taken into account the immense number of subjects treated worldwide. It is difficult to find a clear explanation why are so rare cases of pseudomembranous colitis after eradication therapy reported in the literature, but some hypotheses were put forward: (1) the use of metronidazole, an efficient drug against *C. difficile*; however, several cases of pseudomembranous colitis, as published, occurred after a regimen containing metronidazole<sup>[8-10]</sup>; (2) the short duration of the therapy; (3) almost all treat-

ments are carried out in outpatients (hospitalization is a risk factor for *C. difficile* infection); and (4) many cases with mild clinical disease were most likely not diagnosed, either because the patients did not consult a physician or the physician did not suspect the development of *C. difficile* infection<sup>[10]</sup>.

Over the last decade, *C. difficile* infection rate has increased dramatically worldwide both in incidence and severity<sup>[14,15]</sup>. In addition to broad-spectrum antibiotic therapy, there have been identified many other potential risk factors for *C. difficile* infection (advanced age, female gender, comorbidities, admission to ICU, long hospital stay, immunosuppressive therapy, and PPI use)<sup>[16-21]</sup>. Several studies and recent meta-analyses have shown that PPI therapy is associated with increased risk of *C. difficile* infection<sup>[20-27]</sup>, and United States Food and Drug Administration even issued a safety announcement to inform the public about this possible risk<sup>[28]</sup>. Newly published studies have found that *C. difficile* infection can occur outside the above mentioned well-known risk groups, in the absence of any hospitalization and even in young patients with no comorbidities<sup>[29]</sup>.

All the components of the triple eradication therapy for *H. pylori* (PPI and two antibiotics: clarithromycin and amoxicillin or metronidazole) are potential risk factors for *C. difficile* infection. The most responsible for development of pseudomembranous colitis seems to be clarithromycin, used in both our cases and in most of the published reports<sup>[6,7,10,13]</sup>.

The spectrum of *C. difficile* infection is wide, ranging from mild, self-limiting diarrhea to fulminant pseudomembranous colitis which is associated with significant morbidity and mortality. Most patients with *C. difficile* infection have a mild-to-moderate disease, but some may develop severe forms of disease such as pseudomembranous colitis, or even complicated by toxic megacolon<sup>[7]</sup>. Among variables used to define severe disease, the most important are the presence of pseudomembranes at endoscopy and age over 65 years. Both our cases met the criteria for a severe form of disease, and were treated with vancomycin according to current guidelines recommendations<sup>[30]</sup>.

Our cases, in addition to the ones published, demonstrate that pseudomembranous colitis can occur after a usually well-tolerated triple therapy for *H. pylori* eradication. Despite this very rare complication, it should be underlined that *H. pylori* eradication therapy provides huge benefits and remains effective and generally safe. However, *C. difficile* infection may occur with an eradication therapy for *H. pylori* consisting of two antibiotics and a PPI. Most likely, *C. difficile* infection cases following *H. pylori* eradication therapy are not as rare as reported by literature, considering that a significant proportion of mild form of disease does not come to physician's attention and thus may remain undiagnosed<sup>[31]</sup>. Clinicians should be aware of such complication when prescribing triple therapy for *H. pylori* eradication, and should inform the patients that they may have diarrhea during or after

treatment, and therefore should seek medical advice.

In conclusion, pseudomembranous colitis should be suspected in any patient with watery diarrhea during or after triple therapy for *H. pylori* eradication. Awareness of such complication is particularly important in the actual context when both duration and indications for *H. pylori* eradication therapy have been extended.

### Abstract

Hepatocellular adenoma (HCA) is one of the important complications of glycogen storage disease type I a (GSD- I a) because it can be transformed into hepatocellular carcinoma. Although surgical resection is a standard treatment of choice for solitary HCA, multiple HCAs in GSD- I a patients present as therapeutic challenges for curative treatment. Therefore, treatment strategy according to malignant potential is important in management of HCAs in GSD- I a. The authors present a case of histologically proven multiple HCAs without  $\beta$ -catenin mutations occurred in a GSD- I a patient treated successfully with percutaneous radiofrequency ablation as a minimally invasive therapy.

### INTRODUCTION

Glycogen storage disease type I a (GSD- I a) is an inherited disorder of carbohydrate metabolism caused by glucose-6-phosphatase deficiency in the liver, kidneys and intestinal mucosa<sup>[1]</sup>. Liver diseases associated with GSD- I a include hepatocellular adenoma (HCA) which can lead to considerable morbidity and mortality associated with malignant transformation and intratumoral hemorrhage<sup>[2]</sup>. While HCA associated with oral contraceptives or exogenous androgen is relatively large, single and encapsulated HCAs in GSD- I a tend to be small, multiple and non-capsulated<sup>[3]</sup>. Furthermore, HCAs in GSD- I a tend to transform into hepatocellular carcinoma (HCC) more frequently than sporadic HCAs<sup>[3]</sup>. Rates of transformation into HCC have been reported approximately as being up to 10%<sup>[4]</sup>. Recently, sporadic HCAs have been classified into four subgroups; hepatocytic nuclear factor 1  $\alpha$  mutated HCAs,  $\beta$ -catenin-activated HCAs, inflammatory HCA, and unclassified HCA according to molecular markers and immunohistochemistry<sup>[5]</sup>. Because  $\beta$ -catenin activation is known as a risk factor for malig-

nant transformation, subgroup classification of HCAs has been suggested as an important step in management of HCAs<sup>[6,7]</sup>. Although several strategies for management of multiple HCAs in GSD- I a are suggested in literature, the best treatment is still controversial<sup>[8]</sup>. Surgical resection has been a standard treatment for solitary HCA with high risk of malignancy. However, the role of surgical resection is limited in multiple HCAs in GSD- I a. Liver transplantation could be another treatment option for management of multiple HCAs as well as correction of most metabolic derangement in GSD- I a patients<sup>[9]</sup>. Other options such as ethanol injection and transarterial embolization have been suggested as new and less invasive treatments<sup>[10-12]</sup>. The authors present a case of multiple HCAs without  $\beta$ -catenin mutations in a patient with GSD- I a which were successfully treated by ultrasonography guided percutaneous radiofrequency ablation (RFA).

## CASE REPORT

A 24-year-old male patient was referred for multiple liver masses. He was diagnosed as GSD- I a 10 years ago. He had a family history of two brothers who died of HCC at the age of 22 and 26 years, respectively. His mother died from an undetermined cause in her twenties. After diagnosis, he had never received dietary therapy or other medical treatments. He was undersized with a height of 166 cm and weight of 51 kg. The laboratory findings revealed hyperlipidemia and hyperuricemia after a 12 h fast (Table 1). Serologic tests for viral hepatitis and autoimmune liver disease were all negative. Serum levels of  $\alpha$ -fetoprotein and prothrombin induced by vitamin K deficiency or antagonist-II were 2.4 ng/mL and 35 mAU/mL. Mutation analysis of the glucose-6-phosphatase gene revealed compound heterozygosity for p.Leu216X (c.648G > T) and p.Gly222Arg (c.664G > A) in exon 5. On subsequent gadolinium ethoxybenzyl diethylene triamine pentaacetic acid (Gd-EOB-DTPA; Primovist, Bayer Schering Pharma, Berlin, Germany) enhanced magnetic resonance imaging (MRI), four arterial-phase enhancing nodules were noted in both lobes of liver and these nodules showed clear defects on 20 min hepatobiliary phase (Figure 1). Three nodules revealed the same features with intense homogeneous arterial enhancement, nearly iso-signal intensity with capsular enhancement on 3 min delayed phase, and intermediate high signal intensity on axial T2-weighted image (T2WI). There was no evidence of fat component or internal hemorrhage, or the Atoll sign (Figure 1A-C). One nodule showed heterogeneous signal intensity on 3 min delayed phase, axial T2WI, and 20 min hepatobiliary phase (Figure 1D). These features were consistent with multiple hepatic adenomas associated with GSD- I a. We performed percutaneous liver biopsies on each nodule to identify HCA subtype. Each biopsy specimen underwent standard histopathological examination and immunohistochemistry for  $\beta$ -catenin, glutamine synthetase and amyloid A (Figure 2). Immunohistochemistry confirmed all the adenomas as

inflammatory type HCA without malignant transformation. As all the nodules were small without malignant cells and  $\beta$ -catenin activation, we performed ultrasonography guided RFA as a less invasive therapeutic option. RFA was successfully performed under local anesthesia using a cool-tip electrode with a 3 cm exposed tip (ACT2030, Covidien, Mansfield, MA, United States). Multiple overlapping ablation methods were applied for each adenoma. There was no procedure-related complication after RFA. Three months follow-up computed tomogram scans revealed gradual reduction of the RFA zone without any residual tumor (Figure 3).

## DISCUSSION

Management of HCAs in patients with GSD- I a is not well established because of the rarity of this disease. As patients with GSD- I a survive longer with intensive dietary therapy, they have more chances to develop HCAs in their expanded life span<sup>[13]</sup>. Although there is a case report that HCA in GSD- I a regressed after strict dietary therapy, maintenance of normoglycemia under intensive dietary therapy is insufficient to regress HCAs or reverse malignant transformation because patients with multiple HCAs sometimes showed sudden progression and

**Figure 1** Hepatic adenomas associated with glycogen storage disease type 1a. A: Gd-EOB-DTPA enhanced axial T1-weighted image on arterial phase (left upper) reveals approximately 2 cm intense enhancing mass in the segment 3 of liver (black arrows). The mass shows nearly iso-signal intensity with capsular enhancement on 3 min delayed phase (right upper), intermediate high signal intensity on axial T2-weighted image (left lower), and clear defect on 20 min hepatobiliary phase (right lower); B: Approximately 1.8 cm sized intense enhancing mass on arterial phase (left upper) is noted in the segment 6 of liver. This mass shows suspicious focal eccentric wash-out enhancement (white arrows) on 3 min delayed phase (right upper). This portion reveals relatively low signal intensity on axial T2-weighted image (left lower) and 20 min hepatobiliary phase (right lower), compared to other tumor area. Surrounding rim enhancement in the tumor is seen on 20 min hepatobiliary phase; C: Approximately 1.8 cm arterial enhancing mass (white arrows) is seen in the segment 2 of liver. The mass reveals slightly high signal intensity on 3 min delayed phase (right upper), intermediate high signal intensity on axial T2-weighted image (left lower), and fuzzy defect on 20 min hepatobiliary phase (right lower). Multifocal arteriportal shunts (asterisks) are noted in the segments 3 and 7 of liver; D: Approximately 1.8 cm sized intense enhancing mass (black arrows) on arterial phase (left upper) is noted in the segment 6 of liver. This mass shows slightly high signal intensity with capsular enhancement on 3min delayed phase (right upper), and intermediate high signal intensity on axial T2-weighted image (left lower). On 20 min hepatobiliary phase (right lower), the tumor reveals clear defect with surrounding rim enhancement. Gd-EOB-DTPA: Gadolinium ethoxybenzyl diethylene triamine pentaacetic acid.

**Figure 2** The histological features are consistent with the inflammatory type of hepatocellular adenoma. A: A hepatocellular adenoma in GSD-1a has several unpaired arteries (thick black arrows), sinusoidal dilation (thin black arrows), and steatosis (white arrows), but the atypia of hepatocytes are low without a nuclear pleomorphism; B: A reticulin staining does not show thick hepatic cords; C: The lymphocytic infiltrates are found in a hepatic lobule; D: The lymphocytes infiltrate in the area surrounded a portal and a periportal tracts; E: Staining for glutamine synthetase is diffuse cytoplasmic with focal nuclear expression; F:  $\beta$ -catenin staining does not show abnormal expression. GSD-1a: Glycogen storage disease type I a.

metastatic spread<sup>[3,14-17]</sup>. As HCAs in GSD- I a tend to be multiple, involving both lobes of liver, the ultimate treatment of HCAs in GSD- I a is liver transplantation for management of HCAs and to reverse metabolic derangement<sup>[9,18]</sup>. However, liver transplantation is rarely performed due to uncertainties on timing of transplantation, limited organ availability and combined renal dysfunction with immunosuppression<sup>[13]</sup>. Surgical resection of HCAs is suggested as an effective intermediate therapy for prevention of HCC until liver transplantation<sup>[13]</sup>. However, liver resection in GSD- I a patients showed greater morbidity including intra-abdominal abscess, multi-organ failure, unstable blood glucose control and hemorrhage.

Recently, molecular characterizations of HCAs demonstrated that frequent  $\beta$ -catenin mutations are more

frequently observed in HCAs in GSD- I a and related to increased risk of malignant transformation like sporadic HCAs<sup>[19]</sup>. To assess the risk of malignant transformation, we biopsied each HCA for analysis of subtype of each tumor by immunohistochemistry. All the HCAs were small and inflammatory type with low risk of malignant transformation. There are reports of treatment of HCAs in GSD- I a by transarterial embolization and ethanol injection as a minimal invasive procedure<sup>[11,12]</sup>. As RFA can offer complete necrosis of target lesions compared to transarterial embolization and ethanol injection, we treated HCAs by percutaneous RFA successfully. The present case shows the potential role of RFA in management of multiple HCAs in GSD- I a patients along with risk stratification by pathological examination.

**Figure 3** Computed tomogram follow-up after 3 mo showed gradual reduction of radiofrequency ablation zone. A: Post-RFA follow-up CT revealed gradual contraction of ablated lesion in segment 3 to 1 cm; B: Complete ablation of enhancing lesion in segment 6 was observed in Post-RFA follow-up CT; C: Post-RFA follow-up CT showed complete ablation of 1.8 cm sized tumor in segment 2; D: Post-RFA CT revealed no residual lesion without adjacent organ damage. CT: Computed tomogram; RFA: Radiofrequency ablation.

### Abstract

In a recent article, Longman and Swaminath analyzed our paper on the use of rifaximin in patients with moderately active Crohn's disease (CD). Here we report some considerations concerning their article. The exploratory *post-hoc* subgroup analysis showed that early-stage disease and, differently from that written by Longman and Swaminath, also colonic involvement seemed to be associated with a significant higher efficacy of rifaximin-EIR 800 mg twice daily. Early-stage disease is generally considered as the more easily treatable phase of CD, and the better response to rifaximin in Crohn's colitis is in accordance with the high concentration of bacteria in the colon. In addition, patients with C reactive protein level > 5 mg/L achieved remission more significantly than patients with normal values, thus suggesting that the symptoms were probably caused by inflammation instead of by non-inflammatory causes. We also analyze the role of rifaximin against gut bacteria and the clinical situations that could obtain the best results from antibiotics.

**Key words:** Crohn's disease; Intestinal microbiota; Non-absorbable antibiotic; Rifaximin

**Core tip:** In this letter to the Editor we report some considerations concerning the article entitled "Microbial manipulation as primary therapy for Crohn's disease" written by Longman and Swaminath. In the article the authors analyzed our paper on the use of rifaximin as primary therapy in active Crohn's disease. The *post-hoc* analysis of our study showed that early-stage disease, colonic involvement and a C reactive protein level > 5 mg/L were associated with a significant higher efficacy of rifaximin. We also discuss the role of rifaximin against intestinal bacteria and the clinical situations to explore further in controlled studies with antibiotics.

### TO THE EDITOR

We would like to thank Doctor Longman and Swaminath from Columbia University for their interesting analysis of our article concerning the trial of rifamixin in Crohn's disease (CD)<sup>[1,2]</sup>.

Their expert analysis entitled "Microbial manipulation as primary therapy for Crohn's disease" merits some considerations and one slight correction: (1) The *post-hoc* explorative subgroup analysis has certainly revealed that patients with an early disease (as defined as first diagnosis ≤ 3 years before enrollment in the study) are significantly more likely to achieve remission with rifaximin-EIR 800 mg twice a day compared to placebo, but, differently from what Longman and Swaminath have written, also colonic involvement, and a baseline C-reactive protein (CRP) level > 5 mg/L showed the same statistical significant superiority. The favorable effect of these three factors is biologically plausible. Elevated CRP values suggest that the symptoms, which increase the Crohn's disease activity index values, are probably caused by inflamma-

tion instead of by non-inflammatory causes such as irritable bowel, bile salt diarrhoea or previous surgery. Many previous studies with antibiotics have shown that Crohn's colitis responds better to this therapy than does that in the small bowel location, and this is in accordance with the higher microbial content in the colon. Finally, early disease is more easily treatable because the lesions are mainly inflammatory and the structural damage has usually not yet appeared; (2) Rifaximin is a non-absorbable antibiotic and consequently it should not work on the bacteria attached to the mucosa. Rifaximin can work against bacteria present in the lumen but not against adherent *Escherichia coli* (AIEC), and this fact could be particularly important if AIEC is one of the causes of CD<sup>[3]</sup>. At most rifaximin can reduce the attachment of enteroaggregative *Escherichia coli* by biologically altering the host cell, but it should not be able to counteract the bacteria already adherent to the mucosa<sup>[4]</sup>. A study which explores the efficacy of one antibiotic together with a microbial analysis in order to ascertain which bacteria are involved in the inflammatory process, cannot be limited to investigating the stools flora, given that the bacteria found in the stools probably do not represent the adherent bacteria and could not be responsible for the inflammation; (3) From our study about 50% of the patients maintained clinical remission 12 wk after stopping rifaximin. It is probable, however, that a permanent change of the microbiota does not occur; and (4) Doctors Longman and Swaminath ask how to select patients who could ob-

tain the best benefit from antibiotics. Crohn's colitis and elevated values of acute phase reactants seem the better clinical situation to explore further in controlled studies. Given the possible role of adherent bacteria in causing CD or, at least, in being responsible for symptoms, another very promising situation should be explored: immediately after surgery, when all the diseased tracts have been removed, antimicrobial therapy could obstruct the adherence of bacteria to the mucosa reducing the recurrence of lesions.

### Abstract

Adhesive small bowel obstruction (ASBO) is the most frequently encountered surgical disorder of the small intestine. Up to 80% of ASBO cases resolve spontaneously and do not require invasive treatment. It is important to identify such patients that will benefit from conservative treatment in order to prevent unnecessarily exposing them to the risks associated with surgical intervention, such as morbidity and further adhesion formation. For the remaining ASBO patients, timely surgical intervention is necessary to prevent small bowel strangulation, which may cause intestinal ischemia and bowel necrosis. While early identification of these patients is key to decreasing ASBO-related morbidity and mortality, the non-specific signs and laboratory findings upon clinic presentation limit timely diagnosis and implementation of appropriate clinical management. Combining the clinical presentation findings with those from other diagnostic imaging modalities, such as abdominal X-ray, computed tomography-scan and water-soluble contrast studies, will improve diagnosis of ASBO and help clinicians to better evaluate the potential of conservative management as a safe strategy for a particular patient. Nonetheless, patients

who present with moderate findings by all these approaches continue to represent a challenge. A new diagnostic strategy is urgently needed to further improve our ability to identify early signs of strangulated bowel, and this diagnostic modality should be able to indicate when surgical management is required. A number of potential serum markers have been proposed for this purpose, including intestinal fatty acid binding protein and  $\alpha$ -glutathione S transferase. On-going research is attempting to clearly define their diagnostic utility and to optimize their potential role in determining which patients should be managed surgically.

**Key words:** Adhesive small bowel obstruction; Diagnosis; Clinical management; Biological markers; Intestinal fatty acid binding protein;  $\alpha$ -glutathione S transferase

**Core tip:** Adhesive small bowel obstruction (ASBO) is a frequently encountered disorder of the small intestine following abdominal surgery. Accurately predicting whether ASBO patients can be treated conservatively is required to prevent exposing patients unnecessarily to surgery-related risks, including morbidity and further adhesion formation. Although recent technological developments have improved the ability to identify those patients most fit for conservative management, the remaining patients with moderate findings upon clinical presentation remain a problem. Serum markers of intestinal ischemia are promising candidates for improving early diagnosis and identification of patients with strangulated bowel, who will benefit most from surgical management.

van Oudheusden TR, Aerts BAC, de Hingh IHJT, Luyer MDP. Challenges in diagnosing adhesive small bowel obstruction. *World J Gastroenterol* 2013; 19(43): 7489-7493 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/>

## INTRODUCTION

Small bowel obstruction (SBO) leading to strangulation and potential bowel necrosis is a serious condition that mandates surgical intervention<sup>[1-3]</sup>. Timely diagnosis is essential to prevent the associated morbidity and mortality that manifest as operative management is delayed<sup>[4]</sup>. This fact was highlighted by the adage among surgeons citing “never let the sun rise or set in the case of small bowel obstruction”.

Since up to 80% of SBO cases resolve without incident under conservative treatment<sup>[5,6]</sup>, identification of patients whose obstruction will spontaneously resolve is important to prevent unnecessary surgical intervention and exposure to the risks of procedure-related morbidity and further formation of adhesions<sup>[6,7]</sup>. Recent technological advances in diagnostic modalities have improved the ability to identify patients who are most likely to benefit from conservative treatment; however, accurate and early identification of those patients who will ultimately require surgical intervention remains a challenge, especially when the clinical symptoms are moderate<sup>[2]</sup>.

## BACKGROUND

SBO is the most frequently encountered surgery-related disorder of the small intestine. In up to two-third of SBO cases, adhesions from prior abdominal surgery are implicated as the direct cause, having manifested as adhesive small bowel obstruction (ASBO)<sup>[2,6,8]</sup>. Although the majority of ASBO present within one year after surgery, up to 21% can develop up to ten years later<sup>[9]</sup>. In addition, other causes of SBOs exist, including neoplasia, herniations, inflammatory disease, or congenital disorders. Regardless of the cause, however, obstructed bowel eventually becomes edematous, which leads to bowel ischemia, inflammation, and necrosis in the end-stage and requires surgical resection.

### Clinical presentation

Patients with SBO usually present with a wide range of complaints, such as nausea, vomiting, and intermittent abdominal pain. In most cases, a history of prior abdominal surgery is present<sup>[6,10]</sup>. However, the clinical symptoms only contribute partially to diagnosis of ASBO, and studies have calculated the symptom-related sensitivity and specificity of acute abdominal pain as 75% and 99%<sup>[11]</sup>. One of the more recent studies, evaluating the current diagnostic technologies and clinical routines, found a higher overall sensitivity (88%) but a lower specificity (41%) for this parameter<sup>[12]</sup>; thus, improved diagnostic modalities are still needed. Unfortunately, the clinical symptoms of SBO are also not reliable predictors of the optimal disease management strategy, and distinguishing patients with bowel strangulation who

require prompt surgical intervention remains a particular challenge to clinicians.

### Laboratory findings

Laboratory tests are often used to confirm clinical suspicions and evaluate the degree of illness. The commonly measured inflammatory markers, such as white blood cell (WBC) count and C-reactive protein (CRP)<sup>[13]</sup>, however, cannot distinguish inflammation due to obstruction from other inflammatory syndromes and are therefore of little value in the early diagnosis of ASBO<sup>[14]</sup>. Even in the case of bowel ischemia, as would be seen in bowel strangulation, studies have detected no significant differences in the WBC or CRP levels of patients who benefit from conservative management and those who require surgical intervention, making these markers useless for distinguishing these two categories of patients<sup>[14-16]</sup>.

When progression to ischemia occurs, L-lactate, lactate dehydrogenase (LDH) and creatine kinase (CK) can rise due to hypoperfusion of the intestinal tissue<sup>[15]</sup>. However, large quantities of L-lactate are cleared by the liver during splanchnic hypoperfusion, resulting in L-lactate being increased at a very late stage of the process, when extensive intestinal infarction is already well established<sup>[17]</sup>. From a clinical perspective, a rise in L-lactate level increases sensitivity for detecting bowel ischemia up to 100% and is considered a strong indicator for emergency surgical intervention<sup>[18]</sup>. In contrast, LDH and CK levels rise in any ischemic condition, and are therefore unspecific. D-dimer, however, may serve as an exclusionary indicator for the presence of ischemia, due to its role as an enzymatic degradation product of fibrin, but it also lacks specificity since it can be elevated in numerous other conditions<sup>[14]</sup>.

Since the above-mentioned markers are not specific enough for diagnosis of SBO they are also not useful for determining whether surgical intervention is needed for any particular case. Instead, these markers can be used to simply reflect severity of the disease and may contribute “circumstantial evidence” to support or deny a decision based upon a wide array of clinical findings.

### Imaging techniques

The 2010 Bologna Guidelines for Diagnosis and Management of ASBO arose from an international consensus statement. According to these guidelines, all suspected cases of ASBO should be evaluated by abdominal X-ray (level 2b)<sup>[7]</sup>. Specifically, the presence or absence of classical signs, such as distension, > 3 cm diameter dilatation of the small bowel, perturbed air-fluid levels and absence of colonic gas, is considered a sufficient means of diagnosis, and studies have calculated this approach to have overall sensitivity and specificity ranging from 60%-85%<sup>[6,7]</sup>.

In contrast, Laméris *et al*<sup>[12]</sup> showed that evaluating patients presenting with acute abdominal pain with plain radiography provided no benefit towards improving the above-mentioned sensitivity and specificity, presuming

that there is no role in the diagnostic work-up. Adding ultrasonography (US) after clinical diagnosis, however, was shown to increase the specificity from 41% to 85%. In suspected SBO cases, US can differentiate between ileus and mechanical obstruction, since peristalsis can be observed by this imaging modality<sup>[19]</sup>. Extra-luminal fluid findings are of major clinical importance as they are commonly used to make clinical decisions as to which surgical approach will be most tolerable and beneficial to a particular patient<sup>[20]</sup>. In contrast to these findings, the Bologna Guidelines state that there is limited value for US (level 2c), since entrapment of air in ASBO limits ultrasound transmission, making it a useful diagnostic tool only when applied by technical experts<sup>[2,7]</sup>.

Using computed tomography (CT)-scan as an additional imaging platform to evaluate all patients with inconclusive plain radiologic films has proven highly useful for diagnosing SBO<sup>[2,7,21,22]</sup>. CT-scan has high sensitivity and specificity for SBO (> 92% and 93% respectively); in addition, the additional information provided by CT scanning can help to detect signs of intestinal ischemia or perforation<sup>[6,23-25]</sup>. However, Maglinte *et al*<sup>[26]</sup> reported that CT-scan can be just as sensitive as a plain abdominal x-ray for differentiating between obstruction and non-obstruction (86% *vs* 82% detection levels). It is important to note that the group with possible signs of ischemia remains a clinical challenge, and making a decision for clinical management is still a problem<sup>[10,23,27,28]</sup>.

Magnetic resonance imaging (MRI) seems to have a limited role in diagnosing ASBO. MRI provides similar sensitivity and specificity as CT-scan, but no current guidelines have been established or implemented for applying MRI in standard clinical practice<sup>[2,7,29]</sup>. Interestingly, when combining abdominal films with water-soluble contrast medium, the approach can both make a diagnosis and safely rule-out the presence of a complete obstruction. In this manner, patient evaluation by water-soluble contrast studies can help to predict whether their ASBO can be treated conservatively or will require surgical intervention<sup>[7,10,22,30]</sup>. Besides being a useful diagnostic tool, water-soluble contrast may also have therapeutic potential; its ability to draw fluid into the lumen reduces edema in the gut wall, thereby relieving the obstruction and stimulating peristalsis<sup>[31]</sup>. A randomized controlled trial by Burge *et al*<sup>[3]</sup> showed an appreciable therapeutic effect when gastrografin was applied as the contrast agent to evaluate ASBO patients; specifically, a significantly accelerated resolution of the obstruction was seen in up to 75% of the patients within 24 h after the application. This result may be attributed to the hyperosmolar quality of gastrografin or other contrast mediums. While the precise benefit of contrast mediums reducing the need for surgery have yet to be systematically proven<sup>[30,32,33]</sup>, their relation to reduced length of hospital stay has been demonstrated in several trials<sup>[5,28,31,32]</sup>. Certainly, however, those ASBO patients who show no contrast being able to enter the colon will require surgical treatment.

## NEW DEVELOPMENTS

The limitations of the above-mentioned diagnostic modalities are likely to cause a delay in diagnosis. In recent years, several serum markers with potential to detect ischemic small bowel have been identified<sup>[13,14]</sup>. These markers include factors that are released by damaged enterocytes, such as intestinal fatty acid binding protein (I-FABP) and  $\alpha$ -glutathione S transferase ( $\alpha$ -GST). Enterocytes are rapidly shed in the early phases of intestinal injury and can be readily detected in both urine and plasma, providing promising possibilities for their use as early detection markers<sup>[33]</sup>.

Plasma levels of the cytosolic protein  $\alpha$ -GST rise in conjunction with ischemic intestinal damage; yet, this protein provides variable results as a diagnostic tool, with reported sensitivity ranging from 20%-100% and pooled specificity of 85%<sup>[14,15,34]</sup>. Therefore,  $\alpha$ -GST may be more useful as an exclusion criterion, rather than as an indicator for surgical intervention. The other marker I-FABP, a cytosolic protein found in tissues involved in uptake and consumption of fatty acids, is released immediately by damaged small bowel, making it a very specific marker<sup>[35]</sup>. Patients presenting with SBO but without ischemia show normal levels of serum or urine I-FABP<sup>[36]</sup>. A recent clinical trial of patients with acute abdominal pain demonstrated that serum I-FABP levels were significantly higher in those patients with small bowel ischemia than in either those with non-ischemic small bowel disease or those without small bowel disease<sup>[16]</sup>. Furthermore, a majority (57.7%) of these ischemic patients had strangulated bowel. Thus, I-FABP may have a role in selecting candidates for surgical intervention. Other putative candidate markers are D-lactate and claudin<sup>[15,37,38]</sup>; however, the low specificity of D-lactate and lack of substantial evidence for a role of claudin 3 in SBO makes it difficult to clearly define their potential.

Besides these plasma markers, the prediction model developed by Komatsu *et al*<sup>[39]</sup> has identified older age, presence of ascites, and high-volume nasogastral tube drainage on day 3 as critical factors in patients who initially received conservative treatment. Unfortunately, this study did not include findings from radiographic imaging or oral water-soluble studies in the analysis. Although the prediction model is promising, it is necessary to consider the potential impact of markers specifically released by the obstructed small bowel in an earlier stage.

## CONCLUSION

Despite the remarkable technological advances in diagnosis of ASBO, the challenge of determining how to most effectively and safely manage these cases remains. Our ability to identify patients who can be treated conservatively has improved greatly, but the same has not been achieved for patients who will require emergency surgery, especially when their presenting symptoms are moderate. Serum markers have emerged as promising

candidates for early diagnosis of strangulated bowel, but further research is necessary to clarify their clinical value in the disease management.

### Abstract

High-intensity focused ultrasound (HIFU) is a non-invasive modality that uses an extracorporeal source of focused ultrasound energy. This technique was introduced by Lynn *et al* and is able to induce coagulative necrosis in selected tissues without damaging adjacent structures. Although HIFU has been studied for 50 years, recent technological developments now allow its use for tumours of the liver, prostate and other sites. In liver disease, HIFU has been used to treat unresectable, advanced stages of hepatocellular carcinoma (HCC) and liver metastases. Hepatocellular carcinoma is a serious health problem worldwide and is endemic in some areas because of its association with hepatitis B and C viruses (in 20% of cases). Liver transplantation (LT) has become one of the best treatments available because it removes both the tumour and the underlying liver disease such as cirrhosis (which is present in approximately 80% of cases). The prerequisite for long-term transplant success depends on tumour load and strict selection criteria regarding the size and number of tumour nodules. The need to obtain the optimal benefit from the limited number of organs available has prompted strict selection criteria limited to only those patients with early HCC who have a better long-term outcome after LT. The so-called "bridging therapy" has the aim of controlling disease burden for patients who

are on the organ transplant waiting list. Amongst various treatment options, transarterial chemoembolisation and radiofrequency ablation are the most popular treatment choices. Recently, Cheung *et al* demonstrated that HIFU ablation is a safe and effective method for the treatment of HCC patients with advanced cirrhosis as a bridging therapy and that it reduced the dropout rate from the liver transplant waiting list. In this commentary, we discuss the current value of HIFU in the treatment of liver disease, including its value as a bridging therapy, and examine the potential advantages of other therapeutic strategies.

**Key words:** High-intensity focused ultrasound; Hepatocellular carcinoma; Liver transplantation; Bridging therapy; Waiting list

**Core tip:** High-intensity focused ultrasound (HIFU) is a non-invasive modality used to destroy tissue. It has been used to treat unresectable advanced stages of hepatocellular carcinoma (HCC) and liver metastases. In some HCC cases, liver transplantation has become one of the best treatments because it removes the tumour and the underlying liver disease such as cirrhosis. The so-called "bridging therapy" has the aim of controlling disease burden for patients who are on the organ transplant waiting list. Here, we discuss various treatment options including transarterial chemoembolisation and radiofrequency ablation, and we examine the utility of HIFU as a safe and effective method of bridging therapy that can reduce the dropout rate of patients who are on the liver transplant waiting list.

Mearini L. High intensity focused ultrasound, liver disease and bridging therapy. *World J Gastroenterol* 2013; 19(43): 7494-7499  
Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7494.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7494>

## COMMENTARY ON HOT TOPICS

I have read with great interest the recent article by Cheung *et al*<sup>[1]</sup> reporting their experience in the use of high-intensity focused ultrasound (HIFU) in patients with hepatocellular carcinoma (HCC) and cirrhosis who are waiting for liver transplant. The study aim was to determine whether HIFU could reduce the patient dropout rate.

HIFU is a non-invasive modality that uses an extracorporeal source of focused ultrasound energy. The technique was introduced by Lynn *et al*<sup>[2]</sup>, and it is able to induce coagulative necrosis in targeted tissues without damaging overlying and surrounding vital structures.

Although HIFU has been studied for 50 years, recent technological developments have allowed its use in treating tumours of the liver<sup>[3]</sup>, prostate<sup>[4]</sup> and other sites<sup>[5]</sup>.

HIFU is a highly precise medical procedure that applies high-intensity focused energy to “heat” and “destroy” diseased tissues. Its precision is under investigation for a possible application as “focal” therapy in case of prostate cancer, where whole gland therapy has a negative impact in terms of incontinence and impotence<sup>[6]</sup>.

HIFU is a hyperthermia therapy, which is a class of clinical therapies [including radiofrequency ablation (RFA)] that use high temperature to treat diseases.

HIFU is also a modality of therapeutic ultrasound, involving minimally invasive or non-invasive methods to direct acoustic energy into the body. In addition to HIFU, other modalities include ultrasound-assisted drug delivery, ultrasound haemostasis, ultrasound lithotripsy and ultrasound-assisted thrombolysis.

A clinical HIFU procedure is typically performed in conjunction with an imaging procedure to enable treatment planning and targeting before applying any therapeutic or ablative levels of ultrasound energy. When diagnostic sonography is used, the technique is termed ultrasound-guided focused ultrasound (USgHIFU or USgFUS). Magnetic resonance imaging is also used for guidance; thus, the technique is sometimes called magnetic resonance-guided focused ultrasound, which is often shortened to MRgHIFU or MRgFUS.

Currently, USgHIFU is approved for use in Bulgaria, China, Hong Kong, Italy, Japan, Korea, Malaysia, Mexico, Russia, Romania, Spain and the United Kingdom. MRgHIFU is an approved therapeutic procedure to treat uterine fibroids in Asia, Australia, Canada, Europe, Israel and the United States (Food and Drug Administration, FDA approved). Research on other indications is actively underway, including clinical trials evaluating the effectiveness of HIFU for the treatment of cancers of the brain, breast, liver, bone, and prostate.

From a technical point of view, the ultrasound waves of high-intensity focused ultrasound are generated by high frequency (0.5 to 10 MHz) vibration of a piezoelectric or piezo-ceramic transducer. The ultrasound beams are then focused by spherical arrangement using an acoustic lens or parabolic reflectors into a small, discrete region that corresponds to the focal point. For clinical applications, and similar to ultrasound imaging,

an ultrasound probe is usually coupled by degassed water between the source and patient surface (skin, rectal wall). Because of the comparable acoustic properties of water and tissue, the sound waves should penetrate the surface and the pre-target tissue with only slight absorption, reflection and heating. This phenomenon occurs because the power density of the converging ultrasound increases as it approaches the focal point. The focal region is a 3-dimensional zone, whose area depends on the frequency and the geometry of the source. Generally, the focal area is approximately 10 to 50 mm in length and 1 to 5 mm in diameter.

Based on target volume, the tissue can be ablated by sequentially shifting the focal zone with incremental movements of the transducer. This approach is combined with adjustments of the focal length and is coupled with an immobile organ or with the complex real-time tracking of a moving target (such as liver). The extent of tissue ablation is approximately that of the physical focal zone, although in practice cold spots (cause by blood perfusion in the tissue), beam distortion and beam misregistration are impediments to finely controlled treatments. However, by scanning the target using multiple pulses and multiple focal points, large tissue areas can be ablated.

The effect of acoustic cavitation induced by the ultrasound beam is complex, and acoustic impedance is sometimes unpredictable. However, the result is cell necrosis induced through a combination of mechanical stress and thermal injury.

The mechanical effect is induced by cavitation, a process in which bubbles develop and increase in size to the point at which resonance is achieved. The bubble formation is a consequence of the negative pressure of the ultrasound wave. As the bubbles expand and collapse, high pressures ranging from 20000 to 30000 bars develop and damage nearby cells. The popcorn effect is the typical example of cavitation.

The thermal effect is directly induced by the ultrasound beams, and due to the significant energy deposition at the focus the temperature within the tissue can rise from 65 to 85 °C. The temperature increase destroys tissue by coagulative necrosis. Higher temperatures are typically avoided to prevent boiling of liquids inside the tissue.

Because ultrasound destroys the diseased tissue non-invasively, it is also known as a non-invasive surgery. In liver disease, HIFU has been used for the treatment of unresectable, advanced stages of hepatocellular carcinoma or for the treatment of liver metastases.

Previous studies have shown that HIFU is safe and effective for patients with hepatocellular carcinoma<sup>[7]</sup> and can improve the quality of life of patients with HCC. In a study involving 145 patients with HCC, symptoms improved or pain was relieved in 84.8% of the 145 patients. Additionally, the size of the target tumour shrank by various degrees. The 2-year survival rate was 80% in patients with stage I b HCC, 51.4% in stage II a, and 46.5% in stage III a.

Ng *et al*<sup>[8]</sup> involving 49 patients receiving HIFU for unresectable HCC showed that the technique was effective in 79.5% of cases. The study found that only tumour size ( $\geq 3.0$  cm) was a significant risk factor affecting the complete ablation rate. The 1- and 3-year overall survival rates were 87.7% and 62.4%, respectively. Moreover, HIFU is safe for the treatment of disease adjacent to or surrounding a major liver vessel. The study by Zhang *et al*<sup>[9]</sup> enrolled 39 patients with HCC. All of the treated tumours had a distance between the tumour and main blood vessel (inferior vena cava, main hepatic vein branches, portal vein) of less than 1 cm, and no major blood vessel injury was observed in any subject.

HIFU has been used in combination with transarterial chemoembolisation (TACE) in prior studies. Jin *et al*<sup>[10]</sup> reported their experience of HIFU and transarterial chemoembolisation in 73 patients with unresectable HCC. That study demonstrated that 45.2% patients achieved complete tumour ablation. By multivariate analysis, ablation response ( $P = 0.001$ ) and tumour size ( $P = 0.013$ ) were major prognostic factors in predicting response to therapy. In an interesting randomised trial comparing TACE alone *vs* TACE + HIFU, Li *et al*<sup>[11]</sup> showed that the total effective rate for tumour response was 72.8% in the TACE + HIFU group. This response was significantly higher than in the TACE group alone (44.5%,  $P < 0.05$ ). The corresponding 1-, 2-, 3- and 5-year overall survival rates for the TACE-HIFU group were 72.7%, 50.0%, 31.8% and 11.4%, respectively. These rates were higher than in the TACE alone group (47.2%, 16.7%, 2.8% and 0%, respectively,  $P < 0.01$ ).

HIFU ablation is well tolerated in HCC patients with cirrhosis. According to Cheung *et al*<sup>[12]</sup>, 13% of 100 patients developed 18 complications. Morbidity was mainly caused by skin and subcutaneous tissue injuries in nine cases. Based on the Clavien classification of surgical complications, only four complications were grade 3a, while the other 14 were below this grade. By univariate analysis, only age was found to be an independent factor for poor HIFU tolerance.

HCC is a serious health problem worldwide because of its association with hepatitis B and C viruses. Liver transplantation has become one of the best HCC treatments available because it removes both the tumour and the underlying liver disease.

A prerequisite for the long-term success of a transplantation program depends on tumour load and selection criteria regarding size and number of tumour nodules. The need to obtain the optimal benefit from the limited number of available organs has prompted the use of careful selection criteria to list only those patients with early HCC who have a prediction of superior long-term outcome after LT.

Patients who fulfil the so-called Milan criteria (single tumour  $\leq 5$  cm; two or three tumours, none  $> 3$  cm; no vascular invasion) or the expanded University of California San Francisco criteria (UCSF criteria: single tumour  $\leq 4.5$  cm; two or three tumours, none  $> 4.5$  cm; or total

tumour diameter  $\leq 8$  cm; no vascular invasion) may have a 3-year survival of up to 88%. However, the expansion of these criteria for transplantation is still a topic of discussion.

Other problems arise from the differential between the number of patients on the liver transplant waiting list and the number of available donors. Additionally, there is a time lag between patient inclusion on a waiting list and the available organ. For example, in the United States, more than 2000 candidates die each year while awaiting transplantation.

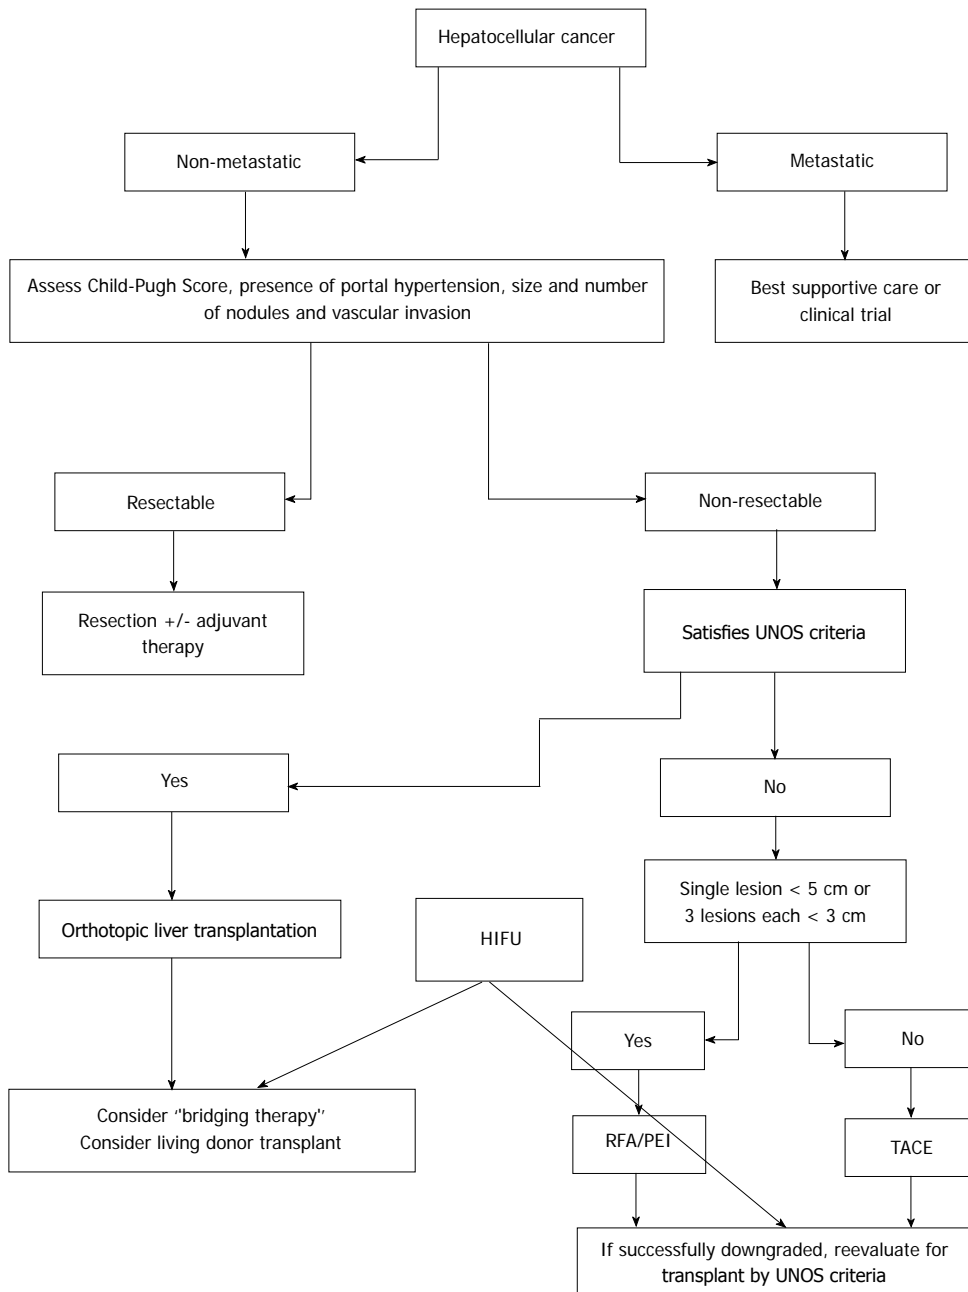

Some therapies for HCC, called “bridge therapy”, have the capacity to “fix” or suspend tumour progression and to allow HCC patients to maintain active candidacy as long as necessary to obtain a liver. Several techniques are employed as bridge therapies for HCC patients awaiting liver transplantation. Treatment options such as TACE and radio frequency ablation (RFA) are the most popular treatment choices as pre-transplant locoregional therapy.

Moreover, other goals of locoregional therapy, *e.g.*, alcohol injection, radiofrequency ablation, transarterial chemoembolisation, transarterial radioembolization, and liver resection, are intended to decrease tumour size and number in patients who initially present with tumours that do not meet locally acceptable criteria for liver transplantation.

The TACE principle is intra-arterial injection of cytotoxic drug combinations (doxorubicin and/or cisplatin and/or mitomycin into the hepatic artery), followed by lipiodol injection, gelfoam for vessel occlusion and degradable microspheres. An aggressive ablation therapy in association with a short transplant waiting time has the potential to optimise the curative intent of liver transplantation in selected cirrhotic patients. Based on the local extension of the disease and the hepatic functional reserve, TACE may be performed as a “complete”, selective or superselective procedure through a microcatheter. Contraindications for TACE include Child-Pugh C liver cirrhosis, presence of multifocal bilobar tumour spread, presence of extrahepatic metastases, portal vein thrombosis or arterio-portal fistula.

TACE has shown excellent outcomes as a bridging therapy. However, only patients with preserved liver function and asymptomatic multinodular tumours without vascular invasion or extrahepatic spread are eligible for TACE because it avoids hepatic failure and severe adverse events<sup>[13]</sup>. TACE has been used as a selective/superselective procedure and has shown excellent results that are superior to a simple lobar approach<sup>[14]</sup>. As a bridging (or down-staging) therapy, selective/superselective TACE induces a histological necrosis in 91.8% of cases and was maximal for tumours  $> 3$  cm.

RFA represents a widely applied method to treat HCC in a palliative intent, or as a “bridging” to liver transplantation. RFA may be performed under ultrasonography, Computed tomography guidance, or during laparoscopic and open surgical procedures. This procedure has more limitations than TACE, including the number of nodules

**Figure 1** Approach to the management of newly diagnosed hepatocellular cancer. Source from Parikh *et al*<sup>[19]</sup>. "Bridging therapy": Surgical resection, radiofrequency ablation (RFA), transcatheter arterial chemoembolization (TACE). High-intensity focused ultrasound (HIFU) as proposal. PEI: Percutaneous ethanol injection; UNOS: United network for organ sharing.

that may be treated (up to three in most cases) or the maximal tumour diameter of the nodules (up to 5 cm). Effective treatment has been achieved<sup>[15]</sup> when 100% tumour necrosis is present. However, it is difficult to reach this goal with tumours exceeding the above-mentioned diameter or number of tumour nodules. Mazzaferro *et al*<sup>[16]</sup> showed that although the complete response rate was high (55%), tumour size (> 3 cm) and time from treatment (> 1 year) predict a high risk of tumour persistence in the targeted nodule.

As a bridging therapy, RFA showed some limitations. Schroeder *et al*<sup>[17]</sup> demonstrated that although the majority of treated patients (62%) had a solitary tumour at the be-

ginning of treatment, tumour progression was observed in a large proportion (38%) of patients. These results limit the role of RFA as a bridging treatment prior to LT.

Yttrium-90 (Y90) microsphere radio-embolisation is a recently FDA-approved, non-surgical procedure used to treat inoperable HCC. This innovative procedure delivers targeted, internal radiation therapy directly to the tumour<sup>[18]</sup>. Some promising results have been reported for this technique either as a "bridging" option before other treatment modalities (partial hepatectomy, liver transplantation) or as a main therapy for patients with diffuse intrahepatic tumour spread. Treatment with Y90 microspheres has the advantage of being able to treat all intrahepatic

HCC lesions, including otherwise undetected tumours. This treatment may also be the alternative to TACE in selected patients with contraindications for TACE.

In conclusion, with increases in waiting times for liver transplantation, it has become common practice to monitor patients to ensure that they remain within the acceptable criteria for liver transplantation. Moreover, the dropout of patients on the waiting list is common because of cancer progression or other medical reasons. Locoregional therapy as a bridging strategy for patients on the waiting list aims to decrease tumour-related dropout rates and to reduce the incidence of recurrent diseases after liver transplantation. Current available techniques show a dropout rate up to 35% for transarterial embolisation and up to 15% for radiofrequency ablation.

Cheung *et al*<sup>[12]</sup> must be congratulated for testing the utility of high-intensity focused ultrasound in this particular setting. The study examined 49 consecutive HCC patients listed for liver transplant by UCSF criteria. Twenty-nine patients received TACE as a bridging therapy, 16 patients received no treatment before liver transplantation, and five patients received HIFU as bridging therapy. The control group of five patients received HIFU but were not on the transplant list. TACE was performed using cisplatin as the chemotherapeutic agent, and it was delivered with Lipiodol, followed by gelfoam particle embolisation. Selective cannulation and embolisation of the feeding arteries of the tumours were performed whenever possible. All of the HIFU treatments were conducted by an experienced hepatobiliary surgeon and radiologist using the JC HIFU system (Chongqing Haifu Technology, Chongqing, China). The system is composed of a real-time diagnostic imaging unit, a therapeutic unit, a degassed water circulation unit, and a computer system. The real-time diagnostic imaging unit provides direct visualisation of the tumour. The therapeutic unit consists of an ultrasound energy transducer that focuses the ultrasound energy at a 12-cm focal point. The degassed water circulation unit provides a medium for ultrasound transmission outside the body. The computer system controls these three units.

Cheung demonstrated that 90% of patients receiving HIFU had complete tumour response, while 10% had partial response. There was no complete or partial tumour response in the TACE group. Fourteen (46%) patients had progressive disease, and 14 (46%) patients had stable disease. The overall dropout rate was 24.1%.

HIFU was shown to be a safe treatment, and none of the patients receiving HIFU as a bridging therapy developed complications due to intolerance after the procedure. The complication rate was 8.2%, and the complications involved mild skin oedema and injury due to energy accumulation at the ultrasound beam pathway.

HIFU ablation is an entirely extracorporeal non-invasive ablative treatment method using focused ultrasound energy. It is capable of causing coagulative necrosis of the targeted HCC *via* intact skin, without the need for surgical incision.

HIFU has been well demonstrated to be an effective ablation modality that is non-invasive. It can effectively reduce the dropout rate from the liver transplant waiting list by providing effective tumour control. The histological proof from the liver explants provides evidence that the necrosis is effective in an *in vivo* model.

Despite the low number of enrolled subjects, the preliminary study by Cheung *et al*<sup>[1]</sup> is interesting and suggests the need for more extensive clinical trials that focus on the use of HIFU as a bridging therapy (Figure 1).

**Key words:** Hepatocellular carcinoma; Innate immunity; Toll-like receptor; Liver cancer; Inflammation

**Core tip:** Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related deaths worldwide. Growing incidence of HCC has generated immense interest to understand the mechanisms of disease at the physiological, cellular and molecular levels with the hope of developing novel therapeutics for the treatment of HCC. In the past few years, it has become clear that innate immunity plays a critical role in the development and progression of HCC. In this review, these new developments and possibilities of developing novel therapeutic options based on this newly gained knowledge are discussed.

## Abstract

Hepatocellular carcinoma (HCC) is the most common form of liver cancer worldwide. It is caused by a variety of risk factors, most common ones being infection with hepatitis viruses, alcohol, and obesity. HCC often develops in the background of underlying cirrhosis, and even though a number of interventional treatment methods are currently in use, recurrence is fairly common among patients who have had a resection. Therefore, whole liver transplantation remains the most practical treatment option for HCC. Due to the growing incidence of HCC, intense research efforts are being made to understand cellular and molecular mechanisms of the disease so that novel therapeutic strategies can be developed to combat liver cancer. In recent years, it has become clear that innate immunity plays a critical role in the development of a number of liver diseases, including HCC. In particular, the activation of Toll-like receptor signaling results in the generation of immune responses that often results in the production of pro-inflammatory cytokines and chemokines, and could cause acute inflammation in the liver. In this review, the current knowledge on the role of innate immune responses in the development and progression of HCC is examined, and emerging therapeutic strategies based on molecular mechanisms of HCC are discussed.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common form of liver cancer, and is the third leading cause of cancer-related deaths worldwide. It accounts for approximately 70%-80% of all primary liver cancer cases<sup>[1]</sup>. A variety of risk factors such as hepatitis viruses, vinyl chloride, tobacco, foodstuffs contaminated with aflatoxin B1 toxin, heavy alcohol intake, nonalcoholic fatty liver disease (NAFLD), diabetes, obesity, oral contraceptives, and hemochromatosis cause HCC<sup>[2]</sup>. Recurrence is quite common in patients who have had a resection, and survival rate is 30%-40% at

five years post-surgery<sup>[2]</sup>. As a recent surveillance, epidemiology, and end results study using the Medicare dataset of elderly patients in the United States has shown, in addition to the human loss, there is a substantial burden of health care expense of illness associated with HCC<sup>[3]</sup>. To underscore this point, the Centers for Disease Control has recently recommended one-time health screening for the entire generation born between 1945 and 1965. The dramatic rise in the incidence of HCC in Western countries in recent years has generated intense efforts to understand the mechanisms of disease at the physiological, cellular and molecular levels with the hope of developing novel therapeutics for the treatment of HCC.

## **PATHOPHYSIOLOGY OF HCC**

The normal liver lobule is formed by hepatocytes, cholangiocytes and various non-parenchymal cells [Kupffer cells (KCs), liver sinusoidal endothelial cells (LSECs), and hepatic stellate cells (HSCs)]. Intrahepatic lymphocytes and liver-specific natural killer (NK) cells are also present in the sinusoidal lumen and perisinusoidal space of Disse<sup>[4]</sup>. Exposure to toxic substances and induction of immune responses in the liver can result in inflammation through the activation of KCs and HSCs, and can cause necrosis. In this process, liver fibrosis and cirrhosis may also occur. Even though the molecular basis for cancer-promoting effect of cirrhosis is unknown, the process of recurrent liver cell necrosis and regeneration with increased cell turn-over renders liver cells more sensitive to the adverse effects of other mutagenic agents<sup>[4]</sup>. Cirrhosis is responsible for significant morbidity and mortality, and is one of the most important risk factors for the development of HCC.

Carcinogenesis is a process that involves the transition of a normal cell into a preneoplastic lesion that develops into malignant tumor<sup>[4]</sup>. Growing evidence suggests that gradual accumulation of mutations and genetic changes in preneoplastic hepatocytes causes malignant transformation that leads to the development of HCC<sup>[5,6]</sup>. Tissue environment also plays a critical role in tumor formation<sup>[7]</sup>. Interaction of different cell types in the tumor stroma with components of the extracellular matrix (ECM), either directly or indirectly result in the acquisition of an abnormal phenotype that causes this transformation. Tumor stroma consists of fibroblasts [also referred to as “cancer-associated fibroblasts (CAFs)”], macrophages (liver resident KCs and other tumor-infiltrating cells), leukocytes, HSCs, endothelial cells, pericytes, neutrophils, and dendritic cells (DCs)<sup>[8]</sup>. Each of these cells produces growth factors, cytokines, chemokines, free radicals, and other tumorigenic substrates that contribute to tumor initiation and progression<sup>[9]</sup>.

In HCC, CAFs are involved in tumor initiation and progression. They produce epidermal growth factor (EGF), hepatocyte growth factor, fibroblast growth factor, interleukin 6 (IL-6), chemokine (C-X-C motif) ligand 12 (CXCL12), and matrix metalloproteases (MMP-3 and

MMP-9)<sup>[10]</sup>. They also produce IL-8, cyclooxygenase 2, and secrete protein acidic rich in cysteine to recruit and stimulate macrophage production, which can further increase the activation of CAFs through the secretion of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and platelet-derived growth factor (PDGF)<sup>[11,12]</sup>. Tumor-associated macrophages (TAMs) are “polarized” into M2 mononuclear phagocyte-like cells by various cytokines [IL-4, IL-10, and transforming growth factor  $\beta$  (TGF- $\beta$ )] present in the tumor microenvironment<sup>[13]</sup>. These M2-like TAMs, in turn, express cytokines (IL-10 and TGF- $\beta$ ), chemokines (CCL17, CCL22 and CCL24), vascular endothelial growth factor (VEGF), and EGF to recruit regulatory T cells (Tregs) and to promote angiogenesis<sup>[14,15]</sup>. KCs are able to impair cluster of differentiation 8<sup>+</sup> (CD8<sup>+</sup>) cytotoxic T lymphocyte (CTL)-mediated immune responses through programmed death ligand 1<sup>[16]</sup>. Moreover, when stimulated with pro-inflammatory cytokines (IL-1 $\beta$ , TNF- $\alpha$  and PDGF), KCs and HSCs produce osteopontin that plays a pivotal role in various cell signaling pathways, which promote inflammation, tumor progression and metastasis<sup>[17,18]</sup>. DCs process antigens and present them to infiltrating CTLs by expressing them on their cell surface. These antigen presenting cells (APCs) possess high endocytic activity, and therefore, are critical for the induction of immune surveillance in tumors, and for immune evasion<sup>[19]</sup>. Such tumor-antigen specific CD8<sup>+</sup> T cell responses were recently shown to suppress the recurrence of HCC<sup>[20]</sup>.

In response to liver injury, HSCs transdifferentiate into myofibroblast-like cells and produce cytokines, chemokines, growth factors, and ECM<sup>[17]</sup>. This phenotypic transformation of HSCs is a key event in the development of hepatic fibrosis<sup>[21]</sup>. Hepatitis B virus (HBV)-encoded X protein, hepatitis C virus (HCV)-encoded non-structural proteins, MMP-9, PDGF, TGF- $\beta$ , Janus kinase (JNK), insulin-like growth factor binding protein 5, and cathepsins (B and D) are potent inducers of HSC activation and proliferation that enhance liver fibrosis and carcinogenesis<sup>[17]</sup>. Endothelial cells express a variety of angiogenic receptors including VEGFR, EGFR, EGF homology domains-2 (Tie-2), PDGFR, and C-X-C chemokine receptors. Tumor-associated endothelial cells express high levels of TGF- $\beta$  in HCC, which act as a chemoattractant for cluster of differentiation 105 (CD105, also known as endoglin), a type I cellular glycoprotein that is a part of the TGF- $\beta$  receptor complex, to promote tumor angiogenesis<sup>[22]</sup>. It has been shown that CD105<sup>+</sup> endothelial cells express increased angiogenesis activity with greater resistance to chemo-therapeutic agents and inhibitors of angiogenesis<sup>[23]</sup>.

Infiltration of T cells into the tumor microenvironment is an important regulator of cancer progression. In HCC tissues, CD4<sup>+</sup>/CD25<sup>+</sup> Tregs impair proliferation and activation of CTLs, degranulation, and production of granzymes (A and B), and perforin<sup>[24]</sup>. In a recent study, the infiltration of these Tregs into the tumors of HCC patients was found to correlate with an increase in

tumor size<sup>[25]</sup>. Other studies have shown that low CD8<sup>+</sup> T cell counts and high Treg numbers correlate with poor prognosis in HCC patients, especially after resection<sup>[26-28]</sup>. More recently, a 14-immune gene signature that drives the infiltration of lymphocytes into tumor has been identified<sup>[29]</sup>. This signature, which includes pro-inflammatory cytokines [TNF- $\alpha$  and interferon (IFN)- $\gamma$ ] and chemokines (CXCL10, CCL5 and CCL2), is a good predictor of patient survival at early tumor stages. In addition, dysfunctional regulation of immune response by excessive neutrophil activity was also reported as a poor prognostic indicator after resection of HCC<sup>[30]</sup>.

## INNATE IMMUNITY

To successfully detect and eliminate invading pathogens by discriminating self from non-self, the mammalian immune system has developed mechanisms that can be divided into two distinct components: the innate immunity and the adaptive immunity. In most multicellular organisms, the highly conserved innate immune system provides the first line of defense to limit infection by detecting pathogens using germline-encoded proteins<sup>[31]</sup>. The adaptive immunity, present only in vertebrates, detects non-self through the recognition of peptide antigens by receptors expressed on the surface of B and T cells<sup>[32]</sup>. The adaptive responses are much more diverse than the innate responses as each B and T lymphocyte clone expresses a distinct antigen receptor that arose by somatic gene rearrangement through a process of evolution<sup>[33]</sup>. Most often innate immune responses emanate from the host cell surface receptor with the recognition of conserved structural motifs termed pathogen-associated molecular patterns (PAMPs) on the surface of microorganisms. Toll-like receptors (TLRs), Nucleotide-binding and oligomerization domain-like receptors (NLRs) and RIG-I-like receptors (RLRs) are the key receptors that recognize a variety of PAMPs<sup>[34]</sup>. While TLRs can recognize bacteria, viruses, fungi and protozoa, NLRs and RLRs detect bacteria and viruses, respectively. All these pattern recognition receptors (PRRs) generate innate immune responses, either by acting alone or in combination with other receptors. The focus of the review is on the role of TLRs as most of the current knowledge on the role of innate immunity in liver diseases has been obtained from studies on the TLRs.

## TLR SIGNALING IN MAMMALIAN CELLS

*Toll* was first identified as a gene important in the establishment of dorsal-ventral orientation during embryonic development in the fruit fly *Drosophila melanogaster*<sup>[35]</sup>. Later, it was found that the Toll protein plays a critical role in the fly's immunity to fungal infections<sup>[35,36]</sup>. The first mammalian homolog of Toll, Toll-like receptor 4 (TLR4), was identified as a PRR required for adaptive immunity<sup>[37]</sup>. Subsequently, TLR4 and other TLRs were shown to play critical roles in generating innate immune

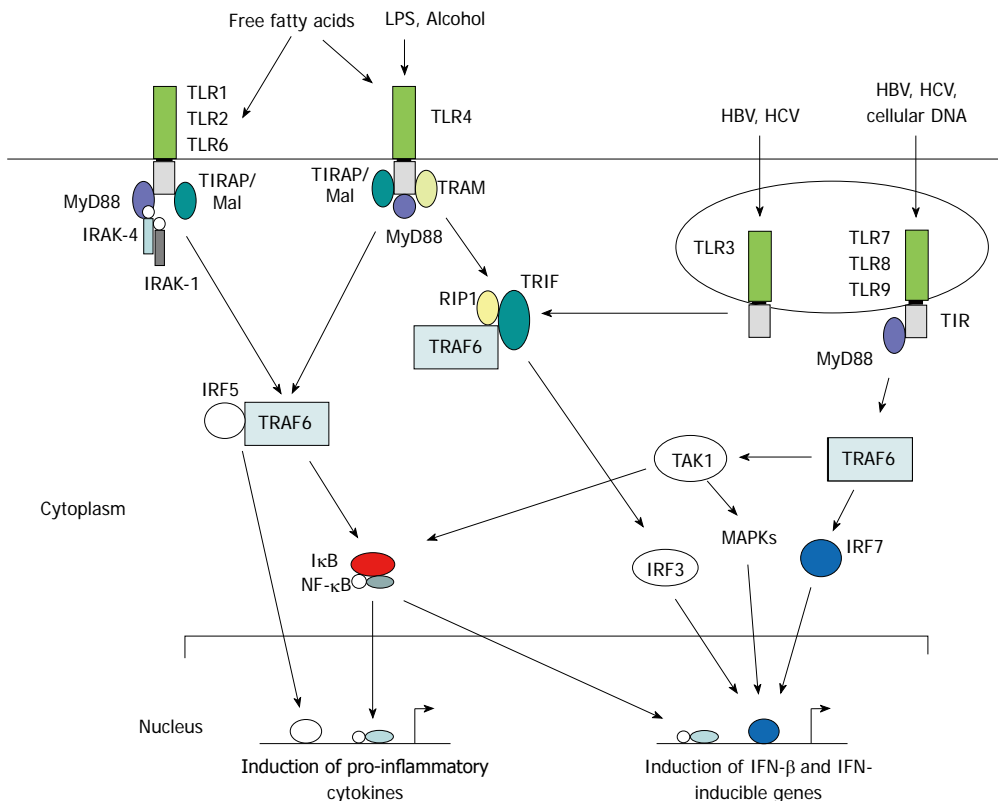

responses against microbial pathogens in mammalian systems. To date, 11 human TLRs and 13 mouse TLRs have been identified, in addition to a number of TLRs in other vertebrates, that recognize a variety of PAMPs and trigger both innate and adaptive immune responses<sup>[32,38]</sup>. TLRs are membrane-bound proteins that contain varying numbers of extracellular leucine-rich repeats and a Toll-IL receptor (TIR) domain in the cytoplasmic region that are highly conserved (Figure 1). They recognize ligands through LRRs and transmit signals through their TIR domain *via* protein-protein interactions with cellular adaptor proteins triggering a cascade of signaling events such as phosphorylation of interleukin-1 receptor-associated kinase 1 (IRAK-1) and activation of Nuclear factor kappa B (NF- $\kappa$ B) or interferon regulatory factor 3 (IRF3), resulting in the production of immune mediators and IFN-inducible genes<sup>[39]</sup>. Thus, a direct or indirect association of a ligand with its cognate TLR serves as a signal to trigger an innate immune response. Each step along the TLR signaling pathways is tightly regulated by a complex mix of phosphorylation and targeted degradation, and sequestering of various signaling molecules is dependent upon the nature of the invading pathogen<sup>[40]</sup>.

In general, vertebrate TLRs were classified into six distinct families based upon amino acid sequence homologies of LRRs<sup>[41]</sup>. Most mammalian cells express low levels of TLRs constitutively in a cell-type specific manner, and interestingly, they can be present in both membrane-bound and soluble forms. For example, the rainbow trout TLR5 is expressed constitutively as a membrane protein but upon induction with the bacterial flagellin, a soluble TLR5 is rapidly induced<sup>[42]</sup>. Normally, TLRs function as homodimers. However, some TLRs form heterodimers with other TLRs to recognize PAMPs. For instance, TLR2 associates either with TLR1 or TLR6 as a heterodimer to recognize triacylated lipoproteins and diacylated lipoproteins, respectively<sup>[32,38,40]</sup>. In addition, cellular membrane protein CD14 enhances the ligand recognition ability of TLR2<sup>[43]</sup>.

## TLR EXPRESSION IN THE LIVER

In the healthy liver, TLR expression is detectable only at very low levels<sup>[44]</sup>. Eight TLRs are expressed in the mammalian liver with varying levels of expression on hepatocytes, KCs, HSCs and LSECs<sup>[45]</sup>. These TLRs not only recognize microbial PAMPs but also the damage-associated molecular patterns (DAMPs) of dying host cells<sup>[46]</sup>. Even though hepatocytes express all TLRs, they are capable of responding to TLR2 and TLR4 ligands only, and these responses are very weak *in vivo*<sup>[47]</sup>. Under inflammatory conditions, however, hepatocyte response to TLR2 ligands was significantly enhanced but the response to TLR4 ligands was still not detectable in these cells<sup>[48]</sup>. LSECs express mRNAs of TLRs 1-9, and respond to various TLR ligands by expressing TNF- $\alpha$ , IL-6, and IFN- $\beta$ <sup>[49,50]</sup>. KCs express all TLRs and respond to a variety of ligands by producing TNF- $\alpha$

**Figure 1** Toll-like receptor signaling in liver cells. Activation of a given TLR pathway is dependent on the nature of the stimulus. LPS: Lipopolysaccharide; TLR: Toll-like receptor; HBV: Hepatitis B virus; HCV: Hepatitis C virus; MyD88: Myeloid differentiation factor 88; IRAK: Interleukin-1 receptor-associated kinase; TIRAP: Toll-interleukin-1 receptor domain containing adaptor protein; TIR: Toll-interleukin-1 receptor; TRAM: TIR-domain-containing adaptor molecule; IRF: Interferon regulatory factor; TRAF: Tumor necrosis factor receptor-associated factor; TAM: Tumor-associated macrophage; TAK: Transforming growth factor  $\beta$ -activated protein kinase; NF- $\kappa$ B: Nuclear factor kappa B; MAPK: Mitogen-activated protein kinase; TRIF: TIR-domain-containing adapter-inducing interferon- $\beta$ ; RIP: Receptor-interacting protein; I $\kappa$ B: Inhibitor of NF- $\kappa$ B; IFN: Interferon.

and IL-6<sup>[51,52]</sup>. When stimulated with ligands for TLRs 1, 2, 4 and 6, they produce IFN- $\gamma$  and promote the proliferation of T cells<sup>[49]</sup>. In response to TLR3 and TLR4 ligands, they produce IFN- $\beta$ , and for ligands against TLR1 and TLR8, they display a high level of major histocompatibility II expression. HSCs express low levels of TLR4 and TLR9, but activation of TLR4 has been shown to induce the expression of TLR2 as well<sup>[49]</sup>. In human HSCs, TLR4 activation results in the production of CCL2, CCL3 and CCL4<sup>[53]</sup>, and their expression of TGF- $\beta$  was implicated in the promotion of hepatic fibrosis<sup>[54]</sup>. Activation of TLR9 by DAMPs induces the differentiation of HSCs and increases the production of collagen<sup>[55]</sup>.

Among the non-parenchymal cells, hepatic DCs can be classified into different subsets as plasmacytoid DCs, myeloid DCs, lymphoid DCs, natural killer DCs, and a mixture of lymphoid and myeloid DCs<sup>[56]</sup>. Differential expression of TLRs in these hepatic DCs varies according to the subset type and the species type. For example, in humans, pDCs express TLRs 1, 3 and 7 only, whereas other DC subsets express all TLRs except TLR9<sup>[57]</sup>. On the other hand, murine pDCs express TLRs 2, 4, 7 and 9 but not TLR3<sup>[58]</sup>.

Hepatic lymphocyte population, which accounts for about 25% of non-parenchymal cells consists of B

cells, NK cells, NKT cells,  $\alpha\beta$ T cells and  $\gamma\delta$ T cells<sup>[59]</sup>. In general, T cells are activated indirectly by TLRs through APCs<sup>[60]</sup>, and NK cells that express TLRs 1 to 9, but not TLR5. They respond to various TLR ligands by producing IL-12<sup>[61]</sup>. Interestingly, expression of TLRs in B cells has no effect on antibody production, and on B cell memory responses<sup>[62]</sup>. However, TLR3 and TLR9 activation in CD4<sup>+</sup> T cells enhances their proliferation<sup>[63]</sup>, and TLR2 serves as a co-stimulatory receptor for antigen-specific T cell development and participates in T cell memory<sup>[64]</sup>.

## INVOLVEMENT OF TLRs IN LIVER DISEASES

Significant amount of evidence in recent years has demonstrated the involvement of TLRs in the pathogenesis of various liver diseases. Most of this evidence comes from the overexpression of TLRs, activation of TLRs causing enhanced disease in animal models, single nucleotide polymorphisms (SNPs) in TLR-coding genes and their adaptors linked to disease susceptibility, and TLR knockout mice being protected from disease<sup>[40]</sup>. Three most common risk factors for the development of HCC for which TLR involvement has demonstrated to play a critical role

in the disease pathogenesis are discussed in this section.

### **Viral hepatitis**

Chronic hepatitis virus infection that affects almost half a billion people worldwide is a major risk factor for HCC. The infectivity of a given virus type varies according to the geographical location<sup>[2]</sup>. Co-infection with one or more viruses may also occur contributing to a higher risk of HCC, albeit it is rare<sup>[35]</sup>. HCV is the most common blood-borne infection in the United States, with nearly 20% of chronically infected individuals developing cirrhosis and HCC<sup>[65]</sup>. It is generally acknowledged that the humoral antibody response contributes to the clearance of circulating HBV particles and the prevention of viral spread within the host while the cellular immune response eliminates infected cells<sup>[66]</sup>. The T cell response to the HBV is vigorous, polyclonal and multispecific in acutely infected patients who successfully clear the virus, and relatively weak and narrowly focused in chronically infected patients, suggesting that clearance of HBV is T cell dependent<sup>[66]</sup>. Persistent HBV infection is characterized by chronic liver cell injury, regeneration, inflammation, widespread DNA damage and insertional deregulation of cellular growth control genes, which, collectively, lead to cirrhosis of the liver and HCC<sup>[66]</sup>. Other factors that could contribute to viral persistence are immunological tolerance, mutational epitope inactivation, T-cell receptor antagonism, incomplete down-regulation of viral replication, and infection of immunologically privileged tissues<sup>[66]</sup>. However, these pathways become apparent only in the setting of an ineffective immune response, which therefore, is the fundamental underlying cause<sup>[66]</sup>. In infected cells, the HBV capsid induces cytokine production *via* TLR2 activation. It was hypothesized that TLR2 activation is involved in viral clearance based on the observation that the administration of adefovir and entricitabine in HBV patients resulted in the up-regulation of TLR2 and reduction in the viral load<sup>[46]</sup>. In HepG2 cells, HBV triggers the production of cholesterol-metabolism genes *via* the TLR2 pathway<sup>[67]</sup>, and inflammatory stress exacerbated hepatic cholesterol accumulation these cells and in mice by disrupting the PPAR-LXR-CYP7A1/ABCA1-mediated bile acid synthesis and cholesterol efflux<sup>[68]</sup>. Interestingly in HBV transgenic mice, activation of TLRs 3-5, 7, and 9, but not TLR2, inhibited HBV replication *via* IFN- $\alpha/\beta$  induction<sup>[69]</sup>.

When immune responses were compared in macrophages of patients who spontaneously cleared HCV with those who were chronically infected, it was found that the TLR3 expression was significantly up-regulated in the former group<sup>[65]</sup>. Individuals who cleared the virus had an elevated expression of IFN- $\beta$  and higher rate of STAT-1 phosphorylation. A significant association of intronic TLR3 SNP (rs13126816) in the clearance of HCV and the expression of TLR3 was found in this study, suggesting that an elevated innate immune response enhances HCV clearance and may offer a potential thera-

peutic option to increase viral clearance<sup>[65]</sup>. TLR2, in combination with TLR1 and TLR8, recognizes core and nonstructural 3 proteins of HCV in immune cells such as macrophages and monocytes, and triggers the production of pro-inflammatory immune mediators TNF- $\alpha$ , IL-6, IL-8, IL-10 and IL-1 $\beta$ <sup>[70]</sup>. On the other hand, HCV NS5 protein is recognized by TLR4 in both hepatocytes and B cells<sup>[71]</sup>. Prolonged activation of KCs in the HCV-infected liver by HCV-encoded proteins causes persistent inflammation resulting in severe liver damage and cancer<sup>[72]</sup>. It was reported recently that the expression of TLR2 and TLR4 was highly elevated in peripheral blood monocytes of HCV patients, and that the number of Tregs was significantly higher in these chronically infected individuals<sup>[73]</sup>. Similar correlation of TLR2 and TLR4 expression, and Treg numbers was also reported in HBV patients<sup>[74]</sup>. In a separate study, a strong correlation was also observed between TLR2/4 expression and TNF- $\alpha$  production causing hepatic inflammation in HCV patients<sup>[75]</sup>. Chronic infection with HBV and/or HCV, and imbalanced immunity contributes to severe inflammation, while TLR activation during this process might be a critical factor of this infection-induced prolonged inflammation. Activation of innate immune responses by viral proteins, and the interaction of HCV with cellular proteins to evade host's immune responses as well as the role of SNPs in TLRs, their adaptors and cytokine genes in altering these immune responses have been extensively reviewed in the literature<sup>[76-78]</sup>.

### **Alcoholic liver disease**

Excessive alcohol consumption that causes alcoholic liver disease (ALD) is a major risk factor for HCC worldwide<sup>[79]</sup>. ALD is an umbrella term used to describe a broad spectrum of liver abnormalities caused by alcohol that include simple steatosis, alcoholic hepatitis, fibrosis and cirrhosis, which can progress to HCC. The pathogenesis of ALD is characterized by processes such as ethanol metabolism-associated oxidative damage, glutathione depletion, abnormal methionine metabolism, ethanol-mediated induction of leakage of gut endotoxins, and inflammation<sup>[79]</sup>. Liver inflammation is known to occur with exposure to a variety of agents, including metabolites of alcohol<sup>[80]</sup>. If hepatic metabolism is impaired to any degree and fails to convert drugs and chemicals to non-reactive or non-immunogenic substances, the metabolic intermediates formed in hepatic tissues may cause liver damage<sup>[81]</sup>. In such cases, KCs and other cell types release cytokines and chemokines that result in the inflammation of the liver. This reaction coupled with deregulated hepatocyte proliferation can contribute to the pathogenesis of HCC<sup>[81]</sup>.

Simple steatosis is a benign condition that progresses to alcoholic steatohepatitis (ASH) in about 10%-20% of cases and is associated with inflammation and liver injury caused by the innate immune responses<sup>[82]</sup>. Both MyD88-dependent and MyD88-independent pathways are activated in ASH, and studies with animal models have demonstrated the up-regulation of inflammatory cytokines

in the serum, and activation of IFN and IFN-responsive genes in ASH<sup>[83,84]</sup>. Blocking of IL-1 receptor, which acts through MyD88, in advanced ASH was shown to confer protective effect in mice suggesting that IL-1 inhibitors may be used in the treatment of ALD<sup>[85]</sup>.

Excessive alcohol consumption increases gut permeability and the translocation of bacteria-derived lipopolysaccharide (LPS, also known as endotoxin) from the gut to the liver<sup>[86]</sup>. In KCs, LPS interacts with TLR4 causing oxidative stress, and the production of pro-inflammatory cytokines and reactive oxygen species (ROS) that induce hepatocellular damage<sup>[83,87]</sup>. However, this effect was not abrogated in MyD88-deficient mice suggesting that MyD88-independent pathways are involved in NF- $\kappa$ B activation by alcohol<sup>[83]</sup>. Even though IRF-3 activation was not affected by chronic alcohol treatment, IRF-7 and IRF-3-inducible genes expression was significantly induced in KCs of alcohol-fed wild type mice<sup>[83]</sup>. The activation of TLR4 has also been demonstrated to occur during the alcohol and HCV synergism<sup>[88]</sup>. Furthermore, alcohol activates complements C3 and C5, following the production of TNF- $\alpha$ , and induces hepatocyte injury<sup>[89,90]</sup>. In addition to Gram-negative bacteria that produce LPS, gut is home to a large number of other microorganisms belonging to eukaryotes, prokaryotes, archaea, and viruses<sup>[91]</sup>. It is therefore likely that Gram-positive bacteria which produce lipoproteins and activate TLR2 signaling, and viruses that activate TLRs 3, 7, 8 and 9 may also leak from the gut to the liver. However, little is known about the activation of these TLRs during alcoholic liver injury.

### Nonalcoholic steatohepatitis

NAFLD is the most common chronic liver disease that affects both adults and children worldwide<sup>[92]</sup>. Like ALD, NAFLD includes a broad spectrum of liver abnormalities ranging from simple steatosis to non-alcoholic steatohepatitis (NASH), which can progress to cirrhosis and HCC. Of these, NASH is characterized by hepatocyte injury, inflammation, and fibrosis<sup>[92-94]</sup>. Most of these disease conditions are diagnosed at a late stage, and some patients also present for the first time with cirrhosis<sup>[92]</sup>. The development of cirrhosis is significantly higher in individuals with NASH when compared to patients with simple steatosis<sup>[92-94]</sup>. Consequently, liver-related mortality is also significantly higher in NASH patients.

NASH shares immunological characteristics with ASH such as the activation of innate immune responses, crosstalk between steatosis and inflammation, activation of TLR4 by LPS and fatty acids, complement activation, production of proinflammatory immune mediators, and alteration in NK and NKT cell number and activity<sup>[95,96]</sup>. In addition, activation of KCs in response to gut microbiota, activation of TLR signaling *via* both MyD88-dependent and -independent pathways, up-regulation of type I IFN and IFN-responsive genes occur in ASH and NASH<sup>[97-100]</sup>. However, recent studies have shown that NASH differs from ASH in certain aspects: insulin resistance, crosstalk between adipose tissue and the liver,

dependence on MyD88 signaling, differential effects in mice due to MyD88 and IL-1 deficiency, and activation of inflammasome<sup>[96]</sup>.

Progression of NASH is associated with the recruitment of T cells and T1 response leading to inflammation<sup>[101]</sup>, and hepatic expression levels of inflammatory mediators are modified in morbidly obese patients even without pathohistological manifestations<sup>[102]</sup>. Accumulating evidence strongly suggests that inflammation causes the progression of NAFLD to NASH, and that innate immunity is involved in the inflammatory response. While TLR2 and TLR9 pathways are critical for the development of NAFLD<sup>[103]</sup>, deletion of either TLR4 or its co-receptor MD-2 dampened (but not abolished) necro-inflammatory activity of steatosis and fibrosis in a mouse model of NASH<sup>[104]</sup>. Furthermore, in NASH, gut microorganisms enter the liver because of the leakage in the intestinal mucosal barrier resulting in inflammation, due to the activation of TLR signaling by intestinal bacteria and their products such as LPS<sup>[45,93]</sup>. It is apparent from these reports that the activation of TLR signaling is an important factor in causing inflammation in NASH, and could be a crucial factor in the progression of NASH to cirrhosis. It was reported that the activation of TLR4 signaling and up-regulation of CD14 resulted in higher responsiveness to LPS and saturated fatty acids in KCs, and resulted in hepatic inflammation and liver complications in NASH patients<sup>[98,105]</sup>.

### Hepatocarcinogenesis

Chronic liver damage caused by excessive inflammation due the exposure to various risk factors often results in the development of fibrosis-associated HCC<sup>[106]</sup>. Since the stimulation of TLR signaling pathways result in the production of proinflammatory immune mediators, it is likely that TLRs are involved in development and progression of hepatocarcinogenesis as well. The activation of TLR signaling in liver diseases leads to the activation of NF- $\kappa$ B and JNK pathways that are critical mediators of tumor-associated cytokine production. NF- $\kappa$ B activation induces the proliferation of tumor cells through the production of TNF- $\alpha$ <sup>[107]</sup>. Tumorigenic effect of JNK in HCC is mediated through the regulation of molecules involved in cell proliferation such as MMPs and cyclins<sup>[108]</sup>. Studies in animal models of HCC have shown that ROS-mediated JNK activation is critical for tumor development<sup>[109]</sup>, and that elevated ROS levels induce hepatocyte cell death<sup>[110]</sup>. Moreover, hepatocyte-specific knockdown of the NF- $\kappa$ B inhibitor I $\kappa$ B kinase subunit NF- $\kappa$ B essential modulator causes spontaneous development of HCC in mice<sup>[111]</sup>. However, interestingly, hepatocyte-specific TGF- $\beta$ -activated protein kinase 1-deficient mice had spontaneous hepatocyte cell death, compensatory proliferation, inflammatory cell infiltration, and fibrosis in the liver<sup>[102,112]</sup>. Collectively, these results demonstrate the involvement of NF- $\kappa$ B-mediated downstream molecules in cellular homeostasis and cancer development in the liver.

## TLR POLYMORPHISMS AND THE RISK OF DEVELOPING HCC

Dysregulation of TLR expression may shift the balance between the production of pro- and anti-inflammatory cytokines, and will have a profound effect on the risk of infection, chronic inflammation and cancer. Recently, Nishalke *et al*<sup>[113]</sup> showed that the frequency of TLR2 -196 to -714del allele was significantly higher in HCV-associated HCC patients than in HCV-infected individuals demonstrating that this deletion plays a role in HCC development. In addition, a number of SNPs have also been identified in every TLR gene. Some of these have been shown to enhance the susceptibility of various cancers in humans<sup>[114]</sup>. However, only a few reports have been published on the role of TLR SNPs in the pathogenesis of HCC. In one such study, Zhang *et al*<sup>[115]</sup>, conducted a genome-wide genotyping of 440794 SNPs in chronic HBV carriers: 355 with HCC and 360 without HCC. They found that one intronic SNP rs17401966 present in the *KIF1B* gene on chromosome 1p36.22 was highly associated with HBV-associated HCC<sup>[115]</sup>. In a recent study, Junjie *et al*<sup>[116]</sup> investigated the association between SNPs of *TLR2* and *TLR9* genes, and the susceptibility of HCC in a cohort of 211 patients that included 172 HBV carriers. They found that two TLR2 SNPs rs3804099 C/T and rs3804100 C/T present in the same exon of *TLR2* were associated with HCC, whereas TLR9 SNPs have no role in tumor development<sup>[116]</sup>. Additional studies are needed to fully understand the involvement of various TLR SNPs in hepatocarcinogenesis.

## MODULATION OF TLR SIGNALING TO ALLEVIATE LIVER INFLAMMATION AND CANCER

Overwhelming evidence on the involvement of TLR signaling pathways in many human diseases has led to the efforts to develop TLRs as vaccine adjuvants<sup>[117,118]</sup> and as therapeutic targets<sup>[119-121]</sup>. As discussed earlier, chronic inflammation, which plays a critical role in the progression of liver diseases and in the development of human cancers, is mediated by TLR activation. Hence, modulation of TLR pathways using various drugs, antibodies, microRNAs (miRNAs), and small molecules that function as TLR agonists and antagonists to reduce liver inflammation and to prevent the progression of liver diseases towards cancer is a promising strategy to combat HCC.

### TLR agonists and antagonists

Initial efforts on the modulation TLR signaling with small TLR mimetics that act as agonists have produced mixed results. Using the TLR2 agonist Pam2Cys as a stimulant *in vitro*, it was shown that hepatoma cell lines HuH7 and HepG2 respond to HBV infection by producing IL-8 and by inhibiting viral replication<sup>[122]</sup>. However, in *in vivo* studies with HBV transgenic mice, it was

found that ligands specific for TLRs 3, 4, 5, 7 and 9, but not TLR2, inhibited HBV replication in the liver<sup>[69]</sup>. On the other hand, intravenous administration of the TLR7 agonist isatoribine significantly reduced viral RNA in HCV patients independent of viral genotype<sup>[123]</sup>. The decrease in viral load in this study coincided with markers indicating a heightened antiviral immune state. In similar experiments, Weeratna *et al*<sup>[118]</sup> and Ma *et al*<sup>[124]</sup> tested TLR7 agonist R-848 and CpG oligodeoxynucleotides containing CpG motifs (CpG ODN) that act as the TLR9 agonists as adjuvants for HBV vaccination in mice using the HBV surface antigen (HBsAg) as a model antigen. This study was based on the notion that the immunostimulatory sequences (ISS) containing CpG motifs would elicit strong Th1 immune responses<sup>[125]</sup>. In their studies, both these groups found that the TLR agonists trigger immune responses that are beneficial to the host<sup>[118,124]</sup>. Along similar lines, Dynavax Corporation has developed a commercial vaccine (Heplisav) against HBV by combining a synthetic ISS sequence called ISS-1018 that acts as TLR9 agonist with the recombinant HBsAg. This vaccine induced seroprotective responses when administered in HBV patients<sup>[126]</sup>. Another CpG ODN containing TLR9, CPG7909, was also successfully tested as an adjuvant to HBV vaccine and is currently undergoing a phase 2 clinical trial<sup>[125,127]</sup>.

In contrast to these TLR agonists, only a few studies have reported successful inhibition of TLR signaling using antagonists. For example, lipid A mimetics that bind directly to TLR4-MD2 were shown to inhibit LPS-mediated activation of TLR4 signaling both *in vitro* and *in vivo*<sup>[128]</sup>. TAK-242, another mimetic that targets the intracellular domain of TLR4, inhibited TLR4-mediated production of nitric oxide and TNF- $\alpha$  in murine and human cells by targeting TLR4-CD4 chimeric receptors<sup>[129]</sup>. Interestingly, however, TAK-242 had no effect on NF- $\kappa$ B activation mediated by MyD88, TRAP, TRIF or TRAM. Recently, Cowden *et al*<sup>[130]</sup> tested two inhibitors of histamine H4 receptor that interacts with TLR4 and found that they reduced TNF- $\alpha$  production and LPS-induced inflammation in mouse livers.

In addition to the strategy of inhibiting TLRs, efforts are also being made to selectively inhibit their adaptors and downstream signaling molecules<sup>[131]</sup>. In such studies, Compound 4a inhibited the interaction of MyD88 protein with the TIR domain of TLRs and type I IL-1 receptor<sup>[132]</sup>, whereas MyD88 inhibitors ST2825 and RO0884 blocked the recruitment of IRAK-1 and IRAK-4 in human cells<sup>[133,134]</sup>. Additionally, ST2825 also suppressed B cell proliferation and differentiation<sup>[133]</sup>. However, the efficacy of these molecules in reducing inflammation in the liver is yet to be determined.

### miRNAs

MiRNAs are a class of small, noncoding RNAs that act as key regulators of many cellular processes. During the past decade, it has been well established that the aberrant expression of a large number of miRNAs correlate with

disease severity and poor prognosis of HCC<sup>[135-144]</sup>. The expression of these “miRNA signatures” are unique for a given disease stage, and were useful in identifying patients with HCC who are likely to develop metastases and recurrence. In recent years, efforts to identify miRNAs involved in the regulation of innate immune genes has resulted in the identification of a few promising miRNA candidates that can be exploited for therapeutic purposes. For example, overexpression of miR-155 which is directly involved in the regulation of more than 30 innate immune genes<sup>[145]</sup> results in the significant reduction of MyD88 expression and IL-8 production induced by *Helicobacter pylori*<sup>[146]</sup>. Interestingly, in bone marrow-derived macrophages and RAW264.7 cells, IL-10 inhibits miR-155 expression after LPS stimulation and dampens inflammatory immune responses in a STAT-3 dependent manner<sup>[147]</sup>.

When THP-1 monocytes were treated with ligands for TLRs 2, 4 and 5, production of TNF- $\alpha$  correlated inversely with the up-regulation of miR-146a<sup>[148]</sup>, and when the targets of miR-146a IRAK-1 or TRAF6 were knocked down, inflammatory responses to TLR2, TLR4 and TLR5 ligands were significantly reduced in these cells suggesting a role for miR-146a in LPS-induced cross-tolerance. Similarly, miR-132 and miR-212 were shown to be involved in TLR2-mediated cross-tolerance through IRAK4 modulation<sup>[149]</sup>. In addition, miR-146a disrupts the translation of TLR4-induced TNF- $\alpha$  production in these cells<sup>[150]</sup>. miR-146b exerts this effect in monocytes by negatively regulating TLR4 *via* a IL-10-mediated STAT3 dependent loop<sup>[151]</sup>. Another study on the expression profiling of endotoxin responsive genes in human monocytes has revealed that miR-146 regulates TLR and cytokine signaling in a NF- $\kappa$ B-dependent manner through a negative feedback regulation loop involving the down-regulation of IRAK-1 and TRAF6 protein levels<sup>[152]</sup>. In THP-1 cells, miR-146a also regulates TLR2 signaling by reducing IRAK-1 and phosphorylated I $\kappa$ B $\alpha$  expression<sup>[153]</sup>.

In another study, miR-181a expression was found to be significantly elevated in mice stimulated with LPS and streptozotocin, which correlated strongly with the expression of inflammatory factors TNF- $\alpha$ , IL-6, IL1 $\beta$  in macrophages suggesting that the inhibition of miR-181a could reduce TLR4-induced inflammation<sup>[154]</sup>. After stimulation with LPS, miR-92a significantly inhibited the activation of JNK/c-Jun pathway and the production of inflammatory cytokines in macrophages by directly targeting mitogen-activated protein kinase kinase 4<sup>[155]</sup>, demonstrating that miR-92a is a negative regulator of TLR-triggered immune responses.

In other studies, Benakanakere *et al*<sup>[156]</sup> demonstrated that miR-105 binds directly to TLR2 and regulates its expression. When keratinocytes were challenged by a TLR2 agonist or when miR-105 was overexpressed, a strong inverse correlation between miR-105 expression and TLR2 protein levels was observed. Similar to miR-105, let-7i was recently shown to bind directly to

TLR4 in cholangiocytes and to control its expression by translational repression<sup>[157]</sup>. In this study, let-7i mimics inhibited *Cryptosporidium parvum* induced TLR4 production. In dendritic cells of mice with colitis, the expression of miR-10a was found to be negatively regulated by the intestinal microbiota, which correlated inversely with the production of IL-12/IL-23p40<sup>[158]</sup>. This finding suggests that miR-10a targets IL-12/IL-23p40 to maintain immune homeostasis.

When stimulated with ligands for TLRs 2-4 miR-147 is induced in murine macrophages<sup>[159]</sup>. Its expression was found to be greater after the activation of TLR4 than that of TLR2 or TLR4, and was dependent on both MyD88 and TRIF. *In vivo*, TLR stimulation induced the expression of miR-147 as a negative-feedback loop mechanism to prevent excessive inflammatory responses<sup>[159]</sup>. Likewise, miR-145 targets the adaptor protein MAL, which facilitates the interaction between TLR and TLR4 with MyD88, and inhibits its expression<sup>[152]</sup>. Recently, Wendlandt *et al*<sup>[160]</sup> demonstrated that miR-200b and miR-200c reduced the expression of MyD88 but had no effect TLR4, IRAK-1 and TRAF6 in HEK293 cells. When miR-200b and miR-200c mimics were overexpressed, LPS-induced expression of IL-6, TNF- $\alpha$ , and CXCL9 was diminished, suggesting that these miRNAs regulate TLR4 signaling *via* MyD88-dependent manner<sup>[160]</sup>. Up-regulated miR-19a and miR-19b were able to inhibit the expression of suppressor of cytokine signaling 1, a gene important in the negative regulation of TLR signaling<sup>[161]</sup>.

Programmed cell death 4 (PDCD4) is a pro-inflammatory protein that suppresses IL-10 production and activates NF- $\kappa$ B. Sheedy *et al*<sup>[162]</sup> found that PDCD4-deficient mice are protected from LPS-induced death and demonstrated that miR-21 targets PDCD4 after LPS stimulation to negatively regulate TLR4 pathway. Recently, Fabbri *et al*<sup>[163]</sup> reported that miR-21 and miR-29b secreted by lung cancer cells in exosomes function as TLR ligands. These miRNAs bind to and activate TLR7 and TLR8 signaling pathways in peritoneal macrophages cells, causing NF- $\kappa$ B activation and secretion of pro-metastatic inflammatory cytokines<sup>[163]</sup>. Secreted miR-21 was also found in the serum of HCC patients and in individuals with chronic hepatitis indicating that miR-21 is a key factor in hepatocarcinogenesis<sup>[164]</sup>. Several other circulating miRNAs have also been identified in the serum of patients with HCC<sup>[165-167]</sup>. Further studies are needed to determine whether any of these miRNAs can be used to modulate the TLR signaling pathways, and to alleviate inflammation in liver tissues.

## CONCLUSION

Hepatocarcinogenesis is a multifactorial disease in which the expression of a large number of genes, proteins, and other molecules from diverse cellular processes is altered<sup>[2]</sup>. Growing evidence suggests that inflammation plays a critical role in the progression of liver diseases to HCC. Therefore, the use of combination therapy that

targets multiple different steps and pathways, rather than a single test or a set of tests, to reduce inflammation is an appropriate therapeutic strategy to combat the development of HCC. Positive therapeutic outcomes achieved with sorafenib that can inhibit receptor tyrosine kinases of multiple signaling cascades<sup>[168]</sup>, as well as evidence that a single molecule miR-26a can significantly reduce HCC without any toxicity<sup>[169]</sup> demonstrate the success of this multi-pronged approach.

Despite recent advances in the use of miRNAs either as antagomirs or in replacement therapy, the field of miRNA therapeutics for HCC is still in its infancy. Only a handful of successful outcomes have been reported so far<sup>[135]</sup>. One such success story was that of MiraVasen, which inhibited the activity of miR-122 and suppressed HCV viraemia with no evidence for viral resistance or side effects in chimpanzees<sup>[170]</sup>. This was the first miRNA-based therapeutic drug developed to treat a liver disease, and is currently being tested by Santaris Pharma (Hørsholm, Denmark) in phase 2 clinical trials<sup>[171]</sup>. The first successful demonstration of miRNA replacement to restore the expression levels of a down-regulated miRNA by delivery to the tumor was reported using a miR-26a-encoding AAV vector in a mouse model of HCC<sup>[169]</sup>. More recently, another miRNA down-regulated in HCC, miR-34a, has been successfully tested using this approach in an orthotopic model of HCC<sup>[172]</sup>. In latter two cases, significant tumor reduction, dramatic protection from disease progression without toxicity, and prolonged survival of animals has been reported. While these reports were aimed to restore a loss of function, similar success has not yet been achieved for HCC treatment using the approaches to inhibit miRNA expression levels. In future investigations, it is important to exercise caution while designing clinical trials with miRNA mimics and TLR inhibitors for targeting multiple genes relevant to the liver diseases because of the concerns about potential toxicity in normal tissues, and as they can cause severe detrimental effects due to imbalances in TLR expression, and cellular functions that could cause immune paralysis leading to development of HCC.

tients listed for LT within the Milan criteria, prolonging the waiting time over 6-12 mo is a risk factor for tumor spread. Bridging treatments are useful in containing tumor progression and decreasing dropout. Furthermore, the response to pre-LT treatments may represent a surrogate marker of tumor biological aggressiveness and could therefore be evaluated to prioritize HCC candidates for LT. Lastly, although a definitive conclusion can not be reached, the experiences reported to date suggest a positive impact of these treatments on both tumor recurrence and post-transplant patient survival. Advanced HCC may be downstaged to achieve and maintain the current conventional criteria for inclusion in the waiting list for LT. Recent studies have demonstrated that successfully downstaged patients can achieve a 5-year survival rate comparable to that of patients meeting the conventional criteria without requiring downstaging.

### Abstract

Several therapeutic procedures have been proposed as bridging treatments for patients with hepatocellular carcinoma (HCC) awaiting liver transplantation (LT). The most used treatments include transarterial chemoembolization and radiofrequency ablation. Surgical resection has also been successfully used as a bridging procedure, and LT should be considered a rescue treatment in patients with previous HCC resection who experience tumor recurrence or post-treatment severe decompensation of liver function. The aims of bridging treatments include decreasing the waiting list dropout rate before transplantation, reducing HCC recurrence after transplantation, and improving post-transplant overall survival. To date, no data from prospective randomized studies are available; however, for HCC pa-

**Key words:** Hepatocellular carcinoma; Bridging treatment; Downstaging; Liver cirrhosis; Liver transplantation; Liver resection; Waiting list; Waiting time; Dropout rate

**Core tip:** The bridging treatments for patients with hepatocellular carcinoma within Milan criteria listed for liver transplantation are useful in decreasing dropout rate from the waiting list and the experiences reported to date suggest a positive impact on post-transplant tumor recurrence and patient survival. The response to treatments may represent a surrogate marker of tumor biological aggressiveness and could be evaluated to prioritize hepatocellular carcinoma candidates in the waiting list. Advanced hepatocellular carcinoma may be downstaged to achieve the current conventional criteria for inclusion in the waiting list and successfully

downstaged patients can achieve an excellent 5-year survival rate.

## INTRODUCTION

Liver transplantation (LT) is the treatment of choice for patients with unresectable hepatocellular carcinoma (HCC) complicating liver cirrhosis because it allows the cure of both the tumor and the underlying chronic liver disease. HCC classified within the so-called Milan criteria (MC) (1 nodule smaller than 5 cm or no more than 3 nodules smaller than 3 cm)<sup>[1]</sup> is recognized everywhere as the standard indication for LT. However, after admission to the waiting list for LT, HCC patients can experience tumor growth beyond the conventional transplant criteria. Indeed, there is a high cumulative probability of drop-out from the waiting list for HCC patients due to intrahepatic or extrahepatic tumor progression. This probability has been reported to range between 7% and 11% at 6 mo and to be approximately 38% at 12 mo following enrollment by two papers published at the end of the 1990s by Llovet *et al*<sup>[2]</sup> and Yao *et al*<sup>[3]</sup>. The probability has been correlated with tumor characteristics, geographic origin, and length of time waiting for LT<sup>[4-6]</sup>.

Allocation policies for HCC patients awaiting LT remain controversial in the era of the model for end-stage liver disease (MELD) for the management of the LT waiting list. Different models have been developed to quantify the risk of death in neoplastic and non-neoplastic patients<sup>[7-11]</sup>. As the neoplastic risk assessment is not considered in MELD, patients with unresectable HCC with a neoplasm fulfilling the MC have been considered exceptions in the American allocation system. According to this rule, patients with T2-HCC fulfilling the MC (a single tumor of 2-5 cm or 2-3 tumors each < 3 cm) enter the waiting list with a MELD score equal to 22 and are therefore given priority over patients with less decompensated disease who enter the waiting list according to their laboratory MELD score (6 to 21). In addition, T2-HCC patients also receive incremental points for every 3 mo spent on the waiting list<sup>[12,13]</sup>. A similar approach has been implemented in other allocation systems<sup>[14,15]</sup>. The 22 threshold has been set to offer to HCC patients the same drop-out probability of patients without malignancy<sup>[16]</sup>. More detailed studies based on a dynamic prognosis parallelism have been published, and more complex allocation models aimed at balancing the risk of death in HCC and non-HCC patients have been proposed; however, they have not been applied in clinical practice<sup>[7,17-21]</sup>. According to these studies, LT can-

didates with HCC have dropout rates lower than non-HCC candidates, although the rate is similar to that of standard MELD candidates with a score of less than 21. Therefore, HCC patients appear to have an advantage in the current system, raising the question of whether a calculated continuous HCC priority score should be developed that also considers some biological features of the tumor such as the  $\alpha$ -fetoprotein (AFP) value, size, and rate of growth<sup>[17,18]</sup>. Indeed, HCC patients with a high AFP level achieve acceptable LT outcomes if their AFP levels can be reduced with locoregional therapy during the waiting period<sup>[22,23]</sup>. Furthermore, an inadequate response to HCC bridging therapy was shown to be a strong predictor of dropout probability in three single-center Italian studies<sup>[10,14,24]</sup>, whereas both the serum AFP level and the response to locoregional therapy were related to tumor recurrence and death in a retrospective international multicenter cohort study<sup>[25]</sup>.

Lastly, the development of the survival-benefit approach, which proposes ranking priority according to the benefit in survival between standard care and LT rather than crude survival figures, changed the perspective of the outcome evaluation system<sup>[26-28]</sup>. The practice most widely used since 2005, which is in accordance with the United Network for Organ Sharing rules, gives HCC patients with unresectable T1 neoplasms (a single nodule smaller than 2 cm) the same priority as patients listed for non-neoplastic diseases.

In this scenario, several therapeutic procedures have been proposed and largely used in the past as bridging neo-adjuvant treatments for patients listed for LT with HCC within the MC<sup>[29]</sup>. The rationale for their use is the possible decrease of the waiting list drop-out rate before transplantation and of HCC recurrence after transplantation, which is less than 15% in patients with HCC within the MC undergoing LT without any prior tumor treatment<sup>[30]</sup>. These beneficial effects could also improve the overall survival of transplanted patients. Both surgical resection and locoregional therapies can be used not only as bridging procedures to LT in T2-HCC patients but also to downstage HCC patients who do not initially meet the conventional transplant criteria<sup>[31]</sup>. According to this approach, patients can be safely listed for LT if they can reach and maintain for an adequate follow-up period the MC or slightly expanded criteria such as the University of California San Francisco criteria (UCSF) (a single HCC  $\leq$  6.5 cm or  $\leq$  3 tumors with the largest being  $\leq$  4.5 cm and a total tumor burden  $\leq$  8 cm)<sup>[32]</sup> or the up-to-7 criteria [HCCs with 7 as the sum of the size of the largest tumor (in cm) and the number of tumors]<sup>[33]</sup>. The aim of downstaging is to select HCC patients with reasonably low rates of tumor recurrence after LT among those who are initially excluded according to the current number-size criteria<sup>[34]</sup>.

In this paper, we analyzed the indications and results of the various neo-adjuvant treatment modalities currently administered to HCC patients awaiting LT to avoid exceeding the MC while on the waiting list as well as those used to downstage patients who do not meet

the conventional transplant criteria.

## NEO-ADJUVANT BRIDGING PROCEDURES FOR PATIENTS WITH HEPATOCELLULAR CARCINOMA AWAITING LIVER TRANSPLANTATION

### *Surgical resection*

Liver resection (LR) can be theoretically used as a first-line bridging procedure to LT. However, in most transplant centers, transarterial chemoembolization (TACE) and percutaneous ablation therapies are the preferred bridging therapies. The theoretical advantages of surgery in this setting are twofold. The first advantage is the best possible control of tumor growth, as TACE and percutaneous treatments do not always achieve complete tumor necrosis. The second advantage is the possibility of selecting patients in whom pathological analysis of the resected specimen shows features suggesting poor prognosis in terms of tumor recurrence, such as undifferentiated histotype, satellitosis, microvascular invasion, or capsular effraction, who should immediately undergo evaluation for LT<sup>[35]</sup>. However, compared to non-surgical therapies, the surgical bridging approach to patients listed for LT implies higher costs, entails more peri-procedural risks, can only be proposed in well-compensated patients without severe portal hypertension, and can make the ensuing LT technically more difficult, with a higher risk of post-operative complications<sup>[36]</sup>.

Moreover, important issues regarding tumor resectability should also be considered. Single exophytic or at least subcapsular neoplasms are easier to resect than multiple neoplasms or those located adjacent to the hilum or vena cava<sup>[37,38]</sup>. Furthermore, a location in the left lobe represents a more favorable condition, and the progress achieved in the laparoscopic resection of the liver has reduced the number of HCC patients with an absolute indication for LT<sup>[39]</sup>. However, the combination of LR and LT over time appears to be a reasonable strategy; HCC patients within the MC who have preserved liver function can undergo LR, limiting LT as a rescue treatment in cases of tumor recurrence or liver function failure (salvage LT)<sup>[40]</sup>. This approach allows a consequent saving of grafts, which can then be more efficaciously transplanted in other patients, and is supported by the discrepancy between the limited donor pool and the enormous number of LT candidates. However, there are important differences in access to LT according to cadaveric organ availability, blood group of the recipient, implementation of a living donor program, and degree of donor-recipient matching<sup>[41-44]</sup>.

Although during the initial experience with LR, the overall survival and disease survival rates of patients undergoing secondary LT after HCC resection were significantly lower (due to higher perioperative mortality unrelated to HCC) than those observed in cirrhotic patients with HCC undergoing primary LT<sup>[45]</sup>, favorable results

have more recently been reported by Belghiti *et al*<sup>[46]</sup>. They showed that postoperative course, complications, and the 3- and 5-year survival rates did not differ significantly between cirrhotic HCC patients undergoing primary LT or secondary LT after resection. Similarly favorable results for salvage LT have been subsequently reported by other groups in patients initially submitted to LR within the MC<sup>[15,47]</sup> or the UCSF criteria<sup>[48]</sup>.

Salvage LT has been shown to be effective not only in the setting of deceased donor LT but also in the setting of living donor LT, particularly in Asian countries. Compared to deceased donor LT, the main advantage of living donor LT is the reduction of the waiting list time, whereas the main drawback is represented by the occurrence of severe life-threatening complications among donors in approximately 1% of cases<sup>[49]</sup>. Indeed, Hwang *et al*<sup>[50]</sup> have shown that the combination of prior recipient hepatectomy and a living donor liver graft is feasible and provides excellent long-term survival in treated patients, and their results have recently been confirmed by other groups<sup>[51,52]</sup>.

Notably, the option of salvage LT cannot be offered to all patients initially treated by LR, primarily due to HCC recurrence overcoming the conventional LT criteria, age over 65 years at the time of recurrence, and the presence of comorbidities preventing the feasibility of LT. In a series reported by Poon *et al*<sup>[53]</sup>, approximately 80% of patients were still eligible for salvage LT at the time of tumor recurrence. In a recent paper by Liu *et al*<sup>[48]</sup>, among 71 patients with HCC recurrence within the UCSF criteria, salvage LT could be performed in 39 patients (54.9%). Compared to 180 HCC patients who underwent primary LT, patients treated with salvage LT for HCC recurrence showed greater intraoperative blood loss and required more blood transfusions; however, perioperative mortality, post-transplant complications, HCC recurrence rates, and overall survival did not differ significantly between the two groups.

### *Transarterial chemoembolization*

TACE is considered the standard treatment for patients with intermediate-stage HCC according to the Barcelona-Clinic Liver Cancer classification<sup>[54]</sup>, and it achieves a partial response in 15%-55% of patients and an improvement of median survival from 16 to 20 mo<sup>[55]</sup>. The most widely used conventional TACE procedure consists of an arterial infusion of a lipiodol emulsion with a chemotherapeutic agent (*e.g.*, doxorubicin or cisplatin) followed by embolization with gelfoam. However, conventional TACE is not a standardized procedure, and the optimal chemotherapeutic/embolizing agent and retreatment strategy have yet to be determined<sup>[56]</sup>. In particular, it is well known that TACE requires treatment repetition either at regular intervals or “a la demande” and that repeating conventional TACE may damage non-cancerous hepatocyte functions and affect the clinical course. Indeed, liver toxicity is a major limitation of conventional TACE regimens, and superselective TACE

is recommended in the setting of patients waiting for LT to minimize ischemic injury to non-tumoral liver tissue. Promising new data have been obtained using drug-eluting beads (DEBs), which are particles of variable size that are able to bind and elute doxorubicin in a predictable manner<sup>[57]</sup>. Compared to conventional techniques, DEBs appear to be a more standardized approach to TACE with less liver-related toxicity and fewer systemic adverse events<sup>[58]</sup>.

TACE has been extensively used in the past as a bridging treatment to LT, and a number of studies have shown that it is an effective therapy in terms of adequate tumor necrosis achievement at explant analysis. Analyzing the largest available series indicates that the rate of patients treated by TACE reaching complete tumor necrosis is quite uniform, ranging between 27% and 57% in patients within the MC<sup>[59-67]</sup>.

Interestingly, the rate of tumor necrosis appears to be higher in patients with single nodules when compared with patients with multiple nodules, in patients submitted to superselective TACE when compared with lobar TACE (complete necrosis achieved in 53.8% *vs* 29.8% of cases, respectively), and in patients with nodules 3-5 cm in size compared with patients with nodules smaller than 3 cm<sup>[65]</sup>. This last finding confirms the result obtained by Alba *et al*<sup>[64]</sup> and may be explained considering that larger nodules are typically fed by larger arteries, whereas in some instances, smaller nodules lack fully developed arterial neoangiogenesis; as a result, chemoembolization may be more effective in the former<sup>[65]</sup>. Accordingly, Kwan *et al*<sup>[66]</sup> have recently shown that the development of > 90% lesion necrosis upon pathological analysis of explanted liver was associated with avid lesion enhancement and the presence of a feeding vessel larger than 0.9 mm in diameter on the pre-TACE visceral angiogram. On post-TACE computed tomography images, a lack of residual contrast enhancement, a decrease in lesion size, a high lesion density due to an accumulation, and a diffuse distribution of ethiodized oil throughout the lesion were also correlated with near-complete lesion necrosis.

A recent small retrospective study compared tumor response in explanted liver after treatment with DEBs or standard TACE. TACE with DEBs achieved complete necrosis in 77% of the lesions, which was significantly higher than that reached after standard TACE (27.2%). More data are needed to address the better performance of DEBs compared to standard TACE in the transplant setting<sup>[68]</sup>.

Another important point to clarify is the evaluation of TACE safety in patients awaiting LT. Because arteritis of the celiac and hepatic arteries may complicate TACE as a result of endovascular trauma caused by guides and catheters, recipients could be exposed after the transplant to an increased occurrence of complications such as arterial thrombosis. However, the prevalence of such serious complications has not been found to be increased in some studies comparing patients with or without TACE performed before LT<sup>[69-71]</sup>.

## Radiofrequency ablation

Radiofrequency thermal ablation (RFA) has gained widespread use over recent years as an effective procedure for small HCCs not amenable to surgical resection. Thermal ablation may be performed using cool-tip or hook needles with comparable results<sup>[72]</sup>. Some studies have described the use of RFA as a bridge to transplantation in HCC patients in recent years. These studies have reported complete tumor necrosis at pathological evaluation of the explanted liver in 47%-75% of cases, with a mean value of 58%<sup>[73-77]</sup>. A clear difference in effectiveness can be observed when analyzing tumors according to size. Indeed, the rate of complete necrosis ranges between 50% and 78% in HCCs up to 3 cm and between 13% and 43% in larger neoplasms<sup>[73-75,77]</sup>. Furthermore, in two studies, a tumor size larger than 3 cm was the only risk factor identified for HCC persistence after treatment<sup>[73,75]</sup>.

Regarding RFA-related complications in the setting of HCC patients awaiting LT, an analysis of the largest available series demonstrated that the procedure is quite safe. In fact, considering 5 large series, the mean rate of post-ablation major complications was only as high as 4.6%, including one case of death due to peritoneal bleeding, two cases of acute peritonitis/cholecystitis, and one case each of severe liver failure treated by urgent transplantation, severe persistent liver failure, biliary stenosis, arterial hemorrhage, and small bowel perforation<sup>[73-76,78]</sup>. Additionally, the risk of tumor seeding at the level of the abdomen wall appears to be low; however, occasional cases of tumor seeding along the needle track diagnosed after LT in patients submitted to RFA as a bridging procedure have been reported in the literature<sup>[79,80]</sup>.

## Other treatments

TACE and RFA are the most used bridging treatments to LT in HCC patients, although other therapeutic options have been proposed (Table 1). Percutaneous ethanol injection (PEI) is the oldest and most used technique for the local treatment of HCC, but it has been rarely used as a bridging treatment to transplantation. In our multicenter survey, the rate of complete necrosis in tumors smaller than 3 cm was 30%<sup>[75]</sup>. Castroagudín *et al*<sup>[81]</sup>, in a series of 20 nodules in 19 patients, showed that in patients with small tumors (*i.e.*, less than 3 cm), ethanol injection induced complete necrosis in 58% of the cases. In a more recent paper, Branco *et al*<sup>[82]</sup> reported a complete necrosis rate of 64% in 59 patients within the MC and a mean tumor size of 2.4 cm (range: 0.5-5.5 cm). In these studies, PEI was not affected by procedure-related major complications and did not provide total necrosis in most tumors larger than 3 cm.

Percutaneous laser ablation (PLA) performed using multiple tiny laser fibers has recently been shown to be an effective technique for the thermal ablation of HCC in patients in whom surgical resection is not possible or appropriate<sup>[83,84]</sup>. We recently showed that in HCC patients awaiting LT, PLA provided results comparable

**Table 1 Advantages and disadvantages of the bridging and downstaging procedures for hepatocellular carcinoma in cirrhotic patients who are candidates for liver transplantation**

	Advantages	Disadvantages
Resection	Higher complete effectiveness than non-surgical procedures More simple in cases with peripheral subglissonian nodules	Unfeasible in patients with decompensated liver disease or severe portal hypertension
TACE	More effective using the selective/superselective technique in well-vascularized nodules with large feeding arteries	Unfeasible in patients with severely reduced portal vein flow, intratumoral arteriovenous fistula, or renal failure (creatinine clearance < 30 mL/min)
TARE	Possible better effectiveness than TACE in cases with multiple nodules	Less experience with TARE than TACE High cost
RFA	More effective in nodules $\leq 3$ cm	Potentially dangerous in patients with impaired clotting parameters or lesions located superficially or near the gallbladder, major bile ducts, or bowel loops
PEI	More effective in nodules $\leq 3$ cm Suitable in patients with impaired clotting parameters or lesions located in dangerous sites for thermal ablation	Less effective than RFA for nodules > 2 cm
PLA	More effective in nodules $\leq 3$ cm Suitable in patients with impaired clotting parameters	Less experience with PLA than RFA Technically complex
MWA	Possible better effectiveness than RFA in nodules $\geq 3$ cm or located near large vessels	Potentially dangerous in cases of lesions located superficially or near the gallbladder, major bile ducts, or bowel loops Less experience with MWA than RFA Potentially dangerous in patients with impaired clotting parameters or with lesions located superficially or near the gallbladder, major bile ducts, or bowel loops

TACE: Transarterial chemoembolization; TARE: Transarterial radio embolization; RFA: Radiofrequency ablation; PEI: Percutaneous ethanol injection; PLA: Percutaneous laser ablation; MWA: Microwave ablation.

to those of RFA; the rate of complete necrosis found at explant analysis in a series of 13 nodules up to 3 cm was 62%<sup>[85]</sup>. Due to the use of fine needles, the possible advantages of PLA in respect to RFA include the treatment of patients with either nodules in high-risk sites (*i.e.*, near vital structures)<sup>[86]</sup> or severe clotting impairment, in whom RFA may be contraindicated, and the lower overall cost of the procedure.

Microwave ablation (MWA) has been shown to be an effective thermal ablation procedure for the percutaneous treatment of HCC. Compared to RFA, this technique could theoretically provide a larger volume of necrosis and be more effective when treating nodules adjacent to large vessels; however, a clear advantage of MWA with respect to RFA has not been demonstrated<sup>[87,88]</sup>. The use of MWA as a bridging procedure to LT or a downstaging procedure in HCC patients appears to be promising. In a recent preliminary study, 6 patients with 6 HCC nodules ranging between 2.5 and 5.0 cm (mean 3.5 cm) in diameter underwent MWA before LT. At explant analysis, all of the nodules showed complete necrosis without intraoperative evidence of tumor spread in all cases or evidence of tumor recurrence at a one-year follow up in the 5 patients who could be evaluated<sup>[89]</sup>.

The effectiveness of transarterial radioembolization (TARE) with 90Yttrium microspheres has recently been evaluated by Riaz *et al.*<sup>[90]</sup>, who studied 38 nodules in 35 patients. Of 15 patients with T2-HCC, none progressed to T3-HCC (one nodule > 5 cm or up to three nodules with one > 3 cm) before LT, whereas 8 of 10 patients were downstaged from stage T3 to stage T2. At explant analysis, 23 of the 38 target lesions (61%) showed complete tumor necrosis, and its achievement was af-

fected by the size of the target lesion; indeed, complete necrosis was detected in 89%, 65%, and 33% of lesions smaller than 3 cm, between 3 and 5 cm, and larger than 5 cm, respectively.

Data regarding the use of external conformal radiotherapy (CRT) as a bridging treatment to LT in HCC patients are scarce. In a recent paper, CRT was delivered in five or six fractions to 10 patients with HCC awaiting LT with tumor diameters ranging from 2.5 to 10.8 cm. Nine patients completed the treatment, and it was well tolerated in all cases. Two tumors remained stable; the rest had 10%-50% regression, which was sustained on follow-up imaging. Five patients underwent LT, and at explant pathology, tumor necrosis ranging between 40% and 90% was demonstrated. No patients showed tumor recurrence after LT (median follow-up period of 6 mo). The main conclusions of the paper were that CRT is a safe and efficacious local bridging therapy for patients with HCC who are on the waiting list for LT and that further studies are warranted to compare the effectiveness of CRT to other local treatment regimens<sup>[91]</sup>.

### Combined treatments

Experiences with combined therapies such as TACE followed by RFA<sup>[92-94]</sup> or RFA shortly after TACE<sup>[95]</sup> have been published in recent years, typically in the setting of unresectable HCC larger than 3 cm. The rationale for the use of combined treatment rather than a single treatment is to reach a higher local tumor control rate due to higher rates of complete tumor necrosis. In this context, the question arises of how TACE and RFA should be sequenced. The advantage of performing TACE prior to RFA is the reduced heat-sink effect with the ability to create larger ablation zones more easily. The advan-

tage of using TACE after RFA is that RFA generates a hyperemic rim surrounding the ablation area, which can consequently be targeted by transarterial means more effectively. The approach of combined treatment may be applied even as a bridge to LT. A recent experience with combined TACE followed by RFA in a series of 44 HCC patients within the MC reported the absence of major complications and a 76.9% rate of complete necrosis in the 16 patients with 26 nodules who underwent LT<sup>[96]</sup>.

## IMPACT OF BRIDGING TREATMENTS ON DROPOUT FROM THE LIVER TRANSPLANTATION WAITING LIST

The impact of bridging treatments on waiting list dropout is uncertain due to the absence of prospective comparative studies, but the dropout data of treated patients should be compared with the features of HCC patients awaiting LT without any bridging treatment. In the latter case, the dropout rates were greater than 30% 12 mo after being added to the list<sup>[2,3]</sup>. In 2006, Lesurtel *et al*<sup>[97]</sup> published an interesting paper dealing with the usefulness of TACE in HCC patients undergoing LT according to the criteria of evidence-based medicine. The question was whether TACE impacted the waiting list dropout rate. They found insufficient evidence to answer this question. Hayashi *et al*<sup>[61]</sup> reported a discouraging 35% dropout rate in patients with TNM stage 1 or 2 HCC and a mean waiting time of 340 d after treatment with TACE. Similarly, among 54 listed HCC patients who underwent TACE prior to LT, Maddala *et al*<sup>[98]</sup> revealed drop-out rates of 15% and 25% at 6 and 12 mo, respectively. However, the most recent series including patients treated with TACE before LT have indicated that the dropout rate due to tumor progression is lower and ranges between 3.0% and 9.3%, with a mean waiting time on the transplantation list exceeding 6 mo in the largest available studies<sup>[63,64,69]</sup> (Table 2).

Less data are available in this setting for patients submitted to RFA. In a preliminary study published in 2002, Fontana *et al*<sup>[99]</sup> reported a dropout rate of 21% over a mean waiting period of 7.9 mo among 33 patients treated with RFA prior to LT. In more recent papers including larger numbers of patients, the dropout rate due to HCC progression was found to be 0% after a mean waiting time of 9.5 mo in one study<sup>[73]</sup> and 5.8% at 12 mo in another study<sup>[74]</sup> (Table 2). In a large study including only HCC patients within the MC awaiting LT, 77 patients who underwent RFA were compared to 93 patients without any bridging treatment; a non-specific trend toward a higher dropout rate for tumor-specific events was detected among RFA patients (21% *vs* 11%), but the mean waiting time was significantly higher in the RFA group. Using survival analysis modeling, there was no significant difference in the time to dropout between the RFA and no-treatment groups for all causes<sup>[78]</sup>.

Encouraging data have been reported following the application of multimodal schedules of treatment; in a series of 44 listed HCC patients within the MC who systematically underwent TACE followed by RFA, the intention-to-treat cumulative dropout rates were 5.5% and 11.0% at 12 and 24 mo, respectively<sup>[96]</sup>.

Lastly, the short-term response to bridging treatment has recently been reported to be crucial in the prediction of dropout. In a recent report by De Giorgio *et al*<sup>[24]</sup>, 170 HCC patients awaiting LT within the MC who underwent percutaneous ablation, TACE, or surgery as a bridging treatment were analyzed. Total tumor diameter and recurrence or persistence of tumor activity at the 6-wk follow-up after therapy were significantly correlated with progression beyond the MC and dropout from the waiting list. The finding of a significantly decreased dropout probability among T2 patients achieving a complete or partial response to bridging treatment compared with patients with an inadequate or no response to treatment has also been confirmed in two other large studies<sup>[10,14]</sup>.

In summary, there is sufficient evidence to conclude that bridging treatments yielding complete or subtotal HCC necrosis on imaging effectively reduce the rate of dropout from the waiting list.

## IMPACT OF BRIDGING TREATMENTS ON RECURRENCE OF HEPATOCELLULAR CARCINOMA AFTER LIVER TRANSPLANTATION

A less than 15% recurrence rate has been reported for HCC in patients within the MC undergoing LT without any treatment<sup>[30]</sup>. Whether the application of bridging therapies while on the waiting list decreases this rate is controversial. Again, prospective multicenter comparative studies are lacking in this field, and the only available data were obtained in single-center retrospective case series.

Regarding TACE, in a cohort of 111 HCC patients undergoing LT (54 treated preoperatively with TACE), Majno *et al*<sup>[59]</sup> showed that downstaging of tumors > 3 cm and total necrosis of the nodule at explant analysis were associated with better 5-year disease-free survival than either an inadequate response to TACE or no TACE before LT. Thereafter, low recurrence rates of 7.6% and 10.7% were reported in two large series of HCC patients within the MC who were treated with TACE before LT<sup>[63,64]</sup>. A clear trend toward longer recurrence-free survival has also been observed by Millonig *et al*<sup>[63]</sup> in patients with complete tumor necrosis when compared with patients with viable tumor at explant analysis. More recently, Tsochatzis *et al*<sup>[67]</sup> evaluated 150 consecutive patients with HCC within the MC who underwent LT. Sixty-seven patients (45%) underwent transarterial embolization (TAE) with polyvinyl alcohol particles or TACE before LT, and the remaining 83 patients were not treated before

HCC: Hepatocellular carcinoma; LT: Liver transplantation; RFA: Radiofrequency ablation; MC: Milan criteria; NA: Not available; TACE: Transarterial chemoembolization; PEI: Percutaneous ethanol injection; UNOS: United Network for Organ Sharing; TARE: Transarterial radio embolization; TAE: Transarterial embolization.

LT. HCC recurrence after LT was significantly lower in the TAE-TACE group (6%) than in the no TAE-TACE group (18.1%) (Table 2). Furthermore, post-transplant HCC recurrence was independently associated with no neo-adjuvant transarterial therapy and the total radiological size of the HCC nodules.

HCC recurrence after LT has been evaluated in 7 studies of patients who underwent RFA as the only bridging treatment. In total, 231 patients were evaluated over follow-up periods of 15-41 mo (mean 28 mo). Overall, HCC recurrence was detected in 8 patients (3.5%), and the rate of recurrence ranged between 0% and 13%<sup>[73-78,99]</sup> (Table 2).

Some recent single-center studies appear to confirm a positive impact of bridging treatments on HCC recurrence after LT. In a series of 147 HCC candidates (38% outside the MC) who underwent RFA, TACE, or multimodal treatment before LT, a complete or partial response was observed in 57.8% of cases. Transplanted patients with stable disease or no response to pre-LT HCC treatment had a significant 6-fold increase in tumor recurrence after LT compared with patients with a complete or partial response (13% *vs* 2%)<sup>[10]</sup>. In another study that included 315 HCC patients who were candidates for LT (17% outside the MC) and underwent TACE, RFA, PEI, or surgical resection, a

complete response to treatment was observed in 49.1% of cases; transplanted patients with a partial or no response to bridging treatments showed a significantly higher risk of HCC recurrence compared with patients with a complete response (19.4% *vs* 5.5%)<sup>[14]</sup>. Among 137 transplanted patients (42 outside the MC) who underwent locoregional bridging treatments such as resection, TACE, RFA, and PEI before LT, AFP > 400 ng/mL was the only significant pre-transplant factor linked to HCC recurrence after LT. Conversely, the use of locoregional treatments was a significant protective factor, and the best 5-year tumor-free survival was observed in patients within the MC who underwent locoregional treatment<sup>[100]</sup>. Lastly, within a group of 93 consecutive HCC patients (36 beyond MC) who underwent LT, 59 underwent pre-transplant TACE or RFA. The 5-year tumor-free survival did not significantly differ between treated and untreated patients (78% *vs* 68%). However, among the treated patients, the presence of more than 50% necrosis of the target lesions at explant analysis was associated with a significantly better 5-year tumor-free survival rate (96% *vs* 21%)<sup>[101]</sup>.

Overall, a trend toward a decreased recurrence rate after LT appears to emerge in patients achieving a total or subtotal response to the treatment administered before LT.

## IMPACT OF BRIDGING TREATMENTS ON SURVIVAL AFTER LIVER TRANSPLANTATION

Independent of the treatment administered, a key question remains to be answered: do bridging treatments improve survival in HCC patients who undergo LT? There is insufficient evidence of a beneficial effect of TACE because data obtained from prospective randomized studies are lacking<sup>[97]</sup>. A multicenter retrospective case control study from France compared 100 HCC patients who underwent TACE before transplantation and 100 HCC patients transplanted without any prior treatment. The 5-year survival (59% in both groups) and 5-year disease free survival (69% *vs* 64%) rates were not significantly different. At explant analysis, greater than 80% total or subtotal HCC necrosis was found in 30% of treated patients, and this subgroup showed a non-significant trend toward a better 5-year survival compared with a matched untreated control group (63% *vs* 54%)<sup>[62]</sup>. It can be reasonably argued that patients with total/subtotal tumor necrosis might receive a significant survival benefit from TACE before LT, perhaps due to a decreased risk of post-transplant HCC recurrence. This hypothesis appears to have been confirmed in a study by Millonig *et al*<sup>[63]</sup> that included 116 HCC patients who underwent TACE before transplantation. Most of the patients were within the MC, and complete tumor necrosis was found in 27% of the cases. The 5-year survival rate was higher in patients with completely necrotic tumors than in patients with partial necrosis (86% *vs* 66%), although this difference did not reach statistical significance.

The influence of neo-adjuvant treatments on post-LT survival should be analyzed independent of the treatment used; however, the only available data come from single-center retrospective series and provide contradictory results. In a study by Bharat *et al*<sup>[102]</sup>, 46 HCC patients undergoing various bridging treatments before LT were compared to 46 matched HCC patients transplanted without any treatment. The 5-year survival rate was significantly higher in the treated group (82% *vs* 52%), although the survival advantage was evident only for patients with T2-T4 tumors, not for patients with T0-T1 tumors. Even the 5-year disease-free survival rate was slightly higher in the treated group (84% *vs* 76%), although this difference was not significant. In a study by Lao *et al*<sup>[103]</sup>, 91 untreated HCC patients who underwent LT were compared to 33 patients with HCC who underwent TACE, RFA, or PEI before LT. HCC recurred only in 9 untreated patients, and the only factors significantly linked to tumor recurrence were a MELD score < 14, AFP > 1000 ng/mL, and the absence of pre-LT bridging treatment. The disease-free survival showed a non-significant trend toward a better outcome in treated patients, whereas the cumulative survival did not differ. Heckman *et al*<sup>[104]</sup> compared the outcomes of 50 HCC patients undergoing bridging therapy before LT to those of 73 HCC patients transplanted without any

prior treatment; they found a non-significant trend toward improved 5-year survival in treated patients (81% *vs* 71%). Porrett *et al*<sup>[79]</sup> compared 30 treated patients to 33 untreated patients before transplant. Their study failed to show any survival difference between the groups, but it should be noted that only 20% of the treated patients had complete HCC necrosis at explant analysis. Lastly, in the previously cited study by DuBay *et al*<sup>[78]</sup>, no differences in 5-year overall or tumor-free survival from the list date or transplant were identified when comparing 77 patients treated with RFA to 93 matched untreated patients. No data were provided about the achievement of complete necrosis in the ablated tumors at explant analysis.

Although a definitive conclusion cannot be made, a positive impact of pre-LT treatments on post-LT survival could be present. Indeed, in the United States, data on liver transplant activity for HCC from 1997 to 2006 demonstrated a higher 3-year post-LT survival in patients who underwent ablative procedures compared with patients who did not<sup>[105]</sup>. Moreover, studies reporting no difference between treated and untreated patients also tend to report shorter waiting times for LT<sup>[29]</sup>.

## DOWNSTAGING OF HCC BEYOND THE CONVENTIONAL LIVER TRANSPLANTATION CRITERIA

Downstaging of HCC to within the MC or the UCSF criteria is an attractive alternative to expanding the tumor size limits for LT. Theoretically, the downstaging process allows the selection of tumors with a more favorable biology that will likely respond to downstaging treatments and will also do well following LT<sup>[106]</sup>.

In recent years, several papers have been published defining successful downstaging as fulfilling the MC<sup>[107-114]</sup> or the UCSF criteria<sup>[106]</sup>. However, different criteria for successful treatment have been used in other studies, including fulfilling the MC without a serum AFP level higher than 400 ng/mL<sup>[115]</sup>, a 30%-50% decrease in the size of treated nodules<sup>[60,116]</sup>, or no tumor progression during the downstaging treatment in patients with well or moderately differentiated HCC<sup>[4,117]</sup> (Table 3). In some of these studies, only TACE<sup>[60,108,110,112-114]</sup> or transarterial chemoinfusion<sup>[107]</sup> was used as the downstaging procedure, whereas in other studies, a multimodal approach was used, including TACE, RFA, PEI, or surgical resection<sup>[4,106,114,115,117]</sup>. TARE as a single downstaging procedure was retrospectively compared to TACE in a study by Lewandowski *et al*<sup>[109]</sup>. Better performance was observed for TARE in terms of the downstaging success rate and 3-year intention-to-treat post-HCC treatment survival.

Significant factors for unsuccessful downstaging related to biological tumor features have been reported by some of these papers. In the study by Yao *et al*<sup>[106]</sup>, AFP > 1000 ng/mL was the only significant negative prognostic factor. Barakat *et al*<sup>[111]</sup> showed that the mean

<sup>1</sup>Patients with vascular invasion or extrahepatic tumor spread at baseline excluded in all series. HCC: Hepatocellular carcinoma; LT: Liver transplantation; TACE: Transarterial chemoembolization; MC: Milan criteria; NA: Not available; RFA: Radiofrequency ablation; PEI: Percutaneous ethanol injection; WD: Well differentiated; MD: Moderately differentiated; UCSF: University of California San Francisco; AFP:  $\alpha$ -fetoprotein; TARE: Transarterial radio embolization; UNOS: United Network for Organ Sharing; TACE: Transarterial chemoembolization; mRECIST: Modified Response Evaluation Criteria in Solid Tumors; TAE: Transarterial embolization; HIFU: High-intensity focused ultrasound; pts: Patients.

AFP level and the rate of infiltrative tumors were significantly higher in patients who did not achieve successful downstaging. An AFP level lower than 100 ng/mL and the 3-year survival probability calculated using the Metroticket calculator<sup>[33]</sup> were the only independent predictors of successful downstaging in the study by Bova *et al*<sup>[113]</sup>. An AFP slope > 15 ng/mL per month and tumor progression according to the Modified Response Evaluation Criteria in Solid Tumors (mRECIST)<sup>[118]</sup> were independent risk factors for HCC recurrence and patient death in an international retrospective multicenter European study performed by Lai *et al*<sup>[25]</sup> that included

MC-within (316 cases) and MC-outside (116 cases) patients who underwent LT after locoregional therapy. We should also highlight that after successful downstaging, some authors have recommended that patients undergo a 3-mo observation period before listing to assess the stability of neoplastic disease<sup>[4,106,115]</sup>. This “test of time” will identify rapidly recurring lesions, vascular invasion, and distant metastasis, thereby decreasing the risk of tumor recurrence and poor overall results after LT<sup>[34]</sup>.

Overall, according to the presently available data, the successful downstaging rate ranges between 24% and 71% (Table 3). The proportion of patients transplanted

ranges between 10% and 67%, and the average waiting time to LT ranges between 2 and 10.9 mo<sup>[29]</sup>. Additionally, the reported survival rates range from 78.8% to more than 90% and from 54.6% to 93.8% at 3 and 5 years, respectively<sup>[119]</sup>. Two prospective studies have demonstrated that survival after LT in patients with large tumors successfully downstaged within the MC<sup>[115]</sup> or the UCSF criteria<sup>[106]</sup> is similar to that of patients who initially met the criteria for transplantation. Six studies<sup>[4,60,107,108,114,116]</sup> compared patients who were downstaged successfully within the MC with those who initially met the MC. Five of these studies<sup>[4,107,108,114,116]</sup> reported no significant difference in absolute or disease-free survival between groups, whereas one study<sup>[60]</sup> reported that patients who were downstaged successfully had significantly worse survival at 1, 2, and 5 years after LT. Lastly, in a recent study, no significant differences in postoperative complications, tumor recurrence, or survival rate were reported between two groups of patients with advanced HCC who underwent deceased donor LT (52 patients) or living donor LT (31 patients) after successful downstaging therapy<sup>[42]</sup>.

## CONCLUSION

Currently, locoregional therapies play a crucial role in the treatment of patients awaiting LT. For patients listed within the MC (stage T2-HCC), a delay of LT over 6-12 mo without bridging treatment is a well-recognized risk factor for tumor progression and dropout from the list or interval dissemination with post-transplant tumor recurrence<sup>[2,3,16]</sup>. For this reason, the optimal strategy for T2-HCC patients awaiting LT should be to transplant within 6 mo without pre-transplant therapy<sup>[120]</sup>. However, if a longer waiting time is needed, following the current guidelines of the American Association for the Study of Liver Disease and the European Association for the Study of the Liver for the treatment of HCC<sup>[121,122]</sup> and the recommendations of a recent international consensus conference on the management of HCC patients who are LT candidates<sup>[123]</sup>, the use of bridging treatments is recommended, as several studies in recent years have documented their usefulness in preventing tumor progression. There is, however, no evidence that bridging treatments are useful in patients with T1-HCC<sup>[123]</sup>.

In patients who underwent previous liver resection and experienced tumor recurrence but are within the currently accepted transplant criteria or those with liver function failure, salvage LT using deceased donor livers yields an acceptable long-term survival rate and can be considered<sup>[6,25]</sup>. Salvage LT using living donors has also been successfully performed in centers with high-volume living donor programs, and they appear to provide long-term results comparable to those obtained using deceased donor grafts<sup>[48]</sup>.

Regarding non-surgical bridging therapies, no recommendation can be made for one type of locoregional therapy over others<sup>[123]</sup>. However, RFA could be the first-

line treatment for lesions up to 3 cm, in which complete tumor necrosis has been shown in more than 50% of cases at explant analysis. The risk of major complications related to RFA in this patient setting appears to be quite low, but it is good clinical practice to limit needle insertions and to avoid the treatment of superficially located lesions. PEI appears to show lower efficacy and can be reserved for small lesions located in sites considered “dangerous” for RFA (*e.g.*, near the gallbladder or bowel loops). TACE should be preferred for treating lesions > 3 cm because its effectiveness appears to be better in well-vascularized tumors with large feeding arteries; selective and superselective TACE should be preferred, and the possible advantage of DEBs-TACE over lipiodol-TACE should be investigated in future studies. Multimodal treatment strategies, including sequentially applied TACE and RFA, appear to be promising, although the role of alternative treatments such as PLA, MWA, TARE, and CRT needs to be investigated in a larger number of patients. Regardless, all ablation procedures should be better evaluated with caution in patients with decompensated liver function to avoid irreversible liver failure and severe complications precluding LT.

The response of HCC to neoadjuvant treatments should be evaluated using the mRECIST criteria<sup>[118]</sup>. The RECIST criteria<sup>[124]</sup> were amended to the mRECIST in 2008<sup>[125]</sup> in the setting of HCC based on the concept that the evaluation of the treatment response should consider the amount of necrosis when estimating the decreased tumor load, not only the reduction in tumor size. However, it should also be considered that computed tomography and magnetic resonance imaging, which are currently used to assess the results of the ablation bridging procedures, tend to overestimate treatment effectiveness. In several studies, the concordance in the diagnosis of complete necrosis between the last imaging evaluation before LT and the pathological assessment at explant analysis of the target lesions has been reported to range between 50% and 83%; this is primarily due to the persistence of microscopic avascular neoplastic foci that are primarily located peripherally and cannot be detected by contrast-enhanced imaging techniques<sup>[74,75,77,85,106,115,126,127]</sup>.

Although no solid conclusions may be drawn due to the absence of prospective comparative studies, it appears reasonable to state that bridging treatments decrease the dropout rate from the waiting list of T2-HCC patients and could have a positive impact on post-LT HCC recurrence and overall survival, at least in patients with complete or subtotal necrosis of the targeted lesions and a longer waiting period<sup>[29,105]</sup>. Furthermore, the response to pre-LT treatments may represent a surrogate marker of tumor biology and should be considered in the selection and prioritization of candidates for LT. That is, the transplant priority of T2-HCC candidates could be reduced after successful bridging therapy and a 3-6 mo period of observation confirming inactive neoplastic disease, and patients showing stable or progressive disease after treatment could then be prioritized.

However, if an advantage is given on the waiting list to non-responding patients, a worsening in the outcome of LT in terms of overall survival, primarily due to an increased incidence of HCC recurrence after transplantation, should be considered. Whether this risk is acceptable is a matter of debate, and this issue should be further addressed in future studies<sup>[14,29,128]</sup>.

HCC downstaging using exclusively TACE or multimodal sequential therapies to meet the conventional criteria for LT among carefully selected patients yields promising results in terms of overall and disease-free survival. In particular, some recent papers have demonstrated that patients successfully downstaged within the MC or the UCSF criteria can achieve a 5-year survival rate comparable to that of patients meeting the above-mentioned criteria without requiring downstaging<sup>[123]</sup>. A follow-up period of 3 mo demonstrating stable disease after successful downstaging is suggested before inclusion on the waiting list for transplantation.

## Abstract

Numerous reports have identified a dysbiosis in the intestinal microbiota in patients suffering from inflammatory bowel diseases (IBD), yet the mechanism(s) in which this complex microbial community initiates or perpetuates inflammation remains unclear. The purpose of this review is to present evidence for one such mechanism that implicates enteric microbial derived proteases in the pathogenesis of IBD. We highlight and discuss studies demonstrating that proteases and protease receptors are abundant in the digestive system. Additionally, we investigate studies demonstrating an association between increased luminal protease activity and activation of protease receptors, ultimately resulting in increased intestinal permeability and exacerbation of colitis in animal models as well as in human IBD. Proteases are essential for the normal functioning of

bacteria and in some cases can serve as virulence factors for pathogenic bacteria. Although not classified as traditional virulence factors, proteases originating from commensal enteric bacteria also have a potential association with intestinal inflammation *via* increased enteric permeability. Reports of increased protease activity in stools from IBD patients support a possible mechanism for a dysbiotic enteric microbiota in IBD. A better understanding of these pathways and characterization of the enteric bacteria involved, their proteases, and protease receptors may pave the way for new therapeutic approaches for these diseases.

**Key words:** Protease; Proteinase; Protease associated receptor; Enteric microbiota; Epithelial barrier

**Core tip:** It is currently accepted that an enteric dysbiosis (alteration of the normal bacterial flora) is involved in the pathophysiology of inflammatory bowel diseases (IBD). One of the suggested mechanisms that ties an intestinal dysbiosis to the pathophysiology of IBD involves the release of enteric bacterial proteases that interact with protease activated receptors on epithelial cells, resulting in intestinal barrier dysfunction and exposure of the enteric immune system to luminal antigens. We have reviewed the literature that examined the role of microbial proteases and their enteric receptors in the pathogenesis of IBD, their suggested pathways of action, and discuss future therapeutic implications.

## INTRODUCTION

Inflammatory bowel diseases (IBD), collectively known as Crohn's disease (CD) and ulcerative colitis (UC), are caused by dysregulated immune responses towards microbial antigens in a genetically predisposed host. The incidence of UC and CD has been increasing worldwide in developed and in developing countries<sup>[1,2]</sup>. These diseases are highly prevalent in the United States affecting 1.4 million individuals<sup>[3]</sup> and are associated with reduced quality of life<sup>[4,5]</sup>, and psychological co-morbidity<sup>[6]</sup>. Current estimates for IBD associated treatment costs in the US are \$6.3 billion<sup>[7]</sup>, but the initiating events of IBD and causes of disease exacerbation remain unclear. It is postulated that one potential mechanism involves disruption of the epithelial barrier, and exposure of a genetically defective immune system to enteric microbial antigens. Consistent with this hypothesis are animal models of colitis that use chemical disruption of the epithelial barrier with trinitrobenzene sulphonic acid (TNBS), dextran sodium sulfate or non-steroidal anti-inflammatory drugs (NSAIDs). Additionally, disruption of the intestinal epithelial barrier by exposure of susceptible patients to NSAIDs (blockers of prostaglandins synthesis) is a known risk factor that can trigger intestinal inflammation<sup>[8]</sup>. In line with this observation, in animal studies, the use of a prostaglandin receptor agonist preserved the intestinal epithelial barrier structure and function, maintained mucous secretion by goblet cells, and prevented the development of colitis<sup>[9]</sup>.

Proteases, peptidases, or proteolytic enzymes, are a class of enzyme that catalyze the cleavage of peptide bonds in other proteins in the presence of H<sub>2</sub>O (hydrolysis). Proteases act as both positive and negative effectors of several biological processes either broadly as catalysts of protein degradation or specifically as selective agents that control physiological processes<sup>[10]</sup>. The importance of proteases is highlighted in the human genome where 2%-4% of genes encompass the *degradome*<sup>[11]</sup>. In bacteria, proteases are involved in numerous biological processes, such as those associated with metabolism, development, and virulence. Additionally, these enzymes can disrupt mucosal barriers, provide a metabolic advantage, and modulate the host immune response. The high prevalence of proteases in enterobacteria suggests that proteases play important roles in pathogenesis<sup>[12]</sup>. Both mammalian and bacterial proteases have been implicated in the pathogenesis of IBD, usually through disruption of the epithelial barrier. In pathogenic bacteria, many proteases are virulence factors that aid in bacterial invasion into host cells and cause infectious colitis. However, accumulating evidence shows that commensal enteric microorganisms also produce proteases that possess the ability to disrupt the epithelial barrier<sup>[13,14]</sup>. These commensal proteases may be involved in the pathogenesis of IBD in the context of a genetically predisposed host and/or when an intestinal microbial dysbiosis occurs. Our aim in this review is to provide an overview of current studies that suggest potential mechanisms in which microbial proteases may play a role in the pathogenesis of IBD.

## PROTEASE CLASSIFICATION

Proteases frequently exist as multi-domain proteins, with catalytic activity restricted to a single structural domain. Although these enzymes appear to have a specific function (*i.e.*, hydrolysis of proteins), they exhibit vast diversity in their action and structure and are not easily categorized by general systems of enzyme nomenclature. Thus, proteases are broadly subdivided into two major groups, exopeptidases and endopeptidases. Exopeptidases cleave the peptide bond proximal to the amino or carboxy termini of the substrate, whilst endopeptidases cleave peptide bonds distant from the termini of the substrate. Proteases are further classified into five distinct groups on the basis of the chemical nature of the groups responsible for their catalytic activity, namely; aspartic, cysteine/thiol, metallo-, serine, and unidentified proteases<sup>[15]</sup>. In order to generate a comprehensive classification system for proteases, Rawlings and Barrett<sup>[16]</sup> developed a method to classify this group of enzymes based on the type of reaction they catalyze, the chemical nature of their catalytic site, and their evolutionary structure. This approach is a hierarchical system where classification levels were summarized as peptidases (*i.e.*, serine proteases), families and clans. This system initially recognized 84 families of proteases; however the subsequent massive accumulation of amino acid sequence data and three-dimensional structures of proteases from the scientific community warranted an updated classification system that was easily accessed for academic studies. Thus, based on the system outlined by Rawlings and Barrett<sup>[16]</sup> the MEROPS database was developed<sup>[17]</sup>. Along with data regarding protease classification, the MEROPS database also provides information regarding classification of protein inhibitors of peptidases<sup>[18]</sup>, small-molecule inhibitors<sup>[19]</sup>, and a collection of known protease cleavage sites and substrates<sup>[20]</sup>.

### Microbial proteases

Proteases are found in all forms of life suggesting that they are vital for the survival of all organisms. Microorganisms produce a vast array of aspartic, cysteine, metallo-, and serine proteases. Microbial aspartic proteases are specific for aromatic or bulky amino acid residues on both sides of a peptide bond. They are broadly divided into two groups: pepsin- and rennin-like enzymes. Cysteine proteases generally are only active in the presence of reducing agents. Some bacterial cysteine proteases are notable for their role in virulence and the inflammatory response they illicit<sup>[21]</sup>. Metalloproteases are characterized by the requirement for a divalent metal ion for their activity. These proteases are summarized into neutral and alkaline groups based on their specificity of action<sup>[22]</sup>. Serine proteases are characterized by the presence of a serine group in their active site and have broad substrate specificity. The complex microbial community in the human gut (referred to as the intestinal microbiota) is a substantial source of serine, cysteine, and metallo-proteases<sup>[23-25]</sup>. This is exemplified by the reduction of colonic bacteria

densities and protease activity by oral administration of antibiotics to mice<sup>[26]</sup>. By analyzing the protease activity of representative enteric bacterial strains and human fecal samples it has previously been suggested that the activity of specific classes of proteases present in human feces are likely to originate from *Bacteroides*, *Streptococcus*, and *Clostridium* species<sup>[27]</sup>. However, to date only one study has reported the correlation between specific groups of proteases and the abundance of enteric bacterial taxa using modern molecular methods. Carroll *et al.*<sup>[28]</sup> used high throughput sequencing of the 16S rRNA gene and correlated the abundances of specific bacterial families with fecal tryptic activity in stool samples from healthy individuals and IBS patients. This study found positive associations between *Lachnospiraceae*, *Streptococcaceae* and *Lactobacillales* with fecal protease activity, and a negative correlation with *Ruminococcaceae*. However, to date microbial proteases have been mainly exploited for commercial purposes. For example, bacterial alkaline proteases are characterized by their high activity at an alkaline pH and their broad substrate specificity, thus, making them ideal for use in the detergent industry<sup>[29]</sup>. In addition, most academic studies have focused on bacterial proteases as potential virulence factors in pathogenic bacteria<sup>[30]</sup>. However, little is known regarding the relationship between microbial proteases, found in or on the body, and the health of the host. Examples of such microbial proteases that are produced by enteric commensals are specified in Table 1.

## MICROBIAL PROTEASES IN THE PATHOGENESIS OF IBD

The antigenic contents of the intestinal lumen are separated from underlying intestinal tissues by an epithelial barrier that is one cell thick. Pathogenic bacteria have acquired virulence factors, many of which are proteases, that disrupt this barrier and cause infection<sup>[31]</sup>. For example, the serine protease autotransporter of *Enterobacteriaceae* family are generally secreted into the external milieu and are highly prevalent among enteropathogens, including *Shigella* species and all *Escherichia coli* (*E. coli*) pathotypes<sup>[12]</sup>. As there is an established genetic component to IBD<sup>[32]</sup>, it is difficult to identify microbial proteases that are potentially involved in the pathogenesis of these diseases as they would not be categorized in the same manner as traditional virulence factors. Indeed, an overproduction of microbial proteases originating for enteric commensal microbes may not have an effect on a healthy individual, but may play a role in the pathogenesis or perturbation of intestinal inflammation in a population with a genetic predisposition to IBD. Here we discuss four potential mechanisms in which microbial proteases from a non-pathogenic source (the intestinal microbiota) could contribute to the pathogenesis of IBD.

**Table 1 Commensal enteric microbial protease classification and origin**

Protease category	Microbial origin	Protease
Aspartic	<i>Candida albicans</i>	Secreted aspartic proteases <sup>[119]</sup>
	<i>Pseudomonas aeruginosa</i>	Type 4 prepilin peptidase <sup>[120]</sup>
Cysteine	<i>Methanococcus voltae</i>	Preflagellin <sup>[121]</sup>
	Gram positive bacteria	Sortases <sup>[122]</sup>
	<i>Porphyromonas gingivalis</i>	Gingipain <sup>[21]</sup>
	<i>Staphylococcus aureus</i>	Staphopain <sup>[123]</sup>
Metalloprotease	<i>Bacteroides fragilis</i>	Fragilysin <sup>[124]</sup>
	<i>Enterococcus faecalis</i>	Gelatinase <sup>[87]</sup>
	<i>Staphylococcus epidermidis</i>	Elastase <sup>[125]</sup>
	<i>Clostridium perfringens</i>	Collagenase <sup>[13]</sup>
Serine	<i>Helicobacter pylori</i>	High temperature requirement A <sup>[125]</sup>
	<i>Bacillus subtilis</i>	Subtilisin <sup>[126]</sup>

## MICROBIAL PROTEASES AND ADHERENCE AND INVASION TO THE INTESTINAL EPITHELIUM

Bacterial adhesion to intestinal epithelial cells is believed to be one of the first steps used in the pathogenicity of many enteric pathogens. Adhesion enables a microbe to colonize the intestinal epithelium and resist exclusion from the intestine by the mechanical movement of the gut. Adherent and invasive *E. coli* (AIEC) are a group of enteric microbes that are capable of adhering to and invading intestinal epithelial cells<sup>[33]</sup>. AIECs are not classified as enteric pathogens, but exhibit some pathogenic traits in the context of IBD. For example, AIECs isolated from CD patients are able to replicate within macrophages without escaping from the phagosome and without inducing macrophage death<sup>[34]</sup>. Proteases for pathogenic bacteria play a fundamental role in adherence and invasion virulence traits. For example, enteroaggregative *E. coli* (EAEC) expresses a factor referred to as “protease involved in colonization” or Pic. Pic catalyzes gelatin degradation which can be abolished by disruption of the predicted proteolytic active site. This protease is involved in the early stages of pathogenesis and most probably promotes intestinal colonization<sup>[30,35]</sup>. Pic is also essential for biofilm formation in EAEC. The first step of biofilm formation is bacterial adherence to a surface and then intercellular aggregation. In general, intercellular aggregation is mediated *via* the proteolytic processing of bacterial aggregation proteins by means of host or bacterial proteases<sup>[36,37]</sup> ultimately resulting in a biofilm. To date the role of microbial proteases involved in the formation of biofilms in members of the intestinal microbiota have not been investigated in the context of IBD. However, the role of biofilms in AIEC virulence in IBD has begun to emerge. It was reported that biofilm formation indi-

ces were higher amongst AIEC than non-AIEC strains isolated from the intestinal mucosa of CD, UC, and non-IBD controls<sup>[38]</sup>. Additionally, the adhesion and invasion properties of AIECs correlated positively with higher biofilm formation indices. Furthermore, the  $\sigma^E$  factor, which up-regulates genes that encode proteases, periplasmic foldases, and chaperones in response to environmental stresses, plays a pivotal role in biofilm formation in AIECs in the context of CD<sup>[39]</sup>. Thus, proteases may be important in biofilm formation and colonization of commensal enteric bacteria and related to IBD pathogenesis.

## PROTEASE RECEPTORS

Proteases can mediate their activity on mammalian cells through activation of protease receptors. Protease activated receptors (PARs) are a family of 7 transmembrane domain G-protein-coupled receptors (GPCRs) that mediate multiple responses to external stimuli, such as hemostasis, thrombosis and inflammation, and exist in four isoforms (PARs 1-4)<sup>[40-44]</sup>. PARs are activated through proteolytic cleavage of the extracellular N-terminal component of the receptor unmasking a tethered peptide ligand residue that binds with another region of the receptor causing a conformational change<sup>[45]</sup>. The result is an initiation of an intracellular signaling cascade that is diverse and includes calcium mobilization, phospholipase C-dependent production of inositol phosphates and diacylglycerol, Rho and Rac activation, mitogen-activated protein kinase signaling, and gene transcription<sup>[46]</sup>. Alternatively, PARs can be activated through peptide sequences that are homologues to the intrinsic tethered ligand. These synthetic peptides activate PARs without proteolysis of the N-terminal of the receptor in PAR1, PAR2 and PAR4 but not in PAR3<sup>[47]</sup>. The outcome of PAR activation is dependent on the type of ligand (*e.g.*, serine protease, matrix metalloprotease, plasmin, coagulation factors *etc.*), receptor type (PAR1, 2, 3 or 4) and on the type of cell which the PAR is expressed (*e.g.*, epithelial cells, platelets, nerve cells, or leukocytes). PAR activation, signaling and degradation are highly regulated by post translational modifications such as phosphorylation, glycosylation and ubiquitination (for review- Grimsey *et al*<sup>[48]</sup>). In the gastrointestinal (GI) tract, PARs are activated by endogenous proteases secreted by the pancreas (such as trypsin), by cells of the enteric wall (such as mast cells), or by the luminal enteric microbiota. Moreover, PAR expression on the gut epithelium differs between IBD patients and healthy individuals. This may be a result of the type of micro-organisms present in the GI tract and other receptors [such as toll-like receptors (TLRs)] they interact with. For example, on polymorphonuclear (PMN) cells, *Candida albicans* promoted a TLR2-dependent PAR1 activation and expression in contrast to *Aspergillus fumigatus* that suppressed TLR4-dependent PAR2 activation and expression<sup>[49]</sup>. In this regard it is important to note that endogenous host proteases are also PAR specific, *e.g.*, - thrombin activates PAR1<sup>[50]</sup>, PAR3<sup>[40,43]</sup> and PAR4<sup>[44]</sup>, while trypsin activates PAR2<sup>[51]</sup> and PAR4<sup>[52]</sup>.

While the majority of research relating to the relationship between PARs and colitis has examined the role of endogenous activation of PARs by mammalian proteases, the interaction between the enteric microbes, PAR expression and activation and the pathophysiology of colitis have not been extensively studied. The evidence that supports these associations is summarized below.

### PAR1

PAR1 has been implicated in hemostasis, platelet signaling, systemic pro-inflammatory responses (such as vasodilatation, increased vascular permeability and chemotaxis) and induction of analgesia<sup>[53,54]</sup>. PAR1 agonists induce apoptosis of intestinal epithelial cells in a caspase-3-dependent manner, with a concomitant loss of the epithelial barrier function and a consequent increase of permeability to macromolecules and bacteria<sup>[55]</sup>. PAR1 is expressed by enterocytes as well as by other cell types such as endothelial cells, enteric neurons, myocytes and immune cells<sup>[52]</sup>. The expression of PAR1 on the intestinal epithelium is linked to the presence of enteric microbiota<sup>[56]</sup>, and activation of this receptor in the mouse colon leads to colitis<sup>[57,58]</sup>. In addition, PAR1 expression has been reported to be increased in colonic biopsies from IBD patients<sup>[54]</sup>. Altogether, these reports support a role for PAR1 in the pathogenesis of IBD, however it is not clear if the enteric microbiota directly activate PAR1 through release of bacterial proteases. Nonetheless, this mechanism is supported by a study investigating oral epithelial cells, where PAR1 activation by a cysteine protease released by the oral pathogen *Porphyromonas gingivalis* (*P. gingivalis*) caused an up-regulation of pro-inflammatory cytokines<sup>[59]</sup>.

### PAR2

The majority of evidence that points towards an association between PARs and intestinal inflammation involves PAR2. This receptor is localized to the apical and basolateral membrane<sup>[60-62]</sup> of the intestinal epithelium and can be activated by trypsin, tryptase, and bacterial proteases<sup>[63]</sup>. PAR2 is expressed in immune, stromal, endothelial, and intestinal epithelial cells and thus, PAR2-associated inflammation may be a result of multiple, systemic and local pathways. Systemically, this receptor impacts leukocytes by mediating rolling, adhesion, and extravasation<sup>[64]</sup>. When activated on sensory neurons PAR2 mediates pain and edema<sup>[65]</sup>. In the mouse colon, activation of this receptor results in colitis<sup>[60]</sup> that is significantly ameliorated in PAR2-deficient mice<sup>[60,66]</sup>. Additionally, antagonism of PAR2 (by GB88) results in amelioration of colitis in rats that is induced by either TNBS or a PAR2 agonist (SLI-GRL-NH<sub>2</sub>)<sup>[67]</sup>. Thus, most studies indicate that activation of PAR2 leads to an inflammatory response. However, a single study has reported a protective effect of daily intra colonic administration of PAR2 agonist in a TNBS colitis model in rats<sup>[68]</sup>. It is not entirely clear why PAR2 exhibits anti-inflammatory properties in this model; however it may be the result of a chronic PAR2 activation and lo-

cal desensitization, or *via* anti-inflammatory effects on macrophages<sup>[69]</sup>. Additionally, it is not clear which of the various mechanisms that have been implicated in PAR2 activation in the gut is responsible for PAR2-dependent colitis. However, it has been speculated that PAR2-mediated intestinal inflammation is a result of increased levels of PAR2 ligands in the colon of IBD patients. Indeed, in the colon of human IBD patients the natural PAR2 ligands, trypsin<sup>[70]</sup> and tryptase<sup>[71,72]</sup> are elevated compared to healthy controls. Moreover, in human IBD, PAR2 is overexpressed on mast cells<sup>[73]</sup> which have also been implicated in the pathogenesis of PAR2-mediated colitis. In non-IBD patients permeability was found to be proportional to the concentration of tryptase (naturally secreted by mast cells) added to the basolateral surface and not to the mucosal surface of mucosal biopsies<sup>[74]</sup>. These studies support the importance of mast cells in colitis *via* PAR2 activation, however enteric bacteria may also play a role in PAR2 activation in the colon through release of bacterial proteases in the gut lumen<sup>[24]</sup>. Róka *et al.*<sup>[26]</sup> demonstrated increased levels of serine proteases in fecal samples from UC patients and hypothesized that these enzymes originated from luminal bacteria as it was reported that increased fecal protease activity was neither of a mast cells nor pancreatic origin. PAR2 can be activated by enteric bacteria either directly by bacterial proteases, as demonstrated in the oral epithelium by proteases of *P. gingivalis*<sup>[63]</sup> and in infectious colitis by the Toxin A of *Clostridium difficile*<sup>[75]</sup>, or indirectly by bacterial-dependent induction of host proteases<sup>[76]</sup>, as discussed above. Finally, it has been reported that antibiotic treatment directed at the gut microbiota resulted in reduced PAR2 expression suggesting that PAR2 is not only activated by enteric bacteria but its expression is also regulated by the presence of these microbes<sup>[77]</sup>.

### PAR3

The biological significance of PAR3 has not been fully delineated. Structurally, this PAR isotype does not have a C-terminal intra cytoplasmic tail and thus cannot signal through GPCRs. However, PAR3 may serve as a cofactor or co-receptor of other PARs. In mouse platelets, PAR3 functions as a cofactor for PAR4 by presenting thrombin to low-affinity PAR4, thereby resulting in efficient receptor cleavage<sup>[78]</sup>. On endothelial cells PAR3 can regulate PAR activity by forming a heterodimer with PAR1<sup>[79]</sup>. Despite evidence of PAR3 mRNA expression in the small intestine, this receptor's relationship with intestinal inflammation and bacterial proteases are unknown<sup>[40]</sup>.

### PAR4

PAR4 is expressed in the small and large intestine<sup>[44]</sup> and is localized to colonocytes in rats<sup>[80]</sup>. It can be proteolytically activated by thrombin, trypsin and by the neutrophil granule protease cathepsin G<sup>[81]</sup>. Its activation induces leukocyte rolling and adherence, suggesting a pro-inflammatory role for this receptor<sup>[45,82-84]</sup>. Exposure of mouse colons to PAR4 agonists results in increased paracellular

colonic permeability, suggesting that this receptor may be involved in the pathophysiology of IBD<sup>[85]</sup>. In the human colon, expression of PAR4 on epithelial cells is negligible in non-IBD patients but is significantly higher in UC patients. Interestingly, the activity of cathepsin G was increased in the feces of UC patients compared to controls and inhibition of its activity resulted in ameliorated enteric permeability<sup>[85]</sup>. Thus, cathepsin G may mediate PAR4-dependent enteric permeability in UC patients. Nevertheless, a direct effect of bacterial proteases was not examined; therefore it is still unknown whether proteases released by the enteric microbiota contribute to enteric permeability and colitis in a PAR4 dependent manner.

## PROTEASES AND INTESTINAL BARRIER DISRUPTION

The intestinal epithelial barrier is made up of a single layer of cells that are tethered together *via* tight junctions and cell adhesion molecules. Enteric microbes can circumvent the defense of the intestinal epithelial barrier either directly through proteolytic degradation of cell adhesion molecules (such as E-cadherin) or indirectly by regulation of paracellular permeability *via* tight junctions. Intestinal epithelial tight junctions are composed of different protein complexes which consist of trans-membrane and intracellular scaffold proteins (Figure 1).

The trans-membrane proteins include occludin, claudins, and junctional adhesion molecules whose extracellular loops are bound together and intracellular domains interact with scaffold proteins such as zonula occludens (ZO), which in turn are anchored to the actin cytoskeleton. In the intestine the adherence junction protein, E-cadherin, cements epithelial cells together and is a significant factor in maintenance of the epithelial barrier function. The enteric commensal *Enterococcus faecalis* (*E. faecalis*) can induce inflammation in a gnotobiotic *IL-10*<sup>-/-</sup> mouse<sup>[86]</sup> and secretes a protease (gelatinase) which has the capacity to degrade collagen, fibrinogen, fibrin, endothelin-1, bradykinin, LL-37, and complement components C3 and C3a<sup>[87-92]</sup>. The potential of *E. faecalis* gelatinase to damage the intestinal epithelial barrier and cause inflammation in the *IL-10*<sup>-/-</sup> mouse was recently investigated<sup>[14]</sup>. Steck and associates created an *E. faecalis* mutant lacking the *gelE* gene ( $\Delta$ *gelE*). *IL-10*<sup>-/-</sup> mice mono-associated with *E. faecalis*  $\Delta$ *gelE* exhibited significantly lower colonic inflammation when compared to mice mono-associated with wild-type *E. faecalis*. The reduction in colonic inflammation was independent of colonization densities of *E. faecalis* strains. Interestingly, the expression of E-cadherin on epithelial cells in *IL-10*<sup>-/-</sup> mice was reduced in the presence of *gelE* (wild-type *E. faecalis*) but not when *gelE* was absent from *E. faecalis* ( $\Delta$ *gelE*). It was further demonstrated that *E. faecalis* *gelE* can degrade recombinant mouse E-cadherin. These data strongly suggest a mechanism in which a bacterial protease can disrupt the intestinal barrier function and lead

**Figure 1 Model for enteric microbial protease-dependent increased intestinal permeability.** Enteric microbial proteases activate epithelial protease activated receptors (PARs) through release of the tethered ligand. This results in intra-cellular signal transduction and activation of ERK 1, 2 and MAPK. These signaling molecules mediate disruption of tight junctions and consequently cause increased intestinal permeability that enables penetration of microbes and their proteases which can act upon cytokines. Further possible effects of bacterial proteases on the immune response are illustrated in the black box. These mechanisms have been demonstrated for *Porphyromonas gingivalis* in the oral cavity (and not in the gut) where gingipain proteases can enhance Interleukin (IL)-8-dependent attraction of neutrophils (when in their soluble forms) by partially degrading the N-terminal of this cytokine, or inhibit neutrophil activity via complete degradation of IL-8 when associated with the microbial membrane.

to inflammation. This finding is specifically significant to CD pathogenesis where a greater diversity of microbes with gelatinolytic activity was reported when compared to healthy controls<sup>[13]</sup>.

The intestinal microbiota has long been thought of as a significant contributor to the proteolytic activity of stool<sup>[24,27]</sup>. Specifically, Macfarlane *et al.*<sup>[24]</sup> found that the proteolytic activity in the stool from a patient that had undergone a pancreatectomy was comparable to that of the protease activities in stools from individuals that had not undergone surgery to remove their pancreas. This indicates that a source other than the pancreas (*i.e.*, enteric microbes) significantly contributes to the protease activity of the intestine. These observations have been more recently demonstrated by the reduction of colonic bacteria densities and protease activity by oral administration of antibiotics to mice<sup>[26]</sup>. As previously mentioned, increased protease activity has been reported in fecal samples obtained from subgroups of patients suffering from irritable bowel syndrome (IBS) and IBD<sup>[25,93,94]</sup>. Róka *et al.*<sup>[26]</sup> initially saw a four-fold increase in trypsin-like activity in diarrhea-predominant IBS (D-IBS) and UC patients.

Subsequently, it was found that fecal supernatants from D-IBS patients could increase colonic paracellular permeability in the mouse gut<sup>[94]</sup>. The application of D-IBS supernatants to the mouse colon resulted in an increase in phosphorylation of myosin light chain kinase and delayed redistribution of the tight junction-associated molecule ZO-1. Further investigations demonstrated that fecal supernatants from UC patients can affect visceral sensitivity and colonic permeability in mice that was mediated *via* differing protease receptors (see protease receptors in this review). Together these studies suggest a mechanism in which microbial proteases can alter intestinal barrier function by regulating tight-junctions.

## ENTERIC MICROBIAL PROTEASES AND IMMUNE CELL REGULATION

Once the intestinal epithelial barrier has been breached microbes or microbial antigens can potentially traverse into the underlying tissues of the intestine and interact with immune cells, ultimately leading to inflammation. Although enteric microbes are essential environmental

factors for immune cell development, as evidenced by an under established immune system found in germ-free mice<sup>[95]</sup>, the immune system can also be subverted by enteric microorganisms *via* microbial proteases. Bacterial proteases capable of disrupting cytokine signaling can potentially affect the pathogenesis of disease. For example, cysteine protease gingipains K (Kgp) and R (RgpA and RgpB) are produced by *P. gingivalis* and are significant factors in this oral microbe's pathogenesis<sup>[96]</sup>. Soluble gingipains secreted by *P. gingivalis* are capable of cleaving the N-terminus of IL-8 and enhancing this cytokine's activity of attracting neutrophils<sup>[97]</sup>. Additionally, Kgp, RgpA, and RgpB can also instantly degrade IL-8 when these enzymes are associated with membrane vesicles of *P. gingivalis*. This dual role of enhancing and inhibiting immune cell activity by the soluble and membrane-bound forms of these microbial proteases, respectively, may explain the pro- and anti-inflammatory sites found in periodontitis infections. The massive infiltration of neutrophils at periodontitis sites without the elimination of infection may also be explained by the dual roles of these microbial proteases. Another example is that of necrotizing fasciitis caused by *Streptococcus pyogenes* (*S. pyogenes*) that is characterized by an absence of neutrophils within lesions. It has been reported that the relative absence of neutrophils in necrotizing fasciitis lesions were due to restricted proteolysis of the C-terminal of IL-8 by the *S. pyogenes* protease *SlyCEP*<sup>[98]</sup>. Further investigations revealed that cleavage of the IL-8 C-terminal by *SlyCEP* from *S. pyogenes* is sufficient to reduce neutrophil endothelial trans-migration and is fundamental in the promotion of resistance of this microbe to neutrophil killing<sup>[99]</sup>. Given that a homologue of *SlyCEP* has been found in another *Streptococcus* species and no substrates other than cytokines have been identified, it is likely that this microbial protease is an effective weapon used by streptococci to impair bacterial clearance by neutrophils. Enteric microbial proteases can not only affect cytokines that are responsible for attracting the cellular branch of the innate immune system, but can also directly act upon neutrophils, macrophages, monocytes, and natural killer cells. SpeB from *S. pyogenes* has been shown to cause mitochondrial damage and prevent phagocytosis by granulocytes<sup>[100]</sup>. Additionally, a cysteine protease from *Staphylococcus aureus* (SspB) has been shown to selectively cleave CD11b on phagocytes which undergo apoptosis and are subsequently cleared by macrophages<sup>[101]</sup>. Taken together these studies identify microbial proteases from pathogenic and potentially commensal sources important molecules that have the ability to regulate the host immune system *via* specific mechanisms.

## FUTURE FOR MICROBIAL PROTEASES AND IBD

The importance of the enteric microbiota in IBD has been established during the last decade<sup>[102]</sup>. Currently, efforts are being made to decipher the pathways through which bacteria and their products cross-talk with various

cell types in the digestive tract that can potentially mediate inflammatory responses, pain or protection from chronic inflammation. The diversity of bacterial proteases and their effect on the intestinal epithelial, immune cells, and the enteric nervous system through various receptors open new avenues for research and potential therapeutic targets. Characterization of pathogenic proteases in IBD, the bacterial species that produce them and their mechanism of action are required to enhance our capability to understand the pathogenesis of these diseases and therapeutically intervene. Potential targets for therapeutic intervention include the following.

### Specific bacterial groups that carry potentially pathogenic bacterial proteases

The list of specific enteric bacteria that carry bacterial proteases that can disrupt epithelial barrier function and cause colitis in animal models is small and has been discussed earlier in this review. In humans there is even less information. However, the beneficial effects of antibiotics and probiotics in pouchitis<sup>[103,104]</sup> and IBS<sup>[105-107]</sup>, and antibiotics in CD<sup>[108]</sup> are well established. Although the proposed mechanisms for antibiotic and probiotic action are beyond the scope of this review, it is conceivable that one of the mechanisms involves action against protease-producing bacteria that cause increased permeability, pain and activation of the immune response. Future research characterizing these bacteria using high throughput sequencing, proteomics and metabolomics will potentially identify microbial targets for treatment of IBD.

### Bacterial proteases

Production of proteases is not restricted to bacteria. Host derived proteases have an important role in normal physiology of the digestion, immune response, signaling *etc.* Therefore, strategies that target bacterial derived, intraluminal, colonic proteases without harming the host may prove to be beneficial. Novel drugs for IBD could potentially target bacterial protease production or secretion, such as the serine protease autotransporters from *Enterobacteriaceae*<sup>[12]</sup>. This approach was recently demonstrated by Löwer *et al*<sup>[109]</sup> who investigated a specific inhibitor for the *Helicobacter pylori* serine protease. High temperature requirement A (HtrA) is a secreted serine protease that cleaves E-cadherin on the surface of host cells and disrupts the epithelial barrier. Through a receptor-based virtual screening method, they found a specific inhibitor of HtrA activity that was able to prevent *in vitro* cleavage of E-cadherin, without cross reactivity to mammalian proteases. HtrA is a virulence factor for other enteric bacteria, such as *E. coli*, *Shigella flexneri* and *Campylobacter jejuni*<sup>[110]</sup>. Thus, examining the ability of this inhibitor to reduce HtrA activity and its effect on intestinal inflammation and permeability in models of colitis is warranted.

An alternative approach is to use probiotics that can be beneficial through various mechanisms such as favorable metabolic effects on the epithelial cells, anti-bacterial activity or directly through production of protease inhibi-

tors. For example, *Bifidobacterium longum* and *Bifidobacterium breve* produce serine protease inhibitors (serpins)<sup>[111,112]</sup> that may antagonize potentially pathogenic bacteria proteases and may exert at least part of its favorable effects on the colon through this mechanism. Another probiotic micro-organism, the yeast *Saccharomyces boulardii*, produces a serine protease that is beneficial to the host through its activity against *Clostridium difficile* adherence to the gut wall and against its toxin, and thus suppresses bacterial overgrowth and infectious colitis<sup>[113]</sup>. These examples demonstrate that the potential favorable effects of the enteric microbiota on gut inflammation are vast and involve multiple mechanisms that are not yet fully understood.

### Protease activated receptors

PARs can be activated or antagonized by synthetic peptides that are analogous to the tethered ligand, irrespective of proteolytic cleavage of the receptor. Design of new, selective and potent drugs that correspond to the tethered ligand but also contain non-peptidic moieties may become useful in selective activation or inhibition of specific PARs. Activation of PAR2 is associated with colitis in animal models and has been used as a colitis model in rats<sup>[67]</sup> while oral administration of PAR2 antagonist resulted in amelioration of colitis. Although it is not clear if this action antagonizes host or bacterial derived proteases, the advantage of this approach is that it targets the final common receptor of the proteases, regardless of their source (bacterial or mammalian).

An additional approach would be to block PAR associated receptors. There is evidence that PAR signaling by *Candida* or *Aspergillus* on PMNs depends on the presence of TLR 2 and 4<sup>[49]</sup>. Although, similar studies regarding enteric epithelial cells is lacking, it is conceivable that such mechanisms are also required to induce PAR signaling on epithelial cells, and thus may serve as additional potential targets against activation by microbial proteases.

### Inhibitors of downstream molecular pathways

Activation of PARs by bacterial proteases results in diverse and complex signaling pathways. Characterization of specific pathways that may be inhibited to block the pathogenic effect of bacterial proteases without harming host homeostatic pathways, are required. Pepducins are such an evolving therapy<sup>[114]</sup>. Pepducins are lipoprotein molecules, composed of a synthetic peptide sequence (10-20 amino acids) that relates to the GPCR intracellular sequences and of a lipid hydrophobic moiety. The lipid component tethers the pepducin in the lipid bilayer membrane of the cells and enables these molecules to interact with specific and stabilize GPCRs (for review, Dimond *et al.*<sup>[115]</sup>). Specific pepducins that act as antagonists of PAR1 GPCR (P1pal-7) have shown favorable results in pre-clinical trials for lung cancer<sup>[116]</sup>. Additionally, PAR2 GPCR specific pepducin (P2pal-18S) ameliorates experimental pancreatitis through inhibition of PAR2 action that is expressed on pancreatic acinar cells<sup>[117]</sup> and ameliorates inflammation in additional mouse models<sup>[118]</sup>.

## CONCLUSION

In this review we have discussed the putative role and evidence of microbial proteases in inflammatory bowel disease pathogenesis. Proteases are essential for normal physiological development and are involved in numerous processes in our body. They are secreted by various cell types and their receptors are abundant in the gut wall, on immune cells, epithelial cells, and on neuronal cells. A growing amount of evidence supports a role for proteases and their receptors to IBD pathophysiology. The understanding that the enteric microbiota are crucial to disease initiation, and the fact that proteases are secreted by most bacteria and are considered virulence factors in infectious colitis, suggest that perhaps commensal bacterial proteases can also damage epithelial barrier function and may be involved in the initiation and perpetuation of IBD in genetically predisposed patients. Indeed, in this review we have summarized the current evidence that support this notion, the mechanisms through which bacterial proteases can impact the mucosal barrier function (through activation of PAR receptors), and the downstream signal pathways that result in increased epithelial permeability and perhaps in colitis.

However, it is not clear whether the proteolytic activity found in the gut lumen is exclusively of mammalian or bacterial origin. This is complicated by the fact that mammalian proteases, such as pancreatic digestive enzymes, are abundant in the gut lumen, and proteases secreted within the gut wall by leukocytes, such as neutrophils (cathepsin G) or mast cells (tryptase), “spill” into the inflamed gut. These factors may account for some of the discrepancies found between various studies investigating the origin of luminal proteolytic activity and the receptors they activate. Moreover, it is currently difficult to characterize luminal proteolytic activity, and while some research studies examine tryptic activity or gelatinase activity (each of which represents only a portion of the total luminal proteolytic activity) other studies have sought to characterize total luminal protease activity *via* functional assays and through inhibition of specific protease activity. These challenges may also explain why it is not fully clear which PAR isotype mediates increased enteric permeability and inflammation. For example, PAR1 and PAR2 have been implicated in mediating enteric inflammation or permeability by bacterial proteases or mammalian proteases while activation of PAR4 can equally result in increased enteric permeability. It is not improbable to hypothesize that for increased intestinal permeability and colitis to occur there is a multi-factorial hit process that results in activation of multiple PARs simultaneously by different proteases.

Only now we begin to unravel the effects of alterations in the normal enteric microbiota (dysbiosis), and how these “normal” bacteria can potentially induce colitis. The current challenge is to explore which commensal bacteria can secrete proteases that result in damage of the mucosal barrier. Additionally, we need to understand

which microbes are associated with colitis and what the genetically predisposing factors are that “allow” these events to happen. For example, genetic mutations associated with the reduction of mucus production and increased mucosal bacterial adherence, immune abnormalities that result in dysbiosis, and innate immune response defects that cause dysregulated immune responses once the mucosal barrier is breached.

Investigating these aspects through cell lines, mono-associated gnotobiotic animals, Ussing chambers, high-throughput sequencing of microbial DNA, metabolomics and genome wide association studies will enable us to understand the role of enteric microbial proteases in the pathogenesis of IBD and to develop effective targeted therapies that will involve specific enteric bacteria, PARs, and the downstream regulation and host immune response.

**Key words:** Optical biopsy; Confocal endomicroscopy; Endocytoscopy; Dysplasia; Mucosal inflammation; Disease relapse; Mucosal healing; Barrier function

**Core tip:** This is a review of the latest advances in the applications of optical biopsy (either with confocal laser endomicroscopy of endocytoscopy) in inflammatory bowel disease. Clinical indications including assessment of mucosal inflammation, detection of dysplasia and predictors for disease relapse are discussed in detail. Novel research use of optical biopsy for functional mucosal assessment is also discussed.

## Abstract

In this review, we will discuss the use of two optical biopsy modalities in inflammatory bowel disease (IBD). The two techniques reviewed here are confocal laser endomicroscopy and endocytoscopy. We will describe the technical performance of the procedure, discuss the clinical indications for optical biopsy in IBD, and high-

## INTRODUCTION

In the past decade, several advanced endoscopic imaging technologies that enable clinicians to examine the luminal gastrointestinal tract at a microscopic level were introduced. These techniques are called optical biopsies, as they are real-time histologic biopsies of the tissue. These include confocal laser endomicroscopy (CLE) and

endocytoscopy (EC). The CLE and EC systems come as either probe-based (pCLE and pEC) or endoscope-based (iCLE and iEC). In this review, we will describe the technical performance of the procedure, and discuss the clinical indications for optical biopsy in relation to inflammatory bowel diseases (IBD). We will also highlight some active research applications for optical biopsy in our understanding of the pathogenesis of IBD.

## TECHNICAL ASPECTS OF OPTICAL BIOPSY

CLE was introduced in 2003 and allows *in vivo* microscopic imaging of cellular and subcellular structures at approximately 1000-fold magnification<sup>[1]</sup>. The technique is based on tissue illumination with a low power laser after application of fluorescence agents, which can either be applied systemically (*i.e.*, fluorescein sodium) or topically (*e.g.*, acriflavine hydrochloride, cresyl violet). The laser light is reflected from the tissue and then refocused onto the detection system by the same lens, so that only returning light refocused through the pinhole is detected. Therefore, this process decreases the effect of scattered light resulting in the construction of two-dimensional grey-scale images.

Currently, two CE certified and Food and Drug Administration approved CLE-devices are available<sup>[1]</sup>. One is integrated into the distal tip of a standard, high-resolution endoscope (iCLE, Pentax, Tokyo, Japan). The other one is probe based, capable of passage through the accessory channel of any standard endoscope (pCLE, Cellvizio, Mauna Kea Technologies, Paris, France). Both systems use an incident 488 nm wavelength laser (blue laser light) enabling the detection of fluorescence between 205 nm and 585 nm wavelengths.

The iCLE-system collects images at a manually adjustable scan rate of 1.6 frames per second with a resolution of  $1024 \times 512$  pixels, or at 0.8 frames per second with a resolution of  $1024 \times 1024$  pixels with dynamically adjustable depth of scanning ranging from 0 to 250  $\mu\text{m}$ . The examiner can manually adjust the laser power between 0 and 1000  $\mu\text{W}$  and the optical slice thickness is 7  $\mu\text{m}$ , with lateral and axial resolution of 0.7  $\mu\text{m}$  and a confocal image field of view of  $475 \times 475 \mu\text{m}$ . The pCLE-system is a stand-alone confocal probe which is advanced through the working channel of any endoscope and could thereby also being used with high-definition video endoscopes in combination with dye-less chromoendoscopy (*e.g.*, Narrow Band Imaging, Fuji Intelligent Chromo Endoscopy, i-scan) as red-flag techniques.

pCLE-systems are available for different indications throughout the entire gastrointestinal tract and use a fixed laser power and a fixed image plane depth which is dependent on the probe type used. Confocal images are streamed at a frame rate of 12 frames per second. CLE in IBD is mostly being performed by using the ColoFlex Ultra-High Definition probe which requires a 2.8 mm working channel to be advanced through the scope. Lat-

eral resolution is 1  $\mu\text{m}$  and field of view is 240  $\mu\text{m}$  with an imaging plane depth of 65  $\mu\text{m}$ . In addition, a special computer algorithm ("mosaicing") allows reconstruction of single video frames with an increased field of view ( $4 \text{ mm} \times 2 \text{ mm}$ ). Costs for single probes vary and are approximately 100-200 Euro per procedure. Like any other endoscopic technique CLE requires special training in performing the procedure and interpretation of images. Therefore, especially at the beginning, extensive close collaboration with an expert histopathologist is strictly recommended. In addition, when starting with CLE optical biopsies should always be compared with physical biopsies. After an appropriate learning phase, CLE interpretation shows high inter- and intraobserver variabilities as compared to standard histology. Both CLE-systems have unique advantages. Advantages of the integrated system are its higher resolution and the possibility to alter the laser power and imaging plane depth. Advantages of the probe-based system include the possibility of an *ad hoc* usage and a greater versatility of the pCLE probes, which can be used with nearly any endoscopes.

In contrast to CLE, endocytoscopy (EC; Olympus, Tokyo, Japan) is based on the principle of contact light microscopy<sup>[2]</sup>. EC-systems are either integrated into the distal tip of a standard endoscope (iEC) or probe-based (pEC). Through-the-scope pEC-systems require a working channel of at least 3.2 mm. Similar to contact light microscopy, EC requires thorough mucolysis with N-acetyl cysteine followed by staining of the mucosa with absorptive staining agents, like methylene blue, toluidine blue, or cresyl violet. In fact, a combination of different dye agents is often used to acquire optimal tissue contrast<sup>[3]</sup>. After an appropriate time of exposure to the dye (approximately 60 s), repeat washing of the mucosa is necessary to remove the excess contrast dye before endocytoscopic imaging. Repeat staining is mostly necessary while using absorptive contrast agents. Depending on the system used (iEC or pEC), EC visualizes architectural details (*e.g.*, epithelial structure), cellular features (*e.g.*, size and arrangement of cells), and vascular pattern morphology (*e.g.*, size and tortuosity) at a magnification of up to 1390-fold<sup>[2,3]</sup>. Representative image of normal colon mucosa is shown in Figure 1.

## CLINICAL APPLICATIONS: ASSESSMENT OF INFLAMMATION IN IBD

### Endomicroscopy

Accurate assessment of mucosal inflammation in patients with IBD is of crucial importance as mucosal healing has emerged as an important treatment goal and appears to be of paramount importance for optimized medical therapy<sup>[4]</sup>. Various studies and one recent systematic review has shown that mucosal healing as assessed by endoscopy is predictive of reduced disease activity, a decreased need for active treatment, reduced rates of hospitalizations/surgical resections, and is associated with sustained clinical remission<sup>[4-7]</sup>. While standard white-light endoscopy is

Figure 1 Endocytoscopic image at magnification  $\times 1390$  showing one single colonic crypt. Goblet and epithelial cells are clearly evident.

likely an insensitive test for assessment of mucosal healing, being false negative in up to fifty percent of patients, there is an urgent need for new endoscopic imaging techniques allowing assessment of microscopic inflammation even in case of macroscopic non-inflamed mucosa<sup>[8,9]</sup>. In this context CLE was proven to be efficient for real-time *in vivo* assessment of mucosal inflammation by requiring only a short learning curve<sup>[10]</sup>.

One early study investigated the features of CLE in inflamed and non-inflamed rectal mucosa and compared these results to standard histology<sup>[11]</sup>. On CLE, colonic crypts of normal colonic mucosa were small, round and regularly arranged, and the crypt lumens of the colonic glands were small and round. In contrast colonic crypts in non-active ulcerative colitis were small, round and slightly irregular in arrangement and the crypt lumens of the colonic glands were small and round. Inflammatory cells and capillaries were visible in the lamina propria. The colonic crypts in active ulcerative colitis were large, variously shaped and irregular in arrangement and in addition numerous inflammatory cells and capillaries were visible in the lamina propria. Li *et al*<sup>[12]</sup> confirmed these early results in a study including 73 consecutive patients. CLE-assessment of crypt architecture and fluorescein leakage showed good correlation with the corresponding histology results. Of note, more than half of the patients with normal mucosa seen on conventional white-light endoscopy revealed acute inflammation on histology, whereas no patients with normal mucosa or with chronic inflammation seen on CLE showed acute inflammation on histology. Therefore, CLE appears to be a sensitive tool for real-time assessment of inflammatory activity in patients with ulcerative colitis.

For Crohn's disease, our group evaluated in a case-control study whether CLE is feasible for *in vivo* diagnosis of Crohn's disease associated histological changes<sup>[13]</sup>. It was shown that a significantly higher proportion of patients with active Crohn's disease had increased colonic crypt tortuosity, enlarged crypt lumen, microerosions, augmented vascularization, and increased cellular infiltrates within the lamina propria. In quiescent Crohn's disease, a significant increase in crypt and goblet cell number was detected compared with controls. Based on these find-

Figure 2 Endoscope-based confocal laser endomicroscopy of Crohn's disease shows remarkable cell infiltration, disturbed colonic architecture and leakage indicating severe inflammation.

ings, the Crohn's Disease Endomicroscopic Activity Score was proposed, allowing the assessment of Crohn's disease activity *in vivo*, even in macroscopically non-inflamed mucosa. Representative iCLE and pCLE images of Crohn's disease are shown in Figures 2 and 3. Taken these and the above mentioned results into account, CLE is reliable for real time *in vivo* assessment of microscopic inflammation in patients with IBD and macroscopically non-inflamed mucosa.

As most commonly used drugs for treatment of IBD are systemically bioavailable, they cover a potential risk of severe side effects. Therefore, a targeted, individualized approach to inflamed areas of the intestine with specific drugs is highly desirable. In this context, one recent study evaluated the potential of nanoparticle and microparticle uptake into the rectal mucosa of human IBD patients<sup>[14]</sup>. CLE was performed two hours after rectal application of fluorescent-labeled placebo nanoparticles and microparticles to 33 patients with IBD and healthy controls in order to visualize the particles in inflamed mucosal areas. A significantly enhanced accumulation of microparticles was observed in ulcerated areas, whereas nanoparticles were only visible in trace amount on mucosal surfaces of normal patients. Therefore, nanoparticles may enable local drug delivery to intestinal lesions in humans, thereby minimizing the risk of unintended translocation into the blood system. Very recently, our group created a fluorescent labeled antibody for molecular membrane-bound tumor necrosis factor (mTNF) imaging in Crohn's disease patients<sup>[15]</sup>. Topical antibody administration led to detection of intestinal mTNF positive immune cells during CLE. Interestingly, patients with high amounts of mTNF positive cells showed significantly higher short-term response rates at week 12 (92%) upon subsequent anti-TNF therapy as compared to patients with low amounts of mTNF positive cells (15%). This clinical response in the former patients was sustained over a follow-up period of one year and associated with mucosal healing on follow-up endoscopy. These results are promising and offer the exciting potential for individualized therapy for IBD patients using molecular imaging with fluorescent labeled antibodies.

**Figure 3** Probe-based confocal laser endomicroscopy in patient with Crohn's disease without histologic activity. Colonic crypts are regularly arranged with normal shape and size. Micro-vessels within the lamina propria are easily visible. Bar = 20  $\mu$ m.

### Endocytoscopy

Only limited data are currently available on the potential of EC in patients with IBD. One recent article correlated the efficacy between endocytoscopy and conventional histopathology for assessment of microscopic features in patients with ulcerative colitis<sup>[16]</sup>. Fifty-five patients were included and mucosal patterns were evaluated by using EC with  $\times 450$  magnification. Based on EC-findings a scoring system was developed that showed a strong correlation with Matts' histopathological grades. In addition, there was a strong correlation between the conventional Matts' endoscopic grade and Matts' histopathological grade. Furthermore, the newly developed EC-score showed high reproducibility among investigators with a  $\kappa$  value of 0.79. Another recent study determined the reliability of EC for the discrimination of mucosal inflammatory cells and intestinal inflammatory disease activity in patients with IBD<sup>[17]</sup>. In total, 40 patients were included and EC was reliable to distinguish single inflammatory cells, including neutrophilic, basophilic, and eosinophilic granulocytes and lymphocytes. Sensitivity and specificity ranges among different cell types between 60% and 89% and 90% and 95%, respectively. Interobserver agreement among investigators was substantial whereas intraobserver agreement was almost perfect. Moreover, concordance between endocytoscopy and histopathology for grading of intestinal disease activity was 100%.

In conclusion, EC holds significant potential in identifying early signs of mucosal inflammation in real-time by identifying single mucosal inflammatory cells in conjunction with architectural details. Large, prospective multicenter trials evaluating EC for prediction of disease course in IBD are thus highly warranted and anticipated.

## CLINICAL APPLICATIONS: DYSPLASIA DETECTION IN IBD

Patients with IBD are at an increased risk for the development of dysplasia (also known as intraepithelial neoplasia) and colitis associated cancer (CAC). The risk of

developing CAC is comparable for Crohn's colitis and ulcerative colitis patients. In both cases the risk is increased with: duration of colitis, early age of IBD onset, extent of colonic involvement, severity of inflammation, family history of colorectal cancer and particularly the presence of primary sclerosing cholangitis<sup>[18]</sup>. The cumulative risk for developing CAC in primary sclerosing cholangitis associated IBD (PSC-IBD) patients is 33% at 20 years and 40% at 30 years compared to 8% and 18% in IBD without concomitant liver disease<sup>[19]</sup>. Although IBDs contribute only 1%-2% to all cases of colorectal cancer, the cancer-related mortality rate in IBD patients is approximately 15%<sup>[20,21]</sup>.

Colonoscopy with random biopsies, which is the gold standard for CAC screening in long standing IBD, can significantly reduce CAC-related mortality<sup>[22]</sup> and IBD patients undergoing surveillance colonoscopy had detection of neoplasia at an earlier stage, resulting in a better corresponding prognosis<sup>[23]</sup>. The principal limitation with this modality is that neoplasia may not be appreciated in up to a third of colonoscopies<sup>[24,25]</sup>. Taking four-quadrant biopsies is time-consuming and has only moderate sensitivity for neoplasia detection. The efficacy of surveillance for detection of early malignancies could also be questioned from the standpoint of cost and adherence. A population-based analysis of the cost and practice of colonic surveillance of patients with PSC-IBD in Alberta, Canada revealed that only 1/3 of the colonoscopies expected were actually performed, but despite suboptimal surveillance, the incidence of colorectal neoplasia was high. The study also found that the cost of finding one additional case of dysplasia was substantial<sup>[26]</sup>. Moreover, dysplasia in IBD can be found at distant sites from the cancer itself or before the cancer develops and is difficult to recognize on colonoscopy, as it often arises from flat, normal-appearing mucosa<sup>[20]</sup>. Dysplasia can also occur within or near plaque-like lesions or raised polypoid masses, defined as dysplasia-associated lesion or mass (DALM).

Targeted biopsies are an attractive alternative to random biopsies to increase the yield of dysplasia detection. CLE allows evaluation of suspicious lesions at the subcellular level with great detail prior to performing targeted biopsies, thus facilitating earlier diagnosis of CAC. While CLE only covers a limited field of view within the mucosa, pan-CLE of the whole colon is not feasible. Therefore, macroscopic visualization of suspected areas with chromoendoscopy (red flag technique) is useful before performing targeted endomicroscopy<sup>[27,28]</sup>. Prospective evaluation of CLE with concurrent chromoendoscopy predicted neoplasia in a randomized controlled trial of ulcerative colitis patients ( $n = 153$ ) with great accuracy (98%), sensitivity (95%) and specificity (98%). By using methylene-blue aided chromoendoscopy with CLE, the diagnostic yield of neoplasia was increased by 4.75-fold compared with conventional colonoscopy with random biopsies ( $P = 0.005$ ), though 50% fewer biopsy specimens were required<sup>[29]</sup>. Hurlstone *et al.*<sup>[30]</sup> demonstrated

**Figure 4** Probe-based confocal laser endomicroscopy images of (A) normal colonic mucosa; B: Adenomatous polyp with low grade dysplasia. Bar = 20  $\mu$ m; and C: The corresponding histologic image for the adenomatous polyp with dysplasia (magnification  $\times 40$ ).

remarkable results in a smaller ulcerative colitis cohort ( $n = 36$ ), where CLE enabled differentiation of DALM and adenoma-like mass with 97% accuracy and an excellent agreement between endomicroscopy and histopathological diagnosis was found ( $P = 0.91$ ). CLE based, targeted biopsies increased the diagnostic yield of intraepithelial neoplasia by 2.5-fold compared with chromoendoscopy-guided biopsies alone. One recent pilot study of pCLE during colonoscopic surveillance of patients with long-standing ulcerative colitis ( $n = 22$ ) demonstrated that the method is feasible with reasonable diagnostic accuracy<sup>[31]</sup>. A recent meta-analysis of 15 studies of confocal endomicroscopy for dysplasia detection<sup>[32]</sup> showed CLE could distinguish neoplasms from non-neoplasms in IBD patients for surveillance with a sensitivity of 0.83 (95%CI: 0.70-0.92) and specificity of 0.90 (95%CI: 0.87-0.93). Representative pCLE images of adenomatous polyp with low grade dysplasia and corresponding histologic images are shown in Figure 4.

CLE seems to be a particularly promising method for dysplasia detection in PSC-IBD patients. PSC-IBD is recently suggested to represent a specific IBD phenotype characterized by extensive colitis, low inflammatory activity, right-sided colonic inflammation and a high risk

of CAC. Jørgensen *et al*<sup>[33]</sup> showed a difference between the macroscopic and microscopic picture in PSC-IBD: in general the inflammatory activity in these patients was low and was not always visible endoscopically, though it could be seen histologically. Since proximal cancers are more common in PSC-IBD patients<sup>[34,35]</sup> and inflammatory activity is not always visible endoscopically the use of CLE may increase surveillance efficiency particularly in the right colon. One ongoing study evaluates the efficacy of pCLE as a complementary tool to high definition white-light endoscopy (HD-WLE) for the detection of colonic dysplasia in patients with PSC-IBD. Preliminary results ( $n = 25$ ) showed excellent accuracy (99%), sensitivity (93%) and specificity (100%) of pCLE in dysplasia detection that was superior to HD-WLE alone<sup>[36]</sup>. Low-grade intraepithelial neoplasia was found in 20% of patients and 60% of confirmed dysplastic lesions were localized in the right colon. These preliminary results suggest that careful CLE examination of at least the right colon in PSC-IBD patients may be warranted.

## CLINICAL APPLICATIONS: ASSESSMENT OF CELL EXTRUSION AND BARRIER FUNCTION FOR DISEASE RELAPSE

Mucosal healing has emerged as the most important endoscopic predictor of disease relapse in IBD patients. In the pre-biologic era, mucosal healing was associated with lower rate of relapse in ulcerative colitis but not Crohn's disease patients<sup>[6]</sup>. In the biologic era, mucosal healing is predictive of clinical and endoscopic remission for both Crohn's<sup>[7,37]</sup> and ulcerative colitis patients<sup>[38,39]</sup>. The use of optical biopsy in the small bowel in IBD patients have been studied by several groups<sup>[1,40,41]</sup>. The principal finding on CLE that appears to predict disease relapse is epithelial cell extrusion and associated barrier dysfunction<sup>[42,43]</sup>. Using CLE, Kiesslich *et al*<sup>[40]</sup> first reported unambiguous identification of epithelial gaps or extrusion zones in the intestine of patients. Epithelial cell extrusion occurs as part of a normal physiological renewal process of the intestine. Therefore, qualitative description of the presence or absence of epithelial gaps is not sufficient to discern a diseased from a healthy state. We have therefore developed a quantitative measure called epithelial gap density, defined as the total number of epithelial gaps counted normalized to the total number of epithelial cells counted on pCLE images<sup>[41]</sup>. Gap density was validated against conventional multi-photon confocal microscopy and conventional white-light microscopy<sup>[44]</sup>. The gap density was found to be increased in IBD patient<sup>[45]</sup>. More recently, increased gap density and certain types of epithelial gaps were found to be predictive of aggressive disease<sup>[43]</sup> and relapse in IBD patients<sup>[42]</sup>. Thus, qualitative and quantitative studies of epithelial gaps in the small intestine may have a role in defining new management algorithms for IBD patients.

The clinical applications of CLE (both pCLE and

iCLE) in the small intestine of IBD patients have been largely in the evaluation of the terminal ileum<sup>[40,42,43,45]</sup>. The terminal ileum is the preferred site of intestinal evaluation in IBD for a number of reasons: (1) it is within the reach of a standard colonoscope; (2) it is an active site of immunologic activity; (3) it is often the first site of disease in Crohn's patients; and (4) it is usually possible to find endoscopically normal appearing areas, even in patients with active Crohn's ileitis. We have devised a quantitative determination of the density of epithelial gaps or extrusion zone called the epithelial gap density in the terminal ileum<sup>[41,45]</sup>. The epithelial gap density derived using CLE could be validated against multi-photon confocal microscopy and light microscopy<sup>[46]</sup>. Increased epithelial gap density could identify patients at high risk for major events such as hospitalization or surgery in follow up<sup>[43]</sup>. In another recent study, certain types of epithelial gaps were found to be predictive of disease relapse in IBD patients<sup>[42]</sup>. The current evidence seems to suggest that quantification and evaluation of extrusion zones in the terminal ileum of IBD patients have predictive values for disease relapse. However, these are single-centered studies, and there are no multicenter trials to determine the role of CLE in the management of IBD patients.

## RESEARCH APPLICATIONS: FUNCTIONAL MUCOSAL ASSESSMENT IN IBD

The intestinal epithelium functions as a selective barrier to the luminal contents<sup>[47,48]</sup>. The epithelium separates the immune and neural networks of the human intestine from the intestinal microbiota, which comprises an estimated  $10^{13}$  to  $10^{14}$  microorganisms<sup>[49]</sup>. Compromised epithelial barrier expose the subepithelial immune system to resident microbes which induces secretion of pro-inflammatory cytokines, such as tumor necrosis factor (TNF)- $\alpha$ <sup>[50]</sup>, which in turn induces shedding of epithelial cells from the intestine which then further contributes to barrier dysfunction and promotes inflammation<sup>[51]</sup>. Other proinflammatory cytokines, including interleukin (IL)-1 $\beta$ , IL-6, IL-18 and TNF- $\alpha$  have been reported to be increased in active IBD and correlate with endoscopic severity of inflammation<sup>[52,53]</sup>.

Until advances of optical biopsy, either *via* CLE or EC, it was not possible to investigate the interactions between the intestinal epithelium and resident microbiota *in vivo*. Histologic evaluation of the intestinal mucosa is limited by fixation and processing artefacts, including contamination with luminal microbes. CLE was used to identify intramucosal bacteria, and IBD patients were found to have significantly higher distribution of involvement with intramucosal bacteria in the colon and terminal ileum<sup>[54]</sup>. CLE was recently used for molecular imaging to identify single bacteria species and *in vivo* diagnosis of bacteria associated colitis<sup>[55]</sup>.

Barrier dysfunction is another area of research interest for the past few years. Restoration of normal epithelial barrier function which prevent the translocation of

commensal bacteria is the structural basis of mucosal healing<sup>[4]</sup>. Intestinal permeability function as assessed with disaccharide solutions<sup>[56,57]</sup> has not been widely adopted for clinical use. Optical biopsy permits assessment of mucosal barrier function in the appropriate structural context. Studies have shown increased epithelial cell shedding may contribute to barrier dysfunction in the intestine<sup>[42,58]</sup>. The clinical relevance of cell shedding and barrier dysfunction is reflected in the ability of these measures to predict disease relapse and major events in follow up<sup>[42,43]</sup>.

## CONCLUSION

Optical biopsy of the intestine in IBD have been used for a variety of clinical and research indications, and appears to hold significant promise to improve the diagnosis and management of IBD patients. Future large, multi-centered studies are needed to validate these early study findings to facilitate clinical adaptation of this group of new advanced imaging technique.

## Abstract

The use of specific terms under different meanings and varying definitions has always been a source of confusion in science. When we point our efforts towards an evidence based medicine for inflammatory bowel diseases (IBD) the same is true: Terms such as "mucosal healing" or "deep remission" as endpoints in clinical trials or treatment goals in daily patient care may contribute to misconceptions if meanings change over time or definitions are altered. It appears to be useful to first have a look at the development of terms and their definitions, to assess their intrinsic and context-independent problems and then to analyze the different relevance in

present-day clinical studies and trials. The purpose of such an attempt would be to gain clearer insights into the true impact of the clinical findings behind the terms. It may also lead to a better defined use of those terms for future studies. The terms "mucosal healing" and "deep remission" have been introduced in recent years as new therapeutic targets in the treatment of IBD patients. Several clinical trials, cohort studies or inception cohorts provided data that the long term disease course is better, when mucosal healing is achieved. However, it is still unclear whether continued or increased therapeutic measures will aid or improve mucosal healing for patients in clinical remission. Clinical trials are under way to answer this question. Attention should be paid to clearly address what levels of IBD activity are looked at. In the present review article authors aim to summarize the current evidence available on mucosal healing and deep remission and try to highlight their value and position in the everyday decision making for gastroenterologists.

**Key words:** Inflammatory bowel disease; Mucosal healing; Deep remission; Treatment targets; Clinical activity

**Core tip:** "Mucosal healing" and "deep remission" have been discussed heavily as "new" treatment goals in inflammatory bowel diseases patients in recent years. This was based on evidence that the long term disease behaviour appears to be better, when mucosal healing is achieved. Unfortunately, a definite proof that therapy escalation for patients in clinical remission not achieving mucosal healing will be beneficial is still lacking. Clinical trials are under way to answer this question. At the moment it appears to be helpful to summarize the current evidence available on mucosal healing and deep remission to support the everyday decision making for gastroenterologists.

## INTRODUCTION

Assessing the activity of inflammatory bowel disease (IBD) is important for our daily practice treating patients with these chronic inflammatory diseases. The assessment of disease activity will guide our therapeutic decision and our choice of medication. Furthermore it is most important for clinical investigations of new treatment options and new drugs. The reduction of disease activity remains the most important endpoint in clinical trials.

However, the discussion on which parameters are most useful for this purpose is still ongoing and unresolved.

Assessment of activity of IBD can be performed on different levels such as clinical activity, biochemical activity (*e.g.* by measuring CRP or fecal calprotectin), endoscopy, and histology. Clinical remission in a given IBD patient does not necessarily imply biochemical, endoscopic, or histologic remission. To evaluate biochemical, endoscopic, and histologic activity, an increasing degree of invasive measures (blood sample, endoscopy, biopsies) is required. Assessing activity in IBD has thereby analogies to the iceberg phenomenon where the clinical assessment on the surface may show clinical remission, but inflammatory activity may still be present on biochemical, endoscopic, and histologic level (Figure 1).

## HISTOLOGICAL REMISSION AS INITIAL DEFINITION OF MUCOSAL HEALING

One of the first scientists and clinicians that used the term “healing” or “mucosal healing” within the field of IBD was Burton I. Korelitz, past chief of the Division of Gastroenterology at Lenox Hill Hospital in New York<sup>[1]</sup>. However, he used this term exclusively with respect to histological changes of the mucosa<sup>[1]</sup>. So when the term “mucosal healing” was introduced into IBD clinic it meant the absence of histological alterations of the mucosa. Korelitz was well aware that healing of IBD is not regarded to be possible as both Crohn’s disease (CD) and ulcerative colitis (UC) are regarded to be chronic diseases without spontaneous healing<sup>[2]</sup>. There may be an absence of symptoms and flares over years but mucosal inflammation may re-occur after remission for years or even decades (Figure 1).

Histological healing is difficult to determine especially in Crohn’s disease as the inflammation may be patchy and a biopsy could miss an inflammatory infiltrate only a few millimeters away<sup>[3]</sup>. Similarly, in UC the histological evaluation of a biopsy may be misleading<sup>[4]</sup>. Histological alterations may be absent from the rectum and sigmoid due to effective topical therapy despite the presence of

Activity assessment in IBD: the iceberg phenomenon

**Figure 1** Activity assessment in inflammatory bowel disease: The iceberg phenomenon. IBD: inflammatory bowel disease.

inflammation further proximal in the colon that may not be obvious to the endoscopist<sup>[4,5]</sup>. Histological healing would mean that we have to be sure that there had been an inflammatory infiltrate at a specific localization that completely disappeared upon therapy (or spontaneously). As is obvious this is hard or even impossible to prove as this would require frequent endoscopies with many biopsy samples and a labeling of former biopsy locations. Due to the impracticability of this approach the overall acceptance of the concept of “histological healing” was very limited<sup>[5]</sup>. Of note, newer techniques such as endomicroscopy suffer from the same shortcomings.

## ENDOSCOPIC REMISSION AS A NEW CONCEPT FOR MUCOSAL HEALING

In contrast to the initial concept of “mucosal healing” as a “disappearance of inflammatory infiltrate”<sup>[2]</sup> recent original manuscripts and reviews on the topic have used the term under different meanings. The “newer” meanings of “mucosal healing” have been summarized again by Korelitz in a critical review<sup>[2]</sup>. One of the “newer meanings” of mucosal healing would be the absence of inflammation (“healed mucosa”) to the eye of the endoscopist, a definition that now has been applied in many clinical trials<sup>[6-16]</sup>.

There is an obvious problem with this definition. One must assume the location of endoscopically normal mucosa has previously been inflamed<sup>[2]</sup>. Certainly this is easier to assess with endoscopy rather than histology as the area of evaluation is larger and small local differences and a patchy pattern would play a less important role. Nevertheless it requires that two endoscopic examinations are compared.

The definition also ignores that in endoscopically normal appearing mucosa there still may be histological inflammation. Another problem of this definition of course is that the inter-observer reproducibility of endoscopic IBD scores usually is very poor<sup>[17]</sup> and depends on the experience of the endoscopist<sup>[18]</sup> regardless of the technique used<sup>[19,20]</sup> (it may be discussed whether a kappa

between 0.7 and 0.8 is satisfying). Usually endoscopic findings are assessed on fixed point scales or described by dichotomous variables (present/absent)<sup>[18,21]</sup>. However, as outlined by de Lange and colleagues “endoscopic features of mucosal inflammation are continuous variables” for which dichotomous decisions are artificial and always require individual decisions<sup>[18]</sup>. The question arises how to interpret endoscopical findings indicating a clearly improved appearance of the mucosa in endoscopy with some or few remaining scattered erosions. A further important question arises with respect to endoscopical findings that cannot be interpreted as present inflammation but as residuals of former inflammation and a lack of complete normalization of the mucosa. Such findings would be pseudopolyps in an otherwise normal-appearing colon.

## BIOCHEMICAL (FECAL MARKERS) REMISSION AS MUCOSAL HEALING

Fecal markers such as calprotectin or lactoferrin correlate very well with the degree and extent of infiltration of the mucosa by leukocytes. A good correlation between fecal calprotectin and the Crohn's Disease Endoscopic Index of Severity (CDEIS) was reported in several studies<sup>[22,23]</sup>. There is also a good correlation of fecal calprotectin with the Simple Endoscopic Score for Crohn's disease (SES-CD) which itself has a strong correlation with the CDEIS (correlation coefficient  $r = 0.920$ ) and an excellent inter-observer reliability ( $\kappa$  coefficients 0.791-1.000)<sup>[24]</sup>.

In ulcerative colitis calprotectin correlates well with disease activity as determined by histology and endoscopy<sup>[25,26]</sup>.

It is a familiar experience to endoscopists that the mucosa may appear completely normal (healed) in patients that still have a markedly elevated fecal calprotectin. This would be an endoscopic remission but not biochemical remission, most likely reflecting a lack of histological remission with neutrophils still being present in the mucosal wall. It has been well established that calprotectin better correlates with histological findings (at least in UC) as compared to serum parameters or endoscopy<sup>[27-29]</sup>.

## MUCOSAL HEALING AND DEEP REMISSION: THE CONFUSED CLINICIAN

Surprisingly, some recent trials have reported a higher relative amount of patients with mucosal healing compared to the percentage of patients with clinical remission, especially in UC<sup>[30]</sup>. In those trials usually the endoscopist defined whether mucosal healing was present. How can this be explained? One reason could be that those patients had concomitant irritable bowel syndrome that was responsible for their complaints but no relevant remaining inflammation (“IBS superimposed on IBD”). The argument is straight forward and logical but it probably does not explain all cases. Firstly, little or no information is available on the

histological remission in those patients. Histological remission - if evaluated by biopsies - again may be patchy and the evaluated biopsies may not be representative. Damage to deeper layers of the mucosa may have occurred that are not visible to the endoscopist's eye. Therefore it has to be challenged whether healed mucosa to the eye of the endoscopist is indeed the “most satisfying objective confirmation to support the clinical response” as outlined by Korelitz<sup>[2]</sup>. As he states the endoscopic healing “might be satisfactory for comparison in time for response to therapy in an individual case, but not for mucosal healing as an entity and certainly not to be used as an index of response to therapy in trials.”<sup>[2]</sup>

To minimize the subjective component many clinical trials now apply the principle of a “central reader”. Not only does this make trials more complicated, more expensive and more time consuming. It substitutes the problem of a bias introduced by many subjective evaluations of the mucosal response to a bias introduced by one subjective interpretation of findings. The intra-observer agreement for many endoscopic scores is not satisfactory. It may well be argued that the subjective criteria used by a central reader may not be accepted by others and that there could be a reduction of bias by a “multi-subjective” view (as we assume is the case for multicenter trials as compared to monocentric studies). Of note, in a recent randomized-controlled trial in patients with UC the conclusion was significantly changed after blinded central review of endoscopic images, suggesting that central reading of endoscopy may be necessary for regulatory purposes<sup>[31]</sup>. However, the question about the best method of objective endoscopic assessment is far from being answered.

Korelitz<sup>[2]</sup> suggested that histological healing should be the “minimal criterion for mucosal healing and preferably this information should be derived from multiple biopsy sites of previous inflammation”. However, this would implicate that the evaluation of inflammation by a pathologist is objective. There have been studies on the inter-observer and intra-observer agreement of pathology findings<sup>[32]</sup>. Those results are not very encouraging. When a number of established criteria were used (excess of histiocytes in combination with a villous or irregular aspect of the mucosal surface and granulomas) experienced pathologists could correctly classify 70% of CD patients and 75% of UC patients<sup>[32]</sup>. Especially in mild disease, there is still dispute as to whether the presence of a “physiological (minor) inflammation” should be regarded as manifestation of IBD or not. Clinically unaffected siblings of IBD patients may show mild histological inflammation and increased cellular activation markers<sup>[33]</sup>. Cell counting will not solve the problem. The request for a “central pathology reader” also is not helpful as the same dilemma as for the central endoscopy reader will occur. Moreover, different pathologists have suggested different criteria to evaluate the presence or absence of “un-normal” inflammation (for an overview see<sup>[3,34-37]</sup>). There is no agreement on that. Geboes for ex-

ample suggested that the presence of neutrophils in the intestinal epithelium is an important discriminator for the presence or absence of inflammation. He therefore suggested that a combination of endoscopy and histology should be used to evaluate the presence of inflammation in IBD patients to finally judge whether mucosal healing has been achieved (see above).

## MUCOSAL HEALING AND DEEP REMISSION: THE CONFUSED SCIENTIST

CD and UC are regarded to be chronic diseases that never disappear. The concept of a healing of a part of the body affected by such a disease subsequently is surprising for scientists working on the elucidation of the pathophysiology of IBD.

However, there is another aspect that is disturbing. There have been reports that even in macroscopically and microscopically normal appearing mucosa specific changes can be found that are characteristic for inflammation or at least changes that could be associated with the pathophysiology<sup>[38-45]</sup>.

Changes of the microbiota in the lumen of the gut have been described in IBD patients despite the absence of detectable inflammation<sup>[46-51]</sup>. Could a “complete deep remission” be possible without normalization of the intestinal microbiome? The mucus layer of the mucosa may be changed also in normal appearing mucosa in endoscopy<sup>[52-56]</sup>. The normal fixation procedure of biopsies and the subsequent H&E staining does not allow evaluation of the mucus layer as it is destroyed during this procedure. A reduced thickness of the mucus layer in UC in remission has been described<sup>[54,56,57]</sup> as well as a reduced secretion of mucin<sup>[52,53,58-60]</sup> or defensins<sup>[61-64]</sup>. The question arises whether the mucosa can be termed as “normal” or “healed” if those changes are still present.

Epithelial cells may have an impaired barrier function despite a lack of inflammatory signs. Cytokine expression and cytokine secretion by immune cells may still be significantly increased despite a normal appearing histology. A normalization of those changes has been termed biochemical healing<sup>[65-68]</sup>. There are no data available with respect to the predictive value of “biochemical healing” and whether this would correlate to a more favorable disease outcome.

The confused scientist, however, is able to imagine a further level of “healing”. In macroscopically normal appearing mucosa with microscopically normal appearing cells that display normal cytokine expression and secretion levels, epigenetic changes may still be present that may trigger pathological responses upon minor stimuli<sup>[69-76]</sup>. Can a persistence of epigenetic changes in otherwise normal mucosa be termed “mucosal healing”? Or do we have to achieve “epigenetic healing” to finally achieve the best outcome possible for our patients? These questions will have to be answered in the future. Currently we are just at the start of investigations into these aspects with the first interesting pieces of the puzzle be-

ing put together.

## MUCOSAL HEALING AND DEEP REMISSION: THE CONFUSED “TRIALIST”

As mentioned above the terms “mucosal healing” and “deep remission” have been used in a number of trials with quite different meanings and definitions. The key confounder is the lack of unequivocal definition(s). Therefore, results and data from those trials with respect to mucosal healing cannot easily be compared. Nevertheless, this is done frequently. In most cases endoscopic investigation is used for the evaluation of “mucosal healing”. One crucial point is whether “mucosal healing” was defined simply as the absence of ulcers when ulcers had been seen previously or whether the absence of ulcerations and ulcers was investigated exactly at a place where those alterations had been found before.

The above is reflected in the way different trials have been reported. In the ACCENT 1 endoscopic sub-study the CDEIS was used for scoring and the complete absence of mucosal ulcerations that were observed at baseline was evaluated<sup>[77]</sup>. In the SONIC study in contrast no clearly defined score was used. Mucosal healing was defined as “complete absence of mucosal ulceration in the colon and terminal ileum”<sup>[78]</sup>. In the “Top-down versus step up” study by Gert D’Haens and coworkers SES-CD was used for the evaluation of mucosal healing which was a secondary endpoint<sup>[79,80]</sup>. Mucosal healing was defined as “absence of ulcers”. In the MUSIC trials again the CDEIS was applied. The definition of mucosal healing was “absence of ulcers and endoscopic remission defined as CDEIS < 6”. In the EXTEND study applying again SES-CD mucosal healing was seen as “absence of mucosal ulceration”<sup>[81]</sup>. As is obvious from those definitions, the question arises whether a few remaining aphthous lesions in a patient with severe and deep ulcers at the beginning of therapy also may be termed mucosal healing.

For UC the IOIBD attempted a consensus for mucosal healing in 2007: “absence of friability, blood, erosions and ulcers in all visualized segments of the gut mucosa”. According to the IOIBD experts the presence of an abnormal vascular pattern is still compatible with mucosal healing or “normal mucosa”. However, also in UC the definitions applied varied widely: In the ACT1 study mucosal healing was a secondary endpoint<sup>[82,83]</sup>. The Mayo endoscopic subscore was used and mucosal healing was defined as “absolute subscore for endoscopy of 0 or 1”<sup>[82,83]</sup>. The same definition was used for ULTRA 2<sup>[84]</sup>.

In studies on the outcome of therapy with 5-aminosalicylic acid the definition of mucosal healing largely defined the number of patients achieving this endpoint (Table 1). As an example, Vecchi *et al.*<sup>[85]</sup> compared mesalazine 4 g orally *vs* 2 + 2 g orally and enema in 2001 in patients with a clinical activity index (CAI) of 4-12 and used an endoscopic Rachmilewitz index < 4 as definition of mucosal healing leading to 58% *vs* 71% of patients

**Table 1 Association between the definitions of remission and mucosal healing and actual healing rates in patients with ulcerative colitis treated with mesalazine**

Author	Design	Study	Timing of endoscopy	Endoscopic index	Def. of MH	No of pat. Achieving MH
Vecchi (2001)	Mc, RCT	Mesalazine 4 g orally <i>vs</i> 2 + 2 g orally and enema	6 wk	Rachmilewitz	Rachmilewitz < 4	58% <i>vs</i> 71%
Malchow (2002)	Mc, db, RCT	Mesalazine 4 g enema <i>vs</i> 1 g foam	4 wk	Rachmilewitz	Rachmilewitz < 2	38% <i>vs</i> 37%
Mansfield (2002)	Mc, db, RCT	Balsalazide 6.75 g <i>vs</i> sulfasal. 3g	8 wk	4 point scale	Score of 0 = normal mucosa	27% <i>vs</i> 25%
Hanauer (2007) Ascend	Mc, db, RCT	Asacol 4.8 g <i>vs</i> 2.4 g	6 wk	Descriptive, no score	Normal endoscopic finding	25% <i>vs</i> 20%
Kamm (2007) MMX	Mc, db, RCT	MMX mes. 4.8 g <i>vs</i> 2.4 g <i>vs</i> placebo	8 wk	Mod. Sutherland index	Mod Sutherland index < 1	77% <i>vs</i> 69% <i>vs</i> 46%
Kruijs (2009)	Mc, db, RCT	Mesalazine 3 g <i>vs</i> 1g x 3	8 wk	Rachmilewitz	Rachmilewitz < 4	71% <i>vs</i> 70%

Mc: Multicenter; db: Double-blind; RCT: Randomized controlled trial; MH: Mesalazine.

**Table 2 One of the problems in endoscopic ulcerative colitis scores is the application of varying criteria**

	Truelove	Baron	Powell-T (St Mark's)	Levine	Rach-milewitz	Modified Baron	Mayo	Sutherland
Erythema						+	+	
Edema				+				
Granularity				+	+	+		
Vascular pattern		+		+	+	+	+	
Friability	+	+	+	+	+	+	+	+
Erosions				+	+		+	
Ulceration				+	+	+	+	
Exudate					+			+
Remission	0	0-1			0-2	0-1	0-1	0

achieving this endpoint<sup>[85]</sup>. In 2002 Malchow compared Mesalazine 4g enema *vs* 1g foam preparation in patients with a CAI > 4 for 4 wk and applied an endoscopic Rachmilewitz index < 2 as definition of mucosal healing leading to rates of 38% *vs* 37%<sup>[86]</sup>. As one would expect, the different definitions used cause huge variation in defined endoscopic mucosal healing rates in patients with UC, which makes the comparison of efficacy of different drugs or formulations extremely difficult.

One of the problems in endoscopic UC scores is the application of varying criteria (see Table 2). The reasons for such different definitions and endpoints may only be speculated. Unfortunately we lack an unequivocal definition; all of the scoring systems published so far have certain limitations, which have led to the introduction of several additional scoring systems. From a patient's and physician's perspective, however, the use of one single scoring system would be most desirable to enable valid comparisons among study outcomes.

## WHAT IS THE ADDITIVE VALUE OF DEEP REMISSION AS COMPARED TO MUCOSAL HEALING?

“Deep remission” is another term that has been discussed as a treatment target in recent years. The definition, however, is unfortunately not clearer than the one of mucosal healing. In the EXTEND study “deep

remission” was defined as clinical remission (CDAI < 150) and complete mucosal healing as defined according to CDEIS<sup>[13]</sup>. It is worthwhile to look a bit closer at this definition. If a patient with CD achieves mucosal healing but still has increased CDAI (no clinical remission) this may be due to superimposed IBS symptoms or the fact that without the presence of inflammation there is some bowel damage such as a fibrotic stricture or an internal fistula which might contribute to increased bowel frequency. Subsequently the lack of clinical remission is important for the patient and his/her clinical management (*e.g.* surgery of the stricture) but not for the medical (anti-inflammatory) management of the disease. Thus, the term “deep remission” in the definition outlined above is not useful and does not provide more information than mucosal healing. In fact - it contributes to confusion of scientists, clinicians and “trialists”.

## HOW CAN WE IMPROVE?

There should be standards on the definition of mucosal healing for clinical studies. It needs to be discussed - and finally decided - whether endoscopic mucosal healing, histologic mucosal healing or a combination of both can be standardized. Once agreement on definitions has been achieved, a given patient could be assessed by a -hopefully- simple binary coded tool that is oriented according to the TNM classification of oncology. A proposal for such a tool is illustrated in Table 3. The number “1”

**Table 3** Proposal of the CBEHI classification to assess Crohn’s disease activity

Activity level	Definition	Code
Clinical activity	Remission: CDAI < 150	C0
	Active: CDAI ≥ 150	C1
Biochemical activity	CRP normal	B0 (CRP)
	Elevated CRP	B1 (CRP)
	Calprotectin < 200 µg/g	B0 (Calpro)
	Calprotectin ≥ 200 µg/g	B1 (Calpro)
Endoscopic activity	Remission: SES-CD < 4	E0
	Active: SES-CD ≥ 4	E1
Histologic activity	Inactive	H0
	Active	H1
Imaging	Inactive: no fistulas, no stenoses	I0
	Active: presence of either fistula and/or stenosis	I1

Example: A Crohn’s disease (CD) patient with C0B0 (CRP) E1H1I0 would have clinical and biochemical remission, but endoscopic and histologic activity.

stands for “active”, “0” for “remission” and “x” for “not assessed”. Of note CD activity assessment would require, in contrast to UC, not only measuring clinical activity, biochemical, endoscopic and histologic activity, but also imaging modalities (presence of fistulas, strictures). This simple approach has the potential to reduce the amount of potentially confusing new definitions to describe different combinations of activities in IBD.

Other definitions of mucosal healing (such as “biological mucosal healing”, “epigenetic mucosal healing”, “mucus layer healing” or “microbiota mucosal healing”) require further studies and prospective trials. At this point they are purely investigational and should not be used in clinical trials.

What would happen if such an agreement cannot be achieved? Then it would not make sense to discuss mucosal healing as a treatment target for IBD any further as this would be a treatment target that lacks a definition and subsequently is blurry, vague and indistinct.

## Abstract

The association between inflammatory bowel disease (IBD) and colorectal cancer (CRC) has been acknowledged for almost a century and is assumedly promoted by a chronic inflammation-driven carcinogenic process in the intestine in combination with a genetic predisposition. The magnitude of the risk of CRC in IBD remains a continuing subject of debate. The early, high risk estimates for CRC in IBD were most likely overestimated due to selected patient populations originating from tertiary referral centers with a disproportional high percentage of patients with severe disease. Later population-based studies calculating risk estimates from a broad spectrum of IBD patients have found the risk to be significantly lower. At present, there is evidence that IBD patients with longstanding and extensive disease with uncontrolled inflammation are those at increased risk. Additional, other recognized risk factors include early age at onset, family history of CRC, and concomitant primary sclerosing cholangitis. A significant amount of effort is put into identifying potential preventive factors of CRC in IBD, including surveillance programs and chemopreventive agents but the individual effect of these remains uncertain. Interestingly, recent studies have reported a decline in risk of CRC over time. Sur-

veillance programs and the new treatment strategies, particular biological treatment might be part of the reason for the observed decline in risk of CRC in IBD over time but future studies will have investigate this assumption.

**Key words:** Inflammatory bowel disease; Colorectal cancer; Risk; Ulcerative colitis; Crohn's disease

**Core tip:** The increased risk of colorectal cancer in inflammatory bowel disease is well established. But what is the true magnitude of this increased risk, does the risk of colorectal cancer differ between ulcerative colitis and Crohn's disease and what are the significant risk factors? Further, recent studies have indicated that the risk of colorectal cancer in patients with inflammatory bowel disease is decreasing over time, potentially due to improved treatment options that lower the inflammatory burden. These are some of the subjects that will be elucidated and discussed in this review.

Andersen NN, Jess T. Has the risk of colorectal cancer in inflammatory bowel disease decreased? *World J Gastroenterol* 2013; 19(43): 7561-7568 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7561.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7561>

## INTRODUCTION

In almost a century it has been recognized that the risk of developing colorectal cancer (CRC) is increased in patients with longstanding inflammatory bowel disease (IBD), and it is estimated that one out of six deaths in ulcerative colitis (UC) patients and one out of 12 of all deaths in patients with Crohn's disease (CD)<sup>[1,2]</sup> is caused

by colorectal cancer. Together with the hereditary syndromes of familial adenomatous polyposis and hereditary non-polyposis colorectal cancer, IBD is in the top-3 high risk conditions for CRC. Both UC and CD carry an increased risk of CRC; however the risk is most extensively studied in UC. The augmented risk of CRC in IBD is assumedly promoted by a chronic, inflammation-driven carcinogenic process in the intestine in combination with a genetic predisposition<sup>[3]</sup>. The prognosis of sporadic CRC and IBD-related CRC is similar with a 5-year survival of 50%<sup>[4]</sup> whereas IBD-related CRC affect younger patients than sporadic CRC (60 years *vs* 70 years)<sup>[4,5]</sup>.

In 1925, Crohn and Rosenberg<sup>[6]</sup> were the first to elucidate the relation between CRC and UC and in 1928, Bagen<sup>[7]</sup> further described 20 cases of colorectal cancer in patients with UC from the Mayo clinic in the United States. In 1971, de Dombal<sup>[8]</sup> reported a cumulative risk of CRC in a population from Leeds with extensive UC to be 5% after 10 years and as high as 41.8% after 25 years. These findings led to the suggestion of cancer prophylactic colonic surgery in UC patients with extensive disease and a disease course of more than 10 years, but this proposal has never been carried out in practice. Since then, substantial effort has been made to elucidate the supposed risk of CRC in IBD and has presented a considerable variety in risk estimates, leading to an ongoing debate concerning the true magnitude of the risk of CRC in IBD. Additionally, novel population-based studies have suggested a decline in risk of IBD-related CRC over time, potentially due to a shift in treatment strategies from the era of sulfasalazine, 5-aminosalicylic acid and corticosteroids, to the era of immunomodulators, such as thiopurines and tumor necrosis factor (TNF)- $\alpha$  antagonists<sup>[5,9]</sup>.

## RISK OF COLORECTAL CANCER IN ULCERATIVE COLITIS

A landmark meta-analysis including 116 studies published by Eaden *et al*<sup>[1]</sup> in 2001, found that the cumulative risk of CRC for UC patients was 2% at 10 years, 8% at 20 years, and 18% at 30 years. However as an important weakness of the meta-analysis the underlying studies were of very different methodology and many factors may have biased results. A main subject, primarily in early studies, has been the selective collection of IBD patients from tertiary referral centers with a high percentage of patients with disproportionately severe disease, thereby potentially introducing referral bias with an overestimation of the risk. This is in line with the findings in a Dutch study, comparing a cohort of 121 IBD patients with CRC from referral centers with a cohort of 160 IBD patients with CRC from general hospitals and confirmed that IBD patients from referral centers represent a subgroup with a more severe IBD-phenotype<sup>[10]</sup>.

In order to approach a more unbiased risk estimate the use of population-based studies is essential with unselected cohorts of patients representing the complete and broad spectrum of disease. An early Swedish popu-

lation-based study by Ekblom *et al*<sup>[11]</sup> including a cohort of 3117 patients with UC and followed from 1922-1983 found 91 cases of colorectal cancer, corresponding to a standardized incidence ratio (SIR) of 5.7 (95%CI: 4.6-7.0). A matched population-based cohort study by Bernstein *et al*<sup>[12]</sup> from 2000 revealed an increased risk of CRC in 2672 UC patients (RR = 2.75; 95%CI: 1.91-3.97) compared with a non-IBD population. In accordance, Söderlund *et al*<sup>[13]</sup> conducted a population-based study of 7607 IBD patients from Sweden diagnosed between 1954 and 1989 and found, for UC patients, a more than 2-fold increased risk of CRC compared to the background population (SIR = 2.7; 95%CI: 2.3-3.2). A Hungarian, population-based study by Lakatos *et al*<sup>[14]</sup> followed 723 UC patients for 8564 person-year from 1974 to 2004 and revealed a cumulative risk of CRC in UC of 0.6% after 10 years, 5.4% after 20 years and 7.5% after 30 years disease duration. Conversely, data from population-based studies originating from Scandinavia, Italy and the United States have reported lower risk estimates. A population-based study from Olmsted County, United States from 2006 found no overall increase in CRC in 378 UC patients (SIR = 1.1; 95%CI: 0.4-2.4), but in the subgroup of patients with extensive colitis the risk was increased 2-fold, although not reaching statistical significance (SIR = 2.4; 95%CI: 0.6-6.0)<sup>[15]</sup>. Winther *et al*<sup>[16]</sup> followed a population-based cohort of UC patients from Copenhagen County, for a median of 19 years and found no increased risk of CRC (standardized morbidity ratio: 1.05; 95%CI: 0.56-1.79). In accordance with this, a population-based study from Italy and a very recent population-based study from Northern Jutland, Denmark, did not find a significant increase in CRC in UC patients<sup>[17,18]</sup>. A recent meta-analysis<sup>[19]</sup>, solely including population-based studies in order to approach an unbiased, general estimate of CRC risk in UC, found that an average of 1.6% of UC patients was diagnosed with CRC during 14 years of follow-up. This corresponds to a 2.4 (95%CI: 2.1-2.7) fold increased risk of CRC in UC. Looking at absolute risk the cumulative risk of CRC was 1.15% after 15 years, 1.69% after 20 years and 2.61% after 25 years disease duration. With 5 out of 8 studies originating from the Nordic countries the low risk has been suggested to be explained by high surgery rates and a high percentage of patients with proctitis in these countries, but this is not supported by the fact that the 3 non-Scandinavian studies revealed similar or even lower risk estimates than the Scandinavian studies. Beaugerie *et al*<sup>[20]</sup> recently published a prospective cohort study on risk of colorectal high-grade dysplasia and CRC among nearly 20000 patients with IBD enrolled in the French observational cohort CESAME (Cancer et Surrisque Associé aux Maladies Inflammatoires Intestinales En France) between May 2004 and June 2005. The authors found a 2-fold higher risk of CRC in IBD patients compared to the general population; a risk that was similar for both UC and CD. Sub-analyses revealed that this increased risk was driven by the relatively small percentage (14.6%) of patients with long-standing extensive colitis (>

10 years disease and > 50% of colon affected) with a SIR of 7 (95%CI: 4.4-10.5) compared with a non-significant increased risk in patients without long-standing extensive colitis (SIR = 1.1; 95%CI: 0.6-1.8). These risk estimates are higher than those originating from population-based studies and it is of importance to notice that data from the CESAME cohort arise from a selected IBD population. The difference in risk estimates from selected population *vs* unselected populations was addressed in a novel meta-analysis stratifying between study design and revealed a 4-fold greater risk of CRC in IBD patients when data originated from referral centers with selected patients compared with data from unselected patients from population-based studies<sup>[9]</sup>.

## RISK OF COLORECTAL CANCER IN CD

In contrast to the risk of CRC in UC patients, which has been comprehensively investigated, the risk of CRC in CD patients remains less explored. As with the risk of CRC in UC, studies on risk of intestinal cancer in CD have revealed inconsistent results with a variation in reported relative risk estimates from 0.8 to 20.0<sup>[21]</sup>.

A meta-analysis from 2005 by Jess *et al*<sup>[22]</sup> exclusively including population-based studies and representing populations from North America, Scandinavia and Israel, estimated a pooled overall SIR for CRC in CD of 1.9 (95%CI: 1.4-2.5). Separate risk estimates for cancer in the colon and rectum resulted in a significant increased risk for colon cancer (SIR = 2.5; 95%CI: 1.7-3.5), whilst a slightly, non-significant increased pooled risk was estimated for rectum cancer (SIR = 1.4; 95%CI: 0.8-2.6). The risk of CRC cancer was significantly increased in CD patients with colonic involvement (SIR = 4.3; 95%CI: 2.0-9.4), non-statistically increased in patients with ileocolonic CD (SIR = 2.6; 95%CI: 0.8-8.2) and not increased in CD patients with pure ileal disease (SIR = 0.9; 95%CI: 0.2-4.1). Another meta-analysis from 2005, by Canavan *et al*<sup>[21]</sup> including both selected and unselected patient series studies, on risk of CRC in CD, reported similar results with an overall pooled RR of 2.5 (95%CI: 1.3-4.7) and only a significant increased risk for CD patients with colonic disease (RR = 4.5; 95%CI: 1.3-14.9). In subgroup analyses on site-specific CD the RR estimate increased for patients with colonic involvement whereas combined RR of CRC in CD patients with ileal disease was not increased (RR = 1.1; 95%CI: 0.8-1.5). A retrospective study by Herrinton *et al*<sup>[23]</sup> calculated risk of CRC cancer in a more recent IBD cohort from the Kaiser Permanente database from 1998 to 2010 and identified 29 incident CRC patients among persons with CD corresponding to a 1.6-fold higher risk of CRC compared with the general Kaiser Permanente population. In the up-dated meta-analysis from 2013 by Lutgens *et al*<sup>[9]</sup> the pooled risk estimate for CRC in CD was slightly increased (SIR = 1.6; 95%CI: 1.2-2.0) when data originated from population-based studies. Yet again, the risk was only increased in patients with colonic involvement, though not reaching statistical significance (pooled SIR = 2.0; 95%CI: 0.3-3.7).

## RISK FACTORS

It is essential, in a clinical aspect to obtain knowledge of potential cancer predictive factors in order to identify subgroups of patients who need closer surveillance or more intense treatment. Known risk factors for CRC in IBD patients include young age at diagnosis, duration and anatomic extent of disease, family history of CRC, concurrent primary sclerosing cholangitis and persisting inflammation of the colon.

## AGE AT ONSET

Young age at onset of colitis has been reported to be an independent risk factor for CRC. Interpretation of existing evidence is complicated as children tend to have more extensive and severe colitis compared with those diagnosed in adult age, and further have a potential for longer disease duration, a risk factor in itself.

The impact of early age at onset of IBD as a risk factor for CRC was assessed in a Danish cohort study by Jess *et al*<sup>[5]</sup>. They found that the risk of CRC varied markedly by age at diagnosis of UC; those diagnosed at childhood or adolescence (age 0-19 years) had the greatest risk (RR = 43.8; 95%CI: 27.2-70.7) followed by those diagnosed in young adulthood (age 20-39 years) with a RR of 2.65 (95%CI: 1.97-3.56). Those diagnosed with UC at the age period from 60-79 years had a risk of CRC that was below that of the background population (RR = 0.76; 95%CI: 0.62-0.92). However, as pointed out by the authors, the absolute risk of CRC was limited even in those diagnosed in young age<sup>[24]</sup>. Patients diagnosed with UC at age 0-19 had an absolute risk of CRC of 1.64% (95%CI: 0.25%-3.00%) after 25 years disease duration and for the group diagnosed at 20-39 years of age this risk was 0.80% (95%CI: 0.39%-1.20%). In matched controls the corresponding 25-year risk estimates were 0.05 (95%CI: 0.03%-0.07%) and 0.47% (95%CI: 0.43%-0.50%), respectively for the two age-groups. These data are supported by a population-based meta-analysis which showed that the standardized CRC incidence ratio was 4 times higher in IBD patients diagnosed at young age (< 30 years) compared with a non-significantly increased risk patients diagnosed at the age of 30 years or older<sup>[9]</sup>, but the meta-analysis did not report absolute risks.

## DISEASE EXTENT AND DURATION

UC patients with pancolitis are at highest risk, left-sided colitis carries a moderate risk, and patients with proctitis and protosigmoiditis are at similar risk of CRC as the background population. Ekblom *et al*<sup>[11]</sup> found that UC patients with pancolitis had a nearly 15-fold increased risk of CRC (SIR = 14.8; 95%CI: 11.4-18.9) as compared to the background population, in contrast to an increased risk of 2.8 for those with left-sided colitis and a non-significant increased risk of 1.7 for those with proctitis. A smaller risk was found in the population-based study by Söderlund *et al*<sup>[13]</sup> exploring the significance of site-

specific inflammation for both UC and CD, on risk of CRC. Within the cohort and compared with UC proctitis the risk of CRC cancer was 2.0 (95%CI: 1.3-3.0) for UC pancolitis, 1.2 (95%CI: 0.7-1.9) for left-sided UC, 0.9 for colonic CD (95%CI: 0.5-1.6) and 0.7 (95%CI: 0.4-1.1) for non-colonic CD. A risk of 5.6 (95%CI: 4.4-7.0) was found for UC pancolitis, compared to an overall risk for UC of 2.7 (95%CI: 2.3-3.2) when comparing with the general population. In accordance, the population-based meta-analysis by Jess *et al*<sup>[19]</sup> reported an overall risk of 4.8 (95%CI: 3.9-5.9) for UC patients with extensive disease. Backwash ileitis in UC, theoretically representing the greatest extent of disease due to ileal involvement, has been reported to carry an additional increased risk of CRC<sup>[25]</sup>, but this has not been confirmed by others<sup>[26]</sup>.

In addition to extent of disease, longer duration of disease is associated with an augmented risk of CRC in IBD. In a Danish, nationwide cohort study by Jess *et al*<sup>[5]</sup> the relative risk of CRC in IBD was low in the first years after diagnosis (except for an implausible high RR the first year after diagnosis, assumedly as a result of differential diagnostic problems or cases of coincidental detection of recent onset IBD in patients diagnosed with CRC), then progressively increasing with duration of IBD reaching the level of the non-IBD population after 8 years. After disease duration of 13 years the RR was significantly higher than the background population, reaching a level around 50% increase with longer follow-up. These results are consistent with the current surveillance guidelines defined by the American Gastroenterological Association<sup>[27]</sup> and the British Society for Gastroenterology<sup>[28]</sup> recommending initiation of surveillance after 8-10 years disease duration for CD and extensive UC and after 15-20 years for patients with left-sided UC. Nevertheless, studies have shown that up to a third of IBD patients develop CRC prior to the initial point of surveillance<sup>[5,20,29]</sup>, thus questioning the efficacy of the present surveillance strategy.

## PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease present in 3%-8% of patients with UC and 1%-3% of patients with CD<sup>[30-32]</sup>, whereas 60%-80% of patients with PSC have IBD<sup>[33]</sup>. In 1992, Broomé *et al*<sup>[34]</sup> were the first to suggest that IBD patients with PCS potentially had an increased risk of CRC. A later study by the same group revealed an absolute cumulative risk of CRC in patients with UC and PSC of 9% after 10 years disease duration, 31% after 20 years and as high as 50% after 25 years; compared with 2%, 5% and 10% in patients with UC alone<sup>[35]</sup>. A meta-analysis published in 2002, including 11 studies concerning risk of CRC in patients with concomitant UC and PSC, revealed that 21% of UC-PSC patients developed CRC compared to 4% of UC patients without PSC, thus giving an odds ratio of 4.8 (95%CI: 3.6-6.4)<sup>[36]</sup>. The risk of CRC in CD patients with PSC is uncertain. A British case control study by

Braden *et al*<sup>[37]</sup> studied risk of CRC in colonic CD/PSC patients and concluded that the presence of PSC did not increase the risk of CRC in patients with colonic CD. Thackeray *et al*<sup>[38]</sup> conducted a retrospective study in order to determine the time-interval between diagnosis of IBD, PSC and CRC and found that IBD-PSC patients developed cancer or dysplasia relatively soon after diagnosis of both IBD and PSC. Interestingly, patients with PSC and IBD typically have mild or asymptomatic pancolitis with prolonged remission and an inactive cause<sup>[39-41]</sup>. Further, studies have reported a more frequent location of cancer in the right colon in patients with IBD-PCS<sup>[42]</sup>. This could suggest a different pathogenesis in the subgroup of IBD patients with PSC compared to IBD patients in general, but these mechanisms remains unidentified.

Due to the high cumulative risk of CRC in IBD patients with PSC, the short time-interval between PSC diagnosis and CRC progression, and the predominately right-sided cancer location, it is recommended that patients with IBD-PSC should initiate an annual surveillance colonoscopy, rather than sigmoidoscopy, program already at time of PSC diagnosis<sup>[43]</sup>.

## FAMILY HISTORY OF COLORECTAL CANCER

Healthy individuals, with a family history of CRC, carry a near 2-fold increased risk of CRC. Few studies have assessed the significance of familial CRC, or IBD on risk of CRC in patients with IBD. A population-based study from Sweden found that a family history of CRC in IBD patients resulted in a doubling of the already increased risk of CRC in IBD, irrespectively of type and extent of IBD<sup>[44]</sup>. Further, sub-analyses revealed that IBD patients with a 1<sup>st</sup>-degree relative diagnosed with CRC before the age of 50 had an even higher risk (RR = 9.2; 95%CI: 3.7-23). A family history of IBD did not increase the risk of CRC.

## SEVERITY OF INFLAMMATION

Under the assumption that inflammation is the promoting factor in development and progression of CRC in IBD it seems evident that the relationship between degree of inflammation and risk of CRC would be comprehensively investigated. Paradoxically, data are sparse. Rutter *et al*<sup>[45]</sup> conducted a retrospective case-control study, using data on histological and endoscopic grade of inflammation from a well-established cancer surveillance program for patients with long-standing, extensive UC from the United Kingdom and found a highly significant correlation between severity of inflammation and the risk of CRC; both when using colonoscopic scores (OR = 2.5,  $P = 0.001$ ) and histological scores (OR = 5.1,  $P < 0.001$ ). These findings were replicated in another retrospective case-control study from Finland, concluding that the risk of dysplasia or CRC is strongly associated with the degree of inflammation in patients with UC<sup>[46]</sup>.

## IS THE RISK OF COLORECTAL CANCER DECREASING?

The management of IBD has changed markedly in the last decades<sup>[47]</sup> not only with advancement in medical treatments, *e.g.*, new biological therapies, surgical treatment options and improved diagnostic tools leading to early detection, but also with implementation of surveillance programs and awareness of the need of adherence to medication from a patient perspective. These factors could potentially reduce the long-term inflammation in IBD patients and thereby reduce the risk of CRC.

Eaden *et al*<sup>[1]</sup> reported in their meta-analysis an increase in incidence of IBD-related CRC over time from 1955 to 2001 by plotting cancer risk against the mid-point of 41 studies, but the result did not reach statistical significance (slope: 0.003,  $P = 0.80$ ). Another meta-analysis reported a decline in risk over time, by pooling results on risk estimates classified by the publication year. They found an incidence rate of 4.29/1000 pyrs in the 1950s compared to an incidence rate of 1.09/1000 pyrs from 2000-2011<sup>[48]</sup>. Several other studies have shown a declining trend in risk over time. Söderlund *et al*<sup>[13]</sup> conducted a population-based study showing time-trends in incidence and mortality of CRC from 1960 to 2004 in 7607 Swedish IBD patients and reported adjusted relative risks of 1.7 (95%CI: 0.6-4.4) from 1960 to 1969, 1.3 (95%CI: 0.7-2.6) from 1970 to 1979, 1.2 (95%CI: 0.7-2.2) from 1980 to 1989, 1.1 (95%CI: 0.7-1.8) from 1990 to 1999, and 1 (reference) from 2000 to 2004, revealing a non-significant, declining trend. Compared to the general population the relative risk declined from a 5-fold increased risk of CRC in IBD in the 1960s to a 2-fold increased risk in the period from 2000 to 2004 ( $P$  for trend = 0.06). The risk of death from CRC decreased significantly during the same time period, both when comparing patients within the cohort and with the general population. Whether this decline in mortality is due to surveillance, better surgical management, better follow-up, or other changes is unanswered. Results from other studies are diverse. Herrinton *et al*<sup>[23]</sup> used data on IBD and CRC from the United States health insurance Kaiser Permanente database to report time-trends over a 14.5 year study period from 1998 to 2010. Results showed no time-trend with incidence rates of CRC per 100000 pyrs, varying from 87.9 in 1998-2001, to 67.0 in 2002-2006 and to 73.9 in 2007-2010 ( $P$  trend = 0.98) but one could argue that this time-interval is too short to reveal any trend over time. In contrast to the results from the United States, a nation-wide cohort study from Denmark revealed a decrease in risk of CRC in IBD over 30 years from 1979 to 2008<sup>[5]</sup>. During 178 million person-years of follow-up, relative risk estimates of CRC in IBD were calculated, adjusted by sex, age and calendar period and subdivided into three time-periods of 10 years from 1979 to 2008. Compared to the general population the overall RR of CRC in UC decreased from 1.34 (95%CI: 1.13-1.58) in 1979-1988 to 1.09 (95%CI: 0.90-1.33) in 1989-1998 and further to 0.57 (95%CI:

0.41-0.80) in 1999-2008. It has been argued that the observed decreased risk could be explained by the initiation of screening of CRC in the general population but first of all there is no systematic screening program for CRC in Denmark before year 2014 and further relative risks compared within the cohort, using the RR in the intermediate period from 1989-1999 as reference (hence enabling adjustment for shorter length of follow-up in recent cohorts) the risk was still significantly reduced (RR = 0.59; 95%CI: 0.39-0.90) in the late period from 1999-2008. When analyzing time-trends in CD no significant changes were observed. Likewise, a study on mortality within the same population revealed a decrease in mortality in UC patients from 1982 to 2010, largely due to a reduction in mortality from gastrointestinal disorders and CRC<sup>[49]</sup>. In addition to the mentioned original studies, an updated meta-analysis by Lutgens *et al*<sup>[9]</sup> found a similar decreasing trend in risk of CRC in IBD over time in meta-regression analyses from 9 population-based studies, but the trend did not reach statistical significance, most likely due to a type II error as only few studies were available for analysis. Overall, there may be a declining risk of CRC in IBD over time and the reason for this observation needs to be studied further.

## CHEMOPREVENTION

Instead of focusing on early detection of neoplasia in IBD, the ideal would be to prevent neoplasia from ever developing. In light of the theory of an inflammation-driven carcinogenic process as a causative factor of IBD-related CRC, medical therapies reducing the inflammatory burden could potentially lower the risk of CRC in IBD. Hence, there has been an increasing interest in detecting chemopreventive agents that can reduce the overall risk of dysplasia and cancer and serve as a complement to current surveillance programs.

5-aminosalicylic acid (5-ASA) is the first line agent for maintenance therapy in mild to moderate UC and it has been shown in *in vitro* studies to have antineoplastic properties by inhibiting the nuclear kappa-B pathway which is involved in tumor progression<sup>[50]</sup>. However, the evidence of a potential chemoprophylactic effect of 5-ASA is contradictory. In 2005 Velayos *et al*<sup>[51]</sup> published a meta-analysis of 9 observational studies (3 cohort, 6 case-control) on effect of 5-ASA in preventing IBD related CRC. Pooled analysis revealed a protective effect of 5-ASA use on risk of IBD-related CRC with an odds ratio of 0.51 (95%CI: 0.37-0.69). Since then several case-control and population-based studies have not been able to detect any chemopreventive effect of 5-ASA<sup>[52-54]</sup>. Recently, Nguyen *et al*<sup>[55]</sup> published a meta-analysis solely including non-referral studies; thereby potentially reducing bias and presenting evidence that is more generalizable. The meta-analysis revealed a pooled adjusted OR of 0.95 (95%CI: 0.66-1.38) for CRC in patients with IBD treated with 5-ASA and based on these results the authors concluded that there does not seem to be a protective effect

of 5-ASA on risk of CRC in IBD.

In addition to 5-ASA, an increasing number of patients are treated with the thiopurine drugs, azathioprine and 6-mercaptopurine. Existing data on the potential chemopreventive effect of thiopurines in IBD are, however, conflicting. In the French CESAME clinical based cohort study the authors investigated the impact of thiopurines on risk of CRC in IBD<sup>[20]</sup>. Almost half of the 19,484 IBD patients had been exposed to thiopurines and among current users the adjusted hazard ratio for CRC was 0.57 (95%CI: 0.24-1.32) thereby revealing no significantly protective effect of thiopurine use on CRC risk in the general IBD population. However, in subanalysis confined to IBD patients with long-standing extensive colitis, current treatment with thiopurines reduced the risk of advanced colorectal neoplasia significantly (CRC and high grade dysplasia combined; HR = 0.28; 95%CI: 0.09-0.89). A Dutch cohort study by van Schaik *et al*<sup>[56]</sup> have further evaluated the effect of thiopurines on risk of CRC in an IBD cohort of 2578 IBD patients of whom 770 were exposed to thiopurines. They found that thiopurine exposure were associated with significantly decreased risk of developing advanced neoplasia (high grade dysplasia and colorectal cancer combined; adjusted HR = 0.10; 95%CI: 0.01-0.75). In a Danish nationwide population-based study by Pasternak *et al*<sup>[57]</sup> from 2013, the effect of thiopurine exposure on risk of CRC was assessed among 43969 IBD patients of whom 12% had been exposed to thiopurines. In contrast to the more selected French study, no difference in risk of CRC was observed among thiopurine exposed *vs* non-exposed patients (adjusted RR = 1.00; 95%CI: 0.61-1.63). Similar results were reported in another large population-based study from the United Kingdom<sup>[58]</sup>.

Recent data from models of experimental colitis have indicated that TNF- $\alpha$  has a tumor promoting effect<sup>[59]</sup>. Few studies have been able to evaluate the effect of the new biological treatments, as TNF- $\alpha$  blockers, on risk of CRC due to the relatively short existence of these agents relative to the latency of CRC. In a Dutch nested case-control study by Baars *et al*<sup>[60]</sup> risk factors for IBD-related CRC were identified by comparing 173 cases of IBD-related CRC (collected from 1990 to 2006) with 393 non-CRC IBD controls. The authors found that use of TNF- $\alpha$  antagonist was a protective factor for the development of CRC (OR = 0.09; 95%CI: 0.01-0.68). In a Danish, nationwide population-based cohort study, the risk of CRC was compared between IBD patients exposed to TNF- $\alpha$  antagonist *vs* non-exposed and revealed no impact of TNF- $\alpha$  antagonist on risk of CRC (adjusted RR = 1.06; 95%CI: 0.33-3.40)<sup>[61]</sup>. The association between TNF- $\alpha$  antagonists and cancer is two-edged with hypotheses on both a tumor-promoting and a tumor preventing effect and future studies are necessary to clarify this aspect.

## CONCLUSION

The absolute risk of CRC in IBD is limited. However,

subgroups of IBD patients with severe, long-standing active disease who do not undergo colectomy and patients with PSC carry a greater risk of CRC than the background population. Overall, it seems evident that to prevent CRC from occurring in IBD, the goal is to minimize severity and extent of inflammation, whereas the methods used to do this (regular follow-up, medical treatment, surgery, and surveillance) act in common and not as single cancer-preventive factors. Whether new treatment strategies, particular biological treatment might be part of the reason for the observed decrease in risk of CRC in IBD over time needs further investigation.

## Abstract

The exact causes of inflammatory bowel disease (IBD) are not yet fully defined. From a vast body of literature, we know that the immune response has long been involved in the pathogenesis of IBD, including both ulcerative colitis and Crohn's disease. A variety of specific alterations can lead to immune activation and inflammation directed to the colon, as revealed by some animal models. Current research has focused on the role of antibodies in downstream events and mechanisms of autoimmunity and inflammation. It is not well known whether the production of antibodies is a serologic consequence of IBD, or if it is a result of barrier dysfunction induced by inflammation. Here, we present a new hypothesis to distinguish the complex links between genetic susceptibility, barrier dysfunction, commensal and pathologic microbial factors and inflammatory response (especially autoantibodies) in the pathogenesis of IBD. To ascertain the hypothesis, we developed a pilot model with the concept of the presence of antibodies against enteric bacterial antigens in IBD. Results confirmed our hypothesis. Our hypothesis suggests the possibility of subcutaneous vaccination of animals with

administration of all or specific enteric bacterial antigens.

**Key words:** Inflammatory bowel disease rat model; Pathogenesis; Barrier dysfunction; Microbial factor

**Core tip:** We present a new hypothesis to distinguish the complex links between genetic susceptibility, barrier dysfunction, commensal and pathologic microbial factors and inflammatory response (especially autoantibodies) in the pathogenesis of inflammatory bowel disease (IBD). In our hypothesis, we suggest that prior activation of adaptive immunity against microbial flora antigens could initiate an IBD-like chronic inflammation if something like ethanol disturbs barrier function. If this hypothesis is supported with further experiments, it would illustrate unknown aspects of IBD pathogenesis. On this basis, we have developed a new immune-based model of IBD with the presence of antibodies against enteric bacterial antigens.

## INTRODUCTION

### Etiology

Investigations have demonstrated that the pathophysiology of inflammatory bowel disease (IBD) is multifactorial, but briefly host (e.g., genetics, intestinal barrier and immune system function) and exogenous factors (e.g.,

normal luminal flora) are two basic themes<sup>[1]</sup>. The normal intestine contains a large number of immune cells in a chronic state of so-called physiologic inflammation to control the gut and to prepare it for any immunologic response. Lack of immune responsiveness to lumen antigens may be a result of oral tolerance<sup>[2]</sup>. Multiple mechanisms are involved in the induction of oral tolerance. For instance, deletion or anergy of antigen-reactive T cells or activation of regulatory CD4 T cells suppresses gut inflammation through secretion of inhibitory cytokines such as interleukin (IL)-10 and transforming growth factor  $\beta$  (TGF- $\beta$ ). In addition, a selectively permeable barrier prevents unwanted solutes, microorganisms, and luminal antigens from confronting the immune system in the internal mucosa<sup>[2-4]</sup>. In IBD, this tolerance is altered and leads to an uncontrolled inflammation; thus, IBD is considered as a breakdown in the regulatory constraints on mucosal immune response to the microbial flora or their products within the intestine. Most of this process is mediated through components of the autoimmune response to self-antigens<sup>[5]</sup>.

A variety of specific alterations can lead to immune activation and inflammation directed to the colon, as revealed in animal models demonstrating murine genetic models (transgenic models). These models showed us that deleting loci of specific cytokines (*e.g.*, IL-2, IL-10, TGF- $\beta$ ) or their receptors or T cell antigen recognition molecules (*e.g.*, T cell antigen receptors) or interfering with intestinal barrier integrity (*e.g.*, mucus glycoprotein, deleting N-cadherin or nuclear factor  $\kappa$ B) leads to inflammation<sup>[4]</sup>.

It has been suggested that the continuous penetration of luminal antigens and unremitting stimulation of the mucosal immune system due to an increased permeability of the intestine epithelial cells may be the primary defect in patients suffering from IBD<sup>[3]</sup>. Therefore, if we consider increased epithelial permeability as the trigger, the tragedy of IBD initiates after a disruption occurring in the mucosal integrity. Then lots of macromolecule antigens in the lumen penetrate into internal compartments of the mucosa and submucosa, and subsequently become recognized by the gut immune system. Later, interstitial macrophages and dendritic cells are locally activated and release cytokines to recruit more macrophages and monocytes from the systemic circulation<sup>[6]</sup>. In normal subjects, this acute response is subsided after controlling the invasion. In genetically susceptible subjects [defects in innate immunity response (*e.g.*, NOD2,  $\alpha$ -defensins mutations)] or in the long-term exposure to penetrated antigens in the situation of persistent integrity perturbations, or if the invader was a specific uncontrollable pathogen (*e.g.*, *Salmonella* sp., *Shigella* sp., *Campylobacter* sp., *Clostridium difficile*), antigen presenting cells (APCs) secrete cytokines, which leads to induction of differentiation in various T-cells. In this way, the adaptive immune response is turned on<sup>[7-11]</sup>. Activation of both TH1 or TH2 leads to an inflammatory response<sup>[12]</sup>. This

ignition can be turned off by the regulatory systems. Generally, recovery is achieved after repair of the first alteration in intestinal permeability.

### Microbial factors

Microorganisms are a likely factor in the initiation of inflammation in IBD<sup>[13]</sup>. However, the unanswered question in this area is whether microorganisms involved in the pathogenesis of IBD are commensal flora or invasive microbial pathogens?

Normal intestinal microflora may contribute to the development of IBD in susceptible individuals. This finding has been demonstrated repeatedly in murine models of IBD<sup>[14,15]</sup>. As an example, animals which are genetically altered (*e.g.*, deficient in IL-2 and IL-10) to be susceptible to IBD do not develop the disease when raised under germ-free conditions<sup>[13]</sup>. Also, intestinal lesions in IBD typically predominate in areas of the highest bacterial exposure (*e.g.*, in distal ileum and colon with  $10^{12}$  organisms/g).

On the other hand, a number of studies have evaluated the possible role of specific infectious agents in the pathogenesis of IBD. This role has been evaluated in two ways: the relation between specific microorganisms and IBD (*e.g.*, presence of specific antibodies in serologic findings of IBD patients<sup>[16]</sup>), and the association between some acute gastroenteritis and IBD<sup>[17]</sup>.

Pathogens that could be directly responsible for initiating IBD are those that the mucosal immune system may fail to control in terms of the inflammatory response (*e.g.*, *Salmonella* sp., *Shigella* sp.). These bacteria are rich in peptides having chemotactic properties (*e.g.*, formyl-methionyl-leucyl-phenylalanine). The superantigens capable of global T-lymphocyte stimulation and subsequent inflammatory response, and those producing toxins (necrotoxins, hemolysins, and enterotoxins), cause mucosal damage<sup>[8,9,16,18]</sup>. In summary, an acute infection with specific pathogens leads to a permanent uncontrollable perturbation in intestinal integrity, even though after the acute phase there is perhaps mediation of some cytokines (*e.g.*, IFN- $\gamma$ ), and permeability changes across the epithelium are induced. This results in continuous exposure and stimulation of the mucosal immune system with commensal flora antigens<sup>[3,19-21]</sup>.

---

## IMMUNE REGULATION AND INFLAMMATORY CASCADE DEFECTS IN IBD

---

As discussed later, the mucosal immune system is normally nonresponsive to luminal contents due to oral tolerance. Once inflammation is initiated, the immune inflammatory response is propagated by T cell activation in the lamina propria. CD4 T cells are of three major types: TH1, TH2, and TH17 cells. The TH1 cells secrete predominantly IFN- $\gamma$ , TNF- $\alpha$ , IL-2, and IL-12, which

activate cell-mediated immunity by CD8 T cells (cytotoxic) resulting in transmural granulomatous inflammation resembling CD. Meanwhile, the TH2 cells can induce B-cell differentiation and humoral immunity by secreting predominantly IL-4, IL-5, and IL-13 with superficial mucosal inflammation features resembling UC<sup>[22]</sup>. TH17 cells secrete predominantly IL-17, IL-6, and granulocyte colony-stimulating factor and seem responsible for neutrophilic recruitment<sup>[5,8,23]</sup>. After activation of these cells, they produce specific cytokines and, consequently, the epithelial barrier permeability (*e.g.*, IFN- $\gamma$ ) is increased. Some of these cytokines have destructive and apoptotic effects on mucosal cells, which eventually allow more antigens to pass and produce more agitation of immune cells amplifying the inflammatory cascade<sup>[3,8]</sup>. In normal situations, an activated response is subsided with regulatory T cells, including designated TH3, Tr1, and CD4, and CD25 cells<sup>[23]</sup>. Their function is blocking or down-regulating the response of TH1 and TH2 either by producing specific cytokines (IL-10 and TGF- $\beta$ ) or *via* cell-cell contact. There is evidence which demonstrates some defects in this regulatory system in IBD-susceptible subjects<sup>[24,25]</sup>.

## INTESTINAL BARRIER DYSFUNCTION

The intestine is covered by a monolayer of simple columnar and non-ciliated epithelial cells that are a type of brush border cells. These are joined together by intercellular and circumferential tight junctions to form a selectively permeable membrane. This barrier prevents unwanted solutes, microorganisms, and luminal antigens from entering the internal parts. They are also part of the immune system, acting as a first-line pathogen-recognition system because they present antigens similar to classical APC. They also express toll-like receptor (TLR) 4 and, furthermore, secrete antimicrobial peptides (*e.g.*, cryptidins and defensins)<sup>[2-4,26]</sup>. However, the epithelial barrier has some guards of the innate immune system to ensure permanent immune responsiveness (*e.g.*, DC, interstitial macrophages)<sup>[27]</sup>. If anything alters the barrier function, lots of luminal antigens could pass through the submucosal layer resulting in recruitment of neutrophils and macrophages. If these cells can control the invasion, it is not necessary to call adaptive immunity components, but if the invasion takes long then adaptive immune response component will be activated. In this process, if the regulatory systems are not able to overcome the inflammatory cascade, the secreted cytokines will deteriorate and amplify the first defect in the epithelial barrier by inducing apoptosis and necrosis in the epithelial cells. In addition, a number of studies have shown that inflammatory cytokines like TNF- $\kappa$  and IFN- $\gamma$  may have a role in increasing intestinal barrier permeability<sup>[3,4,8]</sup>. Some animal models of IBD have shown alterations in barrier function as the first trigger contributing to pathogenesis of IBD. Furthermore, abundant evidence indi-

cates an increased intestinal permeability in IBD patients suggesting the permanent stimulation of the mucosal immune system as the primary defect in the pathogenesis of IBD<sup>[3,28,29]</sup>.

## STEPS OF AUTOIMMUNITY IN IBD

The pathogenesis of IBD and most of its extra-intestinal manifestations is immunologically mediated and appears to be mainly due to an autoimmune-related process<sup>[30,31]</sup>. As discussed, after a permanent alteration in barrier function, various antigens pass through the interstitial space which finally activates T cells. In normal subjects, the response is directed definitively against the specific epitope of antigens, but commensal organisms in the lumen have adhesive antigens (*e.g.*, flagellar antigens) which adhere to the surface proteins of mucosal cells. If there are some predisposing factors, then there is a chance for APCs to process epitopes of these antigens, with parts of the mucosal surface proteins, which activate T lymphocytes against mucosal cell surface protein<sup>[8,31]</sup>. Another scenario happens when the response to the specific epitopes of antigens is cross-reactive to auto-antigens. There is evidence demonstrating relations between precise human leukocyte antigen (HLA) molecules and cross-reactive cellular antigens<sup>[32,33]</sup>. However, in the TH2-mediated immune response in UC, it is thought that perhaps development of self-reactive B cells, which are triggered to produce mucosal IgG autoantibodies, results in an inflammatory response. Meanwhile, TH1 cell-mediated immunity and auto-reactive T cells (CD4 or CD8) may be primed by microbial antigens that are cross-reactive to autoantigens<sup>[34]</sup>.

A long series of studies demonstrated that IBD patients possess autoantibodies, some of which became serologic biomarkers to diagnose or distinguish subtypes of this disease, such as anti-lymphocyte, anti-goblet cell, pancreatic autoantibodies, the autoantibody against tropomyosin isoform 5 (a cytoskeletal protein found in colon epithelial cells), and antibodies against red blood cell membrane antigens that cross-react with enteropathogens such as *Campylobacter* sp.<sup>[31,34,35]</sup>

We will now discuss some of the known autoantibodies in IBD pathogenesis. There is a form of perinuclear antineutrophil cytoplasmic antibody (pANCA) which is non-reactive to myeloperoxidase. It is well defined that 60%-70% of UC patients and 5%-15% of their first-degree relatives are pANCA-positive, whereas this applies to only 2%-3% of the general population. There is a relation between positive pANCA antibody status and severity of UC disease and other complications. Interestingly, pANCA in CD is associated with colonic disease that resembles UC<sup>[31,34,35]</sup>. The definite antigens to which these antibodies are directed have not been identified, but they have cross-reactions with enteric bacterial antigens.

Other studies demonstrated the presence of another

**Figure 1 intestinal barrier dysfunction.** Left (normal conditions): no or few commensal bacteria can pass the normal epithelial barrier and those that pass will be swallowed by interstitial macrophages and dendritic cells; it is not necessary to call for adaptive immune cells. Right: in normal situations, if something breaks the barrier (e.g. pathogens and barrier breaker chemicals like ethanol 30%) lots of commensal bacteria in the lumen will pass through the epithelial layer. This acute invasion will be controlled with recruiting of neutrophils and lymphocytes. Even after activation of B cells or T cells, if the defect in barrier function is resolved, apoptotic pathways will control the activated colonies of lymphocytes.

autoantibody, which is specific to patients with UC; it is an IgG autoantibody bound to a subtype of tropomyosin of colonic epithelial cell antigen. The capability of this antibody to initiate extracellular signal-regulated kinase (ERK) 1/2 signaling and up-regulating of the TLR and production of cytokines, and also the correlation between the titers of this antibody and the severity of colitis, suggest the possibility that such a protein could represent autoantigen- or complement-mediated responses<sup>[13,31]</sup>.

Although the presence of antibodies directed against microbial antigens has been illustrated in the serum of CD patients, a shared epitope among the host antigens is not clearly defined. For example, 55% of CD patients have antibodies against outer membrane porin C of *Escherichia coli*, and 50% have immunoglobulins that are reactive to a homologue of the bacterial transcription-factor families from a *Pseudomonas fluorescens*-associated sequence (I<sub>2</sub>). Around 50% of CD patients have serum reactivity to Cbir1, an immunodominant antigen of the enteric microbial flora. This antigen can strongly induce B cells and CD4<sup>+</sup> T cell responses. Transferring of Cbir1-specific CD4<sup>+</sup> TH1 T cells to C3H/SCID mice generates a severe colitis dependent on exogenous expression of Cbir1 flagellin in the colon. In 60%-70% of CD patients, anti-*Saccharomyces cerevisiae* antibodies have been found. A mannose sequence in the cell wall of this

commensal flora has been defined<sup>[35,36]</sup>.

## HYPOTHESIS

Although the above-mentioned studies support the concept of the presence of antibodies against enteric bacterial antigens in IBD, we propose a model to investigate whether the production of antibodies is a result of barrier dysfunction induced by inflammation or a serologic finding secondary to IBD. The hypothesis would result in a reliable model of IBD studies in animals. Our hypothesis suggests the possibility of subcutaneous vaccination of animals with administration of all or specific enteric bacterial antigens. In this way, production of immunoglobulin against these antigens would prevent intestinal inflammation. Anything that alters the function of this barrier and increases barrier permeability would result in inflammatory responses. To test this hypothesis, we have designed a pilot study and examined the model in male Wistar rats, which were immunized with anaerobic and aerobic enteric bacteria with and without an adjuvant. After assessing the IgG titers in the rats' plasma, well-immunized rats were anesthetized and then chitosan and ethanol were instilled intrarectally as a tight junction opener and a barrier breaker, respectively. This protocol induced a chronic inflammatory response with inflammatory features in the ethanol group with persistent le-

**Figure 2 Steps of autoimmunity.** If anything alters the barrier function, lots of luminal antigens can pass to the submucosal layer. If these cells can control the invasion, it is not necessary to call adaptive immunity components, but if the invasion take longer (e.g., in altered tight junction structure) or there are some defects in innate immunity response (e.g., mutations in Toll-like receptors), T cells are activated. If the regulatory system cannot overcome the inflammatory systems, cytokines and reactive destructive mediators further deteriorate the first defect *via* inducing apoptosis and necrosis in epithelial cells. Activation of T helper type 2 cells leads to a humoral response; also administration of a vaccine of commensal bacteria leads to a humoral immune response to their antigens, so after a disruption in barrier integrity with ethanol, the inflammatory cascade will turn on and induce inflammatory bowel disease in the animal as shown by histopathological findings. TNF: Tumor necrosis factor; TNFR: TNF receptor.

sions. We propose that this model of chronic intestinal inflammation would be a reliable model of human IBD. Of course, further studies would need to prove immunization with specific bacteria (Figures 1 and 2).

## CONCLUSION

In this article, we addressed some known immune derangements involved in the initiation and pathogenesis of IBD. The following general principles are highlighted for better understanding of the possible mechanisms involved in the IBD pathogenesis.

Increased barrier permeability secondary to a genetic susceptibility, a specific infectious pathogen or their toxins and activation of T cells create a positive feedback to amplify the first barrier dysfunction and initiate an inflammatory cascade.

Two common features of autoimmunity processes may differ in activation of autoreactive T or B cells, involving a variety of imbalances in cytokine production and the development of autoantibodies. In IBD, these antibodies are directed against shared enteric flora antigens and epithelial cell-surface proteins.

In this study, we focused on autoantibodies. It is not well defined whether various autoantibodies found in the serologic assessment of IBD patients are destructive or involved in pathogenesis of the disease, or whether they are produced after tissue damage due to releasing of sequestered antigens<sup>[31]</sup>. We suggest that antibodies which

are secreted in UC are catastrophic and are involved in the inflammatory response, but antibodies which are produced in CD are not involved in the pathogenesis and are secreted post-release of sequestered antigens. However, antibodies in both UC and CD patients are involved in extraintestinal complications, while there are various overlaps between these two subtypes.

In our hypothesis, we suggest that prior activation of adaptive immunity against microbial flora antigens in the way described could initiate an IBD-like chronic inflammation (especially in UC). Further experiments are essential to test various aspects of the method and unknown points of IBD pathogenesis.

## Empirical data

After developing the hypothesis, we designed a pilot study. Six groups of male rats containing three rats in each group were considered. An extemporaneous vaccine was prepared with a mixture of heat-treated colonic commensal bacteria, which were obtained from cultured samples, and complete Freund's adjuvant. This vaccine was injected subcutaneously into nine rats on days 0 and day 14. On day 28, a blood sample was taken from each rat to assess immunoglobulin titers. All of the test animals showed an elevated titer. Then these rats were divided into three groups; intra-colonic ethanol 30% was instilled in two groups, and in the third group, normal saline was instilled instead of ethanol and this group was assigned as the vaccine group. The two groups which

**Figure 3** Histological images of colon tissues obtained from different groups. Microscopic evaluation of the trinitrobenzene sulfonic acid (TNBS) group shows villus atrophy, extensive severe transmural inflammation, granuloma with necrosis and crypt destruction, whereas features in the Sham group were normal. Histological examination of the Ethanol group showed a mild crypt distortion and some crypt abscess, whereas features in the Vaccine group were normal. Microscopic evaluation of the Model group showed mucosal inflammation and crypt distortion, branching and some ulceration with moderate to severe crypt destruction in ulcerated regions. Mild focal inflammation, minimal inflammatory cell infiltration and slight crypt branching were observed in the Infliximab group. A: Sham; B: TNBS; C: Ethanol; D: Vaccine; E: Model; F: Infliximab.

received ethanol were: the model group that received no treatment and an infliximab-treated group that received 5 mg/kg per day of infliximab for 10 consecutive days after ethanol instillation. The first of the other three groups consisted of an ethanol group that received intracolonic ethanol 30% with no pre- or post-treatment. An established colitis model was induced with instillation of 10 mg of trinitrobenzene sulfonic acid dissolved in 30% ethanol as the vehicle in another group. And the last group was normal rats (sham group), which received normal saline intracolonic. The animals were sacrificed, and colon samples were removed for histopathological assays. Details of microscopic assessments are described in Figure 3.

IBD exacerbation, and the prognostic implications of CDI in these patients, it is recommended to test all IBD patients hospitalized with a disease flare for *C. difficile*. Treatment includes general measures such as supportive care and infection control measures. Antibiotic therapy with either oral metronidazole, vancomycin, or the novel antibiotic-fidaxomicin, should be initiated as soon as possible. Fecal microbiota transplantation constitutes another optional treatment for severe/recurrent CDI. The aim of this paper is to review recent data on CDI in IBD: role in pathogenesis, diagnostic methods, optional treatments, and outcomes of these patients.

## Abstract

*Clostridium difficile* (*C. difficile*) is the leading cause of antibiotic associated colitis and nosocomial diarrhea. Patients with inflammatory bowel disease (IBD) are at increased risk of developing *C. difficile* infection (CDI), have worse outcomes of CDI-including higher rates of colectomy and death, and experience higher rates of recurrence. However, it is still not clear whether *C. difficile* is a cause of IBD or a consequence of the inflammatory state in the intestinal environment. The burden of CDI has increased dramatically over the past decade, with severe outbreaks described in many countries, which have been attributed to a new and more virulent strain. A parallel rise in the incidence of CDI has been noted in patients with IBD. IBD patients with CDI tend to be younger, have less prior antibiotic exposure, and most cases of CDI in these patients represent outpatient acquired infections. The clinical presentation of CDI in these patients can be unique-including diversion colitis, enteritis and pouchitis, and typical findings on colonoscopy are often absent. Due to the high prevalence of CDI in patients hospitalized with an

**Core tip:** In this review we focus on the role of *Clostridium difficile* (*C. difficile*) in inflammatory bowel disease pathogenesis, the unique clinical aspects of *C. difficile* infections and prognosis in patients with inflammatory bowel disease. We also present the implications of *C. difficile* infections in these patients and review the most recent literature concerning diagnostic methods and treatment.

## INTRODUCTION

The human gut microbiota contains about 10<sup>14</sup> bacterial

cells from more than 1000 different bacterial species<sup>[1,2]</sup> that play an important role in conservation of mucosal innate and adaptive immune function, integrity of the epithelial barrier and nutrient absorption<sup>[3-6]</sup>. Disruption of the gut microbiota (dysbiosis) has been linked with many gastrointestinal conditions<sup>[7,8]</sup>. Accumulating evidence suggests that inflammatory bowel disease (IBD) results from an inappropriate inflammatory response to intestinal microbes in a genetically susceptible host<sup>[9-11]</sup>. Dysbiosis in IBD may also contribute to disease severity, and is correlated with the occurrence of abscesses in patients with Crohn's disease (CD) and need for surgery at a younger age<sup>[12,13]</sup>.

*Clostridium difficile* (*C. difficile*) is an anaerobic gram-positive, spore-forming, toxin-producing bacillus that causes intestinal disease varying from a mild diarrheal illness to severe colitis<sup>[14-16]</sup>. The burden of *C. difficile* infection (CDI) has increased dramatically over the past decade and it is now recognized that *C. difficile* is responsible for 20%-30% of cases of antibiotic associated diarrhea and 50%-75% of cases of antibiotic associated colitis<sup>[17,18]</sup>. *C. difficile* is also the leading cause of nosocomial diarrhea, with incidence ranging from 1:100-1:1000 hospitalized patients<sup>[19,20]</sup>. Loss of intestinal microbial equilibrium, most commonly following antibiotic use, creates an environment susceptible to colonization of *C. difficile* and subsequent CDI<sup>[21,22]</sup>.

IBD has been found to be associated with *C. difficile*<sup>[23-26]</sup>. Patients with IBD are at increased risk of developing CDI, have worse outcomes of CDI-including higher rates of colectomy and death, and experience higher rates of recurrence<sup>[27-30]</sup>. However, it is still not clear whether *C. difficile* is a cause of IBD or a consequence of the inflammatory state in the intestinal environment. The association between IBD and *C. difficile* may be due to different factors, such as drugs that are used for the treatment of IBD that might alter the intestinal flora and promote colonization (including repeat courses of antibiotics), altered immune and nutritional status, frequent hospitalizations, and even genetic predisposition<sup>[31,32]</sup>.

In this review we will try to focus on the role of *C. difficile* in IBD pathogenesis, the unique aspects of *C. difficile* infections in patients with IBD, and the implications for testing and treatment.

### The role of *C. difficile* in IBD

The initial trigger responsible for the onset of IBD is not yet known. A complex interplay between the immune system, environmental factors, such as stress and diet, enteric infections, and genetic factors play a role in the pathogenesis of IBD<sup>[33-35]</sup>. Gut microbiota interacts with both the innate and adaptive immune systems, playing a pivotal role in maintenance and disruption of gut immune quiescence<sup>[36]</sup>. Different bacteria have been implicated in the pathogenesis of IBD, including *Mycobacterium avium paratuberculosis*, enterotoxigenic *Bacteroides fragilis*, adherent/invasive *Escherichia coli*, *Campylobacter jejuni*, *Listeria monocytogenes*, *Chlamydia* sp., *Aeromonas hydrophila*, *Salmonella typhi*, and *C. difficile*<sup>[37-39]</sup>. However, to date there is no con-

clusive evidence that a specific pathogen is responsible for IBD onset or relapse.

*C. difficile* has been found to be associated with IBD. Different studies found that patients with IBD, including ulcerative colitis (UC) and CD, are at increased risk of developing CDI. A study based on a large cohort of IBD patients in the United States found that CDI was more common in UC patients (2.8%) as compared to the general inpatient population (0.4%), and another study reported an adjusted odds ratios for CDI in all IBD, CD, and UC admissions from 1998-2004 to be 2.9, 4.0, and 2.1 respectively<sup>[40,41]</sup>. Since 2003 there has been a dramatic rise in the incidence of CDI with severe outbreaks described in Canada, United States and England, which have been attributed to a new and more virulent strain designated BI/NAP1/027, that has also been found in patients with IBD<sup>[18,42,43]</sup>. A parallel rise in the incidence of CDI in patients with IBD has also been noted. During 1998-2004 CDI rates approximately doubled in CD (9.5 to 22.3/1000 admissions) and tripled in UC (18.4 to 57.6/1000)<sup>[41]</sup>. A retrospective observational study found that the rate of CDI in IBD patients increased from 1.8% in 2004 to 4.6% in 2005, with the majority of patients having colonic IBD<sup>[29]</sup>. More recent studies, found that 5.5%-19% of patients with an IBD exacerbation, tested positive for *C. difficile* infection, and as many as 3.5% of children hospitalized due to IBD, were diagnosed with CDI<sup>[44,45]</sup>. Furthermore, analysis of a registry database suggests that 10% of IBD patients will develop a *C. difficile* infection at some point, and approximately 10% of CDI occur at the time of IBD diagnosis<sup>[46]</sup>. Patients with IBD also have higher rates of asymptomatic carriage of *C. difficile* 8.2% (9.4% in patients with UC and 6.9% in patients with CD), versus 1% in healthy volunteers<sup>[47]</sup>. It is possible, though, that the seemingly increased risk of CDI in patients with IBD is due to increased surveillance of this population for CDI. There are studies that question the role of CDI in IBD. A recent prospective Dutch study found a low prevalence of *C. difficile* in IBD patients and did not find any association of *C. difficile* with disease activity, disease subtype (CD or UC), gender, antibiotic, and immunosuppressive therapy<sup>[48]</sup>.

Though it is still not clear if *C. difficile* causes IBD, it is understood that *C. difficile* can cause an infectious colitis superimposed on IBD, or may precipitate an IBD flare leading to simultaneous inflammatory processes, and it is nowadays considered a risk factor for IBD exacerbation. The association between *C. difficile* and IBD is mediated by a chain of events, including- recurrent hospitalizations, that are a known risk factor for acquisition of *C. difficile* and CDI, medications administered to patients with IBD (including immunomodulatory and antimicrobial agents) that disturb the intestinal flora, thus allowing for *C. difficile* colonization and adherence, and a decreased nutritional status that promotes *C. difficile* infection<sup>[31,32]</sup>. Thus, *C. difficile* can colonize the intestines of these patients and produce its two potent exotoxins: toxin A ("enterotoxin") and toxin B ("cytotoxin") that bind to receptors on intestinal epithelial cells. This activates a cascade of proinflam-

**Table 1 Unique features and clinical implications of *Clostridium difficile* infection in patients with inflammatory bowel disease**

Risk factors
Colonic IBD
Immunomodulatory drugs
In comparison to patients with no IBD: younger age, more community acquired cases, less prior antibiotic exposure
Clinical characteristics
Diarrhea (can be bloody), often mimics a flare of IBD
In patients with ileostomies: acute enteritis( an increase in ileostomy output, nausea, fever and leukocytosis)
In patients with ileal pouch anal anastomosis: pouchitis
Often no pseudomembranes on colonoscopy
Outcomes and complications
Higher rates of toxic megacolon and colonic perforation
Higher rates of colectomies
Longer length of hospital stay
Increased mortality
Diagnosis:
Test for CDI in all IBD patients hospitalized with a disease flare
As in patients with no IBD-one step molecular assays or two step algorithms: screening with EIA for GDH, followed by EIA for toxins and/or a molecular assay
Treatment:
1 Escalation of immunosuppression should be avoided during CDI
2 Antibiotics treatment as in non IBD patients
Mild to moderate disease: oral metronidazole
Severe disease: oral vancomycin + intravenous metronidazole
Fidaxomicin-less recurrences (no data in IBD patients)
3 Fecal microbiota transplantation
Limited data in IBD patients though seems to be effective

IBD: Inflammatory bowel disease; CDI: *Clostridium difficile* infection.

matory cytokines and leukotrienes such as tumor necrosis factor (TNF), interleukin (IL)-6, IL-8, IL-1 $\beta$ , leukotrienes B<sub>4</sub>, and interferon- $\gamma$  leading to apoptosis of gut epithelial cells and increased permeability of the intestinal mucosa, which in turn can play a role in the pathogenesis of IBD<sup>[49,50]</sup>.

So, as elaborated above, there is a possible association between IBD and *C. difficile*, though there are many issues to be resolved, such as: whether CDI is a risk factor for the development of IBD, or the active inflammatory process in patients with IBD predisposes them to CDI, and what are the exact mechanisms that are responsible for this association.

## CDI IN PATIENTS WITH IBD

The unique features and clinical implications of CDI in patients with IBD are summarized in table 1.

### Risk factors

As noted above, patients with IBD are at increased risk for CDI, but this risk varies among different subsets of these patients. One of the major risk factors for CDI in patients with IBD is colonic IBD, either UC or CD with colitis-with 91% of patients with IBD suffering from CDI, reported to have colonic IBD, and a higher incidence of CDI was found in patients with left sided and extensive disease as compared to distal disease<sup>[29]</sup>. Other

risk factors for CDI in patients with IBD are similar to those in the general population, such as- older age, medications (antibiotic/immunosuppressive agents), hospitalization, residence at a long term facility and comorbidities<sup>[21,51,52]</sup>. However, there are a few differences in risk factors for CDI in patients with IBD. IBD patients with CDI tend be younger, and 76% of *C. difficile* infections in these patients represent outpatient acquired infections, as opposed to patients without IBD were the most part of *C. difficile* infections are hospital acquired<sup>[29,53]</sup>. IBD has been found to be a risk factor for outpatient acquired CDI. In a study done in our medical center, on 115 patients with CDI, we found a trend towards a higher rate of IBD in community acquired CDI versus hospital acquired CDI (20.2% *vs* 9.7% , unpublished data).

Also, up to 40% of IBD patients do not have documented antibiotic exposure prior to presentation with CDI<sup>[54]</sup>. Patients with IBD receive various types of immunosuppressive drugs that might predispose to CDI, and steroid treatment has been found to increase the risk of CDI 3 fold in these patients, though other immunomodulatory drugs such as purine analogs, methotrexate and biological agents, have not been consistently found to increase the risk of CDI<sup>[29,41,55,56]</sup>. Combination treatment with different immunomodulatory agents can increase the risk of CDI as was found in pediatric patients receiving concomitant therapy of methotrexate and anti-TNF- $\alpha$ , where 28% of patients developed CDI<sup>[57]</sup>.

### Clinical characteristics

Patients with IBD can have different and unique clinical presentations of CDI. To begin with, the similarity in symptoms between CDI and a flare of IBD (diarrhea, abdominal pain, fever and leukocytosis) make it extremely difficult to distinguish between the two<sup>[29,41]</sup>. *C. difficile* in IBD may also show atypical features such as frequent bloody stools, as opposed to watery stools in patients without IBD. Diarrhea may even be absent in postoperative patients who receive narcotics for pain control and develop paralytic ileus. In IBD patients with ileostomies, *C. difficile* can cause acute enteritis, which can manifest as an increase in ileostomy output, nausea, fever and leukocytosis<sup>[53]</sup>. In patients who have undergone ileal pouch anal anastomosis as treatment for IBD, *C. difficile* infection might be a triggering factor for pouchitis, which presents as an increase of the number of stools per day, with or without constitutional symptoms such as weight loss<sup>[58,59]</sup>. In one study 10.7% of patients with ileal pouch anal anastomosis, presenting with pouchitis, were found to have CDI<sup>[60]</sup>. Another study demonstrated that 18.3% of cases of pouchitis were positive for *C. difficile* toxin, with men 3.5 times more likely than women to develop *C. difficile* pouchitis<sup>[61]</sup>.

Typical findings of CDI on colonoscopy (such as pseudomembranous exudates, which are found in up to 60% of patients with CDI) are often absent in patients with IBD (0%-13% of cases)<sup>[62]</sup>. This might be due to a weakened inflammatory response in the colonic epithelial

environment in patients with chronic active IBD or due to immunosuppressive drugs that hamper the development of pseudomembranes, which are caused by disruption of cellular cytoskeleton by toxins, ulcer formation and leakage of serum proteins, inflammatory cells and mucus.

## Outcomes

*C. difficile* infections have a different and often more severe clinical course in patients with IBD. These patients have higher rates of endoscopies, higher rates of complications such as toxic megacolon and colonic perforation, higher rates of colectomies, longer length of hospital stay, and increased mortality<sup>[29,30]</sup>. Different studies found high rates of colectomies in these patients, ranging from 20% to 45%<sup>[28,29]</sup>, with one study finding a 6 fold increase in bowel surgery in patients with CDI with and without IBD<sup>[30]</sup>. Patients with IBD also experience more recurrences of CDI, than patients without IBD<sup>[29]</sup>. Mortality is also increased in these patients with one study demonstrating a 6%-18% case fatality rate in patients with IBD and CDI *vs* 1.4%-2.1% fatality rate in patients with CDI alone<sup>[40]</sup>. A large study of the inpatient care database in the United States found that hospitalized patients with concurrent CDI and IBD had a 4 times higher mortality rate than those admitted for IBD or CDI alone<sup>[63]</sup>.

All of these special aspects of CDI in patients with IBD should cause physicians to be alert to the possibility of CDI in a patient with an IBD exacerbation and prompt rapid diagnosis and treatment.

## Diagnosis

CDI is a clinical diagnosis supported by laboratory findings. As mentioned before, it is often difficult to distinguish between CDI and an exacerbation of IBD, because of the similarity in symptoms, and moreover, IBD patients may have a different clinical presentation of CDI. Laboratory findings in both CDI and IBD are also similar, including: leukocytosis, hypoalbuminemia, and fecal leukocytosis<sup>[53]</sup>. Endoscopic findings that are typical for CDI, such as colonic pseudomembranes, are also lacking in most patients with IBD that present with CDI<sup>[28]</sup>. As noted above, patients with IBD and CDI often acquire the infection in the outpatient setting and in many there is no previous documented antibiotic exposure<sup>[29,53]</sup>.

Due to the high prevalence of CDI in patients hospitalized with an IBD exacerbation, the suspected causal association between CDI and flare of IBD, and the prognostic implications of CDI in these patients, it is recommended by the American college of gastroenterology CDI Guidelines Task Force, to test all IBD patients hospitalized with a disease flare for *C. difficile*<sup>[64]</sup>. Also, the European Crohn's and Colitis Organization guidelines recommend testing for *Clostridium difficile* infection in patients with severe or refractory UC<sup>[65]</sup>. Patients should be tested even in the absence of traditional risk factors such as antibiotic exposure.

There are various laboratory tests used in the diag-

nosis of CDI. Only loose, watery, or semi-formed stool should be tested for *C. difficile* and specimens should be kept at 4 °C if delay in testing is anticipated due to degradation of *C. difficile* toxin at room temperature<sup>[66,67]</sup>. The different tests that have been used to date are<sup>[68-70]</sup>: (1) Selective anaerobic culture: the most sensitive diagnostic method, cannot distinguish toxin-producing strains from non-toxin producing strains, time and labor consuming and thus reserved for epidemiologic studies<sup>[71]</sup>; (2) Cell culture cytotoxicity neutralization assay: detects the presence of toxin B in stool by its cytopathic effects in a cell or tissue culture, is time consuming, with a sensitivity of 65%-90%, and is rarely performed today<sup>[71]</sup>; (3) enzyme immunoassay (EIA) for *C. difficile* toxins A and B: sensitivity for toxins A and B is 60%-75% and specificity is higher (up to 99%)<sup>[72,73]</sup>. Was the routine diagnostic assay for CDI in most microbiology laboratories in recent years, but due to its low sensitivity, is not recommended today as the initial diagnostic assay<sup>[70]</sup>; (4) EIA for *C. difficile* glutamate dehydrogenase (GDH), an enzyme produced in all *C. difficile* strains: sensitivity of 75% > 90%, but cannot differentiate between toxin positive and toxin negative strains<sup>[74]</sup>; and (5) Polymerase chain reaction (PCR): detect toxin A and B genes, are highly sensitive and specific<sup>[75,76]</sup>, and provide rapid results (within as little as 1 h).

Current recommendation for CDI diagnosis implement either one step molecular assays or two step algorithms with screening with EIA for GDH, followed by EIA for toxins and/or a molecular assay<sup>[67,68]</sup>. In patients with IBD, there is no evidence to date, that testing for CDI should be done differently. A recent retrospective study that compared the frequency and clinical outcomes of IBD inpatients with CDI, found that a greater percentage of patients tested positive by PCR for toxin B as compared with ELISA for toxins A + B, but the clinical outcomes were the same, regardless of method of testing<sup>[77]</sup>. More research is needed to determine the optimal diagnostic test for CDI in patients with IBD. Due to high rates of asymptomatic colonization of *C. difficile* in patients with IBD, only patients with significant diarrhea should be tested for CDI.

## Treatment

Treatment of CDI includes general measures such as supportive care with attention to correction of fluid losses and electrolyte imbalances, cessation of the inciting antibiotic as soon as possible (if possible), implementation of infection control policies-including hand hygiene with soap and water which is more effective than alcohol-based hand sanitizers in eradication of *C. difficile* spores<sup>[67,78]</sup>. Antimotility agents such as loperamide and opiates have traditionally been avoided in CDI for fear of decreasing toxin clearance and increasing the risk of ileus and/or megacolon, but the evidence that they cause harm is equivocal<sup>[79]</sup>.

Specific antibiotic therapy should be started as soon as possible, and empiric therapy is indicated pending results of diagnostic testing if the clinical suspicion is high and

when severe or complicated CDI is suspected. Currently, there are several drugs in use for treatment of CDI including: metronidazole (oral or intravenous), vancomycin (oral or per rectum), oral rifaximin, and a newer drug- oral fidaxomicin. A Cochrane systematic review from 2011 found no statistically significant difference in efficacy between vancomycin and other antibiotics including metronidazole, fusidic acid, nitazoxanide or rifaximin<sup>[80]</sup>. The updated guidelines for the treatment of CDI released by the Infectious Diseases Society of America and the Society for Healthcare epidemiology of America suggest that the initial choice of treatment should be determined based on the severity of illness and depending if it is a first episode of CDI or a recurrence<sup>[69]</sup>. There are different scoring systems to assess the severity of illness, including the severity score index that consists of 9 criteria, each accounting for one point: altered mental status, white blood cell count > 20000 or < 1500, albumin < 2.5 mg/dL, ascites or colitis by imaging, mean arterial pressure < 65 mmHg, fever > 38.3 °C, tachycardia > 110 bpm and admission to intensive care unit. 1-3 points indicates mild disease, 4-6 points moderate disease, and ≥ 7 points severe disease<sup>[81]</sup>. For an initial episode of mild to moderate CDI-metronidazole, at a dose of 500 mg orally 3 times per day for 10-14 d, is considered the drug of choice. Vancomycin at a dose of 125 mg orally 4 times per day for 10-14 d is the drug of choice for an initial episode of severe CDI. Vancomycin, administered 500 mg orally 4 times per day (and 500 mg in approximately 100 mL normal saline per rectum every 6 h as a retention enema, if ileus is present) with or without intravenously administered metronidazole 500 mg intravenously every 8 h, is the regimen of choice for the treatment of severe, complicated CDI. Treatment of the first recurrence of CDI is usually with the same regimen as for the initial episode but should be stratified by disease severity. Treatment of the second or later recurrence of CDI is with vancomycin therapy using a tapered and/or pulse regimen<sup>[67]</sup>.

Recent studies of fidaxomicin, 200 mg orally twice daily, compared with oral vancomycin, demonstrated non inferiority of clinical response after 10 d of treatment and superior sustained responses with a decrease in recurrences (13% *vs* 24% with vancomycin treatment)<sup>[82]</sup>. Among patients who received concomitant antibiotics, treatment with fidaxomicin resulted in higher cure rates (90% *vs* 79.4%) and lower recurrence rates (16.9% *vs* 29.2% with vancomycin)<sup>[83]</sup>. Due to these and other findings, fidaxomicin might be a promising treatment for patients with risk factors known to portend relapse and severe infection<sup>[84]</sup>, though two different economical analyses reported conflicting results of the cost effectiveness of using fidaxomicin as first-line treatment for CDI<sup>[85,86]</sup>.

In patients with IBD and CDI, there are no guidelines or evidence from prospective studies to suggest that one antibiotic regimen is better than another. Failure rates of up to 50% have been reported in IBD patients treated with metronidazole<sup>[87]</sup>. Considering the worse outcomes of patients with IBD and CDI, some institutions use

vancomycin as first line therapy in these patients. In a single center study, where vancomycin was adopted as first line therapy in IBD patients with CDI, colectomy rates decreased from 45.5% to 25% within 1 year after the change of policy<sup>[88]</sup>. There are no data as of yet regarding the use of fidaxomicin in the IBD patient population, though in another group of immune suppressed patients-recipients of solid organ and hematopoietic stem cell transplantation, fidaxomicin achieved over all cure rates in 86% of episodes and recurrence rate was 7%<sup>[89]</sup>.

Concomitant use of immunomodulators is another unresolved issue in patients with IBD and CDI. A retrospective multicenter European study comparing hospitalized IBD patients with CDI treated with antibiotics and immunomodulators or antibiotics alone, found that the primary outcome of complications including colectomy or death within 3 mo occurred in 12% of patients treated with both, as compared to none of the patients treated with antibiotics alone<sup>[90]</sup>. The use of 2 or more immunomodulators further increased the risk of complications. In a survey of North American gastroenterologists, there was significant disagreement on whether combination antibiotics and immunomodulators or antibiotics alone should be given in patients with an IBD flare and CDI<sup>[91]</sup>. The American College of Gastroenterology CDI task force, has given a conditional recommendation, with low quality supporting evidence, that ongoing immunosuppression can be maintained in patients with CDI, although escalation of immunosuppression should be avoided<sup>[64]</sup>.

Fecal microbiota transplantation (FMT) through retention enemas, rectal tube, colonoscopy, nasogastric and nasoduodenal tubes, or upper endoscopy is another option for treating recurrent CDI through restoration of a healthy microbiome in the lower gastrointestinal tract. Different studies have reported success rates of FMT approaching 90% in patients with recurrent CDI<sup>[92,93]</sup>. A randomized prospective trial, found that duodenal infusion of donor feces following vancomycin treatment was significantly more effective for the treatment of recurrent CDI than the use of vancomycin alone<sup>[94]</sup>. Data on the use of FMT among IBD patients is limited, though a recent systematic review found that out of 12 patients with IBD and CDI treated with FMT, all became toxin negative, with symptomatic resolution in 11 out of 12 patients<sup>[95]</sup>. A recent review of FMT<sup>[96]</sup> notes that though there are no guidelines concerning FMT for treatment of CDI in patients with IBD, after FMT and eradication of *C. difficile*, the severity of IBD is gradually reduced with improved responses to medications for IBD. FMT is considered a safe treatment, though a recent paper reported a case of a flare of UC in a patient who received FMT for CDI<sup>[97]</sup>.

In patients after restorative proctocolectomy and ileal pouch anal anastomosis that present with *C. difficile* pouchitis, treatment is empirical because there are no published prospective trials. Studies suggest that metronidazole is not completely protective against CDI of

the pouch, as this infection has developed in patients on metronidazole therapy, thus in these patients vancomycin might be considered as first line therapy<sup>[59]</sup>.

## CONCLUSION

Patients with IBD are at increased risk of developing CDI and having worse outcomes, including higher rates of colectomy and death. There has also been a rise in the percentage of patients with IBD that suffer from CDI during recent years, even in those lacking classic risk factors for CDI. Patients with IBD often present with unique and more severe symptoms of CDI. Diagnosis of CDI in patients with IBD warrants a high index of suspicion and physicians should be alert to the possibility of CDI in any patient with an IBD exacerbation. All hospitalized patients with a flare of IBD should be tested for CDI and antibiotic treatment should be initiated rapidly, especially in severe cases, where vancomycin is the treatment of choice. More studies are needed to better understand the pathogenetic role of CDI in IBD exacerbations, to define what are the best diagnostic methods for CDI in these patients, to assess the efficacy of newer treatments such as fidaxomicin in patients with CDI and IBD, and to better address the question of concurrent treatment with immunomodulatory agents.

### Abstract

Intraperitoneal carcinomatosis (PC) may occur with several tumor entities. The prognosis of patients suffering from PC is usually poor. Present treatment depends on the cancer entity and includes systemic chemotherapy, radiation therapy, hormonal therapy and surgical resection. Only few patients may also benefit from hyperthermic intraperitoneal chemotherapy with a complete tumor remission. These therapies are often accompanied by severe systemic side-effects. One approach to reduce side effects is to target chemotherapeutic agents to the tumor with carrier devices. Promising experimental results have been achieved using drug-eluting beads (DEBs). A series of *in vitro* and *in vivo* experiments has been conducted to determine the suitability of their extravascular use. These encapsulation devices were able to harbor CYP2B1 producing cells and to shield them from the hosts im-

mune system when injected intratumorally. In this way ifosfamide - which is transformed into its active metabolites by CYP2B1 - could be successfully targeted into pancreatic tumor growths. Furthermore DEBs can be used to target chemotherapeutics into the abdominal cavity for treatment of PC. If CYP2B1 producing cells are proven to be safe for usage in man and if local toxic effects of chemotherapeutics can be controlled, DEBs will become promising tools in compartment-based anticancer treatment.

**Key words:** Compartment based therapy; Intraperitoneal; Drug-eluting beads; Carcinomatosis; Hyperthermic intraperitoneal chemotherapy; Glioblastoma; Pancreatic cancer; CYP2B1; Ifosfamide

**Core tip:** Intraperitoneal carcinomatosis occurs with several tumor entities and prognosis is usually poor. Besides standard therapy, only few patients may benefit from hyperthermic intraperitoneal chemotherapy. The treatment may cause severe systemic side-effects. One different approach to target chemotherapeutic agents to the tumor employs carrier devices. Contemplable carriers are drug-eluting beads (DEBs). DEBs can be used to transfer drugs or pro-drug converting enzymes directly to the tumor. Furthermore, DEBs can successfully target chemotherapeutics into the abdominal cavity for *ip* treatment. When local toxic effects are controlled, DEBs are effective tools in compartment-based therapy.

## CLINICAL BACKGROUND

Peritoneal carcinomatosis (PC) is a disseminated tumor stage, which is observed in patients with ovarian, pancreatic, gastric and colorectal cancer. With median survival rates of 3.1 mo for gastric cancer and 5.2 mo for colorectal cancer, respectively<sup>[1]</sup>, the prognosis is usually poor<sup>[2]</sup>.

Survival is prolonged by new agents used in palliative chemotherapy. With the availability of oxaliplatin, irinotecan, bevacizumab, and cetuximab the 5-year survival has significantly increased over the last decade<sup>[3-7]</sup>.

Although some patients seem to benefit from these drugs, the physical and psychological strain for patients suffering from PC remains high. In addition to the commonly known side effects of chemotherapy<sup>[8]</sup>, patients show a variety of symptoms originating from PC itself, ranging from abdominal pain, nausea and obstipation up to bowel obstruction and obstructive uropathy<sup>[9]</sup>.

## EVALUATION OF PRESENT TREATMENT

The treatment of peritoneal carcinomatosis requires an interdisciplinary and multimodal approach. Modern therapy combines cytoreductive surgery (CRS), radiation therapy and systemic chemotherapy, depending on the origin of the tumor<sup>[10-12]</sup>. Unfortunately survival rates remain low<sup>[1,13]</sup> at the cost of frequently observed dose limiting side-effects<sup>[8]</sup>.

Since tumor spread into the abdominal cavity may also be considered as an early step of dissemination - comparable to liver metastasis in colorectal carcinoma - and not as a state of generalized systemic disease<sup>[14-16]</sup>, one approach may be to resect all detectable tumor nodules and target drugs directly to the peritoneal cavity<sup>[17]</sup>.

The surgical procedure removes all macroscopic tumor manifestations by combination of different peritonectomy procedures, including greater omentectomy, splenectomy, left upper quadrant peritonectomy, right upper quadrant peritonectomy, lesser omentectomy, cholecystectomy with stripping of the omental bursa, pelvic peritonectomy with sleeve resection of the sigmoid colon, and antrectomy<sup>[18-21]</sup>, as well as parietal peritonectomy<sup>[22,23]</sup>. After the resection, the dissolved chemotherapeutic agent and carrier solution are heated up to 42 °C and pumped through the abdominal cavity for 40-90 min<sup>[24]</sup>. Since the abdomen remains opened, it is possible for the surgeon to support the circulation in the abdominal cavity manually<sup>[25]</sup>. This procedure is followed by thorough lavage, anastomosis of resected bowel segments and closure of the abdominal wall<sup>[24]</sup>.

A survival benefit using CRS and hyperthermic intraperitoneal chemotherapy (HIPEC) has been shown<sup>[26]</sup>. Verwaal *et al.*<sup>[27]</sup> reported a 3-year survival of 38% in their patients. A more recent follow up of the same cohort shows similar survival rates<sup>[28]</sup>. Median progression-free survival was 7.7 mo in the control arm and 12.6 mo in the HIPEC arm. A 5-year survival of 45% was found in patients, in which R1 resection could be achieved. This

indicates that CRS combined with HIPEC is superior to systemic chemotherapy alone. Nevertheless the findings of Franko *et al.*<sup>[29]</sup> suggest, that CRS combined with HIPEC as well as systemic chemotherapy alone have their roles in the multidisciplinary approach treating peritoneally disseminated cancer.

In selected patients even a long term survival may be possible, with CRS and HIPEC being a curative approach in disseminated colorectal carcinoma<sup>[28,30]</sup>.

The HIPEC procedure itself is demanding for most of the patients. Even though the median survival rates increased, the 30-d mortality rate of 4.8% and a morbidity rate reaching up to 55% are high<sup>[31]</sup>. The surgery itself and severe systemic side-effects may lead to deterioration of health or death<sup>[32,33]</sup>. Given that, the inclusion criteria to receive CRS and HIPEC remain strict. The peritoneal surface has to be the only site of disease dissemination<sup>[27]</sup> and the preoperative assessment<sup>[34]</sup> should suggest a high likelihood of achieving complete cytoreduction (CC-0)<sup>[35]</sup>. Therefore only patients with medium-sized intraperitoneal tumor nodules and a limited distribution within the abdomen are selected<sup>[36]</sup>. Patients have to be physically fit to endure this extensive procedure. Considering that peritoneal carcinomatosis only becomes symptomatic in advanced stages, where CC-0 or CC-1 can rarely be achieved, only few highly selected patients have access to this approach<sup>[37]</sup>. Excluded patients are left with systemic chemotherapy.

Alternative techniques have been investigated to target chemotherapeutic agents to the body cavities without the strain of surgery. These are promising approaches to circumvent both the systemic side effects and the hazard of an extensive surgical procedure.

## DRUG-ELUTING BEADS

### Bead characteristics

Promising carriers for contemplanable agents such as doxorubicin, irinotecan or mitoxantrone are drug-eluting beads (DEB).

By far the most commonly used product in clinic is DC Bead™, which are microspheres comprised of a sulphonate-modified polyvinyl-alcohol hydrogel. They are available in sizes from 70-700 µm<sup>[38]</sup> and can be loaded with doxorubicin (DOX), irinotecan (IRI) or mitoxantrone (MTX)<sup>[39]</sup>. When drug-loaded, the product provides an accurate dosage of drug per unit volume of beads *in vitro*<sup>[38]</sup>, which they release *via* ion exchange constantly over weeks<sup>[40,41]</sup>. *In vitro*, the beads are robust and maintain their size and shape after drug loading<sup>[42]</sup>. This is a prerequisite for DEBs, since damage of the beads may cause rapid liberation and significant systemic distribution of the encapsulated drug or adverse effects by the debris itself.

The surface of the DEBs itself is inert and did not cause any immune reaction in control groups treated with unloaded beads<sup>[39,43]</sup>. Furthermore the biomechanical engineered material is able to shield its content from the immune system<sup>[44,45]</sup>.

### Present field of application

DEBs are used in clinical practice for trans-arterial chemoembolisation (TACE) of hypervascularized tumors<sup>[46]</sup>, such as hepatocellular carcinoma (HCC) and liver metastasis. By administering them selectively into the tumor-feeding vessels, the route for essential nutrients is obstructed and high levels of antineoplastic drugs can be reached within the tumor<sup>[47]</sup>.

As the procedure itself can be carried out under local anesthesia, morbidity and complication rates are low<sup>[48]</sup>, TACE has become the standard palliative approach in patients with unresectable HCC<sup>[49-51]</sup>. The objective response rates range from 70%-75%<sup>[52,53]</sup> at a low rate of complications<sup>[53]</sup>. This suggests a good risk-benefit ratio.

For both associated side effects<sup>[54]</sup> and progression free survival<sup>[55]</sup> as well as overall disease control<sup>[54,55]</sup>, doxorubicin-loaded DC beads (DOXDEB™) produced the most promising results.

## DEBS IN EXTRAVASCULAR USE

Since DEBs are able to liberate agents continuously *in vitro*<sup>[56]</sup> they can also serve as drug carriers for extravascular application if the beads are directly instilled into the compartments.

### Intracerebral therapy

The median survival of rats with experimental glioblastoma multiforme (GBM) could be successfully prolonged using doxorubicin polymers<sup>[57]</sup>. This demonstrated a superior effect of chemotherapeutic carriers as compared to *iv* administration of the free drug. The most efficient drug - namely doxorubicin - caused the most severe side effects. Intracerebral hemorrhage and edema as well as hemiparesis were observed<sup>[57]</sup>. A significantly longer median survival could be achieved in patients with GBM using carmustine warfers<sup>[58]</sup>, but they did not affect the recurrence-free survival times<sup>[59]</sup>. These findings justified the idea of compartment-based therapy, but also called for new delivery systems and alternative antineoplastic drugs in return.

Baltes *et al*<sup>[60]</sup> showed that the intracerebral administration of DEBs is safe for use depending on the loaded drug. Both doxorubicin- and irinotecan-loaded DEBs significantly improved survival time in a rat BT4Ca GBM model. Doxorubicin again caused severe side effects<sup>[57]</sup> whereas irinotecan seemed to selectively affect only the cancer cells and not healthy brain tissue<sup>[61,62]</sup>. These findings could be confirmed in follow-up experiments where alginate was used as a viscosity modifier to secure the administration of the beads into the tissue<sup>[63]</sup>.

### Intrapancreatic therapy

The efficacy of irinotecan- and topotecan-loaded DEBs have been evaluated by use of a modified MTS assay and in a PSN-1 mouse xenograft model of pancreatic cancer by direct injection at the tumor site. Topotecan was shown to be more potent than irinotecan in the *in*

*vitro* cell assay, had reasonable efficacy and tolerability at 0.2-0.4 mg doses but was lethal at doses of 0.83-1.2 mg. Irinotecan however, was well tolerated even with repeated injections of doses from 3.3-6.6 mg and displayed good efficacy<sup>[64]</sup>. A similar study evaluated combinations of doxorubicin, irinotecan, topotecan and rapamycin DEBs and demonstrated synergistic activity for certain drug combinations, in particular doxorubicin and rapamycin<sup>[65]</sup>.

Feasibility for the clinical application of the direct intratumoral delivery of a compartment-based therapy was first demonstrated by delivery of a reservoir of a thermosensitive gel containing paclitaxel (Oncogel®) into the pancreas by use of ultrasound-guided endoscopic needle injection<sup>[66,67]</sup>. This approach has been subsequently adapted for the administration of irinotecan-loaded DEBs suspended in alginate into the tail of the pancreas of a healthy pig. The therapy was well tolerated up to doses of 300 mg of irinotecan, with only localized pancreatic tissue reactions on histopathologic review<sup>[68]</sup>.

### Intraperitoneal therapy of peritoneal carcinomatosis

An elegant approach to target drugs to a tumor is to administer them as pro-drugs and activate them intratumorally. The active metabolites are formed by enzymes which are selectively injected into the tumor.

Routinely, ifosfamide has been used *via iv* application in pancreatic cancer treatment<sup>[69,70]</sup>. After administration cytochrome P450 2B1 (CYP2B1) produced by hepatocytes, transforms ifosfamide into 4-OH-ifosfamide, which results in the active compounds phosphoramidate mustard and acrolein<sup>[71]</sup>. *In vitro* preparation and direct administration of the active compounds are limited due to their short half life (45 min)<sup>[72]</sup>.

Löhr *et al*<sup>[73]</sup> used encapsulated feline kidney cells, engineered to produce CYP2B1<sup>[74]</sup>, to target activated ifosfamide into pancreatic carcinoma<sup>[73]</sup>. Therefore, cells were encapsulated in cellulose sulphate<sup>[75]</sup> for immobilization and to protect them from the immune system when injected into the tumor. To model a pancreatic cell-like carcinoma PaCa-44 human pancreatic tumor cells were injected subcutaneously into nude mice. All mice received ifosfamide *iv*, one group received intra-tumorous injection of encapsulated CYP2B1 producing cells and one group received nonencapsulated cells. Tumor growth was impaired in all mice receiving ifosfamide. However, the most significant tumor reduction was detectable in the group that had received encapsulated cells. Complete macro- and microscopic tumor remission could be achieved in 20% of the animals. Although the same dosages of ifosfamide were used in both groups, the apoptotic rate of tumor cells was three times higher in the group receiving encapsulated cells. Furthermore these animals appeared healthier than the ones receiving nonencapsulated cells. Müller *et al*<sup>[43]</sup> were able to reproduce these results using a CYP2B1 producing cell line of human origin. This cell line did not produce potentially harmful retroviruses<sup>[76]</sup> and is immune resistant<sup>[77]</sup>.

The approach worked for other tumor entities as

**Figure 1** Peritoneal metastasis. A: Beads accumulate in the mesentery of the small bowel (arrows). Animals show a complete tumor remission; B: Control animal with disseminated peritoneal carcinomatosis induced by Panc02 cells.

well. Samel *et al.*<sup>[78]</sup> showed, that similar results could be achieved in Balb/c mice carrying peritoneal tumor nodules, induced by syngenic C-26 cells injected into the abdominal cavity. This cell line is highly malignant and rapidly forms tumor nodules on the peritoneum. Again, in some animals a complete response was achieved. One major drawback of this approach is the use of genetically engineered cells. These cells may maintain a malignant potential. It remains to be shown if they can be safely applied to patients.

Therefore, an easier approach directly employs encapsulated chemo agents. *In vitro* tests with wild-type C-26 murine colon-carcinoma cells showed potent tumor toxicity for free DOX, IRI and MTX and the encapsulated drugs when combinations of the chemotherapeutic agents and DEBs were tested<sup>[39]</sup>. For free IRI and MTX the inhibition of cell growth was superior to their encapsulated forms. The proportion of apoptotic cells was significantly higher for free DOX as well as for DOXDEB™ when compared to the other two agents. Both DOX and MTX showed a dose-depending induction of apop-

tosis, whereas IRI did not show any significant effect.

*In vivo* tests followed after determining appropriate concentration levels<sup>[39]</sup>. For better detection of micrometastases and for tumor load quantification, C-26 cells had been transfected with the marker protein enhanced green fluorescent protein as described<sup>[78,79]</sup>. All animals developed disseminated PC. Thereafter, animals were treated with free and encapsulated DOX and MTX. Best tumor reduction was obtained when splitting the DEB application into three sessions. Complete tumor remission could be obtained. Weight loss and mortality of the subjects was significantly higher in the groups which were treated with the corresponding free drugs, suggesting a lower toxicity in the DEB groups.

The results obtained in this model of colorectal tumor, could be reproduced for pancreatic carcinoma dissemination (Figure 1). Yagublu *et al.*<sup>[80]</sup> used a model of peritoneally metastasized panc02 pancreatic carcinoma cells in C57 black6 mice. Treatment was performed with free and encapsulated DOX, IRI and MTX. The free drug was more potent in decreasing tumor cell growth and inducing apoptosis than the encapsulated drugs *in vitro*. Again, *in vivo* free drug administration caused more weight loss and significantly higher lethality than the encapsulated drug, while no relevant differences in antitumoral activity could be observed.

To test the safety of the intraperitoneal injection and therapy using the DOXDEB™ a large animal trial was carried out<sup>[81]</sup>. Black-headed meat-sheep received an application of DOXDEB™ into the abdominal cavity. Up to 50% of the maximal cumulative dose suggested for male humans were used in one single intraperitoneal injection<sup>[82]</sup>. DEBs were injected using a verres needle. Upon autopsy, no DEBs were distributed *via* blood or lymphatic vessels. Beads remained on the peritoneum, immobilized by a fibrin layer (Figure 2A and B). No evidence for organ-related damage or systemic toxicity was observed. This is remarkable, as cardio toxicity<sup>[83-87]</sup> and myelosuppression<sup>[88-91]</sup> are frequently described with the systemic use of doxorubicin, along with less severe side effects such as stomatitis, alopecia, nausea and vomiting<sup>[90]</sup>. The systemic distribution of DOX followed a three-compartment-model omitting a rapid and high peak, in comparison to *iv* administration. Serum levels reached a steady-state 360 min after application with a half-life of 615 h. Some sheep did not reach the end point and developed a chemical peritonitis<sup>[82,92,93]</sup> (Figure 3). By circumventing the systemic administration and its accompanying side effects, local toxicity was the only limiting factor. This underlines the importance of drug choice when it comes to DEB therapy within the intraperitoneal compartment.

## CONCLUSION

There is convincing evidence that drug-eluting beads can be employed in an extravascular environment for a compartment-based therapy. In several tumor models, the carrier devices showed convincing tumor control and

**Figure 2** Doxorubicin-eluting beads. A: HE-stained, magnification  $\times 50$ : A layer of fibrin (between arrows) immobilizing the doxorubicin-loaded DC beads (DOXDEB™) on the livers surface; B: HE-stained, magnification  $\times 100$ : DOXDEB™ in layer of fibrin and surrounded by lymphocytes immobilizing it on mesenteric connective tissue.

**Figure 3** Chemical peritonitis. Autopsy of an animal 28 d after installation of *ip* doxorubicin-loaded drug-eluting beads: Situs with greater omentum and intestinal loops with fibrinous adhesions, amber-colored ascitic fluid.

side-effects were less likely to occur. Also, encapsulation devices can be used to transform pro-drugs into their active metabolites within or in vicinity of the tumor. Here, drug-eluting beads successfully immobilized transforming-enzyme producing cells and protected them from the host immune system. However, the application of genetically engineered cell lines remains a major safety concern.

Intraperitoneal application of DEBs is a small procedure which can be safely performed under local anesthesia. Within the abdominal cavity DEBs show predictable liberation characteristics, remain inert and do not distrib-

ute *via* blood or lymphatic vessels.

Compartment-based therapy could be considered as a favorable treatment option for palliative patients with a deteriorated general condition, who are not eligible for HIPEC. Local toxicity is a limiting factor. Other drugs - for example irinotecan - have to be tested in a large animal model to further investigate local reactions.

If the adverse effects of the loaded substances are controlled, the extravascular use of drug-eluting beads is a promising future approach in compartment-based tumor therapy.

### Abstract

Ischemia-reperfusion injury (IRI) remains an unresolved and complicated situation in clinical practice, especially in the case of organ transplantation. Several factors contribute to its complexity; the depletion of energy during ischemia and the induction of oxidative stress during reperfusion initiate a cascade of pathways that lead to cell death and finally to severe organ injury. Recently, the sirtuin family of nicotinamide adenine dinucleotide-dependent deacetylases has gained increasing attention from researchers, due to their involvement in the modulation of a wide variety of cellular functions. There are seven mammalian sirtuins and,

among them, the nuclear/cytoplasmic sirtuin 1 (SIRT1) and the mitochondrial sirtuin 3 (SIRT3) are ubiquitously expressed in many tissue types. Sirtuins are known to play major roles in protecting against cellular stress and in controlling metabolic pathways, which are key processes during IRI. In this review, we mainly focus on SIRT1 and SIRT3 and examine their role in modulating pathways against energy depletion during ischemia and their involvement in oxidative stress, apoptosis, micro-circulatory stress and inflammation during reperfusion. We present evidence of the beneficial effects of sirtuins against IRI and emphasize the importance of developing new strategies by enhancing their action.

**Key words:** Sirtuin 1; Sirtuin 3; Ischemia-reperfusion injury; Oxidative stress; Apoptosis

**Core tip:** Sirtuins are responsible for the regulation of protein activation by deacetylating a range of proteins that play important roles in the pathophysiology of various diseases. The present review summarizes the beneficial effects of sirtuins 1 and 3, the two most prominent sirtuins involved in mammalian energy homeostasis and oxidative stress. We conclude that both sirtuins might be attractive targets for counteracting the detrimental effects of ischemia-reperfusion injury.

### INTRODUCTION

Sirtuins belong to the highly conserved class III histone

deacetylases with homology to the yeast silent information regulator 2. To date, seven sirtuins have been described in mammals. They possess nicotinamide adenine dinucleotide (NAD<sup>+</sup>)-dependent deacetylase activity, with the exception of sirtuin 4 (SIRT4) which has only ADP-ribosyltransferase activity, and SIRT1 and SIRT6 which have not only deacetylase activity but also relatively weak ADP-ribosyltransferase activity<sup>[1]</sup>. Their enzymatic activity depends on their protein expression levels, the availability of NAD<sup>+</sup> and the presence of proteins that modulate sirtuin enzymatic activity. For instance, SIRT1 expression increases during starvation or when cells are exposed to conditions of oxidative stress and DNA damage<sup>[2,3]</sup>.

Sirtuins are found in several subcellular locations, including the nucleus (SIRT1, SIRT6, and SIRT7), cytosol (SIRT2), and mitochondria (SIRT3-SIRT5). In some studies, however, SIRT1 has been found to possess cytosolic activity, and SIRT2 has been found to be associated with nuclear proteins<sup>[4]</sup>.

Several recent studies have shown that sirtuins regulate a wide variety of cellular processes, such as gene transcription, metabolism and cellular stress response<sup>[5-7]</sup>. SIRT1, the most studied member of the family, plays an important role in several processes ranging from cell cycle regulation to energy homeostasis<sup>[8,9]</sup>. SIRT3 has recently been reported to have a considerable impact on mitochondrial energy metabolism and function<sup>[10,11]</sup>. In this review, we will focus mainly on SIRT1 and SIRT3 functions in ischemia-reperfusion injury (IRI).

IRI is one of the most significant problems in graft injury, contributing to primary graft dysfunction or non-function after organ transplantation<sup>[12-14]</sup>. Many factors contribute to IRI. First of all, the loss of oxygen supply during ischemia results in the reduction of adenosine triphosphate (ATP) synthesis and subsequent changes in ion influx, acidosis and cell swelling which may eventually lead to cell death. The restoration of blood flow is followed by an excessive acute inflammatory response triggering the reperfusion injury. Although the ischemic insult causes significant damage in cells, the tissue injury generated during reperfusion is much more severe. On reperfusion, oxygen is suddenly available, and metabolism proceeds rapidly, resulting in a sudden production of reactive oxygen species (ROS), cytokines and chemokines which increase the accumulation of inflammatory cells (monocytes, dendritic cells and granulocytes). In combination with excessive nitric oxide (NO), ROS are able to induce DNA damage and activate various types of cell death pathways<sup>[15-17]</sup>.

Understanding the mechanisms involved in the pathogenesis of IRI is the first step to mitigate its adverse effects. Sirtuins are known to regulate many important processes in cell physiology, including those affecting IRI, such as cellular metabolism and stress response. This makes them potentially appealing targets for therapeutic interventions against IR-induced injury.

## ROLE OF SIRTUINS IN ISCHEMIA

The low energy state during ischemia results in activation

of adenosine monophosphate protein kinase (AMPK), a fuel-sensing enzyme that is positively regulated by an increased ratio of adenosine monophosphate to ATP. When AMPK is activated, it stimulates processes that restore ATP levels (*e.g.*, fatty acid oxidation) and inhibits other processes that consume ATP (*e.g.*, protein synthesis)<sup>[18]</sup>. The activity of sirtuins is directly related to the metabolic state of the cell due to their dependence on NAD<sup>+</sup>. Suchankova and collaborators found that glucose-induced changes in AMPK are linked to alterations in the NAD<sup>+</sup>/reduced nicotinamide adenine dinucleotide ratio and SIRT1 abundance and activity<sup>[19]</sup>. These results may suggest a possible interaction between AMPK and SIRT1 in ischemic conditions. Indeed, an activator of AMPK, 5-aminoimidazole-4-carboxamide-1- $\beta$ -D-ribofuranoside, has been found to improve IRI and increase SIRT1 expression in the rat kidney<sup>[20]</sup>. Furthermore, enhancing the activity of SIRT1 through the application of resveratrol, a SIRT1 activator, has been demonstrated to protect against cerebral ischemia<sup>[21]</sup>.

Another element that plays an essential role in triggering cellular protection and preventing metabolic alterations caused by oxygen deprivation is hypoxia-inducible factors (HIFs). Mammals possess three isoforms of HIF $\alpha$ , of which HIF1 $\alpha$  and HIF2 $\alpha$  are the most structurally similar and the best characterized. During hypoxia, protein levels of HIF2 $\alpha$  increase slightly, but it presents significant activation, which suggests that its activity is regulated by additional post-translational mechanisms. One of these post-translational modulations may be deacetylation, since in hypoxic Hep3B cells SIRT1 deacetylates lysine residues in the HIF2 $\alpha$  protein, enhancing its transcriptional activity<sup>[22]</sup>.

Additionally, SIRT1 interacts with HIF1 $\alpha$ , but in this case SIRT1 represses HIF1 $\alpha$  transcriptional activity<sup>[23]</sup>. Under hypoxic stress, decreased cellular NAD<sup>+</sup> downregulates SIRT1, increases HIF1 $\alpha$  acetylation, and thereby promotes the expression of HIF1 $\alpha$  target genes<sup>[23]</sup>. Interestingly, other studies have shown that HIF2 $\alpha$  compete with HIF1 $\alpha$  for binding to SIRT1<sup>[24]</sup>. Moreover, it has been demonstrated that SIRT6 is also linked to HIF1 $\alpha$  by repressing the transcription of HIF1 $\alpha$  target genes<sup>[25]</sup>.

Likewise, the effects of SIRT3 appear to be protective in the context of hypoxic stress in human cancer cells. SIRT3 overexpression resulted in decreased ROS production, impediment of HIF1 $\alpha$  stabilization and subsequent suppression of tumorigenesis<sup>[26,27]</sup>. However, the effect of SIRT3 in HIF1 $\alpha$  stabilization in IRI has not been reported to date.

One of the most important factors involved in the metabolic control regulated by SIRT1 is peroxisome proliferator-activated receptor- $\gamma$  coactivator 1 $\alpha$  (PGC1 $\alpha$ ), a transcriptional co-activator of many nuclear receptors and transcriptional factors. SIRT1 functionally interacts with PGC1 $\alpha$  and deacetylates it, thus inducing the expression of mitochondrial proteins involved in ATP-generating pathways<sup>[28]</sup>. Increased PGC1 $\alpha$  activity is also associated with lower levels of oxidative damage during

ischemia, as shown by the decrease ROS scavenging in rodents lacking PGC1 $\alpha$  subjected to global ischemia<sup>[29]</sup>. Furthermore, the uncoupling protein 2 (UCP2), an inner mitochondrial membrane protein, regulates the proton electrochemical gradient and in neuronal cells PGC1 $\alpha$  is required for the induction of UCP2 and subsequent protection against oxidative stress<sup>[30]</sup>. It has also been shown that enhanced activity of SIRT1 during ischemic preconditioning (IPC) or resveratrol preconditioning confers protection against cerebral ischemia by reducing UCP2 levels, which results in increased ATP levels<sup>[21]</sup>. However, a more recent study associated the protective effect of resveratrol against oxidative stress in cerebral ischemia with increased levels of SIRT1/PGC1 $\alpha$  and UCP2<sup>[31]</sup>. Moreover, the exact role of UCP2 during ischemia is not fully understood, as studies of its effects have produced conflicting results<sup>[32-35]</sup>.

## ROLE OF SIRTUINS IN REPERFUSION

Deprivation of oxygen to the grafts during ischemia induces severe lesions, but the most important damage is caused during reperfusion, when oxygen entry to the organ is restored. During reperfusion, the cellular metabolism returns to aerobic pathways, which results in the generation of a wide variety of ROS, including superoxide, hydrogen peroxide and reactive nitrogen species, such as peroxynitrite. ROS are mainly produced in mitochondria and trigger several phenomena, including accumulation of Ca<sup>2+</sup>, caspase activation, cytokine upregulation, lipid, protein and DNA damage<sup>[36-38]</sup>. ROS can be eliminated by enzymatic pathways including manganese superoxide dismutase (MnSOD), catalase (Cat) and peroxidases. Imbalance between ROS generation and elimination produces oxidative stress<sup>[15,16]</sup>.

Various reports in cardiomyocytes have demonstrated the protective role of SIRT1 against oxidative stress<sup>[39,40]</sup>. Hearts overexpressing SIRT1 were more resistant to oxidative stress in response to IRI, as SIRT1 upregulated the expression of anti-oxidants like MnSOD and thioredoxin 1<sup>[41]</sup>. SIRT1 also deacetylated Forkhead box-containing protein O (FoxO) 1 transcription factor, inducing its nuclear translocation and subsequent transcription of anti-oxidant molecules<sup>[41,42]</sup>. Moreover, the question of whether SIRT1 can induce the transcription of other FoxO transcription factors, like FoxO3 $\alpha$ , has not yet been investigated. However, the levels of SIRT1 activation are decisive for its protective role, as very high cardiac SIRT1 expression induces mitochondrial dysfunction and increases oxidative stress<sup>[39]</sup>. Furthermore, in a model of kidney IRI, the protective effect of SIRT1 against oxidative stress has also been demonstrated since SIRT1 upregulated Cat levels and maintained peroxisome number and function<sup>[43]</sup>.

Although mitochondrial sirtuins (SIRT3-SIRT5) have not been studied as extensively as SIRT1, an increasing body of evidence indicates the importance of SIRT3 in mitochondrial biology and function. Lombard *et al*<sup>[44]</sup>

demonstrated that SIRT3 is the dominant mitochondrial deacetylase, as a significant number of mitochondrial proteins are hyperacetylated in SIRT3<sup>-/-</sup> mice. SIRT3 deacetylates and thus enhances the activity of various proteins that appear to be an important part of the anti-oxidative defense mechanisms of mitochondria, such as MnSOD<sup>[45,46]</sup>, regulatory proteins of the glutathione and thioredoxin system<sup>[50]</sup>.

Transcriptional upregulation of the antioxidant enzymes MnSOD, Cat and peroxiredoxin can also be achieved by FoxO3 $\alpha$  transcription factor, which is translocated to the nucleus after being deacetylated by SIRT3<sup>[51,52]</sup>. Furthermore, SIRT3 is necessary for the enhanced expression of cytochrome c, which presents peroxidase- and superoxidase-scavenging capacity<sup>[47,49,53]</sup>. However, a similar anti-oxidant effect of SIRT3 in models of IRI has not yet been established.

A wide array of functional alterations develop in mitochondria during reperfusion injury<sup>[36,54]</sup>. In healthy cells, their primary function is the provision of ATP through oxidative phosphorylation in order to meet the high energy demands. There is increasing evidence of the involvement of a multi-protein complex called the mitochondrial permeability transition pore (mPTP) in the decline in mitochondrial function, which is a common finding during reperfusion injury<sup>[55-57]</sup>. SIRT3 is known to deacetylate the regulatory component of the mPTP, cyclophilin D, and thereby reduce its activity and the subsequent mitochondrial swelling in the heart<sup>[58]</sup>. It has also been shown that SIRT4 interacts with the adenine nucleotide translocator, another component of mPTP, and that SIRT5 deacetylates cytochrome c, but the physiological importance of these interactions has not yet been established<sup>[59,60]</sup>, especially in models of IRI.

Microcirculatory alterations play an important part in IRI. During the ischemic period, vascular hypoxia can cause increased vascular permeability. After reperfusion, complement system activation, leukocyte-endothelial cell adhesion and platelet-leukocyte aggregation further aggravate microvascular dysfunction<sup>[61]</sup>.

NO produced by endothelial NO synthase (eNOS) is a key regulator of endothelial function, as it opposes the vasoconstrictive actions of endothelins and provokes vasodilatation. Thus, it can abrogate the microcirculatory stress generated during reperfusion<sup>[62]</sup>. However, NO produced by inducible NO synthase (iNOS) exacerbates IRI through the NOS-derived superoxide production or the generation of peroxynitrite<sup>[12]</sup>. There is a large body of evidence in favor of the relationship between eNOS and SIRT1; SIRT1 interacts and modifies the acetylation state of eNOS, resulting in the activation of the enzyme<sup>[63-65]</sup>. In SIRT1<sup>+/-</sup> hearts subjected to IRI SIRT1 was associated with eNOS activation<sup>[66]</sup>. SIRT1 activation by resveratrol protected against subacute intestinal IRI by reducing the NO production through iNOS<sup>[67]</sup>. Moreover, various experimental models showed that resveratrol inhibits endothelin-1 levels, providing better regulation of vascular tone<sup>[68-70]</sup>. However, a recent study in human umbilical vein endothelial cells

has shown that the inhibitory effects of resveratrol on endothelin-1 levels are SIRT1-independent<sup>[71]</sup>.

## ROLE OF SIRTUINS IN IRI-ASSOCIATED INFLAMMATION

IRI results in a profound inflammatory tissue reaction with immune cells infiltrating the tissue. The damage is mediated by various cytokines, chemokines, adhesion molecules, and compounds of the extracellular matrix. The expression of these factors is regulated by specific transcription factors with nuclear factor kappa B (NF- $\kappa$ B) being one of the key modulators of inflammation. After activation, the transcription factor migrates to the nucleus and enhances the transcription of pro-inflammatory genes potentiating the inflammatory response. This is followed by an infiltration of lymphocytes, mononuclear cells/macrophages, and granulocytes into the injured tissue<sup>[72-74]</sup>.

In this way, SIRT1 plays an important role in neuro-protection against brain ischemia by deacetylation and subsequent inhibition of p53 and NF- $\kappa$ B pathways<sup>[75]</sup>. In SIRT1<sup>+/+</sup> hearts subjected to IRI SIRT1 was correlated with decreased acetylation of NF- $\kappa$ B and possible prevention of inflammation<sup>[66]</sup>. Moreover, the anti-inflammatory action of SIRT1 by deacetylating NF- $\kappa$ B and thus inhibiting the expression of endothelial adhesion molecules has also been demonstrated in human aortic endothelial cells<sup>[74]</sup>.

## SIRTUINS: CELL SURVIVAL OR DEATH?

Apoptotic cell death is a well known mechanism involved in IRI which occurs *via* activation of caspases that cleave DNA and other cellular components<sup>[16,17,76]</sup>. There is evidence that SIRT1 is associated with longevity in mammals and enhances mammalian cell survival under stress conditions *via* regulating the specific substrates<sup>[77-79]</sup>. In fact, several studies have mentioned the anti-apoptotic effect of SIRT1 in IRI. SIRT1 deacetylates known mediators of apoptosis, such as the tumor-suppressor p53, resulting in inhibition of its transcriptional activity<sup>[80,81]</sup>. SIRT1 also deacetylates the DNA repair factor Ku70<sup>[2,82,83]</sup>, thus Ku70 prevents the translocation of Bax, a pro-apoptotic B cell lymphoma-2 (Bcl-2) family protein, to the mitochondria. In ischemic kidney and brain SIRT1 has been identified as an important survival mediator, given that increased SIRT1 was associated with reduced p53 expression and apoptosis<sup>[75,84]</sup>. SIRT1 also modulates apoptosis-related molecules through the deacetylation of the FoxO family of transcription factors. During IRI in heart-specific SIRT1<sup>+/+</sup> transgenic mice, SIRT1 induces nuclear translocation of FoxO1, which upregulates the anti-apoptotic factors Bcl-2 and Bcl-like X and down-regulates Bax<sup>[41]</sup>. As regards other members of the FoxO family, Brunet *et al.*<sup>[85]</sup> revealed a dual role of SIRT1 in the cell cycle depending on stress conditions; SIRT1 inhibited the ability of FoxO3 to induce cell death, thus promoting cell survival and, surprisingly, it also increased the

ability of FoxO3 to induce cell cycle arrest and resistance to oxidative stress.

A possible pro-apoptotic role of SIRT1 in IRI has not been reported previously. However, studies in human embryonic kidney cells have revealed that SIRT1 can promote cell death by inhibiting NF- $\kappa$ B in response to tumor necrosis factor alpha<sup>[86]</sup>. Further investigation is required to define the conditions under which SIRT1 may promote apoptosis.

Apoptotic pathways are known to be initiated during reperfusion upon the opening of the mPTP which leads to the release of caspase-activating molecules<sup>[87,88]</sup>. Since SIRT3 is located in the mitochondria, it may be involved in anti-apoptotic pathways. In this regard, SIRT3 protects various types of cells from apoptotic cell death triggered by genotoxic or oxidative stress<sup>[89-92]</sup>. The pro-apoptotic role of SIRT3 has also been associated with tumor suppression and restraint of ROS<sup>[93]</sup>. However, SIRT3 has also been reported to contribute to Bcl-2- and JNK-related apoptotic pathways in human colorectal carcinoma cells<sup>[94]</sup>. In any case, the potential anti-apoptotic mechanisms of SIRT3 during IRI are yet to be elucidated.

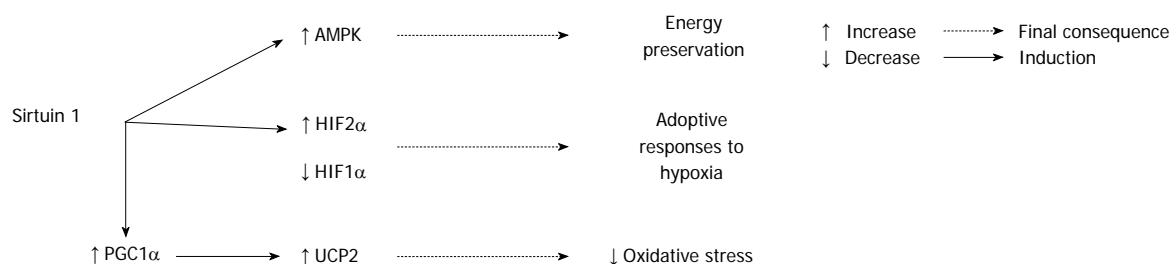

## CONCLUSIONS AND PERSPECTIVES

A wide range of pathological processes contribute to IRI. Particularly during organ transplantation, IRI contributes to early graft dysfunction. For this reason, it is important to gain additional mechanistic insight into the molecular mechanisms underlying this injury. In the past few years, sirtuins have emerged as critical modulators of various cellular processes, including those that contribute to the pathogenesis of IRI.

In this paper, we have reviewed the signaling pathways of SIRT1 and SIRT3 protection in IRI. SIRT1 has been shown to exert its beneficial effect against oxidative stress, hypoxic injury or inflammation associated with IRI by activating FoxO1, PGC1 $\alpha$  and HIF2 $\alpha$  or by inhibiting NF- $\kappa$ B transcription factors (Figures 1 and 2). SIRT3's protective role in IRI is mainly mediated by activating FoxO3 $\alpha$  and mitochondrial anti-oxidant enzymes (Figure 2). Investigations that can further determine other intracellular signaling, trafficking and post-translational modifications by SIRT1 and SIRT3 in a variety of cell systems and environments will allow us to translate this knowledge into effective treatment strategies that will be applicable in multiple disorders.

Numerous studies have demonstrated key roles for SIRT1 and SIRT3 in brain, heart and kidney IRI. However, the protective effect of these sirtuins against ischemic processes in other organs such as the liver has not yet been demonstrated. The relevance of SIRT3 in the hepatic metabolism has been confirmed in a study showing that its overexpression in hepatocytes decreased the accumulation of lipids *via* AMPK activation<sup>[95]</sup>. Furthermore, deletion of hepatic SIRT1 resulted in hepatic steatosis, hepatic inflammation and endoplasmic reticulum stress<sup>[96]</sup>. Since SIRT1 and SIRT3 have been shown

**Figure 1** Protective role of sirtuin 1 during ischemia. Sirtuin 1 (SIRT1) activates adenosine monophosphate protein kinase (AMPK) as a cell response to counteract the energy deficiency. SIRT1 upregulates hypoxia-inducible factor 2 $\alpha$  (HIF2 $\alpha$ ) and downregulates HIF1 $\alpha$  to increase their transcriptional activity. SIRT1 upregulates peroxisome proliferator-activated receptor- $\gamma$  coactivator, leading to enhancement of anti-oxidant capacity of uncoupling protein 2 (UCP2). PGC1 $\alpha$ : Peroxisome proliferator-activated receptor- $\gamma$  coactivator.

**Figure 2** Protective role of sirtuin 1 and suggestive role of sirtuin 3 during reperfusion. Sirtuin 1 (SIRT1) inhibits inflammation through inhibition of nuclear factor kappa B and activates endothelial nitric oxide synthase for a better microcirculation. SIRT1 downregulates apoptosis through multiple pathways, for example, inhibiting p53 transcriptional activity or favoring the binding between Ku70 and Bax. SIRT1 also enhances forkhead box-containing protein O 1 (FoxO1) transcriptional activity, resulting in Bax downregulation and in the upregulation of B cell lymphoma-2 and Bcl-like X. Deacetylation of FoxO1 by SIRT1 also results in lessening oxidative stress, whereas the same effect may be achieved by deacetylation of forkhead box-containing protein 3 alpha (FoxO3 $\alpha$ ). Sirtuin 3 (SIRT3) is suggested to contribute to decrease in oxidative stress either by a direct interaction with mitochondrial anti-oxidant enzymes [manganese superoxide dismutase (MnSOD), thioredoxin system (Trx), cytochrome (Cyt)] or by enhancing FoxO3 $\alpha$  to transcribe MnSOD and Cat. Mitochondrial permeability transition pore (mPTP) may also be inhibited by SIRT3 and result in less production of oxidative stress. NF- $\kappa$ B: Nuclear factor kappa B; eNOS: Endothelial nitric oxide synthase; Bcl-2: B cell lymphoma-2; Bcl-xL: Bcl-like X; Bax: Bcl-2-associated X; Cat: Catalase.

to exert a beneficial effect in regulating hepatic fatty acid metabolism, it would be interesting to investigate their role in the context of liver transplantation. Currently, the shortage of organs for transplantation has obliged physicians to utilize marginal grafts, including grafts with moderate steatosis. Steatotic livers exhibit a more severe inflammatory reaction and more exacerbated oxidative stress and consequently a higher vulnerability to IRI<sup>[12]</sup>. Thus, activating SIRT1 and SIRT3 might be a potential strategy to protect steatotic livers from IRI as well as to expand the donor pool for liver transplantation. In fact, in preliminary studies our group observed that SIRT1 is involved in the protective mechanisms against IRI elicited by IPC in fatty livers.

For this reason, both surgical and pharmacological

strategies should be developed to enhance the activity of sirtuins and thus mitigate the detrimental effect of IRI. Recent studies have highlighted the important role of SIRT1 in IPC-mediated protection in the heart and brain; in IPC brain, SIRT1 prevents neuronal death<sup>[97]</sup>, whereas during cardiac IPC, SIRT1 regulates HIF1 $\alpha$  protein levels<sup>[98,99]</sup>. A recent review has also associated SIRT1 with the protective effects of hyperbaric oxygen preconditioning against apoptosis in the rat brain<sup>[100]</sup>. However, it is still to be established whether SIRT1 contributes to the protective effects of preconditioning through the regulation of other signalling pathways. Furthermore, its possible implication in IPC related mechanisms in other organs, including the liver or kidney, remains to be elucidated.

Nor has the potential role of sirtuins in cold ischemia

and reperfusion yet been established. In the context of liver IRI, a previous study by our group demonstrated that during normoxic reperfusion, after cold ischemia, the presence of NO favors HIF1 $\alpha$  accumulation, also promoting the activation of other cytoprotective proteins, such as heme oxygenase-1<sup>[101]</sup>. Among these cytoprotective proteins, SIRT1 may be ideally suited to enhance the protective effect.

This review summarizes the basic mediators of IRI influenced by the action of SIRT1 and SIRT3 and highlights the importance of their regulation. Future research should aim to elucidate the complete action of all members of the sirtuins family in IRI, and to develop pharmacological strategies that can allow their action to be modulated.

### Abstract

Cystic formations within the liver are a frequent finding among populations. Besides the common cystic lesions, like simple liver cysts, rare cystic liver lesions like cystadenocarcinoma should also be considered in the differential diagnosis. Thorough knowledge of each entity's nature and course are key elements to successful treatment. Detailed search in PubMed, Cochrane Database, and international published literature regarding rare cystic liver lesions was carried out. In our research are included not only primary rare lesions like cystadenoma, hydatid cyst, and polycystic liver disease, but also secondary ones like metastasis from gastrointestinal stromal tumors lesions. Up-to date knowledge regarding diagnosis and management of rare cystic liver lesions is provided. A diagnostic and therapeutic algorithm is also proposed. The need for a multidisciplinary approach by a team including radiologists and surgeons familiar with liver cystic entities, diagnostic tools, and treatment modalities is stressed. Patients with cystic

liver lesions must be carefully evaluated by a multidisciplinary team, in order to receive the most appropriate treatment, since many cystic liver lesions have a malignant potential and evolution.

### INTRODUCTION

Cystic lesions within the liver have been reported to occur in up to 5% of the population<sup>[1]</sup>. Most of them are common and benign, but the possibility of a rarer cystic liver lesion, such as hepatobiliary cystadenoma (HC) or hepatobiliary cystadenocarcinoma (HCA), should not be overlooked. They can present with general or specific symptoms depending of the nature of the lesion, or they

can be silent and discovered accidentally<sup>[2]</sup>. In fact, most are found incidentally on imaging studies and tend to have a benign course, but a minority may cause symptoms, and rarely may be associated with serious morbidity and mortality<sup>[2]</sup>. The aim of our review is to focus upon the diagnostic and therapeutic algorithm of rare cystic lesions, including cystadenomas/cystadenocarcinomas, hydatid disease, polycystic liver disease, and metastatic neoplasms from the view of surgeons specialized in hepatobiliary surgery.

## CYSTADENOMA AND CYSTADENOCARCINOMA

It is estimated that cystic neoplasms constitute approximately 5% of liver cysts, among which the malignancy is about 5%<sup>[2,3]</sup>. The overall incidence among hepatic malignant tumors is lower than 0.41%<sup>[2,3]</sup>. About 200 cases of HC, and a little more than half as many HCa, have been reported in the literature<sup>[4]</sup>.

More than 85% of HC are reported in women, and typically in middle-aged persons in the fifth decade of life. HC is an unusual cystic lesion accounting for less than 5% of all biliary neoplasms<sup>[2,4]</sup>. The incidence of HCa is approximately 1 per 10 million patients. Malignant transformation is known to occur from HC to HCa. Older patients in the sixth decade of life are more likely to present with malignant tumors<sup>[2,4]</sup>.

The histogenesis of HC is unknown, although a congenital origin is generally favored. A reactive process to some focal injury is still debated<sup>[5,6]</sup>. Pathologically, HC are multiloculated cysts with a stratified or pseudo-stratified non-ciliated columnar or cuboidal epithelium that contains mucous-producing cells. Papillary infolding is frequently present, and the mesenchyma underlying the tumor is usually hyper cellular, often with ovarian-appearing cells (85%-90%)<sup>[7-9]</sup>. The pre-malignant progression of HC is based on the histologic presence of intestinal metaplasia (IM), characterized by the presence of numerous goblet cells<sup>[10,11]</sup>. HC can easily be distinguished histologically from HCa, where a loss of epithelial nuclear stratification and a tubulo-papillary architecture with nuclear pleomorphism and atypia predominates. The malignant epithelium is multilayered with numerous papillary projections, and the confirmation of an invasion of the stroma confirms the diagnosis of HCa.

Regardless of the various diagnostic modalities, such a lesion (HC) may be difficult to distinguish preoperatively from an HCa<sup>[12]</sup>.

The majority of HC is asymptomatic and discovered incidentally during radiographic studies, or they can present with symptoms related to tumor compression of adjacent organs due to their large size<sup>[2]</sup>. Patients presenting with symptoms generally complain of abdominal pain, abdominal distension, or a palpable mass. Less common presentations include intra-cystic hemorrhage, rupture, and fever from secondary bacterial infection. Any patient presenting with recurrence of liver cysts after treatment

should be suspected of having a neoplastic cyst until proven otherwise<sup>[12]</sup>.

HC and HCa should be differentiated from benign cystic hepatic lesions, including simple hepatic cyst, hepatic abscess, and echinococcal (hydatid) cyst. Simple hepatic cysts usually lack septa. Though hepatic abscesses and echinococcal cysts may appear similar to cystadenocarcinoma on diagnostic imaging, both infectious diseases are easily diagnosed through clinical and laboratory findings. Improvements in imaging techniques have helped to identify HC and HCa.

Ultrasound is an excellent modality that may delineate a simple cyst from other cystic lesions. Additionally, needle aspirates can be performed under ultrasound guidance. Simple cysts appear as anechoic unilocular fluid-filled space with imperceptible walls and posterior acoustic enhancement. A simple cyst is defined as a well-demarcated water attenuation lesion that does not enhance after the administration of intravenous contrast<sup>[2,4]</sup>.

Contrast enhanced ultrasound (CEUS) is useful in assessing the vascularity of a mural nodule and making a distinction between a mural or septal nodule and intracystic debris<sup>[13]</sup>. In conventional ultrasound cystic lesions with solid components (septae, wall, mural nodule), this represents a wide range of rare entities like HC and HCa, as well as more common entities like simple liver cysts (after bleeding or with cell detritus), liver abscesses, or necrotic liver tumors<sup>[13]</sup>. CEUS can be informative regarding the vascularity of solid parts of a cystic lesion. Simple cysts, which are unclear in conventional ultrasound, might be identified in CEUS<sup>[13]</sup>. A cystic liver lesion without vascularization is most probably benign. CEUS is helpful in evaluating nodule vascularity and facilitates the final diagnosis<sup>[13]</sup>.

On conventional ultrasound, a HC typically appears hypoechoic, with thickened irregular walls and occasional internal echoes. Xu *et al*<sup>[13]</sup>, Lin *et al*<sup>[14]</sup>, and Anderson *et al*<sup>[15]</sup> describe it as a well-defined unilocular, or more typically multilocular, cystic mass with mural or septal nodules in rare cases. On CEUS, a HC presents with septa enhancement during the arterial phase and hypo-enhancement during the portal and late phases<sup>[13,14]</sup>. Cystadenocarcinoma, on the other hand, appears as a multilocular cystic mass with mural or septal nodules with thick and coarse calcifications on the septa on conventional ultrasound, while appearing on CEUS with septa enhancement during the arterial phase, mural or septal nodules enhancement and hypo-enhancement during the portal or late phase<sup>[13,14]</sup>. Xu *et al*<sup>[13]</sup> reported that on CEUS there is no significant difference between cystadenoma and cystadenocarcinoma regarding enhancement pattern and extent. Simple cysts, unlike HC, are virtually never septated<sup>[2,4]</sup>. Ultrasonography (US) is a very useful initial investigation in these patients as it demonstrates cystic lesions with thin internal septations, debris, projections, or mural nodes, and it can in most cases accurately distinguish simple from neoplastic cysts (Figure 1A).

Differential diagnosis between HC and HCa is dif-

**Figure 1** Ultrasound image. A: Showing an anechoic mass in the liver (light blue arrow), with a rather thin capsule (cystadenoma); B: Showing two echinococcal cysts. The first on the right (red arrow-right image) appears as an anechoic mass with hydatid sand (type CE1) (white arrow-right image), while in the second (on the left), the detached and folded endocyst membrane is obvious (type CE3) (white arrow-left image).

ficult. Although the presence of mural nodularity is not pathognomonic for cystadenocarcinoma, the absence of mural nodularity is suggestive of cystadenoma<sup>[15,16]</sup>. The diameter of the mural nodule (when it exists) in cystadenomas is much smaller (less than 1.0 cm) than mural or septal nodules in cystadenocarcinomas (larger than 1.0 cm)<sup>[13]</sup>. It seems that the presence of the internal septations and a mural or septal nodule, as well as the nodule diameter, might be diagnostic clues for differentiation between cystadenoma and cystadenocarcinoma<sup>[13]</sup>. The other differential-diagnostic characteristic between HC and HCa is that cystadenomas are more typically multilocular cystic lesions and cystadenocarcinomas more typically unilocular cystic or solid lesions<sup>[13]</sup>.

Computed tomography (CT) is another useful modality to evaluate a cystic lesion of the liver. On a CT scan, a cystadenoma may be unilocular, multilocular, or may have septations. In a study from Vogt *et al*<sup>[3]</sup>, all patients demonstrated septations within the cyst at the CT scan. The cyst wall is usually thickened or irregular, in contrast to a simple cyst. A cystadenoma may also have a smooth external surface and a thin wall (Figure 2A).

Magnetic resonance imaging (MRI) is very useful, as it demonstrates a well-defined lesion that does not enhance after the administration of intravenous gadolinium. On T1 images, the cyst shows a low signal; conversely on T2 weighted images, a very high intensity signal is observed. However, no specific information is gained towards pseudo-ovarian stroma detection<sup>[17]</sup>.

Despite the various diagnostic modalities, it remains difficult to distinguish HCs from HCa on preoperative imaging; however, a significant solid component on the cystic wall suggests invasive malignant disease. Furthermore, HC can evolve into HCa after long periods lasting more than 10 years<sup>[18,19]</sup>.

Liver enzymes and bilirubin are usually normal unless the biliary tree is compressed. The elevation of alkaline phosphate and bilirubin occurs in cases of bile duct obstruction. Carbohydrate antigen 19-9 may be elevated, but CEA and  $\alpha$ -fetoprotein are usually normal<sup>[3,20]</sup>. It has been reported that most patients with cystadenocarcino-

ma have normal serum concentrations of CEA and CA 19-9. Moreover, the serum concentrations of these tumor markers can be elevated in patients with HCa as well. Therefore, these serum tumor markers cannot distinguish HCa from HC.

Some authors have reported that fine needle aspiration cytology of the cyst contents is a good method for diagnosing cystic lesions<sup>[5,16]</sup>. In many studies, however, no malignant cells were recovered in patients with HCa who underwent intraoperative cytology examination. Thus, this procedure rarely generates a definitive diagnosis and carries the risk of pleural or peritoneal dissemination, and should therefore be avoided, especially when surgery is planned. The fluid of the cystic cavity often consists of a high-molecular-weight glycoprotein called mucin. However, hemorrhagic, bilious, clear, and mixed fluid contents have also been observed<sup>[5,16]</sup>. Aspiration and cyst fluid analysis for CEA and Ca 19-9 has been proved more useful than serum analysis<sup>[5,16]</sup>. Cyst fluid demonstrates marked, but variable, elevation in Ca 19-9 and moderate elevation of CEA<sup>[5,16]</sup>. Elevation of these cyst fluid tumor markers has high specificity and sensitivity in distinguishing HC from simple and echinococcal cysts.

HC has been treated by marsupialization, internal Roux-en-Y drainage, repeated needle aspirations, fenestration, or partial resection. All these methods have been associated with high rates of recurrence and complications including sepsis, continued growth, and progress to malignancy. Although the rate of malignant transformation is relatively low (5%-10%), all suspected HCs must be excised<sup>[16,21]</sup>. Liver resection with clear margins is strongly indicated due to the possibility of synchronous appearance of HCa at the borders of the cyst<sup>[16,21]</sup>. Enucleation is also acceptable. Reports supporting resection cite the low associated mortality of the procedure and the permanent relief of symptoms<sup>[16,21]</sup>.

The majority of HC can be completely and safely excised by enucleation, including those that are centrally located. Once the cyst has been decompressed and the proper plane identified, enucleation can proceed without

**Figure 2** Computed tomography image. A: In liver segment IV there is a large cystic lesion (black arrow) causing compression with dilatation of biliary ducts (light blue arrows) in the left liver lobe. Peripheral contrast enhancement (light green arrow) as well as a nodule (pink arrow) is evident in this case of cystadenoma; B: Echinococcal disease evaluated. Two lesions are evident. The first in liver segment I appears as a multilocular cystic lesion (black arrow) and the second in liver segment VI as a calcified mass with irregular margins (white arrow); C: Demonstrates direct infiltration of a liver hydatid cyst in the adjacent peritoneal surface and abdominal wall (light blue arrow); D: A typical case of multicystic disease with liver (light blue arrow) and kidney (pink arrow) involvement were very well depicted; E: Showing two large cystic-appearing liver lesions (light blue arrows) in a case of a metastatic pancreatic cystadenocarcinoma that is also evident (pink arrow); F: A large cystic lesion (light blue arrow) with a small solid component at the periphery (pink arrow), as well as two small hypodense liver lesions (black arrows), are seen on this image, in a case of proven gastrointestinal stromal tumors metastatic lesions.

significant blood loss. If the possibility of hemorrhage is high due to adjacent major venous vascular structures, enucleation can be completed with either inflow occlusion (Pringle maneuver) or total vascular exclusion. In the era of laparoscopic surgery, a laparoscopic frozen section biopsy of the cyst wall is feasible. If the frozen section is consistent with a simple, benign cyst, laparoscopic partial excision is adequate. If the biopsy demonstrates HC, then complete excision is necessary. However, frozen section biopsies are not always accurate due to inconsistency and discontinuity of the pathological epithelium<sup>[3,7,22]</sup>. Frozen sections cannot definitely exclude or confirm the diagno-

sis of HC, especially in the case of HCa<sup>[3,7]</sup>.

The only potentially curative treatment for HCa is complete removal, usually by a major liver resection with 1-cm margins. Reported survival rates for HCa range from 25% to 100% (87% disease free) at 5 years<sup>[4]</sup>. It has been reported that patients with HCa who have invasion of the liver parenchyma or neighboring organs have a poor prognosis<sup>[4]</sup>. Asahara *et al* have reported that the prognosis of patients with HCa is poor when the tumor lacks mesenchymal stroma<sup>[2,4]</sup>. Absence of mesenchymal stroma in HCa appears to be associated with aggressive disease behavior (*i.e.*, rapid dissemination or distant metastasis)<sup>[2,4]</sup>.

## HYDATID DISEASE

Human cystic echinococcosis, or hydatid cyst disease, is a zoonosis caused by the larval cestode *Echinococcus granulosus*, *Echinococcus multilocularis*, or *Echinococcus vogeli*. *E. granulosus* produces unilocular cystic lesions, whereas *E. multilocularis* and *E. vogeli* produce multilocular alveolar cysts<sup>[23,24]</sup>. Dogs are the definitive hosts for *E. Granulosus*, with sheep being the major intermediate host (yaks, goats, and camels are other relevant intermediate hosts). Man is only incidentally infected when ingesting tapeworm eggs<sup>[24]</sup>. The eggs penetrate the intestinal wall, with the resulting larvae infiltrating the blood and lymphatic circulation system. Then, through the portal vein into the liver, lungs, and other tissues, the larvae develop into hydatid cysts<sup>[25,26]</sup>.

The liver is the most frequent site for the cystic lesions (52%-77%) seen in hydatid disease, followed by the lung (10%-40%), brain, and other viscera<sup>[24,26,27]</sup>. The disease may remain silent for many years before coming into medical attention as an incidental imaging finding, or it may present with complications.

The diagnosis of uncomplicated hepatic hydatid disease is based on clinical suspicion, with special attention paid to factors such as the patient's residence, place of origin and occupation in order to identify high-risk patients. The symptoms depend on the size, location, and development stage of the cyst<sup>[26,28]</sup>. Pain in the right upper quadrant or the epigastrium is the most common symptom, whereas hepatomegaly and a palpable mass are the most common signs. Nonspecific symptoms such as fatigue, fever, nausea, or dyspepsia may also be present. Patients with complicated hepatic hydatid disease may present with fever, jaundice, or anaphylactic symptoms, depending on the complication<sup>[26,29]</sup>.

Acute cholangitis is the most common syndrome when the hydatid cysts rupture in the biliary tract. Rupture of a cyst may produce fever, pruritus, eosinophilia, or fatal anaphylaxis<sup>[23]</sup>. Lower chest pain, a productive cough, and hemoptysis are the most frequent symptoms when there is thoracic involvement. Biliptysis is diagnostic of a biliobronchial fistula<sup>[25]</sup>.

General blood tests are not specific except in complicated disease, whereas a high white blood cell count with eosinophilia are possible findings. Hepatic parameters are normal except in the case of biliary compression<sup>[30]</sup>. Serologic tests such as hemagglutination, latex agglutination, and enzyme-linked immunosorbent assay (ELISA), are associated with a high incidence of false-negative and false-positive results<sup>[28]</sup>. Nevertheless, the detection of specific antigens and immune complexes of the cyst with ELISA yields a positive result in more than 90% of patients. Specific IgE antibodies are demonstrated with ELISA and the radioallergosorbent test is positive in the presence of active disease. Confirmatory tests such as arc-5 immunoelectrophoresis and immunoblotting use parasite-specific antigens. The positivity rate with arc-5 immunoelectrophoresis is as high as 91.1%<sup>[26,29]</sup>. The Casoni and Weinberg tests are no longer used for the diag-

nostic workup, mainly due to their low sensitivity<sup>[29]</sup>.

The indirect immunofluorescence assay (IFA) first reported by Coudert *et al* is specific and sensitive, especially in cases of hepatic cystic hydatidosis. This easy-to-do assay can be achieved in less than 2.5 h and is the most sensitive test in more than 95% of patients with hepatic cystic hydatidosis<sup>[30]</sup>. The diagnosis of hydatidosis by molecular biology is based on the polymerase chain reaction and the technique needs to be evaluated. Based on the choice of primers and probes, molecular biology can differentiate *E. granulosus* from *E. multilocularis* in clinical samples<sup>[30]</sup>.

False-positive results have been described in some patients with tumors, for which there is no explanation as yet, whereas false-negative results are observed when cysts are calcified, even if fertile and corresponding to the lack of antigenic stimulation. Serologic tests do not supplant clinical or imaging investigations but they can, however, confirm the hydatid origin of a cyst. Specific antibodies increase 4-6 wk after surgery, after which they decrease slowly for the next 12-18 mo. The decrease in specific antibodies is too irregular to be a good witness of recovery or relapse, however. Persistently high specific antibody titers or a secondary increase in the antibody titers 6 to 12 mo after surgery indicate a relapse<sup>[30]</sup>.

Standard chest and abdomen radiographs may reveal an elevated diaphragm and concentric calcifications in the cyst wall. Liver scanning was an important diagnostic tool during the 1970s. Since then, US and CT have replaced scanning and are considered the first choice in the diagnostic armamentarium. These methods are helpful for determining complications as well<sup>[29]</sup>. MRI and endoscopic retrograde cholangiopancreatography (ERCP) can prove helpful during the diagnostic approach.

US, a noninvasive, readily available, sensitive, and cost-effective imaging technique, should be the diagnostic method of choice. US is helpful for defining the internal structure, number, and location of the cysts and the presence of complications (Figure 1B). The specificity of US is in the range of 90%. Several authors have proposed an ultrasonographic classification of hepatic hydatid disease (Table 1)<sup>[26,31]</sup>. Classification was standardized by the World Health Organization-International Working Group on Echinococcosis (WHO-IWGE) in 2001 (Table 2)<sup>[26]</sup>. According to the five categories noted in the classification of Gharbi types: II and III are characteristic of hydatid cysts, types I and V are suggestive of hydatid cysts in endemic areas, and type IV simulates a pseudotumor<sup>[25]</sup>.

CT is a helpful tool for confirming the diagnosis, essentially when an ultrasound examination shows a type IV sonographic pattern<sup>[25]</sup>. It provides information equivalent to that derived by US, but it shows the location and depth of the cyst within the liver more accurately (Figure 2B and C). Moreover it can reveal calcified cystic walls<sup>[28]</sup>, daughter cysts, and exogenous cysts, as well as evaluate their volume and density. CT is essential for planning surgical treatment, especially when a minimally invasive approach is to be used<sup>[26,29]</sup>. Imaging findings on CT depend on the stage of cyst growth and the *Echinococcus* species

Table 1 Gharbi classification of cystic hydatid disease

Type	Ultrasonographic features and patterns
I	Pure fluid collection
II	Fluid collection with a split wall (water-lily sign)
III	Fluid collection with septa (honeycomb sign)
IV	Heterogeneous echographic patterns
V	Reflecting thick walls

Table 2 World Health Organization-Informal Working Group on Echinococcosis

Type	Ultrasonographic features and patterns
CL	Unilocular cystic lesion with uniform anechoic content, cyst wall not visible
CE1	Unilocular cystic lesion with uniform anechoic content, cyst wall visible, snowflake sign
CE2	Multivesicular, multiseptated cysts, daughter cysts present, honeycomb sign
CE3	Unilocular cyst containing liquid with a floating membrane inside, daughter cysts may be present, water-lily sign
CE4	Cysts with heterogeneous hypoechoic or hyperechoic degenerative contents, no daughter cysts
CE5	Cysts characterized by a thick calcified wall, which is arch-shaped, producing a cone-shaped shadow; degree of calcification varies from partial to complete

involved. Hepatic involvement by *E. multilocularis* is characterized by a different appearance than *E. granulosus*, consisting of an infiltrating solid mass composed of multiple cysts and indistinct margins. Infection by *E. granulosus* usually forms a single cyst, with or without daughter cysts<sup>[23]</sup>.

Although MRI can be helpful for demonstrating the lesion in the liver (Figure 3), it does not provide additional information in hepatic lesions and is not cost-effective when compared with either US or CT<sup>[26,29]</sup>. However, both CT and MRI have high specificity and sensitivity in the detection and differential diagnosis of hepatic cysts and extracapsular (satellite) cysts<sup>[28]</sup>.

The ideal treatment for hepatic hydatid disease should completely eliminate the parasite and prevent recurrence of the disease with minimum morbidity and mortality. There are three available therapeutic modalities for hepatic hydatid cysts; systemic chemotherapy, surgery, and the treatment known as “puncture, aspiration, injection, reaspiration” (PAIR). Chemotherapy and PAIR are recommended as alternatives to surgery, especially for patients who cannot tolerate or refuse surgery. However, surgery is still the first choice of treatment for hepatic hydatid cysts. Selection of the most appropriate treatment depends on the patient’s health status, the nature of the cyst(s) (considering number, size, location, and presence of complications), and the available resources and expertise<sup>[26]</sup>.

Mebendazole (MBZ) was the first benzimidazole carbamate agent found to have *in vivo* activity in hydatid disease. The drug interferes with mechanisms of glucose absorption through the wall of the parasite, leading to

Figure 3 Magnetic resonance T1-w image shows an echinococcal cyst as a multiloculated cystic liver lesion, indicative of the presence of daughter cysts (light blue arrow). A second smaller unilocular lesion with peripheral contrast enhancement is also seen (pink arrow).

glycogen depletion and subsequent degenerative changes in the mitochondria and endoplasmic reticulum of the germinal cells<sup>[32]</sup>. Albendazole (ABZ) is more active *in vitro* than MBZ and has improved gastrointestinal absorption and bioavailability, as well as reports of better clinical results<sup>[32]</sup>. Although orally administered, ABZ results in high serum concentrations and penetration into cyst contents is erratic. Currently, ABZ chemotherapy as the primary treatment may be considered for patients who are not acceptable candidates for surgery, have inoperable, recurrent, peritoneal or multiple liver cysts within the whole liver, have multiple cysts in several organs, refuse surgery or percutaneous drainage, and perhaps, for asymptomatic individuals<sup>[32]</sup>.

Both drugs may decrease the size of hydatid cysts and lead to the sterilization of cyst contents in some cases; however, without concomitant drainage, clinical and radiographic resolution is unpredictable and occurs in less than half of treated patients<sup>[24]</sup>. Hepatic and hematologic toxicities are the most frequent serious adverse effects of ABZ and MBZ. Treatment of hepatic cystic echinococcosis with MBZ or ABZ alone is not as effective as a combined chemotherapy-drainage approach<sup>[24,33]</sup>. Clinical and radiographic improvement (in most studies defined as a > 25% reduction in cyst size, membrane separation, or cyst calcification) is seen frequently, but complete cure (*i.e.*, cyst disappearance) generally occurs in less than half of patients treated with anti-parasitic monotherapy<sup>[24,33]</sup>.

According to the WHO guidelines, chemotherapy is indicated for inoperable primary liver or lung echinococcosis, for patients with multiple cysts in two or more organs, and for peritoneal cysts. Another important indication for chemotherapy is the prevention of secondary echinococcosis. Preoperative use of ABZ or MBZ can reduce the risk of recurrence of cystic echinococcosis and facilitate the operation. Concomitant chemotherapy is also recommended for PAIR. Chemotherapy is contraindicated for large cysts that are at risk of rupture (superficially situated, infected cysts) and for inactive or calcified cysts<sup>[34]</sup>.

The usually recommended oral dosage of ABZ is

10-15 mg/kg per day in two divided doses for several 1-mo courses separated by 14-d intervals. The usual oral dosage of MBZ is given as 500 mg tablets in daily doses of 40-50 mg/kg (in three divided doses) for at least 3-6 mo. Better intestinal absorption of benzimidazole compounds is gained by administering it with a fat-rich meal or by combining it with cimetidine. Medical and laboratory examinations for adverse reactions are initially necessary every 2 wk and then monthly<sup>[35]</sup>.

A third antiparasitic agent, praziquantel, has had limited use in the treatment of hydatid cysts of the liver. The drug increases the permeability of the parasite's cell membrane to calcium, resulting in strong contractions and paralysis of the musculature leading to detachment from host tissue. In humans, it has favorable pharmacokinetics when given in a dose of 50 mg/kg either once weekly or every two weeks. There are few clinical studies documenting the efficacy of praziquantel in humans, however several of these have suggested that the use of praziquantel in combination with MBZ or ABZ is more effective and perhaps, more rapid than with benzimidazole alone (47.4% *vs* 36.4%) after only 2-6 mo of drug therapy<sup>[24]</sup>.

Surgery was defined as the only definitive and curative modality by the WHO-IWGE in 1996<sup>[33]</sup>. The goals of surgery in hydatid disease are to inactivate the cestode parasites, evacuate the cyst cavity, remove the germinal layer, and obliterate the residual cavity. Surgical interventions consist of open conservative, radical, and laparoscopic approaches<sup>[24]</sup>. Conservative techniques involve drainage, marsupialization, capitonnage, deroofting, partial simple cystectomy, and open or closed total cystectomy with or without omentoplasty<sup>[24]</sup>. The conservative procedures are safer and easier to perform<sup>[25]</sup>. Radical procedures include total pericystectomy, partial hepatectomy, or lobectomy<sup>[24]</sup>. Although it seems logical that radical operations would be associated with higher intra- and postoperative morbidity but less frequent recurrence, recent studies have shown that radical surgery is not associated with a high complication rate<sup>[26]</sup>.

Laparoscopic drainage of hepatic hydatid cysts is a "minimally invasive" surgical technique that appears safe and effective. It has the theoretic advantages of a shorter hospital stay, lower incidence of wound infection, and less postoperative pain, but the disadvantages of difficult accessibility to the various locations, increased risk of cyst content spillage, and the difficulty of aspirating the cyst content of the thick, degenerated cyst contents, especially in some WHO-IWGE CE3 and CE4 cysts. Thus, choosing the best candidates for the laparoscopic approach requires careful evaluation of the cystic disease<sup>[25,26]</sup>. Whichever technique is used, a benzimidazole agent is best administered before any surgery in an attempt to sterilize the cyst contents and reduce the risk of anaphylaxis and dissemination<sup>[24]</sup>.

Meticulous packing of the operative field is necessary irrespective of the surgical technique employed, as is the use of solutions that kill the infective scoleces and

protoscolices of the parasite residing within the hydatid cyst, or potentially leaking from the cyst during surgical manipulation. Various scolicidal solutions used in surgical (and percutaneous) approaches include: hypertonic saline (3%-20%), povidone-iodine, hydrogen peroxide, iodine, formalin, silver nitrate, ethyl alcohol, and ABZ. These scolicides can be used alone or in combination<sup>[24]</sup>.

Potential major complications associated with the surgical treatment of hepatic hydatid cysts include postoperative hemorrhage, bile exudation from the residual cyst cavity, incisional fistula formation, cholangitis, wound infection, sepsis, incisional fistulae, pulmonary complications such as pneumonia and pulmonary embolization, complications of anesthesia, and death<sup>[24]</sup>.

ERCP is used as a diagnostic and therapeutic tool in the management of biliary tract-complicated hepatic hydatid cysts. Preoperatively, ERCP defines biliary tract-related complications and allows the assessment and management of acute conditions, including acute cholangitis and biliary obstruction, so that elective surgery can be performed later. When combined with sphincterotomy, this drains the cyst cavity and helps prevent postoperative biliary fistula. Postoperatively, ERCP allows visualization of distorted anatomy in recurrent cases, helps clarify the etiology of ongoing or recurrent biliopancreatic symptoms and biochemical abnormalities, allows endoscopic management of a biliary fistula, and enables treatment of secondary biliary strictures by stenting<sup>[26]</sup>.

The treatment modality that we prefer using in our department with optimal results is the evacuation of the cavity with careful removal of the laminated membrane and the daughter cysts in order to avoid spillage. The cyst cavity is obliterated by omentoplasty or capitonnage, and the site is drained externally by suction catheter. Partial cystectomy and internal drainage with a Roux-en-Y intracystic hepaticojunostomy is performed when large ducts had been disrupted due to large cysts. Preoperative ERCP is performed when communication between the cyst cavity and biliary tree is suspected, and endoscopic sphincterotomy is performed in cases of obstruction.

The minimally-invasive technique of puncture, aspiration of cyst, injection of hypertonic saline and/or absolute alcohol, and re-aspiration (PAIR), described initially by Voros *et al*<sup>[28]</sup> and Falagas *et al*<sup>[32]</sup>, is an alternative to major interventional procedures. PAIR treatment satisfies all the goals of surgery in hydatid disease, but substitutes germinal membrane sclerosing and separation using scolicides for surgical removal. PAIR drainage is best performed under continuous ultrasonographic or CT guidance.

Patients undergoing PAIR typically receive oral ABZ that is administered 24-4 h before intervention and 15-30 d after intervention according to cyst size<sup>[34]</sup>. Different scolicidal solutions can be used in PAIR, although hypertonic saline is most commonly employed. Hypertonic saline (in 5%-30% concentrations) exerts its scolicidal effect by creating a strong osmotic gradient across the outer cuticular membrane of the protoscolex, which

**Figure 4** Image. A: Computed tomography image in a case of multicystic disease, showing two large dominant cysts causing mild intrahepatic biliary dilatation (black arrows); B: Magnetic resonance cholangiopancreatography image shows multiple hepatic cysts (light blue arrows) while the common bile duct seems compressed between the two larger cysts (black arrow).

causes its lysis. For multiseptate Type III cysts or large cysts over 6 cm in size, some authors advocate the use of absolute alcohol because it is a more effective sclerosing agent than hypertonic saline, may destroy daughter cysts not killed by saline, and may also result in a more rapid involution of the cyst cavity. Alcohol should not be used, however, if pre-existing biliary communication is suspected or documented, as the agent may cause a chemical cholangitis<sup>[33]</sup>.

With PAIR, cyst fluid or operative tissue specimens are immediately subjected to cytologic, histopathologic, and parasitologic examinations after aspiration or catheter drainage in order to confirm the diagnosis and assess the success of the drainage procedure.

Complications after PAIR therapy, such as infections, are generally well tolerated and can be managed with systemic antimicrobial therapy. Leakage during drainage may lead to fever, urticaria, transient hypotension, or anaphylaxis, but these can be anticipated and effectively managed with antipyretics, IV fluids, antihistamines, and subcutaneous epinephrine. Cyst-biliary communications (biliary rupture and fistula formation) developing after PAIR and caused by cyst decompression, can usually be managed endoscopically<sup>[24]</sup>. For patients who underwent PAIR as a primary procedure, a total complication rate of 14.7% and a recurrence rate of 1.57% have been reported<sup>[28]</sup>.

In conclusion, compared to patients undergoing surgical intervention for cystic hepatic echinococcosis, PAIR plus ABZ is associated with greater clinical and parasitologic efficacy, less major and minor morbidity whenever it is indicated (*i.e.*, for non-echoic lesion  $\geq 5$  cm in diameter (CE1), cysts with daughter cysts (CE2), and/or with detachment of membranes (CE3). Surgery may be reserved for patients with hydatid cysts refractory to PAIR because of secondary bacterial infection or difficult-to-manage cyst-biliary communication or obstruction<sup>[24,34]</sup>.

## POLYCYSTIC LIVER DISEASE

Polycystic liver disease (PLD) is inherited as an autosomal

dominant trait presenting in adulthood and is more common in women<sup>[36]</sup>. Autosomal dominant polycystic disease is genetically heterogeneous, with mutations in two distinct genes predisposing to the combination of renal and liver cysts (AD-PKD1 and AD-PKD2)<sup>[36,37]</sup>. PLD is genetically linked to protein kinase C substrate 80K-H and SEC63<sup>[38]</sup>. The cysts in PLD can also increase in size and number during pregnancy or simultaneously with the use of exogenous female steroid hormones<sup>[39]</sup>.

Most patients are asymptomatic and do not require treatment. Some patients develop massive hepatic cystic disease and become clinically symptomatic, which is associated with increased liver volume and adjacent visceral compression. Usually patients suffer from chronic dull abdominal pain, satiety, weight loss, dyspnea, physical disability, and descensus<sup>[36,40]</sup>. Liver function tests are usually normal except for mild elevation in ALP or  $\gamma$ -GT<sup>[36,40]</sup>. Liver failure or complications of advanced liver disease, such as infection or intracystic hemorrhage, are rare. Less than 5% of patients have acute medical complications. These consist of cyst hemorrhage, rupture, infection, uterine prolapse due to displacement, obstructive jaundice, portal hypertension, ascites, and Budd-Chiari syndrome<sup>[19,36,40-42]</sup>. Even with marked hepatosplenomegaly and portal hypertension, liver function is well preserved in PLD. Ascites may be present and usually results from hepatic venous flow obstruction. Diagnosis is confirmed with US and CT imaging (Figure 2D), which along with MRI provides the surgeon with valuable preoperative information, such as the location of infected or hemorrhagic cysts that may be responsible for symptoms<sup>[40]</sup> (Figure 4). Treatment should be considered in cases of persistent symptoms or associated complications.

Cyst aspiration with sclerosis, open or laparoscopic cyst fenestration, combined hepatic resection and fenestration, liver transplantation, and recent medical treatment with somatostatin analogues, are possible therapeutic options based on the type of PLD<sup>[19,36,40,42-46]</sup>. Aspiration, combined with ethanol instillation to induce sclerosis of the cyst lining epithelium, can be effective in patients with a few dominant cysts (Type I PLD - few large cysts

greater than 7 cm). Open or laparoscopic cyst fenestration with omentoplasty is another modality of treatment that can be performed in patients with more diffuse PLD (Type II -multiple medium cysts 5-7 cm in diameter). Patients with small cysts throughout the liver have a greater risk of persistence and/or recurrence of symptoms<sup>[19,42]</sup>. Postoperative morbidity consists of temporary ascites, pleural effusion, and rarer biliary leakage<sup>[40]</sup>.

Combined hepatic resection and fenestration is more effective for reducing the hepatic mass and relieving gastric compression. This procedure has an advantage in the case of massive hepatomegaly with associated gastric compression<sup>[40,47,48]</sup>. Resection addresses the problem of liver mass, but poses significant risk of bile duct injury, vascular compromise, and liver insufficiency, as cysts markedly distort intrahepatic anatomy. In particular, ascites has been troublesome due to continued cyst secretion from residual fenestrated cysts, disruption of intrahepatic lymphatics, and partial venous outflow obstruction. Candidates for combined resection/fenestration should have at least two adjacent liver segments not affected by cysts and have normal liver function. Furthermore, these patients should be managed by experienced hepatobiliary surgeons at institutions with advanced intensive care, as well as interventional radiological and gastroenterology support.

Liver transplantation has been performed in rare cases, especially when the above-mentioned interventions are not an option. In patients who harbor diffuse PLD, orthotopic liver transplantation (OLT) is effective, but inherently assumes the risks of long-term immunosuppression and rejection. OLT is indicated for patients with progressive PLD after resection/fenestration, patients with concurrent liver dysfunction and renal failure, and patients with diffuse PLD without segmental sparing. Although symptomatic relief from hepatomegaly occurred in all surviving patients, long term follow up addressing quality of life, hepatorenal function, immunosuppressive complications, and survival is limited<sup>[42,49]</sup>.

Regarding the results of invasive methods, in case series it is noted that aspiration and sclerosis of individual liver cysts reduced liver volume by 19% in patients with 1 or more large dominant liver cysts<sup>[50]</sup>. Reduction of liver volume is reported to be as high as 12.5% when laparoscopic fenestration is used, but the complication rate reported is also high (0%-33%)<sup>[51-55]</sup>.

The drawbacks of invasive procedures in treating PLD are their partial effectiveness, their related morbidity and mortality and, most importantly, the fact that they do not change the natural course of the disease as symptoms recur due to growth of new cysts or re-growth of treated ones<sup>[41]</sup>.

Several studies have reported the positive effects of somatostatin analogues in decreasing liver and kidney growth in PKD and ADPLD over a treatment period of minimum 6 mo<sup>[43-46]</sup>.

Somatostatin may reduce cyst development through

several mechanisms<sup>[45]</sup>: (1) by inhibiting secretin release from the pancreas<sup>[56]</sup>; (2) by inhibiting secretin-induced cAMP generation and fluid secretion in cholangiocytes<sup>[57-59]</sup>; (3) by vasopressin-induced cAMP generation and water permeability in collecting ducts<sup>[60-63]</sup> by its effects on Gi protein-coupled receptors; and (4) by suppressing the expression of IGF-1, vascular endothelial growth factor, and other cystogenic growth factors and downstream signaling from their receptors<sup>[60-64]</sup>.

Ruggenti *et al.*<sup>[43]</sup> in 2005 showed that kidney volume increased by 2.2%-3.7% during active treatment with octreotide LAR compared with 5.9%-5.4% ( $P < 0.01$ ) while on placebo. Octreotide LAR (40 mg intramuscularly every 4 wk) was given for 6 mo in 12 adult polycystic kidney disease (ADPKD) patients with advanced renal disease (mean total kidney volume 2435 mL, mean serum creatinine 1.9 mg/dL)<sup>[43]</sup>.

In 2009, van Keimpema *et al.*<sup>[44]</sup>, tested lanreotide for treating PLD (120 mg subcutaneously every 4 wk) for 6 mo in 54 patients with PLD (32 ADPKD and 22 AD-PLD). He concluded that liver volume decreased by 2.9% (from 4606 to 4471 mL) in the lanreotide group, whereas it increased by 1.6% (from 4689 to 4895 mL) in the placebo group ( $P < 0.01$ )<sup>[44]</sup>. In the 32 patients with ADPKD, total kidney volume decreased by 1.5% (from 1000 to 983 mL) in the lanreotide group, whereas it increased by 3.4% (from 1115 to 1165 mL) in the placebo group ( $P < 0.02$ )<sup>[44]</sup>.

The results of the clinical trial reported in 2010 by Hogan *et al.*<sup>[45]</sup> showed that administration of octreotide LAR for 1 year induced a moderate but significant reduction in liver volume, inhibited the growth of polycystic kidneys, and improved quality of life in patients with ADPKD and/or ADPLD, with low toxicity and few side effects.

In 2012, Hogan *et al.*<sup>[46]</sup> reported their results in treating patients with PLD with Octreotide LAR for 2 years. He concluded that his study further substantiates the positive effects of somatostatin analogs in reducing TLV (6.08% overall reduction in TLV in the first year), demonstrating their safety and efficacious over a 2-year period in individuals with ADPKD or ADPLD, many of whom had chronic renal insufficiency<sup>[46]</sup>. While OctLAR inhibited renal enlargement within the first year of treatment, it appeared to lose effectiveness during Year 2. While the results of OctLAR therapy on TLV were clearly positive and results on TKV may show some benefit, he did not detect any positive effect of OctLAR on GFR<sup>[46]</sup>.

The administration of octreotide or lanreotide has been generally well tolerated in all studies, with mostly mild, predictable, and dose-dependent gastrointestinal side effects. Patients undergoing long-term octreotide treatment should be monitored for cholelithiasis symptoms or signs; a known complication<sup>[45,65]</sup>. Alopecia, symptomatic bradycardia, and steatorrhea are other known adverse events associated with somatostatin analogue treatment<sup>[66-73]</sup>.

## CYSTIC METASTASES

Many cystic tumors may metastasize to the liver (*e.g.*, pancreatic or ovary cystadenocarcinomas) (Figure 2E). Other liver metastatic lesions which can appear cystic usually originate from rapidly growing hypervascular tumors (sarcoma, melanoma, and neuroendocrine tumors) and appear so due to necrosis and cystic degeneration<sup>[74]</sup>. Despite the fact that these metastatic sites often show cystic characteristics, in most cases the differential diagnosis between them and benign liver cysts is easily made with the contribution of computed tomography.

Of particular interest are the liver metastases from gastrointestinal stromal tumors (GIST) that may appear cystic even before treatment (Figure 2F).

GIST is the most common mesenchymal tumor of the gastrointestinal tract, accounting for 1%-3% of all gastrointestinal malignancies<sup>[75-77]</sup>. GIST can arise anywhere along the GI tract, but is most common in the stomach (50%-70%) and small bowel (25%-35%)<sup>[78]</sup>.

Despite its less aggressive pathologic nature, GIST can metastasize after a long remission period. When GIST originates in the small bowel it behaves in a more aggressive manner. The most common site for metastases is the liver and the peritoneal cavity<sup>[76,77,79]</sup>, but it can also occur in bones, lungs, skin, and lymph nodes. Data from the MD Anderson Cancer Center report 18% of patients presented with metastatic disease<sup>[80]</sup>. Liver metastases are commonly multiple, distributed in both lobes, and more frequently detected synchronously with the primary tumor than metachronously. Case reports showed further metachronous liver metastases being detected after more than 10 years (13 years after gastrectomy for gastric GIST, 17 years after resection for retroperitoneum GIST, and 12 years after surgery for rectal GIST)<sup>[77]</sup>.

GIST mostly affects males between the ages 40 and 70 and are usually found incidentally. Features at clinical presentation depend on tumor size. Large or advanced lesions may present with a variety of clinical findings, including bleeding, abdominal pain, early satiety, bowel obstruction, or perforation. Bowel obstruction is reported in up to 30% of clinical series, but accounts for less than 10% of presentations in most reports<sup>[81]</sup>.

The initial workup should include history and physical examination, appropriate imaging (*i.e.*, chest, abdominal and pelvic CT with contrast and/or MRI), endoscopy in selected cases of primary gastric mass, endoscopic ultrasound, liver function tests, full blood counts, and surgical assessment of tumor resectability. On CT scans, metastases within the liver developed lower attenuation than that of the normal surrounding parenchyma. Liver metastases are hypervascular in 92% of patients, and rapidly become cystic following therapy with imatinib.

GIST and GIST liver metastases are soft and fragile, and biopsy may cause tumor hemorrhage or dissemination. The decision to obtain a biopsy should be based on data regarding the stage of the disease and the clinician's suspicion of other malignancies. If the diagnosis is in doubt, neo-adjuvant therapy using IM is put under con-

sideration, but if there is synchronous metastatic disease, then biopsy is essential<sup>[77]</sup>.

Before 2001, the only effective therapy was surgery alone. The development of clinically effective inhibitors targeting the trans-membrane receptor tyrosine kinase KIT radically changed the management of advanced (locally advanced and metastatic) disease. IM, a selective inhibitor of tyrosine kinase, has revolutionized the management of this disease in recent years. Laboratory studies revealed significant molecular heterogeneity among GIST<sup>[82-84]</sup>. In 2010, a meta-analysis showed that most patients with different genotypes of GIST and KIT exon 11-mutants benefit from the individualized treatment of imatinib<sup>[85]</sup>.

Imatinib has become the first line treatment for recurrent and/or metastatic disease<sup>[79]</sup>. Another meta-analysis comparing the efficacy of imatinib given either once (400 mg) or twice daily, revealed that the higher dose offers a progression-free survival advantage among patients with exon 9 mutations<sup>[86]</sup>, but that the overall survival was the same in the two groups of patients.

Nowadays imatinib therapy and surgical intervention are combined to give patients better disease free and survival rates. Surgical intervention in patients responding to medical therapy may provide a complete cure<sup>[87,88]</sup>. Complete pathological response to imatinib alone occurs in less than 5% of patients<sup>[87,88]</sup>. Surgery has the best results when offered to patients with lesions responsive to 6 mo imatinib therapy. CT with or without PET can be used to assess the therapeutic effect. MSKCC patients with lesions responsive to imatinib in one study had a 2-year progression free survival of 61% and a 2-year overall survival of 100% after surgical resection. In contrast, the 2-year survival was 36% in patients resistant to imatinib therapy<sup>[89]</sup>. Raut *et al.*<sup>[90]</sup> also reported that debulking surgery may prolong survival in patients who are either responsive to imatinib or have limited radiographic progression, but it has poor or no result in patients with progressive metastatic disease. Gronchi *et al.*<sup>[91]</sup> reported in 2007 that surgery may be of value to patients who develop responsive or stable disease while on preoperative imatinib therapy.

Regarding the timing of surgical resection, Suzuki *et al.*<sup>[92]</sup> reported a complete resection rate of 31.4% after IM therapy for a period of 6.9-37.5 mo (mean 10 mo). They also emphasized that surgical resection for IM- responsive recurrent or metastatic disease should be considered as early as possible before the development of progression and secondary resistance to IM<sup>[92]</sup>. Surgical resection 6-12 mo after the start of IM treatment is recommended among responders<sup>[79]</sup>. However a large tumor may prohibit resection because of the risk of postoperative liver failure. An option to counteract this phenomenon is the use of portal vein embolization (PVE). In general, the median time for detection of further metastases following resection of liver metastases, is 12 mo after the initial hepatectomy<sup>[77,79]</sup>. Therefore, careful evaluation of the liver is critical during the first year post-hepatectomy.

Radio-frequency ablation, microwave ablation, and

hepatic artery embolization are other treatment modalities that can normally be used in patients with unresectable disease or in those who cannot undergo surgical excision due to co-morbidities.

## CYSTIC HEPATOCELLULAR CARCINOMA

Rarely hepatocellular carcinoma (HCC) can have a cystic appearance, due to necrosis and cystic degeneration in cases of rapidly growing tumors. Co-existing liver cirrhosis and specific HCC imaging characteristics, such as hypervascularity of solid components and tumor invasion of the portal and hepatic veins, can help to reach the correct diagnosis<sup>[74]</sup>. Typically the conventional ultrasound would reveal a heterogeneous echogenic lesion with a hypoechoic rim and peripheral or internal arterial flow signals in a liver cirrhosis background. The CEUS would reveal a heterogeneous hyper-enhancement during the arterial phase and hypo-enhancement during the portal and late phases<sup>[14]</sup>.

## CAROLI DISEASE

Caroli disease (CD) is a benign congenital disorder, characterized by unilobular or bilobular segmental cystic dilatation of the intrahepatic biliary tract. The first report was by Todd in 1818, but Jacques Caroli in 1958 defined the disease precisely with its different types<sup>[93]</sup>. The estimated incidence of Caroli disease is 1 in 1000000, with males and females being equally affected and more than 80% of patients presenting before 30 years of age<sup>[94]</sup>.

There are two forms of the disease, one associated with congenital hepatic fibrosis, also called Caroli syndrome, and the other a simple form occurring alone. Recent studies suggest that the simple form may be as common as congenital hepatic fibrosis<sup>[95,96]</sup>. It is characterized by segmental cystic dilatation of the intrahepatic ducts, increased incidence of biliary lithiasis, cholangitis, and liver abscesses. Absence of cirrhosis and portal hypertension is typical<sup>[94]</sup>. Various renal disorders have been described in association with this liver disease, including autosomal polycystic kidney disease, medullary sponge kidney, and medullary cystic disease<sup>[93,95]</sup>.

Mode of inheritance is still unclear, but in the majority of cases it is transmitted in autosomal recessive fashion<sup>[93]</sup>. Caroli disease is associated with an increased risk of cholangiocarcinoma, with the reported incidence of malignancy ranging from 5% to 10%. The estimated risk is 100 times greater than that of the general population and is triggered by long-standing inflammation and chronic injury of the biliary epithelium<sup>[94,97]</sup>. Although present from birth, the disease usually remains asymptomatic during the first 20 years, and may also remain so throughout life<sup>[94]</sup>. However when symptomatic, a significant number of these patients present significant loss in their quality of life and clinical course.

The disease is frequently noted by recurrent fever, jaundice, and/or pain in the right hypochondrium<sup>[97]</sup>. A

literature review found recurrent acute cholangitis as the main mode of presentation in 64% of patients<sup>[94]</sup> and the most life-threatening complication of CD. Usually caused by gram-negative bacilli, it has a recurrent course and, despite different antibiotic associations, medical treatment is often not satisfactory<sup>[93]</sup>. Patients with Caroli syndrome, on the other hand, usually present early in life, with complications of portal hypertension, mainly variceal bleeding, hypersplenism, or portal hypertension in 20%-50% of cases<sup>[97]</sup>.

Laboratory studies typically show an elevation of serum alkaline phosphatase, direct bilirubin, and a leukocytosis with a predominance of neutrophils. Hepatic synthetic function is well-preserved initially, but may be affected by progressive liver damage due to recurrent cholangitis and biliary obstruction. Coagulopathy from vitamin K malabsorption may occur in cholestatic patients<sup>[94]</sup>.

Histologically, the main macroscopic and microscopic features of CD are: non-obstructive, localized dilatation of the bile ducts; intraluminal bulbar protrusions of the ductal wall and intra ductal vascular tracts containing patent portal venous; and hepatic arterial channels that traverse the true lumen and terminate within the lumen<sup>[94]</sup>. The diagnosis of CD therefore rests on demonstrating that the cystic lesions are in continuity with the biliary tree. This can be done by imaging studies such as isotope scan, MRCP, CT scan, US, ERCP, and PTC.

The classical finding of CD is finding that a cold area on 99mTc sulfur colloid scan becomes hot on 99mTc DISIDA scan<sup>[94]</sup>. MRCP presents advantages in depicting the entire biliary tree. Three main patterns of CD are identified in MRCP: (1) multiple cystic ectasias connected with fusiform dilatations; (2) isolated fusiform dilatations with multiple calculi; and (3) solitary dilatation of the left bile ducts with cysts and multiple calculi<sup>[93]</sup> (Figure 5).

A CT scan shows central dot signs in CD patients. The fibrovascular bundles containing portal vein radical and a branch of hepatic artery bridging the saccule appear as central dots or a linear streak. This central dot sign described on a CT scan is suggested as a pathognomonic finding in CD, and can also be demonstrated on US<sup>[94]</sup>. ERCP is the method with the highest sensitivity in the diagnosis of CD. The cholangiographic features of Caroli disease are well established as saccular or fusiform dilatation of the intrahepatic bile ducts. Irregular bile duct walls, strictures, and stones may be present. Therefore, direct cholangiography is considered the method of choice for an accurate diagnosis of CD<sup>[94]</sup>. With PTC, the diagnosis can be made confidently when the large intrahepatic branches have focal or segmental involvement with cystic outpouchings in which the contrast medium collects. False-positive findings are rare when PTC is used<sup>[93]</sup>.

The treatment of CD depends on the clinical features and location of the biliary abnormalities. It seems more than justified to advocate a rather aggressive surgical strategy in symptomatic patients who have had several

Figure 5 A case of Caroli disease. A: On computed tomography. A large intra-biliary stone (black arrow) is evident in the dilated ducts (red arrows); B: On magnetic resonance imaging. A large intra-biliary stone (pink arrow) is evident in the dilated ducts (blue arrows).

futile conservative treatment attempts<sup>[98]</sup>. The localized forms, which involve either the whole of the left or the right half of the liver, are curable by surgery. They should be treated by hemi-hepatectomy, left or right, with associated treatment of any problem affecting the common duct<sup>[94]</sup>. The procedure is associated with low morbidity and virtual no mortality. There is no report of malignant tumors arising after surgical resection<sup>[98]</sup>.

Diffuse involvement of both lobes can be treated with conservative management in asymptomatic patients, with appropriate antibiotics for cholangitis and ursodeoxycholic acid therapy for litholysis in cases of intrahepatic cholelithiasis, endoscopic therapy (sphincterotomy for clearance of intrahepatic stones), and internal biliary bypass procedure<sup>[94]</sup>. These patients in whom there is no indication for liver resection or transplantation should at least be followed up regularly on an outpatient basis to detect any kind of deterioration or malignant transformation as early as possible<sup>[98]</sup>.

Bilateral disease complicated by recurrent cholangitis, cirrhosis, or both, together with symptoms of associated hepatic fibrosis, do not find the same solution, and it is often difficult to manage. Emergency surgery in the presence of acute cholangitis and deteriorating liver function is associated with high mortality (20%–40%) and morbidity (44%–80%)<sup>[94]</sup>.

It seems that liver transplantation or living donor transplantation is an effective therapeutic option and possibly the only and ultimate management option for these patients with end-stage diffuse Caroli disease providing gratifying long-term results<sup>[94,97,98]</sup>. OLT has become a therapeutic option which, aside from the better long-term outcome, can prevent the development of cholangiocarcinoma<sup>[96]</sup>.

## DISCUSSION

Liver cystic lesions consist of a heterogeneous group of disorders. Rare liver cystic lesions such as cystadenoma, hydatid cyst, polycystic liver disease, Caroli disease, and cystic liver metastases pose several dilemmas to the practicing surgeon or physician. It is very important that

awareness and a high index of suspicion for rare diseases and HC are present, so as to provide as accurate a diagnosis as possible. Since our diagnostic tools have become more powerful and accurate, our adequate knowledge of the nature, evolution, confirmation, and treatment of all the possible pathological entities in the differential diagnosis becomes more necessary than ever.

The use of CEUS in diagnoses of liver lesions has shown promising results, providing more accurate images than conventional ultrasound<sup>[99–102]</sup>. The discrimination between malignant and benign lesions is easier and more accurate than in a conventional ultrasound.

Complete non-enhancement throughout three phases of CEUS or sustained enhancement in the portal and late phases is noticed in most benign lesions<sup>[14]</sup>. Conversely, hypoenhancement in the late phase is seen in malignancies<sup>[14]</sup>. Real time CEUS improves the capability of discrimination between benign and malignant complex cystic focal liver lesions<sup>[14]</sup>. It has been shown that CEUS can greatly improve the diagnostic accuracy of focal liver lesions compared with conventional ultrasound<sup>[14]</sup>.

Contrast-enhanced ultrasound has also been used for diagnostics of the biliary system. In 2009, Xu<sup>[100]</sup> summarized the methodology, image interpretation, enhancement pattern, clinical usefulness, and indications for CEUS in the biliary system.

The first important step, regarding liver cystic lesions, is to make a definitive diagnosis of the nature of the cystic lesion. The second is determining whether the patient's symptoms are related to the cystic lesion. The third is deciding whether and when to initiate therapy for the lesion. Finally, a number of treatment options are available, leading to the fourth issue, which is deciding the appropriate therapy for the patient.

Ideally the cystic liver lesions should be handled by a multidisciplinary team familiar with liver diseases, consisting of interventional radiologist, interventional gastroenterologist, surgeon, clinical oncologist, and pathologist. In our opinion this is the way that even rare entities can be identified and treated promptly. The algorithm used in our department for managing such cystic lesions is provided in Figure 6.

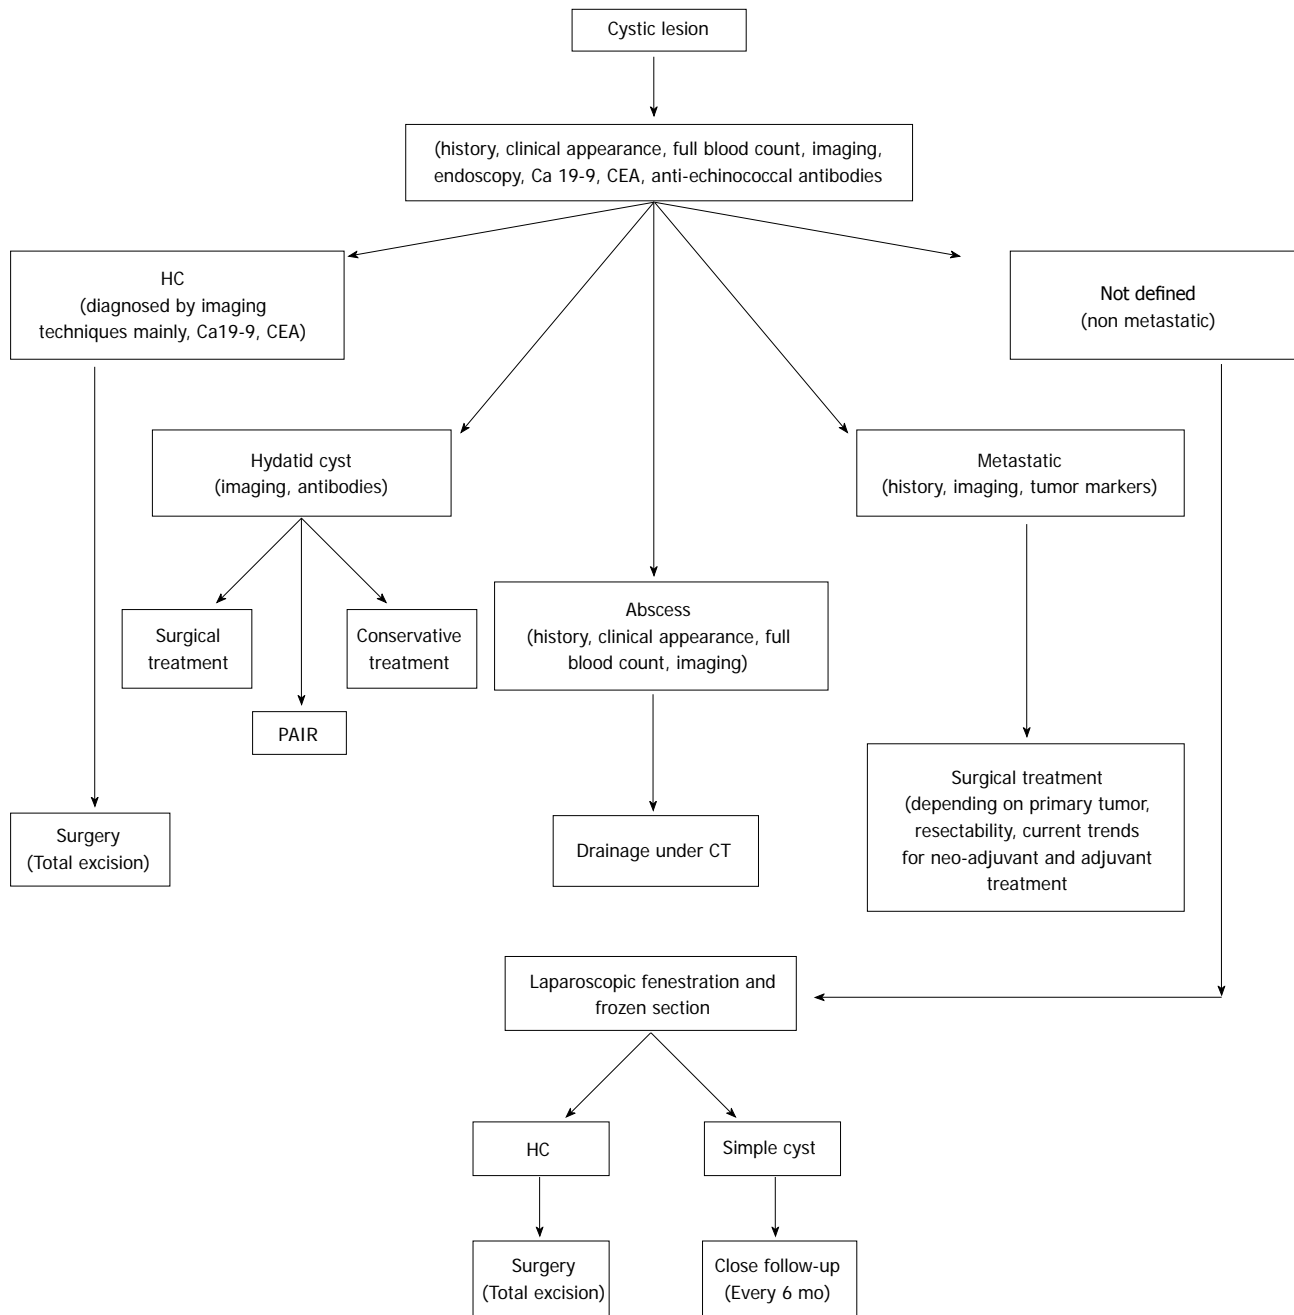

Figure 6 Liver cystic lesions management algorithm.

## CONCLUSION

Cystic liver lesions require accurate pre-treatment diagnosis in order to select the appropriate therapy for each patient, as they can represent benign or malignant formations. It is best that a specialized team deals with cystic liver lesions so that diagnosis and treatment are accurate and focused. Specifically, rare entities require accurate diagnosis and management, as they can pose a malignant impact.

chain amino acids (BCAAs) are decreased in patients with liver cirrhosis, and the amino acids imbalance could affect the clinical picture of the disease and the prognosis of the patients. However, there are few comprehensive reviews on the biological activities of BCAAs. In this review, we summarize the biological activities of BCAAs, and discuss possible applications of BCAAs for the management of patients with advanced liver diseases with a list of clinical trials of BCAA administration.

### Abstract

Branched chain amino acids (BCAAs) have been shown to affect gene expression, protein metabolism, apoptosis and regeneration of hepatocytes, and insulin resistance. They have also been shown to inhibit the proliferation of liver cancer cells *in vitro*, and are essential for lymphocyte proliferation and dendritic cell maturation. In patients with advanced chronic liver disease, BCAA concentrations are low, whereas the concentrations of aromatic amino acids such as phenylalanine and tyrosine are high, conditions that may be closely associated with hepatic encephalopathy and the prognosis of these patients. Based on these basic observations, patients with advanced chronic liver disease have been treated clinically with BCAA-rich medicines, with positive effects.

### INTRODUCTION

The three branched chain amino acids (BCAAs), leucine, isoleucine and valine, are among the nine essential amino acids for humans. Recent studies have revealed the functions of these BCAAs, and they have been administered for the treatment of advanced liver diseases. In this review, we summarize current understanding of the biological properties of BCAAs and review the results of clinical application of BCAAs to treat patients with liver diseases.

### BASIC ASPECTS OF BCAAS IN LIVER

#### *Serum concentration of BCAAs in patients with chronic liver diseases and liver cirrhosis*

Serum concentrations of BCAAs are decreased, while the concentrations of the aromatic amino acids (AAAs) phenylalanine and tyrosine are increased, in patients with advanced liver diseases, resulting in a low ratio of BCAAs to AAAs, a ratio called the Fischer ratio<sup>[1]</sup>. A low Fischer ratio has been associated with hepatic encephalopathy (HE). The imbalance of amino acids tends to become more marked with the progression of liver diseases, and aminograms are useful for assessing the prognosis of cir-

rhotic patients with or without hepatocellular carcinoma (HCC)<sup>[2,3]</sup>. Moreover, a simplified Fischer ratio, the BCAA to tyrosine ratio (BTR), has been reported useful for predicting serum albumin concentration one year later<sup>[4]</sup>. These data indicate that amino acid imbalance, either low Fischer ratio or BTR, is a marker for progression of liver diseases, and that correcting this ratio may have therapeutic potential, not only for nutritional improvement, but also for HE, in patients with advanced liver diseases.

### **Gene expression and mitochondrial biogenesis**

In mice, BCAA-rich diets have shown to up-regulate the expression of peroxisome proliferator-activated receptor (PPAR)  $\gamma$  coactivator-1 $\alpha$  (PGC-1 $\alpha$ ), a master regulator of mitochondrial biogenesis and the defense system against reactive oxygen species (ROS), and of sirtuin-1, a member of the sirtuin family linked to life span extension, enhanced mitochondrial biogenesis, and decreased ROS production, leading to the prolongation of the lifespan of male mice<sup>[5]</sup>. BCAAs have also been shown to induce the activation of genes involved in antioxidant defenses and inhibition of ROS production, as well as to induce the hepatic expression of mRNA encoding 8-oxoguanine DNA glycosylase 1, an enzyme involved in repair of oxidative DNA damage, in a rat model of liver injury, indicating that BCAAs are involved in the induction of antioxidant DNA repair<sup>[6]</sup>.

In various cell lines, BCAAs, especially leucine, have been shown to activate the mammalian target of rapamycin (mTOR) signals, stimulating the synthesis of proteins, including albumin, and of glycogen<sup>[7]</sup>. The ability of leucine to enhance glucose metabolism was confirmed in normal rats and in a rat cirrhosis model. BCAA activation of mTORC1 has also been associated with cell growth<sup>[8]</sup> and PGC-1 $\alpha$ -mediated mitochondrial gene expression<sup>[9]</sup>. BCAAs have been shown to up-regulate PPAR- $\gamma$  and uncouple (UCP) 2, reducing triglyceride concentrations in mouse livers<sup>[10]</sup>. These findings suggest that BCAAs may have a therapeutic effect on metabolic disorders and/or obesity.

### **Apoptosis and regeneration of hepatocytes**

BCAA supplementation was shown to delay the progression of CCl<sub>4</sub>-induced chronic liver injury in a rat model by reducing hepatic apoptosis<sup>[11]</sup>. On the other hand, BCAAs promoted hepatocyte regeneration in a rat model of hepatectomy<sup>[12]</sup>. Moreover, BCAAs were reported to stimulate the production of hepatocyte growth factor<sup>[13]</sup>. Taken together, these findings indicate that supplementation with BCAAs, by reducing hepatocyte apoptosis and promoting liver regeneration, may result in rapid recovery from liver injury.

### **Albumin synthesis**

BCAAs activate mTOR and subsequently increase the production of eukaryotic initiation factor 4E-binding protein-1 and ribosomal protein S6 kinase, which upregulate the synthesis of albumin<sup>[14-16]</sup>. Furthermore, leucine stimulates the nuclear importation of polypyrimidine-

tract-binding protein, which binds to albumin mRNA and increases its translation<sup>[17]</sup>.

### **Insulin resistance**

BCAAs were shown to improve homeostasis model assessment scores for insulin resistance (HOMA-IR) and beta cell function (HOMA-%B) in patients with chronic liver disease, indicating that BCAAs can ameliorate insulin resistance<sup>[18]</sup>. In mice lacking the gene encoding mitochondrial BCAA aminotransferase, an enzyme that catalyzes BCAAs, serum BCAA concentrations were elevated. In those mice, fasting blood glucose and insulin concentrations were decreased and HOMA-IR was significantly lower than in wild-type mice<sup>[19]</sup>. Furthermore, administration of leucine or isoleucine improved insulin sensitivity in mice with high-fat diets<sup>[20,21]</sup>. BCAAs were also shown to temporarily increase plasma insulin concentrations in healthy young men, although plasma glucose concentrations were not altered<sup>[22]</sup>.

Several organs are involved in the mechanism by which BCAAs improve insulin resistance. In the liver, BCAAs increase the liver X receptor/sterol regulatory element binding protein-1c pathway and subsequently activate liver-type glucokinase and glucose transporter. Furthermore, BCAAs suppress hepatic expression of glucose-6-phosphatase<sup>[23]</sup>. In adipose tissue, leucine increases insulin-induced phosphorylation of Akt and mTOR, increasing glucose uptake<sup>[24]</sup>. In skeletal muscle, BCAAs promote glucose uptake through activation of phosphatidylinositol 3-kinase (PI3K) and protein kinase C and subsequent translocation of glucose transporter to the plasma membrane<sup>[25]</sup>. In addition, BCAAs increase PPAR- $\gamma$  and subsequent UCP2 in liver and UCP3 in muscle, stimulating oxidation of free fatty acids. Thus, BCAAs improve insulin resistance through interactions in organs targeted by insulin.

### **Liver cancer cells**

The direct effects of BCAAs on liver cancer cells have been analyzed in culture systems. Increased concentrations of BCAAs in culture medium were reported to suppress the proliferation of HCC cell lines<sup>[26]</sup>. Moreover, all three BCAAs were found to accelerate insulin-induced vascular endothelial growth factor (VEGF) mRNA degradation at the post transcriptional level, downregulating VEGF expression during the development of HCCs<sup>[27]</sup>. BCAAs were also shown to induce apoptosis of liver cancer cell lines by inhibiting insulin-induced PI3K/Akt and NF $\kappa$ B pathways through mTORC1- and mTORC2-dependent mechanisms<sup>[28]</sup>. Moreover, BCAAs may inhibit obesity-related hepatocarcinogenesis by suppressing the stimulatory effect of visfatin, an adipokine with a critical role in HCC proliferation<sup>[29]</sup>.

Insulin was found to induce cell proliferation through activation of the mitogen-activated protein kinase pathway<sup>[30]</sup>, and BCAAs inhibit insulin signals by suppressing the expression of insulin-like growth factor<sup>[31]</sup>. BCAAs have been reported to decrease insulin resistance-induced

expression of endothelial growth factor and to subsequently suppress tumor angiogenesis<sup>[32]</sup>. Collectively, these data suggest that BCAAs inhibit the proliferation of HCC cells or hepatocarcinogenesis through multiple mechanisms.

### Immunity

Immunity and nutrition are closely associated, and several studies have indicated the importance of BCAAs during lymphocyte proliferation or dendritic cell maturation. Depletion of any of the three BCAAs from the culture medium was shown to markedly inhibit phytohemagglutinin-induced lymphocyte proliferation<sup>[33]</sup>, with removal of valine from the culture medium completely abolishing lymphocyte proliferation. In contrast, increased concentrations of BCAAs in the culture medium did not significantly affect lymphocyte proliferation, indicating that, although the BCAAs are requisite for lymphocyte proliferation, there are optimal concentrations. On the other hand, BCAAs have little effect on macrophage functions.

*In vivo* studies have also shown the importance of BCAAs for immunity. We previously analyzed the effects of a BCAA-rich diet on immune system functions in the spleen and liver of rats<sup>[34]</sup>. We found that addition of BCAAs to the diet increased the numbers of intrahepatic lymphocytes and stimulated natural killer (NK) cell activity and lectin-dependent cytotoxic activities in the liver. Interestingly, the number of intrahepatic lymphocytes was positively correlated with valine concentrations in plasma and the liver. BCAAs, especially valine, are also involved in the maturation of dendritic cells. For example, valine was found to dose-dependently increase the allostimulatory capacity of IL-12 production by monocyte-derived dendritic cells (DCs) obtained from both healthy volunteers and cirrhotic patients with chronic hepatitis C virus (HCV) infection<sup>[35]</sup>. These findings suggest that valine may have therapeutic potential in HCV-infected cirrhotic patients by restoring immune system activities, which may lead to inhibit hepatocarcinogenesis<sup>[35,36]</sup>. In patients with cirrhosis, BCAA administration increases the numbers of hepatic lymphocytes and restores the phagocytic activity of neutrophils and the NK activity of lymphocytes<sup>[37]</sup>. In addition, BCAAs increased the number of blood lymphocytes in postsurgical patients<sup>[38,39]</sup>, and significant correlations were observed between the serum concentration of BCAAs and the survival rates of the patients with sepsis<sup>[40]</sup>. These data indicate that BCAAs are closely associated with the maturation and function of various immune cells.

## CLINICAL APPLICATION OF BCAAS IN LIVER DISEASES

### BCAAs for liver cirrhosis

The liver is a central organ for nutrient metabolism, and patients with chronic liver diseases may develop various metabolic and nutrition disorders<sup>[41]</sup>. Patients with cirrhosis frequently show protein and energy deficiency. Protein

deficiency leads to hypoalbuminemia, inducing ascites and edema, whereas energy deficiency decreases fat and muscle mass and causes muscle weakness, decreasing the quality of life of patients with cirrhosis<sup>[42]</sup>. Several clinical trials have suggested that BCAA supplementation improves the prognosis of cirrhotic patients<sup>[43,44]</sup>. For example, a multicenter randomized trial from Italy showed that oral BCAA supplementation in patients with advanced cirrhosis prevented progressive hepatic failure and improved surrogate markers and perceived health status<sup>[44]</sup>. Furthermore, a large scale post marketing clinical study in Japan showed that oral BCAA administration significantly reduced the occurrence of complications associated with poor prognosis, such as liver failure, ruptured esophageal varices, HCC, and death, compared with patients who received diet therapy with defined daily food intake (HR = 0.67, 95%CI: 0.49-0.93)<sup>[43]</sup>. Furthermore, BCAA supplementation in patients with advanced cirrhosis may improve abnormal glucose tolerance in addition to improving serum albumin concentration<sup>[45]</sup>, and a randomized study showed that oral BCAA was effective in patients with both compensated and decompensated cirrhosis, maintaining or increasing serum albumin concentrations<sup>[46]</sup>. Oral BCAA treatment has also been reported to improve protein malnutrition in patients, especially during the early stages of liver cirrhosis, increasing serum albumin level to 3.5-3.9 g/dL and increasing total hepatic parenchymal cell mass<sup>[47-49]</sup>. BCAA treatment also improved nutritional status and reduced the frequency of albumin infusion in children with end-stage liver disease<sup>[50]</sup>. Taken together, these findings indicate that BCAA supplementation is effective in improving nutritional status in cirrhotic patients, regardless of patient age or disease stage.

Furthermore, BCAA supplementation was reported to improve the quality of life in cirrhotic patients. Two randomized trials showed that BCAA supplementation improved the Short Form-36 scores of general health perception compared with control groups<sup>[43,44]</sup>. Another randomized study showed that BCAA-enriched supplements improved weakness and fatigue compared with ordinary foods<sup>[51]</sup>. BCAA-enriched supplementation has also been reported to improve sleep disturbance<sup>[52]</sup>.

Accelerated fat oxidation and a catabolic state after fasting, represented as a decreased respiratory quotient (RQ), are frequently observed in patients with cirrhosis<sup>[53]</sup>. Late evening snack supplementation with a BCAA mixture was found to improve RQ, nutritional state and glucose intolerance<sup>[53,54]</sup>. The energy efficiency of BCAAs is higher than that of glucose or fatty acids, suggesting that BCAAs may be the preferred energy substrate for patients with cirrhosis<sup>[55]</sup>. Others also reported that late evening snacks with BCAAs were useful in improving protein metabolism and lipolysis in cirrhotic patients<sup>[56]</sup>.

Thus, BCAA supplementation for advanced cirrhotic patients improves nutritional status and quality of life. The guidelines of the European Society for Clinical Nutrition and Metabolism and the Study Group for the Standardization of Treatment of Viral Hepatitis Includ-

ing Cirrhosis of the Ministry of Health, Labour and Welfare of Japan recommend BCAA supplementation in the treatment of patients with advanced cirrhosis<sup>[57,58]</sup>.

### BCAAs for hepatic encephalopathy

HE is a major complication of cirrhosis associated with poor prognosis and quality of life, and often occurs repeatedly. Elevated blood ammonia is seen in patients with HE, and ammonia is one of the pathogenic factors for the development of HE<sup>[59]</sup>. Unfortunately, infusion of BCAAs was reported to increase venous blood ammonia in most patients with liver failure<sup>[60]</sup>. Thus, the effects of BCAAs on HE may not be associated with blood ammonia levels, especially when administered intravenously. HE may also be caused by a decreased plasma ratio of BCAAs to AAAs. In patients with advanced cirrhosis, HE frequently occurs after gastrointestinal bleeding, perhaps due to an absence of isoleucine and an abundance of leucine in hemoglobin molecules, leading to HE by way of BCAA antagonism<sup>[61]</sup>. Treatment with BCAAs may therefore have a beneficial effect on patients with hepatic encephalopathy mainly by compensating decreased ratio of BCAAs to AAAs, but not by reducing serum ammonia levels. A systematic review reported that BCAAs appeared to have a modest effect in improving encephalopathy without adverse events, although convincing evidence was not supplied<sup>[62]</sup>. Two randomized studies also showed that BCAAs did not clearly prevent HE in patients with advanced cirrhosis, although BCAAs prevented the progression of hepatic failure<sup>[43,44]</sup>. Furthermore, postoperative BCAA treatment could not prevent postoperative hepatic encephalopathy<sup>[63]</sup>. A recent randomized, double-blind, multicenter study evaluating the effect of BCAAs on HE found that BCAAs did not decrease the recurrence of HE but improved minimal HE and muscle mass<sup>[64]</sup>. Moreover, a systematic review showed that oral (RR = 1.44; 95%CI: 1.07-1.94) but not intravenous (RR=1.12; 95%CI: 0.91-1.39) administration of BCAAs improved HE manifestations<sup>[65]</sup>. Non-absorbable disaccharides such as lactulose or lactitol also improved the manifestations of HE (RR = 1.99; 95%CI: 1.14-3.48) and prevented clinically overt HE (RR = 0.26; 95%CI: 0.17-0.41), suggesting that non-absorbable disaccharides be used as the first line treatment of HE and BCAAs may be considered as a second line treatment<sup>[65]</sup>.

Recently, a systematic review with meta-analyses on the effect of oral BCAAs for the treatment of HE was published<sup>[66]</sup>. The review has revealed that supplementation of oral BCAAs in cirrhotic patients inhibits the manifestation of HE, especially in patients with overt HE rather than those with minimal HE, but showed no effect on the survival of those patients<sup>[66]</sup>. Thus, oral administration of BCAAs is the treatment of choice in cirrhotic patients with HE, especially in combination with non-absorbable disaccharides.

### BCAAs for hepatocellular carcinoma

Clinical studies have suggested that BCAA supplementa-

tion can help in the management of HCC. Prolonged surgical stress and advanced malignancy can result in systemic catabolism and muscle wasting, with BCAA supplementation having the potential to improve these conditions<sup>[67]</sup>.

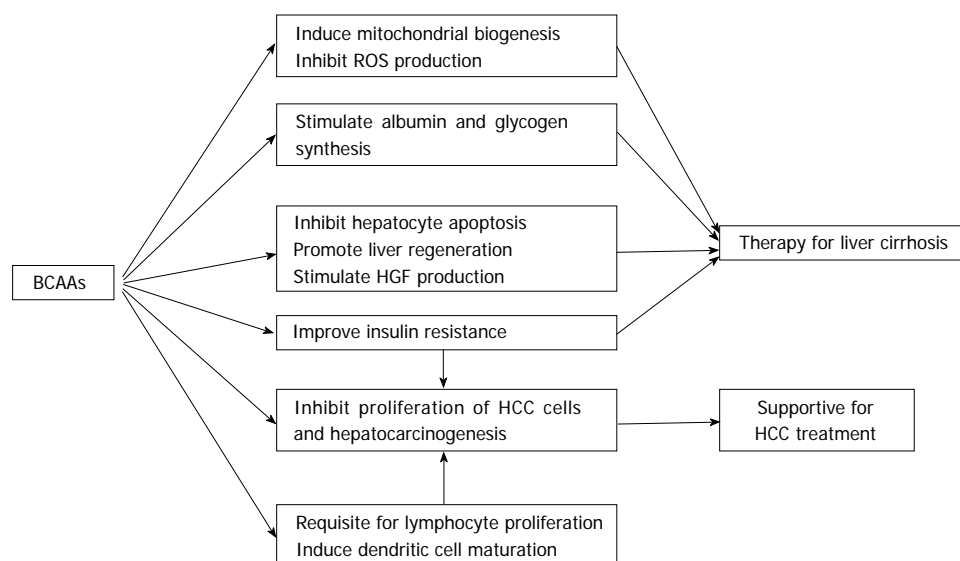

A randomized control trial in obese, HCV-infected patients with cirrhosis showed that BCAA supplementation reduced the frequency of development of HCC, by approximately 30% over 3 years<sup>[68]</sup>. In addition, a second randomized trial in patients with compensated liver cirrhosis due to HCV showed that oral BCAAs reduced the incidence of HCC (15.8% *vs* 25.0%)<sup>[69]</sup>. A retrospective analysis in patients with cirrhosis showed that the incidence of HCC was significantly lower in patients who did than did not receive BCAAs (HR = 0.416, 95%CI: 0.216-0.800, *P* = 0.0085)<sup>[70]</sup>. Furthermore, combinations of BCAAs and angiotensin-converting enzyme inhibitors may prevent the development of HCC in patients with insulin resistance<sup>[71]</sup>.

Perioperative nutritional support, especially enteral rather than parental nutrition, was found to improve the prognosis of cirrhotic patients by reducing complications following hepatectomy<sup>[72,73]</sup>. Recently, a randomized trial showed that BCAA supplementation after hepatectomy promoted rapid improvement in protein metabolism and inhibited progression to liver cirrhosis<sup>[74]</sup>. Furthermore, another randomized trial showed that oral BCAA supplementation after hepatectomy for HCC significantly reduced the 30 month recurrence of HCC (28.5% *vs* 55.7%, *P* = 0.044)<sup>[75]</sup>. Perioperative BCAA treatment in patients undergoing hepatectomy was also shown to contribute to shorter hospital stay and quicker improvement of liver function during the early postoperative period<sup>[76]</sup> and to improve postoperative quality of life by restoring and maintaining nutritional status and whole-body kinetics<sup>[77]</sup>.

The effect of BCAAs on HCC recurrence after radio-frequency ablation (RFA) remains unclear. Two prospective studies showed that BCAA supplementation improved nutritional state and liver function, but its effect on HCC recurrence was not determined<sup>[78,79]</sup>. However, a recent retrospective study showed that oral BCAA supplementation after RFA improved 1 year (61.8% *vs* 52.0%) and 3-year (28.0% *vs* 12.0%) progression-free survival rates compared with a control group after RFA (*P* = 0.013)<sup>[80]</sup>.

Oral BCAA supplementation after chemoembolization also prevents the decrease of liver function after treatment and improves the quality of life, although its ability to prevent HCC recurrence was not determined<sup>[81,82]</sup>. Oral BCAA treatment before chemoembolization was found useful in maintaining hepatic functional reserve<sup>[83]</sup>. A randomized trial also found that oral BCAA supplementation improved nutritional status by increasing BCAA concentration during radiotherapy for HCC<sup>[84]</sup>.

Thus, BCAA supplementation for patients with HCC is of clinical importance in the preservation of liver function and quality of life during treatment, although it is unclear whether BCAAs directly prevent HCC.

**Figure 1** Mechanism of action of branched chain amino acids in liver diseases. BCAAs: Branched chain amino acids; ROS: Reactive oxygen species; HGF: Hepatocyte growth factor; HCC: Hepatocellular carcinoma.

**Table 1** Prospective randomized trials of branched-chain amino acid administration for advanced liver diseases

Object	Time	No.	Major outcome	Ref.
Cirrhosis	2 yr	646	Improve event-free survival and QOL. Increase serum albumin levels.	[43]
Cirrhosis (advanced)	1 yr	174	Improve event-free survival. Lower hospital admission. Improve the Child-Pugh score and QOL.	[44]
Cirrhosis (decompensated)	24 wk	281	Increase serum albumin levels.	[45]
Cirrhosis	2 yr	65	Maintain serum albumin levels.	[46]
Cirrhosis (early)	2 yr	65	Maintain serum albumin levels.	[49]
Cirrhosis	3 mo	48	Increase serum albumin levels. Improve energy metabolism.	[51]
Cirrhosis (HCV)	168 wk	39	Reduce hepatic carcinogenesis in patients with compensated cirrhosis with a serum albumin level of < 4.0 g/dL.	[69]
Cirrhosis (HCV, obese)	2 yr	622	Reduce hepatic carcinogenesis in patients with BMI of 25 or higher and with an alpha-fetoprotein level of 20 ng/mL or higher.	[68]
Cirrhosis (pre liver transplant)	3.3 yr	50	Preserve hepatic reserve functions. Lower complications associated with cirrhosis.	[99]
Cirrhosis after an episode of HE	56 wk	116	Not decrease recurrence of HE. Improve minimal HE and muscle mass.	[64]
Cirrhosis after hepatectomy	1 yr	43	Improve hepatic metabolism after hepatectomy. Inhibit progression to cirrhosis.	[74]
HCC after hepatectomy	6.5 mo	56	Reduce early recurrence of HCC.	[75]
HCC after hepatectomy	12 wk	44	Shorten hospital stay. Quicker improvement of liver functions.	[76]
After hepatectomy	12 mo	76	Improve post operative QOL.	[77]
HCC after RFA	12 mo	35	Improve nutritional state and QOL.	[78]
HCC after RFA	12 wk	30	Improve liver functions.	[79]
HCC undergoing chemoembolization	12 mo	84	Increase serum albumin levels, reduce morbidity, and improve QOL.	[81]
HCC undergoing chemoembolization	2 wk	56	Prevent reduction of liver functions.	[82]
HCC during radiotherapy	10 wk	30	Increase serum albumin levels.	[84]

QOL: Quality of life; HCV: Hepatitis C virus; HE: Hepatic encephalopathy; HCC: Hepatocellular carcinoma. RFA: Radiofrequency ablation.

### Acute liver injury

Although BCAAs have no proven benefit in patients with acute liver injury, enteric nutritional support is essential<sup>[85]</sup>. Several animal studies have shown that BCAAs may prevent acute liver injury<sup>[86-88]</sup>, although its effects in humans are as yet undetermined. BCAA concentrations have been reported to be increased, unaltered or decreased following acute liver injury<sup>[89,90]</sup>. In alcoholic hepatitis, parentally or enterally administered hyperalimentation with or without BCAAs did not show survival benefits<sup>[91]</sup>.

### HCV infection

Insulin resistance occurs frequently in patients infected with HCV and is associated with various complications, such as steatosis, disturbances in glucose metabolism, and carcinogenesis<sup>[92]</sup>. BCAAs, especially leucine or isoleucine, have been shown to have beneficial effects on glucose metabolism<sup>[93]</sup>. A randomized study showed that BCAA treatment of patients with chronic hepatitis C and insulin resistance improved HbA1c concentrations in patients with marked peripheral insulin resistance, although

BCAA did not significantly affect parameters of glucose metabolism or lipid profiles<sup>[94]</sup>. A multicenter randomized control trial showed that BCAAs prevented the development of HCC in obese, HCV-infected patients<sup>[68]</sup>. Furthermore, BCAA treatment can restore impaired interferon signaling caused by malnutrition through the mTOR and FoxO pathways in patients with chronic hepatitis C<sup>[95]</sup>. Interestingly, valine was reported to reduce HCV viral load, possibly by enhancing DC function or interferon signaling<sup>[96]</sup>. Thus, BCAA supplementation may be useful for adherence to interferon therapy in patients with chronic hepatitis C and may enhance the effects of interferon in these patients<sup>[97]</sup>.

### Liver transplantation

Protein-energy malnutrition is commonly found in patients with end-stage liver disease requiring liver transplantation and is a risk factor for posttransplant morbidity. A report of 50 recipients undergoing living donor liver transplantation (LDLT) showed that absence of preoperative BCAA treatment was an independent risk factor for postoperative severe infection and in-hospital death<sup>[98]</sup>. Kawamura *et al.*<sup>[99]</sup> reported that early interventional oral BCAAs might prolong the liver transplant waiting period by preserving hepatic reserve in patients with cirrhosis. A retrospective analysis also showed that BCAA treatment before LDLT may reduce the incidence of posttransplant bacteremia<sup>[100]</sup>.

### Other clinical problems related to management of liver diseases

**Insulin resistance:** Increased insulin resistance is found in patients with chronic liver diseases and is a therapeutic target associated with malnutrition and hepatocarcinogenesis. BCAAs are thought to act on insulin target organs, such as skeletal muscles, adipose tissue, and the liver<sup>[101]</sup>. BCAA infusion was reported to decrease plasma glucose concentrations in patients with advanced liver cirrhosis<sup>[102]</sup>, and oral BCAA administration was recently shown to reduce both blood glucose concentrations<sup>[103,104]</sup> and insulin resistance in patients with chronic liver diseases, especially in men<sup>[19,105]</sup>. More recently, long-term BCAA supplementation was shown to improve glucose tolerance in patients with nonalcoholic steatohepatitis (NASH)-related cirrhosis, and may be an alternative treatment for NASH<sup>[106]</sup>.

## CONCLUSION

BCAAs are involved in various biological activities (Figure 1), and prospective randomized clinical trials showing possible effectiveness of BCAAs in the management of chronic liver diseases are summarized in Table 1. Supplementation with BCAAs may be a promising therapeutic option for patients with chronic liver diseases, although more analyses are needed to determine their basic mechanisms of action.

### Abstract

Pregnancy is a special clinical state with several normal physiological changes that influence body organs including the liver. Liver disease can cause significant morbidity and mortality in both pregnant women and their infants. Few challenges arise in reaching an accurate diagnosis in light of such physiological changes. Laboratory test results should be carefully interpreted and the knowledge of what normal changes to expect is prudent to avoid clinical misjudgment. Other challenges entail the methods of treatment and their safety for both the mother and the baby. This review summarizes liver diseases that are not unique to pregnancy. We focus on viral hepatitis and its mode of transmission, diagnosis, effect on the pregnancy, the mother, the infant, treatment, and breast-feeding. Autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, Wilson's disease, Budd Chiari and portal vein thrombosis in pregnancy are also discussed. Pregnancy is rare in patients with cirrhosis because of the metabolic and hormonal changes associated with

cirrhosis. Variceal bleeding can happen in up to 38% of cirrhotic pregnant women. Management of portal hypertension during pregnancy is discussed. Pregnancy increases the pathogenicity leading to an increase in the rate of gallstones. We discuss some of the interventions for gallstones in pregnancy if symptoms arise. Finally, we provide an overview of some of the options in managing hepatic adenomas and hepatocellular carcinoma during pregnancy.

### INTRODUCTION

Although not unique to pregnancy, liver diseases reviewed here can have significant consequences on pregnant women and their infants.

Approach to the diagnosis of liver conditions in preg-

**Table 1** Normal physiological alterations in liver tests in pregnancy

Test	First trimester	Second/third trimesters
Albumin	↓	↓
ALT	N	N
AST	N	N
Total bilirubin	↓	↓
Alkaline phosphatase	N	↑
GGT	N	↓
5'-nucleotidase	N	May increase in second and third trimesters
Fasting total bile acids	N	N
Prothrombin time	N	N

N: No change; ↑: Increase; ↓: Decrease; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: Gamma-glutamyl transpeptidase.

nant women should take into consideration the physiological changes during pregnancy that allow for normal fetal development. Sex hormones such as estrogen and progesterone increase progressively during pregnancy. This increase has an influence on hepatic metabolic, synthetic, and excretory functions<sup>[1]</sup>. During late pregnancy, biliary excretion of few compounds can be reduced. Furthermore, reduction in serum protein concentrations secondary to reversible hemodilution resulting from expanding plasma volume while pregnant is reflected by alterations in some liver function tests (Table 1).

Whereas nausea and vomiting are common in early pregnancy, those should not be considered normal in the second or third trimesters and ought to be investigated<sup>[2]</sup>. Jaundice and generalized pruritus are not normal features in pregnancy. Spider nevi and palmar erythema were found up to 66% and 63% respectively by the end of normal pregnancy in one study<sup>[3]</sup>. Most of those were reversible after delivery.

Unique aspects such as the effect of the disease on pregnancy, the effect of the pregnancy on disease progression, the use of specific therapies during pregnancy, and issues related to breast-feeding are discussed.

## VIRAL HEPATITIS AND PREGNANCY

### Hepatitis A virus

Hepatitis A virus (HAV) is an RNA virus that transmits through fecal-oral route, usually through contaminated water or food. Overall incidence is 9.1 per 100000 in the United States and less than 1:1000 pregnancies. Clinical presentation ensues within 2-4 wk of exposure. Generally, HAV does not result in chronic infection. Acute hepatitis A starts with prodromal symptoms including anorexia, malaise, nausea and vomiting, and progresses into jaundice and elevated liver transaminases. Presence of HAV immunoglobulin M (IgM) antibodies confirms the acute infection. Management is supportive care including optimizing hydration and nutrition. Rarely acute hepatitis A can lead to fulminant hepatic failure. Inactivated HAV vaccine and immunoglobulin prophylaxis are safe in pregnancy<sup>[4]</sup>. Although vertical transmission has been reported,

**Table 2** Interpretation of hepatitis B blood tests

Test	HBsAg	Anti-HBs	Total Anti-HBc	Anti-HBc IgM	HBV DNA
Acute infection	+	-	+	+	+
Resolved infection	-	+	+	-	-
with natural immunity	-	+	-	-	-
Immunity through vaccination	-	+	-	-	-
Chronic infection	+	-	+	-	+/-
Different possibilities <sup>1</sup>	-	-	+	-	-

<sup>1</sup>Could represent resolving acute infection, resolved infection (most likely), chronic infection with low viral load or false positive. HBsAg: Hepatitis B surface antigen; Anti-HBs: Hepatitis B surface antibody; Total anti-HBc: Total hepatitis B core antibody; Anti-HBc IgM: Hepatitis B core antibody immunoglobulin M; HBV: Hepatitis B virus.

intrauterine transmission is rare<sup>[5-7]</sup>. Fecal-oral transmission during birth is possible. No cases of teratogenicity were reported, but maternal complications such as preterm labor were described. Susceptible woman should receive vaccination. Breast-feeding is not contraindicated in acute hepatitis A with following appropriate hygiene measures.

### Hepatitis B virus

Hepatitis B virus (HBV) is a DNA virus that is highly infectious and transmits through intravenous route, sexual contact, and vertically from the mother to her fetus. It can present both as an acute or chronic infection. Pregnancy does not affect the course of infection directly. Fortunately, since universal children vaccination for hepatitis B was implemented in 1992, the numbers of vertically transmitted chronic hepatitis B cases, and its complications such as hepatocellular carcinoma have dropped<sup>[8-10]</sup>. Prenatal screening for HBV is standard of care in many countries including the United States. Those susceptible should be vaccinated. Pregnant women exposed to HBV should receive HBV immunoglobulins (HBIG) within 72 h of exposure in addition to the vaccination series. Infants with infected mothers should receive both immunoglobulins and vaccination series at the time of delivery. While acute infection can present with a viral syndrome and jaundice such as that of acute hepatitis A infection, chronic infection is usually asymptomatic and diagnosis can be made relying on serum serology testing. A summary of the tests used in hepatitis B diagnosis and their interpretation is displayed in Table 2.

Treatment should follow guidelines published by medical societies such as the American Association for the Study of Liver Disease (AASLD)<sup>[11]</sup>, the European Association for the Study of the Liver<sup>[12]</sup>, or the Asian Pacific Association for the Study of the Liver<sup>[13]</sup>. In the United States, we recommend referring infected pregnant women to the state's perinatal hepatitis B prevention program<sup>[14]</sup>, that is CDC-funded (centers for disease control and prevention), and to liver specialists for optimizing counseling and treatment.

There are seven Food and Drug Administration (FDA)-approved medications for the treatment of hepatic

**Table 3 Food and Drug Administration approved medications for hepatitis B treatment**

Generic name	Trade name	Company	Approved for HBV treatment
Interferons			
Interferon $\alpha$ -2b, recombinant	Intron® A	Schering Corporation/ Merck and Co	1992
Perinterferon $\alpha$ -2a	Pegasys®	Genentech/Roche group	2005
Nucleosides/nucleotides			
Lamivudine <sup>1</sup>	EPIVIR-HBV®	GlaxoSmithKline	1998
Adefovir dipivoxil	HEPSERA™	Gilead Sciences	2002
Entecavir	BARACLUDE™	Bristol-Myers Squibb	2005
Telbivudine <sup>2</sup>	TYZEKA™	Novartis	2006
Tenofovir <sup>2</sup>	Viread	Gilead Sciences	2008

<sup>1</sup>Pregnancy risk category C, can be used in the third trimester; <sup>2</sup>Pregnancy risk category B. HBV: Hepatitis B virus.

tis B (Table 3) in non-pregnant patients. Interferon use is contraindicated in pregnancy. Tenofovir and Telbivudine belong to pregnancy risk category B; all others belong to category C. The choice to treat or not should be weighed in light of benefits versus risks for both the mother and her fetus. Those with higher viral load (serum HBV DNA  $> 10^8$  copies/mL) were at higher risk for vertical transmission in one study<sup>[15]</sup>. Wen *et al*<sup>[16]</sup> showed recently that the adjusted odds ratio of transmission for each log<sub>10</sub> copy/mL increase, is 3.49 ( $P = 0.001$ ), with predictive rates of infection at maternal viral load levels of 7, 8, and 9-log<sub>10</sub> copies/mL of 6.6% ( $P = 0.033$ ), 14.6% ( $P = 0.001$ ), and 27.7% ( $P < 0.001$ ), respectively. Therefore, it is reasonable to treat those women or women with previous infected children, especially towards the end of pregnancy (from week 28 and up), with risk category B drugs or Lamivudine (increases birth defects if used in 1<sup>st</sup> trimester)<sup>[17,18]</sup>. In a meta-analysis, significant drop in the risk of vertical transmission was found in those who succeeded to lower HBV DNA below  $10^6$  copies/mL<sup>[18]</sup>. Telbivudine was used safely and with good efficacy in reducing transmission (0% *vs* 8%;  $P = 0.002$ ) in a recent study<sup>[19]</sup>.

Although cesarean section is proposed as a measure to lower the risk of transmission, particularly in women with high viral loads towards term, there is a conflicting evidence regarding choosing cesarean section versus vaginal delivery to lower the risk of vertical transmission<sup>[20,21]</sup>. Breast-feeding should be encouraged for infants receiving HBIG and vaccination<sup>[22-25]</sup>. On the other hand, no adequate evidence of the safety of breast-feeding in mothers receiving antiviral therapy is available and women on antiviral therapy with lamivudine, telbivudine or tenofovir should be discouraged from breast-feeding<sup>[26-28]</sup>.

### Hepatitis C virus

With prevalence around 1.6%, chronic hepatitis C infection continues to present a big public health concern in the United States. The majority of those patients, left untreated, will progress to cirrhosis with expected peak in prevalence around the year 2030, with expected medical cost exceeding \$85 billion<sup>[29]</sup>. Generally, all high-risk patients should be screened for hepatitis C virus (HCV) following CDC and AASLD guidelines. Those include

children born to HCV infected mothers. While there is no approved medicine to treat chronic hepatitis C in pregnant women, those should be referred to liver experts for education regarding options of treatment after delivery and preventive measures to slow the progression of the disease. HCV antibodies ELISA testing is a sensitive test and carries high positive predictive value in high-risk patients. Diagnosis can be confirmed using HCV RNA polymerase chain reaction (PCR). There are several therapies for hepatitis C that are under investigation currently. Some of those could prove safe to use in pregnancy in the future. Pregnant women with hepatitis C should be educated about the mode of transmission and how to reduce the risk, smoking cessation, alcohol abstinence, and vaccination for hepatitis A and hepatitis B. They should also be screened for hepatitis B and human immunodeficiency virus (HIV) infection. Women undergoing treatment for hepatitis C, or those with partners undergoing treatment for hepatitis C, should avoid pregnancy by using at least 2 forms of barrier contraception, for the period of treatment and 6 mo after.

Infants of hepatitis C infected- mothers were at higher risk for low birth weight, being small for gestational age, or requiring intensive care upon birth in one report<sup>[30]</sup>. The risk of vertical transmission is approximately 4%. This risk increased up to 19.4% when co-infected with HIV<sup>[31-35]</sup>. High viral load also increase the risk for vertical transmission. HCV transmission could occur through viral transcytosis across trophoblast cells mediated by HCV receptors expressed on trophoblasts or through some form of injury that influences the placental barrier<sup>[36]</sup>. Although there were few reports of increased risk of transmission with premature rupture of membrane, more than 6 h before delivery, mode of delivery was not found to change the risk of hepatitis C transmission<sup>[31,37-39]</sup>. As the new era of direct antiviral agents is evolving, treating hepatitis C during pregnancy may become an option and thus the possibility of reducing the risk of transmission<sup>[40]</sup>.

Breast-feeding is considered safe when nipples are not cracked or bleeding according to CDC recommendations.

### Hepatitis D virus

Hepatitis D virus (HDV) is an RNA virus that requires

hepatitis B surface antigen for replication. Anti-HDV antibodies establish the diagnosis. Although vertical transmission is possible, hepatitis D is preventable by preventing HBV transmission<sup>[41]</sup>.

### **Hepatitis E virus**

Hepatitis E virus (HEV) is an RNA virus that is usually transmitted through fecal-oral means, although transmission via infected blood products and vertical transmission has been reported<sup>[42]</sup>. It is usually a self-limiting disease in immunocompetent patients. Hepatitis E can cause significant disease in patients with chronic liver disease and can present in a chronic form leading to fibrosis in immunocompromised individuals<sup>[43]</sup>. Pregnant women in highly endemic areas are particularly at risk with up to 60% developing fulminant hepatic failure with a maternal death rate of up to 31%<sup>[44,45]</sup>. A review from Bangladesh suggests it is responsible for 9.8% of pregnancy-related deaths<sup>[46]</sup>. On the other hand, the severity of the disease was not different between pregnant and non-pregnant women in non-endemic places such as the United States and Europe. A report suggested that such variance in severity between endemic and non-endemic areas might be related to different genotypes of HEV<sup>[47]</sup>. Other studies suggested that pregnancy per se is not a poor prognostic factor for those who developed acute liver failure<sup>[48]</sup>. To a lesser extent, hepatitis E is prevalent in some western countries, particularly genotype 3.

Vertical transmission was described up to 78.9% with infant mortality of 40%<sup>[42]</sup>. The level of viremia appears to be associated with the severity of the disease during pregnancy<sup>[49]</sup>. Despite such high mortality, current treatment remains supportive. Pregnant woman seeking travel to endemic areas should be counseled about the risk of hepatitis E, and be advised to avoid unpurified water, uncooked fruit, vegetables, and shellfish.

Hepatitis E vaccines have been developed and evaluated in trials but has not been approved for commercial use yet. Their utility is yet to be determined<sup>[50-54]</sup>.

### **Herpes simplex virus**

32 out of 137 cases of herpes simplex virus (HSV) hepatitis were pregnant women in one report, suggesting their susceptibility<sup>[55]</sup>. Although rare, HSV hepatitis carries a very high mortality (39%) if inappropriately treated<sup>[56]</sup>. Providers should have high index of suspicion in this patient group in the appropriate clinical setting; elevated liver transaminases usually 100 times upper level of normal with typically normal or mildly elevated bilirubin (anicteric hepatitis)<sup>[57-60]</sup>. Serology testing including anti-HSV IgM should be ordered. HSV PCR can be ordered as well to confirm diagnosis. Recent study has revealed that HSV DNA load correlated with liver transaminase levels and disease severity<sup>[61]</sup>. Although no strong evidence to support starting Acyclovir in patients with indeterminate acute liver failure, clinicians should consider empirical therapy with acyclovir when HSV hepatitis is

suspected<sup>[59]</sup>. Liver biopsy with appropriate immunohistochemistry staining can be useful, but usually is avoided because of its invasive nature, coagulopathy and because of the potential delay in results/treatment.

## **AUTOIMMUNE HEPATITIS AND PREGNANCY**

Autoimmune hepatitis is a disease characterized by elevated liver aminotransferases, hypergammaglobulinemia, and positive serum autoantibodies. Autoimmune hepatitis and pregnancy (AIH) is more common in females, especially those in childbearing ages. It can happen during pregnancy and may not follow consistent pattern. Normalization of liver aminotransferases has been described in patients with no treatment<sup>[62]</sup>. This normalization could be related to the immunotolerant state that predominates pregnancy. On the other hand, flare-ups have been reported during and after pregnancy<sup>[63]</sup>. Prematurity and fetal-loss were described in those patients<sup>[64]</sup>. A link was observed between antibodies to soluble liver antigen/liver-pancreas and ribonucleoprotein/Sjögren's syndrome A and adverse outcomes<sup>[65]</sup>. Inadequate disease control in the year prior to pregnancy and the absence of treatment during pregnancy were associated with unfavorable outcomes in a recent study<sup>[66]</sup>.

Although the patients should be counseled about possible adverse outcomes, pregnancy appears to be safe in well-controlled AIH women<sup>[67]</sup>. Special considerations should be given to the postpartum period as flare-ups may occur frequently, and treatment should be resumed preemptively two weeks before delivery and maintained thereafter<sup>[68]</sup>. Immunosuppressive therapy with steroids and agents such as azathioprine is the mainstay for treatment of AIH. Azathioprine use during pregnancy is generally safe (despite reports of birth defects in animal models)<sup>[64]</sup>.

## **PRIMARY BILIARY CIRRHOSIS/PRIMARY SCLEROSING CHOLANGITIS AND PREGNANCY**

There is limited data about pregnancy in patients with primary biliary cirrhosis. Reports have ranged from normal course of pregnancy and good fetal outcomes to poor prognosis for both mother and fetus<sup>[69,70]</sup>. Earlier diagnosis and the use of ursodeoxycholic acid (UDCA) in treatment, which has been used safely in pregnancy, have been linked to favorable outcomes<sup>[71]</sup>. Primary sclerosing cholangitis did not appear to reduce fertility and resulted in good outcomes, in one report. UDCA was successfully used to control pruritus in this cohort<sup>[72]</sup>.

## **WILSON'S DISEASE AND PREGNANCY**

Wilson's disease is an autosomal recessive disease with

**Table 4 Options for portal hypertension management in pregnancy**

Esophageal varices	Nonselective $\beta$ -blockers Endoscopic and ligation and/or sclerotherapy TIPS: Data on TIPS and pregnancy is limited
Ascites	Sodium (salt) restriction, diuretics
Hepatic encephalopathy	Lactulose, rifaximin

TIPS: Transjugular portosystemic shunt.

prevalence of 1:30000 to 1:50000<sup>[73]</sup>. It affects hepatic copper transport with inhibition of biliary excretion, resulting in excess circulating copper and deposition in organs such as the liver and the brain. Cases of reduced fertility and recurrent spontaneous abortions in untreated women were reported<sup>[74]</sup>. Chelation therapy using *D*-penicillamine or trientine, or the use of zinc to reduce intestinal absorption of copper, have been the mainstay therapy for Wilson's disease. Zinc has been used with minimal teratogenicity during pregnancy<sup>[75]</sup>. Although teratogenic effects of *D*-penicillamine in humans and animals, and teratogenic effects of trientine in animals were described<sup>[76,77]</sup>, therapy should not be discontinued as this can result in severe hemolysis, worsening of liver function and even death. Even though zinc dosages can be maintained during pregnancy, AASLD recommends lowering *D*-penicillamine and trientine to the minimum needed (usually 25%-50% of the pre-pregnancy dose)<sup>[78]</sup>, particularly towards term to aid in wound healing. Baseline dosages can be resumed postnatal. The mother should be counseled, and both the mother and her fetus should be monitored closely during pregnancy. Breast-feeding is discouraged as *D*-penicillamine can be harmful to the infant and safety has not been established with trientine and zinc.

## GALLSTONES AND PREGNANCY

Physiological changes during pregnancy particularly hormonal changes lead to decrease in contractility of the gallbladder and changes in bile content, with increase in cholesterol saturation, resulting in increase in lithogenicity of the bile<sup>[79]</sup>. Incidence of gallstones is up to 12% in pregnant women<sup>[80]</sup>. Those typically remain asymptomatic. The patient can present with biliary pain, gallstone pancreatitis, or less likely acute cholecystitis. Other manifestations such as choledocholithiasis and cholangitis can also happen. Management is mostly conservative with hydration and antibiotics if indicated. In more severe cases, cholecystectomy can be indicated. Endoscopic retrograde cholangiopancreatography (ERCP) can also be used with taking precautions to minimize radiation exposure of the fetus. In general, surgical procedures are the safest in the second trimester. ERCP was reported to be associated with higher risk for preterm pregnancy and low birth-weight when performed in the first trimester. Post-ERCP pancreatitis rate was higher in pregnancy than general population<sup>[81-85]</sup>.

## CIRRHOSIS/ PORTAL HYPERTENSION AND PREGNANCY

Pregnancy in cirrhotic women is rare, probably because of low prevalence of cirrhosis in reproductive age group (45 in 100000) and also due to amenorrhea and anovulation, likely related to metabolic and hormonal derangements<sup>[86]</sup>. The physiological increase in plasma volume during pregnancy can worsen portal hypertension, resulting in increase risk of variceal bleeding. Variceal bleeding can happen in up to 38% of cirrhotic pregnant women. This is even higher in those with known portal hypertension. Those with known varices have a 78% chance of bleeding<sup>[87]</sup>. AASLD recommends screening for esophageal varices by the second trimester, as the risk of bleeding appears to be highest at that time. Women with cirrhosis planning to become pregnant should be screened before conception by endoscopy and prophylaxis (with nonselective beta blockers) should be started as recommended by AASLD guidelines. Complications of portal hypertension in pregnancy can be as high as 50% resulting in high mortality rate of up to 18%, and higher risk for fetal loss<sup>[88]</sup>. Pregnancy should be avoided in women with previous history of variceal bleeding and liver insufficiency. Means such as early forceps delivery or vacuum extraction should be considered to prevent excessive straining during vaginal delivery. Management options of complications of portal hypertension are summarized in Table 4. All medications used during pregnancy should be checked as of which risk category they fall under according to the FDA classification before prescribing (Tables 5 and 6).

## HEPATOCELLULAR ADENOMA AND PREGNANCY

The incidence of hepatocellular adenoma has increased since the introduction of oral contraceptives. There is a link between pregnancy and liver adenomas secondary to higher levels of hormones<sup>[89]</sup>. Rupture of adenomas has resulted in maternal mortality of a 44% and fetal loss of 38% in one study<sup>[90]</sup>. Adenoma rupture risk increases towards the end of pregnancy<sup>[91]</sup>. Women with adenomas > 5 cm or those with previous complications with adenomas, should avoid subsequent pregnancies. Those pregnant with smaller adenomas should be monitored closely with serial ultrasound imaging. If the lesion is progressively enlarging, or 5 cm in size or bigger, surgical resection should be considered<sup>[90]</sup>. Radiofrequency ablation is another modality that can be used in the treatment of hepatic adenomas<sup>[91-93]</sup>. Close monitoring of the lesion should continue in the postpartum period as well.

## HEPATOCELLULAR CARCINOMA AND PREGNANCY

Although rare, hepatocellular carcinoma has been reported during pregnancy. Fibrolamellar variant of hepatocel-

**Table 5** The Food and Drug Administration pregnancy risk categories of medicines

Pregnancy category	Definition
A	Controlled studies show no risk
B	Animal studies show no risk, and there are no human controlled studies. Or animal studies may have revealed an adverse effect that was not reproduced in human controlled studies
C	No human studies and either animal studies show an adverse effect or there are no studies available. Use if the risk is justified
D	Positive evidence of risk in human studies, only if the potential benefits outweigh the risk
X	Contraindicated in pregnancy: Risk is confirmed in animal and human studies and outweighs any advantage

**Table 6** Food and Drug Administration pregnancy risk categories of some liver disease medications

Medicine	Pregnancy category	Medicine	Pregnancy category
Nadolol	C	Ribavirin	X
Propranolol	C	Telaprevir	B
Rifaximin	C	Boceprevir	B
Lactulose	B	Tenofovir	B
Furosemide	C	Entecavir	C
Spironolactone	C	Telbuvudine	B
Corticosteroids	B	Adefovir	C
Azathioprine	D	Lamivudine	C
Cyclosporin	C	Acyclovir	B
Mycophenolate mofetil	D	Ursodeoxycholic acid	B
Tacrolimus	C	Penicillamine	D
Sirolimus	C	Trientine	C
Antithymocyte globulin	C	Zinc sulfate	C
Pegylated interferon	C (contraindicated in pregnancy)	Interferon alpha 2b	C (contraindicated in pregnancy)

lular carcinoma (HCC) was also reported<sup>[94-96]</sup>. Pregnant women with HCC can have shorter median survival than those non-pregnant. Higher levels of estrogen and immune suppression during pregnancy can play a role with HCC progression<sup>[97]</sup>. Modalities such as surgical resection and radiofrequency ablation can be used in selected patients. Limited data are available about the management of hepatocellular carcinoma in pregnancy.

## HEPATIC VEIN THROMBOSIS/PORTAL VEIN THROMBOSIS AND PREGNANCY

Budd-Chiari syndrome (BCS) is rare in pregnancy but can have grave consequences for both the mother and her fetus. The physiological hypercoagulable state can contribute in BCS development in pregnancy. Other predisposing factors are factor V Leiden mutation and prothrombin gene mutations. BCS entails thrombosis of the hepatic vein resulting in passive congestion of the hepatic sinusoids leading to ischemia and portal hypertension. Low molecular weight heparin should be started if no contraindications. Extreme measures such as portacaval shunting and liver transplantation during pregnancy were reported<sup>[98,99]</sup>. Subsequent pregnancies are not absolutely contraindicated with appropriately treated disease. The mother should be counseled about the possible maternal and fetal unfavorable outcomes.

Portal vein thrombosis (PVT) is rare and can also occur during pregnancy. Local causes such as cirrhosis, intra-abdominal infections, or malignancies may predispose to PVT. Systemic disorders resulting in hypercoagulable state

such as factor V Leiden mutation, anti-phospholipid syndrome, or myeloproliferative disorders should be also excluded. In acute portal vein thrombosis, anti-coagulation should be used for 3 mo at the least. Patients with chronic portal vein thrombosis should be screened for gastroesophageal varices and should be treated accordingly<sup>[100]</sup>.

## CONCLUSION

Pregnant women can have a variety of liver diseases with different incidences. Clinicians should be aware of the clinical presentations and be able to manage those conditions with special attention to the peculiarities in relation to the mother and her infant. In this review we have summarized several of the liver diseases that can happen during pregnancy and offered an overview of their management.

### Abstract

Pregnancy is a special clinical state with several normal physiological changes that influence body organs including the liver. Liver disease can cause significant morbidity and mortality in both pregnant women and their infants. This review summarizes liver diseases that are unique to pregnancy. We discuss clinical conditions that are seen only in pregnant women and involve the liver; from Hyperemesis Gravidarum that happens in 1 out of 200 pregnancies and Intrahepatic Cholestasis of Pregnancy (0.5%-1.5% prevalence), to the more frequent condition of preeclampsia (10% prevalence) and its severe form; hemolysis, elevated liver enzymes, and a low platelet count syndrome (12% of pregnancies with preeclampsia), to the rare entity of Acute Fatty Liver of Pregnancy (incidence of 1 per 7270 to 13000 deliveries). Although pathogenesis behind the development of these ailments are not fully understood, theories have been proposed. Some propose the special physiological changes that accompany pregnancy as a precipitant. Others suggest a constellation of factors including both the mother and her fetus that come together to trigger those unique conditions. Reaching a

timely and accurate diagnosis of such conditions can be challenging. The timing of the condition in relation toward which trimester it starts at is a key. Accurate diagnosis can be made using specific clinical findings and blood tests. Some entities have well-defined criteria that help not only in making the diagnosis, but also in classifying the disease according to its severity. Management of these conditions range from simple medical remedies to measures such as immediate termination of the pregnancy. In specific conditions, it is prudent to have expert obstetric and medical specialists teaming up to help improve the outcomes.

### HYPEREMESIS GRAVIDARUM

Although nausea and vomiting of pregnancy affect up to 90% of pregnancies, hyperemesis gravidarum (HG) oc-

curs in approximately 1 out of every 200 pregnancies<sup>[1]</sup>. Women with HG present with severe and persistent vomiting in the first trimester that can cause dehydration, metabolic disturbances, and nutritional deficiencies. HG may result in weight loss and ketonuria. Risk factors for HG include multiple gestations, molar pregnancies, fetal anomalies such as hydrops fetalis and trisomy 21<sup>[2,3]</sup>. Not all women with HG develop liver disease. Half of the patients who require hospitalization for HG suffer from liver disease<sup>[4]</sup>. HG was the cause in up to 94% of pregnant women with elevated liver transaminases in their first trimester in one series<sup>[5]</sup>. Veenendaal *et al*<sup>[6]</sup> conducted a meta-analysis that showed women with HG are more likely to have low birthweight < 2500 kg (OR = 1.42; 95%CI: 1.27-1.58), small for gestational age (OR = 1.28; 95%CI: 1.02-1.60), and premature delivery (OR = 1.32; 95%CI: 1.04-1.68) than those with no HG. On the other hand, no correlations with Apgar scores, congenital anomalies or perinatal death were identified. Some of those poor outcomes were more likely in pregnant women with low gestational weight gain (< 7 kg)<sup>[7]</sup>.

### Pathogenesis

Despite several hypotheses, the pathogenesis of liver disease in HG is not well understood and likely multifactorial. Starvation injury was proposed as an etiology since 1968<sup>[8,9]</sup>. Over expression of cytokine-producing cells was implicated as a potential cause for pregnancy-related liver diseases such as preeclampsia and HG. Other hypotheses predicted damage to the liver resulting from impaired maternal or fetal mitochondrial fatty acid oxidation, implicating deficiency in long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) as a reason for accumulation of fatty acids in the placenta and eventually causing liver damage<sup>[10]</sup>. Other report linked fetal deficiency of hepatic carnitine palmitoyltransferase I, the enzyme responsible for transporting long chain fatty acids from the cytoplasm of cells across the outer mitochondrial membrane, to HG<sup>[11-16]</sup>.

### Clinical presentation

The clinical presentation of HG with liver disease can range from mild aminotransferase elevation to rarely severe elevation. No fulminant hepatic failure has been reported with HG<sup>[17,18]</sup>. Patients usually are acutely ill with signs of dehydration. Rarely, it can present with jaundice and electrolyte disturbances such as hypokalemia and hyponatremia as well as metabolic alkalosis and erythrocytosis. It seems that the severity of nausea and vomiting correlates well with the degree of liver enzymes elevation<sup>[4]</sup>. No specific abdominal ultrasound findings are associated with HG. Liver biopsy may show necrosis, steatosis or bile plugs<sup>[19,20]</sup>, and usually is not indicated.

### Management

Patients with HG usually require hospitalization for intravenous fluid replacement, anti-emetics, bowel rest, and possible parenteral nutrition.

### Prognosis

Hyperemesis gravidarum is usually a reversible condition with no permanent damage to the liver and almost never fatal.

## INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis of pregnancy (ICP) is a reversible condition of cholestasis that happens usually in the third trimester. Findings such as pruritus, high serum bile acids levels, and abnormal liver function tests usually resolve after delivery. ICP is more prevalent in Scandinavian and South American countries<sup>[21,22]</sup>. Prevalence in Europe, United States, Canada and Australia is 0.1% to 1.5%<sup>[23]</sup>. In a recent review, although no causality effect can be claimed, ICP was associated with an increase in the risk of developing hepatobiliary diseases later in life, such as hepatitis C, cirrhosis, and gallstones. Having underlying chronic liver disease (hepatitis C or chronic hepatitis) increased the odds of developing ICP<sup>[24]</sup>.

### Pathogenesis

Genetic predisposition and hormonal factors have been implicated in the pathogenesis of ICP. The familial tendency and the observation of clustering of ICP in families led to the belief that genetics play a role in its development. Although some studies revealed results connecting MDR3 (*ABCB4*) gene with ICP, several other studies failed to demonstrate such relation<sup>[25-29]</sup>. Other genes such as *ABCB11* and *ATP8B1* were examined but showed weaker linkage to ICP<sup>[30-32]</sup>. Explaining ICP on a molecular basis in relation to sex hormones has gained interest<sup>[33]</sup>. The facts that ICP happens late in pregnancy and has a higher incidence in multiple gestation pregnancies, and that it resolves after delivery when sex hormones levels fall, make a logical connection between sex hormones and ICP. The estrogen metabolite estradiol-17 $\beta$ -glucuronide and differences in progesterone metabolites between pregnant women with and without ICP were also implicated<sup>[34-38]</sup>.

### Clinical presentation

ICP usually commences in the third trimester although earlier start in the second trimester has been reported<sup>[39]</sup>. The most common symptom is pruritus. Severity of pruritus increases at night and can involve the palms and soles. Other symptoms include steatorrhea, malabsorption of fat-soluble vitamins, and weight loss. ICP seems also to increase the incidence of gallstones and cholecystitis<sup>[40]</sup>. ICP tends to return in subsequent pregnancies with variable severity<sup>[41]</sup>. Elevated fasting serum bile acids level (> 10  $\mu$ mol/L) confirms the diagnosis. Aminotransferases can be elevated as well up to 2-10 folds<sup>[42]</sup>. Alkaline phosphatase levels might not be helpful due to higher physiological levels in late pregnancy. Clinical jaundice is detected in 10%-15% of the cases only and bilirubin levels rarely exceed 100  $\mu$ mol/L<sup>[23,43]</sup>. As in all

cholestatic patients, women with ICP tend to have higher low-density lipoprotein cholesterol and triglycerides<sup>[44]</sup>. Liver biopsy can reveal bland cholestasis (intrahepatic cholestasis without parenchymal inflammation). Liver biopsy is usually not indicated.

### Management

Bile acids sequestrants such as cholestyramine, antihistamines and opioid antagonists have been used to alleviate the pruritus. Cholestyramine is an exchange resin that binds bile acids and other anions in the intestine and increases their fecal excretion. Cholestyramine does not improve biochemical parameters or fetal outcomes in ICP<sup>[45]</sup>. *S*-adenosyl-methionine has shown limited efficacy in ICP<sup>[46,47]</sup>. Ursodeoxycholic acid (UDCA) is the first line therapy for ICP. UDCA has shown significant decrease in serum bile acids, serum aspartate aminotransferase and alanine aminotransferase, serum bilirubin, and was effective for pruritus<sup>[48-50]</sup>. Weekly non-stress testing did not prove to make a difference in ICP-related fetal deaths<sup>[51]</sup>. Some studies suggested 40  $\mu\text{mol/L}$  as a cutoff level of bile acids, after that fetal complications may happen<sup>[52,53]</sup>. Others did not observe such correlation until bile acids are  $> 100 \mu\text{mol/L}$ <sup>[54]</sup>. No evidence is strong enough to recommend early delivery (at 37 wk of gestation) for mothers with high bile acids levels, although this strategy is still used in some practices<sup>[55]</sup>.

### Prognosis

Although ICP is a benign condition for the mother, poor fetal outcomes can occur. In some studies ICP resulted in premature births up to 60%. Other complications such as fetal distress and intrauterine fetal death were reported at 61% and 1.6% respectively<sup>[23,39,56]</sup>. The onset of pruritus and higher maternal fasting serum bile acids were associated with higher risk for premature delivery<sup>[57]</sup>.

## ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) is a rare but a serious condition that is unique to pregnancy and happens in the third trimester. AFLP can lead to significant maternal and fetal morbidity and mortality<sup>[20,58]</sup>. Although rare, incidence of 1 per 7270 to 13000 deliveries, outcomes can be grave with acute liver failure and death<sup>[20,59-61]</sup>.

### Pathogenesis

Until recently the pathogenesis of AFLP was unknown and still has not been fully elucidated. However, molecular advances over the past decade suggest that AFLP may result from mitochondrial dysfunction. Defects in fetal mitochondrial fatty acid  $\beta$ -oxidation have been linked to development of maternal AFLP, particularly fetal defects in LCHAD, which is part of the mitochondrial trifunctional protein (MTP) complex<sup>[14,62-66]</sup>. In a retrospective study, Ibdah *et al.*<sup>[14]</sup> examined the association between MTP defects in children and liver disease in their mothers during pregnancy in 24 families with documented pe-

diatric defects in MTP. Fifteen of 24 women (62%) were diagnosed to have had maternal liver disease consistent with AFLP, although in two cases a clear distinction between AFLP and hemolysis, elevated liver enzymes, and a low platelet count (HELLP) syndrome was not possible. Nine of the 24 women had normal pregnancies. All 15 pregnancies with maternal liver disease were associated with fetal LCHAD deficiency. Molecular analysis revealed a common LCHAD mutation, G1528C in the offspring of women who developed AFLP. The results from this study show that when carrying a fetus that is LCHAD deficient, the mother has a high risk of developing AFLP. In a subsequent study, Ibdah *et al.* evaluated fetal genotypes and pregnancy outcomes in 83 pregnancies in 35 families with documented pediatric MTP defects<sup>[66]</sup>. This study provided further evidence that carrying a fetus with LCHAD deficiency is associated with a high risk for developing AFLP. With the growing evidence suggesting that carrying an LCHAD-deficient fetus is associated with AFLP, it was recommended that neonates born to pregnancies complicated by AFLP be tested for the common G1528C mutation and that this testing when done early after birth can be lifesaving as it may identify LCHAD-deficient children before they manifest the disease allowing early dietary intervention by institution of a diet low in fat, high in carbohydrate, and by substitution of the long chain fatty acids with medium chain fatty acids (for complete review on the association between AFLP and pediatric LCHAD deficiency<sup>[61]</sup>).

The precise mechanism by which an LCHAD deficient fetus causes AFLP in a heterozygote mother is still unclear. However, several factors appear to contribute to this fetal-maternal interaction. First, the heterozygosity of the mother for an MTP defect reduces her capacity to oxidize long chain fatty acids. Second, third trimester is accompanied by changes in metabolism, an increased lipolysis, and a reduction in mitochondrial fatty acid oxidation, all increase the susceptibility of the mother who carries a fetus with LCHAD deficiency. Thus it has been speculated that potentially hepatotoxic long-chain 3-hydroxyacyl fatty acid metabolites, produced by the affected fetus or placenta, accumulate in the maternal circulation<sup>[61]</sup>.

### Clinical presentation

Although there were few reports of AFLP starting in the second trimester, it usually presents in the third trimester between the 30<sup>th</sup> and 38<sup>th</sup> week of gestation<sup>[67-70]</sup>. It is more frequent in primiparous women and can return in subsequent pregnancies<sup>[12,62,71]</sup>. Nonspecific symptoms such as nausea, vomiting, headache, and fatigue can be the initial presentation. Right upper quadrant pain or epigastric pain can occur. Jaundice common and early jaundice may indicate severe disease<sup>[72]</sup>. Other features such as hypoglycemia, renal failure, coagulopathy, ascites, and encephalopathy were reported frequently. AFLP can result in maternal and fetal demise<sup>[73]</sup>. Although hypertension can be present, severe hypertension is likely

**Table 1 Proposed (Swansea) diagnostic criteria for acute fatty liver of pregnancy**

Vomiting	Abdominal pain
Polydipsia/polyuria	Encephalopathy
Elevated bilirubin	Hypoglycaemia
Elevated uric acid	Leucocytosis
Ascites or bright liver on US	Elevated transaminases
Elevated ammonia	Renal impairment
Coagulopathy	Microvesicular steatosis on liver biopsy

To meet the criteria the patient should have 6 or more of these clinical findings. Source: Ref. [80], with permission; US: Ultrasound scan.

secondary to the reduction in peripheral vascular resistance associated with liver failure. AFLP is a medical and obstetric emergency and diagnosis relying on clinical and laboratory findings should be prompt. Liver biopsy can be helpful in early and mild cases of AFLP especially if diagnosis is not clear<sup>[74]</sup>. Liver biopsy is not necessarily needed and should be avoided in more severe cases where the risk of bleeding is high and prompt therapeutic intervention is needed. Although elevated aminotransferases is expected, the severity of liver dysfunction is not always reflected by the degree of elevation. Alkaline phosphatase is usually elevated. Other findings such as leukocytosis, thrombocytopenia, disseminated intravascular coagulopathy (DIC), abnormal prothrombin time, partial thromboplastin time, and normal fibrinogen can occur<sup>[74-76]</sup>. Ketonuria and proteinuria can be present. Elevated blood urea nitrogen and creatinine indicate renal insufficiency. Low serum albumin and hypoglycemia can occur. Uric acid and ammonia levels can be increased. Hyperuricemia can be an early indicator and develop before hyperbilirubinemia<sup>[77,78]</sup>. In comparison with diffuse or microvesicular steatosis, Swansea criteria had a sensitivity of 100% (95%CI: 77-100) and specificity of 57% (95%CI: 20-88), with positive and negative predictive values of 85% and 100% in one report (Table 1)<sup>[79-81]</sup>. Ch'ng *et al*<sup>[80]</sup> proposed a set of clinical findings, known as Swansea criteria, to help reach the diagnosis of AFLP. Those diagnostic criteria have not been validated in different populations. Liver biopsy usually displays microvesicular steatosis<sup>[82]</sup>. Electron microscopy can show mitochondrial disruption. Imaging studies can be useful to exclude other pathologies; but have limited utility in the diagnosis of AFLP.

### Management

Stabilization of the mother and early recognition and delivery are the keys for successful management. Close monitoring and management of associated complications is necessary to improve outcomes. Plasmapheresis was used in few series in severe cases with reported success<sup>[83,84]</sup>.

### Prognosis

AFLP is severe disease with high maternal (18%) and fetal (23%) mortality. Prenatal diagnosis can provide

**Table 2 Hemolysis, elevated liver function tests, and low platelet counts syndrome diagnostic criteria**

HELLP class	Tennessee classification	Mississippi classification
1	Platelets $\leq 100 \times 10^9/L$ AST $\geq 70$ IU/L LDH $\geq 600$ IU/L	Platelets $\leq 50 \times 10^9/L$ AST or ALT $\geq 70$ IU/L LDH $\geq 600$ IU/L
2		Platelets $\leq 100 \times 10^9/L$ , $\geq 50 \times 10^9/L$ AST or ALT $\geq 70$ IU/L LDH $\geq 600$ IU/L
3		Platelets $\leq 150 \times 10^9/L$ , $\geq 100 \times 10^9/L$ AST or ALT $\geq 40$ IU/L LDH $\geq 600$ IU/L

AST: Aspartate aminotransferase; Source: Haram *et al.* BMC Pregnancy and Childbirth 2009 9:8 doi:10.1186/1471-2393-9-8; ALT: Alanine aminotransferase; HELLP: Hemolysis, elevated liver function tests, and low platelet counts; LDH: Lactate dehydrogenase.

benefit for both the mother and her fetus in subsequent pregnancies.

## PREECLAMPSIA/ECLAMPSIA AND HELLP SYNDROME

Preeclampsia is a syndrome that is unique to pregnancy. Manifestations include hypertension and proteinuria, and can result in fetal growth retardation. By far, preeclampsia is the most common serious medical disorder in pregnancy with prevalence up to 10%. It is associated with up to 20% of maternal mortality in developed countries<sup>[85,86]</sup>. Organ involvement such as liver, brain and kidneys signifies severe disease. Elevated aminotransferases occurs up to 10% of severe preeclampsia cases<sup>[86,87]</sup>. Although preeclampsia can start as early as the second trimester, liver involvement is mainly seen in the third trimester. Severe preeclampsia can be life threatening to the mother and can result in fetal morbidity and mortality. Eclampsia usually refers to preeclampsia with seizures. HELLP syndrome is a variant of severe preeclampsia that happens in up to 12% of patients with preeclampsia, and entails constellation of findings including hemolysis, elevated liver aminotransferases of and low platelet counts. Table 2 shows the diagnostic criteria of HELLP syndrome.

### Pathogenesis

In reviewing liver biopsies and autopsies of cases with preeclampsia, eclampsia and unclassified toxemia, from the Armed Forces Institute of Pathology between 1920 and 1984, Rolfes *et al*<sup>[88]</sup> reported that despite that large cerebral and midbrain hemorrhages, extensive thrombosis and infarction as well as cerebral edema with herniation were the major causes of deaths, liver disease contributed to 17 deaths out of the 102 cases reviewed. Extensive periportal lesions producing widespread parenchymal hemorrhage and necrosis were described. Large areas of infarction, wide bands of fibrin replacing liver cells, extravasation of red blood cells, and capillary

**Table 3** Preeclampsia associated liver diseases

	Severe preeclampsia and eclampsia	HELLP syndrome	Acute fatty liver of pregnancy
Time	After gestational week 22	Late second trimester to early postpartum	Third trimester
Prevalence	Increases in multiple gestation (5%-7%)	0.10%	Increases in male fetus, multiple gestations, primiparous women (0.01%)
Findings	High blood pressure; proteinuria; edema; seizure; renal failure; pulmonary edema	Abdominal pain, nausea/vomiting, overlap with findings in preeclampsia	Abdominal pain, nausea/ vomiting, jaundice, hypoglycemia and hepatic failure
Tests	Platelets > 70000; urine protein > 5 g/24 h; abnormal liver enzymes (10%)	Low platelets; hemolysis; elevated liver enzymes; prothrombin time may remain normal; normal fibrinogen	Platelets < 100000; AST and ALT 300-1000 U/L; low antithrombin III; high prothrombin time; low fibrinogen; high bilirubin; DIC
Management	Blood pressure control; beta-blockers, methyldopa, magnesium sulfate, early delivery	Prompt delivery 5% maternal death 1% hepatic rupture	Prompt delivery; liver transplant ≤ 10% maternal death
Outcome	1% maternal death	1%-30% fetal death	Up to 45% fetal death

HELLP: Hemolysis, elevated liver function tests, and low platelet counts; DIC: disseminated intravascular coagulation; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

**Table 4** Complications of preeclampsia/hemolysis, elevated liver function tests, and low platelet counts syndrome

Maternal complications	Neonatal complications	Labor complications
Eclampsia	Fetal death	Preterm labor
HELLP syndrome	Prematurity	
Hepatic subcapsular hematoma, infarction or rupture	IUGR	
Acute renal failure	Respiratory distress syndrome	
Stroke, cerebral hemorrhage, edema and herniation	Intraventricular hemorrhage	
Pulmonary edema and acute respiratory distress syndrome	Sepsis	
Laryngeal edema		
Retinal detachment		

HELLP: Hemolysis, elevated liver function tests, and low platelet counts; IUGR: Intrauterine growth retardation.

thrombi were also seen. Histological changes of the liver in HELLP syndrome include periportal or focal parenchymal necrosis with hyaline deposits of fibrin-like material in the sinusoids<sup>[89]</sup>. Other molecular mechanisms such as vascular remodeling and placentation, immunological factors, and fatty acid oxidation defects were proposed as potential factors in the development of this spectrum of diseases<sup>[12,71,90-92]</sup>.

### Clinical presentation

Preeclampsia, HELLP syndrome, and acute fatty liver of pregnancy share similar presentations and differentiating between the three entities can be difficult. All present late in pregnancy and can have similar clinical features. Clinical presentation followed by typical laboratory findings can help in reaching the diagnosis. Although it may be reasonable to do an ultrasound of the liver for pregnant women with abnormal liver enzymes, imaging studies such as computed tomography and magnetic resonance imaging are rarely useful in making the diagnosis. Such

studies can have a role in diagnosing complications such as liver infarcts, hematomas, and liver rupture<sup>[93]</sup>. Table 3 presents a comparison between the three preeclampsia-associated liver diseases in pregnancy.

### Management

Successful management strategies rely on early diagnosis and prompt intervention. Women with severe preeclampsia or HELLP syndrome should be hospitalized and closely monitored in labor and delivery units, and placed on bed rest with good blood pressure control (systolic blood pressure < 155 and diastolic blood pressure < 100)<sup>[94]</sup>. The use of intravenous magnesium sulfate to prevent seizures is recommended. Close monitoring of mental status and appropriate use of imaging studies as indicated can help in identifying complications early. Prompt delivery can be the only effective therapy. Timing of delivery should be based on gestational age (reflecting the degree of fetal maturity) and the severity of the disease (maternal morbidity and mortality). Prompt delivery is indicated if the syndrome develops after 34 wk of gestation or earlier if complications occur, such as multi-organ dysfunction, liver infarction or hemorrhage, DIC, renal failure, suspected abruption of placenta, or fetal compromise<sup>[95-97]</sup>. Fetal lung maturity is not achieved before 34 wk of gestation. Therefore making a determination about terminating the pregnancy before 34 wk of gestation can be difficult<sup>[96,98-102]</sup>. Although a favorable effect on the platelet count and the aminotransferases levels has been observed, it's not clear if corticosteroids alter the course of the disease, and therefore their use remains controversial<sup>[101,103,104]</sup>. Betamethasone 12 mg intramuscularly every 24 h twice or four doses of intramuscular dexamethasone 6 mg every 12 h is recommended for enhancing fetal maturity<sup>[101]</sup>. Fetal and maternal complications are listed in Table 4.

### Prognosis

Although not very common, preeclampsia and HELLP syndrome remain a significant cause of morbidity and mortality for both pregnant women and their fetuses. With a maternal mortality of 1% in severe preeclampsia

sia, up to 5% in HELLP syndrome, and up to 30% fetal death rate, early diagnosis and prompt delivery remain the only effective treatment strategy.

### Abstract

Pregnancy in patients with advanced liver disease is uncommon as most women with decompensated cirrhosis are infertile and have high rate of anovulation. However, if gestation ensued; it is very challenging and carries high risks for both the mother and the baby such as higher rates of spontaneous abortion, prematurity, pulmonary hypertension, splenic artery aneurysm rupture, postpartum hemorrhage, and a potential for life-threatening variceal hemorrhage and hepatic decompensation. In contrary, with orthotopic liver transplantation, menstruation resumes and most women of childbearing age are able to conceive, give birth and lead a better quality of life. Women with orthotopic liver transplantation seeking pregnancy should be managed carefully by a team consultation with transplant hepatologist, maternal-fetal medicine specialist and other specialists. Pregnant liver transplant recipients need to stay on immunosuppression medication to prevent allograft rejection. Furthermore, these medications need to be monitored carefully and continued throughout pregnancy to avoid potential adverse effects to mother and baby. Thus delaying pregnancy 1 to 2 years after

transplantation minimizes fetal exposure to high doses of immunosuppressants. Pregnant female liver transplant patients have a high rate of cesarean delivery likely due to the high rate of prematurity in this population. Recent reports suggest that with close monitoring and multidisciplinary team approach, most female liver transplant recipient of childbearing age will lead a successful pregnancy.

**Core tip:** This review provides an up-to-date summary of literature in the field of liver transplantation and pregnancy. It outlines the outcomes of pregnancy prior to and after orthotopic liver transplantation. Furthermore, it provides input on preconception counseling for mothers contemplating pregnancy after liver transplantation, risks of immunosuppression, and safety of breastfeeding.

Hammoud GM, Almashhrawi AA, Ahmed KT, Rahman R, Ibdah JA. Liver diseases in pregnancy: Liver transplantation in pregnancy. *World J Gastroenterol* 2013; 19(43): 7647-7651 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7647.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7647>

### INTRODUCTION

Liver transplantation is considered to be the treatment of choice for patients with advanced liver disease. Since the first pregnancy in a transplant recipient in 1958, pregnancy in recipients of solid organ transplants has become increasingly common. In the setting of decompensated

cirrhosis, pregnancy is very uncommon as most women are infertile and have anovulation and secondary amenorrhea. However, once liver transplantation is performed, liver transplant recipients possess an improved quality of life, their hormonal imbalance return to a normal state, ovulation resumes and pregnancy may ensue if contemplated. The first successful pregnancy in a liver graft recipient was reported in 1978<sup>[1]</sup>. Given the improving success of liver transplantation over the past two decades and decreasing levels of immunosuppression, most solid organ transplant recipients lead happy and healthy lives with an average 1-year survival rate of greater than 85% for most indications.

## **PATHOGENESIS**

Women with decompensated liver disease commonly have menstrual dysfunction. In fact, menstrual abnormalities may be the first signs of chronic liver disease in females with chronic liver disease. In cirrhotic state, hypothalamic-pituitary dysfunction is associated with an inadequate response to the gonadotropin-releasing hormone agonists and clomiphene citrates as well as diminished gonadotrophin release relative to the reduced levels of circulating sex steroids<sup>[2]</sup>. Furthermore, serum levels of estradiol and testosterone are increased in patients with portosystemic shunts. Thus pregnancy in decompensated cirrhosis is very uncommon. Obstetrical syndromes associated with transplantation may depend on several factors such as defective deep placentation, underlying maternal diseases, uterine vascular bed and effect of immunosuppressive therapy on uteroplacental arteries<sup>[3]</sup>. Reports from the the National Transplantation Pregnancy Registry (NTPR) revealed that immunosuppressive medication is associated with an increased risk of miscarriage, prematurity, intrauterine growth retardation, and low birth weight<sup>[4]</sup>.

## **MATERNAL AND FETAL OUTCOMES IN PREGNANT FEMALE PATIENTS WITH ADVANCED LIVER DISEASE**

Pregnancy is associated with increase in portal pressure. During pregnancy, a hypervolemic state develops leading to an increase in portal flow and elevation of portal venous pressure transmitted to the collateral veins with increased risk of esophageal variceal bleeding<sup>[5,6]</sup>. The outcome of pregnancy in 339 patients with cirrhosis was reported in a large population-based study from 1993 to 2005<sup>[7]</sup>. Maternal and fetal mortality were much higher than the general population (1.8% *vs* 0%,  $P < 0.0001$ ; 5.2% *vs* 2.1%,  $P < 0.0001$ ) respectively. The rate of hepatic decompensation occurred in 15% and patients with cirrhosis were more likely to deliver by cesarean delivery (42% *vs* 28%; adjusted OR = 1.41; 95%CI: 1.06-1.88). Similarly, the spontaneous abortion rate in cirrhotic patients is approximately 15%-20%.

## **MATERNAL AND FETAL OUTCOMES IN PREGNANT FEMALE LIVER TRANSPLANT RECIPIENTS**

Most outcome data on pregnancy during and after liver transplantation are obtained from the NTPR. The NTPR was established in 1991 at Thomas Jefferson University in Philadelphia, Pennsylvania, to study the outcomes of pregnancies in transplant recipients in North America, including female transplant recipients and those fathered by male transplant recipients. Since then many other reports and case series have been reported and published. A retrospective study from a single institution evaluated a total of 115 gestations in 37 women with liver transplant (LT) and in 34 women with kidney transplant. The authors found 81 (70%) of all gestations were successful, 15 (13%) were terminated, and there were 19 (17%) spontaneous abortions and 2 (2%) intrauterine deaths<sup>[8]</sup>. Deshpande *et al*<sup>[9]</sup> reported in a systematic review and meta-analysis outcome of 450 pregnancies in 306 LT recipients in comparisons with the general United States population as well as kidney transplant recipients. The post-LT live birth rate was higher than the live birth rate for the US general population (76.9% *vs* 66.7%, 95%CI: 72.7%-80.7%). The post-LT miscarriage rate was lower than the miscarriage rate for the general population (15.6% *vs* 17.1%, 95%CI: 12.3%-19.2%). Moreover, these rates were similar to the post-kidney transplant rates. The rates of pre-eclampsia, cesarean section delivery and preterm delivery were higher than the rates for the US general population (21.9% *vs* 3.8%, 95%CI: 17.7%-26.4%; 44.6% *vs* 31.9%, 95%CI: 39.2%-50.1%; and 39.4% *vs* 12.5%, 95%CI: 33.1%-46.0%) respectively. Moreover, these rates were lower than those for post-kidney transplant recipients. The overall mean birth weight for newborns of LT recipients was less than the birth weight for the United States general population (2866 g *vs* 3298 g). More notably, the authors found that the mean gestational age and mean birth weight seems significantly greater for liver transplant versus kidney transplant recipients and the risk of hypertension during pregnancy seems also lower for liver transplant than kidney transplant recipients<sup>[9]</sup>. In another recently published study by Alvaro *et al*<sup>[10]</sup> from a single center in Spain, the authors analyzed the impact of pregnancy among 1341 liver transplant recipients from April 1986 to April 2011. Thirty pregnancies commenced among 18 liver transplant recipients during the follow-up. Sixteen patients (88%) became pregnant beyond a year after orthotopic liver transplantation. The post-LT live birth was 66.6% and the post-LT abortions were 26.6%. There were no maternal deaths encountered during pregnancy or the postpartum period. However, fetal deaths were observed in 6% of LT recipients. The most common maternal complications during pregnancy were preeclampsia (15%), viral reactivation (15%), acute rejection episodes (10%), infections (10%), and high blood pressure (5%)<sup>[10]</sup>. Table 1 shows a summary of maternal and fetal outcomes in female liver transplant recipients from selected reports and studies<sup>[11]</sup>.

Sirolimus	C

## PRECONCEPTION COUNSELING

Pregnancy after liver transplant should be considered as a high-risk pregnancy and should be monitored closely by a team of a transplant hepatologist and experts in obstetrics and fetal medicine. Female liver transplant recipients who are planning of becoming pregnant should be counseled on optimal timing of pregnancy, mode of delivery and risks associated with immunosuppressive therapy. Furthermore, they should also be counseled on methods of contraception if pregnancy is not contemplated. Immunosuppressive agents are at their nadir one-year post liver transplantation and thus risk of allograft rejection is low. Furthermore, renal and liver functions tend to be stabilized during that period and thus it is ideal to delay pregnancy till patient is on a maintenance immunosuppression 1 to 2 years after transplantation to minimize fetal exposure to high doses of immunosuppressants<sup>[14,20]</sup>.

As per mode of delivery, vaginal delivery appears to be safe. However, high rates of cesarean section have been reported in female liver transplant patients (45.8%<sup>[12]</sup>, 71%<sup>[21]</sup>, 35%<sup>[22]</sup>, 38%<sup>[18]</sup> and 44.6%<sup>[9]</sup>) signifying the high rates of prematurity in this population. It is not known whether a particular immunosuppressive therapy is associated with increased rate of cesarean section. If pregnancy is not contemplated in young females of childbearing age, contraceptive method is advised particularly in the first few months post liver transplantation. Barrier methods possess low risk of systemic side effects. Intrauterine devices are generally discouraged due to their

potential infection complications. Furthermore, oral contraceptives did not appear to impair liver function or glucose metabolism after its introduction within 6 mo to 7 years post transplantation<sup>[23]</sup>.

## IMMUNOSUPPRESSION IN LIVER TRANSPLANT PREGNANT RECIPIENTS

There is no consensus on the optimal maintenance regimen for transplant recipients. The use of immunosuppressive therapy after liver transplantation is unavoidable. Therefore, women planning to conceive after transplantation should be counseled about the risks such therapy may pose on them and their fetuses. All immunosuppressive medication cross the placenta and enter fetal circulation and could potentially have deleterious effects in utero. Despite the fact that immunosuppressive agents such as Azathioprine, Cyclosporine, and Mycophenolic acid, were teratogenic in animals, the risk of birth defects was not statistically different between those who received immunosuppressive medications and those who did not. Birth defects have been reported with Calcineurin inhibitors<sup>[8,12,19]</sup>. Renal dysfunction and rates of pre-eclampsia appears higher with cyclosporine therapy<sup>[12,24]</sup>. No matter what immunosuppressive therapy is chosen based on maternal allograft function and laboratory assay, patients treated with either calcineurin inhibitors cyclosporine or tacrolimus should have serial blood tests in pregnancy to follow medication levels and to assess hepatic and renal function while avoiding unnecessary toxicity. Table 2 shows the food and drug administration classification of risk of medication and their categories in pregnancy<sup>[25]</sup>.

## BREASTFEEDING IN FEMALE LIVER TRANSPLANT RECIPIENTS ON IMMUNOSUPPRESSIVE THERAPY

The American academy of pediatrics advises that breast-

feeding mothers can use prednisone and other glucocorticoids safely. Infant exposure to tacrolimus in milk is very low and that maternal tacrolimus therapy may be compatible with breastfeeding. Data collected from the NTPR indicated no adverse outcomes in infants who were breastfed during maternal cyclosporine use. There is insufficient evidence in the literature to suggest that women taking azathioprine should refrain from breastfeeding. Nevertheless, mothers may be discouraged to breast feed in the first few months post transplantation where immunosuppressive therapy is at high serum level.

## CONCLUSION

Pregnancy after liver transplantation, although considered a high risk pregnancy, has an acceptable outcome for both mother and baby. With the return of fertility following transplantation, accurate family planning advice is essential. To date there is no evidence of specific structural malformations among children born to female liver transplant recipients, but there appears to be increased risk of prematurity and low birth weight after solid organ transplantation. Multidisciplinary team approach is of utmost importance to ensure smooth pregnancy. The NTPR data and others have revolutionized our understanding of the outcomes of pregnancy in this high risk population. We encourage physicians in the field to continue to report their outcome to the transplant registry.

### Abstract

Exclusive enteral nutrition (EEN) is well-established as a first line therapy instead of corticosteroid (CS) therapy to treat active Crohn's disease (CD) in children. It also has been shown to have benefits over and above induction of disease remission in paediatric populations. However, other than in Japanese populations, this intervention is not routinely utilised in adults. To investigate potential reasons for variation in response between adult studies of EEN and CS therapy. The Ovid database was searched over a 6-mo period. Articles directly comparing EEN and CS therapy in adults were included. Eleven articles were identified. EEN therapy remission rates varied considerably. Poor compliance with EEN therapy due to unpalatable formula was an issue in half of the studies. Remission rates of studies that only included patients with previously untreated/new CD were higher than studies including patients with both existing and new disease. There was limited evidence to determine if disease location, duration of disease or age of diagnosis affected EEN therapy outcomes. There is some evidence to support the use of EEN as a treatment option for a select group of adults, namely those

motivated to adhere to an EEN regimen and possibly those newly diagnosed with CD. In addition, the use of more palatable formulas could improve treatment compliance.

**Key words:** Exclusive enteral nutrition; Crohn's disease; Adults

**Core tip:** Exclusive enteral nutrition (EEN) is an established treatment for children with active Crohn's disease (CD). At present, this therapy is used sparingly in adult patients outside of Japan. In reviewing the published literature regarding the use of EEN in adult patients, this article highlights evidence supporting the use of EEN as a treatment option for selected patients: namely those motivated to adhere to an EEN regimen and those newly diagnosed with CD. The role of EEN in adult patients with CD should now be re-examined, with particular regard to treatment protocols and the use of more palatable polymeric formulae that may enhance compliance.

### INTRODUCTION

Crohn's disease (CD) is an incurable inflammatory bowel disease (IBD) characterised by inflammation of the gastrointestinal tract, which leads to chronic symptoms such as diarrhoea, abdominal pain and rectal bleeding<sup>[1]</sup>. The peak age of diagnosis is between 15 and 30 years of age,

leading to many years of disease and associated morbidity. Standard first line treatment in adults newly diagnosed with CD is corticosteroid (CS) therapy, which is effective at inducing remission or response in approximately 85% of patients<sup>[2]</sup>. However, CS therapy has many well documented acute side-effects: furthermore there are numerous long term adverse effects due to repeated or continual use of CS<sup>[3]</sup>. Also, CS resistance can occur in 8%-22% of patients and CS dependency occurs in 15%-36% of patients<sup>[4]</sup>. Alternative therapies that can effectively induce and maintain disease remission without short and long term side effects are desirable.

Exclusive enteral nutrition (EEN) is the provision of 100% of a person's nutritional requirements from a liquid nutrition formula either orally or *via* a feeding tube. EEN is usually provided for 6-8 wk and then usual diet is gradually reintroduced<sup>[5]</sup>. In children with CD, EEN has been shown to be an effective and feasible alternative to CS<sup>[6]</sup>. In addition to avoiding the adverse effects of CS exposure, EEN provides additional benefits over and above those provided by CS. EEN therapy is associated with higher rates of mucosal healing<sup>[7]</sup>, altered intestinal flora<sup>[8]</sup>, greater weight gain<sup>[9]</sup>, improved vitamin D status<sup>[10]</sup>, enhanced bone turnover<sup>[11]</sup>, an early rise in Insulin-like growth factor 1<sup>[12]</sup>, and better quality of life after treatment<sup>[13]</sup>. There are few long term follow up studies post EEN, but those that have been conducted in children indicate that EEN may improve time to relapse<sup>[14]</sup>. The administration of supplementary enteral nutrition (SEN) once disease remission is achieved has been shown to be beneficial in maintaining remission compared with a free diet in Japanese adults<sup>[15]</sup> and children<sup>[16]</sup>.

However, in adult CD populations, EEN is generally not seen as a first line therapy for newly diagnosed or those with a flare of pre-existing CD. European<sup>[2]</sup> and North American<sup>[17]</sup> clinical guidelines only recommend EEN if a patient declines drug therapy or as an adjunctive therapy to support nutrition, rather than as a primary therapy. These recommendations are primarily based on the results of a Cochrane systematic review of six randomised controlled trials including 192 patients treated with EEN and 160 patients treated with CS<sup>[18]</sup>. The review found a pooled OR of 0.33 (95%CI: 0.21-0.53) in favour of CS and concluded that CS were superior to EEN in the induction of remission of disease. In contrast to these guidelines, recent Japanese experience demonstrates efficacy in that setting<sup>[15]</sup>.

It is not clear why the benefits of EEN therapy seen in paediatric populations are not achieved in adults. We aimed to review the published literature reporting the use of EEN as a primary therapy for active CD in adults and examine potential reasons for this apparent discrepancy.

## SEARCH

The Ovid database was searched from September 2012 to March 2013 for articles published between 1946 and now. Key search terms were: "CD", "Crohn disease",

"EEN" and "enteral nutrition". Abstracts were scanned and articles in English that compared enteral nutrition with CS treatment in adults were considered relevant. Studies were excluded if enteral nutrition was not the sole source of nutrition, enteral nutrition was provided as well as other medication (for example, antibiotics), the study included children, or the study did not compare CS and EEN. A manual search was also completed of reference lists of articles retrieved, relevant review articles and meta-analyses on the topic.

## RESEARCH

### Study characteristics

Eleven studies published between 1984 and 2002 were identified that compared EEN with CS treatment in adults (Table 1). Two were abstracts<sup>[19,20]</sup> and the rest were full articles. The studies were conducted in Europe, North America and Asia: three in England<sup>[19,21,22]</sup>, one in Spain<sup>[23]</sup>, one in Greece<sup>[20]</sup>, one in Italy<sup>[24]</sup>, one in the United States<sup>[25]</sup>, one in Japan<sup>[26]</sup> and three<sup>[27-29]</sup> were multi-centre European trials. All but two studies enrolled a mix of patients with newly diagnosed CD (naïve to prior treatment) and existing CD. All but one study compared one enteral nutrition formula with CS therapy.

The studies utilised a range of nutritional products, in varying regimens, as summarised in Table 2. Eight of the studies used elemental formula and three studies used polymeric formula. Most formulas were a 1 kcal/mL concentration apart from one which used a 1.5 kcal/mL formula. Duration of EEN treatment ranged from 2-6 weeks but most studies used EEN therapy for four weeks. Mode of delivery of the EN formula was either orally, or *via* a nasogastric tube (NGT) if not tolerated orally, or continuous feeding *via* an NGT or nasoduodenal tube. Nutritional composition of the formulas was quite different depending on the type and brand of formula used. All formulas had relatively similar amounts of protein (14%-22% of total energy), whereas fat content varied considerably (1%-35% of total energy). Carbohydrate content varied relative to fat content (49%-82% of total energy).

The only study that compared two different enteral formulas and CS was published by Gassull *et al*<sup>[27]</sup>. They compared two EEN formulas that were the same except for the predominant type of fat: one was high in oleic acid and the other was high in linoleic acid. Study recruitment was ended prematurely because less than 33% of the high oleic acid formula group had achieved disease remission and the remission rate was significantly different from that of the other treatments.

CS protocols also ranged between the evaluated studies. Usual initial CS dosage was between 0.5 mg/kg per day and 1.0 mg/kg per day, with subsequent weaning courses. CS were given orally in two studies<sup>[23,27]</sup> but the route of administration was not published in the majority of studies. Two studies administered CS and sulfasalazine concurrently<sup>[28,29]</sup>.

<sup>1,2</sup>Gassull *et al* had two EEN arms: <sup>1</sup>High oleic fatty acid formula; <sup>2</sup>High linoleic fatty acid formula. CD: Crohn's disease; CDAI: Crohn's disease activity index; CS: Corticosteroids; EEN: Exclusive enteral nutrition; HBI: Harvey Bradshaw Index; NS: Non-significant; VHAI: Van Hees activity index.

Disease remission criteria

Three remission criteria were used across the 11 studies - the CD Activity Index (CDAI), the Harvey Bradshaw Index (HBI), and the Van Hees Activity Index (VHAI). The CDAI score uses a seven day history of general well-being, abdominal pain, loose stools, presence of abdominal mass and CD complications, anti-diarrhoeal use, haematocrit and weight<sup>[30]</sup>. The HBI is based on a one day history of general well-being, abdominal pain, loose stools and presence of abdominal mass and CD complications<sup>[30]</sup>. It correlates well with the CDAI (*r* = 0.8)<sup>[30]</sup>. Clinical remission is usually defined as a CDAI of less than or equal to 150 points or a HBI of less than or equal to 4 points<sup>[30]</sup>. Of the four studies that used the CDAI to define remission one used this criteria, one used a decrease of more than 100 points and two used either a CDAI of less than 150 or a decrease of 40% or more. Five studies used the HBI to define disease remission, the cut-offs used by each study were different.

The VHAI is calculated using serum albumin and erythrocyte sedimentation rate, body mass index, abdominal mass, gender, fever, loose stools, bowel resection and CD complications. The VHAI correlates moderately (*r* = 0.67) with the CDAI<sup>[31]</sup>. Both studies that used the VHAI used the same cut-off of less than 120 to define disease remission.

Remission of disease

Remission was achieved with EEN therapy on an intention to treat basis in 20%-100% of patients and 30%-100% of patient on CS therapy (Table 1). Seven of the 11 studies found no significant difference between EEN and CS treatment to induce disease remission<sup>[19,20,22,25,27]</sup>. Of those patients who completed the course of EEN therapy disease remission was achieved in 23%-100% of patients and in 30%-100% of patients that completed CS treatment<sup>[19,20]</sup>. Those that did not complete the course of EEN therapy were

usually started on CS therapy.

### Withdrawal from treatment

Withdrawals from treatment varied between studies. EEN study group withdrawals were mostly due to unpalatable enteral nutrition formula. The number of withdrawals for this reason was as high as 41% of the EEN group in one study but 0% in other EEN study groups. Occasionally patients had to withdraw as they required urgent surgery. Withdrawals from CS groups were much lower. Common reasons cited for withdrawing were side effects, non-compliance with treatment or the patient needing urgent surgery.

### Disease location

All 11 of the studies recorded the disease location of patients. The majority of patients had ileocolonic disease and smaller numbers had ileal or isolated colonic disease. No studies found disease location to be associated with the likelihood of achieving disease remission using EEN or CS therapy.

### Age of participants

The age of the participants was recorded differently across the 11 studies. The mean age of patients enrolled in the studies was 27.5-34.7 years old. Inclusion of older adults aged more than 50 years of age was not uncommon. Only one study included mostly younger adults (mean 21.0 ± 3.3 years)<sup>[26]</sup>.

## DISCUSSION

EEN is rarely used in adults with active CD, apart from in Japan. Its use is usually reserved for those patients who

do not want to use CS therapy, as an adjunctive therapy or where other treatment options have failed. Since the first studies with adults in the 1980s and 1990s much more is known about the way in which EEN therapy induces disease remission in children and how SEN therapy can assist in maintenance of disease remission. It is timely to readdress the possible reasons for the discrepancy between results from adult and paediatric studies that have compared EEN and CS therapy.

### Disease remission criteria

The disease remission criteria used by researchers can have a profound impact on the study results. Comparison of disease remission rates between studies is challenging when disease remission is not universally defined. Five of the 11 studies used the HBI to measure disease remission<sup>[19,21,22,24,26]</sup>. Two of the studies that used the HBI did not describe their remission criteria<sup>[21,22]</sup>, however the mean HBI of participants after the EEN intervention was less than 4, which corresponds with standard interpretations of clinical remission. Another study used a HBI cut off of less than six points with 100% of participants in both the EEN and CS therapy groups achieving remission in this study<sup>[19]</sup>. The fourth study to use the HBI used a cut-off of 0-1 points to define disease remission<sup>[26]</sup>. Only 30% of patients in the CS group achieved remission using this criterion compared with 80% of the EEN group. It is unknown if a more liberal cut-off would have increased the number of patients achieving disease remission in the CS group. Regardless of the HBI cut-off used at least 80% of the EEN group participants (that completed the course of EEN) in each of the five studies achieved disease remission.

Four of the 11 studies used the CDAI to measure dis-

ease remission<sup>[20,25,28,29]</sup>. The remission rates of the EEN therapy group in all four studies were low (40%-53%), with the two larger studies concluding that, on an intention to treat basis, CS therapy induces disease remission in significantly more patients than EEN therapy<sup>[28,29]</sup>. In two of the studies at least one third of the patients withdrew from the EEN group due to unpalatable formula<sup>[25,29]</sup>. Withdrawals from the CS groups were much lower (20% or less). Of those that did complete the course of EEN therapy only 40%-71% of patients achieved disease remission, whereas remission was achieved in 62%-98% of those that completed the course of CS therapy.

The disease remission rates of the two studies that used the VHAI to define disease remission were quite different. Gassull *et al.*<sup>[27]</sup> hypothesised that the formula high in linoleic acid, an n-6 polyunsaturated fat, would be less effective than a high monounsaturated fatty acid formula because n-6 fatty acids are pro-inflammatory precursors. Of the 20 patients enrolled in the high oleic acid EEN group only 20% achieved disease remission after 4 wk of therapy, compared with 52% of the high linoleic acid group and 79% of those using CS therapy. It seems that the fat content of EEN formulae may affect the efficacy of EEN therapy. The other study that used the VHAI to define disease remission found that EEN therapy was as effective as CS therapy: 80% of those on EEN therapy achieved disease remission compared with 88% of those using CS therapy<sup>[23]</sup>.

The criteria used to define disease remission should not impact greatly on the results of the study; however, in this case, the studies can be grouped into three categories based on the remission criteria applied. The studies that used the HBI found that EEN therapy was at least as effective as CS therapy in inducing disease remission. The two larger studies that used the CDAI found that CS therapy was superior to EEN therapy while two studies with small participant numbers found no significant difference. There may be differences in study protocols between studies with higher and lower patient numbers that could influence patient outcomes. Finally, the two studies that used the VHAI found that there was no significant difference between a high, or a moderate, polyunsaturated polymeric formula and CS therapy, but that a high monounsaturated formula was significantly less effective ( $P < 0.001$ ) than CS therapy at inducing disease remission.

### Newly diagnosed CD

There is some evidence to suggest that EEN therapy is more effective in newly diagnosed CD patients compared with patients who have existing CD. Differences in treatment response rates according to time since diagnosis are not limited to EEN therapy. Response and remission rates achieved with biologic therapy are greater in children than adults<sup>[32]</sup> which may, in part, be due to the duration of disease prior to initiation of the treatment. Similarly, adults with a shorter duration of CD are more likely to respond and achieve remission with biologic

therapy<sup>[32]</sup>. Also the use of immune-modulators early in the disease course in adults and children has been shown to reduce the probability of long term CS and intestinal surgeries<sup>[33]</sup>.

Two adult studies have compared EEN with CS therapy in treatment-naïve patients<sup>[22,26]</sup>. In both studies, 80% of those treated with EEN achieved disease remission after 4-6 wk of an elemental diet (comparable to remission rates in those treated with CS). Other adult studies comparing EEN with CS have not differentiated between patients with newly diagnosed CD and existing CD in their analyses. One study mentioned that both of the newly diagnosed CD patients responded to EEN treatment<sup>[20]</sup>, but the numbers enrolled in the study were too small to show if there was a statistically significant difference in response to treatment between the two groups. A study of 22 patients treated with EEN found that EEN therapy was as effective in newly diagnosed patients as those with existing disease<sup>[21]</sup>, although 40% of patients did not complete the course of EEN. The authors do not indicate how many of those that completed EEN treatment had existing or newly diagnosed disease. The two larger multi-centre European trials did not differentiate between those that had and not had received previous CD treatment<sup>[28,29]</sup>.

Paediatric research suggests that EEN is more effective in treating newly diagnosed CD than existing CD<sup>[9]</sup>. Day *et al.*<sup>[9]</sup> showed that, of 15 newly diagnosed CD patients, 12 (80%) entered remission after eight weeks of EEN, whereas only seven of the 12 (58%) children with long-standing disease entered remission ( $P > 0.05$  by fisher's exact test). In other paediatric studies with newly diagnosed CD patients disease remission was achieved in 79%-93% of those that completed EEN treatment and 70%-79% on an intention to treat basis<sup>[7,34]</sup>.

### Duration of CD

Longer duration of CD is associated with more complications including tissue scarring, fistulae, abscess, strictures, perianal disease and bowel resections<sup>[35]</sup>. EEN therapy has been shown to induce disease remission by reducing mucosal inflammation<sup>[36-38]</sup>. Complications of CD are often non-inflammatory in nature; therefore, EEN may be less effective in treating these patients. Interestingly, a case series of three children with perianal disease at diagnosis found that EEN (used in combination with surgery and antibiotics) was effective at inducing disease remission and assisted in the healing of perianal disease<sup>[39]</sup>. EEN was used as a maintenance therapy in all three children without return of perianal disease. A clinical trial has not been conducted to further investigate the potential role of EEN in the management of perianal CD.

Overall, studies in adult patients of EEN compared with CS therapy have not excluded patients with complicated disease. Usual exclusions included imminent surgery, intestinal perforation, ileus, abscesses, massive bleeding, short bowel syndrome with ileostomy and, in

some cases, previous surgery. The presence of other complications of existing CD such as scarring, perianal disease or previous bowel surgery is not detailed in the adult literature. It is impossible to ascertain whether those who did not respond to EEN therapy had more or less complications than those who did respond. Furthermore, the studies had only small numbers of patients within each disease sub-group and were unable to conduct in-depth statistical analysis of these sub-groups.

### Adherence

Non-adherence with EEN treatment was a limiting factor in the success of EEN therapy in many studies. A number of reasons for non-adherence of adult CD patients with EEN therapy have been postulated including poor taste of the formula, lack of support and poor motivation to complete the treatment.

Un-palatability of the EN formula was the most common reason for non-adherence in the studies performed to date. Many early studies that compared EEN with CS treatment used elemental formulas. The difference between polymeric and elemental formulas is that the protein fraction in polymeric formula is in its whole form rather than as individual amino acids or peptides in semi-elemental formulas and elemental formulas tend to have a low total fat content. Polymeric formula has been shown to be as effective as elemental at inducing disease remission<sup>[40,41]</sup>. Elemental formulas have a distinctive smell and flavour mainly due to the presence of amino acids, which have a bitter flavour. Bitterness is negatively correlated with palatability, whereas sweetness and sourness are positively correlated with palatability<sup>[42]</sup>. Fat content may also affect the palatability of the formula<sup>[43]</sup>. The elemental formulas used in the studies were low fat (1%-3% TE) compared with semi-elemental (9%-33% TE) and polymeric (32%-35% TE) formulas. Hence polymeric formulas are thought to be more palatable. However, there is limited research comparing the palatability of the two formula types. A retrospective study of children who received elemental formula from 1992-2001 and children who received polymeric formula from 2000-2004 found that adherence to treatment did not differ between the two groups but that those receiving polymeric formula were less likely to need a nasogastric tubes (NGT) inserted to deliver the feed<sup>[44]</sup>.

The mode of delivery of the formula may also play a role in patient compliance. Many studies with high adherence rates administered elemental formulas *via* NG or nasoduodenal tubes rather than orally. More recent paediatric studies have encouraged oral intake of polymeric formula and use of NGT only if needed<sup>[7,9,34]</sup>. For free living (non-hospitalised) patients, taking the formula orally may be more socially acceptable. Elemental and polymeric formulas have been shown to be as equally effective at inducing remission of disease in children<sup>[40]</sup> and adults<sup>[18]</sup>.

Studies that used elemental formulas given exclusively *via* NG or nasoduodenal tubes had low rates of non-

adherence (0%-13%)<sup>[26,28]</sup>. Whereas studies that reported high rates of non-adherence (33%-41%) used elemental or semi-elemental formulas given orally and if a patient did not tolerate EEN orally a NGT was placed.<sup>[21,25,29]</sup>

However, three of the six studies using elemental or semi-elemental diet orally reported higher adherence rates<sup>[19,22,24]</sup>. Two of these studies<sup>[19,24]</sup> only used EEN for 2 wk and patients were given a peptide based semi-elemental formula (Peptamen) orally rather than an amino acid-based elemental formula. Of the 19 patients using EEN in these two trials, only 1 patient was non-adherent with the treatment. The third study, by O'Moráin *et al.*<sup>[22]</sup> was one of the first to compare EEN to CS treatment. Patients were asked to take the elemental formula orally for four weeks and if they could not tolerate it a NGT was placed. Of the 11 patients in the EEN group, two (18%) could not tolerate the formula orally or *via* a NGT.

Of the three adult studies that used polymeric formula, two administered it *via* NG or nasoduodenal tubes with 100% adherence<sup>[20,23]</sup>. The third study used a polymeric powder (a high oleic and high linoleic acid formulation) given orally or *via* NGT if not tolerated orally<sup>[27]</sup>. Non-adherence with the treatment was 17%-25%. No published adult studies have used a ready-to-drink polymeric formula given orally. There are, however, various studies with children that have shown that polymeric formulas are palatable orally. Borrelli *et al.*<sup>[7]</sup> studied 19 children with CD who drank an isocaloric polymeric formula (Modulen) as their sole source of nutrition for 10 wk. Thirteen children took the formula orally; four required overnight feeding *via* a NGT, in addition to taking it orally during the day, to meet their nutritional requirements and two children could not manage to take the required volume of formula orally or *via* a NGT. Of the 17 children that successfully completed the 10 wk intervention 15 (88%) achieved disease remission. Day *et al.*<sup>[9]</sup> studied 27 children with CD who were prescribed EEN with isocaloric polymeric formula (Modulen or Osmolite) for up to 8 wk. Nineteen children managed the required volume of formula orally, five needed to take some of the formula *via* a NGT and three could not tolerate the required volume orally or *via* a NGT. Of the 24 children who completed at least 8 wk of EEN, 19 entered remission (79%).

Both of these paediatric studies used an isocaloric polymeric formula. It appears that the major reason for non-adherence in these cohorts was difficulty tolerating the volume required for nutritional requirements rather than un-palatability. It is not clear whether the volume required to meet an adult's nutritional requirements (*e.g.*, 1600-2400 mL of ready-to-drink isocaloric polymeric formula per day) may lead to poor adherence. The use of a concentrated polymeric formula, (*e.g.*, 1.5 kcal/mL formula), may help alleviate this issue.

If adherence with and response to EEN treatment of 90% and 80%, respectively, can be achieved in adults EEN may be a viable treatment option. Ready-to-drink polymeric formula, which may be more palatable orally

than elemental or semi-elemental formulas and more convenient and portable than powdered options, could provide an option for adults with CD wishing to reduce their exposure to CS, induce disease remission and potentially attain the benefits associated with EEN therapy that have been confirmed in children.

### Disease location

Disease location is thought to affect the efficacy of EEN therapy. In particular, colonic disease may be more refractory to treatment than disease with ileal involvement. However, due to the small participant numbers in most adult EEN studies there has been insufficient statistical power for subgroup analyses. A pooled meta-analysis of mainly adult studies from the 1980s and 1990s found that there was insufficient data to perform subgroup analyses by disease location<sup>[18]</sup>.

Some paediatric studies have specifically investigated the impact of disease location on response to EEN therapy. Afzal *et al.*<sup>[13]</sup> studied 65 children aged 8-17 years old with newly diagnosed CD of which 12 had ileal disease, 39 had ileocolonic disease and 14 had isolated colonic disease. They found that disease remission was harder to induce with EEN therapy in patients with colonic disease - remission achieved in 50% compared with 82% in those with ileocolonic disease and 92% in those with ileal CD ( $P = 0.02$ ). They also used colonoscopy to assess mucosal healing after EEN therapy and found that there was no improvement in colonic mucosal inflammation in those with colonic or ileocolonic disease.

Conversely, Buchman *et al.*<sup>[3]</sup> investigated the effect of disease location on remission rates after EEN therapy and found that colonic CD responded just as well as ileocolonic disease. Their study included 114 children (median age 11.6 years), all with recently diagnosed CD. Nineteen patients had colonic disease, four had ileal disease, 29 had ileocolonic disease, 49 had upper gastrointestinal tract disease and 9 had disease that could not be classified using the Vienna classification. Of those with colonic disease 79% went into remission after eight weeks of EEN therapy compared with 86% with ileocolonic disease, 88% with upper gastrointestinal disease and only 25% with ileal disease. It should be noted that there were only 4 patients with ileal disease compared with at least 20 in the other three groups. Further evidence is needed to confirm whether CD location affects the efficacy of EEN.

### Age of patient

Current guidelines suggest that EEN therapy is more appropriate to use in paediatric rather than adult patients<sup>[6,18]</sup>. There are no studies in adults that have assessed whether age affects response to EEN therapy. Although the mean age of adults included in the 11 studies evaluated here was approximately 30 years, the age range varied substantially and was not always published. Of those that did publish the age range of patients it was common to include patients aged 20 up to 50 or 60<sup>[19,22,25]</sup>.

It is unknown if age affects response to EEN therapy or compliance with treatment.

## CONCLUSION

Initial reports demonstrated that EEN was effective in inducing remission in adults with active CD and proposed this intervention as an alternative to CS therapy. However, subsequent larger studies failed to reproduce these results. Since then many studies have been conducted in paediatric populations and numerous benefits over and above achieving disease remission have become apparent. It appears that non-compliance with EEN treatment in early studies adversely affected the efficacy of EEN compared with CS therapy. There is also evidence to support a possible role of EEN with a specific group of adult patients - those newly diagnosed disease and, possibly, those with ileal involvement. Further research with this group is warranted. The use of polymeric formulas provided orally, which has not previously been studied in adult patients, may improve treatment compliance and allow adult patients to reap the many other benefits of EEN that have been shown in children over and above achieving disease remission and improving nutritional status.

**Key words:** IgG4-related sclerosing cholangitis; Primary sclerosing cholangitis; IgG4; Sclerosing cholangitis

**Core tip:** IgG4-related sclerosing cholangitis (IgG4-SC) has become a third distinct clinical entity of sclerosing cholangitis. The diffuse cholangiographic abnormalities observed in IgG4-SC may resemble those observed in primary sclerosing cholangitis (PSC), and the presence of segmental stenosis suggests cholangiocarcinoma (CC). IgG4-SC responds well to steroid therapy, whereas PSC is only effectively treated with liver transplantation, and CC requires surgical intervention. IgG4-SC should be carefully diagnosed based on a combination of characteristic clinical, serological, morphological, and histopathological features after cholangiographic classification and targeting of a disease for differential diagnosis.

### Abstract

IgG4-related sclerosing cholangitis (IgG4-SC) is often associated with autoimmune pancreatitis. However, the diffuse cholangiographic abnormalities observed in IgG4-SC may resemble those observed in primary sclerosing cholangitis (PSC), and the presence of segmental stenosis suggests cholangiocarcinoma (CC). IgG4-SC responds well to steroid therapy, whereas PSC is only effectively treated with liver transplantation and CC requires surgical intervention. Since IgG4-SC was first described, it has become a third distinct clinical entity of sclerosing cholangitis. The aim of this review was to introduce the diagnostic methods for IgG4-SC. IgG4-SC should be carefully diagnosed based on a combination of characteristic clinical, serological, morphological, and histopathological features after cholangiographic classification and targeting of a disease for differential diagnosis. When intrapancreatic stenosis is detected, pancreatic cancer or CC should be ruled out. If multiple intrahepatic stenoses are evident, PSC should be distinguished on the basis of cholangiographic findings and liver biopsy with IgG4 immunostaining. Associated inflammatory bowel disease is suggestive of PSC. If stenosis is demonstrated in the hepatic hilar region, CC should be discriminated by ultrasonography, intraductal ultrasonography, bile duct biopsy, and a higher cutoff serum IgG4 level of 182 mg/dL.

Nakazawa T, Naitoh I, Hayashi K, Miyabe K, Simizu S, Joh T. Diagnosis of IgG4-related sclerosing cholangitis. *World J Gastroenterol* 2013; 19(43): 7661-7670 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7661.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7661>

### INTRODUCTION

IgG4-related sclerosing cholangitis (IgG4-SC) is a characteristic type of sclerosing cholangitis, with an unknown pathogenic mechanism. Patients with IgG4-SC display increased serum IgG4 levels<sup>[1]</sup> and dense infiltration of IgG4-positive plasma cells with extensive fibrosis in the bile duct wall<sup>[2]</sup>. Circular and symmetrical thickening of the bile duct wall is observed in the areas without stenosis that appear normal on cholangiography, as well as in the stenotic areas<sup>[3]</sup>. IgG4-SC has been recently recognized as an IgG4-related disease. IgG4-SC is frequently associated with autoimmune pancreatitis (AIP). IgG4-related dacryoadenitis/sialadenitis and IgG4-related retroperitoneal

fibrosis are also occasionally observed in IgG4-SC<sup>[4-7]</sup>. However, some IgG4-SC cases do not involve other organs<sup>[8]</sup>. IgG4-SC is most common in elderly men. Obstructive jaundice is frequently observed in IgG4-SC. The clinical and radiological features of IgG4-SC are resolved by steroid therapy, although its long-term prognosis is not clear<sup>[9-12]</sup>. The diffuse cholangiographic abnormalities observed in IgG4-SC may resemble those observed in primary sclerosing cholangitis (PSC), and the presence of segmental stenosis suggests cholangiocarcinoma (CC). IgG4-SC responds well to steroid therapy, whereas PSC is effectively treated only with liver transplantation, and CC requires surgical intervention. It is also necessary to rule out secondary sclerosing cholangitis (SSC) caused by diseases with an obvious pathogenesis.

Precise diagnosis is needed before choosing appropriate treatments. Therefore, this paper provides a review of the clinical and pathological characteristics of IgG4-SC, focusing on its differential diagnosis from other biliary diseases such as PSC and CC.

## CLASSIFICATION OF SC

SC has been classified into two categories: PSC and SSC. IgG4-SC has sometimes been described as an isolated biliary tract lesion, even in the absence of pancreatic involvement, and has thus been established as a distinct clinical entity. Therefore, we propose that SC should now be classified into three categories: PSC, IgG4-SC, and SSC. We have identified three reasons why IgG4-SC should be considered independent of other forms of SSC. First, steroid therapy is highly effective for IgG4-SC, which is in contrast to the other types of SC. Second, in comparison with the other forms, IgG4-SC is the most frequently encountered in daily clinical practice. Third, the characteristics of IgG4-SC need to be fully discriminated from those of the other three intractable diseases, that is, pancreatic cancer (PCa), PSC, and CC.

With regard to the diagnosis of SC, SSC should be initially ruled out. Thereafter, IgG4-SC should be suspected, the serum IgG4 level measured, and further exploration for pancreatic involvement or other IgG4-related systemic disease, conducted. Finally, compatibility with the PSC criteria should be ascertained.

### PSC

The following diagnostic criteria for PSC, which were proposed by the Mayo Clinic, have been widely used<sup>[13]</sup>: typical cholangiographic abnormalities involving the intrabiliary and extrabiliary trees, compatible clinical and biochemical findings, and exclusion of other causes of SSC. Liver biopsy had been used in the past to help confirm diagnosis, but its diagnostic specificity and sensitivity have become controversial. Nevertheless, liver biopsy is useful in the diagnosis of small duct PSC, for patients with suspected PSC but normal cholangiographic findings, and for the exclusion of other cholestatic diseases.

Characteristic inflammatory bowel diseases (IBDs) are

frequently observed in PSC patients. Standard ursodeoxycholic acid doses lead to improvements in biochemical abnormalities but not in histological findings, cholangiographic appearance, or patient survival. Liver transplantation is considered effective for end-stage liver disease because of PSC and is associated with improved patient survival. PSC usually leads to cirrhosis, with a mean survival time of 12-17 years.

### IgG4-SC

Recently, IgG4-SC has attracted much attention with the emergence of clinical characteristics that distinguish it as a new clinical entity. The diffuse cholangiographic abnormalities observed in association with AIP may resemble those observed in PSC, and the segmental stenosis suggest CC. IgG4-SC responds well to steroid therapy compared with the other two types of SC.

We have previously reported on the differences between IgG4-SC and PSC<sup>[9]</sup>. The age at clinical onset is significantly older for patients with IgG4-SC. Among the chief complaints in IgG4-SC, obstructive jaundice, reflecting marked concentric stenosis of the large bile duct, is most frequently observed. However, in Japan, patients with PSC who present without symptoms after liver injury are identified by physical examination<sup>[14]</sup>.

An elevated serum IgG4 level is a characteristic feature of IgG4-SC<sup>[15]</sup>. In patients with IgG4-SC, the pancreas is the most common organ involved other than the liver. Patients with IgG4-SC have multiorgan involvement, including sclerosing sialadenitis, retroperitoneal fibrosis, and mediastinal lymphadenopathy<sup>[4-7]</sup>.

### SSC

SSC is a chronic cholestatic biliary disease that can develop after a diverse range of insults to the biliary tree. SSC is considered to develop as a consequence of known injuries or secondary to pathological processes of the biliary tree. The etiology of SSC can usually be identified, although the exact pathogenesis often remains speculative. The most frequently described causes of SSC are long-standing biliary obstruction, surgical trauma to the bile duct, and ischemic injury to the biliary tree in liver allografts.

The different types of SSC have been described in the diagnostic criteria established by the Mayo Clinic<sup>[13]</sup>. Two reviews of SSC cases have been published<sup>[16,17]</sup>. IgG4-SC was previously classified into SSC. We classified the etiology of SSC based on three review articles<sup>[13,16,17]</sup> (Table 1). There are few studies comparing patients with SSC and PSC. A 10-year retrospective review (1992-2002) by the Mayo Clinic identified 31 patients with SSC<sup>[18]</sup>. The documented etiologies in their series included surgical trauma from cholecystectomy, intraductal stones, recurrent pancreatitis, and abdominal injury. Nine of their patients with SSC ultimately required liver transplantation, and four died. In their series, when compared with matched controls with PSC, the patient transplant-free survival was significantly shorter.

**Table 1 Etiology of secondary sclerosing cholangitis**

Congenital	Caroli's disease Cystic fibrosis
Chronic obstruction	Choledocholithiasis Biliary strictures (secondary to surgical trauma, chronic pancreatitis) Anastomotic strictures in liver graft Neoplasms (benign, malignant, metastatic)
Infectious	Bacterial cholangitis Recurrent pyogenic cholangitis Parasitic infection (cryptosporidiosis, microsporidiosis) Cytomegalovirus infection
Toxic	Accidental alcohol, formaldehyde, hypertonic saline instillation in the bile ducts
Immunologic	Eosinophilic cholangitis Acquired immunodeficiency
Ischemic	Vascular trauma Post-traumatic sclerosing cholangitis Post-transplantation hepatic artery thrombosis Hepatic allograft rejection (acute, chronic) Intra-arterial, chemotherapy-related injury Transcatheter arterial embolization therapy
Infiltrative disorders	Systemic vasculitis Amyloidosis Radiation injury Sarcoidosis Systemic mastocytosis Hypereosinophilic syndrome Hodgkin's disease

## IgG4-SC DIAGNOSIS

### Cholangiographic classification

IgG4-SC displays various cholangiographic features similar to those of PCa, PSC, and CC. The characteristic features of IgG4-SC can be classified into four types based on the stricture regions revealed by cholangiography and differential diagnosis (Figure 1)<sup>[19,20]</sup>. Type 1 IgG4-SC displays stenosis only in the lower part of the common bile duct and thus should be differentiated from chronic pancreatitis, PCa, and CC. Type 2 IgG4-SC, in which stenosis is diffusely distributed throughout the intrahepatic and extrahepatic bile ducts, should be differentiated from PSC and is further subdivided into two subtypes: type 2a, characterized with narrowing of the intrahepatic bile ducts with prestenotic dilation; and type 2b, characterized by the narrowing of the intrahepatic bile ducts without prestenotic dilation and reduced bile duct branches, which is caused by marked lymphocytic and plasmacyte infiltrations into the peripheral bile ducts. Type 3 IgG4-SC is characterized by stenosis in the hilar hepatic lesions and the lower part of the common bile duct. Type 4 IgG4-SC presents with strictures of the bile duct only in the hilar hepatic lesions. The cholangiographic findings of types 3 and 4 IgG4-SC should be discriminated from those of CC.

### Serum IgG4 level

Serum IgG4 level has been reported to be a useful marker for discriminating AIP from other pancreatic diseases.

A cutoff IgG4 level of 135 mg/dL is widely used as part of the diagnostic criteria for AIP. However, twice the upper limit of normal is also recommended to discriminate AIP from PCa. In the international consensus diagnostic criteria for AIP, once or twice the upper limit of normal is included in levels 1 and 2 diagnoses, respectively<sup>[21]</sup>.

Only a few reports have been published concerning the cutoff IgG4 level in the diagnosis of IgG4-SC. We published for the first time, the diagnostic criteria for IgG4-SC based on a comparative study<sup>[22]</sup>. The cutoff IgG4 level of 135 mg/dL is useful in discriminating IgG4-SC from PCa and PSC. However, this cutoff level displayed lower specificity in discriminating IgG4-SC from CC. Oseini *et al*<sup>[23]</sup> evaluated the utility of serum IgG4 level in distinguishing IgG4-SC from CC. They reported that among their 126 patients with CC, 17 (13.5%) had elevated (> 140 mg/dL) and four (3.2%) had a > 2-fold increase (> 280 mg/dL) in serum IgG4 levels. PSC was present in 31/126 CC patients, of whom seven (22.6%) had an elevated serum IgG4 level. The authors concluded that some patients with CC, particularly PSC, had elevated serum IgG4 levels and diagnosis using a twofold higher cutoff serum IgG4 level may not reliably distinguish IgG4-SC from CC. However, a cutoff level fourfold higher than the upper limit of normal had 100% specificity for IgG4-SC.

We recently established a cutoff serum IgG4 level to differentiate IgG4-SC from the three other diseases (type 1 IgG4-SC *vs* PCa, type 2 IgG4-SC *vs* PSC, and type 3 IgG4-SC *vs* CC) using serum IgG4 levels measured in nine Japanese high-volume centers<sup>[24]</sup>. The cutoff obtained from receiver operator characteristic (ROC) curves displayed similar sensitivity and specificity to those of 135 mg/dL when all the IgG4-SC cases and controls were compared. However, a new cutoff value was established when IgG4-SC subgroups and controls were compared. A cutoff level of 182 mg/dL can increase the specificity to 96.6% (a 4.7% increase) for distinguishing types 3 and 4 IgG4-SC from CC. A cutoff level of 207 mg/dL might be useful for completely distinguishing types 3 and 4 IgG4-SC from CC.

Alswat *et al*<sup>[25]</sup> demonstrated that serum IgG4 levels could efficiently detect patients with IgG4-SC after excluding SC patients with AIP. However, previously reported IgG4-SC cases without pancreatic involvement displayed no marked increase in serum IgG4 level compared with patients with AIP-associated IgG4-SC. Hamano *et al*<sup>[8]</sup> demonstrated modestly high serum IgG4 levels (119, 122, and 195 mg/dL) in three IgG4-SC cases without an obvious pancreatic mass.

Elevated serum IgG4 level is considered a characteristic feature of IgG4-SC<sup>[1]</sup>. However, Mendes *et al*<sup>[26]</sup> measured the serum IgG4 level in 127 patients with PSC and found that it was elevated in 12 (9%). The patients with elevated IgG4 levels had higher levels of total bilirubin and alkaline phosphatase, higher PSC Mayo risk scores, and lower incidence of IBD. It is important to note that the time to liver transplantation was shorter in

**Figure 1 Cholangiographic classification of IgG4-related sclerosing cholangitis and differential diagnosis.** Stenosis is located only in the lower part of the common bile duct in type 1; stenosis is diffusely distributed in the intra- and extra-hepatic bile ducts in type 2. Type 2 is further subdivided into two. Extended narrowing of the intrahepatic bile ducts with prestenotic dilation is widely distributed in type 2a. Narrowing of the intrahepatic bile ducts without prestenotic dilation and reduced bile duct branches are widely distributed in type 2b; stenosis is detected in both the hilar hepatic lesions and the lower part of the common bile ducts in type 3; strictures of the bile duct are detected only in the hilar hepatic lesions in type 4. IDUS: Intraductal ultrasonography; EUS-FNA: Endoscopic ultrasound-guided fine needle aspiration; IBD: Inflammatory bowel disease.

the patients with elevated IgG4 levels (1.7 years *vs* 6.5 years,  $P = 0.0009$ ). As only one of the patients in their series had an abnormal pancreatogram, the documented cases appeared to conform to the diagnosis of IgG4-SC. Therefore, clinical trials in which patients with PSC are evaluated for IgG4 and patients presenting elevated levels are treated with corticosteroids should be considered.

### Other organ involvement

The concept of IgG4-related disease has been established internationally<sup>[27]</sup>. IgG4-SC is included in the IgG4-related disease category. Serum IgG4 level elevation and tissue infiltration with IgG4-positive plasma cells are common threads that connect a variety of apparently disparate conditions observed previously in multiple organs. Certain clinical and pathological features help define IgG4-related disease and distinguish it from its potential mimics. IgG4-related disease is a fibroinflammatory condition characterized by a tendency to form tumefactive lesions, a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, storiform fibrosis, frequent but not invariable elevations in serum IgG4 level, and a swift initial response to glucocorticoids, provided that tissue fibrosis has not supervened.

The pancreas was the first organ in which IgG4-related disease was identified, but the disease has now been described in virtually every organ system: the biliary tree, salivary glands, orbital tissues (*e.g.*, lacrimal gland, extraocular muscles, and retrobulbar space), kidneys, lungs, lymph nodes, meninges, aorta, breast, prostate, thyroid gland, pericardium, retroperitoneum, and skin.

Association with AIP is a useful finding in the diagnosis of IgG4-SC. In one study, 59 (95%) of 62 patients with IgG4-SC had associated AIP, with high prevalence<sup>[21]</sup>. Ghazale *et al*<sup>[15]</sup> reported an incidence rate of AIP association of 92% in 53 patients with IgG4-SC, which was a comparatively large sample. However, focal-

type AIP sometimes displays similar imaging findings to those of PCa, making discrimination between the two diseases difficult<sup>[28]</sup>. The sensitivity rates of diagnostic criteria for AIP have been reported to range from 80% to 92%<sup>[29]</sup>. Therefore, useful diagnostic criteria need to be established for IgG4-SC when it is not associated with AIP or when diagnosis of AIP is unclear. IgG4-SC is occasionally associated with other systemic IgG4-related diseases including symmetrical dacryoadenitis/sialadenitis and retroperitoneal fibrosis. These associations are helpful in the accurate diagnosis of IgG4-SC.

### Pathological features

In IgG4-SC, fibroinflammatory involvement is observed mainly in the submucosa of the bile duct wall, whereas the epithelium of the bile duct is intact<sup>[2]</sup>. However, slight injury and/or neutrophil infiltration are occasionally observed in IgG4-SC with associated secondary cholangitis. PSC should be ruled out if inflammation is observed, particularly in the epithelium of the bile duct wall. The characteristic pathological findings of IgG4-SC were first reported as “lymphoplasmacytic sclerosing pancreatitis with cholangitis”<sup>[30]</sup>. Abraham *et al*<sup>[31]</sup> reported frequent fibroinflammatory involvement of the gallbladder and common bile duct in patients with lymphoplasmacytic sclerosing pancreatitis. Zen *et al*<sup>[2]</sup> revealed that the bile duct wall in IgG4-SC had pathological features similar to those of AIP, displaying dense infiltrations of lymphocytes and IgG4-positive plasma cells, with extensive fibrosis and obliterative phlebitis. They classified IgG4-SC into six categories according to the extent of inflammation and association with an inflammatory pseudotumor. IgG4-positive plasma cells are sparse in the affected bile ducts in PSC, and the luminal side of the bile ducts, including lining biliary epithelial cells, is preferentially affected compared with IgG4-SC. In PSC, the fibrosis is denser and older, whereas in IgG4-SC, the entire bile

**Figure 2** Schematic illustration of comparison of cholangiographic (primary sclerosing cholangitis vs IgG4-related sclerosing cholangitis) findings<sup>[28]</sup>. The schematic comparison of cholangiographic findings between IgG4-related sclerosing cholangitis (SC) and primary sclerosing cholangitis (PSC). IgG4-related SC displays segmental and long strictures and stricture of the lower common bile duct, whereas PSC displays band-like strictures (1–2 mm), beaded appearance (short and annular stricture alternating with normal or minimally dilated segments), pruned-tree appearance (diminished arborization of intrahepatic duct and pruning), and diverticulum-like outpouching (outpouchings resembling diverticula, often protruding between adjacent strictures). 1: Band-like stricture; 2: Beaded appearance; 3: Pruned-tree appearance; 4: Diverticulum-like outpouching; 5: Segmental stricture; 6: Long stricture with prestenotic dilation; 7: Stricture of lower common bile duct.

duct wall and periductal tissue are affected. However, a recent study by Zhang *et al.*<sup>[32]</sup> revealed that 23 (23%) of 98 liver explants with PSC had periductal infiltration with abundant IgG4-positive plasma cells [10/high-power field (HPF)] in the hilar area.

### Differential diagnosis of IgG4-SC based on cholangiographic classification

IgG4-SC displays various cholangiographic features similar to those of PCa, PSC, and CC<sup>[9]</sup>. The differential diagnosis based on cholangiographic classification is sufficient in clinical practice because the useful modalities depend on the cholangiographic types (Figure 1)<sup>[20]</sup>.

Type 1 IgG4-SC should be differentiated from chronic pancreatitis, PCa, and CC. The modalities useful for differential diagnosis are intraductal ultrasonography (IDUS)<sup>[3]</sup>, endoscopic ultrasound-guided fine-needle aspiration for the pancreas<sup>[33]</sup>, and cytological examination and/or biopsy of the bile duct<sup>[3,34]</sup>.

Type 2 IgG4-SC should be differentiated from PSC. The modalities useful for differential diagnosis are cholangiography<sup>[35]</sup>, evaluations for associated IBD<sup>[9,12]</sup>, and liver biopsy<sup>[36,37]</sup>. Our discriminant analysis formula for cholangiographic features, including age, was able to discriminate type 2 IgG4-SC from PSC<sup>[35]</sup>. Band-like strictures, a beaded or “pruned tree” appearance, and diverticulum-like outpouching are significantly more frequent in PSC cases. In contrast, segmental strictures, long strictures with prestenotic dilation, and strictures of the lower common bile duct are significantly more common in IgG4-SC. These differences are illustrated in Figure 2. The characteristic cholangiographic features reflect the underlying pathological processes involved in each condition. In PSC, obliterative fibrosis is the main cause of biliary stenosis, creating short strictures. In contrast, in

IgG4-SC, severe lymphoplasmacyte infiltration into bile ducts in the long region is the main cause of biliary stenosis, resulting in long strictures (Figure 3).

In contrast, Kalaitzakis *et al.*<sup>[38]</sup> reported that diagnosing IgG4-SC by cholangiography displayed high specificity but poor sensitivity and may have led to the misdiagnosis of IgG4-SC as PSC or CC.

Associated ulcerative colitis is suggestive of PSC. IBD is present in only 0%–6% of patients with IgG4-SC<sup>[9,12,15]</sup>. IBD is usually not a feature associated with type 1 AIP, unlike the frequent association of IBD with type 2 AIP<sup>[23]</sup>. IBD associated with PSC represents a third phenotype in western countries<sup>[39]</sup>. Backwash ileitis, rectal sparing, and low disease activity appear to be features that characterize IBD when it is associated with PSC<sup>[39,40]</sup>.

The histological features of IgG4-SC on liver biopsy are distinctive and, in conjunction with IgG4 immunohistochemical staining, help distinguish IgG4-SC from PSC<sup>[36,41]</sup>. We have already reported that liver needle biopsy is especially useful for distinguishing IgG4-SC from PSC in patients with cholangiographically evident intrahepatic biliary strictures<sup>[37]</sup>. Four (57%) of seven patients with type 2 IgG4-SC presented infiltration with  $\geq 10$  IgG4-positive plasma cells per HPF in liver biopsy samples, whereas none of the PSC patients presented this feature.

Types 3 and 4 IgG4-SC need to be discriminated from CC. The modalities useful for the differential diagnosis of types 3 and 4 IgG4-SC are endoscopic procedures<sup>[42]</sup> such as endoscopic ultrasonography, IDUS<sup>[3,43]</sup>, cytological examination, and/or biopsy of the bile duct<sup>[3,34]</sup>. Although we described how type 2 IgG4-SC could be discriminated from PSC on the basis of characteristic cholangiographic features, cholangiography cannot discriminate the segmental stricture of types 3 and 4 IgG4-SC from CC. Therefore, we applied our discriminant analysis formula for cholangiographic features to discriminate between only type 2 IgG4-SC and PSC.

IDUS findings such as circular-symmetrical wall thickening, smooth outer margin, smooth inner margin, and homogeneous internal echo at the stenotic area were useful for the diagnosis of IgG4-SC. The most characteristic IDUS finding in the IgG4-SC cases was thickening of the bile duct wall, which appeared normal on cholangiography<sup>[3]</sup>. Bile duct wall thickening spread continuously from the intrapancreatic bile duct to the upper bile duct in most cases. To differentiate IgG4-SC from CC, 0.8-mm thickness of the bile duct wall that appeared normal on a cholangiogram was the best cutoff as indicated by ROC curves. The sensitivity, specificity, and accuracy were 95%, 90.9%, and 93.5%, respectively, when the cutoff value was 0.8 mm. No CC cases had a bile duct wall thicker than 1 mm. The sensitivity, specificity, and accuracy were 85%, 100%, and 87%, respectively, when the cutoff value was set at 1 mm. We considered a 1-mm thickness as an optimal cutoff wall thickness to completely exclude CC.

Ghazale *et al.*<sup>[15]</sup> reported the usefulness of endoscopic biliary biopsy for diagnosis of IgG4-SC. They

**Figure 3** Cholangiogram displaying stenosis in the intrahepatic ducts (A-1) and hilar hepatic lesions (B-1); intraductal ultrasonography revealing bile duct wall thickening in areas with stenosis (1) and without (2).

reported that 14 (88%) of 16 patients had immunostaining results indicating abundant IgG4-positive cells ( $> 10$  IgG4-positive cells/HPF) in bile duct biopsy specimens. Furthermore, they considered that the absence of malignant cells in the presence of an inflamed mucosa with many IgG4-positive plasma cells provided histological evidence to support the diagnosis of IgG4-SC. However, we were unable to diagnose any case as IgG4-SC on the basis of hematoxylin-eosin and elastin-van Gieson staining alone<sup>[3]</sup>. Abundant IgG4-positive plasma cells were observed in only three (18%) of 17 patients. We were able to diagnose IgG4-SC in only three patients (18%) on

the basis of its characteristic histopathological features. However, it was possible to rule out CC by transpapillary biopsy. In addition, one of 11 CC cases presented with abundant IgG4-positive plasma cells. Zhang *et al.*<sup>[32]</sup> also reported that abundant IgG4-positive plasma cells were evident in seven (18%) of 38 cases of CC. Harada *et al.*<sup>[44]</sup> reported that CC cells could play the role of nonprofessional antigen-presenting cells and Foxp3-positive regulatory cells, inducing IgG4 reactions *via* the production of interleukin-10 indirectly and directly, respectively.

We could rule out CC by transpapillary biopsy. The superficial nature of endoscopic biopsy specimens lim-

its usefulness for demonstrating the characteristic histological features of IgG4-SC. However, Kawakami *et al.*<sup>[34]</sup> reported that the diagnostic rate from ampullary and bile duct biopsies was 52% (15/29 cases) based on the threshold of 10 IgG4-positive plasma cells per HPF, and that bile duct biopsy was valuable for patients with swelling of the pancreatic head. Ampullary biopsy is sometimes useful in the diagnosis of AIP and IgG4-SC<sup>[45,46]</sup>.

Itoi *et al.*<sup>[47]</sup> reported that cholangioscopy was useful in differentiating IgG4-SC from PSC and that monitoring patterns of proliferative vessels on video peroral cholangioscopy may be useful in differentiating IgG4-SC from CC.

### Treatment and prognosis

Although some patients responded to biliary drainage or surgical resection, IgG4-SC displays a good response to steroid therapy, as is the case for pancreatic lesions.

Nishino *et al.*<sup>[11]</sup> reported that bile duct stricture improved to various degrees in all 10 patients treated by steroid therapy but persisted in the lower part of the bile duct in four patients. Hirano *et al.*<sup>[48]</sup> reported that steroid therapy could reduce AIP-related unfavorable events and that multivariate analysis indicated that steroid therapy and obstructive jaundice at onset were significant factors predictive of unfavorable events. Thus, early introduction of steroid therapy is recommended, especially for patients with obstructive jaundice. Ghazale *et al.*<sup>[15]</sup> reported the clinical courses after steroid treatment ( $n = 30$ ), surgical resection ( $n = 18$ ), and conservative management ( $n = 5$ ). Relapses occurred in 53% of cases after steroid withdrawal, whereas 44% relapsed after surgery and were further treated with steroids. The presence of proximal extrahepatic/intrahepatic strictures was predictive of relapse. Steroid therapy normalized liver enzyme levels in 61% of patients, and it was possible to remove biliary stents in 17 of 18 patients. Fifteen patients treated with steroids for relapse after steroid withdrawal responded to the treatment, and seven treated with additional immunomodulatory drugs reportedly remained in steroid-free remission. Topazian *et al.*<sup>[49]</sup> reported that biliary strictures in one patient improved after rituximab therapy and thus the biliary stents were removed. However, the role of immunomodulatory drugs for relapse warrants further study. In one of our series, six of seven cases of IgG4-SC without steroid therapy and IgG levels  $> 2000$  mg/dL were associated with significantly higher incidence of recurrence or progression<sup>[50]</sup>.

Morphological and functional changes in the liver and bile ducts in IgG4-SC during long-term observation have not yet been reported. Our long-term follow-up of IgG4-SC cases without steroid therapy revealed that two patients developed portal obstruction and liver atrophy but no sign of liver cirrhosis or failure<sup>[51]</sup>. Ghazale *et al.*<sup>[15]</sup> reported that four of 53 patients displayed portal hypertension and liver cirrhosis during their clinical courses. It is possible that persistent jaundice without steroid administration could result in liver failure, thus necessitating

orthotopic liver transplantation. However, further study is needed to elucidate the long-term outcome of IgG4-SC.

### Steroid trial

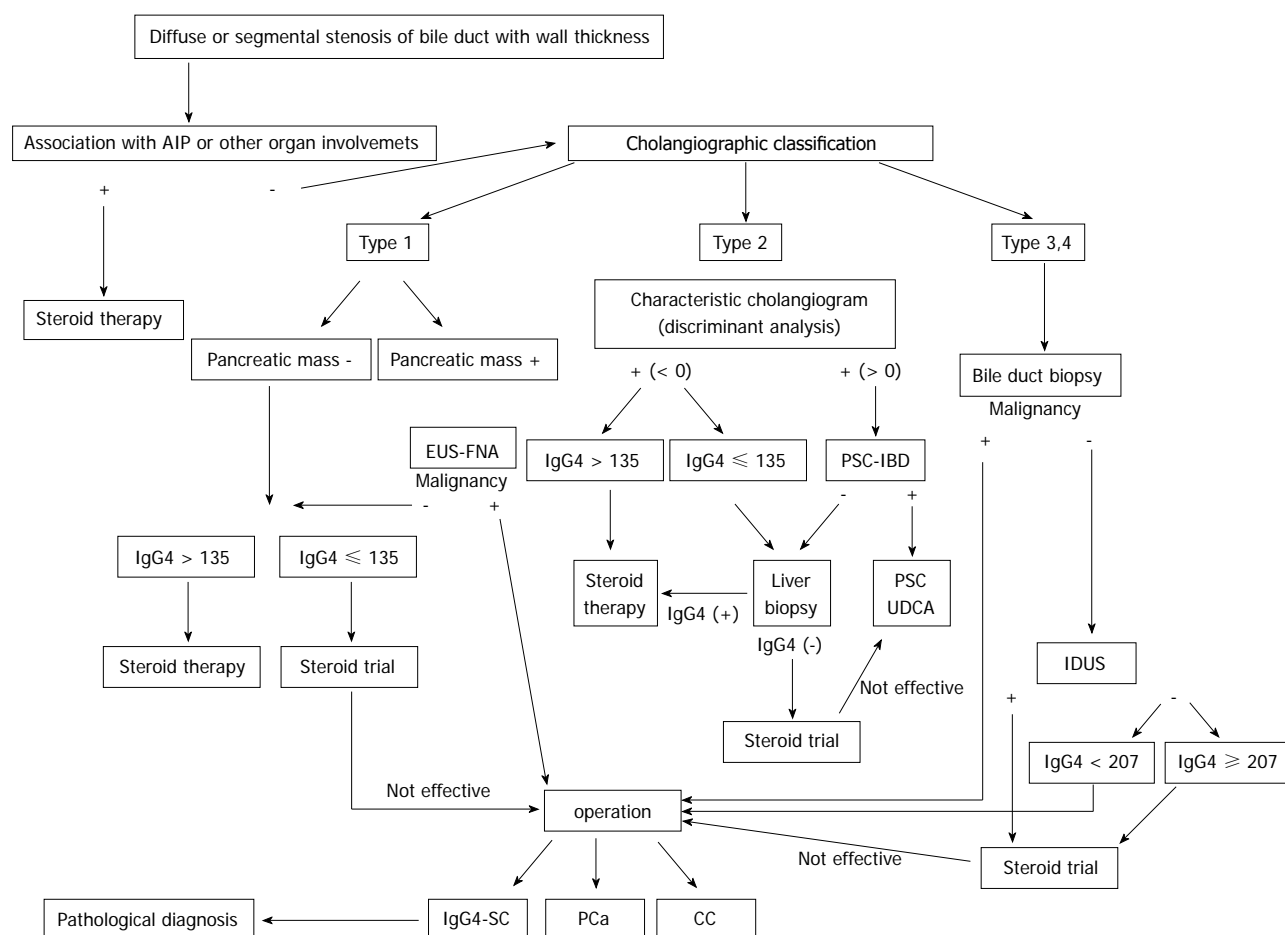

Although, generally, diagnosis should be made before starting therapy, a steroid trial is needed in some cases<sup>[52]</sup>. If a diagnosis cannot be clearly established in type 2 IgG4-SC, then a steroid trial is recommended. If malignancy is not confirmed by bile duct biopsy in types 3 and 4 IgG4-SC and bile duct wall thickening that appears normal on a cholangiogram, a steroid trial is an option. No reports on any steroid trial for IgG4-SC have been published thus far. A short-term steroid trial should be performed carefully only by specialists in pancreatic and biliary diseases. In addition, steroid pulse therapy is also an option<sup>[53]</sup>. Advanced-stage IgG4-SC may sometimes be unresponsive to steroid therapy because cases of AIP and IgG4-SC show a predominantly inflammatory nature at the early stage, followed by relatively less inflammation but marked fibrous scarring later. This should be kept in mind when attempting a steroid trial for IgG4-SC diagnosis<sup>[54]</sup>. The time frame for a steroid trial for IgG4-SC remains unknown. When a cholangiogram is indicative of type 1, 3 or 4 IgG4-SC, IgG4-SC should be discriminated from PCa or CC. It is important not to delay the timing of surgery by performing a long-term steroid trial. If a cholangiogram is indicative of type 2 IgG4-SC, IgG4-SC should be discriminated from PSC. Sufficient time should be devoted to a steroid trial only if an increased risk of biliary infection can be avoided.

### Diagnostic criteria

Only three sets of diagnostic criteria for IgG4-SC have been proposed<sup>[15,20,24]</sup>. AIP should be clinically discriminated only from PCa. However, IgG4-SC should be discriminated from all of the three intractable diseases, that is, PCa, PSC, and CC. Therefore, diagnostic criteria that take into account the differential diagnosis between these three intractable diseases need to be established<sup>[22]</sup>. Our diagnostic criteria provide a concrete diagnostic algorithm for IgG4-SC (Figure 4). Association with AIP and other organ involvements are common useful diagnostic parameters in all three IgG4-SC types. Characteristic cholangiogram, liver biopsy and exclusion of IBD are useful parameters in type 2 IgG4-SC. IDUS findings, exclusion of malignancy by bile duct biopsy and a serum IgG4 cut-off level of 207 mg/dL were useful parameters in type 3 and 4 IgG4-SC. Although, generally, diagnosis should be made before starting therapy, a steroid trial is needed in some cases.

The HISORT criteria for the diagnosis of IgG4-SC<sup>[15]</sup> are based on the characteristic features of IgG4-SC on histological, imaging, and serological examination; other organ involvement; and response to steroid therapy, which parallel the HISORT criteria established for AIP<sup>[55]</sup>.

The Research Committee of IgG4-related Diseases and the Research Committee of Intractable Diseases of Liver and Biliary Tract, in association with the Ministry

**Figure 4** Algorithm for management of IgG4-related sclerosing cholangitis (cited from [22]). CC: Cholangiocarcinoma; PSC: Primary sclerosing cholangitis; IgG4-SC: IgG4-related sclerosing cholangitis; IDUS: Intraductal ultrasonography; EUS-FNA: Endoscopic ultrasound-guided fine needle aspiration; IBD: Inflammatory bowel disease; UDCA: Ursodeoxycholic acid.

of Health, Labor and Welfare, Japan, and the Japan Biliary Association, proposed clinical diagnostic criteria for IgG4-SC in 2012<sup>[20]</sup>. These diagnostic criteria also include the concept of differential diagnosis based on cholangiographic classification.

## CONCLUSION

Since IgG4-SC was first described, it has become a third distinct clinical entity of SC. IgG4-SC should be carefully diagnosed based on a combination of characteristic clinical, serological, morphological, and histopathological features after cholangiographic classification and targeting of a disease for differential diagnosis.

### Abstract

**AIM:** To examine the efficacy of telbivudine (LdT) + adefovir (ADV) *vs* continuation of lamivudine (LAM) + ADV in patients with LAM-resistant chronic hepatitis B (CHB) who show a suboptimal response to LAM + ADV.

**METHODS:** This was a randomized, active-control, open-label, single-center, parallel trial. All eligible patients were enrolled in this study in Severance Hospital, Yonsei University College of Medicine, Seoul, South Korea, between March 2010 and March 2011. Hepatitis Be antigen (HBeAg)-positive CHB patients whose serum hepatitis B virus (HBV) DNA remained detectable despite at least 6 mo of LAM + ADV therapy were included. Enrolled patients were randomized to either switching to LdT (600 mg/d orally) plus ADV (10 mg/d orally) (LdT + ADV group) or to continuation with LAM (100 mg/d orally) plus ADV (10 mg/d orally) (LAM + ADV group), and were followed for 48 wk. One hundred and six patients completed the 48-wk treatment period. Serum HBV DNA, HBeAg status, liver biochemistry and safety were monitored at baseline and week 12, 24, 36 and 48.

**RESULTS:** The duration of prior LAM + ADV treatment was 18.3 (LdT + ADV) and 14.9 mo (LAM + ADV), respectively ( $P = 0.131$ ). No difference was seen in baseline serum HBV DNA between the two groups [3.66 (LdT + ADV) *vs* 3.76 (LAM + ADV)  $\log_{10}$  IU/mL,  $P = 0.729$ ]. At week 48, although there was no significant difference in the mean reduction of serum HBV DNA from baseline between LdT + ADV group and LAM + ADV group ( $-0.81$  *vs*  $-0.47$   $\log_{10}$  IU/mL,  $P = 0.167$ ), more patients in the LdT + ADV group had undetectable HBV DNA levels compared to those in the LAM + ADV group (30.2% *vs* 11.5%,  $P = 0.019$ ). Three patients with LdT + ADV treatment and 2 patients with LAM + ADV treatment achieved HBeAg loss. The patients in both groups tolerated the treatment well without serious adverse

events. The proportion of patients with estimated glomerular filtration rate  $\geq 90$  mL/min per  $1.73\text{ m}^2$  in the LdT + ADV group increased from 49.1% (26/53) at baseline to 58.5% (31/53) at week 48, while that in the LAM + ADV group decreased from 37.7% (20/53) at baseline to 30.2% (16/53) at week 48.

**CONCLUSION:** The switch to LdT + ADV in suboptimal responders to LAM + ADV showed a significantly higher rate of virologic response at week 48. These results suggest that LdT + ADV could be a therapeutic option for patients who are unable to use enofovir disoproxil fumarate for any reason.

© 2013 Baishideng Publishing Group co., Limited. All rights reserved.

**Key words:** Chronic hepatitis B; Antiviral resistance; Suboptimal response; Telbivudine; Lamivudine

**Core tip:** A suboptimal response is common in patients treated with lamivudine (LAM) + adefovir (ADV) combination therapy and it has also become a new challenge for the management of chronic hepatitis B (CHB) patients. We commenced this study with the effect of telbivudine (LdT) + ADV combination therapy as a rescue therapeutic option in LAM-resistant CHB patients with suboptimal response to LAM + ADV. Our results demonstrated that switching from LAM + ADV to LdT + ADV resulted in superior virologic response, renoprotective effect and similar safety profiles at week 48. These results suggest that LdT + ADV could be a therapeutic option for patients who are unable to use enofovir disoproxil fumarate for any reason.

Efficacy of switching to telbivudine plus adefovir in suboptimal responders to lamivudine plus adefovir. *World J Gastroenterol* 2013; 19(43): 7671-7679 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i43/7671.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7671>

## INTRODUCTION

Worldwide, over 400 million people suffer from chronic hepatitis B (CHB). Patients with CHB have a 15%-40% life-time risk of developing cirrhosis, hepatic decompensation and hepatocellular carcinoma (HCC)<sup>[1,2]</sup>. High hepatitis B virus (HBV) DNA concentration in serum in patients with CHB is known as an independent risk factor for disease progression to cirrhosis and HCC<sup>[2,3]</sup>. Therefore, the treatment goal of antiviral therapy for CHB is to achieve complete suppression of viral replication as rapidly as possible<sup>[4-6]</sup>, because prolonged viremia on therapy can lead to a higher risk of future antiviral drug resistance and therapeutic failure as well as disease progression<sup>[2,7,8]</sup>.

Lamivudine (LAM) has been widely used for treatment

of CHB since its first approval at 2002. However, a major limitation of LAM is the development of LAM-resistant YMDD-motif mutations in the viral DNA polymerase, the prevalence of which increases progressively to about 70% after 4 years of treatment<sup>[9]</sup>. In patients resistant to LAM, add-on combination therapy with LAM and adefovir (ADV) has resulted in lower rates of virologic breakthrough and additional development of genotypic resistance than when switching to ADV or entecavir<sup>[10,11]</sup>. Thus, LAM + ADV combination therapy has been recommended as a rescue therapy in patients with LAM resistant viral strains in many Asian countries, for its considerable effectiveness, lower resistance and affordable price<sup>[5]</sup>.

Unfortunately, a substantial proportion of patients treated with LAM + ADV combination therapy show a suboptimal virologic response<sup>[10-12]</sup>. Because there has been evidence that this suboptimal response to antiviral therapy might have clinical relevance to higher risk of developing resistance to long-term antiviral treatment, suboptimal response to nucleotide analogues (NAs), in addition to drug resistance, has also become a new challenge for the management of CHB patients<sup>[13-15]</sup>. However, there is no standard optimal strategy for the management of suboptimal response to NA therapy at present. Many practice guidelines suggest a combination treatment regimen with tenofovir disoproxil fumarate (TDF) which is a NA with a high barrier to resistance as a highly potent rescue therapeutic option<sup>[4,6]</sup>. TDF, however, remains largely unavailable in Asian countries. Thus, several trials with various combination regimens for these populations have been proceeded<sup>[16,17]</sup>, and the results suggested consistently that combination therapy rather than switching to another drug offers a potentially attractive therapeutic option.

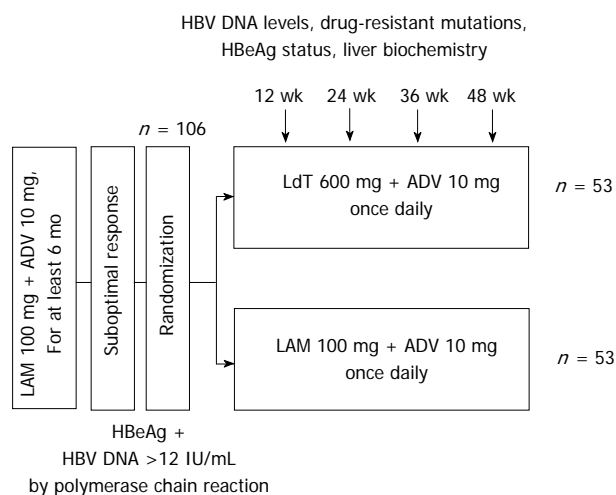

Telbivudine (LdT) is one of the licensed NAs which is structurally related to LAM and highly selective for HBV DNA and inhibits viral DNA synthesis with no effect on human DNA or other viruses<sup>[18]</sup>. The Gestation Linked to Obesity and Environment (GLOBE), the largest trial in CHB, demonstrated that LdT is superior to LAM for all efficacy measures over 2 years of therapy<sup>[19,20]</sup>. Another trial showed a superior viral suppressive effect of LdT even to ADV in treatment naïve CHB patients<sup>[21]</sup>. In addition, LdT + ADV combination treatment showed better outcomes against LAM-resistant HBV than ADV alone<sup>[22]</sup>. Therefore, LdT is a therapeutic option in LAM-resistant hepatitis B patients with suboptimal response to LAM + ADV combination therapy.

In this study, we directly compared the antiviral efficacy of switching to LdT + ADV combination vs LAM + ADV continuation in hepatitis Be antigen (HBeAg) positive LAM-resistant hepatitis B patients who showed suboptimal response to LAM + ADV combination treatment.

## MATERIALS AND METHODS

### Patients

Patients eligible for this study were men and women, aged over 20 years, positive for serum hepatitis B surface antigen (HBsAg) for at least 6 mo, and positive for HBeAg.

**Figure 1** Flow diagram of study participants. LMA: Lamivudine; ADV: Adefovir; LdT: Telbivudine; HBV: High hepatitis B virus; HBeAg: Hepatitis Be antigen.

Inclusion criteria were confirmed mutations in the HBV polymerase gene that confers resistance to LAM (rtM204V/I and/or rtL180M), and serum HBV DNA concentration > 12 IU/mL after combination treatment with LAM (100 mg/d) plus ADV (10 mg/d) for at least 6 mo that was ongoing at the time of randomization. Patients were expected to have well-preserved liver function (Child-Pugh score  $\leq 6$ ) and no history of ascites, variceal bleeding, or encephalopathy.

Patients were excluded if they had previous or current HCC; prior treatment with an antiviral agent other than LAM and/or ADV; coinfection with hepatitis C, hepatitis D, or human immune deficiency virus; concurrent systemic corticosteroids or other immunosuppressive agents; history of alcohol or substance abuse; or other current liver diseases, prior organ transplantation, or a history of malignancy within 3 years.

### Study design

This was a randomized, active-control, open-label, single-center, parallel trial. All eligible patients were enrolled in this study in Severance Hospital, Yonsei University College of Medicine, Seoul, Korea, between March 2010 and March 2011. Patients were randomized to either switching to LdT (600 mg/d orally) plus ADV (10 mg/d orally) (LdT + ADV group) or to continuation with LAM (100 mg/d orally) plus ADV (10 mg/d orally) (LAM + ADV group), and were followed for 48 wk. Randomized patients were evaluated at baseline and week 12, 24, 36 and 48. At each visit, hematology, biochemistry, and prothrombin time/international normalized ratio were assessed. HBV DNA level was measured at baseline and week 12, 24, 36 and 48, using a real-time Polymerase Chain Reaction assay (Abbott Laboratories, Chicago, IL) with a linear dynamic detection range of 12 to  $1 \times 10^9$  IU/mL. Multiplex Restriction fragment mass polymorphism (RFMP) assays of the HBV genome were performed to detect LAM and ADV resistance mutations at baseline and at times as needed<sup>[23]</sup>. Because over 98%

of South Korean patients with CHB have HBV genotype C<sup>[24,25]</sup>, HBV genotype was not determined. HBeAg and anti-HBeAb were assessed at baseline and at week 48, using commercially available enzyme immunoassays (Abbott Laboratories)<sup>[26,27]</sup>. The upper limit of normal (ULN) alanine aminotransferase (ALT) was defined as 40 IU/L. Occurrences of adverse events were assessed at every visit through week 48.

The study was conducted in accordance with the ethical principles of the Declaration of Helsinki and the Guidelines for Good Clinical Practice as well as local regulatory requirements. This study was approved by the Institutional Review Board of Yonsei University of Medical College, and written informed consent was obtained from all patients. This study was registered at ClinicalTrials.gov, number NCT01270165 (<http://www.clinicaltrials.gov/ct2/show/NCT01270165>).

### Study endpoints

The primary endpoint was the proportion of patients in each treatment group who achieved virologic response (serum HBV DNA concentration of < 12 IU/mL) at week 48. Secondary endpoints included mean reduction from baseline in serum HBV DNA concentration at week 48, the proportion of patients with normalized serum ALT levels, HBeAg loss or seroconversion at week 48, and emergence of resistance mutation to drug during study period.

### Statistical analysis
