The variables were expressed as mean with SD or ranges, or *n* (%), as appropriate. The  $\chi^2$  or Fisher's exact test and the Mann-Whitney *U* test were used to compare categorical and continuous variables, respectively. Paired related data were analyzed using the Wilcoxon paired test. A two-sided *P* value < 0.05 was considered to indicate statistical significance. All statistical analyses were performed with SPSS 18.0 (SPSS Inc., Chicago, IL, United States).

## RESULTS

### Baseline characteristics of patients

One hundred and ten patients were screened from March 2010 to March 2011, and 106 were randomized (53 in each group). All patients completed 48 wk of treatment after randomization; thus, data from all 106 patients randomized were available for the intention-to-treat analysis (Figure 1).

Overall baseline characteristics of all patients as well as of each group are shown in Table 1. Twenty-four (22.6%) patients had cirrhosis with well-preserved liver function. The mean (SD) serum HBV DNA levels was 3.71 (1.46) log<sub>10</sub> IU/mL. The mean (ranges) duration of LAM + ADV treatment prior to randomization was 17.1 (6-45) mo. At baseline, all patients had LAM resistance mutations, including 27 (25.5%) with rtM204I alone, 1 (0.9%) with rtM204I + rtM204V, 28 (26.4%) with rtM204I + rtL180M, 28 (26.4%) with rtM204V + rtL180M and 22 (20.8%) with rtM204I + rtM204V +

rtL180M. There were no genotypic mutations of ADV in all patients at the baseline. Demographic and laboratory characteristics were similar between the two treatment groups, and mean (SD) serum HBV DNA levels in the LdT + ADV group and LAM + ADV group were 3.66 (1.65) log<sub>10</sub> IU/mL and 3.76 (1.25) log<sub>10</sub> IU/mL, respectively ( $P = 0.729$ ). There was no difference in the mean duration of prior LAM treatment as well as that of LAM + ADV treatment prior to randomization between the two groups (prior LAM period, 31.5 mo *vs* 33.5 mo,  $P = 0.695$ ; LAM + ADV period prior to randomization, 18.3 mo *vs* 14.9 mo,  $P = 0.131$ ).

### Virologic response

The efficacy of treatment in the LdT + ADV and LAM

+ ADV groups are summarized and compared in Table 2 and Figures 2-4. During treatment, the number of patients who achieved virologic response (serum HBV DNA level of < 12 IU/mL) gradually increased to 16 (30.2%) patients at week 48 in the LdT + ADV group. In contrast, the number of patients with virologic response in the LAM + ADV group was consistently lower than those in the LdT + ADV group from week 12 to week 48, and only 6 (11.5%) patients in the LAM + ADV group showed virologic response at week 48. The primary efficacy endpoint, the proportion of patients who achieved HBV DNA level of < 12 IU/mL at week 48, differed significantly between the two groups (30.2 % *vs* 11.5 %, respectively,  $P = 0.019$ ) (Figure 2 and Table 2).

<sup>1</sup>Reduction of hepatitis B virus (HBV) DNA from baseline; <sup>2</sup>Defined serum HBV DNA of < 12 IU/mL; <sup>3</sup>Defined as a < 1 log<sub>10</sub> IU/mL reduction in serum HBV DNA level from baseline at 24 wk; <sup>4</sup>Upper normal limit of ALT, 40 IU/L; <sup>5</sup>Among patients who have elevated ALT levels at baseline. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; LAM: Lamivudine; ADV: Adefovir. HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis Be antigen.

**Figure 4** Mean reduction of serum hepatitis B virus DNA levels from baseline. Mean hepatitis B virus (HBV) DNA (log<sub>10</sub> IU/mL) were plotted over time. Error bars indicate the standard deviation (<sup>a</sup>*P* value < 0.05). LAM: Lamivudine; ADV: Adefovir; LdT: Telbivudine.

ADV group was significantly lower than that of the LAM + ADV group at week 12 and week 24 [3.05 (1.51) log<sub>10</sub> IU/mL *vs* 3.84 (1.35) log<sub>10</sub> IU/mL at week 12, *P* = 0.011; 2.79 (1.52) log<sub>10</sub> IU/mL *vs* 3.65 (1.44) log<sub>10</sub> IU/mL at week 24, *P* = 0.003] (Table 2 and Figure 3). However, there was no statistically significant difference in serum HBV DNA levels between the LdT + ADV group and the LAM + ADV group [2.85 (1.73) log<sub>10</sub> IU/mL *vs* 3.29 (1.49) log<sub>10</sub> IU/mL at 48 wk, *P* = 0.168] (Figure 3).

The mean reduction of serum HBV DNA levels from baseline to week 12 or week 24 was significantly greater in the LdT + ADV than in the LAM + ADV group (-0.68 log<sub>10</sub> IU/mL *vs* 0.07 log<sub>10</sub> IU/mL; *P* < 0.001, -0.88 log<sub>10</sub> IU/mL *vs* -0.11 log<sub>10</sub> IU/mL; *P* < 0.001, respectively) (Figure 4 and Table 2). At week 48, however, there was no significant difference in the mean reduction of serum HBV DNA from baseline between the LdT + ADV group and the LAM + ADV group (-0.81 log<sub>10</sub> IU/mL *vs* -0.47 log<sub>10</sub> IU/mL, *P* = 0.167; Table 2 and Figure 4).

The number of patients with virologic nonresponse, defined as < 1 log<sub>10</sub> IU/mL reduction in serum HBV DNA level from baseline at week 24, was significantly lower in the LdT + ADV group than in the LAM + ADV

group [33 (62.3%) *vs* 48 (90.6%), respectively, *P* = 0.001] (Table 2). A total of 8 patients experienced virologic breakthrough ( $\geq 1$  log<sub>10</sub> IU/mL increase in serum HBV DNA from nadir during treatment), 4 patients in the LdT + ADV group and 4 patients in the LAM + ADV group. Most of them (6/8) had poor compliance for taking medication, and there was no new emergence of drug resistance for LAM or ADV in the RFMP examination conducted at the time of virologic breakthrough.

### Biochemical and serologic response

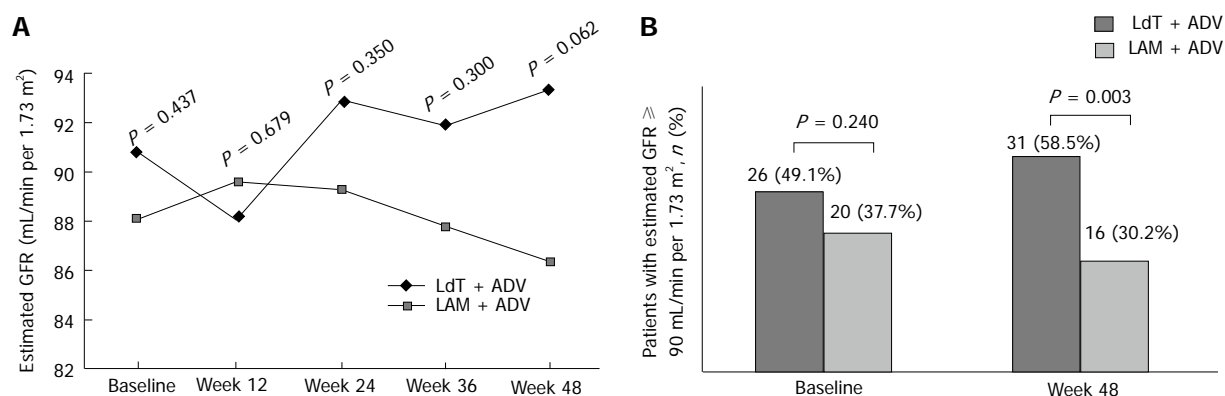

The proportion of patients with normal serum ALT levels at week 48 did not differ significantly between the LdT + ADV group and the LAM + ADV group (75.5% *vs* 71.7%, respectively; *P* = 0.768) (Table 2). Among patients with elevated ALT at baseline, the proportion of patients achieving normalized ALT at week 48 in the LdT + ADV group and LAM + ADV group were 57.1% (8/14) and 21.4% (3/14), respectively, and the difference showed borderline significance between the two groups (*P* = 0.053) (Table 2).

Three patients (5.7%) in the LdT + ADV group and 2 patients (3.8%) in the LAM + ADV group became HBeAg negative at week 48 (*P* = 0.648; Table 2). No patient achieved loss of HBsAg during the treatment period.

### Safety

The majority of patients in the LdT + ADV and LAM + ADV groups tolerated the treatment well without serious adverse events. No patient required dose reduction or discontinuation of treatment due to an adverse event. No patient experienced ALT flare ( $> 10 \times$  ULN), increased serum creatinine kinase level of  $> 150$  U/L, or serum phosphorus level of  $< 1.5$  mg/dL during the treatment period. Neither group reported decompensated cirrhosis or hepatocellular carcinoma from baseline to week 48.

No patient was found to have an elevation of creatinine  $\geq 0.5$  mg/dL. The mean estimated glomerular filtration rate (eGFR) is shown in Figure 5A. Although statistical significance did not exist, eGFR in the LdT + ADV group tended to increase during the treatment pe-

**Figure 5** Estimated glomerular filtration rate over time in the two groups (A), and proportion of patients with estimated glomerular filtration rate  $\geq 90$  mL/min per  $1.73 \text{ m}^2$  at baseline and week 48 (B). LAM: Lamivudine; ADV: Adefovir; HBV: High hepatitis B virus; LdT: Telbivudine. GFR: Glomerular filtration rate

riod, whereas that in the LAM + ADV group tended to decrease. The proportion of patients with eGFR  $\geq 90$  mL/min per  $1.73 \text{ m}^2$  in the LdT + ADV group increased from 49.1% (26/53) at baseline to 58.5% (31/53) at week 48, while that in the LAM + ADV group decreased from 37.7% (20/53) at baseline to 30.2% (16/53) at week 48. The proportion of patients with eGFR  $\geq 90$  mL/min per  $1.73 \text{ m}^2$  was significantly higher in the LdT + ADV group than in the LAM + ADV group at week 48 (58.5% *vs* 30.2%;  $P = 0.003$ ) (Figure 5B). Twenty-six percent (7/27) of the patients with baseline eGFR  $< 90$  mL/min per  $1.73 \text{ m}^2$  shifted to eGFR  $\geq 90$  mL/min per  $1.73 \text{ m}^2$  after 48 wk of LdT + ADV treatment, as compared to 15.2% (5/33) in the LAM + ADV group ( $P = 0.299$ ).

## DISCUSSION

This study is the first study that provides a direct comparison of the antiviral efficacy of LdT + ADV and LAM + ADV in HBeAg-positive LAM resistant CHB patients who have suboptimal response to LAM + ADV. The results of this study show that treatment with LdT + ADV significantly suppressed HBV replication and more patients with LdT + ADV achieved virologic response compared to those with LAM + ADV after 48 wk of treatment. The difference in viral suppressive effect between the two groups was greatest at week 24, which decreased gradually thereafter.

The combination of LAM and ADV has been recommended as a treatment option for patients with LAM resistant CHB<sup>[4-6]</sup>. Because of the unavailability of TDF in many Asian countries, ADV has been used widely as a combination treatment regimen. However, due to the weak antiviral activity of ADV<sup>[28]</sup> and poor susceptibility for drug-resistant viral strains, suboptimal response is particularly common in patients who received LAM + ADV<sup>[29,30]</sup>. Evidence has shown that the persistence of suboptimal response during long-term antiviral treatment is associated with the emergence of multi-drug resistant viral strains, which could result in poorer clinical outcomes<sup>[31,32]</sup>. Thus, management of a suboptimal response to antiviral therapy has recently been of new concern,

and combination with other NAs rather than switching to monotherapy offers a potentially attractive therapeutic option<sup>[33,34]</sup>.

Based on the superior efficacy of LdT over LAM shown in the GLOBE trial<sup>[35]</sup>, a recent study examined switching patients who remained viremic under LAM treatment to LdT and demonstrated that early ( $\leq 24$  wk) switch to LdT improves virologic outcomes in CHB patients with persistent viral replication under LAM treatment<sup>[36]</sup>. In addition, previous two independent short-term studies on patients with poor response to ADV monotherapy demonstrated that a higher proportion of patients in the LdT + ADV group achieved a virological response at week 24 than did patients in the LAM + ADV group<sup>[37,38]</sup>. Based on these prior reports, we conducted this study to investigate the efficacy of switching to LdT + ADV as a substitute therapeutic option for patients who showed a suboptimal response to LAM + ADV combination treatment.

In our study, patients who were switched to LdT + ADV had a superior virologic response at 48 wk compared to those who continued LAM + ADV treatment (30.2% *vs* 11.5%,  $P = 0.019$ ). At 48 wk, the mean serum HBV DNA level was lower and the mean reduction from baseline was greater in the LdT + ADV group than in the LAM + ADV (2.85 log<sub>10</sub> IU/mL *vs* 3.29 log<sub>10</sub> IU/mL and -0.81 log<sub>10</sub> IU/mL *vs* -0.47 log<sub>10</sub> IU/mL, respectively), but the differences between the two groups were not statistically significant ( $P = 0.168$  and  $P = 0.167$ , respectively). As described in Table 2, however, differences of both the mean serum HBV DNA levels and the mean reduction of HBV DNA levels from baseline were significant at 12 wk and 24 wk. These results are ascribable to a different rate of decline in serum HBV DNA levels between the two groups. When we analyzed the rate of decline between adjacent time points in the respective treatment groups, we found that there were no statistically significant declines of serum HBV DNA levels as times go by in the LAM + ADV group (Figure 6). Continuing LAM + ADV with suboptimal response offers little antiviral benefit to patients with LAM-resistant HBV and as much as 90.6% of patients who continued on LAM + ADV re-

**Figure 6** Serial changes of mean serum hepatitis B virus DNA levels. Serum hepatitis B virus DNA levels decreased significantly not only from baseline to 12 wk but also from 12 wk to 24 wk in the LdT + ADV group. LAM: Lamivudine; ADV: Adefovir; HBV: High hepatitis B virus; LdT: Telbivudine.

remained as virologic non-responders (defined as  $< 1 \log_{10}$  IU/mL reduction in baseline serum HBV DNA level at 24 wk) at week 24. In contrast, serum HBV DNA levels decreased significantly not only from baseline to 12 wk but also from 12 wk to 24 wk in the LdT + ADV group ( $P < 0.001$  and  $P = 0.049$ , respectively) (Figure 6). This suggests that the viral suppressive effect emerged in the LdT + ADV group particularly during the early treatment period.

Considering the significantly decreased serum HBV DNA level in the LdT + ADV group during the early treatment period, we speculated the good virologic response in this group may be related to the effect of LdT, because evidence in treatment-naïve patients demonstrates that LdT could significantly increase the rate of virologic response compared to LAM as well as ADV<sup>[19,39,40]</sup>. However, the rate of serum HBV DNA level decline in the LdT + ADV group decreased and became dull at the later part of the study period, which is from week 24 to week 48. It might be correlated to diminished susceptibility to NAs and generally unsatisfying clinical outcomes in a pretreated population with drug-resistant HBV compared to a treatment-naïve population<sup>[41-43]</sup>. Another possible explanation is that the emergence of ADV-resistant HBV strains following suboptimal response to LAM + ADV might attenuate the superior viral suppressive effect of LdT to that of LAM in these study patients. This is supported by a recent study which reported no differences in virologic and biochemical responses in the comparison of two treatments, LdT + ADV and LAM + ADV, in CHB patients with suboptimal response to ADV monotherapy<sup>[44]</sup>.

HBeAg loss is the key goal of antiviral therapy for HBeAg-positive CHB patients, which indicates good prognosis, including lower rates of cirrhosis and slower disease progression<sup>[3,6,45,46]</sup>. In our study, we reported quite low rates of HBeAg loss, with 5.7% in the LdT + ADV group and 3.8% in the LAM + ADV group, suggesting that this pretreated population is particularly refractory to serologic response. It has been reported that HBeAg loss is less common in patients with LAM-resistant mutation

than in those with wild-type HBV, regardless of the adequate rescue therapy<sup>[41-43]</sup>.

Both treatments were well tolerated and showed similar safety profiles. Patients who switched from LAM + ADV to LdT + ADV did not experience any additional spectrum of adverse effects. Interestingly, we found that the patients in the LdT + ADV group showed a favorable effect of improved renal function compared to those in the LAM + ADV group during the treatment period. Although the mechanism has not been clarified, there have been several reports that LdT treatment is associated with renoprotective effects in patients with CHB<sup>[47,48]</sup>. Considering the risk of renal impairment of ADV, the renoprotective effect of LdT could be complementary in patients who were treated with ADV for a long term period.

There are some limitations in this study. First, this prospective study has small sample size and a potential bias. Relatively short follow-up duration was another limitation. Thus, further well controlled studies with sufficient size and longer duration of follow-up are needed.

In conclusion, this trial demonstrated that switching from LAM + ADV to LdT + ADV in LAM-resistant CHB patients with suboptimal response resulted in superior virologic response, renoprotective effect and similar safety profiles at week 48. These results suggest that CHB patients with LAM-resistant HBV and suboptimal response to LAM + ADV treatment should be considered for switching to other combination regimens using more potent drugs. LdT + ADV could be a therapeutic option for patients who are unable to use TDF for any reason. However, a stronger rescue combination therapy should be investigated in this population.

## ACKNOWLEDGMENTS

This study was supported by the Liver Cirrhosis Clinical Research Center, a grant from the Korea Healthcare Technology R and D project, Ministry of Health and Welfare, South Korea (HI10C2020), and a grant to the Bilateral International Collaborative R and D Program from the Ministry of Trade, Industry and Energy, Republic of Korea. ## COMMENTS

### Background

A substantial proportion of patients treated with lamivudine (LAM) + adefovir (ADV) combination therapy show a suboptimal virologic response. Because there has been evidence that this suboptimal response to antiviral therapy might have clinical relevance to higher risk of developing resistance to long-term antiviral treatment, suboptimal response to nucleotide analogues, in addition to drug resistance, has also become a new challenge for the management of chronic hepatitis B (CHB) patients. However, there is no standard optimal strategy for the management of suboptimal response to nucleotide analogue therapy at present.

## Research frontiers

This study is the first study that provides a direct comparison of the antiviral efficacy of telbivudine (LdT) + ADV and LAM + ADV in hepatitis Be antigen-positive LAM resistant CHB patients who have suboptimal response to LAM + ADV.

## Innovations and breakthroughs

Our results demonstrated that switching from LAM + ADV to LdT + ADV in LAM-resistant CHB patients with suboptimal response resulted in superior virologic response, renoprotective effect and similar safety profiles at week 48.

## Applications

From our study, it was suggested that LdT + ADV could be a therapeutic option for patients who are unable to use tenofovir disoproxil fumarate for any reason.

## Peer review

The authors described a comparison of combination therapy of telbivudine plus adefovir vs lamivudine plus adefovir. This is the first comparison study about these 2 different combination therapies. This information is very important for future antiviral therapy of chronic B hepatitis. Furthermore, the study design is well organized and data is analyzed very well.

### Abstract

**AIM:** To evaluate whether 8-bromo-7-methoxychrysin (BrMC), a synthetic analogue of chrysin, inhibits the properties of cancer stem cells derived from the human liver cancer MHCC97 cell line and to determine the potential mechanisms.

**METHODS:** CD133<sup>+</sup> cells were sorted from the MHCC97 cell line by magnetic activated cell sorting, and amplified in stem cell-conditioned medium to obtain the enriched CD133<sup>+</sup> sphere forming cells (SFCs). The stem cell properties of CD133<sup>+</sup> SFCs were validated by the tumorsphere formation assay *in vitro* and the xenograft nude mouse model *in vivo*, and termed liver cancer stem cells (LCSCs). The effects of BrMC on LCSCs *in vitro* were evaluated by MTT assay, tumorsphere formation assay and transwell chamber assay. The effects of BrMC on LCSCs *in vivo* were determined using

a primary and secondary xenograft model in Balb/c-nu mice. Expressions of the stem cell markers, epithelial-mesenchymal transition (EMT) markers and  $\beta$ -catenin protein were analyzed by western blotting or immunohistochemical analysis.

**RESULTS:** CD133<sup>+</sup> SFCs exhibited stem-like cell properties of tumorsphere formation and tumorigenesis capacity in contrast to the parental MHCC97 cells. We found that BrMC preferentially inhibited proliferation and self-renewal of LCSCs ( $P < 0.05$ ). Furthermore, BrMC significantly suppressed EMT and invasion of LCSCs. Moreover, BrMC could efficaciously eliminate LCSCs *in vivo*. Interestingly, we showed that BrMC decreased the expression of  $\beta$ -catenin in LCSCs. Silencing of  $\beta$ -catenin by small interfering RNA could synergize the inhibition of self-renewal of LCSCs induced by BrMC, while Wnt3a treatment antagonized the inhibitory effects of BrMC.

**CONCLUSION:** BrMC can inhibit the functions and characteristics of LCSCs derived from the liver cancer MHCC97 cell line through downregulation of  $\beta$ -catenin expression.

**Key words:** Liver cancer; Cancer stem cell; 8-bromo-7-methoxychrysin; Self-renewal;  $\beta$ -catenin

**Core tip:** We successfully obtained liver cancer stem cells (LCSCs) from the liver cancer MHCC97 cell line by employing the combination of magnetic activated cell sorting and tumorsphere culture. We showed for the first time that 8-bromo-7-methoxychrysin (BrMC), a synthetic analogue of chrysin, could preferentially inhibit proliferation and self-renewal, suppress epithelial-mesenchymal transition and invasion of LCSCs, and further eradicate LCSCs *in vivo*. The results of this study support the use of BrMC for liver cancer chemopreven-

tion or chemotherapy.

Quan MF, Xiao LH, Liu ZH, Guo H, Ren KQ, Liu F, Cao JG, Deng XY. 8-bromo-7-methoxychrysin inhibits properties of liver cancer stem cells *via* downregulation of  $\beta$ -catenin. *World J Gastroenterol* 2013; 19(43): 7680-7695 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7680.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7680>

## INTRODUCTION

Human liver cancer is the fifth most common cancer in the world and the third leading cause of cancer-related death<sup>[1,2]</sup>. Although surgery, liver transplantation or chemotherapy offers the possibility of prolonged survival for liver cancer patients, mortality still remains high, largely due to recurrence and drug-resistance<sup>[3,4]</sup>. According to the cancer stem cell hypothesis, this is thought to be due to the survival of a population of chemoresistant cells within the tumor, the cancer stem cells (CSCs) in liver cancer, that are able to regenerate the tumor following chemotherapy<sup>[5]</sup>. However, most currently available therapeutic approaches, including chemotherapy and radiotherapy, lack the ability to effectively kill these CSCs, which may eventually lead to the disease relapse and metastasis<sup>[6,7]</sup>. A number of previous studies have suggested that CD133, originally identified as a hematopoietic stem cell marker, could be used to isolate liver cancer stem cells (LCSCs) from human liver cancer cell lines, xenograft tumors and primary liver cancer specimens<sup>[8-13]</sup>. These CD133<sup>+</sup> liver cancer cells possess many stem cell properties, including extensive proliferation, self-renewal, and differentiation into the bulk of cancer cells. Thus, this minor subpopulation of CD133<sup>+</sup> LCSCs may contribute to the high recurrence rate of liver cancer. Therefore, the identification of a compound that can target LCSCs is one of the main steps in improving overall survival of liver cancer patients.

More recently, a number of studies have found that several dietary compounds can directly or indirectly inhibit cancer stem cell self-renewal pathways<sup>[14]</sup>. For example, natural flavonoid, genistein and a synthetic derivative of daidzein, N-t-boc-daidzein, have been reported to possess inhibitory activity against prostate and epithelial ovarian CSCs, respectively<sup>[15,16]</sup>. Chrysin (5,7-dihydroxyflavone), a naturally widely distributed flavonoid, has been shown to possess promising effects on the inhibition of proliferation and induction of apoptosis in a variety of cancer cells<sup>[17]</sup>. 8-bromo-7-methoxychrysin (BrMC) is a synthetic derivative of chrysin, and our previous study demonstrated the effect of BrMC in inhibiting proliferation and induction of apoptosis in colon, gastric and liver cancer cells was stronger than that of chrysin<sup>[18-21]</sup>.

In this study, we investigated the inhibitory effects of BrMC on the characteristics of LCSCs. We showed for the first time that BrMC was able to inhibit cancer

stem cell-like properties of LCSCs and eliminate LCSCs *in vivo*. We also found that BrMC significantly decreased  $\beta$ -catenin expression in LCSCs and knockdown of  $\beta$ -catenin expression could synergize the inhibition of self-renewal of LCSCs induced by BrMC. Together, our results indicated that the downregulation of  $\beta$ -catenin expression appeared to contribute to the inhibitory effects of BrMC on the properties of LCSCs.

## MATERIALS AND METHODS

### Cell culture and reagents

The human liver cancer MHCC97 cell line was purchased from Fuxiang Biotechnology Co., Ltd. (Shanghai, China). MHCC97 cells were maintained in DMEM supplemented with 10% fetal bovine serum, 100 U/mL penicillin and 100  $\mu$ g/mL streptomycin (Invitrogen Life Technologies, Carlsbad, CA, United States) in an incubator containing 5% CO<sub>2</sub> at 37 °C. Wnt3a-conditioned medium was prepared as described by Willert *et al.*<sup>[22]</sup>. BrMC was synthesized as described previously<sup>[18]</sup>. MTT was purchased from Sigma (St. Louis, MO, United States). Fetal bovine serum was from Hangzhou Sijiqing Biological Engineering Materials Co., Ltd. (Hangzhou, China). Trypsin and DMSO were from Amersco Company (Solon, OH, United States). Antibodies used in this study were as follows: rabbit polyclonal antibodies against ZO-1 (Abcam, Cambridge, MA, United States), mouse monoclonal antibodies against N-cadherin (Upstate Co., Lake Placid, NY, United States), Vimentin (Neo Markers, Fremont, CA, United States), E-cadherin (BD Transduction Labs, Lexington, KY, United States),  $\beta$ -catenin and CD44 (Cell Signaling Technology Inc., Danvers, MA, United States),  $\beta$ -actin (Sigma Chemical Co., St Louis, MO, United States), and horseradish peroxidase-conjugated goat anti-mouse secondary antibody (Santa Cruz Biotechnology, Santa Cruz, CA, United States).

### Cell sorting and flow cytometry

Cell sorting was performed on MHCC97 cells using the cell surface marker CD133<sup>+</sup> with magnetic activated cell sorting (MACS) separation columns (Miltenyi Biotec, Bergisch Gladbach, Germany) according to the manufacturer's protocol. Cells were trypsinized and washed with PBS, and suspended in Phosphate buffered saline (PBS) containing 0.5% Bovine Serum Albumin (BSA). 100  $\mu$ L Fc receptor (FCR) Blocking Reagent (anti-CD133 antibody) and 100  $\mu$ L CD133-conjugated MicroBeads (AC133, Cell Isolation Kit, Miltenyi Biotec) per 10<sup>8</sup> cells were subsequently added to the sample and incubated in parallel for 30 min on ice. After washing the cells, CD133 positive and negative fractions were each isolated through MACS separation columns. The quality of sorting was controlled by flow cytometry analysis for CD133 expression using PE-conjugated anti-human CD133 antibody and isotype control mouse IgG2b-PE (Biolegend, San Diego, CA, United States). The single cell suspension was cultured in stem cell-conditioned medium (DMEM/F12

medium supplemented with  $1 \times B27$ , 20 ng/mL EGF, 20 ng/mL bFGF, 0.4% BSA, 4  $\mu$ g/mL Insulin, 100 U/mL penicillin and 100  $\mu$ g/mL streptomycin; Invitrogen) for the following assays.

### Tumorsphere culture

Single-cell suspensions were suspended at a density of 2000 cells/mL in stem cell-conditioned medium and seeded into ultralow attachment 24-well plates (Corning, NY, United States). When the diameter of the spheroid reached 50  $\mu$ m, suspension cultures were passaged every 6 d. Colonies were counted at 10 different views under a microscope (Nikon, Japan). The volume of the spheroid was estimated using  $V = (4/3) \pi R^3$ . Experiments were repeated 3 times with duplication in each experiment.

### Western blotting analysis

The procedures for preparation of whole cell lysates and western blotting analysis have been previously described<sup>[23]</sup>. Mouse anti-human  $\beta$ -catenin, N-cadherin, vimentin, E-cadherin, ZO-1, CD133, CD44 and  $\beta$ -actin antibodies were used as primary antibodies. Signals were visualized using chemiluminescent substrate (ECL; Amersham, Arlington Heights, IL, United States).  $\beta$ -actin was used as an internal control. Images were scanned, followed by densitometry analysis with UN-SCAN-IT software (Silk Scientific Inc., Orem, UT, United States).

### MTT assay

CD133<sup>+</sup> sphere-forming cells (SFCs) or parental MHCC97 cells were seeded in a 96-well plate pre-coated with 0.6% agarose at a density of 5000 cells/well as described previously<sup>[24]</sup>. One day after plating, various concentrations of BrMC (0.1, 0.3 1.0, 3.0 or 10.0  $\mu$ mol/L) were added to each well and the culture continued for 48 h. After removal of the medium, cells were incubated with 5 mg/mL of MTT for 4 h. Cells were then extracted with acidic isopropanol and the absorbance at 570 nm ( $A_{570}$ ) was measured by means of an enzyme-labeling instrument (EXL-800 type). The relative cell proliferation inhibition rate = (average  $A_{570}$  of the experimental group/average  $A_{570}$  of the control group)  $\times$  100%.

### Matrigel invasion assay

The invasion ability of tumor cells was examined *in vitro* using a transwell chamber system with 8.0  $\mu$ m pore polycarbonate filter inserts (Corning Coster, Cambridge, MA, United States). The lower side of the filter was coated with 10  $\mu$ L gelatin (1 mg/mL), and the upper side was coated with 10  $\mu$ L of Matrigel. Parental MHCC97 cells or LCSCs ( $2 \times 10^3$ ) were placed in the upper part of the filter. 10% fetal bovine serum was added in the lower part of the chamber as a chemical attractant. The chamber was then incubated at 37 °C for 48 h. Cells that could not invade through the filter were removed with a cotton swab. The cells in the lower part of the chamber were fixed with methanol and stained with crystal violet. The invasiveness of tumor cells was determined by counting

the total number of cells on the lower side of the filter at 100  $\times$  magnification. In the drug-intervention experiment, cells were pretreated with different concentrations of BrMC for 24 h prior to the transwell chamber assay.

### In vivo tumorigenicity experiments

Pathogen-free Balb/c-nu mice aged 5-6 wk were purchased from Shanghai Laboratory Animal Center (Shanghai, China). All animal studies were performed in accordance with the standard protocols approved by the Ethical Committee of Hunan Normal University and the Committee of Experimental Animal Feeding and Management. Mice were randomly divided into 3 groups (4 mice/group) and maintained under standard conditions, according to the standard protocols. Cells were suspended in serum free-DMEM/Matrigel (BD Biosciences, San Jose, CA, United States) mixture (1:1 volume). Each recipient Balb/c-nu mouse was inoculated subcutaneously with various numbers of CD133<sup>+</sup> SFCs ( $2 \times 10^3$ ,  $1 \times 10^4$  and  $1 \times 10^5$  cells) in one flank and parental MHCC97 cells ( $1 \times 10^4$ ,  $1 \times 10^5$  and  $1 \times 10^6$ ) in the other. Tumorigenicity experiments were terminated 2 mo after cell inoculation. Tumor size were measured with a caliper, and the volume was calculated using  $V (\text{mm}^3) = L \times W^2 \times 0.5$ . Harvested tumors were imaged and weighed immediately. Specimens from tumor tissue samples were fixed in 10% neutral buffered formalin, processed in paraffin blocks, and sectioned. The sections were stained with hematoxylin and eosin (HE) and examined for the histopathology.

For BrMC treatment studies,  $5 \times 10^4$  LCSCs per mouse were injected subcutaneously. Two weeks after inoculation, animals were randomly divided into 4 groups. One group underwent daily gastric lavage with refined olive oil as control, and the other 3 groups were treated with 12.5, 25 or 50 mg/kg BrMC. After 20 d of treatment, living cells from the primary tumors were dissociated and injected into 3 groups of mice (4 mice per group). Each mouse was implanted with  $5 \times 10^4$  cells from the control group and from the 50 mg/kg BrMC treated group in each flank. The growth of tumors was monitored, and tumor volumes were measured every 3 d. Animals were humanely sacrificed when the larger of the two tumors reached 500 mm<sup>3</sup>.

### Immunohistochemical examination

For immunohistochemical analysis of CD44 and CD133, tissues of the LCSCs derived-tumors in the nude mouse xenograft model were performed with formalin-fixed, paraffin-embedded sectioning as previously described by Moinfar *et al.*<sup>[25]</sup>. After incubation with 1% non-fat dry milk in PBS (pH 7.4), the sections were then reacted with mouse anti-CD44 monoclonal antibody (1:250, Cell Signaling Technology Inc.) or mouse anti-CD133 monoclonal antibody (1:200, Abzoom, Dallas, TX, United States) for 1 h at room temperature followed by incubation with the secondary biotinylated antibody for 30 min. After washing, sections were subsequently incubated with streptavidin-peroxidase for 30 min. Finally, the results were vi-

sualized after a 15-min incubation with diaminobenzidine.

### RNA interference

A control non-specific small interfering RNA (siRNA) (5'-GACTTCATAAGGCGCATGC-3') and  $\beta$ -catenin siRNA (5'-AGCUGAUUUGAUGGACAGTT-3') were synthesized by Shanghai Sangon Biotech Co., Ltd. (Shanghai, China). Transfection of siRNA was carried out with Lipofectamine 2000 (Invitrogen Life Technologies) according to the procedure recommended by the manufacturer. Twenty-four hours after transfection, the cells were treated with DMSO (control) or BrMC at the indicated concentrations for 24 h. The cells were then collected and processed for western blotting and the tumorsphere formation assay.

## RESULTS

### Isolation and characterization of LCSCs derived from MHCC97 cell line

CD133 has previously been classified as a CSC marker in liver cancer. Therefore, we first isolated the CD133<sup>+</sup> subpopulation from MHCC97 cells by MACS. Following sorting, we examined the expression of CD133 by flow cytometry. As shown in Figure 1A, the sorted CD133<sup>+</sup> cells showed a high purity of 57.29%  $\pm$  4.61%, as compared with a purity of 1.02%  $\pm$  0.65% for CD133<sup>-</sup> counterparts and 7.21%  $\pm$  1.34% for non-sorted MHCC97 cells. To establish long-term cultures enriched in stem cells from sorted CD133<sup>+</sup>, we performed the tumorsphere assay by culturing the cells in stem cell-conditioned medium. Within 6 d of culture, we obtained liver cancer spheroids both in CD133<sup>+</sup> cells and parental MHCC97 cells (Figure 1B). As shown in Table 1, the CD133<sup>+</sup> subpopulation exhibited a 2.7- and 2.5-fold enhancement in tumorsphere formation amount and size, respectively, compared with that of parental cells, whereas, CD133<sup>-</sup> counterparts could not grow as spheroids in the nonadherent and serum-free conditions.

To further confirm the stem cell properties and functions of the CD133<sup>+</sup> SFCs, we evaluated their self-renewal capacity and tumorigenic potential. First, we measured the capacity of single cells obtained from these CD133<sup>+</sup> dissociated spheres to form secondary tumorspheres. Within 9 d of culture, we obtained new LCSC spheroids of growing undifferentiated CD133<sup>+</sup> cells (Figure 1C). These suggest an *in vitro* self-renewing capacity of CD133<sup>+</sup> SFCs. In addition, CD133<sup>+</sup> SFCs also expressed an enhanced level of stem cell markers, CD133 and CD44, compared with their parental cells (Figure 1D). Next, we evaluated the tumorigenic potential of CD133<sup>+</sup> SFCs. We investigated the ability of CD133<sup>+</sup> SFCs and parental cells to give rise to tumors in Balb/c-nu mice. As many as  $1 \times 10^6$  parental cells were needed to initiate stable tumor formation 39 d after injection, while, in contrast, as few as  $1 \times 10^4$  CD133<sup>+</sup> SFCs were sufficient to generate visible tumors only 23 d post-injection (Table 2). These data indicate that CD133<sup>+</sup> SFCs, namely LCSCs,

are more tumorigenic than their parental cells *in vivo*. Additionally, HE staining was performed and revealed similar histological characteristics in tumor xenografts derived from CD133<sup>+</sup> SFCs and their parental cells (Figure 1E).

### BrMC inhibits proliferation and self-renewal of LCSCs derived from MHCC97 cell line

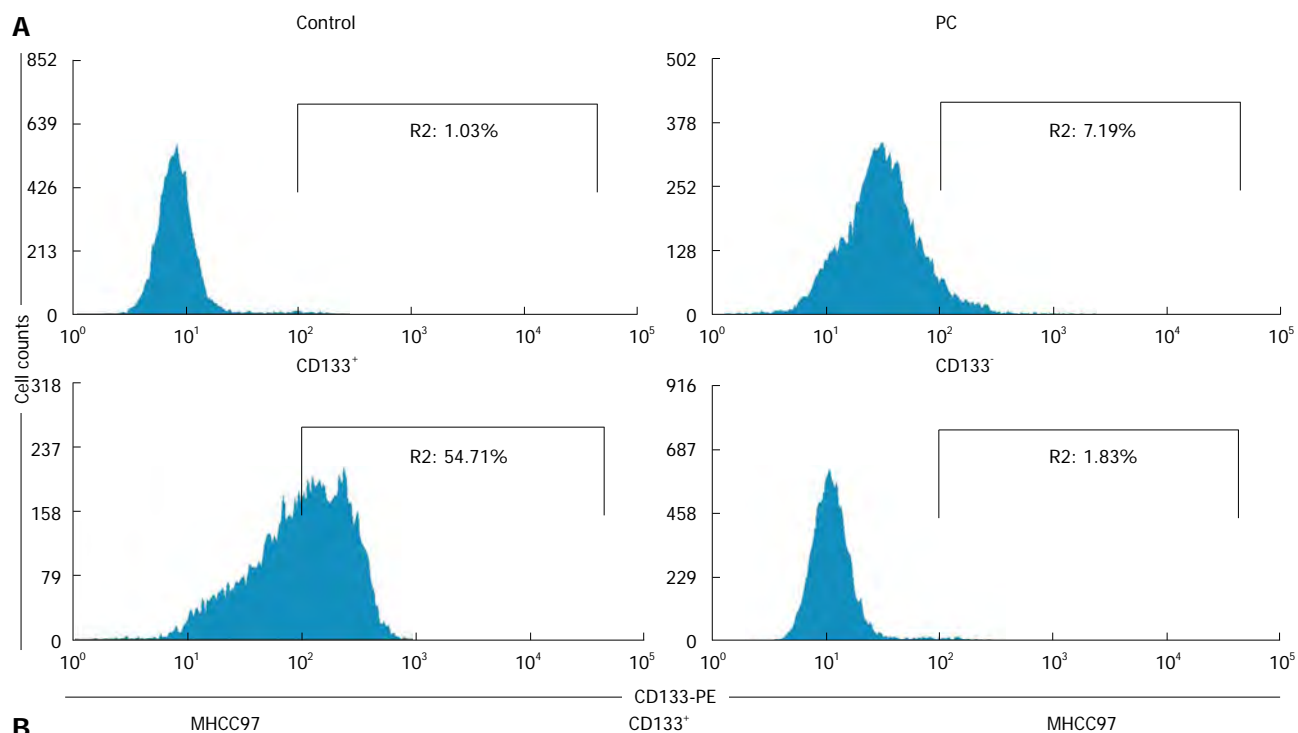

CSCs possess the property of limitless proliferative potential. A number of previous studies have demonstrated that some naturally-occurring polyphenol compounds such as genistein preferentially inhibit proliferation of pancreatic cancer stem cells<sup>[26]</sup>. In this study, we thus evaluated the anti-proliferative effects of BrMC on LCSCs derived from MHCC97 cell line by MTT assay. As shown in Figure 2A, when cells were treated with different concentrations of BrMC for 48 h, BrMC preferentially inhibited proliferation of LCSCs in a dose-dependent manner, with the IC<sub>50</sub> around 0.5  $\mu$ mol/L for LCSCs and 17.9  $\mu$ mol/L for parental MHCC97 cells.

In order to evaluate whether BrMC could suppress the self-renewal of LCSCs derived from the MHCC97 cell line *in vitro*, we treated the primary tumorspheres with varying concentrations of BrMC and then removed the drug and cultured them for another passage to form the secondary spheres. Results showed that BrMC treatment resulted in a decrease both in tumorsphere number and size of LCSCs. Furthermore, a significant decrease in the number and size of the secondary tumorspheres indicated a reduced self-renewal capacity of these LCSCs by BrMC treatment (Figure 2B and C).

### BrMC inhibits Epithelial-mesenchymal transition and invasion of LCSCs derived from MHCC97 cell line

Epithelial-mesenchymal transition (EMT) is an important process during metastasis of LCSCs. Therefore, we sought to examine whether morphological changes existed between LCSCs and parental MHCC97 cells cultured adherently *in vitro*. As observed in Figure 3A, LCSCs exhibited a spindle-like shape, while parental MHCC97 cells displayed a cobble-stone-like phenotype. However, treatment with 0.1  $\mu$ mol/L BrMC suppressed EMT in LCSCs as morphological changes from a spindle-like shape to a cobble-stone-like appearance were displayed. Moreover, similar results were further confirmed by western blotting using specific antibodies against EMT-relative markers. Figure 3B shows that LCSCs expressed higher vimentin and N-cadherin protein levels, which are typically associated with mesenchymal cells, and lower expression of epithelium-associated E-cadherin and ZO-1 proteins. However, BrMC induced the upregulation of epithelial markers E-cadherin and ZO-1 and the downregulation of mesenchymal markers N-cadherin and vimentin after treatment for 24 h of LCSCs derived from MHCC97 cell line.

Since EMT has been identified as being associated with increased cancer cell invasion, we next evaluated the effect of BrMC on cell invasion of LCSCs *in vitro* using a transwell chamber coated with a Matrigel barrier. As

<sup>a</sup>P < 0.05 vs parental MHCC97 cells.

shown in Figure 3C and 3D, BrMC significantly reduced the invasiveness capacity of LCSCs in a dose-dependent manner. These results demonstrated that BrMC possesses inhibitory effects on EMT and invasion in LCSCs derived from MHCC97 cell line.

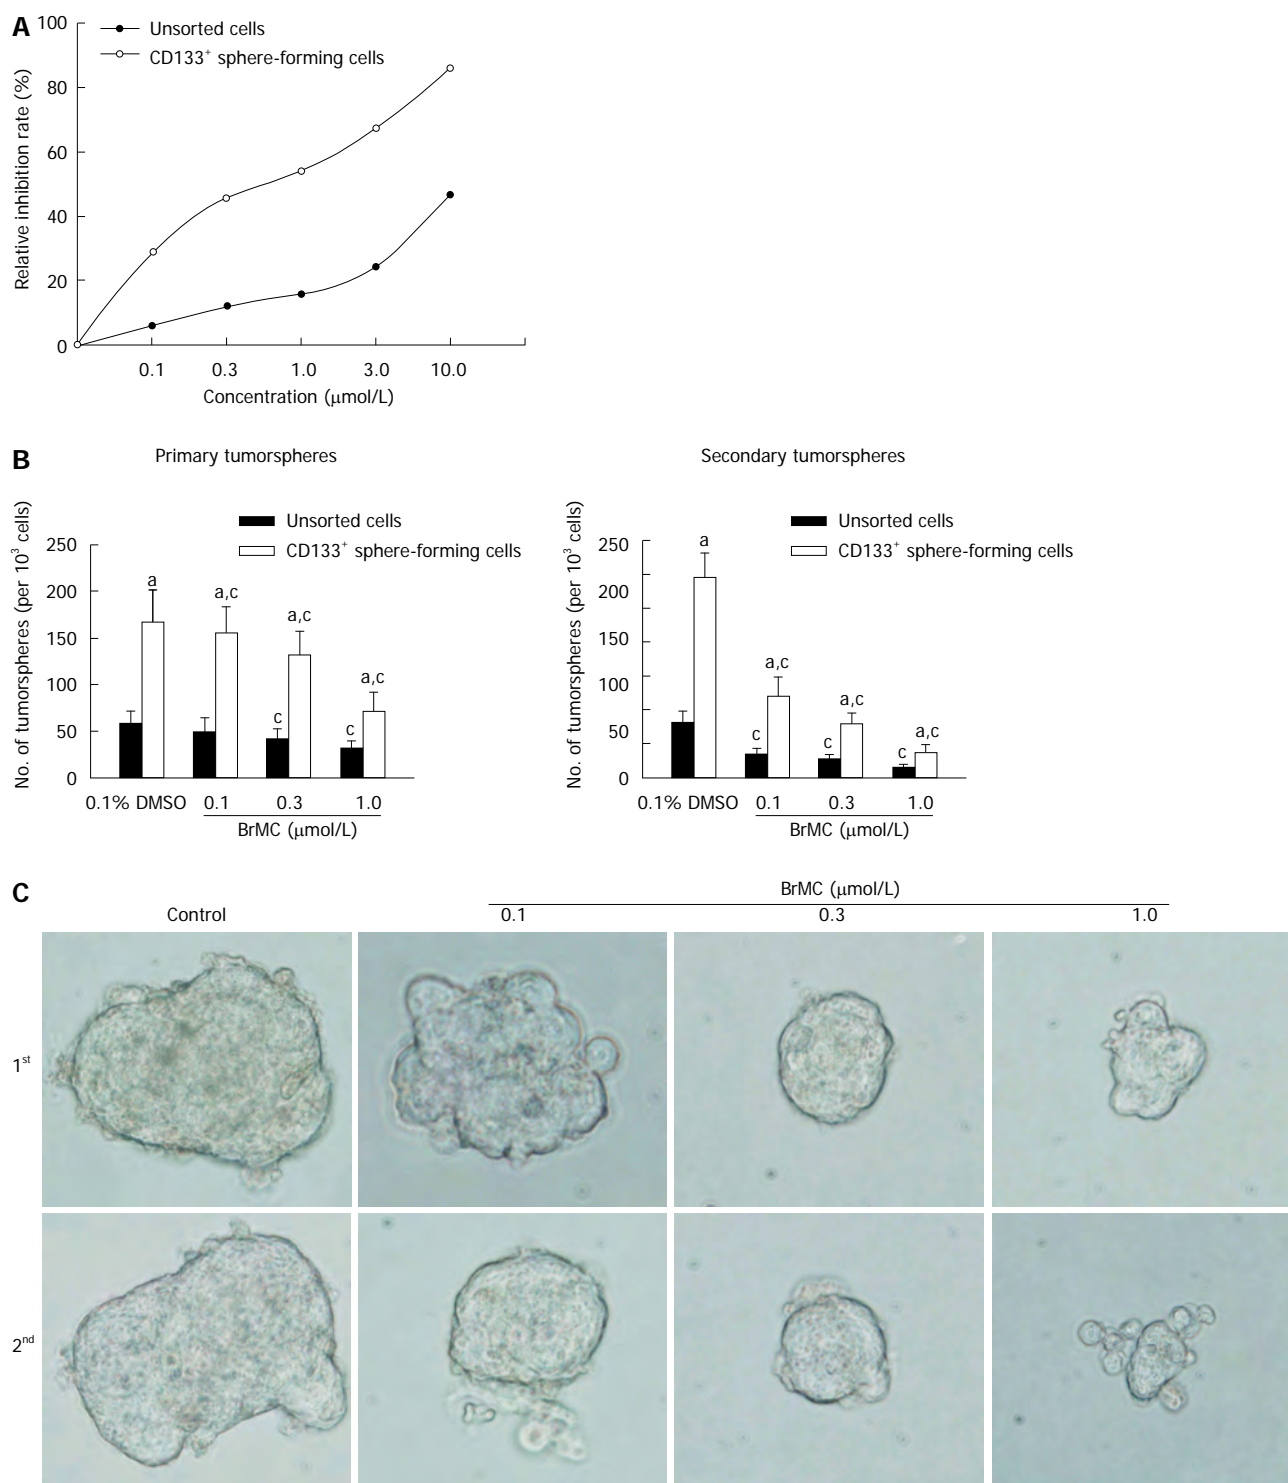

#### BrMC eliminates LCSCs derived from MHCC97 cell line *in vivo*

In order to evaluate whether BrMC could target LCSCs *in vivo*, we utilized the xenograft model of LCSCs from MHCC 97 cells in Balb/c-nu mice. Two weeks after cell inoculation with 5 × 10<sup>4</sup> LCSCs resuspended in Matrigel, animals underwent daily gastric lavage with various concentrations of BrMC. After 20 d of treatment, tumors

in 25 and 50 mg/kg BrMC-treated mice were less than 50% of the size of those in refined olive oil control animals (Figure 4A and B). Immunohistochemical analysis of CD44 and CD133 in LCSC-derived tumors revealed that the LCSC markers CD44 and CD133 were mainly expressed on the cell surface of the cancer cells, and that the tumors derived from CD133<sup>+</sup> SFCs showed significantly higher CD44 and CD133 positive rates than that of tumors derived from parental cells (Figure 4C). Furthermore, BrMC treatment can significantly decrease the CD44 and CD133 expression frequency of the tumors derived from LCSCs (Figure 4D).

To further confirm the results, we investigated the growth of secondary tumors in Balb/c-nu mice inoculated with tumor cells dissociated from primary tumor xenografts. In order to avoid possible variations due to heterogeneity, each recipient mouse was inoculated with 5 × 10<sup>4</sup> cells obtained from 50 mg/kg BrMC-treated tumors and another 5 × 10<sup>4</sup> cells obtained from control tumors in two opposite sides. Interestingly, we found that tumor cells from control animals exhibited rapid tumor re-growth, reaching a final tumor volume of 567–686 mm<sup>3</sup>. However, the tumor cells from 50 mg/kg BrMC-

**Figure 2** Effects of 8-bromo-7-methoxychrysin on cell proliferation and self-renewal. 8-bromo-7-methoxychrysin (BrMC) inhibited proliferation (A), self-renewal (B and C) of liver cancer stem cells derived from MHCC97 cell line (mean  $\pm$  SD,  $n = 3$ ). <sup>a</sup> $P < 0.05$  vs unsorted MHCC97 cells treated with corresponding concentrations of BrMC. <sup>c</sup> $P < 0.05$  vs corresponding 0.1% DMSO treated group. Tumor sphere morphology is shown as the phase contrast image (400  $\times$  magnification).

treated mice mostly failed to generate any tumors up to 33 d after inoculation (Table 3). These results suggest that BrMC was able to eliminate LCSCs in primary tumor xenografts, thereby inhibiting tumor regrowth in secondary inoculated mice.

### BrMC inhibits self-renewal in LCSCs through modulation of $\beta$ -catenin expression

To examine whether BrMC could regulate expression of stem cell markers of LCSCs, we determined the expression of CD44 and CD133 following BrMC treatment

**Figure 3** 8-bromo-7-methoxychrysin inhibition of liver cancer stem cells. 8-bromo-7-methoxychrysin (BrMC) inhibited epithelial-mesenchymal transition (EMT, A and B) and invasion (C and D) of liver cancer stem cells derived from the MHCC97 cell line (mean  $\pm$  SD,  $n = 3$ ). Cell morphological changes associated with EMT are shown as the phase contrast image (200  $\times$  magnification). <sup>a</sup> $P < 0.05$  vs unsorted MHCC97 cells treated with corresponding concentrations of BrMC, <sup>c</sup> $P < 0.05$  vs corresponding 0.1% DMSO treated group.

by western blotting analysis. Results showed that BrMC downregulated CD44 and CD133 expression in a dose-dependent manner (Figure 5A). This was in accordance with our previous immunohistochemical analysis in LCSC-derived tumors (Figure 4D).

CD44 has been shown to be a downstream target of the  $\beta$ -catenin signaling pathway<sup>[27]</sup>. Wnt/ $\beta$ -catenin signaling has been implicated in the maintenance of CSCs of liver cancer<sup>[28]</sup>. Therefore, we measured the expression level of stem cell signal molecule  $\beta$ -catenin in LCSCs and parental MHCC97 cells, and examined whether  $\beta$ -catenin was downregulated by BrMC in LCSCs. Western blotting analysis showed that  $\beta$ -catenin was highly expressed in LCSCs compared with that of parental MHCC97 cells. We also found that BrMC (0.1, 0.3, 1.0  $\mu\text{mol/L}$ ) treatment resulted in a significant decrease in  $\beta$ -catenin expression of LCSCs (Figure 5B).

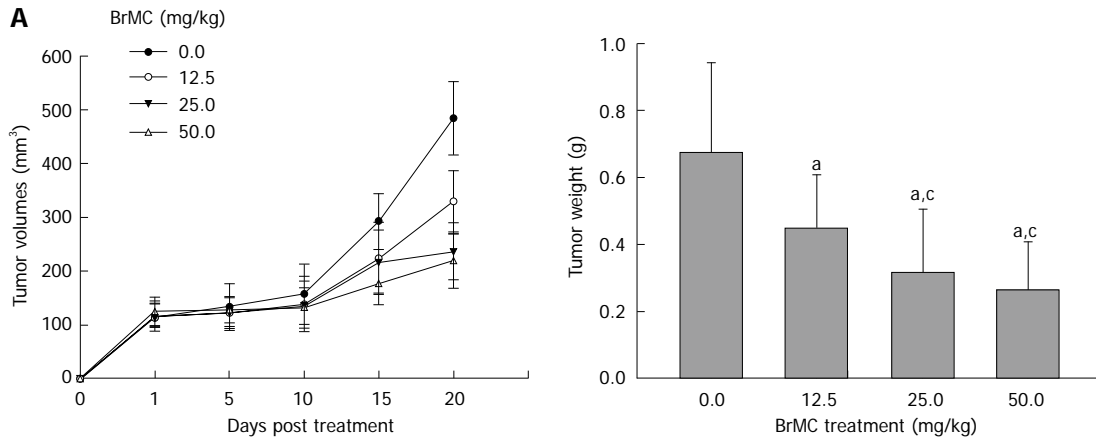

We further determined the role of  $\beta$ -catenin in the maintenance of self-renewal of LCSCs. Silencing of  $\beta$ -catenin by siRNA transfection resulted in less expression of  $\beta$ -catenin protein, as confirmed by Western blotting (Figure 5C). We also found that the downregulation of  $\beta$ -catenin expression significantly decreased the tumorsphere formation ability and inhibited expression of stem cell markers of LCSCs (Figure 5D and 5E). BrMC (0.1  $\mu\text{mol/L}$ ) plus  $\beta$ -catenin siRNA inhibited  $\beta$ -catenin expression to a greater degree compared to either alone (Figure 6A). Moreover,  $\beta$ -catenin siRNA potentiated the BrMC-induced decrease in tumorsphere formation of LCSCs (Figure 6B). We also treated LCSCs with Wnt3a, a ligand known to activate the Wnt/ $\beta$ -catenin pathway. As expected, Wnt3a induced  $\beta$ -catenin stabilization and resulted in a corresponding up-regulation of  $\beta$ -catenin in LCSCs (Figure 6C). This upregulation of  $\beta$ -catenin attenuated BrMC-induced downregulation of  $\beta$ -catenin and stem cell markers and antagonized BrMC-induced inhibition of self-renewal of LCSCs (Figure 6D, 6E and 6F). Taken together, these results provide some molecular

evidence suggesting that the downregulation of  $\beta$ -catenin expression may contribute to the inhibitory effects of BrMC on LCSCs.

## DISCUSSION

Cancer stem cells are defined as a minor population of tumorigenic cells that are capable of continuous self-renewal and differentiation, and undergo unlimited proliferation, giving rise to new tumors<sup>[29,30]</sup>. Therefore, finding compound(s) that are capable of inhibiting or killing the CSCs is extremely important to overcome tumor resistance, reduce relapse, and eventually improve overall survival. Our previous study has shown that BrMC possessed promising inhibitory effects on proliferation and apoptosis of colon, gastric and liver cancer cells. In the current study, we first successfully isolated and identified LCSCs from the liver cancer MHCC97 cell line. Further, we showed for the first time that BrMC could preferentially inhibit proliferation and self-renewal, and suppress EMT and invasion of LCSCs. Moreover, BrMC was able to eradicate LCSCs *in vivo*, as assessed by an *in vivo* tumorigenicity assay using primary and secondary Balb/c-nu mouse models. Secondly, we found that the inhibitory effects of BrMC on stem cell function and properties of LCSCs were mediated by inhibition of  $\beta$ -catenin pathways:  $\beta$ -catenin siRNA transfection and BrMC were synergistic in inhibiting the self-renewal of LCSCs. Conversely, the inhibition of Wnt3a in LCSCs resulted in an opposite effect.

More recently, CD133 has been used as a surface marker of CSCs in various solid tumors, including liver cancer. However, the function of CD133 is not entirely known yet. Thus, the single phenotypic marker CD133 is not sufficient to identify LCSCs. Tumorsphere culture may provide an alternative approach to identify and enrich LCSCs. Under non-adherent serum-free conditions *in vitro*, most tumor cells undergo programmed cell death,

Figure 4 8-bromo-7-methoxychrysin eliminated liver cancer stem cells derived from MHCC97 cell line *in vivo*. whereas the rare CSCs divide to generate multicellular 3-dimensional spheres<sup>[31,32]</sup>. This assay is a powerful tool to enrich CSCs and further assess the functional properties of the isolated CSCs. By employing a combination of this technique and MACS based on the CD133<sup>+</sup> surface marker, we have successfully obtained the putative LCSCs, namely CD133<sup>+</sup> SFCs, from the MHCC97 cell line. We demonstrated that these CD133<sup>+</sup> SFCs possess stem-like properties, including self-renewal, initiation of tumor growth in mice at very low cell numbers and a higher expression level of stem cell marker compared with their parental cells. These data indicated that the method which we used to isolate and indentify LCSCs from liver cancer cell lines may be faster, more economic and effective, compared with methods based on two or more surface markers.

<sup>1</sup>Number of tumors detected/number of injections. BrMC: 8-bromo-7-methoxychrysin

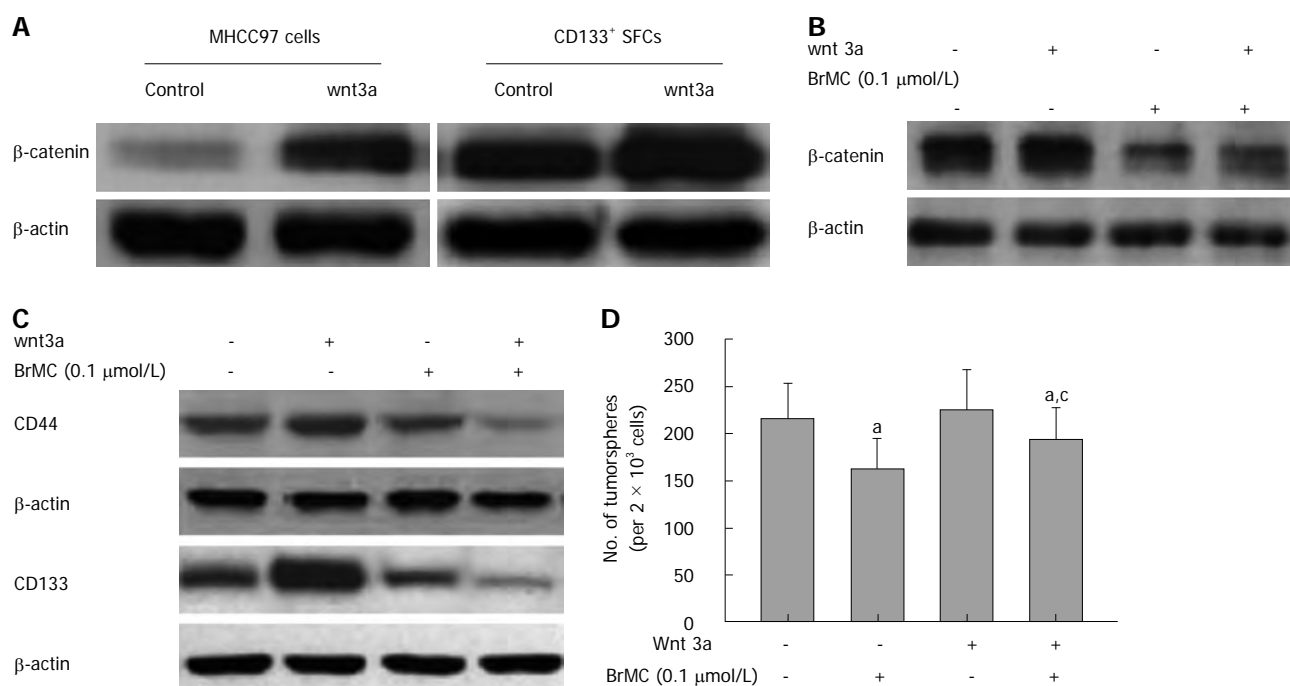

The Wnt/ $\beta$ -catenin pathway is one of the key pathways that modulates stem cell self-renewal<sup>[14]</sup>. For example, overexpression of  $\beta$ -catenin enhanced self-renewal preferentially and mediated radiation resistance of Sca1<sup>+</sup> progenitors in an immortalized mammary gland cell line<sup>[33]</sup>. Hallett *et al.*<sup>[34]</sup> reported that pharmacological inhibitors of Wnt/ $\beta$ -catenin signaling could inhibit the viability and or self-renewal of breast tumor-initiating cells, and target breast tumor-initiating cells in a Her2/Neu mouse model of breast cancer. Consistent with these previous reports, we found that downregulation of  $\beta$ -catenin

**Figure 5**  $\beta$ -catenin siRNA synergized the inhibitory effects of 8-bromo-7-methoxychrysin. 8-bromo-7-methoxychrysin (BrMC) downregulated CD44 and CD133 expression in liver cancer stem cells in a concentration-dependent manner (A).  $\beta$ -catenin was highly expressed in CD133<sup>+</sup> sphere forming cells (SFCs) and was downregulated by BrMC treatment (B).  $\beta$ -catenin siRNA decreased the protein level of  $\beta$ -catenin (C) and stem cell markers (E), and significantly inhibited self-renewal capacity (D) of CD133<sup>+</sup> SFCs (mean  $\pm$  SD,  $n = 3$ ). <sup>a</sup> $P < 0.05$  vs CD133<sup>+</sup> SFCs or control siRNA transfected CD133<sup>+</sup> SFCs. BrMC enhanced  $\beta$ -catenin siRNA induced downregulation of  $\beta$ -catenin expression (F) and inhibition of self-renewal capacity (G) in CD133<sup>+</sup> SFCs (mean  $\pm$  SD,  $n = 3$ ). <sup>a</sup> $P < 0.05$  vs CD133<sup>+</sup> SFCs derived from the MHCC97 cell line. <sup>c</sup> $P < 0.05$  vs 0.1  $\mu$ mol/L BrMC or  $\beta$ -catenin siRNA treated CD133<sup>+</sup> SFCs.

**Figure 6** Wnt3a treatment antagonized the inhibitory effects of 8-bromo-7-methoxychrysin. Wnt3a treatment resulted in an increase in the expression of  $\beta$ -catenin in both liver cancer stem cells (LCSCs) and parental MHCC97 cells (A) and attenuated the effects of 8-bromo-7-methoxychrysin (BrMC) on the expression of  $\beta$ -catenin (B) and stem cell markers (C), and self-renewal capacity (D) of LCSCs derived from the MHCC97 cell line. <sup>a</sup> $P < 0.05$  vs CD133<sup>+</sup> SFCs, <sup>c</sup> $P < 0.05$  vs 0.1 μmol/L BrMC or Wnt 3a alone treated group.

by BrMC resulted in inhibition of CSC function and characteristics of LCSCs, such as significant inhibition of proliferation and self-renewal, suppression of EMT and invasiveness, downregulation of the expression of stem cell markers of LCSCs, and further efficacious promotion of the elimination of LCSCs *in vivo*.

Previous studies have shown that activated Akt was able to phosphorylate Ser9 on GSK3 $\beta$ , which may decrease the activity of GSK3 $\beta$ , thereby leading to stabilization of  $\beta$ -catenin in the cytoplasm<sup>[35]</sup>. Chrysin was reported to induce apoptosis through caspase activation and Akt inactivation in leukemia cells<sup>[36]</sup>. Our previous study also demonstrated that 5,7-dihydroxy-8-nitrochrysin, another synthetic chrysin analogue, could induce activation and nuclear localization of FOXO3a, which was associated with reduced levels of Akt phosphorylation. Therefore, we speculate that the downregulation of  $\beta$ -catenin by BrMC probably occurs *via* reduced levels of Akt and activation of GSK3 $\beta$ , with the consequent degradation of  $\beta$ -catenin. Wnt3a treatment can induce stabilization of  $\beta$ -catenin, with entry into the nucleus and subsequent activation of the  $\beta$ -catenin pathway. Thus, Wnt3a treatment can antagonize the inhibitory effects of BrMC on self-renewal of LCSCs. On the other hand, Su *et al.*<sup>[37]</sup> reported that genistein increases levels of membrane E-cadherin and E-cadherin- $\beta$ -catenin cell adhesion complex, and eventually attenuates  $\beta$ -catenin signaling in mammary epithelial cells. We also found that E-cadherin, an epithelial marker, was upregulated by BrMC in LCSCs. E-cadherin is known to anchor and to sequester  $\beta$ -catenin in the membrane and prevent its

activation. Therefore, we suppose that this inactivation of  $\beta$ -catenin by upregulation of E-cadherin can also contribute to the inhibitory effects of LCSCs by BrMC. Interestingly, the inhibition of  $\beta$ -catenin at the protein level was not optimal, as treatment of  $\beta$ -catenin siRNA can further downregulate  $\beta$ -catenin at the transcription level and synergize the inhibition of self-renewal of LCSCs induced by BrMC.

In conclusion, we have presented supportive evidence for the first time that BrMC, a novel synthetic chrysin analogue, can target LCSCs both *in vitro* and *in vivo*. Furthermore, our study identified the downregulation of  $\beta$ -catenin expression by BrMC as one of the possible mechanisms for its efficacy. These studies support the use of BrMC for liver cancer chemoprevention or chemotherapy. These findings provide a strong rationale for preclinical and subsequent clinical evaluation of BrMC for liver cancer therapy.

## COMMENTS

### Background

Liver cancer is the fifth most common cancer in the world and the third leading cause of cancer-related death. Recent studies indicated that cancer stem cells (CSCs) may be responsible for tumor recurrence and drug-resistance. Therefore, the identification of a compound that can target liver CSCs (LCSCs) is one of the main steps in improving overall survival of liver cancer patients.

### Research frontiers

More recently, a number of studies have found that some dietary compounds can directly or indirectly affect CSC self-renewal pathways. 8-bromo-7-methoxychrysin (BrMC) is a synthetic derivative of chrysin, and their previous study have demonstrated the effect of BrMC on the inhibition of proliferation

and induction of apoptosis in colon, gastric and liver cancer cells was stronger than that of chrysin. However, the inhibitory effects of BrMC on the characteristics of CSCs have not been reported yet.

### Innovations and breakthroughs

The authors firstly showed that BrMC, a novel synthetic chrysin analogue, was able to inhibit cancer stem cell-like properties of LCSCs and eliminate LCSCs *in vivo*. They also found that BrMC significantly decreased  $\beta$ -catenin expression in LCSCs and knockdown of  $\beta$ -catenin expression could synergize the inhibition of self-renewal of LCSCs induced by BrMC. The downregulation of  $\beta$ -catenin expression appears to contribute to the inhibitory effects of BrMC on the properties of LCSCs.

### Applications

The present study provided strong evidences for the first time that BrMC was able to target LCSCs both *in vitro* and *in vivo*. These studies support the use of BrMC for liver cancer chemoprevention or chemotherapy.

### Terminology

Chrysin (5,7-dihydroxyflavone), a naturally wide distributed flavonoid, has been reported to possess anti-cancer activities. BrMC is a novel synthetic chrysin analogue.

### Peer review

This manuscript concludes that 8-bromo-7-methoxychrysin can inhibit the functions and characteristics of liver cancer stem cells derived from liver cancer MHCC97 cell line through downregulation of  $\beta$ -catenin expression. It is a good research with necessary information.

### Abstract

**AIM:** To analyzed whether laparoscopy-assisted percutaneous endoscopic gastrostomy (PEG) could be a valuable option for patients with complicated anatomy.

**METHODS:** A retrospective analysis of twelve patients (seven females, five males; six children, six young adults; mean age 19.2 years) with cerebral palsy, spastic quadriplegia, severe kyphoscoliosis and interposed organs and who required enteral nutrition (EN) due to starvation was performed. For all patients, standard PEG placement was impossible due to distorted

anatomy. All the patients qualified for the laparoscopy-assisted PEG procedure.

**RESULTS:** In all twelve patients, the laparoscopy-assisted PEG was successful, and EN was introduced four to six hours after the PEG placement. There were no complications in the perioperative period, either technical or metabolic. All the patients were discharged from the hospital and were then effectively fed using bolus methods.

**CONCLUSION:** Laparoscopy-assisted PEG should become the method of choice for gastrostomy tube placement and subsequent EN if PEG placement cannot be performed safely.

**Key words:** Percutaneous endoscopic gastrostomy; Laparoscopy-assisted percutaneous endoscopic gastrostomy; Severe kyphosis; Malnutrition; Interposed organs

**Core tip:** Enteral nutrition (EN) is a life-saving procedure, preventing complications associated with malnutrition. The best solution for EN is percutaneous endoscopic gastrostomy (PEG). In some cases, however, creating such access is impossible. In those cases, laparoscopy-assisted PEG should become the method of choice for gastrostomy tube placement and subsequent EN if PEG placement cannot be performed safely.

## INTRODUCTION

Tube enteral feeding is the method of choice when an oral diet is insufficient or impossible for more than seven days, even in patients without apparent malnutrition<sup>[1]</sup>. Tube enteral feeding is also strongly recommended if the latter is present or imminent<sup>[1]</sup>. All these patients should be administered enteral nutrition (EN), and when the oral diet cannot be continued, tube feeding is the best option. Since its introduction by Gauderer in 1980, percutaneous endoscopic gastrostomy (PEG) has become the method of choice for EN in all age groups<sup>[2]</sup>. The primary goal of EN is to improve the patient's well-being by preventing or reversing malnutrition and avoiding its consequences. EN is particularly important in pediatric patients because they need to not only survive but also grow. Neurological disorders place children at a very high risk of malnutrition; hence, this group of patients benefits very quickly from EN. Unfortunately, neurological disorders are very often accompanied by serious distortions in body anatomy.

Problems, such as severe kyphoscoliosis, interposed organs or other forms of distorted anatomy, may prevent effective and safe PEG placement due to an inability to guarantee the three principles of safe PEG placement: endoscopic gastric distension, endoscopically visible focal finger invagination and transillumination<sup>[3,4]</sup>. In such cases, surgical gastrostomy, which is an invasive procedure, is often the only option for EN. However, less invasive measures would be preferable over surgical gastronomy. Our study aimed to determine whether laparoscopy-assisted PEG placement is a useful option for EN in patients with distorted anatomy and who are unable to undergo PEG placement.

## MATERIALS AND METHODS

This study was a retrospective analysis of twelve patients (seven females, five males; mean age 19.2 years), who were treated at the pediatric surgery center in Bialystok, Poznan and Skawina, Poland. Six patients were children, and the remaining six were adults. In all patients, malnutrition requiring nutritional support was diagnosed (body mass index < 14 m<sup>2</sup>/kg), and tube feeding was recognized as the method of choice for EN. In all four patients, PEG placement was impossible due to spastic quadriplegia, severe kyphoscoliosis and interposed organs. Informed consent was collected from all patients. The patients and procedure characteristics are presented in Table 1.

### Technique

PEG tube insertion was performed under general an-

esthesia. A single dose of intravenous antibiotics was given. The patient was positioned in the supine position. After sterilizing the skin on the anterior abdominal wall, a 5-mm port was inserted under the umbilicus using Hasson's open technique<sup>[5]</sup>. Pneumoperitoneum was established *via* a trocar, using carbon dioxide. The intra-abdominal pressure in our patients was 10 mmHg. The peritoneal cavity and the abdominal and gastric walls were inspected for suitable sites for the gastrostomy. After insertion of the gastroscope into the stomach and air insufflation, the gastrostomy site was selected under laparoscopic and endoscopic guidance. The skin was incised above the gastrostomy site with a length of 0.5 cm. A trocar with a needle was pushed through this point into the stomach under complete laparoscopic and endoscopic visualization. The PEG was made using the 'pull' technique: a thread was inserted through the trocar after removing the needle and was then snared. The endoscope was withdrawn by the snare holding the thread. A suitably sized PEG tube was then connected to the thread, and the thread was pulled from the skin incision, pulling the tube into patient's mouth through the esophagus. The PEG tube was retained in the stomach with an internal bolster. An external bolster was placed loosely on the skin<sup>[2,3]</sup>. All the procedures were uneventful and without any intraoperative complications.

## RESULTS

The laparoscopy-assisted PEG insertion was successful in all twelve patients. The mean length of the procedure was 16.5 min. A FloCare PEG tube (Nutricia Ltd., Poland) with a diameter of 14 Cherrier was used as the gastric catheter.

No postoperative complications were observed, and EN was commenced four to six hours after the PEG placement using the bolus method (5 mL × 100 mL). The mean length of the hospital stay was 1.5 d. All the patients were discharged from the hospital and then effectively fed using bolus methods at long-term facilities. The follow-up at twelve months did not reveal any complications. The nutritional status of the patients improved significantly, with the mean BMI reaching 17.5 m<sup>2</sup>/kg (Table 1).

## DISCUSSION

Tube feeding is the method of choice when EN is recommended<sup>[1]</sup>. In most cases, PEG tube insertion is a safe procedure and does not lead to complications<sup>[3,6]</sup>. Fatal outcomes have been reported due to comorbidities when the PEG was inserted in the setting of severe disease<sup>[3,7]</sup>. However, the safe placement of a PEG tube requires a permeable esophagus and transillumination of the stomach through the abdominal wall. Impaired coagulation, severe ascites, peritonitis and local esophageal and general gastrointestinal obstructions are considered to be absolute contraindications<sup>[3,4,8]</sup>. Severe kyphoscoliosis with interposed organs and distorted anatomy are

**Figure 1** A 17-year-old patient with severe kyphoscoliosis (138 degrees on Cobb's scale) with interposed organs.

considered to be relative contraindications<sup>[8-10]</sup> (Figure 1). In patients with severe kyphoscoliosis, the PEG tube cannot be placed in the usual locations due to organ displacement. In our patients, the contraindications for PEG included the translocation of the stomach into the left lower quadrant of the abdomen (3 patients) or into the middle part of the abdomen (1 patient) (Figure 2). Therefore, in patients with severe kyphoscoliosis, patients suffering from hepatomegaly, splenomegaly, obesity or an intra-abdominal or peritoneal tumor, patients with previous abdominal surgery, especially involving the stomach, and patients with advanced esophageal cancer, when transillumination of the stomach is not achieved, there is an indication for laparoscopic, fluoroscopic or sonographic guidance during the PEG tube placement.

The technique for the laparoscopic-assisted PEG procedure was described for the first time by Raaf *et al*<sup>[11]</sup> in 1993. In 1995, Stringel *et al*<sup>[12]</sup> reported a laparoscopic-assisted PEG procedure in 2 children in whom attempts at a simple PEG had failed. There are also other alternative methods for PEG placement when transillumination is not possible. Radiologic techniques have been used successfully in these patients since 1981<sup>[13,14]</sup>. The gastric tubes

can be placed under ultrasound or fluoroscopic guidance<sup>[15-17]</sup>. Recently, the placement of the gastric tubes has used Computed tomography (CT) fluoroscopy guidance, even in combination with simultaneous gastroscopy<sup>[18]</sup>.

Historically, gastroesophageal reflux was also considered to be a contraindication, as concluded by Yaseen *et al*<sup>[19]</sup>. Recent trials have shown that gastroesophageal reflux might actually improve after PEG placement because the PEG creates a type of anterior pseudo-gastropexy<sup>[20,21]</sup>.

Major complications related to PEG include the following: colonic perforation, esophageal tear, small bowel injury, hepatic or splenic injury, tube migration with or without intestinal obstruction, gastrointestinal bleeding and site or generalized infection. These complications have been reported with variable incidences (5%-17%) in published series<sup>[3,4,7,22]</sup>. The most severe complication, with an incidence of 0.0008%-0.04%, is esophageal perforation<sup>[4,23]</sup>. Predisposing factors include anatomic anomalies in up to 50% of cases<sup>[3]</sup>. Patients with displacement of the transverse colon over the anterior gastric wall are predisposed to colonic injury during the PEG procedure<sup>[3,23,24]</sup>. Colonic injury usually presents with peritonitis, and surgery is then required. Additionally, interposition of the splenic flexure between the anterior abdominal and gastric walls may result in gastrocolic-cutaneous fistulae after PEG placement without direct visual monitoring. The PEG tube is placed through the large bowel into the stomach. Such patients may be almost completely asymptomatic except for transient fever and ileus. The management involves PEG tube removal and spontaneous closure of the fistula<sup>[4,25]</sup>. Small bowel injuries are rather rare because the greater omentum separates the small bowel from the upper abdomen. Small bowel volvulus around the PEG usually presents with a small bowel obstruction caused by a gap between the gastric and abdominal walls<sup>[4]</sup>. Hepatic and splenic PEG-related injuries are also rare. In hemodynamically stable patients, a CT scan can confirm the diagnosis. Hemodynamically unstable patients require emergent surgical exploration, placement of hemostatic sutures in the

**Figure 2** Laparoscopy-assisted percutaneous endoscopic gastrostomy placement: An overview of the procedure. A: General view. The arrows indicate the following (respectively): liver, stomach and abdominal wall; B: Marking the puncture site. The arrows indicate the stomach and abdominal walls, and the pressed wall shows the puncture site; C: Introduction of the needle into the stomach under visual control. The arrows show the gastric wall and the trocar for percutaneous endoscopic gastrostomy (PEG) insertion; D: PEG was performed. The arrows indicate the gastric vessels and the trocar.

*liver or a splenectomy*. Severe hemorrhage is a rare complication of PEG (0.02%-0.06%) and is usually due to anticoagulation, antiplatelet therapy or an anatomic anomaly, as observed in our patients<sup>[3,23]</sup>. We did not notice any major complications from the PEG tube insertion in our patients. In our opinion, only continuous laparoscopic monitoring can ensure that the omentum, colon and small bowel will not be interposed between the stomach and the anterior abdominal wall during gastrostomy fixation in extremely malnourished children with severe kyphoscoliosis.

Minor complications, such as superficial skin infections, superficial granulation tissue formation and tube leak, are common and may occur in up to 50% of patients<sup>[3,4,9,26]</sup>. Minor skin infections usually respond to enteral antibiotics, and granulation tissue usually responds to local cautery with silver nitrate swabs. We did not notice any skin infections, tube leaks or granulation tissue formation in our patients. The patients' families and caregivers were taught how to flush the tube after feeding to avoid tube obstruction.

With respect to the laparoscopy, we use Hasson's open method and an optical access trocar to achieve pneumoperitoneum<sup>[5]</sup>. In our opinion, this method decreases the risk of injuries compared with the blind insertion of the Veress needle; however, Hasson's method may cause air leaks and prolong the operative time. In our cases, the mean duration of the operation time from the insertion of the laparoscope to the removal of the laparoscope

did not differ significantly from that of the classic PEG procedure. We did not have continuous air leaks, and the operating time was not prolonged much because of the laparoscopy. Therefore, we have continued to use this technique as the preferred method for inducing pneumoperitoneum in children. Under laparoscopic observation, the stomach can be punctured in the correct location, avoiding the colon or the liver on its way into the gastric lumen. In our study, the laparoscopic-assisted PEG procedures were performed without difficulty. There was no need to maneuver or relocate the interposed organs during the laparoscopy. This procedure, for which the technical aspects are presented in Figure 2, allowed for successful EN. The subsequent EN helped our patients recover from starvation and decreased their malnutrition-related complication ratio.

In conclusion, the laparoscopy-assisted PEG procedure is a valuable method for gastrostomy tube placement in patients in whom an upper endoscopy is possible but PEG cannot be performed safely. In our opinion, laparoscopy-assisted PEG should become the method of choice for children and adults with distorted anatomy.

## COMMENTS

### Background

Enteral nutrition (EN) is a life-saving procedure that prevents the complications associated with malnutrition. Percutaneous endoscopic gastrostomy (PEG) is the method of choice for this type of intervention because the procedure en-

ables tube feeding.

### Research frontiers

PEG placement is not always possible due to technical difficulties, such as interposed organs or kyphosis. This study aimed to analyze whether laparoscopy-assisted PEG could be a valuable option in those patients in whom the standard procedure is impossible due to distorted anatomy.

### Innovations and breakthroughs

For all the patients, the laparoscopy-assisted PEG tube placement was successful, and the EN was started four to six hours after its placement, proving that this technique is safe and effective.

### Applications

Laparoscopy-assisted PEG should become the method of choice for gastrostomy tube placement and subsequent EN if PEG placement cannot be performed safely.

### Peer review

This is an interesting article of case series of laparoscopy-assisted PEG.

need for surgery in patients with Crohn's disease (CD).

**METHODS:** Data of 506 patients with incident CD were analyzed (age at diagnosis:  $31.5 \pm 13.8$  years). Both hospital and outpatient records were collected prospectively with a complete clinical follow-up and comprehensively reviewed in the population-based Veszprem province database, which includes incident CD patients diagnosed between January 1, 1977 and December 31, 2008. Follow-up data were collected until December 31, 2009. All patients included had at least 1 year of follow-up available. Patients with indeterminate colitis at diagnosis were excluded from the analysis.

**RESULTS:** Overall, 73 patients (14.4%) required resective surgery within 1 year of diagnosis. Steroid exposure and need for biological therapy were lower in patients with early limited surgery ( $P < 0.001$  and  $P = 0.09$ ). In addition, surgery rates during follow-up in patients with and without early surgery differed significantly after matching on propensity scores ( $P < 0.001$ , HR = 0.23). The need for reoperation was also lower in patients with early limited resective surgery ( $P = 0.038$ , HR = 0.42) in a Kaplan-Meier and multivariate Cox regression ( $P = 0.04$ ) analysis. However, this advantage was not observed after matching on propensity scores ( $P_{\text{Logrank}} = 0.656$ ,  $P_{\text{Breslow}} = 0.498$ ).

**CONCLUSION:** Long-term surgery rates and overall exposure to steroids and biological agents were lower in patients with early limited resective surgery, but reoperation rates did not differ.

**Key words:** Crohn's disease; Early surgery; Disease course; Disease behavior; Treatment strategy

**Core tip:** An alternative approach may be early limited

### Abstract

**AIM:** To analyze the difference in disease course and

resective surgery in a well-selected group of patients with Crohn's disease. In this population-based study, we found that overall exposure to steroids and biological agents was lower in patients with early limited resective surgery; observed surgery rates were also lower, yet reoperation rates did not differ in the two groups after matching on propensity scores.

## INTRODUCTION

Crohn's disease (CD) has a variable course, but the majority of patients eventually develop penetrating or stricture complications. In addition, several environmental risk factors (diet, smoking, measles, or appendectomy) may contribute to its etiology and course. A significant adverse outcome is the need for surgery. Nevertheless, surgery is not curative in CD. Surgical resection is typically performed for emergency indications (*e.g.*, obstructive symptoms and hemorrhage) or for failure to respond to medical therapy.

Some years ago, a review article reported that the probability of first resective surgery ranged from 38% to 96% in the first 15 years after diagnosis<sup>[1]</sup>. The overall clinical relapse and reoperation rates after initial resective surgery are 50%-60% and 28%-45%, respectively, during the following 15 years. Surgical resection rates over time vary widely among published studies, ranging between 25 and 61% in the first 5 years. Until recently, there was little evidence that disease outcomes for CD had changed over recent decades. Recently, Peyrin-Biroulet *et al.*<sup>[2]</sup> published a systematic review of the natural history of CD in population-based cohorts. According to the authors' conclusions, the impact of changing treatment paradigms with the increased use of immunosuppressants and biological agents on the natural history of the disease was poorly understood. Available data did not suggest a significant change in outcome of CD, with approximately half of patients requiring surgery within 10 years of diagnosis. The risk of postoperative clinical recurrence within 10 years was 44%-55%.

A recent meta-analysis from International Organization for the Study of Inflammatory Bowel Diseases (IOIBD) Epidemiology Task Force reported that the risk of surgery in CD in prebiologic population-based cohorts has been decreasing during the past decade<sup>[3]</sup>. One of the most striking changes was reported by Jess *et al.*<sup>[4]</sup> in a Danish study. The rate of early surgery (within 1 year of diagnosis) has fallen from 35% (1962-1987) to 12% (2003-2004). During this time, there was a significant

change in patient management; namely, increased and earlier use of immunosuppressants and the introduction of biological therapies. The effect of azathioprine (AZA) on disease prognosis was until recently controversial. Two recent population-based reports confirmed that early AZA use is associated with reduced need for surgery according to a Cox regression analysis and propensity score matching in two population-based cohorts from Wales and Hungary<sup>[5,6]</sup>. Furthermore, in a study from France, an association was reported between the duration of anti-tumor necrosis factor (TNF) and AZA therapy and risk for surgery<sup>[7]</sup>. In contrast, in a previous referral center study from France, the need for intestinal surgery did not decrease despite the increased use of immunosuppressants<sup>[8]</sup>. Of note, in this study, AZA therapy was started only after surgery in the majority of patients. Earlier AZA use is only one of the complex changes in patient management. Other changes have also occurred, including a trend toward tight patient monitoring. Moreover, whether the risk of surgery is affected by the more widespread use of biological agents has yet to be demonstrated by population-based studies.

An alternative approach to the predominant strategy of initially using conservative therapy: using limited resective surgery in a selected group of patients as a primary therapeutic option, may prove advantageous. In a study by Aratari *et al.*<sup>[9]</sup>, early surgery at diagnosis in 207 CD patients with ileocecal disease was associated with a more benign postoperative disease course, in comparison to patients receiving delayed surgery. Nevertheless, reoperation rates were not reduced. Thus, in a subgroup of CD patients, early surgery may represent a valid alternative to medical therapy; particularly in patients with limited, isolated, stenotic ileocecal disease.

Therefore, our aim was to analyze the disease course, drug exposure and need for surgery and reoperation in patients with and without early (within 1 year of diagnosis) limited resective surgery in a population-based cohort from Eastern Europe with a complete clinical follow-up.

## MATERIALS AND METHODS

### Patients

A well-characterized Hungarian cohort of 506 patients with incident CD (male/female: 251/255; age at diagnosis:  $31.5 \pm 13.8$  years) diagnosed between January 1, 1977 and December 31, 2008 were included. Follow-up data were collected until December 31, 2009. All patients included had at least 1 year follow-up available. Patients with indeterminate colitis at diagnosis were excluded from the analysis. The clinical data of CD patients are summarized in Table 1.

### Methods

Clinical data were collected every year from the seven general hospitals (departments of internal medicine, surgery, and pediatrics) and gastroenterology outpatient units. The majority of patients [76% of ulcerative colitis (UC) and

94% of CD patients] were monitored at the Csolnok F. Province Hospital in Veszprem, where data were also registered. Disease behavior was updated yearly. A more detailed description of the data collection method, case assessment, the geographical and socioeconomic background of the province, and the results of surgical and medical management, as well as a detailed description of the Veszprem Province inflammatory bowel disease (IBD) Group, was published in previous epidemiological studies<sup>[10-12]</sup>.

The disease phenotype (age at onset, duration, location, and behavior) was determined according to the Montreal Classification<sup>[13]</sup>. The presence of perianal disease and behavior change during follow-up were also registered. Medical therapy was recorded in detail (as defined by the European Crohn's and Colitis Organisation Consensus Report<sup>[14]</sup>). The need for surgery or reoperation and smoking habits were investigated by review of medical files and by questionnaire.

The study was approved by the Semmelweis University Regional and Institutional Committee of Science and Research Ethics and by the Csolnok F. Province Hospital Institutional Committee of Science and Research Ethics.

### Treatment policy

The majority of the patients received maintenance therapy with sulfasalazine or a 5-aminosalicylic acid derivative (mesalazine or olsalazine), if tolerated, especially until the mid-1990s. AZA or 6-mercaptopurine (6-MP) was used in selected cases as maintenance therapy for steroid-dependent and -refractory patients or for patients with fistulizing disease. AZA and 6-MP were typically used following resective surgery until the late 1980s, and later on a more widespread basis beginning in the mid-1990s. Short-term oral corticosteroid treatment was used for clinical exacerbations, usually prednisone 40-60 mg/d, tapered and discontinued over the course of 2-3 mo. Beginning in the mid-1990s, methotrexate was used as second-line immunosuppressive therapy in limited cases. Since the late 1990s, infliximab has been used for both induction and maintenance therapy in selected cases.

Surgical resection was performed for emergency indications (*e.g.*, obstructive symptoms and hemorrhage) and for failure to respond to medical therapy. Surgical techniques have also changed during the follow-up period of this study; laparoscopic surgery became available and more widely used from the late 1990s. Limited resections were more widely used from the mid-1990s than in the past, and there is very limited use of defunctioning ileostomy ( $n = 4$ ) formation in routine management of CD. For the majority of patients in the present study, one of the most experienced IBD surgeons in Hungary performed the operations, while laparoscopic surgery and stricturoplasty were performed only in a minority of cases. The definition of early limited surgery was resection of the terminal ileum or ileocecum within 1 year of diagnosis.

Due to Hungarian health authority regulations, a follow-up visit is obligatory for IBD patients at a specialized

gastroenterology center every 6 mo. Otherwise, under the regulations of the Hungarian National Health Insurance (OEP) system, the right to subsidized therapy is forfeited. Consequently, the relationship between IBD patients and specialists is a close one.

### Propensity score model

The authors used two propensity score models to control further for possible confounders, to quantify the probability of surgery and reoperation in patients who had early limited resective surgery versus those who did not.

In the first propensity model, covariates included in the propensity score were selected according to a two-step process. We first constructed an outcome model identifying independent predictors of early limited resective surgery. Subsequently, we included in the model additional predictors known to be associated with surgical outcome (*e.g.*, age at onset and smoking) irrespective of *P* value. We used multivariate logistic regression to estimate propensity scores of early limited resection for each individual. Goodness-of-fit was evaluated by the Hosmer-Lemeshow test, the *P* values of which were not significant. Using the predicted propensity scores from our model, we attempted to match all early limited surgery to identical CD patients without early limited surgery by 5-to-1 greedy matching<sup>[15]</sup>. Additional analysis in patients with ileum-only disease was also performed.

In the second propensity model, we aimed to analyze the probability of reoperation in patients with and without early surgery in a group of CD patients with a history of at least one resective operation. Using the above two-step process and predicted propensity scores from our model, we attempted to match all early surgery CD patients to identical CD patients with a non-early surgical resection through 5-to-1 greedy matching<sup>[15]</sup>.

### Ethical permission

The study protocol was approved by Semmelweis University Regional and Institutional Committee of Science and Research Ethics and the Csolnok F. Province Hospital Institutional Committee of Science and Research Ethics.

### Statistical analysis

Variables were tested for normality by the Shapiro-Wilk *W* test. Wilcoxon rank sum test,  $\chi^2$  test, and  $\chi^2$  test with Yates correction and logistic regression were used to test differences in disease phenotype between subgroups of UC and CD patients for dichotomous variables. Kaplan-Meier survival curves were plotted for analysis with log rank and Breslow tests to determine probability of surgical resection. Additionally, Cox regression analysis using the enter method was used to assess the association between categorical clinical variables and time to AZA use and surgical requirements. Variables with  $P < 0.2$  in univariate analysis were included in the multivariate testing. To control further for possible confounders, we developed a propensity score models (see below) for quantifying the probability of reoperation in patients with

and without early limited resective surgery<sup>[15]</sup>. Matching on propensity scores is one technique commonly used to control for measured confounders in observational studies.  $P < 0.05$  was considered significant. Results for continuous variables were expressed as median (lower and upper quartile) unless otherwise stated. For the statistical analysis, SPSS version 20.0 was used (SPSS, Chicago, IL, United States).

## RESULTS

### Patient phenotype

Five hundred and six residents in Veszprem Province were diagnosed with CD in the 32-year period. Follow-up information was collected up to December 31, 2009, equaling 5758 patient-years of follow-up. The clinical characteristics and disease course according to the year of diagnosis is shown in Table 1. There were significant differences in disease phenotype, drug exposure, and smoking habits in the patient groups diagnosed in the early period and thereafter. Overall, exposure to AZA, systemic steroids and biological agents (after 1998 only) was 45.8%, 68.6% and 9.5%, respectively. Total AZA exposure increased in the subsequent cohorts despite shorter follow-up.

### Prevalence, predictors of surgery and early limited surgery and drug exposure

A total of 204 (40.7%) patients had at least one resective operation (5 patients with resective surgery due to malignant disease were excluded from analysis). The most common surgical procedures were ileocecal resection ( $n$

**Table 2** Predictors of early limited surgery and drug exposures

	Early surgery	No early surgery	<i>P</i> value	OR (95%CI)
Age at onset (A1)	28.4%	19.0%	0.060	1.69 (0.97-2.96)
Ileal location	59.5%	28.1%	< 0.001	
Colonic location	13.5%	39.9%	< 0.001	
Complicated behavior at diagnosis	85.1%	35.9%	< 0.001	10.2 (5.2-20.1)
Overall steroid exposure	52.7%	71.3%	0.001	0.45 (0.27-0.74)
Steroid-dependent course	2.6%	12.3%	0.070	0.19 (0.03-1.40)
Overall biological exposure	4.1%	10.0%	0.090	0.38 (0.12-1.26)
Overall azathioprine exposure	45.9%	45.8%	> 0.050	

= 93), right hemicolectomy ( $n = 59$ ), segmental colonic resection ( $n = 19$ ), and subtotal colectomy/left hemicolectomy ( $n = 11$  and 8, respectively).

A further 36 (7.1%) patients had other surgical procedures (abscess drainage or fistulectomy). Forty-two (8.4%) patients had two resective operations and 17 (3.4%) had three or more operations for CD during follow-up. Ileocecal resection was the most common procedure overall.

The probability of first intestinal surgery due to non-malignant disease after 1, 5 and 10 years was 14.6%, 30.1%, and 51.6%, respectively, in a Kaplan-Meier analysis. The cumulative probability of resective surgery rate decreased in patients diagnosed in the last decade [Group 1 (1977-1998), Group 2 (1999-2008);  $P_{\text{Logrank}} = 0.022$ , and  $P_{\text{Breslow}} = 0.07$ ].

Overall, 73 patients (14.4%) required resective surgery within 1 year of diagnosis. Ten patients were excluded from further analysis from the early surgery group in whom extensive index surgery was performed. The prevalence of early limited resective surgery did not differ significantly in the three cohorts [Cohort A (diagnosed 1977-1989): 11.3%; Cohort B (1990-1998): 12.8%; and Cohort C (1999-2008): 13.4%]. Predictors of early limited resective surgery were ileal location ( $P < 0.001$ ), colonic location ( $P < 0.001$ ), complicated behavior at diagnosis ( $P < 0.001$ ), and age of onset ( $P = 0.06$ , Table 2).

Overall steroid exposure was significantly lower ( $P = 0.001$ ) in patients with early limited resection despite similar follow-up (median: 12 years). The same trend was observed for steroid dependency ( $P = 0.07$ ) and overall biological agent exposure ( $P = 0.09$ ). In contrast, overall AZA exposure was similar between the two groups. Of note, AZA exposure before surgery was 0% *vs* 28.8% ( $P < 0.001$ ), while TNF-antagonist exposure before surgery was 0% *vs* 4.9% ( $P = 0.05$ ) in patients with and without early limited surgery. In logistic regression analysis, disease location ( $P < 0.001$ ) and disease behavior ( $P < 0.001$ ) were associated with the need for early resective surgery (Table 3).

**Table 3** Factors associated with the need for early limited surgery in logistic regression analysis

### Risk of operation in patients with and without early limited surgery

In a propensity score model, we compared surgery rates between patients with and without early resective surgery. In the early limited surgery model, propensity scores ranged from 0.02 to 0.56 (median: 0.29) in patients with early limited resection (*n* = 63), and from 0.02-0.55 (median: 0.14) in patients without early limited surgery (*n* = 428). Goodness-of-fit was evaluated by the Hosmer-Lemeshow test, and *P* values were non-significant (*P* = 0.653).

Using a 5-to-1 greedy matching algorithm, we were able to match 58 patients from the early resective surgery group to patients with comparable phenotype without early limited resections (Table 4). The observed first resective surgery rate was 12.1%, 33.2%, and 53.6% after 2, 5

**Figure 1** Need for surgery in Crohn's disease patients with and without an early limited surgery after matching on propensity scores. A: All Crohn's disease (CD) patients (*n* = 58), *P*<sub>Logrank</sub> < 0.001, HR = 0.23, 95%CI: 0.11-0.48; B: CD patients with ileal only disease location (*n* = 38). *P*<sub>Logrank</sub> < 0.001, HR = 0.25, 95%CI: 0.11-0.58.

and 10 years of disease duration, respectively, in the latter group. In contrast, the reoperation rate in the former group was 1.8%, 5.8%, and 17.9% after 2, 5 and 10 years (*P*<sub>Logrank</sub> < 0.001, HR = 0.23, 95%CI: 0.11-0.48; Figure 1A).

If the analysis was restricted to patients with ileum-only location (*n* = 38), the observed first resective surgery rate was 21%, 35.3%, and 59.4% in patients without early surgery after 2, 5 and 10 years of disease duration, respectively. In contrast, the observed reoperation rate in the other group was 0%, 5.8%, and 20.8% after 2, 5 and

Figure 2 Need for reoperation in patients with and without early resective surgery ( $P_{\text{Logrank}} = 0.038$ ).

10 years ( $P_{\text{Logrank}} < 0.001$ , HR = 0.25, 95%CI: 0.11-0.58) (Figure 1B).

### Reoperation rates and predictors for reoperation

The need for reoperation in patients with early limited resection at 5 years was 7.5%, at 10 years it was 16.5%, while for those without early resective surgery at 5 years it was 12.9%, and 36.3% at 10 years in a Kaplan-Meier analysis ( $P_{\text{Logrank}} = 0.038$ , Figure 2). In a Cox regression analysis, early limited surgery ( $P = 0.04$ ) was the only factor independently associated with the need for reoperation (Table 5).

### Reoperation rates after matching on propensity scores

In addition, we developed a propensity score model to assess further the need for reoperation in patients with and without early resective surgery. After identifying predictors, multivariate logistic regression was used to estimate propensity scores of early limited resection for each individual. Goodness-of-fit was evaluated by the Hosmer-Lemeshow test and  $P$  values were non-significant ( $P = 0.812$ ). In the early limited surgery model, propensity scores ranged from 0.10 to 0.83 (median: 0.45) in patients with early limited resection ( $n = 63$ ), and from 0.02 to 0.69 (median: 0.30) in patients with non-early surgery ( $n = 126$ ). Using a 5-to-1 greedy matching algorithm, we were able to match 54 out of 63 (85.7%) patients with early limited surgery to patients with non-early surgery. As expected, the prevalence of factors included in the propensity score model was well balanced across surgical groups (data not shown).

The observed reoperation rates did not differ between the two groups (early surgery: 1.9%, 5.9%, and 17.7%; *vs* non-early surgery: 2%, 6.7%, and 25.1%, after 1, 5 and 10

<sup>1</sup>Early resective surgery: Within the year of diagnosis.

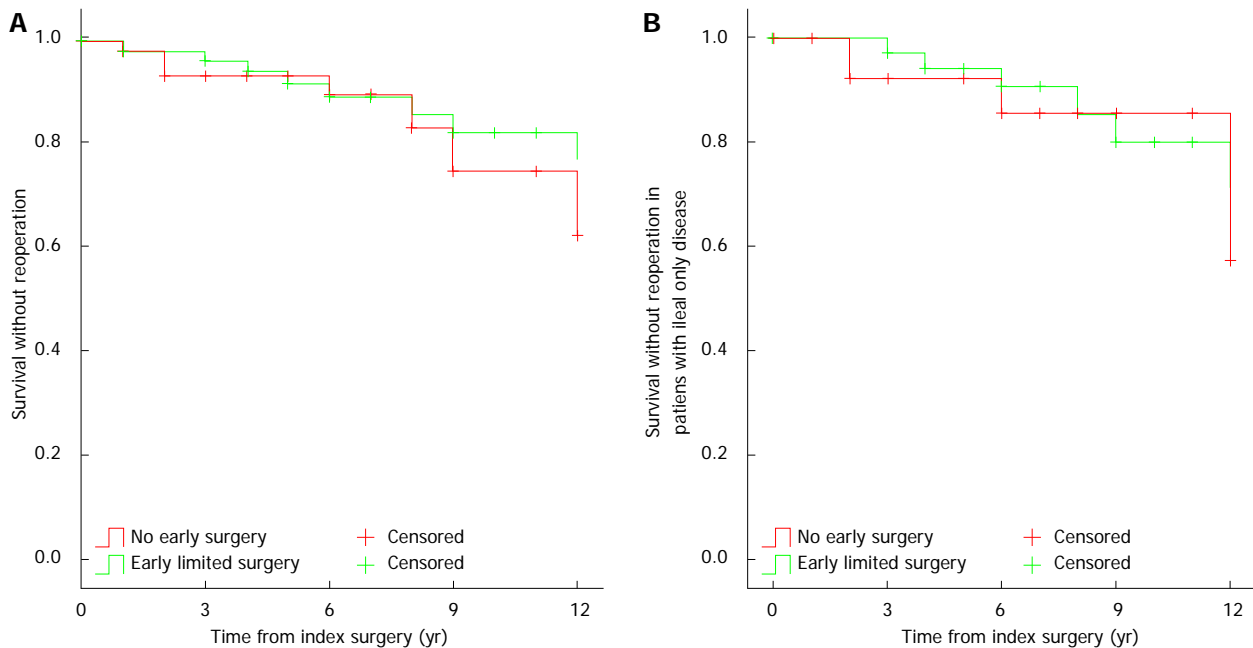

years, respectively,  $P_{\text{Logrank}} > 0.05$ , Figure 3A). Similar results were found if the analysis was restricted to patients with disease limited to the ileum only ( $n = 33$ , early surgery: 0%, 5.8%, and 20%, *vs* non-early surgery: 0%, 7.7%, and 14.3%, after 1, 5 and 10 years, respectively,  $P_{\text{Logrank}} > 0.05$ , Figure 3B).

## DISCUSSION

In the present study, we studied the benefits of early limited resective surgery in patients in a population-based Veszprem Province database. Results from this population-based inception cohort have shown that surgery rates and overall exposure to steroids and biological agents were lower in patients with early limited resective surgery. In contrast, although patients with early limited resective surgery needed less reoperation, by Kaplan-Meier analysis and multivariate Cox regression analysis, in the final propensity-score-matched model, this advantage was lost, and the probability of reoperation was similar in patients with early limited resection and non-early surgery. To the best of our knowledge, this is the first time that the association between early limited resective surgery and reoperation were studied using a propensity score model.

The rates of resective surgery vary significantly according to previous studies with a range from 25% to 61% in the first 5 years. An earlier review article by Walters *et al*<sup>[1]</sup> reported that the probability of first resective surgery was as high as 38%-96% within the first 15 years of diagnosis. The overall recurrence and reoperation rates after first resective surgery is 50%-60% and 28%-45%, respectively, during the subsequent 15 years. More recently, in the IBSEN Study, the cumulative probability of surgery was 13.6%, 27.0% and 37.9%, at 1, 5 and 10 years after diagnosis, respectively, while the risk of reoperation was also lower (9%)<sup>[16]</sup>.

**Figure 3** Need for reoperation in Crohn's disease patients with and without early resective surgery after matching on propensity scores. A: All Crohn's disease (CD) patients ( $n = 54$ ).  $P_{\text{Logrank}} > 0.05$ ; B: CD patients with ileal only disease location ( $n = 33$ ).  $P_{\text{Logrank}} > 0.05$ .

Similarly, in a recent meta-analysis from the IOIBD Epidemiology Task Force, the authors reported that the probability of surgery in CD decreased gradually between 1955 and 2003, even before the advent of the biological era<sup>[3]</sup>. An association with increased and earlier use of immunosuppressants was also suggested in studies from Wales<sup>[6]</sup> and Hungary<sup>[5]</sup>. Ramadas *et al.*<sup>[6]</sup> found that the rates of intestinal surgery decreased during the study period from 59% to 25% within 5 years of diagnosis. There was also a significant reduction in patients having any surgical procedure, from 60% to 35%. Likewise, in a previous referral center study from Hungary, early monotherapy with AZA or combination AZA/biological therapy was associated with a reduced risk for surgery. In earlier published studies from this cohort, the probability of surgical resection was 9.8%, 18.5% and 21.3% after 1, 3 and 5 years, respectively, in patients diagnosed between 2002 and 2006, and a recent decrease in surgical rates (in patients diagnosed after 1998) was observed<sup>[12]</sup>. These changes were associated with increased and earlier use of immunosuppressants<sup>[5]</sup>. Notwithstanding, the change in the use of immunosuppressants could be regarded as a marker of the complex changes in patient management rather than an exclusive factor itself.

Additional predictors of surgery include ileal or colonic disease location, complicated disease behavior, and age at onset - as reported previously in Sweden<sup>[17]</sup> and more recently from the IBSEN cohort<sup>[16]</sup>. Similarly, ileal (HR = 2.35) or ileocolonic (HR = 1.79) location compared to isolated colonic disease, as well as stricturing (HR = 4.33) or penetrating (HR = 3.44) disease at diagnosis, but not perianal disease, were independently associated with time to first surgery in a population-based cohort study from our research group<sup>[18]</sup>. Interestingly, we ob-

served a similar phenotype pattern associated with early limited resection (ileal location,  $P < 0.001$ ; complicated behavior,  $P < 0.001$ ; and age at onset,  $P = 0.06$ ).

However, the risk of surgery, as well as the disease course in patients with primary ileocecal CD, is somewhat different. In an earlier Swedish study, the risk of resective surgery in patients with primary ileocecal CD was 61%, 77% and 83%, after 1, 5 and 10 years of diagnosis, respectively, in 907 patients<sup>[19]</sup>. Relapse rates were 28% and 36% within 5 and 10 years of the first resection, respectively. In an Italian study, clinical and surgical recurrence rates after 5 years were 30.6% and 49.4%, and after 10 years they were 3.6% and 28%, respectively<sup>[20]</sup>. In addition, early surgery (within 3 years of diagnosis) was associated with a longer postoperative course free from clinical recurrence compared with late surgery, but not with reoperation. In the present study, despite higher rates of ileal and complicated disease in patients with early limited surgery, the overall need of steroids (OR = 0.45,  $P < 0.001$ ) during follow-up was lower, and there was a similar tendency for steroid-dependent disease course ( $P = 0.07$ ) and need for biological agents ( $P = 0.09$ ). In contrast, the overall use of AZA was similar in both groups, which may represent an active therapeutic decision by the treating physician rather than a marker of negative disease outcome. Of note, median follow-up was similar for both groups (12 years). We defined early surgery as that performed within 1 year of diagnosis, to avoid a potential bias due to early medical therapy. Of note, a positive effect of early aggressive medical therapy was already observed in patients in whom AZA was started within 18 mo of diagnosis, in a previous study in this cohort<sup>[5]</sup>. In addition, since reoperation rates may be lower in patients with extensive initial surgery due to the anatomical situa-

tion, we excluded these patients from the final analysis.

Comparable data were reported by Aratari *et al*<sup>[9]</sup>. In that study, early limited surgery at diagnosis was associated with less clinical recurrence - defined as need for steroids and lesions documented by endoscopy or radiology ( $P = 0.01$ ), and less need for immunosuppressants ( $P = 0.05$ ), but reoperation rates were not significantly different. Immunosuppressants were started in only 16.2% of patients with early or late surgery, confirming that the medical approach reported by the authors was much more conservative compared to the present study. In addition, the need for immunosuppressants was interpreted as a negative outcome. In another Italian study, the disease course of CD patients diagnosed during emergency surgery was compared to patients without emergency surgery<sup>[21]</sup>. The authors reported that the disease course was more benign in patients requiring surgery at diagnosis, by both univariate and multivariate analysis. Similar to the present study, surgery rates were significantly lower in patients operated on at diagnosis (in the present study with early limited surgery) compared to patients without surgery at diagnosis (in the present study without early limited surgery after matching on propensity scores). Observed surgery rates in the Italian study were 14% and 30% in the surgery-at-diagnosis group and 30% and 44% in the non-early surgery group, respectively. Of note, this design mimics clinical trials comparing two treatment algorithms: (1) early limited resective surgery; and (2) medical therapy but no early surgery. Observed surgery and drug exposure rates were clearly different. However, a different interpretation of our results may be that 40%-45% of patients could avoid surgery despite a similar patient phenotype within 10 years of diagnosis, while in the other group, all patients started with a limited operation. In addition, in the non-early surgery group, only 25.6% of patients received early AZA therapy. Thus, their therapeutic strategy was far from optimized. Moreover, reoperation rates were also analyzed in the present study, which would be very difficult in a clinical trial due to the need for long term follow-up. These were lower in patients with early limited resection versus those without early limited resection by Kaplan-Meier ( $P_{\text{Logrank}} = 0.038$ ) and Cox regression ( $P = 0.04$ ) analysis but the difference was lost after matching on propensity scores. Cost-benefit was not analyzed but with the increasing exposure to biological agents in certain CD populations<sup>[22]</sup>, these studies are urgently awaited.

The authors are aware of the possible limitations of the present study. One such potential limitation is the partially retrospective nature of the study, which may have led to bias in data interpretation. However, data were collected prospectively since 1985 and intestinal resection can be considered an unbiased and solid criterion, even retrospectively, because the indications for surgical intervention are well established. Another possible criticism may be the definition of early surgery. In this subgroup, patients presented partly with a short history of subacute or even acute symptoms. In these patients,

the timing of surgery was determined by the clinical presentation and not by the physician's strategic decision. However, this was also the case for a proportion of non-early surgical patients. Patient management has also changed significantly with regard to surgery techniques (laparoscopy) and imaging (availability of computed tomography and magnetic resonance imaging) that could have potentially affected therapeutic decision making, including indication for surgery. However, in the present study, one leading surgeon performed the majority of the operations and laparoscopic surgery and stricturoplasty was performed only in a minority of the cases. Similarly, there was only limited use of defunctioning ileostomy formation in routine management of CD during the follow-up period. Finally, postoperative management has significantly changed during the follow-up period, including routine endoscopy evaluation and prophylactic therapy; although in our analysis, we matched the groups for decade of diagnosis. In addition, there is accumulating evidence that anti-TNF therapies may reduce the number of operations<sup>[7,23]</sup>, although this was not a universal finding<sup>[24,25]</sup>. Exposure to biological agents was limited in the present study, and most of these patients received induction-only or intermittent infliximab therapy. In contrast, the strengths of this study include the long-term, comprehensive, validated data capture, and the use of both propensity score matching and multiple Cox regression analysis to overcome the limitations present in any partly retrospective study, thereby enabling unbiased analysis. Moreover, a follow-up of several years is needed to assess the reoperation rates, especially in patients without early limited resection, which is almost impossible in a clinical trial.

In conclusion, early limited resective surgery was associated with a lower risk for surgery and lower overall exposure to steroids and biological agents in this population-based cohort but it was not preventive for reoperations after matching on propensity scores. In addition, the similar exposure to immunosuppressants in the two groups may be interpreted as an active medical decision rather than a negative disease outcome. Conversely, resective surgery could be avoided in 40%-45% of CD patients with a similar disease phenotype without an early limited surgery within 10 years of diagnosis.

## COMMENTS

### Background

The optimal initial therapy in patients with limited, isolated, stenotic ileocecal Crohn's disease (CD) is debated. In some cases, early surgery may represent a valid alternative to medical therapy.

### Research frontiers

There are only limited data available on the disease course, including drug exposures, operation and reoperation rates in patients with and without an early limited resective surgery. In addition, data are lacking from population-based cohorts.

### Innovations and breakthroughs

The present long-term, population-based study in a well-characterized cohort of patients with CD has found that the overall exposure to steroids and biologicals was lower in patients with early limited resective surgery, observed surgery

rates were also lower, yet reoperation rates were not different in the two groups after matching on propensity scores

### Applications

Understanding the disease course in this subgroup of patients with CD may lead to more optimized patient management and follow-up.

### Terminology

Disease phenotype is categorized according to the Montreal classification and includes age at onset location and. Early limited surgery was defined as a resective surgery within the year of diagnosis and affecting only the terminal ileum and cecum.

### Peer review

This is good research. To add impact, adding in other centres in Europe should be considered in future.

### Abstract

**AIM:** To assess co-stimulatory and co-inhibitory markers of dendritic cells (DCs) in hepatitis C virus (HCV) infected subjects with and without uremia.

**METHODS:** Three subject groups were included in the study: group 1 involved 50 control subjects, group 2 involved 50 patients with chronic HCV infection and group 3 involved 50 HCV uremic subjects undergoing hemodialysis. CD83, CD86 and CD40 as co-stimulatory markers and PD-L1 as a co-inhibitory marker were assessed in peripheral blood mononuclear cells by real-time polymerase chain reaction. Interleukin-10 (IL-10) and hyaluronic acid (HA) levels were also assessed. All

findings were correlated with disease activity, viral load and fibrogenesis.

**RESULTS:** There was a significant decrease in co-stimulatory markers; CD83, CD86 and CD40 in groups 2 and 3 *vs* the control group. Co-stimulatory markers were significantly higher in group 3 *vs* group 2. There was a significant elevation in PD-L1 in both HCV groups *vs* the control group. PD-L1 was significantly lower in group 3 *vs* group 2. There was a significant elevation in IL-10 and HA levels in groups 2 and 3, where IL-10 was higher in group 3 and HA was lower in group 3 *vs* group 2. HA level was significantly correlated with disease activity and fibrosis grade in group 2. IL-10 was significantly correlated with fibrosis grade in group 2. There were significant negative correlations between co-stimulatory markers and viral load in groups 2 and 3, except CD83 in dialysis patients. There was a significant positive correlation between PD-L1 and viral load in both HCV groups.

**CONCLUSION:** A significant decrease in DC co-stimulatory markers and a significant increase in a DC co-inhibitory marker were observed in HCV subjects and to a lesser extent in dialysis patients.

**Key words:** Hepatitis C virus; Uremia; Hemodialysis; Dendritic cells; CD83; CD86, CD40; PD-L1; Interleukin-10; Hyaluronic acid

**Core tip:** An assessment of the gene expression of co-stimulatory and a co-inhibitory marker (CD83, CD86, CD40, PD-L1) was conducted in patients with hepatitis C virus (HCV) infection and their correlations with viral load, hepatitis activity score and fibrosis grade were determined. There was a significant decrease in dendritic cell (DC) co-stimulatory markers in HCV infected

subjects, where HCV uremic subjects exhibited a lower degree of reduced co-stimulatory markers. There was a significant increase in the DC co-inhibitory marker in HCV infected subjects, where HCV uremic subjects exhibited a lower degree of increased co-inhibitory marker. All DC markers were significantly correlated with HCV viral load, hepatitis activity index and fibrosis score.

## INTRODUCTION

Hepatitis C virus (HCV) infection is a major public health problem, with an estimated global prevalence of 3% occurring in about 180 million carriers and approximately 4 million people are newly infected annually<sup>[1]</sup>. It is estimated that up to 70% of individuals exposed to HCV develop viral persistence<sup>[2,3]</sup>. On average, over half a million people in Egypt are infected by HCV annually, far more than any other country in the world, according to a new study published in 2010<sup>[4]</sup>.

A high prevalence of HCV has been reported among hemodialysis (HD) patients worldwide. The prevalence of HCV infection among HD patients is significantly higher than healthy blood donors and the general population<sup>[5]</sup>. HD patients may be at risk for HCV due to the involvement of multiple routes of infection, especially poor blood screening of transfused blood, low standard of dialysis procedures and the need to apply infection control practices.

Patients who spontaneously clear HCV infection have strong and broad T cell responses, while patients with chronic HCV have weak and functionally impaired responses characterized by poor proliferation, impaired cytotoxicity and reduced cytokine secretion after antigen exposure<sup>[6,7]</sup>. Dendritic cells (DCs) are efficient and potent antigen presenters and activators of antigen-specific T cells and adaptive immunity<sup>[8]</sup>. Defective DC activation of T cells may underlie poor T cell responsiveness in HCV infection, and may, in part, determine the response to therapy<sup>[9,10]</sup>.

Human peripheral blood DCs are currently categorized into two major subsets: myeloid DCs (mDCs) and plasmacytoid DCs (pDCs). mDCs are effective antigen presenters to T cells and secrete interleukin 12, while pDCs are the most potent secretors of antiviral type-I interferons such as interferon  $\alpha$  (IFN- $\alpha$ )<sup>[11]</sup>. DCs migrate to sites of inflammation, sample antigens, and integrate generic microbial danger signals *via* innate immune receptors, named pathogen recognition receptors (PRRs)

that recognize pathogen-associated molecular patterns<sup>[12]</sup>. Signals from PRRs combine with signals from inflammatory cytokines to activate DCs, causing up-regulation of co-stimulatory molecules such as CD40 and CD86. DCs then migrate to lymphoid tissue where they activate antigen-specific CD4 and CD8 T cells by presenting antigens on major histocompatibility complex (MHC) class I and II molecules<sup>[13,14]</sup>.

Reports of global immune dysfunction in HCV infection are controversial; some authors have found faulty responses to general PRRs stimulation including decreased IFN $\alpha$  and IL12 secretion, reduced CD86 expression, decreased HLA-DR (MHC class II) and impaired stimulation of T cells in mixed lymphocyte reaction compared with normal controls<sup>[13]</sup>. Specific HCV proteins such as core and E2 can cause DC dysfunction in tissue culture models<sup>[14]</sup>. Other authors, including those using direct *ex vivo* human samples or a chimpanzee model of HCV have found no defects<sup>[15,16]</sup>. It has been consistently shown in HCV infection that pDC and mDC numbers are reduced in the peripheral compartment compared with normal controls, whereas reports have described increased numbers of DCs in the livers of HCV patients, suggesting hepatic DC sequestration<sup>[17-20]</sup>. The unresolved controversies listed above highlight the need for further study of DCs in HCV infection.

With regard to HD patients with HCV, some researchers reported altered monocyte-derived DC function in patients on HD<sup>[21]</sup>. However, reports on the natural history of hepatitis C in HD patients vary. Several studies stated that HCV disease activity in HD patients is mild, and is not progressive, perhaps due to immunological abnormalities in these patients<sup>[22]</sup>.

The present study was conducted to assess DC response to HCV infection *via* assessment of the gene expression of co-stimulatory markers (CD83, CD86, and CD40) and a co-inhibitory marker (PD-L1) in pDCs and mDCs, and to study the correlations between DC functions and viral load, hepatitis activity score and fibrosis grade.

## MATERIALS AND METHODS

The present study was conducted in the Hepatic Virology Center, Kasr Al-Ainy, Faculty of Medicine, Cairo University. The study involved Group I which included 50 healthy subjects of both genders aged 18-40 years representing the control group and 100 adult age- and sex-matched patients with HCV-related chronic liver disease (CLD).

The patients selected had to comply with the following inclusion criteria: HCV antibody-positive serum and HCV RNA-positive serum by reverse transcription polymerase chain reaction (RT/PCR) for more than 6 months. All patients had to comply with the following exclusion criteria: coinfection with HBV and HCV, hepatocellular carcinoma, severe psychiatric disease, serious co-morbid conditions, HIV-positive patients defined as

having a positive reaction to anti-HIV-1/2 (EIA), auto-immune hepatitis (positive reaction to antinuclear, anti-smooth muscle, anti-mitochondrial and anti-liver-kidney microsomal antibodies), schistosomiasis mansoni (patients with no previous history and negative stool examination), no previous history of regular use of hepatotoxic drugs or alcohol abuse (> 40 g of alcohol/d).

HCV patients were categorized into two groups: Group 2 included 50 HCV subjects with related CLD who were candidates for interferon therapy, and Group 3 included 50 HCV uremic subjects undergoing HD.

Patients were subjected to full clinical examination and abdominal ultrasonography. The following parameters were assessed in all subjects: serum levels of IL-10 and hyaluronic acid (HA) to assess fibrosis, as these parameters have been shown to be accurate in predicting significant fibrosis, severe fibrosis, and cirrhosis with area under characteristic curves (AUCs) of 0.73, 0.77 and 0.97, respectively. Moreover, accurate HA level cut-offs were defined for predicting significant fibrosis, severe fibrosis, and cirrhosis<sup>[23]</sup>. In addition, HA was an accurate noninvasive marker in predicting significant fibrosis in patients with hepatitis C on HD.

Quantitative gene expression of CD83, CD86, CD40 and PD-L1 in peripheral blood mononuclear cells was assessed by real-time PCR<sup>[24-27]</sup>. Histopathological examination of liver biopsy was performed using the Metavir scoring system for grading inflammation and staging fibrosis<sup>[28]</sup>.

Whole blood samples were collected from all subjects. Serum was separated for assessment of HA and IL-10 levels by ELISA kits supplied by Corgenix Inc. (Westminster, CO, United States) according to the manufacturer's recommendations.

The peripheral blood mononuclear cell layer (buffy coat) was isolated using Histopaque-1077 (Sigma, St. Louis, MO, United States) and centrifuged at 400 *g* for 30 min. Total RNA was isolated from the buffy coat using RNeasy purification reagent (Qiagen, Valencia, CA, United States). cDNA was generated from 5 µg of total RNA extracted with 1 µL (20 pmol) antisense primer and 0.8 µL superscript AMV reverse transcriptase for 60 min at 37 °C. The relative abundance of mRNA species was assessed using the SYBR® Green method on an ABI prism 7700 sequence detector system (Applied Biosystems, Foster City, CA, United States). PCR primers were designed with Primer-BLAST Software<sup>[29]</sup>, (<http://www.ncbi.nlm.nih.gov/tools/primer-blast>) for RNA sequences from GenBank (Table 1). All primer sets had a calculated annealing temperature of 60 °C. Quantitative RT-PCR was performed in duplicate in a 25 µL reaction volume consisting of 2X SYBR Green PCR Master Mix (Applied Biosystems, United States), 900 nmol/L of each primer and 2-3 µL of cDNA. Amplification conditions were 2 min at 50 °C, 10 min at 95 °C and 40 cycles of denaturation for 15 s and annealing/extension at 60 °C for 10 min. Data from real-time assays were calculated using the v1.7 Sequence Detection Software from PE Biosystems

(Foster City, CA, United States). Relative gene expression of CD83, CD86, CD40 and PD-L1 mRNA was calculated using the comparative Ct method as previously described. All values were normalized to the glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene and reported as fold change over background levels detected in the control group.

### Statistical analysis

The SPSS program version 16.0.1 (SPSS Inc., Chicago, IL, United States) was used. Numerical data were expressed as mean ± SD. For comparisons between treatment groups, the null hypothesis was tested by a single-factor ANOVA for multiple groups or unpaired *t* test for two groups. Comparisons were considered statistically significant if *P* < 0.05. Spearman correlations were assessed between certain studied parameters.

## RESULTS

The results showed that there was a significant decrease in all co-stimulatory markers; CD83, CD86 and CD40 in group 2 (HCV subjects) and in group 3 (HCV subjects on HD) in comparison to control subjects. Co-stimulatory markers were significantly higher in group 3 in comparison to group 2. With regard to PD-L1, there was a significant increase in groups 2 and 3 in comparison to control subjects. PD-L1 was significantly lower in group 3 as compared to group 2 (Figure 1). This was reflected in viral load, where significant negative correlations were observed between all co-stimulatory markers and viral load in groups 2 and 3, except CD83 in dialysis patients (Figure 2)

The findings in the present study showed a significant elevation in IL-10 and in HA levels in groups 2 and 3, where IL-10 was more significantly elevated in group 3 and HA was significantly lower in group 3 in comparison to group 2 (Figure 3).

Figure 1 Relative quantitative gene expression of CD83, CD86, CD40 and PD-L1 in all study subjects expressed as mean  $\pm$  SD. <sup>a</sup> $P < 0.05$  in both hepatitis C virus (HCV) patient groups vs control group; <sup>c</sup> $P < 0.05$  in the HCV patient group vs HCV uremic patients on hemodialysis.

In group 2, the results showed that there was a significant correlation between HA and hepatitis activity score as well as grade of fibrosis;  $P < 0.001$ . No correlation between IL-10 levels and hepatitis activity score was observed, whereas, there was a significant positive correlation between IL-10 and fibrosis grade,  $P < 0.001$  (Figure 4). Biopsy samples were not taken from group 3 patients (HCV on dialysis).

The results showed that there were significant negative correlations between all co-stimulatory markers and viral load in groups 2 and 3, except CD83 in dialysis patients. There was a significant positive correlation between PD-L1 and viral load in both HCV groups (Figure 2).

Of the 50 non-uremic patients who were candidates for interferon therapy only 4 remained PCR positive for HCV after treatment.

## DISCUSSION

The results of the present study showed that in HCV infected subjects peripheral blood mononuclear cells exhibited lower expression of co-stimulatory markers; CD83, CD86, and CD40 and higher expression of a co-inhibitory marker; PD-L1 in comparison to healthy control subjects. Various studies have assessed DC function in HCV infection. Some have reported that DC function was impaired in HCV infection, which was identified by impaired allostimulatory capacity, decreased DC frequencies, increased mDC IL-10 secretion and decreased IL-12 secretion, as well as decreased pDC IFN- $\alpha$  secretion, while others did not<sup>[15,17,30]</sup>.

Our findings coincide with the results reported by MacDonald *et al.*<sup>[12]</sup>, who stated that monocyte-derived DCs from patients with chronic HCV infection were significantly defective in their capacity to up-regulate the expression of surface molecules involved in antigen presentation (HLA-DR, CD86, CD40) and a classical marker

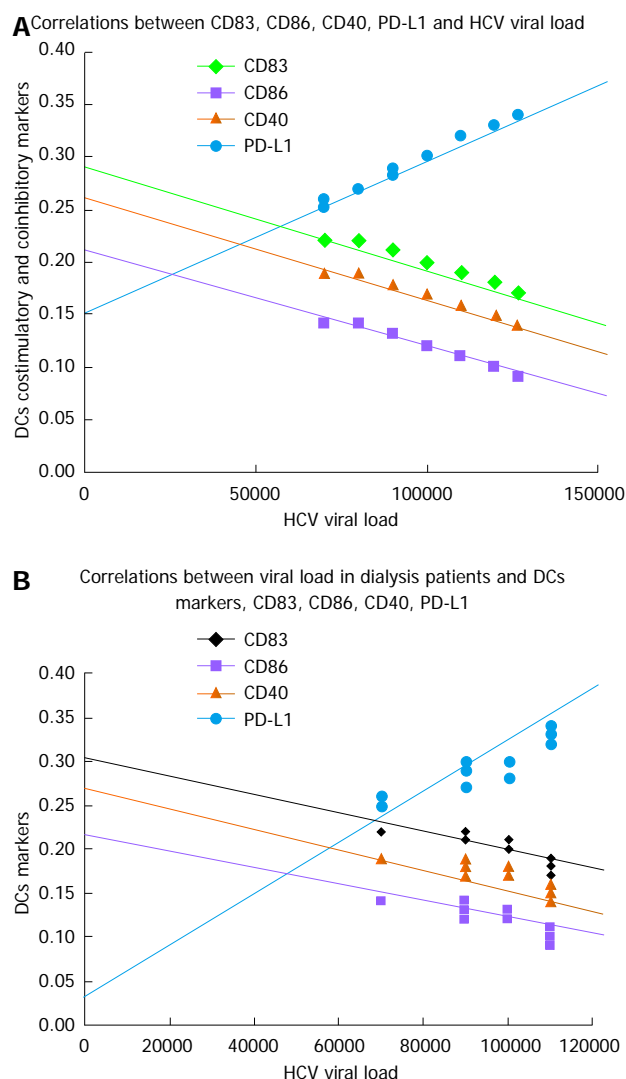

Figure 2 Correlations. A: Between hepatitis C viremia and CD83.  $r = -0.98$ ,  $P < 0.001$ , CD86:  $r = -0.866$ ,  $P < 0.001$ , CD40:  $r = -0.98$ ,  $P < 0.001$ , PD-L1:  $r = 0.889$ ,  $P < 0.001$ ; B: Between hepatitis C viremia in uremic patients on hemodialysis and CD83.  $r = -0.096$ ,  $P > 0.05$  NS, CD86:  $r = -0.588$ ,  $P < 0.05$ , CD40:  $r = -0.946$ ,  $P < 0.001$ , PD-L1:  $r = 0.663$ ,  $P < 0.05$ . HCV: Hepatitis C virus; DC: Dendritic cell

of DC activation (CD83) and at physiological ratios of DCs to T cells, and decreased their ability to present antigen in allogeneic mixed lymphocyte reaction (MLR) assays. More recently, Shen *et al.*<sup>[24]</sup> reported that impaired HCV-specific T cell immunity was associated with the persistence of HCV infection. DC dysfunction was believed to be involved in impaired T cell immunity, but the mechanisms are not understood. The results showed that the expression of both co-stimulatory markers (CD83, CD86, and CD40) and a co-inhibitory marker (PD-L1) was imbalanced in HCV-infected patients compared with healthy controls. The PD-L1/CD86 ratio was increased and positively correlated with PD-L1 expression on DCs in HCV-infected patients. The allostimulatory capacity of DCs was impaired and inversely correlated with PD-L1 expression and the PD-L1/CD86 ratio. These findings agree with our study and suggest that the effect of inhibitory marker PD-L1 overwhelmed the effect of co-

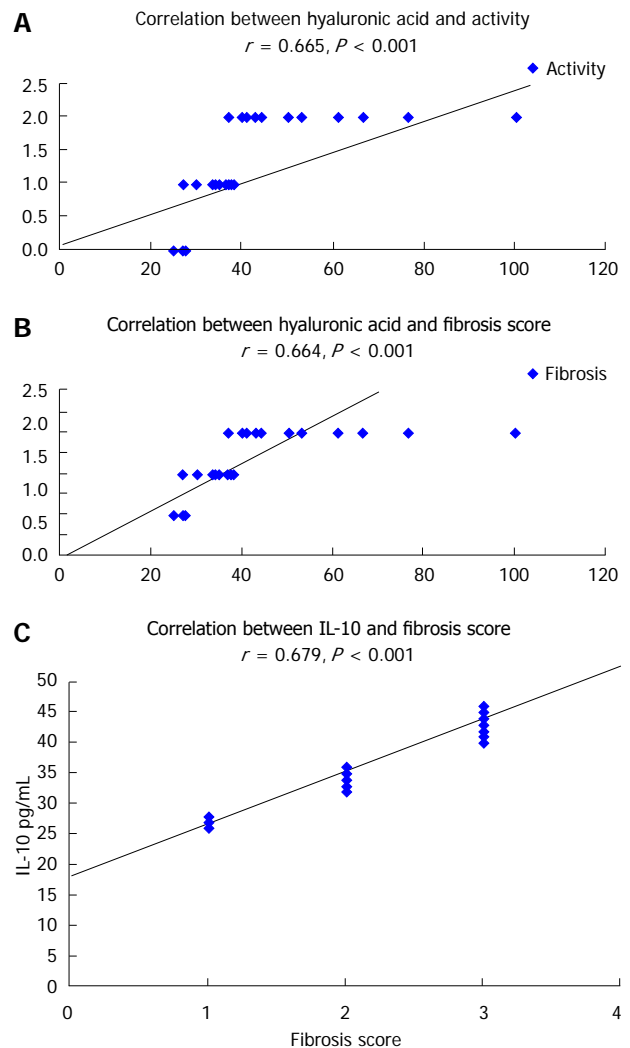

**Figure 3** Serum levels of hyaluronic acid (ng/mL) and interleukin-10 (pg/mL) in all study subjects expressed as mean  $\pm$  SD. <sup>a</sup> $P < 0.05$  vs control group, <sup>c</sup> $P < 0.05$  in the hepatitis C virus (HCV) patient group vs HCV uremic patients on hemodialysis. IL-10: Interleukin-10.

stimulatory markers and down-regulated DC-T activation in HCV-infected patients.

HCV may inhibit the immune response of DCs, hindering the adaptive response from T cells<sup>[31]</sup>. It was hypothesized that DC dysfunction may determine the response to PEG-IFN/ribavirin therapy. In the study by Mengshol *et al.*<sup>[32]</sup>, the authors found that pDCs and mDCs were decreased compared to normal controls, consistent with prior studies in HCV and similar to prior studies of patients with HIV<sup>[33]</sup>.

In the present study, the results of HA assessment revealed a significant elevation in HCV infected subjects in comparison to the healthy control group. Moreover, HA levels were positively correlated with hepatitis activity score and grade of fibrosis. These findings can be explained by a recent study conducted on another virus by Spahn *et al.*<sup>[34]</sup>, who stated that ineffective CD8 (+) T cell immunity to adeno-associated virus can result in prolonged liver injury and fibrogenesis. More recently, Jiao *et al.*<sup>[35]</sup> determined whether liver DCs play a role in enhancing regression of liver fibrosis in murine carbon tetrachloride-induced liver injury. They found that conditional DC depletion soon after discontinuation of the liver insult led to delayed regression of fibrosis and reduced clearance of activated hepatic stellate cells, the key fibrogenic cells in the liver. Conversely, DC expansion induced either by Flt3L (fms-like tyrosine kinase-3 ligand) or adoptive transfer of purified DCs accelerated liver fibrosis regression. DC modulation of fibrosis was partially dependent on matrix metalloproteinase (MMP)-9, as MMP-9 inhibition abolished the Flt3L-mediated effect and the ability of transferred DCs to accelerate regression of fibrosis. In contrast, transfer of DCs from MMP-9-deficient mice failed to improve fibrosis regression. Another study conducted by Ryan *et al.*<sup>[36]</sup> proved that in HCV chronically infected subjects, a single nucleotide polymorphism in a c-type lectin expressed by DCs,

**Figure 4** Correlation analysis. A: Between hyaluronic acid levels and hepatitis activity score ( $P < 0.001$ ); B: Between hyaluronic acid levels and fibrosis score ( $P < 0.001$ ); C: Between interleukin-10 (IL-10) levels and fibrosis score ( $P < 0.001$ ).

CD209, was associated with more advanced liver disease and with significantly higher liver fibrosis scores.

With regard to IL-10 levels in our study, the findings revealed significantly elevated IL-10 levels in HCV infected subjects in comparison to healthy controls. Moreover, IL-10 levels were positively correlated with fibrosis grade. These findings agree with results reported by Díaz-Valdés *et al.*<sup>[37]</sup>, who stated that high levels of IL-10 present in chronic HCV infection are associated with the poor antiviral cellular immune responses found in these patients. To overcome the immunosuppressive effect of IL-10 on antigen-presenting cells such as DCs, they developed peptide inhibitors of IL-10 and found that IL-10 inhibiting peptides have important applications in enhancing anti-HCV immune responses by restoring the immunostimulatory capabilities of DCs.

With regard to HD patients, Choi *et al.*<sup>[21]</sup> found that surface expression of major histocompatibility complex class II, CD83, and CD86, and chemokine receptor CCR7 in monocyte derived dendritic cells (moDCs) was

not different between HD patients and healthy controls. Furthermore, moDCs from HD patients produced significantly higher amounts of IL-6, IL-8, IL-1b, and TNF- $\alpha$  when stimulated by cytokine cocktails compared to healthy controls. Abnormalities in cytokine production by moDCs in ESRD patients have also been reported in several previous studies<sup>[38,39]</sup>. Verkade *et al.*<sup>[39]</sup> also demonstrated a marked increase in IL-15 production, a known stimulatory cytokine for DCs, while IL-10 and IL-12p70 levels were not different. In addition, mature moDCs from HD patients showed significantly enhanced allogeneic T cell proliferation compared to healthy controls. These findings could explain our results which showed a significantly lower degree of reduced co-stimulatory markers as well as a significantly lower degree of elevated co-inhibitory marker in HD patients as compared to HCV subjects without uremia.

In conclusion, a significant decrease in DC co-stimulatory markers in HCV infected subjects was observed, where HCV uremic subjects exhibited a lower degree of reduced co-stimulatory markers. There was a significant increase in the DC co-inhibitory marker in HCV infected subjects, where HCV uremic subjects exhibited a lower degree of elevated co-inhibitory marker. All DC markers were significantly correlated with HCV viral load, hepatitis activity index and fibrosis score.

## COMMENTS

### Background

Defective dendritic cell (DC) activation of T cells may underlie poor T cell responsiveness in hepatitis C virus (HCV) infection, and may, in part, determine the response to therapy. It has been consistently shown in HCV infection that plasmacytoid DCs (pDCs) and myeloid DCs (mDCs) numbers are reduced in the peripheral compartment compared with normal controls. Other reports have described increased numbers of DCs in the livers of HCV patients, suggesting hepatic DC sequestration. The unresolved controversies listed above highlight the need for further study of DCs in HCV infection. With regard to hemodialysis (HD) patients with HCV, some researchers have reported altered monocyte-derived dendritic cell function in patients on HD. However, reports on the natural history of hepatitis C in HD patients vary. Several studies stated that HCV disease activity in HD patients is mild, and is not progressive, perhaps due to immunological abnormalities in these patients. The present study was conducted to assess DC response to HCV infection with and without uremia via assessment of the gene expression of co-stimulatory markers (CD83, CD86, and CD40) and a co-inhibitory marker (PD-L1) in pDCs and mDCs, and to study the correlations between DC functions and viral load, hepatitis activity score and fibrosis grade.

### Research frontiers

Researchers have recently explored the mechanisms by which DC function is regulated during HCV infection, leading to impaired antiviral T cell responses and so to persistent viral infection. Recently, DC-based vaccines against HCV have been developed. Several studies describe the current understanding of DC function during HCV infection and explore the prospects of DC-based HCV vaccines. In particular, they describe the biology of DC, the phenotype of DC in HCV-infected patients, the effect of HCV on DC development and function, studies on new DC-based vaccines against HCV infection, and strategies to improve the efficacy of DC-based vaccines.

### Innovations and breakthroughs

A recent study stated that the immature pDC phenotype and sustained pDC and mDC hyperresponsiveness are associated with spontaneous resolution of acute HCV infection. Several investigators found that injection of DCs presenting viral proteins constitutes a promising approach to stimulate T cell immunity

against HCV. They also describe the strategy implemented to enhance antigen loading and immunostimulatory functions of DCs used in the preparation of therapeutic vaccines.

### Applications

Assessment of DC functions in HCV patients may be applicable to anticipate the response to HCV standard of care therapy and to assign patients to specific therapeutic protocols. DC-based immunotherapy may be used in selected HCV cases with poor therapeutic response, high fibrosis index and high hepatitis activity score.

### Terminology

Plasmacytoid DCs (pDCs), myeloid DCs (mDCs), interferon  $\alpha$  (IFN $\alpha$ ), pathogen recognition receptors (PRRs), pathogen-associated molecular patterns (PAMPs), co-stimulatory markers (CD83, CD86, and CD40), a co-inhibitory marker (PD-L1), matrix metalloproteinase (MMP).

### Peer review

Interesting subject with sufficiently large cohorts to detect difference in response to Hepatitis C infection in those with liver disease vs others under dialysis treatment for chronic kidney failure. The key finding that there is "a significant decrease in dendritic cell co-stimulatory markers in HCV infected subjects, where HCV uremic subjects exhibited lower degree of the decrease. There was a significant increase in dendritic cell co-inhibitory marker in HCV infected subjects, where HCV uremic subjects exhibited lower degree of the elevation." If proved in an individual HCV patient may prove important in directing management of HCV infected persons.

### Abstract

**AIM:** To evaluate the clinical characteristics of non-variceal upper gastrointestinal hemorrhage (NGIH) in patients with chronic kidney disease (CKD).

**METHODS:** From 2003 to 2010, a total of 72 CKD patients (male  $n = 52$ , 72.2%; female  $n = 20$ , 27.8%) who had undergone endoscopic treatments for NGIH were retrospectively identified. Clinical findings, endoscopic features, prognosis, rebleeding risk factors, and mortality-related factors were evaluated. The characteristics of the patients and rebleeding-related data

were recorded for the following variables: gender, age, alcohol use and smoking history, past hemorrhage history, endoscopic findings (the cause, location, and size of the hemorrhage and the hemorrhagic state), therapeutic options for endoscopy, endoscopist experience, clinical outcomes, and mortality.

**RESULTS:** The average size of the hemorrhagic site was  $13.7 \pm 10.2$  mm, and the most common hemorrhagic site in the stomach was the antrum ( $n = 21$ , 43.8%). The most frequent method of hemostasis was combination therapy ( $n = 32$ , 44.4%). The incidence of rebleeding was 37.5% ( $n = 27$ ), and 16.7% ( $n = 12$ ) of patients expired due to hemorrhage. In a multivariate analysis of the risk factors for rebleeding, alcoholism (OR = 11.19,  $P = 0.02$ ), the experience of endoscopists (OR = 0.56,  $P = 0.03$ ), and combination endoscopic therapy (OR = 0.06,  $P = 0.01$ ) compared with monotherapy were significantly related to rebleeding after endoscopic therapy. In a risk analysis of mortality after endoscopic therapy, only rebleeding was related to mortality (OR = 7.1,  $P = 0.02$ ).

**CONCLUSION:** Intensive combined endoscopic treatments by experienced endoscopists are necessary for the treatment of NGIH in patients with CKD, especially when a patient is an alcoholic.

**Key words:** Chronic kidney diseases; Gastrointestinal hemorrhage; Endoscopy; Peptic ulcer; Alcoholics

**Core tip:** Patients with chronic kidney disease (CKD) have increased hemorrhagic complications, including nonvariceal upper gastrointestinal hemorrhage (NGIH). These individuals also have a higher risk of rebleeding than patients without renal dysfunction. Initial intensive

combined endoscopic treatments by experienced endoscopists are necessary for the treatment of NGIH in patients with CKD, especially when a patient is an alcoholic. Factors of the consumption of alcohol, endoscopic monotherapy, and endoscopists' lack of experience are associated with rebleeding, which is the most important factor for the prediction of mortality in CKD patients with NGIH.

Characteristics of nonvariceal upper gastrointestinal hemorrhage in patients with chronic kidney disease. *World J Gastroenterol* 2013; 19(43): 7719-7725 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7719.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7719>

## INTRODUCTION

The hemostasis rate of nonvariceal upper gastrointestinal hemorrhage (NGIH) is 90%<sup>[1]</sup>. However, rebleeding develops in approximately 20% of patients, and the mortality rate has been reported as ranging from 6%-25%<sup>[1-8]</sup>. In patients with chronic kidney disease (CKD), gastrointestinal hemorrhage is a common complication<sup>[9]</sup>, and hemorrhage from the upper gastrointestinal tract from these patients accounts for 7.8%-12.2% of patients with total upper gastrointestinal hemorrhage<sup>[10]</sup>. Peptic ulcer is the most common cause of upper gastrointestinal hemorrhage in CKD, followed by erosive gastritis, esophagitis, vascular ectasia, and angiodysplasia<sup>[9,12]</sup>. Several reports have suggested that the prevalence of peptic ulcer in patients with CKD is higher than in the general population<sup>[13,14]</sup>. Many studies on the outcome of and risk factors for peptic ulcer bleeding in patients with normal renal function have been reported. However, there are few studies on the outcome of acute hemorrhage due to peptic ulcer and the risk factors for rebleeding in patients with CKD<sup>[10,12]</sup>.

Although the pathogenesis of hemorrhage in patients with CKD is not completely understood, three hypotheses have been proposed to explain the mechanism. First, uremic platelet dysfunction is believed to be the most important factor<sup>[12,15]</sup>. Second, a high rate of platelet dysfunction may be responsible for the increased frequency of rebleeding compared with the frequency in patients without renal dysfunction<sup>[9,16,17]</sup>. Lastly, previous studies on peptic ulcer and upper gastrointestinal hemorrhage in patients with renal dysfunction have suggested that hemorrhage in these patients is associated with acid secretion and mucosal integrity<sup>[11,18-20]</sup>. Moreover, hemodialysis, heparin use, abnormal platelet function, and anemia could be related to NGIH in patients with end-stage renal disease (ESRD), although the evidence is limited. Thus, the objective of this study was to evaluate the clinical characteristics of upper gastrointestinal ulcer hemor-

rhage in CKD patients and to determine the risk factors for rebleeding in patients undergoing endoscopic therapy.

## MATERIALS AND METHODS

### Patients

Between December 2003 and December 2010, a total of 72 CKD patients (M:F = 52:20, mean age:  $63.9 \pm 11.1$ ) who had undergone endoscopic therapy for NGIH were retrospectively evaluated. CKD was defined according to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines for nephrologists, which describe the presence of either kidney damage or decreased renal function (glomerular filtration rate  $< 60$  mL/min per  $1.73 \text{ m}^2$ ) for more than 3 mo. ESRD was defined as chronic kidney failure (glomerular filtration rate  $< 15$  mL/min per  $1.73 \text{ m}^2$ ) treated by dialysis. Patients who were not treated with endoscopic management and who had mallory-weiss syndrome were excluded. The clinical and endoscopic characteristics of patients with rebleeding were reviewed and compared with the characteristics of patients without rebleeding. Data were recorded for the following variables: gender, age, dialysis use, the method of dialysis, alcohol use and smoking history, past hemorrhage history, endoscopic findings (the cause, location, and size of the hemorrhage and the hemorrhagic state), endoscopic therapy, endoscopist experience, clinical outcomes, and mortality. Written informed consent to treatment was obtained from each patient. The study was performed in accordance with the Helsinki Declaration.

The patients' vital signs were checked every 10 min before endoscopy, every 2 h for the 24 h after endoscopy, and every 6 h after follow-up endoscopy. The hemoglobin level was checked more than once per day, and a blood transfusion was performed if the hemoglobin level decreased to below 9 g/dL. Rebleeding was defined as fresh hematemesis, fresh melena with blood pressure  $< 100$  mmHg, a drop in the hemoglobin level of more than 2 g/dL, or endoscopic confirmation of hemorrhage or pathologic lesions necessitating endoscopic management within 7 d after initial therapy. The hemorrhagic state was classified into five groups based on Forrest's classification: active pumping, active oozing, vessel exposure, red clots, and black clots.

### Endoscopic therapy

All of the patients presented to the hospital with NGIH and underwent an endoscopic examination within 24 h. Endoscopic management for peptic ulcer bleeding was performed. Intravenous proton pump inhibitors (PPIs) were prescribed to promote healing of the lesion before and after endoscopic therapy. Levin tube irrigation with more than 3000 cc of normal saline was performed before initial endoscopy. Thirteen experienced gastroenterologists ( $> 6000$  cases of endoscopy) performed therapeutic endoscopic procedures for NGIH during the study period. The therapeutic options used to treat NGIH were

1:10000 epinephrine injection, fibrin glue (Greenplast, Green Cross, Chung won, South Korea) injection, hemoclipping, electrocoagulation, endoscopic band ligation, and argon plasma coagulation. The patients were scheduled for a follow-up endoscopic examination within 24 h. If their general condition was not suitable for endoscopy, the follow-up examination was delayed. At the follow-up examination, oral intake was initiated, and endoscopic biopsy and *Helicobacter pylori* (*H. pylori*) tests were performed. If active bleeding or vessel exposure was observed during the follow-up endoscopic examination, this event was considered as rebleeding, and second endoscopic hemostasis was attempted. If continuous bleeding developed, not controlled by endoscopic hemostasis, operational or interventional radiologic management was performed. During fasting periods, intravenous pantoprazole sodium as a 40 mg bolus was supplied twice per day. After starting oral intake, a standard dose of oral PPIs was administered every morning for 6–8 wk. If the tests for *H. pylori* were positive, eradication medications (PPI + amoxicillin + clarithromycin) were administered for 7 d. Laboratory tests, abdominal ultrasonography, and routine abdominal X-ray were performed after the procedure to evaluate possible complications, including rebleeding or perforation.

### Statistical analysis

The  $\chi^2$  test and Student's *t* test were used to evaluate baseline characteristics. Categorical variables were analyzed by the  $\chi^2$  test, and continuous variables were assessed by the Student's *t* test. Univariate analysis and multivariate logistic regression were used to detect independent risk factors related to rebleeding during follow-up periods and prognosis. A *P* value < 0.05 was considered as significant for all tests. Analyses were performed using SPSS software, version 18.0 (SPSS Inc., Chicago,

## RESULTS

### Characteristics of patients

During the 4-year study period, 72 CKD patients with peptic ulcer hemorrhage were identified. The clinical characteristics of these patients are summarized in Table 1. The mean age of the patients with CKD was 63.9 ± 11.1. In total, 61 (84.7%) patients were experiencing their first hemorrhagic episode; 8 (11.1%) patients, their second; and 3 (4.2%) patients, their third. In this study, 50 (69.4%) ESRD patients were detected, of whom 45 (90%) patients were undergoing hemodialysis, and 5 (10%) were undergoing peritoneal dialysis. The initial systolic blood pressure of the patients was 128.7 ± 40.0 mmHg, and the diastolic blood pressure was 75.9 ± 16.5 mmHg. The hemoglobin level of the patients was 7.4 ± 2.0 g/dL, and the platelet count was 208 ± 156 (10<sup>9</sup>/L).

All of these patients were managed by endoscopy for peptic ulcer hemorrhage. The endoscopic findings and treatments of these patients are shown in Table 2. The mean ulcer size (mm) was 13.7 ± 10.2, and the hemorrhagic location the stomach in 48 (66.7%) cases and the duodenum in 24 (33.3%) cases. The most common hemorrhagic site in the stomach was the antrum (43.8%).

The therapeutic method of endoscopy was injection for 27 (37.5%) patients, coagulation for 8 (11.1%) patients, clipping for 5 (6.9%) patients, and combination therapy for 32 (44.4%) patients. The most common combination was epinephrine and glue injection (*n* = 11), followed by epinephrine injection and coagulation (*n* = 10) and epinephrine injection and clipping (*n* = 10). The mean number of years of experience of the endoscopists was 3.5 ± 2.7 years. The total number of patients with rebleeding was 27 (37.5%), and hemorrhage-related death was observed in 12 patients (16.7%, Table 2).

### Univariate analysis of risk factors for rebleeding

The incidence of rebleeding was 37.5% (*n* = 27), and

Smoking (Yes/no)	15/12	14/31	< 0.05

<sup>1</sup>mean ± SD. NS: Not significant; CKD: Chronic kidney disease; ESRD: End-stage renal disease; INR: International normalized ratio; Hb: Haemoglobin.

16.7% (*n* = 12) of patients expired due to bleeding. In the univariate analysis of clinical risk factors for rebleeding, there was no statistically significant difference in gender, age, dialysis method, or previous hemorrhage history between the rebleeding and the no-rebleeding groups (Table 3). Alcohol consumption was noted for 15/27 (55.6%) patients in the rebleeding group and 10/45 (22.2%) patients in the no-rebleeding group (*P* < 0.01). Additionally, smoking was reported by 15/27 (55.6%) patients in the rebleeding group and 14/45 (31.1%) patients in the no-rebleeding group (*P* < 0.01). The univariate analysis of endoscopic risk factors for rebleeding is shown in Table 4. Hemorrhagic states, ulcer sizes, and therapeutic methods were not significantly different between the rebleeding and the no-rebleeding groups. However, the number of years of experience of the endoscopists was 2.8 years for the rebleeding group and 4.0 years for the no-rebleeding group, which was a statistically significant difference (*P* < 0.05). In an analysis according to the endoscopists' status, being a doctor on fellowship was associated with rebleeding compared with being a doctors on the faculty (OR = 2.1, *P* = 0.02).

#### Multivariate analysis of risk factors for rebleeding and mortality

In the multivariate analysis of risk factors for rebleeding, the consumption of alcohol, endoscopic monotherapy, and endoscopists' lack of experience were associated with rebleeding development (Table 5). The alcohol-consuming group had an OR of 11.19 (*P* = 0.02) for rebleeding compared with the non-alcohol-consuming group. Although therapeutic methods were not associated with rebleeding in the univariate analysis, combination endoscopic treatment was associated with less frequent development of rebleeding in the multivariate analysis (OR = 0.06, *P* = 0.01). The experience of endoscopists

was significantly associated with the development of rebleeding in the multivariate analysis (OR = 0.56, *P* = 0.03). The risk factor associated with prognosis was rebleeding alone (OR = 7.10, *P* = 0.02, Table 6).

## DISCUSSION

Patients with CKD have increased hemorrhagic complications<sup>[10]</sup>. Additionally, there are a higher rebleeding risk and greater mortality in patients on dialysis than in patients without renal dysfunction<sup>[11]</sup>. The current study investigated peptic ulcer hemorrhage in CKD patients and found that these individuals are at high risk of rebleeding. In this study, the rebleeding rate in patients with CKD was 37.5%. This result is higher than for the CKD (14%) or normal renal function (12%) group and similar to rebleeding in ESRD patients (38%) in a previous study<sup>[12]</sup>. Moreover, the result is higher than the rate determined for Korean CKD patients (14.3%) in another study<sup>[21]</sup>. However, the definition of rebleeding differed. In the present study, rebleeding was confined to episodes within 7 d after endoscopic therapy, whereas there was no clear statement about time in previous studies, in which even rebleeding at 30 d after the first hemorrhage was included<sup>[12]</sup>. Taking these results together, CKD patients have a higher risk of rebleeding than patients without renal dysfunction, with approximately more than one third of CKD patients experiencing rebleeding.

NGIH is associated with high mortality. The mortality of NGIH complicating acute renal dysfunction is 68.3% and of NGIH complicating severe liver cirrhosis (LC) is 68.4%<sup>[22,23]</sup>. In the present study, the mortality of CKD patients with NGIH was 16.7%. This result is higher than the 13% value determined in a Taiwanese study and

<sup>1</sup>Reference category. NS: Not significant; INR: International normalized ratio; Hb: Haemoglobin B.

the 8.6% value reported in another Korean study<sup>[10,21]</sup>. In particular, rebleeding was related to the mortality of the CKD patients (OR = 7.1,  $P = 0.02$ ). According to a study that used nationwide inpatient samples from the United States, mechanical ventilation, severe sepsis, disseminated intravascular coagulation, cancer, age (> 65 years), coagulation defects, and venous thromboembolism were predictors of mortality in patients with ESRD and NGIH<sup>[24]</sup>. However, that study did not include rebleeding in the statistical analysis, although other studies have emphasized the importance of this parameter<sup>[12,21,24]</sup>. Overall, rebleeding is the most important factor for the prediction of mortality in CKD patients with NGIH, and the prevention of rebleeding should be a goal of clinical practice.

Regarding risk factors for rebleeding, the experience of endoscopists was one of the main factors (OR = 0.56,  $P = 0.03$ ). In a retrospective study in Canada, ESRD itself and ulcer with high-risk stigmata were the factors associated with rebleeding<sup>[12]</sup>. However, the experience of endoscopists was not analyzed. According a study of risk factors for rebleeding in NGIH patients, regardless of renal function, lower hemoglobin levels, endoscopist inexperience (< 2 years of experience), and comorbidity with CKD or LC were the associated factors<sup>[25]</sup>. These results indicate that insufficient or inappropriate endoscopic management by inexperienced endoscopists could result in rebleeding in CKD patients with NGIH. Moreover, considering that emergency endoscopic hemostasis procedures are frequently performed at night or on holidays by only one endoscopist, without the help of colleagues, intensive endoscopic treatments are important.

Combined endoscopic management was associated with a reduced risk of rebleeding in this study (*vs* monotherapy, OR = 0.06,  $P = 0.01$ ). Recent studies have suggested that combined endoscopic hemostasis treatments are superior to single treatments<sup>[26,27]</sup>. In a study of the risk factors for rebleeding in NGIH patients, regardless of renal function, combination therapy (injection + thermal therapy) was associated with lower mortality compared with injection therapy alone<sup>[25]</sup>. These results

**Table 6** Multivariate analysis for risk factors of prognosis

Variables	P value	OR
Age	NS	1.07

<sup>1</sup>Reference category. NS: Not significant.

are consistent with the findings of our study. Among the endoscopic therapeutic options, injection therapy ( $n = 27$ , 67.5%) was preferred over thermal ablation ( $n = 8$ , 20%), such as argon plasma coagulation or electrocoagulation, when used as single method in this study. This preference was due to concerns about tissue injury or loss in thermal therapy, which could result in rebleeding in patients with a hemorrhagic tendency. Another finding of this study was that being an endoscopic doctor on fellowship was associated with rebleeding compared with being a doctor on the faculty (OR = 2.1,  $P = 0.02$ ). Overall, intensive endoscopic treatment by experts using a combined method can result in better outcomes in CKD patients with NGIH.

Another finding of this study was related to alcohol use. In the multivariate analysis of risk factors for rebleeding, alcohol use was demonstrated to be an important risk factor (OR = 11.19,  $P = 0.02$ ). Additionally, the most common hemorrhagic site was the lesser curvature of the antrum of the stomach. *H. pylori* infection was detected in only 33.3% of patients. The exact mechanism underlying the association of alcohol use and *H. pylori* with NGIH in patients with CKD is not understood. However, endoscopists have to pay more attention when a patient is an alcoholic because of rebleeding risk, which is associated with high mortality.

There are several limitations of this study. First, it was retrospective study, and a small number of patients were evaluated. Second, hospital stay and blood transfusion, which were evaluated in other studies<sup>[12,28]</sup>, were not assessed. Further studies are needed to improve outcomes in CKD patients with NGIH.

In conclusion, initial intensive combined endoscopic treatments by experienced endoscopists are necessary for the treatment of NGIH in patients with CKD, especially when a patient is an alcoholic, as rebleeding after endoscopic treatment is a risk factor for mortality.

## COMMENTS

### Background

Peptic ulcer is the most common cause of upper gastrointestinal hemorrhage in chronic kidney disease (CKD). Additionally, there are a higher rebleeding risk and greater mortality in patients on dialysis than in patients without renal dysfunction. Many studies on the outcome of and risk factors for peptic ulcer

bleeding in patients with normal renal function have been reported. However, there have been few studies on the outcome of acute hemorrhage due to peptic ulcer and on the risk factors for rebleeding in patients with CKD.

### Research frontiers

According to a study that used nationwide inpatient samples from the United States, mechanical ventilation, severe sepsis, disseminated intravascular coagulation, cancer, age (> 65 years), coagulation defects, and venous thromboembolism were predictors of mortality in patients with end-stage renal disease and nonvariceal upper gastrointestinal hemorrhage (NGIH).

### Innovations and breakthroughs

In the previous study on predictors of mortality in patients with ESRD and NGIH, rebleeding was not determined to be a major predictor of mortality. However, only rebleeding was related to mortality (OR = 7.1,  $P = 0.02$ ) in the current study. Moreover, alcoholism (OR = 11.19,  $P = 0.02$ ), the experience of endoscopists (OR = 0.56,  $P = 0.03$ ), and combination endoscopic therapy (OR = 0.06,  $P = 0.01$ ) compared with monotherapy were significantly related to rebleeding after endoscopic therapy in this study.

### Applications

Initial intensive combined endoscopic treatments by experienced endoscopists are necessary for the treatment of NGIH in patients with CKD, especially when a patient is an alcoholic. These factors are associated with rebleeding, which is the most important factor for the prediction of mortality in CKD patients with NGIH.

### Peer review

This is a well done study. It is an important topic. The manuscript is interesting, well done and well written.

### Abstract

**AIM:** To investigate the events associated with the apoptotic effect of *p*-Coumaric acid, one of the phenolic components of honey, in human colorectal carcinoma (HCT-15) cells.

**METHODS:** 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium-bromide assay was performed to determine the antiproliferative effect of *p*-Coumaric acid against colon cancer cells. Colony forming assay was conducted to quantify the colony inhibition in HCT 15 and HT 29 colon cancer cells after *p*-Coumaric acid treatment. Propidium iodide staining of the HCT 15 cells using flow cytometry was done to study the changes in the cell cycle of treated cells. Identifica-

tion of apoptosis was done using scanning electron microscope and photomicrograph evaluation of HCT 15 cells after exposing to *p*-Coumaric acid. Levels of reactive oxygen species (ROS) of HCT 15 cells exposed to *p*-Coumaric acid was evaluated using 2', 7'-dichlorofluorescein-diacetate. Mitochondrial membrane potential of HCT-15 was assessed using rhodamine-123 with the help of flow cytometry. Lipid layer breaks associated with *p*-Coumaric acid treatment was quantified using the dye merocyanine 540. Apoptosis was confirmed and quantified using flow cytometric analysis of HCT 15 cells subjected to *p*-Coumaric acid treatment after staining with YO-PRO-1.

**RESULTS:** Antiproliferative test showed *p*-Coumaric acid has an inhibitory effect on HCT 15 and HT 29 cells with an IC<sub>50</sub> (concentration for 50% inhibition) value of 1400 and 1600  $\mu\text{mol/L}$  respectively. Colony forming assay revealed the time-dependent inhibition of HCT 15 and HT 29 cells subjected to *p*-Coumaric acid treatment. Propidium iodide staining of treated HCT 15 cells showed increasing accumulation of apoptotic cells ( $37.45 \pm 1.98$  vs  $1.07 \pm 1.01$ ) at sub-G<sub>1</sub> phase of the cell cycle after *p*-Coumaric acid treatment. HCT-15 cells observed with photomicrograph and scanning electron microscope showed the signs of apoptosis like blebbing and shrinkage after *p*-Coumaric acid exposure. Evaluation of the lipid layer showed increasing lipid layer breaks was associated with the growth inhibition of *p*-Coumaric acid. A fall in mitochondrial membrane potential and increasing ROS generation was observed in the *p*-Coumaric acid treated cells. Further apoptosis evaluated by YO-PRO-1 staining also showed the time-dependent increase of apoptotic cells after treatment.

**CONCLUSION:** These results depicted that *p*-Coumaric acid inhibited the growth of colon cancer cells by inducing apoptosis through ROS-mitochondrial pathway.

**Key words:** Honey; Apoptosis; Rhodamine-123; Sub-G1; Merocyanine; *p*-Coumaric acid; Reactive oxygen species

**Core tip:** This article describes apoptotic effect of *p*-Coumaric acid, one of the phenolic components of honey, against colon cancer cells. *p*-Coumaric acid treatment resulted in the inhibition of proliferation and colony forming ability of human colorectal carcinoma (HCT-15) and HT 29 cells. Major events associated with growth-inhibition are increasing reactive oxygen species generation, increasing lipid layer breaks and a fall in Mitochondrial membrane potential. Further, membrane blebbing and shrinkage of *p*-Coumaric acid exposed HCT 15 cells insinuated apoptosis. Hence our results depicted that *p*-Coumaric acid is a prospective candidate for chemoprevention of colon cancer.

## INTRODUCTION

Phenolic compounds are present in various dietary agents. Consumption of such agents has been linked to improve various disease conditions like cancer, diabetes and cardiac disorders. Diet is believed to be much influential in explaining the susceptibility to cancer. Most interestingly, colon cancer is more vulnerable to diet because these epithelial cells are chronically exposed to these dietary agents<sup>[1,2]</sup>. Since, cancer of colon is among the most common malignancy among the Western and Asian nations, research communities explore various new dietary agents rich in phenolic compounds to purge this malignancy.

In our laboratory, experiments in studying the preventive effect of honey against colon cancer had been constantly done. Previous results depicted honey could inhibit the colon cancer cell proliferation. Antiproliferative effect was found to vary with the phenolic content present in the honey<sup>[3-5]</sup>. Since honey containing higher phenolic content was found to induce apoptosis significantly, the scope of this research was extended to study the apoptosis induced by one of the phenolic components of honey, *p*-Coumaric acid, against the colon cancer cells.

*p*-Coumaric acid is the abundant isomer of cinnamic acid and also widely found in edible plants such as peanuts, tomatoes, carrots etc. *p*-Coumaric acid is reported to have antitumor and anti-mutagenic activities<sup>[6,7]</sup>. In a study, *p*-Coumaric acid along with the combination of hydrocaffeic acid found to reduce the UV-B oxidation damage in human conjunctival cells *in vitro* and in cornea and sclera of rabbits *in vivo*<sup>[8]</sup>. In one of the latest studies, the ability of *p*-Coumaric acid to protect rat's heart against doxorubicin (DOX)-induced oxidative stress

was investigated. It showed that *p*-Coumaric acid could reduce the DOX-induced high serum levels of lactic dehydrogenase and creatine phosphokinase<sup>[9]</sup>. In one of the most recent studies, effect of *p*-Coumaric acid against the colonic epithelial cells (Caco-2) was studied. *p*-Coumaric acid at a concentration of 1500  $\mu$ mol/L was found to inhibit the proliferation of Caco-2 cells by 43%-75% after 24-72 h of treatment<sup>[10]</sup>. However, literature available does not depict the mechanism of *p*-Coumaric acid induced apoptosis in colon cancer cells.

Apoptosis is the major form of cell death accompanied by morphological changes like membrane blebbing and shrinkage of cells. Further, events like nuclear and chromatin condensation, DNA fragmentation and segregation of apoptotic bodies were the characteristic features of apoptosis. Reactive oxygen species (ROS) is involved in various biochemical functions like cell proliferation and apoptosis. Recent studies reported ROS mediated apoptosis is accompanied with the loss of mitochondrial membrane potential<sup>[11,12]</sup>.

This current study, deals with the growth inhibitory effect of *p*-Coumaric acid in colon cancer cells. Further, an attempt has been made to explore the ROS and mitochondrial dependent mechanism in the apoptosis induced by the *p*-Coumaric acid.

## MATERIALS AND METHODS

### Reagents

DMEM, RPMI-1640, fetal bovine serum (FBS), *L*-glutamine, sodium pyruvate, nonessential amino acids, vitamin solution, penicillin and streptomycin were obtained from Life Technologies, Inc., Grand Island, NY, United States. 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium-bromide (MTT), propidium iodide, mercury orange, rhodamine-123, RNase and *p*-Coumaric acid were purchased from Sigma-Aldrich, United States. Merocyanine 540 and YO-PRO-1 were obtained from Invitrogen Inc, United States.

### Cell culture

Colon carcinoma cell line HT 29 and human colorectal carcinoma (HCT-15) (Organ: Colon, Disease: Colorectal adenocarcinoma; Organism: Human; procured from National Centre for Cell science, Pune, India) was grown in DMEM and RPMI medium respectively, supplemented with 10% FBS, *L*-glutamine, penicillin, sodium pyruvate, nonessential amino acids and vitamin solution. Adherent monolayer cultures of HCT 15 were maintained in T-25 flasks and incubated at 37 °C in 5% carbon dioxide (CO<sub>2</sub>). The cultures were free of mycoplasma and maintained no longer than 12 wk after recovery from frozen stocks.

### Cell proliferation assay

Thiazolyl blue tetrazolium bromide (MTT) assay was carried out as follows: Cells were trypsinized, counted and 1000 cells were seeded per well in 96-well plate. The following day, 100  $\mu$ L of medium containing the desired

concentration of *p*-Coumaric acid was added to the appropriate wells. The cells were then kept at 37 °C in 5% CO<sub>2</sub> for the desired length of time. Control used in these experiments was untreated cells kept for 48 h. For all the experiments performed below, control cells remained untreated and kept for the same duration as the longest time-point of the respective experiment. At this point, 100 µL of (5 mg/mL) MTT reagent was added to each well, and the plate was placed at 37 °C in the incubator for 2 h. 200 µL of dimethyl sulfoxide was added to each well, after aspirating the supernatant. Colored formazan product was assayed spectrophotometrically at 570 nm using enzyme-linked immunosorbent assay plate reader<sup>[12]</sup>.

### Colony forming assay

HCT 15 and HT 29 cells were treated with *p*-Coumaric acid at a concentration of 1400 and 1600 µmol/L respectively for definite time periods (12, 24 and 48 h) and collected by trypsinization. The cells were counted and seeded again in triplicate on a 6-well tissue culture plate with 3000 cells/well. The cells were cultured for 15 d with growth media replaced after every two days. The cells were stained with 0.5% crystal violet (in methanol) and colonies were counted<sup>[12]</sup>.

### Cell cycle analysis

After the appropriate treatment with *p*-Coumaric acid, HCT 15 cells were washed with phosphate-buffered saline, then resuspended in 50 µg/mL propidium iodide containing 0.1% sodium citrate with 0.1% Triton X-100 for 20 min at 4 °C. Cells were then analyzed by flow cytometry (FACScan; Becton Dickinson Immunocytometry Systems), and the sub-G<sub>1</sub> fraction was used as a measure of the apoptotic cells. Control used in the experiments was untreated cells kept for 48 h. Analysis was performed in linear amplification mode in case of cell cycle analysis. Remaining experiments of flow cytometry were performed in logarithmic amplification mode unless otherwise stated<sup>[13]</sup>.

### Estimation of ROS generation

Dichlorofluorescein-diacetate (DCFH-DA) was cleaved by the intracellular nonspecific esterase to form DCFH. DCFH are oxidized by ROS to form the fluorescent compound DCF. *p*-Coumaric acid treated cells (1400 µmol/L) were harvested using trypsin/EDTA and resuspended in PBS. Working solution (20 µmol/L) of DCFH-DA was directly added cells and then it was incubated at 37 °C for 15 min. Cells were washed and resuspended in PBS and kept on ice immediately before analyzing by flow cytometry<sup>[12]</sup>. This fluorescent intensity of DCF was measured and correlated with the ROS generated in the cells.

### Determination of mitochondrial membrane potential

HCT 15 colon cancer cells were treated with *p*-Coumaric acid (1400 µmol/L) for different time points. After-

wards, cells were harvested and resuspended in 1 mL of rhodamine-123 (5 µg/mL) for 1 h at 37 °C. The intensity of fluorescence from rhodamine-123 was measured by flow cytometry<sup>[12]</sup>.

### Detection of membrane lipid organization

Colon cancer cells (HCT 15) were treated with *p*-Coumaric acid (1400 µmol/L) for different time points. Cells were harvested and re-suspended in 1 mL of merocyanine 540 (10 µg/mL) for 15 min at 37 °C. The intensity of fluorescence was measured by flow cytometry<sup>[13]</sup>.

### YO-PRO-1 staining

YO-PRO-1 permits analysis of apoptotic cells without interfering cell viability. After treatment with *p*-Coumaric acid (1400 µmol/L), the cell pellets were mixed in 1 µmol/L YO-PRO-1 for 20 min at room temperature. After incubation intensity was measured using flow cytometry<sup>[13]</sup>.

### Scanning electron microscope and photomicrograph images

Fixed amount of HCT 15 cells were seeded in a sterilized glass slide and incubated for 24 h. *p*-Coumaric acid at a concentration of 1400 µmol/L was added for 48 h time interval. After incubation, cells were harvested by using trypsin/EDTA and centrifuged for 5 min at room temperature. Then the supernatant was decanted and pellet was dried. Pellet was treated with 2.5% glutaraldehyde in distilled water for 45 min in hybrid oven shaker at 37 °C. Cells were washed thrice with PBS for 5 min and then dehydrated by ethyl alcohol of different concentration (30%, 50%, 70%, 95% and 100%) for 5-10 min. Fixing of cells was done with hexamethyl disilazane and the sample was taken for scanning electron microscope analysis. Photomicrograph images of HCT 15 and HT 29 cells were acquired using microscope.

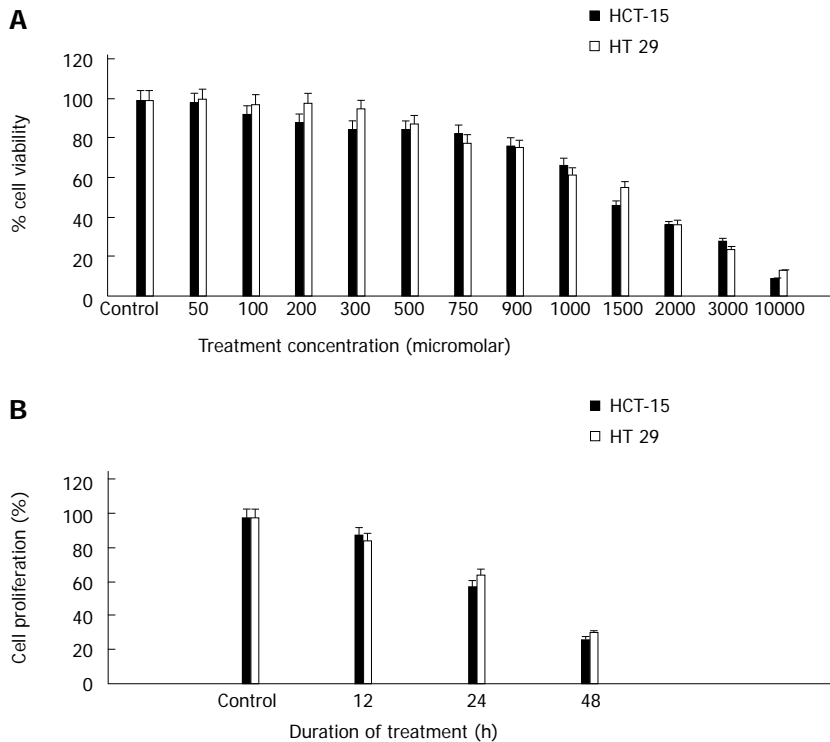

### Statistical analyses

All values are expressed as the mean ± SE. Figures were plotted using Graphpad Prism software. All experiments were performed three times independently (biological triplicates). One-way ANOVA was performed to find statistical significance.

## RESULTS

### MTT assay

MTT assay of treated cells was performed after 48 h of treatment. Colon cancer cells (HCT 15 and HT 29) growth was inhibited in a dose-dependent manner. Both HCT-15 and HT-29 cell growth were inhibited significantly with an IC<sub>50</sub> of around 1400 µmol/L and 1600 µmol/L respectively (Figure 1A). HCT 15 cells were found more sensitive to *p*-Coumaric acid, however at higher concentrations both cell lines were found to be equally affected. Statistical analysis showed that *p*-Coumaric acid treatment results in significant inhibition (*P*

**Figure 1** Antiproliferative effect, colony inhibitory of *p*-Coumaric acid against colon cancer cells. A: Both human colorectal carcinoma (HCT-15) and HT-29 cells grown in 96-well plate were treated with various concentration of *p*-Coumaric acid (0-10000  $\mu\text{mol/L}$ ) diluted in the media for 48 h. The mean of the percentage cell viability (% of control) along with their standard error is indicated; B: After various incubation periods of *p*-Coumaric acid treatment, colonies formed were stained with 0.5% crystal violet and counted, and percentage of survival was calculated by normalizing the values. Data reported as the mean  $\pm$  SE from three different observations. Mean differences are significant at 12, 24 and 48 h.

$< 0.05$ ) compared with untreated control cells at 200  $\mu\text{mol/L}$  and 500  $\mu\text{mol/L}$  for HCT 15 and HT 29 cells respectively (Figure 1A).

#### Colony forming assay

*p*-Coumaric acid treated HCT 15 cells showed a maximum of 94, 67, 32 colonies after 12, 24 and 48 h of treatment. Untreated HCT 15 cells produced a maximum of 105 colonies. Similar experiment with HT29 cells displayed a maximum of 131, 101, 51 colonies after 12, 24 and 48 h treatment whereas the control HT 29 cells produced 154. A time-dependent inhibition of colony formation was clearly evident from this experiment (Figure 1B). There was a significant reduction ( $P < 0.05$ ) in the number of colonies formed under the various time intervals examined (both HCT 15 and HT 29 cells) when compared with corresponding untreated cells (Figure 1B).

#### Cell cycle analysis

Cell populations were tabulated among the sub- $G_1$ ,  $G_0/G_1$ , S and  $G_2/M$  phases of the cell cycle. It showed an increasing sub- $G_1$  arrest from 1.00% (control) to 37.45% after 48 h (Table 1). Statistical analysis of the sub- $G_1$  column indicated significant increase ( $P < 0.05$ ) of cells in the sub- $G_1$  phase insinuating apoptosis increases with the time-dependency.

#### ROS generation

ROS levels were increased significantly after treatment. The increasing mean fluorescent intensity was found to be 116, 141, and 185 during 12, 24 and 48 h respectively. Untreated control cells showed an intensity of 96 after 48 h. ROS intensity after 48 h treatment was almost double the intensity of the control cells. Moreover, the differences in the ROS levels at various h examined were significant, compared to control with a  $P$  value of less than 0.05 (Figure 2).

#### Mitochondrial membrane potential

The decreasing mean fluorescent intensity was found to be 147, 91 during 6 and 12 h of treatment respectively. Untreated control cells showed an average intensity of 229 after 12 h. From the results, it was observed that *p*-Coumaric acid treatment reduced the potential by 2.5 fold after 12 h. There was also statistically significant reduction ( $P < 0.05$ ) of potential at the estimated intervals compared to untreated cells (Figure 3A).

#### Lipid layer breaks

Untreated cells displayed a mean intensity of 33 after 6 h. Treated cells showed 37 and 50 after 3 and 6 h respectively (Figure 3B). It is evident from the above results that treated cells displayed an increase in the lipid layer breaks.

**Figure 2** *p*-Coumaric acid induced reactive oxygen species generation. Human colorectal carcinoma (HCT-15) cells were cultured in the presence or absence of *p*-Coumaric acid for the specified time points. Dichlorofluorescein-diacetate fluorescence intensity was detected by using flow cytometry. Data is representative of three independent experiments and the mean differences are significant at 12, 24 and 48 h.

**Table 1** Cell cycle distribution of human colorectal carcinoma-15 cells after *p*-Coumaric acid treatment

Time in h	Sub G <sub>1</sub> <sup>1</sup>	G <sub>0</sub> /G <sub>1</sub>	S	G <sub>2</sub> /M
Control	1.07 ± 1.01	42.82 ± 1.92	8.03 ± 1.23	40.07 ± 2.85
12 h	5.98 ± 1.17	23.06 ± 3.15	10.29 ± 4.01	46.67 ± 1.89
24 h	16.46 ± 2.03	23.92 ± 1.74	9.91 ± 3.29	39.03 ± 1.58
48 h	37.45 ± 1.98	12.79 ± 4.45	4.9 ± 3.82	17.12 ± 4.65

<sup>1</sup>Mean differences are significant at  $P < 0.05$ . Data represents mean  $\pm$  SD.

### Photomicrograph and scanning electron microscope images

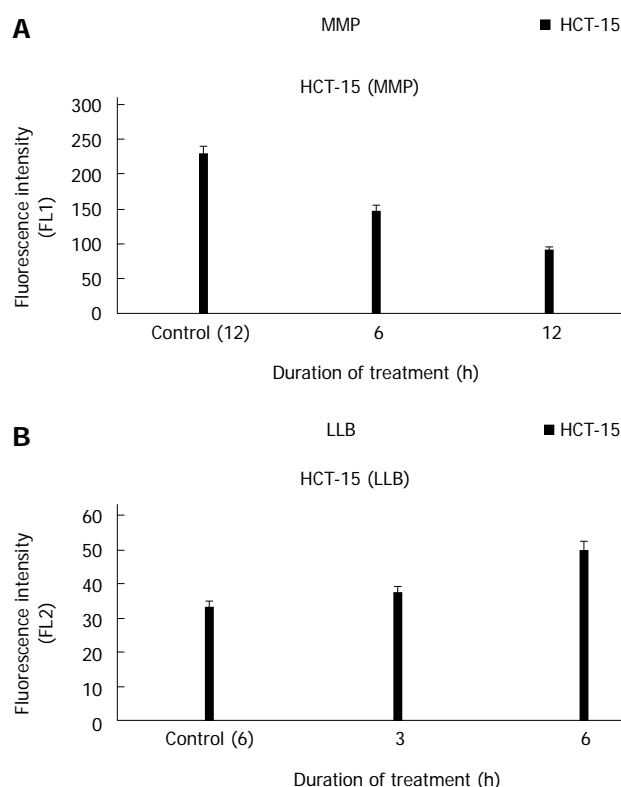

Scanning electron microscope (SEM) images of *p*-Coumaric acid treated cells (48 h) showed typical signs of apoptosis like membrane blebbing and shrinkage as indicated by arrow marks. Normal cells were found almost spherical without marked shrinkage (Figure 4A). This was further corroborated with the photomicrograph images (Figure 4B).

### Yo-Pro-1 staining

The percentage of cells distributed in M2 population signifying apoptosis increased depending upon the duration of treatment. It was found to be 20, 33 after 24 and 48 h of *p*-Coumaric acid treatment. M2 phase population of untreated control cells was found to be 8% after 48 h (Figure 5).

## DISCUSSION

Diet consumption and cancer have been linked by various studies<sup>[14,15]</sup>. They postulated that consistent pattern of consumption of diets which are rich in vegetables and fruits may reduce the risk of cancer. Phenolic compounds, one of the classes of non-nutritive phytochemicals, are widely distributed in our foods and suggested to have preventive effect against various disease conditions like cancer, diabetes and several cardiac disorders<sup>[16,17]</sup>.

**Figure 3** Events associated with growth-inhibitory effect of *p*-Coumaric acid. A: Human colorectal carcinoma (HCT-15) cells were treated with *p*-Coumaric acid for specified time-periods and then mitochondrial membrane potential were determined using rhodamine-123 by flow cytometry. Mean differences are significant at 6 and 12 h compared with untreated control cells ( $P < 0.05$  vs untreated control cells); B: HCT 15 cells were treated with *p*-Coumaric acid and evaluated using merocyanine 540 to quantify the lipid layer breaks (LLBs). Data is representative of three independent experiments and mean differences are significant at 3 and 6 h compared with untreated control cells ( $P < 0.05$  vs untreated control cells). MMP: Mitochondrial membrane potential.

From our laboratory, it was showed that honey rich in phenolic content was able to induce apoptosis significantly in colon cancer cells. Hence, in this research the effect of *p*-Coumaric acid, one of the phenolic constituents of honey, induced apoptosis in colon cancer cells was studied.

*p*-Coumaric acid inhibited the proliferation of colon cancer cells. Both HCT-15 and HT-29 cell growth were inhibited significantly with an  $IC_{50}$  of around 1400  $\mu$ mol/L and 1600  $\mu$ mol/L respectively. This was similar to the previously published report on the antiproliferative effect of *p*-Coumaric acid against Caco-2 cells<sup>[10]</sup>. Bioavailability of phenolic constituents is a major factor when we would like to examine the effect of *p*-coumaric acid in *in vivo*. In one of the researches, it was showed that bioavailability of coumaric acid after consumption of 200 g plum is in the range of 28-230 mg/serving<sup>[18]</sup>. In a colonic volume of 200 mL, this would yield a concentration in the range of 850 to 7000  $\mu$ mol/L. Hence, it is believed that estimated  $IC_{50}$  values against these colon cancer cells are achievable internally. Human diet is complex and the supply of coumaric acid from different diets has to be evaluated simultaneously to have an idea

**Figure 4** Morphological assessment of *p*-Coumaric acid treated cells. A: Human colorectal carcinoma (HCT-15) cells were treated with *p*-Coumaric acid for 48 h and the cells were observed under scanning electron microscope. Treated cells showed membrane blebbing and shrinkage compared to untreated normal control cells; B: HT 29 and HCT 15 cells were subjected to *p*-Coumaric acid treatment for 48 h and observed under light microscopy. Treated cells displayed apoptotic features like blebbing and shrinkage compared to untreated normal control cells.

about its bioavailability. To add further, bioavailability varies among the individuals and this makes estimation of intakes and prediction of physiological range of phenolics in body fluids is a mammoth task. The biggest drawback is that bioavailability of *p*-Coumaric acid will be in pulses depending upon the food intake whereas in cell culture environments it is constant<sup>[10]</sup>.

*p*-Coumaric acid significantly inhibited the colony formation *in vitro*. This is indispensable, since most of the chemotherapeutic drugs were shown to inhibit the colony formation<sup>[12]</sup>. The effect of *p*-coumaric acid against intestinal epithelial cells (IEC) isolated from the mouse was evaluated. It was found that *p*-Coumaric acid was not toxic to these cells. Even at a higher concentration of 5.1 mmol/L nearly 80% cells were viable (results not shown). Sparing nature of *p*-Coumaric acid against mouse IEC was interesting and would warrant further study with normal human colonic cells.

Mitochondrial malfunction is one of the key events occurring at the initial stages of apoptosis. Studies reported a fall in the mitochondrial membrane potential

during apoptosis induced by various chemotherapeutic drugs. Mitochondrial membrane potential of *p*-Coumaric acid treated cells using rhodamine-123 showed decreasing intensity, confirming the mitochondrial malfunction. ROS is involved in various biochemical functions like cell proliferation and apoptosis. Generally, ROS stress is oncogenic and it is found to increase the metabolic activity. It also stimulates further ROS generation through mitochondrial respiratory chain and maintains the cancer phenotype. On the other hand, high dose of ROS for prolonged duration could induce cellular damage and apoptosis<sup>[19,20]</sup>. Hence by utilizing time and dose-dependent ROS generation, we can trigger cell death by using exogenous ROS-generating agents. Our experiment involving DCFDH-DA staining indicated increasing ROS generation in the *p*-Coumaric acid treated cells. Hence, *p*-Coumaric acid may be considered as a potential exogenous candidate (generating ROS) to induce apoptosis in colon cancer cells.

The most notable property of phenolic phytochemicals is that they have antioxidant activity. This is due to

**Figure 5 Apoptosis evaluation using Yo-Pro-1 dye by flow cytometry.** Human colorectal carcinoma (HCT-15) cells were treated with *p*-Coumaric acid for specified time points. The distribution of cell population changed according to the exposure time as indicated by M1 and M2. Percentage of M2 population depicting apoptosis increased on the basis of the duration of treatment. Data is representative of three independent experiments and the differences in the values of M2 were significant at 24 and 48 h ( $P < 0.05$  vs untreated control cells) compared to untreated control cells.

the ability of phenolic hydroxyl groups which can provide hydrogen atoms in scavenging the ROS. Hence it is suggested that phenolic phytochemicals could scavenge the ROS molecules and inhibit the mitogen activated protein kinase (MAPK) signaling and blocking the nuclear factor kappaB and activator protein 1 activation which eventually lead to inhibit cancer cell proliferation. Although antioxidant properties of phenolic phytochemicals were explained for its mechanism of inhibiting cancer cells, they also show pro-oxidant activity under certain experimental conditions<sup>[21]</sup>. ROS generation was observed in the cell culture media containing EGCG, quercetin and gallic acid in both time and concentration-dependent manner<sup>[22]</sup>. In our case, *p*-Coumaric acid was also found to increase ROS generation in a time-dependent manner. Hence, treating the cancer cells with *p*-Coumaric acid can produce significant ROS resulting stressful or cytotoxic effects. Excess of ROS generation by phenolic phytochemicals induces apoptosis through MAPK activation. Simultaneously, increased p53 activation was mediated by Ras/MAPK kinase/MAPK pathway as observed in the apoptosis of EGCG and resveratrol<sup>[23,24]</sup>. Hence, we hypothesize that the increased ROS generation may result in the activation of p53 in the *p*-Coumaric acid treated cells. This may in-turn would have caused the up-regulation of Bax and down-regulation of Bcl2 which are the down-stream targets of p53 resulting in apoptosis.

Apoptosis, a distinguished form of cell death, is characterized by membrane blebbing and DNA fragmentation. Electron Microscopy is used as a golden standard in detecting apoptosis<sup>[25-27]</sup>. In our case, both scanning electron microscope and photomicrograph images of *p*-Coumaric acid treated cells showed typical membrane blebbing and shrinkage portraying apoptosis. Sub-G<sub>1</sub> arrest of cell cycle is considered as a sign of apoptosis<sup>[28-30]</sup>. *p*-Coumaric acid treatment showed increasing accumulation of cells in the sub-G<sub>1</sub> phase confirming

apoptosis. This was similar to the most anticancer drugs which induced apoptosis by arresting the cells at sub-G<sub>1</sub> phase<sup>[31-33]</sup>. At an early stage of apoptosis, there will be considerable damage to plasma membrane and the lipid layer will be disorganized. Nowadays in addition to the nuclear and morphological assessment, lipid layer perturbations in plasma membrane can also insinuate apoptosis. Merocyanine staining of treated cells for lipid layer organization showed increasing fluorescence intensity depicting apoptosis. This observation was similar to eugenol induced apoptosis shown recently<sup>[13]</sup>.

In conclusion, *p*-Coumaric acid exerted antiproliferative activity against colon cancer cells like HT 29 and HCT 15. Both the cell lines growth was repressed significantly by inducing apoptosis. Apoptosis induced by *p*-Coumaric acid involved various physical and biochemical changes. To enumerate, cells showed membrane blebbing and shrinkage as depicted by SEM and photomicrograph images. Earlier lipid layer breaks were associated with the *p*-Coumaric acid induced apoptosis. Cell cycle progression was arrested at sub-G<sub>1</sub> phase by *p*-Coumaric acid treatment. Mitochondrial membrane potential of treated cells also showed a decrease after *p*-Coumaric acid treatment. Moreover, there was increase in the ROS generation and lipid layer breaks after treatment. These results insinuate that *p*-Coumaric acid inhibited the growth of colon cancer cells by inducing apoptosis through ROS-mitochondrial pathway. However, further experiments in preclinical and clinical settings will promote this as a likely candidate for chemoprevention of colon cancer.

## ACKNOWLEDGMENTS

Jaganathan SK acknowledges the directors' (Mr. Raguram, Dr. Lakshmana Prabhu, and Mr. Sugumaran) invaluable support and their constant encouragement. Authors acknowledge the efforts of Dr. Joseph Thomas for providing his valuable comments for English-editing service. Thanks to Ms. Bhuvaneswari S and Mr. Joseph Raja for checking this paper.

## COMMENTS

### Background

Consumption of phenolic components has been linked to improve various disease conditions like cancer, diabetes and cardiac disorders. Diet is believed to be much influential in explaining the susceptibility to cancer. Most interestingly, colon cancer is more vulnerable to diet because these epithelial cells are chronically exposed to these dietary agents. Honey has been reported to possess protective effect in many inflammatory diseases and oxidative stress-related injuries. Recent works from the laboratory showed phenolic components of honey were attributed with inherent potential to inhibit colon cancer cells. In this article *p*-Coumaric acid, one of the phenolic components of honey, has been examined for its growth inhibitory effects.

### Research frontiers

Chemotherapy utilizes antineoplastic or dietary agents for treating colon cancer. However, there is still a continuous search for novel agents with improved efficiency. To their knowledge *p*-Coumaric acid, one of the phenolic components of honey, have never been examined for its inhibitory mechanism against colon

cancer.

### Innovations and breakthroughs

Events associated with the inhibitory nature of *p*-Coumaric acid are clearly highlighted in this manuscript. Authors have shown that *p*-Coumaric acid inhibited the colon cancer cells in dose-dependent manner. Further it was deciphered that *p*-Coumaric acid induced apoptosis is accompanied with increasing reactive oxygen species (ROS) levels, a fall in the mitochondrial membrane potential and increased lipid layer breaks. Hence authors concluded that *p*-Coumaric acid inhibited the growth of colon cancer cells by inducing apoptosis through ROS-mitochondrial pathway.

### Applications

*p*-Coumaric acid induced apoptosis in colon cancer cells through ROS-mitochondrial pathway. Hence, further experiments in preclinical and clinical settings will promote *p*-Coumaric acid as a plausible candidate for chemoprevention of colon cancer.

### Peer review

This work describes the events associated with the growth-inhibitory effect of *p*-Coumaric acid in colon cancer cells. Since *p*-Coumaric acid is one of the phenolic components of honey, the study has a clear interest in the field of chemoprevention of colon cancer. The results of this study are interesting and demonstrate that *p*-Coumaric acid has antiproliferative activity against colon cancer cells inducing apoptosis and causing physical and biochemical changes.

### Abstract

**AIM:** To determine the prevalence of *SLC25A13* mutations in the Thai population.

**METHODS:** A total of 1537 subjects representing the Thai population were screened for a novel pathologic allele p.Met1? (c.2T > C) and six previously known common *SLC25A13* mutations: [I] (c.851\_854delGTAT), [II] (g.IVS11 + 1G > A), [III] (c.1638\_1660dup), [IV] (p.S225X), [V] (IVS13 + 1G > A), and [XIX] (g.IVS16ins3kb) using a newly developed TaqMan and established HybProbe assay, respectively. Sanger sequencing was employed for specimens showing an aberrant peak to confirm the targeted mutation as well as the unknown aberrant peaks detected. Frequencies of the mutations identified were compared in each region. Carrier frequency and disease prevalence of citrin deficiency caused by *SLC25A13* mutations were estimated.

**RESULTS:** p.Met1? was identified in the heterozygous state in 85 individuals, giving a carrier frequency of 1/18, which suggests possible selective advantage of this variant. The question of p.Met1? homozygote lethality remains unanswered which may serve as an explanation as to why this homozygote has yet to be identified in patients/controls even with high allele frequency. The p.Met1? mutation has rarely been studied in populations other than Thai and Chinese; therefore, may have been overlooked. Development of the TaqMan assay in the present study would allow a simple, rapid, and cost-effective method for mass screening. Heterozygous mutations: [XIX] and [I] were identified in 17 individuals, giving a carrier rate of 1/90 and a calculated homozygote rate of 1/33000. Two novel variants, g.IVS11 + 17C > G and c.1311C > T, of unknown clinical significance were identified at low frequency.

**CONCLUSION:** This study highlighted the current underestimation of citrin deficiency and suggests the possible selective advantage of the p.Met1? allele.

## INTRODUCTION

Citrin deficiency (CD) is a genetic disorder inherited in an autosomal recessive pattern<sup>[1]</sup>. It is caused by mutations in the *SLC25A13* gene encoding the citrin protein, a mitochondrial aspartate-glutamate carrier, isoform 2 (AGC2) and is expressed mainly in the liver<sup>[2-5]</sup>. The major function of AGC2 is to export mitochondrial aspartate in exchange for cytosolic glutamate<sup>[5]</sup> and is involved in several metabolic pathways with major contributions to the urea cycle and malate-aspartate shuttle<sup>[1,6,7]</sup>.

There are three distinct age-dependent clinical phenotypes of CD: the mild phenotype of neonatal intrahepatic cholestasis caused by citrin deficiency [Neonatal Intrahepatic Cholestasis caused by Citrin Deficiency (NICCD), Online Mendelian Inheritance in Man (OMIM): 605814], asymptomatic period or failure to thrive and dyslipidemia in young children, and a fatal phenotype of type II citrullinemia [Adult Onset Type II Citrullinemia (CTLN2), OMIM: 603471] in older children and adults (11-80 years)<sup>[1,8,9]</sup>. Misdiagnosed or mistreated CTLN2 patients usually have poor outcomes that often result in death due to hyperammonemic encephalopathy<sup>[8]</sup>.

CD is a panethnic disorder, but is relatively more common among East Asian populations. The carrier prevalence among Japanese and Chinese populations has been reported to be approximately 1/65<sup>[10-16]</sup>. Despite its high prevalence, clinical features and metabolic profiles are diverse among patients, thus making correct diagnosis difficult<sup>[1,17,18]</sup>. A definitive diagnosis of CD typically requires DNA sequencing analysis of the *SLC25A13* gene, which is time consuming and costly. Alternative methods such as polymerase chain reaction restriction fragment length polymorphisms, GeneScan and SNaPshot have

been adapted to detect mutations in the *SLC25A13* gene<sup>[4,13,14,16,18-20]</sup>. Recently, Kikuchi *et al.*<sup>[21]</sup>, reported a new method for identifying common mutations using a real-time polymerase chain reaction (PCR)-based technique combined with melting curve analysis using HybProbes. This method appears to be a rapid and economical approach that is also suitable for the use with a high-throughput platform<sup>[21]</sup>.

Over 30 *SLC25A13* mutations have been described<sup>[13,14,19]</sup> and our group has previously shown that mutation [I] was the most common (8/10) mutated allele identified among NICCD Thai infants with the remaining identified as mutations [III] (c.1638\_1660dup) and [XIX] (g.IVS16ins3kb)<sup>[16]</sup>. In addition, the heterozygous state of a novel p.Met1? (c.2T > C) variant was identified in an infant with idiopathic cholestasis and in 3 out of 100 healthy controls<sup>[16]</sup>. This variant was also observed in Chinese control individuals with equivalent carrier prevalence<sup>[20]</sup>. The pathogenic property of p.Met1? has been confirmed in a yeast model of CD and this mutant exhibits loss of citrin function<sup>[22]</sup>. Here, we conducted a detailed investigation to capture the true prevalence of CD in the Thai population given the small number of Thai patients with CD that have been characterized at the molecular level and with a high prevalence of p.Met1? carriers in an earlier study.

## MATERIALS AND METHODS

### Subjects

Eligible DNA samples were anonymous specimens previously stored and obtained through the Thai 4<sup>th</sup> National Health Examination Survey, during August 2008 and March 2009 by the National Health Examination Survey Office, Health System Research Institute. Sample size was calculated based on the estimated carrier prevalence of *SLC25A13* mutations, 1/110, which was derived from a previous patient-based study<sup>[16]</sup>. Using the Power and Sample Size Calculations Program (version 3.0.43), for alpha error of 10% and power of 90%, the target sample size needed to achieve statistical significance was 669. Even in a worst case scenario (carrier rate of 1/200) with the same alpha error and power of testing, the minimum sample size required was 1337. To offset sample loss due to insufficient DNA quantity or the degradation of DNA extract quality, 15%-20% additional specimens were added to the sample size. A computer-based simple randomization was used to randomly select samples from each of the five regions in Thailand including; Bangkok, Central, Northeastern, Northern and Southern (Figure 1). The number of samples from each region was in accordance to the population distribution reported by the National Statistical Office ([www.nso.go.th/](http://www.nso.go.th/)). This ensured an avoidance of ascertainment bias of the study population since there may or may not have been the possibility of ethnic differences of the *SLC25A13* variants among subpopulations in Thailand. Moreover, Thais from the Southern region of the country are more ethnically re-

Figure 1 Map of Thailand and geographic distribution.

lated to Malay descendents and those from the North-eastern region are more ethnically related to descendants of Laos and Cambodia. In total, 1569 specimens were received for the study following the approval of Ramathibodi Hospital institutional review board.

#### Detection of the *p.Met1?* allele by TaqMan assay

Real-time PCR using hydrolysis probes that were specific to each allele were employed to detect the *p.Met1?* mutation. Probes and primers were designed according to the *SLC25A13* gene sequence (GenBank accession no. NM\_014251). Primer sequences were 5' GTCAGT-GGGTCCCGCAGTC 3' and 5' GCACCCCATTTT-GCTCCG 3' as a forward and reverse primer, respectively. The probe for detecting the wild-type allele was tagged with 6-FAM at the 5' end, whereas the mutant allele contained VIC. Sequences of the wild-type and mutant probes were 6-FAM 5'AACCGGGGCGAATCATG-GCG 3' minor groove binder (MGB) and VIC 5'AACCGGGGCGAATCACGGCG 3' MGB, respectively.

Each real-time PCR reaction contained 0.9  $\mu\text{mol/L}$  of each primer, 0.25  $\mu\text{mol/L}$  of each probe, 20 ng of genomic DNA and 5  $\mu\text{L}$  of TaqMan<sup>®</sup> Genotyping Master Mix (Applied Biosystem). The thermal profile started with an initial denaturation at 95 °C for 10 min followed by 55 amplification cycles at 30 s, and denaturation at 95 °C. Finally, annealing and extension for 90 s at 62 °C. The ViiA<sup>™</sup> 7 System (Applied Biosystem) was used for detection. Positive samples were confirmed using PCR-

*EagI* restriction digest as previously established<sup>[16]</sup>.

#### Detection of six common mutations by HybProbe assay

Six common mutations accounting for 91%-100% of the mutant alleles previously reported in Japanese, Chinese, and Thai patients were selected for screening in the present study<sup>[14,16,21]</sup>. These mutations were: [I] (c.851\_854delGTAT), [II] (g.IVS11+1G>A), [III] (c.1638\_1660dup), [IV] (p.S225X), [V] (IVS13 + 1G > A) and [XIX] (g.IVS16ins3kb). HybProbe assays were performed using probes and primers for *SLC25A13* previously validated<sup>[21]</sup>. Real-time PCR was performed using a LightCycler 480 (Roche Applied Science). A 10- $\mu\text{L}$  real-time PCR reaction contained 0.5  $\mu\text{mol/L}$  of each forward and reverse primer (except 0.1  $\mu\text{mol/L}$  of reverse primer in the probe-primer set B), 0.2  $\mu\text{mol/L}$  of each donor and acceptor probe, 20-40 ng of genomic DNA and 5  $\mu\text{L}$  of LightCycler 480 probe Master (Roche Applied Science) or Premix Ex Taq<sup>™</sup> (Perfect Real Time) (Takara Bio Company). All positive samples were confirmed using PCR-*Hpy*CH4IV restriction digest for mutation [I]<sup>[16]</sup>, long-range PCR for mutation [XIX]<sup>[14]</sup>, and/or direct sequencing (Research Center, Ramathibodi Hospital). Long range PCR conditions were as follows: 94 °C for 5 min; 35 cycles of 98 °C for 20 s, 60 °C for 30 s, 68 °C for 15 min; 72 °C for 20 min and 15 °C for  $\infty$ . It should be noted that conventional nomenclature of mutations of the *SLC25A13* gene has been widely used; therefore, to ensure that the readers would easily grasp the mutation type concept, conventional nomenclature was used alongside standard nomenclature.

#### Statistical analysis

Fisher's Exact test was used to determine the statistical difference for the frequencies of the mutant alleles identified in different geographic regions. A *P* value of < 0.05 was considered statistically significant. Analysis of variance to compare sex and age distribution among regions was performed using the SPSS program (version 16.0, SPSS Inc., Chicago, IL, United States).

## RESULTS

Complete DNA specimens from 1537 individuals were included in the analysis, 758 males (mean age  $47 \pm 21$  years) and 779 females (mean age  $49 \pm 21$  years), with an overall mean age of  $48 \pm 21$  years. Sex and age distribution were not significantly different in the five different regions, although the mean age of subjects from the Northeastern region was slightly higher than those from the other areas of the country.

#### High prevalence of *p.Met1?* allele in the Thai population

The *p.Met1?* allele was found in 85 individuals giving a 1/18 carrier frequency. This mutation was evenly distributed throughout geographic regions (Table 1). One of these individuals was compound heterozygous with mutation [I]; however, since the specimens in our analy-

<sup>1</sup>One individual was found with compound heterozygote of Mutation [ I ] (c.851\_854 delGTAT) and p.Met1?; <sup>2</sup>Statistical analysis using Fischer's Exact test giving P value for comparison of the carrier prevalence identified across the regions. NA: Not available.

sis were anonymous it was impossible to determine the phenotype of this person.

### Carrier frequency of six other *SLC25A13* mutations

A total of 17 individuals were heterozygotes for mutant alleles. Excluding the p.Met1? variant, 8 mutation [ I ] and 9 mutation [XIX] (Table 1) were observed, giving a 1/90 carrier rate. Frequencies of mutations [ I ] and [XIX] identified in each region were not statistically different ( $P = 0.180$  and  $0.067$ , respectively). The four other mutations were not found. Melting point analysis revealed four specimens with heterozygous peaks that were distinct from mutation [ II ] (IVS11 + 1G > A) (Figure 2A). Sequencing of these specimens revealed a novel single nucleotide polymorphism (SNP), IVS11 + 17C > G. This SNP was located in the anchor-probe binding sequence. Prediction by NNSplice<sup>[23]</sup> ([http://www.fruitfly.org/seq\\_tools/splice.html](http://www.fruitfly.org/seq_tools/splice.html)) indicated no change in the splice-site score.

Screening of mutation [V] revealed one specimen with an abnormal melting peak (Figure 2B) where direct sequencing revealed an SNP, c.1311C > T, at the binding site of the reporter probe. This novel variant was located at the last base of a codon and at the last base of exon 13, likely resulting in a synonymous change, c.C437C. The calculated donor splice score remained unchanged (0.97) suggesting that this variant is likely to be a rare polymorphism.

## DISCUSSION

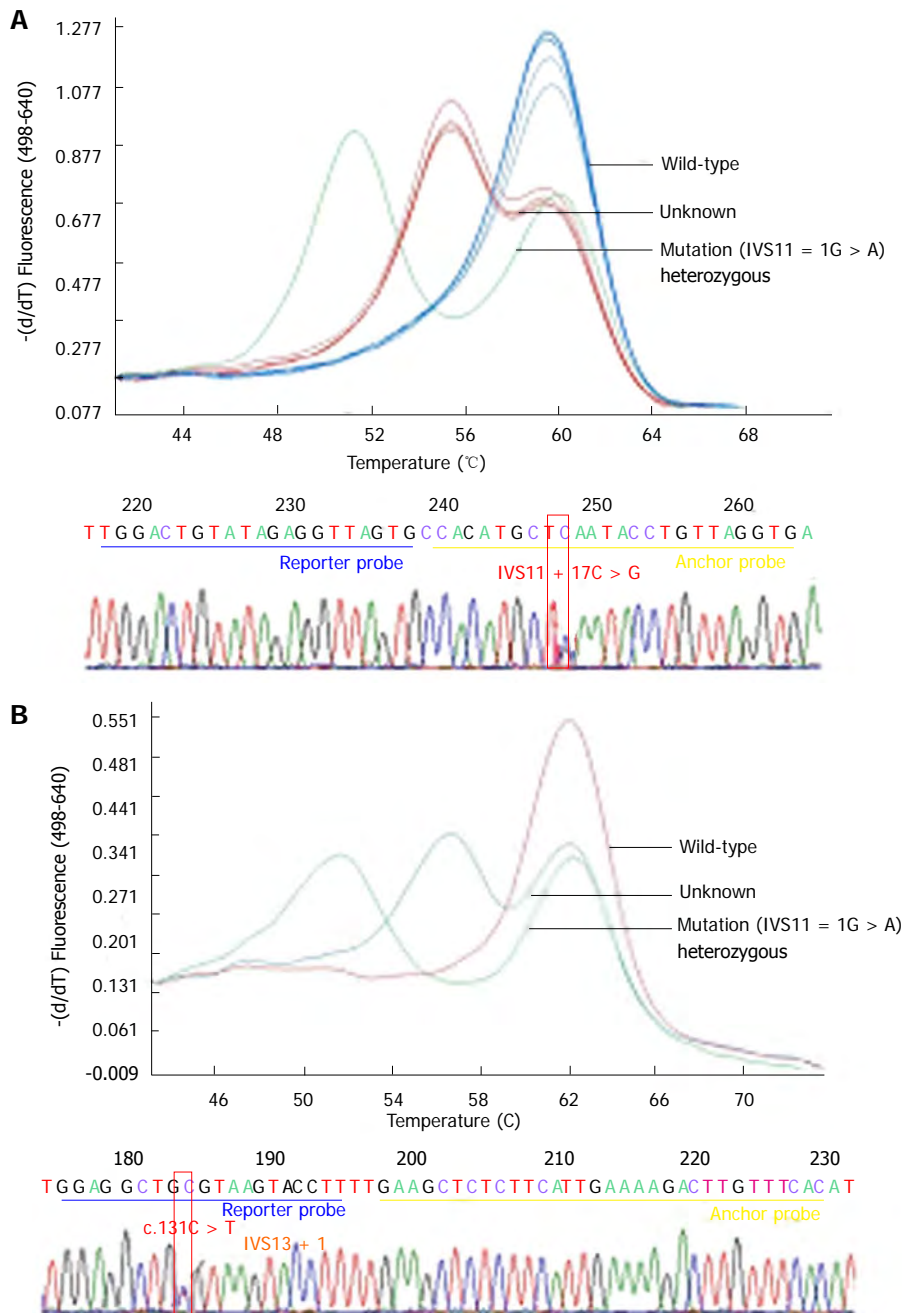

We have demonstrated a carrier rate of at least 1 in 90, and a homozygote/compound homozygote rate of 1 in 33000 for the known and previously identified *SLC25A13* mutations, excluding the p.Met1? variant among the general Thai population. This number is different, although similar, to the estimated carrier prevalence of 1/110 and homozygotes/compound homozygote rate of 1/48000 that was obtained from the only other available patient-based study<sup>[16]</sup>. Our findings are also consistent with the prevalence of *SLC25A13* homozygotes/compound heterozygotes of 1/17000 in the Japanese population and the disease frequency of 1/17000-34000 for NICCD, and 1/100000-230000 for CTLN2<sup>[8,24,25]</sup>.

No studies of the p.Met1? variant had been carried out prior to the recent description in affected and unaffected populations of China and Thailand<sup>[8,14-16,20]</sup>. This mutant allele has a high carrier frequency of 1/18 and a predicted homozygote rate of 1/1300. Based on our analysis, approximately 50000 individuals homozygous for p.Met1? are predicted to be present in the Thai population. Proven deleterious effects of the p.Met1? variant in a yeast model<sup>[22]</sup> and identification of a compound heterozygote between (paternally inherited) p.Met1? and the (maternally inherited) *SLC25A13* pathologic allele (r.16\_212dup) in a Chinese NICCD patient<sup>[20]</sup> supports the pathogenicity of the p.Met1? allele. When taking the p.Met1? allele into account with the other six previously described common mutations identified in the present study, a very high carrier rate, 1 in 15, and homozygote rate, 1 in 900, is predicted for *SLC25A13* mutations.

Patient- and population-based analyses of the prevalence of the p.Met1? variant in other ethnic backgrounds would help reveal its clinical relevance in CD and other disorder (s), if any. Based on the yeast model, the p.Met1? variant is expected to cause citrin protein production loss. It is also possible that in the p.Met1? variant, an alternative translation initiation site may produce a truncated citrin protein lacking 34 amino acid residues. However, the loss of the 34 N-terminal citrin residues causes the mislocalization and impaired function of the aberrant protein<sup>[22]</sup>, indicating that even if this truncated protein was produced, it would not contribute to normal citrin activity. Currently, we have not identified a p.Met1? homozygotic individual and it is possible that p.Met1? may lead to embryonic lethality, similar to homozygotes of the Southeast Asian Ovalocytosis mutant allele in the anion-exchanger 1<sup>[26,27]</sup>. Several questions regarding the p.Met1? mutation still remain unanswered. Despite its deleterious nature in the yeast model, high prevalence in Thai and Chinese populations from tropical areas, resistance to infectious diseases, and unexplainable unidentified homozygotes in patients even with a high allele frequency, its clinical pathology in humans, ethnic and regional prevalence, selective advantage against infectious diseases, and its lethality warrant further study.

There are two noteworthy limitations of the current study: subject age and the investigation of other

**Figure 2** Novel variants in the anchor probe binding sites, detected using the HybProbe assay. A: Upper panel shows unknown heterozygous melting peaks distinguishable from mutation [II] (IVS11 + 1G > A) the heterozygous positive control; lower panel is a sequenogram, confirming a variant IVS11 + 17C > G; B: Upper panel shows an aberrant heterozygous melting peak deviated from mutation [V] (IVS13 + 1G > A) heterozygote; lower panel indicates a sequenogram, confirming a novel variant c.1311C > T.

mutations. Given that 48 million people in Thailand are represented in our study, based on the inclusion age of 15 or older, over 1455 individuals may possibly have CD considering the confirmed disease causing mutations (excluding p.Met1?). The carrier rate derived from the present study may be underestimated due to the age of the population and mutations screened. Subjects involved in the study were living adults with an average age of 48 years. Some homozygotes/compound heterozygotes might not have survived prior to the start of the survey due to severe phenotypes, and thus would not have been included in our analysis. However, the age of the subjects may not have such a significant effect on the results of this study since the severe phenotype is relatively rare. Another limitation of the present study was that only six mutations were screened, thus the contribution of other

mutations was not included in our analysis. The other two less common mutations among the Chinese and Japanese population: [VI] (c.1799\_1800insA) and [VIII] (c.1801G > T)<sup>[21]</sup> were not selected for screening due to budget limitations.

CD is relatively common in East Asian populations<sup>[13,14]</sup>. Data from this study suggest that it is also common in Thais. While our analysis did not reveal any significant changes in mutation distribution in the five regions of Thailand, it is possible that an increase in sample size from each region may be necessary to reveal any other variations. CD has also been reported in Vietnamese and Malaysians<sup>[14,15,28]</sup>. Additional population studies in Southeast Asian populations will shed more light on the geographical distribution of this disease.

When considering each individual confirmed disease

causing mutations, [XIX] and [I] were the two leading mutations identified in the general Thai population with equivalent frequency, 9/1537 and 8/1537, respectively (Table 2), whereas patient-based studies indicate a higher frequency of mutation [I] (8/10 mutated alleles)<sup>[16]</sup>. The discrepancy between the frequencies of mutant alleles identified from population-based studies and those obtained from patient-based analyses is also evident in other studies<sup>[13,21]</sup>.

Of the known disease causing mutations, [I] and [XIX] are most common in Thai and Chinese populations, whereas mutations [II] and [I] variants are most common among Japanese populations and patients (Table 2)<sup>[13,14,21]</sup>. In further exploration of this difference in ethnic mutation, when comparing between Chinese and Japanese, there is a possibility that the Thai ethnic background is more closely related to that of the Chinese. This may be linked to the ancient migration of certain Chinese ethnic groups to Thailand<sup>[29]</sup>.

The discovery of g.IVS11 + 17C > G and c.1311C > T variants which are located on the anchor/reporter probe binding sites raised the possibility that an SNP located in the same area may affect the dissociation of probes from the target DNA and interfere with detection of the target SNP. Therefore, direct sequencing should be performed on positive subjects in order to confirm the presence of the target SNP. Moreover, the presence of double SNPs in *αs* could possibly obscure detection of the target SNP; however, this possibility remains to be demonstrated. Bioinformatic analysis of the g.IVS11 + 17C > G and c.1311C > T variants showed no change in splice score or amino acid sequence, suggesting a benign nature of these SNPs. However, the possibility of either being a pathogenic allele cannot be completely excluded

due to its surprisingly low prevalence, 4 and 1 in 1537, respectively.

Overall, this study revealed that CD is not uncommon in the Thai population and there is a high frequency of the p.Met1? allele. Once the optimization for TaqMan/HybProbe analysis for each mutation is complete, it will serve as a rapid, efficient, robust, convenient, and cost-saving method for large scale analysis that will enable general population and newborn screening across the country. This has already been demonstrated by the successful establishment of the TaqMan assay for the p.Met1? mutation. Procedures utilized in the present study should prove valuable in examining the distribution and frequencies of *SLC25A13* mutations including p.Met1? among Southeast Asian populations.

Further investigations are required to establish the clinical relevance of p.Met1? both in patients and controls. Demonstration of the molecular pathogenic mechanism of p.Met1? in human/mammalian models, although it is predicted to be a loss of function mutation<sup>[22]</sup>, will also aid in further understanding. The unusually high frequency of the p.Met1? mutation suggests it may have a role in the predisposition and/or protection of disorder (s), perhaps similar to the selection of red cell polymorphisms in areas endemic for malarial infection<sup>[30-32]</sup>. Our further work will examine the possible connection between the p.Met1? mutation and protection against infectious tropical diseases.

## ACKNOWLEDGMENTS

The authors thank Professors Takeyori Saheki and Keiko Kobayashi for their wholehearted support, Dr. Chusak Okascharoen for statistical advice, and Ms. Porawee Kod-

charin for sample preparation assistance.

## COMMENTS

### Background

Citrin deficiency (CD) leads to three distinct phenotypes; two of which are non-fatal. These phenotypes include: Neonatal intrahepatic cholestasis caused by citrin deficiency, failure-to-thrive and dyslipidemia. The third, a fatal phenotype of type II citrullinemia, has marked elevation of ammonia level mimicking a primary disorder of the urea cycle.

### Research frontiers

Treatment for CD is distinct from other urea cycle disorders. Epidemiological data are needed to predict disease prevalence and aid in creating awareness for diagnosis among physicians. In this study, the authors screened 1537 subjects from the general population for a novel pathologic allele, p.Met1?, and six common mutations using newly developed Taqman and established HybProbe assays. They demonstrated a carrier frequency of 1/18 for p.Met1? allele, and the carrier rate of 1/90 for mutations: [XIX] and [I], and calculated homozygote rate of 1/33000 for the two latter mutations.

### Innovations and breakthroughs

The question of p.Met1? homozygote lethality remains unanswered which may serve as an explanation as to why this homozygote has yet to be identified in patients/controls even with high allele frequency. The p.Met1? mutation has been rarely studied in populations other than the Thai and Chinese and therefore, may have been overlooked. The high carrier rate of p.Met1? suggests the possible selective advantage of this particular allele.

### Applications

The unusually high frequency of the p.Met1? mutation suggests its possible role in the predisposition and/or protection of disorder(s), which is perhaps similar to that of the selection of red cell polymorphisms in endemic areas for malarial infection. The established TaqMan assay would allow for a simple, rapid, and cost-effective method for p.Met1? mass screening.

### Terminology

CD is caused by a mutation in the *SLC25A13* gene encoding for an aspartate-glutamate carrier isoform 2 (AGC2) and is expressed mainly in the liver. The major function of AGC2 is to export mitochondrial aspartate in exchange for cytosolic glutamate and it is involved in several metabolic pathways with major contributions to the urea cycle and malate-aspartate shuttle.

### Peer review

The article covers a topic area of increasing interest. It contains novel information and data affirms on available literature. 1537 subjects from general population were screened for a novel pathologic allele p.Met1? and six common mutations using newly developed Taqman and established HybProbe assays. The study highlighted the current underestimation of citrin deficiency and suggested the possible selective advantage of the p.Met1? allele.

### Abstract

**AIM:** To compare the clinical outcome of single-incision laparoscopic cholecystectomy (SILC) and three-incision laparoscopic cholecystectomy (3ILC) for acute cholecystitis.

**METHODS:** From July 2009 to September 2012, 136 patients underwent SILC or 3ILC for acute cholecystitis at a tertiary referral hospital. One experienced surgeon performed every procedure using 5 or 10 mm 30-degree laparoscopes, straight instruments, and conventional ports. Five patients with perforated gallbladder and diffuse peritonitis and 23 patients with mild acute cholecystitis were excluded. The remaining 108 patients were divided into complicated and uncomplicated groups according to pathologic findings. Patient demog-

raphy, clinical data, operative results and complications were recorded and analyzed.

**RESULTS:** Fifty patients with gangrenous cholecystitis, gallbladder empyema, or hydrops were classified as the complicated group, and 58 patients with acute cholecystitis were classified as the uncomplicated group. Twenty-three (46.0%) of the patients in the complicated group ( $n = 50$ ) and 39 (67.2%) of the patients in the uncomplicated group ( $n = 58$ ) underwent SILC; all others underwent 3ILC. The postoperative length of hospital stay (PLOS) was significantly shorter in the SILC subgroups than the 3ILC subgroups ( $3.5 \pm 1.1$  d vs  $4.6 \pm 1.3$  d,  $P < 0.01$  in the complicated group;  $2.9 \pm 1.1$  d vs  $3.7 \pm 1.4$  d,  $P < 0.05$  in the uncomplicated group). The maximum body temperature recorded at day 1 and at day 2 following the procedure was lower in the SILC subgroups, but the difference reached statistical significance only in the uncomplicated group ( $37.41 \pm 0.56$  °C vs  $37.80 \pm 0.72$  °C,  $P < 0.05$  on postoperative day 1;  $37.10 \pm 0.43$  °C vs  $37.57 \pm 0.54$  °C,  $P < 0.01$  on postoperative day 2). The operative time, estimated blood loss, postoperative narcotic use, total length of hospital stay, conversion rates, and complication rates were similar in both SILC and 3ILC subgroups. The complicated group had longer operative time ( $122.2 \pm 35.0$  min vs  $106.6 \pm 43.6$  min,  $P < 0.05$ ), longer PLOS ( $4.1 \pm 1.3$  d vs  $3.2 \pm 1.2$  d,  $P < 0.001$ ), and higher conversion rates ( $36.0\%$  vs  $19.0\%$ ,  $P < 0.05$ ) compared with the uncomplicated group.

**CONCLUSION:** SILC is safe and efficacious for patients with acute cholecystitis. The main benefit is a faster recovery than that achieved with 3ILC.

**Key words:** Single-incision laparoscopic cholecystectomy; Single-incision laparoscopic surgery; Laparoen-

doscopic single site surgery; Cholecystectomy; Acute cholecystitis; Complicated cholecystitis; Gangrenous cholecystitis

**Core tip:** single-incision laparoscopic cholecystectomy (SILC) is an alternative treatment for uncomplicated benign gallbladder diseases, but its role in acute cholecystitis remains unclear. This comparative analysis of SILC with three-incision laparoscopic cholecystectomy for treating acute cholecystitis represents the largest series to date and proportion of gangrenous cholecystitis patients (30.6%). The well-known drawbacks of SILC - longer operative time and higher cost - were alleviated by the larger paraumbilical incisions facilitating extraction of inflamed gallbladders and reliance on conventional instruments only. The low procedure conversion rate observed for SILC indicated its safety and efficacy for treating acute cholecystitis. SILC providing a faster recovery time was the main benefit to these patients.

Chuang SH, Chen PH, Chang CM, Lin CS. Single-incision vs three-incision laparoscopic cholecystectomy for complicated and uncomplicated acute cholecystitis. *World J Gastroenterol* 2013; 19(43): 7743-7750 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7743.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7743>

## INTRODUCTION

Single-incision laparoscopic cholecystectomy (SILC) is a novel technique comparable to traditional multi-incision laparoscopic cholecystectomy (LC) for uncomplicated benign gallbladder diseases in respect of safety and efficacy<sup>[1-3]</sup>. In addition to well-established cosmetic advantage; decreased post-operative pain and faster recovery are potential benefits<sup>[4-6]</sup>. However, higher complication rates in SILC have been reported<sup>[7-9]</sup>. Therefore, application of this technique in cases of acute cholecystitis should be done with caution<sup>[10]</sup>. Published SILC studies contain a small number of patients with acute cholecystitis<sup>[11-15]</sup>, while reports comparing SILC and traditional LC for acute cholecystitis are very rare<sup>[11]</sup>.

SILC was developed as a step-by-step evolution of three-incision laparoscopic cholecystectomy (3ILC) and two-incision laparoscopic cholecystectomy (2ILC) in March 2010<sup>[16]</sup>. Importantly, only conventional instruments were used. Initially, this procedure was only adopted in patients with simple benign gallbladder disease. Since May 2011, however, SILC has been offered as an optional procedure for acute cholecystitis by our clinical practice. This study compares the clinical outcomes following SILC and 3ILC for acute cholecystitis over a period of 39 mo.

## MATERIALS AND METHODS

From July 2009 to September 2012, 136 consecutive patients with acute cholecystitis underwent cholecystectomy by a single surgeon at a tertiary referral hospital in Hsin-Chu city, Taiwan. Five patients had perforated gallbladder and diffuse peritonitis and were excluded from the analysis. The role of laparoscopic operation in patients with perforated gallbladders and diffuse peritonitis remains controversial<sup>[17-19]</sup>. Twenty-three patients with "mild acute cholecystitis" were also excluded. The clinical course of this disease is similar to that of a biliary colic. To eliminate the bias related to disease severity, the enrolled 108 patients were divided into complicated and uncomplicated groups, according to operative and pathologic findings. Gangrenous cholecystitis, gallbladder empyema or hydrops were defined as complicated cholecystitis, while all other findings were defined as uncomplicated cholecystitis.

Patient demography, clinical data, operative results and complications were recorded. A modified APACHE II was used as the preoperative prognostic score, namely, low risk: < 5 points, intermediate risk: 6-9 points, and high risk: ≥ 10 points<sup>[20]</sup>. The operative time was defined as the interval from initial skin incision to skin closure. Postoperative narcotic use was recorded as the intramuscular pethidine dose (mg) per kilogram of patient body weight (*i.e.*, 1 mg/kg). The postoperative length of hospital stay (PLOS) was defined as the duration between the day of surgery and the day of discharge in the same hospitalization. The total length of hospital stay referred to the total hospitalization duration including readmission for late-onset complications. The maximum body temperature (BT; °C) of each day was recorded from postoperative day 1 to day 4 for patients who were still hospitalized. Any procedure that failed to be fulfilled as scheduled was regarded as converted. The complications were recorded according to the five-grade Clavien-Dindo classification system<sup>[21]</sup>.

### Surgical technique

The details of the surgical techniques have been described previously<sup>[16]</sup>. In SILC, two 5 mm straight instruments and a 5 mm 30-degree rigid laparoscope were inserted into the abdominal cavity *via* three 5 mm ports in a vertical line at a 2 cm paraumbilical incision on the left side. An optional 2 mm right subcostal incision was made for the passage of a transcystic duct catheter to perform an intraoperative cholangiography (IOC). An assistant controlled the retraction grasper in the middle port. The operator controlled the working instrument in the upper port with the right hand and the laparoscope in the lower port with the left hand (self-camera technique). At the end of the procedure, the lower 5 mm port was upgraded to a 10 mm reusable port for specimen extraction into a retrieval bag. All the fascial defects and the skin incision

**Figure 1** Critical view of safety during a single-incision laparoscopic cholecystectomy for acute cholecystitis. Anterior (A) and posterior (B) views are shown. GB: Gallbladder; CA: Cystic artery; CD: Cystic duct; CBD: Common bile duct.

were sutured. In 3ILC, a 10 mm 30-degree rigid laparoscope was inserted *via* a 10 mm reusable port at a 1 cm infraumbilical incision. The 5 mm working instrument and retraction grasper were inserted *via* two separate 5 mm ports at the epigastrium and right flank respectively.

When a severely inflamed gallbladder or dense pericholecystic fibrosis was encountered at an early stage of the procedure, the threshold for using additional port sites was low. A suction irrigation device was used for decompression of a severely distended gallbladder and meticulous dissection in an unclear operative field. Every effort was made to obtain the critical view of safety (Figure 1), following the recommendations by Strasberg *et al.*<sup>[22]</sup>. If the anatomy of the Calot's triangle was obscure, dissection would be started from the gallbladder dome (retrograde cholecystectomy). In difficult situations, the gallbladder neck or posterior wall was not disturbed (subtotal cholecystectomy)<sup>[23,24]</sup>. The cystic duct stump or gallbladder neck was secured with intracorporeal suturing if the diameter was too big or the tissue was too fragile to be clipped. In infrequent cases, the liver bed was packed with gauze temporarily if the monopolar electrocautery had failed to achieve hemostasis. Wound extension to fit a firm and swollen gallbladder was usually carried out at the infraumbilical incision in 3ILC, but it was largely unnecessary in SILC. When a subhepatic drain was placed, it was always removed within 48 h after the operation if there was no bile leakage. After discharge, all the patients attended follow-up periods of more than 1 mo.

### Statistical analysis

Data were analyzed using Pearson's  $\chi^2$  test and Student's *t* test. A *P* value of less than 0.05 was considered statistically significant.

## RESULTS

The complicated group (gangrenous cholecystitis, gallbladder empyema or hydrops) consisted of 50 patients, and the uncomplicated group (acute cholecystitis) consisted of 58 patients. Twenty-three (46.0%) of the patients in the complicated group and 39 (67.2%) of the

patients in the uncomplicated group underwent SILC; the remaining patients all underwent 3ILC. The demographic characteristics, clinical data, and pathologic findings showed no statistically significant differences between the SILC and 3ILC subgroups in either the complicated or uncomplicated groups (Table 1). Patients with gangrenous cholecystitis constituted a major portion of the complicated group (65.2% in the SILC subgroup and 66.7% in the 3ILC subgroup). Preoperative endoscopic retrograde cholangiopancreatography (ERCP) was performed on 13 patients during the same hospitalization to address suspicious concomitant choledocholithiasis (Table 2). Nine of the patients showed a positive result and subsequently underwent immediate therapeutic endoscopic sphincterotomy (EST) for stone clearance. Eleven patients had suspicious concomitant choledocholithiasis without preoperative ERCP and subsequently underwent IOC; the results for all were negative. In cases of positive IOC, common bile duct exploration was performed under laparoscopy.

PLOS and postoperative BT were the only two parameters that displayed a statistical difference between the two subgroups (Tables 2 and 3). The SILC subgroup had a shorter PLOS than the 3ILC subgroup in the complicated and uncomplicated groups ( $P < 0.01$  and  $< 0.05$ , respectively). The SILC subgroups had a lower maximum BT than the 3ILC subgroups on the postoperative day 1 and day 2 (Figure 2), but the difference reached statistical significance only in the uncomplicated group ( $P < 0.05$  for postoperative day 1 and  $P < 0.01$  for postoperative day 2). Additional port sites were needed to fulfill the operations in eighteen patients of the complicated group and eleven patients of the uncomplicated group. Converted to an open cholecystectomy (OC) was not necessary in any case. The conversion rates in the SILC and 3ILC subgroups were similar (34.8% *vs* 37.0% in the complicated group; 17.9% *vs* 21.1% in the uncomplicated group).

Fourteen complications occurred in 11 patients (Table 4). The differences in complication rates between the SILC and 3ILC subgroups were statistically insignificant. Four patients experienced mild pulmonary effusion and/or atelectasis, a grade I complication that resolved spon-

Data are expressed as absolute numbers (percentage) or mean ± SD.

complication. The seven patients with grade II, IIIa and IIIb complications all needed a secondary hospitalization (range: 5-16 d) and recovered uneventfully.

In summary, the complicated group experienced longer operative times ( $P < 0.05$ ), longer PLOS ( $P < 0.001$ ), and higher conversion rates ( $P < 0.05$ ) (Table 5).

## DISCUSSION

SILC, also known as laparoendoscopic single site cholecystectomy, has increased in popularity worldwide in recent years. While multiple studies have reported this novel technique to be as safe as traditional LC for the

treatment of uncomplicated benign gallbladder disease<sup>[1-3]</sup>, some have demonstrated that SILC is associated with a higher complication rate<sup>[7-9]</sup>. Applying SILC in more complex circumstances, such as acute cholecystitis, becomes an interesting angle in which to study SILC in complex circumstances. To date, the published SILC studies have focused on only a small number of patients with acute cholecystitis and comparative studies have been rare<sup>[11-15]</sup>.

According to the 2010 Society of American Gastrointestinal and Endoscopic Surgeons guideline for the clinical application of laparoscopic biliary tract surgery, the indications, contra-indications and preoperative preparation for SILC are the same as those for multi-port cholecystectomy<sup>[17]</sup>. Both procedures should share the same safety standards with a low conversion threshold. We strictly followed these safety guidelines. Before adopting this technique for acute cholecystitis in May 2011, we had performed over 50 complication-free SILC procedures for simple benign gallbladder disease. Additionally, we are proficient at modified techniques to manage gallbladder complications, such as decompression, meticulous dissection with a suction irrigation device, retrograde cholecystectomy, subtotal cholecystectomy, and intracorporeal suturing the cystic duct stump or gallbladder neck. In SILC, a subhepatic drain always passed through an additional port site. Firm, fragile or severely inflamed gallbladders are usually difficult to retract. Therefore, conventional straight instruments were used in our cases, as the more elastic nature of curved or angulated instruments are not suitable. Because we only used conventional instruments, the procedures could be easily and rapidly converted to multi-incision laparoscopic or open operations for safety concerns.

Pathologic findings often have an effect on operative results of LC<sup>[25-27]</sup>. To eliminate this bias, we divided patients into two groups according to disease severity. The comparison between complicated and uncomplicated groups showed significant differences in operative time ( $P < 0.05$ ), PLOS ( $P < 0.001$ ), and conversion rates ( $P < 0.05$ ) (Table 5). The findings implicated that the two groups were different. The difference in complication rates did not reach statistical significance. This may be due to inadequate patient number and low complication rates.

The finding that the SILC subgroups had a shorter PLOS than the 3ILC subgroups was consistent with our previous study (Table 2)<sup>[16]</sup>. Even small traumatic effects can influence postoperative recovery. In case of acute cholecystitis, we followed a rule that patients who tolerated oral feeding well and had a BT under 37.5 °C for more than 24 h should be discharged. In this study, all the patients resumed oral feeding the morning after the operation, and most of them tolerated it well. Accordingly, postoperative fever became the critical factor leading to longer PLOS. The finding that the SILC subgroups had a lower maximum BT than the 3ILC subgroups on the postoperative day 1 and day 2 explained the shorter PLOS in the SILC subgroups (Table 3, Figure 2). Al-

though the difference in maximum BT reached statistical significance only in the uncomplicated group, we were more concerned about the postoperative fever in patients with complicated acute cholecystitis. We tended to associate the febrile episodes with postoperative infection in these patients. Accordingly, the small difference in maximum postoperative BT between the SILC and 3ILC subgroups in the complicated group influenced the PLOS significantly. The occurrence of postoperative fever was related to the inflammatory response to cholecystitis, atelectasis, and postoperative septic sequelae. Considering the similar pathologic distributions (disease severity) and postoperative complication rates in the SILC and 3ILC subgroups, it is possible that atelectasis may account for the difference in postoperative BT. Upper abdominal incision (upper midline or subcostal incisions) is a well-established risk factor for the development of atelectasis after abdominal surgery<sup>[28]</sup>, and traditional multi-incision LC was associated with impaired postoperative pulmonary function and an incidence of atelectasis up to 30% in several studies<sup>[29-31]</sup>. A lower incidence of febrile episodes following LC correlated with improved postoperative pulmonary function and minimal surgical trauma was observed<sup>[32]</sup>. Thus, 3ILC caused more febrile episodes in the first two postoperative days, and small upper abdominal incisions played a role in impaired postoperative pulmonary function (atelectasis) for patients with acute cholecystitis. We hypothesize that the faster recovery following SILC may be derived not from decreased pain severity, but rather location.

The operative duration and pethidine dose showed no significant difference between the two subgroups (Table 2). It is our opinion that the longer SILC duration in our previous study simply reflected an effect of the learning curve<sup>[16,33,34]</sup>. The typical SILC procedure for simple benign gallbladder disease takes less than one hour. In addition, the 1 cm infraumbilical incision in a 3ILC was too small to fit a swollen gallbladder, and it took some time to enlarge the incision during specimen extraction. The operative duration spent in SILC and 3ILC was comparable in most cases, for both simple and complicated gallbladder disease. Although we failed to reveal the difference in postoperative narcotic use between the two subgroups, it is too early to make a conclusion. In our clinical practice, a steady intramuscular pethidine dose is available, but the patients may feel pain in different degrees. To clarify the issue of postoperative pain related to the procedures, more detailed studies are necessary.

The outcome following a converted LC is worse than that following a successful LC<sup>[35,36]</sup>. A qualified laparoscopic surgeon should never hesitate to convert the procedure in an early stage if patient safety is questionable in difficult situations. The high conversion rate in our study (36% in the complicated group and 19% in the uncomplicated group) reflected our safety concerns (Table 5). Consistent with other studies, no procedure was converted to an OC<sup>[23,24]</sup>. The above-mentioned modified laparoscopic procedures for severe cholecystitis, such as

gallbladder decompression, dissection with a suction irrigation device, retrograde cholecystectomy, subtotal cholecystectomy and intracorporeal suturing, might reduce the open conversion rates tremendously without increasing the complication rates.

In conclusion, SILC with conventional instruments is as safe and efficacious as traditional multi-incision LC for both complicated and uncomplicated acute cholecystitis in experienced hands. The complication rate is low, and the major benefit for patients is faster postoperative recovery. Before applying SILC in difficult gallbladders, a surgeon must be proficient in this novel technique for simple gallbladder disease and the modified laparoscopic techniques for severe cholecystitis. A low threshold for converting the procedure should be maintained for patient safety. Further prospective randomized trials are needed to verify our findings.

## ACKNOWLEDGMENTS

We gratefully acknowledge the work of Ms. Yi-Chun Liao, Ms. Chia-Lin Wu and Ms. Jyun-Ya Li in assisting with the data collection. This study was presented at the 21<sup>st</sup> International Congress of the European Association for Endoscopic Surgery in Vienna, Austria, 19-22 June 2013.

## COMMENTS

### Background

Single-incision laparoscopic cholecystectomy (SILC) is a novel technique, with safety and efficacy profiles that are comparable to traditional multi-incision laparoscopic cholecystectomy (LC) for uncomplicated benign gallbladder diseases. For complicated gallbladder diseases, such as acute cholecystitis, the published studies regarding SILC have thus far been conducted with only a small number of patients. Studies comparing SILC and traditional LC for acute cholecystitis are rare, but necessary.

### Research frontiers

Single-incision laparoscopic surgery (SILS; also known as laparoendoscopic single site surgery) is a novel minimally invasive technique, compared with the traditional multi-incision laparoscopic surgery. Besides the obvious cosmetic advantage (producing no visible scar), decreased post-operative pain and faster recovery are the potential benefits of SILS. However, the higher complication rate that accompanies a beginner operator's learning curve must be accounted for when choosing to apply this technique.

### Innovations and breakthroughs

SILC with conventional instruments is as safe and efficacious as traditional multi-incision LC for both complicated and uncomplicated acute cholecystitis when performed by a physician with experienced hands. In particular, the patient benefits are low complication rate and faster postoperative recovery. Before applying SILC in difficult gallbladders, a surgeon must be proficient in this novel technique for simple gallbladder disease and the modified laparoscopic techniques for severe cholecystitis. A low threshold for converting the procedure should be maintained to help ensure patient safety.

### Applications

This study suggests that SILC with conventional instruments can be applied to patients with acute cholecystitis safely and efficaciously, particularly when performed by physicians with experienced hands. Better cosmetic outcome and faster recovery time are major advantages.

### Terminology

Single-incision laparoscopic surgery is a minimally invasive surgical procedure, in which the surgeon operates through a small single entry site - often the navel. As such, this procedure is considered a type of scarless surgery. The SILS

procedure is a good alternative approach (compared to the traditional surgical cholecystectomy procedure) for treating acute cholecystitis, an acute inflammation of the gallbladder characterized by unendurable pain in the right upper abdominal quadrant and is closely correlated with gallbladder stones.

### Peer review

This comprehensive comparative study of SILC and the traditional multi-incision LC treatment approach for acute cholecystitis represents the largest case series investigation of SILC in acute cholecystitis published to date. As well as better cosmetic outcome, SILC was shown to have a faster recovery time and less complications. The postoperative complication of fever remains to be fully understood and may be primarily related to the body's inflammatory response to the cholecystitis rather than the surgical procedure itself. Unfortunately, the well known difference in cost between the two procedures and the longer operating time required by SILC make it difficult to justify further prospective studies.

### Abstract

**AIM:** To investigate whether transanal natural orifice specimen extraction (NOSE) is a better technique for rectal cancer resection.

**METHODS:** A prospectively designed database of a consecutive series of patients undergoing laparoscopic low anterior resection for rectal cancer with various tumor-node-metastasis classifications from March 2011 to February 2012 at the First Affiliated Hospital of Sun Yat-Sen University was analyzed. Patient selection for transanal specimen extraction and intracorporeal anastomosis was made on the basis of tumor size and distance of rectal lesions from the anal verge. Demographic data, operative parameters, and postoperative outcomes were assessed.

**RESULTS:** None of the patients was converted to laparotomy. Respectively, there were 16 cases in the low anastomosis and five in the ultralow anastomosis groups. Mean age of the patients was 45.4 years, and mean body mass index was 23.1 kg/m<sup>2</sup>. Mean distance of the lower edge of the lesion from the anal verge

was 8.3 cm. Mean operating time was 132 min, and mean intraoperative blood loss was 84 mL. According to the principle of rectal cancer surgery, we performed D2 lymph node dissection in 13 cases and D3 in eight. Mean lymph nodes harvest was 17.8, and the number of positive lymph nodes was 3.4. Median hospital stay was 6.7 d. No serious postoperative complication occurred except for one anastomotic leakage. All patients remained disease free. Mean Wexner score was 3.7 at 11 mo after the operation.

**CONCLUSION:** Transanal NOSE for total laparoscopic low/ultralow anterior resection is feasible, safe and oncologically sound. Further studies with long-term outcomes are needed to explore its potential advantages.

**Key words:** Transanal specimen extraction; Natural orifice specimen extraction; Laparoscopic anterior resection; Low/ultra-low anastomosis; Total mesorectal excision

**Core tip:** Natural orifice specimen extraction (NOSE) is an emerging technique that has been recently applied to the field of rectal cancer resection. However, which is the better approach for rectal cancer remains controversial. In this paper, we present our surgical technique and short-term outcomes of transanal NOSE in total laparoscopic low/ultralow anterior resection (L-AR) for patients with rectal cancer. Based on our limited experience, transanal NOSE in L-AR for rectal cancer is feasible, safe and oncologically sound.

## INTRODUCTION

The incidence of rectal cancer is higher in Asia compared with western countries<sup>[1]</sup>. Technically, resection of low rectal cancer may be the most difficult among all colorectal operations.

At present, traditional colorectal surgery has increasingly given way to laparoscopic anterior resection with total mesorectal excision (L-AR/TME). Evidence-based medicine has established that L-AR/TME is a feasible surgical approach for managing rectal cancer. There were similar results in recent short-term therapeutic effects, local recurrence rate and postoperative survival rate between laparoscopic surgery (LS) and traditional open surgery for radical colon cancer<sup>[2]</sup>. Meanwhile, the mean estimated blood loss, discharge time after operation, and postoperative hospital stay were significantly reduced in the LS<sup>[3]</sup>. However, incision of the abdomen is still necessary in order to remove the specimens in LS, which could cause incision infection and increase the incidence of incisional hernia<sup>[4]</sup>.

Natural orifice specimen extraction (NOSE) may be an effective way to address the challenge. NOSE is feasible and safe technically for radical colorectal cancer surgery by traditional laparoscopic techniques, and for removal of the specimens through a natural orifice<sup>[5,6]</sup>.

Total laparoscopic hemicolectomy has been performed successfully by transvaginal NOSE<sup>[7]</sup>. However, due to its innate limitations, transvaginal NOSE is difficult for radical rectal cancer surgery, especially in low rectal cancer. Here, we introduce a technique used for the laparoscopic radical rectal surgery with TME, and the specimen was removed and anastomosis was accomplished through the anus.

## MATERIALS AND METHODS

This study was approved by the ethics committee of the hospital and written informed consent was obtained from the patients. Twenty-one patients with rectal adenocarcinoma underwent the procedure from March 2011 to February 2012 (Table 1). All patients with preoperative diagnosis of rectal cancer were confirmed by endoscopic colonoscopy, pathology, endosonography, and staged by specialized oncologists at our hospital, and preoperatively managed following the guidelines of the National Comprehensive Cancer Network (NCCN). All operations were performed by a single surgeon who was proficient in various laparoscopic colorectal procedures and laparotomy at our hospital.

These patients with tumor stage T4, tumor covering over half of the circumference of the rectum, metastasis in the liver or lungs on preoperative imaging assessment, or body mass index > 28 were excluded.

Three patients whose tumor-node-metastasis

**Table 1 Patient demographic data**

Patient demographic data	Value
Age (yr)	45.4 ± 3.6
Body mass index	23.1 ± 2.8

Mean wexner score	3.7 ± 1.6

Wexner Score was obtained in follow-up at 6 mo.

classification of T3 was confirmed by endosonography, magnetic resonance imaging (MRI) and computed tomography (CT) received three cycles of chemotherapy prior to surgery. Radiotherapy followed by resection was conducted based on the national guidelines. The feasibility of the surgery was reappraised at 2 wk after the treatment. All three patients had symptom relief, the tumor was reduced in size, and there were limited side effects of neoadjuvant chemotherapy.

The day before the operation, all patients underwent systemic bowel preparation, and used prophylactic antibiotics.

### Surgical procedure

**Laparoscopic phase.** The patient was positioned in a modified lithotomy position, and the abdomen was then insufflated with 10-12 mmHg CO<sub>2</sub>. Four ports were used in the following procedure. The first port was a 12-mm blunt-tip for the laparoscope, which was placed in the umbilicus using the minilaparotomy technique. The second to fourth ports were 10-mm operating ports in the right lower quadrant, and two 5-mm ports in the right middle abdomen and left lower quadrant, respectively.

Colon mobilization, lymph node dissection, and mesenteric excision were performed laparoscopically in the usual manner. First, the sacral promontory was separated by ultrasonic scalpel (Harmonic ACE; Ethicon Endo-Surgery, OH, United States) from the right side of the rectum. Second, before the tumor was mobilized, the inferior mesenteric artery was ligated at its point of pedicle from the aorta with a large or oversized Hem-o-lock. The I-III branches of artery and vein of sigmoid were cut off while the marginal artery of the proximal colon was preserved. Next, the inferior mesenteric vein was ligated at the corresponding height to the artery. We mobilized the splenic flexure in two patients because there were existing tensions in the anastomosis. Third, the posterior mesorectal fascia was identified and the dissection was extended to the level of the sacral promontory in the avascular plane. The rectum was fully dissociated to the levator ani muscle plane as far as possible along the Denonvillier's fascia. The fragment of the distal rectum that was located 2 cm above the tumor was clamped with a detachable clip.

We preserved the inferior hypogastric nerves as far as possible during the procedure.

**Perineal phase.** The anus was dilated gently until it

**Figure 1** Surgical procedure. A, B: Dilating the anus with a home-made dilator in which the bottom can be folded; C: Exteriorizing the specimen through the anus; D: Placing the anvil shaft into the stump of the proximal colon; E: Placing the anastomosis body into the anus; F: Completion of manual anastomosis procedure; G: Postoperative appearance of the anus; H: Appearance of abdominal wall 3 mo after surgery.

could accommodate four fingers. A home-made anus dilator and fine silk traction sutures were placed into the proximal lip of the exposed mucosal edge at a vertical orientation, in order to expand the anus and expose the rectum (Figure 1A and B). The level of intended transection had to maintain a margin of 2 cm distal from the tumor<sup>[8]</sup>. After irrigating the rectum with 1 L diluted povidone-iodine solution, we sutured two parallel circle-purse-strings in the distal rectal wall with 2-0 prolene lines through the dilated anus. The upper one maintained a minimal margin of 1-1.5 cm distal from the tumor, while the lower was located in the rectal mucosa at 1 cm above the dentate line. Between the two circle-purse-strings, full-thickness rectal circumferential dissection was extended by ultrasonic scalpel. At this point, the peritoneal cavity was extended circumferentially cephalad as far as possible, and then joined the perineal and laparoscopic

dissection planes.

The stump of the proximal rectosigmoid was exteriorized through the dilated anus and opened stump of the distal rectum (Figure 1C). After clamping with purse string forceps, the section of proximal colon, which had to be maintained at a minimal margin of 10 cm above the tumor, was transected under direct vision. After purse-string suturing, an anvil shaft was placed into the stump of the proximal colon, then it was pushed gently back into the peritoneal cavity (Figure 1D). The purse-string suture was tied to the anvil shaft before connecting it to the central shaft of the circular stapler (CDH 29; Ethicon Endo-Surgery, OH, United States). After tightening the lower circle-purse string, the anastomosis was placed into the anus (Figure 1E). Then the anastomat was fired to create an end-to-end coloanal anastomosis in the usual manner<sup>[9]</sup>. An air test was conducted through the anus.

The stitching was reinforced by bioabsorbable suture if necessary. A pelvic drain was inserted.

We performed the procedure successfully in 16 patients. Due to the low position of the stump of the distal rectum, we performed manual anastomosis and protective loop ileostomy in 5 patients (Figure 1F).

The negative margins were confirmed in all patients by intraoperative frozen biopsy. The mesorectal integrity<sup>[10]</sup> and circumferential situation<sup>[11]</sup> of the resected specimens were evaluated by a senior surgeon and qualified pathologist macroscopically and microscopically, in order to ensure that the tumor had been resected completely. The status of the mesorectal specimens was graded into three categories. We differentiated them as complete (intact mesorectum > 5 cm, while defect of mesentery < 5 mm); nearly complete (intact mesorectum > 5 cm, while defect of mesentery > 5 mm); and incomplete (incomplete mesorectum). We defined a positive margin if the circumferential margin from the tumor was < 2 mm under microscopy.

## RESULTS

We successfully performed the procedure in all 21 patients, and none of them was converted to laparotomy (Table 2). There were 16 and five patients in the low or ultralow anastomosis groups, respectively. According to macroscopic specimen assessment of TME, the status was complete for 18 patients, while nearly complete for three patients. In addition, the circumferential resection margin was negative in all patients (Table 3).

The mean maximum tumor diameter was  $4.6 \pm 1.7$  cm. According to the principle of rectal cancer surgery and no-touch isolation technique, we performed D2 lymph node dissection in 13 patients and D3 dissection in eight patients. The postoperative course was unremarkable in most patients, with prompt return of bowel activity and short postoperative stay, except for one patient who was complicated by anastomotic leakage (Table 4). Anastomotic leakage was confirmed by stools leaking from a drain. He was treated with nil by mouth, decompression of the rectum by transanal drainage, and antibiotic infusion until the leak healed spontaneously. He was discharged on the postoperative day 15.

According to the guidelines of NCCN, all patients with T3/T4 or postoperative node-positive tumors underwent postoperative chemotherapy for 6-9 cycles. The follow-up period ranged from 11 to 23 mo. Follow-up examinations were scheduled at 2 wk and 1, 2, 3, 6, 9 and 12 mo, and every 6 mo thereafter until 5 years. All patients underwent CT of the chest, abdomen, and pelvis every 6 mo and colonoscopy at 12 mo, but remained disease free. All five patients who had handsewn coloanal anastomosis with a diverting ileostomy had their ileostomies reversed at 3-6 mo after the operation, based on the diagnosis of free from tumor recurrence and anastomotic stenosis, which were confirmed by endoscopic colonoscopy, barium enema, MRI, and CT. Anal continence was measured with the validated Wexner fecal incontinence

**Table 2** Intraoperative information

Intraoperative information	Value
Mean operation time (min)	132 ± 85
Mean intraoperative blood loss (mL)	84 ± 15
Mean tumor diameter (cm)	4.6 ± 1.7
Distance of lesion from anal verge (cm)	8.3 ± 3.5
Protective ileostomy	5 (23.8)
Defecation time after operation (d)	2.5 ± 1.4

**Table 3** Patient pathological parameters

Items	Number of cases
Pathological diagnoses	
Well differentiated	10
Poorly differentiated	7
Myxoadenocarcinoma	4
Specimen macro-assessment of TME	21 (radical resection)
Circumferential resection margin	21 (Negative)

T1-4N0M0	7
T1-2N1M0	5
T3-4N1M0	6
T3-4N2M0	3
Lymph nodes harvest (mean)	17.8 ± 4.6
Metastatic lymph nodes (mean)	3.4 ± 1.8

TME: Total mesorectal excision; TNM: Tumor node metastasis

scoring system (0 = perfect continence, 20 = complete incontinence). The mean Wexner score was 3.7 (range 0-5) at > 11 mo after the operation.

## DISCUSSION

In the past 10 years, L-AR has been performed at our hospital according to the principle of TME for patients with low rectal cancer. Traditional large abdominal incision has been replaced gradually by small abdominal incision. L-AR benefits patients not only in terms of cosmetics and postoperative rehabilitation, but also in reducing surgical interference, maintaining immune function and homeostasis, rapid recovery, and relieving psychological stress after surgery. However, L-AR is still considered imperfect due to the requirement for abdominal incision of 5-7 cm at minimum to remove the specimen completely. There are still some complications, such as abdominal incision infection, postoperative somatic pain, and incisional hernia<sup>[12]</sup>. According to bulk analysis of cases, wound infections occurred in 13.5% of patients after L-AR (2.7% trocar and 10.8% extraction site), and incisional hernias developed in 24.3%, and extraction sites accounted for 85.7% of all wound complications<sup>[13]</sup>.

In order to reduce the impact of L-AR incision and eliminate abdominal incision completely, natural orifice transluminal endoscopic surgery (NOTES) has increased in recent years, which can avoid incisional infection and hernia, and achieve better cosmetic results<sup>[14,15]</sup>.

Recently, transvaginal (posterior fornix incision) has been the main approach of NOTES in most colectomy

**Table 4 Postoperative complications *n* (%)**

Length of hospitalization (d)	6.1 ± 2.7
Postoperative complications

The data of fecal incontinence, impotence, and anal stenosis was obtained at 1-year follow-up. UTI: Urinary tract infection.

procedures<sup>[16-18]</sup>. However, there are still some negative factors in low/ultralow rectal cancer which hinder the application of transvaginal approach NOTES. First, there are technical shortcomings, such as lack of experience and technical complexity, additional adjacent organ injury, extended operation time, and specialized equipment requirement, which account for the increased cost of the operation. Second, it is sometimes difficult to remove a larger tumor specimen through the posterior vaginal fornix incision. Third, there are many technical difficulties in achieving sphincter preservation for low/ultralow rectal cancer by the transvaginal approach. Finally, the transvaginal approach is obviously limited to female patients, which is a major hindrance for widespread use of the technique in clinical practice.

As a result, more surgeons have been trying to find new approaches for NOTES in low rectal cancer. With regard to the applicability of NOTES in colorectal surgery, the transanal access route of NOTES is intuitively the optimal one. First, rather than creating an opening through an otherwise healthy organ to perform the rectal anterior resection, enterotomy is carried out on the diseased organ itself. Second, the enterotomy is ultimately closed by incorporating it into a standard colorectal anastomosis, which is the requirement of surgery regardless of whether it is achieved *via* NOTES or standard surgery. Finally, transanal NOTES could have substantial benefits over standard transabdominal approaches<sup>[19]</sup>.

At present, transanal access NOTES in radical colorectal cancer surgery has been completed successfully in animal models, but few surgeons have put it into clinical practice due to potential technical difficulties, such as intra-abdominal intestinal fecal contamination, or increased possibility of infection through the colon lumen. All of these factors may affect the safety of the procedure. For example, clinical reports have confirmed that common complications included wound infection (56.7%), septicemia (31.7%), and enterocutaneous fistula (16.7%) in patients who sustained penetrating colon injuries<sup>[20]</sup>. However, with the improvement in anatomical techniques and equipment, transanal NOTES has been performed for resection of the rectum in pig models *in vivo* or fresh cadavers<sup>[21]</sup>, as well as laparoscopy-assisted

transanal NOTES for left-sided colorectal resection<sup>[22]</sup> and sigmoidectomy<sup>[23]</sup>. Unfortunately, these techniques require expensive equipment, which limits the clinical application of NOTES, especially in developing countries.

As a development of NOTES, transanal NOSE is an emerging technique that has been recently applied to the field of rectal excision. Darzi *et al*<sup>[24]</sup> have described a technique of total laparoscopic left-sided colonic resection and transanal specimen delivery. Franklin *et al*<sup>[25]</sup> have reported that laparoscopic colectomy in patients with stage III colorectal cancer is oncologically adequate. Fukunaga *et al*<sup>[26]</sup> have performed radical rectal cancer surgery with removal of the specimens through the anus, thus avoiding abdominal incision. Transanal specimen extraction can also resolve the problems found in obese patients with short or hypertrophic mesentery, or deep abdominal wall, which have been challenges for transabdominal specimen removal<sup>[27]</sup>. It has been confirmed that transanal NOSE is technically feasible. It may be a bridge between NOTES and the conventional laparoscopic approach for radical colorectal cancer surgery.

Our current experience showed that transanal NOSE, combined with TME and L-AR techniques for rectal cancer, could be adapted for radical tumor resection and minimally invasive surgery. Its technical feasibility and oncological principles have been demonstrated by many surgeons<sup>[28]</sup>. The rectal stump is a “necessary” trauma. We can accurately determine the distal cutting edge of the rectum through the full use the rectal stump. Combination of traditional laparoscopic techniques and removal of specimens through a natural orifice can minimize surgical injury<sup>[29]</sup>. Traditional laparoscopic surgical techniques provide a large operating space, mature technology and broad vision, which allows one to dissect accurately the mesorectal, pelvic visceral and parietal fascia. We can ensure that the inferior mesenteric artery is ligated at the root, in order to block the tumor blood supply and venous drainage, and minimize the chance of metastasis. Care is required to avoid any injury to the mesenteric arcades so as to guarantee an adequate blood supply to the descending colon. The operation was carried out following the “holy plane”, which is placed between the pelvic visceral fascia and rectal fascia propria, and then to the anterior Denonvillier’s fascia. The mesorectum should be completely mobilized while the pelvic autonomic nerve is preserved.

After the anus was fully dilated, we used a home-made anal dilator and fine silk traction sutures to evert the anus and expose the rectum, then placed a protective bag into the anus. In the premise of protecting blood supply of the residual colon, the pre-cut specimen was fully freed in the peritoneal cavity, then gently pulled out through the anus.

We paid attention to protecting the functions of anal sphincter while performing a standard radical resection of rectal cancer. Even if the specimen is a relatively large one, for example, the hypertrophic mesorectum, it can be removed smoothly from the fully dilated anus routinely

without tearing the rectum or damaging the anal sphincter. The anus and rectum can be returned to their normal diameter after the operation (Figure 1H).

When the stump of the proximal rectum was exteriorized through the dilated anus and opened stump of the distal rectum, we transected the proximal colorectum under direct vision<sup>[30]</sup>. After intracorporeal purse-string sutures with 2/0 prolene, we used an anastomat to create an end-to-end coloanal anastomosis in the usual manner. Although some studies have found that the J-pouch is superior to end-to-end reconstruction for low rectal cancer<sup>[9,31]</sup>, the latter resulted in acceptable anal function at 6 mo follow-up in our study, due to the careful protection of the anal sphincter, with no tension and a good blood supply in the anastomotic stoma.

In order to prevent peritoneal seeding and trocar-site metastasis, we implemented the general rules for laparoscopic surgery, such as the no-touch technique, appropriate resection margins, early bagging of the resected specimen, and wound protection into our laparoscopic colorectal procedures. Compared to the traditional laparoscopic techniques, our technique had good cosmetic results and reduced the chance of metastasis in the abdominal wall, without increasing complications<sup>[32]</sup>.

Laurent *et al.*<sup>[33]</sup> reported that the conversion rate of laparoscopic radical resection for low rectal cancer was 15.5%. The conversion rate was higher due to the difficulties experienced in fixing colorectal, separating in the pelvic, unexpected intraoperative bleeding, and failure of the closure device, or anastomosis. However, such difficulties did not jeopardize our treatment due to the elasticity and compliance of the tissue while we used mature laparoscopic techniques to remove the specimens through the anus. With full use of the natural orifice of the anus and rectum, total laparoscopic rectal resection is feasible and safe. Such a technique decreases the abdominal surgery complications, and maintains the operation time and the cost of surgery to those of standard L-AR. It also provides significant improvement of the traditional laparoscopic techniques.

However, the present surgical indications are limited to patients with early cancer. Mesorectal invasion and tumor diameter > 6 cm are not included here due to the lack of a large randomized controlled study for this procedure. The operation field is narrowed and the vision is not clear through the anal approach in some conditions, such as a narrow pelvis or large tumor. Although there are reports of microsurgical resection through the anus<sup>[34]</sup>, there is no specialized surgical instrument to complete the procedures for anus dilation, specimen removal, and distal suturing. There is urgency to develop better-adapted tools such as a modified flexible transanal endoscopic platform, longer and more flexible dissecting instruments, staplers and hemostatic devices to permit safe completion of these procedures without any transabdominal assistance. This technique requires further regulation and improvement.

In our limited experience, transanal specimen extrac-

tion in total laparoscopic low/ultralow anterior resection is feasible, safe, and oncologically sound for selected cases. The majority of patients have an acceptable functional outcome. Further studies with long-term outcomes are needed to explore the potential advantages of this technique.

## COMMENTS

### Background

The incidence of rectal cancer is higher in Asia compared with western countries. Technically, the resection of low rectal cancer may be one of the most difficult among all colorectal surgery procedures.

### Research frontiers

At present, traditional colorectal surgery has increasingly given way to laparoscopic anterior resection with total mesorectal excision (L-AR/TME). Evidence-based medicine has established that L-AR/TME is a feasible surgical approach for managing rectal cancer. There have been similar results recently for short-term therapeutic effects, local recurrence rate, and postoperative survival rate between laparoscopic surgery and traditional open surgery for radical colon cancer.

### Innovations and breakthroughs

This study showed that transanal specimen extraction by total laparoscopic low/ultralow anterior resection is feasible, safe, and oncologically sound for selected cases. The majority of patients had an acceptable functional outcome.

### Applications

There is an urgency to develop better adapted tools such as a modified flexible transanal endoscopic platform, longer and more flexible dissecting instruments, and staplers and hemostatic devices to permit safe completion of these procedures without any transabdominal assistance. This technique needs further standardization and improvement.

### Peer review

This study was interesting and highly innovative in terms of colorectal surgical technique, especially for a surgical rather than gastroenterological audience.

### Abstract

**AIM:** To investigate the function of microRNA-143 (miR-143) in gastric cancer and explore the target genes of miR-143.

**METHODS:** A quantitative real-time reverse transcription-polymerase chain reaction (RT-PCR) analysis was performed to evaluate miR-143 expression in gastric cancer cell lines. After transfecting gastric cancer cells with miR-143-5p and miR-143-3p precursors, Alamar blue and apoptosis assays were used to measure the respective proliferation and apoptosis rates. Cyclooxygenase-2 (COX-2) expression was determined by real-time RT-PCR and Western blot assays after miR-143 transfection. Reporter plasmids were constructed, and a luciferase reporter assay was used to identify the miR-143 binding site on COX-2.

**RESULTS:** Both miR-143-5p and miR-143-3p were sig-

nificantly downregulated in multiple gastric cancer cell lines. Forced miR-143-5p and miR-143-3p expression in gastric cancer cells produced a profound cytotoxic effect. MiR-145-5p transfection into gastric cancer cells resulted in a greater growth inhibitory effect ( $61.23\% \pm 3.16\%$  vs  $46.58\% \pm 4.28\%$ ,  $P < 0.05$  in the MKN-1 cell line) and a higher apoptosis rate ( $28.74\% \pm 1.93\%$  vs  $22.13\% \pm 3.31\%$ ,  $P < 0.05$  in the MKN-1 cell line) than miR-143-3p transfection. Further analysis indicated that COX-2 expression was potently suppressed by miR-143-5p but not by miR-143-3p. The activity of a luciferase reporter construct that contained the 3'-untranslated region (UTR) of COX-2 was downregulated by miR-143-5p ( $43.6\% \pm 4.86\%$ ,  $P < 0.01$ ) but not by miR-143-3p. A mutation in the miR-145-5p binding site completely ablated the regulatory effect on luciferase activity, which suggests that there is a direct miR-145-5p binding site in the 3'-UTR of COX-2.

**CONCLUSION:** Both miR-143-5p and miR-143-3p function as anti-oncomirs in gastric cancer. However, miR-143-5p alone directly targets COX-2, and it exhibits a stronger tumor suppressive effect than miR-143-3p.

**Key words:** Gastric cancer; MicroRNA-143; Anti-oncomir; Cyclooxygenase-2; Apoptosis

**Core tip:** MicroRNA-143 (miR-143) has been reported to be a tumor suppressor. However, the functions of miR-143-5p and miR-143-3p have never been compared. In this study, we found that both miR-143-5p and miR-143-3p function as tumor suppressors in gastric cancer; however, miR-143-5p alone directly targets cyclooxygenase-2, and it exhibits a stronger tumor suppressive effect than miR-143-3p.

Zhang P. MicroRNA-143 suppresses gastric cancer cell growth and induces apoptosis by targeting COX-2. *World J Gastroenterol* 2013; 19(43): 7758-7765 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7758.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7758>

## INTRODUCTION

MicroRNAs (miRNAs) are short (19-24 nt) non-coding RNAs that control target mRNA translation and stability by binding to regulatory sites that are mostly located in the 3'-untranslated region (UTR) of transcripts<sup>[1]</sup>. Numerous miRNAs have been shown to display tumor suppressor activity, while others reportedly act as oncogenes<sup>[2]</sup>. The expression levels of these RNAs are altered in many human tumors, resulting in distinct miRNA networks in various tumor types<sup>[3]</sup>. Some targets of these miRNAs have been identified, but many of the critical cancer proteins and pathways that they regulate remain unknown.

MiR-143 is considered a pivotal regulator of gene expression because it directly targets multiple mRNAs that code proteins involved in cell proliferation, differentiation, survival and apoptosis, including cyclooxygenase-2 (COX-2)<sup>[4]</sup>, V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS)<sup>[5,6]</sup>, B-cell lymphoma 2 (Bcl-2)<sup>[7,8]</sup>, plasminogen activator inhibitor-1 (PAI-1)<sup>[9]</sup>, myosin VI (MYO6)<sup>[10]</sup>, matrix metalloproteinase 13 (MMP-13)<sup>[11]</sup>, DNA (cytosine-5)-methyltransferase 3A (DNMT3A)<sup>[12]</sup> and E twenty-six-like transcription factor 1 (ELK1)<sup>[13]</sup>. The relevance of miR-143 as a putative cancer biomarker is increasing, because this miRNA is downregulated in various human tumors and can suppress tumor growth in cancers of the urogenital system<sup>[7,9,10]</sup>, digestive system<sup>[14-16]</sup>, respiratory system<sup>[17,18]</sup> and nervous system<sup>[19]</sup>, as well as some sarcomas<sup>[11,20]</sup> and B-cell malignancies<sup>[21]</sup>. MiR-143 expression has also been reported to be downregulated in human gastric cancer tissues and cell lines<sup>[22]</sup>. The expression of miR-143 is significantly decreased in stage IV gastric cancer, compared to stages I and II cancers<sup>[23]</sup>. However, the role of miR-143 in gastric cancer and the underlying mechanisms require further investigation.

Among the target genes regulated by miR-143, COX-2 is particularly important. COX, also known as prostaglandin (PG) H2 synthase, is the rate-limiting enzyme in the conversion of arachidonic acid into PGs. COX-2 expression in cells and animal models is associated with tumor cell growth and metastasis, enhanced cellular adhesion and apoptosis inhibition<sup>[24]</sup>. Pharmacologic inhibitors of COX-2 can decrease the growth of certain human tumors<sup>[25,26]</sup> and prevent tumorigenesis in animal models<sup>[27]</sup>. A pathological study showed increased COX-2 expression levels in gastric cancer<sup>[28,29]</sup>. Reduced COX-2 expression in gastric cancer cells led to markedly decreased proliferation and metastatic capability, demonstrating that COX-2 activity is necessary for gastric cancer cell proliferation and metastasis<sup>[30]</sup>. All of the above evidence indicates that COX-2 plays an important role

in gastric cancer. In this study, we investigated the roles of miR-143 and COX-2 in gastric cancer and found that both miR-143-5p and miR-143-3p function as tumor suppressors in gastric cancer; however, miR-143-5p alone directly targeted COX-2 and exhibited a stronger tumor suppressive effect than miR-143-3p.

## MATERIALS AND METHODS

### Cell culture

The human gastric cancer cell lines MKN-1, MKN-7, AGS, SGC-7901 and BGC-823 and the normal gastric epithelium cell line GES-1 were grown in RPMI 1640 medium supplemented with 10% FBS (Hyclone). The cell cultures were incubated in room air at 37 °C in a humidified atmosphere of 5% CO<sub>2</sub>.

### Reverse transcription and real-time polymerase chain reaction to quantify mature miR-143

Total RNA was extracted with TRIzol (Invitrogen). For mature miRNA expression analysis, cDNA was synthesized with the Taqman MiRNA Reverse Transcription kit (Applied Biosystems) and 100 ng of total RNA (100 ng/μL), along with 1 μL of miR-143-5p (Applied Biosystems) or miR-143-3p (Applied Biosystems) specific primers that were supplied with the miRNA Taqman MicroRNA Assay, according to the manufacturer's instructions. Quantitative real-time polymerase chain reaction (PCR) analyses were performed in triplicate on a 7900HT Real-Time PCR System (Applied Biosystems), and the data were normalized to RNU6B (Applied Biosystems) for each reaction. The thermal cycling profile used was as follows: 95 °C for 10 min, followed by 40 cycles of 95 °C for 15 s and 60 °C for 60 s. Quantification was performed according to the standard  $\Delta\Delta CT$  method.

### Transfection of the miR-143 precursor

Cells were seeded 24 h prior to transfection into 24-well or 6-well plates or 6 cm dishes. Hsa-miR-143-5p (Applied Biosystems), hsa-miR-143-3p (Applied Biosystems) or a miRNA mimic control (Applied Biosystems) was transfected with Lipofectamine 2000 (Invitrogen) at a final concentration of 50 nmol/L. The sequences of the mature miR-143-5p and miR-143-3p used in this study were GGUGCAGUGCUGCAUCUCUGGU and UGAGAUAGAAGCACUGUAGCUC, respectively. The cells were harvested at 24 h (for RNA extraction), 48 h (for protein extraction) or 72 h (for apoptosis assays).

### Cell viability assays

An Alamar blue assay was used to measure cell proliferation. This assay is based on the quantitative metabolic conversion of blue, non-fluorescent resazurin to pink, fluorescent resorufin by living cells. After 72 h of incubation, an Alamar blue (Invitrogen) stock solution was aseptically added to the wells to equal to 10% of the total incubation volume. The resazurin reduction in the cultures was determined after a 2-6 h incubation with

Alamar blue by measuring the absorbances at 530-nm and 590-nm wavelengths on a Synergy HT Multi-Mode Microplate Reader (Bio-tek Instruments).

### Apoptosis assay

Following maintenance in culture, the cells were harvested and stained with phycoerythrin-conjugated Annexin V according to the manufacturer's instructions (BD Biosciences). The cells were then analyzed on a FACSCalibur flow cytometer (BD Biosciences). The cells were considered viable if double negative, early apoptotic if positive for Annexin V alone and necrotic or late apoptotic if double positive.

### MiRNA target prediction

RNA22 (<http://cbcsrv.watson.ibm.com/rna22.html>) was used to identify miRNA-target sites in the 3'-UTR of COX-2 mRNA and the corresponding RNA/RNA complexes and folding energies.

### Western blot

Cells were lysed with Radio Immunoprecipitation Assay buffer (Sigma-Aldrich), and the total protein concentration was determined with a Bio-Rad Protein Assay (Bio-Rad). Proteins (40 µg) were separated by 10% SDS/PAGE and electrotransferred onto nitrocellulose membranes. The membranes were then incubated overnight with a COX-2 (Cell Signaling) or poly (ADP-ribose) polymerase (PARP) primary antibody (Cell Signaling) at 4 °C, and subsequently incubated with an HRP-conjugated anti-rabbit secondary antibody (Bio-Rad) for 1 h at room temperature. Protein bands were detected with the Western Blotting Luminol Reagent (Santa Cruz Biotechnology).

### Reverse transcription and real-time PCR to quantify COX-2 mRNA

Total RNA was extracted with TRIzol (Invitrogen). DNase I (Amplification Grade, Invitrogen) and the SuperScript First-Strand Synthesis System for reverse transcription-PCR (RT-PCR) (Invitrogen) were used for cDNA preparation. Primers and probes were ordered from IDT Inc. The following primers and probes were used: COX-2: Primer-F: 5'-CAAATCCTTGCTGTTCCACCCAT-3', Primer-R: 5'-GTGCACTGTGTTTGGAGTGGGTTT-3', Probe: 5'-AAGTGC GATTGTACCCGGACAGGATT-3', β-GUS: Primer-F: 5'-CTCATTTTGAATTTTGCCGATT-3', Primer-R: 5'-CCGAGTGAAGATCCCCCTTTT-TA-3', Probe: 5'-TGAACAGTCACCGACGAGAGT-GCTGG-3'. The reactions were incubated in a 96-well plate at 95 °C for 12 min, followed by 40 cycles of 95 °C for 30 s, 60 °C for 1 min, and 72 °C for 45 s. All reactions were performed in triplicate.

### Luciferase reporter assay

The human COX-2 3'-UTR was amplified and cloned into the XbaI site of the pGL3-control vector (Promega, United States), downstream of the luciferase gene, to

generate the plasmid pGL3-WT-COX2-3'-UTR. pGL3-MUT-5p-COX2-3'-UTR was generated from pGL3-WT-COX2-3'-UTR by deleting the "ACTGTAC" binding site for miR-143-5p. For the luciferase reporter assay, cells were cotransfected with the luciferase reporter vectors and miR-143-5p, miR-143-3p or a miRNA mimic control, using Lipofectamine 2000. A β-actin promoter Renilla luciferase reporter was used for normalization. After 48 h, luciferase activity was analyzed by the Dual-Glo Luciferase Assay System (Promega), according to the manufacturer's protocols.

### Statistical analysis

Experimental results were assessed for significance with one-tailed unpaired *t* tests. A *P* value less than 0.05 was considered significant.

## RESULTS

### MiR-143-5p and miR-143-3p expression is reduced in gastric cancer cells

Using real-time PCR to quantify mature miR-143-5p and miR-143-3p in five human gastric cancer cell lines and a normal gastric epithelium cell line, we found that both the miR-143-5p and miR-143-3p expression levels were markedly reduced in gastric cancer cells (*P* < 0.01; Figure 1A and B). Western blot analysis indicated that COX-2 protein expression was increased in the five human gastric cancer cell lines (Figure 1C); this expression was inversely correlated with the miR-143 levels.

### MiR-143 decreases viability and increases apoptosis in gastric cancer cells

The reduced miR-143 expression in gastric cancer suggests that this miRNA could have anti-proliferative effects. To test this hypothesis, we evaluated the effects of transient transfection with miR-143-5p and miR-143-3p in MKN-1 and BGC-823 gastric cancer cell lines. The Alamar Blue assay, a redox assay similar to the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, showed significant decreases in gastric cancer cell viability following the transfection of either miR-143-5p or miR-143-3p. The decrease in viability after miR-143-5p transfection was greater than that after miR-143-3p transfection (*P* < 0.05; Figure 2A). Additionally, cell counts were significantly decreased after transfection with either miR-143-5p or miR-143-3p (*P* < 0.05; Figure 2B). Consistent with the results of the Alamar Blue assay, miR-143-5p showed a stronger inhibitory effect than miR-143-3p.

An apoptosis assay after transfection with miR-143-5p or miR-143-3p indicated a marked increase in cell apoptosis. Cells transfected with miR-143-5p had a significantly higher apoptosis rate than those transfected with miR-143-3p (*P* < 0.05; Figure 2C and D). Furthermore, both miR-143-5p and miR-143-3p transfection were accompanied by increased levels of cleaved PARP, a product of apoptosis (Figure 2E).

**Figure 1** MicroRNA-143 expression is downregulated in gastric cancer cell lines. **A:** Quantitative real-time polymerase chain reaction analysis was performed in five gastric cell lines and a normal gastric epithelium cell line (GES-1). Mature microRNA-143-5p (miR-143-5p) expression levels were significantly downregulated in gastric cancer cells, compared to normal gastric epithelium cells ( $^bP < 0.01$ ). The mean value from the GES-1 cell line was normalized to 1; **B:** Mature miR-143-3p expression levels were significantly downregulated in gastric cancer cells, compared to normal gastric epithelium cells ( $^bP < 0.01$ ); **C:** Western blot analysis showed that cyclooxygenase-2 protein expression in the five human gastric cancer cell lines inversely correlated with the miR-143 levels. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; COX-2: Cyclooxygenase-2.

### MiR-143 directly inhibits COX-2 expression via its 3'-UTR

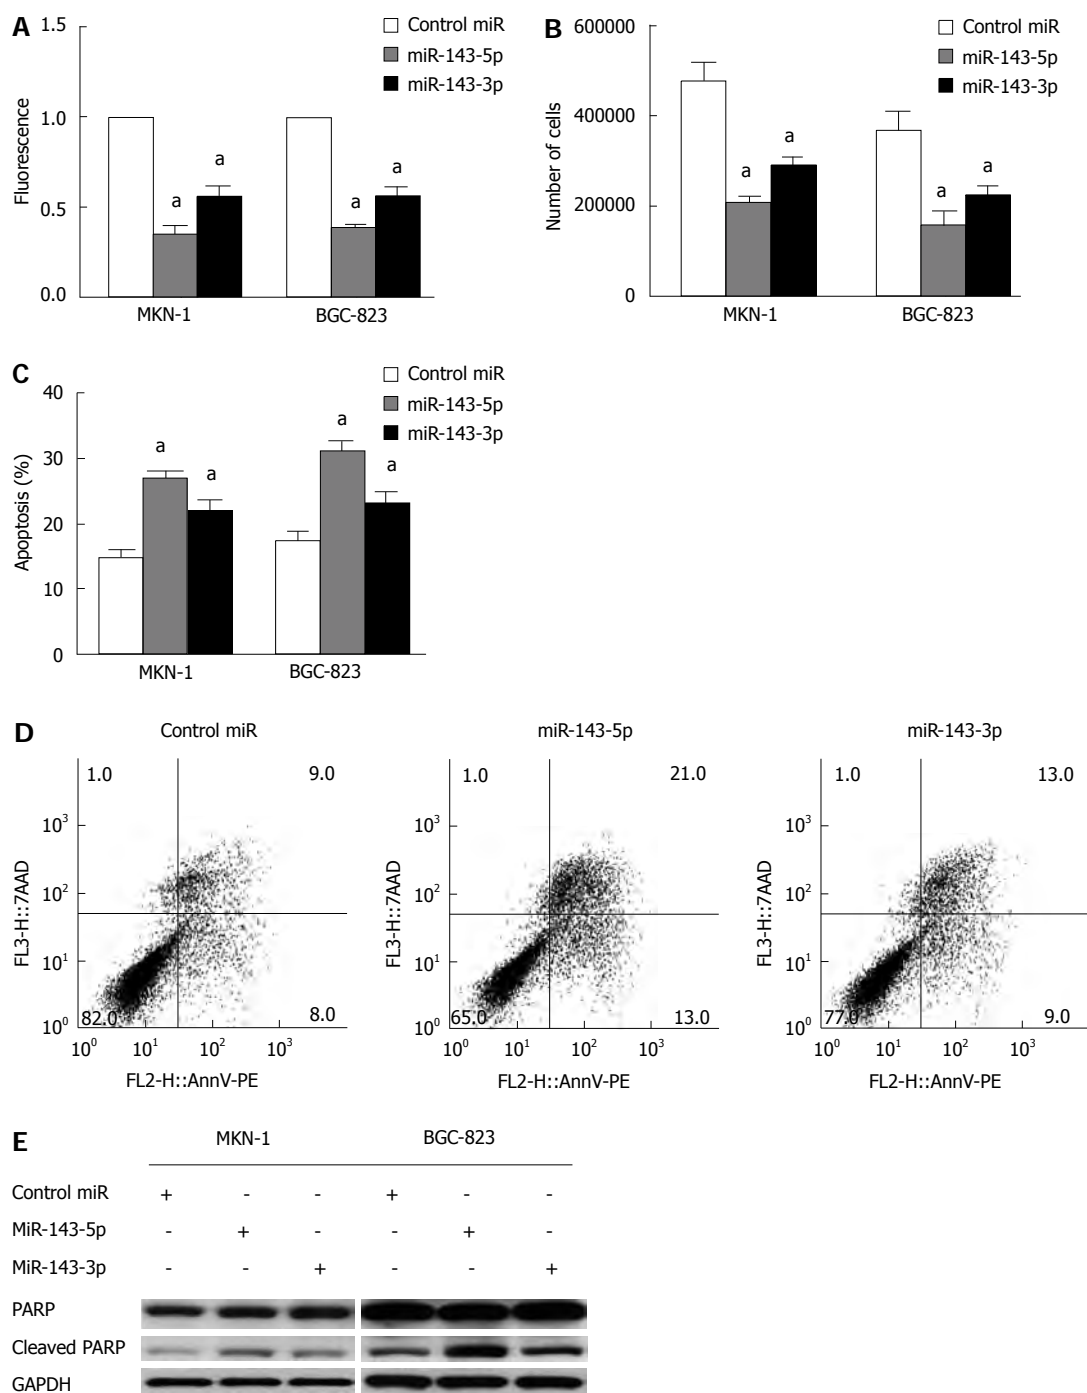

A bioinformatics analysis, conducted with RNA22, indicated that the 3'-UTR of the human COX-2 mRNA (NM\_000963) harbors a putative miR-143-5p binding site (nucleotides 3515-3536) (Figure 3A) but has no miR-143-3p binding site. To assess the inhibitory effects of miR-143 on COX-2, MKN-1 and BGC-823 cells were transfected with miR-143-5p, miR-143-3p or a control. Western blot analysis revealed a profound decrease in the COX-2 protein level after transfection with miR-143-5p but not miR-143-3p (Figure 3B). Consistent with transcriptional inhibition by miRNA, we noted decreased COX-2 mRNA levels after miR-143-5p transfection ( $P < 0.05$ ; Figure 3C).

To confirm the direct action of miR-143 on the COX-2 3'-UTR, transient transfection experiments were performed with the 3'-UTR of COX-2, containing mutated or non-mutated putative miR-143-5p matching sites, downstream of the luciferase open reading frame. Transfection with miR-143-5p inhibited the normalized activity of the COX-2 3'-UTR reporter by 57% ( $P < 0.01$ ), whereas miR-143-3p had no effect on this reporter activity (Figure 3D). In contrast, co-transfection of the mutant reporter plasmid with either miR-143-5p or miR-143-3p had no effect on luciferase activity in the transfected cells (Figure 3E). These results demonstrated that only miR-143-5p bound to the seed sequence present in the 3'-UTR of human COX-2 mRNA to inhibit COX-2 expression.

### DISCUSSION

In the present study, the expression levels of both miR-143-5p and miR-143-3p were found to be downregulated in gastric cancer. This finding is consistent with reports from other research groups<sup>[22,23]</sup>. In a recent report, the authors used real-time RT-PCR and chip assays to analyze 70 paired samples of gastric cancers and benign tissues<sup>[23]</sup>. The authors found that miR-143 was among the most strongly downregulated miRNAs in gastric cancers, compared to benign tissues. The miR-143 expression level was associated with gastric cancer progression and was more significantly reduced in stage IV cancers, compared with stage I and II cancers. Consistent with our observations, a study by Takagi *et al.*<sup>[22]</sup> also indicated that miR-143 was downregulated in gastric cancer cell lines and that transfection with miR-143-3p inhibited the gastric cancer cell viability by targeting ERK5 and AKT. However, the function of miR-143-5p has never been investigated in gastric cancer.

In the miRNA biogenesis pathway, long primary transcripts (pre-miRNAs) that have been transcribed from the genome are processed by the cellular RNase enzyme III Drosha into 60-110-nt structures called precursor miRNAs (pre-miRNA)<sup>[30]</sup>. Pre-miRNAs are cleaved by the RNase III enzyme Dicer-1 to produce short, imperfect, double-stranded miRNA duplexes that are subsequently unwound by helicases to create mature miRNAs. In some cases, two mature miRNAs can be excised from

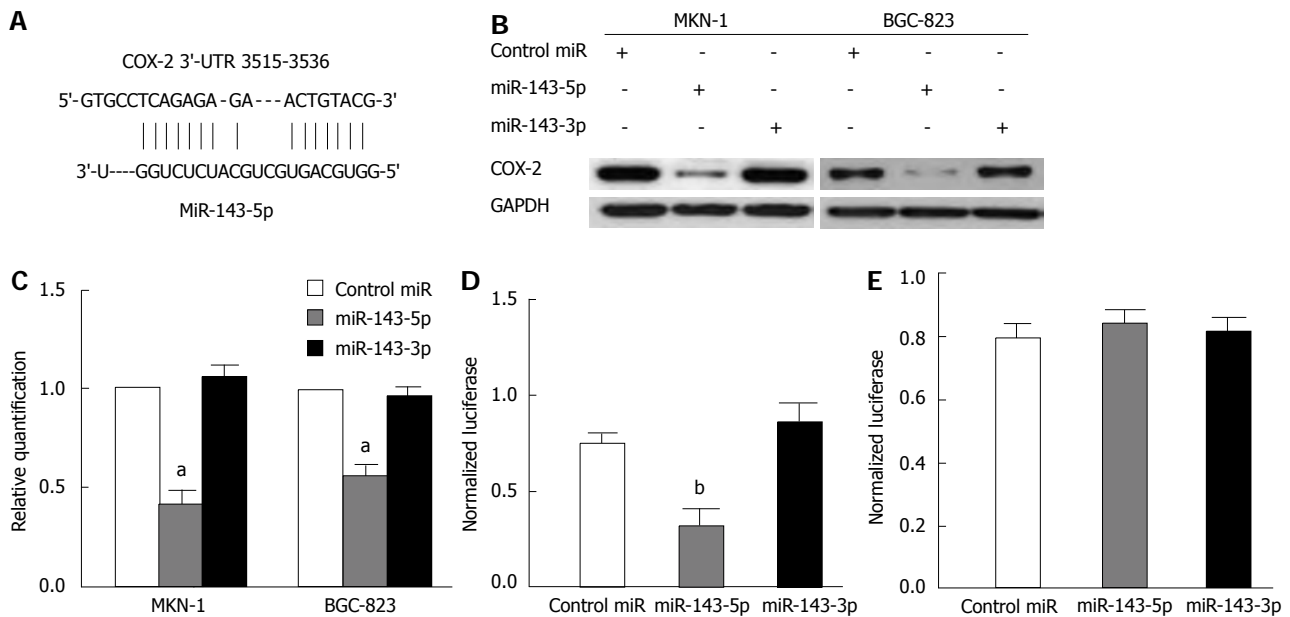

**Figure 2** Transfection with microRNA-143 inhibits gastric cancer cell viability and induces apoptosis. **A:** An Alamar Blue assay was performed 3 d after transfection with microRNA-143-5p (miR-143-5p) or miR-143-3p to measure the viability of MKN-1 and BGC-823 gastric cancer cells. The results showed significant decreases in cell viability following transfection with either miR-143-5p or miR-143-3p ( $P < 0.05$ ); this decrease was greater after miR-143-5p transfection than after miR-143-3p ( $P < 0.05$ ); **B:** Cell counts performed 3 d after transfection into MKN-1 and BGC-823 gastric cancer cells showed decreased cell numbers after transfection with either miR-143-5p or miR-143-3p ( $P < 0.05$ ). Consistent with the results of the Alamar Blue assay, the decrease in cell number after miR-143-5p transfection was greater than that after miR-143-3p transfection ( $P < 0.05$ ); **C and D:** An Annexin V/PE cell apoptosis assay revealed increased apoptosis in gastric cancer cells after transfection with either miR-143-5p or miR-143-3p ( $P < 0.05$ ). Cells transfected with miR-143-5p had a significantly higher apoptosis rate than those transfected with miR-143-3p ( $P < 0.05$ ); **E:** Western blots of PARP protein in MKN-1 and BGC-823 cell lines at 3 d after transfection with miR-143-5p or miR-143-3p. GAPDH was used as a control. The results showed increased expression of cleaved PARP after miR-143-5p and miR-143-3p transfection. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase. PARP: Poly (ADP-ribose) polymerase.

the same stem-loop pre-miRNA<sup>[31]</sup>. These “5p” and “3p” miRNAs, although generated from a single primary transcript, have different sequences and therefore target different mRNAs. In humans, two different mature miRNA

sequences are excised from opposite arms of the stem-loop pre-miR-143 to generate two different miRNAs, hsa-miR-143-5p and has-miR-143-3p. Despite nearly a decade of studies on the roles of miRNA in cancers, the

**Figure 3** MicroRNA-143-5p directly inhibits cyclooxygenase-2 expression. **A:** Sites of miR-143-5p seed matches in the cyclooxygenase-2 (COX-2) 3'-untranslated region (3'-UTR) (nucleotides 3515-3536); **B:** Western blot of COX-2 protein in the MKN-1 and BGC-823 gastric cancer cell lines at 3 d after transfection with miR-143-5p, miR-143-3p or microRNA (miRNA) mimic control. GAPDH was used as a control. The results showed a profound decrease in COX-2 protein expression after transfection with miR-143-5p but not miR-143-3p; **C:** Real-time reverse transcription-polymerase chain reaction to determine COX-2 mRNA expression was performed 2 d after transfection with miR-143-5p, miR-143-3p or a control in MKN-1 and BGC-823. The mean expression in the control group was normalized to 1. Consistent with transcriptional inhibition by miRNA, the COX-2 mRNA level was reduced after miR-143-5p transfection ( $^*P < 0.05$ ); **D:** Normalized activity of the wild-type COX-2 3'-UTR luciferase reporter in BGC-823 cells, 2 d after transfection with miR-143-5p, miR-143-3p or a control. The luciferase activity was significantly decreased by miR-143-5p ( $^*P < 0.01$ ) but not miR-143-3p; **E:** Normalized activity of the mutant-type COX-2 3'-UTR luciferase reporter in BGC-823 cells, 2 d after transfection with miR-143-5p, miR-143-3p or a control. The results showed that cotransfection of the mutant reporter plasmid with miR-143-5p or miR-143-3p had no effect on luciferase activity in the transfected cells. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

comparative roles of strand-specific mature miRNAs that originate from the same stem-loop precursor (5p and 3p) have yet to be fully studied. Previously, a number of studies demonstrated that ectopic miR-143 expression inhibited cancer cells in various types of human tumors<sup>[4,6-8,16,20,22]</sup>. However, the role of miR-143 in gastric cancer has not been fully investigated, and differences between miR-143-5p and miR-143-3p have never been reported.

Our functional analysis of miR-143 expression in gastric cancer cell lines indicated tumor suppressor functions for both miR-143-5p and miR-143-3p. Our data revealed that the restoration of both miR-143-5p and miR-143-3p expression suppressed cell proliferation and promoted apoptosis in gastric cancer cells. The tumor-suppressive effect of miR-143-5p was stronger than that of miR-143-3p.

Further analysis demonstrated that only miR-143-5p directly binds to COX-2 mRNA. The luciferase reporter assay revealed that COX-2 contains a binding site for miR-143-5p but no binding site for miR-143-3p. A recent report also demonstrated different functions of miR-28-5p and miR-28-3p; specifically, miR-28-5p altered the expression of CCND1 and HOXB3, whereas miR-28-3p bound to NM23-H1 in colorectal cancer<sup>[32]</sup>. Our study provides further evidence that strand-specific "5p" and "3p" miRNAs could have different targets. This could explain why miR-143-5p is a stronger tumor suppressor in gastric cancer and suggests the existence of other

potential targets of miR-143-3p. For example, other studies have revealed multiple targets for miR-143, such as KRAS<sup>[5,6]</sup>, Bcl-2<sup>[7,8]</sup>, PAI-1<sup>[9]</sup>, MMP-13<sup>[11]</sup>, DNMT3A<sup>[12]</sup>, ELK1<sup>[13]</sup> and MYO6<sup>[10]</sup>. Further studies are needed to determine other targets of miR-143-5p and miR-143-3p in gastric cancer.

In conclusion, both miR-143-5p and miR-143-3p are downregulated in gastric cancer and function as anti-oncomirs. MiR-143-5p is more strongly tumor suppressive than miR-143-3p. Our data also indicate that COX-2 is a direct target of miR-143-5p but not of miR-143-3p. Further studies are needed to define the detailed mechanisms and identify more miR-143 targets.

## COMMENTS

### Background

MicroRNA-143 (miR-143) is considered a pivotal regulator of gene expression and directly targets multiple mRNAs that code for proteins involved in cell proliferation, differentiation, survival and apoptosis. It is downregulated in various human tumors and suppresses tumor growth in cancers of the urogenital system, digestive system, respiratory system and nervous system, as well as some sarcomas and B-cell malignancies. MiR-143 expression has also been reported to be downregulated in human gastric cancer tissues and cell lines, but the mechanism by which miR-143 regulates cancer cells is not fully clear.

### Research frontiers

MiR-143 has been reported to be a tumor suppressor. However, the role of miR-143 in gastric cancer has not been fully investigated. The functional differences between miR-143-5p and miR-143-3p with regard to cancer have never been reported. In this study, the authors compared the tumor suppressive func-

tions of miR-143-5p and miR-143-3p and explored the associated underlying mechanism.

### Innovations and breakthroughs

This functional analysis of miR-143 expression in gastric cancer cell lines indicated that both miR-143-5p and miR-143-3p act as tumor suppressors. The restoration of either miR-143-5p or miR-143-3p suppressed cell proliferation and promoted apoptosis in gastric cancer cells. The tumor-suppressive effect of miR-143-5p was stronger than that of miR-143-3p. Further analysis demonstrated that only miR-143-5p directly bound to the cyclooxygenase-2 (COX-2) mRNA. The luciferase reporter assay revealed that COX-2 contained a binding site for miR-143-5p but not for miR-143-3p. Western blot showed a profound decrease in COX-2 protein expression after transfection with miR-143-5p but not with miR-143-3p. The data in this article indicate that COX-2 is a direct target of miR-143-5p but not of miR-143-3p.

### Applications

Both miR-143-5p and miR-143-3p function as anti-oncomirs and are downregulated in gastric cancers. MiR-143-5p is more strongly tumor suppressive than miR-143-3p and could be a potential gastric cancer therapeutic target.

### Terminology

MiR-143 is considered a pivotal regulator of gene expression because it directly targets multiple mRNAs that code for proteins involved in cell proliferation, differentiation, survival and apoptosis. It is downregulated in various human tumors and suppresses tumor growth in cancers from the urogenital, digestive, respiratory and nervous system, as well as B-cell malignancies.

### Peer review

The authors examined the effects and mechanisms of miR-143 subtypes on gastric cancer cell lines. They examined the effects of these oncomirs on growth, apoptosis and COX-2 activity. For the most part, the paper is straightforward and well written. The experiments are well described and the results are clearly presented.

### Abstract

**AIM:** To investigate the function of PU.1-silenced semi-mature dendritic cells (DCs) and the possibility of utilizing cell immunity in rat intestinal transplantation.

**METHODS:** DCs were isolated from the bone marrow of F344 rats and cultured using the adherent method. The *PU.1* gene was knocked down in DCs using small interfering RNAs (siRNAs) for 24 h, and the cells were then incubated with lipopolysaccharide for 48 h. The PU.1 siRNA that had the highest silencing efficiency was screened using reverse transcription-polymerase chain reaction and Western blot for further study. The tolerance capacity was analyzed and compared between PU.1-silenced DCs (siRNA PU.1 group), negative control-silenced DCs (siRNA NC group) and immature DCs (control group) both *in vitro* and *in vivo*.

**RESULTS:** Blocking expression of the *PU.1* gene *in vitro* led to a reduction in DC maturation and an increased tolerance capability. PU.1-silenced DCs expressed moderate levels of major histocompatibility complex (MHC)-II and low levels of co-stimulatory molecules, and produced more interleukin (IL)-10, but less IL-12. Compared with the negative control group, surface molecules cluster of differentiation 80 (CD80), CD86 and MHC-II in the siRNA PU.1 group were  $27.0\% \pm 5.6\%$ ,  $23.6\% \pm 4.8\%$  and  $36.8\% \pm 6.8\%$ , respectively, and showed a significantly lower trend ( $P < 0.05$ ). *In vivo* treatment of recipients with PU.1-silenced DCs injected before intestinal transplantation (siRNA PU.1 group), significantly prolonged allograft survival and resulted in better tissue histopathology compared with the siRNA NC group and control group. Mean survival time after transplantation was  $14.3 \pm 3.3$  d in the siRNA PU.1 group ( $P < 0.05$ ).

**CONCLUSION:** PU.1-silenced semi-mature DCs induced partial immune tolerance both *in vitro* and *in vivo*, which could be used as a new strategy to promote transplantation tolerance.

**Key words:** Dendritic cell; PU.1; Tolerance; Intestinal transplantation; Immune tolerance

**Core tip:** The inhibition of dendritic cells (DCs) maturation can promote their tolerogenicity in transplantation. PU.1 is a newly discovered transcription factor which is required for the regulation of dendritic cell maturation in all DCs subsets. We silenced the *PU.1* gene using siRNA and showed, for the first time, that PU.1-silenced DCs had immune tolerance. This may be a new strategy to prevent graft rejection following intestinal transplantation.

Xu XW, Ding BW, Zhu CR, Ji W, Li JS. PU.1-silenced den-

dratic cells prolong allograft survival in rats receiving intestinal transplantation. *World J Gastroenterol* 2013; 19(43): 7766-7771 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7766.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7766>

## INTRODUCTION

Dendritic cells (DCs) are key antigen-presenting cells, which play an important role in regulating adaptive immune responses. Studies have shown that whether immune responses are induced or suppressed greatly depends on the degree of DC maturation and specific subsets<sup>[1,2]</sup>. Immature DCs, which express low levels of major histocompatibility complex (MHC-II) and co-stimulatory molecules, such as cluster of differentiation 80 (CD80), CD86 and CD40, have a lower ability to capture antigens for presentation to specific T cells<sup>[3,4]</sup>. Therefore, various approaches have been explored to inhibit the maturation of DCs and to promote their tolerogenicity<sup>[5]</sup>.

MicroRNA-155 has emerged as an important regulator in the immune system<sup>[6,7]</sup>. MicroRNA (mRNA)-155 knockout mice showed aberrant immune functions, such as defective B and T cell immunity, abnormal function of antigen-presenting cells, and a failure in the production of high-affinity Immunoglobulin G (IgG)<sub>1</sub> antibodies<sup>[8,9]</sup>. These phenotypes are related to the impaired ability of mRNA-155 to target the E-twenty six transcription factor PU.1, which was first discovered to have multiple roles in hematopoiesis. PU.1 is an essential regulator of both cDC and pDC lineages<sup>[10,11]</sup>, and can regulate numerous genes within the myeloid and lymphoid lineages<sup>[12]</sup>. Recent studies have shown that PU.1 can partially direct the important cytokine receptor Flt3 and play a critical role in DC development and function. Therefore, PU.1 is a major and critical regulator of DC maturation.

In this study, we silenced PU.1 expression in rat bone marrow DCs (BM cells) using small interference RNA (siRNA) molecules and stimulated the cells with lipopolysaccharide (LPS) to obtain semi-mature DCs. These semi-mature DCs were then used to determine whether they could induce tolerance and have an effect on intestinal transplantation in rats.

## MATERIALS AND METHODS

### Animals

F344 and Wistar rats (weighing 180-220 g) were purchased from the Vital River Corporation (Beijing, China) and kept under specific-pathogen-free conditions. Animal experiments and maintenance were approved and regulated by the Ethics Committee of Jinling Hospital (Nanjing, China).

### *In vitro* generation of bone marrow-derived immature DCs

BM cells of F344 rats were used for DC generation fol-

lowing the method described by Lutz *et al.*<sup>[13]</sup> and Yang *et al.*<sup>[14]</sup>. Briefly, the femur and tibia were mechanically obtained, and the marrow cells were flushed out using phosphate-buffered saline (PBS). The obtained single cell suspensions were centrifuged, treated with 0.15 mol/L NH<sub>4</sub>Cl for 5 min and washed twice. The harvested BM cells were cultured in six-well plates (density,  $4 \times 10^6$ /mL) in RPMI1640 with 5 ng/mL recombinant rat granulocyte-macrophage colony-stimulating factor and 5 ng/mL interleukin (IL)-4 (Peprotech, NJ, United States). Non-adherent granulocytes were removed after 48 h of culture. From day 3, half of the medium was replaced with fresh medium every other day. On day 7, non-adherent and loosely adherent cells were harvested and identified as immature DCs, which were ready for transfection, and the supernatants were used for cytokine detection.

### Treatment of DCs

For *in vitro* studies, siRNAs targeting the *PU.1* gene were synthesized by Jima Corporation (Shanghai, China)<sup>[10,15]</sup>. The siRNAs were transiently transfected into the cells using Lipofectamine 2000 (Invitrogen, United States) for 24 h according to the manufacturer's instructions. The sequences of a PU.1-specific siRNA were: sense, 5'-AGCGAUCACUAUUGGGAUUTT-3'; and antisense, 5'-AAUCCCAAUAGUGAUCGCUTT-3'. The sequences of a negative control siRNA were: sense, 5'-UUCUCCGAACGUGUCACGUTT-3'; and antisense, 5'-ACGUGACACGUUCGGAGAATT-3'. Transfected DCs were cultured in the presence of 10 µg/mL LPS (Sigma-Aldrich, United States) for a further 48 h. Cells and supernatants were harvested for later use, and the cells were designated as PU.1-silenced-LPS DCs (siRNA PU.1 group), negative control-silenced-LPS DCs (siRNA NC group) or immature DCs (control group).

### Real-time PCR

Total RNA was extracted from cells using Trizol (Invitrogen, United States). RNA (1 pg) was reverse transcribed using an oligo-(dT) primer and reverse transcriptase (Invitrogen). All the measurements were performed in triplicate for each sample and normalized to the β-actin gene. The primer sequences for PU.1 were: forward, 5'-GAGTTTGAGAACTTCCCTGAG-3'; and reverse, 5'-TGGTAGGTCATCTTCTTGCGG-3'. Primer sequences for β-actin were: forward, 5'-ATGGATGACGATATCGCT-3'; and reverse, 5'-ATGAGGTAGTCTGTCAGGT-3'<sup>[15]</sup>.

### Western blot

Cells were homogenized in RIPA lysis buffer and used for Western blot assays. Briefly, equal amounts of protein extracts were boiled in sodium dodecyl sulfate (SDS)-sample buffer for 5 min before being electrophoretically resolved on SDS polyacrylamide gels and transferred to nitrocellulose membranes (Bio-Rad). The membranes were blocked with 5% fat-free dried milk and bovine serum albumin dissolved in Tris Buffered Saline with

Tween-20 for 1 h at room temperature and incubated overnight at 4 °C with antibodies raised against PU.1 (Santa Cruz, United States) according to the manufacturer's instructions. Binding of these primary antibodies was visualized with goat anti-rabbit secondary antibodies (1:2000 dilution; Santa Cruz, Texas, United States). Finally, the membranes were washed and an emitter-coupled logic signal detection kit was used (Amersham, IL, United States) for signal detection.

### Flow cytometric analysis

The following antibodies were purchased from eBioscience Corporation (CA, United States): phycoerythrin (PE)-coupled anti-CD86, PE-coupled anti-CD80 and fluorescein isothiocyanate-coupled anti-MHC-II. OX62-Alexa Fluor was obtained from BioLegend (CA, United States). After 7 d of cultivation, the prepared cells mentioned above were stained using the above antibodies at 4 °C for 30 min in PBS containing 0.1% sodium azide. Phenotypic analysis of DCs was performed on a fluorescence activated cell sorter Calibur flow cytometer equipped with Cell Quest (Becton Dickinson, New Jersey, United States).

### Purification of T cells and mixed lymphocyte reaction

T cells ( $2 \times 10^5$ ) purified from rat splenocytes (responder cells) were plated with immature DCs, PU.1-silenced DCs or negative control-silenced DCs (stimulator cells) at varying ratios. Cells were cultured for 3 d and pulsed with 1  $\mu$ Ci of [ $^3$ H] thymidine (PerkinElmer, Woodbridge, United States) for the final 18 h. The cells were subsequently harvested onto glass fiber filters, and incorporated radioactivity was quantified using a liquid scintillation counter.

### Detection of IL-12p70 and IL-10

The supernatants from each group as described above were collected and the cytokines IL-12p70 and IL-10 were measured by enzyme-linked immunosorbent assay according to the manufacturer's instructions (R and D Systems, Minneapolis, United States).

### Intestinal transplantation and treatment

Recipient Wistar rats, six in each group, were treated with PU.1-silenced DCs, negative control-silenced-LPS DCs or immature DCs from donor F344 rats ( $1 \times 10^6$  cells), seven days prior to intestinal transplantation *via* tail vein injection. Heterotopic intestinal transplantation was performed using the technique described by Zhang *et al.*<sup>[16]</sup>. The state of intestinal health/rejection was monitored and evaluated daily by examining the color of the graft and secretions from the stoma. Recipient rats that died within three days were regarded as technical failures and excluded from further analysis. The allografts were collected from a location 5 cm from the origin of the jejunum on day 5 after transplantation. Tissues from the three groups were sectioned and subjected to HE staining to evaluate morphologic changes.

### Statistical analysis

Data were reported as mean  $\pm$  SD. One-way analysis of variance was used for data analysis within groups. *P* values less than 0.05 were considered significant.

## RESULTS

### *In vitro* silencing of PU.1 with siRNAs

In order to silence the *PU.1* gene in DCs, we constructed three pre-siRNA vectors targeting PU.1 and one vector carrying a negative control siRNA. We incubated synthetic siRNAs with DCs which were induced with GM-CSF and IL-4 for 7 d to validate the efficiency of gene silencing. The most efficient plasmid to silence PU.1 was selected by assaying the PU.1 mRNA and protein expression. Forty-eight hours after transfection, PU.1 expression in the siRNA PU.1 group was reduced by approximately 85% at the protein level compared with the siRNA NC group (Figure 1A).

### Characteristics of semi-mature DCs and expression of cytokines

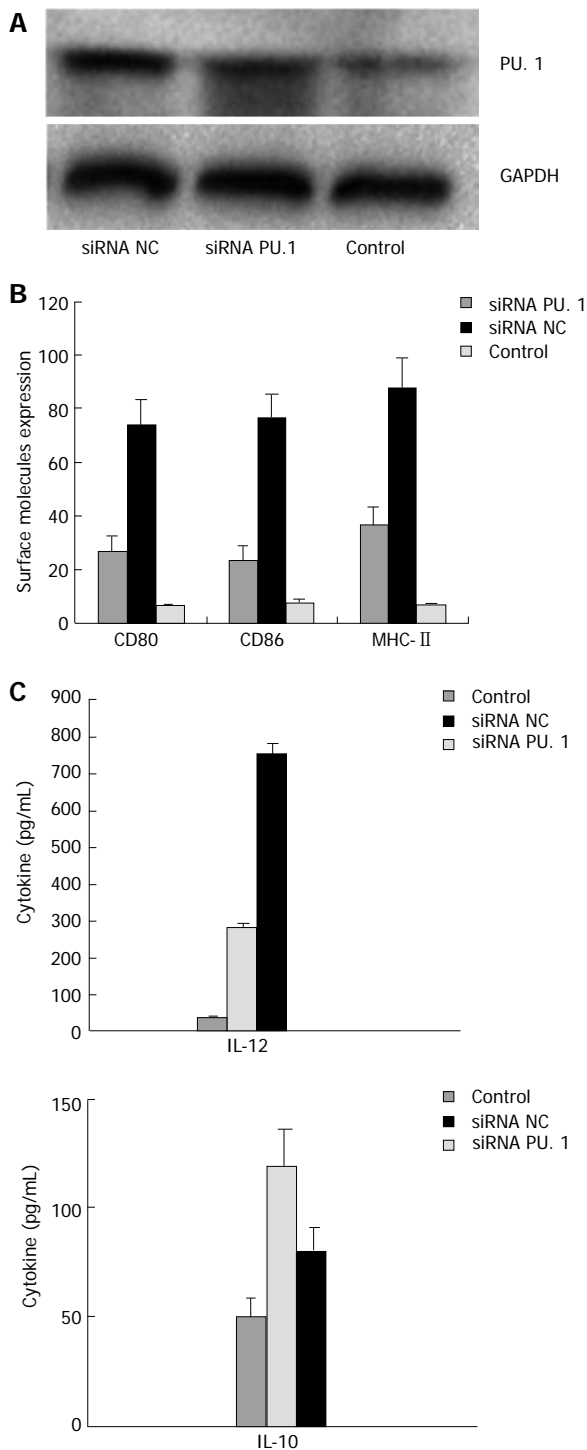

Similar to the characteristics of mature DCs, the DCs in the siRNA NC group also expressed high levels of MHC class II and co-stimulatory molecules. However, in the siRNA PU.1 group, the DCs were semi-mature, with the expression of CD80, CD86 and MHC-II ( $27.0\% \pm 5.6\%$ ,  $23.6\% \pm 4.8\%$  and  $36.8\% \pm 6.8\%$ , respectively) significantly lower than that in the siRNA NC group ( $74.0\% \pm 9.4\%$ ,  $76.5\% \pm 8.7\%$  and  $87.8\% \pm 11.3\%$ , respectively) (Figure 1B,  $P < 0.05$ ). The ability of DCs in the three groups to produce cytokines in cell culture supernatants was also determined, and an opposite trend was noted between IL-12p70 and IL-10 production ( $P < 0.05$ ) (Figure 1C). These data indicate that the PU.1 silencing partially inhibits DC maturation.

### Impaired ability of semi-mature DCs to stimulate T cell proliferation

Purification of T cells and MLR analysis were performed to observe the *in vitro* activity of DCs. The proliferation of Wistar rat splenic T cells in a primary mixed lymphocyte reaction (MLR) in response to stimulation with DCs in the siRNA PU.1 group was significantly reduced compared with that in the siRNA NC group ( $P < 0.05$ , Figure 2), suggesting that PU.1-silenced DCs have an impaired capacity to stimulate T cell proliferation.

### Treatment with PU.1-silenced DCs prolongs allograft survival

Since the results of the *in vitro* study showed that silencing of PU.1 reduced DC maturation and inhibited allogeneic T cell proliferation, we postulated that knockdown of this key transcription factor might prevent graft rejection. To determine this, we treated Wistar recipients with different groups of DCs 7 d before performing intestinal transplantation. While recipient survival was short in the

**Figure 1 Identification of PU.1-silenced dendritic cells *in vitro*.** A: Analyses of PU.1 gene expression by Western blot; B: Flow cytometry analysis of CD80, CD86 and major histocompatibility complex (MHC)-II in dendritic cells; C: Analyses of cell culture supernatants by enzyme-linked immunosorbent assay. CD: Cluster of differentiation; GAPDH: Reduced glyceraldehyde-phosphate dehydrogenase.

siRNA NC group ( $7.8 \pm 1.5$  d,  $n = 6$ ,  $P < 0.05$ ) and the control group ( $8.0 \pm 2.5$  d,  $n = 6$ ,  $P < 0.05$ ), the infusion of siRNA PU.1 DCs significantly prolonged survival ( $14.3 \pm 3.3$  d). Consistent with our surmise, morphological features of acute rejection were prominent in the siRNA NC group and in the control group. Histological examination

**Figure 2 PU.1-silenced dendritic cells suppress allogeneic T cell proliferation.** Bone marrow dendritic cells (DCs) were cultured and transfected with PU.1 siRNA as described. After that, three groups of DCs were collected and co-cultured with allogeneic T cells in a 96-well plate at various ratios as indicated. [ $^3$ H] was added 48 h after coculture, and its incorporation was measured as an indicator of T cell proliferation ( $P < 0.05$  siRNA PU.1 vs siRNA NC group).

showed different degrees of lymphocyte infiltration and villous edema. In contrast, PU.1-silenced DCs delayed and reduced the immune response and injury, with mild lymphocyte infiltration and reduced inflammation observed in the allograft intestine (Figure 3).

## DISCUSSION

Recently, the role of innate immunity in shaping the adaptive response has been focused in transplantation research, and studies have shown that the infusion of donor immature DCs can prolong graft survival after organ transplantation<sup>[17,18]</sup>, mainly because they are capable of inducing tolerance by inducing T cell anergy or apoptosis<sup>[19,20]</sup>. Immature DCs express low levels of MHC II and co-stimulatory molecules and fail to elicit naïve T cells to modulate the adaptive immune response. However, they are not stable *in vivo* and can easily be stimulated to transform into mature DCs through several signaling pathways<sup>[21]</sup>, which limits their preservation and utilization. Recent studies show that by controlling ambient conditions *in vitro*, semi-mature DCs are obtained from immature DCs following LPS stimulation. These cells are phenotypically stable and hard to differentiate or mature. Yang *et al.*<sup>[14]</sup> found that silencing of MyD88, a proximal component of nuclear factor-kappaB (NF- $\kappa$ B) signaling, affected the maturation of immature DCs by increasing the secretion of IL-10 and decreasing the secretion of IL-12p70. The NF- $\kappa$ B signaling pathway plays a critical role in DC maturation, and IL-10 is regarded as an immunosuppressive cytokine which can downregulate the synthesis of a broad range of inflammatory cytokines and inhibit allogeneic T cell proliferation<sup>[22]</sup>. Therefore, the silencing of key factors involved in DC maturation may lead to a stunted capacity to prime the immune response and better stability<sup>[23,24]</sup>. As PU.1 is highly expressed and plays a critical role in DC maturation, suppression of this gene may result in interruption of DC maturation.

**Figure 3** Histopathology of intestinal allograft from recipient rats. Treatment with PU.1 small interference RNA (siRNA) prevents allograft rejection and is associated with mild lymphocyte infiltration and villous damage. Samples from the three groups were compared (magnification  $\times 40$ , scale bar 20  $\mu\text{m}$ ). A: The siRNA PU.1 group; B: The siRNA NC group; C: The control group.

Unsurprisingly, we found that PU.1-silenced semi-mature DCs<sup>[25]</sup> had a better effect in reducing the inflammatory response than immature DCs in an intestinal allograft model.

It is difficult to perform rat intestinal transplantation due to complex microvascular techniques and high mortality. Many animals died of immune rejection within several days. Although immature DCs express low levels of MHC II and determine tolerogenicity, current evidence for the application of immature DCs in rodent transplantation models is equivocal. In our experiment, rat survival, cytokine production and intestinal histological changes were evaluated to test the immunosuppressive function of semi-mature DCs. We found that acute rejection was significantly alleviated on day 5 compared to the controls, along with prolonged survival time and better condition in these rats. Rats in the siRNA PU.1 group showed slowed neointima formation and reduced inflammation and fibrosis in the allograft intestine. These results can be explained by increased secretion of IL-10 and decreased IL-12p70. The increase in IL-10 may play a crucial role in mediating the functions of semi-mature DCs. The surface expression of co-stimulatory molecules, such as CD86, CD80 and CD40, also showed a reduced trend, which is consistent with the results of T-cell proliferation. Thus, our experiments demonstrated that *PU.1* gene silencing induced partial tolerance in this animal transplantation model.

However, we do not know whether the number of semi-mature DCs fluctuated or changed in recipient rats, and whether these DCs reduced the number and maturation of native DCs at the time of small bowel transplantation. More *in vivo* studies in both donors and recipients are required to identify the mechanism related to better graft survival.

In conclusion, we have provided evidence that silencing of the *PU.1* gene can impair DC maturation, inhibit allogeneic T cell proliferation, and induce immunosuppressive activity. Since PU.1 silencing can prolong intestinal transplant survival in rats, it may be used as a new strategy and viable therapeutic option to prevent graft rejection following intestinal transplantation.

## COMMENTS

### Background

As key antigen-presenting cells, whether dendritic cells (DCs) induce or suppress immune responses greatly depends on the degree of DC maturation and specific subsets. MicroRNA-155 has emerged as an important regulator in the immune system, and the transcription factor PU.1 is a direct target of miR-155, which has recently been found to play multiple critical roles in DC maturation and function.

### Research frontiers

PU.1 is a major and critical regulator of DC maturation. However, the mechanism of action of PU.1 in DC maturation and tolerogenicity has not been unequivocally addressed. In this study, the authors silenced the *PU.1* gene using siRNA and demonstrated that PU.1 silencing impaired DC maturation and inhibited allogeneic T cell proliferation. PU.1-silenced DCs also prolonged intestinal transplant survival and improved the general state of the graft.

### Innovations and breakthroughs

Recent reports have highlighted the important role of PU.1 in DC maturation and function. This is the first study to report that PU.1-silenced DCs can induce tolerogenicity, which can be applied in rat intestinal transplantation. Furthermore, the authors' *in vitro* studies suggest that inhibiting a key factor in a given signaling pathway is an effective way of inducing DC tolerogenicity.

### Applications

The authors' finding that PU.1-silenced dendritic cells can prolong intestinal transplant survival in rats suggest that PU.1 silencing may be used as a new strategy and viable therapeutic option to prevent graft rejection following intestinal transplantation.

### Terminology

PU.1 is an EPS transcription factor which was first discovered to play multiple roles in hematopoiesis. Recent studies have shown that PU.1 is an essential regulator of both cDC and pDC lineages and can regulate numerous genes within the myeloid and lymphoid lineages. Such a mechanism is thought to be crucial in inducing stable immature DCs. Not surprisingly, the DCs the authors cultivated in the study showed tolerogenicity both *in vivo* and *in vitro*.

### Peer review

The authors examined the surface molecule expression of PU.1-silenced DCs, T cell proliferation and cytokines of cell culture supernatants. The cells were injected to recipient rats to test the immunogenicity *in vivo*. It revealed that they induced immunosuppressive activity; and the increased interleukin-10 expression may play a crucial role in the semi-mature DC functions and induce immunogenicity. The results are interesting and may supplement molecular mechanism of PU.1.

### Abstract

**AIM:** To investigate the pathogenesis of biliary casts after liver transplantation relative to their morphology and biochemical markers.

**METHODS:** The microstructure of biliary casts was assessed using scanning electron microscopy and Hematoxylin and eosin staining assessed their histology. The expression levels of CD3, CD5, CD34, CD68 and CD79a in these biliary casts were evaluated immunohistochemically.

**RESULTS:** Biliary casts differed widely in their microstructure, with some containing blood vessels positive for CD34 and collagen fibers with positive Masson staining. Large numbers of neutrophils and other inflammatory cells were present, but only on the edge of the biliary casts; although the boundaries were clear without crossover. None of the biliary casts contained T-lymphocytes, B-lymphocytes, macrophages and other inflammatory cells.

**CONCLUSION:** The microcostructure of biliary casts

differed. Bacteria and acute rejection are not clearly related to their formation.

**Key words:** Biliary cast; Biliary cast syndrome; Liver transplantation; Blood vessels; Acute rejection

**Core tip:** This experimental study employed scanning electron microscopy, Hematoxylin and eosin staining and immunohistochemistry to investigate biliary casts following liver transplantation. The results indicated that blood vessels and collagen fibers are present in biliary casts; however, bacteria and acute rejection are not clearly related to their formation, as evidenced by blood vessels positive for CD34 and collagen fibers with positive Masson staining, and no T-lymphocytes, B-lymphocytes, macrophages and other inflammatory cells. Thus, although bile duct injury after liver transplantation is significantly associated with biliary cast formation, their role in acute rejection is unclear.

### INTRODUCTION

Despite advances in the management of patients who have undergone cadaveric liver transplantation, 6%-34% patients experience biliary complications<sup>[1]</sup>. Biliary cast syndrome (BCS), first described in 1975<sup>[2]</sup>, occurs less frequently than biliary sludge and stones, with an incidence of 2.5% after orthotopic liver transplantation<sup>[3]</sup>. Multiple intrahepatic biliary strictures, ductal dilatation,

intrahepatic abscesses, and biliary anastomotic leakage characterize BCS. The clinical symptoms of BCS usually include high fever, jaundice and cholestatic liver enzyme elevation, similar to the symptoms observed in some patients with intrahepatic bile duct stones. Surgical management is the treatment of choice, and endoscopic techniques have been successful and safe in the removal of biliary casts<sup>[4-6]</sup>. Morphologically, biliary casts are a similar shape to bile ducts, appearing as a hardened, dark material in the biliary ductal system. Biliary casts can prevent bile drainage, resulting in biliary obstruction and inducing biliary tract infection. Biliary casts can ultimately cause substantial injury to the liver, with some transplant recipients requiring retransplantation. Although the associations between biliary casts and clinical treatment have been assessed recently, less is known about the associations between biliary casts and biochemical markers. We therefore investigated the pathogenesis of biliary casts after liver transplantation relative to their morphology and biochemical markers.

## MATERIALS AND METHODS

### *Isolation of biliary casts*

We evaluated 15 patients with a history of orthotopic liver transplantation, who were treated in our department for jaundice, recurrent cholangitis and high fever. There were 10 males and 5 females, with a mean age of 52.1 years (range, 34-78 years). Of these patients, five underwent deceased donor liver transplantation for hepatitis B-induced cirrhosis and primary liver cancer, one for primary hepatocellular carcinoma and nine for cirrhosis during the decompensated period. Choledochoscopy and duodenoscopy have been used frequently to assess patients with biliary complications after liver transplantation<sup>[7,8]</sup>. Patients with T-tube fistulae can be evaluated by insertion of a cholangioscope directly into the common hepatic duct, whereas patients without T-tube fistulae are evaluated preferably by percutaneous transhepatic cholangioscopy or endoscopic retrograde cholangiopancreatography<sup>[9]</sup>. The distal aspect of the cast was secured using a basket, allowing each cast to be successfully removed as a single piece. All the casts were stored in liquid nitrogen.

### *Scanning electron microscopy*

Following their isolation, biliary casts that were kept at room temperature were rinsed in sterile normal saline solution, fixed with 10% neutral formalin for 12 h at 4 °C, rinsed in 0.1 mol/L phosphate buffer (pH 7.0) and dehydrated through a graded series of ethanol (10 min each at 10%, 30%, 50%, 70% and 90%, and 15 min each three times at 100%). After critical point drying at 30 °C with CO<sub>2</sub> for 6 h, the samples were mounted, coated with 1-μm gold particles and evaluated using a Hitachi S 4800 field emission scanning electron microscope at 2 kV.

### *Histological and immunohistochemical examination*

Biliary casts stored in liquid nitrogen were rinsed in sterile

normal saline solution, fixed with 10% neutral formalin for 12 h at 4 °C, embedded in paraffin, cross-sectioned into 10 mm slices and placed onto glass slides. Some of these histological sections were stained with hematoxylin and eosin (HE) and Masson trichrome, according to standard procedures. The remaining histological sections were deparaffinized, rehydrated, incubated in 3% hydrogen peroxide/absolute methanol for 5 min to block endogenous peroxidase activity and rinsed in distilled water. Nonspecific binding of antibodies was blocked by incubation with 5% normal goat serum for 10 min at room temperature. After washing, the sections were incubated with primary rabbit antibodies against human CD3, CD5, CD34, CD68 and CD79a, overnight at 4 °C. The sections were subsequently incubated with biotinylated secondary antibody for 30 min at 37 °C, with streptavidin biotin complex reagent for 30 min at 37 °C, and with DAB Plus reagent for 10 min, with the sections repeatedly washed with PBS, pH 7.4, between incubations. The sections were counterstained with hematoxylin, mounted and examined by optical microscopy. All antibodies and reagents for immunohistochemistry were purchased from the Beijing Zhongshan Golden Bridge Biotechnology Company, Beijing, China.

## RESULTS

### *Biliary casts have a variety of morphological structures*

Morphologically, biliary casts have a cordlike, columnar, dendritic shape within the biliary ductal system (Figure 1A). Scanning electron microscopy, however, showed that biliary casts were present in a variety of forms: irregular sheets composed of imbricated accumulations (Figure 1B); honeycombs with porous structures and adherent crystalline substances (Figure 1C); and filamentous structures (Figure 1D).

### *Biliary casts contain blood vessels and collagen fibers*

HE staining revealed large numbers of lacunae containing bilirubin, tubiform (Figure 2A) and filamentous structures (Figure 2B). To determine the composition of the tubiform and filamentous structures, we incubated these sections with antibodies to cell markers and with Masson stain. We found that the tubiform structures were positive for CD34 (Figure 2C), whereas the filamentous structures were positive for Masson stain (Figure 2D). These findings indicated that the tubiform structures were blood vessels and the filamentous structures were collagen fibers.

### *Formation of biliary casts is not related to inflammatory response*

HE staining showed large numbers of neutrophils and other inflammatory cells on the edge of the biliary casts; however, the boundaries were clear without crossover, and no inflammatory cells were present within the biliary casts (Figure 2E). Scanning electron microscopy showed no evidence of bacteria or bacterial debris on the surface of the biliary casts.

**Figure 1** Morphology of biliary casts. A: Cordlike, columnar and dendritic shapes of biliary casts within the biliary ductal system; B: A biliary cast in the shape of an irregular sheet composed of imbricated accumulation ( $\times 10000$ ); C: A biliary cast in the shape of a honeycombs with porous structures and adherent crystalline substances ( $\times 10000$ ); D: A biliary cast in the shape of filamentous structures ( $\times 10000$ ).

### Immune rejection is not significantly related to biliary cast formation

Acute rejection generally occurs 1 to 3 wk after liver transplantation. To determine the relationship between immune rejection reactions and biliary cast formation, we incubated the biliary cast samples with antibodies to CD3, CD5, CD68, and CD79a. None of the biliary casts was positive for any of these markers, indicating that these biliary casts did not contain T-lymphocytes, B-lymphocytes and macrophages.

## DISCUSSION

Physically and morphologically, biliary casts appear as dark, hardened material in the shape of bile ducts within the biliary ductal system, but differ from bile duct stones. Scanning electron microscopy showed that biliary casts appear in a variety of forms, including irregular sheets composed of imbricated accumulations; honeycombs with a porous structure and adherent crystalline substances; and filamentous structures. Although bile duct stones and biliary casts have a similar microstructure<sup>[10]</sup>, their mechanism of formation differs significantly. Biliary casts that form after liver transplantation are not caused by a single pathogenic factor, but may be associated with late functional rehabilitation, biliary strictures and obstruction, acute rejection, recurrent cholangitis, cold and warm ischemia times, hepatic ischemia and reperfusion injury<sup>[3,11-13]</sup>.

Bilirubin has been reported to be the primary component of biliary casts (approximately 10%-50%), followed by bile acid synthesis products and cholesterol, with protein comprising only 5%-10%<sup>[14]</sup>. In comparison, we observed large amounts of bilirubin, as well as blood vessels and collagen fibers, consistent with our earlier findings. Choledochoscopy showed a large number of flocs in bile duct cellulose 5 mo after transplantation, with histopathological examination showing that these flocs were composed of cellulose, bile duct epithelial cells and necrotic inflammatory cells. These elements then become structureless, with biliary casts observed in the bile ducts 9 mo after transplantation<sup>[15]</sup>. The presence of blood vessels and collagen fibers in the biliary casts was related to injury to the bile duct mucosa. The extent of bile duct injury during orthotopic liver transplantation differs, with cold preservation/reperfusion injury being the most important initiator of bile duct tree injuries and vessel plexus damage. Bile duct injury may, therefore, be associated with microcirculatory disturbances surrounding the bile ducts<sup>[16]</sup>; however, the specific mechanisms underlying bile duct injury require further investigation.

Acute rejection after liver transplantation generally occurs 1 to 3 wk postoperatively. Typical clinical symptoms include unexplained fever, loss of appetite, poor spirit, liver pain, progressively deepening jaundice, and elevated bilirubin and transaminase. The diagnosis mainly depends on liver puncture biopsy and pathology. Biliary casts and acute rejection after transplantation have

**Figure 2** Histological and immunohistochemical examination of biliary casts. A: Histological examination of a biliary cast, showing tubiform structures (HE staining  $\times 100$ ); B: Histological examination of a biliary cast, showing filamentous structures (HE staining  $\times 100$ ); C: A biliary cast with tubiform structures positive for CD34 (brown color,  $\times 100$ ); D: A biliary cast with filamentous structures positive for collagen fibers (Masson staining  $\times 100$ ); E: A biliary cast showing peripheral positivity for neutrophils and other inflammatory cells (HE staining,  $\times 100$ ).

a similar time of onset and similar clinical symptoms. However, biliary casts generally form at least 1 mo after transplantation<sup>[17]</sup>. Liver recipients with high serum concentrations of soluble major histocompatibility complex class I related chain A (sMICA) tend to develop BCS more easily than recipients with normal post-transplant sMICA concentrations<sup>[18]</sup>. We hypothesized that the formation of biliary casts was related to acute rejection and that T lymphocytes, B lymphocytes and macrophages would be present in biliary casts. However, we found that these cells were absent from biliary casts arising after liver transplantation, similar to the findings in patients who underwent non-liver transplantation<sup>[19,20]</sup>. Therefore, our findings suggest that acute rejection after liver transplantation was not significantly associated with biliary cast formation.

Electron microscopic examination of cholesterol

calculi showed the presence of bacteria in the core and periphery of cholesterol stones, suggesting that bacteria may be involved in initiating the formation of cholesterol stones<sup>[21,22]</sup>. Patients with biliary casts usually have recurrent episodes of cholangitis. *Escherichia coli*, which has glucuronidase activity and can grow in cultures of biliary casts, can degrade conjugated bile acids and conjugated bilirubin, yielding free bile acids and free bilirubin, respectively. Free bile acids and free bilirubin are relatively insoluble and are not present in the bile of patients. Damage to the bile duct mucosa can result in their precipitation into biliary casts, suggesting that a number of factors, including infection, supersaturation with cholesterol and mucosal damage, may be involved in bile cast formation after liver transplantation<sup>[2]</sup>. To assess the relationship between bacteria and biliary casts, we evaluated biliary casts using scanning electron mi-

croscopy. However, neither bacteria nor bacterial debris was observed in the interior or surface of biliary casts. Large numbers of neutrophils were observed on the periphery of biliary casts, but the boundaries were clear and there were no neutrophils or similar cells within the mold. The multiplication of bacteria in an environment of poor bile drainage and cholestasis caused by biliary casts may therefore induce recurrent fever, obstructive jaundice and other complications. Biliary tract infections may be secondary pathological changes following biliary cast formation, rather than being the direct cause of mold formation. Therefore, when treating patients who experience complications after liver transplantation, anti-infectious agents may only alleviate the symptoms. The removal of the biliary casts may therefore be primary.

## COMMENTS

### Background

Biliary casts are infrequent complications after liver transplantation, resulting in various clinical symptoms. Although the associations between biliary casts and clinical treatment have been assessed recently, less is known about the associations between biliary casts and biochemical markers.

### Research frontiers

The current pathogenesis study of biliary casts after liver transplantation mostly concentrated on clinical aspects. Biliary casts were not caused by a single pathogenic factor, but may be associated with late functional rehabilitation, biliary strictures and obstruction, acute rejection, recurrent cholangitis, cold and warm ischemia times, hepatic ischemia and reperfusion injury.

### Innovations and breakthroughs

The results indicated that blood vessels and collagen fibers are present in biliary casts; however, bacteria and acute rejection are not clearly related to their formation, as evidenced by blood vessels positive for CD34 and collagen fibers with positive Masson staining, and the absence of T-lymphocytes, B-lymphocytes, macrophages and other inflammatory cells.

### Applications

These findings indicate that bile duct injury is clearly associated with biliary cast formation after liver transplantation; however, bacteria and acute rejection were not significantly related to their formation.

### Terminology

Biliary cast syndrome, first described in 1975, occurs less frequently than biliary sludge and stones, with an incidence of 2.5% after orthotopic liver transplantation. Orthotopic liver transplantation refers to a procedure in which a failed liver is removed from the patient's body and a healthy donor liver is transplanted into the same location. Biliary casts are infrequent complications after liver transplantation, resulting in various clinical symptoms.

### Peer review

The authors analyzed the pathogenesis of biliary casts after liver transplantation relative to their morphology and biochemical markers. These findings indicate that bile duct injury was clearly associated with biliary cast formation after liver transplantation, but that bacteria and acute rejection are not clearly related to their process of bile duct injury. Therefore, it is an interesting study. The analytical approaches are described in detail, and the results are impressive.

### Abstract

**AIM:** To investigate whether a virus constitutively expressing active Akt is useful to prevent cirrhosis induced by carbon tetrachloride (CCl<sub>4</sub>).

**METHODS:** Using cre-loxp technique, we created an Ad-myr-HA-Akt virus, in which Akt is labeled by a HA tag and its expression is driven by myr promoter. Further, through measuring enzyme levels and histological structure, we determined the efficacy of this Ad-myr-HA-Akt virus in inhibiting the development of cirrhosis induced by CCl<sub>4</sub> in rats. Lastly, using western blotting, we examined the expression levels and/or phosphorylation status of Akt, apoptotic mediators, endothelial nitric oxide synthase (eNOS), and markers for hepatic stellate cells activation to understand the underlying mechanisms of protective role of this virus.

**RESULTS:** The Ad-myr-HA-Akt virus was confirmed using polymerase chain reaction amplification of inserted

Akt gene and sequencing for full length of inserted fragment, which was consistent with the sequence reported in the GenBank. The concentrations of Ad-myr-HA-Akt and adenoviral enhanced green fluorescent protein (Ad-EGFP) virus used in the current study were  $5.5 \times 10^{11}$  vp/mL. The portal vein diameter, peak velocity of blood flow, portal blood flow and congestion index were significantly increased in untreated, saline and Ad-EGFP cirrhosis groups when compared to normal control after the virus was introduced to animal through tail vein injection. In contrast, these parameters in the Akt cirrhosis group were comparable to normal control group. Compared to the normal control, the liver function (Alanine aminotransferase, Aspartate aminotransferase and Albumin) was significantly impaired in the untreated, saline and Ad-EGFP cirrhosis groups. The Akt cirrhosis group showed significant improvement of liver function when compared to the untreated, saline and Ad-EGFP cirrhosis groups. The Hyp level and portal vein pressure in Akt cirrhosis groups were also significantly lower than other cirrhosis groups. The results of HE and Van Gieson staining indicated that Akt group has better preservation of histological structure and less fibrosis than other cirrhosis groups. The percentage of apoptotic cell was greatly less in Akt cirrhosis group than in other cirrhosis groups. Akt group showed positive HA tag and an increased level of phosphorylated Akt as well as decreased levels of Fas. In contrast, Caspase-3 and Caspase-9 levels in Akt group were significantly lower than other cirrhosis groups. Noticeable decrease of DR5 and  $\alpha$ -SMA and increase of phosphorylated eNOS were observed in the Akt group when compared to other cirrhosis groups. The NO level in liver was significantly higher in Akt group than other cirrhosis groups, which was consistent with the level of phosphorylated eNOS in these groups.

**CONCLUSION:** This study suggest that Ad-myr-HA-Akt virus is a useful tool to prevent CCl<sub>4</sub>-induced cirrhosis in rat model and Akt pathway may be a therapeutic target

for human cirrhosis.

**Key words:** Adenovirus; Akt; Gene transfer; Apoptosis; Cirrhosis; Carbon tetrachloride; Rat

**Core tip:** In the present study, we have demonstrated for the first time that Ad-myr-HA-Akt virus was a useful tool to prevent carbon tetrachloride-induced cirrhosis in rat model. Our data obtained at different levels, from function to histological changes, apoptosis rate of hepatocytes, activation of hepatic stellate cells, deposition of collagen, portal vein pressure and NO level, which were all consistently and collectively supported the hypothesis that introduction of Ad-myr-HA-Akt virus inhibits the development of cirrhosis.

Amelioration of carbon tetrachloride-induced cirrhosis and portal hypertension in rat using adenoviral gene transfer of Akt. *World J Gastroenterol* 2013; 19(43): 7778-7787 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7778.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7778>

## INTRODUCTION

It has been found that massive apoptosis of hepatocytes resulted in activation of hepatic stellate cells (HSC), which produce collagen and ultimately lead to the fibrosis and cirrhosis<sup>[1-5]</sup>. Accordingly, inhibiting hepatic apoptosis is considered as an important strategy to prevent cirrhosis<sup>[6-10]</sup>. Previous research showed that Akt plays a crucial role in preventing Fas signaling-mediated hepatic apoptosis, and that over-expression of Akt was capable of preventing hepatic apoptosis<sup>[11,12]</sup>. Therefore, we intended to establish a recombinant vector carrying *Akt* gene to inhibit cirrhosis in a rat model.

Adenovirus can effectively express genes of interest. Accordingly it has been widely used as vector for gene therapy<sup>[13-18]</sup>. Recently, Cre-loxp system has been used to create replication-defective virus and successfully used in creating therapeutic virus with recombinant gene<sup>[19-22]</sup>. In the present study, using cre-loxp technique, we created an Ad-myr-HA-Akt virus, in which Akt is labeled by a Hemagglutinin (HA) tag and its expression is driven by myr promoter. We further determined that this Ad-myr-HA-Akt virus was capable of inhibiting the development of cirrhosis induced by carbon tetrachloride (CCl<sub>4</sub>). Lastly, we examined the expression level and/or phosphorylation status of Akt, apoptotic mediators, endothelial nitric oxide synthase (eNOS), and markers for HSC activation. Our results indicated that introduction of Ad-myr-HA-Akt virus was able to prevent hepatocyte apoptosis and subsequent cirrhosis in a rat CCl<sub>4</sub>-induced cirrhosis model.

## MATERIALS AND METHODS

### Preparation of recombinant adenoviral vector carrying Akt

According to the method that has been published<sup>[23]</sup>, a replication-defective adenovirus vector was constructed in HEK293 cell with co-transfection of pCD316 plasmid, pBHGloxΔE1 and 3Cre (Invitrogen, United States). The details have been previously published. The vector of interest was selected with polymerase chain reaction (PCR) amplification of inserted *Akt* gene using the following primer pair as show: F: 5'-GGGAATTCATGGGATGCGTGTGTAGC-3'; R: 5'-GGGGATCCTCAGGCCGTGCCGCTGGCCGAGTA-3'. The PCR thermal condition consisted of 94 °C 5 min, 30 cycles of 94 °C 30 s, 58 °C 30 s, 72 °C 1 min, and a final extension at 72 °C 5 min. The amplified gene was further confirmed with DNA sequencing (Sunbiotech Co., Ltd, ABI 3730, Beijing). adenoviral enhanced green fluorescent protein (Ad-EGFP) was purchased from Stratagene (CA, United States) and used as a control vector for tracking the distribution of virus after introduced to animal. The concentration of recombinant adenovirus was measured with tissue culture infective dose method as previously reported<sup>[24]</sup>.

Plasmids were amplified in DH5a competent cells and purified using a commercial kit (Qiagen). Viruses were prepared in HEK293 cells (Qiagen, GmbH, Hilden, German), which contain the necessary gene for the virus package. Specifically, one day prior to the transfection, HEK293 cells were seeded at a concentration of  $10 \times 10^6$  in 10 mL complete dulbecco's modified eagle medium and cultured overnight. Upon transfection, 1 mg/mL plasmid stock was taken and adjusted into a volume of 1600 μL, 150 μL calcium phosphate was added to the same tube, mixed well and incubated at room temperature for 20 min. The resultant mixture was slowly added into HEK293 cell culture. The dish was gently moved and swirled to allow the even distribution of virus in culture. Cells were further cultured for 16 h. The supernatant was discarded and replaced with fresh medium. After a 2-d culture, cells were examined under a fluorescence microscope (E80i, Nikon, Japan) for the green fluorescent protein (GFP<sup>+</sup>) cells. Cells were harvested and lysed using freezing (-70 °C) and thawing (37 °C) twice. The resultant mixture was centrifuged at 10000 g for 10 min. The supernatant with virus was collected and stored at -70 °C for future infection of target cells.

### Rat cirrhosis model and experiment groups

Fifty male rats (weight  $220 \pm 20$  g) were purchased from Animal Center of Hunan Agriculture University (Hunan, China). Rats were housed under  $25 \pm 2$  °C and a 12-h light/dark cycle in microisolator cages. Ten rats were randomly selected and used for the normal control. The remaining 40 rats were subjected to the induction of cirrhosis using CCl<sub>4</sub> as previously reported<sup>[25]</sup>. These rats were further randomly divided into 4 groups ( $n = 10$  per

group). One group did not receive additional treatment, the other three groups received saline, Ad-EGFP, Ad-myr-HA-Akt ( $3.0 \times 10^{11}$  vp in 1 mL saline), respectively, *via* tail vein injection at 2 wk after cirrhosis induction. The treatment was repeated at 6 wk. Accordingly, the experiment groups of rats were defined as follows: normal control, untreated cirrhosis, saline cirrhosis, EGFP cirrhosis and Akt cirrhosis. All surgical procedures were completed in accordance with the guidelines on the care and use of laboratory animals for research purposes by the Central South University Xiangya Medical School's Animal Care and Use Committee. Mice were anesthetized with chloral hydrate (*iv*) for all surgical procedures.

### Hemodynamic and ultrasound parameters

Three days after treatment, five rats from each experimental groups (normal control group, untreated cirrhosis, saline cirrhosis, Ad-EGFP and Akt cirrhosis) were restricted from food with free access to water for 12 h. Rats were anesthetized by *iv* infusion of 2.5% chloral hydrate (50 gtt/min). Then, diameter (D) and peak velocity of blood flow (V) in portal was measured using ultrasound system (SIMENS Co., Ltd, Acuson Seguoia 512, Germany). The blood flow (Q) and congestion index (CI) was calculated using the following formulas:  $Q = 0.57\pi D^2/4V \times 60$ , and  $CI = \pi D^2/4V$ , respectively. Using a blood pressure device (RBP-1B, Sino-Japan friendship clinical medicine institute), the tail mean arterial pressure was recorded.

### Analysis of liver function and histological changes

Eight weeks after cirrhosis induction, 1 mL of blood from each rat was collected from portal vein and subjected to analysis for alanine aminotransferase (ALT); aspartate aminotransferase (AST) and albumin (ALB) levels using a automatic biochemical analyzer (Spotchem SP4430, Arkray, Kyoto, Japan). Using aseptic techniques, laparotomy was performed, the portal vein was exposed, and portal vein pressure was measured with catheterization. Then rats were sacrificed and the right lobe of the liver was removed and stored in liquid nitrogen for future analysis. Liver tissue sections were subjected to HE staining for cellular and tissue structure as well as Van Gieson (VG) staining for collagen deposition. Hepatic hydroxyproline (Hyp), which is the main constituent of collagen protein, was used to estimate the degree of hepatic fibrosis, was measured with a commercial kit following manufacture's protocol (Jiancheng Biological product institute, Nanjing, China). The stained sections were examined and photographed under a microscope equipped with a digital photograph acquiring system (E80i, Nikon, Japan). Hyp and liver function markers were measured with an automatic machine (Beckman LX20, United States).

### Flow cytometry analysis

Apoptosis of hepatic cells was detected using Annexin-V-fluorescein isothiocyanate (FITC)/Propidium iodide (PI) double staining and flow cytometry analysis. The

cells were harvested and resuspended in Annexin-V binding buffer and further incubated with 5  $\mu$ L of Annexin V-FITC and 10  $\mu$ L of PI for 10 min at room temperature in the dark, followed by cytometric analysis (EPICS XL, Beckman Coulter, United States) within 30 min of staining. All experiments were performed in triplicate.

### Western blotting

Using a protein extraction kit (Biovision, CA, United States), whole-cell extracts were prepared from frozen liver tissue. Protein concentration of the extracts was determined by the Bradford method with a kit purchased from Biovision (United States). Forty micrograms of protein were separated on 10% sodium dodecyl sulfate-polyacrylamide gels and were electronically transferred onto a polyvinylidene difluoride membrane (Roche Diagnostics, Mannheim, Germany). The membrane was blocked in a standard western blotting procedure. Briefly, the membrane was blocked with 7.5% milk in tris-buffered-saline with tween (TBST) buffer [20 mmol/L Tris-HCl (pH 7.6), 137 mmol/L NaCl, 0.05% Tween 20], then probed with a primary antibody [anti-Akt, anti-phospho-Akt-Ser-473 (p-Akt) Akt, p-Akt, Fas, DR5 and HA, purchased from Cell Signaling Technology (Beverly, MA, United States). After washing with TBST buffer, the membrane was further incubated with HRP-conjugated goat anti-rabbit secondary antibody (1:20000, KPL, United States). The protein bands were visualized using an enhanced chemiluminescence detection system, LumiGLO (KPL, United States).  $\beta$ -actin (NeoMarkers, Fremont, CA, United States) was used as a loading control and normalization reference for quantification.

### Measurement of NO

Nitric acid reductase method was used to measure hepatic NO using a commercial kit (CST, United States), following the manufacture manual. Briefly, 1 g of rat liver tissue stored in the liquid nitrogen was thawed and homogenized at 4 °C in the saline at a concentration of 100 g/L. Following centrifuge (1000 r/min for 5 min), the supernatant was used for the nitric acid reductase reaction to measure product of  $\text{NO}_2^-$  and  $\text{NO}_3^-$ , which indirectly represent the level of NO.

### Examination of transplanted GFP<sup>+</sup> cells

GFP<sup>+</sup> cells in the host were examined at 8 wk after induction of cirrhosis. Mice was euthanized and infused with normal saline until the liver became pale. The liver, spleen, heart, lung, brain and kidney were collected, cryostat sectioned at a thickness of 2  $\mu$ m, and examined for GFP<sup>+</sup> cells under a fluorescence microscope (E80i, Nikon, Japan). A fraction of the tissues from the above organs were also formalin-fixed, paraffin-embedded, continuously sectioned for H and E (hematoxylin and eosin) staining and histological analysis.

### Statistical analysis

## RESULTS

### Preparation of Ad-myr-HA-Akt virus and transfer to rats

As detailed in the method, the Ad-myr-HA-Akt virus was confirmed using PCR amplification of inserted Akt gene and sequencing for full length of inserted fragment, which was consistent with the sequence reported in the GenBank. The concentrations of Ad-myr-HA-Akt and Ad-EGFP virus used in the current study were  $5.5 \times 10^{11}$  vp/mL. The virus was introduced to animal through tail vein injection. According to the control vector with expression of green fluorescent protein (GFP), the distribution of virus was mainly in the liver (Figure 1).

### Hemodynamic results of portal vein in different experimental groups

Five rats from each group (normal control group, untreated cirrhosis, saline cirrhosis, Ad-EGFP, and Akt cirrhosis groups) were subjected to measure portal vein diameter (D) and peak velocity of blood flow (V) and calculation of portal Q and CI (Figure 2). As shown in the Table 1, these parameters were significantly increased

**Table 3** Portal vein pressure, mean arterial pressure and heart rate in each experiment group at the end of the treatment

in untreated, saline and Ad-EGFP cirrhosis groups when compared to normal control. In contrast, these parameters in the Akt cirrhosis group were comparable to normal control group.

### Ad-myr-HA-Akt virus was able to preserve liver function and reduce portal hypertension

Eight weeks after cirrhosis induction, blood samples from portal vein were collected and subjected to the measurement of ALT, AST and ALB. As shown in the Table 2, compared to the normal control, the liver function was significantly impaired in the untreated, saline and Ad-EGFP cirrhosis groups. However, the Akt cirrhosis group showed significant improvement of liver function (lower levels of the four parameters) when compared to the untreated, saline and Ad-EGFP cirrhosis groups. Consistently, the Hyp level (Table 2) and portal vein pressure (Table 3) in Akt cirrhosis groups were also significantly lower than other cirrhosis groups (untreated, saline and Ad-EGFP). Of note, Mean arterial pressure and heart rate did not show significant differences among the groups.

### Ad-myr-HA-Akt virus significantly reduced the liver fibrosis

To determine whether the above observations were derived from the histological changes of liver, we examined cellular and tissue structure and collagen deposition using HE and VG staining, respectively (Figure 3). Our results indicated that Akt group has better preservation of histological structure and less fibrosis than other cirrhosis groups. Collectively, these data supported that Ad-myr-HA-AKT virus was efficient in inhibiting the development of cirrhosis induced by CCl<sub>4</sub>.

### Ad-myr-HA-Akt virus inhibited apoptosis of hepatocytes

To confirm the reduction of liver fibrosis was related to the reduction of apoptosis of hepatocytes, we doubly stained hepatocytes with PI and Annexin V to detect the apoptosis rate in each experimental group. As shown in Figure 4, the percentage of apoptotic cell was greatly less in Akt cirrhosis group than in other cirrhosis groups (2.5%-3.9% reduction). These results suggested that

Figure 1 Tissue distribution of transferred viruses in the host. Representative micrographs from each organ (as designated) are shown for the presence of green fluorescent protein (GFP), which is a marker for the presence of the recombinant virus. GFP was primarily observed in the liver (top panel) and rarely present in other organs.

Figure 2 Measurement of hemodynamic parameter of portal vein. Representative graphs for identifying portal vein and measurement of hemodynamic parameters using ultrasound.

amelioration of liver function and fibrosis in Akt may be involved in the reduction of apoptosis of hepatocytes.

#### ***Ad-myr-HA-Akt virus inhibited apoptotic mediators***

Next, to confirm the apoptosis, we measured the expression levels of apoptotic mediators using Western blotting. As shown in Figure 5A, Akt group showed positive HA tag and an increased level of phosphorylated Akt

(p-Akt) as well as decreased levels of Fas. The levels of p-Akt and Fas are comparable in Akt cirrhosis group and normal control group. In contrast, Caspase-3 and Caspase-9 levels in Akt group were significantly lower than other cirrhosis groups (untreated, saline and Ad-EGFP groups). These results suggested that introduction of Ad-myr-HA-Akt virus resulted in the inhibition of Fas-mediated apoptotic pathway, which presumably led to the

Figure 3 Histological changes in rat with cirrhosis induced by CCl<sub>4</sub>. Livers from rats in each experimental group were collected 8 wk after CCl<sub>4</sub> treatment, sectioned, and subjected to HE and van gieson staining for tissue structure and collagen deposition. While cirrhosis groups without treatment or received saline or ad-enhanced green fluorescent protein treatment show structure disruption and nodule formation as well as remarkable deposition of collagen, cirrhosis group with Akt virus transfer show well preserved tissue structure and less collagen, both of which are comparable to normal control (magnification × 100).

Figure 4 Flow cytometry analysis for hepatocyte apoptosis in each experimental group. Single hepatocytes from each experiment groups were prepared at 2 wk after CCl<sub>4</sub> treatment, and subjected to double staining of Propidium iodide (PI) and Annenin V to detect the dead and apoptotic cell. Representative data from each group are shown with designated name. Double positive cell with PI and Annenin V were considered as apoptotic dead cells and its percentage is listed in the right up-per quadrant of the plot.

<sup>a</sup>P < 0.05 (*vs* normal control); <sup>c</sup>P < 0.05 (*vs* Untreated group); <sup>d</sup>P < 0.05 (*vs* Saline group); <sup>e</sup>P < 0.05 [*vs* enhanced green fluorescent protein (EGFP) group]. No difference was detected among Untreated, Saline and EGFP groups.

reduction of the apoptosis of hepatocytes.

#### Ad-myr-HA-Akt virus inhibited activation of hepatic stellate cell and increased the levels of eNOS activity and NO production

To understand the mechanism underlying the hepatocyte apoptosis and fibrosis of liver, we further measured two markers (DR5 and α-SMA) for the activation of HSC and the levels of eNOS and its phosphorylation status that is correlated to the NO production. Noticeable decrease of DR5 and α-SMA (Figure 5A) and increase of phosphorylated eNOS (Figure 5B) were observed in the Akt group when compared to other cirrhosis groups (untreated, saline and Ad-EGFP). As shown in Table 4, the NO level in liver was significantly higher in Akt group than other cirrhosis groups (untreated, saline and Ad-EGFP), which was consistent with the level of phosphorylated eNOS in these group. Collectively, these results suggested that introduction of Ad-myr-HA-Akt virus blocked the activation of HSC and maintained NO level, which may subsequently reduced liver fibrosis and blood vessel resistance following the damage from CCl<sub>4</sub>.

## DISCUSSION

Fas is one of the most important receptors on cell sur-

face to mediate apoptosis<sup>[26-29]</sup>. It has been shown that FasL-Fas pathway is an important cascade leading to hepatocyte apoptosis, which in turn activates HSC that produce collagen<sup>[11-5]</sup>. Song *et al*<sup>[30]</sup> showed that block of Fas signaling pathway could inhibit the development of cirrhosis. Akt plays important roles in regulating cell survival through inhibiting Fas-mediated apoptosis<sup>[11,12]</sup>. In the current study, we utilized the constitutive expression of active form of Akt to block cirrhosis induced by CCl<sub>4</sub>. The efficacy of this virus was firstly confirmed at the level of liver function. Furthermore, using multiple approaches, we examined whether the transfer of Akt *via* this virus in liver could result in the molecular alterations that favor the survival of hepatocyte and/or disfavor the fibrosis. Our data indicated that Ad-myr-HA-Akt virus was a useful tool to prevent CCl<sub>4</sub>-induced cirrhosis in rat model.

Encouragingly, the data obtained at different levels, from function to histological changes, apoptosis rate of hepatocytes, activation of HSC, deposition of collagen, portal vein pressure and NO level, which were all consistently and collectively supported the hypothesis that introduction of Ad-myr-HA-Akt virus inhibits the development of cirrhosis. First, all measured parameters for liver function were consistent with reduced hepatocyte apoptosis: the introduction of Akt virus led to increased expression of Akt and its phosphorylation, decreased expression of apoptotic mediators (Caspase-9 and Caspase-3) and ultimately preserved liver functions (enzyme levels). Second, the portal vein pressure was consistent with the histological structure as well as NO levels. The introduction of Akt virus led to reduction of formation of liver nodules, portal vein pressures and increased level of NO, which is directly correlated with vasodilation. Third, the level of specific marker (Hyp) for the liver fibrosis was consistent with the amount of deposition of collagen and the expression of α-SMA and DR5, markers for activated HSC.

While the introduction of Ad-myr-HA-Akt virus led to the rescue of phosphorylated Akt level as well as in-

**Figure 5** Western blotting analysis for apoptotic mediators and activation of hepatic stellate cells and endothelial nitric oxide synthase level. **A:** Apoptotic mediators and activation of HSC; Liver tissue from each group of rats were homogenized and subjected to measurement for the levels of Akt, phosphorylated Akt (p-Akt), Fas, Caspase-9 and Caspase-3, and HSC activation markers, DR5 and  $\alpha$ -SMA, as designated in the figure. **B:** eNOS level; Liver tissues from each group of rats were homogenized and subjected to the measurements for Akt, pAkt, eNOS and phosphorylated eNOS (p-eNOS). Blotting of HA was used to confirm the expression of recombinant HA-Akt protein, and  $\beta$ -actin was used for the loading control. Data are representative of 3 experiments. hibition of apoptotic pathway in the liver of rat cirrhosis model. However, several issues remain to be addressed regarding the application of this virus for the treatment for cirrhosis. First, the efficacy of this form of virus in other type of cirrhosis, especially those chronically developed remains to be determined. In addition, regarding the development of the cirrhosis, it was thought that HSC activation plays a crucial role in producing collagen<sup>[1-5]</sup>. While we speculate that reduced HSC activation in Akt group may be a subsequent outcome of reduced hepatocyte apoptosis, it is unknown whether the introduction of Akt-virus has a direct effect on HSC activation. Furthermore, we observed that rats in the cirrhosis groups without treatment or received saline or Ad-EGFP treatment showed a noticeable reduction of phosphorylated Akt level, suggesting that the damage of hepatocytes following CCl<sub>4</sub> treatment may also be involved in the disruption of Akt signaling pathway. Lastly, one of the risks of the constitutive activation of Akt is the increased susceptibility to tumorigenesis. We could not conduct a long-term study to determine the time of virus clearance and evalu-

ate the risk of tumor development. As future directions, we will further determine the application of this virus in other forms of cirrhosis and assess its side effects.

## ACKNOWLEDGEMENTS

We thank Dr. Liwu Gou (Buffloa Roswell Park institute, New York State University, United States) for providing pcDNA3.1-myr-HA-Akt.

## COMMENTS

### Background

Massive apoptosis of hepatocytes result in activation of hepatic stellate cells (HSC), which produce collagen and ultimately lead to the fibrosis and cirrhosis. Inhibiting hepatic apoptosis is considered as an important strategy to prevent cirrhosis. Akt plays a crucial role in preventing Fas signaling-mediated hepatic apoptosis, and that over-expression of Akt was capable of preventing hepatic apoptosis.

### Research frontiers

The progress in understanding mechanisms of cirrhosis brings the development of effective therapies closer to reality. Points of therapeutic intervention may include: (1) removing the injurious stimuli; (2) suppressing hepatic inflammation; (3) down-regulating stellate cell activation; and (4) promoting matrix degradation. The future prospects for effective treatment are more promising than ever for the millions of patients with chronic liver disease worldwide.

### Innovations and breakthroughs

To date, there have been a number of studies regarding the therapeutic implication of hepatic cirrhosis. However, the research about the strategy to block apoptotic signaling pathway are limited. In this study, the authors created an Ad-myr-HA-Akt virus and determined the efficacy of this virus in inhibiting the development of cirrhosis induced by CCl<sub>4</sub> in rats. The authors confirmed that that introduction of Ad-myr-HA-Akt virus was not only able to ameliorate the liver cirrhosis but also to reduce the portal vein pressure.

### Applications

These results could be the basis for further studies to understand the pathogenesis of hepatic cirrhosis. The conclusion suggest that Akt pathway may be a therapeutic target for human cirrhosis.

### Terminology

HSC, also known as perisinusoidal cells or Ito cells are pericytes found in the perisinusoidal space of the liver. Substantial evidence now exists to recognize HSCs as the main matrix-producing cells in the process of liver cirrhosis. Liver injury of any etiology will ultimately lead to activation of HSCs, which undergo transdifferentiation to fibrogenic myofibroblast-like cells.

### Peer review

Authors demonstrated that Akt improved liver histology and function and reduced portal venous pressure, liver apoptosis and collagen levels is useful for accurate understanding the progress of hepatic cirrhosis and also give a feasible target for the therapy of cirrhosis.

### Abstract

**AIM:** To investigate the expression of insulin-like growth factor-1 (IGF-1)/insulin-like growth factor-1 receptor (IGF-1R) in colorectal cancer (CRC) tissues and to analyze their correlation with lymphangiogenesis and lymphatic metastasis.

**METHODS:** Immunohistochemistry was used to evaluate IGF-1 and IGF-1R expression and lymphatic vessel density (LVD) in 40 CRC specimens. The correlation between IGF-1/IGF-1R and LVD was investigated. Effects of IGF-1 on migration and invasion of CRC cells were examined using transwell chamber assays. A LoVo cell xenograft model was established to further detect the role of IGF-1 in CRC lymphangiogenesis *in vivo*.

**RESULTS:** Elevated IGF-1 and IGF-1R expression in CRC tissues was correlated with lymph node metastasis ( $r = 0.715$  and  $0.569$ , respectively,  $P < 0.05$ ) and tumor TNM stage ( $r = 0.731$  and  $0.609$ ,  $P < 0.05$ ). A higher LVD was also found in CRC tissues and was correlated with lymphatic metastasis ( $r = 0.405$ ,  $P < 0.05$ ). A positive correlation was found between LVD and IGF-1R expression ( $r = 0.437$ ,  $P < 0.05$ ). Transwell assays revealed that IGF-1 increased the migration and invasion of CRC cells. *In vivo* mouse studies showed that IGF-1 also increased LVD in LoVo cell xenografts.

**CONCLUSION:** IGF-1/IGF-1R signaling induces tumor-associated lymphangiogenesis and contributes to lymphatic metastasis of CRC.

**Key words:** Colorectal cancer; Insulin-like growth factor-1; Insulin-like growth factor-1 receptor; Lymphangiogenesis; Lymphatic metastasis

**Core tip:** Insulin-like growth factor-1 (IGF-1) and its receptor, insulin-like growth factor-1 receptor (IGF-1R), are frequently overexpressed in many types of tumors including colorectal cancer. A recent study (Björndahl *et al*, 2003) showed that both IGF-1 and IGF-2 could potentially stimulate lymphatic vessel growth in the mouse cornea. However, equivalent evidence on IGF-1 in solid tumors is lacking. Here, we show that IGF-1/IGF-1R signaling induces tumor-associated lymphangiogenesis *in vivo* and contributes to lymphatic metastasis of colorectal cancer. Findings from the present study provide further evidence to support the involvement of IGF-1/IGF-1R signaling in lymphangiogenesis in solid tumors.

## INTRODUCTION

Lymphatic metastasis is one of the most common metastatic routes of colorectal cancer (CRC). When cancer spreads, it is much harder to treat successfully. The presence or absence of lymph node involvement is one of the most important factors that determine the long-term outcome of cancer patients<sup>[1-3]</sup>. There is a complex process that a tumor cell must go through before metastasis can occur<sup>[4,5]</sup>. Excessive formation of new lymphatic vessels in CRC is a key step in metastatic progression<sup>[5,6]</sup>. However, the factors triggering lymphangiogenesis and the detailed molecular mechanisms are poorly understood.

Insulin-like growth factor-1 (IGF-1) and its receptor (IGF-1R) are frequently overexpressed in many types of tumors including CRC<sup>[7-10]</sup>. Increasing evidence suggests that amplified IGF-1/IGF-1R signaling not only is associated with an increased relative risk for cancer development, but also contributes to cancer cell survival, invasion, metastasis and resistance to chemotherapeutic drugs<sup>[7,10]</sup>. In addition to their roles in the development and progression of cancer, the IGF-1/IGF-1R signaling system can also induce lymphangiogenesis<sup>[11,12]</sup>. In a recent study, Björndahl *et al.*<sup>[11]</sup> reported that both IGF-1 and IGF-2 could potently stimulate lymphatic vessel growth in the mouse cornea. However, direct evidence showing the involvement of IGF-1/IGF-1R signaling in lymphangiogenesis in solid tumors is lacking.

In the present study, we found that IGF-1 and IGF-1R were significantly overexpressed in CRC tissues compared with adjacent normal tissues using an immunohistochemical (IHC) assay. Using a lymphatic endothelial-specific antibody marker D2-40<sup>[3,13]</sup>, we found that lymphatic vessel density (LVD) was significantly higher in CRC tissues. The levels of IGF-1, IGF-1R and LVD were all significantly correlated with lymphatic metastasis. In addition, a positive correlation was found between LVD and IGF-1R. These results suggest that the IGF-1/IGF-1R axis might promote lymph node metastasis of CRC by induction of lymphangiogenesis. To further explore its role in lymphangiogenesis, we created a LoVo cell (a human colon cancer cell line) xenograft model and showed that IGF-1 treatment resulted in an increase in the LVD *in vivo*. Together, our findings demonstrate that IGF-1/IGF-1R signaling can induce lymphangiogenesis in CRC and may facilitate lymphatic metastasis in CRC patients.

## MATERIALS AND METHODS

### Tissue samples

Forty CRC and adjacent normal tissue samples were

obtained from randomly selected patients undergoing surgical resection without preoperative neoadjuvant chemoradiotherapy between January 2011 and June 2011 at Shaoxing People's Hospital. Their average age was 68.5 years (range, 44 to 83 years). Of these patients, 9 had well-differentiated adenocarcinoma, 20 had moderately differentiated adenocarcinoma, and 11 had poorly differentiated adenocarcinoma. Twenty-five patients had stage I-II disease and 15 had stage III-IV disease according to the tumor-node-metastasis (TNM) classification defined by Union for International Cancer Control (UICC)<sup>[14]</sup>. D2 radical resection was performed in 3 patients and D3 radical resection was performed in 37 patients. The number of lymph nodes resected was 9-22.

### Immunohistochemical staining

Tissue sections were stained using the Envision System (DakoCytomation, Carpinteria, CA, United States) according to manufacturer's instructions. Mouse monoclonal antibodies against human IGF-1, IGF-1R, or D2-40 were obtained from Abcam (Cambridge, United Kingdom). Intensity of immunostaining signals was evaluated in 8 fields under a light microscope (Olympus Optical, Tokyo, Japan). Statistical analysis was carried out in accordance with a previous study<sup>[15]</sup>. In short, total staining of IGF-1 and IGF-1R were scored as the product of the staining intensity (on a scale of 0-3: negative = 0, weak = 1, moderate = 2, strong = 3) and the percentage of cells stained (0 = 0%, 1 = 1%-25%, 2 = 26%-50%, 3 = 51%-100%), which resulted in a scale of 0-9. Two independent pathologists scored each sample without prior knowledge of the patient's clinical information and outcome.

### Cell culture and IGF-1 treatment

The human CRC cell line LoVo was obtained from the American Type Culture Collection and maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS), 2 mmol/L L-glutamine, 100 U/mL penicillin, and 100 U/mL streptomycin in a 5% CO<sub>2</sub> incubator at 37 °C. For IGF-1 treatment, media were replaced with fresh serum-free medium containing 50 ng/mL IGF-1 (PeproTech) when cells were grown to 30% confluency. An IGF-1 stock solution was prepared in PBS, and thus, PBS in serum-free medium was used as a control.

### Migration and invasion analysis

The migration and invasion of CRC cells were examined using non-coated or matrigel-coated transwell culture chambers (8 µm pore size, Corning, NY, United States) 48 h after IGF-1 treatment. For migration assays, 1 × 10<sup>5</sup> cells were seeded in the top non-coated chamber and incubated at 37 °C for 8 h. For invasion assays, 5 × 10<sup>4</sup> cells were seeded in the top Matrigel-coated (BD Biosciences, Bedford, MA, United States) chambers and incubated at 37 °C for 24 h. In both assays, cells were suspended in serum-free Roswell Park Memorial Institute (RPMI)-1640 medium in the upper chamber, and the lower chamber was filled with RPMI-1640 medium containing 5% FBS. After incubation, the top chambers were wiped with cot-

ton wool to remove the non-migratory or non-invasive cells. Cells on the underside of the membrane were fixed in methanol for 30 min, stained with 0.1% crystal violet, and counted under a microscope (Eclipse TS100, Nikon, Japan).

### Xenograft and IGF-1 treatment

Four-week-old BALB/c nude mice (18–22 g) were used in this study. LoVo cells in the logarithmic phase of growth were adjusted to a density of  $5 \times 10^7$ /mL, and 0.2 mL of cell suspension was subcutaneously injected into the flank of the mice. On the second day after LoVo cell transplantation, the mice were randomized into either a treatment or a control group, with ten mice in each group. Referring to previous reports<sup>[16–19]</sup>, IGF-1 (50 µg/kg) was administered every day by intraperitoneal injection in the treatment group. The mice in the control group received the same amount of normal saline. Three weeks after treatment, the cancer tissues were dissected from the nude mice for measurement of LVD.

### Measurement of LVD

LVD in tissue sections was quantitatively analyzed using the EnVision system with the specific lymphatic endothelial cell marker, D2-40, which allows for accurate discrimination of lymphatic vessels from blood vessels<sup>[3,13]</sup>. Five fields with the most abundant lymphatic regions (hot spots) were chosen by light microscopy at 40 × magnification. The LVD was then assessed by counting all stained vessels at 200 × magnification. Single immunoreactive endothelial cells or endothelial cell clusters separated from other microvessels were counted as a vessel according to previous procedures<sup>[20]</sup>. The average number of lymphatic vessels in five selected fields was taken as the LVD on the slide.

### Statistical analysis

All statistical analyses were performed using SPSS (version 12.0, SPSS Inc, United States). Student's *t* test test, Mann-Whitney *U* test and  $\chi^2$  test were used for statistical analyses. Spearman's rank correlation was used for corre-

lation analysis. *P* values < 0.05 were considered statistically significant.

## RESULTS

### Up-regulation of IGF-1 and IGF-1R in colorectal cancer

Immunohistochemistry analysis was performed to examine the expression of IGF-1 and IGF-1R in CRC samples. IGF-1 and IGF-1R were weakly or negatively stained in tumor-adjacent normal tissues. In contrast, they were weakly or moderately stained in well-differentiated CRC tissues, and moderately or strongly stained in moderately and poorly differentiated CRC tissues (Table 1 and Figure 1). As expected, expression of IGF-1 was detected primarily in the cytoplasm and IGF-1R was detected on the membrane (Figure 1). Furthermore, the expression of IGF-1 and IGF-1R was correlated with lymph node metastasis ( $r = 0.715$  and  $0.569$ , respectively;  $P < 0.05$ ) and TNM stage ( $r = 0.731$  and  $0.609$ , respectively;  $P < 0.05$ ). These results indicate that elevated expression of IGF-1/IGF1R parallels CRC progression.

### Correlation between LVD and expression of IGF-1/IGF-1R

It was reported that LVD is an indicator of lymphangiogenesis<sup>[3,21]</sup>. D2-40 is a specific lymphatic endothelial cell marker for the evaluation of LVD in human cancers<sup>[3,13]</sup>. Using IHC, we found that D2-40 was localized in the cytoplasm and membrane of lymphatic endothelial cells (Figure 2). LVD was significantly higher in CRC tissue as compared to non-tumor tissue ( $11.45 \pm 3.03$  vs  $3.25 \pm 1.28$ ,  $P < 0.05$ ). LVD in tumor tissues with lymph node metastasis was higher than that in tissues without metastasis ( $12.67 \pm 4.09$  vs  $10.72 \pm 1.90$ ,  $P < 0.05$ ) (Table 2 and Figure 2). Lymphatic vessel invasion was also detected in CRC tissue (Figure 2B and C). There was a significant correlation between LVD and lymphatic metastasis ( $R = 0.405$ ,  $P < 0.05$ ). In addition, a statistically significant correlation was also found between LVD and IGF-1R ( $R = 0.437$ ,  $P < 0.05$ ). These results suggest that the IGF-1/IGF-1R system might promote lymph node metastasis of CRC through induction of lymphangiogenesis.

### IGF-1 increases migration and invasion of LoVo cells

In transwell migration assays, a significantly higher number of cells migrated through the chamber membrane after IGF-1 treatment ( $196.4 \pm 21.6$  vs  $96.4 \pm 11.2$ ,  $P < 0.05$ , Figure 3A). Similar results were obtained in the transwell invasion assays. Cells which migrated through the matrigel and chamber membrane increased in the IGF-1-treated group ( $163.6 \pm 19.4$  vs  $72.5 \pm 9.1$ ,  $P < 0.05$ , Figure 3B). These results indicated that IGF-1 increased the migration and invasion potential of CRC cells.

### Effects of IGF-1 on LVD of LoVo cell xenografts in nude mice

To assess whether IGF-1 affected lymphangiogenesis in CRC *in vivo*, LoVo cells were implanted subcutaneously

**Figure 1** Immunohistochemical staining of insulin-like growth factor-1 and insulin-like growth factor-1 receptor in colorectal cancer tissues. A: Tumor-adjacent normal tissues; B: Moderately differentiated CRC and C, poorly differentiated CRC ( $\times 200$ ). IGF-1: Insulin-like growth factor-1. IGF-1 R: Insulin-like growth factor-1 receptor; CRC: Colorectal cancer.

into nude mice. Three weeks after daily IGF-1 or vehicle administration, tumor tissues were removed and measured. IHC analysis using anti-D2-40 antibodies revealed that LVD of LoVo cell xenografts was significantly higher in the IGF-1 group than in the control group ( $10.7 \pm 3.3$  vs  $6.4 \pm 2.9$ ,  $P < 0.05$ , Figure 4).

## DISCUSSION

The importance of lymph node metastasis in cancer pro-

Figure 3 Effect of insulin-like growth factor-1 on the migration and invasion of LoVo cells after 48 h treatment. A: Cell migration; B: Cell invasion ( $\times 200$ ). IGF-1: Insulin-like growth factor-1.

Figure 4 Effect of insulin-like growth factor-1 on lymphatic vessel density in LoVo cell xenografts in nude mice after treatment with insulin-like growth factor-1. gression has been well established and is considered one of the most important prognostic factors<sup>[1,2,22,23]</sup>. Recently, there is growing evidence that tumor lymphangiogenesis plays an important role in this process<sup>[5,6]</sup>. However, the detailed molecular mechanisms that regulate lymphangiogenesis remain largely unknown. In the present study, we have shown that IGF-1/IGF-1R signaling can induce tumor-associated lymphangiogenesis, and therefore, may facilitate further lymphatic metastasis of CRC.

IGF-1 and its receptor IGF-1R are frequently expressed in many solid tumors and have been implicated in cancer metastasis<sup>[7,24-26]</sup>. In 1999, Hakam *et al*<sup>[27]</sup> showed that IGF1-R plays a role in the evolution of colorectal adenoma to carcinoma and favors the metastasis of CRC.

In a recent study, Wu *et al*<sup>[28]</sup> reported that IGF-1 is critical in activating and sustaining an inflammatory response in the liver which is needed for CRC hepatic metastasis. In the present study, we found that IGF-1 and IGF-1R protein expression was elevated in CRC tissues, and their expression was correlated with clinical stage and lymphatic metastasis, which is consistent with the reported data.

Lymphangiogenesis, the formation of new lymphatic vessels, is a key process in lymphatic invasion and metastasis<sup>[29]</sup>. Numerous studies have shown that LVD is an indicator of lymphangiogenesis and represents a tool to determine the metastatic risk of neoplasia<sup>[3,21,29]</sup>. A study by Cacchi *et al*<sup>[1]</sup> revealed that CRC could induce lymphangiogenesis and a higher LVD could increase the

capability of cancer cells to invade the lymphatic system. In another study, Matsumoto *et al.*<sup>[30]</sup> reported that both LVD and lymphatic vessel invasion were related to an adverse outcome in CRC. Similar results were obtained in this study. In addition, lymphatic vessel invasion was also detected in CRC tissue by IHC staining. Moreover, a statistically significant correlation was found between LVD and the level of IGF-1R in CRC tissue. This suggests that IGF-1/IGF-1R signaling probably facilitates metastasis of CRC by inducing tumor-associated lymphangiogenesis.

Recently, a number of lymphangiogenic factors which stimulate the proliferation of lymphatic vessels and lymphangiogenesis have been identified, including vascular endothelial growth factor (VEGF)-A, VEGF-C, VEGF-D, fibroblast growth factor 2, and platelet-derived growth factors<sup>[11,31]</sup>. Most of these lymphangiogenic factors were shown to be directly or indirectly regulated by IGF-1<sup>[11,12,32]</sup>. These findings prompted us to hypothesize that IGF-1/IGF-1R signaling promotes lymphangiogenesis. In 2005, Björndahl *et al.*<sup>[11]</sup> reported that both IGF-1 and IGF-2 could stimulate lymphatic vessel growth in the mouse cornea. However, to date, it is still unclear whether a similar correlation exists in solid tumors. Here, we showed that IGF-1 could also induce lymphangiogenesis in CRC. The spread of metastasis then occurs through the new lymphatic vessel system in the tumor.

Tumor lymphangiogenesis and metastasis to lymph nodes are a complex process and a number of growth factors are involved in these events. IGFs are particularly interesting regulators due to their multiple roles in promoting tumor growth<sup>[33-35]</sup>. Here, the *in vivo* studies provided direct evidence that the IGF-1/IGF-1R axis can also induce lymphangiogenesis in solid tumors. However, so far, it is not known whether the IGF-1/IGF-1R axis directly acts on lymphatic endothelial cells to induce lymphangiogenesis or indirectly *via* other growth factor/receptor systems. In addition, the detailed mechanisms underlying lymphangiogenesis associated with the IGF-1/IGF-1R system are largely unknown. Therefore, additional efforts are warranted to study the relationship between IGF-1/IGF-1R and lymphangiogenesis in cancer.

In summary, we found that the IGF-1/IGF-1R system can induce tumor-associated lymphangiogenesis and facilitate lymphatic metastasis of CRC. Findings from the present study provide further evidence supporting the involvement of IGF-1/IGF-1R signaling in lymphangiogenesis in solid tumors. In addition, we also found that increased expression of IGF-1 and IGF-1R is correlated with tumor differentiation in human CRC. Our findings and others suggest that the IGF-1/IGF-1R axis plays critical and diverse roles in promoting tumor progression. Taken together, the IGF-1/IGF-1R axis is a potentially useful target for the treatment of cancer and metastasis.

growth factor-1 (IGF-1) and insulin-like growth factor-1 receptor (IGF-1R) are frequently overexpressed in many types of tumors including colorectal cancer. In addition to their role in the development and progression of cancer, the IGF-1/IGF-1R signaling system can also induce lymphangiogenesis.

### Research frontiers

A recent study (Björndahl *et al.*, 2003) showed that both IGF-1 and IGF-2 potentially stimulated lymphatic vessel growth in the mouse cornea. However, equivalent evidence in solid tumors is lacking.

### Innovations and breakthroughs

The authors of this paper demonstrate that the IGF-1/IGF-1R system can induce tumor-associated lymphangiogenesis in colorectal cancer (CRC) and contributes to its lymphatic metastasis, thus providing a novel mechanism for lymphangiogenesis in solid tumors.

### Applications

The findings of this study are of value in further explaining the molecular mechanisms of lymphangiogenesis in CRC. The IGF-1/IGF-1R axis may be a potential target for the treatment of cancer and metastasis.

### Terminology

IGF-1 is a hormone similar in molecular structure to insulin. It plays an important role in child growth and continues to have anabolic effects in adults. The role of IGF-1 in promoting cancer has been investigated for many years. Increasing evidence suggests that IGF-1 not only is associated with an increased relative risk for the development of cancer, but also contributes to cancer cell survival, invasion, metastasis and resistance to chemotherapeutic drugs.

### Peer review

The authors examined the expression of IGF-1/IGF-1R in CRC tissues and its correlation with lymphangiogenesis and lymphatic metastasis. The study revealed that IGF-1/IGF-1R signaling system induces lymphangiogenesis in CRC and contributes to lymphatic metastasis of CRC. The results are interesting and provide further evidence that IGF-1/IGF-1R signaling is involved in lymphangiogenesis in solid tumors.

### Abstract

**AIM:** To study the differential expression of Annexin A1 (ANXA1) protein in human gastric adenocarcinoma. This study was also designed to analyze the relationship between ANXA1 expression and the clinicopathological parameters of gastric carcinoma.

**METHODS:** Purified gastric adenocarcinoma cells (GAC) and normal gastric epithelial cells (NGEC) were obtained from 15 patients with gastric cancer by laser capture microdissection. All of the peptide specimens were labeled as  $^{18}\text{O}/^{16}\text{O}$  after trypsin digestion. Differential protein expressions were quantitatively identified between GAC and NGEC by nanoliter-reverse-phase liquid chromatography-mass/mass spectrometry (nano-RPLC-MS/MS). The expressions of ANXA1 in GAC and NGEC were verified by western blot analysis. The tissue microarray containing the expressed ANXA1 in 75 pairs of gastric carcinoma and paracarcinoma specimens was detected by immunohistochemistry (IHC). The relationship between ANXA1 expression and clinicopathological parameters of gastric carcinoma was analyzed.

**RESULTS:** A total of 78 differential proteins were identified. Western blotting revealed that ANXA1 expression was significantly upregulated in GAC ( $2.17/1$ ,  $P < 0.01$ ). IHC results showed the correlations between ANXA1 protein expression and the clinicopathological parameters, including invasive depth (T stage), lymph node metastasis (N stage), distant metastasis (M stage) and tumour-lymph node metastasis stage ( $P < 0.01$ ). However, the correlations between ANXA1 protein expression and the remaining clinicopathological parameters, including sex, age, histological differentiation and the size of tumour were not found ( $P > 0.05$ ).

**CONCLUSION:** The upregulated ANXA1 expression may be associated with carcinogenesis, progression, invasion and metastasis of GAC. This protein could be considered as a biomarker of clinical prognostic prediction and targeted therapy of GAC.

**Key words:** Gastric cancer; Annexin A1 protein; Pro-

teomics; Tissue microarray; Immunohistochemistry

**Core tip:** The anti-inflammatory protein Annexin A1 (ANXA1) mediates various important physiological and pathophysiological processes. Evidence has shown that ANXA1 is related to the development and progression of human multi-tumours. However, the ANXA1 expression in gastric adenocarcinoma of Chinese patients and the relationship between this protein and its clinicopathological parameters remain unclear. In the present study, the ANXA1 expression in gastric adenocarcinoma of Chinese patients was investigated by proteomics and western blot analysis. Authors examined 75 pairs of gastric adenocarcinoma and paracarcinoma tissues by tissue microarray to determine the presence of ANXA1 by immunohistochemistry. They found that ANXA1 expression was upregulated and involved in human gastric adenocarcinoma invasion and metastasis. Our findings suggested that ANXA1 might be used as a valuable biomarker in clinical diagnosis, prognostic prediction and targeted therapy of gastric cancer.

## INTRODUCTION

Gastric cancer (GC) is a common digestive tract cancer because of the lack of early diagnosis strategies; a previous study revealed that GC cases are usually diagnosed when the disease is at an advanced stage<sup>[1]</sup>. On the basis of metastasis, recurrence and other causes, the treatment and prognosis of GC remain poor. Therefore, effective biomarkers of GC should be determined; the mechanism of incidence and development should also be investigated to promote early diagnosis, effective treatment and prognosis improvement of GC.

Annexin A1 (ANXA1) is a key member of the A subfamily and belongs to the multi-gene family of Annexins. ANXA1 exhibits calcium-mediated phospholipid binding properties and participates in many physiological and pathological processes. Further studies have shown that ANXA1 is abnormally expressed in various tumours. This abnormal expression is closely related to tumorigenesis, development, invasion and metastasis of human tumours. The expression of ANXA1 in tumours is tissue specific; for instance, a low ANXA1 expression is observed in oesophageal squamous cell carcinoma<sup>[2]</sup>, whereas a high expression is found in colorectal cancer<sup>[3]</sup>. The relationship between ANXA1 expression in GC and GC invasion as well as metastasis remains unclear. ANXA1 also exhibits a low expression in GC and negatively correlates with invasion and metastasis<sup>[4]</sup>. However,

other studies have revealed opposite results<sup>[5,6]</sup>.

We performed laser capture microdissection (LCM) to investigate the relation of ANXA1 expression in GC to the clinical parameters and to obtain purified gastric adenocarcinoma cells (GAC) and normal gastric epithelial cells (NGEC). <sup>18</sup>O/<sup>16</sup>O was used to label the digested peptides in the mixture of GAC and NGEC. Nanoliter-reverse-phase liquid chromatography-mass/mass spectrometry (nano-RPLC-MS/MS) was performed to identify and quantify the differentially expressed proteins. Nano-RPLC-MS/MS was also conducted to validate the results of proteomics. To verify the differential protein expression of ANXA1, we performed western blot. Immunohistochemistry (IHC) was performed to detect the expression of ANXA1 in 75 pairs of tissue microarray of GC tissues and paracarcinoma tissues. This study aimed to analyze the correlations of ANXA1 with clinical pathological parameters, including age, gender, differentiation degree, metastasis, invasion depth, tumour-lymph node metastasis (TNM) staging and tumour size (maximum diameter). This study also investigated the relations and possible mechanisms of the expression differences of ANXA1 protein in carcinogenesis, progression and prognosis of GC.

## MATERIALS AND METHODS

### Specimen collection and handling

Fifteen cases of GAC and paired gastric mucosa tissues were obtained from the First Affiliated Hospital of Xinjiang Medical University from June 2009 to October 2009 and used as the surgical resection specimens. Six female and nine male subjects aged 40-81 years (mean age of 56 years) and classified in TNM stages I to IV participated in this study. GC and paragastric mucosa tissues (located away from the primary tumour > 5 cm) with a size of approximately 1.0 cm<sup>2</sup> were obtained within 30 min of surgical resection. The tissues were washed immediately and repeatedly with normal saline to remove blood and other tissues. Afterwards, these tissues were stored at -80 °C in a refrigerator for future proteomics and western blot analysis. Informed consent was obtained from the patients to allow the collection and use of the samples. The procedures were also reviewed and approved by Xinjiang Medical Ethics Committee.

### LCM for target cells and protein sample preparation

Frozen sections of GAC and paragastric mucosa tissues (8-10 μm) were prepared, affixed on LCM-specific film slides, fixed with 75% ethanol and stained with methyl green dye (Sigma-Aldrich, United States). The LCM system (Leica AS, Germany) was manipulated to determine GAC and NGEC. Tissue cell lysate was added and the total proteins of the purified GAC and NGEC were extracted. 2D Quant Kit (Amersham Biosciences, Sweden) was used to determine the protein concentration. We performed 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) to pre-separate the total proteins of cleaved GAC and NGEC with a sample

loading volume of 100 µg. The gel was then stained with Coomassie R-250. The parallel gel bands were cut to obtain 36 pairs of protein gel bands. The obtained bands were washed, bleached, dehydrated, reduced with dithiothreitol (Amersham Biosciences, Sweden), alkylated with IAA and vacuum dried by centrifugation. Trypsin (Promega Corporation, United States) was added to initiate digestion. The peptides were extracted, mixed and dried. Afterwards,  $^{18}\text{O}/^{16}\text{O}$  notation was performed by adding 8 µL of  $\text{H}_2^{18}\text{O}$  (or  $\text{H}_2^{16}\text{O}$ ; Huayi Isotope Corporation, Jiangsu) and 2 µL of acetonitrile (Sigma-Aldrich Inc., United States) to the mixed polypeptides, which also contained immobilized trypsin (Pierce, United States). The resulting mixture was then incubated at 37 °C for 24 h. At the end of the labelling reaction, 1 µL of formic acid was added to terminate the reaction.

### Protein identification and mass data analysis

The mobile phase solution A (0.1% formic acid in water) was added into Eppendorf tubes containing different peptide mixtures, shaken and centrifuged. The supernatant was extracted and added into a tapered bottom vial in the Ultimate FAMOS LC system autosampler. Isolation was performed using nano-RPLC-MS/MS instrument, in which an auxiliary pump was used to load the samples with mobile phase solution A at a flow rate of 20 µL/min for 10 min. The samples were then loaded in a pre-column and desalted. The pre-column was switched and connected to a capillary analytical column for gradient elution using the solvent gradient as follows: solution B [water/acetonitrile (v/v) containing 0.1% formic acid], 5% B, 0-10 min; 5%-90% B, 55 min; 90% B, 5 min; and 90%-0% B, 10 min. After equilibrium was reached for 15 min, separation was performed. Nanoliter analytical column flow rate was approximately 250 nL/min; therefore, the eluent could be placed directly in the Electrospray ionization ion Q-TOF mass spectrometer (Micromass Corporation, United Kingdom) for analysis. The standard peptide Glu-Fibrino peptide B was used as an external calibration standard of the mass spectrometer. The mass data provided peaklist files in Masslynx 4.0 software of the local Mascot 2.0 IPI database to search the protein database and identify the proteins. Quantitative analysis was performed in Masslynx according to the following procedures: the MS spectra containing the peptides used for quantification were obtained from the total ion chromatograph to integrate and form the spectrum of quantitative analysis;  $^{16}\text{O}/^{18}\text{O}$  ratio was then calculated according to Eq. (1)<sup>[7]</sup>.

### Detection of differential ANXA1 expression levels by Western blot

Fifteen pairs of microdissected and purified GAC and NGEAC were added to the tissue lysate pre-cooled at 4 °C, vortexed and cleared in an ice bath for 30 min. Afterwards, the samples were centrifuged at 12000 r/min and 4 °C for 30 min. The supernatant (the total cellular protein) was then transferred to a new tube. The protein con-

centration was determined using Bradford method and the total protein was determined by separation *via* 10% PAGE at 100 V for approximately 2 h (loading volume of 40 µg). The protein was electronically transferred to a Polyvinylidene difluoride membrane. Rabbit anti-human ANXA1 antibody (1/500) was added and incubated at 4 °C overnight. HRP-labeled goat anti-mouse secondary antibody (1/2000) incubated at room temperature for 2 h was also added. Enhanced chemiluminescence reagent lightening, developing and fixing were conducted. The obtained images were scanned to calculate the relative expression levels of the differential proteins in Quantity One software.

### Immunohistochemical detection of the tissue microarray of ANXA1 expression

A total of 75 pairs of human GC tissue microarray (Shanghai Outdo Biotech Co., Ltd., China), including paired GC tissues and paraGC tissues were obtained from 50 males and 25 females aged 30-84 years (average age of 63.6 years). Among these subjects, 12 cases were in Phase I, 25 cases in Phase II, 32 cases in Phase III and 4 cases in Phase IV stage cases (according to the TNM classification Standard, 7<sup>th</sup> edition, developed by the International Union Against Cancer in 2009). The clinical pathological data were complete: the cases showing tumours that invaded the submucosa, muscularis, serosa and serosa were 6, 13, 46 and 10, respectively. A total of 34 cases showed high amounts of moderately differentiated adenocarcinoma and 41 cases showed low amounts of undifferentiated adenocarcinoma. No lymph node metastasis was observed in 30 cases, but lymph node metastasis was present in 45 cases. Distant metastasis was absent in 69 cases, but 6 patients exhibited distant metastasis. According to SP method and the manufacturer's instructions, tissue microarrays were subjected to conventional dewaxing hydration and retrieved using citrate antigen. Afterwards, 3%  $\text{H}_2\text{O}_2$ -formaldehyde was used to block endogenous peroxidase. ANXA1 primary antibody (1/100) was added and incubated at 4 °C overnight. The biolabelled secondary antibody and streptavidin-peroxidase solution were added. Each sample was washed with PBS and incubated at room temperature. The sample was then stained with DAB staining, restained with haematoxylin and eosin, dehydrated with graded alcohol and mounted using neutral gum. The primary antibody was replaced with PBS as the negative control sample; the known positive reaction chip was used as the positive control sample. IHC staining score was based on Formowitz comprehensive scoring method<sup>[8]</sup> and determined according to the staining intensity and percentage of positive cells in each section. Staining intensity was scored as follows: no staining, 0; pale yellow, 1; brownish-yellow, 2; and tan, 3. At least 10 high-power fields ( $\times 200$ ) were randomly selected for each point and at least 1000 cells were counted. Among the total number of cells, the following percentages were obtained: 5% positively-stained cells scored as 0; 5%-25% scored as 1; 26%-50% scored as 2; 51%-75% scored as 3;

separate by 1D SDS-PAGE, gel digestion, extraction and <sup>18</sup>O labelling. These proteins were then identified by nano-RPLC-MS/MS. According to the standard differential proteins (where 2 < <sup>18</sup>O/<sup>16</sup>O ratio < 0.5), a total of 78 differential proteins were identified, in which the expressions of 42 proteins, including ANXA1, ANXA2, ANXA4, Protein S100-A9, and HSP 90-α2 were up-regulated in GC. By contrast, the expressions of 36 proteins were downregulated in GC, including RKIP, ADP/ATP translocase 2 and L-lactate dehydrogenase B. These differentially expressed proteins function as metabolic enzymes, enzyme proteins, cytoskeletal proteins, and signal transduction proteins; other proteins also exhibit unknown functions, in which ANXA1 expression was 2.17 times higher in GAC than in NGEC (Figure 1).

#### Western blotting analysis identification of the differential expression of ANXA1

β-actin was used as the internal standard in western blot and the maximum gray value of the strip was set as 1. The other gray value was divided by the maximum gray value, and the obtained ratio corresponded to the relative protein expression level. The results showed that ANXA1 was upregulated at a higher extent in GAC than in NGEC (*P* < 0.01). The quantitative relationships calculated from the grayscale analysis were the same as the proteomic analysis results (Figure 2, Table 1).

#### ANXA1 protein expression in tissue microarray of GC and para-tissues

IHC was performed to detect 150 points of the tissue microarray in human GC. The results showed that ANXA1 protein was positively expressed mainly in the cytoplasm and the nuclei of GC tissues and paratissues (normal mucosa). Positive expression was also observed in the stroma. ANXA1 protein was highly expressed in GC. The negative, weakly positive, moderately positive and strongly positive expression rates in GC and para-

Table 2 Annexin A1 expression in normal gastric mucosa and gastric carcinoma by immunohistochemistry n (%)

GAC	75	23 (30.7)	11 (14.7)	26 (34.7)	15 (20.0)			

*P* < 0.01 vs normal gastric mucosa group (NGEC). GAC: Gastric adenocarcinoma cells.

tissues were: 30.7%, 14.7%, 34.7% and 20.0% vs 49.3%, 33.3%, 17.3% and 0%, respectively (*w* = 4599.0, *P* < 0.01; Table 2) The ANXA1 expression was significantly related to the invasion depth, lymph node metastasis, distant metastasis and TNM staging (*P* < 0.01). By contrast, ANXA1 expression was not significantly related to age, gender, histological grade and tumour size (*P* > 0.05; Figure 3, Table 3).

## DISCUSSION

The mortality rate of GC ranks second among the mortality rates of malignant tumours and approximately 75 million people die of stomach cancer worldwide yearly<sup>[9]</sup>. The five-year survival rate of GC is only 20%-30%, and the five-year survival rate of radical resection of early GC can reach 90%-95%<sup>[10]</sup>. Molecular markers are considered as one of the most sensitive and effective indicators of tumour diagnosis, recurrence, metastasis and prognosis prediction. Therefore, the molecular markers closely associated with the development of GC and the relative pathogenesis should be determined in the early diagnosis of GC to improve treatment outcomes. Proteomics technology has an important function in the identification of tumour-related protein species in cancer development as well as in the discovery of tumour molecular markers and therapeutic targets. The present study employed simple LCM to solve problems about tumour proteomics heterogeneity, in which the purified cells exhibiting > 90% homogeneity were rapidly obtained. Using the advanced <sup>18</sup>O stable isotope labelling/MS quantitative proteomics technique, we set the normal gastric mucosa and GC tissue of humans as the targets in this study to screen and identify the differentially expressed proteins. A total of 78 differentially expressed proteins were found and 42 of such proteins were highly expressed in GC cell compared with NGEC. By contrast, 36 differentially expressed proteins were found at lower concentrations. These results provided information about differentially expressed proteins and the mechanism of GC carcinogenesis, development and screening of molecular markers.

During the screening of the identified differential proteins, ANXA1 was significantly upregulated in GC. ANXA1 is involved in various physiological and pathological processes, such as cell signal transduction, cell proliferation, differentiation and apoptosis as well as inflammation and immune response. Previous studies found that ANXA1 is upregulated in breast cancer<sup>[11]</sup>,

Figure 3 Representative immunohistochemical staining patterns of Annexin A1 expression in gastric carcinoma and normal gastric mucosa. A: Strongly positive staining; B: Moderately positive staining; C: Weakly positive staining; D: Negative staining (immunohistochemical staining × 400).

ANXA1: Annexin A1; TNM: Tumour-lymph node metastasis.

lung cancer<sup>[12]</sup>, pancreatic cancer<sup>[13]</sup>, colorectal cancer<sup>[3,14]</sup> and bladder cancer<sup>[15]</sup>. By contrast, ANXA1 is downregulated in oral squamous cell carcinoma as well as nasopharyngeal, laryngeal and other head and neck cancer<sup>[16-18]</sup>,

oesophageal squamous cell carcinoma<sup>[2]</sup> and prostate cancer<sup>[19]</sup>. The dysfunction of ANXA1 is closely related to breast cancer, lung cancer, and pancreatic cancer as well as in other tumour invasion and metastasis. There-

fore, ANXA1 is considered as a risk factor affecting the survival of patients. Wang *et al.*<sup>[20]</sup> used an immunohistochemical method and found that ANXA1 expression is 39% higher in the stomach/gastroesophageal junction adenocarcinoma and closely correlated with the pathological staging and distant metastasis of tumour, *i.e.*, higher clinical stages, particularly in distant lymph node metastasis, correspond to higher ANXA1 expression levels; higher tumour recurrence rates correspond to lower survival rate. This result suggested that the upregulation of ANXA1 could be used as a prognosis indicator in the stomach-oesophageal junction adenocarcinoma. Currently, the expression and function of ANXA1 in GC remain controversial.

In this study, quantitative proteomics was performed to screen ANXA1, revealing that ANXA1 was expressed 2.17 times higher in GC than in normal gastric mucosa. Western blotting and IHC of the tissue microarray also revealed the same results as proteomics analysis. In particular, the results showed that ANXA1 was significantly expressed at a higher extent in GC tissues than in paratissues; further analysis about the relations of ANXA1 and clinical parameters of human GAC revealed that ANXA1 expression was upregulated in tumour-penetrating serosa and thus invaded the paratissues. This result is different from human GAC normally confined to the mucosa, submucosa and muscularis; human GAC also possibly invaded the tumour in the lower serosa. ANXA1 was also highly expressed in human GAC with lymph node metastasis and distant metastasis compared with human GAC without lymph node metastasis and distant metastasis. As TNM staging increased, the positive expression rate of ANXA1 increased. However, no relationship was observed among ANXA1, patient's age, gender, histological grade and tumour size. This result suggested that ANXA1 was closely related to the biological behaviour of human GAC and involved in the development, invasion and metastasis of human GAC. Currently, the mechanism by which ANXA1 functions in the biological behaviour of GC remains unclear. Cheng *et al.*<sup>[21]</sup> reported that ANXA1 can regulate GC invasion by mediating formyl peptide receptor (FPR)/extracellular signal-regulated kinase/integrin protein  $\beta$ -1 bind protein pathway; all of the three FPRs are involved in the regulation process. Kang *et al.*<sup>[11]</sup> further found that *ANXA1* gene can decrease the activity and protein expression of matrix metalloproteinase-9 (MMP-9) transcriptional promoter by inhibiting the activity of nuclear factor  $\kappa$ -B. MMP-9 also has an important function in GC invasion and metastasis. Vascular endothelial growth factor (VEGF) is another important factor regulating angiogenesis, and angiogenesis is important in tumour growth and metastasis. Pin *et al.*<sup>[22]</sup> found that VEGF-induced cell migration and angiogenesis of miR-196a can change the expression level of ANXA1, which is controlled by p38-ANXA1 signal conduction pathway. The function of *Helicobacter pylori* (*H. pylori*) infection in GC has also been demonstrated, showing that *H. pylori* can change the cellular ANXA1

localization<sup>[23]</sup>. This result suggests that ANXA1 may be involved in *H. pylori* infection-induced GC. Furthermore, these results can explain the possible mechanism by which ANXA1 participates in GAC biological behaviour to some extent.

A few reports about ANXA1 in GC have been published. For instance, Yapar *et al.*<sup>[4]</sup> conducted an immunohistochemical study and found that ANXA1 expressed in GC is 56.3% higher than that in paratissues; this expression is also positively correlated with tumour invasion and lymph node metastasis; a high ANXA1 expression suggests poor prognosis of GC. Jorge *et al.*<sup>[6]</sup> performed RT-PCR and immunohistochemistry, revealing that ANXA1 mRNA and protein expressions are increased in GC compared with normal gastric mucosa. The results of the present study are consistent with those in the aforementioned previous studies, although other studies have revealed contrasting results. In some studies, ANXA1 is downregulated in GC<sup>[4,24]</sup> and negatively correlated with tumour staging and lymph node metastasis<sup>[4]</sup>. The reasons may be described as follows: (1) different test conditions, antibodies, and test methods; and (2) different samples or different types and pathological staging parameters of GC samples. The intracellular ANXA1, which is mainly in the cytoplasm, is possibly redistributed at different stimulations. For example, ANXA1 likely enters the nucleus as induced by an epidermal growth factor (EGF) under oxidation conditions or heat shock; by contrast, ANXA1 is transferred to the membrane and then secreted out of the cells as stimulated by GC or phorbol-12-myristate-13-acetate<sup>[25,26]</sup>. Therefore, the upregulation and downregulation of ANXA1 in GC may be associated with different stages of GC pathology. Different levels of EGF and GC *in vivo* may possibly induce cellular ANXA1 relocation. ANXA1 may also be involved in GC occurrence and development *via* different pathways and mechanisms.

In summary, the present study provided valuable information to clarify GC pathogenesis. This study also presented the basic foundation to screen cancer biomarkers. After the differential proteins of GC were initially screened, the results suggested that identification and function *in vivo* and *in vitro* of some important differential proteins require further studies. Given that ANXA1 was also expressed in gastric stromal cells, ANXA1 expression in GC may be difficult to assess by IHC. Nevertheless, the study on immunohistochemical tissue microarray revealed the relationship between ANXA1 and GC clinicopathological parameters. We found that the upregulation of ANXA1 in human GAC was closely related to the depth of tumour invasion, lymph node metastasis, distant metastasis and TNM stage. The results also suggested that ANXA1 was possibly involved in tumour invasion and metastasis. The high expression of ANXA1 suggested poor prognosis of GC. The mechanism by which ANXA1 participated in the GC biological behaviour should be further studied. With the continuous development of this research, ANXA1 may be used in early

cancer detection, diagnosis and treatment. ANXA1 may also become an indicator of cancer prognosis and a new target of cancer therapy, thereby providing new ideas of GC diagnosis and treatment.

## COMMENTS

### Background

Gastric cancer (GC) is a common digestive tract cancer because of the lack of early diagnosis strategies; a previous study revealed that GC cases are usually diagnosed when the disease is at an advanced stage.

### Research frontiers

During the screening of the identified differential proteins, Annexin A1 (ANXA1) was significantly upregulated in GC. ANXA1 is involved in various physiological and pathological processes, such as cell signal transduction, cell proliferation, differentiation and apoptosis as well as inflammation and immune response. Previous studies found that ANXA1 is upregulated in breast cancer, lung cancer, pancreatic cancer, colorectal cancer and bladder cancer. By contrast, ANXA1 is downregulated in oral squamous cell carcinoma as well as nasopharyngeal, laryngeal and other head and neck cancer, oesophageal squamous cell carcinoma and prostate cancer.

### Innovations and breakthroughs

The study performed laser capture microdissection to investigate the relation of ANXA1 expression in GC to the clinical parameters and to obtain purified gastric adenocarcinoma cells (GAC) and normal gastric epithelial cells (NGEC).  $^{18}\text{O}/^{16}\text{O}$  was used to label the digested peptides in the mixture of GAC and NGEC. Nanoliter-reverse-phase liquid chromatography-mass/mass spectrometry was performed to identify and quantify the differentially expressed proteins.

### Applications

ANXA1 may be used in early cancer detection, diagnosis and treatment. ANXA1 may also become an indicator of cancer prognosis and a new target of cancer therapy, thereby providing new ideas of GC diagnosis and treatment.

### Peer review

This study is realistic significance to the GC, This manuscript is well written. The data is interesting and worthy for publication.

### Abstract

**AIM:** To compare the outcome of acid reflux prevention by Dor fundoplication after laparoscopic Heller myotomy (LHM) for achalasia.

**METHODS:** Electronic database PubMed, Ovid (Evidence-Based Medicine Reviews, EmBase and Ovid MEDLINE) and Cochrane Library were searched between January 1995 and September 2012. Bibliographic citation management software (EndNote X3) was used for extracted literature management. Quality assessment of random controlled studies (RCTs) and non-RCTs was performed according to the Cochrane Handbook for Systematic Reviews of Interventions 5.1.0 and a modification of the Newcastle-Ottawa Scale, respectively. The data were analyzed using Review

Manager (Version 5.1), and sensitivity analysis was performed by sequentially omitting each study.

**RESULTS:** Finally, 6 studies, including a total of 523 achalasia patients, compared Dor fundoplication with other types of fundoplication after LHM (Dor-other group), and 8 studies, including a total of 528 achalasia patients, compared Dor fundoplication with no fundoplication after LHM (Dor-no group). Dor fundoplication was associated with a significantly higher recurrence rate of clinical regurgitation and pathological acid reflux compared with the other fundoplication group (OR = 7.16, 95%CI: 1.25-40.93,  $P = 0.03$ , and OR = 3.79, 95%CI: 1.23-11.72,  $P = 0.02$ , respectively). In addition, there were no significant differences between Dor fundoplication and no fundoplication in all subjects. Other outcomes, including complications, dysphagia, postoperative physiologic testing, and operation-related data displayed no significant differences in the two comparison groups.

**CONCLUSION:** Dor fundoplication is not the optimum procedure after LHM for achalasia. We suggest more attention should be paid on quality of life among different fundoplications.

**Key words:** Laparoscopic Heller myotomy; Dor fundoplication; Gastroesophageal reflux; Achalasia; Meta-analysis

**Core tip:** Laparoscopic Heller myotomy (LHM) is commonly used to treat achalasia and an antireflux procedure is added after LHM for prevention of gastroesophageal reflux (GER). However, there is no consensus on whether Dor fundoplication is the optimum procedure after LHM for the prevention of GER. We conducted this meta-analysis to assess Dor fundoplication com-

pared with non-fundoplication surgery or other types of fundoplication surgery for achalasia. The results indicated higher recurrence rate of clinical regurgitation and pathological acid reflux in Dor fundoplication indicating that Dor fundoplication is not the optimum procedure for the prevention of GER after LHM in achalasia patients.

Wei MT, He YZ, Deng XB, Zhang YC, Yang TH, Jin CW, Hu B, Wang ZQ. Is Dor fundoplication optimum after laparoscopic Heller myotomy for achalasia? A meta-analysis. *World J Gastroenterol* 2013; 19(43): 7804-7812 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7804.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7804>

## INTRODUCTION

Achalasia has generally been accepted as an autoimmune esophageal motility disorder resulting from the loss of inhibitory nerve endings in the myenteric plexus of the esophagus<sup>[1]</sup>. Pathophysiologically characterized by poor relaxation of lower esophageal sphincter (LES) and aperistalsis of the esophageal body, achalasia presents mainly relevant symptoms such as dysphagia, regurgitation, heartburn, and chest pain. The commonly used treatment of achalasia involves medicine therapy, endoscopic pneumatic dilation, and surgical myotomy with the aim of eliminating the high LES pressure. Previous studies have reported better long-term satisfaction with surgical myotomy than with drug medicine therapy or pneumatic dilation<sup>[2-4]</sup>. Kostic and colleagues in 2007 also demonstrated the superiority of laparoscopic Heller myotomy (LHM) to pneumatic dilation for achalasia patients<sup>[5]</sup>. As a result, LHM is routinely considered an option for achalasia patients.

However, although LHM has been previously demonstrated to have positive long-term outcomes for achalasia patients, gastroesophageal reflux (GER) after LHM is commonly regarded as one of the main failures of surgical treatment. For this reason, many surgeons suggest the addition of a fundoplication to LHM for the prevention of acid reflux, and anterior 180° Dor fundoplication is currently well recognized as the best choice<sup>[6]</sup>. Recently, in 2012, a review conducted by Mayo reconfirmed the efficacy of anti-acid reflux fundoplication following LHM both on pH monitoring and symptom relief; however, the clinical differences between Dor fundoplication and posterior 270° Toupet fundoplication have not been verified. In addition, the Mayo review provides limited evidence without pooling available data from the included studies<sup>[7]</sup>. Thus, it also remains controversial that Dor fundoplication is the optimum procedure for the prevention of postoperative GER after LHM in achalasia patients.

To address these issues, our team conducted the following meta-analysis to compare Dor fundoplication plus LHM with LHM alone (Dor-no group) and LHM

plus other types of fundoplication (Dor-other group), namely, 270° Toupet and 360° Nissen fundoplication. The assessed outcomes included: (1) the primary endpoints of postoperative GER, dysphagia, and perforation; and (2) the secondary endpoints of other symptoms, quality of life, operation-related data, complications, and postoperative physiologic testing.

## MATERIALS AND METHODS

This meta-analysis was conducted following the Cochrane Handbook for Systematic Reviews of Interventions 5.1.0 (updated March 2011) to ensure data quality (<http://www.cochrane.org/training/cochrane-handbook>).

### Search for studies

Electronic databases PubMed, Ovid (EBM Reviews, EmBase and Ovid MEDLINE) and Cochrane Library were searched. Moreover, previously published reviews on the topic of interest were obtained and checked. We traced the reference list of relevant articles and used Google Scholar to find potential studies. The search terms were as follows: combined terms of “fundoplication” and “achalasia” using [Mesh] or [Keyword]. The electronic search was up to September 2012 from January 1995 with no limitation on language.

### Study selection

Study designs included random controlled studies (RCTs), clinical controlled studies, cohort studies, case-control studies, and case series.

The inclusion criteria were as follows: (1) diagnosis of achalasia confirmed in an adult patient; (2) the surgical procedure compares Dor fundoplication with other fundoplication types (none, Toupet and Nissen); (3) laparoscopic Heller myotomy; and (4) available data for each comparison. We excluded: studies including (1) achalasia in children and pregnancy; (2) one type of fundoplication; (3) special surgical procedure such as anterior 120° wrap or Watson wrap<sup>[8]</sup>; and (4) studies lacking available data.

We imported the search results into bibliographic citation management software (EndNote X3). Two reviewers independently screened studies by reading titles and abstracts to roughly identify potential reports. The full texts of articles for all references identified as matching the inclusion criteria were obtained. Inclusion criteria were applied to the full texts. Disagreement was resolved through discussion and asking for advice from corresponding authors. The flow chart of study selection was made following the PRISMA statement (<http://prisma-statement.org/statement.htm>).

### Data extraction and quality assessment

Two reviewers independently extracted data from eligible studies, and any disagreement was adjudicated by discussion or consulting the corresponding author. Base-

**Table 1 Checklist of quality assessment and scoring of non-random controlled studies**

Checklist
Selection
Is the subject definition adequate or described? (if yes, one star)
Were the subjects representative of the total population? (one star, if truly or obviously; no stars if subjects were selected group or not described)
Comparability
Did the study have no differences between Dor fundoplication and no fundoplication or other types of fundoplication? Major factors for consideration were age, gender, symptoms, preoperative therapy (pneumatic dilation and botulin toxin injection), and preoperative diagnostic test (endoscopy parameter and barium swallow) (if yes, two stars; one star if there were no other differences between the two groups even if one or more of these five characteristics was not reported; no star was assigned if the two groups differed)
Outcome assessment
Clearly defined outcome of interest (if yes, one star)
Adequacy of follow-up (one star if less than 20% of achalasia patients lost to follow-up, otherwise no stars)

line information included first author, published year, fundoplication type, study design, region, numbers of cases, and mean age among other parameters. Furthermore, the following outcome data were extracted: (1) the primary outcomes of GER-related clinical regurgitation and pathological acid reflux, dysphagia, and perforation; and (2) the secondary endpoints included other symptoms, quality of life, operation-related data (operation time and hospital stay time), complications, postoperative physiologic testing (LES pressure, DeMeester score and percent total time  $\text{pH} \leq 4$ ).

Quality assessment of RCTs was performed by two reviewers according to the Cochrane Handbook for Systematic Reviews of Interventions 5.1.0 based on the following aspects: random sequence generation, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other sources of bias. Three bias levels including low risk, high risk and unclear were assigned to every study aspect. Studies with more “low risk” bias assignments were recognized as superior. For non-random controlled studies, a modification of the Newcastle-Ottawa Scale (NOS)<sup>[9,10]</sup> was used as an assessment tool for selection, comparability and outcome assessment. Out of a total of six scores, studies valued more than four stars were recognized as being moderate to high quality. The detailed checklist is shown in Table 1.

### Statistical analysis

The data were analyzed using Review Manager (Version 5.1). OR or RD and MD were used for analyzing dichotomous data and continuous data, respectively. Heterogeneity was measured with the  $I^2$  index and  $P$  value. A random effect model was used when  $I^2 > 50\%$ . Otherwise, a fixed-effect model was considered. SD was estimated by a formula when only a range was reported: Estimate SD = Range/4 ( $15 < n < 70$ ); Range/6 ( $n > 70$ )<sup>[11]</sup>. The value of  $P < 0.05$  was considered to indicate statistical significance. Sensitivity analysis was performed by sequentially omitting each study.

## RESULTS

### Characteristics of pooled studies

A total of 731 potential abstracts were identified in

the primary search of the electronic databases. A flow diagram of the detailed selection process is shown in Figure 1. Finally, 6 studies (2 RCTs and 4 non-RCTs), including a total of 523 achalasia patients, compared Dor fundoplication with other types of fundoplication (Toupet and Nissen fundoplication) after LHM, and 8 studies (3 RCTs and 5 non-RCTs), including a total of 528 achalasia patients, compared Dor fundoplication with no fundoplication after LHM<sup>[12-24]</sup>. In the 5 RCTs, two reported the same population group but differed in the main outcomes. Thus, we just extracted useful data integrated from both articles<sup>[19,23]</sup>. In addition, in the 8 non-RCTs, two studies were conducted by the same research group, who reported on the achalasia population with short- and long-term outcomes, and we chose the latter for our meta-analysis<sup>[15,24]</sup>. In one non-RCT, we divided the pooled data into two comparisons from the three reported subgroups<sup>[20]</sup>. In terms of non-Dor fundoplication, surgical fundoplication included 2 studies that used Nissen fundoplication, 4 studies with Toupet fundoplication and no fundoplication was used in the other studies. Table 2 offers the baseline characteristics of all studies.

### Quality judgments of studies

In the pooled studies, 5 were RCTs, and 8 were non-RCTs. We used two methods to assess the quality of RCTs and non-RCTs, respectively. Table 3 lists the quality of RCTs according to the Cochrane Handbook for Systematic Reviews of Interventions 5.1.0. All the studies described the random sequence generation method used. Two studies generated sequence using a permuted block size of 4. Two used computer-generated random numbers, and 1 used a random number table generated in Microsoft Excel. In regards to allocation concealment, 3 studies used sealed opaque envelopes, 1 used Random Allocation Software version 1.0, and 1 study was unclear about the allocation concealment method used. In term of blinding, double blinding is difficult, and risks were judged by whether the outcome was likely influenced by the lack of blinding. In the 5 RCTs, only two trials reported double blinding of all recruited patients and researchers involved in the evaluation. Concerning selective reporting, although the protocol of each study was unavailable, the published outcomes included all the outcomes detailed in the method. Other sources of bias

were unclear in the included RCTs.

In term of the 8 non-RCTs, Table 4 lists the evaluation stars of each study followed by the modified NOS. In the selection of patients, one study included patients without continuity, which could hardly represent the total population<sup>[22]</sup>. Three studies (two studies reported the same patients group) received no stars in the domain of adequacy of follow-up, with a follow-up of 63.7%<sup>[20]</sup> and 30% (postoperative manometer), respectively<sup>[15,24]</sup>. Overall, all studies were evaluated as being moderate to high quality.

### Outcomes in the Dor-other group

**Primary endpoints:** With respect to clinical regurgitation, 3 non-RCTs reported the available number of achalasia patients<sup>[13,18,20]</sup>, and a fixed-effect model was used in the subgroup meta-analysis. Dor fundoplication was appraised to have a significantly higher recurrence rate of clinical regurgitation compared with other types of fundoplication (OR = 7.16, 95%CI: 1.25-40.93,  $P$  = 0.03 and heterogeneity  $I^2$  = 0%) (Figure 2A). One study, which did not have an available number of achalasia patients, reported no significant difference in regurgitation frequency score ( $P$  = 0.546)<sup>[24]</sup>.

In the pathological acid reflux analysis, 1 RCT and 2 non-RCTs were pooled, and a fixed-effect model was used<sup>[13,17,18]</sup>. The odds ratio was 3.79 in the Dor fundoplication group compared with the other fundoplication group (95%CI: 1.23-11.72,  $P$  = 0.02 and heterogeneity  $I^2$  = 0%).

Perforation was estimated in 2 RCTs and 1 non-RCT, and a fixed-effect model was used. The subgroup analysis indicated no significant differences in the Dor-other group (RD = -0.00, 95%CI: -0.04-0.04,  $P$  = 0.94, heterogeneity  $I^2$  = 0%) (Figure 2A).

Considering dysphagia, no significant symptom relief benefit was found for Dor fundoplication compared with other types of fundoplication, and a random-effect model was used (OR = 1.19, 95%CI: 0.16-8.67,  $P$  = 0.86 and heterogeneity  $I^2$  = 77%) (Figure 2B). One study that lacked information on the number of acha-

<sup>1</sup>Random-effect model; <sup>2</sup>Fixed-effect model. RCT: Random controlled trial.

lasia patients reported no significant difference in the dysphagia frequency score and a significant difference in the dysphagia severity score ( $P = 0.465$  and  $P = 0.003$ , respectively)<sup>[24]</sup>. No publication bias was observed in the funnel plot of studies when reporting dysphagia in the two comparisons (Figure 2C).

**Secondary endpoints:** In regards to the other symptoms, one study reported bloating, chest pain, and heartburn recurrence frequency score without any significance difference in the Dor-other group<sup>[24]</sup>. With regard to quality of life, one multicenter RCT assessed the outcome using an SF-36 questionnaire and ten health-related domains<sup>[17]</sup>. No significant score difference was observed in the Dor fundoplication group compared with the other fundoplication group in five and seven domains of the total ten domains, respectively. Another prospective study in the Dor-other group reported that the SF-36 score ranged from 0-100, and the two compared types of fundoplication scored  $70.5 \pm 4.06$  and  $72.3 \pm 4.53$  each with a  $P$  value  $> 0.5$ <sup>[13]</sup>.

Postoperative physiologic testing including LES pressure, DeMeester score, and percent total time pH  $\leq 4$  displayed no obvious significant difference in the Dor-other group. Considering the relatively high heteroge-

neity, the random effect model was applied in all three outcomes. In the subgroup analysis of surgery time, Dor fundoplication took significantly less time than the other types of fundoplication, and the estimated hospital stay time was not different in the comparison group. The details are shown in Table 5.

In addition to perforation, other complications were described as follows: Di Martino *et al*<sup>[13]</sup> reported intra-operatively 1 mucosal tear and 2 cervical subcutaneous emphysema occurrences and postoperatively reported 2 pulmonary atelectasis occurrences in the Dor fundoplication group, intra-operatively 1 pneumothorax occurrence, and postoperatively 1 urinary retention occurrence in the other fundoplication group. Wright *et al*<sup>[24]</sup> reported 1 urinary retention occurrence in the Dor fundoplication group compared with none in the other fundoplication group. Another 2 studies reported no complications in either group<sup>[17,18]</sup>.

### Outcomes in the Dor-no group

**Primary endpoints:** With respect to clinical regurgitation, two non-RCTs were validly pooled without displaying any significant difference in the Dor-no group (OR = 0.51, 95%CI: 0.09-2.92,  $P = 0.32$  and heterogeneity  $I^2 = 0\%$ )<sup>[16,20]</sup>. A fixed-effect model was applied in this

analysis. Two studies without an available number of achalasia patients reported no significant differences of dysphagia severity score<sup>[14,22]</sup>.

In the pathological acid reflux analysis, one RCT indicated that Dor fundoplication was associated with an obviously lower pathological acid reflux rate than no fundoplication (OR = 0.11, 95%CI: 0.02-0.59,  $P = 0.01$ )<sup>[19]</sup>.

Perforation was estimated in 1 RCT and 3 non-RCTs, and a fixed-effect model was used<sup>[12,14,16,19]</sup>. Subgroups were evaluated with no significant differences in Dor-no group (RD = 0.02, 95%CI: -0.04-0.07,  $P = 0.59$  and heterogeneity  $I^2 = 0\%$ ) observed.

Considering dysphagia, no significant symptom relief benefit was found for Dor fundoplication compared with no fundoplication (OR = 1.73, 95%CI: 0.52-5.72,  $P = 0.37$  and heterogeneity  $I^2 = 0\%$ ), and a fixed-effects model was used (Figure 2B). Of two studies that did not provide the number of patients, one reported significantly less severe dysphagia in the Dor fundoplication group<sup>[22]</sup>, and the other reported no difference<sup>[12]</sup>.

**Secondary endpoints:** Concerning other symptoms, there was no obvious difference in heartburn in the Dor-no group in two studies<sup>[12,24]</sup> and a lower recurrence rate in Dor fundoplication compared with no fundoplication in one study<sup>[22]</sup>. No significant difference in chest pain was found in 2 studies<sup>[12,22]</sup>, and 1 study reported vomiting without difference and a lower choking rate in the Dor fundoplication group compared with the no fundoplication group<sup>[22]</sup>. With regard to symptom satisfaction, Dempsey reviewed the consecutive patients with 86% satisfaction in the Dor-no group, which was not significantly different than the Dor group<sup>[12]</sup>. Tapper and colleagues selectively reviewed their patients and found a slightly higher satisfaction rate in the no fundoplication group compared with the Dor group (89% and 75%, respectively)<sup>[22]</sup>.

Similar to the results in the Dor-other group, postoperative physiologic testing and hospital stay time displayed no obvious significance in the Dor-no group. In addition, Dor fundoplication took significantly more time than no fundoplication on surgery time ( $P = 0.005$ ). Complications were rarely reported in the Dor-no group, except for 2 studies mentioning no complications in this comparison<sup>[14,19]</sup>.

## DISCUSSION

Since the description of minimal invasive treatment for achalasia by Shimi *et al.*<sup>[25]</sup>, LHM has gained world-wide popularity and is increasingly regarded as the standard treatment for achalasia by surgeons and gastroenterologists. Furthermore, the routine application of fundoplication following LHM has been identified as useful for protection of postoperative GER<sup>[4,6,26]</sup>. Dor fundoplication, with the advantage of a simple procedure and covering of the mucosa, is being accepted as the first-line type of fundoplication for achalasia in most regions. However, some opponents of Dor fundoplication have

reported no significant benefit with regard to the clinical outcomes when Dor fundoplication was added to LHM, and they recommend posterior or even total fundoplication, such as posterior 270° Toupet fundoplication and total 360° Nissen fundoplication, be added to LHM for better long-term outcome<sup>[12,27]</sup>. Thus, there is no consensus on whether Dor fundoplication is the optimum procedure after LHM for achalasia.

Our group conducted this meta-analysis to provide evidence for fundoplication choice on achalasia surgery. Finally, we found a significantly higher clinical and pathological acid reflux rate in for Dor fundoplication than for other types of fundoplication, although no significant difference was found between Dor fundoplication and no fundoplication. Our results contradict the conventional concept that Dor fundoplication after LHM is the optimal choice for achalasia. However, caution should be taken care to explain the pooled results because of the limitations of our study.

Postoperative GER was the main evaluation used to assess the efficacy of Dor fundoplication for achalasia. GER includes clinical regurgitation symptoms and pathological acid reflux, which was defined as more than 4.2% total time per 24-h period for which  $\text{pH} \leq 4$  or as a DeMeester score of  $\geq 18$  for 24 consecutive hours. Our results demonstrate that Dor fundoplication provides no beneficial clinical regurgitation palliation compared with fundoplication, and, in addition, it leads to a significantly higher clinical regurgitation rate than the other types of fundoplication examined. These results may be explained by the fact that Dor fundoplication may add less resistance than Toupet or Nissen fundoplication, which allows acid to flow through the loose esophagogastric junction more easily. In addition, though the pH testing in two comparison groups indicated no significant difference, the clinical regurgitation symptoms result is supported by the pathological acid reflux outcome, which also demonstrates that Dor fundoplication resulted in more acid reflux than the other fundoplication types. It should be noted that our pooled clinical regurgitation results exclude one study without available data that might affect the outcome<sup>[24]</sup>.

With regard to dysphagia, Dor fundoplication displayed no significant dysphagia relief difference compared with either the other types of fundoplication or no fundoplication. Campos and colleagues suggested that dysphagia relief is independent of whether a fundoplication is performed<sup>[2]</sup>. Their conclusion is consistent with our pooled outcome that Dor fundoplication did not produce a lower recurrence of dysphagia than the other types of fundoplication, and we also found no obvious difference in postoperative dysphagia when comparing the Dor and Dor-no groups. The relative lack of change in the mucosa fibrosis around the dissected esophagus between the different types of fundoplication may explain this finding, although we have found no significant difference on LES pressure. As the Heller muscle is dissected whether LHM alone or LHM plus fundoplication

is performed, the pressure changes associated with the follow-up procedure may not be significantly different between fundoplication types. Furthermore, a study designed by Rohof on efficacy of treatment for achalasia indicates distensibility of the esophagogastric junction should recommend as better parameter of treatment for achalasia rather than LES pressure<sup>[28]</sup>.

As the most dangerous and latest complication, perforation is the main outcome we focus on. In the pooled outcomes, we failed to find that Dor fundoplication had a lower perforation rate when used for achalasia treatment. As previous studies have reported, perforation was highly related with perioperative therapy, especially pneumatic dilation, and the occurrence is more predicted by the number and duration of dilations<sup>[29]</sup>. The restricted number of pooled studies and small participant size might decrease the power of these outcomes. In addition, just the fact that observation studies were included may be somewhat responsible for these results.

The surgery time differences can be easily explained by the fact that the more complex surgical procedures and difficulties associated with the other types of complex fundoplication surgeries require more time to perform than Dor fundoplication. The recovery of achalasia patients accounts for many factors: disease itself, surgery, and complications, among others. Our pooled hospital stay time outcome indicates that surgery type has little influence on recovery. Because of the relatively skillful clinicians and the standardized nature of the surgical procedures, no perioperative surgery-related death was found for any surgical type.

Finally, in the sensitivity analysis, the primary pooled estimation of the outcomes is consistent with that of the sensitivity analysis when one study was extracted out, and this result may indicate our pooled results had good quality.

There are some limitations in this meta-analysis: (1) some indirect data acquirement methods were used, such as when dealing with the SD from range; (2) relatively high heterogeneity of data was estimated for the secondary outcomes, especially in postoperative physiological testing. This may be derived from differences in technology used in different regions and countries; (3) RCTs and non-RCTs were pooled for some outcomes because of the lack of available data and studies; and (4) though, we searched for studies without language limitation, the pooled studies were all published in English, which may be responsible for part of the observed heterogeneity.

In summary, we identified a significantly higher recurrence rate of clinical regurgitation and pathological acid reflux for Dor fundoplication than for other types of fundoplication after LHM for achalasia, although no significant difference was found between Dor fundoplication and no fundoplication. Therefore, we conclude that Dor fundoplication after LHM is not the optimum procedure for achalasia and suggest that more attention should be paid on quality of life among different fundoplication approaches.

## COMMENTS

### Background

Achalasia is generally regarded as an autoimmune esophageal motility disorder resulting from the loss of inhibitory nerve endings in the myenteric plexus of the esophagus, and laparoscopic Heller myotomy (LHM) is commonly used as the main surgical treatment. However, although LHM has been previously shown to have positive long-term outcomes for achalasia patients, gastroesophageal reflux (GER) after LHM is often one of the main failures of treatment.

### Research frontiers

In recent years, anterior 180° Dor fundoplication has been recommended after LHM for the prevention of acid reflux. However, LHM alone or LHM plus other types of fundoplication (e.g., posterior 270° Toupet and total 360° Nissen fundoplication) have also been reported to have different benefits compared with LHM plus Dor fundoplication. Thus, there is no consensus on whether Dor fundoplication is the optimum procedure after LHM for the prevention of GER.

### Innovations and breakthroughs

Dor fundoplication did not display any obvious benefit in relation to dysphagia and other symptoms versus non-fundoplication or other types of fundoplication surgery. Conversely, the pooled Dor fundoplication results indicated a higher recurrence rate for clinical regurgitation and pathological acid reflux compared with other types of fundoplication (95%CI: 1.25-40.93, and  $P = 0.03$  and 95%CI: 1.23-11.72, and  $P = 0.02$ , respectively), although no significant difference was found between Dor fundoplication and no fundoplication. The results of this meta-analysis indicate that Dor fundoplication after LHM should not be routinely recommended for achalasia.

### Applications

This present meta-analysis demonstrates that Dor fundoplication after LHM is not the optimum procedure for achalasia. To prevent postoperative GER, complex types of fundoplication, such as Toupet and Nissen fundoplication, may be added after LHM for the treatment of achalasia.

### Peer review

LHM is commonly used to treat achalasia, but GER is a frequent side effect, and an antireflux surgical technique is normally used. The aim of this meta-analysis was to assess Dor-fundoplication compared with non-fundoplication surgical techniques and other types of surgical fundoplication. The paper is well designed and demonstrates the difficulty in assessing and standardizing the published data. The paper is slightly difficult to read, but the graphs and tables facilitate comprehension. This meta-analysis gives the readers relevant reliable data for the selection of fundoplication surgical techniques after LHM.

### Abstract

Mesenteric venous thrombosis (MVT) is a rare but life threatening form of bowel ischemia. It is implicated in 6%-9% of all cases of acute mesenteric ischemia. The proportion of patients with primary (or idiopathic) MVT varies from 0% to 49%, with a decrease in frequency secondary to more recent availability of newer investigations for hypercoagulability. The presence of factor V Leiden (FVL) and prothrombin G20210A mutations (PGM) have been well documented in these cases. However, there have been scarce case reports describing MVT in heterozygotes of both these mutations occurring simultaneously and its implications on long term management. Our case describes acute MVT in a previously asymptomatic young patient with no prior history of venous thromboembolism. The patient was found to be heterozygous for FVL and PGM and treated with lifelong anticoagulation with warfarin (goal international normalized ratio: 2-3) and avoidance of hormonal contraceptives.

**Key words:** Mesenteric vein thrombosis; Prothrombin

gene; Factor V Leiden; Heterozygous; Anticoagulation; Oral contraceptives

**Core tip:** The common presence of two thrombophilic defects increases the thrombotic risk several folds above the risk of a single defect and these tend to occur at an earlier age as seen in our case. Also the risk of recurrent thrombosis is significantly increased among these heterozygotes. Indefinite anticoagulation with oral anti-coagulants (goal International Normalized Ratio = 2-3) is recommended for high risk patients like our case with thrombosis at unusual sites (*e.g.*, mesenteric vein), and heterozygosity for both factor V Leiden and prothrombin G20210A mutations. These patients should avoid any hormonal therapy and family members should be screened for underlying prothrombotic condition.

Mesenteric vein thrombosis in a patient heterozygous for factor V Leiden and G20210A prothrombin genotypes. *World J Gastroenterol* 2013; 19(43): 7813-7815 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7813.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7813>

### INTRODUCTION

Mesenteric venous thrombosis (MVT) is a rare but life threatening form of bowel ischemia, responsible for 6%-9% of all acute mesenteric ischemia. The presence of factor V Leiden (FVL) and prothrombin G20210A mutations (PGM) have been well documented in these cases. However, there have been scarce case reports describing MVT in heterozygotes of both these mutations occurring simultaneously and its implications on long term management.

### CASE REPORT

A 22-year-old Caucasian female presented to the emer-

gency department with progressively worsening, colicky left upper quadrant abdominal pain for 4 d with radiation to her back, associated with some nausea. She denied any history of fever or changes in bowel movements. Past medical history was significant for Polycystic Ovarian syndrome treated with oral contraceptives. She denied personal or family history of thrombosis. Physical exam was significant for tenderness on left upper quadrant of abdomen without guarding, rigidity or rebound tenderness. Complete blood count and electrolytes were within normal limits. A computed tomography (CT) scan of the abdomen revealed possible superior mesenteric vein (SMV) thrombosis without evidence of bowel ischemia (Figure 1). Patient was started on enoxaparin (1 mg/kg twice daily) with bridging to warfarin. Subsequent CT angiography confirmed the initial diagnosis of SMV thrombosis. Surgical intervention was not indicated due to lack of bowel ischemia. Workup for possible vasculitis, including antinuclear antibody, Anti-neutrophil cytoplasmic antibody, titers of hepatitis B, hepatitis C, and Human Immunodeficiency Virus screening were all negative. Hypercoagulable evaluation including protein-C and S, antithrombin III, anticardiolipin antibodies were all negative. However she was found to have heterozygous mutations for both prothrombin G20210A and FVL. She was discharged on warfarin with a therapeutic level of anticoagulation. She was advised to have lifelong anticoagulation with warfarin [goal International Normalized Ratio (INR) = 2-3] and avoidance of hormonal contraceptives.

## DISCUSSION

MVT is a rare but potentially life threatening cause of mesenteric ischemia with high recurrence rates<sup>[1,2]</sup>. It is implicated in 6%-9% of all cases of acute mesenteric ischemia<sup>[1,3,4]</sup>. Predisposing conditions including myeloproliferative disorders, neoplasia, hereditary hemorrhagic telangiectasia, paroxysmal nocturnal hemoglobinuria, inherited thrombophilias, oral contraceptive pill (OCP) use, pancreatitis, recent abdominal surgery or local intraabdominal infections can be identified in most patients<sup>[5]</sup>. When no underlying etiology is identified, MVT is described as primary or idiopathic. The proportion of patients with primary (or idiopathic) MVT varies from 0% to 49%, with a decrease in frequency secondary to more recent availability of newer investigations for hypercoagulability. Abdominal pain is the most common symptom, especially with acute thrombosis, whereas chronic MVT usually manifests as portal hypertension or diagnosed incidentally by imaging. The increasing use of CT for the investigation of abdominal pain and anticoagulation for the treatment of acute MVT have improved outcomes in these patients<sup>[6]</sup>. Surgery and bowel resection may occasionally be needed for patients with bowel infarction, perforation, and peritonitis. The management of patients with chronic MVT is aimed at reducing complications of portal hypertension<sup>[4,6]</sup>.

The present case is of interest in that acute MVT was

**Figure 1** Contrast-enhanced computed tomography scan. It shows decreased attenuation within the superior mesenteric vein (arrow), immediately below the portal confluence, compatible with venous thrombosis.

the initial presentation in a patient with combined heterozygosity for FVL mutation and the G20210A prothrombin gene variation in the face of oral contraceptive use. The association of each of these mutations with thrombotic disease has been well established. Among Caucasian patients presenting with an initial episode of idiopathic deep venous thrombosis, 12%-20% will be found to be heterozygous for the FVL mutation and 6% heterozygous for the prothrombin G20210A gene variation as compared to 6% and 2% respectively, in asymptomatic Caucasian controls<sup>[7]</sup>. A recent retrospective study by Amitrano *et al*<sup>[5]</sup> noted a high prevalence of thrombophilic genotypes (75%): FVL (25%), prothrombin G20210A gene (25%), and MTHFR prothrombotic defects (50%) in patients with acute mesenteric vein thrombosis. Double heterozygotes of FVL mutation and the prothrombin G20210A gene variation have been shown to be associated with a greater risk of venous thrombosis than either defect alone. Also the age at the first episode of venous thromboembolism in double heterozygotes was significantly younger than those without both gene defects (34.7 years *vs* 40.6 years;  $P < 0.01$ ) in observational and meta-analytic studies. Finally, use of OCPs was associated with a significantly increased risk of thrombosis over those not using them (OR = 16.97, 95%CI: 3.95-72.80)<sup>[8-11]</sup>.

It seems plausible that in our case, MVT was induced by OCPs on the background of her hematological disorders leading to a hypercoagulable state. The common presence of two thrombophilic defects increases the thrombotic risk several folds above the risk of a single defect and these tend to occur at an earlier age which was also seen in our case<sup>[10]</sup>. Also the risk of recurrent thrombosis is significantly increased among these heterozygotes. Indefinite anticoagulation with oral anticoagulants (with goal INR = 2-3) is recommended for high risk patients like our case with thrombosis at unusual sites (*e.g.*, mesenteric vein), and heterozygosity for both FVL and PGM<sup>[9,12,13]</sup>. These patients should avoid any hormonal therapy including OCPs due to increased risk of blood clots. It may also be advised to screen the family members for underlying prothrombotic condition, even with a

first episode of idiopathic venous thrombosis<sup>[7,11]</sup>.

**Key words:** Gastrointestinal stromal tumor; Enterohepatic fistula; Therapeutic embolization; Bleeding; Ileal gastrointestinal stromal tumor

**Core tip:** Gastrointestinal stromal tumor (GIST) with fistula is a rare condition, however, it can be seen during treatment. Herein we report a case of an enterohepatic fistula that occurred after therapeutic embolization of liver mass originated from ileal GIST.

### Abstract

Gastrointestinal stromal tumor (GIST) is a rare mesenchymal tumor of the gastrointestinal tract that has been associated with the formation of fistulas to adjacent organs in few case reports. However, GIST with enterohepatic fistula has not been reported. Here we report the case of an enterohepatic fistula that occurred after embolization of a liver mass originating in the distal ileum. An 87-year-old woman was hospitalized for melena. On initial conventional endoscopy, a bleeding focus in the gastrointestinal tract was not found. Because of massive hematochezia, enteroscopy was performed through the anus. A protruding, ulcerative mass was found in the distal ileum that was suspected to be the source of the bleeding; a biopsy sample was taken. Electrocoagulation was not successful in controlling the bleeding; therefore, embolization was performed. After embolization, the patient developed a high fever and severe abdominal tenderness with rebound tenderness. Follow-up abdominopelvic computed tomography

Development of enterohepatic fistula after embolization in ileal gastrointestinal stromal tumor: A case report. *World J Gastroenterol* 2013; 19(43): 7816-7819 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7816.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7816>

### INTRODUCTION

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor originating in the digestive tract. GISTs are thought to arise from the interstitial cells of Cajal in the normal myenteric plexus<sup>[1]</sup>. GISTs most commonly occur in the stomach (60%), followed by the jejunum and ileum (30%), duodenum (5%), colon and rectum (5%), and, rarely, the esophagus and appendix<sup>[2]</sup>. However, they account for less than 1% of all gastrointestinal (GI) tumors<sup>[3]</sup>. It is estimated that up to 6000 new

**Figure 3 Angiographic findings (post-embolization state).** Angiography shows that the hepatic mass (arrows) was not supplied by the right hepatic artery after embolization.

cases are diagnosed in the United States every year<sup>[4,5]</sup>.

Before the late 1990s, these mesenchymal tumors arising in the GI tract were most often classified as smooth muscle tumors or neural tumors. In the 1990s, investigators noted similarities between GIST cells and the interstitial cells of Cajal, a group of cells located in the muscularis propria and around the myenteric plexus throughout the GI tract. These tumors may not cause any symptoms unless they are in a certain location or grow to a certain size. GISTs are often found because they cause bleeding into the GI tract. Other symptoms can result from the mass effect of the tumor causing abdominal discomfort, nausea, vomiting or early satiety. The critical determinants of GIST behavior include tumor size, mitotic rate, and location<sup>[6]</sup>. The liver is the most common site of metastasis from GISTs, and liver metastases are a major determinant of patient survival<sup>[7,8]</sup>. Complications such as abscess formation, fistulae or perforation are rare but can be seen during treatment<sup>[9,10]</sup>.

Here we describe the case of a patient with ileal GIST with an enterohepatic fistula caused by tumor necrosis after therapeutic embolization for the control of active bleeding.

## CASE REPORT

An 87-year-old woman was admitted to the emergency department because of melena that occurred the day before. She had been taking antihypertensive medica-

tion for 7 years and was not taking aspirin or other antiplatelet agents. She had a history of cholecystectomy, total abdominal hysterectomy, and right hemicolectomy due to GI bleeding. At admission, her vital signs were stable; laboratory findings showed anemia with a serum hemoglobin concentration of 7.8 g/dL and leukocytosis with a white blood cell count of 14000/mm<sup>3</sup>. A definite bleeding focus was not found on upper endoscopy and total colonoscopy. On a subsequent capsule endoscopy, a small amount of fresh blood was seen in the small bowel but the exact bleeding site was not identified. Abdominopelvic computed tomography (CT) showed a 5.7 cm × 5.2 cm heterogeneous enhancing mass in segments V and VI of the liver (Figure 1) adjacent to the distal ileum and multiple ill-defined low-attenuation lesions that were thought to represent metastases.

On the 9<sup>th</sup> day of hospitalization, she showed massive hematochezia. Single-balloon enteroscopy was performed through the anus, and a large protruding mass with central ulceration, which was suspected to be the bleeding focus, was found on the distal ileum (Figure 2). After an enteroscopic biopsy of the ileal mass was taken, active bleeding occurred that was not controlled by enteroscopic electrocoagulation. The patient refused surgical treatment for the active ileal bleeding. Therapeutic angiography was performed; however, no extravasation of the contrast was found in the inferior mesenteric or superior mesenteric arteries. Because a liver mass adja-

**Figure 5** Abdominopelvic computed tomography findings after embolization. Internal necrosis and direct communication (arrows) with the small bowel were identified in the liver mass. A: Axial view; B: Coronal view.

cent to the small bowel had been seen on the abdominopelvic CT, it was suspected that the protruding mass in the distal ileum originated from the suspected malignant liver mass. Based on the assumptions that the bleeding lesion originated from the hepatic mass and was supplied by the hepatic artery, a branch of the right hepatic artery was embolized, and there was no evidence of additional bleeding in the GI tract (Figure 3).

The biopsy specimen showed that the ileal mass was a GIST with more than 20 cells undergoing mitosis per 20 high-power fields (Figure 4). After the embolization, the patient developed fever and right upper quadrant pain. On repeated abdominopelvic CT 5 d after embolization, newly developed internal necrosis and a direct communication with distal ileum were identified in the previously seen liver mass (Figure 5).

Segmental resection of the distal ileum and unlooping of the liver mass were undertaken, and fistula formation between the liver mass and the distal ileum was found intraoperatively. The gross specimen of the resected ileum showed a large fistula orifice that connected with the adjacent liver (Figure 6). Histopathologic examination of the surgical specimen obtained from the resected distal ileum and adjacent liver mass showed that both specimens were identical with GIST on immunohistochemical staining. After the operation, the patient refused chemotherapy and was transferred to a convalescent hospital. She died 6 mo later of multiple organ failure after recurrent GI sepsis.

## DISCUSSION

GISTs with intraperitoneal rupture or organ invasion have rarely been reported<sup>[11]</sup>. Nonetheless, an enterocolic fistula can be caused by prior surgery, malignancy, and infection<sup>[12,13]</sup>. In similar situations, albeit very rarely, enterohepatic fistulas can develop with GISTs.

We presented a case of an enterohepatic fistula that occurred after embolization of a metastatic liver mass from a malignant GIST. An active bleeding site was not found on initial upper endoscopy and colonoscopy. Abdominopelvic CT demonstrated a 5.7 cm liver mass adjacent to the small bowel.

On initial workup, there was no evidence suggesting that the hepatic mass was the source of the GI bleeding. After enteroscopy by the anal approach because of the patient's massive hematochezia, we found an exophytic mass that was thought to be connected with the hepatic mass and the cause of the bleeding. Therefore, embolization of the right hepatic artery supplying the liver mass was performed. However, within 24 h of arterial embolization, the patient developed fever and right upper quadrant abdominal pain, indicating that fistula formation between the liver mass and distal ileum occurred.

As the patient had undergone several previous abdominal operations, we assumed there was a strong possibility that intraabdominal adhesions were present, specifically between the small bowel and liver. High mitotic rates ( $> 20$  per 20 high power field) also suggested

**Figure 6** Gross findings of resected segment of the distal ileum. It showed a large fistula orifice (arrow) which connected with the adjacent liver, as proven by food material in the liver mass.

that the tumor was likely to be invasive. Therefore, it was highly probable that the primary ileal tumor directly invaded the adjacent liver and then developed multiple hepatic metastases. Embolization of the right hepatic artery was performed to control the patient's massive hematochezia, and necrosis of the hepatic tumor gradually organized into a fistula.

There have been several cases of GIST with abscess formations, perforations, or various fistulas<sup>[9,14-17]</sup>. However, GIST with a hepatic fistula is a unique presentation that has not been reported to our knowledge.

Watanabe *et al.*<sup>[9]</sup> presented a similar case of GIST with a vesicocutaneous fistula during treatment with sunitinib. Sunitinib has anti-tumor and anti-angiogenic effects that cause necrosis, similar to our case in which arterial embolization induced visceral necrosis, with a resulting fistula in both cases.

In conclusion, we have reported a case of an enterohepatic fistula that occurred after embolization of a metastatic liver mass in an ileal GIST. It is important that physicians consider the possible complications, such as fistula, perforation and abscess formation, during treatment of highly invasive GISTs.

poor prognosis. Its pathogenesis has not been elucidated. We herein report a case of an early-stage SCP involving successful treatment and a good prognosis. The patient was a 48-year-old Chinese man with a 5-mo history of vague abdominal pain. Ultrasonography revealed a 93 mm × 94 mm × 75 mm mass of mixed echogenicity in the tail of the pancreas. Laboratory test results were within the normal range, with the exception of an obviously increased pretreatment neuron-specific enolase level. The plasma transforming growth factor (TGF)β1 and interleukin-11 levels were obviously increased according to enzyme-linked immunosorbent assay. Microscopically, the excised tumor tissue comprised cancer cells and mesenchymal cells. Immunohistochemical analysis was positive for α-1-antichymotrypsin, pan-cytokeratin, cytokeratin 19, cytokeratin 8/18, and vimentin and negative for CD68 and lysozyme. The pathogenetic mechanism of this case shows that TGFβ1 may regulate the epithelial-to-mesenchymal transition in SCP. With early eradication of the tumor and systemic therapy, this patient has been alive for more than 3 years without tumor recurrence or distant metastasis. This case is also the first to show that TGFβ1 may regulate the epithelial-to-mesenchymal transition in early-stage SCP.

### Abstract

Sarcomatoid carcinoma of the pancreas (SCP) is a very rare pathological type of carcinoma that usually has a

mesenchymal transition in SCP. This case is also the first to show that TGF $\beta$ 1 may regulate the epithelial-to-mesenchymal transition in early-stage SCP.

Ren CL, Jin P, Han CX, Xiao Q, Wang DR, Shi L, Wang DX, Chen H. Unusual early-stage pancreatic sarcomatoid carcinoma. *World J Gastroenterol* 2013; 19(43): 7820-7824 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i43/7820.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i43.7820>

## INTRODUCTION

Microscopically, sarcomatoid carcinoma of the pancreas (SCP) comprises mostly anaplastic cells and is strikingly sarcoma-like in appearance<sup>[1]</sup>. SCP may originate from many different organs, such as the pancreas, lung, liver, and esophagus<sup>[2-8]</sup>. Confirmation of this disease is often based on the pathological diagnosis. Advanced radiographic studies are also good tools with which to support the diagnosis of sarcomatoid carcinoma<sup>[2]</sup>. Early diagnosis and eradication of the tumor is important for a better prognosis of malignant sarcomatoid carcinomas.

It has been proposed that during malignant progression, carcinoma cells undergo an epithelial-to-mesenchymal transition (EMT), which is a vital step in the formation of pancreatic ductal adenocarcinoma (PDAC)<sup>[9]</sup>. The etiology of SCP is unknown. The *EML4-ALK* fusion gene was reportedly involved in the development of a sarcomatoid carcinoma of the lung<sup>[10]</sup>. *ALK* gene amplification is a nonrandom and clonally related event in a subset of pulmonary sarcomatoid carcinomas, but its biologic rationale deserves further investigation<sup>[11]</sup>. The mechanism of the formation of SCP and its metastasis remains unknown.

## CASE REPORT

A 48-year-old Chinese man suffered from vague abdominal pain for 5 mo. He had no evidence of jaundice, hematuria, vomiting, or fever, but abdominal swelling and chest distress were present. He had no smoking or drinking habits, and no history of malignant or other diseases. Ultrasonography revealed a 93 mm  $\times$  94 mm  $\times$  75 mm mass of mixed echogenicity in the tail of the pancreas (Figure 1). Computed tomography (CT) showed displacement of the retroperitoneal organs by the mass (Figure not shown).

Laboratory test results, including a blood count, serum biochemistry, and urinalysis, were within the normal ranges. The levels of 11 common serum tumor markers, including CA19-9, CEA, and CA242, were normal, except that NSE was obviously increased before any treatment (Table 1). The plasma transforming growth factor (TGF) $\beta$ 1 and Interleukin (IL)-11 levels were higher than those of the healthy controls, patients with PDAC, and

**Table 1 Pretreatment serum tumor markers**

Tumor markers	Index	Normal range

	PanINs	7949 (6655-11404)	10
	HC	6865 (3272-22463)	11
IL-11	SCP	58	1
	HC	22 (10-42)	11

SCP: Sarcomatoid carcinoma of the pancreas; HC: Healthy control; PDAC: Pancreatic ductal adenocarcinoma; PanINs: Pancreatic intraepithelial neoplasias; TGF: Transforming growth factor; IL-11: Interleukin-11.

patients with pancreatic intraepithelial neoplasias (PanINs) (Table 2).

Surgery was performed, and the tumor was completely resected. The mass measured 10 cm  $\times$  8 cm  $\times$  3.5 cm and had cystic features after the excision. The section containing the solid tumorous tissue was pale in color. Microscopically, the excised tumor tissue comprised cancer cells and mesenchymal cells, with dispersion of atypical cells and obvious karyokinesis. Some were fusiform in shape and some were multinucleated giant cells (Figure 1A and B). Therefore, SCP was pathologically diagnosed. The neighboring lymph nodes and incisional margin were free of tumor cells. Immunohistochemical study results showed that the tumor cells were positive for vimentin,  $\alpha$ -1-antichymotrypsin (AACT), cytokeratin 19, cytokeratin 18 (Figure 1C), and pan-cytokeratin (Figure 1D) and negative for CD68 and lysozyme (data not shown). Thus, an early-stage SCP was diagnosed.

The preoperative diagnosis was cystadenoma in the tail of the pancreas. Seven months after surgical excision, there was no evidence of tumor recurrence or metastasis. Digital subtraction angiography interventional chemotherapy was then implemented. Gemcitabine (1.4 g), oxaliplatin (150 mg), and floxuridine (1.0 g) were intravenously injected *via* the superior mesenteric artery and celiac trunk artery. After 28 mo of follow-up, a

**Figure 1** Hematoxylin and eosin stained sections, immunohistochemical test and ultrasonography diagnosis. routine check-up and CT scan revealed that the patient was in good condition and free of tumor recurrence and metastasis. Because the patient had the opportunity to be treated in the early stage of the disease, he is in good condition and has been alive for more than 3 years without tumor recurrence or metastasis.

## DISCUSSION

Sarcomatoid carcinoma is a rare and very aggressive malignant tumor comprising a mixture of carcinomatous and sarcomatous elements<sup>[12]</sup>. Areas of spindle cells arranged in a storiform pattern were present<sup>[13]</sup>. The tumor demonstrated cellular patterns similar to those present in tumors of mesenchymal origin in the case. In the

present case, many cells undergoing heterotypic division were seen in the tissue specimen, and karyokinesis was frequent. Some cells were fusiform in shape, and some were pleomorphic giant cells. This change into pleomorphic giant cells was the most frequent sarcomatoid transformation encountered<sup>[1]</sup>. Compared with ordinary pancreatic carcinomas, malignant giant cell tumors of the pancreas appear to have a distinctive behavior characterized by local invasiveness, a reluctance to metastasize, and a more favorable prognosis when resected<sup>[1]</sup>. Immunohistochemical study results showed that the tumor cells were positive for vimentin, AACT, pan-cytokeratin, cytokeratin 19, and cytokeratin 8/18 and negative for CD68 and lysozyme. Some authors reported that the tumor cells in sarcomatoid carcinoma were positive for

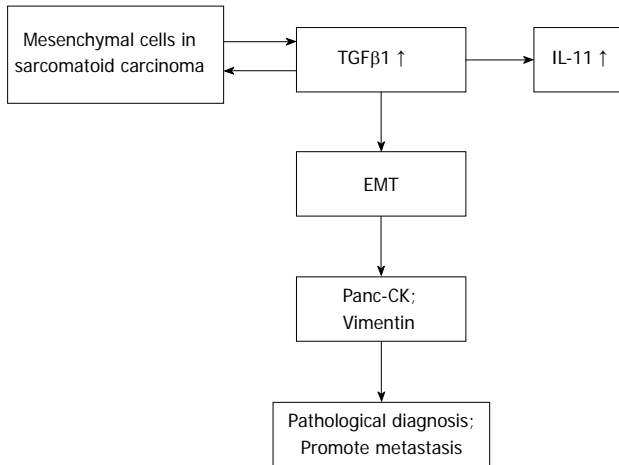

Figure 2 Mechanism of transforming growth factor $\beta$ 1 regulating the epithelial-to-mesenchymal transition of sarcomatoid carcinoma of the pancreas. TGF: Transforming growth factor; EMT: Epithelial-to-mesenchymal transition; IL-11: Interleukin-11.

CK, S-100 protein,  $\alpha$ 1-antitrypsin,  $\alpha$ 1-chymotrypsin, anti-CA19-9, and SMA. No cells were positive for vimentin or desmin<sup>[14]</sup>. Vimentin-positive tumor cells are of mesenchymal origin in sarcomatoid carcinoma and are also seen in inflammatory myofibroblastic tumor of the prostate, another rare malignant disease<sup>[15]</sup>. In the present case, both epithelial and mesenchymal markers were positive. The process of EMT may play an important role in the formation of SCP. TGF $\beta$  signaling plays a dual role in oncogenesis. TGF $\beta$  can sometimes function as a tumor suppressor gene that inhibits the proliferation of normal epithelial cells, while in other tumor types it functions as an oncogenic gene. This dual function implies that the activity of TGF $\beta$  is highly dependent on the cellular context, pathological type, and specific environment<sup>[16-21]</sup>. In this case, the TGF $\beta$ 1 level was markedly higher than those in patients with PDAC and PanINs and in HCs. TGF $\beta$ 1 may regulate the EMT pathway in pancreas cells and promote the formation of SCP. The plasma IL-11 level in the present patient was obviously higher than that of the healthy controls. IL-11 is a TGF $\beta$  target gene. IL-11 stimulates the production of the osteoclastogenic factors RANKL and granulocyte macrophage-colony stimulating factor in osteoblasts. Induction of IL-11 and CTGF expression by TGF $\beta$  is mediated by the SMAD pathway<sup>[22]</sup>. TGF $\beta$ 1 could be an important driving force during the sarcomatoid transdifferentiation of clear cell renal cell carcinoma<sup>[23]</sup>. The combination of early diagnosis of sarcomatoid carcinoma, eradication of the tumor, and systemic therapy may provide a chance of a good prognosis. Whether postoperative patients in the early tumor stage require chemotherapy may be controversial. High levels of NSE, TGF $\beta$ 1, and IL-11 in the serum or plasma may help in the early diagnosis of SCP. TGF $\beta$ 1 may play an important role in tumor metastasis (Figure 2) and some papers support our hypothesis<sup>[24,25]</sup>. In view of the complex biologic behavior of SCP, continued real-time monitoring of the clinical course of the

disease is strongly recommended.

### Abstract

Acute alcoholic hepatitis (AAH) is characterised by deep jaundice in patients with a history of heavy alcohol use, which can progress to liver failure. A clinical diagnosis of AAH can be challenging to make in patients without a clear alcohol history or in the presence of risk factors for other causes of acute liver failure. Other causes of acute on chronic liver failure such as sepsis or variceal haemorrhage should be considered. Liver biopsy remains the only reliable method to make an accurate diagnosis. However, there is controversy surrounding the use of liver biopsy in patients with AAH because of the risks of performing a percutaneous biopsy and limitations in access to transjugular biopsy. We review the existing literature and find there are few studies directly comparing clinical and histological diagnosis of AAH. In the small number of studies that have been conducted the correlation between a clinical and histological diagnosis of AAH is poor. Due to this lack of agreement together with difficulties in accessing transjugular liver biopsy outside tertiary referral centres and research institutions, we cannot advocate universal biopsy for AAH but there remains a definite role for liver biopsy where there is clinical diagnostic doubt or dual pathology. It

also adds value in a clinical trial context to ensure a homogeneous trial population and to further our understanding of the disease pathology. Further prospective studies are required to determine whether non-invasive markers can be used to accurately diagnose AAH.

**Key words:** Alcoholic hepatitis; Liver biopsy; Diagnosis; Prognosis; Transjugular liver biopsy

**Core tip:** Acute alcoholic hepatitis (AAH) is a clinical syndrome of jaundice and coagulopathy in a patient with a recent history of heavy alcohol consumption. Clinical diagnosis is challenging and transjugular liver biopsy remains the gold standard. Here we discuss the literature which demonstrates there is a lack of agreement between clinical and histological diagnosis. This, together with limited availability of transjugular liver biopsy makes it impossible to advocate universal biopsy in all suspected cases of AAH. We suggest further research is conducted to prospectively compare histological and clinical parameters and to develop a reliable and accurate non-invasive diagnostic tool.

Dhanda AD, Collins PL, McCune CA. Is liver biopsy necessary in the management of alcoholic hepatitis? *World J Gastroenterol* 2013; 19(44): 7825-7829 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/7825.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7825>

### INTRODUCTION

Acute alcoholic hepatitis (AAH) is a severe manifestation of alcoholic liver disease and is associated with a high short term mortality of 35% if untreated<sup>[1]</sup>. The clinical syndrome is characterised by a history of excessive alco-

hol consumption (> 80 g ethanol/d in males and > 60 g ethanol in females) and a recent onset of deep jaundice, which can lead to progressive liver failure. Symptoms are usually non-specific such as fatigue, weakness and anorexia but there is usually tender hepatomegaly and often fever, ascites and encephalopathy<sup>[2,3]</sup>. These features can also be seen in many hazardous drinkers making AAH challenging to diagnose clinically. Histology remains the gold standard in diagnosing AAH with well described features of steatosis, hepatocyte injury and neutrophil infiltration<sup>[4,5]</sup>. However, there are difficulties in access to transjugular liver biopsy and subsequent expert histopathology review limiting its utility.

Indeed, there is controversy over whether histology is essential in the diagnosis of AAH with the American Association for the Study of Liver Disease and European Association for the Study of the Liver offering different guidance<sup>[6,7]</sup>. Here, we discuss the existing evidence regarding liver biopsy in the management of AAH.

## DIFFERENTIAL DIAGNOSIS OF AAH

Obtaining an accurate alcohol history is notoriously difficult but especially so in patients with potential AAH who are often unable to provide an accurate history due to symptoms of encephalopathy or acute alcohol withdrawal. Where there is uncertainty regarding recent heavy alcohol consumption as much evidence as possible should be obtained from relatives and friends or failing that primary or secondary care records. In all situations it is important to consider the differential diagnosis of acute liver failure including acute viral hepatitis, autoimmune hepatitis, Wilson's disease and drug induced liver injury. These factors can also co-exist in patients with heavy alcohol consumption, most commonly hepatitis C infection, which has been reported as a co-factor in up to 25% in one cohort<sup>[8]</sup>. Although clues to the diagnosis can be ascertained from the history and laboratory tests, in complex cases or where there is diagnostic doubt a liver biopsy often supplements the clinical information.

Studies which included histological diagnosis as an entry requirement have shown a variation in the prevalence of cirrhosis in patients with AAH from 65%-95%<sup>[9,10]</sup>. Therefore a minority of patients may present with AAH without features of chronic liver disease making it important to exclude other causes of acute liver failure.

However, in patients with chronic liver disease the key challenge in making a diagnosis of AAH is in differentiating it from other causes of acute on chronic liver failure (ACLF).

## ACUTE ON CHRONIC LIVER FAILURE

ACLF is an increasingly recognised entity which, although not formally defined, has been the subject of 2 recent consensus meetings<sup>[11,12]</sup>. Both groups describe the condition as an acute deterioration in a patient with chronic liver disease associated with jaundice and coagulopathy<sup>[12]</sup>

and high 3-mo mortality due to multiorgan failure<sup>[11]</sup>. In patients with alcohol-related cirrhosis AAH can be the precipitating cause of ACLF but other precipitants must be excluded especially gastrointestinal haemorrhage and sepsis of any source.

A recently published large multicentre prospective observational study was conducted to help establish diagnostic criteria for ACLF among European patients<sup>[13]</sup>. In 197 patients with alcohol-related liver disease (ALD) who met the criteria for ACLF, alcohol consumption within the preceding 3 mo was considered the precipitating event in 69 (35%) but because only small numbers underwent liver biopsy a histological diagnosis of alcoholic steatohepatitis (ASH) could not be made in these cases. The other commonest precipitants were bacterial infection and gastrointestinal haemorrhage.

Further information can be obtained from studies in patients with ACLF who underwent liver biopsy. In a series of 68 patients with acute decompensation of ALD 36 had a clinical diagnosis of AAH but only 18 of these (50%) had corresponding histological features of ASH, while a further 13 (19%) had histological ASH without clinical AAH<sup>[14]</sup>. In a separate study of 54 ALD patients admitted to hospital with ACLF a precipitating cause could only be identified in 30 (56%): 13 due to alcohol, 12 sepsis and 5 variceal bleeds<sup>[15]</sup>.

These studies demonstrate that AAH is not always the cause of ACLF in patients with ALD; other causes of acute decompensation must be sought.

## LIVER BIOPSY IN AAH PATIENTS

ASH, originally defined by an international consensus group, was described as the presence of steatosis, hepatocyte injury (ballooning and apoptosis) and polymorphonuclear infiltration<sup>[5]</sup>. Additional features of Mallory-Denk bodies and intraparenchymal cholestasis are observed but not necessary for diagnosis<sup>[16]</sup>. However, these characteristic changes of ASH can be seen in patients with ALD without the clinical syndrome of AAH or even active alcohol consumption. As described above 13 out of 68 (19%) patients with acute decompensation of ALD had histological ASH without corresponding clinical AAH<sup>[14]</sup>. ASH has also been noted in explant tissue from patients transplanted for ALD who were presumed to be abstinent. In 1 study ASH was noted in 32 of 148 (22%) explants from ALD patients including 25 who declared abstinence from alcohol for more than 6 mo<sup>[17]</sup>. A Spanish group reported 36 out of 68 (53%) explants from ALD patients had ASH, which was not associated with a reduced survival<sup>[18]</sup>. Therefore, it is important to be clear about terminology: we recommend the use of ASH to apply to the histological diagnosis while AAH should refer to the clinical syndrome.

In patients with severe AAH, many with deranged coagulation and significant ascites, the risks of performing a percutaneous liver biopsy are increased and a transjugular route is required. This is a well described and safe to per-

form procedure<sup>[19]</sup> which should be considered standard practice in hepatology centres<sup>[20]</sup>. In a systematic review of over 7500 transjugular liver biopsies minor bleeding (not requiring blood transfusion) and major complications were similar to the percutaneous approach (6.5% and 0.6% respectively) and death was rare at 0.09%<sup>[21]</sup>. No specific subgroup analysis was performed in those with coagulopathy as the indication but in 183 patients with congenital coagulopathy there was no mortality and the minor and major haemorrhagic complication rates were similar to the whole group (6% and 0.5% respectively). Sufficient biopsy material allowed a histological diagnosis to be made in 96.1% of samples with a median number of 2.7 passes<sup>[21]</sup>. In 132 patients presenting with AAH transjugular biopsy allowed accurate histological interpretation in 100% of cases with a mean length of 19 mm of tissue<sup>[22]</sup>.

Unfortunately little attention has been paid to the timing of biopsy in AAH, which is usually unreported in clinical trials. Early biopsy, as is the practice of several liver centres (median time of 3 d in 1 centre)<sup>[22]</sup>, may be more sensitive in confirming the diagnosis of AAH. Further studies are required to establish the optimal timing of liver biopsy.

Interpreting a liver biopsy specimen requires appropriate expertise and experience with access to specialist histopathologists but there still remains interobserver error. In patients with severe AAH and background cirrhosis this error has been shown to be minimal in one study with a high degree of concordance between 2 histopathologists ( $\kappa = 0.77$ )<sup>[23]</sup>. However, this was based in a specialist hepatology centre with expert liver pathologists and was lower in patients without cirrhosis ( $\kappa = 0.65$ ).

Access to transjugular liver biopsy is variable and generally only available in tertiary referral centres and academic institutions. Transferring patients between centres only to obtain a liver biopsy is logistically challenging, may increase the risk to the patient and is associated with additional costs.

## HISTOLOGICAL SCORES TO DETERMINE PROGNOSIS

There is evidence that some of the histological characteristics as well as liver expressed soluble factors, such as chemokines and interleukins, can be used to predict clinical outcome from AAH. This could assist clinical decision making and guide treatment choices. Steatosis < 20% is an independent predictor of poor outcome<sup>[24]</sup> and polymorphonuclear cell infiltrate is associated with severity of AAH<sup>[25]</sup> and is correlated with 1 year survival<sup>[10]</sup>. Liver tissue interleukin-8, a potent neutrophil chemoattractant, correlates with neutrophil infiltration and biochemical markers of outcome<sup>[26,27]</sup>. Intercellular adhesion molecule-1, a leukocyte adhesion molecule associated with T helper cell recruitment to sites of inflammation, is elevated in AAH versus fatty liver and its level correlates with histological hepatocellular damage<sup>[28]</sup>. CXC family chemokine expression correlates with prognosis<sup>[25]</sup>

and CCL2 is elevated in AAH<sup>[29]</sup>. However, a histological scoring system combining these multiple parameters has not been developed and many of these individual predictors have not been validated nor are they routinely used outside a research setting. A histological severity score including K8/18 staining (a marker for hepatocyte ballooning) shows good accuracy for predicting 90-d survival but has not yet been validated in a second cohort<sup>[14]</sup>. Only 1 validated AAH histology score has been published in abstract form, finding that fibrosis stage, polymorphonuclear infiltrate, cholestasis and the presence of megamitochondria predicted 90 d mortality<sup>[30]</sup>. Further studies in this area are required to establish a reliable and reproducible histological scoring system that predicts clinical outcome.

## USING CLINICAL SCORES TO DIAGNOSE AAH

An accurate non-invasive clinical test for AAH remains elusive. There are a host of different clinical scoring systems in the literature which have been developed to determine severity and likely benefit from glucocorticoid therapy (modified discriminant function<sup>[31]</sup>), prognosis (Glasgow Alcoholic Hepatitis Score<sup>[32]</sup>) or response to glucocorticoids (Lille score<sup>[33]</sup>). Little work has been conducted to examine how accurate these clinical scores are by comparing them to histological data. An abstract describing a literature review of 39 randomized controlled trials (RCTs) in AAH (11 of which had histological ASH as an entry criteria) suggested that overall 84.5% had histological ASH but this could be enriched to 96% if a minimum bilirubin level of 80  $\mu\text{mol/L}$  was used<sup>[34]</sup>. Another study (also published only as an abstract) found that 70% of patients with a clinical diagnosis of AAH with an MDF  $\geq 32$  had histological confirmation of ASH<sup>[35]</sup>. Further work to prospectively compare clinical and histological diagnosis of AAH is needed and to establish whether non-invasive methods of diagnosing AAH can be used accurately. One such study is currently underway in a United Kingdom RCT (STOPAH; ISRCTN reference number: ISRCTN88782125), which intends to compare histological and clinical parameters as part of a secondary analysis. This pragmatic study, which aims to reflect everyday United Kingdom clinical practice, includes all patients with a clinical diagnosis of severe AAH (defined as recent onset jaundice with a bilirubin > 80  $\mu\text{mol/L}$  and heavy alcohol consumption within the last 2 mo of > 80 g/d in men and > 60 g/d in women with a discriminant function  $\geq 32$ ) without the requirement for a biopsy. Liver histology from the subgroup that has a biopsy as part of an institution's standard clinical care will be compared to clinical parameters using this robust clinical definition of AAH.

## CONCLUSION

Whilst it is clear that liver biopsy remains the recommended gold standard to diagnose ASH<sup>[6]</sup> and has the

potential to be used as a prognostic indicator, opinion remains divided on its practical clinical utility. Liver biopsy in this group of patients is as safe to obtain by the transjugular route and provides sufficient tissue to make a histological diagnosis compared to the percutaneous route. It is mandatory where there is diagnostic uncertainty and is useful where cirrhosis is not clinically suspected. However, the widespread clinical utility of liver biopsy is limited by the lack of provision of transjugular liver biopsy in non-specialist centres and cannot therefore be recommended to form part of routine practice outside these centres. In addition, the timely specialist interpretation that is essential to make the diagnosis of ASH is also generally restricted to specialist centres. Efforts need to be made to improve clinical diagnostic accuracy and studies are required to prospectively compare histological and clinical features in patients with AAH. There is the suggestion that accuracy can be improved by using a high cut-off of bilirubin  $> 80 \mu\text{mol/L}$ <sup>[34]</sup> but this also requires prospective validation, which may be provided by the STOPAH clinical trial.

Liver biopsy in AAH plays an important role in a research context: it can improve the homogeneity of the study population and reduce the risk of type II error. It allows researchers to study the mechanisms of alcohol mediated liver damage and identify new targets for therapy. However, including only patients with histological ASH may not actually reflect the patient population we treat in everyday clinical practice but only a highly selected subgroup. Until a reliable non-invasive diagnostic method for the clinical syndrome of AAH has been developed and validated, clinical trials should continue to include patients defined by a robust clinical definition of AAH.

In summary, we recommend the clinical use of transjugular liver biopsy in patients with severe AAH only where there is irresolvable diagnostic uncertainty and as a research tool to further our understanding of the mechanisms and pathology of the disease.

Received: June 21, 2013

Revised: September 12, 2013

Accepted: October 19, 2013

Published online: November 28, 2013

The number of countries of origin of *WJG* authors was 65, 66, 61, 65 and 60 for the period 2008-2012. Authors from 66 countries cited a total of 3194 of the 4409 papers, and these citations were found in 1140 journals.

**CONCLUSION:** The results suggest that *WJG* has stayed on the track of normal international publication and all the indices of this journal are stable and reasonable.

### Abstract

**AIM:** To understand the changes and development of *World Journal of Gastroenterology (WJG)* in recent years.

**METHODS:** The Journal Citation Report (JCR) and SCI-E database of the ISI Web of Knowledge were used to search the articles and data of related indices in *WJG* during 2008-2012. Bibliometric methods were used for statistical analysis of the author's degree of collaboration, collaboration rate, the first author's publications, high-productivity authors, the authors' origins in each year; the distribution of the countries and journals of the authors citing *WJG* papers was also analyzed. In addition, the indices related to this journal in each year were compared with the data from 6 SCI journals in the field of gastroenterology in the 2012 volume.

**RESULTS:** A total of 4409 papers in *WJG* were examined in this study. For the period 2008-2012, the self-citation rate was 8.59%, 6.02%, 5.50%, 4.47% and 5.21%. Of a total of 3898 first authors, 3526 published 1 paper, 291 published 2 papers, 59 published 3 papers, and 22 published 4 or more papers. The origin of *WJG* authors covered the six continents, and the majority came from Asia, Europe and North America.

**Core tip:** A total of 4409 articles were examined to explore the development of *World Journal of Gastroenterology (WJG)* during 2008-2012. Based on analysis of the relevant indices, this study not only discussed the development and changes of *WJG* in recent years, but also the characteristics of the published papers and the authors' origins. Furthermore, we performed analyses involving several journals of gastroenterology. The results show that all the indexes of this journal are stable and reasonable, and *WJG* has developed into one of the important journals in the field of gastroenterology.

Yang H, Chen YX. Improvement analysis of article quality in *World Journal of Gastroenterology* during 2008-2012. *World J Gastroenterol* 2013; 19(44): 7830-7835 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/7830.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7830>

### INTRODUCTION

Journal quality evaluation is an important subject of concern to both editors and readers. Although the evaluation indexes are frequently the citation data of the papers

in a given journal such as the total citation frequency, impact factor and so on, paper publication data for the journal, such as the number of papers and authors' origins can also reflect the journal's academic status in the relevant disciplines. *World Journal of Gastroenterology* (WJG) is an English journal founded in 1995 and published by Baishideng Publishing Group. In 2005 and 2008, 2 papers analyzed the multiple indexes of WJG for the periods of 1998-2004 and 2001-2007, respectively<sup>[1,2]</sup>. Following the above 2 papers, this study compared and analyzed the various indexes of the papers published in WJG in each year from 2008-2012 and the citations of these papers. We also selected 6 internationally renowned journals of gastroenterology including *American Journal of Gastroenterology*, *BMC Gastroenterology*, *Gastroenterology*, *Journal of Clinical Gastroenterology*, *Journal of Gastroenterology* and *Scandinavian Journal of Gastroenterology* for comparative analysis of the relevant indexes with WJG. Based on analysis of the above indexes, this study intended to determine not only the development and changes of WJG in the past several years, but also the characteristics of the published papers and the origins of the authors of this journal.

## MATERIALS AND METHODS

The Journal Citation Report (JCR) of ISI Web of Knowledge<sup>[3]</sup> and SCI-E<sup>[4]</sup> database were employed. The JCR database was searched to identify the number of references, the number of self-citations, the self-citation rate, and other indicators in WJG during 2008-2012. The SCI-E database was retrieved to identify the papers included in WJG every single year from 2008 to 2012; in addition, the relevant items including Title, Author, Source, Document Type, Times Cited, and Addresses were analyzed. Bibliometric methods were utilized for statistical analysis of the author's degree of collaboration, the collaboration rate, the first author's productivity, high-production authors, the authors' geographic areas and/or country related to this journal in each year; the distribution of the countries and journals for the authors citing WJG papers was also analyzed. In the meantime, the 2012 issues of *American Journal of Gastroenterology*, *BMC Gastroenterology*, *Gastroenterology*, *Journal of Clinical Gastroenterology*, *Journal of Gastroenterology*, *Scandinavian Journal of Gastroenterology* and WJG were retrieved and compared. The comparative indexes included the number of annual publications, the author's degree of collaboration, the collaboration rate, the number of countries of origin for all the authors, the proportion of papers written by native authors, the impact factor in 2012, discipline ranking and self-citation rate. Meanwhile, comparative analysis with WJG was carried out to determine the relative performance of various indexes of WJG.

## RESULTS

### Basic situation of WJG in 2008-2012

WJG published 48 issues yearly in 2008-2012, and during the period SCI-E indexed 1200, 964, 916, 762 and 1008

WJG items in the respective years, giving a total inclusion of 4850 items; the included 5 types of items were article, review, editorial, letter and biography. The number of indexed articles and reviews was 1112, 863, 813, 677 and 944 in the respective years, a total of 4409 papers. The results and conclusion of our research are from the analysis of these 4409 papers. Table 1 lists the number of references, the average number of references in each paper, the number of self-citations in the journal, the average number of self-citations and the self-citation rate.

### Description of the authors of WJG papers between 2008 and 2012

There were 26600 authors from 4409 papers. Table 2 lists the distribution of the number of co-authors (mono-authorship and co-authorship), and 3898 were first authors; 3526 (90.46% of 3898 first authors) published 1 paper, 291 (7.47%) 2 papers, 59 (1.51%) 3 papers, 11 (0.28%) 4 papers, and 11 (0.28%) 5 or more papers. Table 3 shows the authors who published 5 or more papers.

### Distribution of author's geographic area and main country

According to the 6 continents geographically, the authors' addresses were mainly located in Asia, Europe and North America (Figure 1). Table 4 lists the number of papers published by authors of the top 15 countries. Of the top 15 countries, there were 5 countries in Asia, 7 in Europe, 2 in North America and 1 in South America.

### Distribution of the countries and journals for authors citing WJG papers

Authors from 66 countries cited 3194 of the papers (72.44%), with a total of 19872 citations. The authors from the United States of America were the top and responsible for 4716 citations (23.73% of the total); authors from China ranked second and were responsible for 3088 citations (15.54%); the third was Japan with 1617 citations (8.14%). The top 15 countries were responsible for 18889 citations (95.06% of the total cited) (Figure 2). These citations were from 2083 journals, and the top 15 of these journals gave 3373 citations (16.97% of the total) (Table 5).

### Comparison of the relevant data of gastroenterological journals

The data of the JCR database can be used to analyze the citation status of journals, we can evaluate the quality of the journals in each discipline. The Gastroenterology and Hepatology category of JCR 2012 Science Edition included 74 journals, and mean value of impact factor of these journals was 3.115. The 7 representative journals are *American Journal of Gastroenterology*, *Gastroenterology*, *BMC Gastroenterology*, *Journal of Clinical Gastroenterology*, *Journal of Gastroenterology*, *Scandinavian Journal of Gastroenterology*, and WJG; of these, 3 journals are from North America, 2 from Europe, and 2 from Asia. Table 6 lists the number of papers, author's degree of collaboration,

**Table 1** Literature indexes for papers published in *World Journal of Gastroenterology* between 2008 and 2012

Year	No. of papers	No. of references	Average No. of references	No. of self-citations in the journal	The mean No. of self-citations in each paper	Self-citation rate

author's collaboration rate, geographical distribution of the authors, proportion of articles contributed by domestic authors, 2012 impact factor (IF), discipline ranking of the journal by IF, and self-citation rate for these 7 journals in 2012.

## DISCUSSION

The publishing frequency of *WJG* was stable during 2008-2012, without significant changes in the annual number of papers published and the average number of papers in each issue. The average number of references in each paper increased gradually while the self-citation rate decreased gradually year by year. When compared with 2004, the average number of references in each paper in 2012 increased by 8.9<sup>[1]</sup>, while the self-citation rate per article decreased by 0.73<sup>[1]</sup> in 2012; all the indexes were in a satisfactory state.

The degree of collaboration increased slightly while the

**Table 6 Data comparisons of the 7 representative gastroenterology journals in 2012**

Journal name	Articles published in 2012	Cooperation degree in 2012	Cooperation rate in 2012	Geographical distribution of authors	Ratio of articles contributed by domestic authors	2012 impact factor	Ranking of discipline impact factors	Self-citation rate in 2012
<i>Am J Gastroenterol</i>	190	7.50	94.74	32	United States 45.16	7.553	7	3.36
<i>BMC Gastroenterol</i>	165	7.35	98.79	36	China 21.21	2.11	42	2.6
<i>Gastroenterology</i>	278	10.55	97.48	44	United States 44.25	12.821	1	2.2
<i>J Clin Gastroenterol</i>	154	6.41	96.10	24	United States 38.96	3.203	23	3.1
<i>J Gastroenterol</i>	140	9.53	98.57	22	Japan 76.43	3.788	17	3.34
<i>Scand J Gastroenterol</i>	179	6.40	98.88	35	Sweden 21.79	2.156	40	3.29
<i>World J Gastroenterol</i>	944	6.31	96.72	58	China 35.67	2.547	34	5.21

collaboration rate decreased slightly during 2008-2012. The collaboration degree for each respective year was 5.85, 5.88, 6.20, 5.96 and 6.31; the mean collaboration degree was 6.03 and increased by 0.15 when compared with 5.88 during 2001-2007<sup>[2]</sup>. The collaboration rate for each year was 95.59%, 96.76%, 96.56%, 96.90% and 96.72%; the mean collaboration rate was 96.44%. In contrast with the slight increase in collaboration degree during 2008-2012, the collaboration rate during this period decreased by 1.22% when compared with the 97.66% during 2001-2007.

The origin of the authors diversified and the proportion of authors with 1 paper increased, but the high-productivity authors did not increase. During 2008-2012, 3526 authors published 1 paper in *WJG* accounting for 90.46% of the total authors, and 22 authors published 4 papers or more accounting for 0.56%. The core author group of this journal has yet to increase.

The number of author geographic areas increased: the origin of *WJG* authors became increasingly diversified; the authors came from 87 countries across the 6 continents of the world. Asia, Europe and North America were the main origins of the authors; and the proportion of authors from Asia was relatively stable; the number of papers contributed by authors from Asia was 672 (60.60%), 500 (58.07%), 473 (58.18%), 398 (58.88%) and 603 (63.88%) in respective years. The number of authors from Europe and North America changed little in each year and only decreased slightly in 2012. The number of papers contributed by authors from North America was slightly higher when compared with the data during 2006-2007<sup>[2]</sup> but the number was slightly lower during 2011-2012. The number of author countries exceeded 60 in each year; these authors came from a total of 87 countries and/or regions. The origin of the first authors of *WJG* became increasingly diversified and the number of originating countries increased when compared with the data of the period of 2001-2007.

The distribution of the author countries tended to be balanced: authors from the top 15 countries published 3742 (84.87%) papers. The proportion of papers published by Chinese authors showed an annual incremental trend, which coincided with an overall increase in the number of scientific publications in China. The ranking of the top 15 countries have changed; the contemporary top 5 countries were China, Japan, United States, South

Korea and Italy. The international trend in the origin of *WJG* authors increased significantly.

During 2008-2012, 72.44% of all *WJG* papers were cited; although the time factor of 2012 may be responsible for the relatively lower number of citations, and therefore affected the citation rate of *WJG*, but the rate reflected the fairly satisfactory quality of *WJG* papers. The authors citing these papers were distributed among 66 countries or regions; American authors were ranked first and accounted for 23.73%, while Chinese authors were ranked second and accounted for 15.54%. The significant impact of *WJG* around the world was evidenced by the fact that 1140 journals cited *WJG* papers, and the distribution of the citing journals was dispersed widely.

The changes in *WJG* in the past 5 years were compared with another 6 journals of gastroenterology at the same time. *WJG* had the highest number of annual publications; authors' degree of collaboration in *WJG* was slightly lower than that of the other 6 journals, while the collaboration rate was within a reasonable range; the origin of *WJG* authors was the most diversified, and has gradually expanded from the predominant Chinese author group at the early stage to Asia and even the entire world across the 6 continents. Based on the data in JCR 2012, *WJG* ranked fifth of the 7 journals of gastroenterology; its self-citation rate declined and all other indexes were fairly reasonable.

In summary, *WJG* is attracting the attention of gastroenterologists globally, with authors scattered among 87 countries across the 6 continents. It has become a stage for gastroenterologists around the world to demonstrate their research findings. The author's geographic areas and countries are widely distributed, and all the indexes of this journal are stable and reasonable. *WJG* has embarked onto the track of normal internationalized publication, although it is still necessary to cultivate the core author group for the journal to establish its stable research characteristics.

## COMMENTS

### Background

The paper publication data of a journal can reflect a journal's academic status in the relevant disciplines, and the evaluation of journal quality is paid more and more attention by both editors and readers. In 2005 and 2008, two papers analyzed the multiple indices of *World Journal of Gastroenterology (WJG)* for the periods 1998-2004 and 2001-2007. Therefore, it was necessary to analyze the

relevant indexes and make an objective evaluation of journal quality in recent years.

### Research frontiers

Although the evaluation indexes are frequently the citation data of the papers in a given journal such as the total citation frequency, impact factor and so on, the paper's publication data of the journal such as the number of papers and author's origin can also reflect the journal's academic status in the relevant disciplines.

### Innovations and breakthroughs

Based on analysis of the relevant indexes, the authors only studied the development and changes of *WJG* during 2008-2012, but also the characteristics of the published papers and the origin of the authors of this journal.

### Applications

The results indicate that *WJG* has become an international publication, and gastroenterologists around the world can report their research findings in this journal.

### Terminology

The impact factor of a journal is a measure of the citations to science and social science journals, and is frequently used as a proxy for the importance of a journal to its field, with journals with higher impact factors deemed to be more important than those with lower ones.

### Peer review

Commendable effort. Much needed analysis to establish the position of *WJG* in the field of gastroenterology and hepatology. In this interesting paper, authors

performed analyses involving several journals of gastroenterology. All aspects of comparison are presented sufficiently. Statistical analysis of the study made clear and demonstrate that *WJG* has developed into one of the important journals in the field of gastroenterology.

techniques, a significant number of non-coding RNAs (ncRNAs) associated with HCC, particularly caused by HCV infection, have been found to be differentially expressed and to be involved in pathogenesis of HCV-associated HCC. In this review, we focus on recent studies of ncRNAs, especially miRNAs and lncRNAs related to HCV-induced HCC. We summarize those ncRNAs aberrantly expressed in HCV-associated HCC and highlight the potential uses of ncRNAs in early detection, diagnosis and therapy of HCV-associated HCC. We also discuss the limitations of recent studies, and suggest future directions for research in the field. miRNAs, lncRNAs and their target genes may represent new candidate molecules for the prevention, diagnosis and treatment of HCC in patients with HCV infection. Studies of the potential uses of miRNAs and lncRNAs as diagnostic tools or therapies are still in their infancy.

## Abstract

Hepatitis C virus (HCV) infection is one of main causes of hepatocellular carcinoma (HCC) and the prevalence of HCV-associated HCC is on the rise worldwide. It is particularly important and helpful to identify potential markers for screening and early diagnosis of HCC among high-risk individuals with chronic hepatitis C, and to identify target molecules for the prevention and treatment of HCV-associated-HCC. Small non-coding RNAs, mainly microRNAs (miRNAs), and long non-coding RNAs (lncRNAs) with size greater than 200 nucleotides, are likely to play important roles in a variety of biological processes, including development and progression of HCC. For the most part their underlying mechanisms of action remain largely unknown. In recent years, with the advance of high-resolution of microarray and application of next generation sequencing

**Key words:** MicroRNA; Long non-coding RNAs; Non-coding RNAs; Hepatitis C virus; Hepatocellular carcinoma

**Core tip:** Regulatory non-coding RNAs (ncRNAs), mainly microRNAs (miRNAs) and long non-coding RNAs (lncRNAs), are likely to play important roles in a variety of biological processes, including development and progression of hepatitis C-induced hepatocellular carcinoma (HCC). In this review, we focus on recent studies of ncRNAs, especially miRNAs and lncRNAs associated with hepatitis C virus (HCV)-induced HCC. We summarize those ncRNAs aberrantly expressed in HCV-induced HCC and highlight the potential of these ncRNAs to aid in early detection, diagnosis and therapy of HCV-induced HCC. Further, we discuss the limitations of current studies, and suggest future directions for research in the field.

Hou W, Bonkovsky HL. Non-coding RNAs in hepatitis C-induced hepatocellular carcinoma: Dysregulation and implications for early detection, diagnosis and therapy. *World J Gastroenterol* 2013; 19(44): 7836-7845 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i44/7836.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7836>

## INTRODUCTION

Non-coding RNAs (ncRNAs) are transcribed RNA molecules with little or non-protein coding capacity; they represent approximately 97% of RNAs in higher eukaryotic organisms. ncRNAs include structural or house-keeping ncRNAs such as transfer RNA, ribosomal RNA, small nuclear RNA and small nucleolar RNA, as well as regulatory ncRNAs, which function to regulate gene expression. Based on transcript size, regulatory ncRNAs are classified into two major groups, small ncRNAs such as microRNAs (miRNAs), approximately 22 nucleotides (nt) in length, and long non-coding RNAs (lncRNAs) with sizes longer than 200 nt (Figure 1). Based upon a large number of experimental studies carried out over the past decades or two, it is now generally well-accepted that miRNAs play an important role in the regulation of gene expression primarily through post-transcriptional destabilization, translational repression of target mRNAs which bear complementary sites, or a combination of these two mechanisms<sup>[1-4]</sup>. With the development of next generation sequencing (NGS) techniques, a growing number of lncRNAs have been identified, characterized and functionally annotated<sup>[5,6]</sup>. lncRNAs are still among the least well-understood of transcripts. Several lines of evidence have suggested that lncRNAs are biologically functional rather than transcriptional “noise”<sup>[5,6]</sup>. Thus, lncRNAs have recently enjoyed increased and deserved attention, although the underlying mechanisms by which they function remain largely unexplored and unifying theories regarding their actions are still vague. ncRNAs including miRNAs and lncRNAs have been reported to be associated with cancer, including hepatocellular carcinoma (HCC), a highly prevalent and deadly cancer because of its frequent recurrence and/or metastasis.

HCC is among the most frequent forms of cancer worldwide, and its incidence is increasing rapidly. This increase is related to several factors. Chief among these are chronic hepatitis B and C (CHC) infections, and fatty liver disease. Indeed, hepatitis C virus (HCV) infection is one of the leading underlying causes of HCC, increasing the risk for HCC development by nearly 17-fold compared to healthy individuals<sup>[7,8]</sup>. In recent decades and especially in recent years, HCC incidence has increased sharply, and has been attributed largely to HCV infection. HCV-induced HCC typically develops in the setting of cirrhosis (advanced chronic liver diseases), although it does also occur in the absence of cirrhosis. Similarly, the development of HCC has been observed in mice expressing HCV transgenes in the absence of appreciable

hepatic inflammation and fibrosis, suggesting that HCV infection is likely to have direct and unique cancer-promoting effects, which may be different from other carcinogenic factors such as those due to hepatitis B virus (HBV) and fatty liver disease. Understanding and insight into unique ncRNAs involved in HCV-induced HCC may suggest new approaches for diagnosis, prevention and treatment of HCV-induced HCC. To date, there have been few reports on differentially expressed lncRNAs in HCV-induced HCC. In this review, we will summarize recent studies regarding ncRNAs related to HCV-induced HCC. We will then address the potential utility of these ncRNAs in early detection, diagnosis and therapy of HCV-associated HCC. Finally, we will discuss the limitations of current knowledge, and suggest future directions for research in this field.

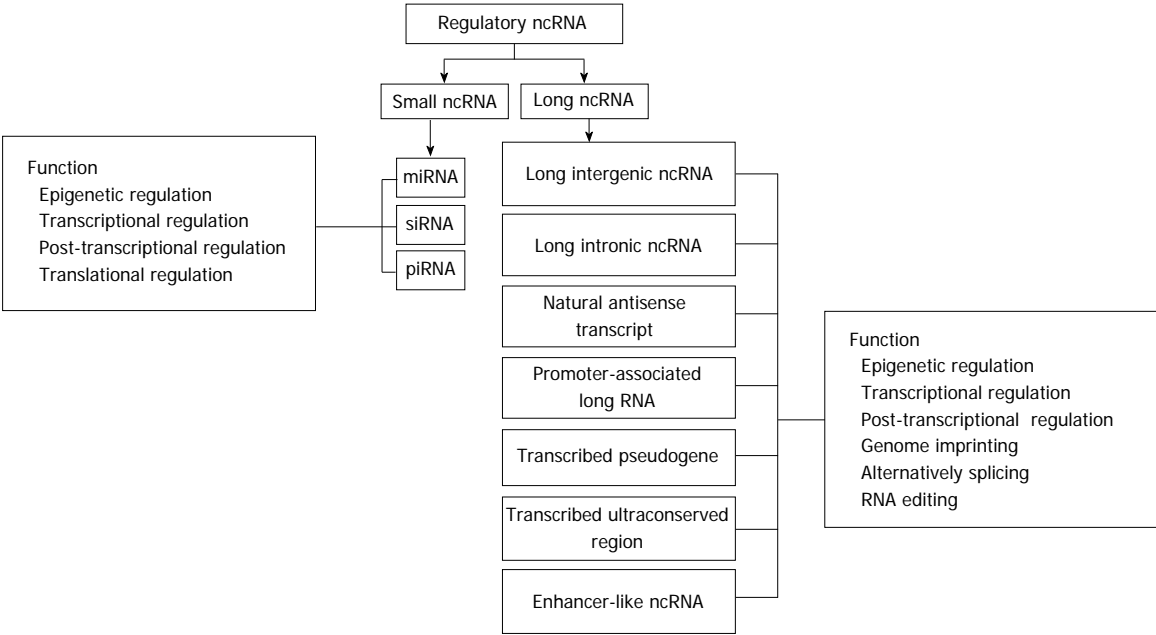

## DYSREGULATED NCRNAS IN HCV-INDUCED HCC

### microRNAs

miRNAs regulate gene expression primarily through post-transcriptional repression<sup>[3,4,9,10]</sup>. Sequence complementarity in the 6-8 base pair “seed regions” at the end of miRNA-mRNA heteroduplexes seem to determine the specificity of miRNA-target RNA interactions<sup>[11]</sup>. miRNAs are likely to play significant roles in the development and progression of cancers, including HCC<sup>[12,13]</sup> and HCV replication<sup>[9,14-16]</sup>. Identification and characterization of dysregulated miRNAs specific to HCV-induced HCC in tissue- and biofluid-based studies are important and helpful to reveal therapeutic targets or diagnostic markers, in particular, molecular signatures for the detection and early diagnosis of HCC among HCV patients in high-risk groups. The miRNAs reported differentially expressed in HCV-induced HCC are summarized in Tables 1 and 2, and we now summarize their known biological functions, and the molecular mechanisms and pathways in which they might be involved.

### Up-regulated miRNAs

miRNAs profiling studies in HCV-induced HCCs compared with paired controls have found that a number of miRNAs are significantly elevated in HCV-induced HCCs, compared with normal controls. miR-1269 is the most increased in HCV-associated HCCs in contrast to normal livers, HCV-associated cirrhosis, or HBV-associated liver failure. Up-regulation of miR-1269 has also been found in other cancers such as breast cancer<sup>[17]</sup>, colorectal cancer<sup>[18]</sup> and laryngeal squamous cell carcinoma (LSCC), one of the most common head and neck malignancies with no significant difference between tumors with and without lymphatic metastasis, suggesting that miR-1269 did not affect metastasis of LSCC. Thereto date there have been few, if any, reports on function and role of miR-1269 in HCC. Nevertheless, the increased expression of miR-1269 in HCV-induced HCC when compared with controls suggests that this miRNA may have an on-

**Figure 1 Classification of regulatory non-coding RNA and function in gene regulation.** Regulatory non-coding RNA (ncRNAs) are divided into two major groups based on transcript size, small ncRNAs such as microRNA, small interfering RNA and piwi-interacting RNA (piRNA), as well as long ncRNAs with size greater than 200 nt. Both small ncRNA and long ncRNA have important regulatory function in gene expression. miRNA: microRNA; siRNA: small interfering RNA; piRNA: piwi-interacting RNA.

Table 1 Summary of microRNAs significantly up-regulated in hepatitis C virus-induced hepatocellular carcinoma				
ncRNAs	Chromosomal location	Differential expression level	Clinical relevance	Ref.
Liver miRNAs				
miR-1269	4q13.2	15.7-fold, HCV-associated HCC (n = 9) <i>vs</i> normal livers (n = 12) and other liver diseases [HCV-associated cirrhosis (n = 10), HBV-associated accurate liver failure (n = 4)], P < 0.05	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-224	Xq28	10.7-fold, HCV-associated HCC (n = 9) <i>vs</i> normal livers (n = 12) and other liver diseases [HCV-associated cirrhosis (n = 10), HBV-associated accurate liver failure (n = 4)], P < 0.05	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-452	Xq28	10.1-fold, HCV-associated HCC (n = 9) <i>vs</i> normal livers (n = 12) and other liver diseases [HCV-associated cirrhosis (n = 10), HBV-associated accurate liver failure (n = 4)], P < 0.05	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-224-3p	Xq28	8.1-fold, HCV-associated HCC (n = 9) <i>vs</i> normal livers (n = 12) and other liver diseases [HCV-associated cirrhosis (n = 10), HBV-associated accurate liver failure (n = 4)], P < 0.05	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-221	Xp11.3	3.7-fold, HCV-associated HCC (n = 9) <i>vs</i> normal livers (n = 12) and other liver diseases [HCV-associated cirrhosis (n = 10), HBV-associated accurate liver failure (n = 4)], P < 0.05	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-122	18q21.31	> 2-fold, HCV-associated HCC (n = 43) <i>vs</i> normal livers (n = 3), P < 0.01; HCV associated dysplastic nodules (n = 9) <i>vs</i> normal livers (n = 3), P < 0.05	Potential therapeutic target molecule to prevent HCV-induced HCC	[30]
miR-100	11q24.1	> 2-fold, HCV-associated HCC (n = 43) <i>vs</i> normal livers (n = 3); HCV associated dysplastic nodules (n = 9) <i>vs</i> normal livers (n = 3)	Potential therapeutic target molecule to prevent HCV-induced HCC	[30]
miR-10a	17q21.32	> 2-fold, HCV-associated HCC (n = 43) <i>vs</i> normal livers (n = 3); HCV associated dysplastic nodules (n = 9) <i>vs</i> normal livers (n = 3)	Potential therapeutic target molecule to prevent HCV-induced HCC	[30]
Urinary miRNAs				
miR-625	14q23.3	> 3-fold, HCV-associated HCC (n = 32) <i>vs</i> normal urine samples (n = 12), P < 0.05	Potential marker for the detection/early diagnosis of HCC among high-risk HCV patients	[33]
miR-532	Xp11.23	> 3-fold, HCV-associated HCC (n = 32) <i>vs</i> normal urine samples (n = 12), P < 0.05	Potential marker for the detection/early diagnosis of HCC among high-risk HCV patients	[33]
miR-618	12q21.31	> 3-fold, HCV-associated HCC (n = 32) <i>vs</i> normal urine samples (n = 12), P < 0.05	Potential marker for the detection/early diagnosis of HCC among high-risk HCV patients	[33]

HCV: Hepatitis C virus; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; miRNAs: MicroRNAs; ncRNAs: Non-coding RNAs.

**Table 2** Summary of microRNAs down-regulated in hepatitis C virus-induced hepatocellular carcinoma

ncRNAs	Chromosomal location	Differential expression level	Clinical relevance	References
Liver miRNAs				
miR-199a-5p	19q13.3	7.2-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-199a-3p	19q13.3	6.9-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-199b-3p	19q13.3	6.2-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-214	1q24.3	5.5-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-198	19p13.3	Approximately 5-fold, HCV-associated HCC ( $n = 43$ ) <i>vs</i> normal livers ( $n = 3$ ), $P < 0.01$ ; HCV-associated Dysplastic nodules ( $n = 9$ ) <i>vs</i> normal livers ( $n = 3$ ), $P < 0.01$	Potential therapeutic target molecule to prevent HCV-induced HCC	[30]
miR-139-3p	11q13.4	4.6-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-139-5p	11q13.4	4.4-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-424-3p	Xq26.3	3.9-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-125a-5p	19q13	3.7-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-130a	11q12.1	2.9-fold, HCV-associated HCC ( $n = 9$ ) <i>vs</i> normal livers ( $n = 12$ ) and other liver diseases [HCV-associated cirrhosis ( $n = 10$ ), HBV-associated accurate liver failure ( $n = 4$ )], $P < 0.05$	Potential therapeutic target molecule to prevent HCV-induced HCC	[32]
miR-145	5q32	> 2-fold; HCV-associated HCC ( $n = 43$ ) <i>vs</i> normal livers ( $n = 3$ ); HCV associated dysplastic nodules ( $n = 9$ ) <i>vs</i> normal livers ( $n = 3$ )	Potential therapeutic target molecule to prevent HCV-induced HCC	[30]
Urinary miRNAs				
miR-516-5p	19q13.42	> 3-fold, HCV-associated HCC ( $n = 32$ ) <i>vs</i> normal urine samples ( $n = 12$ ), $P < 0.05$	Potential marker for early diagnosis of HCC among high-risk HCV patients	[33]
miR-650	22q11.22	> 3-fold, HCV-associated HCC ( $n = 32$ ) <i>vs</i> normal urine samples ( $n = 12$ ), $P < 0.05$	Potential marker for early diagnosis of HCC among high-risk HCV patients	[33]

HCV: Hepatitis C virus; HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; miRNAs: MicroRNAs; ncRNAs: Non-coding RNAs.

cogenic role in HCV-induced HCC.

Interestingly, miR-224, miR-224-3p and their precursor are significantly up-regulated in HCV-associated HCCs compared to normal livers, HCV-associated cirrhosis and HBV-associated liver failure. miR-452, also significantly up-regulated in HCV-induced HCC, was recently shown to be coordinately expressed with its neighboring miR-224 in HCC through epigenetic mechanisms<sup>[19]</sup>. The DNA that encodes miR-224 is located on the X-Chromosome. miR-224 has been reported to be a cancer-related miRNA, including in HCC. Wang *et al.*<sup>[20]</sup> identified and validated the apoptosis inhibitor 5 (API-5) as a specific target gene for miR-224. Additionally, SMAD family member 4 (*SMAD4*) has been identified as another target gene for miR-224. Over-expression of miR-224 increases the concentration of SMAD4 protein in murine granulosa cells, while SMAD4 RNA levels remain unchanged, suggesting a post-transcriptional role

for miRNA-224<sup>[21]</sup>. It is likely that miR-224 plays a role in cell proliferation, migration, invasion, and anti-apoptosis in HCC, and is involved in hepatocarcinogenesis by directly binding to its validated gene targets such as *API-5*, *SMAD4*, *etc.*<sup>[20,22,23]</sup>.

miR-122, a liver specific miRNA, is the most abundant miRNA expressed in hepatocytes (accounting for approximately 70% of total miRNAs) and the most extensively studied miRNA in liver diseases. miR-122 has major effects on several enzymes of cholesterol metabolism<sup>[24,25]</sup>. Unexpectedly, miR-122 was also shown to be required for HCV replication<sup>[14,16]</sup>. The effects of miR-122 depend upon the context and location of its cognate seed sequence binding sites. The sites in the 5' region are mostly associated with up-regulation of expression, whereas those in the 3' untranslated region are mostly associated with repression of expression<sup>[26]</sup>. miR-122 exerts several functions in the HCV life cycle<sup>[27,28]</sup>. Recent

studies have shown that miR-122 acts to protect HCV genome from degradation, and therefore stabilizes HCV RNA by decreasing activity of the cytosolic exonuclease Xrn1<sup>[27,28]</sup>. The role of miR-122 in HCC has been controversial. Some but not all studies suggest that miRNA-122 is preserved and increased specifically in HCV-associated HCC<sup>[12,29,30]</sup>. Nevertheless, a decrease in expression of miR-122 or undetectable miRNA-122 in human hepatoma cell lines such as HepG2 and Hep3B cell has been observed<sup>[31]</sup>. In parallel with these observations, overexpression of miR-122 inhibits anchorage-independent growth, migration, invasion and tumor formation in nude mice<sup>[31]</sup>. This needs to be further studied in the future.

### Down-regulated miRNAs

The miR-199 family members including miR-199a-5p, miR-199a-3p and miR-199b are the most down-regulated miRNAs in HCV-induced HCC compared to normal livers, HCV-associated cirrhosis and HBV-associated liver failure<sup>[32]</sup>. miR-199a/b-3p is the third most highly expressed miRNA in the liver<sup>[34]</sup>, and was also found to be consistently decreased in HCC patients with HBV infection<sup>[34]</sup> and alcohol consumption<sup>[35]</sup>. Its decrement significantly correlates with poor survival of HCC patients<sup>[34]</sup>. Down-regulation of miR-199a-3p results in a pronounced increase in cell proliferation while overexpression miR-199a-3p inhibits cell proliferation by imposing G<sub>1</sub> cell cycle arrest<sup>[36]</sup>. The target mRNAs for the miR-199a-3p have been predicted using bioinformatic approaches and validated experimentally. For example, mammalian target of rapamycin (mTOR) has been identified as one of important targets for miR-199a-3p binding. Through negative regulation of oncogenic mTOR, miR-199a-3p inhibits tumor proliferation<sup>[37]</sup>.

miR-214 has been reported to be down-regulated by 5.5-fold in HCV-induced HCC compared to normal livers, HCV-associated cirrhosis and HBV-associated liver failure<sup>[32]</sup>. The down-regulation of miR-214 has been reported in HCC<sup>[20,38,39]</sup> and other cancers such as cervical cancer, whereas increase in miR-214 was found to significantly reduce growth of Hela cells<sup>[40]</sup>. In addition, reduced level of miR-214 is associated with invasion, stem-like traits and early recurrence of HCC<sup>[41]</sup>. Re-expression of miR-214 significantly suppressed the growth of HCC cells *in vitro* and reduced the tumorigenicity *in vivo*<sup>[41]</sup>. In the same study, the enhancer of zeste homologue (EZH2) and  $\beta$ -catenin (CTNNB1) were identified and validated as two functional target mRNAs of miR-214. Silencing miR-214 increased stem-like cells through activation of CTNNB1. Furthermore, the up-regulation of EZH2, CTNNB1 and the down-regulation of E-cadherin (CDH1), known to inhibit cell invasion and metastasis in HCC patients, correlated with earlier recurrent HCC and were independent predictors of poor survival.

### LncRNAs

The discovery of lncRNAs ushered in a new and exciting area of study, although at the time lncRNAs were first

found, they were considered to be merely transcriptional “noise”<sup>[5]</sup>. Recently, with fast development and application of NGS techniques, the numbers of lncRNAs continues to grow at a rapid pace, and it is increasingly clear that lncRNAs are a new class of regulators of gene expression, being involved in diverse biological processes and human diseases such as cancer. The association of lncRNAs with HCC has been studied and summarized<sup>[42]</sup>, although the mechanisms whereby effects of the lncRNAs are realized are largely unknown. Analysis of the differentially expressed lncRNAs in HCCs (underlying etiology not specified) have revealed that a number of lncRNAs such as HOTAIR<sup>[43-46]</sup>, HEIH<sup>[47]</sup>, MVIH<sup>[48]</sup>, MALAT-1<sup>[49]</sup>, HULC<sup>[50-52]</sup>, H19<sup>[53-55]</sup>, CUDR<sup>[56]</sup>, YIYA<sup>[57]</sup>, lncRNA-Dreh<sup>[58]</sup>, lncRNA-LET<sup>[59]</sup> and MEG3<sup>[60,61]</sup> are associated with HCC. Most of these lncRNAs are up-regulated in HCCs, but less expressed or undetectable in normal controls. HCC patients with HOTAIR expression had significantly poorer prognoses and larger primary tumor sizes than those without HOTAIR expression<sup>[46]</sup>. Moreover, introduction of HOTAIR into human liver cancer cells promoted more rapid proliferation compared to controls<sup>[46]</sup>. Functional gene annotation analysis of TUC338 indicated predominant effect on genes involved in cell growth in both human and murine cells, suggesting that TUC338 plays a critical role in regulation of transformed cell growth and in the pathobiology of HCC<sup>[62]</sup>. Lai *et al.*<sup>[49]</sup> found up-regulation of MALAT-1 in both liver cancer cell lines and HCC patient samples. HCC patients with high level of MALAT1 had a significantly increased risk of tumor recurrence after liver transplantation. MVIH was identified to be related to frequent microvascular invasion and higher tumor-node-metastasis stages as well as to decreased overall survival. In addition, in mouse models it promoted tumor growth and intrahepatic metastasis by activating angiogenesis<sup>[48]</sup>. The expression level of HEIH in HBV-induced HCCs is significantly associated with recurrence and is an important independent prognostic factor for survival<sup>[47]</sup>. Further studies indicated that HEIH plays a key role in the regulation of zeste homologue 2 (EZH2) and that this association was required for the repression of EZH2 target genes, suggesting that HEIH is an oncogenic lncRNA that promotes tumor progression<sup>[47]</sup>. Thus far, few studies have been focused on lncRNAs specific to HCV-induced HCC although HCV infection is one of the major causes of HCC, and HBV and HCV cause hepatocarcinogenesis by different mechanisms.

## CLINICAL IMPLICATIONS FOR DIAGNOSIS AND THERAPY

miRNAs, lncRNAs and their target genes comprise a large and still growing number of candidate molecules for the prevention, diagnosis and treatment of HCC in patients with HCV infection, and studies of the potential use of miRNAs and lncRNAs as therapeutic or diag-

nostic approaches is still in its infancy. In this section, we mainly discuss clinical potentials of miRNAs and lncRNAs for HCV-induced HCC diagnosis and therapy.

### **miRNAs and lncRNAs to aid in diagnosis of HCV-induced HCC**

The biomarkers currently available for screening and early diagnosis of HCC, including serum alpha-fetoprotein (AFP), des-gamma-carboxyprothrombin, and AFP-L3 fraction or assaying cells from tissue biopsy by needle aspiration and surgical resection, suffer from numerous limitations<sup>[63,64]</sup>. Most patients chronically infected with HCV are asymptomatic for many years, and the average time to develop HCC after onset of HCV infection is about 28 years. The long latency period between initial HCV infection and development of HCC provides an important time window of opportunity for individuals to be monitored for disease progression and intervention. Therefore, the development of more reliable markers for diagnosis of HCC at an early stage and better approaches for HCC screening and early detection are urgently needed. The recent study from Abdalla *et al.*<sup>[33]</sup> to identify urinary miRNAs as biomarkers specific for early detection of HCV-induced HCC, appears to be attractive and promising. The significantly up-regulated and down-regulated urinary miRNAs as listed in Tables 1 and 2 can be considered as promising candidate miRNA urinary markers for the early detection and diagnosis of HCV-induced HCC among high-risk HCV patients (Genotype 4). Of the identified miRNAs, miR-618 was found to have a sensitivity of 64% and a specificity of 68% for detecting HCC among HCV-positive individuals, whereas the sensitivity and specificity of urinary miR-650 were 72% and 58%, respectively. Also worthy of note, miR-618/650 in tandem improved the specificity to 75%, greater than the traditional methods based on serum levels of AFP. The urinary miRNAs signatures found in this study may be of great value and applied for the early diagnosis of HCC, before the onset of disease in high-risk patients infected with HCV. However, it is noted that this study was carried out in patients infected with HCV genotype 4, the most prevalent HCV genotype in Egypt. The potential for their use in the early diagnosis of HCC caused by different HCV genotypes other than genotype 4 needs further investigation and independent confirmation. So far, few studies have been reported regarding on lncRNAs signatures in biofluids specific to HCV-induced HCC, which may represent an exciting area for future exploration.

### **miRNAs and lncRNAs for HCV-induced HCC therapy**

Recent studies have suggested the exciting possibility that ncRNAs may represent a novel therapeutic strategy for human diseases. The miR-122 antagonist, miravirsin, a locked nucleic acid-modified DNA phosphorothioate antisense oligonucleotide that sequesters mature miR-122 in a highly stable heteroduplex, already has shown promising results in phase 2a clinical trials at seven international sites. In this clinical study, Janssen

*et al.*<sup>[65]</sup> evaluated the safety and efficacy of miravirsin in 36 patients with chronic HCV genotype 1 infection. This landmark study demonstrated that the use of miravirsin produced prolonged dose-dependent reductions in HCV RNA with no evidence of development of viral resistance. Meanwhile, targeting a number of other miRNAs such as miR-33a/b for the treatment of atherosclerosis<sup>[66,67]</sup>, miR-208/449 for chronic heart failure, miR-34 and the let-7 miRNA for cancer, await entering clinical trials. In addition, Coelho *et al.*<sup>[68]</sup> has recently demonstrated a new therapeutic approach to transthyretin amyloidosis by RNA interference (RNAi). In this phase I clinical trial, a potent antitranssthyretin small interfering RNA was encapsulated in lipid nanoparticles, delivered to human hepatocytes, and resulted in a significant reduction of transthyretin, establishing proof of concept for RNAi therapy<sup>[68]</sup>.

As summarized and discussed earlier in this review, many of the significantly dysregulated cellular miRNAs as listed in Tables 1 and 2, and currently found to be involved in the modulation of cell growth, apoptosis and invasiveness, can be considered as potential therapeutic targets for HCV-induced HCC therapy. The overexpression of these specific mature miRNAs can be achieved by synthetic miRNAs mimics or expression vectors. When inhibition of the selected miRNAs is desirable, antagomir or antisense oligos complementary to the specific miRNAs can be used. However, the introduction of the miRNA-based agents into clinical trials and the development of new therapeutic agents are hampered by a number of factors. The major road block is still the big challenge of developing a small animal model used in biomedical research to understand roles of ncRNAs in the pathogenesis of HCV-induced HCC. Among nonhuman species, only chimpanzees have thus far been capable of being infected with HCV, and disease in them is generally relatively mild. Most recently, Dorner *et al.*<sup>[69]</sup> has reported a breakthrough and milestone in development of a genetically humanized mouse model for HCV research, in which the entire HCV life cycle can be completed and immune system is fully functioning. This genetically humanized mouse model will allow us to gain new insights into not only an important biology of HCV but also carcinogenesis of HCC caused by HCV. Additional challenging factors remain which slow the progress of the miRNA-based agents into clinical trials and new drugs. The dysregulated miRNAs in HCV-induced HCC as discussed earlier in this review were identified in individual studies, lacking consensus among the different reports, having been attributed to the differences among miRNA probe, staging and grade of malignancy of the tumor and different HCV genotypes. Therefore, there is still a long way to go before the miRNA-based therapy can be used in the clinic in the prevention and treatment of HCV-induced HCC.

## **CONCLUSION**

As we summarized and discussed in this review, the re-

cent findings of roles of ncRNAs in not only regulating HCV life cycle but also their contribution to pathogenesis of HCV-induced HCC have been remarkable, despite the fact that we may have unveiled only a small portion of the very large number of ncRNAs; this is probably especially true for lncRNAs. We are only beginning to understand the nature and extent of the involvement of lncRNAs in disease. Recently, a number of lncRNAs have been found to be aberrantly regulated in cancer, including HCC<sup>[42-48,53-55,57,59-62]</sup>. However, at the present time there are no reports on aberrantly lncRNAs exclusively associated with HCV-induced HCC, and thus remain a large unexplored and undefined area, which may allow us to better understand the role of lncRNAs in the pathogenesis of HCV infections and HCC and to identify better therapeutic targets and more sensitive diagnostic markers.

The intracellular ncRNAs that were significantly altered in HCV-induced HCC have been proposed to be potential molecular targets for therapy to combat HCV and HCV-induced HCC. Furthermore, over the past years, extracellular ncRNAs, particularly ncRNAs in exosomes, have risen to be promising as biomarkers with diagnostic or prognostic value. Exosomes (30-100 nm in diameter) are one of the class of microvesicles found in biofluids, including blood, ascites fluid, urine, culture media of cell cultures, *etc.* Exosomes carry with them various nucleic acids, including ncRNAs (*e.g.*, miRNAs and lncRNAs) and proteins from their cells of origin, which allow us to achieve access to molecular information about their cell-of-origin without biopsying or destroying the actual cells themselves<sup>[70-80]</sup>. This is of particular importance because direct cellular biopsy may be difficult or otherwise unattainable for screening high-risk populations, such as screening for HCC in CHC patients. It is highly anticipated that future studies on exosomal ncRNAs in different stages of HCC in HCV patients, which reflect the stepwise carcinogenic process from preneoplastic lesions to HCC may unveil better and reliable markers to aid in HCC early diagnosis among CHC patients and tracking of disease progression, which may directly benefit patients affected with HCC. Furthermore, there is a possibility that ncRNAs in exosomes may be taken by hepatocytes as a part of the cell-to-cell communication to spread HCV and promote carcinogenic signal transduction among hepatocytes, and therefore studies on exosomal ncRNAs associated with HCV-induced HCC may suggest novel molecular targets to help prevent and treat HCV-induced HCC patients.

In conclusion, the recent discovery of ncRNAs ushered in exciting and novel area to explore. Meanwhile, challenges to investigators are obvious: With respect to ncRNAs in HCV-induced HCC, in-depth knowledge on functional roles for ncRNAs in HCV-induced HCC through well-designed studies are required to shed light on the molecular pathways of carcinogenesis and to aid in truly exploiting the potential of ncRNAs to serve as molecular targets or markers with a real value. Would it

be possible in the future to use exosomal ncRNAs from body fluids such as blood, ascites or urine, for screening and early diagnosis of HCC among HCV patients at high-risk? Could we successfully slow or prevent the development of HCC in HCV patients using selected ncRNA antagonists or mimics as novel approaches?

HCV treatment for PWID, a pressing need exists to develop strategies to engage these individuals into HCV care. In this article, we propose several strategies that can be pursued in an attempt to engage PWID into HCV management. We advocate that multidisciplinary approaches that utilize health care practitioners from a wide range of specialties, as well as co-localization of medical services, are strategies likely to result in increased numbers of PWID entering into HCV management. Pursuit of HCV therapy after stabilization through drug treatment is an additional strategy likely to increase PWID engagement into HCV care. The full impact of direct acting antivirals for HCV will only be realized if innovative approaches are pursued to engage all HCV infected individuals into treatment.

## Abstract

Despite a high prevalence of hepatitis C virus (HCV) infection, the vast majority of persons who inject drugs (PWID) have not engaged in HCV care due to a large number of obstacles. Education about the infection among both PWID and providers remains an important challenge as does discrimination faced by PWID in conventional health care settings. Many providers also remain hesitant to prescribe antiviral therapy due to concerns about adherence and relapse to drug use resulting in reinfection. Presently, however, as a result of improvements in treatment efficacy combined with professional society and government endorsement of

**Core tip:** Despite persons who inject drugs (PWIDs) representing the majority of the hepatitis C virus (HCV) disease burden, few receive treatment for HCV. Barriers to treatment uptake exist at multiple levels. Co-localization of HCV management with substance abuse facilities may result in greater treatment uptake for PWID.

Zeremski M, Zibbell JE, Martinez AD, Kritz S, Smith BD, Talal AH. Hepatitis C virus control among persons who inject drugs requires overcoming barriers to care. *World J Gastroenterol* 2013; 19(44): 7846-7851 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i44/7846.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7846>

## INTRODUCTION

Hepatitis C virus (HCV) infection is a leading cause of chronic liver disease affecting more than 120 million people worldwide<sup>[1,2]</sup> and at least 3.2 million in the United States<sup>[3-5]</sup>. Among HCV-exposed individuals, up to 80% will develop chronic infection that can ultimately lead to hepatic fibrosis, cirrhosis, hepatocellular carcinoma and death<sup>[6]</sup>. The prevalence of cirrhosis is estimated to increase from 25% in 2010 to 45% by 2030 in untreated patients with chronic HCV infection, and liver-related deaths are projected to increase by 175% over the next decade<sup>[7]</sup>. Currently, HCV is the leading indication for liver transplantation in the United States<sup>[8]</sup>.

As the virus is most effectively transmitted via blood, injection drug use is currently the primary route of HCV transmission in the United States and other developed countries. Among persons who inject drugs (PWID), estimated HCV prevalence ranges from 30% to 70%, depending on frequency and duration of use, while incidence ranges from 16% to 42% per year<sup>[9,10]</sup>. Additionally, up to 20% of human immunodeficiency virus (HIV)-infected PWID in the United States are co-infected with HCV<sup>[11]</sup>. A recent study predicted that for a PWID population with 20% baseline chronic HCV prevalence, treatment rates of 5, 10, 20 or 40 per 1000 annually can lead to a 15%, 30%, 62% and 72% reduction in prevalence after 10 years, respectively<sup>[12]</sup>. The same authors have also estimated that novel treatments, expected to result in viral clearance rates of 90%, can halve HCV prevalence of 25%, 50%, and 65% within 15 years with treatment rates of 15, 40, or 76 per 1000 PWIDs annually<sup>[13]</sup>. Therefore, addressing HCV infection among PWID is a crucial step toward its successful control and prevention.

Despite the fact that PWID represent the majority of the HCV disease burden in developed countries, only 21%-65% have been evaluated for HCV, with less than 20% of evaluated patients receiving treatment<sup>[14-16]</sup>. Moreover, while the majority (> 70%) of PWID initially express willingness to undergo HCV treatment, only a minor percentage (1%-6%) actually receives therapy<sup>[14,16,17]</sup>. A variety of factors limit enrollment of PWID into HCV care and treatment. Identification of these barriers is therefore a key step toward formulating interventions to increase access to HCV care for PWID. Our goal in this article is to highlight the obstacles to providing HCV care to PWID and to propose interventions by which these barriers can be overcome.

## BARRIERS TO HCV TREATMENT IN PWID

Obstacles to providing HCV care to PWID emanate from patients, health care providers and the health care system<sup>[18]</sup> (Table 1). One of the most important patient level obstacles to receiving care is lack of HCV-related knowledge resulting in a low perceived need for treatment. Between 65%-75% of HCV-infected patients are unaware of their status<sup>[19]</sup>. While many patients are aware that treatment for HCV exists, few are cognizant that it

**Table 1 Most common barriers to engagement of persons who inject drugs into care for hepatitis C virus infection**

Domain	Specific barrier
Patient-level	Low perceived treatment need
	Fear of side effects
	Lack of knowledge of serostatus
	Fear of liver biopsy
	Needles may promote relapse
	Coexisting mental health diagnosis
Physician-level	Lack of insurance, poverty, low socioeconomic status
	Concerns about reinfection
	Biases against PWID
	Adherence concerns
	Dual diagnoses
Health system-level	Navigation can be complex
	Mistrust between PWID and medical community
	High cost of HCV treatment
	Stigmatization in health care venues

HCV: Hepatitis C virus; PWID: Persons who inject drug.

is curative. Some PWID are reluctant to undergo liver biopsy, an invasive procedure that has been frequently required prior initiation of HCV treatment. The presence of needles that are required for interferon injection might also be an obstacle to treatment in some persons who previously injected drugs. Additionally, many PWID perceive treatment-related side effects to be worse than the virus itself. Finally, mistrust of the health care system and difficulty keeping medical appointments may also contribute to PWID's unwillingness to initiate HCV therapy<sup>[14]</sup>. PWID are also more likely to be uninsured, have limited access to health care services, be affected by poverty, and have reduced social support<sup>[20]</sup>.

Provider barriers also contribute to low rates of treatment provision to PWID. Patients who report injecting drugs are less likely to be referred for HCV evaluation and less likely to receive HCV treatment<sup>[21,22]</sup>. Many health care providers remain hesitant to treat patients with a history of drug use due to concerns about adherence to the therapeutic regimen. Some providers avoid treatment of PWID due to the misconception that reinfection occurs at a high level following relapse to injection drug use<sup>[23]</sup>. Finally, people with drug addiction have been perceived as challenging patients because they are more likely to be dually diagnosed with psychiatric co-morbidities, such as depression and anxiety, compared to non-addicted individuals<sup>[24]</sup>.

The health care system itself may pose numerous obstacles to HCV treatment of PWID. The United States health care system is complex and the referral and scheduling process, as well as insurance and payment issues, can be difficult to navigate. Long-seated, distrusting relations between PWID and the medical community have contributed to feelings of stigmatization among those seeking HCV treatment. PWID often experience health care providers as judgmental, unresponsive to their medical needs, and disdainful, all of which serve as systemic barriers to care.

Finally, high cost of HCV therapy is another treatment barrier. For example, the estimated total cost of

telaprevir-based therapy, including the cost of side effect management, can be as high as \$147000<sup>[25]</sup>. Although this problem is not specific to PWID, it certainly affects them to a greater extent compared to general population, particularly as PWID are more likely to be uninsured and to have less financial resources.

Excluding PWID from HCV treatment contradicts current recommendations issued by several United States governmental and relevant professional organizations. Governmental bodies, including the Institute of Medicine (IOM)<sup>[26]</sup> and the Department of Health and Human Services (HHS)<sup>[27]</sup>, now advocate for increased awareness and resources to address the issue of disparities in HCV treatment for PWID. Professional organizations such as the American Association for the Study of Liver Disease (AASLD)<sup>[28]</sup>, have stated in their guidelines that PWID should be treated for HCV. Yet despite these recommendations, PWID are frequently excluded from therapy by the health care system.

## OVERCOMING THE OBSTACLES TO HCV TREATMENT FOR PWID

Through advances in HCV management, we are now experiencing partial resolution of the obstacles to HCV treatment among PWID. The rapid acceleration of HCV treatment toward an all oral regimen with improved efficacy and fewer adverse effects will likely result in the elimination of the liver biopsy as a requirement to initiate treatment. Additionally, the avoidance of needle exposure associated with interferon injection would eliminate anxiety among persons who no longer inject drugs. The onus now moves toward strategy development to address other obstacles in the management of HCV in PWID.

As patient-related obstacles can derive from misconceptions and lack of HCV-related knowledge, appropriately designed educational interventions could prove beneficial in promoting HCV care and treatment. Unfortunately, while nationwide surveys in the United States have documented that most opioid agonist treatment (OAT) facilities provide at least some form of HCV education<sup>[29,30]</sup>, patients infrequently avail themselves of these opportunities<sup>[31]</sup>. Increased awareness of potential benefits of such programs and the addition of patient incentives, such as financial compensation or travel stipends, might increase participation. Peer support groups, directed by treatment-experienced patients, could encourage treatment acceptance and provide emotional support through shared treatment experiences. Support from mental health and allied health professionals to assist with procurement of social and mental health services, temporary disability, accessing Medicaid, and obtaining transportation, may potentially increase involvement in HCV treatment. These interventions can be incorporated into an individualized treatment plan to maximize adherence rates and successful outcome achievement.

Other obstacles to provision of HCV care and treatment result from lack of HCV-related knowledge and

misconceptions among health professionals regarding PWID. These barriers may be overcome by provider education about PWID or by close collaboration between health care providers from diverse specialties<sup>[32]</sup>. Involvement of a multidisciplinary team consisting of representatives of hepatology, addiction medicine, generalists, and mental health experts in the treatment of HCV for PWID has been shown to result in increased treatment efficacy<sup>[32]</sup>. Besides direct interaction for the purposes of patient care, mentoring programs conducted between HCV specialists, substance abuse treatment staff, and peers could increase knowledge and build the skills necessary to treat this population. Mentoring programs could be conducted in person or via telemedicine.

A recent meta-analysis demonstrated that HCV treatment outcomes among PWID were improved among those treated for opioid addiction compared to untreated individuals<sup>[32]</sup>. In addition, rates of successful treatment outcomes for PWID were shown to be almost identical to outcomes achieved in registration trials<sup>[32,33]</sup>. However, while occasional drug use does not impact on adherence, treatment completion or treatment efficacy, frequent drug use (daily or every other day) does<sup>[34]</sup>. Consequently, successful outcomes for HCV are more likely to be achieved if PWID who inject frequently are initially stabilized for their addiction and subsequently undergo HCV therapy.

By co-localizing both HCV preventive and treatment services at venues where PWID receive care for drug addiction, uptake of HCV services might increase. For example, due to annual HCV serologic testing in some OAT facilities, HCV-infected patients have been more readily identifiable. At present, however, offsite referral to HCV specialty-care clinics is a common practice among drug treatment providers<sup>[29,35]</sup>. However, its effectiveness is limited as the majority of referred patients often fail to schedule or appear at appointments<sup>[14,36,37]</sup>. Yet, OAT facilities that do offer on-site HCV evaluation and treatment have achieved improved outcomes<sup>[38-41]</sup>. Similar findings have been previously reported for HIV-infected PWID, many of whom voluntarily use primary care services if they are offered onsite in OAT facilities<sup>[42]</sup>. Unfortunately, a recent study of substance abuse treatment programs affiliated with academic medical centers conducted through the National Drug Abuse Treatment Clinical Trials Network found a significant lack of comprehensive HCV counseling, testing, and treatment both on-site or by referral<sup>[43]</sup>. The same programs, however, offered significantly more HIV/AIDS-related health services<sup>[44]</sup>.

OAT facilities that do offer integrated HCV care programs may also provide comprehensive on-site primary care services administered by health care providers with training in diverse disciplines including infectious diseases, hepatology, addiction medicine, and mental health<sup>[45-47]</sup>. Many of these programs also offer active case management and have diverse staff consisting of physicians, physician assistants, nurse practitioners, nurses, counselors, and social workers. To improve adherence, some programs utilize directly observed therapy as well

as offering counseling sessions, motivational interviewing, peer-based support groups, and HCV-related education<sup>[45,47-50]</sup>. Improvement over offsite referral has also been achieved through an integrated model combining addiction medicine physicians with hepatologists in a viral hepatitis clinic<sup>[51]</sup>.

Finally, overcoming the financial obstacles for HCV treatment will not be easy, especially in developing countries. In the United States, health care reform will promote integration of specialty services into primary care, promote prevention, and will likely provide an opportunity for development of innovative models for previously medically-marginalized populations such as PWID. In contrast, in developing countries, pharmacy assistance programs will most likely be necessary in order to enable patients to access novel HCV treatments.

## PARALLELS BETWEEN HIV AND HCV

The issue of increasing awareness and funding for HCV treatment among PWID has many similarities to HIV; indeed, HIV treatment is often touted as one of the great medical successes of our time. As the gravity of the emerging HIV epidemic became apparent in the 1980s, national attention and subsequent funds were directed toward combating the infection. Although similarities exist between both viral infections, so do important differences. For example, HCV is curable in a majority of cases while HIV presently requires costly lifelong treatment. Prevention activities among PWID that have been highly effective in controlling HIV have not been as effective in the control of HCV, largely due to limited funding and advocacy<sup>[52]</sup>. Additionally, the ultimate consequences of HCV infection, such as development of end-stage liver disease, hepatic decompensation, or hepatocellular carcinoma leading to liver transplant and subsequent lifelong immunosuppression, are largely preventable through screening and subsequent treatment. With implementation of improved therapies, the HCV field hopes to achieve the same levels of success accomplished by the HIV field.

## CONCLUSION

As many HCV-infected PWID acquired the virus decades ago, they suffer from cirrhosis and other complications of end-stage liver disease with increasing prevalence. Therefore, strategies to increase HCV care and treatment among PWID are critically needed. Achieving higher treatment rates among this population will require overcoming existing barriers at the patient, provider, and institutional levels. Co-localization of HCV management with substance abuse treatment may be a strategy that could facilitate HCV diagnosis as well as promote treatment acceptance and adherence. This approach would reduce the prevalence of end-stage liver disease, viral transmission, and HCV-associated mortality. Additionally, early identification and treatment of HCV infection

is more cost-effective compared to management of end-stage liver disease<sup>[53]</sup>. Tremendous advances are presently occurring in the HCV field, and we hope that PWID will be included in these changes.

### Abstract

Hepatitis C virus (HCV) frequently elicits only mild immune responses so that it can often establish chronic infection. In this case HCV antigens persist and continue to stimulate the immune system. Antigen persistence then leads to profound changes in the infected host's immune responsiveness, and eventually contributes to the pathology of chronic hepatitis. This topic highlight summarizes changes associated with chronic hepatitis C concerning innate immunity (interferons, natural killer cells), adaptive immune responses (immunoglobulins, T cells, and mechanisms of immune regulation (regulatory T cells). Our overview clarifies that a strong anti-HCV immune response is frequently associated with acute severe tissue damage. In chronic hepatitis C, however, the effector arms of the immune system either become refractory to activation or take over regulatory functions. Taken together these changes in immunity may lead to persistent liver damage and cirrhosis. Consequently, effector arms of the immune system will not only be considered with respect to antiviral defence but also as pivotal mechanisms of inflammation, necrosis and progression to cirrhosis. Thus, avoiding Scylla - a strong, sustained antiviral immune response with initial tissue damage - takes the infected host to virus-triggered immunopathology,

which ultimately leads to cirrhosis and liver cancer - the realm of Charybdis.

**Key words:** Natural killer cells; CD4<sup>+</sup> T helper cells; Regulatory T cells; Interferon; Hepatitis C; Hepatic stellate cells; Hepatocytes; Immunoglobulin; Retinoic acid inducible gene-1; Toll like receptors

**Core tip:** This topic highlight on the immunopathogenesis of chronic hepatitis C addresses changes in innate immunity (interferons and natural killer cells), adaptive immunity and immunoregulation (regulatory T cells). Our review provides a succinct but comprehensive overview and presents the concept, that effective antiviral immunity is associated with pronounced acute liver damage, while during chronic infection the arms of immunity will acquire new functions, which will cause and maintain tissue damage. Thus, the immune response becomes part of the mechanisms that eventually lead to progressive inflammation, liver cirrhosis and death in chronic hepatitis C.

### INTRODUCTION

Scylla and Charybdis were two immortal and irresistible sea monsters in Greek mythology believed to live on either side of the Strait of Messina between Sicily and Italy. Scylla was a six-headed supernatural creature - probably

reflecting a shoal that devoured whatever came within her reach, and Charybdis was a whirlpool off the coast of Sicily. Avoiding Charybdis meant passing too close to Scylla and vice versa. According to Homer, the Greek hero Odysseus opted for Scylla when passing the strait, and had to sacrifice six of his companions rather than to risk the loss of his vessel in the whirlpool. Thus, being “between Scylla and Charybdis” means to be forced to make a choice between two equally unpleasant evils.

This allegory matches the challenge of the human immune system when defending against a viral infection, such as hepatitis C which has a high potential to establish chronic persistence. On one hand a strong and efficient immune response rapidly clears the virus; accepting the risk of severe tissue damage from immune-mediated destruction. On the other hand a less vigorous response allows for viral persistence and facilitates a low-level smoldering inflammation, which eventually results in progressive liver disease and ultimately death of the individual. In line with this analogy, acute self-limited hepatitis C is frequently associated with symptomatic disease and jaundice, while chronic hepatitis C often establishes in the absence of any characteristic symptoms<sup>[1,2]</sup>. Studies in various expression systems (cell culture or transgenic mice) indicate that hepatitis C virus (HCV) is not directly cytopathic, and viral replication may occur in the absence of any detectable inflammatory reaction<sup>[3,4]</sup>. On the other hand, chronic hepatitis C is associated with liver cell damage and intrahepatic inflammatory infiltrates. Of note, hepatocellular damage coincides with the onset of an immune response during acute infection but not with that of viral replication<sup>[5]</sup>. Thus, activation of the immune response is a pivotal factor for the pathogenic processes in hepatitis C leading to progressive tissue injury. Ultimately, hepatic inflammation and progressive fibrosis in chronic hepatitis C may result in cirrhosis and carry a high risk for hepatocellular carcinoma.

## BASIC FACTS

HCV is a hepacivirus of the *Flaviviridae* family. Its genome consists of a single strand positive sense RNA. After cell entry the viral genome is translated into a single polyprotein which is co- and post-translationally cleaved into structural and non-structural proteins by host peptidases and two virus-encoded proteases. Replication involves generation of an antigenomic replication intermediate, and probably intermediate double-stranded RNA (ds-RNA) products, which can trigger intracellular pattern recognition receptors. The new viral genomes are packaged into viral particles by the viral non-structural proteins, which then are released from hepatocytes in association with host lipoproteins. Thus, HCV circulates in blood as a lipoprotein-coated virus<sup>[6]</sup>. During replication HCV is sensed by pattern recognition receptors (PRRs) in the host cell which detect pathogen-associated molecular patterns within viral products. This process then leads to coordinated activation of innate

and adaptive immune responses. Both arms of the immune response work together in an integrated fashion to recognize and defend against HCV infection.

Innate responses to HCV comprise both cellular responses, such as recognition of non-self by various types of natural killer (NK) cells and humoral components, such as induction of a variety of cytokines, especially interferons. These various elements of innate immunity act in a highly integrated fashion as do innate and adaptive immune responses. Thus, development of adaptive B and T cell immunity is shaped by the initial innate responses, in particular interferons and other inflammatory and immunoregulatory cytokines that are induced by viral invasion<sup>[7]</sup>. However, despite these immune defences, hepatitis C becomes chronic in about 70%-80% of acute infections<sup>[8]</sup>. Failing immunity and continued viral persistence lead to sustained inflammatory host responses which then become the key mechanism for tissue injury in chronic hepatitis C.

## INNATE IMMUNITY IN HEPATITIS C

Three types of PRRs are known to detect HCV: (1) the retinoic acid inducible gene- I (RIG- I)-like receptors, RIG- I and melanoma differentiation antigen 5, which sense viral RNA in the cytosol; (2) toll-like receptors (TLRs), such as TLR3, which detects ds-RNA fragments in the endosomal compartment; and (3) the non-traditional pattern recognition receptor protein kinase R (PKR), which binds ds-RNA binding and upon activation promotes interaction with mitochondrial antiviral signaling protein (MAVS) to trigger innate immunity<sup>[9]</sup>.

RIG- I signaling is initiated by binding of the HCV PAMP RNA which consists of an exposed 5'triphosphate and the 3'poly-U/UC-rich untranslated region of the HCV RNA<sup>[10,11]</sup>. These regions are located at opposite ends of the viral genome but are brought together by intra-genomic interactions. In this configuration the viral RNA comes into close contact with RIG- I and induces conformational changes of RIG- I. RIG- I activation leads to the formation of a multi-component complex with MAVS (also termed interferon beta promoter stimulator protein 1 or card adaptor inducing interferon beta, cardiff). Finally, the interferon signaling cascade results in the activation of multiple transcription factors, such as interferon-regulatory factor-3 (IRF-3) and nuclear factor kappa B and production of multiple pro-inflammatory cytokines<sup>[12]</sup>.

HCV dsRNA intermediates, which occur late in HCV replication, have been identified as ligands for TLR3<sup>[13]</sup>. TLR3 signals are transmitted by the adaptor molecule TIR-domain-containing-adaptor-inducing-interferon- $\beta$  (TRIF) and also lead to production of interferons and pro-inflammatory cytokines<sup>[14]</sup>. TLR3 mediated interferon and cytokine responses are considered a secondary innate immune defense after initial RIG- I activation to establish an antiviral state and trigger T cell recruitment in HCV infection.

The ligand for PKR is the structured RNA at the internal ribosomal entry site (IRES) of HCV RNA<sup>[15,16]</sup>. Binding of HCV RNA induces phosphorylation of the  $\alpha$ -subunit of the eukaryotic initiation factor 2 (eIF2 $\alpha$ ). In addition, RNA binding also triggers a kinase-independent signal transduction cascade involving MAVS which finally activates interferon- $\beta$  and interferon-stimulated genes (ISGs)<sup>[9,16]</sup>.

Although HCV can be detected effectively by RIG- I, TLR3 and PKR, it frequently establishes chronic persistence in up to 80% of patients, because it has evolved several mechanisms to counter-act innate immunity. The multi-functional HCV NS3/NS4A protease is a key component of the HCV evasion strategy from innate immunity. Studies in Huh-7 cells indicate that HCV initially activates the RIG- I pathway which is shut down as infection progresses and NS3/NS4 abundance increases<sup>[17]</sup>. In addition to proteolytically processing the HCV polyprotein, NS3/NS4A can block RIG- I signaling, because it cleaves MAVS from intracellular membranes<sup>[18-21]</sup>. This cleavage prevents signal transduction, abrogates interferon induction and facilitates progression to chronic infection. However, other hepatotropic viruses, such as hepatitis A virus also encode proteases that can cleave MAVS but in general do not become chronic<sup>[22]</sup>. Thus, MAVS cleavage alone is not sufficient for viral chronicity. Nevertheless, cleavage of MAVS has been demonstrated in the livers of patients with chronic hepatitis C, and patients with cleaved MAVS revealed reduced interferon pathway activation, although this inverse correlation was rather weak<sup>[23]</sup>.

The NS3/NS4A protease can also cleave TRIF<sup>[24]</sup>, the adaptor protein of the TLR3 pathway, and the relative abundance of this protein is reduced after HCV infection, probably as a result of degradation following its cleavage by NS3/NS4A<sup>[25]</sup>. Although details are insufficiently understood at present, blocking of the TLR3 pathway by HCV also seems to contribute to establishing chronic infection. TLR3-independent sensing of RNA which signals *via* TRIF has also been described, and is likewise blocked by NS3/NS4A targeting of TRIF<sup>[26]</sup>. Finally HCV proteins E2, NS3, NS4A and NS5 provide several strategies to interfere both with PKR signaling and PKR-regulated inhibition of translation<sup>[27-29]</sup>. However, these interactions are complex and the exact mechanisms how they support HCV persistence are still unclear.

Continued triggering of PRR pathways in chronic hepatitis C is likely to contribute to immunopathology, such as hepatic inflammation, fibrosis progression and HCV-associated malignancy. In this context it is interesting to note that HCV proteins core and NS3 also trigger TLR 1-2 and 2-6 dimers<sup>[30,31]</sup>, and there is evidence from genetic epidemiology and functional *in vitro* studies that HCV-TLR interactions might contribute to hepatic fibrogenesis and cirrhosis<sup>[32,33]</sup>, development of liver cancer<sup>[34]</sup>, HCV-associated autoimmunity and B cell lymphoma<sup>[35]</sup>.

## INTERFERONS

HCV recognition by PRRs ultimately leads to induction of antiviral cytokines termed interferons (IFNs). Type I IFNs (several interferons- $\alpha$  and interferon- $\beta$ ) bind to the ubiquitously expressed type I interferon receptor, while type III IFNs [IFN- $\lambda$ 1 alias interleukin (IL)-29, IFN- $\lambda$ 2 alias IL-28A, IFN- $\lambda$ 3 alias IL-28B] have their own receptor consisting of the IL10R2 chain (IL-10 receptor beta chain) and a unique IFN- $\lambda$  receptor chain with a limited expression mainly on hepatocytes<sup>[36,37]</sup>. The type II interferon IFN- $\gamma$  has its own IFN- $\gamma$  receptor. All IFN receptors transmit signals from the cell surface to the nucleus *via* the Jak-STAT pathway to activate interferon stimulated genes (ISGs). Specifically type I and III IFNs induce IFN-stimulated gene factor 3 consisting of phosphorylated STAT1 and 2 proteins and IRF9 which activate the IFN-stimulated response elements (ISRE) of multiple genes contributing to antiviral activity<sup>[38-40]</sup>.

IFN signaling is regulated by suppressors, such as suppressor of cytokine signaling and ubiquitin specific peptidase 18 (USP18) which provide important negative feed-back loops<sup>[41-43]</sup>. USP18 is a protease cleaving ISG15 from its target proteins, also including STAT1<sup>[44]</sup>. ISG15 is conjugated to STAT1 by the sequential action of several enzymes<sup>[45]</sup>. This so-called ISG-ylation and its de-conjugation by USP18 modify signal transduction pathways and immune responsiveness<sup>[46,47]</sup>. However, recently it has been recognized that USP18 suppresses IFN-signaling independently from its de-conjugating activity by interfering with the interaction between Jak1 and the type I IFN receptor<sup>[48]</sup>. USP18 is a major mediator of unresponsiveness to type 1 IFNs in liver cells<sup>[49]</sup>. However, it does not inhibit signal transduction of type II and III IFNs<sup>[50]</sup>.

Activation of the endogenous IFN system in the liver exerts little anti-HCV activity, and it has been well established that patients with high activation of the endogenous IFN system respond poorly to IFN $\alpha$  based therapies<sup>[51-55]</sup>. It has been proposed that expression of HCV proteins inhibits binding of activated STATs to ISRE<sup>[56]</sup>, and Jak-STAT signaling was found to be inhibited both in HCV transgenic mice and liver biopsies from patients with hepatitis C<sup>[57,58]</sup>. Beyond that, phosphorylation and activation of STAT3 is involved in the antiviral IFN activity<sup>[59]</sup>, and STAT3 expression was found to be reduced in HCV-infected livers<sup>[60]</sup>. Indeed, HCV core protein can prevent STAT3 phosphorylation<sup>[57,60,61]</sup>, and this has been associated with HCV resistance to IFN- $\alpha$ <sup>[62]</sup>. Next, HCV-induced PKR activation inhibits cap-dependent translation of antiviral host proteins at the ribosomes owing to phosphorylation of eIF2 $\alpha$  while production of HCV proteins is not impaired, because translation occurs *via* an IRES-dependent mechanism<sup>[63]</sup>. Of note, most studies on endogenous ISG induction in hepatitis C were based on steady state mRNA level measurements rather than determination of protein concentrations<sup>[51-55]</sup>. Finally, HCV proteins might directly inhibit ISG antiviral

effector functions apart from their inhibition of ISG translation. This concept is supported by experimental evidence from knock-out mice which demonstrated that expression of the USP18 leads to a long-term refractory state towards IFN $\alpha$  stimulation<sup>[49]</sup>. Likewise, strong USP18 expression was found in many hepatocytes of patients with chronic hepatitis C and high endogenous IFN activity, when histological specimens were studied<sup>[64]</sup>. At present the cellular sources and involved types of IFNs that maintain long-term ISG expression in chronic hepatitis C are still a matter of debate. IFN- $\lambda$ s are strong candidates as triggers of ISG induction in patients with chronic hepatitis C and endogenous activation of the IFN system, because, unlike all other IFN types, IFN- $\lambda$  mRNA is readily detected in liver biopsies<sup>[53]</sup>, and their action is not inhibited by USP18<sup>[50]</sup>.

In patients with chronic hepatitis C endogenous ISG induction varies considerably between individuals, and this variability, as well as differential responsiveness to exogenous IFN- $\alpha$  is attributed to a combination of viral and host factors. For instance, difficult-to-treat HCV genotypes 1 and 4 induce high levels of endogenous IFN expression in hepatocytes resulting in an IFN-insensitive state that attenuates treatment responses<sup>[65]</sup>. Of note, endogenous ISG induction in Kupffer cells, the resident liver macrophages, is also a strong predictor of treatment responsiveness<sup>[66]</sup>. However, the relationship between baseline ISG induction and treatment outcome is opposite to that observed in hepatocytes: Virtually all non-responders lack baseline induction of ISGs whereas strongly induced ISG expression is found in responders<sup>[67]</sup>. This finding suggests that ISG induction in Kupffer cells may have a protective role for the host concerning both spontaneous HCV elimination and treatment outcomes.

Apart from viral factors genome-wide association studies have identified single nucleotide polymorphisms (SNPs) upstream of the *IFNL3* gene on chromosome 19q13, which are associated with outcomes of HCV infection both under IFN-based therapy of chronic hepatitis C<sup>[68-70]</sup> and disease evolution during acute HCV infection<sup>[71,72]</sup>. Although some initial studies failed to find a relationship between the SNPs and *IFNL3* mRNA expression<sup>[71,73]</sup>, it has meanwhile become clear that SNPs in this region alter IFN- $\lambda$  expression levels<sup>[53,68,70,74-76]</sup>, and the unfavorable minor alleles result in less *IFNL3* expression. Thus, it is quite unlikely that these SNPs simply reflect linkage disequilibrium with some other gene. However, the molecular and cellular mechanisms that underlie this association between outcomes of HCV infection and the *IFNL3* gene locus are not yet understood. It has been proposed that the unfavorable *IFNL3* variants may lead to compromised innate immune functions in particular with respect to natural killer cell activity<sup>[77,78]</sup>. However, given the fact that NK cells do not express type III IFN receptors this hypothesis needs refining<sup>[79]</sup>. In addition, a dinucleotide polymorphism upstream of the *IFNL3* gene has been described, which

can create or disrupt an alternative open reading frame giving rise to a new gene, termed *IFNL4*<sup>[80,81]</sup>. Although it has been proposed that loss of *IFNL4* expression should be protective against HCV, it is as yet not clear if the putative *IFNL4* gene product plays any role for differential immune responses to HCV infection.

## NATURAL KILLER CELLS

NK cells constitute a first line of defence against viral infections. They rapidly recognize and lyse virus-infected cells, inhibit viral replication but also exert immune-regulatory functions. NK cells constitute approximately 30% of resident lymphocytes in a normal liver, and may account for as many as 60% of lymphocytes in HCV infection<sup>[82]</sup>.

Activation of natural killer cells results from the integration of multiple activating and inhibitory signals *via* specific receptors. The most important NK cell receptors (and their cognate ligands) comprise the killer immunoglobulin-like receptor (KIR) family (ligands: HLA-A, -B and -C), the CD94-NKG2A/C complex (ligand: HLA-E), NKG2D (ligands: MIC-A and MIC-B and others) and the natural cytotoxicity receptors NKp30, NKp44 and NKp46<sup>[83]</sup>. In addition, part of these receptors also exerts immune-regulatory functions in subsets of T lymphocytes. NK cells are activated, when there is a relative reduction of inhibitory signals, *e.g.*, down-regulated MHC class I expression on virus-infected cells, or a relative increase in signals from activating receptors, *e.g.*, binding of antibody-coated antigens<sup>[84]</sup>. However, conventional MHC class I expression is not substantially reduced in hepatitis C, and it has been proposed that NK cell functions might be altered by binding of HCV-derived peptides to non-polymorphic restriction molecules, such as HLA-E<sup>[85,86]</sup>. NK cells are recruited to inflammatory sites by a variety of chemokines and can also be stimulated by cytokines, such as IFN- $\alpha$  and ILs 8, 12, 15 and 18<sup>[87]</sup>.

Activated NK cells with potent de-granulation and substantial cytokine production have been described in acute HCV infection<sup>[88,89]</sup>, and there is accumulating evidence to suggest that NK cells play an important role in the antiviral immune response to hepatitis C and later on also in the immune-mediated pathogenesis of chronic hepatitis C. NK cells can inhibit HCV replication *in vitro* both by IFN- $\gamma$  mediated non-cytolytic as well as granzyme/perforin and TRAIL-mediated cytotoxic mechanisms<sup>[90]</sup>. While HCV-infected hepatocytes up-regulate expression of TRAIL receptors<sup>[91]</sup>, *in vivo* IFN $\gamma$ -mediated clearance of HCV might be more important than direct cytotoxicity, because cytolytic elimination of all HCV-infected hepatocytes would lead to extensive liver damage<sup>[92]</sup>. Multi-functional NK cells are also detectable early after HCV exposure in health-care workers and iv drug users, who do not proceed to develop acute hepatitis; suggesting a potentially protective role of NK cells in early HCV infection<sup>[93,94]</sup>. Further support for a pro-

**Figure 1** Central role of natural killer cells in the pathogenesis of hepatitis C. Natural killer (NK) cells regulate fibrosis by killing of activated hepatic stellate cells (HSC), which trigger NK cell activation *via* natural killer cell receptor with extracellular C-type lectin domains (NKG2D) signalling. The release of granzyme/perforin and cytotoxic cytokines, such as tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) induce tissue damage. Interferon- $\gamma$  (IFN- $\gamma$ ) released from NK cells can clear hepatitis C virus (HCV) infection from infected hepatocytes without cytolysis. On the other hand NK cell activity is critically dependent on sufficient supply with interleukin 2 (IL-2) from CD4<sup>+</sup> T cells.

protective role of NK cells in HCV infection comes from genetic studies, where genes encoding the inhibitory receptor KIR2DL3 and its ligand human leucocyte antigen group 1 (HLA-C1) seem to favour both spontaneous and treatment-induced elimination of HCV<sup>[95,96]</sup>. Since the affinity between inhibitory KIR2DL3 and HLA-C1 is weaker than all other combinations, it is reasonable to assume that a lower threshold of activation is needed to trigger KIR2DL3 NK cell responses in HLA-C1 homozygous individuals<sup>[88,97]</sup>. Finally, NK cells can become more activated upon IFN-based therapy and may contribute to HCV elimination by TRAIL-mediated cytotoxic mechanisms<sup>[98]</sup>. Interestingly, responsiveness in this setting again depends on the endogenous IFN- $\alpha$  activation state, since a rapid first phase HCV decline is associated with strong induction of STAT1 phosphorylation, whereas non-responders exhibit reduced STAT1 induction<sup>[99]</sup>. Chronic exposure of NK cells to IFN- $\alpha$  results in preferential STAT1 over STAT4 phosphorylation, which is associated with increased STAT1-dependent cytotoxicity but reduced STAT4-dependent IFN- $\gamma$  production<sup>[99-101]</sup>. These findings correspond to NK cell phenotypes and functional differentiation seen at later stages in IFN- $\alpha$  responders and non-responders<sup>[100,102]</sup>, although patients who achieve a sustained virological response also exhibit substantial NK cell cytotoxicity<sup>[103]</sup>.

NK cells in chronic hepatitis C have been reported to also express altered patterns of NK receptors (Figure 1). Although reported patterns are somewhat inconsistent and may vary between peripheral blood and the liver, altered expression on NK cells has been reported for receptors NKp30, NKp44, NKp46, NKG2A, NKG2C, NKG2D and CD122<sup>[100,104-107]</sup>. In addition, NK cells ex-

press the tetraspanin CD81, a co-receptor of HCV, and *in vitro* binding of the HCV envelope 2 (E2) protein to CD81 has been shown to block antiviral functions of NK cells and to alter their migratory behaviour<sup>[108-111]</sup>. However, the experimental setting of these studies involved cross-linking of HCV E2 on plastic plates, whereas NK cells exposed to intact virions did not exhibit altered functionality<sup>[112]</sup>. Thus, it remains to be elucidated if cross-linking of CD81 by HCV E2 affects functions of NK cells to facilitate chronic infection. A particularly interesting NK cell receptor is NKp46, since it is considered a major activating receptor in hepatitis C, which also has a role in the regulation of adaptive immunity: High expression of NKp46 defines a NK cell subset with high cytotoxic activity and IFN- $\gamma$  production that accumulates in the liver in chronic hepatitis C<sup>[113,114]</sup>. Of note, recently Pembroke *et al.*<sup>[115]</sup> confirmed intrahepatic enrichment of NKp46<sup>+</sup> NK cells in chronic hepatitis C and reported a high (> 80%) frequency of NKp46<sup>+</sup> cells in the liver to be associated with pronounced inflammation in histology. Another important finding of this study was the observation, that expression of NKp46 could predict responses to IFN therapy. Patients with chronic hepatitis C, who successfully cleared their HCV infection, had lower mean frequencies of activated NKp46<sup>+</sup> NK cells than patients who did not respond to therapy. The possible identification of NKp46 as a marker of both IFN-un-responsiveness and hepatic inflammation bears some similarity to the paradoxical relationship between IFN-un-responsiveness and high baseline ISG expression and may be linked to chronic endogenous interferon exposure. On the other hand, unlike Pembroke *et al.*<sup>[115]</sup> the group of Golden-Mason<sup>[113]</sup> reported increased NKp46

expression in white female Americans as opposed to male African-Americans and proposed that a high proportion of functionally active NKp46+ NK cells could explain their higher response to IFN therapy. Thus, the precise role of NKp46+ NK still remains elusive.

Finally, NK cell-mediated cytotoxicity against hepatic stellate cells (HSC) may contribute to the regulation of intrahepatic fibrosis in hepatitis C. HSC store vitamin A, reside in the space of Disse, and produce extracellular matrix proteins upon activation, *e.g.*, upon TLR stimulation, exposure to cytokines or reactive oxygen species<sup>[116]</sup>. HSC activation leads to trans-differentiation into myofibroblasts, which in the mouse also alters the balance in the expression between activating and inhibitory NK cell receptor ligands, so that they become target cells for NKG2D-, TRAIL- and granzyme-mediated killing by NK cells<sup>[117,118]</sup>. NKG2D- and TRAIL-mediated killing by NK cells has now also been reported for human HSC in chronic hepatitis C<sup>[119]</sup>, and CXCR3 + CD56<sup>Bright</sup> as well as NKp46+ NK cells express particularly high cytotoxic capacity against HSC in chronic hepatitis C<sup>[114,120]</sup>. Importantly, when other processes, such as CD4 T cell depletion in HIV/HCV co-infection interfere with the regulation of hepatic fibrosis by NK cells, this may result in accelerated fibrosis progression<sup>[121]</sup>.

## ADAPTIVE IMMUNITY IN HEPATITIS C

A coordinated immune response involving both antibodies and T cell responses is normally required for efficient adaptive immunity. However, in hepatitis C the role of antibodies is complex: Circulating antibodies against structural and non-structural components are generated in virtually all patients irrespective from the outcome of HCV infection. A rapid induction of neutralizing antibodies early in the course of hepatitis C has been demonstrated to contribute to HCV clearance<sup>[122]</sup>, but broad antibody responses usually occur at the stage of chronic infection and are not neutralizing<sup>[123,124]</sup>. Neutralizing antibodies frequently recognize the HCV envelope proteins<sup>[125-127]</sup>. However, these proteins have a high degree of mutational diversity, so that antibody responses are frequently directed against only a single strain or are easily evaded by viral mutations<sup>[124]</sup>. It is also quite likely that glycosylation of HCV proteins and the close association of the virus with lipoproteins further prevent antibody recognition. HCV antibodies are not required to clear HCV infection as has been demonstrated in patients with hypo-gammaglobulinemia<sup>[128]</sup>. HCV antibodies gradually disappear after successful HCV elimination<sup>[129]</sup>. Conversely, there is circumstantial evidence that HCV-specific cellular immune responses can protect individuals at high risk for hepatitis C without seroconversion<sup>[123,130,131]</sup>. Thus, adaptive cell-mediated immunity is considered a key mechanism for resolution of primary HCV infection<sup>[132]</sup>. Cell-mediated immunity involves CD8<sup>+</sup> cytolytic T lymphocytes (CTL), which recognize linear HCV peptides of 8 to 11 amino acids in length

bound to self HLA class I molecules, and CD4<sup>+</sup> T helper lymphocytes, which respond to longer viral peptides bound to class II molecules. Single source outbreaks further support a clear relationship between distinct HLA types and the outcome of HCV infection: patients with HLA-A3, HLA-B27, and HLA-B57 exhibit greater chances to develop protective immunity, thus strengthening the importance of effective antigen presentation and the generation of efficient antigen-specific T cell responses for immune control of HCV infection<sup>[133-136]</sup>.

## T CELL RESPONSES

The most conclusive experiments to suggest an important role for T cells in protective immunity against HCV stem from chimpanzee experiments: Depletion of CD8<sup>+</sup> T cells in animals, which had recovered from previous hepatitis C, resulted in prolonged viraemia, and viral clearance was correlated to recovery of HCV-specific CD8<sup>+</sup> T cells<sup>[137]</sup>. Likewise, depletion of CD4<sup>+</sup> T cells resulted in abrogation of a previously protective immune response<sup>[138]</sup>. In acute hepatitis C strong HCV-specific CTL<sup>[139,140]</sup> and TH1 type CD4<sup>+</sup> T helper cell responses<sup>[141]</sup> have consistently been reported to be closely associated with a self-limited course of HCV infection. Moreover, several groups have reported an inverse relationship between the strength of the CTL response and HCV viral loads<sup>[142-144]</sup> further suggesting that in principle it is possible for cellular immunity to control HCV infection<sup>[145]</sup>. A substantial proportion of individuals who ultimately develop chronic hepatitis C also generate HCV-specific CD4(+) and CD8(+) T cell responses during the early acute phase of infection and may transiently gain some control over HCV<sup>[140,146-149]</sup>. However, early T cell responses decline to almost undetectable levels later on, and initial control over HCV replication is lost. If present, HCV-specific CD4<sup>+</sup> and CD8<sup>+</sup> T cells are detected at only low frequency in peripheral blood although they are somewhat enriched in the liver<sup>[150,151]</sup>. Thus, chronic hepatitis C is characterized by a progressive functional exhaustion and ultimately loss of HCV-specific CD4<sup>+</sup> and CD8<sup>+</sup> T cells<sup>[152,153]</sup>.

Exhausted T cells exhibit a couple of characteristic abnormalities: They show increased expression of inhibitory receptors, such as programmed death-1 (PD-1), cytotoxic T lymphocyte antigen 4 (CTLA-4), T cell immunoglobulin and mucin domain-containing molecule 3, corresponding to up-regulated expression of their cognate ligands in the liver<sup>[154-159]</sup>. Conversely, functional recovery of HCV-specific T cells can be achieved experimentally by the combined blockade of CTLA-4 and PD-1 signalling<sup>[157,160]</sup>.

HCV replicates by an RNA-dependent RNA polymerase which has a high error rate and consequently generates considerable genomic diversity of HCV and T cell escape mutations. Mutations that affect CD8<sup>+</sup> T cell epitopes and proteasomal processing have been observed in several HCV single source outbreaks<sup>[161-163]</sup>.

Due to the exhausted state of T cells new epitope variants rarely elicit strong CD8<sup>+</sup> T cell responses at this stage of infection, and consequently further escape mutation to secondary epitopes are selected infrequently in man and the chimpanzee<sup>[146,164,165]</sup>. Protective T cells seem to target epitopes that do not allow for escape mutations owing to the associated loss of viral replication fitness<sup>[133-135]</sup>. Conversely, T cells that are not stimulated any more after HCV viral escape, do not show features of exhaustion<sup>[166]</sup>. Thus, prolonged exposure appears to be the mechanism that leads to T cell dysfunction in chronic hepatitis C, and T cell exhaustion in hepatitis C seems to follow the same pattern as has been first described in mice for lymphocytic choriomeningitis virus (LCMV) infection<sup>[167,168]</sup>. In this model, persistent high level viremia can be established in susceptible mouse strains by pathogenic virus variants. Initially, mice develop a robust T cell response but fail to eliminate the virus and subsequently exhibit a gradual decline of CD8<sup>+</sup> and CD4<sup>+</sup> T cell responses. T cells undergo T cell exhaustion in this model, and first lose production of IL-2, a cytokine which supports T cell proliferation. Then, cytotoxicity and production of tumour necrosis factor alpha and IFN- $\gamma$  are lost sequentially. Finally, intracellular expression of pro-apoptotic factors, such as Bcl2-interacting mediator (Bim), is up-regulated both in the LCMV model and hepatitis C<sup>[169]</sup>. In analogy to the LCMV model, virus-specific CD4<sup>+</sup> and CD8<sup>+</sup> T cell responses decline in chronic hepatitis C but full exhaustion with deletion of antigen-specific CD8 T cells does not occur, because at least *in vitro* T cell responses can be rescued.

## REGULATORY T CELLS

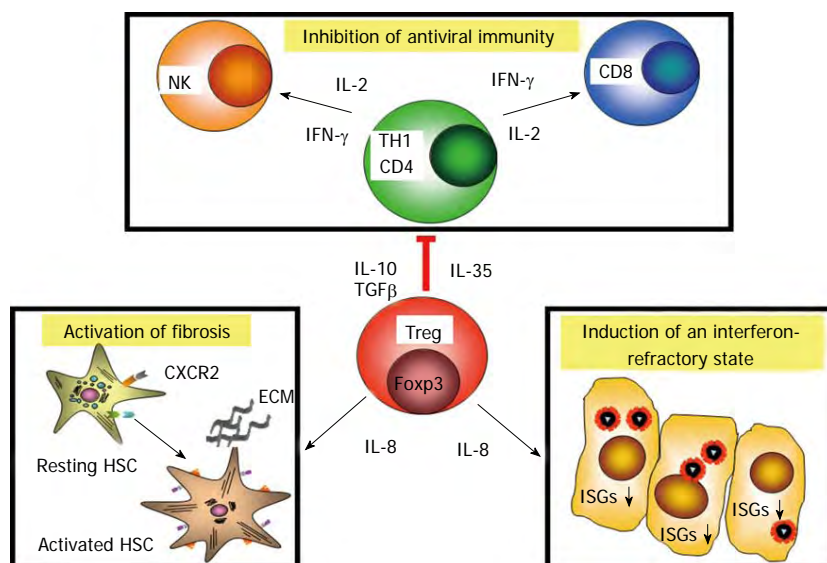

Recently CD8<sup>+</sup> T cells have been reported in the livers of patients with chronic hepatitis C which were considered to represent CD8<sup>+</sup> regulatory T cells, because they secrete IL-10 and suppress *in vitro* proliferation of liver-derived T cells<sup>[170]</sup>. In general, regulatory T cells (Tregs) actively control induction and activity of other immune cells by suppressing their functional activity *via* contact-dependent mechanisms and by release of immunosuppressive cytokines, such as IL-10 and transforming growth factor beta. The major cell type with these properties constitutes CD4<sup>+</sup>CD25<sup>high</sup>CD127<sup>-</sup> T cells, which express the transcription factor Foxp3 (forkhead box P3). They can be divided into thymus-derived natural regulatory T cells, that prevent autoreactivity to self-antigens and induced regulatory T cells, that are generated in the peripheral immune system as a regulatory response to antigenic stimulation. Foxp3<sup>+</sup> Tregs were rarely detected in acute hepatitis C<sup>[171]</sup> and they are also not found in patients who had managed to resolve HCV infection<sup>[172]</sup>, suggesting that effector T cells in acute and self-limited hepatitis C are not under active suppression by Tregs. In chronic hepatitis C, however, numbers of CD4<sup>+</sup> Tregs were increased in the peripheral blood of patients, and depletion of CD4<sup>+</sup> CD25<sup>+</sup> T cells was as-

sociated with increased numbers and function of CD8<sup>+</sup> T cells in *in vitro* assays<sup>[173-176]</sup>. Such regulatory T cells may reduce inflammatory activity and are considered to contribute importantly to preventing immune-mediated pathology in chronic hepatitis C. Functional analysis of regulatory T cell clones generated from patients with chronic hepatitis C revealed that Tregs were directed against HCV antigens and showed the same pattern of HLA class II restriction and epitope specificity as effector T cells<sup>[172]</sup>. Importantly, Treg clones from chronic hepatitis C inhibited *in vitro* proliferation and IFN- $\gamma$  production of autologous reporter T cells *via* release of inhibitory cytokines, such as IL-10 and IL-35. Of note, intrahepatic regulatory T cells in chronic hepatitis C also produced substantial amounts of IL-8, and isolated Tregs as well as Treg clones activated fibrogenic genes of hepatic stellate cells *in vitro*<sup>[177]</sup>. High intrahepatic IL-8 mRNA levels in chronic hepatitis C have been linked with progression of fibrosis<sup>[178,179]</sup> and CD4<sup>+</sup> Tregs are enriched in the liver<sup>[175,177,180-182]</sup>. Moreover, some but not all studies also reported a correlation between numbers of intrahepatic Tregs and the stage of fibrosis. Beyond that, IL-8 counter-acted the antiviral activity of IFN- $\alpha$  in the replicon model by down-regulation the expression of ISGs<sup>[183,184]</sup>. Moreover, *in vitro* studies suggest that part of the superior antiviral activity in IFN/ribavirin combination therapy may be due to preferential inhibition of Tregs by ribavirin<sup>[185]</sup> (Figure 2).

Thus, once the immune system has failed to clear HCV infection, regulatory T cells in chronic hepatitis C seem to exert multiple different effects: they dampen inflammatory responses associated with reduced antiviral activity of the immune system, facilitate HCV persistence, and also contribute to the regulation of fibrosis in the liver.

## CONCLUSION

When an individual becomes infected with HCV, the immune system has to make a choice between Scylla and Charybdis. If it takes a course close to Scylla, it generates strong antiviral immune responses, which eliminates virus infected liver cells by the combined action of its several innate and adaptive defense mechanisms. This may cause extended liver damage and eventually liver failure. To avoid this risk, immune responses may be softer. Then, the virus has a chance to escape from control by immunity, and functions of innate and adaptive immune mechanisms become diverted owing to continued antigenic stimulation. An inflammatory state is induced, which, however, is refractory to stimulation by antiviral cytokines, and NK cells as well as cells in the adaptive immune system take over regulatory functions. Necro-inflammatory and pro-fibrotic activities maintained by diverted immune responses inevitably take a course towards Charybdis, and may ultimately result in liver cirrhosis, liver cancer and death of the individual. Thus, the immune system holds the steer to find the way between

**Figure 2 Multiple activities of hepatitis C virus-specific regulatory T cells in chronic hepatitis C.** Regulatory T cell (Tregs) inhibit antiviral immunity *via* release of immunosuppressive factors, such as interleukin 10 (IL-10), transforming growth factor beta (TGF- $\beta$ ) and interleukin 35 (IL-35). Tregs in hepatitis C are also differentiated towards interleukin 8 (IL-8) production. Release of IL-8 binds to its receptors, such as CXCR2 on hepatic stellate cells (HSC), which become activated and produce extracellular matrix (ECM) components. IL-8 down-regulates interferon-stimulated genes in infected cells and induces an interferon (IFN)-refractory state, which also counter-acts antiviral immunity. ISGs: Interferon-stimulated genes.

Scylla and Charybdis.

## Abstract

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) inhibitors are known to increase reactivation of concurrent chronic hepatitis B, but their impact on the hepatitis C virus (HCV) is controversial. Some conditions of immunosuppression, such as liver transplantation, typically cause an increase in the rate of HCV evolution. Inhibition of TNF- $\alpha$ , a cytokine involved in the apoptotic signaling pathway of hepatocytes infected by HCV, could potentially increase viral replication. Currently available clinical data appear to contradict this hypothesis. A review of medical literature revealed that a total of 216 patients with HCV were exposed to one or more treatments with TNF- $\alpha$  inhibitors, with a median observation time of 1.2 years and 260 cumulative patient-years of exposure. Only three cases of drug withdrawal due to suspected HCV liver disease recrudescence were reported. Treatment with TNF- $\alpha$  inhibitors in patients with HCV infection appears to be safe in the short term, but there are insufficient data to assess their long-term safety. Universal screening for HCV before beginning treatment with TNF- $\alpha$  inhibitors is currently controversial. The presence of HCV is not a contraindication to therapy with TNF- $\alpha$  inhibitors, with the exception of cirrhotic pa-

tients. In cases of cirrhosis, the benefit/risk ratio should be evaluated at the individual level. Prior to treatment with TNF- $\alpha$  inhibitors, patients with HCV should be referred to a hepatologist to determine the necessity of hepatic disease assessment, using liver biopsy or non-invasive methods, and the potential indication for antiviral therapy. In patients with HCV infection who are treated with TNF- $\alpha$  inhibitors, liver function monitoring every three months is advised.

**Key words:** Infliximab; Etanercept; Adalimumab; Hepatitis C virus; Rheumatoid arthritis; Inflammatory bowel disease; Psoriasis

**Core tip:** Our review summarizes data on patients with hepatitis C exposed to tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) inhibitors, thus building a stronger safety profile than previously reported. A comprehensive paragraph on the pathway of TNF- $\alpha$  in hepatitis C virus (HCV) and an overview on immune-mediated damage induced by TNF- $\alpha$  inhibitors (cryoglobulins, autoimmune hepatitis) have been also included. Some controversies regarding the universal screening and monitoring of HCV-RNA were also addressed.

## INTRODUCTION

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is a cytokine involved

in the pathogenesis of inflammatory diseases and in the immune-mediated response to infections, especially against intracellular pathogens. Drugs targeting and inhibiting the biological activity of TNF- $\alpha$ , such as infliximab, etanercept and adalimumab, are increasingly used for the treatment of immune-mediated diseases such as rheumatoid arthritis, inflammatory bowel diseases and psoriasis<sup>[1]</sup>. TNF- $\alpha$  inhibitors increase susceptibility to new or reactivation of concurrent infections. Thus, before its use for therapy, a screening for tuberculosis (with chest radiography and an interferon-gamma release assay) and certain viral infections such as hepatitis B virus (HBV), hepatitis C virus (HCV), cytomegalovirus, and herpes virus is recommended<sup>[2]</sup>.

The potential risk of reactivation of HBV infection during TNF- $\alpha$  inhibitor therapy is well established. Animal studies have demonstrated that TNF- $\alpha$  plays a key role in clearing HBV from infected hepatocytes by synergizing with interferons (IFNs) in the suppression of viral replication<sup>[3,4]</sup>. TNF- $\alpha$  inhibitors can increase HBV replication and reactivate chronic hepatitis, both during and after discontinuation of treatment. It is worth noting that many patients receiving TNF- $\alpha$  inhibitors have been previously or simultaneously treated, even for long periods, with other immunosuppressant agents that further increase the risk of HBV reactivation<sup>[5]</sup>. Hepatitis reactivation has been reported in twenty-three hepatitis B surface antigen (HBsAg)-positive patients treated with TNF- $\alpha$  inhibitors in the absence of prophylaxis (inactive carriers or with unrecognized HBsAg seropositivity), including 9 cases of fulminant hepatitis, 4 deaths and 1 liver transplantation. Furthermore, three HBsAg-negative, hepatitis B core antibody (Anti-HBc)-positive patients presented HBsAg seroreversion followed by a hepatitis flare-up after administration of TNF- $\alpha$  inhibitors<sup>[6]</sup>. The protocol that is currently recommended, borrowed from other clinical situations of pharmacologically induced immunosuppression, includes prophylaxis with lamivudine of all inactive carriers during and for 6-12 mo following therapy with TNF- $\alpha$  inhibitors and quarterly monitoring of HBsAg in HBsAg-negative anti-HBc positive patients<sup>[7,8]</sup>.

In the context of HCV infection, the potential risk of reactivation of infection during therapy with TNF- $\alpha$  inhibitors is controversial. Several clinical reports have shown that chronic hepatitis C usually evolves rapidly in some conditions associated with immunosuppression, such as co-infection with human immunodeficiency virus, hypogammaglobulinemia, and after bone marrow transplantation and, above all, liver transplantation<sup>[9]</sup>. In various other circumstances, *e.g.*, following chemotherapy, hepatitis flare-up does not occur during immunosuppression or after its suspension<sup>[10]</sup>. The inhibition of TNF- $\alpha$ , a cytokine involved in the apoptotic signaling pathway of hepatocytes infected by HCV, could potentially increase viral replication and worsen the course of chronic hepatitis<sup>[11]</sup>. In this review, we present an overview of the relationship between the TNF- $\alpha$  pathway and HCV, summarize the available evidence regarding the safety of TNF- $\alpha$  inhibi-

tor usage in patients with HCV and provide suggestions for the management of therapy in this clinical setting.

## TNF- $\alpha$ PATHWAY IN CHRONIC HCV INFECTION

The role of TNF- $\alpha$  in chronic HCV infection is not well understood. Serum levels of TNF- $\alpha$  and its soluble receptors (sTNF-R55 and sTNF-R75) are significantly higher in HCV-infected patients than in healthy subjects<sup>[12]</sup>. Serum levels of TNF- $\alpha$  correlate with serum transaminase levels, histological activity and fibrosis, but not with serum HCV RNA levels or viral genotype<sup>[13,14]</sup>. Laboratory studies have indicated that the HCV core protein has the potential to inhibit the TNF- $\alpha$ -mediated apoptotic signaling pathway, providing a selective advantage for HCV replication and avoidance of the host antiviral defense mechanism<sup>[15]</sup>. Thus, further suppression of TNF- $\alpha$  by biological drugs may pose a potential threat of excessive viral replication and worsening of chronic HCV infection. In contrast, some studies have postulated that the baseline overexpression of TNF- $\alpha$  is associated with reduced cell capability to respond to IFN signaling and, consequently, to reduced viral clearance<sup>[16]</sup>. Zein *et al.*<sup>[17]</sup> conducted a controlled, double-blind, randomized, placebo trial assessing the effects of etanercept as adjuvant therapy to IFN alfa-2b for 24 wk plus ribavirin in patients with chronic hepatitis C. The 19 patients treated with etanercept achieved sustained virologic response at a significantly higher rate compared to the 25 controls, and treatment was associated with decreased incidence of the most common side effects associated with IFN and ribavirin. This phase II study supported the assumption that etanercept may restore TNF-induced CD4<sup>+</sup> cell impairment and enhance antiviral effects of IFN and ribavirin combination therapy. Large studies of the effects of adjuvant etanercept on therapy with pegylated IFN and ribavirin are currently lacking.

Infliximab is a recombinant human-murine chimeric immunoglobulin-G1 (IgG1) antibody that specifically binds both soluble and membrane-bound precursor forms of TNF- $\alpha$ . Etanercept is a dimeric fusion protein that consists of the extracellular ligand-binding portion of the human 75 kDa TNF receptor linked to the Fc portion of the human IgG1, and binds only soluble TNF- $\alpha$ . Adalimumab is a human-derived recombinant IgG1 monoclonal antibody that binds to TNF- $\alpha$  and blocks the interaction between soluble TNF- $\alpha$  and cell-surface TNF receptors<sup>[18]</sup>. The limited data that are currently available are not sufficient for the assessment of the potential specific differences between the drugs regarding the effect on viral replication.

## CLINICAL EVIDENCE OF THE SAFETY OF TNF- $\alpha$ INHIBITORS IN PATIENTS WITH HCV

We performed a comprehensive review of reports pub-

**Table 1** Safety of tumor necrosis factor- $\alpha$  inhibitors in patients with hepatitis C virus

Drug	Patients with HCV infection ( <i>n</i> )	Mean follow-up (yr)	Patients/yr exposure	Elevation in AST/ALT serum level > 3 ULN	Elevation in HCV-RNA (> 1 log above baseline)	Drug withdrawal due to liver toxicity
Etanercept	153	1.14	174.49	3 <sup>1</sup>	5	2
Infliximab	40	1.59	63.64	2	4	1
Adalimumab	23	0.97	22.43	0	0	0

<sup>1</sup>Elevation of transaminases without concomitant increase of HCV viremia in two cases. HCV: Hepatitis C virus; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ULN: Upper limit of normal.

lished in English between January 2000 and August 2013; patients were evaluated for the following variables: disease, comorbidities, TNF- $\alpha$  inhibitors, previous HCV treatment, concomitant immunosuppressive drugs, liver function tests, HCV-ribonucleic acid (HCV-RNA), histopathological liver findings (when available), complications and outcomes. Patients with HCV are excluded from participation in controlled clinical trials with TNF- $\alpha$  inhibitors. Next, available data regarding the safety of TNF- $\alpha$  inhibitors in patients with hepatitis C, as derived from several case reports and small retrospective cohort studies in the field of rheumatology, dermatology and gastroenterology, in addition to the already mentioned trial of Zein *et al*<sup>[17]</sup>, were evaluated. These findings come from various clinical contexts, in terms of differing uses of concomitant immunosuppressive drugs (in most cases dermatologists tend to employ TNF- $\alpha$  inhibitors in monotherapy, while gastroenterologists and rheumatologists prescribe them in combination with other immunosuppressants), pre-treatment selection of HCV patients, monitoring protocols and differences in the threshold used for discontinuing treatment with TNF- $\alpha$  inhibitors. Furthermore, most of the evidence concerns the measurement of transaminases and viral load, with few reports including a histological evaluation before and after treatment.

Total of 216 patients with hepatitis C were treated with one or more TNF- $\alpha$  inhibitors, with a median observation time of 1.2 years and 260 cumulative patient-years of treatment, a measure of exposure that includes all patients treated and normalizes the different durations of treatment to one year (Table 1)<sup>[19-58]</sup>. The majority of the available safety data concern etanercept. Clinical evidence suggests that the role of TNF- $\alpha$  in the control of HCV replication is modest. Currently, only three cases of drug withdrawal due to clinical suspicion of a worsening of HCV liver disease have been reported. The viral load in most cases remains stable or decreases, and it is difficult to confidently attribute the few cases of serum HCV-RNA increase > 1 log above the baseline value to treatment with TNF- $\alpha$  inhibitors, considering the well-known virological profile of HCV, which shows spontaneous fluctuations > 1 log of HCV-RNA level in 5%-10% of patients<sup>[59]</sup>. Overall, TNF- $\alpha$  inhibitors do not increase transaminase levels or viral load in the short term in patients with hepatitis C. Furthermore, the administration of these drugs has allowed the concomitant use of IFN in some patients with hepatitis C in whom IFN had been previously discontinued due of a worsening of concur-

rent immunomediated diseases such as psoriasis, rheumatoid arthritis or other arthritis. In regard to the long-term safety of TNF- $\alpha$  inhibitors and their impact on the progression of liver fibrosis, the limited available data do not allow for the assessment of this issue. Another area of uncertainty is related to their use in cirrhotic patients; only two cases of patients with cirrhosis who received TNF- $\alpha$  inhibitors have been reported, by Zein and Abdelmalek<sup>[17,36]</sup>, and both cases were without significant side effects.

Another potential concern is the possibility of immune-mediated liver damage induced by TNF- $\alpha$  inhibitors. Emergence of serum auto-antibodies is a common observation in patients treated with TNF- $\alpha$  inhibitors and presents an additional concern in patients with hepatitis C. In the absence of HCV infection, the auto-antibodies induced by such treatments are usually non-organ specific [anti-double-stranded-DNA (dsDNA), rheumatoid factors, anti-cardiolipin] and belong to the IgM class<sup>[60,61]</sup>. Vauloup *et al*<sup>[62]</sup> prospectively evaluated the induction of circulating auto-antibodies during therapy with TNF- $\alpha$  inhibitors in patients with HCV and observed induction of anti-nuclear and anti-dsDNA antibodies, but no induction of anti-tissue antibodies (anti-smooth muscle and anti-liver/kidney/microsome type 1), even in patients with actively replicating chronic hepatitis C. Induction of cryoglobulinemia was also a possibility, and HCV-related mixed cryoglobulinemia usually includes an IgM component. Auto-antibodies emerging during treatment with TNF- $\alpha$  inhibitors are usually clinically silent, possibly due to the low avidity of antibodies to their antigen. Seventeen cases of TNF- $\alpha$ -induced hepatitis without known past history of liver disease have been reported in the literature<sup>[63-78]</sup>. The majority of these cases are secondary to infliximab and resemble autoimmune hepatitis type 1 due to an increased prevalence among females, the more common elevation of autoantibodies related to autoimmune hepatitis type 1 (anti-nuclear, anti-smooth-muscle or anti-dsDNA), the presence of interface hepatitis at liver biopsy, and the strong response to steroid therapy. Some of these patients were subsequently able to tolerate etanercept, suggesting a different potential of the two drugs in inducing immune-mediated liver damage. Indeed, among patients with HCV infection, only one case of granulomatous hepatitis not associated to a rise of serum HCV-RNA, diagnosed after 7 mo of therapy with etanercept, has been reported<sup>[79]</sup>. A TNF- $\alpha$  blockade induces a cytokine imbalance that is rarely responsible

for inducing pulmonary, cutaneous, eye and even hepatic sarcoidosis. Overall, the incidence of autoimmune hepatitis induced by TNF- $\alpha$  inhibitors appears to be low and does not represent a contraindication in the treatment of patients with chronic hepatitis C.

Although observations of transaminase elevation have been documented in the package inserts of TNF- $\alpha$  inhibitors, no direct link between these drugs and liver toxicity has been established to date, with the exception of one single case of acute hepatitis during infliximab treatment, in which the liver biopsy showed signs of toxic damage (intralobular necrosis, ceroid-containing Kupffer cells)<sup>[80]</sup>. For this reason, TNF- $\alpha$  inhibitors present an attractive alternative therapy in some patients with autoimmune diseases, such as psoriasis or rheumatoid arthritis, which are routinely treated with other drugs with well established, likely more severe liver toxicity profiles (cyclosporine, acitretin, methotrexate, leflunomide).

## CLINICAL MANAGEMENT OF TNF- $\alpha$ INHIBITORS IN PATIENTS WITH HCV

Many guidelines recommend screening by means of serum anti-HCV antibodies in all patients undergoing therapy with TNF- $\alpha$  inhibitors, emphasizing that a definitive decision on the safety of TNF- $\alpha$  inhibitors in cases of chronic HCV infection has not been made<sup>[81-83]</sup>. A study conducted in Ireland, a country with a low prevalence of HCV (< 1%), including 215 patients with psoriasis treated with TNF- $\alpha$  inhibitors documented a single case of positivity for antibodies to HCV with undetectable serum HCV-RNA. The authors concluded that, in areas with low prevalence of HCV infection, universal screening should be replaced by targeted screening based on the individual risk factors of each patient<sup>[84]</sup>. Other guidelines state that universal screening should not be definitively recommended, as the risk of HCV reactivation under immunosuppressive drugs appears to be very low<sup>[85,86]</sup>. Before beginning treatment with TNF- $\alpha$  inhibitors, assays for serum alanine aminotransferase (ALT), gamma-glutamyl-transferase and total bilirubin are recommended, bearing in mind that approximately 30% of patients with chronic HCV infection show persistently normal ALT levels<sup>[87]</sup>. In cases of anti-HCV positivity, assessment of HCV-RNA, HCV genotype, cryoglobulins, complete blood count, total protein, albumin, total cholesterol, prothrombin time, creatinine, and urine exam, as well as a liver ultrasound, are also recommended.

TNF- $\alpha$  inhibitors in patients with HCV are not contraindicated, provided that monitoring of liver function tests is performed every three months during treatment. Currently, there is uncertainty in the standards for viral load monitoring (quarterly or only in case of serum transaminase increase). Due to the absence of data regarding cirrhotic patients, TNF- $\alpha$  inhibitors should be used with caution in compensated patients, while they are contraindicated in patients with decompensated liver disease, considering the extremely high risk of potentially fatal severe

infections. In cases of reactivation of hepatitis, patients should be referred to a hepatologist for a differential diagnosis and to consider the potential for TNF- $\alpha$  inhibitor treatment withdrawal.

## CONCLUSION

TNF- $\alpha$  inhibitor treatment in patients with HCV appears to be safe in the short term, but there are insufficient data to assess their long-term safety. A potential concern related to the administration of these drugs is the induction of immune-mediated reactions that potentially involve the liver (cryoglobulinemic syndrome or autoimmune hepatitis), but the incidence of such reactions appears to be low. Universal screening for HCV before beginning treatment with TNF- $\alpha$  inhibitors is currently controversial. The presence of HCV is not a contraindication to therapy with TNF- $\alpha$  inhibitors, except in cirrhotic patients, in whom the benefit/risk ratio should be evaluated at the individual level before treatment is initiated. Before administration of TNF- $\alpha$  inhibitors, patients with HCV should be referred to a hepatologist for the evaluation of the liver disease stage through liver biopsy or non-invasive methods and the potential for antiviral therapy. Liver function tests are advised for patients with HCV at a frequency of every three months during treatment with TNF- $\alpha$  inhibitors.

## WJG 20<sup>th</sup> Anniversary Special Issues (2): Hepatitis C virus

# Relationships between lymphomas linked to hepatitis C virus infection and their microenvironment

Antonino Carbone, Annunziata Gloghini

Antonino Carbone, Department of Pathology, Centro di Riferimento Oncologico Aviano, Istituto Nazionale Tumori, IRCCS, Aviano and Pordenone Hospital, 33081 Aviano, Italy

Antonino Carbone, Member of WHO IARC Monograph Working Group on Biological Agents, 2009 Lyon, France

Annunziata Gloghini, Department of Diagnostic Pathology and Laboratory Medicine, Fondazione IRCCS Istituto Nazionale dei Tumori, 20133 Milano, Italy

Author contributions: Carbone A designed the review; Carbone A and Gloghini A wrote the paper.

Supported by An Institutional grant from Centro di Riferimento Oncologico Aviano for an intramural project "Agenti Infettivi e Tumori" to Carbone A; and an Institutional grant from the Fondazione IRCCS Istituto Nazionale Tumori Milano "Validation of a new algorithm for HPV status assessment in head and neck carcinoma" to Gloghini A

## Abstract

The relationships between lymphomas and their microenvironment appear to follow 3 major patterns: (1) an independent pattern; (2) a dependent pattern on deregulated interactions; and (3) a dependent pattern on regulated coexistence. Typical examples of the third pattern are hepatitis C virus (HCV)-associated marginal zone lymphomas (MZLs) and mucosa-associated lymphoid tissue lymphomas. In these lymphomas, a regulated coexistence of the malignant cells and the microenvironmental factors usually occurs. At least initially, however, tumor development and cell growth largely depend on external signals from the microenvironment, such as viral antigens, cytokines, and cell-cell interactions.

The association between HCV infection and B-cell lymphomas is not completely defined, although this association has been demonstrated by epidemiological studies. MZL and diffuse large B-cell lymphoma are the histotypes most frequently associated with HCV infection. Many mechanisms have been proposed for explaining HCV-induced lymphomagenesis; antigenic stimulation by HCV seems to be fundamental in establishing B-cell expansion as observed in mixed cryoglobulinemia and in B-cell lymphomas. Recently, antiviral treatment has been proved to be effective in the treatment of HCV-associated indolent lymphomas. Importantly, clinically responses were linked to the eradication of the HCV-RNA, providing a strong argument in favor of a causative link between HCV and lymphoproliferation.

## INTRODUCTION

Genetic alterations and abnormal microenvironmental factors are involved in tumor development, cell growth and disease progression. Inflammatory cells and soluble mediators, *i.e.*, cytokines and chemokines, are essential microenvironmental factors that sustain cell growth and invasion, induce angiogenesis and suppress anti-tumor immune functions<sup>[1]</sup>.

In multidimensional studies on hematolymphoid malignancies, a relevant clinical role of the tumor microenvironment has recently emerged, bringing new knowledge and suggesting new ideas and targets for treatment<sup>[2-5]</sup>.

The relationships between lymphomas and their microenvironment appear to follow 3 major patterns: (1) an independent, largely autonomous pattern; (2) a dependent on deregulated interactions pattern; and (3) a dependent on regulated coexistence pattern<sup>[2]</sup>. A typical example of the first pattern is Burkitt lymphoma where all tumor cells proliferate because of permanent *MYC* gene activation. A typical example of the second pattern is classic Hodgkin lymphoma, where Reed-Sternberg cells escape the regulated cell growth- and proliferation-control. Typical examples of the third pattern are Hepatitis C virus (HCV)-associated marginal zone lymphomas (MZLs) and mucosa-associated lymphoid tissue (MALT) lymphomas. In this pattern, a regulated coexistence of the malignant cells and the microenvironment is reminiscent of the pattern that the normal counterpart B cells engage in with their respective microenvironment. At least initially, tumor development and cell growth largely depend on external signals from the microenvironment, such as viral antigens, cytokines, and cell-cell interactions<sup>[6]</sup>.

HCV infection is a worldwide problem. There are important regional differences in the prevalence of HCV infection: the lowest rates are reported in Northern Europe while prevalence estimates exceed 2% in Italy, Japan, Egypt and southern parts of United States<sup>[7]</sup>. Among the carcinogenic viruses recognized by the recent International Agency for Research on Cancer (IARC) monograph Epstein-Barr virus (EBV), human papilloma virus (HPV), human T-lymphotropic virus type I (HTLV-1), and Kaposi sarcoma-associated herpesvirus (KSHV) play a direct role in carcinogenesis encoding oncoproteins which are able to promote cellular transformation<sup>[8,9]</sup>. Conversely, HCV and *Helicobacter pylori* appear to have an indirect role, by inducing a chronic inflammation<sup>[10]</sup>. Hepatitis B virus (HBV) has both a direct and indirect role in promoting hepatocellular carcinoma (HCC); as a matter of fact, chronic HBV carriers can develop HCC without developing cirrhosis.

## PATHOGENETIC ASPECTS

HCV infection is the cause of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma (HCC) (Table 1). HCV infection has been also associated to a spectrum of extra-hepatic lymphoproliferative disorders including

mixed cryoglobulinemia (MC)<sup>[11]</sup>, the most well defined disorder associated with HCV infection, monoclonal gammopathies<sup>[12]</sup> and B-cell lymphomas<sup>[13]</sup>. HCV infection has been associated with B-cell low grade indolent lymphoma, especially of marginal zone origin, as well as with aggressive lymphomas, mainly diffuse large B-cell lymphomas (DLBCL) (Table 2). Authoritative studies have demonstrated that in HCV-infected patients with indolent lymphomas, eradication of HCV with antiviral treatment (AT) could directly induce lymphoma regression, providing a strong argument in favor of a causative link between HCV and lymphoproliferation<sup>[14]</sup>.

## INFLAMMATORY MICROENVIRONMENT

The liver is the main target of HCV infection and the major site of inflammatory events, including recruitment of inflammatory cells.

Occurrence of HCV enrichment in intrahepatic inflammatory infiltrates supports the notion that HCV is directly involved in the emergence and maintenance of these B-cell expansions<sup>[15]</sup>. Intrahepatic B-cell clonalities are invariably associated with extrahepatic manifestations of HCV infection associated B-cell lymphomas.

## HCV AND LYMPHOMAGENESIS

According to the recent IARC monograph on biological agents and carcinogenesis, the association between HCV infection and B-cell lymphomas is not completely defined<sup>[9]</sup>. This association has been demonstrated by epidemiological studies in highly endemic geographical areas<sup>[16]</sup>. The role of HCV infection in lymphomagenesis may be related to the chronic antigenic stimulation of B-cell response, similar to the well characterized induction of gastric MALT lymphoma development by *Helicobacter pylori* chronic infection<sup>[17]</sup>. In fact, chronic HCV infection may sustain a multi-step evolution from MC to overt low grade lymphoma and eventually to high-grade lymphoma<sup>[17]</sup>. During this process, additional genetic aberrations may induce independence from antigenic stimulation. The clonal component of MC is often an IgM with a rheumatoid factor activity that mirrors the expansion of a B-cell monoclonal population not only in bone marrow but also in liver. It has also been suggested that HCV antigens (NS3 and E7 or E2) can play a role in lymphomagenesis<sup>[18,19]</sup>. Recently, it has been published that HCV-related cryoglobulins (either IgM and IgG) are mainly directed against core and NS3 proteins<sup>[20]</sup>. Chromosomal alterations could also play a role in development of HCV-related lymphoproliferative disorders: for instance, MC with or without lymphoma is characterized by translocation t(14; 18) with the overexpression of the antiapoptotic *bcl-2* gene leading to prolonged B-cell survival<sup>[21]</sup>.

Importantly, cytokines and chemokines (IFN $\gamma$ , TNF $\alpha$ , CXCL13 and BAFF in MC<sup>[16]</sup>, as well as osteopontin<sup>[22]</sup>) are involved in the mechanisms of HCV-

induced lymphoproliferation.

## HCV INFECTION AND SPECIFIC LYMPHOMAS

Within indolent lymphoma subtypes, the association with HCV infection has been best characterized in MZLs. Other infectious agents have been involved in the pathogenesis of specific types of MZLs. For examples *Helicobacter pylori*, *Borrelia burgdorferi*, and *Chlamydia psittaci* have been involved in MALT lymphomas arising

in stomach, skin and orbit, respectively<sup>[9]</sup>. Conversely, chronic stimulation by HCV plays a role in development of splenic marginal zone lymphoma (SMZL) and primary nodal marginal zone lymphoma. Primary nodal marginal zone lymphoma is a distinct clinical-pathological subtype characterized by exclusive primary lymph node localization in the absence of extranodal site of involvement (Figure 1).

Splenic and nodal MZL are indolent B-cell lymphomas corresponding to post-germinal center memory B cells that are supposed to derive from marginal zone<sup>[23,24]</sup>. These entities share some morphologic and pathogenic features, but have distinctive clinical presentation, immunophenotype and molecular abnormalities. Histologically, when the marginal zone B cells surround normal follicles with benign mantle zones as a third outer layer, they produce a marginal zone pattern<sup>[25]</sup>. As the marginal zone cells extend outwards into the interfollicular areas, they form confluent clusters resulting in an interfollicular pattern or a diffuse pattern in the absence of any follicles at later stages of the disease<sup>[25]</sup>. The marginal zone cells may also grow inwards into the follicles and produce either partial or complete follicular colonization<sup>[25]</sup> (Figure 1).

Gastric and non-gastric extranodal MZL are typically indolent diseases of middle and advanced age; disseminated disease is present in nearly one-third of cases. Interestingly, three specific MALT lymphoma sites showed an elevated prevalence of HCV infection: salivary glands, skin and orbit<sup>[26]</sup>. The association of HCV infection and salivary glands lymphoma has been clearly demonstrated<sup>[27]</sup>.

Moreover, a study on B-cell lymphoma in patients with Sjögren's syndrome and HCV infection reported an

**Figure 1 Nodal marginal zone lymphoma.** The panel shows an example of nodal marginal zone lymphoma (MZL) with follicular colonization. BCL-2<sup>+</sup> neoplastic cells surround and colonize the germinal center, whereas CD23 highlights the disrupted follicular dendritic cell meshwork. Images were acquired with the Olympus Dot. Slide Virtual microscopy system using an Olympus BX51 microscopy equipped with PLAN APO 2x/0.08 and UPLAN SApo 40x/0.95 objectives.

elevated occurrence of parotid involvement and a high proportion of MALT lymphomas with primary extra-nodal involvement (exocrine glands, liver, and stomach) (Table 2)<sup>[28]</sup>.

Beside MZLs, also LPL/Waldenström's macroglobulinemia (WM) has been associated to HCV infection. However, this association is not completely defined. B-cell chronic lymphoproliferative disorders are defined as the miscellaneous category of lymphoproliferative disorders distinct from chronic lymphocytic. Association of these entities with HCV is not clear. Interestingly, monoclonal B-cell lymphocytosis (MBL), a pre-clinical condition characterized by an expansion of clonal B cells in the absence of frank lymphocytosis, was identified in nearly 30% of HCV-positive subjects with a significantly higher frequency than in the general population.

Recently, a retrospective study of B-cell lymphoproliferative disorders associated with HCV infection found two poorly described groups of cases. The first featured disseminated MZL without splenic MZL features, defying the current MZL classification; the other consisted of monoclonal B lymphocytes in the peripheral blood, bone marrow or other tissues, with no clinical or histological evidence of lymphoma. This pattern requires proper identification in order to avoid the misdiagnosis of the lymphoma<sup>[29]</sup>.

Despite the classical association of HCV with indolent lymphoma, aggressive lymphoma, in particular DLBCL, are emerging as diseases linked to HCV infection. Patients affected by HCV-associated DLBCL display specific presentation with respect to HCV-negative DLBCL. In particular, residual signs of low-grade lymphoma and extranodal disease such as spleen are more frequently detected in HCV-associated DLBCL cases in comparison with HCV-negative DLBCL<sup>[9]</sup>. Unlike indolent B-cell lymphoma, AT seems not to play a central role in the first-line approach for HCV-associated DLBCL, because lymphoma cells are most likely to be independent from

chronic antigenic stimulation due to the acquisition of additional oncogenic lesions. For this reason, HCV-associated DLBCL patients have to be treated with anthracycline-based chemotherapy coupled with rituximab.

## CONCLUSION

Many epidemiological studies have provided evidence that HCV infection is associated with development of indolent and aggressive B-cell lymphoma<sup>[30,31]</sup>. However, the causal association between HCV infection and B-cell lymphomas is not completely defined. The similarities shared by rearranged Ig genes present in B cells from patients with type II MC and malignant B-cells from HCV-positive patients affected by B-cell lymphoma support the possibility that the antigens that promote type II MC and B-cell lymphoma in HCV-positive patients are the same<sup>[32,33]</sup>. These similarities also suggest that type II MC may be a precursor of B-cell lymphoma<sup>[34]</sup>. Type II MC probably plays a central role in the development of B-cell lymphoma in HCV-positive patients with Sjögren's syndrome<sup>[35]</sup>.

Three hypothetical models have emerged to understand the molecular mechanisms of HCV-associated lymphoma development: (1) continuous external stimulation of lymphocyte receptors by viral antigens and consecutive proliferation; (2) direct role of HCV replication and expression in infected B-cells; and (3) permanent B-cell damage, *e.g.*, mutation of tumor suppressor genes, caused by a transiently intracellular virus ("hit and run" theory)<sup>[9,36]</sup>. Other non exclusive hypotheses have been proposed over the past two decades. These hypotheses have variously emphasized the important role played by chromosomal aberrations, cytokines, or microRNA molecules<sup>[37]</sup>. However, the mechanisms by which B-cell lymphomas are induced by HCV remain the subject of debate.

## Abstract

Hepatitis C virus (HCV) is a major health burden infecting 170-210 million people worldwide. Additional 3-4 millions are newly-infected annually. Prevalence of pediatric infection varies from 0.05%-0.36% in the United States and Europe; up to 1.8%-5.8% in some developing countries. The highest prevalence occurs in Egypt, sub-Saharan Africa, Amazon basin and Mongolia. HCV has been present in some populations for several centuries, notably genotypes 1 and 2 in West Africa. Parenteral anti-schistosomal therapy practiced in the 1960s until the early 1980s had spread HCV infection throughout Egypt. Parenteral acquisition of HCV remains a major route for infection among Egyptian children. Insufficient screening of transfusions, unsterilized injection equipment and re-used needles and syringes continue to be major routes of HCV transmission in developing countries, whereas vertical transmission and adolescent high-risk behaviors (*e.g.*, injection drug abuse) are the major routes in developed countries. The risk of vertical transmission from an infected mother to her unborn/newborn infant is approximately 5%. Early stages of

HCV infection in children do not lead to marked impairment in the quality of life nor to cognitive, behavioral or emotional dysfunction; however, caregiver stress and family system strain may occur. HCV slowly progresses to serious complications as cirrhosis (1%-2%) and hepatocellular carcinoma (HCC) especially in the presence of risk factors as hemolytic anemias, obesity, treated malignancy, and concomitant human immune deficiency and/or hepatitis B virus co-infection. HCV vaccine remains elusive to date. Understanding the immune mechanisms in patients who successfully cleared the infection is essential for vaccine development. The pediatric standard of care treatment consists of pegylated interferon- $\alpha$  2a or b plus ribavirin for 24-48 wk. The new oral direct acting antivirals, approved for adults, need further evaluation in children. Sustained virologic response varies depending on the viral load, genotype, duration of infection, degree of aminotransferase elevation, adiposity and single nucleotide polymorphisms of interleukin (IL)-28B locus. The goals of treatment in individual patients are virus eradication, prevention of cirrhosis and HCC, and removing stigmatization; meanwhile the overall goal is decreasing the global burden of HCV. *IL-28B* polymorphisms have been also associated with spontaneous clearance of vertically acquired HCV infection. The worldwide economic burden of HCV for children, families and countries is estimated to be hundreds of millions of US dollars per year. The United States, alone, is estimated to spend 199-336 million dollars in screening, monitoring and treatment during one decade. The emotional burden of having an HCV infected child in a family is more difficult to estimate.

## INTRODUCTION AND EPIDEMIOLOGY

Hepatitis C virus (HCV) is a small, enveloped, positive-sense, single-stranded RNA virus of the *Flaviviridae* family<sup>[1]</sup>. HCV was first cloned in 1989 after more than 6 years of work to extract the virus from infected patients by a group of scientists from California in the United States<sup>[2]</sup>. HCV infection is recognized nowadays as a disease of global importance<sup>[3]</sup>. It is considered a major health and economic burden in adults as well as children in both developing and developed countries<sup>[3,4]</sup>.

Viral hepatitis is the most common cause of liver disease in the world. Acute infections with their sequelae are responsible for 1-2 million deaths/year. Of them 54000 deaths are due to acute HCV infection<sup>[4]</sup>. After acute infection with HCV, as many as 50%-85% of patients fail to clear the virus resulting in chronic infection with 350000 deaths/year and 955000 disability due to related complications such as cirrhosis and liver cancer<sup>[5]</sup>.

A recent systematic review found that globally between 1990 and 2005, the prevalence of people with anti-HCV has increased from 2.3% to 2.8%<sup>[4]</sup>. It is estimated that approximately 210 million individuals, *i.e.*, approximately 3% of the world population, are chronically infected with HCV<sup>[3,6]</sup> and 3-4 millions are newly infected each year<sup>[3]</sup>. Available data indicate that infection with HCV varies considerably by country and region, and the true burden of disease is not well known in many countries, because the capacity is often limited for collecting epidemiologic data<sup>[7]</sup>. The prevalence may vary markedly from one geographic area to another and even within the population assessed<sup>[8]</sup>. The highest prevalence of HCV is in Sub-Saharan Africa (5.3%), followed by the Eastern Mediterranean (4.6%), Western Pacific (3.9%) and South-Eastern Asia (2.15%) regions. Europe is thought to have the lowest prevalence of HCV (1.03%). In North America, prevalence is also low and estimated at 1.6% in the United States and 0.8% in Canada<sup>[9]</sup>.

The study carried out by Uhanova *et al*<sup>[9]</sup> on the epidemiology of HCV in a North American population from

the Canadian province of Manitoba, revealed several important findings: First, the diagnosis of HCV appears to have peaked in 1998 and has been relatively stable thereafter; second, the prevalence of HCV continued to increase amongst both men and women (4.6-fold during the 12-year period of the study). Overall, 84% of all subjects diagnosed since 1991 were alive in 2002, supporting the evidence of the growing burden of HCV; third, with the exception of young adults, males were 1.7 times more often infected than females; fourth, HCV infections were more common in urban centers.

Egypt has the highest worldwide prevalence with 9% countrywide rate; and up to 50% rates in certain rural areas due to specific modes of infection<sup>[10]</sup>. Prevalence in healthy Egyptian children is reported, by our group and others, to range from 1.4% to 5.8%<sup>[11,12]</sup>. Parenteral anti-schistosomal therapy, practiced in the 1960s until the early 1980s, had had a major role in the spread of HCV throughout Egypt<sup>[13]</sup>.

## GLOBAL HCV GENOTYPE DISTRIBUTION

By phylogenetic analysis, 6 distinct genotypes of HCV (denoted 1 to 6) and more than 100 subtypes (denoted 1a, 2c, 3d, 6f, *etc.*) have been described. Each genotype differs in its amino acid sequence by 31%-34%<sup>[14]</sup>. Genotypes 1-3 have a worldwide distribution, whereas 4 is found principally in Egypt, the Middle East and black Africa, 5 in South Africa, and 6 in Asia<sup>[15]</sup>.

Genotype 1 (subtypes 1a and 1b) is by far the most prevalent genotype worldwide, with a higher prevalence of 1b in Europe and 1a in the United States. Genotype 3a is highly prevalent in European intravenous drug abusers<sup>[16]</sup>. This group is currently experiencing an increasing incidence and prevalence of infections related to HCV genotype 4 as well. Genotype 2 is found in clusters in the Mediterranean region<sup>[17]</sup>. Molecular clock analyses suggest that HCV strains have been present in some populations in their respective geographical regions for at least several centuries, notably genotypes 1 and 2 in West Africa and genotype 6 in Southeast Asia<sup>[18]</sup>.

## METHODS OF TRANSMISSION

Prior to the 1990s, the principal routes of HCV infection were via blood transfusion, unsafe injection procedures, and intravenous drug abuse. These modes of acquisition are estimated to account for approximately 70% of cases in industrialized countries. Epidemiological evidence shows that a wave of HCV infection occurred in the 1945-1965 period (baby boomers) in Western countries, as there was an increase in the use of injections, blood products and illicit drugs following World War II<sup>[1]</sup>. Screening of blood products for HCV by means of enzyme immunoassays and now, in an increasing number of countries, by nucleic acid testing (NAT) has virtually eradicated transfusion-transmitted HCV. Currently, new HCV infections are primarily due to intravenous or nasal drug abuse, and to a lesser degree to unsafe medical or

surgical procedures. Parenteral transmission via tattooing or acupuncture with unsafe materials is also implicated in occasional transmissions<sup>[8]</sup>. The risk of heterosexual transmission is low, while recent data indicate that promiscuous male homosexual activity is related to HCV infection<sup>[19]</sup>.

In developing countries, insufficient screening of blood, blood products and parenteral exposure, continue to be the major causes of HCV transmission and are still reported among Egyptian children<sup>[20]</sup>. Unsafe use and re-use of injection equipment in hospitals is still a threat in many parts of Africa<sup>[21]</sup>. Intra-familial transmission may occur, but specific immune responses may be protective against house-hold infection in some children<sup>[22]</sup>.

At present the vertical, maternal-neonatal or perinatal transmission is the most common route of pediatric HCV infection<sup>[23]</sup>. Worldwide, it has been estimated that 60000 HCV-infected infants are born yearly<sup>[24]</sup>. Mother-to-infant vertical transmission of HCV is reported to occur in approximately 5% of cases (with a range of 3%-10%), mostly in the late intrauterine period, at delivery or in the peri-natal period<sup>[1,24]</sup>. Many factors have been reported to influence the transmission rate<sup>[25]</sup>, including maternal high viral load<sup>[26-28]</sup>, labor duration, newborn gender, HCV genotype<sup>[29]</sup>, human immuno-deficiency virus (HIV) co-infection<sup>[24]</sup>, amniocentesis<sup>[30,31]</sup>, fetal scalp monitoring<sup>[32]</sup>, prolonged rupture of membranes<sup>[32,33]</sup> and fetal anoxia around the time of delivery<sup>[28]</sup>.

The role of elective cesarean section to reduce mother-to-infant transmission rates is debated and controversial<sup>[33]</sup> and the guidelines of the European Association for the Study of the Liver (EASL) do not recommend cesarean section to prevent HCV vertical transmission<sup>[8]</sup>. Breast feeding is not considered to be contraindicated in women who are infected with HCV<sup>[34,35]</sup>. In spite that the majority of HCV-infected women do not transmit the virus to their offsprings, maternal uncertainty and guilt always surround possible transmission. Cost-effectiveness analysis based on available epidemiologic data indicates that screening of all pregnant mothers for HCV infection is not cost-effective<sup>[36]</sup>, however high risk mothers should be screened<sup>[25]</sup>.

## NATURAL HISTORY OF INFECTION

In some patients, HCV infection is a self-limited disease and HCV RNA becomes undetectable in most of these cases within 3 to 4 mo after the onset of acute infection<sup>[37]</sup>. Symptoms and signs following acute HCV infection are mild and usually non-specific; and fulminant HCV has not been reported in childhood<sup>[38]</sup>.

Unfortunately spontaneous clearance of HCV occurs only in a minority of cases as 54%-86% of adult patients establish a chronic infection<sup>[39]</sup>. Many chronically infected patients do not know that they have been infected with HCV because infection is largely asymptomatic<sup>[40]</sup>. In the approximately 86% of infected patients who develop a chronic infection, HCV progresses insidiously with 10%-20% progressing to cirrhosis and approximately 7%

of cirrhotic patients developing HCC<sup>[41]</sup>.

Little is known about the characteristics of chronic HCV infection in children. Children rarely require liver transplantation for HCV infection. In the United States, only 133 children were transplanted for chronic HCV infection between 1988 and 2009<sup>[25]</sup>. To date, HCC is extremely uncommon in children with HCV infection<sup>[25]</sup>. Only 2 cases have been reported in children<sup>[42]</sup> and two further cases who had acquired chronic infection in childhood presented as young adults<sup>[43]</sup>, however other unreported cases may exist. HCC complicating HCV infection may develop in the absence of cirrhosis<sup>[44,45]</sup>, a finding of potential importance to pediatric patients<sup>[25]</sup>. Progression of liver affection depends on the viral load, serum aminotransferase levels, gender, ethnicity, obesity, toxins, environmental factors and co-morbid risk factors such as hemolytic anemias, treated malignancy, immunosuppression, and concomitant HIV or hepatitis B virus infection, or genetic factors *e.g.*, single-nucleotide polymorphisms (SNPs) of interleukin (IL)-28B gene locus<sup>[46]</sup>.

Chronic HCV infection in children is associated with a variety of histological patterns of liver disease, generally not as severe as in adults. Indeed in many children, liver biopsy may disclose no obvious histological changes or only mild inflammation and fibrosis. Nevertheless, significant fibrosis or cirrhosis may occur<sup>[47]</sup>. Reports on the histological features and progression of hepatitis C in children are scarce but are generally milder than in adults<sup>[48]</sup>. In 1997, Kage *et al.*<sup>[49]</sup> reported, in a cohort of Japanese children with chronic HCV infection, that liver histopathology presents the same lesions as in adults such as lymphoid aggregates, sinusoidal lymphocytosis and steatosis<sup>[48]</sup>. The stage of fibrosis in this cohort was mild, with only a 3.6% prevalence of bridging fibrosis with architectural distortion, and no cases of cirrhosis<sup>[48]</sup>. This seemingly mild course is in contrast with the findings in some of the earlier clinical reports in which the prevalence of cirrhosis was found to be up to 14%<sup>[50-52]</sup>. In a North American study carried out by Badizadegan *et al.*<sup>[48]</sup>, the characteristic histopathological lesions occurred with approximately the same frequencies in children as have been reported in adults. Necroinflammatory activity was generally mild. Portal fibrosis was present in 78% of the specimens, including fibrous portal expansion (26%), bridging fibrosis (22%), bridging fibrosis with architectural distortion (22%), and cirrhosis (8%). Centrilobular pericellular fibrosis, which has not been previously reported in the context of chronic HCV infection in adults or children, was also a prominent feature in their series, occurring with a similar frequency as steatosis or portal lymphoid aggregates/follicles. They suggested that in spite of mild histological necroinflammatory activity in general, the stage of fibrosis in children can be severe in spite of relatively short duration of infection<sup>[48]</sup>.

## EXTRAHEPATIC MANIFESTATIONS OF HCV

Chronic HCV infection may cause numerous extrahepat-

ic manifestations. Up to 40%-74% of patients with HCV infection develop at least one extrahepatic manifestation during their life time. The disorder with strongest link to HCV infection in adults is mixed cryoglobulinemia<sup>[46]</sup>. Other common symptoms are peripheral polyneuropathy, Raynaud's syndrome and sicca-like symptoms. Seven and a half to 10% of the patients develop a B-cell lymphoma at some point<sup>[53-55]</sup>. The clinically most relevant manifestation of mixed cryoglobulinemia is membranoproliferative glomerulonephritis, which appears in 30%-36% of the cases and significantly increases mortality<sup>[54,55]</sup>. Membranoproliferative glomerulonephritis may occur in children with chronic HCV infection, but unlike in adults, neither cryoglobulinemia nor lymphoma has yet been reported in children<sup>[25]</sup>.

Another important extrahepatic manifestation of HCV infection is the involvement of the central nervous system. About 20%-80% of the patients with chronic HCV infection develop fatigue at some point independent from the severity of hepatitis. Fatigue often is the predominant complaint of the patients and might reduce the quality of life to a large extent. Patients may also develop depression or a general cognitive impairment irrespective of the stage of liver disease<sup>[56]</sup> which may be linked to HCV-induced neuro-inflammation and brain dysfunction<sup>[57]</sup>. These observations raise the issue of learning impairment in children with chronic HCV<sup>[25]</sup>.

Impaired quality of life, potentially severe enough to have a negative effect on learning, has been reported in children with chronic HCV infection including developmental delay, learning disorders, and cognitive deficits less severe than those of attention deficit hyperactivity disorder but still reflecting decreased executive function<sup>[58,59]</sup>.

## COSTS OF INFECTION

Vietri *et al.*<sup>[40]</sup> studied the burden of HCV in Europe and found that HCV patients compared to healthy controls have more impairment in work and non-work activities, and more annual physician visits per patient. Work-productivity impairment due to HCV costs over €7500 per employed patient per year<sup>[40]</sup>. Health-related quality of life was lower among HCV patients. Treatment-naïve HCV patients reported higher work impairment and more frequent physician visits. Each treatment-naïve HCV infected patient incurred €934 in direct costs. Employed treatment-naïve patients reported higher productivity loss per year<sup>[40]</sup>. In comparison, in the United States, Menzin and his group estimated that it costs \$4956/patient in the year following the diagnosis of advanced liver disease secondary to HCV which were largely driven by inpatient costs<sup>[60]</sup>.

There are no precise estimates of the true costs of HCV for a child and family. In one country like the United States, it is likely that several thousand children per year need treatment costing several thousand dollars/child; and it is estimated that in one decade, 26 million dollars will be spent in screening, 117-206 million dollars

in monitoring, 56-104 millions dollars in treatment and the total cost would be about 199-336 million. Worldwide, global costs would be millions of dollars/year<sup>[61]</sup>.

Treatment of a child which results in virus eradication is highly cost-effective because of the higher costs of the long-term consequences of untreated HCV cirrhosis and/or HCC. The small numbers of liver transplants for children with HCV performed each year cost several million dollars. The emotional costs of having an HCV infected child are more difficult to estimate for the child and family; but are real<sup>[61]</sup>.

## PREVENTION

The reduction of global morbidity and mortality related to chronic HCV infection should be a concern to public health authorities, and primary, secondary and tertiary prevention activities should be implemented and monitored in each country, with precise targets set to be reached. A working group was created to assist the World Health Organization in estimating the global burden of disease associated with HCV infection<sup>[3]</sup>. Public awareness of the transmission and prevention of HCV is crucial in decreasing the incidence and prevalence of the disease. Public and physician education in various forms is therefore extremely important. There is a need for implementing evidence-based international guidelines for preventing and managing hepatitis C in children worldwide<sup>[62]</sup>.

One of the major hurdles in the eradication/reduction of the burden of HCV is the lack of hepatitis C vaccine. An effective HCV vaccine remains elusive to date. HCV has been difficult to target with a vaccine because it has many different strains. In addition, HCV mutates rapidly and exists as a complex family of mutated viruses within each infected individual (quasispecies) allowing the infecting virus to escape control by the immune system. This makes it difficult to identify which part of the virus should be targeted for developing a vaccine<sup>[62]</sup>.

Viral and host specific factors contribute to viral evasion and present important impediments to vaccine development. Both, innate and adaptive immune responses are of major importance for the control of HCV infection. However, HCV has evolved ways of evading the host's immune response in order to establish persistent infection. For example, HCV inhibits intracellular interferon (IFN) signaling pathways, impairs the activation of dendritic cells, CD8<sup>+</sup> and CD4<sup>+</sup> T cell responses, induces a state of T-cell exhaustion and selects escape variants with mutations CD8<sup>+</sup> T cell epitopes<sup>[63]</sup>. An effective vaccine will need to produce strong and broadly cross-reactive CD4<sup>+</sup>, CD8<sup>+</sup> T cell and neutralizing antibody (NAb) responses to be successful in preventing or clearing HCV. Vaccines in clinical trials now include recombinant proteins, synthetic peptides, virosome based vaccines, tarmogens, modified vaccinia Ankara based vaccines, and DNA based vaccines. Several pre-clinical vaccine strategies are also under development and include recombinant adenoviral vaccines, virus-like particles, and synthetic peptide

vaccines. Moreover, vaccines may also be used in the future in combination with the recent direct acting antiviral (DAA) drugs enabling IFN-free treatment regimens<sup>[63]</sup>. Indeed understanding the immune mechanisms, particularly HCV-specific cell mediated immune response, of patients who have successfully cleared the infection is essential to design and develop a vaccine<sup>[64]</sup>.

Because there is no vaccine and no post-exposure prophylaxis for HCV, the focus of primary prevention efforts should be safer blood supply in the developing world, safe injection practices in health care and other settings, and decreasing the number of people who initiate injection drug abuse<sup>[6]</sup>. People with known HCV infection should be counseled regarding ways to reduce the risk of transmitting HCV to others, and means of minimizing their risk for HCV-related complications. As part of secondary prevention efforts, HCV-infected people should be referred for medical evaluation and antiviral treatment consideration, and programs ensuring access to these services should be in place<sup>[6]</sup>.

Health education is also essential to reduce the HCV burden, and specific programs should be provided to increase public awareness on transmission and prevention of infection<sup>[62]</sup>.

## TREATMENT

HCV is a potentially curable disease<sup>[65]</sup> with a good percentage of treated patients getting a sustained virologic response (SVR) defined as undetectable serum HCV RNA 24 wk after the end of therapy (and now at 12 wk after the end of therapy<sup>[8]</sup>). Although the available standard of care (SOC) therapy has led to significant improvements in treatment response rates, less than 50% of HCV-infected persons are aware of their diagnosis<sup>[66]</sup>, and among them, only 1%-30% receive treatment. The true rate-limiting factor in achieving better outcomes may turn out to be access to diagnosis and treatment<sup>[66]</sup>.

Multiple barriers may impede the delivery of HCV therapy<sup>[67]</sup>. To increase cure rates, the psychological (psychiatric illness, attitudes and coping skills), lifestyle (alcohol consumption, diet, and exercise), social (income, education, social class, poverty), and other different barriers to treatment adherence and completion must be identified and overcome<sup>[68]</sup>.

For adults, standard IFN has been approved for the treatment of HCV since 1991, Ribavirin (RBV) since 1998 and pegylated-IFN (peg-IFN) since 2002. Nine years had passed before the American Food and Drug Administration (FDA) approved a new drug to be added to the existing SOC, the DAA oral protease inhibitors, boceprevir and telaprevir<sup>[69]</sup>. New drugs under development include other protease inhibitors, the NS5B polymerase and NS5A inhibitors<sup>[70]</sup>. In the coming years, the number of the new drugs will multiply exponentially and pharmaceutical companies have begun to combine them in triple and quadruple regimens (with and without peg-IFN)<sup>[69]</sup>.

In children 3-17 years old, treatment with peg-IFN $\alpha$ -2a or b plus RBV for 24-48 wk is the SOC therapy<sup>[71,72]</sup>, whereas the recently approved DAA still need evaluation in children.

In the United States and most European countries, the current first line therapy for infection with genotype-1 is a combination of peg-IFN alpha plus RBV plus either boceprevir or telaprevir. High SVR rates can be achieved even in those with evidence of fibrosis and cirrhosis, but response is poor in prior null responders, especially those with cirrhosis<sup>[73]</sup>.

Preliminary data from investigational studies suggest the potential for cure rates of 80%-90% in genotype-1 infection using combinations of DAAs and RBV without peg-IFN, but larger studies will be needed to confirm these results across a wider range of populations<sup>[74-76]</sup>.

Quadruple therapy with pegylated-IFN combines BI201335, a protease inhibitor, and BI207127, a non-nucleoside NS5B polymerase inhibitor, with peg-IFN and RBV<sup>[77]</sup>. The only quadruple peg-IFN-free study is the Gilead Sciences all-oral quad regimen<sup>[78]</sup>. It is a phase II study for genotype 1, treatment-naïve patients who are not cirrhotic. It combines GS-5885, GS-9451, tegobuvir, and RBV for 24 wk. The triple peg-IFN-free therapy combines mericitabine, a nucleoside NS5B polymerase inhibitor; danoprevir, a protease inhibitor; ritonavir, a booster for danoprevir; and RBV or placebo<sup>[79]</sup>.

SVR varies considerably from 26%-80% depending on age, duration of infection, viral load, viral genotype, adiposity, hepatic fibrosis iron scores, aminotransferase elevation, compliance with therapy, SNPs of IL-28B gene locus. It was found that a single IL28B genotype SNP rs12979860 determination predicts treatment response in patients with chronic hepatitis C Genotype 1 virus<sup>[80,81]</sup>. IL-28B has been also reported to play a role in spontaneous clearance of HCV genotype 4 in Egypt/North Africa<sup>[82]</sup>. Regarding the HCV genotypes 2 and 3, the polymorphisms rs12979860 and rs8099917 showed significant associations. However, the strength of this association was almost three times lower than for genotypes 1 and 4<sup>[83]</sup>. In addition regarding genotype 2, it was found that the Asian population was solely responsible for this association in rs8099917<sup>[84]</sup>. The generally reduced association for patients with HCV genotypes 2/3 could be related to the high rate of SVR present in these IFN-sensitive genotypes<sup>[85]</sup>.

SNPs of IL-28B gene received considerable interest also for their association with spontaneous clearance of HCV among vertically-infected children<sup>[86]</sup>.

SNPs of IL-28B as well as IL-10 are good predictors of response to IFN/RBV therapy in HCV genotype 4 infected Egyptian children<sup>[87]</sup>.

The combination of serum level of IFN-gamma inducible protein and SNPs of IL-28B can identify patients with acute HCV who are most likely to undergo spontaneous clearance and those in need of early antiviral therapy<sup>[88]</sup>.

SNPs of osteopontin gene were also reported as pre-

dictors for the efficacy of IFN therapy in chronic HCV Egyptian patients with genotype 4<sup>[89]</sup>.

## CONCLUSION

HCV infection is an increasing health and economic burden in adults as well as children, in both developing and developed countries. The natural history and histopathology of HCV-related liver disease in children are still conflicting and variable. Prevention of infection depends on screening of blood with the most sensitive tests, avoiding nosocomial infections, and avoiding injection drug abuse and unprotected sex in adolescents; as well as education. Development of a vaccine preventing HCV infection is of thorough public health importance. The SOC therapy is peg-IFN plus RBV. The SVR is variable (26%-80%) and depends on several viral and host factors. Eradication of HCV in a child (if possible) is cost-effective as it may prevent cirrhosis and HCC; and can have major family, public health and global benefits.

## Abstract

It has been reported that the direct binding of hepatitis C virus (HCV) and/or the replication of HCV in the extrahepatic organs and, especially, lymphoid cells, might affect the pathogenesis of extrahepatic diseases with HCV infection. More than one decade ago, several reports described the existence of HCV-RNA in peripheral blood mononuclear cells. Moreover, many reports describing the existence of HCV in B lymphocytes and B cell lymphoma have been published. In addition to B lymphocytes, it was reported that HCV replication could be detected in T lymphocytes and T cell lines. Among the extrahepatic diseases with HCV infection, mixed cryoglobulinemia-related diseases and autoimmune-related diseases are important for understanding the immunopathogenesis of HCV persistent infection. Moreover, HCV persistent infection can cause malignant lymphoma. The biological significance of lymphotropic HCV has not yet become clear. However, several candidates have been considered for a long time. One is that lymphotropic HCV is an HCV reservoir that might contribute to the recurrence of HCV infection and difficult-to-treat disease status. The other important issue is the carcinogenesis of the lymphoid cells and disturbances of the immune responses. Therefore, the extrahepatic

diseases might be induced by direct interaction between HCV and lymphoid cells. In this article, we summarize various studies showing the direct effect of HCV on lymphoid cells and discuss the biological significance of lymphotropic HCV.

## INTRODUCTION

An estimated 130-170 million people are infected with hepatitis C virus (HCV) worldwide<sup>[1]</sup>. Around 75% of the patients with acute HCV infection undergo chronic HCV infection and are subsequently at risk of progressing to hepatic fibrosis, cirrhosis and hepatocellular carcinoma (HCC)<sup>[1,2]</sup>. Persistent infection of HCV involves not only the liver but also various extra-hepatic organs<sup>[3-7]</sup>. HCV can infect hepatocytes, lymphoid cells, and probably other cells through CD81 and receptor candidates<sup>[8]</sup>. Moreover, the expression of microRNA (miR)-122 facilitates efficient replication of HCV in nonhepatic cells<sup>[9]</sup>. These reports indicated that the direct binding of HCV and/or the replication of HCV in the extrahepatic organs, especially lymphoid cells, might affect the pathogenesis of

extrahepatic diseases with HCV infection. Among the extrahepatic diseases with HCV infection, mixed cryoglobulinemia (MC)-related diseases and autoimmune-related diseases are important for understanding the immunopathogenesis of HCV persistent infection<sup>[10-13]</sup>. Moreover, HCV persistent infection could cause malignant lymphoma<sup>[4]</sup>. The status of a disease might depend on the direct interaction between HCV and lymphoid cells<sup>[6,14-17]</sup>. The biological significance of lymphotropic HCV has not yet become clear. However, several candidates have been considered for a long time. One is that lymphotropic HCV is an HCV reservoir that might contribute to the recurrence of HCV infection and difficult-to-treat disease status<sup>[18-23]</sup>. The other important issue is the carcinogenesis of the lymphoid cells and disturbances of the immune responses<sup>[8,14,24-28]</sup>. Previously, Sung *et al*<sup>[29]</sup> reported a lymphotropic HCV strain that was isolated from B cell lymphoma. This lymphotropic HCV strain can infect and replicate in established B cell lines and primary B lymphocytes<sup>[29]</sup>. Moreover, we reported that T cell lines and primary naïve T lymphocytes were infected with this HCV strain<sup>[8,25,26]</sup>. In these studies, we demonstrated that lymphotropic HCV had various effects, especially on T cell development and proliferation. Therefore, understanding of the direct effects of HCV on the lymphoid cells is needed to clarify the immunopathogenesis of HCV persistent infection. In this report, we summarize various studies showing the direct effect of HCV on lymphoid cells and discuss the biological significance of lymphotropic HCV.

## ROLE OF VIRUS RESERVOIR

### *HCV infection in peripheral blood mononucleated cells*

More than one decade ago, several reports described the existence of HCV-RNA in peripheral blood mononucleated cells (PBMCs)<sup>[30,31]</sup>. The detection rate of HCV-RNA in PBMCs was increased if the patients were infected with human immunodeficiency virus (HIV) and HCV<sup>[31]</sup>. This phenomenon indicated that immune-suppressive circumstances and/or HIV antigen might enhance the replication activity of HCV in lymphoid cells<sup>[32]</sup>. HIV-1 accessory protein transactivator of transcription (TAT) can activate HCV replication by upregulating IP10 production. Moreover, it was reported that continuous release of HCV by PBMCs was detected in HCV-infected patients, especially in HIV co-infected patients<sup>[18]</sup>. The detection of HCV-RNA in the PBMCs from HIV-HCV co-infected patients could contribute to the recurrence of HCV viremia after pegylated-interferon and ribavirin treatment. It was reported that the presence of positive/negative strand HCV RNA at the end of treatment is associated with relapse among HCV-HIV co-infected patients<sup>[33]</sup>. In addition to HCV-HIV co-infected patients, a low level of HCV replication could be detected in peripheral lymphoid cells from HCV mono-infected patients after antiviral treatment<sup>[20,23]</sup>. Moreover, it was reported that

HCV persisting at low levels long after therapy-induced resolution of chronic hepatitis C could remain infectious<sup>[20]</sup>. This continuous viral presence could result in the persistence of humoral and cellular immunity for many years after treatment and could present a risk of infection reactivation.

### *Responsible lymphocyte subsets as a viral reservoir*

It has been reported that HCV replication could be detected in various kinds of lymphoid cells. Many reports describing the existence of HCV in B lymphocytes and B cell lymphoma have been published<sup>[5,29,34]</sup>. Recently, one group reported that CD19<sup>+</sup> B lymphocytes had significantly higher viral loads than CD14<sup>+</sup> monocytes<sup>[35]</sup>. Among B lymphocytes, CD27<sup>+</sup> memory B lymphocytes were more resistant to apoptosis than CD27<sup>-</sup> B lymphocytes. CD27<sup>+</sup> B lymphocytes might be a candidate subset of the HCV reservoir in chronic hepatitis C (CH-C)<sup>[36]</sup>. In addition to B lymphocytes, it was reported that HCV replication could be detected in T lymphocytes and T cell lines<sup>[20,37,38]</sup>. We also reported that a lymphotropic HCV strain could infect T cell lines and primary human naïve CD4<sup>+</sup> T lymphocytes<sup>[8,25,26]</sup>. HCV infects hepatocytes, lymphoid cells, and probably other cells through CD81 and several candidate receptors. The expression of CD81 could be detected in B cells, T cells, and monocytes, indicating that these types of cells are potential targets of HCV infection. Recently, one group reported that HCV infection of human T lymphocytes is mediated by CD5<sup>[39]</sup>. In contrast to T lymphocytes, hepatocytes do not express CD5. Therefore, the mechanism of HCV lymphotropism might be different from that of HCV hepatotropism. Moreover, the other candidate receptors were analyzed using HCV-prone and resistant T cell lines, PBMCs, primary T cells, Huh7.5 cells and HepG2 cells<sup>[40]</sup>. CD5 and CD81 expression coincided with lymphotropism and that of occludin with the permissiveness of T cell lines, but probably not primary T lymphocytes<sup>[40]</sup>.

In addition to B and T lymphocytes, it has been reported that HCV can infect monocytes, especially CD14<sup>+</sup>CD16<sup>+</sup> monocytes, but not CD14<sup>+</sup>CD16<sup>-</sup> monocytes<sup>[41]</sup>. The detection of HCV-RNA in monocytes was reported in HCV-HIV co-infected patients and HCV-monoinfected patients<sup>[19]</sup>. HIV might facilitate the infection/replication of HCV in human macrophages<sup>[42]</sup>. One group reported the frequent compartmentalization of HCV in circulating CD19<sup>+</sup> B lymphocytes and CD14<sup>+</sup> monocytes<sup>[43]</sup>. Moreover, it was reported that immature and mature dendritic cells are susceptible to HCV genotype 1 infection, supporting at least HCV RNA replication *in vitro*<sup>[44]</sup>. Another group reported that replicative-strand HCV-RNA was detected in peripheral blood dendritic cells<sup>[28]</sup>. Although other lymphoid cells might be susceptible to HCV infection<sup>[45,46]</sup>, these reports suggested that B and T lymphocytes, monocytes, and dendritic cells could be reservoirs for HCV.

## DIRECT EFFECT OF HCV ON THE CARCINOGENESIS OF LYMPHOID CELLS

Many reports have focused on the relevance of HCV infection and B-cell lymphoma, especially non-Hodgkin lymphoma (NHL)<sup>[4,47]</sup>. Compared to the high association between HCV infection and HCC, epidemiologic reports on the relationship between HCV and NHL show a moderate risk for the development of lymphoma. However, no association between HCV and NHL was also reported in low HCV prevalence countries<sup>[48,49]</sup>. Different hypotheses have been suggested to explain the difference in the HCV-NHL prevalence: (1) Geographic differences in the HCV genotype distribution might contribute to differences in the HCV-NHL prevalence; (2) The duration of persistent infection of HCV might influence the carcinogenesis of lymphoid cells; and (3) Studies in low prevalence countries might not have included enough patients to detect the association. However, meta-analyses indicated a significant association between HCV and B-NHL<sup>[48,50]</sup>.

Many groups reported the mechanisms of lymphomagenesis. However, we have to understand that HCV-infected patients with MC are at a higher risk of developing HCV-NHL<sup>[51]</sup>. MC could be an intermediary step in the development of NHL. Although, different theories have been proposed to explain the mechanism of HCV-induced lymphomagenesis, we can classify most of the theories into two categories. One of them is direct HCV binding with B lymphocytes. The external stimulation of lymphocyte receptors (CD19, CD21, CD81, B-cell receptor) by HCV antigen might induce a proliferation signal<sup>[52]</sup>. The HCV-core protein induces the production of interleukin (IL) 6 in CD14<sup>+</sup> cells *via* Toll like receptor 2 and leads to increased B cell proliferation<sup>[53]</sup>. In addition to the classical cytokine proliferation signal, the down regulation of miR-26b, an miRNA known to have tumor-suppressive properties, was found in splenic marginal zone lymphoma with HCV persistent infection<sup>[54]</sup>. This theory was supported by the phenomenon of lymphoma remission when the HCV antigens are removed by treatment. In addition to the proliferation signal, HCV-E2 CD81 on B cells triggers the enhanced expression of activation-induced cytidine deaminase (AID), which could contribute to enhancing the mutation frequency<sup>[14]</sup>. The other category of lymphomagenesis mechanism is HCV infection and/or replication in B lymphocytes. It has been reported that the replication of HCV in B lymphocytes could induce error-prone DNA polymerase zeta, polymerase iota, and AID, which contribute to enhancing the mutation frequency<sup>[14]</sup>. Moreover, the cellular DNA damage and mutation were mediated by nitric oxide and reactive oxygen species<sup>[55,56]</sup>. In addition to *in vitro* study, interferon regulatory factor-1-null mice with inducible and persistent expression of HCV structural protein showed a high incidence of lymphoma and lymphoproliferative diseases<sup>[57]</sup>. In this mouse model, the overexpression of apoptotic related genes and aberrant cytokine

production were detected in the first step of carcinogenesis. Another group also reported that the expression of HCV-core protein could increase the incidence of lymphoma in transgenic mice<sup>[58]</sup>. Moreover, it has been reported that persistent expression of the full genome of HCV in B cells induces the spontaneous development of B-cell lymphoma *in vivo*<sup>[59]</sup>. HCV transgenic mice that expressed the full HCV genome in B cells showed a 25% incidence of diffuse, large B-cell non-Hodgkin lymphomas. Although the relationship between HCV persistent infection and lymphomagenesis could become clarified by various epidemiological studies, the mechanism of lymphomagenesis still needs to be considered carefully.

## DIRECT EFFECT OF HCV ON THE IMMUNE EVASION

Many studies have described a failure of the innate and cellular immune response, including type 1 helper T cells (Th1) hypo-responsiveness, cytotoxic T lymphocytes (CTL) exhaustion, excessive function of CD4<sup>+</sup>CD25<sup>+</sup>FOXP3<sup>+</sup> regulatory T cells, failure of dendritic cell function, occurs in HCV persistent infection<sup>[60-69]</sup>. Among the numerous mechanisms, the lymphoid cells, *via* direct binding and/or infection in B cells, T cells, NK cells and DCs *etc.*, should be considered, especially in HCV persistent infection<sup>[8,25-28,70-73]</sup>. In our previous study, we used SB-cell lines that continuously produce infectious HCV virions in culture. The virus particles produced from the culture had a buoyant density of 1.13-1.15 g/mL in sucrose and could infect primary human PBMCs and an established B-cell line *in vitro*<sup>[29]</sup>. This lymphotropic HCV strain was useful to investigate the biological significance of HCV replication in lymphoid cells. In this *in vitro* system, HCV could infect and transiently replicate in T cells and HCV replication suppressed the interferon (IFN)- $\gamma$ /STAT-1/T-bet signaling due to the reduction of STAT-1 and inhibition of its activation<sup>[26]</sup>. Moreover, HCV replication in T cells suppressed cellular proliferation and enhanced susceptibility to Fas signaling by inhibiting CD44v6 signaling and expression<sup>[25]</sup>. In addition to cell lines, we used primary T lymphocytes to analyze the biological meaning of lymphotropic HCV<sup>[8]</sup>. Another group reported that HCV core protein modulates the transcription of *IL-2* promoter in T lymphocytes by activating the nuclear factor of activated T lymphocyte pathway<sup>[74,75]</sup>. Moreover, the expression of HCV core protein could induce Ca<sup>2+</sup> oscillations that regulate both the efficacy and information content of Ca<sup>2+</sup> signals<sup>[74]</sup>. In addition to HCV replication in T cells, Yao *et al*<sup>[76]</sup> reported that the direct binding of HCV core to gC1qR on CD4<sup>+</sup> and CD8<sup>+</sup> T cells leads to impaired activation of Lck and Akt. We could also detect a relationship between HCV core protein and immune suppression in HCV persistent infection<sup>[77]</sup>. Double filtration plasmapheresis for CH-C patients could reduce the amounts of HCV core proteins in the peripheral blood and on the surface of T lymphocytes<sup>[77]</sup>. Moreover, it has been reported that the

engagement of gC1qR on DCs by HCV core limits the induction of Th1 responses and may contribute to viral persistence. Another group reported that NK cell-derived cytokines secreted in the presence of HCV cc showed a diminished antiviral effect that correlated with a reduction of IFN- $\gamma$ <sup>[72]</sup>. DCs play essential roles in the triggering of primary antiviral immune reactions. DCs are the most potent activators of CD4 T cells for supporting Th1 differentiation, which is important for the cellular immune response. Several reports described that persistent HCV infection is associated with an allostimulatory defect of monocyte-derived DC<sup>[67,70]</sup>. These reports supported that HIV/HCV co-infected patients were difficult-to-control in comparison with HCV mono-infected patients, since lymphotropic HCV is frequently detected in HIV/HCV co-infected patients<sup>[78]</sup>. Co-infection with HCV and HIV is associated with increased HCV replication and a more rapid progression to severe liver disease, including the development of cirrhosis and HCC.

## DIRECT EFFECT OF HCV ON IMMUNE STIMULATION

We need to focus not only on the suppression of the immune system but also on the stimulation of the immune system, since the prevalence of cryoglobuline-related and autoimmune-related diseases is much higher than in healthy subjects<sup>[10,79]</sup>. HCV core protein activates interleukin-2 gene transcription through the nuclear factors of activated T cells pathway<sup>[75,80]</sup>. IL-2 has a role in T cell proliferation. Recently, we reported that lymphotropic HCV and high frequency of Th17 cells were detected in CH-C patients with pyoderma gangrenosum-like lesions<sup>[16]</sup>. In that report, the eradication of HCV could improve the immunological status and pyoderma gangrenosum-like lesions. A study regarding the relationship between lymphotropic HCV and autoimmune diseases is ongoing in our laboratory. Another group reported that HCV-core induced STAT3 activation might play a role in the alteration of inflammatory responses in human monocytes<sup>[81]</sup>. Moreover, HCV infection of macrophage/monocytes *in vitro* might be associated with the induction of cytokines tumor growth factor- $\alpha$  and IL8. In addition to T lymphocytes and monocytes, Machida *et al*<sup>[17,27]</sup> reported that HCV could induce immunoglobulin hypermutation in B lymphocytes. These reports together suggest that HCV could stimulate an unfavorable immune response. As for the understanding of autoimmune diseases, HCV persistent infection might be one of the representative models of viral-induced autoimmune diseases.

## CONCLUSION

Although various reports have described the direct effects of HCV on lymphoid cells, few have addressed whether the disturbance of the immune system induced by the direct binding and/or infection of HCV on lymphoid cells might coordinately influence the pathogenesis of

HCV persistent infection. In this article, we summarized various reports indicating the direct effects of HCV on lymphoid cells. In addition to the direct effect of HCV, the indirect effects of HCV on lymphoid cells could influence the pathogenesis of HCV persistent infection. Therefore, we must treat a vast array of data to clarify the real pathogenesis of HCV persistent infection. Recently, the technologies of deep sequencing, immunoassays with increased numbers of multicolor flow cytometry analyses, and chimera mice with human lymphocytes have been developed. These technologies, together with previous data, might be able to clarify the direct effects of HCV on lymphoid cells.

## ACKNOWLEDGMENTS

The authors are grateful to Professor Lai MM (Keck School of Medicine, USC), who was the previous mentor of the first author and kindly provided SB-HCV strain, and Dr. K Machida (Keck School of Medicine, USC) who was a previous coworker of the first author and gave valuable insights regarding lymphotropic HCV.

## Abstract

This review focuses on research findings in the area of diagnosis and pathogenesis of hepatitis C virus (HCV) infection over the last few decades. The information based on published literature provides an update on these two aspects of HCV. HCV infection, previously called blood transmitted non-A, non-B infection, is prevalent globally and poses a serious public health problem worldwide. The diagnosis of HCV infection has evolved from serodetection of non-specific and low avidity anti-HCV antibodies to detection of viral nucleic acid in serum using the polymerase chain reaction (PCR) technique. Current PCR assays detect viral nucleic acid with high accuracy and the exact copy number of viral particles. Moreover, multiplex assays using real-time PCR are available for identification of HCV-genotypes and their isotypes. In contrast to previous methods, the newly developed assays are not only fast and eco-

nomic, but also resolve the problem of the window period as well as differentiate present from past infection. HCV is a non-cytopathic virus, thus, its pathogenesis is regulated by host immunity and metabolic changes including oxidative stress, insulin resistance and hepatic steatosis. Both innate and adaptive immunity play an important role in HCV pathogenesis. Cytotoxic lymphocytes demonstrate crucial activity during viral eradication or viral persistence and are influenced by viral proteins, HCV-quasispecies and several metabolic factors regulating liver metabolism. HCV pathogenesis is a very complex phenomenon and requires further study to determine the other factors involved.

## INTRODUCTION

Hepatitis C virus (HCV) was first characterized by Choo *et al*<sup>[1]</sup> and Kuo *et al*<sup>[2]</sup> in 1989. It was soon identified as the main causative agent of the disease previously known as post transfusion non-A, non-B hepatitis virus infec-

tion. HCV has been found to be an important cause of liver disease and remains a major public health problem worldwide. According to the World Health Organization, nearly 3% of the world population has been infected with HCV. Therefore, more than 170 million people are chronic carriers of HCV and at high risk of developing liver cirrhosis and/or hepatocellular carcinoma (HCC). Three to 4% of chronically infected individuals develop fatal HCC. Currently, HCC caused by HCV infection is considered an indication for liver transplantation<sup>[3-5]</sup>.

HCV was the leading cause of post-transfusion and community-acquired non-A, non-B hepatitis until characterization of the virus in 1989 and the introduction of blood screening in 1990. The initiation of blood screening for HCV has markedly reduced its incidence. However, it still remains a significant problem in intravenous drug abusers. HCV infection is the most common cause of liver transplantation in adults. HCV and HIV-1 frequently co-infect humans and it has been estimated that as many as 18% of HIV-infected persons are also infected with HCV<sup>[4]</sup>.

HCV is an enveloped RNA virus and belongs to the genus Hepacivirus of the family Flaviviridae. The HCV genome consists of 9.6-kb single-stranded RNA of positive polarity and a single open reading frame of 9033-9099 nucleotides flanked by a conserved 5' and 3' noncoding region (NCR) at the ends. Its genome codes for a long polyprotein of approximately 3000 amino acids<sup>[6]</sup> which is processed co-translationally and post-translationally to yield structural proteins (core, envelope E1, and E2) and non-structural (NS) proteins (NS1/p7, NS2, NS3, NS4A, NS4B, NS5A and NS5B)<sup>[7]</sup>. The envelope proteins (E1 and E2) are the outer surface proteins of the viral particles and play important roles in virus entry into the host cell. NS5B is a variable region of the HCV genome and codes for an RNA-dependent RNA polymerase (RdRp).

RNA polymerase lacks proof reading activity and this may alter the detection, sensitivity to interferon anti-viral activity and pathogenicity of the virus (Figure 1)<sup>[8]</sup>.

Like several other viruses, the RNA virus has a high degree of heterogeneity<sup>[5]</sup> that varies 30%-35% among different genotypes. Based on previous studies, six major genotypes and more than 120 subtypes of HCV have been characterized to date<sup>[9]</sup>. These HCV genotypes have distinct geographic distributions, with genotype 1 and 2 frequently found worldwide<sup>[10]</sup>. In India, genotype 3 is reported to be the most prevalent, followed by genotype 1<sup>[11,12]</sup>. Different HCV genotypes have important epidemiological implications. Despite nucleotide sequence divergence between genotypes, they remain quite similar in their transmission pattern, persistence and disease development<sup>[13]</sup>. Although genetic variation is attributed to several factors, two major theories *i.e.*, the Darwinian and Neutral evolution theories are thought to be the prominent theories in causing genetic diversity in HCV<sup>[13]</sup>. The nucleotide sequence variability is distributed throughout the viral genome. Regions encoding envelope proteins

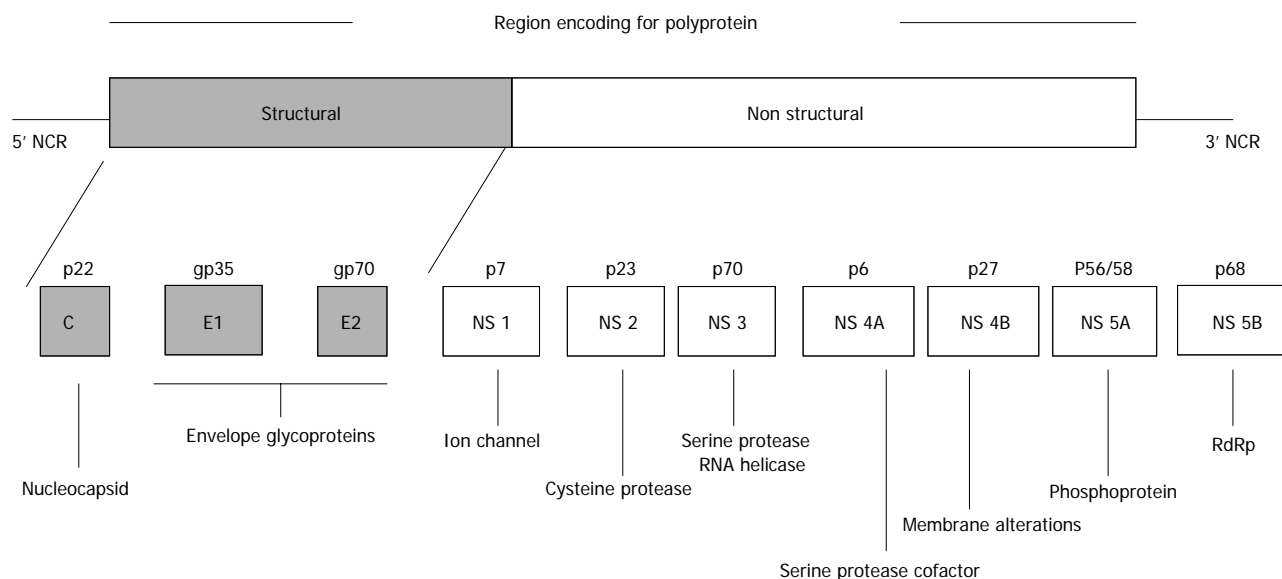

(E1, E2) and NS-1 are the most variable, whereas the 5' NCR is the most conserved region.

HCV patients show a poor response to antiviral therapy based on the combination of pegylated interferon (IFN)- $\alpha$  and ribavirin. Only 40%-50% of patients infected with HCV genotype-1 and 80% of those infected with genotype-2 or 3 achieve a sustained virological response (SVR) with this regimen<sup>[14]</sup>. The recent use of direct acting anti-viral (DAA) molecules, which are active on HCV during treatment, has led to a substantial improvement in SVR rates in HCV genotype-1 infected patients. However, this may lead to the selection of resistant virus if DAA molecules are used alone<sup>[15]</sup>. Moreover, there is a high relapse rate of HCV infection after discontinuation of therapy. Recently, host genetic factors including human leukocyte antigen (HLA) and cytokine genes have been implicated in HCV infection or persistence<sup>[16]</sup>. Genetic polymorphism of cytokine genes including IFN- $\gamma$ , tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-10, IL-20 and SNPs in the promoter region of osteopontin gene, have been found to be crucial in determining the therapeutic outcome of HCV infection<sup>[17]</sup>. Therefore, every effort is being made to understand the pathogenesis of HCV infection to create a therapeutic model for an effective treatment against HCV. Although recent reports describe the development of *in vitro* replication systems leading to the production of infectious viral particles<sup>[18,19]</sup>, there is currently no cell culture model suitable for synthesizing vaccines based on killed or attenuated virus. All efforts have been focused on sub-unit vaccines, composed of one or several antigens, either in the form of recombinant proteins, synthetic peptides or vectored vaccines. The earliest vaccine developed for HCV was that by the Chiron group<sup>[20]</sup>. However, very little progress was noted in this direction in subsequent years.

This article reviews the major aspects of HCV infection including the diagnosis and pathogenesis of HCV infection. Both of these aspects have a strong association with therapy, thus, newer means of accurate diagnosis and a better understanding of HCV infection pathogenesis may allow the development of a therapeutic model. This article attempts to update readers regarding the information available on these two aspects to date.

## DIAGNOSIS OF HCV INFECTION

During HCV infection, every attempt is made to diagnose and differentiate acute from chronic hepatitis C infection. Acute HCV infection is typically mild. It is often not diagnosed, and the infection may be recognized only when it becomes chronic<sup>[21]</sup>. The diagnostic tests used, including the presence of anti-HCV antibodies in serum, cannot differentiate between acute and chronic HCV infection because anti-HCV IgM, used as marker of acute infection, is variable in acute infectious disease and is also detected at high rates in patients with chronic HCV infection<sup>[22,23]</sup>. The diagnostic procedures for hepatitis C virus infection used in laboratories are based on the detection

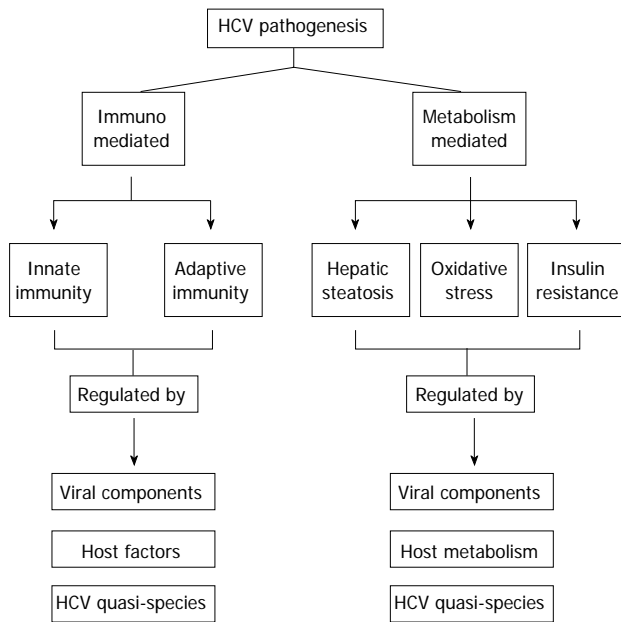

**Figure 1** Proteins encoded by the hepatitis C virus genome. Genome organization of hepatitis C virus showing the structure of the viral genome, including the long open reading frame encoding structural and nonstructural proteins, and 5' and 3' non-coding regions (NCRs). [Source: Monica A *et al.* *Expert Rev Mol Med* 2003; 5].

of anti-HCV antibodies against recombinant HCV proteins using enzyme immunoassay (EIA) and chemiluminescence immunoassay. Non-structural and recombinant antigens are used in these assays. Four different generations of anti-HCV test kits have been developed to date. The first generation EIA detected antibodies against the nonstructural proteins (NS4) with recombinant antigen c100-3. Subsequently, the second generation assay was developed and this included antigens from the core region (c22-3), the NS3 region (c33c) and a part of c100-3 (5-1-1) from the NS4 region. The third-generation EIA included an additional antigen from the NS5 region and a reconfiguration of the core and NS3 antigens. However, all these anti-HCV assays had the disadvantages of giving high false positive results and a lack of sensitivity to detect antibodies during the window period. In addition, these antibody-based assays could not distinguish between acute, past and chronic infections. This was followed by the development of supplementary tests involving the recombinant immunoblot assay (RIBA) which was commercialized. This assay contained recombinant antigen (c33c, NS5) and synthetic peptides (5-1-1, c100 and c22). Similarly, a few other commercial assays, known as third generation immunoassays incorporated HCV antigens from the core region, E2 hypervariable region, NS3 region, NS4A, NS4B and NS5A region. All these recombinant immunoblot assays were used as supplementary tests to the anti-HCV assays. Similar to EIA, the RIBA had the disadvantages of difficulty in performance and a high percentage of indeterminate results. Therefore, these are no longer used in diagnostic laboratories. Recently, fourth generation anti-HCV assays incorporating additional nonstructural proteins are being used as screening tests<sup>[24]</sup>. These kits for anti-HCV detection target different HCV antigens and detect more than five primary antibodies to ensure the specificity and sensitivity

of the detection kit.

Anti-C22c and anti-C33c may be the first HCV antibodies to appear during the acute phase of the disease, which is defined by elevated alanine aminotransferase (ALT) levels and/or clinical symptoms<sup>[25]</sup>. Anti-NS5 appears somewhat later, while anti-C100-3 is the last antibody to be detected in acute self-limited HCV infection. The diagnosis and differentiation of acute from chronic HCV infection poses another problem. Patients chronically infected with one HCV-genotype develop acute hepatitis on infection with another genotype. Multiple episodes of acute hepatitis were observed in polytransfused thalassemic children reinfected with different HCV genotypes<sup>[26,27]</sup>. Therefore, discrimination between acute and chronic infection in the same patient is sometimes very difficult. HCV RNA in the serum or liver appears to be the earliest detectable marker of acute HCV infection, preceding the appearance of anti-HCV by several weeks<sup>[25]</sup>. HCV viremia may persist despite the normalization of serum ALT levels. Thus, the use of ALT levels in the diagnosis of HCV is not helpful. However, HCV RNA in serum usually lasts for fewer than 4 mo in patients with acute self-limited HCV infection. The average time from transfusion to sero-conversion is approximately 11 to 12 wk with EIA-1 (Enzyme immunoassay-1) and 7 to 8 wk with EIA-2 (Enzyme immunoassay-2). Now attempts are being made to develop EIA assays to differentiate HCV sub-types<sup>[28]</sup>. Patients with post-transfusion chronic non-A, non-B hepatitis develop anti-HCV antibodies in the majority of cases. Anti-HCV antibodies are not neutralizing, especially with HCV envelope proteins E1 and E2<sup>[29]</sup>. High levels of anti-C100-3 were correlated with high titers of circulating HCV in chimpanzees<sup>[30]</sup>. Therefore, the development and persistence of diagnostic antibodies to HCV seem to reflect concomitant virus replication and consequently a high

**Figure 2** Regulation of hepatitis C virus pathogenesis by host immunity and metabolic factors. HCV: Hepatitis C virus.

potential for infectivity.

HCV RNA is frequently detected in patients with chronic hepatitis C and in patients carrying anti-HCV antibodies. A study carried out in Hong Kong demonstrated that 83% of anti-HCV positive patients were viremic when HCV RNA was determined using polymerase chain reaction (PCR) with two different sets of primers for noncoding regions<sup>[27]</sup>. Similarly, in another study, 98 of 100 patients with chronic non-A, non-B liver disease were positive for antibodies by EIA-2, but all 100 patients were positive for HCV RNA by PCR. With the currently available EIA systems, chronic HCV infection can readily be identified in most patients. Measurement of HCV RNA by PCR does not substantially increase the numbers of patients found to have chronic HCV infection<sup>[31]</sup>. Following the introduction and wider use of real-time PCR, it is now easier to diagnose and monitor the progress of HCV viremia in a very short time period<sup>[32]</sup>. In addition, the use of multiplex PCR by real time is another advancement in the detection of possible hepatitis viral co-infections in single attempt analysis<sup>[33]</sup>.

Based on published information regarding various aspects of HCV infection including the currently available diagnostic assays and therapeutic regimens, the American Association for the Study of Liver Diseases and Centers for Disease Control and Prevention, United States have approved a document as “practice guidelines” for use in the diagnosis and treatment of HCV infection. This is an important document and describes details of the guidelines to be followed for laboratory diagnosis of acute/chronic HCV infection<sup>[34]</sup>.

## PATHOGENESIS OF HCV INFECTION

HCV is a non-cytopathic virus<sup>[35]</sup> that enters the liver cell

and undergoes replication simultaneously causing cell necrosis by several mechanisms including immune-mediated cytolysis in addition to various other phenomena such as hepatic steatosis, oxidative stress and insulin resistance. The proteins/peptides encoded by different sub-genomic regions of the HCV genome and their quasispecies influence the above mechanism, and thus, have a significant role in HCV pathogenesis and disease causation. A brief description of HCV pathogenesis in the light of these factors is given in the following section (Figure 2).

### Viral entry

HCV is a blood-transmitted virus that reaches the liver *via* circulation. The entry of HCV isolates requires at least 4 host-derived factors including scavenger receptor class B type I, Occludin, Claudin-I (CLDN1) and CD81. In addition, CLDN6 and CLDN9 have been shown to substitute for CLDN1 as HCV entry factors in human non-liver cells<sup>[36]</sup>. The CD81 molecule on host cell surfaces acts as a viral receptor, which binds with the viral particle and facilitates its entry in the liver cell<sup>[37,38]</sup>. CD81 is expressed on the surface of almost all nucleated cells and complexes with a variety of other cell-surface receptors such as CD19 and CD21 on B cells, and sends a costimulatory signal to the cells<sup>[39]</sup>. The viral envelop protein, E2, binds to the major extracellular loop of CD8<sup>[40]</sup>. HCV shows multi-site binding and can also bind to several other molecules such as the receptor for low-density lipoprotein, the dendritic cell (DC)-specific intercellular adhesion molecule 3-grabbing non-integrin (DC-SIGN), and its liver counterpart<sup>[41,42]</sup>. E2 is the most variable viral protein, and therefore, its interactions with CD81 have been reported to be strain-specific<sup>[43]</sup>. It has two hyper variable regions, HVR-1 and HVR-2 which undergo frequent mutations, possibly due to virus-neutralizing antibodies and HCV-specific cytolytic T lymphocytes (CTLs). HCV also has a high mutation rate due to the lack of proofreading ability of its RNA-dependent RNA polymerase. Therefore, HCV exists in several distinct, but closely related virus species within an infected individual. These species are called HCV quasispecies.

## HOST IMMUNITY

### Innate immunity

Innate immunity presents a first line defense for the control of HCV infection as it does for several other viral infections. During HCV infection, cells produce Type 1 IFN which prepares and induces the cells to resist infection, check viral replication, promote adaptive immunity and activate natural killer (NK) cells, DCs and Kupffer cells *etc.* Once inside the cell, the innate immunity *vs* HCV is triggered through host recognition of viral macromolecular motifs, known as pathogen-associated molecular patterns (PAMPs), as non-self by cellular pathogen recognition receptors. These receptors includes toll-like receptors (TLRs) and retinoic acid-inducible gene-I (RIG-I) like receptors (RLRs)<sup>[44]</sup>. RIG-I binds PAMP on

HCV-RNA and activates interferon regulatory factor-3 (IRF-3) for expression of IFN- $\alpha/\beta$  and anti-viral/interferon stimulated genes (ISGs)<sup>[45]</sup>. The secreted IFN and cytokines then activate NKs, DCs and Kupffer cells *etc.* These cells also play a significant role in mounting T/B cell-based immunity<sup>[46]</sup>. The PAMP region lies on the 3' untranslated region (UTR) of HCV and induces RIG-1 signaling<sup>[47]</sup> that results in a RIG-1 interaction with IFN- $\beta$  promoter stimulator (IPS-1) which causes activation of IRF-3 and nuclear factor  $\kappa$ B (NF $\kappa$ B).

HCV can effectively evade innate immunity resulting in persistent viral infection. This occurs because HCV has evolved to counteract the RIG-1 pathway<sup>[48]</sup> and thus evade the immune challenge. This phenomenon is the reason for chronicity in the majority of HCV infected patients. For this, the non-structural proteins of HCV *i.e.*, NS3 and NS4A form a complex which activates the NS protease domain to target cleavage of IPS-1. After cleavage, IPS-1 can no longer signal downstream to activate IRF-3 and NF $\kappa$ B and the infected cells no longer produce IFN- $\beta$  or express ISGs<sup>[49]</sup>.

NK cells, a major arm of innate immunity, play an important role in eradication of HCV. The liver is enriched in NK cells that are usually activated in an early phase of HCV infection. The activated NK cells recruit virus-specific T cells and induce antiviral immunity in the liver. They also eliminate virus-infected hepatocytes directly by cytolytic mechanisms and indirectly by secreting cytokines including IFN- $\gamma$  and TNF- $\alpha$ . These cytokines induce an antiviral state in host cells. Surprisingly, HCV has evolved multiple strategies to counter the host's NK cell response. It is interesting that activated NK cells contribute toward liver injury, while inactive or compromised NK cells permit the virus to continue invasion<sup>[50]</sup>.

### Adaptive immunity

After entry and replication of the virus inside liver cells, the viral molecules are transported to the endoplasmic reticulum and associate with major histocompatibility complex (MHC) molecules, which are finally transported to the cell surface. These molecules on the cell surface are recognized by T cells for their immune action. The majority of CTLs are CD8<sup>+</sup> and recognize antigens presented on MHC class I molecules. Approximately 10% of CTLs are CD4<sup>+</sup> which recognize antigens presented on MHC II molecules. These CTLs eliminate cells infected with virus. However, HCV is reported to have evolved mechanisms to avoid recognition by CTLs. They either reduce the expression of MHC molecules or prevent the viral peptide from presentation at the cell surface. Thus, CTLs play a major role in viral eradication<sup>[51]</sup> and immunopathogenesis of HCV infection<sup>[52]</sup>.

In another pathway of the disease mechanism, the destruction of HCV-infected hepatocytes release HCV fragments that are taken up by myeloid DCs. These DCs migrate to the draining lymph nodes and express HCV antigens on HLA class II molecules. Subsequently, they increase expression of costimulatory molecules (CD80,

CD86) which interact with and activate antigen-specific helper T (Th) cells<sup>[53]</sup>. These activated Th cells promote the maturation of DCs and increase the expression of CD40 ligand and TNF- $\alpha$ . The mature DCs induce T-cell activation by overexpression of their surface molecules. They also enhance antigen presentation capacity *via* HLA-I and production of cytokines that stimulate T-cell activation. IL-12 has been shown to play an important role in stimulating IFN- $\gamma$  production from activated T cells<sup>[54,55]</sup>, and thus, induces development of the type 1 (Th1) immune response characteristic of CTL activation. The effector CTLs release perforin, granzyme, and TNF- $\alpha$ , or express Fas ligand, and initiate a direct attack on HCV-infected hepatocytes<sup>[56,57]</sup>.

The hepatocytes infected with HCV and DCs produce Type I IFNs which suppress viral replication by inducing enzymes such as 2'-5' oligoadenylate synthetase (OAS) and RNA-dependent protein kinase (PKR) in hepatocytes<sup>[58]</sup>. The plasmacytoid DC recognizes HCV-related markers through TLR-7, which interacts with single-stranded RNA<sup>[59]</sup>. The TLR-signaling up-regulates PDC-triggering receptor expressed on myeloid cells (PDC-TREM) which induce further production of IFN- $\alpha$ <sup>[60]</sup>. Activated OAS destroys viral RNAs, whereas PKR inhibits forming polysomes of viral mRNA<sup>[58]</sup>. When HCV-specific CTL responses are not strong enough to eradicate the virus this leads to persistent infection<sup>[61]</sup>.

Successful clearance of HCV during acute HCV infection depends on the rise, vigor and persistence of the Th1 immune response<sup>[62,63]</sup>. Patients who developed a strong Th1 response showed efficient viral clearance and a self-limited disease course. In contrast, those who lacked IL-12 and IFN- $\gamma$  production invariably developed chronic persistence of the virus. The majority of patients fail to control the infection and develop a chronic infection with a variable degree of hepatitis and viremia<sup>[64,65]</sup>. Experimental studies have also demonstrated that HCV components induce an antigen processing mechanism and IFN-stimulated genes in infected livers<sup>[66-68]</sup>. Impaired function of DCs, as antigen-presenting cells in inducing immunity, may be responsible for the impaired immune responses. Various studies have reported that viral proteins including HCV core, E1, and NS3 inhibit DC maturation<sup>[69,70]</sup>. HCV infects DCs through the binding of HCV E2 protein and thereby suppress DC function in promoting an antiviral effect<sup>[41,71]</sup>.

CTLs activated by viral proteins, not only kill virus-infected cells, but also contribute to virus control through a noncytolytic mechanism by secreting cytokines, *e.g.*, IFN- $\gamma$ , IFN- $\alpha/\beta$  and TNF- $\alpha$ . These cytokines induce an antiviral state in host cells. This also renders uninfected cells resistant to infection and prevents viral replication. The progression of the majority of infected persons to chronic infection suggests inability of the antiviral immunity to contain this infection. There may be several reasons for this failure, including the emergence of escape variants as a result of a high rate of virus mutations, decreased production of antiviral cytokines or "stunning"

of HCV-specific CTLs, a compromised cytolytic potential of the CTLs and antagonistic peptides<sup>[72]</sup>.

It is important to note here that the HCV genome in a single host is a dynamic population of different, but closely related genomes, designated quasispecies. The generation of quasispecies is usually ascribed to high variation in hyper variable region-1 (HVR-1) during viral replication<sup>[73]</sup>. In acute resolving hepatitis, HVR-1 shows very little variation, as compared to that in chronic hepatitis<sup>[74]</sup>. HVR-1 induces anti-HCV neutralizing antibodies<sup>[75,76]</sup> and HVR-1 specific CD4<sup>+</sup> and CD8<sup>+</sup> T cells<sup>[77,78]</sup>. Using the responding host cellular immune response differentially, HVR-1 favors viral escape<sup>[79,80]</sup>. HVR-1 variations result from the action of a continuous immune-driven positive selection<sup>[81,82]</sup>. Thus, HVR-1 complexity helps in the virus adaptive strategy to escape the immune onset. HCV clearance is associated with a vigorous HCV specific CD4<sup>+</sup> and CD8<sup>+</sup> T cell response in the acute phase of infection. In contrast, viral persistence is associated with a weak and dysfunctional virus specific T cell response<sup>[79-83]</sup>. T cell failure and HCV immune evasion have been explained in several reports<sup>[84-86]</sup>.

### Role of T regulatory cells in adaptive immunity

Recent studies have suggested a possible role for different regulatory T cell populations in HCV persistence. These studies showed a higher frequency of CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells in the blood and CD4<sup>+</sup>FoxP3<sup>+</sup> T cells in the liver of chronically HCV infected patients<sup>[87-89]</sup>. CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells suppress HCV specific CD8<sup>+</sup> T cell and CD4<sup>+</sup> T cell proliferation as well as CD8<sup>+</sup> T cell IFN- $\gamma$  secretion<sup>[87,90-92]</sup>. After HCV antigen stimulation, Treg cells secrete IL-10 and transforming growth factor- $\beta$  (TGF- $\beta$ ) which suppress virus specific T cell responses<sup>[91-93]</sup>. CD4<sup>+</sup>CD25<sup>+</sup> Treg cells obtained from chronically HCV infected patients demonstrated greater suppressive activity against HCV specific CD8<sup>+</sup> T cells compared to Treg cells isolated from acute HCV infected patients. However, the suppressive effect observed in patients who successfully cleared the virus was still significant<sup>[90]</sup>. Another study showed that the frequency of CD4<sup>+</sup>CD25<sup>+</sup>FoxP3<sup>+</sup> Treg cells and their suppressive capacity against virus specific T cell responses were as high in HCV recovered chimpanzees as those in persistently HCV infected chimpanzees<sup>[94]</sup>. This observation requires further in-depth studies to explore the actual suppressive effect of Treg cells during HCV infection. Induction of Treg cells by HCV antigens was first demonstrated by the response of CD4<sup>+</sup> T cell to HCV core protein. HCV-specific IL-10 secreting T cells were detected in the blood of chronic HCV infected persons<sup>[95]</sup>. Regulatory CD8<sup>+</sup> T cells may play an important role in chronic HCV infection. HCV-specific CD8<sup>+</sup>CD25<sup>+</sup>FoxP3<sup>+</sup> T cells from the blood of chronically infected patients suppress HCV-specific T cell responses *via* TGF- $\beta$  secretion. The blockade of TGF- $\beta$  markedly enhanced HCV specific IFN- $\gamma$  secretion by CD4<sup>+</sup> and CD8<sup>+</sup> T cells<sup>[96]</sup>.

Few other studies have shown that chronic HCV in-

fection results in exhaustion or impairment of HCV-specific CD8<sup>+</sup> T cells. During chronic HCV infection, CD8<sup>+</sup> T cells fail to proliferate or secrete antiviral cytokines including IFN- $\gamma$ . This phenomenon is promoted by a lack of CD4<sup>+</sup> T cells and the expression of immunomodulatory cytokines such as IL-10<sup>[97]</sup>. The major cause of HCV-specific CD8<sup>+</sup> T cell impairment is ascribed to the expression of inhibitory receptors such as Programmed death-1, lymphocyte-activation gene-3 (a protein related to CD4), CTLA-4 (a member of the CD28 receptor family), T-cell immunoglobulin mucin-3 and 2B4 on HCV-specific CD8<sup>+</sup> T cells in blood and liver<sup>[98]</sup>. Expression of these inhibitory receptors is associated with low levels of CD127 expression and impaired proliferation and differentiation of T cells. Thus, different mechanisms contribute to the dysfunction of HCV-specific CD8<sup>+</sup> T cells in chronic HCV infection.

In addition to cytotoxic T lymphocytes, humoral immune response against viral and cellular components during HCV infection is also present. Patients positive for HCV RNA and/or anti-HCV antibodies have type I anti-liver kidney microsome antibodies, which also recognize cytochrome P450 (CYP) 2D6. The patient's liver is infiltrated with auto reactive mononuclear cells, which recognize CYP2D6. It is interesting that the viral core protein residues 178-187 bear sequence homology with human cytochrome P450 (CYP2A6 and CYP2A7) residues 8-17<sup>[96]</sup>. Although HCV is a hepatotropic virus and infects hepatocytes, viral genome and its replicative intermediates are frequently present in peripheral blood mononuclear cells and lymphoid tissues of chronically infected persons. The viral glycoprotein E2 has been implicated in the oligoclonal expansion of several lymphoma cells<sup>[99]</sup>. The most common rheumatic and cutaneomucous symptoms in HCV-infected patients include fatigue, arthralgia, paraesthesia, myalgia, pruritus, and the sicca syndrome<sup>[100]</sup>.

## ROLE OF VIRAL PROTEINS AND GENOTYPES

The role of structural and non-structural components of the HCV virion has been explained by variation in their interactions with metabolites affecting pathogenic pathways leading to liver damage. HCV-core protein has a prominent role in all these interactions as compared to envelope and non-structural proteins. Moreover, when the mechanism of this interaction was studied in relation to various HCV genotypes, it was observed that different genotypes behave differently to regulate all these pathogenic pathways.

The role of NS5A and E2 region was found be important. NS5A has a role in viral replication, inactivating PKR<sup>[101-104]</sup>, blocking the apoptotic pathway, binding of growth factor receptor-bound protein 2<sup>[105,106]</sup> and induction of anti-inflammatory interleukin secretion<sup>[107,108]</sup>. Similarly, E2 protein inhibits PKR<sup>[109,110]</sup>. The region of NS5A which interacts with PKR, shows clustering of amino acid changes during IFN treatment and plays an

important role in the evasion mechanism<sup>[111]</sup>. Furthermore, this association varies with genotype and thus, alters their sensitivity to IFN treatment. NS5A remains under strong immune selection, has T- and B-cell epitopes and possibly, in combination with individuals' HLA, selects immune cells to produce sensitivity/resistance to IFN therapy<sup>[112]</sup>. The functional activity of NS5A towards immune selection is clearly governed by the HCV-genotypes and varies accordingly. The response of genotype 2 and 3 to IFN treatment may be due to individuals recognizing the NS5A protein immunologically<sup>[113]</sup>.

Binding of HCV E2 protein to DCs induces their maturation. Several HCV viral proteins, including core, NS3, NS5A and NS5B proteins, have been shown to inhibit DC functions<sup>[69]</sup>. Consequently, the functions of both CD4<sup>+</sup> Th cells and CD8<sup>+</sup> CTLs are impaired in chronic HCV patients. This has been suggested to be one of the mechanisms that HCV utilizes to weaken host immune responses and spread the infection. Indeed, many clinical studies have shown that in chronic HCV patients, not only the functions of DCs are impaired<sup>[113,114]</sup>, the functions of both CD4<sup>+</sup> and CD8<sup>+</sup> T cells are also impaired<sup>[115]</sup>. A similar inductive effect of E2 protein was also reported in other cell types, including T cells, B cells<sup>[116]</sup>, hepatocytes<sup>[117]</sup> and hepatic stellate cells<sup>[118]</sup>.

The role of HCV genotypes in the progression of liver disease is one of the most controversial areas of HCV research. In patients with chronic HCV, infection with genotype-1b is reportedly associated with a more severe liver disease and a more aggressive course than the infection with other HCV genotypes. Similarly, it was found that HCV genotype-1b was significantly more prevalent among patients with liver cirrhosis and those with decompensated liver disease requiring liver transplantation than among those with chronic active hepatitis C<sup>[119-121]</sup>. Although this is indirect evidence, it suggests an association between HCV genotype-1b and the development of these complications. HCV genotype-1b is a marker for more severe HCV associated liver disease, because it reflects a longer time of infection than a mere aggressive form of hepatitis C.

## METABOLIC CONDITIONS AFFECTING HCV PATHOGENESIS

In addition to immune mediated HCV pathogenesis, there are several other clinical and metabolic conditions that have a strong association with HCV pathogenesis. These include HCV-induced insulin resistance, oxidative stress and hepatic steatosis. The following is a brief description of the conditions affecting HCV pathogenesis:

### HCV-induced insulin resistance

HCV infection influences overall metabolism leading to increased steatosis, fibrosis, inflammation, apoptosis and insulin resistance (IR)<sup>[122,123]</sup> during the course of the disease. The resulting IR shows a modulating impact on liver pathogenesis by HCV infection<sup>[124]</sup>. IR increases the

*de novo* lipogenesis *i.e.*, fatty acid (FA) synthesis *via* over-expression and maturation of SREBP-1c. This in turn, increases the activities of lipogenic enzymes including Acetyl CoA carboxylase and FA synthase. At the same time, intermediates of triglyceride biosynthesis also activate inhibitors of insulin signaling. For example, activation of protein kinase C- $\epsilon$  by phosphorylating insulin receptor substrate, and thus inhibiting phosphatidylinositol-3,4,5-triphosphate<sup>[125]</sup>, inhibits Akt translocation by ceramides *etc.*<sup>[126]</sup>. HCV-core protein, either directly or *via* increased secretion of TNF- $\alpha$ , causes IR<sup>[127,128]</sup>. The HCV core can activate inhibitors of insulin signaling including mammalian target of rapamycin<sup>[129]</sup> and suppressor of cytokine signaling (SOCS)-3 and C-Jun N-terminal kinase (JNK)<sup>[130,131]</sup>. The activation of JNK by HCV core may follow a direct or indirect proinflammatory cytokine-mediated mechanism.

### HCV-associated oxidative stress

Oxidative stress is reported to be an important part of HCV-induced liver damage. Previous studies investigated the role of different molecular components of HCV structure in modulating oxidative stress during HCV infection. HCV-core protein present within the outer membrane of mitochondria induces oxidation of glutathione and promotes Ca<sup>2+</sup> uptake into mitochondria. Clément *et al.*<sup>[96]</sup> explained the molecular mechanism and demonstrated that following glutathione oxidation, there is increased reactive oxygen species (ROS) production by mitochondrial electron transport complex I and III. The HCV non-structural protein, NS5A, promotes ROS production in the membrane of endoplasmic reticulum (ER) by activating the release of Ca<sup>2+</sup> from ER, thereby inducing oxidative stress<sup>[97]</sup>. NS3 protein induces ROS production by activation of NADPH oxidase<sup>[97]</sup>. Increased ROS production and consequent oxidative stress is evident by the presence of markers of increased oxidative stress in the blood. Levels of 8-hydroxy deoxyguanosine and 4-hydroxy-2-nonenol are increased in HCV infection<sup>[132,133]</sup>. Similarly, few studies have shown reduced levels of glutathione during HCV infection. Another study showed that the serum level of thioredoxin, a marker of oxidative stress, was significantly reduced in HCV infection<sup>[134-136]</sup>.

The presence of oxidative stress has been noted in different types of hepatitis including hepatitis B. However, there is a marked increase in oxidative stress (OS) in HCV infection<sup>[132]</sup>. Several studies have shown that structural components of HCV induce effective OS<sup>[132]</sup>. HCV-core and non-structural components, NS3 and NS5A proteins, directly induce OS<sup>[137-139]</sup>. Core protein is involved in OS generation *via* oxidation of mitochondrial glutathione and uptake of Ca<sup>2+</sup> into mitochondria<sup>[139,140]</sup> thus, changing the permeability of its membrane<sup>[141]</sup>. Electron transport complex I increases production of ROS and redistributes cytochrome from mitochondria to the cytosolic fraction<sup>[93]</sup>. NS5A is associated with the ER membrane<sup>[142]</sup> and activates signal transducer transcription and NF $\kappa$ B<sup>[107]</sup>. These activations lead to inflammation,

immune response and apoptosis<sup>[143]</sup>. Similarly, NS3 triggers ROS by activating NADPH oxidase 2 in mononuclear and polymorphonuclear phagocytes<sup>[144]</sup> which increase apoptosis of hepatocytes<sup>[144]</sup>. All these reports conclude that the structural and non-structural components of HCV induce a significant increase in OS that results in liver damage during HCV infection.

### HCV-induced steatosis

HCV infection is reported to have a strong association with hepatic steatosis. There are several other factors also responsible for steatosis, which include alcohol consumption, obesity, and diabetes<sup>[145-147]</sup>. Studies on steatosis in relation to hepatotropic viruses demonstrated that HCV infection directly causes steatosis in some patients<sup>[148]</sup>. Studies in experimental animals have shown that HCV-core protein promotes liver steatosis<sup>[149,150]</sup>. Furthermore, when steatosis was studied in relation to HCV-genotypes, it was noted that although steatosis is induced by all HCV-genotypes, it appears more prominent and frequent with HCV-genotype 3 infection<sup>[151-153]</sup>. In patients carrying genotype-3 infection, there was a good correlation between the level of steatosis and HCV replication<sup>[153,154]</sup> and the presence of HCV-core in the liver. In addition, steatosis resolves in patient with genotype-3 when treated successfully with anti-viral therapy as compared to those with non-genotype-3 who remain steatotic<sup>[155,156]</sup>. Steatosis reappears with relapse of infection<sup>[155]</sup>. This clearly demonstrates that some HCV-genotypes have more steatogenic potential. Subsequent studies<sup>[157]</sup> indicated that genotype-3 interferes with very low-density lipoprotein (VLDL) secretion. Core protein, which promotes lipid accumulation in hepatocytes<sup>[158,159]</sup>, was more efficient from genotype-3 compared to core protein from genotype-1.

All these reports concluded that HCV causes steatosis in three different ways: (1) Impaired secretion of lipids from hepatocytes; (2) Increased *de novo* synthesis of free fatty acids (FFAs); and (3) Impaired FA degradation. The first aspect of HCV-induced steatosis was proposed due to the impaired secretion of VLDL. To substantiate this, reports from different studies demonstrated a decreased level of apolipoprotein B and cholesterol in chronic HCV infected patients<sup>[159,160]</sup>. These low levels pointed to HCV disturbing the assembly and secretion of VLDL from the liver<sup>[161]</sup>. Another important aspect in this relationship was increased *de novo* synthesis of FFAs in the presence of HCV infection. In this context, it is suggested that HCV upregulated the sterol regulatory element binding protein-1c (SREBP-1c) signaling pathway<sup>[158]</sup> with NS2 and NS4B proteins inducing SREBP at the transcriptional level<sup>[162,163]</sup>. SREBP was also induced by expression of HCV core protein. Studies in chimpanzees infected with HCV also demonstrated that HCV increased the activity of lipogenic enzymes such as ATP citrate lyase<sup>[164]</sup>. HCV-core, in particular, activates and helps in cellular lipid synthesis<sup>[164]</sup>, possibly *via* its binding with retinoid receptor.

HCV-induced steatosis is also due to impaired FA

degradation by HCV. Expression of HCV-core protein is reported to reduce the expression of peroxisome proliferation activated receptor- $\alpha$  (PPAR $\alpha$ ), a nuclear receptor involved in FA degradation and down-regulation of mitochondria  $\beta$ -oxidation<sup>[165]</sup>. Genotype-3 shows significant down-regulation of PPAR $\alpha$  as compared to genotype-1<sup>[166,167]</sup>. HCV-core protein also down-regulates PPAR $\alpha$  and therefore, is more effective when from genotype-3 as compared to genotype-1. The core protein from genotype-3 also down-regulated the PPAR $\gamma$  and up-regulated SOCS-7 in human hepatoma cells<sup>[167]</sup>. These data clearly show that HCV-core protein may modulate the expression of various genes responsible for FA degradation *via* down-regulation of PPARs.

## CONCLUSION

HCV infection, previously known as blood borne non-A, non-B infection, is a serious public health problem worldwide. The diagnosis of HCV is based on the detection of anti-HCV antibodies and/or viral nucleic acid in serum. Studies over the last few years have developed assays not only for the accurate serodiagnosis of infection, but also identification of HCV serotypes. The pathogenesis of HCV infection is quite complex and regulated by host immunity as well as several metabolic activities influencing liver function. Whereas both innate and adaptive immunity are involved in the pathogenic action of HCV, the cytotoxic lymphocytes are crucial in deciding the eradication or persistence of viral particles. Moreover, the persistence of HCV infection is also affected by viral proteins, HCV isotypes and liver metabolism. In order to understand HCV pathogenesis further investigations are needed.

## ACKNOWLEDGMENTS

We thank and appreciate the financial aid provided by ICMR, New Delhi, India to conduct this study. We are also thankful to Mrs. Suman Rawat for preparing this manuscript.

## Abstract

In the 1970s, scientists learned of a new pathogen causing non-A, non-B hepatitis. Classical approaches were used to isolate and characterize this new pathogen, but it could be transmitted experimentally only to chimpanzees and progress was slow until the pathogen was identified as hepatitis C virus (HCV) in 1989. Since then, research and treatment of HCV have expanded with the development of modern biological medicine: HCV genome organization and polyprotein processing were delineated in 1993; the first three-dimensional structure of HCV nonstructural protein (NS3 serine protease) was revealed in 1996; an infectious clone of HCV complementary DNA was first constructed in 1997; interferon and ribavirin combination therapy was established in 1998 and the therapeutic strategy gradually optimized; the HCV replicon system was produced in 1999; functional HCV pseudotyped viral particles were described in 2003; and recombinant infectious HCV in tissue culture was produced successfully in 2005. Recently, tremendous advances in HCV receptor discovery, understanding the HCV lifecycle, decryption of the HCV genome and proteins, as well as new anti-HCV compounds have been reported. Because HCV is difficult

to isolate and culture, researchers have had to avail themselves to the best of modern biomedical technology; some of the major achievements in HCV research have not only advanced the understanding of HCV but also promoted knowledge of virology and cellular physiology. In this review, we summarize the advancements and remaining scotomas in the molecular virology and epidemiology of HCV.

**Key words:** Hepatitis C virus; Hepatitis C virus lifecycle; Molecular virology; Hepatitis C virus models; Epidemiology

**Core tip:** The review summarizes the advancements, as well as remaining scotomas, in the molecular virology of hepatitis C virus (HCV). We emphasize the contributions of HuH-7 hepatocellular carcinoma cell line to development of the HCV replicon, cell culture-derived HCV, and HCV pseudoparticles. In addition, we reiterate the importance of epidemiological issues because accurate assessment of HCV-related disease burden has been overlooked. This review provides a history of the fight against HCV, which has required scientists to avail themselves to the best of modern biomedical technology, which in turn has enriched our knowledge of virology and cellular physiology.

## INTRODUCTION

The hepatitis C virus (HCV) is an enveloped, single-

stranded, positive-sense RNA virus, classified as a *Hepacivirus* within the *Flaviviridae* family<sup>[1-3]</sup>. The 9.6-kb RNA genome contains one long open reading frame (ORF) flanked by 5' and 3' untranslated regions (UTR)<sup>[4-6]</sup>. The single ORF encodes an approximately 3000 amino acid (aa) polyprotein that undergoes co- and post-translational cleavage by host and viral proteases to yield 10 viral proteins, not including the F protein<sup>[7,8]</sup>. The structural proteins, nucleic acid-binding nucleocapsid core protein and envelope proteins (E1 and E2/P7) are encoded by 25% of the N-terminal portion of the genome<sup>[9]</sup>. The remaining 75% of the genome encodes the non-structural proteins, NS2, NS3, NS4A, NS4B, NS5A and NS5B<sup>[9]</sup>.

Humans are the primary reservoir of HCV<sup>[10]</sup>. HCV transmission occurs primarily through exposure to infected blood and the majority of individuals with persistent infection develop chronic hepatitis, which can progress to cirrhosis or hepatocellular carcinoma<sup>[11-13]</sup>. Different from other viruses, such as influenza A viruses and human immunodeficiency viruses, HCV is difficult to isolate and culture<sup>[14-16]</sup>. Since HCV was identified in 1989<sup>[1]</sup>, basic research on HCV has been being hindered by the absence of reliable, reproducible, and efficient culture systems<sup>[11]</sup>. Recently, tremendous advances in understanding the HCV replicon<sup>[15,16]</sup>, the pseudo-typed HCV viral particle<sup>[17]</sup>, cell based culture systems<sup>[18,19]</sup>, receptors<sup>[20-24]</sup>, life cycle<sup>[25,26]</sup>, structural biology and HCV therapy strategy<sup>[27-29]</sup> have been gained. However, several scotomas in the molecular virology and epidemiology of HCV remain to be elucidated. This review summarizes the advancements and remaining scotomas in the molecular virology and epidemiology of HCV.

## MAJOR PROGRESS IN FIGHTING HCV

Since HCV was identified in 1989<sup>[1]</sup>, virological research has led to a great deal of progress in the pathogenesis, diagnosis, treatment, control and prevention of the disease<sup>[11,30]</sup>. Since virus elimination is the ultimate goal of viral disease therapy, here we emphasize two major recent achievements in hepatitis C treatment. The first achievement was the development of direct-acting antiviral (DAA) agents, which are inhibitors of the HCV protease<sup>[31-37]</sup>. Although peginterferon and ribavirin remain vital components of therapy, the emergence of DAA agents has led to an unprecedented improvement in sustained virologic response rates to approximately 94%<sup>[30,38]</sup>. This is indicative of two milestones in virology: a therapy with the highest documented antiviral effects and optimism that the virus could be eliminated by medications. The second achievement is the identification of several single-nucleotide polymorphisms associated with spontaneous and treatment-induced clearance of HCV infection<sup>[39,40]</sup>. This discovery is also a milestone because only the rare single nucleotide polymorphisms of rs12980275 and rs8099917, near the interleukin28B gene, have any reported biological effect<sup>[39,40]</sup>.

## CURRENT HCV MODELS

The *in vitro* and *in vivo* models for HCV have evolved significantly since the discovery of the virus. With any virus, cell-based culture systems and animal models are the essential tools for virological study, vaccine development, and antiviral drug discovery. Many viruses, such as the influenza virus, are easy to isolate and culture in cell lines<sup>[41,42]</sup>; however, HCV is difficult to isolate and propagate<sup>[15,16,18,19]</sup>. Before HCV was identified, many virologists had attempted to isolate and culture the pathogen of non-A, non-B hepatitis using traditional cell-based approaches<sup>[43]</sup>. After struggling for decades, it was determined that HCV could only survive in human or chimpanzee fetal liver cells and hepatocytes or human peripheral blood mononuclear cells<sup>[44-49]</sup>. These cells are inconvenient to obtain and have a finite lifespan in culture, so even though these early studies showed that HCV was selective with a narrow host range<sup>[50,51]</sup>, these methods made little contribution to HCV research (Table 1).

Defeated by classical approaches to isolate HCV, virologists were forced to reproduce the HCV lifecycle using split models, which included the HCV genome RNA replication model (HCV replicon)<sup>[15,16]</sup>, HCV structural proteins model (virus-like particle, VLP)<sup>[52]</sup> and HCV pseudotyped viral particles model<sup>[17]</sup> (Table 1). In 1999, Bartenschlager's group in Germany established a HCV replicon system<sup>[15]</sup>, followed soon after in 2000 by Rice's group in the United States<sup>[16]</sup>. These models simulated the structure of the subgenomic selectable HCV replicons composed of the HCV 5'-UTR, the gene encoding the neomycin phosphotransferase or firefly luciferase, the encephalomyocarditis virus internal ribosome entry site, the region encoding HCV NS2-5B or NS3-5B, the authentic 3'-UTR, and the 12-16 5'-terminal codons of the core<sup>[15,16]</sup>. The replicon could replicate autonomously in hepatic cell cultures (*e.g.*, HuH7 cell line)<sup>[15,16]</sup>, leading to a series of experiments that examined the function of 5'- and 3'-UTR and NS3 to NS5B in HCV genome replication, described the viral life cycle, and led to the development of antiviral drugs<sup>[27]</sup>. The HCV replicon was able to replicate itself within the cell; however, it was not capable of producing infectious viruses<sup>[27]</sup>. Furthermore, this replicon was not able to reproduce in HuH-7 cells with high efficiency and for an extended period of time<sup>[50]</sup>. Virologists attempted to improve the replication efficiency and modify the robust HCV replicon using several methods, including adaptive mutation hunting, to reduce the non-HCV genome and increase the HCV genome composition, by attempting to replace various wild HCV strains of different genotypes<sup>[27,50,53]</sup>.

Pseudotyped viral particles are commonly known as lentiviral vectors. These vectors are composed primarily of three viral elements; the gag-pol, which forms the viral structure, recognizes the viral genome and is responsible for the genome lifecycle; the viral mimic genome, which provides the genome elements that will be recognized

Table 1 Summary of *in vitro* and *in vivo* models for hepatitis C virus

<i>In vitro</i> and <i>in vivo</i> models	Established year	Advantages	Deficiencies
<i>In vitro</i>			
Cultivation of HCV	1993-1999	Achieved cultivation of HCV in human foetal liver cells, human hepatocytes or PBMC. Illustrated HCV is quite species selective and has a narrow range of hosts	Requires specific cellular factors to support viral lifecycle. Primary human and chimpanzee hepatocytes or highly differentiated cells dependent. Most of them have yielded limited success. Poor reproducibility and low levels of HCV replication
HCV replicon	1995-2000	Provided a cell-based model for the study on HCV genome replication	
HCV VLP	1998-1999	Rare evidence to support that HCV structural proteins core, E1, and E2 could form VLP	
HCVpp	2003	Provided a convenient and feasible tool for studies on viral entry, HCV receptor, neutralizing antibody, etc.	
HCVcc	2005	A break through in production of infectious hepatitis C virus in tissue culture	
<i>In vivo</i>			
Chimpanzee	1979	The only recognized animal model for HCV study, played a critical role in HCV discovery and play an essential role in defining the natural history of HCV	Chimpanzees differ from humans in their course of infection, that chronic carriers do not develop cirrhosis or fibrosis, limited availability, cost performance, and public resistance
Tree shrew	1998	Might be a succedaneum for chimpanzees	Persistent HCV infection could not be established and only 25% of infected animals developed transient or intermittent viremia. Germ line was not available to a small animal model
Chimeric human liver mouse	2001	Exhibited prolonged infection with high viral titers following inoculation with HCV isolated from human serum. HCV can be transmitted horizontally. Drug evaluation	Since the mice were immunodeficient, they were not appropriate models to study HCV pathogenesis
Genetically humanized mouse	2011	Represents the first immunocompetent mice model for HCV study. Allows for the studies of HCV coreceptor biology <i>in vivo</i>	Operation is difficult

HCVpp: Hepatitis C virus (HCV) pseudotyped viral particles; VLP: Virus like particle; HCVcc: Cell culture derived HCV.

by gag-pol and ensures complete viral RNA metabolism; and the envelope proteins, which are presented onto the artificial viral particle<sup>[54-58]</sup>. Additionally, a lentiviral vector contains a reporter gene inserted into the artificial viral genome. Although the lentiviral vector was used widely in gene transduction, presenting an HCV envelope protein functionally in this viral particle was not considered. Virologists tried to generate the HCV VLP<sup>[52]</sup>, because classic virological experience told us that VLP of a certain virus could be produced by cloning and expressing virus structural proteins, and Liang's group at the National Institutes of Health (Bethesda, MD) was successful in establishing the HCV-like particles using a baculovirus expression vector system<sup>[52]</sup>. In 2003, French virologist Bartosch *et al*<sup>[17]</sup> produced HCV pseudoparticles (HCVpp) using viral elements derived from murine leukemia virus. The HCVpp system led to advanced studies that identified a neutralizing antibody against HCV<sup>[59]</sup>, explored HCV receptors and described the structure and function of the HCV envelope proteins<sup>[60-63]</sup>. In 2005, the Japanese virologist Wakita obtained a genotype 2a HCV strain (JFH-1) from a Japanese patient with a rare case of fulminant hepatitis C<sup>[18]</sup>. Based on the experience and methods accumulated in studying the HCV replicon, Wakita and his group rescued HCV in the HuH7 cell line, which was designated as HCVcc, for cell-culture-derived HCV<sup>[18]</sup>. HuH-7 cells infected with cloned

and *in vitro* transcribed JFH-1 genomes produced viruses that were capable of infecting naïve HuH-7 cells<sup>[18]</sup>. In addition, the virus particles could be neutralized with a monoclonal antibody against the viral glycoprotein E2<sup>[18]</sup>. The study was the first *in vitro* experiment that showed the complete lifecycle of HCV. More importantly, virus obtained from the cell cultures was highly infectious in chimpanzees and immunodeficient mice with partial human livers<sup>[64]</sup>. As early as the 1970s, it was known that the etiological agent responsible for non-A and non-B hepatitis could be transmitted to chimpanzees<sup>[65]</sup>, and chimpanzees were subsequently recognized as the only animal model of HCV<sup>[66]</sup> (Table 1). Chimpanzees played a critical role in defining the natural history of HCV<sup>[66]</sup> and since they are closely related to humans, any study of chimpanzees could reflect more closely what happens in humans than other animal models. However, chimpanzees that are chronic carriers of HCV do not develop cirrhosis or fibrosis<sup>[66,67]</sup>, which are the most important consequences of HCV infection in humans. Because chimpanzee studies are expensive and restricted by ethical responsibilities<sup>[67]</sup>, scientists diverted their attention to other small animal models, such as the tree shrew and a chimeric human liver mouse. Xie *et al*<sup>[68]</sup> demonstrated that *Tupaia* could be infected by HCV when severely immunosuppressed; however, persistent

HCV infection could not be established and only 25% of infected animals developed transient or intermittent viremia<sup>[51]</sup>. By genetically manipulating the urokinase-type plasminogen activator transgenic mouse, Mercer *et al*<sup>[69]</sup> transplanted normal human hepatocytes into severe combined immunodeficient mice carrying a plasminogen activator transgene. The chimeric mice exhibited prolonged infection with high viral titers following inoculation with HCV isolated from human serum<sup>[69]</sup>. Since the mice were immunodeficient, they were not appropriate models for investigation of HCV pathogenesis, although they were useful in assessing the activity of antiviral drugs, as well as neutralizing antibodies<sup>[51]</sup> (Table 1).

Mouse models of HCV provided little information about the human hepatocellular factors required for HCV entry. Thus, Ploss *et al*<sup>[24]</sup> introduced human CD81, scavenger receptor type B class 1, claudin 1, and OCLN genes into mice using a recombinant adenovirus expression system. They found that mice expressing these human factors were sufficient for HCV infection<sup>[24]</sup>. This system allowed for the investigation of HCV co-receptor biology *in vivo* and evaluation of passive immunization strategies and, therefore, represented the first immunocompetent small animal model for HCV<sup>[70]</sup> (Table 1).

## SCOTOMAS IN MOLECULAR VIROLOGY

Although much progress has been made in all aspects of HCV research in the last few decades, we are still far from achieving the ultimate goal of complete HCV control and prevention. Thus, a better understanding of the HCV life cycle is essential to optimize the antiviral strategy. As mentioned above, the major challenges to HCV research are that HCV is difficult to isolate and culture, and no vaccine is available<sup>[14-16,71]</sup>. However, rather than summarizing the many achievements in HCV research, we have chosen to enumerate the scotomas in HCV molecular virology.

### Structural biology of the HCV particle

Since HCV was first proposed to be a distinct infectious pathogen, virologists of that era attempted to visualize this enigmatic microbe using electron microscopy<sup>[43]</sup>. Different from other hepatitis viruses, including hepatitis A virus, hepatitis B virus and hepatitis E virus and the other viruses within the *Flaviviridae* family<sup>[43]</sup>, no clear electron microscope image of HCV was reported until Chisari's and Rice's groups provided high-resolution images of highly enriched cell culture-derived HCV (HCVcc) particles in 2010 and 2013, respectively<sup>[72,73]</sup>. The reason for the difficulty in observing the crude HCV particle in HCV-harboring tissue remains unclear. The viral titer should not be an issue since viral copies in blood samples produced by HCV RNA are  $> 10^6/\text{mL}$ <sup>[74]</sup>. Serum-derived HCV particles are associated with the lipoprotein components apolipoprotein A-I (apoA-I), apoB-48, apoB-100, apoC-I and apoE<sup>[75]</sup>. The interaction between virus particles and serum lipoproteins suggests that HCV may form

hybrid lipoviral particles<sup>[75]</sup> that facilitate virus entry into hepatocytes and protect the virus from the host immune response. In addition, the lipoprotein components might affect the morphological observation of crude HCV particles by electron microscopy. Our current knowledge of HCV morphology indicates that HCV particles are 40-80 nm in diameter, pleiomorphic, lack obvious symmetry or surface features and contain electron-dense cores<sup>[72,73]</sup>. The lack of details describing the overall architecture of HCV limits the ability of molecular biologists to study HCV structural biology and topology.

### Molecular virology of HCV structural proteins

A quarter of the N-terminal region of the HCV polyprotein encodes the core structural protein and glycoproteins E1 and E2, which are believed to be incorporated into the HCV particle<sup>[17]</sup>. Based on general virological knowledge, the core protein should be a major component of the viral capsid, responsible for viral genome RNA recognition, binding and packaging<sup>[27]</sup>. Glycoproteins E1 and E2 located in the viral surface are also called envelope proteins; E1 and E2 are responsible for receptor recognition, receptor binding, endocytosis and membrane fusion<sup>[27]</sup>. The mature core protein contains a positively charged N-terminal RNA binding domain and a C-terminal domain that consists of two amphipathic helices and a palmitoylated cysteine residue to facilitate peripheral membrane binding<sup>[27]</sup>. Antibodies against core proteins are important for HCV serological detection<sup>[43]</sup>. Previous studies demonstrated that the core protein is involved in many pathogenic processes<sup>[43]</sup>. Furthermore, the core protein induces hepatocellular carcinoma in transgenic mice<sup>[76]</sup> and is a potent inhibitor of RNA silencing-based antiviral response<sup>[77]</sup>. However, the basic function of the core protein in capsid formation remains unknown. Although the region between amino acids 82 and 102 contains a tryptophan-rich sequence involved in homotypic core proteins interaction<sup>[78]</sup>, the HCV core particle had not been successfully produced. *In vitro* nucleocapsid reconstitution experiments using the 1-124 or 1-179 core segments and structured RNA molecules have yielded irregular particles larger than those reported by the limited electron microscopy observations<sup>[79]</sup>. Scientists in China at Xiamen University successfully generated human papillomavirus VLP<sup>[80]</sup>, hepatitis E virus VLP<sup>[81]</sup> and hepatitis B virus core capsids but failed to produce the HCV capsid (personal communication). In addition, the crystal structure of the HCV core protein is not yet available (Table 2).

E1 and E2 are type I transmembrane glycoproteins assumed to be class II fusion proteins, with N-terminal ectodomains of 160 and 334 amino acids, respectively, and a short C-terminal transmembrane domain of approximately 30 amino acids<sup>[27,43]</sup>. Studies of HCVpp have indicated that 14 amino acids from the HCV core and 12 amino acids from the E1 C-terminus are required for E1 and E2 function<sup>[62]</sup>. The hemagglutinin and neuraminidase of influenza A viruses matches each other in a

Table 2 Summary of the properties of hepatitis C virus structural proteins

	Core	E1	E2	p7
Genome location	342-914	915-1490	1491-2579	2580-2769
Translation processing site		Rough ER		
Amino acid composition	191	192	363	63
Molecular weight (kDa)	21-23	33-35	70-72	7
Glycosylation	No	Yes	Yes	No
Cleavage		ER signal peptidase and SPP		
Crystal structure		Not available		
Functional unit	Dimer	Heterodimer?		Revealed Hexamer
Common function	Viral particle formation. Core, E1 and E2, together with p7 and NS2, are required for virus assembly (assembly module)			
Unique function	Capsid protein, viral particle formation, viral genome recognizing and packaging. Interacts with cLDs in early viral particle formation process. Counters host antiviral factors and involves pathogenesis	Envelope glycoproteins, interact with SRB1, CD81, CLDN1, OCLN, <i>etc.</i> to trigger viral entry. Promote fusion with the endosomal membrane. Counter host immune response <i>via</i> hypervariable regions		Viroporin. Has key roles in organizing the virus assembly complex. p7-NS2 complex interacts with the NS3-4A enzyme to retrieve core protein from cLDs to form viral particle
Major scotomas	How do the core form the viral capsid? The signals and processes that mediate RNA packaging are largely unknown. What impeded us to resolve the structure of the viral glycoproteins? What is the real process in HCV entry? How are these receptors and co-receptors temporally and spatially used to ensure the early infection processes?			

Start co-ordinates based on H77 (accession number, NC\_004102). SRB1: Scavenger receptor class B member 1; CD81: Tetraspanin CD81; CLDN1: The tight junction protein claudin 1; OCLN: The tight junction protein occludin; cLDs: Cytosolic lipid droplets; ER: Endoplasmic reticulum; SPP: Signal peptidase and signal peptide peptidase; HCV: Hepatitis C virus. The molecular weights of E1 and E2 refer to the glycosylated forms.

relative slack manner regardless of gene homology<sup>[54-58]</sup>, while the matching pattern of HCV E1 and E2 is relatively strict. We separated E1 and E2 of HCV genotypes 1a, 1b, and 2a into two individual expression plasmids and replaced the transmembrane domains of 1b and 2a E1 and E2 with that of genotype 1a. The complementation features of E1 and E2, as well as the contributions of both the ecto- and transmembrane domains to the formation of the E1E2 complex, were evaluated using the HCVpp system<sup>[63]</sup>. We found that 1aE2 could not only complement its native 1aE1 but also 1bE1; in genotype 1b, glycoprotein complex formation is dependent primarily on the overall biological characteristics of the intact native E1 and E2; in genotype 2a, although the interaction of intact native E1 and E2 is critical for the formation of the glycoprotein complex, the ectodomain made a greater contribution than did the transmembrane domain<sup>[63]</sup>. This study suggested that E1 and E2 formed a functional envelope protein complex dependent on E1 and E2 expression<sup>[63]</sup>. E1 and E2 are assembled as non-covalent heterodimers<sup>[82,83]</sup>, although the number of E1 molecules necessary to aggregate with E2 for biological function has not been elucidated. We highlight this scotoma because the envelope proteins of many viruses do not function simply in a 1:1 ratio<sup>[54-58]</sup> and viral proteins are not translated in equal numbers<sup>[43]</sup>. A lack of understanding of this point will impede receptor discovery, regardless of how many receptors and co-receptors are identified<sup>[75]</sup>. The crystal structure of the dengue virus glycoprotein, which is another member of the *Flaviviridae* family, was revealed in 2004<sup>[84]</sup>. By contrast, virologists failed to produce the HCV E1 or E2 crystal, which limits our understanding of the biological characteristics of HCV envelope proteins. Since one of the most important biological functions of HCV envelope proteins is

membrane fusion, E1 and E2 are assumed to be class II fusion proteins<sup>[83]</sup>. This assumption has been challenged by recent studies suggesting that HCV and pestiviruses share an uncharacterized mechanism of membrane fusion<sup>[85]</sup>. These contradictory issues are common in HCV research and await further advances in our understanding of HCV virology (Table 2).

Molecular virology of non-structural HCV proteins

HCV proteins can be categorized into an assembly module (from core to NS2) and a replication module (from NS3 to NS5B) on the basis of viral essential functions<sup>[27,75]</sup>. Details on the function of structural and non-structural HCV proteins are lacking due to the limitations of *in vitro* models. There is also some controversy on topics such as whether the assembly module is necessary for viral particle formation or whether p7 is a structural or non-structural protein. Although the HCV replicon system provided solid evidence that non-structural proteins activate HCV RNA replication *in vitro*<sup>[15,16]</sup>, some unresolved issues remain. These include why it is not possible to turn this system into a fully competent HCV cell culture model or why all replicons, except for the genotype 2a JFH-1 clone, contain cell-culture-adaptive mutations that when introduced back into viral genome, render it non-infectious in chimpanzees<sup>[67]</sup>.

The p7 polypeptide is a small, 63-aa intrinsic membrane protein with a double-membrane-spanning topology in which its N- and C-terminal ends face the ER lumen<sup>[27]</sup>. Recent data indicate that p7 can mediate membrane ion permeability and form hexamers<sup>[86,87]</sup>. The three-dimensional structure of a hexameric p7 channel revealed a highly tilted, flower-shaped protein architecture with six protruding petals oriented toward the ER lumen<sup>[86,87]</sup>. These structural and membrane-permeability

Table 3 Summary of the properties of hepatitis C virus non-structural proteins

	NS2	NS3	NS4A	NS4B	NS5A	NS5B

Cleavage						
Crystal structure	C-terminal (aa904-1026) was solved					
Functional unit	Homodimer	Monomer or oligomer	Monomer	Not available	Revealed Homodimer	Revealed Monomer
Common function			Replication module			
Unique function	A metal-dependent proteinase, many functions dependent on the interaction with P7 and NS3. Participation in proteolytic cleavage at the NS2-NS3 junction of the polypeptide. Both the TMDs and protease domain of NS2 are required for the production of virus particles	The DAA targeting protein, NS3 was anchored in ER membrane by cofactor NS4A. NS3-4A complex has serine-type protease activity and NTPase/RNA helicase activities. Nonspecific cleavage of two critical interferon induction proteins: MAVS and TRIF	The central portion of NS4A, residues 21-32, intercalates into NS3 and activates the protease activity by stabilizing this protease subdomain and contributing to the substrate recognition site. The C-terminal acidic portion of NS4A interacts with the NS3 helicase and other HCV proteins and contributes to RNA replication as well as assembly	A master organizer of replication complex formation. NTPase activity? RNA binding?	Produced as multiple phospho-variants. RNA-binding phosphoprotein involved in RNA replication. Phosphorylation of a specific serine residue within the C-terminus by CK II $\alpha$ is essential for virus assembly. The interaction of NS5A with the cLD-bound core protein is the key steps in HCV assembly	RNA-dependent RNA polymerase
Major scotomas	How HCV particles are organized? What is the accurate duty of each nonstructural protein in viral lifecycle? How do the nonstructural proteins utilize host cellular factors for its own survival? Why					

Start co-ordinates based on H77 (accession number, NC\_004102). Aa: Amino acid; TMD: Transmembrane domain; CK II: Casein kinase II; cLD: Cytoplasmic lipid droplet; LDL: Low-density lipoprotein; VLDL: Very-low-density lipoprotein; MAVS: Mitochondrial antiviral signaling protein; TRIF: TIR-domain-containing adaptor inducing interferon; HCV: Hepatitis C virus.

properties suggest that p7 belongs to the viroporin family and could play an important role in viral particle release and maturation<sup>[86,87]</sup>. However, the role of p7 in calcium and ion metabolism is unknown. Furthermore, HCVpp with or without p7 showed no changes in viral particle formation and pp infectivity<sup>[62,63]</sup>. A study of the closely related GB virus B, which infects tamarins and has an analogous but larger protein, p13, showed that p13 is processed into two components p6 and p7, and that p6 was dispensable while p7 was essential for infectivity<sup>[88]</sup>.

NS2 is a metal-dependent proteinase, whose functions are dependent on the interaction with p7 and NS3<sup>[27]</sup>. Although the NS2 protease is dispensable for RNA replication, NS2 participates in proteolytic cleavage at the NS2-NS3 junction of the polypeptide<sup>[27]</sup>. The transmembrane and protease domains of NS2 are required for infectious virus assembly<sup>[89]</sup>. Why NS2 is critical for viral particle formation remains unknown and the interactions between NS2 and other structural and non-structural viral proteins to form an unknown viral particle formation network should be explored (Table 3).

NS3 is a 70-kDa multifunctional protein anchored by the cofactor NS4A<sup>[27,89]</sup>. NS2/NS3 junction cleavage is essential to liberate fully functional NS3 protein<sup>[27,89]</sup>. NS3-4A is a non-covalent complex, with a serine protease located in the N-terminus (aa 1-180) and an NTPase/RNA helicase in the C-terminus (aa 181-631)<sup>[27,89]</sup>. The substrate specificity of NS3-4A is low and causes non-specific cleavage of host proteins; *e.g.*, mitochondrial antiviral-signaling (MAVS) and TIR domain-containing adaptor inducing interferon  $\beta$  (TRIF), and thus might impact host IFN response<sup>[90]</sup>. The central portion of NS4A, residues 21-32, intercalates into NS3 and activates the protease activity by stabilizing this protease subdomain and contributing to the substrate recognition site<sup>[27]</sup>. The C-terminal acidic portion of NS4A interacts with the NS3 helicase and other HCV proteins and contributes to RNA replication, as well as assembly<sup>[27]</sup>. The DAAs telaprevir and boceprevir<sup>[31-37]</sup> are inhibitors targeting the NS3-4A protease that displayed promising effects in clinical trials, indicating that the NS3-4A protease is critical for viral life cycle (Table 3).

NS4B is a poorly characterized hydrophobic 27-kDa protein<sup>[27]</sup> comprised of a 66-aa N-terminal portion, a 120-aa central portion, and a 70-aa C-terminal portion<sup>[91]</sup>. Four transmembrane-spanning regions were predicted in the central portion, while the N-terminal portion plays an important role in assembly of a functional replication com-

plex<sup>[27,91]</sup>. Einav *et al*<sup>[92,93]</sup> and Thompson *et al*<sup>[94]</sup> demonstrated that NS4B harbors NTPase activity and has a role in viral assembly.

NS5A is a 447-aa membrane-associated protein that plays an important role in modulating HCV RNA replication and particle formation<sup>[91]</sup>. NS5A can be detected in basally phosphorylated and hyper-phosphorylated forms with molecular weights of 56- and 58-kDa, respectively<sup>[95,96]</sup>. NS5A is comprised of four domains: a N-terminal membrane anchor and three domains separated by two low complexity sequences<sup>[27,91]</sup>. The three separated domains are domain 1, aa 36-213; domain 2, aa 250-342 and domain 3, aa 356-447. Domains 1 and 2 are involved in RNA replication and domain 1 is involved in cellular lipid drop binding, domain 3 is essential for viral assembly and is involved in interaction with the core protein accumulated in cellular lipid drops<sup>[27,91]</sup>. Although studies showed that NS5A is critical for HCV RNA replication, deletions in D2 and D3 are tolerated in RNA replication<sup>[97]</sup>, and viable replicons and viruses harboring GFP insertions displayed no change on HCV RNA replication<sup>[98]</sup>. Phosphorylation of a specific serine residue within C-terminal by casein kinase II  $\alpha$  is essential for virus assembly<sup>[99]</sup>. The interaction of NS5A with the cytosolic lipid droplets-bound core protein is a key step in HCV assembly<sup>[97,100,101]</sup>.

NS5B is an RNA-dependent RNA polymerase (RdRp). Its crystal structure was revealed in 1999<sup>[102]</sup>, the active site is highly conserved and located in the palm subdomain<sup>[91]</sup>. The low substrate specificity allows for the incorporation of ribavirin into nascent RNA. Thus, ribavirin remains a perfect RNA analog in HCV therapy<sup>[103]</sup>. Although recombinant NS5B is available and its crystal structure is known<sup>[104,105]</sup>, its role in HCV RNA replication remains unclear (Table 3).

### 5'-non-translated regions and 3' non-translated regions

Viral non-translated regions (NTRs) and non-coding regions, harbor important biological functions, involving viral genome reorganization, replication, translation initiation, and viral assembly<sup>[106]</sup>. The HCV 5'NTR contains 341 bp (H77 strain, NCBI Reference Sequence: NC\_004102.1)<sup>[107]</sup>. The predicted secondary structure of the HCV 5'NTR consists of four domains (domains I-IV, numbered from 5' to 3'), and the largest domain III was further categorized into sub-domains a-f<sup>[107]</sup>. The major functional unit in the HCV 5'NTR is an IRES, which includes three domains (II-IV)<sup>[106-109]</sup>. Initiation of protein synthesis in host cells utilized by HCV is different from mRNA translation in eukaryotes because HCV initiates viral protein synthesis *via* its IRES, which is known as internal translation initiation. This process is a cap-independent mechanism of recruiting, positioning and activating the host cellular protein synthesis machinery driven by the HCV IRES<sup>[106-109]</sup>, which is relatively weak in directing protein translation compared to the IRESs of other viruses, and may contribute to an insufficient host immune response<sup>[110]</sup>. Although structural and biochemical stud-

ies of the IRES found in HCV have provided the most detailed information thus far regarding the mechanism of IRES driven translation, unresolved issues remain. For example, it is unknown whether the HCV IRES acts as one determining factor for hepatotropism or how the HCV 5'NTR interacts with the 3'NTR to support HCV RNA replication and polyprotein translation. Additionally, the biological impact of the NTR to each hepatitis virus remains unclear since the HCV NTRs have a different structure compared to those of hepatitis A and E viruses. Finally, the interaction of miR-122 with the HCV 5'NTR to facilitate replication of viral RNA remains to be fully elucidated<sup>[111]</sup>.

The 3' terminal of any genome is technically difficult to identify and the available complete sequence of the HCV 3'NTR is unusual. The 3' UTR is divided into three structurally distinct domains from 5' to 3', an upstream variable region of about 40 nucleotides, a long poly (U)-poly (U/UC) tract and a 98-nucleotide (3' X) sequence that forms three stem-loop structures<sup>[43,106]</sup>. The long poly (U)-poly (U/UC) tract was a major obstacle to obtaining an HCV genomic clone because no known DNA polymerase could amplify this region and the fidelity of a reverse transcriptase in this region was suspect. The function of the 3' UTR remains to be determined<sup>[43,106]</sup>. It may play an important role in minus intermediate RNA and genome RNA synthesis during HCV RNA replication<sup>[43,106]</sup> since variable region deletions of RNA replicons could replicate, albeit at a much lower level<sup>[112]</sup>. However, deletion of either the poly (U/UC) or the 3' X was not viable, which suggested that the poly (U/UC) and 3'X regions are critical for HCV RNA replication<sup>[107]</sup>.

### HuH7 cell line

HCV researchers should be familiar with the human hepatocellular carcinoma cell line HuH-7, also known as Huh7 or HuH7. This cell line is critical because the HCV replicon, HCVcc, and HCVpp are all dependent on this cell line or its derivatives, indicating that it harbors all critical factors for HCV replication, assembly, budding and entry<sup>[43,113-115]</sup>. HuH-7 is a well-differentiated hepatocyte-derived hepatocellular carcinoma cell line that originated from a liver tumor in a 57-year-old Japanese male in 1982 (<http://huh7.com/>). It was established by scientists at Okayama University of Japan in the 1980s (<http://cellbank.nibio.go.jp/legacy/celldata/jcrb0403.htm>). HuH-7 remains the only hepatocellular carcinoma cell line that can fully support the HCV life cycle. Improvements in hepatocellular carcinoma cell line isolation could provide more effective HCV-supporting cell lines; alternatively the advances in induced pluripotent stem cells could result in a breakthrough in HCV culture and isolation.

## SCOTOMAS IN EPIDEMIOLOGY OF HCV

HCV carries a large disease burden in some countries and is the second most studied virus. Most HCV infections are subclinical with a long and insidious disease

**Table 4 Epidemiological features of hepatitis C virus infection**

Epidemiological index	Current consensus
Source of infection	Chronic HCV carriers
Route of transmission	HCV transmission occurs primarily through exposure to infected blood. Past: Receiving infected blood or organ transplantation, from accidental exposure to infected blood, and sexual transmission in persons with high risk behaviours. Present: HCV is usually spread by sharing infected needles with a chronic HCV carrier, and some people acquire the infection through nonparenteral means that have not been fully defined.
Susceptible population	General population
Incubation period	Average 6-10 wk
Prevalence and incidence	3% of the world's population have HCV
Rate of chronic infection	Up to more than 80%
Outcome of chronic infection	10%-20% of chronic HCV carriers may develop into cirrhosis and liver failure. 1%-5% of chronic HCV carriers are associated with the development of hepatocellular carcinoma
Molecular epidemiology	HCV is classified into eleven major genotypes (designated as 1-11), many subtypes (designated a, b, c, etc.), and about 100 different strains (numbered 1, 2, 3, etc.) based on the genomic sequence heterogeneity. Genotypes 1-3 have a worldwide distribution. Types 1a and 1b are the most common, accounting for about 60% of global infections. Type 2 is less frequently represented than type 1. Type 3 is endemic in southeast Asia and is variably distributed in different countries. Genotype 4 is principally found in the Middle East, Egypt, and central Africa. Type 5 is almost exclusively found in South Africa, and genotypes 6-11 are distributed in Asia.
Stability	HCV is inactivated by exposure to lipid solvents or detergents, heating at 60 °C for 10 h or 100 °C for 2 min in aqueous solution, formaldehyde (1:2000) at 37 °C for 72 h, $\beta$ -propiolactone and UV irradiation.
Vaccine	Not available

HCV: Hepatitis C virus.

course. However, epidemiological surveillance of HCV is relatively weak compared to some acute respiratory transmission diseases ([http://www.who.int/influenza/surveillance\\_monitoring/en/](http://www.who.int/influenza/surveillance_monitoring/en/)).

Chronic HCV carriers are the only reservoir of HCV since chimpanzees could be infected with HCV only experimentally<sup>[43,106]</sup>. HCV transmission occurs primarily through exposure to HCV-infected blood<sup>[43,106]</sup>. Blood transfusion, solid organ transplantation from an infected donor, and unsafe medical practices were the major transmission routes before HCV was identified in 1989<sup>[43,106]</sup>. Beginning in the early 1990s, strict screening of blood donors and precise control over the blood supply were implemented by national governments<sup>[43,106,116]</sup>. The majority of HCV infections are now limited to specific subpopulations, such as intravenous drug users and patients with certain hemopathies<sup>[117]</sup>. Although unsafe medical practices, occupational exposure to infected blood, maternal-fetal transmission, sex with an infected person and high-risk sexual practices are believed to be HCV transmission routes, the rate of acquisition of infection by these routes is low<sup>[118]</sup>. The average incubation period is 6-10 weeks and most virologists and hepatologists consider that up to 80% of HCV infected persons do not eliminate HCV spontaneously<sup>[43,106]</sup>. Cirrhosis and liver failure develop in 10%-20% of chronic HCV carriers; 1%-5% of chronic HCV carriers develop hepatocellular carcinoma<sup>[43,106]</sup> (Table 4).

The World Health Organization estimates that up to 3% of the global population is infected with HCV (<http://www.who.int/csr/disease/hepatitis/Hepc.pdf>), and the peak disease burden is expected around 2020<sup>[119]</sup>. However, these estimations lack sufficient evidence. Firstly, it is hard to track the origin of the data since most authors citing this statistic used inaccurate citations.

Secondly, the HCV serological detection kit has undergone at least three iterations<sup>[117]</sup>. The first test developed in 1990 detected antibody to a single epitope within the core protein by enzyme linked immunosorbent assay and provided data on 170 million HCV carriers, even though it was plagued by poor sensitivity<sup>[43]</sup>. Third-generation enzyme immunoassays included antibodies against multiple antigens, which increased the sensitivity significantly<sup>[43]</sup>, although no large-scale serological investigations have been performed. In China, a nationwide HCV serological survey performed in 2006 showed the prevalence of anti-HCV antibodies to be < 0.5% among more than 80000 Chinese subjects<sup>[116]</sup>. Furthermore, the rates of HCV were much lower than those of hepatitis B among clinical inpatient and outpatient populations, which was significantly different from a Japanese population<sup>[119,120]</sup>. Epidemiology is important because it will provide basic knowledge of disease and inaccurate epidemiological data will lead to inaccuracies in our knowledge of the disease burden, natural history and therapeutic efficacy.

The number of people that will become chronic carriers after HCV infection remains unknown. Scientists believe that as many as 40%-80% of HCV infections will develop into chronic infections<sup>[121-123]</sup> (Table 3). While these estimates are also likely inaccurate, how and when people are infected must be determined to ascertain a more precise figure. One recent cross-sectional study performed in intravenous drug users challenged the current assumptions regarding the rate of chronic infection; in that study as many as 77.8% of individuals cleared HCV infection without the need for anti-viral therapy<sup>[117]</sup>.

### Abstract

Extended hepatectomy, or liver transplantation of reduced-size graft, can lead to a pattern of clinical manifestations, namely "post-hepatectomy liver failure" and "small-for-size syndrome" respectively, that can range from mild cholestasis to irreversible organ non-function and death of the patient. Many mechanisms are involved in their occurrence but in the recent past, high portal blood flow through a relatively small liver vascular bed has taken a central role. Therefore, several techniques of inflow modulation have been attempted in cases of portal hyperperfusion first in liver transplantation, such as portocaval shunt, mesocaval shunt, splenorenal shunt, splenectomy or ligation of the splenic artery. However, high portal flow is not the only factor responsible, and before major liver resections, preoperative assessment of the residual liver function is necessary. Techniques such as portal vein embolization or portal vein ligation can be adopted to increase the future liver volume, preventing post-hepatectomy liver failure. More recently, a new surgical procedure, that combines *in situ* splitting of the liver

and portal vein ligation, has gradually come to light, inducing remarkable hypertrophy of the healthy liver in just a few days. Further studies are needed to confirm this hypothesis and overcome one of the biggest issues in the field of liver surgery.

**Key words:** Small-for-size syndrome; Liver transplantation; Extended hepatectomy; Liver failure; Cirrhosis

**Core tip:** In this review we focus on the small-for-size syndrome and post-hepatectomy liver failure, the most feared complications of liver surgery, fundamentally similar in pathogenesis and clinical manifestations, occurring when the residual liver is not large enough to accommodate the markedly increased portal vein blood flow. Our aim is to simplify a concept, which has been a major concern in hepatic surgery for some time. Many efforts have been and are being made to overcome such an important problem in this field.

Liver function impairment in liver transplantation and after extended hepatectomy. *World J Gastroenterol* 2013; 19(44): 7922-7929 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/7922.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7922>

### INTRODUCTION

The liver is a unique organ, capable of regeneration and functional recovery after parenchymal injury. When the volume is too small to satisfy the metabolic demand, the liver loses this peculiar ability, resulting in delayed synthetic dysfunction with poor bile production, coagulopathy, prolonged cholestasis and intractable ascites, which can lead to septic complications and high mortality. The

term “small-for-size syndrome” (SFSS) was first<sup>[1]</sup> coined in liver transplantation as a consequence of size mismatch between graft and recipient, an event occurring especially in the setting of living donor liver transplantation (LDLT) or split liver transplantation<sup>[2]</sup>, where the use of partial grafts has gained worldwide acceptance to overcome the shortage of cadaveric organs. However, the same concept can also be applied to the field of liver resection, where patients with marginally resectable tumors are at high risk of developing post-hepatectomy liver failure (PHLF)<sup>[3]</sup>, a clinical manifestation comparable to the SFSS.

## DEFINITION

There is not full consensus about the definition of SFSS. It was introduced in 1996 by Emond *et al*<sup>[1]</sup> and regarded the clinical manifestation following transplantation of small grafts in LDLT. The term SFSS on the basis of personal working experience, and no threshold values of liver function tests, was suggested. In 2005, Dahm *et al*<sup>[4]</sup> proposed a more precise definition. These authors described SFSS after liver transplantation as the presence of two of the following criteria recorded on three consecutive postoperative days: serum bilirubin > 100  $\mu\text{mol/L}$  (6 mg/dL), international normalized ratio (INR) > 2 and presence of encephalopathy grade III or IV. The small-for-size syndrome usually occurs during the first postoperative week and is diagnosed after the exclusion of other causes such as technical complications (*e.g.*, arterial or portal occlusion, outflow congestion, bile leak) and/or rejection or infections (*e.g.*, cholangitis, sepsis).

The same concept is applicable to the field of hepatic surgery, where extended resections can lead to the development of PHLF. Many different definitions of PHLF have been proposed in the literature<sup>[5-7]</sup>. In trying to propose a more standardized definition, in 2011, Rahbari *et al*<sup>[7]</sup> suggested a simple and easily applicable definition of PHLF as a “postoperative acquired deterioration in the ability of the liver to maintain its synthetic, excretory and detoxifying functions, which are characterized by an increased INR and concomitant hyperbilirubinemia on or after postoperative day 5”. They differentiated severity in three grades (A, B, C), according to whether changes in clinical management of the patient or invasive treatments are required. It is of interest that even if SFSS and PHLF can be viewed as the same manifestation of liver function impairment, the two terms and their relative definitions are currently separated. It would probably be of interest to join the two definitions into a single one, but at present no suggestions, regarding this topic, are present in the literature.

## PATHOPHYSIOLOGY

The magnitude of the effect of increased portal flow after hepatectomy on the development of PHLF, though recognized, is currently not yet well established and most

of the studies regarding this topic come from the transplantation experience.

High portal blood venous flow (PVF) has gained a central role in the pathogenesis of SFSS. Under normal physiological conditions, portal vein blood flow accounts for 75% of total hepatic inflow, or 90 mL/min per 100 g of liver tissue, while the hepatic artery contributes for 20%-25%<sup>[8]</sup>. The portal vein lacks intrinsic auto-regulation. Hence, after extended hepatectomy or transplantation of small grafts, the remnant liver is subjected to the portal flow destined to a whole liver, through a reduced micro-vascular bed<sup>[9]</sup>. Such a substantial increase of PVF and shear-stress on sinusoidal lining cells is inversely related to graft size. In > 75% partial hepatectomy, PVF increases by more than twice the baseline values, resulting in PHLF, with high morbidity and mortality<sup>[10]</sup>. Although shear-stress is considered to be a necessary stimulus for hepatic regeneration<sup>[11]</sup>, excessive forces can be detrimental to both the function and survival of the reduced-size organ: the result is damage of sinusoidal spaces with release of inflammatory cytokines, responsible for progressive hepatocyte necrosis<sup>[12]</sup>. Pathological findings include hepatocyte ballooning, tremendous mitochondrial swelling, irregular large gaps between sinusoidal lining cells, and collapse of the space of Disse<sup>[13]</sup>.

Although portal vein pressure (PVP) is considered a reliable predictor of graft failure<sup>[14]</sup>, the latter and PVF do not run parallel to each other; furthermore, the lack of correlation between graft weight/recipient body weight ratio (GRWR) and PVP has been investigated<sup>[15]</sup>.

Blood flow regulation, which allows a steady rate of hepatic perfusion, depends not only on the classical arterial intrinsic regulation but also on an inverse relationship between portal and hepatic arterial flow, also known as hepatic arterial buffer response (HABR)<sup>[16]</sup>. When the portal blood flow increases, this leads to an elevated wash-out of adenosine levels in the space of Mall, contracting the hepatic artery<sup>[17]</sup>. Adenosine is unlikely to be the sole vascular regulator and other vaso-active compounds may contribute to HABR<sup>[18]</sup>. The consequences of such a diminished arterial blood flow manifest in the peripheral circulation as a centrilobular microvesicular steatosis or infarcts, or, in severely affected cases, as ischemic cholangitis in the hilum<sup>[19]</sup>. Hence, the clinical manifestations can range from mild cholestasis to liver failure. However, the optimal rate needed to sustain liver regeneration and function, without damage to the liver, is still not known and further experimental studies on animal models are needed.

## PREOPERATIVE PREDICTION

Hepatectomy remains the first curative option for neoplasms of the liver. The mortality rate after major liver resections, *i.e.*, the removal of three or more Couinaud segments, ranges from 3% to 7% in non-injured liver parenchyma and increases up to 32% in patients with cirrhosis<sup>[20]</sup>. Thus, the extent of parenchymal resection

**Table 1 Predictive factors of small-for-size syndrome and post-hepatectomy liver failure**

Liver volume	Liver function	Patient-related	Other
FLR/TLV	CHILD-PUGH	CALI	Cholestasis
GRWR or GV/SLV	HVPG	Age > 65 yr <sup>[37]</sup>	Liver stiffness <sup>[31]</sup>
	ICG	Male sex <sup>[37]</sup>	Donor factors <sup>[44]</sup>
	MEGX <sup>[30]</sup>	Diabetes mellitus <sup>[37]</sup>	

FLR: Future liver remnant; TLV: Total liver volume; GRWR: Graft weight-recipient body weight ratio; GV: Graft volume; SLV: Standard liver volume; HVPG: Hepatic vein pressure gradient; ICG: Indocyanine green clearance; MEGX: Monoethylglycinexylidide; CALI: Chemotherapy-induced liver injury.

is an essential parameter in establishing both the operability of each patient and the risk of PHLF and this, to date, is still a subject of debate, probably due to different methods of measurement, variability in the segment volumetric distribution and degree of underlying disease.

The 3D volumetric computed tomography reconstruction allows preoperative calculation of the liver volume, even of the single segments, and, more important, of the future liver remnant (FLR). With a normal function, FLR should range between 20% and 30% of total liver volume, whereas smaller volumes are correlated with increase of liver failure and infections<sup>[21,22]</sup>. Care must be taken when an underlying liver disease pre-exists. In “injured” livers, (steatosis, cholestasis, fibrosis, cirrhosis or chemotherapy) the FLR should be greater than 30%-40%<sup>[23]</sup>. Therefore, an accurate preoperative assessment of liver function is needed.

In patients with cirrhosis, the Child-Pugh score and the hepatic vein pressure gradient are the two most important restrictive criteria in selecting candidates for surgery<sup>[24,25]</sup> even if they do not provide precise assessment of liver resectability<sup>[26]</sup>. Metabolic tests based on the detoxifying properties of the liver have the advantage of providing a more reliable estimation of the hepatic function, and they are based on quantitative measures. Indocyanine green clearance is the most popular test<sup>[27]</sup>, especially in Eastern countries, where it constitutes the pillar of preoperative algorithms for liver resection<sup>[28,29]</sup>. Other quantitative tests, such as the monoethylglycinexylidide<sup>[30]</sup> test, have led to good prediction of PHLF, but they have gained less popularity and are not routinely used. A simple and non-invasive method of measurement of liver stiffness (Fibroscan<sup>®</sup>) has recently been gaining broad consensus for predicting PHLF in selected patients<sup>[31]</sup>, but further studies are needed to establish its potential role in patient selection for surgery.

Chemotherapy-induced liver injury is common in patients that received chemotherapy for colorectal liver metastases, and the two typical patterns are sinusoidal injury (sinusoidal obstruction syndrome) in oxaliplatin-based regimens, and steatohepatitis (CASH), associated with irinotecan treatment<sup>[32]</sup>. More than 6 cycles of oxaliplatin need a longer time interval before major hepatectomy, even though accountability for PHLF still remains a matter of debate<sup>[33]</sup>, whereas irinotecan is associated with

an increased risk of peri-operative mortality after hepatectomy<sup>[34]</sup>. Biopsy of the liver before surgery might be helpful to assess the grade of steatosis or the histological features of CASH, thus defining more precise windows between drug administration and surgery.

Cholestasis impairs liver regeneration, and levels of bilirubin above 2.9 mg/dL are related to a higher rate of liver failure after major hepatectomy<sup>[35]</sup>. Nevertheless, the use of preoperative biliary drainage is still controversial, except for acute cholangitis or small FLR that are candidates for portal vein embolization<sup>[36]</sup>, in which case biliary drainage is highly recommended. Besides such patient-related factors, others, like age > 65 years, male sex and diabetes mellitus, are related to a high risk of PHLF<sup>[37]</sup>. Obesity is not per se a major predictor of liver failure<sup>[38]</sup>.

In the setting of transplantation, liver volume assessment is represented by the GRWR or graft volume/standard liver volume ratio (GV/SLV): in LDLT safe thresholds are at least 0.8% of GRWR or 30%-40% of GV/SLV<sup>[2,39,40]</sup>, with greater values in patients affected by portal hypertension or advanced chronic liver disease. There are reports on the successful use of smaller grafts<sup>[41]</sup>, but in association with some intraoperative inflow modulations: a case report of a left lobe LDLT as low as 0.34% of GRWR underwent splenectomy and did not develop post-operative SFSS<sup>[42]</sup>. In liver transplantation, size is not always the sole factor responsible for graft post-transplant liver function<sup>[43]</sup>, because graft quality is likewise important in order to avoid liver dysfunction or other complications. Aside from basic requirements for donor livers, the following donor factors have a negative impact on graft prognosis: age > 50 years, prolonged intensive care unit stay > 5 d, hypernatremia, prolonged cardiac/respiratory arrest and long ischemia times, administration of high dosage of vasopressors, severe systemic sepsis, steatosis > 30%, anatomic variations in vascular structure and, obviously, abnormal liver function, particularly with elevated serum bilirubin and gamma glutamyltransferase<sup>[44]</sup>.

Prediction of SFSS and PHLF is feasible and is based on the calculation of liver volume up to the assessment of liver function. Evaluation of patient status can help to find the best candidate for surgery. In the field of liver transplantation, donor characteristics also have to be taken into account, defining which grafts are at higher risk of developing SFSS than others. A list of the above mentioned factors is shown in Table 1.

## ATTENUATING SFSS IN LIVER TRANSPLANTATION

In the presence of high portal blood flow and/or small grafts (GRWR < 0.8%), several different technical flow manipulations can be performed to overcome graft hyperperfusion and reduce PVF, although there is no full consensus about their indications: portocaval shunt, mesocaval shunt, splenorenal shunt, splenectomy or ligation of the splenic artery. Boillot *et al*<sup>[45]</sup> reported the first

successful mesocaval shunt with downstream ligation of the superior mesenteric vein in a left lobe transplantation (GRWR of 0.61%), based on previous experimental studies on pigs.

Hemi-portocaval shunt, *i.e.*, anastomosis between the left or the right portal branch and the inferior vena cava in a permanent fashion, is advocated by Troisi *et al.*<sup>[10]</sup> whenever the PVF at reperfusion exceeds three-four times the one recorded in the donor. None of the patients undergoing such a graft inflow modulation developed SFSS, with significant decrease of portal vein flow.

The effects of splenic flow diversion have been investigated in the presence of portal hypertension (PVP > 20 mmHg)<sup>[15]</sup> and/or of portal hyperperfusion (PVF > 250 mL/min per gram)<sup>[46]</sup>. However, when PVF exceeds 500 mL/min per gram, portosystemic shunt cannot be avoided.

Both splenic artery ligation (SAL) and splenectomy can be performed and are comparable in terms of outcome and overall survival<sup>[47]</sup>, although for the latter, septic complications must always be taken into account. Splenectomy is considered superior to SAL for the purpose of increasing white balance and platelet count after LDLT, which is not achieved by SAL alone.

Splenic artery embolization represents a valid alternative to achieve portal decompression<sup>[48]</sup>. Furthermore, a linear correlation between PVF and graft-to-recipient spleen size ratio has been found, thus including the spleen size as a likely predictor of post-transplant portal hyperperfusion and SFSS<sup>[49]</sup>.

Techniques of graft inflow modulation account for a certain risk of steal phenomenon<sup>[50]</sup>: portal vein thrombosis, encephalopathy, septic complications or hampered liver regeneration are described as principal side effects. It remains an open question whether and when portosystemic shunts should be removed<sup>[51]</sup>, since hypoperfusion, as well as hyperperfusion, can also be detrimental for liver function.

According to the definition of Dahm *et al.*<sup>[4]</sup>, who stated that SFSS should be considered as a distinct entity, outflow obstruction per se should be excluded as a possible trigger, as it may reduce the hepatic function. However, one of the most discussed topics concerns the reconstruction of the middle hepatic vein (MHV) in right lobe grafts, since congestion of anterior segments (V-VIII) may lead to graft dysfunction<sup>[52]</sup>. A graft with inclusion of the MHV has been demonstrated to be technically and physiologically superior, but the use of this technique should be limited to selected cases in LDLT due to an increased risk for donor safety<sup>[53]</sup>. For MHV reconstruction, several transplant centers use various types of vascular grafts, with a predilection for large caliber autologous vessels (*i.e.*, the superficial femoral vein), or also cryopreserved venous or arterial grafts<sup>[54]</sup>.

future metabolic demand, a number of strategies can be adopted to increase the liver volume, preventing post-hepatectomy liver failure. Portal vein embolization (PVE) has become the most standardized procedure due to its safety and feasibility: it consists in the occlusion of portal flow ipsilateral to the lesion, inducing hypertrophy in the contralateral lobe. Makuuchi *et al.*<sup>[55]</sup> first used this technique in 1982 to extend the limits of hepatic resection, thus increasing the number of cases suitable for curative surgery: in this early report, 14 patients underwent pre-operative PVE followed by major liver resection 6-41 d after embolization, with no occurrence of postoperative liver failure. After almost 30 years, the indications of PVE are still very poorly standardized: many authors indicate a residual liver volume less than 30% of total liver volume or up to 40% in injured livers as the critical threshold<sup>[56,57]</sup>. Surgery is usually performed 2-8 wk after PVE, with future liver remnant volume increased by 10%-46%. From 70% to 100% of patients who underwent PVE, hemi-hepatectomy or extended hepatectomy could be performed. Following resection, the perioperative morbidity and mortality was less than 15% and 0%-7%, respectively<sup>[58-60]</sup>.

Portal vein ligation (PVL) represents a good alternative, although there are no controlled studies clearly showing the superiority of PVE *vs* PVL. Portal vein ligation requires laparotomy and, furthermore, the volume gain is often limited due to formation of collaterals between the two different lobes<sup>[20]</sup>. PVL is not considered such a standardized and safe procedure as PVE, but patients who are candidates for 2-stage hepatectomy can benefit from this technique<sup>[61,62]</sup>, recently adopted in a new surgical approach aimed at enhancing and accelerating the regeneration of the remnant liver<sup>[63]</sup>. In 2009, Schnitzbauer *et al.*<sup>[63]</sup> reported on a case series of 25 marginally resectable patients with massive involvement of the right lobe by neoplastic nodules, on which an innovative 2-step technique was carried out. In the first step, right portal vein ligation and *in situ* splitting of the liver on the right side of the falciform ligament was performed; in the second step, after a median time interval of 9 d, extended hepatectomy (right trisectionectomy) was completed. The observed median increase in volume of the left lobe was 74%, but morbidity and mortality were significant (68% and 12%, respectively). Thereafter, the so-called advanced liver partition and PVL for staged hepatectomy, also known by the acronym ALPPS<sup>[64]</sup>, has spread to many centers worldwide: the obtained median increase in volume ranges from 74% up to 87%, with surgery usually performed 5-30 d after the first step. However, mortality rates of 13%-22% are still reported<sup>[65-68]</sup>. Although the procedure is innovative and attractive, these latter figures make it imperative to increase the number of patients treated with this strategy to better define its feasibility and limits<sup>[69]</sup>.

In addition to the above, more studies are needed to understand the exact mechanisms of hepatic regeneration, also through biopsy of the remnant liver before and after hepatectomy, and measurements of portal flow

## ATTENUATING PHLF IN EXTENDED HEPATECTOMY

If the remnant liver volume is not sufficient to meet the

and pressure should be provided. In fact, although the preserved functional capacity of the hypertrophied remnant liver could be established with functional tests (*e.g.*, indocyanine green clearance) and through the uptake of  $^{99m}\text{Tc}$  dimethyl iminodiacetic acid<sup>[64]</sup>, excessive portal flow represents one of the main problems, determining a possible discrepancy between the relevant increase in volume and the amount of actually functioning parenchyma. de Santibañes *et al*<sup>[70]</sup>, in 2012, claimed that the diseased right hemi-liver, left in place, acts as an auxiliary liver to assist the future liver remnant for the first and critical week after resection, but in true auxiliary transplantation, both the portal and arterial flows to two hemi-livers are maintained. Thus, contrary to auxiliary transplantation, in which the growth and functional recovery may progress harmonically with a real portal flow modulation, this phenomenon is not certain after extended hepatectomy with a small residual parenchyma. In other words, how can this “beneficial” re-direction of the entire portal flow to a “small-for-size” remnant liver comply with established principles of portal flow modulation in small-for-size transplantation? Research in animal models clearly shows that a portocaval shunt has a positive effect in attenuating liver injury after extensive hepatectomy, suggesting that a slower regeneration following reduction of portal flow may be more advisable than faster regeneration associated with temporary portal hyperflow<sup>[71,72]</sup>. In this view, more insights on the mechanisms and features of liver regeneration are needed to better understand the potential benefit of portal flow modulation to prevent postoperative liver failure<sup>[64]</sup>.

## PHARMACOLOGICAL INTERVENTIONS

Many drugs have been demonstrated to be effective in attenuating SFSS after living donor liver transplantation of small grafts, but most of them have been tested only in animal models<sup>[73,74]</sup>, whereas clinical trials on human beings are still lacking. Furthermore, pharmacological portal flow modulation has been investigated: shear-stress attenuation has been achieved by somatostatin<sup>[75]</sup>, through down-regulation of the endothelin-1 (sinusoidal vasoconstrictor) and up-regulation of heme-oxygenase-1 (vasodilator and antioxidant). Nitric oxide pathway activation seems to be protective against ischemia-reperfusion injury both in liver resection and liver transplantation<sup>[76]</sup>. Therapeutic agents promoting liver regeneration, such as serotonin, are still a matter of debate for their controversial role<sup>[77]</sup>. Recently, autologous bone marrow stem cells have been used to increase liver regeneration prior to major liver resection. In particular, an enhanced parenchymal growth after portal vein embolization through the portal injection of CD133<sup>+</sup> cells (in the non-embolized hepatic lobe) has been demonstrated, with a subsequent improvement of outcome after surgery<sup>[78]</sup>. Even though the specific effect of CD133<sup>+</sup> cells is not completely understood<sup>[79]</sup>, this approach is intriguing due to the possibility of combination with other techniques

favoring post-transplant or post-hepatectomy liver function recovery, such as procedures of portal flow modulation.

## CONCLUSION

Post-hepatectomy liver failure and small-for-size liver syndrome can be viewed as two sides of the same coin, since both of them can lead to an identical pattern of clinical manifestations, that is cholestasis, impairment of coagulation and development of ascites, and that can range up to irreversible organ non-function and death of the patient. Safe thresholds of remnant liver volume differ between liver transplantation and after extended hepatectomy, probably due to graft denervation, immunosuppressive therapy and severity of ischemia-reperfusion injury. However, preoperative assessment of liver function and size is crucial, while intraoperative recording of hemodynamic changes, before and after hepatectomy or liver transplantation, should be mandatory in order to perform inflow modulation, if necessary. Other strategies, which include pharmacological perioperative protection of the liver and stem cell injection, are being explored, but further studies are needed before they can be applied in the clinical field.

**Key words:** Exocrine pancreatic insufficiency; Chronic pancreatitis; Gastric surgery; Pancreatic surgery; Pancreatic neoplasms; Risk factors; Clinical studies

**Core tip:** Pancreatic exocrine insufficiency represents a condition related to pancreatic and extrapancreatic disease. We have reviewed the evidence related to the pathophysiological aspects of exocrine pancreatic diseases and we have also reported the recommendations for treating this condition in the most common pancreatic and extrapancreatic diseases. Pancreatin minimicrospheres is a drug which is cost-effective according to a survey of Polish patients, but studies demonstrating its cost-efficacy in Italy are necessary.

### Abstract

This is a medical position statement developed by the Exocrine Pancreatic Insufficiency collaborative group which is a part of the Italian Association for the Study of the Pancreas (AISP). We covered the main diseases associated with exocrine pancreatic insufficiency (EPI) which are of common interest to internists/gastroenterologists, oncologists and surgeons, fully aware that EPI may also occur together with many other diseases, but less frequently. A preliminary manuscript based on an extended literature search (Medline/PubMed, Cochrane Library and Google Scholar) of published reports was prepared, and key recommendations were proposed. The evidence was discussed at a dedicated meeting in Bologna during the National Meeting of the Association in October 2012. Each of the proposed recommendations and algorithms was discussed and an initial con-

### INTRODUCTION

This is a medical position statement developed by the Exocrine Pancreatic Insufficiency collaborative group

which is a part of the Italian Association for the Study of the Pancreas (AISP). We covered the main diseases associated with exocrine pancreatic insufficiency (EPI) of common interest to internists/gastroenterologists, oncologists and surgeons, fully aware that EPI may occur in many other diseases, but less frequently (Giardia and HIV infections, lymphoma, Whipple's disease, amyloidosis).

## LITERATURE SEARCH METHODS

A preliminary manuscript based on an extended literature search (Medline/PubMed, Cochrane Library and Google Scholar) of published reports was prepared, and key recommendations were proposed. A MESH term "EPI" was used for the search on Medline/PubMed and key words (exocrine pancreatic insufficiency) were used for both Cochrane Library and Google Scholar. A total of 1465 manuscript were retrieved on Medline/PubMed, 64 on Cochrane Library and 1234 on Google Scholar. After deduplication only 282 papers regarding the specific aims of the study were selected and 151 were utilized. The evidence and recommendations were discussed at a dedicated meeting in Bologna during the National Meeting of the Association in October 2012 in which was present 130 participants. Each of the proposed recommendations and algorithms was discussed and an initial consensus was reached. The final draft of the manuscript was then sent to the AISP Council for approval and/or modifications. All concerned parties approved the final version of the manuscript in June 2013.

## PHYSIOLOGY OF PANCREATIC DIGESTION OF NUTRIENTS

The pancreatic secretion is a clear fluid liquid, 97% of which is water and electrolytes<sup>[1]</sup>, and 3% proteins. In turn, these are made up of proteins (3%) mainly represented by proteases (80%), amylase (7%), lipase (4%) and nucleases (1%)<sup>[2]</sup>. The normal absorption of nutrients involves a complex mixture of digestive enzymes and bile salts, and an intact intestinal mucosa to enable the uptake of these hydrophobic complexes. Under normal condition, all major pancreatic enzymes act simultaneously with postprandial chyme decrease during duodenal-ileal transit<sup>[3]</sup>; the rate of intraluminal degradation differs widely among the major enzymes due to their different stability regarding inactivating mechanisms<sup>[4]</sup>. Pancreatic amylase is a very stable enzyme, probably because of its high resistance to enzymatic proteolysis<sup>[5]</sup>; the majority of that released into the duodenum reaches the terminal ileum in an active form<sup>[4,6,7]</sup> whereas approximately 60% of the protease activities released into the duodenum are delivered to the mid-jejunum, and only between 20% and 30% reach the terminal ileum<sup>[4]</sup>. As regards lipolytic enzymes, lipase is most susceptible to inactivation during small intestinal transit. In the absence of triglycerides, a large proportion of lipase activity is also lost between the duodenum and the jejunum, and only small quantities

**Table 1 Causes of pancreatic insufficiency**

### Chronic pancreatitis

Primary pancreatic insufficiency
Agenesis of the pancreas
Congenital pancreatic hypoplasia
Shwachman-Diamond syndrome
Johanson-Blizzard syndrome
Adult pancreatic lipomatosis or atrophy
Isolated lipase or colipase deficiency
Pancreatic resection
Pancreatic cancers
Secondary pancreatic insufficiency
Mucosal small bowel disease: Decreased cholecystokinin release
Somatostatinoma or exogenous somatostatin analog intake: Decreased pancreatic secretion
Gastrinoma: Intraluminal destruction of enzymes
Surgery and Billroth II anastomosis: Poor mixing or decreased hormone release, disturbance of innervations
Periampullary tumors (pancreatic duct obstruction)

Modified from reference 155.

are delivered to the terminal ileum<sup>[4,5]</sup>. After ingestion, dietary lipids are initially emulsified in the stomach and then hydrolyzed by the action of gastric and pancreatic lipase and colipase; hydrolyzed lipids are then aggregated into micelles or liposomes with the addition of bile salts in the duodenum and jejunum, the micelles are absorbed across the intact intestinal villi by both active and passive processes and, finally, packaged into chylomicrons within intestinal epithelial cells and transported to the circulatory system via the lymphatic system<sup>[8]</sup>.

## MECHANISMS OF EXOCRINE PANCREATIC INSUFFICIENCY

Exocrine pancreatic insufficiency results from a progressive loss of acinar pancreatic cells which leads to the secretion of an insufficient amount of digestive enzymes into the duodenum. As indicated in Table 1, chronic pancreatitis is the most well-known cause of EPI<sup>[9]</sup> but also several other conditions, such as partial or total surgical resection of the gland, loss of function of pancreatic tissue or obstruction of the main pancreatic duct as well as diabetes, celiac disease, inflammatory bowel diseases, and gastrectomy should also be considered. Maldigestion results when exocrine (mainly lipase and trypsin) pancreatic function is reduced by more than 90%; other pancreatic and extra-pancreatic causes of maldigestion are reported in Table 2<sup>[10]</sup>.

## CLINICAL MANIFESTATION AND ASSESSMENT OF EXOCRINE PANCREATIC INSUFFICIENCY

### Patient complaints

Patients with steatorrhea typically report an increase in daily bowel movements, with fatty, bulky stools which are

**Table 2 Pathogenesis of maldigestion**

Mechanism	Explanation
Decreased pancreatic production	Lack of functional tissue or decreased endogenous neurohormonal stimulation
Decrease in delivery	Pancreatic duct obstruction
Decreased activation	Low duodenal pH
Premature enzymatic degradation	Decreased contact time due to increased motility, impaired interaction with chyme and biliary salts, and intestinal bacterial overgrowth

difficult to flush away. This occurs mainly after high fat-containing meals and is sometimes not a daily symptom. As steatorrhea occurs after meals, it typically happens 2 to 3 times a day in individuals with a normal lipid-content diet. Weight loss and anorexia may also develop over time due to malnutrition.

### Physical examination

Chronic malabsorption results in weight loss, such as temporal scalloping, interosseous wasting, and lack of subcutaneous fat. Nail leukonychia due to hypoalbuminemia may be present in the late stages of chronic malabsorption. Signs of liposoluble vitamin lack may appear; ecchymoses due to clotting abnormalities in the case of vitamin K deficiency, ataxia and peripheral neuropathy resembling Friedreich ataxia due to vitamin E deficiency, abnormalities of night blindness and xerophthalmia (dry corneas) due to vitamin A deficiency; contraction or muscle spasms, osteomalacia and osteoporosis may also occur due to hypocalcemia. Examination of the stool is an important tool for recognizing steatorrhea.

### Investigations

Exocrine pancreatic function is currently diagnosed using two groups of tests, usually referred to as direct and indirect (or tubeless) tests; the principal tests are reported in Table 3. The most sensitive test is a direct test based on aspiration of the pancreatic contents during secretin or secretin-cholecystokinin/cerulein administration<sup>[11]</sup>; this test is only available in a few centers, it is invasive and is not indicated in clinical practice. Other tests currently available in clinical practice are indirect tests. At present, fecal elastase-1 determination is the most diffuse test for screening pancreatic exocrine insufficiency<sup>[12]</sup>, usually using a monoclonal test<sup>[13]</sup>. This test does not require the withdrawal of enzyme supplementation therapy and is based on analysis of a single stool sample. Concentrations of elastase-1 less than 200 µg/g in feces are compatible with exocrine pancreatic insufficiency and less than 100 µg/g are indicative of severe pancreatic insufficiency<sup>[14]</sup>. The <sup>14</sup>C-triolein breath test and the cholesteryl-[1-<sup>13</sup>C] octanoate breath test have been used for assessing fat malabsorption<sup>[15]</sup>; the D-xylose test (normal serum D-xylose concentration greater than 1.33 mmol/L 1 h after an oral dose of D-xylose) for exploring the malabsorption of carbohydrates, and fecal chymotrypsin excretion (normal > 6 U/g) for evaluating the malabsorption of proteins<sup>[12]</sup>.

Two other tests, not presently available commercially, are the N-benzoyl-L-tyrosyl-p-aminobenzoic acid (PABA) test and the pancreolauryl test which are based on the recovery of an ingested dose of PABA and fluorescein dilaurate from the urine<sup>[16]</sup>. In clinical trials, objective confirmation of excess fecal fat may be undertaken, and the following methods are usually used<sup>[9]</sup>: Sudan staining of random homogenized stool, steatocrit and quantitative fat analysis. Sudan staining evaluates the number and size of fat globules per high-power field (hpf), and the test results are scored as normal ( $\leq 20$ /hpf, 1 to 4 micrometers in size), moderately increased ( $> 20$ /hpf, 1 to 8 µm in size) and definitely increased ( $> 20$ /hpf, 6 to 75 µm in size)<sup>[17]</sup>. Compared to chemical fat analysis, Sudan staining has a sensitivity of 94% and a specificity of 95% for diagnosing abnormal fecal fat excretion<sup>[18]</sup>. Steatocrit is a quantitative measurement of fat and is expressed as a proportion of an entire centrifuged homogenized stool sample<sup>[19]</sup>. A spot acid steatocrit level (normal < 10%) has been reported as having a sensitivity of 100% and a specificity of 95% when compared to 72-h quantitative fat analysis<sup>[20]</sup>. The best reported method is the 72-h fat chemical analysis using the van de Kamer method. The patients need to keep a food diary to ensure that adequate dietary fat (100 g/d) is consumed during the test; the normal output is less than 7 g of fat per 24-h period<sup>[21]</sup>. Coefficient of fat absorption (CFA) should be used to better quantify the steatorrhea; it is calculated using the following equation:  $CFA (\%) = 100 [(mean\ fat\ intake - mean\ stool\ fat)/mean\ fat\ intake]$ <sup>[22]</sup>; in healthy subjects, the CFA is usually greater than 80%<sup>[23]</sup>.

A new assessment for pancreatic malabsorption which takes into consideration some serum parameters reflecting nutritional status (magnesium < 2.05 mg/dL, reduced serum levels of prealbumin, albumin, retinol binding protein, ferritin, and hemoglobin) has recently been reported<sup>[24]</sup>, but it requires further validation<sup>[25]</sup>.

Finally, bioelectrical impedance has been proposed for assessing nutritional status in patients with pancreatic cancer<sup>[26]</sup>. This method is based on the different conductive and resistive properties of the various body tissues; it is not invasive, it is inexpensive and it can be performed at the bedside. In brief, fixed low-voltage and high-frequency alternating current introduced into the body is conducted through the fluid compartment of the fat-free mass and it is able to measure both body resistance and capacitance. Capacitance causes the current to lag behind the voltage, creating a phase shift; this shift is quantified geometrically as the angular transformation of the capacitance: resistance ratio, also called phase angle.

### Pancreatic enzyme replacement therapy

In order to avoid maldigestion and ameliorate the nutritional status of patients with EPI, the cornerstone of treatment is pancreatic enzyme replacement therapy (PERT). Available formulations contain pancreatic enzymes encapsulated in microgranules or minimicrospheres with a pH sensitive coating in order to either

**Table 3** Indirect diagnostic tests for evaluating pancreatic exocrine insufficiency

Test	In favour	Against
CFA	Gold standard	72 h stool collection; 100 g standard diet; no simultaneous PERT; not pancreas specific
Acid steatocrit	Linear correlation with CFA also in a single sample; Good as screening	High fat diet needed; 24-72 h stool collection is ideal
Fecal elastase 1	Single stool sample; PERT can be continued	Poor sensitivity in mild EPI, watery stools and small bowel disease
<sup>13</sup> C-mixed triglyceride breath test	Simple; Also for mild forms of EPI and therapy assessment	Requires further validation
Fecal chymotrypsin	Good for compliance control; Single small stool sample	Sensitivity low for clinical practice (chymotrypsin is variably inactivated during intestinal transit); not for mild EPI; watery stools decrease enzyme activity; PERT must be discontinued
Secretin-enhanced magnetic resonance cholangiopancreatography	Morphological and semi-quantitative functional changes	Requires further validation
Nutritional status (magnesium < 2.05 mg/dL, ↓ prealbumin, ↓albumin, ↓retinol binding protein, ↓ferritin, ↓hemoglobin)	Simple	Requires further validation

CFA: Coefficient of fat absorption; PERT: Pancreatic enzyme supplementation therapy; EPI: Pancreatic exocrine insufficiency.

prevent the release and the subsequent inactivation of enzymes by gastric acidity or to release the enzymes into the intestinal lumen where the pH is higher and optimal for the digestion and absorption of food. Currently, the Italian guidelines also suggest minimicrospheres to be the ideal pancreatin formulation<sup>[9]</sup>.

The initial recommended dose of pancreatic extract which should be given is 40000-50000 units of lipase per meal and 25000 U per snack, and this dose should be progressively increased until the steatorrhea is totally or sufficiently reduced<sup>[27,28]</sup>; this dosage should be maintained over time.

### Dietary and drug recommendation

Food intake should be distributed between three main meals per day, and two or three snacks. The pancreatic extracts should be ingested during the meals.

Even if a diet which is low in fat reduces steatorrhea and improves maldigestion, it restricts caloric intake and is not a good option.

Medium-chain triglycerides (MCTs) have not been shown to be effective in patients suffering from chronic pancreatitis with EPI. Moreover, their poor palatability and high cost reduce patient compliance. Evidence exists that MCTs also require enzyme supplements for proper digestion and absorption<sup>[29]</sup>. They should be used only in patients with persistence of symptoms or weight loss despite adequate enzyme supplementation<sup>[30]</sup>. Medium-chain triglycerides have been proposed in PERT non-responders as an “ultima ratio”. The quantity of energy administered by MCTs is limited (ca 8.3 kcal/g) and the dose must be increased slowly in order to achieve intestinal adaptation, even when using enteral nutrition<sup>[31]</sup>. However, trials have shown no advantage between a normal balanced diet and MCT-enriched preparations<sup>[29,32,33]</sup>.

A diet rich in fiber content is contraindicated because the fibrous material will interfere with proteolytic and amylolytic enzyme activity; lipolytic activity is most af-

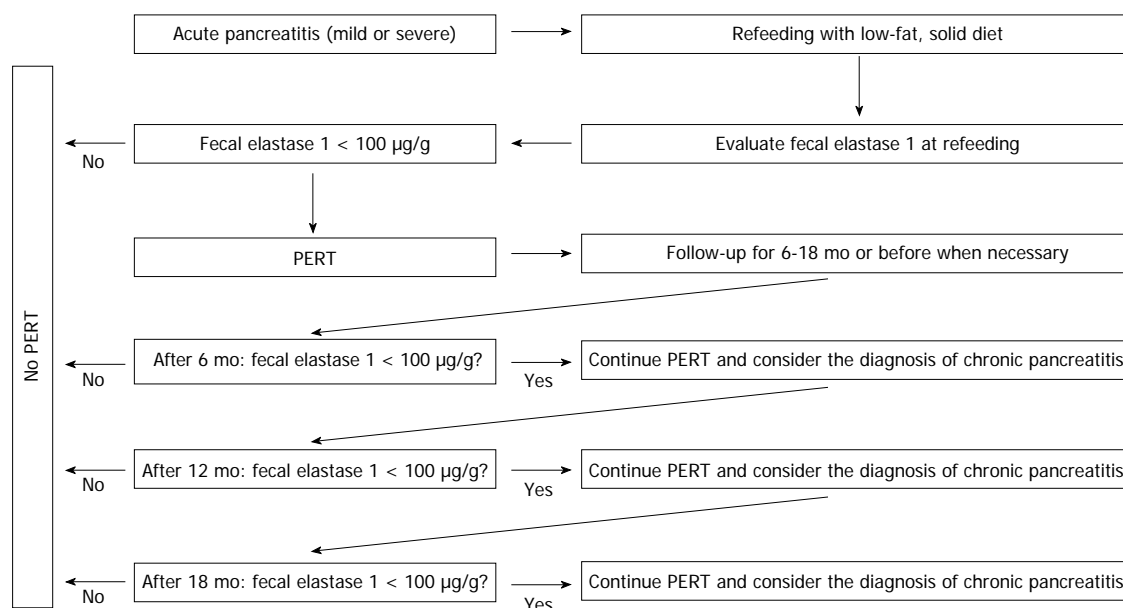

fected<sup>[30,34]</sup>, whereas enzymes contained in gastroprotected minimicrospheres can be assumed also with food having a pH less than 5.5. Acid-suppressing agents should be utilized only in patients who continue to experience symptoms of maldigestion despite the adequate administration of PERT<sup>[35]</sup>.

### Goal of the treatment

Steatorrhea in severe pancreatic insufficiency is very difficult to resolve completely, and only a 60%-70% reduction is usually achieved using PERT<sup>[36]</sup>. This may be due the fact that there are numerous interactions between pancreatic maldigestion, intestinal ecology and intestinal inflammation; consequently, to the methods of achieving optimal management of pancreatic maldigestion need to be fully re-evaluated, considering not only the correction of pancreatic insufficiency using PERT and, the best duodenal pH to allow for the optimal efficacy of these extracts, but also the decontamination of the intestinal lumen, the supplementation of bile acids and, probably, the use of probiotics to attenuate intestinal inflammation in chronic pancreatitis patients<sup>[37]</sup>. Fat soluble vitamins and micronutrients, such as zinc and selenium, should be routinely assessed and administered whenever necessary<sup>[38]</sup>.

### Warnings regarding PERT

An appropriate clinical response to PERT does not allow predicting a normal nutritional status in patients with chronic pancreatitis. Up to 2/3 of patients with an apparently good clinical response have some residual nutritional deficiency<sup>[39]</sup>. Crushing, chewing or holding the pancreatic extract capsules in the mouth may cause local irritation. The fine powder of the pancreatic enzymes may also be irritating to the nasal mucosa and the respiratory tract and can precipitate an asthma attack. Extremely high doses of pancreatic extracts have been associated with hyperuricemia and hyperuricosuria<sup>[40]</sup>. Submucosal

**Figure 1** Algorithm for monitoring and treating exocrine pancreatic insufficiency in patients hospitalized for acute pancreatitis. PERT: Pancreatic enzyme replacement therapy.

strictures in the proximal colons of children with cystic fibrosis have been reported (“fibrosing colonopathy”), and it is now recommended that not more than 10000 units of lipase per kg of body weight per day be given to children<sup>[41]</sup>; to our knowledge, this complication has been never reported in adults<sup>[42]</sup>.

## RECOMMENDATION FOR SPECIFIC DISEASES

### Acute pancreatitis

In Italy, there are approximately 20000 admissions per year for acute pancreatitis (AP)<sup>[43]</sup>. Acute pancreatitis is an inflammatory disease most commonly caused by gallstones or alcohol abuse, and is associated with significant morbidity and mortality<sup>[44]</sup>. Pathological values of fecal elastase-1 have been found in 12.0% of patients with AP (9.3% with mild and 2.7% with severe pancreatitis). Pathological fecal elastase-1 was not significantly related to sex, age or day of refeeding. Finally, only 4.0% of patients may have severe EPI (*i.e.*, fecal elastase-1 concentrations less than 100 µg/g). Thus, in selected cases (approximately 800 Italian AP patients per year), there is the need for enzyme supplementation during refeeding if the elastase-1 fecal determination is clearly abnormal<sup>[45]</sup>. The suggestion is that these patients be monitored for EPI for at least 6-18 mo and treated with oral pancreatic enzymes at a dosage of 40000-50000 U per meal and 25000 U per snack unless otherwise indicated<sup>[27]</sup> (Figure 1).

### Chronic pancreatitis

The greatest benefit of PERT is in the patients who excrete more than 15 g of fecal fat per day or have weight loss<sup>[46,47]</sup>. However, German and Spanish guidelines treat patients with a daily fecal fat output < 15 g in the pres-

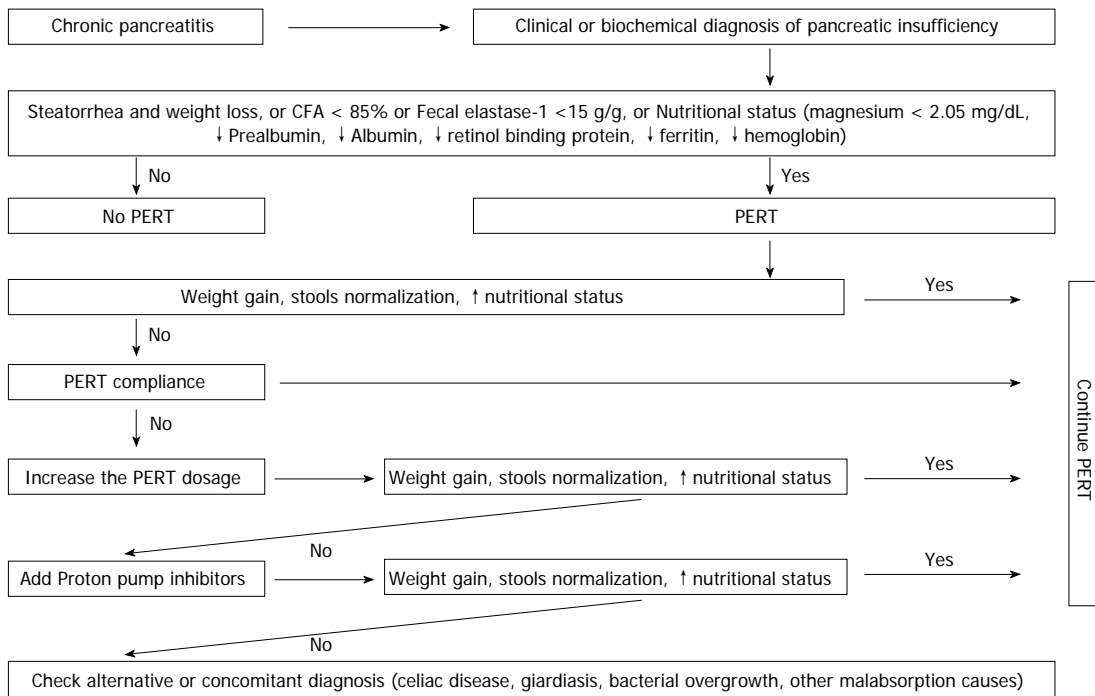

ence of symptoms of malabsorption (weight loss, osteopenia, loss of muscular mass)<sup>[9,31,48,49]</sup>. Alcohol should also be avoided to prevent additional impairment of the pancreatic exocrine function<sup>[50]</sup>.

The initial dose of pancreatic enzymes should be 40000 units as a starting dose for a meal and 20000 units for a snack<sup>[9,31,48,51]</sup>.

Increasing doses of PERT are recommended in non-responder patients<sup>[9,48,51]</sup>. Furthermore, acid suppression is also suggested to ensure optimal enzymatic delivery into the duodenum, despite the lack of clinical trials<sup>[52]</sup>. Moreover, as reported by Domínguez-Muñoz *et al*<sup>[53]</sup>, gastric acid inhibition avoids bile acid precipitation and allows lipase release in the proximal gut. It has been shown that patients with EPI respond properly to PERT if bicarbonate secretion is preserved and/or gastric secretion reduced. Calcium and magnesium-containing antacids should be avoided as they produce soaps, precipitate with glycine conjugated bile salts in the intestine and worsen steatorrhea<sup>[54]</sup>.

Lack of patient compliance may be a cause of treatment failure and can be discovered by measuring fecal chymotrypsin<sup>[55]</sup>. If chymotrypsin activity in the stool is low, the patient should be educated to take supplements during or just after meals<sup>[9,56]</sup>. Intestinal bacterial overgrowth, found in up to 40% of the patients with chronic pancreatitis<sup>[57,58]</sup>, intestinal giardiasis or other intestinal malabsorption disorders, should be ruled out in non-responder patients.

Parameters to be used for the assessment of therapy include clinical improvement/normalization of nutritional parameters and clinical symptoms<sup>[9,24]</sup>. In non-responder patients, laboratory methods for assessing fat absorption (CFA, C-13 mixed triglyceride breath test) may be used. Fat soluble vitamin deficiency should be

**Figure 2 Algorithm for monitoring and treating exocrine pancreatic insufficiency.** Algorithm for monitoring and treating exocrine pancreatic insufficiency summarized from Italian<sup>[9]</sup>, German<sup>[47]</sup> and Spanish<sup>[31]</sup> guidelines, and a synopsis of the guidelines<sup>[51]</sup>. CFA: Coefficient of fat absorption; FE1: Fecal elastase-1; PERT: Pancreatic enzymes replacement therapy; PPI: Proton pump inhibitor.

corrected parenterally<sup>[9]</sup>.

Before starting PERT, evaluation of the fasting glucose levels and quantification of the malabsorption is suggested, if possible. Moreover, determining glucose fasting levels during the first 1-2 wk of treatment is also suggested<sup>[51]</sup>. An algorithm for PERT in chronic pancreatitis patients is summarized in Figure 2.

### Unresectable pancreatic ductal adenocarcinoma

The prevalence of EPI is high but of moderate degree in the majority of cases; it has been reported that 65% of pancreatic cancer patients have fat malabsorption, and 50% protein malabsorption<sup>[59,60]</sup>. The causes of the EPI are mainly related to the obstruction of and/or the loss of the pancreatic parenchyma<sup>[61]</sup>. Thus, the most important predictors of the onset of EPI malabsorption in pancreatic cancer patients are the site of the tumor in the pancreatic head, the tumor replacing at least 90% of the normal pancreatic tissue and main duct obstruction<sup>[62-64]</sup>.

Even if the most widely accepted prognostic factors in unresectable pancreatic carcinoma are the presence of metastases and the value of CA 19-9 at presentation<sup>[65,66]</sup>, the prognostic factor “weight loss” has received particular attention from the “Eastern Cooperative Oncology Group” study<sup>[66]</sup> and in this study the weight loss ranged from 30% in patients with non-Hodgkin’s lymphoma to 87% in patients with gastric cancer; patients with pancreatic cancer showed weight loss in 65% of cases and it correlates with worsening of the performance status even if this factor was not a negative prognostic factor for survival<sup>[66]</sup>. In contrast, a more recent retrospective study found a direct relationship between the percentage

of weight loss and the risk of death, with a value greater than 7 times the expected value when the decrease exceeded 10%<sup>[67]</sup> and these data were confirmed by a retrospective study regarding 58 patients with unresectable pancreatic carcinomas showing that a phase angle of less than 5 degrees was a negative prognostic factor<sup>[26]</sup> and by a prospective non-randomized study enrolling 194 patients with unresectable advanced pancreatic cancer showing that a value of fecal elastase-1 less than 20 µg/g was a negative prognostic factor for survival. Of interest, a value of fecal elastase-1 of less than 20 µg/g and extremely severe pancreatic insufficiency were found more frequently in the group of patients with tumors in the head of the pancreas<sup>[68]</sup>.

The main question is whether replacement therapy with pancreatic enzymes and nutritional therapy have a positive impact on the quality of life and survival in patients with advanced pancreatic cancer. Pancreatic enzyme replacement therapy can partially prevent weight loss in patients with unresectable tumors of the pancreatic head, at least in the period before biliary endoprosthesis placement<sup>[69]</sup>. Two different phase II studies have shown that, in patients with advanced pancreatic cancer, having a weight loss of more than 5% in the previous 4 wk and a body mass index of less than 19, parenteral nutrition improved all nutritional parameters, as evaluated by the bioelectrical impedance without, however, reaching normality<sup>[70,71]</sup>.

The algorithm for monitoring EPI and malnutrition in unresectable pancreatic ductal adenocarcinoma patients is reported in Figure 3. Of course, appropriate amounts of pancreatic extracts should be administered during each

meal (40000-50000 U of lipase) and per snack (25000 U).

Diabetes mellitus

Exocrine pancreatic insufficiency was demonstrated in approximately 50% of patients with insulin-dependent diabetes, and in 30%-50% of those with non insulin-dependent diabetes<sup>[72-78]</sup>. Nine prospective reports evaluated EPI by means of fecal elastase-1 estimation in patients with either type-1 or type-2 diabetes<sup>[79-87]</sup> (Table 4) and included 2770 diabetic patients, 837 of them (30%) with type-1, and the remaining 1933 with type-2 diabetes mellitus (DM). Overall, fecal elastase-1 concentrations were abnormal (*i.e.*, < 200 µg/g) in 904 patients (32.6%) and the impairment was mild (*i.e.*, fecal elastase-1 > 100 but < 200 µg/g) in 439 patients (15.8%, overall); severe EPI (< 100 µg/g) was documented in 465 (16.8%). Of the 904 diabetics with abnormal fecal elastase-1, exocrine

impairment was mild in 48.9%, and severe in 51.4%. The prevalence of EPI differed slightly between type 1 and type 2 DM. Abnormal (< 200 µg/g) fecal elastase-1 concentrations were found in 346 (41.3%) of 837 type 1 diabetic patients, and in 558 (28.9%) of 1933 type 2 diabetic patients, a 12.4% difference in prevalence rates. More patients with type 1 DM (188 of 837, 22.5%) had signs of severe EPI, as compared to the 14.3% rate (277 of 1933) in type 2 DM. Exocrine pancreatic insufficiency is usually only of a mild to a moderate degree, and will not lead to clinically overt steatorrhea in the majority of diabetics. Thus, the clinical relevance of EPI and the role of functional tests in these patients are questionable. However, patients with DM frequently suffer from a wide range of abdominal complaints which contribute to impairment of the quality of life<sup>[88]</sup>. Although data are controversial, at least some of these symptoms may be attributable in

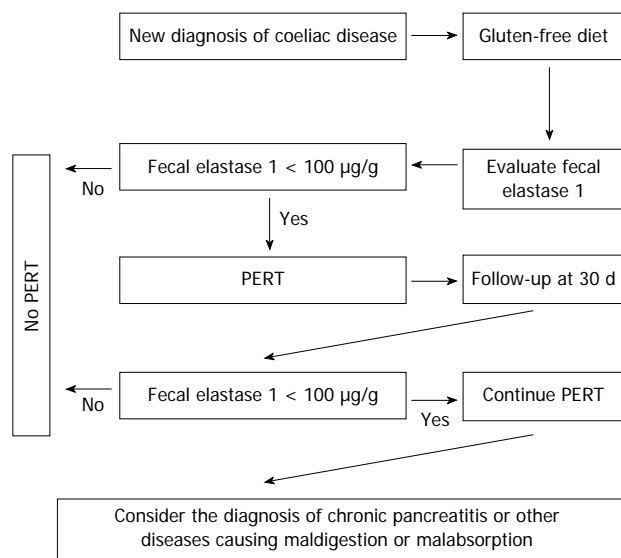

**Figure 4** Algorithm for monitoring and treating exocrine pancreatic insufficiency in patients with diabetes mellitus. PERT: Pancreatic enzymes replacement therapy.

part to EPI (mild to moderate) and might respond to enzyme treatment<sup>[81,89-94]</sup>. Thus, pancreatic tests should be part of the diagnostic work-up in patients with symptoms and do not respond to simple therapeutic measures. As reported in Figure 4, patients with fecal elastase-1 < 100 µg/g should be given pancreatic enzymes in adequate daily doses (40000-50000 U of lipase) administered during meals. Treatment improves symptoms significantly, the supply of soluble fat vitamins is normalized, and the risk of osteoporosis is reduced. Enzyme replacement therapy might have an impact on glucose metabolism since it can reduce the insulin requirement and contribute to improved control of the glucose metabolism, but the evidence is contradictory<sup>[93,94]</sup> as improvement of glucose metabolism was not seen in all studies<sup>[95,96]</sup>.

### Celiac disease

The prevalence of adult celiac disease (CD) in the general population is reported to be 1%-2%<sup>[96-99]</sup>; diarrhea remains a common presenting symptom<sup>[100]</sup> and it is usually attributed to continued gluten ingestion; however, other causes of chronic diarrhea in patients who are compliant with their gluten-free diet exist, and one of them is exocrine pancreatic insufficiency. Using a secretin test, it has been found a mild reduction in the pancreatic secretion of bicarbonates and pancreatic enzymes (especially lipase) in untreated celiac patients these alterations revert to normal after going on a gluten-free diet; mild pancreatic insufficiency is present in about 40% of untreated CD patients and severe pancreatic insufficiency in 10%<sup>[101,102]</sup>. More recently, other authors using tubeless test, such as fecal chymotrypsin or elastase 1 determination and the C mixed-triglyceride breath test, confirmed that pancreatic insufficiency in untreated CD patients in percentages ranging from 11.4% to 56.2%<sup>[103-107]</sup>.

It has also been suggested exocrine pancreatic func-

**Figure 5** Algorithm for monitoring and treating exocrine pancreatic insufficiency in patients with celiac disease. PERT: Pancreatic enzymes replacement therapy.

tion impairment may be related to the degree of mucosal villous atrophy and that the level of fecal elastase may improve once the mucosa has recovered after an appropriate gluten-free diet<sup>[104,108]</sup>. In addition, it seems that pancreatic insufficiency does not depend on nutritional status<sup>[105]</sup>. Regarding the use of PERT in these patients, the data come from a double blind randomized study carried out on children showing that pancreatic enzyme therapy is certainly useful in the first 30 d after the diagnosis of CD<sup>[106]</sup>. In fact, after 30 d of a gluten-free diet associated with pancreatic extracts, body weight significantly increases with respect to patients treated with only a gluten-free diet. Similar results were obtained in a longitudinal study<sup>[109]</sup>. The conclusion is that pancreatic enzyme therapy is certainly useful in the first 30 d after the diagnosis of CD and that enzyme supplementation may possibly be discontinued as symptoms improve and fecal elastase-1 concentrations normalize. The dosage of pancreatic extracts should be 40000-50000 U per meal and 25000 U per snack. In CD patients who continue to experience clinical steatorrhea despite being on a gluten-free diet, a search for possible exocrine pancreatic insufficiency must be carried out<sup>[110]</sup>. In addition, we should bear in mind that, in adult CD patients have a risk developing chronic pancreatitis more than 3 times as compared to general population and there is also an increased need for PERT<sup>[111]</sup>. An algorithm for PERT in CD is reported in Figure 5.

### Inflammatory bowel diseases

**Crohn's disease:** About 35% of the patients with Crohn's disease have an impaired exocrine pancreatic function<sup>[112]</sup> and no relationship are present between exocrine pancreatic insufficiency and age or nutritional status. Interestingly, patients having steatorrhea had a defect of lipase output ranging from 10% to 67% and, especially in this

latter group of patients, the use of PERT was hypothesized. In patients with Crohn's disease, enzyme activities were not correlated to the duration of disease or to the extent or localization of a previous bowel resection<sup>[113]</sup>. The lowest enzyme values were found in patients with the most extensive bowel involvement, and they were significantly lower than in patients with disease confined to the terminal ileum. Thus, the factors related to the impaired pancreatic function in Crohn's disease seem to be disease activity, and the localization and extent of the disease. Finally, patients with Crohn's disease may have an autoimmune involvement of the pancreatic gland and those having positive serum pancreatic autoantibodies may also have impaired exocrine pancreatic function more frequently<sup>[114]</sup>. However, we have no evidence that PERT can be utilized in patients with Crohn's disease and exocrine pancreatic insufficiency to improve the maldigestion present in these patients.

**Ulcerative colitis:** Pancreatic exocrine insufficiency, assessed using a secretin-cerulein test, may be present in about 40%-50% of patients with ulcerative colitis<sup>[112,115,116]</sup> especially during a active phase of the disease and the majority of patients with pancreatic insufficiency had active disease with loose stools; thus, the reduced fecal elastase-1 concentration could have been due to dilution of the enzyme and not to pancreatic involvement. In addition, in those patients who were also studied during the remission phase of the disease and had a solid stool, the fecal elastase-1 concentration became normal<sup>[112]</sup>. More recently, the possibility of autoimmune pancreatitis associated with ulcerative colitis has been reported. Thus, it is possible that only a small number of ulcerative colitis patients having severe pancreatitis insufficiency due to autoimmune pancreatitis may benefit from PERT.

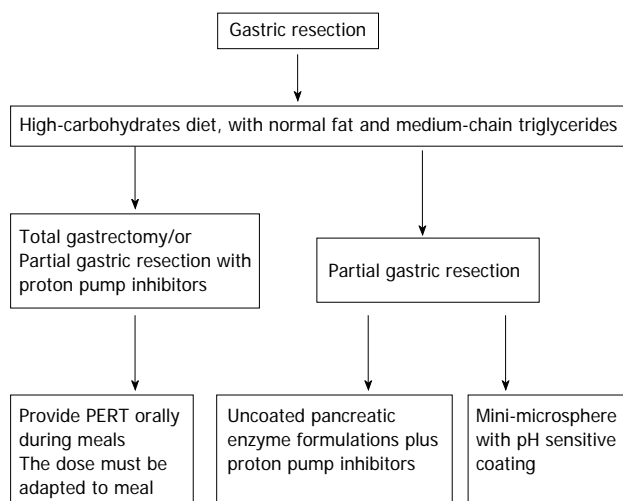

### Gastric surgery

Exocrine pancreatic insufficiency is a common clinical problem after gastric surgery<sup>[117]</sup>. The side effects of gastric resections, in particular total gastrectomy, include diarrhea, anorexia, weight loss and EPI that are responsible for a global status of malnutrition, malabsorption and maldigestion<sup>[118]</sup>. Malnutrition is considered one of the major complications after gastric surgery for gastric cancer<sup>[119]</sup> and EPI contributes to the pathogenesis of global malnutrition. After gastric surgery, EPI can result from various causes, such as a deficient trituration of nutrients, altered gastric emptying, alteration of pancreatic denervation and post-cibal asynchrony<sup>[120,121]</sup>.

Any surgical procedure, such as total or subtotal gastrectomy, total or subtotal pancreatectomy, with or without duodenal resection (*e.g.*, in the context of a Whipple procedure), causing distortion in the anatomic-physiology of digestion can be responsible for EPI<sup>[122-127]</sup>. Several events can be considered as being responsible for EPI after gastrectomy. Alterations of gastric relaxation due to the absence of nervous gastric reflexes; the absence of nervous gastric stimulation responsible for pancreatic

secretion caused by the lack of fundus relaxation and the reduction of exocrine pancreatic secretion due to the absence of cholecystokinin after intestinal resection. Rapid gastric emptying and asynchrony between gastric emptying and biliopancreatic secretion due to new tracts of various reconstructions, bacterial overgrowth after gastrectomy, extensive denervation of the pancreas due to lymph node dissection and truncal vagotomy are the most frequent alterations involved in the pathogenesis of EPI<sup>[123,128,129]</sup>. The latter has been shown to cause mild to moderate EPI by itself<sup>[130,131]</sup>. In 1996, Friess *et al.*<sup>[123]</sup> demonstrated that 100% of patients develop severe primary EPI three mo after a total gastrectomy. Chymotrypsin and trypsin were the most severely deficient enzymes after gastric surgery, with a decreased production of up to 91% three mo after surgery. Low levels of gastrin and postprandial pancreatic polypeptides, and high levels of cholecystokinin were also reported<sup>[123]</sup>. Exocrine pancreatic insufficiency is reported in both total and partial gastrectomy; Büchler *et al.*<sup>[127]</sup> demonstrated that the pancreolauryl test was pathological in 47%-64% of patients after Billroth-I surgery and in 64%-70% after Billroth-II surgery. On the contrary, Heptner *et al.*<sup>[124]</sup> reported EPI after gastric resection in only 30% of patients, even if the pancreolauryl test was abnormal in 90% of these patients. Armbricht *et al.*<sup>[132]</sup> conducted a double-blind, crossover study of 15 patients who underwent surgery for gastric cancer (total gastrectomy) and compared PERT with a placebo. The authors concluded that PERT reduced massive steatorrhea and improved stool consistency after total gastrectomy. Nevertheless, Bragelmann and co-workers reported an overall improvement in abdominal symptoms, fecal frequency and fecal consistency when following 52 institutionalized patients with a fecal fat output greater than or equal to 14 g/d after gastric resection for cancer, but no differences were found regarding body mass index, bowel habits or fat malabsorption<sup>[133]</sup>. Interestingly, Huddy and coworkers found that EPI contributes to postoperative morbidity after an esophagectomy, and that these patients can benefit from PERT<sup>[134]</sup>.

The main goal of the therapy in patients suffering from EPI is to reverse all the secondary events caused by enzyme deficiency (Figure 6). Therapeutic efficacy is closely connected with two important aspects: time and dosage of the pancreatic enzymes administered, and dietary changes<sup>[135]</sup>. Nutritional changes should include a high carbohydrate diet, with normal fat and medium-chain triglycerides<sup>[136]</sup>. It is also recommended that a personalized diet be created after major gastrointestinal surgery in order to prevent weight loss, anorexia, inflammation and changes in homeostasis<sup>[53]</sup>. Following a total gastrectomy and in patients receiving therapy with proton pump inhibitors (PPIs) for some reason, unprotected pancreatin powder is preferred<sup>[120]</sup>. In addition to dietary changes it is mandatory to resort to PERT, orally ingested, during meals. The dose must be adapted to the meal and should not be less than 40000-50000 U of lipase per meal<sup>[135]</sup>. For partial gastric resection, patients receiving

**Figure 6** Algorithm for treating exocrine pancreatic insufficiency in patients who undergo gastric resection. PERT: Pancreatic enzymes replacement therapy.

uncoated pancreatic enzyme formulations should also require simultaneously administered proton pump inhibitors<sup>[53]</sup> since lipase is irreversibly deactivated by gastric acid. However, the administration of PPIs can improve fat digestion even in patients who do not benefit from PERT<sup>[53]</sup>. Several authors agree with the need for liposoluble vitamin supplementation, especially for patients with severe EPI<sup>[135]</sup>.

### Pancreatic resections

Suggestions on this topic are based on a consensus reached by the experts and are not fully based on data coming from literature. Partial or total pancreatectomy (TP) is frequently associated with EPI. In this setting, PERT is essential for maintaining adequate digestion. In a TP, the removal of the entire pancreatic parenchyma produces inevitable exocrine failure while, in a partial pancreatectomy, the severity of EPI depends on both the underlying disease, the preoperative pancreatic function, and the extent and type of the resection. Most importantly, any pancreatic neoplasm can be associated with chronic obstructive pancreatitis (focal or extended) which might affect pancreatic function/secretion, leading to EPI before any type of resection.

### Extent and type of the resection

**Pancreaticoduodenectomy:** Anatomical changes secondary to reconstruction after a pancreaticoduodenectomy (PD) lead to important physiological alterations which frequently correlate with the severity of postoperative EPI. A PD (either Whipple or pylorus-preserving) is associated with several and complex patho-physiological events such as: (1) disturbance of gastric fundus relaxation caused by the disappearance of antro-fundic and duodeno-fundic reflexes; (2) the absence of neurally stimulated pancreatic excretion caused by the lack of fundus relaxation; (3) the reduction of cholecystokinin-mediated stimulation of pancreatic secretion secondary

to duodenal resection; (4) large and hard to digest nutrient particles reaching the jejunal lumen due to resection of the distal stomach (Whipple procedure); (5) reduction in exocrine pancreatic secretion due to pancreatic head resection; and (6) asynchrony between the gastric emptying of nutrients and bilio-pancreatic secretion as a result of anatomical reconstruction<sup>[122,128,137,138]</sup>.

For these reasons, every patient who is candidate for a PD should be considered at increased risk for EPI regardless of the underlying disease<sup>[128,139]</sup>. Therefore, it has been suggested that, after PD, PERT be given to all patients with pancreatic cancer, especially those with impending adjuvant therapy. Furthermore, it should be considered that pancreatic cancer is often associated with obstructive chronic pancreatitis, a preoperative risk factor for the development of EPI by itself<sup>[128,139]</sup>. The development of pancreatic insufficiency after PD could also be related to the different techniques used for the pancreatic anastomosis<sup>[117,140,141]</sup>.

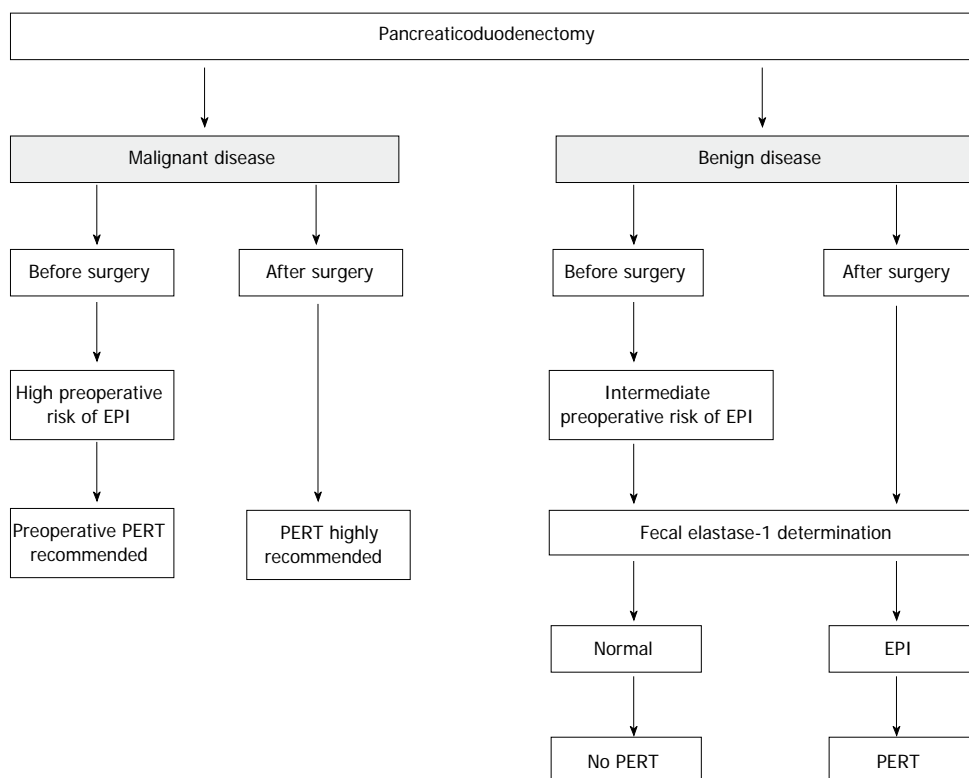

**Distal pancreatectomy:** Distal pancreatectomy (DP) is the procedure of choice for treating lesions affecting the body-tail of the gland. A DP may affect pancreatic exocrine function depending on the amount of normal tissue removed<sup>[142,143]</sup>. Based on these data, permanent postoperative EPI, as a result of parenchymal loss from pancreatic resection, was not observed and these conclusions have been subsequently confirmed<sup>[139]</sup>.

### Atypical resections: Middle pancreatectomy and enucleation

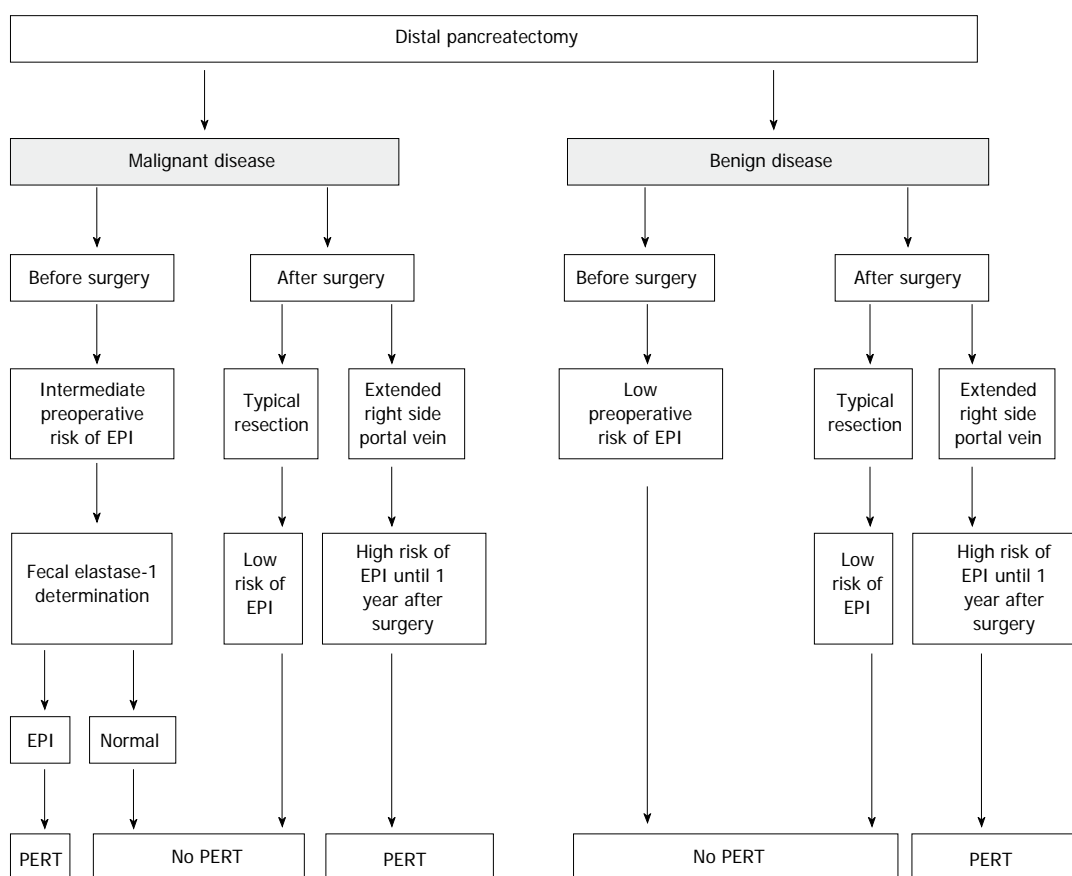

Atypical resections are usually performed for benign or borderline pancreatic tumors, such as small (< 2 cm) pancreatic neuroendocrine tumors, cystic papillary tumors, low grade intraductal papillary mucinous neoplasms and serous cystic adenomas. Enucleation is usually performed for tumors smaller than 2 cm located in any part of the pancreas but sufficiently far from the main pancreatic duct. A MP is indicated for neoplasm in the neck of the pancreas which could not be safely enucleated<sup>[139,144-146]</sup>. Using the <sup>13</sup>C-mixed triglyceride breath test (normal test > 5%), it has been found an EPI rate of 5% after a median follow up of 71 mo<sup>[147]</sup>. In addition, Crippa *et al.*<sup>[148]</sup>, after a median follow-up of 54 mo, observed a rate of clinical EPI of 5% in a cohort of 100 patients who had undergone MP for benign or borderline tumors. The authors compared this result with an EPI rate of 15.6% in patients who underwent an extended left pancreatectomy (at the right side of the superior mesenteric vein), the alternative surgical procedure to MP for lesions located in the pancreatic neck. These data are consistent with those of others<sup>[149,150]</sup>.

### Treatment of EPI in pancreatic resection

It has been reported that in patients undergoing a pylorus-preserving pancreaticoduodenectomy for pancreatic neoplasia, gastro-protected microspheres were less effective than those in patients who had undergone a classic Whipple technique<sup>[151]</sup> probably because microspheres are retained in the stomach. One of the few randomized

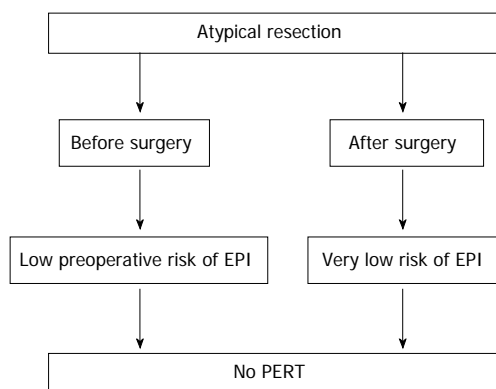

**Figure 7** Algorithm for monitoring and treating exocrine pancreatic insufficiency in patients who receive pancreaticoduodenectomy. EPI: Exocrine pancreatic insufficiency; PERT: Pancreatic enzyme replacement therapy.

**Figure 8** Algorithm for monitoring and treating exocrine pancreatic insufficiency in patients who undergo distal pancreatectomy. EPI: Exocrine pancreatic insufficiency; PERT: Pancreatic enzymes replacement therapy.

**Figure 9** Algorithm for monitoring and treating exocrine pancreatic insufficiency in patients who undergo atypical resection of the pancreas. EPI: Exocrine pancreatic insufficiency; PERT: Pancreatic enzymes replacement therapy.

studies explaining the efficacy of pancreatic extracts for the control of malabsorption was carried out on a small group of patients with chronic pancreatitis who had undergone a pancreatic resection with longitudinal pancreaticojejunostomy<sup>[152]</sup> and showed that treatment with pancreatic extracts ameliorated not only the nitrogen balance but also the fat and protein absorption. Another randomized controlled double-blinded crossover study explored the comparative efficacy of two pancreatin preparations of gastroprotected microspheres with different doses in pancreatectomized patients having chronic pancreatitis<sup>[153]</sup>. All patients were stabilized before enrollment in the study with a standard dose of pancreatic extracts. After this stabilization period, 56% of the patients still had a fecal fat excretion greater than 7 g/d, and 38% greater than 15 g/d. The results demonstrated that there was a significant relationship between fecal fat excretion, fecal volume and evacuation frequency but there was no relationship between fecal fat excretion, and abdominal pain or malabsorption. Both the pancreatin standard dose and the elevated dose demonstrated equal efficacy; in pancreatectomized patients, high dose pancreatic extracts significantly reduced the number of capsules needed per day with a better compliance to substitutive therapy. From the clinical point of view, pancreatic enzyme replacement therapy needs to be routinely considered and based on pragmatic clinical evaluation of the patient<sup>[22,38,63]</sup>. The suggested algorithms for PERT in patients undergoing surgery, according to the type of pancreatic resection, are reported in Figures 7-9, taking into consideration that the dosage should be no less than 40000-50000 U of lipase per meal and 25000 per snack.

## CONCLUSION

We should point out that there is a paucity of information regarding some areas of managing EPI there is a lack of good quality of literature. Finally, studies on the economic aspects of this treatment with the different formulations commercially available are also necessary; it has been calculated that the treatment of chronic pan-

creatitis-related EPI with pancreatin minimicrospheres is cost-effective according to a survey of Polish patients but it is necessary that these results also be evaluated for the Italian National Health System<sup>[154]</sup>.

### Abstract

In spite of the introduction in therapy of highly effective biological agents, glucocorticoids (GCs) are still employed to induce remission in moderate to severe inflammatory bowel diseases (IBD), but considerable inter-individual differences in their efficacy and side effects have been reported. The effectiveness of these drugs is indeed very variable and side effects, particularly severe in pediatric patients, are common and often unpredictable: the understanding of the complex gene regulation mediated by GCs could shed light on the causes of this variability. In this context, microRNAs (miRNAs) represent a new and promising field of research. miRNAs are small non-coding RNA molecules that suppress gene expression at post-transcriptional level, and are fine-tuning regulators of diverse biological processes, including the development and function of the immune system, apoptosis, metabolism and inflammation. Emerging data have implicated the deregulated

**Core tip:** Studies on microRNAs (miRNAs) and pharmacogenomics represent a promising investigation topic that could increase the understanding of the pharmacology of steroids in inflammatory bowel diseases (IBDs) and possibly in other diseases. A number of studies have shown that glucocorticoids (GCs) can modify the expression profiles of different miRNAs, however, the obtained results have been highly variable, and to date it is not possible to recognize a specific miRNA pattern regulated by GCs. Moreover, existing studies employed techniques based on the use of reverse transcription quantitative polymerase chain reaction and microarrays, through the analysis and quantification of already known miRNAs. Using next generation sequencing technologies, it could be possible to detect novel, still unrecognised miRNAs, and identify new miRNA isoforms (iso-miRs) as well. This innovative approach could be a valuable tool for a better understanding of the role

of miRNAs to predict steroid response in IBDs. In the future, the increased availability and the reduced costs of RNA profiling should enable the clinicians to stratify patients on specific miRNA biomarkers before starting GC treatment.

## INTRODUCTION

To date, a curative pharmacological therapy for inflammatory bowel diseases (IBD) does not exist and the therapeutic approach is mainly aimed at controlling inflammation, with drugs capable of inducing and maintaining remission. Despite the introduction in therapy of highly effective biological agents, in IBD patients with moderate to severe disease glucocorticoids (GCs) are effective in inducing remission and are still considered the standard for treatment<sup>[1]</sup>. In spite of the large clinical use, the benefits of these agents are often narrowed by high inter-individual variability. Given the high incidence of suboptimal response, associated with a significant number of side effects, the identification of subjects that are most likely to respond poorly to these agents is extremely important. However, the mechanisms of this variability are scarcely understood and there is presently no means to predict the response in advance<sup>[2-5]</sup>; in this context, microRNAs (miRNAs) represent a new and promising field of research.

miRNAs are small (18-24 nucleotides) non-coding RNAs, which bind the 3'UTRs and the coding exons of their target genes and inhibit gene expression<sup>[6]</sup> either by messenger RNA (mRNA) cleavage (most common in plants) or by translational repression (most common in metazoan)<sup>[7,8]</sup>. According to the miRNA database miRBase, 1872 precursors and 2578 human mature miRNA sequences have been published (<http://www.mirbase.org><sup>[9,10]</sup>) and we are only on the verge of understanding their physiological impact on gene regulation. A single miRNA can regulate a multitude of mRNAs (approximately 200), and each mRNA can be regulated by multiple miRNAs<sup>[11,12]</sup>; overall, it is predicted that protein production for at least 20% of all human genes is regulated by miRNAs<sup>[13,14]</sup>.

By affecting gene regulation, miRNAs are likely to be implicated in the control of diverse biological processes, such as cellular proliferation and apoptosis<sup>[10,15-17]</sup>, stem cell differentiation<sup>[15,18-20]</sup>, and organ development and morphogenesis<sup>[21,22]</sup>; in addition a strong association between miRNA expression dysregulation and induction of cancer has been shown<sup>[23-26]</sup>. Moreover, miRNAs have important regulatory roles in the innate and adaptive immune system<sup>[27-29]</sup>, and characteristic miRNA expression

profiles have been demonstrated even in IBD<sup>[30-33]</sup>.

There is a lot of interest in identifying the role of miRNAs in the modulation of drug response<sup>[34]</sup>, but studies about this topic are still very limited, and the possible correlation between miRNAs expression and variability on GC response in IBD patients has not yet been examined. A better knowledge of miRNAs role could lead to their use as biomarkers for IBD, and consequently, to the development of new strategies for therapy personalization in these diseases.

This review tries to highlight the altered regulation of proteins involved in GC molecular mechanism by miRNAs in different diseases and *in vitro* models, and their potential role as molecular markers useful for predicting in advance GC response.

## GLUCOCORTICOIDS IN INFLAMMATORY BOWEL DISEASES

GCs are effective inhibitors of cytokine secretion and T-cell activation, and are consequently largely employed in different inflammatory conditions, including IBD. Despite the introduction of novel therapies, these agents are still currently used for induction of remission in moderate to severe IBDs, however, a wide variability in response to these agents is evident and, in these diseases, GC resistance or dependence is particularly frequent. Among the adult IBD population, a prospective analysis has described the 1-year outcome in patients with Crohn's disease (CD) treated with a first oral prednisone course (40-60 mg/d) and tapering to a maintenance dose of 10-15 mg/d<sup>[35]</sup>. Prolonged steroid response was obtained in 44% of patients, 36% of subjects were steroid dependent while 20% of subjects did not respond and were steroid resistant; a high frequency of surgery was reported within 1 mo after steroid treatment. Similar results have been obtained in a retrospective American study: immediate outcomes for CD and ulcerative colitis (UC), respectively, were complete remission in 58% and 54% of cases, partial remission in 26% and 30%, resistance in 16% of patients<sup>[36]</sup>. In paediatric IBD patients, clinical reports have shown that up to 90% of subjects has a rapid improvement of symptoms when prednisone treatment is given; however, after 1 year, only 55% of patients were still in remission and were considered steroid responsive. In around 38% of patients, steroid therapy could not be discontinued as patients experienced an increase of disease activity when the dose was reduced (steroid dependent)<sup>[37]</sup>.

Demographic and/or clinical markers<sup>[36,38,39]</sup> have been evaluated and related with this variability in GC response, but results have not been consistently replicated. Genetic and epigenetic markers are likely to complement clinical and demographic predictors: phenotypes resulting from genetic changes and regulation can markedly influence drug pharmacokinetics or alter drug efficacy and/or toxicity profiles. The identification of genetic biomarkers that can be useful for classifying the disease and help to improve therapy is paramount.

## MOLECULAR MECHANISM OF GC ACTION

The effects of GCs are mediated by the glucocorticoid receptor (GR)- $\alpha$ , a member of the nuclear receptor superfamily of ligand-dependent transcription factors<sup>[40,41]</sup>. The human GR gene is encoded on chromosome 5q31.3 and consists of nine coding exons<sup>[42]</sup>. Alternative splicing of exon 9 generates two receptor isoforms, GR- $\alpha$  and GR- $\beta$ <sup>[43-46]</sup>. GR- $\beta$  is not able to bind GCs, resides constitutively in the nucleus of cells, has a longer half-life than GR- $\alpha$ , and does not transactivate GC-inducible reporter genes<sup>[47]</sup>. It has been suggested<sup>[48,49]</sup> that cell specific expression and function of GR isoforms may explain the tissue and individual selective actions of GCs.

The function of GR is conditioned by chaperone and co-chaperone proteins that form a molecular heterocomplex with the GR itself<sup>[50,51]</sup>, required for proper ligand binding, receptor activation and transcription: abnormalities in proteins that make up the heterocomplex may contribute to altered GC responsiveness<sup>[52,53]</sup>. Several studies have demonstrated differences in the heterocomplex gene expression profiles in steroid resistant in comparison with responder patients, but it is not clear if this different expression is the cause of the variability in response or the consequence of GC treatment<sup>[54-59]</sup>. After GC binding and dissociation from heterocomplex proteins, the GR translocates into the nucleus; translocation is mediated by specific nuclear transport factors that belong to the importin  $\beta$  family of nuclear transporters, and in particular by importin 13<sup>[60]</sup>. The activated receptor then binds as homodimer two palindromic DNA-binding sites, the so-called glucocorticoid responsive elements (GREs), localized in the promoter region of target genes<sup>[61-63]</sup>. As a consequence of DNA binding, GCs can induce trans-activation and trans-repression processes: binding to positive GREs leads to activation of the transcription of anti-inflammatory [*e.g.*, interleukin 10 (IL-10), Annexin 1] as well as of regulator proteins involved in metabolic processes (*e.g.*, enzymes of gluconeogenesis)<sup>[64-66]</sup>. The second mechanism of GC action is trans-repression<sup>[67]</sup>, which leads to a reduced expression of immune-regulatory and proinflammatory proteins such as cytokines [IL-1, IL-2, IL-6, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ )] and prostaglandins<sup>[68]</sup>, and is believed to be responsible for the majority of beneficial anti-inflammatory effects.

Steroid hormones can regulate gene expression post-transcriptionally, by destabilizing mRNAs<sup>[69]</sup>. In addition, these hormones can induce rapid non genomic effects within the cytoplasm; for example, they induce the release of Src kinase from the GR heterocomplex, resulting in lipocortin activation and inhibition of arachidonic acid release<sup>[70,71]</sup>, and alter cytoplasmic ion content<sup>[72,73]</sup>.

## miRNAS AND GC RESPONSE

### miRNA regulation by GCs

It has been demonstrated that activation of GR by GCs

might induce or repress specific miRNAs in various target genes. The majority of studies have evaluated the effect of GCs on miRNA expression levels in tumor leukemic cells, during GC induced apoptosis<sup>[74]</sup>.

Rainer *et al.*<sup>[75]</sup> have correlated miRNA levels with expression data of their host genes in cell lines and clinical samples of children with acute lymphoblastic leukemia (ALL) undergoing systemic GC monotherapy. At least 5 miRNAs were significantly regulated by GC therapy. Importantly, the miR-15/16 cluster, which induces cell cycle arrest, was up-regulated by GCs in a subset of ALL patients and cell lines, consistent with the known apoptotic effect of GCs in immature lymphoblasts. Indeed, overexpression of miR-15b/16 increased GC sensitivity in leukemia cell lines whereas silencing miR-15b/16 with inhibitors decreased GC sensitivity *in vitro*.

Another study in a T-cell lymphoma cell line has shown that GC treatment repressed the expression of the miRNA cluster miR-17-92, which results in elevated protein expression of Bim, a proapoptotic member of the B-cell lymphoma-2 family (Bcl-2). Overexpression of miRNA cluster miR-17-92 decreased Bim induction, and attenuated GC mediated apoptosis, while cluster knockdown increased Bim induction and GC mediated apoptosis<sup>[76]</sup>. These findings suggest a novel mechanism that could contribute to the induction of lymphocyte apoptosis by GCs.

Harada *et al.*<sup>[77]</sup> demonstrated that in the leukemic cell line RS4; 11 dexamethasone down-regulated miRNA levels; miR17HG was rapidly down-regulated, and chromatin immunoprecipitation demonstrated that the promoter is a target of GC transcriptional repression; in particular, the miR-17-92 cluster was identified as a prime target for dexamethasone induced repression. In the sensitive leukemia cell line SUP-B15, but not in the resistant line REH, dexamethasone reduced the expression of the miR-17 family and concomitantly increased its target protein Bim. Up-regulation or inhibition of miR-17 resulted in a decrease and increase, respectively in Bim protein levels and in dexamethasone induced cytotoxicity. Down-regulation of miR-17 levels was observed in *ex vivo* patients' leukemia cells that underwent dexamethasone induced apoptosis<sup>[77]</sup>.

Another recent study<sup>[78]</sup>, by genome wide miRNA microarray on diagnostic bone marrow samples of ALL pediatric patients treated with GCs, identified a reduced expression of miR-355 as the most significant miRNA abnormality associated with poor outcome. Moreover, the authors demonstrated that exogenous expression of miR-355 in ALL cells increases sensitization to prednisolone-induced apoptosis. MAPK1 was identified as a target of miR-355, and the MEK/ERK inhibitor treatment increased GC induced cytotoxicity through the activation of Bim.

Smith *et al.*<sup>[79]</sup> have demonstrated that miRNAs are repressed during GC induced apoptosis of primary rat thymocytes, and further demonstrated the repression

of the miRNA processing enzymes Dicer, Drosha and DGCR8/Pasha. Silencing of Dicer expression in two human leukemic lines significantly enhanced GC induced apoptosis, while overexpression of the GC-repressed miR-17-92 polycistron reduced apoptosis.

Among the few studies that have considered the effect of GCs on miRNA expression in non tumor cells, Ledderhose *et al.*<sup>[80]</sup> in native and CD3/CD28 stimulated cells from healthy volunteers, demonstrated that miR-24 is expressed in human T cells, and expression is increased 1.7 fold upon stimulation. Hydrocortisone significantly enhanced by 3 fold the miRNA induction<sup>[80]</sup>.

In human corneal fibroblast treated for 16 h with dexamethasone, genome microarray and microRNA analyses were used to evaluate gene and miRNA expression. In response to treatment with the steroid, 261 genes were up-regulated and 123 were down-regulated more than three-fold. Several miRNAs, including miR-16, miR-21 and miR-29C were up-regulated, whereas miR-100 was down-regulated by the steroid, suggesting a posttranscriptional control of gene expression through miRNAs<sup>[81]</sup>.

Studies of the miRNAs profile on mucosal biopsies of patients with eosinophilic esophagitis, before and after successful treatment with GCs were conducted by Lu and collaborators<sup>[82]</sup>; of the 377 miRNA sequences examined, 32 miRNAs were significantly up-regulated and 4 down-regulated in the biopsies obtained before treatment compared to samples obtained after GC therapy. miR-214 was the most up-regulated (150 fold) and miR-146b-5b, 146a, 145, 142-3p and 21 were up-regulated by at least 10 fold.

Williams *et al.*<sup>[83]</sup>, using a highly sensitive reverse transcription-polymerase chain reaction, measured 277 miRNAs in airway biopsies obtained from normal subjects and mild asthmatic patients before and after one month twice daily treatment with inhaled budesonide. No significant difference in miRNA expression was evident in the airway biopsies of normal and asthmatic subjects, and, despite improved lung function, no change in miRNAs expression was evident after one month budesonide treatment. However, a specific miRNA expression profile was observed in different cell types (alveolar epithelial cells, airway smooth muscle cells, alveolar macrophages, lung fibroblasts).

Finally, in a recent study<sup>[84]</sup>, activated human CD4<sup>+</sup> T cells from healthy donors were exposed *in vitro* to 1  $\mu$ mol/L of methylprednisolone and changes in miRNA and mRNA expression profiles were analyzed by microarrays; a number of steroid responsive genes and miRNAs were identified. Further studies with qPCR, flow cytometry and ELISA, demonstrated that methylprednisolone increased the expression of miR-98 and suppressed the levels of predicted targets, including the pro-inflammatory cytokine IL-13 and three TNF receptors FAS, FASL, and TNF receptor superfamily member 1B (TNFRSF1B); these data suggest that methylprednisolone acts through miR-98 to inhibit specific pro-inflammatory targets<sup>[84]</sup>.

### GR as miRNA target

The role of miRNAs in the regulation of the GR has been examined, indeed, computational studies showed that the 3' UTR of the GR is predicted to contain numerous seed regions recognized by a variety of miRNAs<sup>[85]</sup>.

Using a combination of *in silico* prediction of miRNA binding sites, miRNA overexpression studies and mutagenesis of the GR 3'UTR, Vreugdenhil and collaborators<sup>[86]</sup> found that miR-18 and miR-124a bind GR mRNA and decrease GR activity in neuronal tissues. These miRNAs were tested for their ability to alter the translational activity of GR and reduce GR protein levels in cell cultures *in vitro*; miR-18 and miR-124a overexpression reduced GR protein levels and impaired the activation of the GR responsive gene glucocorticoid-induced leucine zipper (GILZ). In addition these authors have demonstrated by miRNA reporter assay that miR-124a is able to bind to the predicted seed region in the GR 3' UTR.

Ledderose *et al.*<sup>[80]</sup> have investigated the role of miR-124 in the regulation of GR expression; these authors have studied the influence of the GR isoforms (the active isoform  $\alpha$ , and the dominant negative non-ligand-binding isoform  $\beta$ ) on GC effects in human T-cells, and found that, in patients with critical illness-related corticosteroid insufficiency, miR-124 specifically down-regulated GR- $\alpha$ : a slight increase of miR-124 and a reduction of GR- $\alpha$  was observed in patient T-cells compared to healthy controls. The authors suggested a novel miR-124-mediated mechanism in the down-regulation of GR- $\alpha$  in patients with critical illness-related corticosteroid insufficiency, that could explain, at least in part, GC resistance in this disease.

Tessel *et al.*<sup>[87]</sup> have identified and characterized miR-130b as an important down-regulator of GR in GC-resistant multiple myeloma cell line: the overexpression of this miRNA was also associated with a decreased regulation of the downstream GC controlled gene GILZ, suggesting this mechanism as one of the possible causes of resistance to GCs.

### miRNA involved in IBD

The pathophysiology of IBD is not yet clear, and genetic, epigenetic, infectious and immunological factors seem to play a role. It has been suggested that the gastrointestinal inflammation is the result of an altered activation of the immune system to a luminal factor, such as intestinal flora, in genetically predisposed subjects.

Among the many biological processes regulated by miRNAs, it is now accepted that these small non coding RNAs contribute to the maintenance of immunological homeostasis at mucosal sites<sup>[88,89]</sup>. The role of miRNAs in the pathogenesis of IBD has been thoroughly considered (see recent reviews<sup>[32,90,91]</sup>), and it has been suggested that these small non coding RNAs represent an important player in the complex interactions which results in IBD clinical features. Of particular interest is the observation that miRNA expression changes during tissue progres-

sion from normal to inflamed and varies according to the type and evolutionary stage of IBD<sup>[92]</sup>. Indeed, a number of studies have identified a specific differential expression of miRNAs in IBD and unique miRNA expression profiles for the different subtypes of IBDs, both in human tissues collected by colonoscopic biopsies and in peripheral blood samples, have been demonstrated<sup>[32,90,91]</sup>.

It has been argued that genetic polymorphisms in miRNAs, as well as in miRNA target genes can affect their regulatory function and, consequently, the expression level of their target mRNAs. Most studies have described an association between SNPs in miRNA genes and human cancers<sup>[93-98]</sup>, and only recently the association between mRNA related SNPs and the risk of IBD has been examined<sup>[99]</sup>. Bioinformatic approaches have been used to analyze the association between diseases-linked SNPs, miRNAs and mRNAs: SNP data derived from genome wide association studies that were correlated with miRNA, revealed a CD phenocode comprising rs11209026, rs7807268, rs254215, rs2542151 in miR-125, rs11805303 in miR-519, and rs6908425 in miR-181<sup>[30]</sup>. Of interest, miR-181, miR-519 and miR-119 could target mRNAs encoded by genes involved in the importin pathway, whereas miR-181 and miR-125 are potential regulators of components of inflammasome pathway. Both importin and inflammasome are involved also in GC molecular mechanism: importin is a nuclear transport protein responsible for the translocation of the complex GR-GC into the nucleus<sup>[2]</sup>, and variants in inflammasome gene have been correlated with steroid resistance in pediatric IBD patients<sup>[100]</sup>.

An association between rs3746444 in miR-499 and UC susceptibility has been observed in 170 Japanese patients: this SNP may alter the function or expression of miR-499, altering the regulation of target mRNAs related to inflammatory immune responses, and influencing the pathophysiological features of UC<sup>[101]</sup>. Of particular interest is the observation that the rs3746444 AG genotype was associated also with steroid dependence and refractory phenotype, whereas the rs3746444 AA genotype was inversely related to hospitalization time, steroid dependence, and refractory phenotype. In addition, the rs11614913 TT genotype held a significantly higher risk of refractory phenotype.

## CONCLUSION

There is a lot of interest in identifying the role of miRNAs in the modulation of drug response, but studies about this topic are still very limited, and the possible correlation between miRNAs expression and variability in GC response in IBD patients has not yet been extensively examined. Studies about miRNAs and pharmacogenomics may represent a promising investigation topic that could increase the understanding of the pharmacology of steroids in IBDs and possibly in other diseases.

A number of studies have shown that GCs can modify the expression profile of different miRNAs, however,

the obtained results have been highly variable. The differences observed can possibly be ascribed to the different tissues or cell lines analysed or different experimental protocols, and to date it is not possible to recognize a specific miRNA pattern regulated by GCs.

miRNA regulation by GCs in IBDs has never been analyzed in clinical prospective studies, in which patients are followed from diagnosis and throughout steroid therapy: the identification of miRNAs differently expressed as a consequence of GC treatment in comparison to diagnosis, could be an important innovative approach. This type of study design will reduce to the minimum the effect of confounding factors and results should be easier to translate into clinical practice.

Moreover, existing studies employ techniques based on the use of reverse transcription quantitative PCR and microarrays, based on the analysis and quantification of already known miRNAs. Using next generation sequencing technologies it should be possible to detect novel, still unrecognised miRNAs, and identify new miRNA isoforms (iso-miRs) as well.

In the future, the increased availability and the reduced costs of RNA profiling should enable the clinicians to stratify patients on specific miRNA biomarkers before starting GC treatment. This will allow the personalization of therapy, avoiding a treatment doomed to failure, increasing efficacy and reducing toxicity.

### Abstract

Colorectal cancer (CRC) is the fourth most commonly diagnosed cancer and the second leading cause of cancer death in both men and women in the United States, with about 142820 new cases and 50830 deaths expected in 2013. Metastatic disease (mCRC) remains a challenge for oncologists worldwide due to its potential comorbidities. Recently, chemotherapy regimens containing 5-fluorouracil, leucovorin, oxaliplatin and irinotecan combinations are a standard of care in the metastatic disease. Currently, biological therapies involving vascular endothelial growth factor and epidermal growth factor receptor pathways, such as bevacizumab and cetuximab, have emerged as good option for improving mCRC patient survival. Now, aflibercept plus standard chemotherapy has also been approved in second line regimen for mCRC patients. Our review will discuss novel biological drugs and their indications for mCRC patients and will bring future perspectives in this regard.

### INTRODUCTION

Colorectal cancer (CRC) is the fourth most commonly diagnosed cancer and the second leading cause of cancer death in both men and women in the United States, with about 142820 new cases and 50830 deaths expected in 2013<sup>[1]</sup>. In Europe, CRC represents the second most common cancer and leading cause of cancer death, in both genders combined<sup>[2]</sup>. Consequently, CRC is considered a prominent global health problem.

Usually, early CRC has no symptoms, and this is why screening is so important. Moreover, almost all symptoms (*i.e.*, change in bowel habits, general abdominal discomfort, weight loss with no apparent cause, constant tiredness) are not well specific. Consequently, CRC might be diagnosed when a patient has symptoms or as a result of a screening program<sup>[3]</sup>. Colonoscopy is the main diagnostic tool for primary screening due to its great benefit on either flexible sigmoidoscopy or guaiac fecal occult

blood test<sup>[4]</sup>.

The 1- and 5-year relative survival rates for patients with CRC are respectively 83.2% and 64.3%, considering all stages. Additionally, ten years after diagnosis, survival continues to decline to 57.6%<sup>[3]</sup>. The most important problem remains disease relapse following surgery since, commonly, it is the cause of death in these patients<sup>[3]</sup>. This fact becomes relevant when we observe that when CRC are detected at a localized stage, the 5-year relative survival rate is 90.1% and, after disease involves adjacent organs or lymph nodes, the 5-year survival rate falls to 69.2%. Moreover, when cancer has spread to distant organs, the 5-year survival rate is 11.7%<sup>[5]</sup>.

Many patients have metastatic disease (mCRC) initially not suitable for resection<sup>[6]</sup>. The majority of patients with mCRC cannot be cured, and the goals of chemotherapy for them are to prolong survival, improve quality of life and provide palliation, when applicable<sup>[7]</sup>. Over the past years, the outcome of these patients has been improved, with median survival reaching almost 24 mo<sup>[6,8]</sup>.

The liver is the most common site of hematogenous metastasis in CRC, and its appearance is a frequent event for patients with CRC and remains a major cause of cancer-related death<sup>[9]</sup>. Approximately 25% of patients present synchronous liver metastasis at time of diagnosis, and another 25% of patients will develop liver metastases during the course of their disease, usually within a 2-year period after initial surgical treatment of their primary tumor<sup>[10]</sup>. The only potentially curative treatment for patients with liver metastasis is surgical resection, which results in a 5-year survival rate of 36%<sup>[11]</sup>. Nevertheless, 70% of these patients will suffer a relapse after resection of their hepatic metastasis, with the majority in the first 2 years after surgery and the remaining continuing to occur up to 10 years<sup>[12]</sup>.

Over the past years, the development and incorporation of agents that target angiogenesis in clinical practice have led to improvements in the treatment of mCRC, with benefits in progression-free survival (PSF) and overall survival (OS) in these patients<sup>[13]</sup>. This paper aims to review the impact of known and new anti-angiogenic therapies for mCRC, especially those which target vascular endothelial growth factor (VEGF) pathways.

### Angiogenesis and CRC-molecular mechanisms

Blood vessel formation comprises two main types: vasculogenesis and angiogenesis. During early embryonic development, vasculogenesis is the process responsible for the formation of the primary vasculature of the body, which consists in the formation of blood vessels from endothelial cell progenitors (*i.e.*, hemangioblasts)<sup>[14]</sup>. On the other hand, angiogenesis is a complex and highly regulated biological process that refers to the formation of new vascular segments. During this process, the combination of sprouting, splitting, and remodeling of the existing vessels occurs<sup>[15]</sup>. Physiologically angiogenesis occurs under tight regulation by a wide range of pro-angiogenic inducers, such as growth factors, chemokines,

angiogenic enzymes, endothelial-specific receptors, and adhesion molecules as well as various antiangiogenic factors including angiostatin, endostatin, thrombospondin, canstatin, and pigment epithelium-derived factor<sup>[16]</sup>. As blood vessels are needed to supply nutrients and oxygen to tissues, angiogenesis plays an essential role in normal growth and development. Nevertheless, imbalances between the angiogenic mediators and inhibitors may result in the development of pathologies, as cancer<sup>[17]</sup>.

In order to continue grow and metastasize, tumors need to continually acquire an adequate blood supply, which is accomplished by inducing angiogenesis<sup>[18]</sup>. Since Folkman recognized, in the early 1970s, the therapeutic potential for the inhibition of angiogenesis process in cancer, angiogenesis has been largely studied<sup>[19]</sup>.

Figure 1 shows the main angiogenic mechanisms related to VEGF pathways. The VEGF family, which plays a critical role in tumor angiogenesis<sup>[20]</sup>, includes six members: VEGF-A, -B, -C, -D, -E and placental growth factor (PlGF)<sup>[21]</sup>. VEGF-A, also known as VEGF, is the most important member and the major physiologic and pathologic mediator of angiogenic mechanism<sup>[20]</sup>. The *VEGF-A* gene, located on chromosome 6 (6p21.3), undergoes alternative splicing to yield mature isoforms of 121, 145, 165, 183, 189, and 206 amino acids<sup>[22-24]</sup>. *In vivo*, only three isoforms have been related to angiogenesis, VEGF<sub>121</sub>, VEGF<sub>145</sub> and VEGF<sub>165</sub>. The latter has been demonstrated to be a predominant isoform secreted by malignant and benign cells<sup>[25]</sup>. VEGF signals, mainly through VEGF receptor 2 (VEGFR-2) which is tightly expressed by endothelial cells, are involved in angiogenesis. VEGF binds to VEGF receptor 1 (VEGFR-1), with approximately 10 times the affinity of VEGFR-2 binding. However, its signal-transducing properties are extremely weak<sup>[26]</sup>.

Most solid tumors present hypoxic regions as they grow and, thus, outweigh their blood supply. The results of the cellular adaptation to hypoxic microenvironment are aggressive disease, resistance to therapy, and decreased patient survival<sup>[27]</sup>. The transcription factor hypoxia-inducible factor-1 (HIF-1 or HIF) is the most important regulator of the hypoxic response, which up-regulates expression of proteins involved in the regulation of several aspects of tumor biology, such as oxygen transport, iron metabolism, glycolysis, glucose transport, cell survival and proliferation, angiogenesis, invasion and metastasis<sup>[28,29]</sup>. VEGF is one of several proangiogenic factors directly activated by HIF-1 and acts to promote new blood vessel formation and thereby provide the re-establishment of oxygen and nutrient supply<sup>[27]</sup>.

Paracrine mechanisms generated through VEGF production by tumor cells may also influence angiogenesis pathways. However, those cells cannot adequately respond to VEGF directly since they do not have enough cell surface VEGF receptors for that purpose. In contrast, endothelial cells recruited during angiogenesis express numerous VEGF receptors, but produce little or no detectable VEGF ligand. In this context, the amount of

7957

ways but also by other pathways including Notch, angiopoietins and integrins<sup>[20]</sup>. The Notch pathway, an intercellular signaling pathway, influences many biological processes, including cell fate determination, cellular differentiation, proliferation, survival and apoptosis<sup>[37,38]</sup>. There are four Notch cell-surface receptors (Notch-1, -2, -3 and -4) and five Notch membrane-anchored ligands [Jagged-1, Jagged-2, Delta-like (Dll)-1, -3, and -4], expressed by various cell types. Both ligand and receptor are transmembrane proteins with large extracellular domains that consist of epidermal growth factor (EGF)-like repeats. Notch is synthesized as a precursor protein that is processed in the Golgi before being transported to the cell surface, where it resides as a heterodimer. Interaction of Notch receptors with Notch ligands, between two bordering cells, initiates a series of successive proteolysis cleavages. The first cleavage, mediated by ADAM-family metalloproteases such as ADAM10 or tumor necrosis factor  $\alpha$ -converting enzyme (TACE), generates a substrate for cleavage by the gamma-secretase complex. This cleavage leads to the release of Notch intracellular domain (NICD) from the cell membrane. This protein fragment, then, translocates into the nucleus and operates as a cofactor to regulate transcription of Notch target genes<sup>[39]</sup>. The induction of Dll4-Notch signaling acts as a mechanism intended to prevent excessive angiogenesis and to control the development of new blood vessels<sup>[40]</sup>.

Vascular endothelial cells express Notch 1 and Notch

4 receptors and the Jagged-1, Dll1, and Dll4 ligands. Among these, Dll4 is expressed exclusively by endothelial cells<sup>[20]</sup>. Dll4 is usually induced by VEGF as a negative-feedback regulator of vascular growth. In contrast to VEGF blockade, which results in a loss of many tumor vessels and an apparent normalization of the remaining vessels of the tumor, DLL4 blockade results in a striking increase in these vessels. Paradoxically, this increased vascularity is associated with decreased tumor growth, even for tumors that are highly resistant to blockade of VEGF<sup>[41]</sup>. Since VEGF induces Dll4 and Dll4 induces vascular quiescence and differentiation, and down-regulates VEGFR-2<sup>[42]</sup>, it is obvious that the balance of these two pathways may be important to the development and outcomes of therapeutic acting in these pathways<sup>[43]</sup>.

Recently, the angiopoietins have emerged as important regulators of angiogenesis<sup>[16]</sup>. The human angiopoietin family comprises Ang-1, -2 and -3, all of which act as ligands for endothelial cell-specific tyrosine kinase receptor Tie2, expressed principally on the vascular endothelial cells<sup>[44-46]</sup>.

Ang-1, which is predominantly expressed in perivascular cells such as pericytes, vascular smooth muscle cells, fibroblasts and tumor cells, binds to Tie2 receptor as an antagonist. Upon binding of Ang-1, Tie-2 receptor autophosphorylates, leading to stimulation of various intracellular signaling pathways which promote endothelial cell survival and the maintenance of an endothelial barrier and a quiescent vasculature. Mural cells, such as vascular smooth muscle cells and pericytes, constantly produce Ang-1 under physiological conditions, and maintain vascular stabilization and maturation<sup>[47]</sup>. On the other hand, Ang-2 produced by the endothelium, acts as an antagonist for Tie2 by competing with Ang-1<sup>[45]</sup>. It induces vascular destabilization and vessel proliferation. VEGF and angiopoietins have complementary roles in angiogenesis. In the presence of VEGF, Ang-2 stimulates tumor angiogenesis by promoting vessel destabilization, whereas in the absence of VEGF, Ang-2 promotes endothelial cell death and vessel regression<sup>[48]</sup>.

Blockade of Tie-2 pathway has been more difficult than blockade of the VEGF pathway, due to the complexity of agonistic and antagonistic ligands for the same receptor. Moreover, it has been a challenge to find and design effective and specific drugs against Tie-2 or angiopoietins<sup>[20]</sup>.

Fibroblast growth factor (FGF)/FGF receptor (FGFR) signaling is involved in multiple cellular processes, such as proliferation, anti-apoptosis, drug resistance, and angiogenesis<sup>[49]</sup>. FGFs are heparin-binding growth factors that are part of a family that comprises 23 members (FGF-1 to -23), of which only 18 are functional ligands for FGFR in humans. The members of the FGFR family (FGFR-1 to -4) share a common domain architecture consisting of extracellular immunoglobulin-like domains and a cytoplasmic tyrosine kinase domain<sup>[50]</sup>. Although FGF1 and FGF2 are among the first discovered molecules that contribute to angiogenesis, some mem-

bers of the VEGF ligand family and VEGFR are now accepted to play a main role in driving embryonic vascularization, angiogenesis and lymphangiogenesis<sup>[51]</sup>. Nevertheless, both FGFs and VEGF cooperate to promote angiogenesis. FGF-2 induces the expression of VEGF in vascular endothelial cells, while the blockade of VEGF reduces the expression of endogenous FGF-2, suggesting a positive feedback mechanism. Furthermore, inhibition of FGFR-1 and FGFR-2 activity can reduce tumor vascularization as well as VEGF expression. Therefore, promotion of angiogenesis by FGFs may be dependent of crosstalk between FGF-VEGF signaling pathways<sup>[52]</sup>.

EGF signaling is initiated by the binding of EGF family members to the extracellular domain of erythroblastic leukemia viral oncogene homologue (ErbB) receptors. The ErbB receptor tyrosine kinase family comprises 4 members, namely, EGF receptor (EGFR)/ERBB1/HER1, ERBB2/HER2, ERBB3/HER3 and ERBB4/HER4<sup>[53]</sup>. The major contributors of these receptors are a complex signaling cascade that modulates growth, signaling, differentiation, adhesion, migration and survival of cancer cells<sup>[54]</sup>.

The EGF family members bind to the ErbB receptors and are classified into 3 groups based on their receptor affinities: in the first group, EGF, transforming growth factor- $\alpha$ , amphiregulin (AR), and epigen (EPG), specifically bind to EGFR; in the second group, betacellulin (BTC), heparin-binding EGF (HB-EGF), and epiregulin (EPR), which exhibit dual specificity, bind to both EGFR and ErbB4; and the third group, which includes neuregulins (NRGs), forms two subgroups on the basis of their capacity to bind ErbB3 and ErbB4 (NRG-1 and NRG-2) or only ErbB4 (NRG-3 and NRG-4)<sup>[53,55]</sup>. On binding, ErbBs form homo or heterodimers and initiate multiple pathways involving effectors including rat sarcoma viral oncogene homologue (RAS)/mitogen-activated protein kinase, phosphatidylinositol 3-kinase-AKT, mammalian target of rapamycin, signal transducer and activator of transcription, SRC tyrosine kinase, phospholipase C- $\gamma$ 1/protein kinase C (PKC) and p27. The activation of these pathways plays a relevant role in several aspects of development and tissue homeostasis<sup>[54]</sup>. Increased EGFR signaling is particularly common in several cancers, including CRC, through one or more of the family members<sup>[56]</sup>. EGFR and its family members, due to their vast role in the progression of cancer, have emerged as attractive candidates for anti-cancer therapy.

## TREATMENT OF mCRC

Nowadays, there are many therapeutic strategies approved by the Food and Drug Administration (FDA) for the management of mCRC: 5-fluorouracil (5-FU), leucovorin (LV), irinotecan, capecitabine, oxaliplatin, regorafenib, ziv-aflibercept, and the monoclonal antibodies bevacizumab, cetuximab, and panitumumab. Of these drugs, only few have FDA-approved indications for use as monotherapies and reveal activity as a single agent

**Table 1 Clinical trials and main anti-angiogenic drugs in metastatic disease**

mCRC: Metastatic colorectal cancer; PFS: Progression-free-survival; OS: Overall survival; ORR: Overall response rate; FOLFIRI: 5-fluorouracil + leucovorin + irinotecan; mFOLFOX6: 5-fluorouracil + leucovorin + oxaliplatin; HR: Harzard ratio.

against CRC, including fluoropyrimidines (5-FU and capecitabine), irinotecan, cetuximab, and panitumumab.

The combination chemotherapy is the only standard for first-line treatment of mCRC. Regardless of which regimen is used, outcome may be maximized in patients who receive, alone or in combination, 5-FU, LV, irinotecan, and oxaliplatin sometime during the course of treatment. These chemotherapy regimens have been extensively studied in phase II and III trials, both as first- and second-line therapies<sup>[57,58]</sup>. Tables 1 and 2 summarizes current and future trials on mCRC anti-angiogenic therapies.

### Antiangiogenic drugs

Bevacizumab is a humanized monoclonal antibody that binds and inactivates VEGF, preventing angiogenesis and, hence, tumor growth and proliferation. Bevacizumab contains human framework regions and the complementarity-determining regions of a murine antibody that inhibits all active isoforms of VEGF<sup>[59]</sup>. Currently, bevacizumab is the only agent specifically targeting the VEGF pathway for the treatment of CRC<sup>[60]</sup>.

Over the past decades, many trials have investigated bevacizumab in mCRC. It has been studied with different active chemotherapy and biological agents, as well as in multiple treatment setting, sequencing and duration<sup>[61]</sup>.

The phase II trial conducted by Kabbinavar *et al*<sup>[62]</sup> compared two doses of bevacizumab plus 5-FU/LV (low-dose bevacizumab: 5 mg/kg every 2 wk; high-dose bevacizumab: 10 mg/kg every 2 wk) with 5-FU/LV alone in 104 patients untreated. Compared with the 5-FU/LV control arm, treatment with bevacizumab (at both dose

levels) plus 5-FU/LV resulted in a higher response rate (RR) (control arm: 17%; low-dose arm: 40%; high-dose arm: 24%), longer median time to disease progression (control arm: 5.2 mo; low-dose arm: 9.0 mo; high-dose arm: 7.2 mo), and longer median survival (control arm: 13.8 mo; low-dose arm: 21.5 mo; high-dose arm: 16.1 mo). Based on these results, in the most subsequent phase III trials on mCRC the 5 mg/kg bevacizumab dosing is chosen<sup>[61]</sup>.

The phase III AVF 2107 trial (NCT00109070) randomized 813 patients to receive IFL plus either bevacizumab 5 mg/kg (*n* = 402) or placebo (*n* = 411), every 2 wk. The addition of bevacizumab compared with IFL alone provided significantly clinical and statistical improvement in median OS (20.3 mo *vs* 15.6 mo; HR = 0.66, *P* < 0.001), PFS (10.6 mo *vs* 6.2 mo, HR = 0.54, *P* < 0.001) and overall response rate (ORR) (44.8% *vs* 34.8%, *P* = 0.004)<sup>[13]</sup>.

In the NO16966 phase III trial (NCT00069095), with 2 × 2 factorial design, 1401 patients with mCRC were randomized to receive FOLFOX or XELOX and then bevacizumab or placebo. Median PFS was significantly increased when bevacizumab was added (9.4 mo in bevacizumab group *vs* 8.0 mo in placebo group; HR = 0.83, *P* = 0.0023). Median OS was 21.3 mo in the bevacizumab group and 19.9 mo in the placebo group (HR = 0.89, *P* = 0.077), and RR was similar in both arms. A planned subset analysis demonstrated significant improvement of PFS with bevacizumab in the XELOX subgroup (*P* = 0.0026), as opposed when FOLFOX4 (*P* = 0.187) was added. Safety results showed that grade 3 or higher adverse events were slightly higher in the bevacizumab

**Table 2** Current clinical trials considering anti-angiogenic therapies for colorectal cancer

	Trial	Phase	Line	Therapy/arms	Status of trial
Bevacizumab	NCT01321957	II	1 <sup>st</sup>	FOLFOX + bevacizumab <i>vs</i> FOLFOX + bevacizumab + irinotecan	Currently recruiting participants
	NCT00819780	II	1 <sup>st</sup>	Panitumumab + mFOLFOX6 <i>vs</i> bevacizumab + mFOLFOX6	Ongoing, but not recruiting participants
	NCT01531595	II	1 <sup>st</sup>	3 cycles of XELOX + bevacizumab alternating with 3 cycles of XELIRI + bevacizumab	Currently recruiting participants
	NCT01067053	II	1 <sup>st</sup>	Bevacizumab + capecitabine + oxaliplatin - 6 cycles; after the first 6 cycles of treatment, continuing only with bevacizumab and capecitabine	Ongoing, but not recruiting participants
	NCT01765582	II	1 <sup>st</sup>	FOLFOXIRI + bevacizumab <i>vs</i> Sequential FOLFOXIRI + bevacizumab <i>vs</i> FOLFOX + bevacizumab	Currently recruiting participants
	NCT01006369	II	-	FOLFOX6 + bevacizumab + hydroxychloroquine <i>vs</i> XELOX + bevacizumab + hydroxychloroquine	Currently recruiting participants
	NCT01417494	II	1 <sup>st</sup>	Chemotherapy (FOLFIRI, FOLFOX, LV5FU2) + bevacizumab <i>vs</i> Chemotherapy (FOLFIRI, FOLFOX, LV5FU2)	Currently recruiting participants
	NCT01532804	II	2 <sup>nd</sup>	FOLFOX6 + bevacizumab (day 1 = day 15, 12 cycles) <i>vs</i> Raltitrexed + oxaliplatin + bevacizumab ( day 1 = day 21, 8 cycles)	Currently recruiting participants
	NCT00952029	II / III	1 <sup>st</sup>	FOLFIRI + bevacizumab and during the chemotherapy-free interval maintenance with bevacizumab <i>vs</i> FOLFIRI + bevacizumab and during the chemotherapy-free interval NO maintenance	Currently recruiting participants
Cetuximab	NCT01640405	III	1 <sup>st</sup>	mFOLFOX6 + bevacizumab <i>vs</i> FOLFIRI + bevacizumab	Currently recruiting participants
	NCT00444678	II	-	Cetuximab + capecitabine + oxaliplatin	Ongoing, but not recruiting participants
	NCT01251536	II	1 <sup>st</sup>	Cetuximab (standard dose: 250 mg/m <sup>2</sup> weekly) <i>vs</i> Cetuximab (dose escalation: days 22 and 29-350 mg/m <sup>2</sup> , from day 36 onwards - 500 mg/m <sup>2</sup> weekly)	Currently recruiting participants
	NCT01718808	II	1 <sup>st</sup>	Cetuximab + capecitabine <i>vs</i> Cetuximab	Currently recruiting participants
	NCT01867697	II	1 <sup>st</sup>	Cetuximab (biweekly) + FOLFIRI (continuously) <i>vs</i> Cetuximab (biweekly) + alternating FOLFIRI and mFOLFOX6	Currently recruiting participants
	NCT00640081	II	1 <sup>st</sup>	Intermittent chemotherapy plus intermittent cetuximab treatment (12 wk), plus cetuximab followed by a period off all therapy; reintroduction of the same chemotherapy and cetuximab regimen (12 wk after initial progression off treatment) <i>vs</i> Intermittent chemotherapy plus continuous cetuximab treatment (12 wk), plus cetuximab followed by a period of withdrawal of the chemotherapy, but continued weekly cetuximab monotherapy with reintroduction of the same chemotherapy regimen to the cetuximab (12 wk after initial progression off chemotherapy treatment)	Ongoing, but not recruiting participants
	NCT00479752	II	1 <sup>st</sup>	FOLFOX4 + cetuximab (initial dose: 400 mg/m <sup>2</sup> in week 1, followed by weekly doses of 250 mg/m <sup>2</sup> ) <i>vs</i> FOLFOX4 + cetuximab (500 mg/m <sup>2</sup> every 2 wk)	Ongoing, but not recruiting participants
	NCT00482222	III	1 <sup>st</sup>	Oxaliplatin/fluoropyrimidine <i>vs</i> oxaliplatin/fluoropyrimidine + cetuximab pre and post surgery	Currently recruiting participants
	NCT00433927	III	1 <sup>st</sup>	FOLFIRI + cetuximab <i>vs</i> FOLFIRI + bevacizumab	Ongoing, but not recruiting participants
Panitumumab	NCT01228734	III	1 <sup>st</sup>	Cetuximab + FOLFOX4 <i>vs</i> FOLFOX4	Ongoing, but not recruiting participants
	NCT01030042	III	2 <sup>nd</sup>	FOLFOX4 followed, after progression, by irinotecan + cetuximab <i>vs</i> Cetuximab + irinotecan	Currently recruiting participants
	NCT00885885	II	-	Panitumumab + FOLFOX4 <i>vs</i> Panitumumab + FOLFOX4	Ongoing, but not recruiting participants
	NCT01215539	II	1 <sup>st</sup>	Panitumumab + capecitabine + oxaliplatin	Currently recruiting participants
	NCT01126112	II	1 <sup>st</sup>	Panitumumab (6 mg/kg every 2 wk )	Ongoing, but not recruiting participants
	NCT00819780	II	1 <sup>st</sup>	Panitumumab + mFOLFOX 6 <i>vs</i> bevacizumab + mFOLFOX 6	Ongoing, but not recruiting participants
	NCT01328171	II	1 <sup>st</sup>	FOLFOXIRI + panitumumab <i>vs</i> FOLFOXIRI	Currently recruiting participants
	NCT01508000	II	1 <sup>st</sup>	mFOLFOX6 (6 cycles after and before surgery) + surgery <i>vs</i> mFOLFOX6 + bevacizumab (6 cycles after and before surgery) + surgery <i>vs</i> mFOLFOX6 + panitumumab (6 cycles after and before surgery) + surgery	Not yet open for participant recruitment
	NCT01814501	II	2 <sup>nd</sup>	5-FU + irinotecan + panitumumab	Currently recruiting participants
	NCT00940316	II	2 <sup>nd</sup>	Erlotinib + panitumumab + irinotecan (treatment repeats every 2 wk) <i>vs</i> Erlotinib + panitumumab (treatment repeats every 2 wk) <i>vs</i> Erlotinib + panitumumab	Currently recruiting participants
	NCT00364013	III	1 <sup>st</sup>	FOLFOX + panitumumab <i>vs</i> FOLFOX	Ongoing, but not recruiting participants

	NCT01910610	III	1 <sup>st</sup>	FOLFIRI + cetuximab, followed by oxaliplatin-based chemotherapy + bevacizumab <i>vs</i> OPTIMOX + bevacizumab, followed by irinotecan-based chemotherapy + bevacizumab, followed by an anti-EGFR agent (cetuximab +/- irinotecan or panitumumab) with or without irinotecan	Not yet open for participant recruitment
Aflibercept	NCT01669720	II	2 <sup>nd</sup>	Aflibercept <i>iv</i> (4 mg/kg every 2 wk)	Currently recruiting participants
	NCT01652196	II	1 <sup>st</sup>	Aflibercept <i>iv</i> + mFOLFOX 6 <i>iv</i> (days 1 and 15; repeats every 28 d)	Currently recruiting participants
	NCT01802684	II	1 <sup>st</sup>	Induction therapy (sequence #1) Regimen: Aflibercept + mFOLFOX7 - 6 cycles (3 mo) Maintenance after induction (sequence #2) First phase (sequence #2A); Regimen: Aflibercept + fluoropyrimidine (simplified LV5FU2 or capecitabine) - 6 cycles (3 mo) Second phase (sequence #2B); Regimen: Aflibercept +/- fluoropyrimidine (simplified LV5FU2 or capecitabine) - until PD or limiting toxicity Reintroduction (sequence #3); Regimen: Aflibercept + mFOLFOX7 - 6 cycles (3 mo) Maintenance after reintroduction (sequence #4); Regimen: Aflibercept + fluoropyrimidine - until PD or limiting toxicity	Not yet open for participant recruitment
	NCT01882868	II	2 <sup>nd</sup>	Aflibercept <i>iv</i> + FOLFIRI Aflibercept + FOLFIRI (every 2 wk)	Currently recruiting participants
	NCT01889680	II	1 <sup>st</sup>	mFOLFOX6 + aflibercept (every 14 d for 6 cycles) plus 5-FU/LV (every 14 d) <i>vs</i> mFOLFOX6 + aflibercept (every 14 d for 6 cycles) plus 5-FU/LV + aflibercept (every 14 d)	Not yet open for participant recruitment
	NCT01646554	II / III	1 <sup>st</sup>	mFOLFOX6 and SURGERY 6 cycles before and 6 cycles after surgery consisting in: Hour 0: Oxaliplatin 85 mg/m <sup>2</sup> <i>iv</i> 2-h infusion; Hour 0: Folinic acid 400 mg/m <sup>2</sup> (DL form) or 200 mg/m <sup>2</sup> (L form) <i>iv</i> 2-h infusion; Hour 2: 5-FU 400 mg/m <sup>2</sup> <i>iv</i> bolus over 2-4 min; Hour 2: 5-FU 2400 mg/m <sup>2</sup> given as a continuous infusion over 46 h; On day 1 of a 14 d cycle <i>vs</i> mFOLFOX6 + aflibercept and surgery; 6 cycles before and 6 cycles after surgery consisting in: Hour 0: Aflibercept 4 mg/kg intravenous infusion 1-h; Hour 1: Oxaliplatin 85 mg/m <sup>2</sup> 2-h infusion; Hour 1: Folinic acid 400 mg/m <sup>2</sup> (DL form) or 200 mg/m <sup>2</sup> (L form) 2-h infusion; Hour 3: 5-FU bolus 400 mg/m <sup>2</sup> <i>iv</i> bolus over 2-4 min; Hour 3: 5-FU 2400 mg/m <sup>2</sup> given as a continuous infusion over 46 h; Day 1 of a 14 day cycle	Not yet open for participant recruitment
	NCT01661270	III	2 <sup>nd</sup>	Aflibercept <i>iv</i> (day 1 of each cycle, every 2 wk) + FOLFIRI <i>vs</i> Placebo <i>iv</i> (day 1 of each cycle, every 2 wk) + FOLFIRI	Currently recruiting participants
	NCT01571284	III	2 <sup>nd</sup>	Aflibercept IV (every 2 wk) + FOLFIRI	Currently recruiting participants
	NCT01670721	III	2 <sup>nd</sup>	Aflibercept IV (on day 1) + FOLFIRI administered as follows: dI-leucovorin infusion over 2 h on day 1; Irinotecan: infusion over 90-min infusion, on day 1, followed by bolus 5-FU and 5-FU continuous infusion over 46 h or as individualized by physician's clinical judgment; Treatment cycle to be administered every 2 wk	Currently recruiting participants
Brivanib	NCT01367275	II	2 <sup>nd</sup>	Brivanib (800 mg orally daily days 1-14) + Irinotecan <i>iv</i> (180 mg/m <sup>2</sup> on day 1)	Ongoing, but not recruiting participants
Cediranib	NCT00588900	II	2 <sup>nd</sup>	Irinotecan <i>iv</i> (days 1 and 8) + Cediranib oral (days 1-21)	The recruitment status of this study is unknown because the information has not been verified recently
Ramucirumab	NCT01111604	II	2 <sup>nd</sup>	mFOLFOX-6 <i>vs</i> mFOLFOX-6 + ramucirumab (8 mg/kg <i>iv</i> infusion, administered every 2 wk) <i>vs</i> mFOLFOX-6 + icrucumab (15 mg/kg <i>iv</i> infusion, administered every 2 wk)	Ongoing, but not recruiting participants
	NCT01183780	III	2 <sup>nd</sup>	FOLFIRI + ramucirumab (8 mg/kg administered intravenously every 2 wk) <i>vs</i> FOLFIRI + placebo	Currently recruiting participants
Regorafenib	NCT01298570	II	2 <sup>nd</sup>	Regorafenib (160 mg, <i>po</i> , daily, per 7 day cycle) + FOLFIRI (day 1 and day 15 of each 28 d cycle) <i>vs</i> Placebo (oral administration, days 4-10 and days 18-24 of 28 day cycle +) + FOLFIRI (day 1 and day 15 of each 28 d cycle)	Currently recruiting participants
	NCT01289821	II	1 <sup>st</sup>	Day 1 and day 15 of each cycle: 85 mg/m <sup>2</sup> oxaliplatin + folinic acid (either 400 mg/m <sup>2</sup> D/L-folinic acid or 200 mg/m <sup>2</sup> L-folinic acid), <i>iv</i> + 400 mg/m <sup>2</sup> 5 FU <i>iv</i> + 2400 mg/m <sup>2</sup> 5 <i>iv</i> ; Days 4 to 10 and days 18 to 24: regorafenib 160 mg (four 40 mg tablets)	Ongoing, but not recruiting participants
	NCT01875380	II	1 <sup>st</sup>	Regorafenib (orally, 160 mg per day for 3 wk, followed by 1 wk of rest)	Not yet open for participant recruitment
	NCT01103323	III	2 <sup>nd</sup>	Regorafenib (160 mg per oral once daily for 3 wk on 1 wk off of every 4 wk cycle) <i>vs</i> Placebo (per oral once daily for 3 wk on 1 wk off of every 4 wk cycle)	Ongoing, but not recruiting participants
	NCT01584830	III	2 <sup>nd</sup>	Regorafenib [3 wk on/1 wk off (160 mg <i>od po</i> )] Placebo [3 wk on/1 wk off (160 mg <i>od po</i> )]	Ongoing, but not recruiting participants
	NCT01853319	III	2 <sup>nd</sup>	Regorafenib (160 mg per oral every day for 3 wk of every 4 wk cycle)	Not yet open for participant recruitment
	NCT01538680	III	2 <sup>nd</sup>	Regorafenib (160 mg <i>po</i> every day for 3 wk on, 1 wk off)	Expanded access is currently available for this treatment

Semaxanib	NCT00021281	III	1 <sup>st</sup>	Semaxanib <i>iv</i> (on days 1, 4, 8, 11, 15, 18, 22, 25, 29, 32, 36 and 39) + irinotecan <i>iv</i> , leucovorin calcium <i>iv</i> , fluorouracil <i>iv</i> (on days 1, 8, 15, and 22) (every 6 wk) <i>vs</i> Irinotecan <i>iv</i> , leucovorin calcium <i>iv</i> , fluorouracil <i>iv</i> (on days 1, 8, 15, and 22) (every 6 wk) <i>vs</i> Semaxanib <i>iv</i> (on days 1, 4, 8, 11, 15, 18, 22, 25, 29, 32, 36 and 39) + irinotecan <i>iv</i> (days 1, 15 and 29) + leucovorin calcium <i>iv</i> , fluorouracil <i>iv</i> (on days 1, 2, 15, 16, 29 and 30) <i>vs</i> Irinotecan <i>iv</i> , leucovorin calcium <i>iv</i> , fluorouracil <i>iv</i> (on days 1, 8, 15, and 22) (every 6 wk)	The recruitment status of this study is unknown because the information has not been verified recently
Sorafenib	NCT01715441 NEXIRI 2	II	2 <sup>nd</sup>	Irinotecan 180 mg/m <sup>2</sup> <i>iv</i> with cross over to irinotecan and sorafenib combination at progression <i>vs</i> Sorafenib 400 mg twice daily with cross over to irinotecan and sorafenib combination at progression <i>vs</i> Irinotecan 120 mg/m <sup>2</sup> <i>iv</i> at cycle 1, 150 mg/m <sup>2</sup> at cycle 2 and 180 mg/m <sup>2</sup> at cycle 3 + sorafenib 400 mg twice daily from cycle 1	Currently recruiting participants
	NCT01471353	II	2 <sup>nd</sup>	Sorafenib 200-400 mg <i>po</i> twice daily on days 1-21 (dose escalation scheme) + capecitabine 1000 mg/m <sup>2</sup> <i>po</i> twice daily on days 1-14 repeated every 21 d	Currently recruiting participants
	NCT00826540	II	2 <sup>nd</sup>	Sorafenib twice daily on days 1-5 and 8-12 + bevacizumab <i>iv</i> on day 1	Ongoing, but not recruiting participants
	NCT00839111	II	2 <sup>nd</sup>	Sorafenib (400 mg twice daily from day 3 to day 14, day 17-28) + FOLFIRI	The recruitment status of this study is unknown because the information has not been verified recently
	NCT01290926	II	2 <sup>nd</sup>	Sorafenib (200 mg in the morning, 400 mg in the evening) + capecitabine (850 mg/m <sup>2</sup> twice daily)	The recruitment status of this study is unknown because the information has not been verified recently
	NCT00326495	II	2 <sup>nd</sup>	Oral sorafenib (400 mg by twice daily) plus cetuximab (400 mg/m <sup>2</sup> , week 1; 250 mg/m <sup>2</sup> <i>iv</i> , weekly)	Currently recruiting participants
Sunitinib	NCT00936832	II	1 <sup>st</sup>	FOLFIRI (on days 1, 15, and 29) + oral sunitinib (on days 1-28). (repeats every 6 wk)	The recruitment status of this study is unknown because the information has not been verified recently

Research on July 25, 2013 (<http://clinicaltrials.gov>). 5-FU: 5-fluorouracil; FOLFIRI: 5-fluorouracil + leucovorin + irinotecan; mFOLFOX6: 5-fluorouracil + leucovorin + oxaliplatin; HR: Hazard ratio.

group (30% *vs* 21%)<sup>[63]</sup>.

In the phase III MAX study, 471 patients with previously untreated and unresectable mCRC were randomly assigned to the following arms: capecitabine alone, capecitabine plus bevacizumab, or capecitabine, bevacizumab, and mitomycin. Median PFS was 5.7 mo for the capecitabine arm, 8.5 mo for the capecitabine-bevacizumab arm, and 8.4 mo for the capecitabine-bevacizumab-mitomycin arm. Thus, there was statistical improvement in PFS between the capecitabine arm and the other two arms (capecitabine *vs* capecitabine-bevacizumab: HR = 0.63,  $P < 0.001$ ; capecitabine *vs* capecitabine-bevacizumab-mitomycin: HR = 0.59,  $P < 0.001$ )<sup>[64]</sup>. Based on these results, in United States and Europe, bevacizumab in association with standard chemotherapy has been approved for first-line treatment of KRAS-mutant mCRC or for second-line treatment of KRAS-wild type patients previously treated with anti-EGFR drugs.

Despite those interesting benefits reported in previous trials, researchers and clinicians should be knowledgeable about toxicities, such as for hypertension and bleeding.

### Anti-EGFR agents

Cetuximab and panitumumab are two EGFR inhibitors currently indicated as monotherapy in patients with wild-type KRAS tumors as a first or second-line treatment<sup>[65]</sup>. Only cetuximab is indicated in combination with irinotecan, and has been approved for use in first-line in Europe

as mono-therapy or in combination with chemotherapy<sup>[66]</sup>.

Cetuximab is a recombinant human-murine chimeric IgG1 monoclonal antibody that binds to the extracellular region of the EGFR with high specificity and with higher affinity than EGF on normal and tumor cells<sup>[67]</sup>.

A phase II clinical trial conducted by Tabernero *et al*<sup>[68]</sup> assessed 43 patients who received cetuximab and FOLF-FOX4 as first-line chemotherapy. RR was 72%; median PFS was 12.3 mo and median OS was 30 mo. Cetuximab did not increase the characteristic toxicity of FOLFOX4 and was collectively well tolerated. The most commonly reported grade 3 or higher adverse events were diarrhea, neutropenia, and paresthesia.

The OPUS study, also a phase II trial (NCT00125034), included 337 patients who were randomized to receive FOLFOX4 with cetuximab ( $n = 169$ ) or alone ( $n = 168$ ) in first-line chemotherapy<sup>[69]</sup>. In 93% of measured KRAS patient samples, 57% were KRAS-wild type. Patients whose tumors were KRAS-wild type who received cetuximab plus FOLFOX4 had a 2.6-fold increased odds ratio of response (ORR: 57% *vs* 34%, OR = 2.551,  $P = 0.0027$ ) and a 43% decrease in the risk of disease progression (median PFS 8.3 mo *vs* 7.2 mo, HR = 0.567,  $P = 0.0064$ ) compared with those who received FOLFOX4 alone. Also, median OS was improved by the addition of cetuximab to FOLFOX4 for patients in that group (22.8 mo *vs* 18.5 mo, HR = 0.855,  $P = 0.39$ ). On the other hand, patients whose tumors carried KRAS mutations who

received cetuximab plus FOLFOX4 had a decreased odd of response (34% *vs* 53%, OR = 0.459,  $P = 0.0290$ ) and a higher risk of disease progression (median PFS 5.5 mo *vs* 8.6 mo, HR = 1.720,  $P = 0.0153$ ) compared with those who received FOLFOX4 alone<sup>[70]</sup>.

In the phase III CRYSTAL study (NCT00154102), 1198 patients who received cetuximab plus FOLFIRI ( $n = 599$ ) or FOLFIRI alone ( $n = 599$ ) were included. The addition of cetuximab to chemotherapy significantly reduced the risk of progression by 15% (8.9 mo *vs* 8.0 mo, HR = 0.85,  $P = 0.048$ ) and improved ORR (46.9% *vs* 38.7%, OR = 1.40,  $P = 0.048$ ). On the other hand, no significant difference in median OS between the two treatment groups was observed (19.9 mo *vs* 18.6 mo, HR = 0.93,  $P = 0.31$ )<sup>[71]</sup>. In that study, *KRAS* and *BRAF* mutations were detected in 37% and 6% of patients, respectively. The addition of cetuximab to FOLFIRI in patients with wild-type *KRAS* resulted in significant improvement in median OS (23.5 mo *vs* 20.0 mo, HR = 0.796,  $P = 0.0093$ ), median PSF (9.9 mo *vs* 8.4 mo, HR = 0.696,  $P = 0.0012$ ), and RR (57.3% *vs* 39.7%, OR = 2.069,  $P < 0.001$ ) compared with FOLFIRI alone. These results showed the role of *KRAS* mutation status as a powerful predictive biomarker for the efficacy of cetuximab plus FOLFIRI. Concerning grade 3 or 4 adverse events, they were more common with use of regimen with cetuximab and included skin reactions, infusion reactions and diarrhea<sup>[72]</sup>.

In the phase III study NORDIC V II (NCT00145314), 571 patients with mCRC were randomized to one of the following three arms: continuous FLOX alone or with cetuximab or intermittent FLOX with continuous weekly cetuximab. No differences were found in RR, median PFS or OS in patients receiving cetuximab, either in *KRAS*-mutant or -wild-type<sup>[73]</sup>.

In the phase III trial MRC COIN, 1630 patients were randomized to receive oxaliplatin-based chemotherapy (FOLFOX or XELOX) with or without cetuximab. The determination of *KRAS* mutation was performed in 1316 (81%) patients and it was identified in 729 (55%) patients<sup>[74]</sup>. Patients with wild-type *KRAS* tumors showed no improvements in median OS for cetuximab combined with chemotherapy when compared with chemotherapy alone (17.0 mo *vs* 17.9 mo, HR = 1.038,  $P = 0.68$ ) or PFS (8.6 mo *vs* 8.6 mo, HR = 0.96,  $P = 0.60$ ); however, there was an increase in ORR (57% *vs* 64%,  $P = 0.049$ ). Furthermore, there was a potential benefit with improvement in PFS for wild-type *KRAS* patients who received cetuximab plus infused 5-FU (HR = 0.72,  $P = 0.037$ ) but not cetuximab plus capecitabine (HR = 1.02, 95%CI: 0.82-1.26,  $P = 0.88$ )<sup>[74]</sup>.

Based on those trials, cetuximab in addition with standard chemotherapy has been approved in United States and Europe for wild-type *KRAS* mCRC patients in first-line regimen. It is important to monitor toxicity profile such as skin rash, diarrhea, nausea and mucositis in order to provide a good tolerability for patients. Regular medical visits before each cycle and support medication could

help address this concern.

Panitumumab is a recombinant human IgG2k monoclonal antibody that binds EGFR and prevents receptor dimerization, tyrosine autophosphorylation of EGFR, and the activation of downstream signaling molecules<sup>[75]</sup>.

The phase III trial PRIME (NCT00364013) included 1183 patients without prior chemotherapy for mCRC, who were randomly assigned to receive FOLFOX4 with or without panitumumab therapy. In the wild-type *KRAS* subgroup, panitumumab plus FOLFOX4 produced a significantly improved median PFS compared with FOLFOX4 alone (9.6 mo *vs* 8.0 mo, respectively; HR = 0.80,  $P = 0.02$ ). Nevertheless, a non-significant increase in median OS was found for panitumumab plus FOLFOX4 versus FOLFOX4 alone (23.9 mo *vs* 19.7 mo, respectively, HR = 0.83,  $P = 0.072$ ). In the mutant *KRAS* subgroup PFS was significantly reduced in the panitumumab plus FOLFOX4 arm when compared with the FOLFOX4 alone arm (HR = 1.29,  $P = 0.02$ ), and median OS was 15.5 mo *vs* 19.3 mo, respectively (HR = 1.24,  $P = 0.068$ )<sup>[76]</sup>.

As a conclusion, the use of cetuximab or panitumumab for wild-type *KRAS* mCRC patients will depend on the patient fitness, toxicity profile and drug wiliness in each circumstance. Both drugs are safe and prove to improve OS in the metastatic setting.

### Double monoclonal antibody therapy

The efficacy of bevacizumab and anti-EGFR agents in first-line treatment of mCRC encouraged two clinical trials of double monoclonal antibody therapy<sup>[77]</sup>.

In the phase III PACCE (NCT00115765) study, a total of 1053 patients were randomized to receive first-line chemotherapy [oxaliplatin/5-FU/LV ( $n = 823$  patients) or irinotecan/5-FU/LV ( $n = 230$  patients)] and bevacizumab with or without panitumumab. The study was discontinued early after a planned interim analysis showed reduced PFS and increased toxicity in the panitumumab arm. In the final analysis, median PFS (10.0 mo *vs* 11.4 mo for the panitumumab and control arms, respectively, HR = 1.27) and OS (19.4 mo *vs* 24.5 mo for the panitumumab and control arms, respectively) were shorter in the panitumumab arm in the entire study cohort as well as in the subset with wild-type *KRAS*. Grade 3/4 adverse events in the oxaliplatin (panitumumab *vs* control) cohort included skin toxicity (36% *vs* 1%), diarrhea (24% *vs* 13%), infections (19% *vs* 10%), and pulmonary embolism (6% *vs* 4%)<sup>[78]</sup>.

Similarly, in the phase III CAIRO2 trial, 755 patients with previously untreated mCRC were randomly assigned to receive capecitabine, oxaliplatin, and bevacizumab (CB regimen,  $n = 378$  patients) or the same regimen plus weekly cetuximab (CBC regimen,  $n = 377$  patients). The addition of cetuximab to XELOX plus bevacizumab resulted in shorter PFS in the entire study cohort (10.7 mo in the CB group *vs* 9.4 mo in the CBC group,  $P = 0.01$ ) and in the wild-type *KRAS* subset compared with XELOX plus bevacizumab. No difference in OS (20.3 mo in the CB group *vs* 19.4 mo in the CBC group,  $P = 0.16$ )

or ORR (50.0% in the CB group *vs* 52.7% in the CBC group,  $P = 0.49$ ) was verified between treatment arms. Patients treated with cetuximab who had tumors bearing a mutated *KRAS* gene had significantly decreased PFS as compared with cetuximab-treated patients with wild-type *KRAS* tumors (8.1 mo *vs* 10.5 mo,  $P = 0.04$ ) or patients with mutated *KRAS* tumors in the CB group (8.1 mo *vs* 12.5 mo,  $P = 0.003$ ). Grade 3 or 4 adverse events were more frequent in the CBC group, which were attributed to cetuximab-related adverse cutaneous effects<sup>[79]</sup>.

On the basis of these studies, double monoclonal antibody therapy with bevacizumab and an anti-EGFR agent is not recommended<sup>[77]</sup>.

### Management of liver metastasis

In order to determine the treatment strategy for hepatic metastases of CRC, it is important to verify the presence of one of three situations: metastases are readily resectable; metastatic disease is initially considered to be unresectable, principally due to location; or liver metastases are unlikely ever to become resectable<sup>[80]</sup>. Surgical resection undoubtedly remains the gold standard for the treatment of resectable colorectal liver metastases because it improves patient's prognosis if the metastases are resectable. When surgery is not indicated for hepatic metastases, chemotherapy is the first-choice treatment. In cases where surgical resection becomes possible and chemotherapy is effective, the long-term prognosis may be good<sup>[81]</sup>.

For patients with initially resectable disease, with good prognostic factors, one approach is immediate surgical resection and another is perioperative chemotherapy such as FOLFOX4<sup>[82,83]</sup>. Today, chemotherapy before surgery, even in patients with resectable metastases, can increase the complete resection rate, facilitate limited hepatectomies, improve postoperative recovery, treat micrometastases, provide a test of chemoresponsiveness, identify aggressive disease, spare ineffective therapy and prolong relapse-free survival<sup>[80]</sup>.

In potentially resectable colorectal liver metastases, neoadjuvant chemotherapy, infused 5-FU/LV, in combination with either irinotecan or oxaliplatin, as well as triple cytotoxic drug therapy, *e.g.*, FOLFOXIRI, and more recent combination chemotherapy regimens with targeted agents cetuximab and bevacizumab, should be considered to enhance the chance of cure of patient with initially unresectable liver metastases<sup>[80,82]</sup>.

In liver metastases that are unlikely to ever become resectable, palliative chemotherapy based on FOLFOX4/XELOX, FOLFIRI, with or without biological therapies, should be considered. In this setting, the possibility of doing a resection should not be excluded<sup>[82]</sup>.

showed in Tables 1 and 2. Further down, we will discuss the main trials in each field.

### Aflibercept

Aflibercept (Ziv-aflibercept, VEGF-Trap) is a recombinant VEGFR-antibody protein generated by the fusion of second immunoglobulin (Ig) domain of the VEGFR-1 and the third Ig domain of the VEGFR2 to the Fc domain of human IgG1<sup>[84]</sup>. In contrast to bevacizumab, which only binds to VEGF-A and forms multimeric complexes, aflibercept traps the different isoforms of VEGF-A, with approximately 1000-fold higher affinity than bevacizumab. In addition, aflibercept binds to VEGF-B and PlGF<sup>[85]</sup>. This VEGF-Trap effectively suppresses tumor growth and vascularization *in vivo*, resulting in stunted and almost completely avascular tumors<sup>[84]</sup>.

To investigate the potential role of aflibercept in the first-line treatment of mCRC with chemotherapy, the phase II AFFIRM trial (NCT00851084) recruited 236 patients who had never received therapy for mCRC or angiogenesis inhibitors. A total of 117 patients received mFOLFOX6 alone and 119 received mFOLFOX6 plus aflibercept (4 mg/kg *iv* every 2 wk). This study showed similar efficacy of FOLFOX plus aflibercept *vs* FOLFOX alone with respect to ORR (49.1% *vs* 45.9%, respectively) and median PFS (8.48 mo *vs* 8.77 mo, respectively)<sup>[86]</sup>.

The purpose of the phase III randomized, placebo-controlled clinical trial VELOUR (NCT00561470) was to investigate the efficacy and safety of aflibercept plus FOLFIRI in the second-line treatment of mCRC after oxaliplatin failure. 614 participants were randomly assigned to receive aflibercept (4 mg/kg intravenously; 612 patients) or placebo (614 patients) every 2 wk in combination with FOLFIRI. Median OS was 13.50 mo for aflibercept and 12.06 mo for placebo ( $HR = 0.817$ ,  $P = 0.0032$ ). Adding aflibercept to FOLFIRI also increased PFS relative to placebo plus FOLFIRI ( $HR = 0.758$ ,  $P = 0.0001$ ), with median PFS times of 6.90 mo *vs* 4.67 mo, respectively. The ORR in the aflibercept group was 19.8% compared with 11.1% in the placebo group ( $P = 0.001$ ). Grade 3/4 adverse events with an at least 2% higher incidence with aflibercept versus placebo were diarrhea, asthenia/fatigue, stomatitis/ulceration, infections, hypertension, gastrointestinal/abdominal pain, neutropenia/neutropenic complications and proteinuria<sup>[87]</sup>. Approximately one third of study participants had previously been treated with bevacizumab (187 in the placebo and 186 in the aflibercept group). Aflibercept produced a consistent trend towards prolonged OS ( $P = 0.7231$ ) and PFS ( $P = 0.6954$ ), regardless of prior use of bevacizumab. The incidence of adverse events in the aflibercept arm was similar in patients with prior bevacizumab (100%) to those without (98.9%), with a similar incidence of grade 3/4 events (82.5% and 83.9%, respectively). Results of this subgroup analysis showed that the addition of aflibercept to FOLFIRI leads to a consistent trend of increased OS and PFS, regardless of prior bevacizumab use<sup>[88]</sup>.

## TARGET THERAPIES-OTHERS

Others drugs are also under investigation or have been recently approved for the use in the metastatic setting, as

### Brivanib

Brivanib alaninate (BMS582664) is an oral, potent selective inhibitor of both the FGF and VEGF family of receptors<sup>[89]</sup>. Besides its antiangiogenic activity from blocking VEGFR-2 and -3, its ability to disrupt FGF receptors (FGFRs) -1, -2 and -3 has been suggested to circumvent primary and/or acquired resistance to VEGF blockade, and block FGF-dependent tumor proliferation<sup>[90]</sup>. In pre-clinical studies using *in vivo* tumor xenograft models of CRC resistant to bevacizumab, the strong antiangiogenic effects and antitumor activity of brivanib<sup>[91]</sup> were established. Phase I studies evaluated brivanib in combination with cetuximab in advanced gastrointestinal malignancies, including CRC, and demonstrated good tolerability and some evidence of clinical activity<sup>[92,93]</sup>.

A phase III study (NCT00640471) was carried out to evaluate combined use of brivanib and cetuximab without chemotherapy in third-line therapy for mCRC. A total of 750 patients were randomly assigned to treatment: 376 on brivanib plus cetuximab arm and 374 on placebo plus cetuximab arm. Patients included in this trial had wild-type *K-RAS*, had received prior fluoropyrimidine, and had been treated with irinotecan and oxaliplatin. Despite positive effects on PFS (5.0 mo in brivanib arm and 3.4 mo in placebo arm-HR = 0.72,  $P < 0.001$ ) and objective response, cetuximab plus brivanib increased toxicity and did not significantly improve OS in patients with metastatic, chemotherapy-refractory, wild-type *K-RAS* colorectal cancer (8.8 mo in brivanib arm and 8.1 mo in placebo arm-HR = 0.88,  $P = 0.12$ ). A total of 51 patients in brivanib arm and 27 patients in placebo arm had complete or partial response, yielding ORR of 13.6% and 7.2% for brivanib and placebo arms, respectively. The difference in ORR was statistically significant, supporting the brivanib plus cetuximab combination ( $P = 0.004$ ). The median duration of response was 5.8 mo in brivanib arm and 5.4 mo in placebo arm ( $P = 0.04$ ). Incidence of grade 3 or higher adverse events was 78% in brivanib arm and 53% in placebo arm, particularly fatigue, hypertension, rash, abdominal pain, diarrhea, dehydration, and anorexia. Hematologic adverse events were uncommon in both arms<sup>[90]</sup>.

### Cediranib

Cediranib (AZD2171) is a highly potent and selective inhibitor of the three VEGFRs and has a half-life suitable for once-daily oral dosing<sup>[94]</sup>. Cediranib is currently in phase III development for the first-line treatment of mCRC. The clinical development program includes two global phase II / III studies (HORIZON II and HORIZON III) in the first-line treatment setting, and a phase II study in second-line treatment.

HORIZON II (NCT00399035) is a randomized phase II / III trial aimed to compare chemotherapy (FOLFOX or XELOX) with cediranib or placebo as first-line therapy in patients with mCRC. In this study, cediranib plus chemotherapy significantly improved PFS (HR = 0.84) but not OS (HR = 0.94) or ORR, compared

with placebo plus chemotherapy.

HORIZON III (NCT00384176) incorporated a phase II / III study design. An end-of-phase-II analysis of efficacy and safety was undertaken to determine whether the study should continue into the phase III part. In this study, a randomized comparison of mFOLFOX6 in combination with cediranib versus mFOLFOX6 in combination with bevacizumab as first-line chemotherapy was made in patients with mCRC.

### Ramucirumab

Ramucirumab (IMC-1121B) is a fully humanized IgG1 monoclonal antibody that binds with high affinity to the extracellular VEGF-binding domain of VEGFR-2. Ramucirumab binds to a VEGFR-2 epitope involved in ligand binding and blocks VEGF ligands from binding this site and activating the receptor<sup>[95]</sup>. The inhibition of VEGF-stimulated VEGFR-2 activation provides ramucirumab significant antitumor activity in a range of malignancies in animal models as a single agent or in combination with other therapeutics<sup>[96]</sup>.

Several studies assessing ramucirumab in mCRC are currently underway (Table 2), without reported results. In a phase II study (NCT00862784) participants were treated with ramucirumab (8 mg/kg infusions every 2 wk) in combination with mFOLFOX6 as first-line therapy. In another phase II study (NCT01111604), patients with disease progression on an irinotecan-based, first-line chemotherapy regimen (FOLFIRI or CAPIRI) received mFOLFOX-6 alone or in combination with ramucirumab (8 mg/kg infusions every 2 wk). The phase II study NCT01079780 evaluated the combination of ramucirumab, cetuximab, and irinotecan versus cetuximab and irinotecan in patients with mCRC and progression following a bevacizumab-based regimen. A phase III study (NCT01183780) evaluates the role of ramucirumab, in combination with FOLFIRI chemotherapy, in patients with progression following first-line combination therapy with bevacizumab, oxaliplatin, and a fluoropyrimidine. Soon, ramucirumab may show its place in the current clinical practice scenario.

### Regorafenib

Regorafenib (BAY 73-4506) is an oral multikinase inhibitor that blocks the activity of multiple protein kinases, including kinases involved in the regulation of tumor angiogenesis (VEGFR-1, -2, and -3, and angiopoietin-1 receptor), oncogenesis (KIT, RET, RAF1, BRAF, and BRAFV600E), and the tumor microenvironment (PDGFR and FGFR)<sup>[97]</sup>. Preclinical studies (both *in vitro* and *in vivo*) showed a broad spectrum of antitumor activity of Regorafenib as a result of its ability to block several angiogenic, stromal and oncogenic kinases<sup>[98]</sup>.

The phase III trial CORRECT (NCT01103323) investigated the use of regorafenib in 760 patients who had received all locally approved standard therapies and had progressed during or within 3 mo after the last standard therapy. Patients were randomized in a 2:1 ratio to

receive regorafenib (160 mg orally daily for 3 out of 4 wk;  $n = 500$ ) versus placebo (3 wk on and 1 wk off;  $n = 253$ ), respectively. Randomization was based on pre-allocated block sizes and patients were stratified by previous treatment with VEGF-targeting drugs, time from diagnosis of metastatic disease ( $\geq 18$  or  $< 18$  mo), and geographical region. This study reported an increase in OS for regorafenib-treated patients against best supportive care, after progression on standard therapy (6.4 mo *vs* 5.0 mo, respectively, HR = 0.77, one-sided  $P = 0.0052$ ). Also, median PFS was 1.9 mo *vs* 1.7 mo when compared with placebo (HR = 0.49, one-sided  $P < 0.000001$ ). After the interim analysis, the study was unblinded and patients were allowed to cross over to the regorafenib arm. Treatment-related adverse events occurred in 93% of patients in the regorafenib arm and in 61% of those in the placebo arm. The most common grade 3 or higher side effects related to regorafenib were hand-foot skin reaction (17%), fatigue (10%), diarrhoea (7%), hypertension (7%), and rash or desquamation (6%)<sup>[99]</sup>. Based on the CORRECT study, regorafenib received approval from the FDA in October 2012 for the treatment of chemorefractory mCRC patients. However, we believe that this drug should be provided only in a specific context due to the modest results reported on OS benefit and pharmaco-economic evaluation.

### Semaxanib

Semaxanib (SU5416) is a potent, specific and competitive (with respect to ATP) inhibitor of the tyrosine kinase activity of Flk-1/KDR. Semaxanib was shown to inhibit VEGF-dependent mitogenesis of human endothelial cells, without inhibiting the growth of a variety of tumor cells *in vitro*<sup>[100,101]</sup>.

A clinical phase III study (NCT00004252) studied the combination of 5-FU/LV with semaxanib or alone, as a first-line therapy for mCRC patients. Although the study had already been completed, its results are not yet known.

### Sorafenib

Sorafenib is an oral multikinase inhibitor with anti-proliferative and anti-angiogenic effects. It inhibits the activity of the serine/threonine kinases c-Raf and B-Raf; the mitogen-activated protein kinases MEK and ERK; VEG; PDGFR; the cytokine receptor c-KIT; the receptor tyrosine kinases Flt-3 and RET; and the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway<sup>[102]</sup>. *In vivo* and *in vitro* studies showed that sorafenib inhibits tumor growth and disrupts tumor microvasculature through antiproliferative, antiangiogenic, and/or proapoptotic effects<sup>[103]</sup>.

In the double-blind placebo-controlled phase II study RESPECT (NCT00865709), the addition of sorafenib to mFOLFOX6 was evaluated. 198 patients were randomized to receive sorafenib (400 mg *bid*) ( $n = 97$ ) or placebo ( $n = 101$ ), combined with mFOLFOX6 every 14 d. Median PFS was 9.1 mo for the sorafenib arm and 8.7 mo for the placebo arm (HR = 0.88,  $P = 0.46$ ). Similar

results were observed in the subgroup analyses: in patients with wild-type *KRAS*, the median PFS was 9.5 mo *vs* 9.2 mo, respectively (HR = 0.84), with corresponding medians of 7.8 mo *vs* 7.6 mo, respectively, in the mutant *KRAS* subgroup (HR = 0.96). In patients with wild-type *BRAF*, the median PFS was 9.2 mo *vs* 9.0 mo, respectively (HR = 0.91), and the median PFS for patients with mutant *BRAF* was 8.6 mo *vs* 7.3 mo, respectively (HR = 0.89). There was no difference between treatment arms for median OS (17.6 mo in the sorafenib arm *vs* 18.1 mo in the placebo arm-HR = 1.13,  $P = 0.51$ ). In patients with wild-type *KRAS*, median overall survival was 19.9 mo *vs* 16.8 mo, respectively (HR = 0.89), and 17.0 mo *vs* 19.4 mo, respectively, in patients with mutant *KRAS* (HR = 1.29). In patients with wild-type *BRAF*, median overall survival was 18.8 mo *vs* 18.3 mo, respectively (HR = 1.09), and 13.9 mo *vs* 11.9 mo, respectively, in patients with mutant *BRAF* (HR = 0.46). The most common grade 3/4 adverse events in the sorafenib and placebo arms were neutropenia (48% *vs* 22%), peripheral neuropathy (16% *vs* 21%), and grade 3 hand-foot skin reaction (20% *vs* 0%). Treatment discontinuation because of adverse events was 9% and 6%, respectively. Generally, dose intensity (duration and cumulative doses) was lower in the sorafenib arm than in the placebo arm. This study did not detect a PFS benefit with the addition of sorafenib to first-line FOLFOX6 for mCRC, and *KRAS* and *BRAF* status did not seem to impact treatment outcomes. These results do not support further development of sorafenib in combination with mFOLFOX6 in molecularly unselected patients with mCRC<sup>[104]</sup>.

The clinical phase II study FOSCO (NCT00889343) studied the combination of FOLFOX6 or FOLFIRI with sorafenib or alone, as a second-line therapy in mCRC patients. Although the study had already been completed, its results are not yet known.

### Sunitinib

Sunitinib malate (SUTENT) is an oral, multitargeted tyrosine kinase inhibitor that selectively inhibits the VEGFR and PDGFR family members, as well as stem-cell factor receptor (KIT), glial cell line-derived neurotrophic factor receptor (rearranged during transfection; RET), colonystimulating factor receptor (CSF-1R), and FMS-like tyrosine kinase-3<sup>[105-107]</sup>.

In a phase III trial (NCT00457691), 768 patients with mCRC were randomly assigned to receive intravenous FOLFIRI (every 2 wk) plus sunitinib (37.5 mg/d, 4 wk on, 2 wk off) ( $n = 386$ ) or placebo ( $n = 382$ ). Median PFS was 7.8 mo in the sunitinib plus FOLFIRI arm and 8.4 mo in the placebo plus FOLFIRI arm (HR = 1.095;  $P = 0.807$ ), indicating a lack of superiority for sunitinib plus FOLFIRI. Median OS was 20.3 mo in the sunitinib arm and 19.8 mo in the placebo arm (HR = 1.171, one-sided stratified Log-rank  $P = 0.916$ ). In addition, the ORR in the sunitinib arm failed to be significantly better than that in the placebo arm (32% *vs* 34%;  $P = 0.683$ ). The study failed to demonstrate superiority for FOLFIRI plus sunitinib.

tinib. Sunitinib plus FOLFIRI was associated with more grade  $\geq 3$  adverse events and laboratory abnormalities when compared to FOLFIRI plus placebo [neutropenia (68% *vs* 30%), diarrhea (16% *vs* 8%), thrombocytopenia (11% *vs* 1%), anemia, stomatitis, fatigue, hand-foot syndrome and febrile neutropenia)]. In addition, more deaths as a result of toxicity (12 *vs* 4) and significantly more dose delays, dose reductions and treatment discontinuations occurred in the sunitinib arm<sup>[108]</sup>.

A phase II, open-label, single-arm study (NCT00668863) investigated oral sunitinib (37.5 mg/d 4 wk on, 2 wk off) combined with intravenous FOLFIRI (every 2 wk) for the first-line treatment of Japanese patients with unresectable or metastatic CRC. Median PFS was 6.7 mo by independent review and 7.2 mo by investigator assessment. ORR was 36.6% by independent review and 42.3% by investigator assessment. There was a high incidence of adverse events such as neutropenia (97.2%), leukopenia (97.2%); thrombocytopenia (84.5%), diarrhea (78.9%), nausea (78.9%), decreased appetite (74.6%) and fatigue (66.2%). Furthermore, almost 20% of patients discontinued study treatment permanently, due to adverse events and over 90% of required temporary interruptions of study treatment to perform treatment for related toxicities. The study was closed early when the concurrent phase III study of first-line sunitinib plus FOLFIRI in non-Japanese patients with mCRC was stopped due to futility, as discussed previously.

### Vatalanib

Vatalanib (PTK 787/ZK 222584; PTK/ZK) is a potent, orally active angiogenesis inhibitor that interferes with the kinase activity of all three VEGF receptors, acting as a competitive inhibitor at the ATP-binding site of the receptor kinase. This inhibition is reversible, highly selective for VEGFRs and translates to growth inhibition in a variety of different experimental tumor models. Although tumor regression did not occur, an attenuation of tumor growth was observed<sup>[109]</sup>.

In the clinical phase III trial CONFIRM1 (NCT00056459), 1168 patients with untreated mCRC were randomly assigned 1:1 to receive FOLFOX4 plus vatalanib or placebo. This study showed that the addition of vatalanib to FOLFOX4 did not improve PFS (7.7 mo in vatalanib arm and 7.6 mo in placebo arm: HR = 0.88,  $P = 0.118$ ) or OS (21.4 mo in vatalanib arm and 20.5 mo in placebo arm: HR = 1.08,  $P = 0.260$ ) and no statistically significant differences between the two treatment groups were observed in ORR (42% in vatalanib arm and 46% in placebo arm). Furthermore, vatalanib increased toxicity and more patients withdrew from treatment because of events other than disease progression in the vatalanib arm. Incidence of adverse event was 85.3% in vatalanib group and 77.5% in placebo group, particularly neutropenia, hypertension, and diarrhea. Concerning grade 3 or higher adverse events, the most notable differences were noted for hypertension (23.0% *vs* 6.8%, respectively), diarrhea (15.4% *vs* 11.1%, respectively), dizziness (7.4%

*vs* 2.3%, respectively), and pulmonary embolism (5.7% *vs* 1.7%, respectively)<sup>[110]</sup>.

The CONFIRM 2 (NCT00056446) was a phase III trial aimed to compare treatment with vatalanib plus FOLFOX4 versus placebo plus FOLFOX4 in patients with previously treated mCRC, whose disease had recurred or progressed during or within 6 mo of treatment with irinotecan in combination with a fluoropyrimidine. The median OS was 13.1 and 11.9 mo (HR = 1.00,  $P = 0.957$ ). Median PFS was longer with vatalanib than with placebo (5.6 and 4.2 mo, respectively; HR = 0.83,  $P = 0.013$ ). Treatment-related adverse events occurred in 81.4% patients in vatalanib arm and in 71% of those in placebo arm. The most common grade 3 or higher side effects related to vatalanib were neutropenia, hypertension, diarrhea, fatigue and nausea<sup>[111]</sup>.

## CONCLUSION

Nowadays, mCRC treatment remains a challenge for oncologists worldwide. Over last three decades, mCRC treatment has come from fluoropyrimidine based chemotherapy to the addition of innovative chemotherapies regimen combination, such as FOLFOX, FOLFIRI, XELOX, XELIRI, 5-FU + LV, and innovative biologic therapies, such as bevacizumab, cetuximab and panitumumab. More recently, Afibercept was approved for combination with standard chemotherapy in second line regimens for mCRC patients. Therefore, many options are now available with a powerful capacity to improve survival for metastatic patients. Thus, we should be aware for those previous mentioned innovative opportunities to fit them for each patient according to the adequate indication and tolerability. Also, pharmaco-economic studies are warranted to provide useful tools for public health entities, which might allow better clinical decisions, especially when willing those advances in research.

### Abstract

Alcoholism and cirrhosis, which are two of the most serious health problems worldwide, have a broad spectrum of clinical outcomes. Both diseases are influenced by genetic susceptibility and cultural traits that differ globally but are specific for each population. In contrast to other regions around the world, Mexicans present the highest drinking score and a high mortality rate for alcoholic liver disease with an intermediate category level of per capita alcohol consumption. Mexico has a unique history of alcohol consumption that is linked to profound anthropological and social aspects. The Mexican population has an admixture genome inherited from different races, Caucasian, Amerindian and

African, with a heterogeneous distribution within the country. Thus, genes related to alcohol addiction, such as dopamine receptor D2 in the brain, or liver alcohol-metabolizing enzymes, such as alcohol dehydrogenase class I polypeptide B, cytochrome P450 2E1 and aldehyde dehydrogenase class 2, may vary from one individual to another. Furthermore, they may be inherited as risk or non-risk haplogroups that confer susceptibility or resistance either to alcohol addiction or abusive alcohol consumption and possibly liver disease. Thus, in this era of genomics, personalized medicine will benefit patients if it is directed according to individual or population-based data. Additional association studies will be required to establish novel strategies for the prevention, care and treatment of liver disease in Mexico and worldwide.

**Key words:** Alcohol; Genes; Alcoholism; Alcohol dependence; Alcohol addiction; Alcohol abuse; Alcoholic liver cirrhosis; Anthropology

**Core tip:** Alcoholism and liver disease are leading global health problems. However, the severity and outcome of liver disease appear to vary between individuals and populations. In the present review, we analyze the general scope of alcohol consumption and its relationship with the pattern of drinking score in different countries. We focus on the development of alcoholism in Mexico, which has a strong historical background, and emphasize the need to understand the genetic and environmental factors affecting each population or geographical region of the world.

## INTRODUCTION

The human history of alcohol consumption has been documented for several thousand years<sup>[1]</sup>. Alcohol was undoubtedly the result of a fortuitous coincidence that occurred when fruits, grains and flower stalks were fermented for a long time. People may have begun to experience pleasure and happiness after tasting alcoholic beverages<sup>[1,2]</sup>.

Alcoholic beverages are obtained from different sources, depending on the region of the world. Traditionally, must and wines are produced from grapes of the Middle East and Europe, whisky is made from various grains and sake is obtained from rice in Asia. In Mexico, “pulque” was introduced first, followed by tequila, which are made from the maguey and agave plants, respectively<sup>[3,4]</sup>.

Historically, alcohol-based beverages have served as a source of needed nutrients and have been widely used for their medicinal, antiseptic and analgesic properties. However, during the last century, alcohol abuse has increased in several countries, thereby augmenting the rate of accidents and liver diseases. The range of liver diseases secondary to alcohol consumption is extensive, including acute alcoholic hepatitis, alcoholic liver disease (ALD), cirrhosis and hepatocellular carcinoma<sup>[5]</sup>. Different factors may affect the development of alcoholic liver damage, including the dose, duration and type of alcohol consumption, drinking patterns, gender and ethnicity<sup>[1,6-8]</sup>. Other associated risk factors include obesity, iron overload, concomitant viral hepatitis infection<sup>[1,7,9]</sup> and genetic factors<sup>[7,8]</sup>. Nonetheless, the degree of the association among alcohol consumption, morbidity and mortality due to ALD varies among individuals and populations worldwide. Alcohol consumption and ALD are linked to specific genetic and environmental factors that are prevalent in each population. However, which factors and how they are involved in both alcohol addiction and the adaptation of hepatic genes capable of metabolizing large amounts of ethanol without developing liver disease are challenging questions.

In this comprehensive review, we revisit the information on the worldwide consumption of alcohol and patterns of drinking associated with liver disease, emphasizing the history of alcoholism in Mexico and the differences in the genetic and environmental backgrounds with respect to alcoholism and liver disease among the different countries, with a focus on the genetic factors involved in alcohol dependence and alcohol abuse as well as liver-metabolizing enzymes.

## WORLDWIDE ALCOHOL CONSUMPTION

The World Health Organization (WHO) published the total adult per capita alcohol consumption (liters of pure alcohol consumption/year) by distinct geographical

regions of the world<sup>[10]</sup>. Three primary categories, high (10-12 L and > 12 L), intermediate (7.5-9.99 L and 5-7.49 L) and low (2.5-4.99 L and < 2.5 L), were created to compare alcohol consumption among different countries.

The countries with the highest alcohol consumption are located primarily in Europe (Czech Republic, United Kingdom, Ireland, Germany, France, Portugal and the Russian Federation) but also in other regions, such as South Korea, Australia, Nigeria, Uganda and Argentina. The intermediate category includes countries located in the Americas, such as the United States, Canada, Mexico, Chile, Brazil and Colombia, a few African countries, such as Cameroon, South Africa, Namibia and Botswana, and Norway in Europe. The low alcohol consumption category includes several countries within the Eastern Mediterranean region and Asia, generally representing those countries where religious beliefs prohibit alcohol consumption.

However, there have been different trends in the last 50 years regarding alcohol consumption in countries worldwide. Although several countries have increased alcohol consumption, others have decreased alcohol consumption (Figure 1). Furthermore, since 2008, the WHO has been in the process of drafting a global strategy to reduce the harmful use of alcohol<sup>[11]</sup>. These observations led us to analyze the effectiveness of these strategies to avoid or decrease alcohol consumption and to improve the understanding of the biological and social events involved in the drinking habits of alcohol in Mexico compared with other regions of the world.

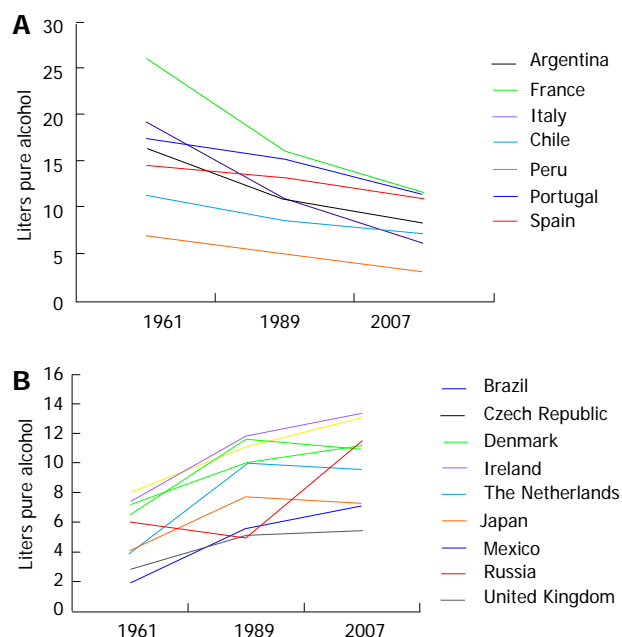

## MORTALITY DUE TO ALD

To address these concerns, we examined the mortality related to ALD within several countries. Interestingly, there is a discrepancy between mortality related to ALD and the per-capita alcohol consumption<sup>[12]</sup>; *e.g.*, Mexico is one of the countries with the highest mortality rate due to ALD but is not included among the countries with the highest alcohol consumption<sup>[12]</sup>. However, global comparisons among different populations are limited because not all countries report mortality related to ALD<sup>[12]</sup>.

## PATTERN OF DRINKING SCORE

The pattern of drinking score is a composite scale that ranges from 1 to 5 and focuses primarily on the degree of risk associated with how the alcohol is consumed rather than the amount of alcohol consumed. To build this scale, the following indicators are used: quantity of alcohol consumed by occasion, festive drinking, proportion of drinking events that involve becoming drunk, proportion of drinkers who drink daily, drinking with meals and drinking in public places<sup>[13]</sup>.

Unlike alcohol consumption, which is measured by the amount of pure alcohol per capita/year, the pattern of drinking score is closely related to ALD. For example, the countries with the highest pattern of drinking score

**Figure 1** Trends of per-capita alcohol consumption in different countries. A: Countries that decreased consumption per capita since 1961 to 2007; B: Countries that increased consumption per capita since 1961 to 2007.

are Kazakhstan, Mexico, the Russian Federation, South Africa and Ukraine, and the countries with a lower-risk pattern of drinking are Portugal, Spain, France, Italy and Germany<sup>[13]</sup>.

Taken together, alcohol consumption indicators, mortality rates and pattern of drinking scores, which all may contribute to ALD, are heterogeneous worldwide<sup>[12,13]</sup>. Thus, because ALD is a multifactorial problem, researchers should consider the anthropological and historical aspects prevalent among the different societies.

## ALCOHOL CONSUMPTION IN MEXICO

### Early history of alcohol consumption

To understand the interaction between the evolutionary and genetic changes associated with specific environments, it is necessary to know when and how these events occurred among the different populations. In the case of Mexico, the establishment of a sedentary lifestyle required approximately 5000 years<sup>[14,15]</sup>. During this period, the Mesoamericans began the domestication of the well-known staple foods of Mexico, such as maize (*Zea mays* L.), beans (*Phaseolus* spp), squash and pumpkin (*Cucurbita* spp) and chili (*Capsicum* spp). This process was accompanied by the discovery and consumption of fermented alcoholic beverages made from a number of endemic agave plants (*Agave* spp). The origin of alcoholic beverages, as described by the Aztecs, was a mythical love story between two deities, “Mayahuel” and “Quetzalcóatl” (Figure 2)<sup>[16-18]</sup>.

The core of the mature agave plant produces a honey water, or “aguamiel”, rich in amino acids and proteins<sup>[19]</sup>, which once fermented, produces the traditional alcoholic beverage. The Nahuas in their native language named the

**Figure 2** The tale of Mayahuel. The ancient gods gathered in the heavens understood that their people got bored eating only maize and chili; thus, they sent Quetzalcóatl, the god of the winds, to bring the young and beautiful goddess Mayahuel, granddaughter of a “tintzimitl”, a star who attempted to prevent the sun from rising. Quetzalcóatl and Mayahuel fell in love and together promised that they would give their people a magic plant to recover their happiness. Meanwhile, the evil grandmother noticed that Mayahuel had disappeared; thus, she and other “tintzimitl” went down to the earth to find her. Mayahuel and Quetzalcóatl were hidden in the form of a tree with two arms (branches); one arm was Mayahuel, and the other was Quetzalcóatl. When the grandmother found them, she cut Mayahuel’s arm into many small pieces, but not Quetzalcóatl’s, who was then transformed into a human again. Nothing could be done for Mayahuel, so Quetzalcóatl buried the leftover pieces in the ground and wept for his loss deeply. Finally, from these parts, the maguey was born. The mature maguey “cries” the honey-water, or “aguamiel”, that emerges from the center of the plant, representing the tears of Quetzalcóatl. “Octli polihuhqui” is the fermented nectar of the maguey that brings happiness. Thus, Mayahuel in the Nahuatl language stands for all that surrounds the maguey<sup>[16,17]</sup>. Mayahuel may be considered a dual deity. On the one hand, she represented a woman with many breasts who nourished many children, the 400 rabbits (“Centzon Totochtin”); thus, she was associated with the earth and fertility. On the other hand, she was associated with drunkenness and adultery. This mythological symbol had such great influence that one day of the month was devoted to the rabbit, and those born on that specific date were destined to either be a drunk or commit adultery<sup>[17,18]</sup>.

former “iztac octli” and the latter “octli polihuhqui”<sup>[20]</sup>. However, when the Spaniards arrived on the continent, “octli polihuhqui” was phonetically derived as the term “pulque”<sup>[20,21]</sup>.

The “octli” but not “octli polihuhqui” served as nourishment for the elderly and sick and for women after childbirth<sup>[22]</sup>. The “octli” and perhaps the “octli polihuhqui” were given to all family members, including babies and children, in public ceremonies<sup>[17]</sup>. The “octli polihuhqui” was also used for medicinal purposes as an antidepressant or as an anesthetic before human sacrifice<sup>[16,18]</sup>.

Additionally, the early Mexicans were familiar with the effects of the abuse of “octli polihuhqui”; thus, excessive drinking was strictly prohibited by law primarily during the religious holidays, and a death penalty was implemented<sup>[17]</sup>. The Aztec rulers often declared that the abuse of “octli polihuhqui” was the source and beginning of all evil and all ruin<sup>[17]</sup>. Unfortunately, these laws were not reinforced after the 15<sup>th</sup> century, granting a tolerance of the abusive consumption of alcoholic beverages during the colonial period<sup>[4,23]</sup>.

The rich history of the consumption of “pulque” by the Mexicans over many centuries is an essential compo-

Figure 3 Main types of alcoholic beverages consumed by geographical region in Mexico.

ment of the framework that is required to understand the relationship among the Mexican genome, alcoholism and liver disease at present.

### **Alcohol consumption in Mexico at present**

Mexico is one of the leading countries with a high mortality rate due to liver diseases in the world<sup>[10]</sup>. The National Health Secretariat reported an average of 25000 cases of cirrhosis per year from 2000 to 2010<sup>[24]</sup>. The primary etiologies of cirrhosis are alcohol, followed by hepatitis C infection and non-alcoholic steatohepatitis<sup>[25-27]</sup>.

For Mexico, the WHO reported that the amount of alcohol consumed is 8.4 L of pure alcohol per capita among individuals older than 15 years of age, which corresponds to an intermediate category as previously described<sup>[10]</sup>. However, if this parameter is applied only to drinkers, alcohol consumption increases to 27.1 L, which is similar to what had been reported in countries with the highest levels of alcohol consumption per capita<sup>[10]</sup>.

However, the pattern of drinking score shows a better scope of alcoholism among the Mexican population. By examining the amount of alcohol consumed by occasion, we observed that alcohol consumption occurs primarily during the weekends<sup>[28]</sup>, unlike in Europe where they drink wine almost daily, at lunch or dinner.

Hepatologists may advise their patients not to drink any alcoholic beverage to maintain a healthy liver. However, a large proportion of adults around the world drink alcoholic beverages<sup>[1,5,6]</sup>. Thus, the recommendation to avoid liver damage is that the amount of alcohol consumed should be equal or less than 2 drinks per occasion (20-40 g ethanol), not more than 4 drinks per day and not more than 10 to 12 drinks per week, allowing the liver to rest at least 1 or 2 d<sup>[1,5,6]</sup>. Furthermore, it has been suggested that the number of alcoholic drinks should be less in women than in men because women have a higher risk for developing ALD<sup>[1,5,6]</sup>.

However, each weekend, approximately 30 million Mexicans have been estimated to consume more than five drinks per occasion (more than 80 g of ethanol),

with another 10 million consuming at least one alcoholic drink daily. However, alcohol abuse has been detected in 5 million people with a strong dependence on alcohol<sup>[28]</sup>.

The average Mexican begins consuming alcohol before the age of 18 years perhaps because of a strong cultural influence. Studies conducted in the western region of Mexico have shown that 61.4% of the 12- to 17-year-old have already begun to drink alcohol<sup>[27]</sup>. The primary types of alcoholic beverages consumed in Mexico are beer, tequila and “pulque”, and other distilled beverages are consumed in a lower proportion<sup>[27-30]</sup>. However, the distribution of alcoholic beverage preferences is heterogeneous. Thus, in central Mexico, “pulque” is preferred, in contrast to tequila in the west or beer in the northern and southern parts of the country (Figure 3). These preferences are associated with the historical cultural background of each region and may be related to the mortality caused by cirrhosis. The mortality rate in central Mexico is greater than 30/100000, followed by the north at less than 10/100000 and the west at less than 5/100000<sup>[30,31]</sup>.

In western Mexico, young people begin to drink beer either during the weekend or at any social or religious event, such as weddings, coming-of-age parties and christenings. After the initiation of alcohol use, the number of beers consumed per occasion over the weekend ranges from 4 to 6 (80-100 g); this number gradually increases to 20-24 beers/355 mL each (300-360 g of alcohol)/occasion per person over a period of approximately 10 years. The second stage involves the combination of beer with tequila or any other distilled beverage during a period of 8 to 10 years. During this stage, the amount of alcohol consumed ranges from 380 to 640 g daily. In the third stage, alcohol dependence is severe, and patients may or may not present with cirrhosis. By this time, they drink an average of 510 g of alcohol per day (450-720 g)<sup>[26,32-34]</sup>.

The time between the initiation of alcohol use and the diagnosis of cirrhosis is 23 to 30 years<sup>[26,35]</sup>. However, we have identified two distinct age peaks of clinical cirrhosis. In the first group, patients are young, approximately 30 years old, and a plausible genetic predisposition to liver cirrhosis has been proposed to be involved. In the second group, the average age is approximately 45 years<sup>[33]</sup>. Compared to other countries, Mexico, according to our findings, may have the youngest people with alcoholic cirrhosis in the world. Apparently, the Apo E2<sup>[33]</sup> and FABP2<sup>[36]</sup> gene polymorphisms may be involved in the early onset of ALD among the Mexican population.

### **Clinical profile of Mexican patients with ALD**

The majority of patients with ALD seek medical attention in the advanced stages of the disease with a Child-Pugh score of C and multiple complications, such as encephalopathy, variceal bleeding, infections and ascites<sup>[25,27,35]</sup>. These clinical characteristics are present in the two primary age groups of patients with alcoholic cirrhosis<sup>[33]</sup>. Furthermore, the patients with alcoholic cirrhosis continue to drink high amounts of alcohol after diagnosis

and may die earlier in life due to clinical complications<sup>[25]</sup>. This observation may be one of the foremost reasons why hepatocellular carcinoma is rare in Mexico compared with other regions of the world<sup>[37,38]</sup>, in conjunction with other environmental factors<sup>[39]</sup>.

ALD has been associated with nutritional deficiencies and malnutrition worldwide<sup>[40]</sup>. However, preliminary data from a reference center in western Mexico have shown that obesity is also present. Among 90 patients, 17% of the alcoholic cirrhotic patients were malnourished, whereas overweight and obesity were detected in 33% of the patients, with another 50% of normal weight<sup>[35]</sup>. These data are consistent with the fact that Mexico has the highest prevalence of obesity<sup>[41]</sup>, thus adding a new risk factor for liver disease. Furthermore, in this group of patients, 34% of the patients had drug additions, which is an increasing social and health problem<sup>[35]</sup>.

Thus, the combination of alcoholism, obesity, drugs and, in several cases, viral hepatitis B or C, leads us to explore specific strategies for treatments and prevention programs to detect cirrhosis at early stages of the disease.

## GENETICS OF ALCOHOL DEPENDENCE OR ALCOHOL ABUSE

In recent decades, researchers have been using various strategies to identify genes that may be associated with alcohol dependence or alcohol abuse. Studies based on candidate genes<sup>[42-45]</sup> or linkage disequilibrium were followed by the advances in genotyping that have resulted in the widespread use of genome-wide association studies<sup>[46,47]</sup>. Previous studies in families, twins and adoption studies have shown that approximately 40%-60% of the variance in the risk for developing alcoholism can be explained by genetic factors<sup>[43-47]</sup>. However, the interactions between genes and several environmental factors have led experts in the field to identify at least two types of alcoholism: (1) a more severe, more genetic and early-onset type of alcoholism; and (2) a less severe, more environmental and late-onset type of alcoholism<sup>[48-52]</sup>.

Regarding the role of genetic factors in the susceptibility to alcohol dependence and alcohol abuse, research has primarily aimed to study the expression of brain and liver genes. For example, the major brain genes that modulate the neuroadaptive mechanism that translates alcohol stimuli into pleasure, anxiety or cravings are opioid receptor mu 1<sup>[53-55]</sup>, catechol-O-methyltransferase<sup>[56]</sup>,  $\gamma$ -aminobutyric acid receptor A<sup>[57,58]</sup>, 5-hydroxytryptamine (serotonin) receptor adenylate cyclase-coupled<sup>[59,60]</sup>, cholinergic receptor muscarinic 2<sup>[61,62]</sup>, vesicular monoamine transporter 2<sup>[63-65]</sup> and dopamine receptor D2<sup>[48,66-68]</sup>.

In the liver, several alcohol dehydrogenase (ADH) enzymes, primarily alcohol dehydrogenase class I polypeptide B (ADH1B)<sup>[52]</sup>, cytochrome P450 2E1 (CYP2E1)<sup>[69]</sup> and aldehyde dehydrogenase class 2 (ALDH2)<sup>[52,70]</sup>, and other minor ADHs, such as ADH1C<sup>[71]</sup> and ADH4<sup>[72]</sup>, have been related to alcohol metabolism and alcoholism. The three major enzyme genes express variants with different

catalytic activities ( $V_{\max}$ ) and Michaelis constants ( $K_m$ ); thus, their ability to metabolize substrates is variable.

The combination of the allelic profile of these brain and liver genes may affect the risk of or protection against alcohol dependence or alcohol abuse as well as the amount of alcohol metabolized in the liver and the susceptibility to liver damage. Variances in the distribution of these gene polymorphisms may mark phenotypic differences among populations for the aforementioned features. Hence, for this review, the biological functions of dopamine receptor D2 (DRD2), ADH1B, CYP2E1 and ALDH2 are briefly described, and their global allelic frequencies are compared, including those reported for the Mexican population.

### DRD2

Alcohol has a stimulatory effect on the dopaminergic neurons of the ventral tegmental area. Dopamine is captured by DRD2 in these neurons in the nucleus accumbens, causing a pleasant effect that is integrated into the mesolimbic system<sup>[48,67,68]</sup>.

The DRD2 *Taq I A1* polymorphism consists of a T/C nucleotide substitution (rs1800497) that alters the *Taq I* restriction site located 10541 bp downstream of the termination codon. Several studies have investigated the association of this gene polymorphism with alcohol dependence. *Taq I A1* allele carriers reportedly have lower amounts of DRD2 receptors than the *Taq I A2* carriers<sup>[73]</sup>. Thus, *A1* allele patients require higher amounts of alcohol to achieve the desired effect<sup>[66-68,74-76]</sup>. In additional studies, the association between the *A1* allele *Taq I* and alcohol use disorders has been corroborated in some but not in others. However, in several meta-analyses, a significant association between Caucasian *A1* allele carriers and alcohol addiction has been found<sup>[48,77]</sup>.

The allelic distribution of DRD2 displays a wide range of frequencies worldwide<sup>[74-79]</sup>, but the highest prevalence of the *A1* allele is found among the Amerindian Pima (83%) and Mayas (71%) from Mexico<sup>[80,81]</sup> (Figure 4).

### ADH1B

The *ADH1B* gene has a polymorphic site, resulting in the Arg47His substitution (rs1229984). The *A2* allele (ADH1B His47) confers a 100-fold higher catalytic activity to the ADH1B enzyme than the *A1* allele (ADH1B Arg47). The *A2* allele carriers have a higher ethanol oxidation capacity than the *A1* carriers. However, the *A2* carriers have a higher acetaldehyde production that leads to an alcohol-flushing response that has been considered to be protective.

The protective effect of the *A2* allele against alcohol dependence is well known in the East Asian population<sup>[82]</sup>. A study conducted in a cohort of pregnant women from England demonstrated that the *A2* carriers consumed less alcohol before pregnancy, had less incidents of binge drinking during pregnancy and were abstainers during the first trimester of gestation<sup>[83]</sup>. However, al-

Figure 4 Frequency of Taq I A dopamine receptor D2 polymorphisms in different countries. <sup>1</sup>HapMap.

though this allele apparently reduces the risk of alcohol dependence, it may confer a substantial risk of chronic liver disease, especially among heavy drinkers<sup>[84]</sup>.

In contrast, *A1* allele carriers do not present with the rapid production of acetaldehyde, which eliminates the alcohol-flushing response. A study conducted in a large cohort of individuals from Copenhagen revealed that *A1* allele homozygotes drank more alcohol and had a higher risk for developing alcohol dependence<sup>[85]</sup>. The *A1* allele has also been associated with alcohol dependence in several other studies<sup>[86-88]</sup>.

### CYP2E1

The *CYP2E1* gene, which encodes the enzyme that oxidizes ethanol in the microsomal oxidation system, is essential in the pathophysiology of ALD. Alcohol consumption induces the expression of *CYP2E1*, which is directly involved in the primary oxidation pathway of this substrate, displacing the enzymatic activity of *ADH1B* ( $K_m$ : 8-10 mmol/L for *CYP2E1* vs 0.2-2.0 mmol/L for *ADH1B*)<sup>[69,89]</sup>.

The *C2* allele, which is less common, has a C/T transition at nucleotide position -1019 within the 5' terminal regulatory region. The *C2* allele is associated with a 100-fold higher transcription activity, higher protein concentration and increased enzyme activity, which lead to a faster rate of alcohol oxidation<sup>[90,91]</sup>.

The *C2* allele carriers have been demonstrated to consume excessive amounts of alcohol, which may be caused by the high transcriptional activity of *CYP2E1*. *C2* allele carriers metabolize ethanol (alcohol) to acetaldehyde at a higher rate. Acetaldehyde is a highly toxic and mutagenic metabolite that increases oxidative stress by producing reactive oxygen species and lipid peroxides, such as 4-hydroxy-2,3-nonenal, 4-hydroxy-2,3-alkenals and malondialdehyde<sup>[92]</sup>. An association between an increased risk for ALD and alcoholic cirrhosis has been reported among the carriers of the *C2* allele<sup>[93-95]</sup>, several of whom belong to the mestizo population of western Mexico<sup>[96]</sup>.

### ALDH2

The *ALDH2* gene encodes the primary mitochondrial

isoform enzyme that oxidizes acetaldehyde to acetate in the liver<sup>[70,97]</sup>. The C/G transition in exon 12 of *ALDH2* causes an amino acid substitution of glutamic acid for lysine at position 487 (*ALDH2* Glu487Lys, rs671). The *A2* allele (*ALDH2* Lys487) has little or null enzymatic activity. This deficiency leads to the accumulation of acetaldehyde and consequently provokes a flushing response, which discourages alcohol drinking<sup>[97]</sup>. Because flushing is an undesirable symptom, it confers relative protection against abusive alcohol consumption. An association between *A2* allele carriers and a lower risk for alcohol dependence and reduced alcohol use has been reported<sup>[98]</sup>.

With regard to the distribution of the polymorphisms of the liver alcohol-metabolizing genes, all present contrasting frequencies among different population groups (Figure 5A-C). Among Asians, the *ADH1B* gene displays the highest frequency of the *A2* protective allele, with 78% in Japan and 69% in China. In contrast, the lowest frequency for the *A2* allele was detected in Germany and Mexico, at 4% and 3%, respectively (Figure 5A)<sup>[91,99-105]</sup>, wherein the frequency of the *A1* allele associated with alcohol dependence was much higher.

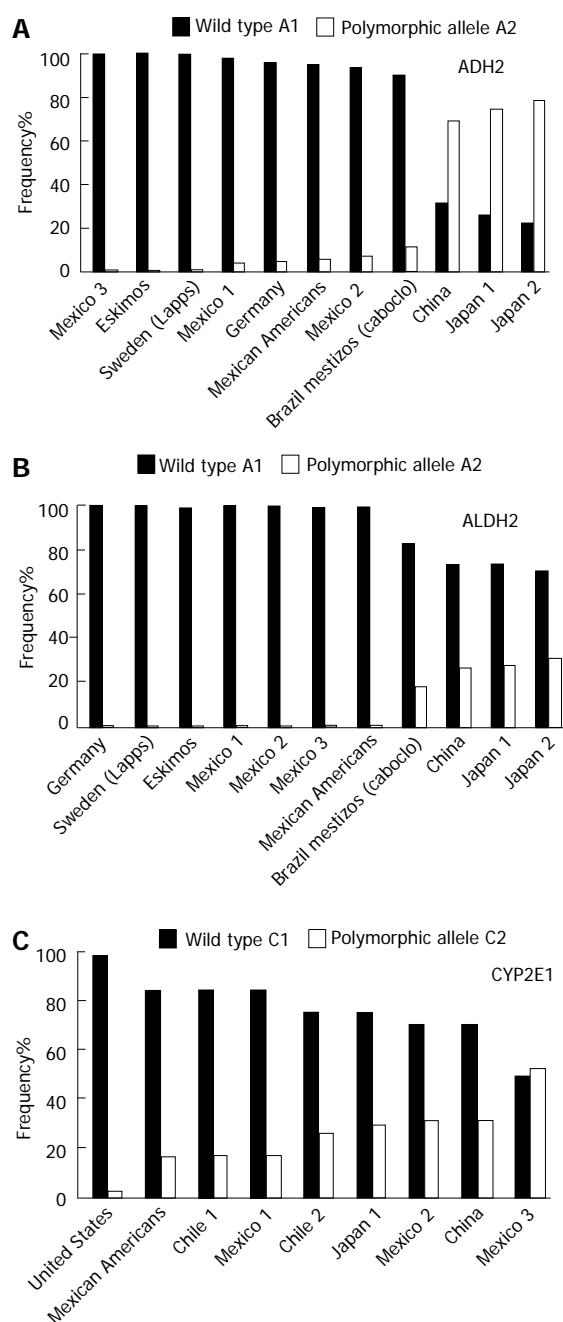

The *C2* allele for the *CYP2E1* gene has a frequency of approximately 30% in Japan and China and 2% in the United States. In Chile and Mexico, the frequency is 16% among the mestizo population (Figure 5B)<sup>[91,93,94,105-108]</sup>. Interestingly, among the Amerindians of western Mexico, such as the "Huichol" people, this gene polymorphism shows a prevalence of 50%, which is the highest rate reported to date<sup>[91]</sup>.

The highest frequency of the *A2* allele for the *ALDH* gene has been reported in China (29%) and Japan (26%). In Germany, Sweden and Mexico, its frequency is extremely low or absent<sup>[91,99-105]</sup>, which could explain, to some extent, the high amount of alcohol consumption that has been reported in those countries.

We could speculate that the selective evolution of both the brain and liver genes was not necessarily directed only by the exposure to alcohol. For example, liver cytochrome genes metabolize a large variety of xenobiotics, whereas those expressed in the brain fulfill the addiction criteria. However, an alternative point of view is to consider these genes as part of a general survival mechanism. Thus, the basic biological necessities of life, such as food (sugars, e.g., glucose) or sexual reproduction, are ensured and rewarded by pleasure; however, these necessities may not be driven by pleasure exclusively.

## CONCLUSION

At the end of the last century, we began to understand how liver genes are involved in the metabolism of ethanol and how cerebral genes are related to addictions. Additional genetic studies, including genome-wide association studies, will corroborate the association of specific alleles with alcoholism and ALD. The next step may be a personalized medicine strategy for the prevention, diagnosis and treatment of liver diseases. However, as aforementioned in this review, genes and environmental

**Figure 5** Frequency of polymorphisms of enzymes that metabolize alcohol. A: Alcohol dehydrogenase 2 (ADH2); B: Aldehyde dehydrogenase class 2 (ALDH2); C: Cytochrome P450 2E1 (CYP2E1) in different countries. A-B: Mexico 1: Western Mexico; Mexico 2: Native from Mexico "Otomi"; Mexico 3: Native from Mexico "Huicholes"; Japan 1: Rural country; Japan 2: Mestizos from Japan; C: Mexico 1: Western Mexico; Mexico 2: North an central Mexico; Mexico 3: Native from Mexico "Huicholes"; Chile 1: Mestizos; Chile 2: Native from Chile "Mapuches".

factors are involved in the development of ALD, which requires an in-depth analysis of the different populations. Therefore, the data found in several regions of the world may not correlate to populations from different geographic areas.

Mexicans are an admixture population that has inherited specific alleles from different races, predominantly Caucasian, Amerindian and African<sup>[109,110]</sup>. Based on the

current data on allelic frequencies in different countries, the Mexican population has a particular genetic profile that may explain the epidemiological and clinical manifestations of alcohol-related liver diseases. Thus, the expectation that the different allelic variants of the aforementioned genes (*DRD2*, *ADH2*, *CYP2E1* and *ALDH2*) will express themselves individually is plausible. However, considering these alleles as a haplogroup may generate risk or non-risk phenotypes related to liver disease, as well as to proneness towards or resistance against the high intake of alcohol. Haplogroups that could confer a non-risk phenotype for alcoholism and liver damage could be *DRD2*\*A2, *ADH2*\*A2, *CYP2E1*\*C1, *ALDH2*\*A2 and *DRD2*\*A2, *ADH2*\*A1, *CYP2E1*\*C1, *ALDH2*\*A2 because they are related to non-addiction plus flushing by the accumulation of acetaldehyde, exhibiting a protective effect. The haplogroups that could confer risk phenotypes for alcoholism and liver damage could be *DRD2*\*A1, *ADH2*\*A1, *CYP2E1*\*C1, *ALDH2*\*A1 and *DRD2*\*A1, *ADH2*\*A1, *CYP2E1*\*C2, *ALDH2*\*A1 because these are related to addiction plus the efficient metabolism of alcohol but exposure to acetaldehyde. This observation may explain why some patients who consume heavy amounts of alcohol per day (> 80 g/d) for more than 20 years do not have liver damage, whereas others with a less than or equal to consumption level and less exposure suffer liver damage and even die from cirrhosis or its complications<sup>[1,6,7]</sup>. However, additional studies are required to demonstrate the association between these hypothetical allelic profiles and the clinical outcomes of alcohol-dependent patients in Mexico and worldwide.

### Abstract

Hepatic resection had an impressive growth over time. It has been widely performed for the treatment of various liver diseases, such as malignant tumors, benign tumors, calculi in the intrahepatic ducts, hydatid disease, and abscesses. Management of hepatic resection is challenging. Despite technical advances and high experience of liver resection of specialized centers, it is still burdened by relatively high rates of postoperative morbidity and mortality. Especially, complex resections are being increasingly performed in high risk and older patient population. Operation on the liver is especially challenging because of its unique anatomic architecture and because of its vital functions. Common post-hepatectomy complications include venous catheter-related infection, pleural effusion, incisional infection, pulmonary atelectasis or infection, ascites, subphrenic infection, urinary tract infection, intraperitoneal hemorrhage, gastrointestinal tract bleeding, biliary tract hemorrhage, coagulation disorders, bile leakage, and liver failure. These problems are closely related to sur-

gical manipulations, anesthesia, preoperative evaluation and preparation, and postoperative observation and management. The safety profile of hepatectomy probably can be improved if the surgeons and medical staff involved have comprehensive knowledge of the expected complications and expertise in their management. This review article focuses on the major post-operative issues after hepatic resection and presents the current management.

**Key words:** Hepatectomy; Postoperative complication; Management

**Core tip:** Despite technical advances and high experience of liver resection of specialized centers, it is still burdened by relatively high rates of postoperative morbidity and mortality. Common post-hepatectomy complications include fever, hemorrhage, bile leakage, liver failure, pleural effusion, and subphrenic infection. The aim of this study was to summary the causes for post-hepatectomy complications and to discuss the prevention and treatment trick for postoperative complications.

Jin S, Fu Q, Wuyun G, Wuyun T. Management of post-hepatectomy complications. *World J Gastroenterol* 2013; 19(44): 7983-7991 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/7983.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7983>

### INTRODUCTION

The era of hepatic surgery began with a left lateral hepatic lobectomy performed successfully by Langenbuch in Germany in 1887. Since then, hepatectomy has been widely performed for the treatment of various liver diseases, such as malignant tumors, benign tumors, calculi in the intrahepatic ducts, hydatid disease, and abscesses.

Operation on the liver is especially challenging because of its unique anatomic architecture and because of its vital functions. Despite technical advances and high experience of liver resection of specialized centers, it is still burdened by relatively high rates of postoperative morbidity (4.09%-47.7%) and mortality (0.24%-9.7%)<sup>[1-16]</sup> (Table 1). Common post-hepatectomy complications include fever, hemorrhage, bile leakage, liver failure, pleural effusion, and subphrenic infection, which we will discuss.

## POSTOPERATIVE FEVER AND INFECTIONS

### *Venous catheter-related infection*

Deep-vein catheterization is routinely performed for hepatic surgery, and venous catheter-related infection is the most common cause of fever after hepatectomy. This source of fever should be considered if the fever cannot be attributed to some other cause. If it cannot, the catheter should be immediately removed and its tip cultured, so that appropriate antibacterial therapy can be instituted promptly<sup>[17-21]</sup>.

### *Pleural effusion*

Reactive pleural effusion may occur after hepatectomy and usually is the result of diaphragmatic injury, obstruction of thoracic venous or lymphatic systems, or surgical manipulation on the hepatic coronary ligament (usually causing a subphrenic fluid collection). The pleural effusion, which most often occurs in the right chest, can cause fever even though it is aseptic. X-ray and ultrasound examinations should be performed promptly in febrile patients in order to determine whether a pleural effusion has developed. If only a small effusion is present it may spontaneously resolve, and if the patient has no significant symptoms or signs, no special treatment will be needed; otherwise, thoracic puncture and drainage of the effusion should be carried out<sup>[22-24]</sup>.

### *Incisional infection*

Incisional infection usually occurs within 1 wk after operation. Swelling and exudation at the incision site, or in the case of severe infection, dehiscence of the wound may be seen. If infection is found, the sutures and necrotic tissue should be removed and adequate drainage established. Antibiotics may be prescribed to help control the infection. If wound dehiscence is present, tension sutures may be placed<sup>[25-27]</sup>. Albumin may be administered intravenously in order to help relieve intra-abdominal pressure if present<sup>[28]</sup>.

### *Pulmonary atelectasis or infection*

Postoperative atelectasis or pulmonary infection most commonly presents 3-5 d after the operation. Symptoms and signs may include chest tightness, shortness of breath, and cyanosis. Surgical trauma, prolonged bed rest, and limited coughing because of incisional pain are the major factors predisposing to pulmonary atelectasis or infection. The findings of hypoxemia, determined by blood-gas anal-

ysis, and abnormalities seen on chest X-ray films, will assist in making the diagnosis. If the pulmonary infection progresses to pneumonia, the patient may have fever, cough, and pulmonary rales; increased bronchovascular shadows and pulmonary consolidation may be seen on chest X-ray films. Analgesic drugs may be given to relieve patient's pain and to facilitate deep breathing; bronchial lavage may be performed for relief of airway obstruction; and antibiotics may be prescribed after sputum culture and testing bacteria for drug sensitivity<sup>[28-30]</sup>.

### *Ascites*

Ascites is common in hepatectomy patients who have associated liver malfunction or cirrhosis. Ascitic fluid may drain from the incision site or the drainage tube<sup>[31]</sup>. Accumulation of much ascites may result in imbalance of water and electrolytes. Paracentesis for treatment of the ascites usually is not recommended; administration of diuretics and albumin is preferred. However, if the ascites is suspected of being infected and the source of fever, diagnostic paracentesis under ultrasonic guidance should be performed<sup>[32-35]</sup>.

### *Subphrenic infection*

Subphrenic infection is a severe complication of hepatectomy, usually resulting from incomplete or premature removal of a subphrenic fluid collection or a bile leak. Fever, tenderness in the upper abdomen, and abdominal muscle tension are the major manifestations of subphrenic infection. Septicopyemia or septicemia may develop if infection is severe, which may occur with pleural effusion or pulmonary atelectasis<sup>[36]</sup>. Thorough drainage of the fluid, in addition to anti-inflammatory therapy, is critical in the treatment. Ultrasonic guidance may be useful in the aspiration of subphrenic fluid collections or in the evacuation of abscesses. Open operation may be needed if the infection is severe<sup>[37]</sup>.

### *Urinary tract infection*

Fever, back pain and bladder irritation are the common symptoms of upper urinary tract infection. In contrast, fever is not common in lower urinary tract infection, which is usually manifested by dysuria and urinary frequency and urgency. Treatment of the urinary infection includes anti-inflammatory medications, oral hydration, and medications to relieve cystospasm and symptoms of bladder irritation.

## POSTOPERATIVE HEMORRHAGE

### *Intraperitoneal hemorrhage*

The incidence of intraperitoneal hemorrhage ranges from 4.2% to 10%<sup>[6,38-41]</sup>. Three common reasons for intraperitoneal hemorrhage are: (1) bleeding from the surfaces of the residual liver, which may be a consequence of arterial branch truncation or congestion of the hepatic vein due to stenosis or ligation; (2) incomplete intraoperative hemostasis, which sometimes is due to inappropriate

**Table 1** Summary of studies investigating the post-hepatectomy mortality and morbidity

Ref.	Journal	Date of publication	Country of study	NO. of Patients studied	Disease's diagnosis	Mortality and morbidity of hepatectomy
Savage <i>et al</i> <sup>[1]</sup>	<i>Ann Surg</i>	December 1991	United States	300	Liver trauma or liver tumors	The operative mortality was 19% (1962-1979) or 9.7% (1980-1988), and the overall complication rate was 12.3%
Wu <i>et al</i> <sup>[2]</sup>	<i>Zhonghua Waike Zazhi</i>	May 2002	China	1762	Liver cancer	The total mortality was 0.40%, and the total complication rate was 4.09%
Ishikawa <i>et al</i> <sup>[3]</sup>	<i>Hepatogastroenterol</i>	November-December 2002	Japan	139	HCC	The mortality within 30 postoperative days was 2.2%, and complication morbidity was 40.2%
Descottes <i>et al</i> <sup>[4]</sup>	<i>Surg Endosc</i>	January 2003	France	87	Benign liver tumors	There was no postoperative mortality, and the postoperative complication rate was 5% (laparoscopic liver resection)
Dimick <i>et al</i> <sup>[5]</sup>	<i>Arch Surg</i>	January 2003	United States	569	Malignant or benign liver disease	The overall in-hospital mortality rate was 4.8%
Benzoni <i>et al</i> <sup>[6]</sup>	<i>Hepatobiliary Pancreat Dis Int</i>	November 2006	Italy	287	HCC or liver metastasis	In-hospital mortality rate was 4.5%, and the morbidity rate was 47.7%
Benzoni <i>et al</i> <sup>[7]</sup>	<i>Hepatogastroenterol</i>	January-February 2007	Italy	134	HCC	In-hospital mortality rate was 7.4%, and the morbidity rate was 47.7%
Mullen <i>et al</i> <sup>[8]</sup>	<i>J Am Coll Surg</i>	May 2007	United States	1059	Noncirrhotic patients	The complication rate was 43%, and the 90-d all-cause mortality rate was 4.7% (1.9% patients died of causes unrelated to the liver)
McKay <i>et al</i> <sup>[9]</sup>	<i>Ann Surg Oncol</i>	May 2008	Canada	1107	Liver tumor	In-hospital mortality rate was 6.0%, and an overall complication rate was 46%
Feng <i>et al</i> <sup>[10]</sup>	<i>World J Gastroenterol</i>	December 2008	China	827	Benign hepatic lesion	In-hospital mortality rate was 0.24%, and the postoperative complication rate was 13.54%
Tomuş <i>et al</i> <sup>[11]</sup>	<i>Chirurgia (Bucur)</i>	May-June 2009	Romania	50	Benign hepatic lesion	There was no mortality, and the morbidity rate was 18%
Cescon <i>et al</i> <sup>[12]</sup>	<i>Ann Surg</i>	June 2009	Italy	1500	Malignant or benign disease	Overall mortality was 3%, and the morbidity was 22.5%
Huang <i>et al</i> <sup>[13]</sup>	<i>Chin Med J (Engl)</i>	October 2009	China	2008	Malignant or benign liver disease	The overall hospital mortality was 0.55%, and the overall postoperative complication rate was 14.44%
Mathur <i>et al</i> <sup>[14]</sup>	<i>J Gastrointest Surg</i>	August 2010	United States	3960	Liver tumor	The overall mortality rate was 2.5%, and the overall complication rate was 23.3%
Sato <i>et al</i> <sup>[15]</sup>	<i>J Gastroenterol</i>	October 2012	Japan	5270	HCC	In-hospital mortality was 2.6%, and the postoperative complication rate was 14.5%
Dan <i>et al</i> <sup>[16]</sup>	<i>Chirurgia (Bucur)</i>	November-December 2012	Romania	133	Benign or malignant tumors	The overall mortality rate was 2.25%

HCC: Hepatocellular carcinoma.

manipulation of the hepatic vein root or trauma to the diaphragm, and increased intrathoracic pressure and vena cava pressure which may lead to bleeding; and (3) vascular sutures loosened or fallen off, an event which usually is ascribed to elevated pressure in the vena cava from patients' body movement, such as turning over or coughing severely. Detachment of the ligature on the short hepatic veins may cause a gap in the vena cava wall. Postoperative intraperitoneal hemorrhage usually occurs within 48 h, and from the residual liver's surface or the diaphragm. Thorough intraoperative hemostasis is critical and must be ascertained before the operation is concluded. When the root of the hepatic vein is manipulated during the operation, hemorrhage from the vein or anterior to the inferior vena cava should be carefully sought by increasing the intrathoracic pressure artificially. Mattress sutures with hepatic needles should be used for the hemostasis, and the traumatized surface can be covered with hemostasis film, gelatin sponge, biological glue, or omentum as means of achieving additional hemostasis<sup>[42]</sup>. The pres-

ence of persistent bloody drainage might indicate that intraperitoneal clots have formed, which may occlude abdominal drains, leading to abdominal distention. Close monitoring of vital signs and transfusion of whole blood, platelets, and plasma are usually recommended as long as the patient's blood pressure and pulse remain stable. Otherwise, secondary open surgery should be considered<sup>[43]</sup>. We recommend that open surgery to attain hemostasis be performed if blood loss exceeds 1000 mL/h for more than eight hours. In summary, correct timing for operations on infected liver sections, careful manipulation during operation, and thorough hemostasis and drainage are critical for success in attaining hemostasis.

### Coagulation disorders

Five common causes of coagulation disorders associated with hepatectomy are: (1) functional failure of the residual liver due to prolonged ischemia, especially in the presence of cirrhosis<sup>[44]</sup>; (2) massive intraoperative bleeding, or blood transfusion of more than 4000 mL;

(3) consumption of coagulation factors and platelets due to severe infection; (4) overdose of heparin after hepatic artery or portal vein catheterization; and (5) cardiopulmonary bypass or extracorporeal circulation<sup>[45,46]</sup>. Coagulation time, prothrombin time, platelet count, and fibrinogen level should be tested to aid in making the diagnosis of a postoperative coagulation disorder, and the 3P test may be performed if necessary<sup>[47]</sup>. Expansion of the circulating blood volume and transfusion of fresh blood should be carried routinely once a coagulation disorder is confirmed, and prompt administration of fibrinogen, prothrombin complex, fresh platelets, and plasma cold precipitates also is important<sup>[48-50]</sup>. Protamine can be administered to neutralize the heparin if it has been overdosed.

### Gastrointestinal tract bleeding

The common causes of gastrointestinal tract bleeding after hepatectomy are: (1) stress ulcer, the most common; (2) portal hypertension due to liver cirrhosis; and (3) congestion of gastrointestinal organs because of secondary portal hypertension due to the limited volume of the residual liver. Gastrointestinal tract bleeding usually occurs within two weeks after operation. It may be manifested by the passage of brown or bloody drainage, hematemesis, melena, deterioration of vital signs, and abdominal pain. If the bleeding is mild, nasogastric suctioning and administration of proton pump inhibitors and hemostatic drugs may be adequate treatment. Somatostatin and ulinastatin may be given if the bleeding is massive. Operation should be considered if the blood pressure and pulse are unstable, or if hemorrhage persists after 48 h of aggressive treatment<sup>[51-54]</sup>.

### Biliary tract hemorrhage

Iatrogenic bile duct injury is the most common cause of biliary tract hemorrhage after hepatectomy. Surgical maneuvers, including operating in the hepatic portal region, bile duct exploratory surgery, and placement of T-tubes in the biliary ducts could result in biliary tract hemorrhage. Other common causes are mucosal erosion ulcer and coagulation disorders due to biliary tract infection and inflammation. The major manifestations of biliary tract hemorrhage are right upper quadrant gripping pain, upper gastrointestinal bleeding, and obstructive jaundice. Usually, bleeding of this kind can be treated effectively with appropriate hemostasis, antibiotics, and supportive measures. For patients who have massive biliary tract bleeding or whose bleeding site is unclear (after hepatic artery angiography), explorative operation should be carried out<sup>[55-59]</sup>.

## BILE LEAKAGE

The incidence of bile leakage ranges from 4.0% to 17%<sup>[60-63]</sup>. Common causes of postoperative bile leakage are: (1) truncation of the distal bile duct in the residual liver, the most common cause; (2) leakage at the bile duct-intestinal anastomosis, or incomplete suture around the

T-tube; and (3) injury of the bile duct from inappropriate surgical technique. A retrospective analysis by Yoshioka *et al.*<sup>[64]</sup> of 505 hepatectomy cases found that the incidence of bile leakage was 6.7%, with three independent risk factors: (1) multiple hepatectomy ( $P = 0.002$ , OR = 3.439; 95%CI: 1.552-7.618); (2) traumatized liver surface  $\geq 57.5 \text{ cm}^2$  ( $P = 0.004$ , OR = 5.296; 95%CI: 1.721-16.302); and (3) intraoperative bleeding  $\geq 775 \text{ mL}$  ( $P = 0.01$ , OR = 2.808; 95%CI: 1.280-6.160)<sup>[64]</sup>. Another analysis by Sadamori *et al.*<sup>[65]</sup> of 359 hepatectomy cases found that operative time  $\geq 300 \text{ min}$  was an independent risk factor for bile leakage after hepatectomy. To help predict if postoperative bile leakage will occur, the residual liver can be covered with wet gauze, which may show the presence of minimal bile seepage. To help avoid postoperative bile leakage, biological glue can be applied to the surface of the residual liver, and a C tube can be placed in the cystic duct for decompression<sup>[66,67]</sup>. Intraoperatively, bile leakage might be revealed with the use of indocyanine green fluorescein<sup>[68-70]</sup>. Close postoperative monitoring is mandatory and should include observing for abdominal pain, rebound tenderness, muscle tension, and bile leakage from the drainage tube. Bile leakage also may be evident by the presence of bile in the peritoneal drainage (the concentration of bilirubin in the bile will be higher than in serum). In addition, computed tomography (CT) visualization can be used to determine if the bile duct is occluded and, if so, where the occlusion is located. A drainage tube can remain in the bile duct if there is no sign of peritonitis; the bile leakage may resolve spontaneously within two months. However, if peritonitis develops, open surgery should be performed as soon as possible for thorough cleaning of the abdominal cavity and repair of the damaged common bile duct. Antibiotics may be administered for control of infection, and supportive treatment should be given as usual after a major operation<sup>[71,72]</sup>. It has been reported that bile leakage occurred in 14 of 96 patients who underwent hepatectomy; nine were treated successfully without operation, but five required a second operation. In general, non-operative treatment was sufficient if the results of ERCP and CT were negative for bile leakage, but operative intervention was needed if conservative therapy failed<sup>[73]</sup>.

## LIVER FAILURE

Liver failure is a severe postoperative complication of hepatectomy. It is closely associated with active hepatitis, cirrhosis, limited residual liver tissue, massive intraoperative hemorrhage, the mode and duration of hepatic portal vein occlusion, the kind of anesthesia used, and perioperative medication used. An incidence of liver failure after hepatectomy of about 0.70%-33.83% has been reported<sup>[74-77]</sup>, and the failure was related to inadequate residual liver tissue and functional capacity<sup>[78,79]</sup>. Comprehensive therapy for liver failure includes postoperative supplementation with albumin, fibrinogen or prothrombin complex; intravenous nutrition; and transfusion of

fresh blood. Prognosis is poor if coagulation disorders develop. Presently, the most effective therapy for liver failure is liver transplantation, but it is associated with a high mortality rate in patients with liver cirrhosis and, therefore, it remains a controversial treatment choice in this circumstance<sup>[80-86]</sup>. Generally, prevention of liver failure is felt to be more important than treatment of it. Some common preventive measures are: careful preoperative assessment of the liver's functional reserve and institution of measures to improve the liver function. Prevention of intraoperative bleeding and the need for blood transfusion also are important in preventing liver failure. In one report, the incidence of postoperative complications increased significantly when the intraoperative blood loss exceeded 1200 mL<sup>[11]</sup>. Several methods can be used to reduce the chance of intraoperative bleeding: CUSA<sup>[87-89]</sup>, heat solidification technology<sup>[90-93]</sup>, reduction of central venous pressure<sup>[94-96]</sup>, and blocking of hepatic portal blood inflow (with or without control of hepatic blood outflow)<sup>[97-101]</sup>. For patients with liver cirrhosis, the volume of residual liver and the time of portal occlusion must be strictly assessed. Also, the method used for occluding blood flow to the liver must be appropriately selected. It has been recommended that half hepatic blood flow occlusion should be used for patients with cirrhosis, and hepatic blood inflow occlusion without hemihepatic artery control (hemi-hepatic artery-preserved portal occlusion) used if half occlusion is difficult or inadequate. Hepatic blood inflow occlusion without hemihepatic artery control is simple for operation, with less damage to the liver function; more importantly, the effect of the blood flow blocking is equivalent to the half-hepatic blood flow blocking<sup>[102,103]</sup>. The procedure for inflow occlusion is the following: the hepatic artery is exposed first, to separate the right and left hepatic arteries from the root of the artery. To restrict blood flow to the right half of the liver, the hepatic portal vein, bile duct, and the right hepatic artery should be tightened together with a catheter; the opposite arrangement is used for restricting blood flow to the left half of the liver, except that the left hepatic artery, instead of the right hepatic artery, is occluded<sup>[98]</sup>. It is important that the patient receive sufficient oxygen throughout the perioperative period, and that hepatotoxic drugs are avoided.

After hepatectomy, the patient should be closely monitored, with particular attention to abnormalities in levels of consciousness, liver function, the volume and character of drainage fluid, acid-base balance, and serum lactic acid levels. In general, during the first postoperative day, the ideal levels of serum hepatic transaminases, total bilirubin, and prothrombin activity can be expected to remain below 1000 IU/mL, about 2 mg/dL, and about 50%, respectively. Acidosis is very common in liver failure, so the level of serum lactic acid should be carefully monitored. Serum bilirubin level should rapidly decrease; if the level increases abruptly after the second postoperative day the risk of hepatic failure increases. Currently, there is not a unified definition of liver failure after hepa-

tectomy. The international hepatic surgery research team has proposed a definition based on the normal postoperative course of serum bilirubin concentration and international normalized ratio (INR), reflecting the ability of the liver to maintain its synthetic, excretory, and detoxifying functions. Postoperative liver failure is defined as an increased INR and hyperbilirubinemia (according to the normal limits of the local laboratory) on or after postoperative day 5<sup>[104]</sup>. The severity of post-hepatectomy liver failure is graded based on its effect on clinical management; grade A failure requires no change in the patient's clinical management; grade B failure requires deviation from the usual management but does not require invasive therapy; grade C requires invasive treatment<sup>[104]</sup>.

## CONCLUSION

In conclusion, hepatectomy still has significant associated complications and mortality. These problems are closely related to surgical manipulations, anesthesia, preoperative evaluation and preparation, and postoperative observation and management. The safety profile of hepatectomy probably can be improved if the surgeons and medical staff involved have comprehensive knowledge of the expected complications and expertise in their management.

steatosis and changes in lipid and carbohydrate metabolism similar to those produced in chronic inflammatory conditions described in metabolic syndrome in humans. Dysbiosis and bacterial translocation in this experimental model suggest the existence of a portal hypertensive intestinal microbiome implicated in both the splanchnic and systemic alterations related to prehepatic portal hypertension. Among the systemic impairments, aortopathy characterized by oxidative stress, increased levels of proinflammatory cytokines and profibrogenic mediators stand out. In this experimental model of long-term triple portal vein ligated-rats, the abdominal aortic proinflammatory response could be attributed to oxidative stress. Thus, the increased aortic reduced-nicotinamide-adenine dinucleotide phosphate [NAD(P)H] oxidase activity could be associated with reactive oxygen species production and promote aortic inflammation. Also, oxidative stress mediated by NAD(P)H oxidase has been associated with risk factors for inflammation and atherosclerosis. The splanchnic and systemic pathology that is produced in the long term after triple partial portal vein ligation in the rat reinforces the validity of this experimental model to study the chronic low-grade inflammatory response induced by prehepatic portal hypertension.

### Abstract

Splanchnic and systemic low-grade inflammation has been proposed to be a consequence of long-term prehepatic portal hypertension. This experimental model causes minimal alternations in the liver, thus making a more selective study possible for the pathological changes characteristic of prehepatic portal hypertension. Low-grade splanchnic inflammation after long-term triple partial portal vein ligation could be associated with liver steatosis and portal hypertensive intestinal vasculopathy. In fact, we have previously shown that prehepatic portal hypertension in the rat induces liver

**Key words:** Portal hypertension; Inflammation; Aortopathy; Hepatic steatosis

**Core tip:** Triple partial portal vein ligation in the rat induces in the long term (22 mo) both splanchnic alterations, *i.e.*, liver steatosis and portal hypertensive intestinal vasculopathy associated with a portal hypertensive microbiome, and systemic alterations, *i.e.*, a wound-like inflammatory aortic response. These alterations support this experimental model of prehepatic portal hypertension for studying the pathophysiological mechanisms involved in the low-grade inflammatory response produced.

Splanchnic-aortic inflammatory axis in experimental portal hypertension. *World J Gastroenterol* 2013; 19(44): 7992-7999 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/7992.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.7992>

## INTRODUCTION

Portal hypertension is the most severe complication that develops in cirrhotic patients and is a leading cause of mortality worldwide<sup>[1]</sup>. Ascites, hepatorenal syndrome, life-threatening gastroesophageal bleeding, portosystemic encephalopathy and sepsis, derived from shunting of portal blood into the systemic circulation through neoformed collateral vessels, are the most serious and frequent clinical complications<sup>[1]</sup>.

Portal hypertension is defined as an increase in portal blood pressure and is determined from the hepatic venous pressure gradient or pressure difference between the portal vein and the inferior vena cava<sup>[2]</sup>. The impairments arising from this pathological increase in portal pressure constitute the portal hypertensive syndrome<sup>[3]</sup>.

## EXPERIMENTAL PORTAL HYPERTENSIVE MODEL

The partial portal vein ligation experimental model in the rat is generally used to study portal hypertension since it has the lowest degree of hepatic impairment because portal hypertension is extrahepatic<sup>[4]</sup>. The surgical technique is simple and is based on making a calibrated stenosis of the portal vein<sup>[5]</sup>. If it is assumed that the intensity of the portal hypertension is determined by the resistance to the inflow produced by the constriction of the portal vein, this model of prehepatic portal hypertension could be improved by increasing the initial resistance to blood flow. With this objective in mind, we have modified this surgical technique by increasing the length of the stenosed portal tract with three equidistant calibrated stenosis<sup>[6]</sup>.

This experimental model causes minimal alternations in the liver, thus making a more selective study possible for the pathological changes characteristic of prehepatic portal hypertension<sup>[4,6]</sup>. The experimental model of partial portal vein ligation is generally studied in the short-term, *i.e.*, 2-4 wk<sup>[4]</sup>. However, studying the late phases could be of great interest since the mechanisms involved and the related complications could be more similar to those found in chronic liver diseases in humans<sup>[1,2]</sup> which are related to the chronicity of portal hypertension, among other factors.

## INFLAMMATORY RESPONSE RELATED TO PORTAL HYPERTENSION

Much evidence shows how inflammation contributes to

the initiation and maintenance of portal hypertension<sup>[7,8]</sup>. Furthermore, early and chronic partial portal vein ligated-rats show hemodynamic and metabolic impairments, where the etiopathogeny is of an inflammatory nature<sup>[7,8]</sup>. Consequently, it could be hypothesized that chronic hemodynamic, vascular and metabolic changes in rats with prehepatic portal hypertension could have an inflammatory origin, most probably subsequent to splanchnic inflammation. In this way, the endothelial inflammatory mechanotransduction induced by portal hypertension could be the first step in the production of an inflammatory response in the intestinal wall. Thus, the early splanchnic endothelial disorder could induce, in turn, an inflammatory intestinal phenotype that would be linked to both phenomena: the gut microbiota alteration as well as the vasomotor impairments that are responsible for the splanchnic hyperdynamic circulation (Figure 1).

Furthermore, prehepatic portal hypertension induces the development of portal hypertensive enteropathy with inflammatory cell infiltration, particularly mast cells<sup>[9,10]</sup>, which is reduced by the prophylactic administration of anti-inflammatory drugs, like budesonide and ketotifen<sup>[8,11]</sup>. Since the basic structural alteration found in portal hypertensive enteropathy is angiogenesis, the very appropriate name of "hypertensive portal intestinal vasculopathy" has been proposed<sup>[12]</sup>.

The formation of new blood vessels could be a key mechanism in the pathogenesis of prehepatic portal hypertension<sup>[8]</sup>. Mast cells are involved in the regulation of physiological and pathological vasculogenesis by producing mediators, such as heparin, histamine, tryptase, transforming growth factor- $\beta$ 1, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukins and cytokines, such as vascular endothelial growth factor<sup>[13]</sup>. The ability of mast cells to promote the synthesis and selective release of different angiogenic mediator molecules<sup>[14]</sup> would explain their participation in the splanchnic remodeling related to experimental prehepatic portal hypertension<sup>[8-10]</sup>. Lastly, intestinal mast cells are also a potent source of multiple chemokines and play an important role in immune regulation<sup>[15,16]</sup>.

We have previously shown that prehepatic portal hypertension in the rat induces liver steatosis and causes changes in lipid and carbohydrate metabolism similar to those produced in chronic inflammatory conditions described in metabolic syndrome in humans<sup>[17-19]</sup>. Long-term portal hypertensive rats show a decrease in plasma adrenocorticotrophic hormone and corticosterone<sup>[20]</sup>. Glucocorticoids, such as cortisol and corticosterone, are pluripotent hormones that are vital in the host adaptation to stress. They are also essential for maintaining normal vascular tone, endothelial integrity and vascular permeability. Thus, the decrease in corticosterone in portal hypertensive rats could have deleterious effects on vascular systems. In addition, cortisol clearance is increased in individuals with fatty liver, and cortisol clearance is in turn inversely correlated with insulin sensitivity<sup>[21]</sup>. Therefore, in rats with portal hypertension, in which liver steatosis is present, a decreased stress responsiveness could be re-

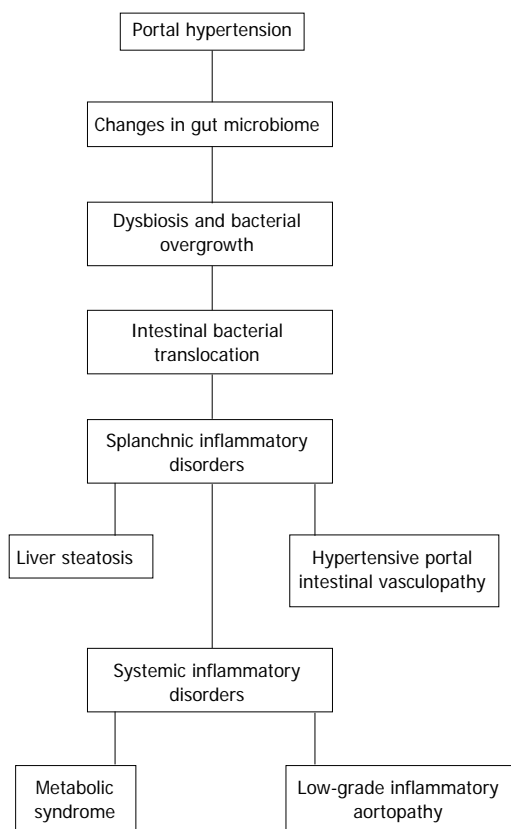

Figure 1 Splanchnic and systemic alterations in rats with prehepatic portal hypertension produced by triple partial portal vein stenosis.

lated to an impaired metabolic feedback system. The decreased neuroendocrine response to stress and systemic chronic inflammation would be another link between disordered lipid metabolism and inflammation in the evolution of this experimental model<sup>[22]</sup>. So, rats with long-term portal hypertension presenting systemic low-grade inflammation and decreased responsiveness to stress could inappropriately switch carbohydrate metabolism to predominant lipid metabolism, thus inducing body energy imbalance and ultimately, hepatic steatosis and metabolic syndrome<sup>[18,19]</sup>. Consequently, data from animal models proved that mast cells are directly involved in diet-induced obesity, diabetes and metabolic syndrome<sup>[23]</sup>.

The association of liver steatosis and metabolic syndrome with inflammation is well documented<sup>[24]</sup>. Hence, we could hypothesize that inflammation, probably of splanchnic origin, could be the pathophysiologic link between the metabolic syndrome with liver steatosis and aortic vascular disease in portal hypertensive rats. The association between metabolic and atherogenic alterations with a proinflammatory aortic phenotype could suggest the possibility that portal hypertension might constitute a novel risk factor for cardiovascular disease<sup>[20,25]</sup> (Figure 1).

## PORTAL HYPERTENSIVE INTESTINAL MICROBIOME

Bacterial intestinal translocation occurs in acute portal

hypertension<sup>[26]</sup> and in chronic portal hypertension in the adult partial portal vein ligated rat<sup>[27]</sup> when there are associated precipitating factors, such as hemorrhagic shock<sup>[28]</sup>. However, in chronic (1 mo) prehepatic portal hypertension by triple partial portal vein ligation, there are gut microflora alterations with less positive cultures of *Enterococci* and lactic acid bacteria, associated with bacterial translocation to the mesenteric lymph nodes<sup>[29]</sup>. Bacterial overgrowth in the intestinal tract may be the most important factor in bacterial translocation, in particular when associated with splanchnic inflammation and increased intestinal permeability, secondary to portal hypertension<sup>[29]</sup>. It has also been proposed that bacterial translocation may render the gut a “cytokine-releasing” organ that, at the same time, would induce nitric oxide overproduction and the development of the hyperdynamic circulatory state. At the same time, this is one of the progressive characteristics of portal hypertension<sup>[30]</sup>. Bacterial overgrowth could also be caused by delayed transit, mucosal hypoperfusion and oxidative damage, which increases intestinal permeability and induces the transmural passage of bacteria in portal hypertensive rats<sup>[31,32]</sup>.

Although microbial communities reside on all mammal body surfaces, including the skin and respiratory, gastrointestinal and genitourinary tracts, the largest collection of microbes reside in the gut<sup>[33]</sup>. The intestinal microbiome is considered more than just a simple organ of the mammal body. Cooperative interactions between intestinal microbes and their hosts typically involve microbial participation in host functions such as defense, metabolism, and reproduction<sup>[34]</sup>. However, communications between the host and its gut microbiota are altered in pathophysiological processes, especially if associated with inflammation, including portal hypertension<sup>[35]</sup>. Diseases mediated by the inflammatory response could induce a change in the relationship of the rat body with gut microbiota, the significance of which is unknown<sup>[35]</sup>.

Inflammatory conditions, such as splanchnic inflammation related to portal hypertension, could induce a change in the mammalian organism and gut microbiota relationship. In particular, splanchnic inflammation not only could alter gut microbiota composition, but also cause epithelial and endothelial permeability of the intestinal bacteria to increase bacterial products, such as toxins<sup>[34]</sup>. Bacterial translocation secondary to portal hypertension could lead to bacterial overgrowth and disruption of gut homeostasis<sup>[29]</sup>. This results in a “leaky gut” syndrome, with translocation of gut bacteria and bacterial products, also called pathogen-associated molecular patterns or PAMPs, to systemic sites, that finally results in systemic complications<sup>[34-37]</sup>.

Gut microbiota in rats with portal hypertension could contribute to the development of liver steatosis and metabolic syndrome. The gut microbiota may be involved in hepatologic conditions including non-alcoholic fatty liver disease<sup>[33]</sup>. Thus, bacterial products, including endotoxins, can affect Kupffer cells, hepatocytes and hepatic stellate cells, which participate in the initiation and progression of non-alcoholic fatty liver disease<sup>[38]</sup>. Gut microbiota

**Figure 2** Aortic abdominal wall microscopic images in long-term (22 mo) sham-operated rat (A) and in a triple partial portal vein ligated-rat (B). The aortic wall in the rat with portal hypertension is enlarged, has more fibrosis, with collagen deposition in the middle layer, a greater loss of the smooth muscular cell nucleus and much thinner elastic fibers than in the aortic wall of the sham-operated rat. They are also distributed in an irregular manner (Masson,  $\times 40$ ).

could also contribute to the development of hypertensive portal intestinal vasculopathy. Recent results suggest that the increased intestinal vascularization is mediated through microbiota-induced angiopoietin-1 expression in the intestinal epithelium<sup>[39]</sup>.

Gut microbiome responses to portal hypertension could be a central event in the pathogenesis of splanchnic, *i.e.*, liver steatosis and enteropathy, and systemic inflammatory conditions. However, it has been also suggested that microbiome changes could alter host-microbiome interactions to mitigate disease<sup>[33]</sup> (Figure 1).

## WOUND-LIKE INFLAMMATORY AORTIC RESPONSE

Long-term experimental prehepatic portal hypertension represents a risk factor of an inflammatory nature for aortic disease development<sup>[20,25]</sup>. Triple partial portal vein ligation in the rat induces an abdominal aortic inflammatory response 22 mo after the operation. These portal hypertensive rats show significant histological changes, in particular in the middle layer of the aortic wall. The elastic fibers lose their orderly circumferential arrangement. The interstitial connective tissue is enlarged with fibrosis and associated with a dramatic decrease in the number of smooth muscle cells. Finally, immature collagen also increases with the degeneration of connective tissue<sup>[20]</sup> (Figure 2).

In this experimental model of long-term triple portal vein ligated rats, the abdominal aortic proinflammatory response could be attributed to oxidative stress. In this way, the increased aortic reduced-nicotinamide-adenine dinucleotide phosphate [NAD(P)H] oxidase activity<sup>[20]</sup> could be associated with reactive oxygen species production and promote aortic inflammation<sup>[40]</sup>. Also oxidative stress mediated by NAD(P)H oxidase has been associated with risks factors for inflammation and atherosclerosis<sup>[41]</sup>.

In chronic portal hypertensive rats, over-activation of endothelial nitric oxide synthase (eNOS) might cause aortic nitric oxide overproduction<sup>[20,25]</sup>. Upregulation of eNOS has also been seen in the aorta of short-term por-

tal vein stenosed and biliary cirrhotic rats, respectively<sup>[42]</sup>. It has been suggested that an increased basal release of nitric oxide has a major role in the pathogenesis of vasodilation and vascular hypocontractility associated with portal hypertension<sup>[7]</sup>. Lipopolysaccharide (LPS) administration to cirrhotic rats increases aortic eNOS activation but, on the contrary, decreases eNOS protein expression and activity in superior mesenteric arteries. These results may explain the worsening of the hyperdynamic state in cirrhosis during septic shock by direct LPS-induced eNOS activation in large systemic vessels, and its inhibition in concomitant small splanchnic vasculature<sup>[43]</sup>.

The essential role of reactive oxygen species in the chronic inflammatory response has led to the view that reactive oxygen species promote inflammation<sup>[44]</sup>. Reactive oxygen species can increase the expression of inducible genes leading to the synthesis of cytokines, chemokines, chemokine receptors and adhesion molecules. These actions rely on transcription factors, such as nuclear factor  $\kappa$ B (NF- $\kappa$ B)<sup>[44]</sup>. Aortic overproduction of proinflammatory cytokines, including TNF- $\alpha$ , interleukin-1 $\beta$  (IL-1 $\beta$ ), and IL-6 in chronic portal hypertensive rats, associated with an increased NF- $\kappa$ B/NF- $\kappa$ B inhibitor (I $\kappa$ B) ratio supports the existence of a proinflammatory abdominal aortic response. If so, reactive oxygen species or TNF- $\alpha$  could induce activation of the I $\kappa$ K (I $\kappa$ B kinase) complex resulting in phosphorylation of I $\kappa$ B, subsequent translocation of NF- $\kappa$ B to the nucleus and expression of NF- $\kappa$ B responsive genes (Figure 3).

Proinflammatory cytokines, cytokine-dependent pathways and immune cells have been implicated in the development of cardiovascular diseases, *i.e.*, atherosclerosis, coronary artery disease, chronic heart failure and hypertension<sup>[44]</sup>. Thus, a large body of evidence supports the involvement of common proinflammatory cytokines in the development and progression of a systemic low-grade inflammation affecting the cardiovascular system. In addition, these low-grade inflammatory cardiovascular diseases can be aggravated when a new inflammatory process, either of infectious origin or autoimmune nature, is added<sup>[45,46]</sup>. This is the reason why it could also be considered that prehepatic portal hypertension produces

**Figure 3 Aortic inflammatory mediators in triple partial vein ligated-rats at 22 mo after postoperative evolution.** Increased aortic mRNA expression of tumoral necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 $\beta$  (IL-1 $\beta$ ) and IL-6, are associated with the increased expression of mRNA levels of the nuclear factor  $\kappa$ B (NF- $\kappa$ B)/NF- $\kappa$ B inhibitor (I $\kappa$ B) ratio. SO: Sham-operated rats; PPH: Prehepatic portal hypertensive rats. <sup>a</sup> $P < 0.05$ , statistically significant value in regards to SO-rats.

**Figure 4 Aortic profibrogenic mediators in triple partial vein ligated-rats at 22 mo of postoperative evolution.** Increased abdominal aortic expression of matrix metalloproteinase (MMP)-9, collagen I and connective tissue growth factor (CTGF). SO: Sham-operated rats. PPH: Prehepatic portal hypertensive-rats. <sup>a</sup> $P < 0.05$ , statistically significant value in regards to SO-rats.

a low degree inflammatory cardiovascular response, which could be aggravated when a new inflammatory process (acute-over-chronic) is added, particularly infections or hepatic insufficiency<sup>[8]</sup>.

Mast cells stand out among the potential mediators of the low-grade inflammatory response supposedly involved in metabolic and vascular diseases in the experimental model of prehepatic portal hypertension<sup>[3,9]</sup>. Nonetheless, these results obtained in the short-term evolution of portal hypertensive rats cannot be extrapolated to long-term portal hypertensive rats. Thus, a study of

the role of the splanchnic subpopulations of mast cells in chronic portal hypertensive rats would be interesting, given that the gut, particularly with impaired intestinal barrier function, plays an important pathophysiological role in chronic inflammation in cardiovascular diseases<sup>[47]</sup>. In particular, mast cells play a key role in experimental atherosclerosis and can modulate the inflammatory aortic response through numerous proinflammatory mediators, including TNF- $\alpha$ , IL-6 and metalloproteinases<sup>[48,49]</sup>. In addition, mast cell chymase also functions as an angiotensin-converting enzyme, particularly in rodents and there-

Figure 5 Chronic splanchnic alterations, liver steatosis and enteropathy, secondary to long-term triple partial portal vein stenosed rats are associated with oxidative stress, inflammatory cytokines and profibrogenic mediators in abdominal aorta. NAD(P)H: Reduced-nicotinamide-adenine dinucleotide phosphate; MMP: Matrix metalloproteinases; TPVL: Triple partial portal vein stenosed; NF-κB: Nuclear factor κB; TNF-α: Tumor necrosis factor-α; IL: Interleukin; CTGF: connective tissue growth factor; MMP-9: Matrix metalloproteinase 9.

fore contributes to aortic fibrosis<sup>[50]</sup> (Figure 4).

Lastly, enhanced aortic mRNA expression of oxidative and inflammatory mediators are associated with increased aortic expression of collagen I and connective tissue growth factor (CTGF) in long-term portal hypertensive rats<sup>[20,25]</sup>. Increased aortic CTGF expression could regulate aorta collagen remodeling, and therefore enhance the synthesis of extracellular matrix proteins, particularly type I collagen. In turn, CTGF could activate the NF-κB pathway and increase proinflammatory gene expression<sup>[51]</sup>. These results suggest the existence of a proinflammatory and a profibrotic aortic phenotype in long-term prehepatic portal hypertensive rats (Figures 4 and 5).

## CONCLUSION

In summary, rats with long-term portal hypertension with liver steatosis and hypertensive portal intestinal vasculopathy also suffer a low-grade abdominal aortic inflammation associated with fibrosis.

### Abstract

**AIM:** To characterize the nuclear import of hepatitis B virus (HBV) polymerase (P) and its relevance for the viral life cycle.

**METHODS:** Sequence analysis was performed to predict functional motives within P. Phosphorylation of P was analyzed by in vitro phosphorylation. Phosphorylation site and nuclear localization signal (NLS) were destroyed by site directed mutagenesis. Functionality of the identified NLS was analyzed by confocal fluorescence microscopy and characterizing the karyopherin binding. Relevance of the structural motives for viral life cycle was studied by infection of primary *Tupaia* hepatocytes with HBV.

**RESULTS:** We identified by sequence alignment and functional experiments a conserved bipartite NLS con-

taining a casein kinase II (CK II) phosphorylation site located within the terminal protein domain (TP) of the HBV polymerase. Inhibition of CK II impairs the functionality of this NLS and thereby prevents the nuclear import of the polymerase. Binding of the import factor karyopherin- $\alpha$ 2 to the polymerase depends on its CK II-mediated phosphorylation of the bipartite NLS. In HBV-infected primary *Tupaia* hepatocytes CK II inhibition in the early phase (post entry phase) of the infection process prevents the establishment of the infection.

**CONCLUSION:** Based on these data it is suggested that during HBV infection the final import of the genome complex into the nucleus is mediated by a novel bipartite NLS localized in the TP domain of HBV polymerase.

**Key words:** Hepatitis B virus; Nuclear localization signal; Casein kinase II; Trafficking; Replication

**Core tip:** The mechanism mediating import of the hepatitis B virus (HBV) genome into the nucleus is still not fully understood. We describe the identification and characterization of a bipartite nuclear localization signal (NLS) in the HBV polymerase that harbours a phosphorylation site for casein kinase II (CK II). Integrity of the phosphorylation site is crucial for the functionality of the NLS. Moreover, inhibition of CK II prevents karyopherin- $\alpha$ 2 from binding to the polymerase and thereby the import of the polymerase is impaired. Analysing the viral life cycle we observed that inhibition of CK II blocks the import of the genome into the nucleus resulting in impaired cccDNA formation and so the establishment of the viral infection is prevented.

## INTRODUCTION

Infection with human hepatitis B virus (HBV) can cause acute or chronic inflammation of the liver. At present there are about 400 million chronically infected people worldwide. Moreover, persistently infected individuals have an increased risk of developing primary hepatocellular carcinoma (HCC)<sup>[1-6]</sup>. HBV is the prototype member of the hepadnaviridae family, which encompasses members isolated from woodchucks, ground squirrels and avian viruses isolated from *e.g.*, pekin duck, grey heron and stork.

The HBV polymerase (P) has four domains (Figure 1A). The terminal protein domain (TP) contains the tyrosine residue that primes DNA synthesis and covalently links P to the viral DNA<sup>[7-9]</sup>. The spacer domain has no known function other than to connect the terminal protein domain with the rest of P. The spacer domain, however, harbors at aa position 320 a thrombin cleavage site. This generates the possibility that not a full length protein, but a truncated polymerase is linked to the HBV genome due to intracellular proteolytic processing<sup>[10]</sup>. The reverse transcriptase domain and the RNase H domain contain the two enzymatic active sites catalyzing the reverse transcription of the RNA template to DNA and degradation of the RNA template.

Regarding the life cycle of HBV one open question concerns the fate of the viral nucleocapsid after the virus has entered the cell. There is evidence that the virus enters the cell by receptor mediated endocytosis and at the end of this process the nucleocapsid is released into the cytoplasm<sup>[11,12]</sup> and transported towards the nuclear pore complex<sup>[13,14]</sup>. Productive viral infection requires the transport of the HBV genome into the nucleus where the conversion into cccDNA occurs<sup>[15]</sup>.

The phase of nuclear entry is not fully understood. It is discussed that the intact viral capsid shuttles the genome-polymerase complex into the nuclear basket of the nuclear pore complex<sup>[16-18]</sup> where a partial disassembly of the DNA-loaded nucleocapsid leads to a release of the polymerase-linked genome<sup>[13,19-21]</sup>. The polymerase-genome complex is too big for free diffusion through the nuclear pore complex.

Due to the facts that although P is too big for free diffusion through the nuclear pore complex the polymerase-genome complex is imported into the nucleus and that a fraction of P protein is found within the nucleus<sup>[22-24]</sup> we examined the P protein for conserved motifs that could play a role for nuclear import and aimed

to characterize the nuclear import of HBV polymerase-genome complex.

## MATERIALS AND METHODS

### Cell lines and culture conditions

The human hepatoblastoma cell lines HuH-7<sup>[25]</sup> and HBV producing cell line HepG2.2.15<sup>[26]</sup> were cultured in D-MEM medium containing 10% (v/v) fetal calf serum (FCS), 500 U/L penicillin and 100 mg/L streptomycin (PAA, Pasching, Austria). Inducible HBV producing cell line HepAD38<sup>[27]</sup> were cultivated like HepG2.2.15 but with 400 mg/L G418, 50 µmol/L hydrocortisone and 2.5 mg/L insulin (Sigma-Aldrich, Sneeze, Germany), additionally.

### Subcellular fractionation

Subcellular fractionation was performed as described<sup>[28,29]</sup>.

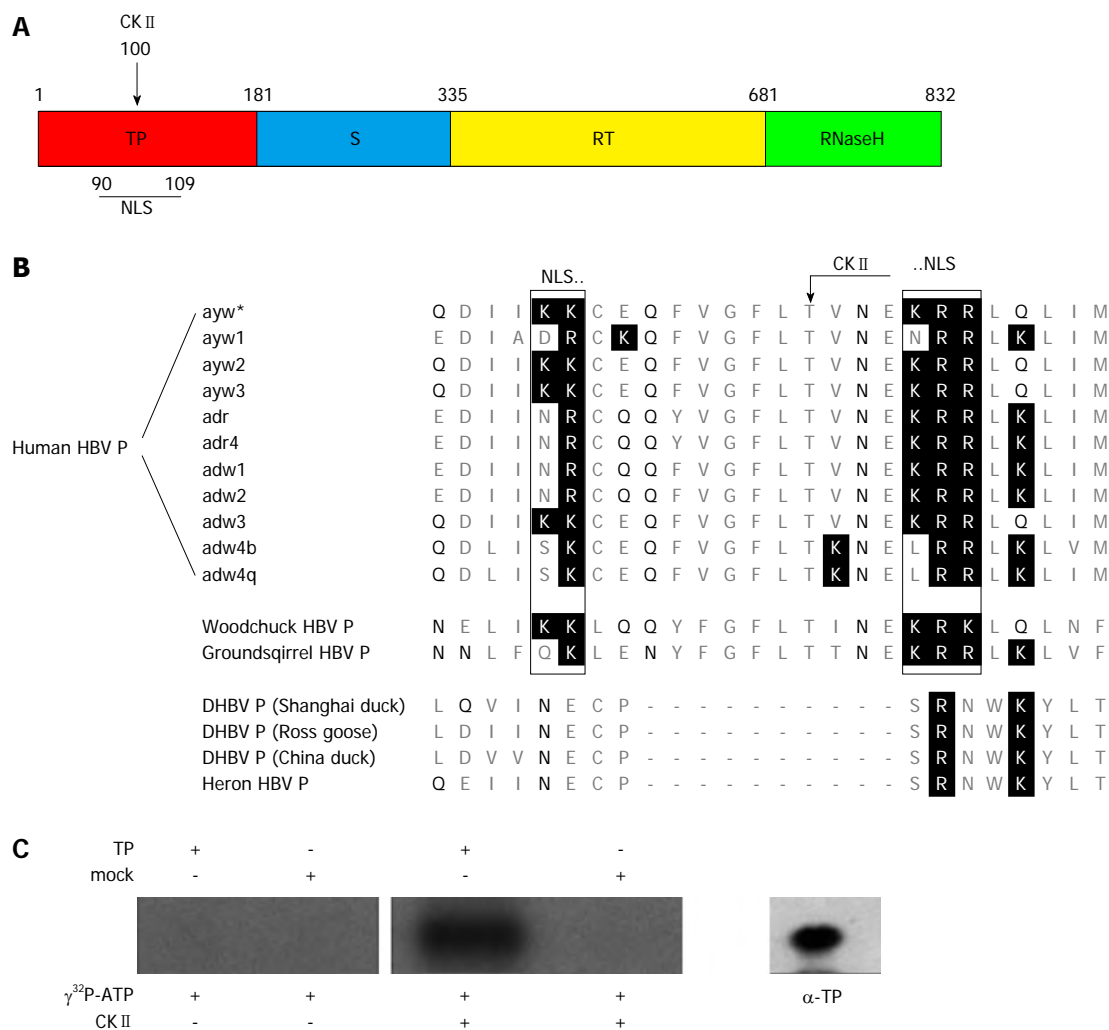

### Infection of primary hepatocytes

Primary *Tupaia belangeri* hepatocytes were isolated, cultivated and infected as described<sup>[30,31]</sup>. Trypsin treatment for removal of attached viral particles was performed as described<sup>[12,31-33]</sup>. HBeAg and HBsAg synthesis were analysed 120 h after infection.

### Generation of expression constructs

Plasmids were sub-cloned in *Escherichia coli* strain DH5α. The relevant mutations in the listed primer sequences are highlighted, restriction sites underlined and the corresponding backward primer sequences of mutation primers are reverse complementary to the forward primer if not cited otherwise.

The 1.2 fold HBV genome pJO19 (subtype ayw, genotype D) was derived from plasmid pSM2<sup>[26]</sup> by a stepwise truncation of the plasmid with *BseA* I and *Aat* II. Mutant versions of the wild type genome with alterations in the polymerase coding sequence were generated based on pJO19: The CK II recognition site deficient genome pJO19[T100I] was generated using primer ΔCK II\_fw (5'-CAG TTT gTA ggC CCA CTC ATA gTT AAT gAg AAA AgA AgA TTg CAA TTA ATT ATg CCT gCC), the pseudophosphorylated genome pJO19[T100D] was generated with primer \*CK II\_fw (5'-CAG TTT gTA ggC CCA CTCg ACg TTA ATg AgA AAA gAA gAT TgC AAT TAA TTA TgC CTg CC), the genome with an inactivated NLS pJO19[K105D,K106S] was generated with forward primer ΔNLS\_fw (5'-ggC CCA CTC ACA gTT AAT gAg CAg TCT AgA TTg CAA TTg ATT ATg CCT g). GFP wild type expression was obtained by pEGFP-N1 (BD, Heidelberg, Germany). The N-terminal fusions of NLS signals to GFP were generated from a modified version of pEGFP-N1 (pJO21). In pJO21 the first base of the transcriptional START of the GFP reading frame was deleted by site directed mutagenesis to prevent wild type GFP expression using primer GFP Δstart\_fw (5'-CCA CCg gTC gCC ACC Tgg TgA gCA

**Figure 1** Sequence alignment of the hepatitis B virus polymerase from various virus subtypes and species. **A:** Scheme of the hepatitis B virus (HBV) polymerase showing the different domains. The terminal protein domain (TP) is shown in red, the spacer domain (S) in blue, the reverse transcriptase domain (RT) in yellow and the RNase H domain in green. The numbers designate the amino acids referred to HBV genotype D. The positions of the casein kinase II (CK II) phosphorylation site and of the bipartite nuclear localization signal (NLS) identified in this study (see Figure 1B) are indicated; **B:** This figure shows amino acid alignment of Q86-M111 referred to the sequence of subtype ayw\*, which was used in this study. Basic amino acids are highlighted by a black background and polar ( $\delta^+$ ) amino acids are highlighted by black letters. A conserved protein kinase CK II recognition site (arrow) was identified in orthohepadnaviruses at Thr100 (protein kinase CK II: T/S-X-X-E/D; X = any amino acid). A bipartite nuclear localization signal was identified in *orthohepadnaviruses*, which is flanking the CK II recognition site by its two basic amino acid clusters (rectangles). All identified putative motifs were not found in the aligned P proteins of the compared *avihepadnaviruses*; **C:** Purified TP domain and mock purified proteins (empty vector products) were incubated with [ $\gamma$ - $^{32}$ P] ATP and recombinant protein kinase CK II. To control auto-phosphorylation TP domain was incubated with [ $\gamma$ - $^{32}$ P] ATP in absence of the kinase. The protein specificity was verified by Western blotting using a TP specific antibody ( $\alpha$ -TP) on a separate lane. All experiments were performed in triplicate. One representative is shown.

Agg gCg Agg). The plasmid pNLS<sub>NP</sub>-GFP was generated by amplifying human nucleoplasmin from a cDNA library. The polymerase chain reaction (PCR) product was flanked by terminal *Bgl*/II sites, which were generated by primer N-NLS-3fw (5'-TTT AgA TCT gTT CAg ggC CAg TgC) and primer N-NLS-3bw (5'-TTT AgA TCT TTT TAC TTT TTT CTg Tgg). The PCR product was ligated to the *Bam*HI cut pJO21. An engineered *Bgl*/II site followed by an optimized Kozak sequence<sup>[34]</sup> with transcriptional START was inserted immediately upstream of the NLS sequence by site directed mutagenesis using forward primer N-NLS-4fw (5'-ggA TgT gAA ACT CTT AAg TAg ATC TCg CCA CCA Tgg gAA AgC ggT CTg CCC CTg g). The dispensable upstream sequence was removed by a *Bgl*/II digest. Analogue to pNLS<sub>NP</sub>-GFP, the plasmid pNLS<sub>TP</sub>-GFP was generated by amplifying

the putative NLS of the TP domain from pJO19 using forward primer TP-NLS-3fw (5'-CCC ggA TCC ATg CCC CTA TCC TAT CAA CAC) and backward primer TP-NLS-3bw (5'-TTT AgA TCT TCT TTT CTC ATT AAC Tg). The upstream *Bgl*/II site, the Kozak signal and the transcriptional START was inserted using primer TP-NLS-4fw (5'-CCT AAT ATA CAT TTA CAC CAA gAC AgA TCT CgC CAC CAT ggT gAA AAA ATg TgA ACA gTT TgT Agg C).

The P-expression constructs were generated based on pJO19 or the corresponding mutants by PCR and subcloned in the pCDNA.3 eukaryotic expression vector.

#### Site-directed mutagenesis

was performed as described<sup>[35]</sup> by amplification of the whole plasmid using *Pfu* Turbo Hotstart DNA-Poly-

merase (Invitrogen, Karlsruhe, Germany). All synthetic oligonucleotides are purchased by Tib-Molbiol, Berlin, Germany.

### Purification of recombinant proteins

The coding sequence for the TP domain (amino acid 1-181) of HBV polymerase was amplified by PCR and inserted into the eubacterial expression vector pQE60 (Qiagen, Hilden, Germany), which encodes a C-terminal His-tag. Expression was performed at room temperature to reduce the formation of inclusion bodies. The soluble fraction of recombinant TP was purified by affinity chromatography on a Ni-NTA column under native conditions as described recently<sup>[36]</sup>. TP protein inclusion bodies were solved using 6 mol/L guanidine hydrochloride. Ni-NTA affinity purification under denaturing conditions was performed as described<sup>[37]</sup>. For further purification the TP containing fractions were pooled, dialyzed to buffer A<sub>MS</sub> (6 mol/L urea, 20 mmol/L sodium acetate, 2% (v/v) ethanol, pH 5.5) and polished by cationic exchange chromatography using a pre-packed Tricorn MonoS column (GE Healthcare, Freiburg, Germany). The elution was performed by a linear gradient over 20 column volumes (cv) between buffer A<sub>MS</sub> and A<sub>MS</sub> containing 1 mol/L sodium chloride.

### In vitro phosphorylation

experiments were performed using highly purified *E. coli* produced terminal protein domain dialyzed against kinase buffer (25 mmol/L Tris-HCl, 25 mmol/L beta-glycerophosphate, 10 mmol/L MgCl<sub>2</sub>, 1 mmol/L DTT, pH 7.5). Phosphorylation was started by addition of 10 µCi [ $\gamma$ -<sup>32</sup>P] ATP and recombinant human CK II (Merck, Darmstadt, Germany). After 30 min incubation at 30 °C the reaction was stopped by addition of SDS sample buffer and heat treatment (5 min, 95 °C). Proteins were separated by 12% (v/v) SDS-PAGE and detected by autoradiography.

On column phosphorylation of was performed using polished, denatured TP from the cationic exchange chromatography. After addition of 20 mmol/L 2-mercaptoethanol and 100 mmol/L Tris, pH 8 the TP containing fraction was incubated for 1 h at room temperature with 2 cv Ni-NTA agarose, which was pre-washed with buffer A<sub>D</sub> (6 mol/L urea, 100 mmol/L Tris, pH 8.0). The coupling efficiency was 90%, which was determined by optical density at 280 nm. Equal amounts of TP-agarose were loaded on two empty chromatography columns. A controlled refolding of TP was initiated by a 30 cv linear gradient of buffer A<sub>D</sub> to buffer R (20 mmol/L Tris, 134 mmol/L sodium chloride, 10% (v/v) glycerol, 10% (v/v) sucrose, 20 mmol/L 2-mercaptoethanol, 0.1% (v/v) Tween-20, pH 7.5). The buffer was changed by a 10 cv linear gradient to buffer K (20 mmol/L Tris, 50 mmol/L potassium chloride, 10 mmol/L imidazole, 20 mmol/L 2-mercaptoethanol, 20 mmol/L beta-glycerol phosphate, 0.1 mmol/L sodium ortho-vanadate, 0.1% (v/v) Tween-20, pH 7.5). 2500 U recombinant protein kinase CK II (Merck, Darmstadt, Germany) was injected together with 200 µmol/L GTP in buffer K and the

column was incubated for 3 h at 28 °C. The reaction was stopped by washing the column with 5 cv buffer K.

### Binding partner fishing

Six confluent grown 175 cm<sup>2</sup> culture flasks of HuH-7 cells were lysed by sonification in TBS buffer including protease inhibitor cocktail (1 mmol/L PMSF, 5 mg/L aprotinin, 1 mg/L pepstatin, 4 mmol/L leupeptin, 1 mmol/L EDTA). The crude lysate was cleared by centrifugation at 20000 rpm in a TST41 rotor. The lipid content of the supernatant was reduced by precipitation of the proteins at 75% (w/v) ammonium sulfate. The protein pellet was resolved in TBS buffer and desalted by gel filtration using a HiTrap Desalting column (GE Healthcare, Freiburg, Germany). The desalted 75% (w/v) ammonium sulfate fraction of HuH-7 cell lysate was diluted in buffer B (20 mmol/L Tris, 25 mmol/L beta-glycerol phosphate, 1 mmol/L ortho-vanadate, 20 mmol/L 2-mercaptoethanol, 0.1% (v/v) Tween-20, pH 7.5). Equal amounts of this protein solution were injected to the two terminal protein bound columns and to a blank column only loaded with nickel-agarose. After washing the three columns for 5 cv with buffer B the binding partners were eluted by 1 mol/L sodium chloride and analyzed by western blotting using antibody karyopherin- $\alpha$ 2 (C-20) purchased from Santa Cruz, Heidelberg, Germany.

### Kinase inhibitor experiments

HepG2.2.15 cells were seeded in 6-well plates with an initial density of  $5 \times 10^5$  cells/well. Three days after cell seeding CK II inhibitor DMAT (Merck, Darmstadt, Germany) was added to the consumed cell culture medium for 2.5 h. After washing with phosphate buffered saline the cells were incubated for additional 18 h with consumed cell culture medium from the non-HBV producing cell line HuH-7, supplemented with the same concentration of DMAT as already pre-treated. The concentration of the solvent dimethyl sulfoxide (DMSO) was kept at 0.7% (v/v) in all investigated samples.

### HBV quantification

Virus genomes were extracted from cell culture supernatant using High Pure Viral Nucleic Acid Kit and determined by LightCycler PCR (Roche, Mannheim, Germany) using a HBx specific probe<sup>[38]</sup>. cccDNA was extracted from HBV infected *Tupaia* hepatocytes according standard protocols for genomic DNA extraction with phenol/chloroform<sup>[39]</sup>. Southern blotting of HBV DNA using a HBV specific <sup>32</sup>P labeled probe was performed as described<sup>[31]</sup>.

### Endogenous polymerase reaction

HuH-7 cells ( $3 \times 10^5$ ) were seeded in 6-well plates and transfected with 2 µg HBV DNA using Fugene 6 (Roche, Mannheim, Germany). The enveloped viral particles were precipitated 5 d after transfection by sheep anti-HBs polyclonal serum (kindly gift from Klaus-H. Heermann, University Goettingen, Dept. Virology, Germany) and swollen protein-A sepharose beads (Sigma-Aldrich,

Sleeze, Germany) from the cell culture supernatant. The endogenous polymerase reaction (EPR) reaction was performed as described<sup>[40]</sup> using 10  $\mu$ Ci [ $\alpha$ -<sup>32</sup>P] dCTP (GE Healthcare, Freiburg, Germany) for the labeling.

### Confocal laser scanning microscopy

HuH-7 cells ( $5 \times 10^4$ ) were grown on cover slides in 24-well plates and fixed with 4% formaldehyde/PBS for 30 min at 25 °C. For visualization of actin filaments, the cells were stained with FITC-labelled phalloidin (Sigma, Munich, Germany). Staining was performed as described<sup>[41,42]</sup>. Rabbit-derived polyclonal TP-specific or spacer domain-specific sera were used for detection of P. Confocal laser scanning microscopy (CLSM) immunofluorescence was performed using the Zeiss LSM 510 microscope (Zeiss, 20  $\times$  and 63  $\times$  objectives).

## RESULTS

### Identification of conserved motifs on HBV polymerase

Previous data of our lab based on cell permeable HBV capsids<sup>[13]</sup> and studies by M Kann's lab<sup>[21]</sup> argue against the concept that intact viral capsids<sup>[17]</sup> or HBcAg shuttles the genome-polymerase complex into the nucleus<sup>[16,20]</sup>. Based on the data from the TLM-nucleocapsid model system it can be assumed that a partial disassembly of the capsid occurs within the nuclear pore complex or in a perinuclear domain that leads to a release of the genome complex. This raises the question about the final import of the polymerase linked genome into the nucleus.

Sequence analysis of HBV polymerase subtype ayw predicted the existence of a bipartite nuclear localization signal within the terminal domain (TP) (amino acid K90-K91, K104-R106) (Figure 1A). Moreover, a phosphorylation site for CK II (T100) was found within the putative NLS (Figure 1B). The family hepadnaviridae encompasses two genera: orthohepadnavirus and avihepadnavirus. Further analysis revealed that the bipartite NLS and the enclosed CK II phosphorylation site are conserved within the *orthohepadna* viruses but not within the *avihepadna* viruses (Figure 1C). The existence of a functional NLS would enable the transfer of the genome-polymerase complex through the nuclear pore complex into the nucleus.

### TP domain is phosphorylated by CK II *in vitro*

To control experimentally whether the predicted phosphorylation site indeed can be phosphorylated by CK II *in vitro* phosphorylation was performed. Thereto, highly purified recombinant TP domain was incubated with [ $\gamma$ -<sup>32</sup>P] ATP in the presence of CK II. To exclude any phosphorylation by contaminating kinases the purified TP domain was incubated as described above, but CK II was omitted. As an additional control a mutated TP domain was used in which the predicted CK II phosphorylation site was destroyed by a T to A conversion at aa position 100. Figure 1B shows a significant specific phosphorylation of the TP domain only if CK II is present.

In case of the controls no significant phosphorylation was observed. To confirm the identity of the phosphorylated species with the TP domain Western blotting analysis was performed (Figure 1C, right panel). This indicates that the predicted kinase recognition site on the terminal protein is indeed accessible for phosphorylation.

### P protein harbors a functional bipartite NLS, which depends on phosphorylation

To study the functionality of the TP-derived putative bipartite NLS HuH-7 cells were transfected with an expression plasmid encoding for a fusion protein of the putative NLS and GFP (NLS<sub>P</sub>-GFP). As a positive control served a 17 aa long prototype NLS (K142 to K158) derived from human nucleoplasmin (gi114762) fused to the amino terminus of GFP (NLS<sub>NP</sub>-GFP). The intracellular distribution of the GFP fluorescence was quantified by confocal laser scan microscopy in living cells. Compared to wild type GFP expression, which was found evenly distributed within the cell (Figure 2A), the level of NLS<sub>P</sub>-GFP was approximately 30% higher in the nucleus than in the cytosol (Figure 2B). In case of the positive control (NLS<sub>NP</sub>-GFP) an about 75% elevated level of GFP specific fluorescence in the nucleus was observed (Figure 2C). This confirms that the predicted sequence indeed acts as a functional NLS. To analyze a putative relevance of CK II-dependent phosphorylation for the functionality of the TP-derived NLS, NLS<sub>P</sub>-GFP producing cells were incubated for 2 h with CK II inhibitor DMAT prior analysis by confocal microscopy. The quantification of GFP fluorescence revealed that presence of the CK II inhibitor prevented the directed nuclear enrichment of the NLS<sub>P</sub>-GFP (Figure 2D). Comparable results were obtained for cells expression the NLS<sub>P</sub>-GFP(T100A) mutant. An equal distribution comparable to GFP was observed (data not shown).

To study the relevance of the identified bipartite NLS for the subcellular distribution of the HBV polymerase cells were transfected with an expression construct encoding for HBV polymerase and analyzed by confocal immunofluorescence microscopy or subjected to cell fractionation. The immunofluorescence microscopy shows that in HBV P overproducing cells a fraction was found within the nucleus. However, in cells overexpressing the T100A mutant that destroys the CK II phosphorylation site the nuclear-localized fraction disappeared and the P was exclusively found in the cytoplasm (Figure 2E). Western blotting analysis of the cytoplasmic and of the nuclear fraction confirmed that in addition to the cytosolic fraction a significant amount of P was detectable in the nucleus. However in cells treated with DMAT or overexpressing the T100A mutant of the putative CK II phosphorylation site no P-specific signal was detectable in the nuclear fraction (Figure 2F).

Taken together these results indicate that the HBV polymerase harbors a bipartite nuclear localization signal which functionality is dependent on CK II-mediated phosphorylation.

**Figure 2** Hepatitis B virus polymerase harbors a functional nuclear localization signal in the terminal protein domain. A-D: HuH-7 cells were transfected with (A) the negative control wild type green fluorescent protein (GFP) (pEGFP-N1), (B) a positive control: GFP fused to a prototype bipartite nuclear localization signal (NLS) of human nucleoplasmin, (C) GFP fused to the putative bipartite NLS of hepatitis B virus (HBV) P protein, (D) the same as (C) but cells were treated with  $10 \times \text{IC}_{50}$  of casein kinase II (CK II) inhibitor 2-Dimethylamino-4,5,6,7-tetrabromo-1H-benzimidazole (DMAT) 2 h prior analysis. The fluorescence was measured in living cells by confocal laser scan analysis. The central layer (out of 6) was quantitated along the red indicated line and displayed in the corresponding graph of the lower panel as relative fluorescence intensity [I]. Differences of mean fluorescence intensities in the cytoplasm and within the nucleus (indicated as black line in the graph) were calculated and are indicated in percent. One representative cell for each fusion protein is shown; E: Confocal immunofluorescence microscopy of HuH-7 cells transfected with an expression vector encoding wt P or the mutant  $\Delta\text{CK II}$  (= T100I) that is not phosphorylated by CK II. For detection of P (red) a rabbit-derived spacer domain-specific serum was used. Nuclei were stained with DAPI (blue); F: HuH-7 cells were transfected with the indicated expression vectors and left untreated or treated with  $10 \times \text{IC}_{50}$  of CK II inhibitor DMAT 5 h prior analysis. Transfection with pCDNA.3 served as control. Cells were lysed, the cytosolic and nuclear fraction were isolated by differential centrifugation and analyzed by western blotting. For detection of P a TP-domain specific serum was used. Detection of hexokinase and of lamin served as loading control and as control for the purity of the subcellular fractions. All experiments were performed in triplicate. One representative is shown.

### Binding of karyopherin- $\alpha 2$ to TP depends on CK II mediated phosphorylation

Karyopherin- $\alpha 2$  is an essential factor for NLS-mediated nuclear import. Therefore, it was investigated whether the

data described above are reflected by an increased binding of karyopherin- $\alpha 2$  to *in vitro* phosphorylated TP as compared to unphosphorylated TP. Equal amounts of terminal protein domain were immobilized on two columns.

**Figure 3 Binding of karyopherin-α2 to terminal protein depends on casein kinase II mediated phosphorylation.** The interaction of soluble protein fraction of HuH-7 cells to immobilized terminal protein (TP) domain was investigated by western blotting of the sodium chloride eluted fractions 2-4. Karyopherin-α2 bound only to the casein kinase II (CK II) pre-treated TP column (upper panel). FP: Flow through of the CK II treated TP column; F: Flow trough of the untreated TP column.

One column was *in vitro* phosphorylated by CK II and its substrate GTP the other and a blank control column were treated equally without the addition of the kinase. The pretreated columns were equilibrated and loaded with the desalted 75% (w/v) ammonium sulfate fraction of HuH-7 cell lysate. Finally, binding partners were eluted by sodium chloride and the eluted fractions were analyzed by Western blotting using a karyopherin-α2 specific antibody. Interestingly, karyopherin-α2 was only found in the eluate of the column with CK II pre-treated TP (Figure 3). This indicates clearly that *in vitro* binding of karyopherin-α2, the key enzyme for nuclear import, is dependent on CK II phosphorylation of the terminal protein.

#### **Inhibition of CK II impairs HBV replication in primary Tupaia hepatocytes**

To study the relevance of the NLS and of the CK II phosphorylation site for the HBV life cycle the HBV P protein was mutated based on a recombinant 1.2 fold HBV genome (subtype ayw) by site directed mutagenesis. The changes in the DNA sequence did not affect other reading frames or regulatory elements.

In the NLS-deficient mutant (ΔNLS) the NLS is inactivated by manipulating the basicity of the downstream cluster to K105D and K106S. The putative CK II recognition site on the P protein is destroyed by a T100I substitution (ΔCK II), whereas a pseudo-phosphorylated mutant was generated by a T100D conversion (CK II\*). However, the attempt to produce mutant virus by transfection of HepG2 or HuH-7 cells with the respective 1.2 fold genomes failed in case of ΔNLS and of the ΔCK II mutant (Figure 4A). In both cases significant less virus was produced (about hundredfold) as compared to the wt genome or the mutant encoding the CK II\* mutant. In a transfection experiment the nuclear import is not the limiting step. It can be concluded that mutations affecting the integrity of the NLS motive or of the CK II phosphorylation site cause secondary effects affecting the functionality of the polymerase. Therefore a direct analysis of the relevance of the NLS and of the CK II substrate domain based on mutated virus was not possible.

The *in vitro* data described above had shown that the functionality of the NLS identified in the TP-domain depends on the CK II-dependent phosphorylation (Figure 2). To study the relevance of CK II-dependent phosphorylation of the TP domain for HBV life cycle primary Tupaia hepatocytes were infected with wtHBV particles for 8 h. Adherent HBV particles were removed

by trypsin treatment as described above. After infection the cells were grown for 36 h in the presence of the cell permeable small molecular CK II inhibitor DMAT and the virus replication was analyzed by quantification of HBsAg and HBeAg secretion (Figure 4B). Moreover secreted viral particles were quantified by real time PCR. Both approaches revealed that inhibition of CK II by DMAT caused a strong and significant reduction of virus replication. This was further confirmed by analysis of cccDNA formation in infected PTHs. Inhibition of CK II by increasing concentrations of DMAT abolishes cccDNA formation (Figure 4B).

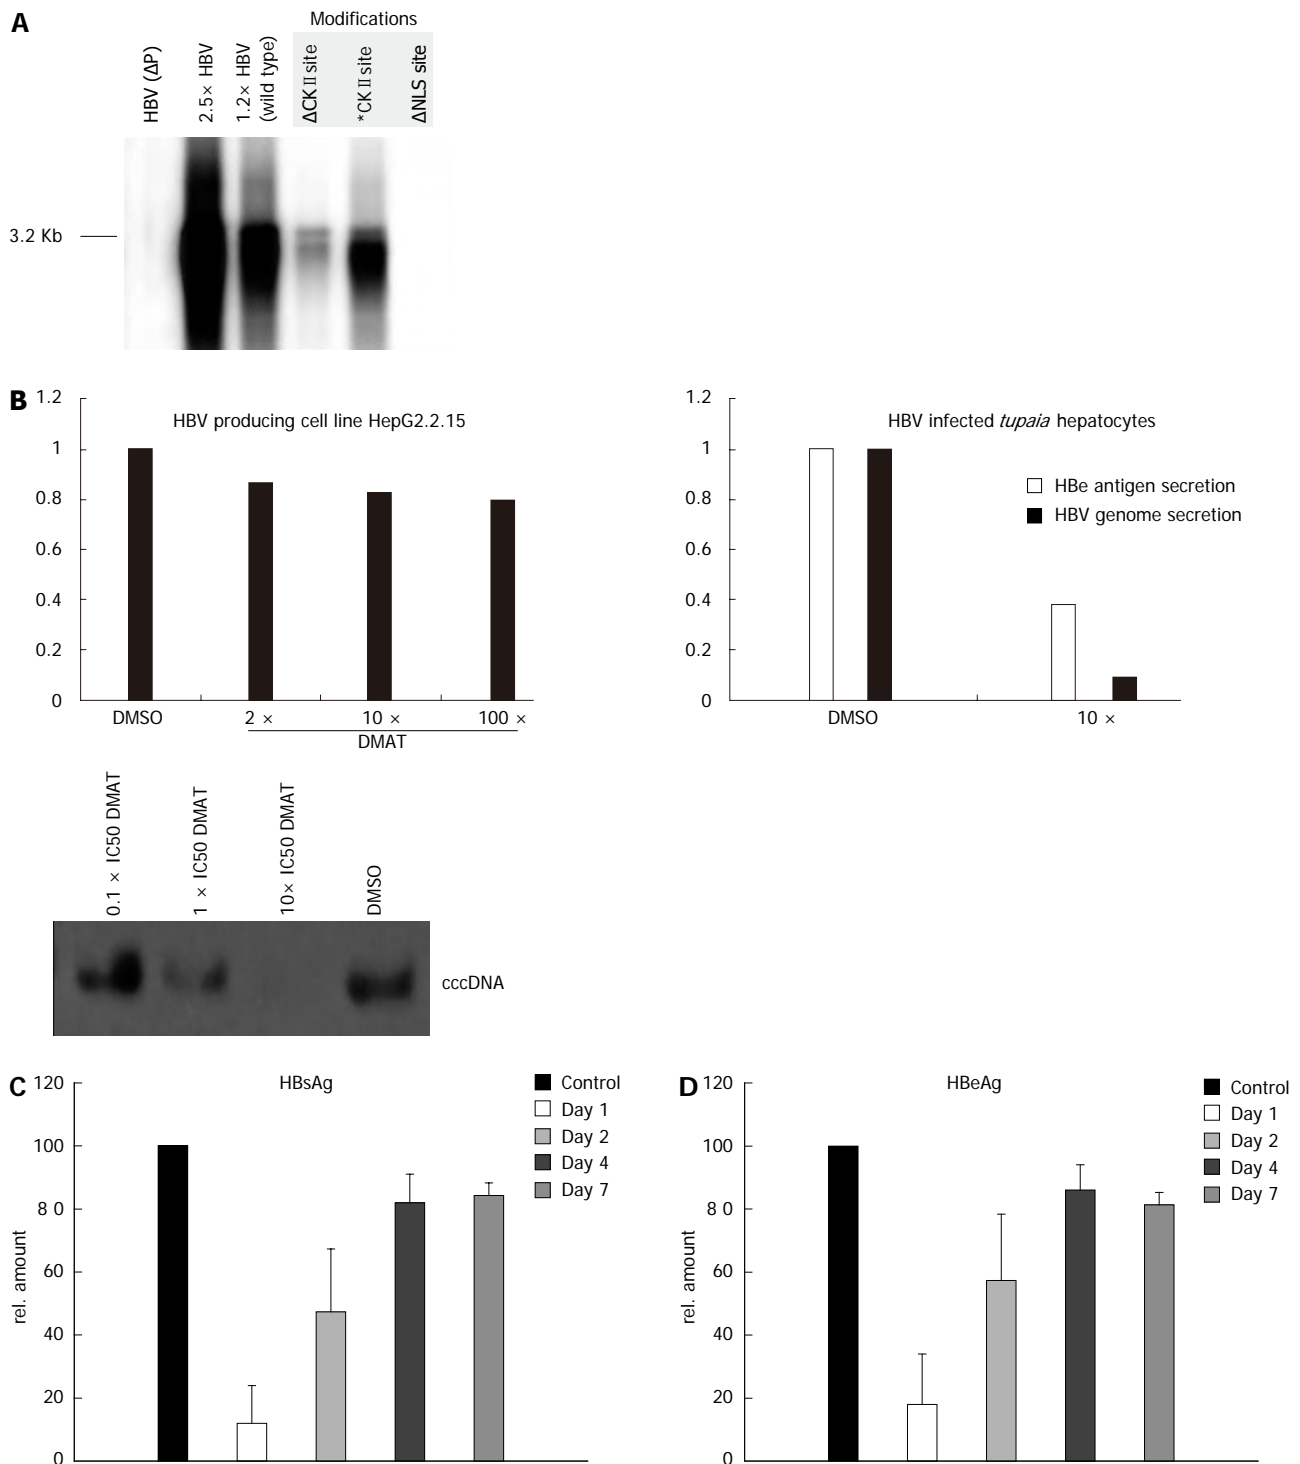

For a more detailed analysis primary Tupaia hepatocytes were infected as described above. One, two, four and seven days after infection the hepatocytes were grown for 36 h in the presence of the cell permeable small molecular CK II inhibitor DMAT and the virus replication was analyzed by quantification of HBsAg and HBeAg secretion (Figure 4C and D). Both approaches revealed that inhibition of CK II by DMAT at 1 and 2 d after infection caused a strong and significant reduction of virus replication, while inhibition after 4 and 7 d *pi* resulted only in a small reduction of virus replication.

To control the specificity of the observed effect the constitutively HBV expressing cell line HepG2.2.15 were instrumental. This cell line harbors a stably integrated HBV genome. Due to the stable integration of the genome the re-import of *de novo* synthesized genomes plays a minor role for maintaining the pool of transcriptional templates. Therefore, inhibition of polymerase import should exert a small effect. HepG2.2.15 cells were treated with DMAT, HBeAg and HBsAg secretion were analyzed by ELISA and virus secretion was quantified by LightCycler PCR (Figure 4B). Under these conditions inhibition of CK II with DMAT did slightly but not significantly reduce virus secretion as compared to the solvent control (Figure 4B). Comparable results were obtained for the cell line HepAD38 (data not shown).

Taken together these data provide indirect evidence that the functionality of the NLS in the TP domain of P is required for the import of the viral genome into the nucleus.

## **DISCUSSION**

It is well as established that HBV replicates its genome inside the nucleus (recent reviews<sup>[18,43,44]</sup>). This raises the question about the post entry transport of the genome complex to and about its final import into the nucleus.

**Figure 4** Casein kinase II inhibition impairs hepatitis B virus replication in infected primary *Tupaia* hepatocytes. **A:** HuH-7 cells were transfected with mutant versions of a 1.2 fold hepatitis B virus (HBV) genome. After 5 d the secreted viral particles were precipitated with a HBs specific antibody and the containing 3.2 kb HBV genomes were visualized by the radioactive tracer [ $\alpha$ - $^{32}$ P] dCTP incorporated using the endogenous polymerase activity. The unphosphorylated form of the casein kinase II (CK II) recognition site in the P protein was simulated by a T100I substitution ( $\Delta$ ) and the pseudo-phosphorylation was simulated by a T100D substitution (\*) in the 1.2 fold HBV wild type genome. The nuclear localization signal (NLS) was inactivated by mutating the downstream basic cluster (K105D and K106S) on the P protein. A 2.5  $\times$  HBV genome and a P deficient genome [HBV (P-)] served as controls; **B:** Primary *Tupaia* hepatocytes were infected with HepAD38 derived HBV and post infection treated for 36 h with solvent DMSO or 2-Dimethylamino-4,5,6,7-tetrabromo-1H-benzimidazole (DMAT) ( $10 \times \text{IC}_{50}$ ). Twelve days after infection the HBV genome secretion was measured by Lightcycler polymerase chain reaction. The cccDNA content of infected *Tupaia* hepatocytes that were incubated for 36 h with the indicated amounts of DMAT was visualized by Southern blot using a HBV specific probe. The specificity of DMAT incubation was analyzed by 2 h inhibitor pre-treatment of the stably HBV transfected cell line HepG2.2.15 followed by treatment of 36 h with  $10 \times \text{IC}_{50}$  CK II inhibitor DMAT ( $\text{IC}_{50}$  in rat liver = 150 nmol/L) and genome secretion was compared to the solvent control DMSO measured by Lightcycler PCR. All experiments were performed in triplicate. The figure shows one representative experiment; **C, D:** Primary *Tupaia* hepatocytes were infected with HepAD38-derived HBV and at day 1, day 2, day 4 and day 7 treated for 36 h DMAT ( $10 \times \text{IC}_{50}$ ). Twelve days after infection the HBV replication was measured by HBeAg or HBsAg-specific enzyme linked immunosorbent assay. The bars represent the standard deviation.

Previous reports discussed whether the final import of the assembled nucleocapsid in the nucleus harboring the genome complex can occur<sup>[17]</sup>. More recent reports provide evidence that the mature nucleocapsid disassembles in the nuclear pore complex and the final import of the genome complex could be mediated by an association with HBcAg oligomers that harbor in their C-terminal domain a NLS<sup>[20,21,44-47]</sup>. For DHBV it was described that completion of plus-strand DNA synthesis triggers genomic DNA deproteinization and conformational changes of the nucleocapsid. This could lead to the exposure of a NLS within the core and thereby could enable the import of the rcDNA<sup>[48]</sup>. In this context it is interesting to mention that the presence of the identified NLS is not conserved for the genus avihepadnavirus.

Recently we developed cell permeable HBV nucleocapsids as a vehicle for gene transfer (Brandenburg *et al.*<sup>[13]</sup>). Based on this system it was observed that neither HBcAg dimers nor nucleocapsids were visible in the nucleus of TLM-nucleocapsid treated cells although an efficient expression of the packaged, P-linked genome occurred suggesting that neither the nucleocapsid nor HBcAg dimers mediate the final import of the genome complex. Therefore the question arose about an alternative import mechanism: with about 90 kDa the covalent complex of HBV polymerase and genome clearly exceeds the size that freely can pass the nuclear pore complex.

In this context it is interesting that previous *in vitro* experiments have shown that the HBV genome complex can be efficiently imported into the nucleus. However if the complex is deproteinized, the naked genome fails to enter efficiently the nucleus<sup>[23]</sup>. These data suggest that the genome-linked polymerase could be relevant for the nuclear entry process.

The bipartite NLS identified in the TP domain of P could mediate the entry of the genome complex into the nucleus. The functional analysis of the genome complex revealed that the predicted NLS indeed has the potential to act as a nuclear localization signal. However, compared to other nuclear localization signals the TP-derived NLS is not a strong signal. This might reflect the different functions of P<sup>[18]</sup>. On the one hand P recognizes in the cytoplasm the *de novo*-synthesized 3.5 kb mRNA<sup>[43,49]</sup> and on the other hand the genome associated Pol is assumed to mediate by its NLS the entry of the genome complex into the nucleus. It is obvious that a too strong NLS signal might counteract the RNA-recognizing function in the cytoplasm. Yet, it was described that in duck HBV replicating cells in addition to the encapsidated polymerase non-encapsidated polymerase exists<sup>[24]</sup>. The major fraction of the non-encapsidated duck HBV polymerase is found in the cytoplasm a smaller fraction however can be detected within the nucleus<sup>[24]</sup>. Interestingly, in cells overexpressing HBV polymerase in the absence of other viral proteins a fraction of HBV polymerase is found within the nucleus, co-localized with the p11 protein of PML bodies<sup>[22]</sup>.

A further interesting feature is the CK II phosphorylation site localized in the center of the bipartite NLS.

The functionality of the HBV polymerase-derived NLS depends on the CK II-mediated phosphorylation. CK II is not a very tightly regulated kinase<sup>[50]</sup>. It can be assumed that CK II exerts a housekeeping phosphorylation function<sup>[51]</sup>. If subcellular localization and function of HBV polymerase is subjected to a tight control, it is not likely that CK II exerts this function. It is tempting to speculate that phosphatases could play an important role to regulate the subcellular localization and thereby function of HBV polymerase. CK II phosphorylation is reported to influence subcellular localization of various nuclear proteins<sup>[52]</sup>. For example CK II phosphorylation upstream of the NLS of simian virus 40 T-antigen enhances its nuclear import up to 40 fold<sup>[53]</sup>. But immediate phosphorylation one or two amino acid upstream of the crucial amino acid of classical monopartite NLS seems to have inhibitory effects on karyopherin binding due to a disturbance of the NLS basicity<sup>[54]</sup>. In case of bipartite nuclear localization signals this correlation is not evident. For example the spacer of the functional bipartite NLS of the *Agrobacterium tumefaciens* protein nopaline contains four negative charged aspartates, one even immediate located at the downstream basic cluster<sup>[55]</sup>. On the other hand an increase of the hydrophobicity of the 10-12 amino acid spacer seems to decrease its functionality<sup>[56]</sup>.

In transfection experiments it was found that destruction of the NLS or of the CK II-site almost completely abolishes HBV replication. Under these experimental conditions the import of the viral genome into the nucleus does not represent the limiting step. The plasmid DNA freely moves into the nucleus. However this observation suggests that perturbation of this domain has further effects on the polymerase function. Since the  $\Delta$ NLS and  $\Delta$ CK II-mutants were replication deficient it was not possible to study the replication of the respective mutant viruses. The *in vitro* data however have shown that the functionality of the TP-derived NLS requires the functionality of CK II. Based on this it could be shown that inhibition of CK II in the early phase of the infection abolished the establishment of HBV infection while inhibition of CK II in a later phase of the infection or in a stable system had no effect on HBV replication.

In conclusion we demonstrate the presence of a bipartite NLS within the TP domain of P and provide evidence for a novel model describing the import of the HBV genome into the nucleus.

## ACKNOWLEDGMENTS

We thank Sabine Mac Nelly for excellent preparation of the *Tupaia* primary hepatocytes.

## COMMENTS

### Background

Human hepatitis B virus (HBV) enters the cell by receptor mediated endocytosis and at the end of this process the nucleocapsid that harbours the viral genome is released into the cytoplasm and transported towards the nuclear pore complex. Establishment of a productive viral infection requires the transport of the HBV genome that is covalently linked to the polymerase into the nucleus. In the

nucleus the partial- double stranded DNA genome is converted to covalently closed circular (ccc) double stranded DNA.

### Research frontiers

The phase of nuclear entry is not fully understood. It is discussed that the intact viral capsid shuttles the genome-polymerase complex into the nuclear basket of the nuclear pore complex. Here, after a partial disassembly of the nucleocapsid the polymerase-linked genome is released. The polymerase-genome complex however is too big to pass freely through the nuclear pore complex. This raises the question about the import mechanism.

### Innovations and breakthroughs

The identification and characterization of a bipartite NLS in the HBV polymerase that harbours a phosphorylation site for casein kinase II (CK II) is described in this manuscript. The integrity of the phosphorylation site is crucial for the functionality of the NLS. Moreover, inhibition of CK II prevents karyopherin  $\alpha 2$  from binding to the polymerase. Thereby the import of the polymerase is impaired resulting in inhibited cccDNA formation that prevents the establishment of the viral infection. The data identify novel structural and functional prerequisites for the establishment of HBV infection.

### Applications

The data describe a potential novel target for antiviral that could block the establishment of a HBV-infection.

### Peer review

In this work, they identified a novel NLS located in the terminal protein domain of HBV polymerase and defined a CK II phosphorylation site (threonine) which is adjacent to the NLS. This paper is well written.

### Abstract

**AIM:** To assess the acceptance, safety and efficacy of care and treatment for chronic hepatitis C (CHC) in drug addicts.

**METHODS:** We designed a multidisciplinary, phase IV prospective cohort study. All illicit drug users (IDUs) visited a Territorial Addiction Service (SerT) in the District of Brescia, and hepatitis C antibody (HCVAb) testing positive were offered as part of a standardised hepatologic visit in our Gastroenterology Unit. Patients with confirmed CHC and without medical contraindications were administered peginterferon alfa-2b 1.5 µg/kg per week plus ribavirin (800-1400 mg/d) for 16-48 wk. All IDUs were unselected because of ongoing addiction and read and signed an informed consent form.

Virologic responses at weeks 4 and 12 of therapy, at the end of treatment and 24 wk after the end of treatment were the main measures of efficacy. Adherence was estimated according to the 80/80/80 criteria.

**RESULTS:** From November 2007 to December 2009, 162 HCVAb+ IDUs were identified. Sixty-seven patients (41% of the initial cohort) completed the diagnostic procedure, and CHC was diagnosed in 54 (33% of the total). Forty-nine patients were offered therapy, and 39 agreed (80% of acceptance rate). The prevalent HCV genotype was type 1, and the HCV RNA baseline level was over 5.6 log/mL in 61% of cases. Five patients dropped out, two because of severe adverse events (SAEs) and three without medical need. Twenty-three and 14 patients achieved end of treatment responses (ETRs; 59%) and sustained virologic responses (SVRs; 36%), respectively. Thirty-one patients were fully compliant with the study protocol (80% adherence). The prevalence of host and viral characteristics negatively affecting the treatment response was high: age over 40 years (54%), male gender (85%), overweight body type (36%), previous unsuccessful antiviral therapy (21%), HCV genotype and viral load (60% and 62%, respectively), earlier contact with HBV (40%) and steatosis and fibrosis (44% and 17%, respectively). In a univariate analysis, alcohol intake was associated with a non-response ( $P = 0.0018$ , 95%CI: 0.0058-0.4565).

**CONCLUSION:** Drug addicts with CHC can be successfully treated in a multidisciplinary setting using standard antiviral combination therapy, despite several "difficult to reach, manage and treat" characteristics.

© 2013 Baishideng Publishing Group Co., Limited. All rights reserved.

**Key words:** Chronic hepatitis C; Addiction; Antiviral therapy; Interferon; Multidisciplinary

**Core tip:** The paper reports results from a clinical trial on the management of chronic hepatitis C (CHC) in illicit drug users (IDUs). Two key elements characterise the trial: (1) the study was performed by a multidisciplinary team; and (2) the patients were unselected because of ongoing addiction. We assessed the acceptance of care and treatment for CHC among IDUs, who are classically considered to be a “difficult to reach and manage” group. For the IDUs accepting antiviral treatment, we analysed results on safety, efficacy and adherence and on the prevalence of negative prognostic factors affecting the virologic response to address whether IDUs are also “difficult to treat” patients.

## INTRODUCTION

Hepatitis C virus (HCV) is estimated to chronically infect more than 180 million people worldwide, with approximately 4 million carriers in Europe alone<sup>[1]</sup>. The prognosis of chronic hepatitis C (CHC) is related to fibrosis progression, and the development of cirrhosis varies from 5%-25% over an average period of 30 years<sup>[2]</sup>. According to a recently validated mathematical model, morbidity and mortality from HCV are expected to rise in 2010 and to peak between 2030 and 2035<sup>[3]</sup>. The main reasons for this negative forecast are the low rates of screening for HCV and of treatment for CHC. The World Health Organization has defined chronic infection with HCV as a public health problem of primary importance, and during a consensus meeting in May 2010, all health authorities were invited to strive to prevent, identify and rapidly treat the infection<sup>[1]</sup>.

In developed countries, HCV is mainly transmitted by needles during drug injections, and illicit drug users (IDUs) are considered to be the largest group affected by HCV, accounting for 20%-50% of cases of chronic infection<sup>[4]</sup>. A recent paper estimating viral transmission showed, for the first time, that HCV “super-spreading” is led by IDUs. According to this estimation model, each infected IDU is likely to infect approximately 20 other people, half of whom will be infected within 2 years of the initial infection<sup>[5]</sup>.

International authorities on liver diseases (*i.e.*, the National Institutes of Health since 2002, the American Gastroenterological Association since 2006 and the American Association for the Study of the Liver since 2009) recommend the treatment of CHC in IDUs and encourage clinical studies in chronically infected IDUs “to evaluate the safest and most effective treatment, factors favouring compliance, risk of relapse, side-effect profile and the

impact of methadone maintenance treatment”<sup>[6-8]</sup>.

Despite international recommendations, several barriers to treating IDUs persist not only among physicians but also among IDUs<sup>[9,10]</sup>. Physicians’ concerns mainly include IDUs’ chaotic lifestyle; IDUs’ possibly poor adherence to treatment; difficulties in the management of the psychiatric side effects of treatment, which are believed to be more frequent among IDUs; and the risk of re-infection after HCV eradication<sup>[10]</sup>. The risk of relapse into addiction due to interferon (IFN)-driven mood changes and the use of needles in CHC therapy, is also described as a relative contraindication to IFN treatment in IDUs, although the data from prospective trials on this risk are scarce<sup>[11,12]</sup>. Concerns about antiviral therapy for CHC are also present among IDUs: their conception of illness and death is often different, for cultural reasons, from the beliefs of the general population, and information on the natural history and treatment challenges of HCV is inexact or incomplete<sup>[10]</sup>. Moreover, factors including precarious working conditions, a lack of fixed abode, undocumented migrant status and social isolation can affect access to care and treatment for liver diseases, and special efforts may be necessary to reach IDUs in their social environment<sup>[13]</sup>. In our recent review on the subject<sup>[14]</sup>, we report that due to the barriers to treatment, most published prospective trials on the treatment of CHC in IDUs involve limited numbers of patients, ranging from 11-71, have no standardised intervention protocol and are mainly restricted to abstinent patients.

As an overview, IDUs are perceived as patients who are difficult to reach for social reasons and difficult to manage because of lifestyle. Moreover, no previous study has assessed whether IDUs are also difficult to treat because of the presence of negative prognostic factors, either viral or host-related, affecting the rate of success of antiviral therapy. For these difficulties to be addressed, and to successfully be able to contact, manage and treat these patients, a multidisciplinary approach is mandatory. This approach should involve health professionals engaged in the management of addiction and dedicated hepatologists with a highly personalised approach to patient care.

We performed a prospective clinical study designed to maximise IDUs’ access to treatment for HCV infection by involving both the physicians directly engaged in the management of addiction and the specialised hepatologist in our unit and by avoiding “a priori” exclusion criteria for antiviral therapy of active IDUs. The main objectives of the study were to specifically evaluate the rate of access to clinical care; the acceptance, safety and efficacy of antiviral treatment for CHC; and the prognostic factors for responses to standard antiviral therapy in a large cohort of IDUs, who were unselected because of ongoing addiction.

## MATERIALS AND METHODS

### Study design

We designed a multidisciplinary, phase IV prospective

cohort study. The multidisciplinary approach was ensured by close collaboration between six Territorial Addiction Services (SerT) of the Local Health Authority of the District of Brescia (ASL) and our Gastroenterology Unit (GU, Spedali Civili and University of Brescia). The physicians of the SerT were responsible for the identification of patients with hepatitis C antibody (HCVAb) positivity among those individuals visiting the SerT clinic. Based on the protocol definition, patients with “ongoing addiction problems”, actively using illicit drugs and/or alcohol or in a supportive/substitution treatment program, were all considered to be subjects. The SerT physicians were also responsible for collecting all demographic, social, psychological and addiction data in a standardised case report form. The patients selected by the SerT physicians were instructed to call a dedicated telephone number to make an appointment for an initial standard hepatologic evaluation in the GU, including a medical visit, laboratory tests and ultrasound evaluation. The aims of the hepatologic evaluation were to confirm HCV-related chronic hepatitis, to assess the severity of liver disease and to evaluate eligibility for antiviral treatment. A liver biopsy was not routinely performed. The patients with confirmed CHC and meeting standard criteria for HCV therapy<sup>[8]</sup> were offered antiviral treatment with pegylated interferon and ribavirin, according to the study protocol for treatment, and were asked to sign an informed consent form. To improve adherence, a mobile telephone number was activated for all patients on antiviral treatment, with a physician on call every day from 8 a.m. to 1 p.m.

### Selection criteria

The inclusion criteria were as follows: over 18 years of age, HCV RNA detected with a sensitive polymerase chain reaction (PCR) (cut-off of determination 50 IU/mL; COBAS Amplicor HCV test, Roche Diagnostics, Branchburg, NJ, United States) and confirmed on at least two occasions over a period of 6 mo, compensated liver disease (Child-Pugh score  $\leq 5$ ), absence of major medical contraindications to antiviral therapy (including malignancies, severe cardiac illness and uncontrolled psychiatric condition), willingness to avoid pregnancy during the entire treatment period and during the 6 mo after the last ribavirin dose intake, ability to read and sign a written informed consent form and willingness to adhere to the study protocol for treatment. Patients with suspected or confirmed idiosyncratic reactions to interferon or ribavirin were excluded.

### Treatment protocol

The study protocol for treatment consisted of peginterferon alfa-2b (12 kDa) 1.5  $\mu\text{g/kg}$  per week plus ribavirin 800-1400 mg according to body weight (800 mg for  $< 65$  kg, 1000 mg for 65-80 kg, 1200 mg for 81-105 and 1400 mg for  $> 105$  kg) divided into two daily administrations.

The duration of the treatment was 24 wk for HCV genotypes 2/3 and 48 wk for HCV genotypes 1/4. The achievement of a rapid virologic response (RVR; HCV

RNA  $< 50$  IU/mL at week 4 of therapy) was regarded as an indication for short-term therapy in all naïve patients fulfilling the criteria of no dose reduction during the first 4 wk of therapy, low baseline viral load (HCV RNA  $< 600000$  IU/mL) and the absence of cirrhosis. The short-term scheme consisted of 16 wk for HCV genotypes 2/3 and 24 wk for HCV genotypes 1/4. Treatment was discontinued prematurely, according to international rules<sup>[8]</sup> (at week 12 if the HCV RNA level drops by  $< 2$  Log and at week 24 if the HCV RNA level is  $> 50$  IU/mL); in the case of virologic breakthrough; in the presence of severe adverse events (SAEs); or upon patients' request, with no need for explanation. In the case of a virologic breakthrough, HCV genotyping [line probe assay (LIPA), Bayer HealthCare, Tarrytown, NY, United States] was performed to exclude mixed/new HCV infections.

Adverse reactions to interferon and/or ribavirin were managed according to international guidelines<sup>[8]</sup>, and the use of erythropoietin and leucocyte growth factors was allowed, according to the current Italian Drug Agency (AIFA) recommendations.

The timetable of the study was as follows: a medical visit including a general physical examination, an assessment of body mass index, the administration of AUDIT-C for screening for at-risk alcohol-related behaviour and a Hamilton Test for scoring anxiety and depression. The measurement of the complete blood count and the alanine aminotransferase (ALT), aspartate aminotransferase (AST) and  $\gamma$ -glutamyl transferase (GGT) levels was requested every 4 wk during treatment and 24 wk after the end of therapy. Blood tests, including for thyroid function (FT4 and TSH), autoimmunity (ANA, AMA, LKM and ASMA) and liver function (albumin, PT and bilirubin), were mandatory at the beginning and every 12 wk of treatment. Quantitative and qualitative assays for HCV RNA were requested at week 0-4-12 and at week 4-12-24 of treatment, at the end of therapy and 24 wk after the end of therapy, respectively.

### Outcome measures

Access to liver care was calculated as the proportion of IDUs attending the first hepatologic visit and completing the diagnostic procedure among all HCVAb+ IDUs screened by the SerT and showing interest in this opportunity. Access to therapy was evaluated as the proportion of patients starting antiviral therapy among the eligible patients. The main measure of safety was the rate of withdrawal for SAEs, according to the Common Terminology Criteria for Adverse Events v3.0<sup>[15]</sup>. The main outcome measure of efficacy was the sustained virologic response (SVR; HCV RNA persistently  $< 50$  IU/mL 24 wk after treatment discontinuation) among the treated patients. Secondary efficacy measures were the achievement of an RVR, an early virologic response (EVR; HCV RNA  $< 50$  IU/mL at week 12 of therapy) and an end of treatment response (ETR; HCV RNA  $< 50$  IU/mL at the end of therapy). Adherence was estimated according to the 80/80/80 criteria (80% of pegylated interferon,

80% ribavirin cumulative dosage and 80% of the duration of therapy<sup>[16]</sup>).

### Ethics

The entire study design was evaluated by the Ethics Committee of Spedali Civili of Brescia and fully approved on July 31<sup>st</sup>, 2007. The study was registered with EudraCT, number 2008-001283-37.

### Statistical analysis

Treatment efficacy was measured according to the intention to treat (ITT) criteria, including all patients who had received at least one dose of interferon and one dose of ribavirin after signing the informed consent form. For statistical analyses, an unpaired t-test and Fisher's exact test were used when appropriate using GraphPad Prism, version 5.0 (Graph Pad Software, Inc., San Diego, CA, United States). Logistic regression analysis was performed to assess the effect of baseline features on efficacy and was completed using Stata software (version 7, StataCorp LP, College Station, TX, United States). A *P* value < 0.05 was accepted to reject the null hypothesis.

## RESULTS

### Identification of the cohort

From November 2007 to December 2009, a cohort of 162 HCVAb+ IDUs was identified by six SerT in the District of Brescia. Most patients were Italian males with a low level of education. At the time of recruitment, one third of the patients were unemployed, and one quarter

A smoking habit was concomitant in 100% of patients: < 5 cigarettes/d in 4%, 5-10 cigarettes/d in 12%, 11-20 cigarettes/d in 54% and > 20 cigarettes/d in 30%. SerT: Territorial Addiction Service.

had comorbidities (Table 1). The prevalent type of addiction was intravenous injection of heroin, with a mean duration of 13 years. Most patients were on opiate substitution treatment, with 66% on methadone and 12% on buprenorphine. All patients in methadone maintenance therapy received a dose lower than 100 mg/d (Table 2). Most IDUs who received information about HCV infection from health operators, the press or television were not confident about their knowledge and had moderate worries about the side effects of HCV therapy (Table 3).

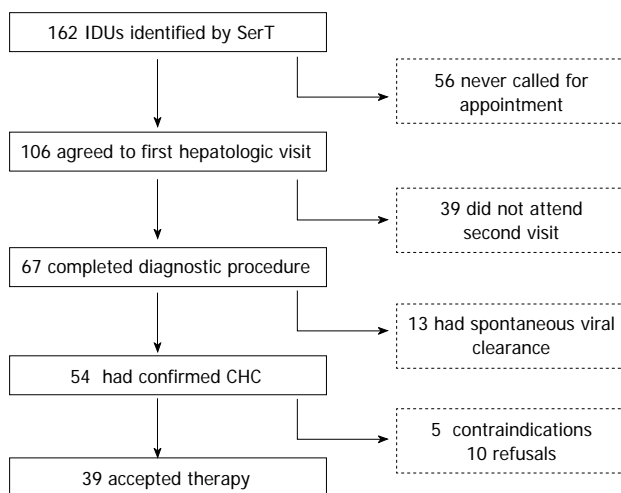

### Access to care and treatment

Patient disposition, according to the study protocol, is reported in Figure 1. Access to the first hepatologic work-up was observed in 106 patients, which was 65% of the initial cohort. Although 56 IDUs expressed interest in the opportunity for a dedicated medical examination to a SerT doctor, these individuals never called our clinic for an appointment. Sixty-seven patients completed the diagnostic procedure, or 41% of the initial cohort, corresponding to 63% of patients visiting our clinic for an initial evaluation. Patients who did not adhere to the diagnostic protocol (39 IDUs) were all contacted by telephone by a physician (BZ), and these patients all preferred to postpone the medical procedures because of

HCV: Hepatitis C virus; SerT: Territorial Addiction Service.

**Figure 1** Patient disposition according to the study protocol. CHC: Chronic hepatitis C; IDU: Illicit drug user; SerT: Territorial Addiction Service.

other priorities.

CHC was confirmed in 54 IDUs (33% of the total), of which 13 patients had a confirmed HCV RNA-negative test, with an estimated rate of spontaneous clearance of 19%. Five patients had medical contraindications to specific antiviral therapy (two cases of decompensated cirrhosis, one case of hepatocellular carcinoma, one case of pregnancy and one case of uncontrolled severe psychiatric illness). The remaining 49 patients were offered specific treatment for CHC, and 39 accepted and signed the informed consent form (80% acceptance rate). Two patients never started treatment after signing the informed consent form and were thus excluded from the ITT analysis, and two patients, one with HCV genotype 1a and the other with HCV genotype 3a, relapsed after the end of therapy and asked for a second cycle of anti-

**Figure 2** Hepatitis C virus genotypes (A) and baseline hepatitis C virus RNA levels (B) in 36 patients (the dotted line indicates the 5.6 Log/mL cut-off value for high viral load).

ral therapy (after a 6-mo wash-out period). We therefore report results for 39 treatments in 37 patients.

### Baseline characteristics of treated patients

The virologic features of the treated patients are reported in Figure 2. The most represented HCV genotype was type 1 (13 patients with 1a and seven with 1b). The HCV RNA baseline level, available in 36 of 39 patients, was over 5.6 Log/mL in 22 cases (61%). In total, 36% of our patients were active illicit drug users, mainly using heroin; approximately one third had a history of depression; one quarter had a pathologic Hamilton score for anxiety or depression; four patients were addicted to alcohol; and seven patients had an AUDIT-C at-risk score (Table 4). As reported in Table 5, several prognostic factors negatively affecting the outcome of antiviral therapy for CHC were well represented among our treated IDUs. These factors included age over 40 years, male gender, overweight body type, previous unsuccessful HCV antiviral treatment, unfavourable HCV virologic genotype or viral load, earlier contact with HBV, steatosis and progression to cirrhosis.

### Safety

Two SAEs occurred during the study period, leading to therapy discontinuation: a case of psychosis and a case of pneumonia with suspected tuberculosis at weeks 4 and 10, respectively. Three patients dropped out without

Ultrasonography suggestive of steatosis	44%
Ultrasonography suggestive of cirrhosis	17%

HBcAb: Hepatitis B core antibody; HCV: Hepatitis C virus; BMI: Body mass index.

medical need and were lost to follow-up; all dropouts occurred within the first 8 wk of antiviral treatment. Sixteen (41%) and 17 (44%) patients needed a dose adjustment of pegylated interferon and ribavirin, respectively. In six patients (15%), the use of erythropoietin was offered. The use of leucocyte grown factors was not necessary for any patient. One patient became pregnant during the 6 mo after the end of therapy and decided on an abortion for personal reasons.

### Efficacy

In the ITT analysis, 23 patients achieved an ETR (59%), and nine (23%) relapsed during the 6 mo after the end of therapy. Fourteen patients achieved an SVR (36%), seven of whom were infected with an unfavourable HCV genotype (Figure 3). The HCV RNA serologic clearance rates at weeks 4 and 12 are reported in Figure 4. Short-term therapy was offered to nine patients, according to the study protocol, and did not negatively affect the SVR rate based on univariate analysis.

Figure 3 Percentage of end of treatment responses and sustained virologic responses in the entire cohort and according to Hepatitis C virus genotype (G). ETR: End of treatment response; SVR: Sustained virologic response.

Figure 4 Percentage of rapid virologic responses and early virologic responses in the entire cohort and according to Hepatitis C virus genotype (G). RVR: Rapid virologic response; EVR: Early virologic response.

### Adherence and prognostic factors for response

According to our adherence definition, 31 patients (80%) were compliant with the study protocol.

In the univariate logistic regression analysis, the active use of cocaine and/or heroin, ongoing substitution treatment, the type of substitution treatment, the presence of comorbidity, spoken language and male gender did not affect the rate of the SVR, whereas alcohol intake was associated with a non-response ( $P = 0.0018$ , 95%CI: 0.0058-0.4565), independent of the dose and type of alcoholic beverage.

## DISCUSSION

Our study indicates that antiviral treatment for CHC in IDUs is safe and effective and that a multidisciplinary approach is a key element of the care of such patients. We have considered three main aspects of this issue to understand whether these patients are, as generally perceived, difficult to reach, manage or treat.

### Are IDUs difficult to reach?

IDUs, together with migrants and prison inmates, are regarded as special population groups. As recommended by an official position paper on behalf of several Italian scientific societies<sup>[13]</sup>, in such vulnerable people, specific intervention is mandatory to identify, prevent and treat chronic viral infections of the liver. In our approach, collaboration with the territorial services involved in the care of addicts was the key means of reaching IDUs (of whom 6%-15% were migrants) who were at risk of exclusion from medical care for social reasons. In total, 65% of IDUs with HCVAb positivity and identified by physicians of the SerT agreed to and received a dedicated medical visit that, even in the case of patients not receiving treatment, provided an instructive opportunity for counselling on HCV transmission, the prevention of liver complications, healthy lifestyle and available therapeutic protocols. In contrast, 56 IDUs (35% of the total cohort identified by the SerT) never called for an appointment, despite an initial statement of interest in the project. Moreover, after the first medical evaluation, 39 patients (37% of the patients who agreed to the first visit) never completed the diagnostic procedure, even after encouragement by direct telephone contact with a physician. Because of incomplete procedures, clinical and laboratory data were not sufficient to confirm an active HCV infection and to stage liver disease in 95 patients (59% of the initial cohort). Such a finding indicates that difficulties in reaching and motivating this population of patients persist even in the context of a well-organised multidisciplinary approach.

### Are IDUs difficult to manage?

Concerns about treating IDUs are mainly due to suspicion of low adherence, the risk of SAEs (typically psychiatric) and the inability to follow therapeutic prescriptions<sup>[10]</sup>. In our study, adherence was high and comparable to the adherence reported for clinical trials in the general population<sup>[17,18]</sup>. The use of a psychiatric questionnaire to monitor depression and anxiety was well accepted; one patient received antidepressant therapy before starting antiviral treatment, and paroxetine was offered to another patient after 12 wk of antiviral treatment. The patient with a psychotic reaction completely recovered after the withdrawal of antiviral treatment without consequences or the need for psychiatric drugs. These data on the psychiatric safety of CHC treatment in IDUs, as previously suggested by other studies<sup>[19-22]</sup>, are encouraging.

An important feature of our study was the inclusion of people who were actively addicted, with no period of mandatory abstinence; 36% of our enrolled patients continued to use illicit drugs (mainly heroin and cocaine) during the study protocol. Despite this “difficult to manage” characteristic, the data on safety, efficacy and adherence are encouraging. Moreover, logistic regression failed to demonstrate a negative correlation with the viral response to therapy in patients who were actively addicted during antiviral treatment. Only alcohol consumption was relat-

ed to a lower SVR rate, and this finding confirms the role of alcohol consumption in the impairment of antiviral treatment efficacy, which has already been demonstrated in the general population<sup>[23]</sup>.

Although IDUs are considered to be poorly motivated to undergo medical care, the multidisciplinary setting and strict collaboration among the different physicians involved in the care of the IDUs led to a high rate of access to therapy; 76% of patients with confirmed CHC started treatment. Such a rate was markedly higher than the rate previously reported in studies in the general population<sup>[10]</sup>.

### Are IDUs difficult to treat?

Adherence to treatment was high (80%), and despite few withdrawals for safety reasons, the overall SVR of 36% was lower than expected for the general population. This “efficacy” goal must be observed in light of several “difficult to treat” characteristics in our study population<sup>[24]</sup>. Among our IDUs, viral features such as HCV genotype 1 and a high baseline level of viremia were prevalent. Moreover, 40% of our patients tested positive for HBcAb<sup>[25]</sup>. Male gender, an overweight body type and an age over 40 were frequent. Other unfavourable factors affecting the virologic response were a relatively high prevalence of steatosis and cirrhosis in 44% and 17%, respectively, of patients. Most patients had been addicted for over 10 years, and no patient was identified and treated during the acute phase of the infection. In total, 21% of patients experienced the failure of at least one antiviral treatment for CHC. A few of these features are not modifiable (HCV genotype, viral load and gender), whereas other features could be modified by a more prompt strategy of intervention (younger age, shorter duration of infection and lower score of fibrosis).

In conclusion, IDUs with HCV-related CHC, actively using illicit drugs and/or opioid substitution treatment, can be successfully treated in a multidisciplinary setting with a standard antiviral combination of ribavirin and pegylated interferon, with good adherence and a good safety profile. IDUs’ “difficult to reach, manage and treat” characteristics should not be used to contraindicate antiviral therapy. An appropriate multidisciplinary setting is a key factor in overcoming the “difficult” characteristics of these patients, with a strategic aim of reducing HCV circulation in the largest reservoir of this viral infection. Whether treatment will benefit from upcoming new antiviral agents is currently under study in our unit.

## COMMENTS

## Background

Hepatitis C virus (HCV) infection is a common condition worldwide with prevalence of 3%. Illicit drug users (IDUs) are regarded as an important reservoir of this infection and as “super-spreaders”. HCV infection is a progression disease possibly leading to chronic liver disease and ultimately to end stage liver disease. Is therefore important to identify strategy to eradicate infection particularly in the reservoir-population? Concerns about therapy of HCV infection in these populations are present in both physicians and IDUs.

## Innovations and breakthroughs

The investigators report that within a multidisciplinary setting involving both liver and addiction specialists nearly half of identified HCV+ IDUs accept hepatologic counseling and nearly a quarter accept treatment. Eighty percent of treated patients are adherent to treatment according to 80/80/80 rule. Sustained virological response is achieved in a proportion similar of that reported in registration trials, is not influenced by ongoing addiction, but is negatively affected by alcohol consumption. Incidence of psychiatric and organic side effects is not different from that reported in the general population.

## Applications

This article supports the concept that barriers to HCV therapy of IDUs can be overcome in the context of a multidisciplinary team, and that in this clinical context adherence and efficacy of therapy is similar as in the general population. The study highlights the point that the risk of HCV spreading by the super-spreaders IDUs can be reduced and that their habits can not be used as an argument to withhold antiviral therapy.

## Peer review

The study includes challenging for ethical difficulty of HCV treatment. It's very interesting and authors may applaudable effort on this study. Of course, opposite opinions for HCV treatment on addicts may exist, nonetheless this study indicates possibility of HCV treatment for some addicts if patients can receive enough support from medical profession. Although this study may raise an ethical issue, it will give a strong impact to readers and make fascinating reading.

### Abstract

**AIM:** To investigate the expression of the hepatitis B virus (HBV) 1.3-fold genome plasmid (pHBV1.3) in an immortalized mouse hepatic cell line induced by SV40 T-antigen (SV40T) expression.

**METHODS:** Mouse hepatic cells were isolated from mouse liver tissue fragments from 3-5 d old Kunming mice by the direct collagenase digestion method and cultured *in vitro*. The pRSV-T plasmid was transfected into mouse hepatic cells to establish an SV40LT-immortalized mouse hepatic cell line. The SV40LT-immortalized mouse hepatic cells were identified and transfected with the pHBV1.3 plasmid. The levels of hepatitis B sur-

face antigen (HBsAg) and hepatitis B e antigen (HBeAg) in the supernatant were determined by an electrochemiluminescence immunoassay at 24, 48, 72 and 96 h after transfection. The expressions of HBsAg and hepatitis B c antigen (HBcAg) in the cells were investigated by indirect immunofluorescence analysis. The presence of HBV DNA replication intermediates in the transfected cells and viral particles in the supernatant of the transfected cell cultures was monitored using the Southern hybridization assay and transmission electronic microscopy, respectively.

**RESULTS:** The pRSV-T plasmid was used to immortalize mouse hepatocytes and an SV40LT-immortalized mouse hepatic cell line was successfully established. SV40LT-immortalized mouse hepatic cells have the same morphology and growth characteristics as primary mouse hepatic cells can be subcultured and produce albumin and cytokeratin-18 *in vitro*. Immortalized mouse hepatic cells did not show the characteristics of tumor cells, as alpha-fetoprotein levels were comparable ( $0.58 \pm 0.37$  vs  $0.61 \pm 0.31$ ,  $P = 0.37$ ). SV40LT-immortalized mouse hepatic cells were then transfected with the pHBV1.3 plasmid, and it was found that the HBV genome replicated in SV40LT-immortalized mouse hepatic cells. The levels of HBsAg and HBeAg continuously increased in the supernatant after the transfection of pHBV1.3, and began to decrease 72 h after transfection. The expressions of HBsAg and HBcAg were observed in the pHBV1.3-transfected cells. HBV DNA replication intermediates were also observed at 72 h after transfection, including relaxed circular DNA, double-stranded DNA and single-stranded DNA. Furthermore, a few 42 nm Dane particles, as well as many 22 nm subviral particles with a spherical or filamentous shape, were detected in the supernatant.

**CONCLUSION:** SV40T expression can immortalize mouse hepatic cells, and the pHBV1.3-transfected SV40T-immortalized mouse hepatic cell line can be a new *in vitro* cell model.

**Key words:** SV40 T-antigen; Mouse hepatic cell; Hepatitis B virus 1.3-fold genome plasmids; Immortalized; Liposomes; Transfection

**Core tip:** This study established a new immortalized mouse hepatic cell line through the transfection of the pRSV-T plasmid. SV40 T-antigen (SV40LT)-immortalized mouse hepatic cells had the same morphology and biological characteristics as primary mouse hepatic cells. SV40LT-immortalized mouse hepatic cells could be transfected with the pHBV1.3 plasmid, which caused the hepatitis B virus (HBV) genes to replicate in SV40LT-immortalized mouse hepatic cells. The expressions of hepatitis B surface antigen and hepatitis B c antigen, as well as the presence of HBV DNA replication intermediates, were observed in the pHBV1.3-transfected cells. This cell model will contribute to the research of HBV and the evaluation of anti-viral drugs *in vivo*.

Expression of hepatitis B virus 1.3-fold genome plasmid in an SV40 T-antigen-immortalized mouse hepatic cell line. *World J Gastroenterol* 2013; 19(44): 8020-8027 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/8020.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.8020>

## INTRODUCTION

Chronic hepatitis B (CHB) is a severe public health problem that affects more than 400 million people worldwide and causes more than one million deaths annually<sup>[1]</sup>. Recent studies have shown that the correlation between serum hepatitis B virus (HBV) DNA levels and the risk of developing cirrhosis and hepatocellular carcinoma (HCC) is stronger than other baseline or virologic parameters<sup>[2]</sup>. The ultimate long-term goal of therapy is to achieve a “durable response” to prevent hepatic decompensation, reduce or prevent progression to cirrhosis and/or HCC, and prolong survival<sup>[3]</sup>. Moreover, it has now become clear that continuous suppression of HBV replication can revert liver fibrosis or even cirrhosis in most patients<sup>[4]</sup>.

Treatment of hepatitis B depends on several factors, such as the stage of disease, the presence or absence of the “e” antigen, and the potential for drug resistance and subsequent inability to use a medicine, particularly in the advanced stages of chronic disease of the liver. Therefore, it is very important to evaluate these factors at the time the decision is made regarding the type and duration of treatment<sup>[5]</sup>. Interferon alpha-2a and interferon alpha-2b (IFN 2a and 2b)-based therapies have been used for many years as the preferential treatment approaches for cases with low levels of HBV DNA and high levels of alanine aminotransferase (ALT)<sup>[6-8]</sup>. The goal of treatment

is to activate an immune response leading to hepatitis B e antigen (HBeAg) seroconversion<sup>[9]</sup>. This type of treatment, as the first option to modulate the immune system, aims to achieve elimination or remission.

However, this course of treatment results in a high cost, and also produces many adverse side effects, such as anaemia, a significant decrease in hemoglobin, vomiting, cold sweats and nausea<sup>[10]</sup>. Previous studies have reported that only about one out of three patients receives IFN therapy<sup>[11-13]</sup>. Furthermore, nucleoside analogues cannot completely eliminate the virus, and may lead to the mutation of the virus<sup>[14]</sup>. Thus, the development of new antiviral treatments remains a major research task. Additionally, new suitable HBV-infected animal cell models are urgently required to evaluate new treatment strategies. Therefore, this study aimed to establish a new immortalized mouse hepatic cell line induced by SV40 T-antigen (SV40T) expression, and to investigate the expression of the HBV 1.3-fold genome plasmid (pHBV1.3) in the established SV40T-immortalized mouse hepatic cell line.

## MATERIALS AND METHODS

### *Establishment of SV40T-immortalized mouse hepatic cell line*

Kunming mice (3-5 d old) were provided by the clinical drug trial-based Animal Laboratory of Shandong University. Livers were collected from these mice, and mouse hepatic cells were isolated from the liver tissue fragments by the direct collagenase digestion method<sup>[15]</sup>. The isolated cells were cultured in the 1640 culture medium (Gibco) supplemented with 10% fetal bovine serum (FBS) (Gibco), 100 IU/mL penicillin and 100 mg/mL streptomycin, and placed in the incubator with 5% CO<sub>2</sub> and 37 °C. All animals received humane care in compliance with the Principles of Laboratory Animal Care. The protocol was approved by the Animal Care and Use Committee.

The pRSV-T plasmid<sup>[16]</sup> was provided by Professor Reddel RR of the Australia Children's Medical Research Institute. The pRSV-T plasmid was transfected into primary mouse hepatic cells according to the instructions of the liposome transfection kit (Invitrogen, Grand Island, United States). Twenty-four hours later, the 1640 culture medium with 10% FBS was added. Forty-eight hours later, it was replaced by the 1640 culture medium supplemented with 10% FBS and 500 µg/mL G418. Cells were passaged every 5 d at a ratio of 1:2.

An SV40 monoclonal antibody (Thermo, Waltham, United States) was used to detect the SV40T antigen and its distribution in SV40T-transfected cells by the indirect immunofluorescence assay. Primary mouse hepatic cells were employed as the negative control.

An inverted phase contrast microscope and an electron microscope were used to observe the morphology and ultrastructure of the SV40T-transfected mouse hepatic cells.

The supernatants of primary and immortalized mouse hepatic cell cultures were collected. The levels of ALT,

**Figure 1** SV40 T-antigen-immortalized mouse hepatic cells ( $\times 200$ ). A: SV40 T-antigen (SV40T)-immortalized mouse hepatic cells visualized by an inverted phase contrast microscope; B: SV40T antigen immunofluorescence in mouse hepatic cells; C: SV40T-immortalized mouse hepatic cells visualized by an electron microscope.

aspartate aminotransferase (AST) and alpha-fetoprotein (AFP) were determined by an automatic biochemical analyzer (Beckman, Boulevard Brea, United States). Primary cultured mouse hepatic cells were employed as the control.

After total RNA extraction of primary and SV40T-transfected hepatic cells with an RNA extraction kit (Invitrogen), reverse transcription polymerase chain reaction (RT-PCR) was used to determine albumin (ALB) mRNA levels as previously described<sup>[17]</sup>.

Western blotting was used to detect the presence of cytokeratin-18 (CK-18) in primary and SV40T-transfected mouse hepatic cells (22<sup>nd</sup> generation). Rabbit anti-mouse cell CK-18 was the primary antibody employed and horseradish peroxidase-conjugated goat anti-rabbit immunoglobulins (IgG) was used as the secondary antibody. These two antibodies were purchased from Boster Biological Technology, Ltd (Wuhan, China).

### Transfection

pHBV1.3<sup>[18]</sup> was provided by Professor Yin-Ping Lu of Huazhong University of Science and Technology. pHBV1.3 contains a 1.3-fold HBV genome (ayw subtype). Following the instructions of the Lipofectamine 2000 transfection kit (Invitrogen), the pHBV1.3 plasmid was transfected into SV40T-immortalized cells (22<sup>nd</sup> generation).

### Electrochemiluminescence

The supernatants of the pHBV1.3-transfected cell cultures were collected at different times. An AXSYM automatic electrochemiluminescence immunoassay analyzer (Abbott) was used to quantify the levels of HBsAg and

HBcAg.

### Indirect immunofluorescence

pHBV1.3-transfected cells were seeded in 24-well plates. The cells were washed with PBS three times and fixed with 4% paraformaldehyde at 4 °C for 20 min. The cells were then washed with PBS three times again and incubated with PBS-diluted 10% goat serum for 30 min. Then the indirect immunofluorescence assay was performed using a fluorescence kit. Mouse anti-HBcAg and mouse anti-HBsAg were purchased from Millipore Corporation, while fluorescein Isothiocyanate-conjugated goat anti-mouse IgG was purchased from Southern Biotech (Birmingham, United States).

### Southern hybridization and transmission electronic microscopy

At 72 h post-transfection, a DNA extraction of pHBV1.3-transfected cells was performed for Southern hybridization analysis. The probe was the digoxigenin-labeled 3.2 kb HBV DNA<sup>[19]</sup>. The Southern kit was purchased from Roche (Indianapolis, United States). Southern hybridization was carried out according to the manufacturer's instructions.

At 72 h after transfection, the supernatants of pHBV1.3-transfected cell cultures were collected. JEOL transmission electronic microscopy (JEM-1200EX Electron Microscope) was used to visualize the cells and photographs were taken.

### Ethics statement

Animals were maintained and experiments were conducted in accordance with the Institutional Animal Care and Use Committee, Shandong University, and with the

Figure 2 Levels of alanine aminotransferase, aspartate aminotransferase and alpha-fetoprotein in the cell culture supernatant. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; AFP:  $\alpha$ -fetoprotein.

1996 Guide for the Care and Use of Laboratory Animals (Institute of Laboratory Animal Resources on Life Sciences, National Research Council, National Academy of Sciences, Washington DC, United States). The study was approved by the Institutional Animal Care and Use Committee at Shandong University (approval no. SDU003341201).

### Statistical analysis

The data are presented as means  $\pm$  SD. Comparisons between groups of data were performed using Student's *t*

Figure 4 Levels of hepatitis B surface antigen and hepatitis B e antigen in the cell culture supernatant. HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; pHBV1.3: Hepatitis B virus 1.3-fold genome plasmids.

test. A difference with *P* value  $< 0.05$  was considered to be statistically significant. Data were analyzed with the SPSS 11.0 statistical software package (SPSS Inc.; Chicago, IL, United States).

## RESULTS

### Evaluation of SV40T-immortalized mouse hepatic cell line

The epithelial cell-like positive clones were found 30 d after the mouse hepatic cells were transfected with a SV40T-expressing plasmid (pRSV-T) by lipofection; these cells were an adherent monolayer and flat-shaped and presented in a polygonal, cluster-like multi-cell arrangement (Figure 1A). The SV40T mouse hepatic cells displayed the typical morphology and structure of hepatic cells, and many glycogen granules, mitochondria and endoplasmic reticulum structures were clearly visible under the electron microscope (Figure 1C). Furthermore, the splitting dual-core cells reflected the *in vitro* proliferation and differentiation processes of the transfected hepatic cells (Figure 1C). Cells were passaged every five d at a ratio of 1:2 for 38 generations, and no change in cell morphology was observed.

After SV40T transfection, the SV40 T-antigen immunofluorescence of the mouse hepatic cells gradually increased, and was visible 30 d after transfection. Matte-like fluorescence could be clearly detected in the cytoplasm, along with granular-like fluorescence in the nucleus (Figure 1B).

The quantified levels of ALT, AST and AFP in the supernatant of the cultures are shown in Figure 2. The levels of ALT, AST and AFP in the supernatant of mouse hepatic cell and SV40T-transfected hepatic cell cultures were  $5.93 \pm 1.47$  *vs*  $6.21 \pm 1.38$  ( $t = 0.481$ ,  $P = 0.636$ ),  $7.36 \pm 1.21$  *vs*  $6.96 \pm 1.79$  ( $t = 0.643$ ,  $P = 0.527$ ) and  $0.76 \pm 0.21$  *vs*  $0.65 \pm 0.24$  ( $t = 1.318$ ,  $P = 0.201$ ), respectively ( $n = 12$ ). No significant difference in the levels of ALT, AST and AFP was observed between the mouse hepatic cell and SV40T-transfected hepatic cell cultures (*P*

**Figure 5** Analysis of hepatitis B surface antigen and hepatitis B c antigen expression in hepatitis B virus 1.3-fold genome plasmids-transfected cells by immunofluorescence microscopy ( $\times 200$ ). A: Hepatitis B surface antigen (HBsAg) observed in the hepatitis B virus 1.3-fold genome plasmids (pHBV1.3)-transfected cells at 24 h post-transfection; B: Hepatitis B c antigen (HBeAg) observed in the pHBV1.3-transfected cells at 24 h post-transfection; C: HBsAg observed in HepG2.215 cells (positive control); D: HBsAg observed in untransfected SV40 T-antigen (SV40T)-immortalized cells (negative control); E: HBeAg observed in HepG2.215 cells (positive control); F: HBeAg observed in untransfected SV40T-immortalized cells (negative control).

> 0.05).

Following the total RNA extraction of SV40T-transfected hepatic cells (22<sup>nd</sup> generation) and RT-PCR, the ALB mRNA was apparent as a bright band at 475 bp (Figure 3A), indicating that SV40T-immortalized mouse hepatic cells had the ability to express ALB mRNA. Mouse hepatic cells were employed as the positive control.

Following the protein extraction of SV40T-transfected hepatic cells (22 generation), SDS-PAGE and Western blotting were carried out. Immunoblotting of SV40T-transfected hepatic cells demonstrated their expression of CK-18, and mouse hepatic cells, employed as the positive control, also displayed immunoreactivity for CK-18, as expected (Figure 3B).

#### **Expression of pHBV1.3 in SV40T-immortalized mouse hepatic cells**

The levels of HBsAg and HBeAg in the supernatant were monitored 24, 48, 72 and 96 h after pHBV1.3 transfection. The results of this analysis are shown in Figure 4. The levels of HBsAg and HBeAg in the supernatant continuously increased after transfection of pHBV1.3, though they both began to gradually decrease after 72 h.

The expression of HBsAg and HBeAg were observed in the pHBV1.3-transfected cells at 24 h after transfection by immunofluorescence microscopy, with expression reaching a peak at 72 h. HBsAg was mainly observed in

the cytoplasm, while HBeAg was detected in both the cytoplasm and nucleus, especially in the former (Figure 5). HBV DNA replication intermediates, including rcDNA, dsDNA and ssDNA, were also observed 72 h after transfection (Figure 6). Furthermore, a few 42 nm Dane particles, as well as many 22 nm subviral particles with a spherical or filamentous shape, were observed in the supernatant (Figure 6).

## **DISCUSSION**

The development of another HBV *in vitro* cell model would provide a very important tool to study the biological characteristics of HBV, the pathogenesis of hepatitis B, the mechanism of carcinogenesis by HBV infection, and carry out *in vitro* anti-HBV drug screening. 2.2.15 cells, a stable cell line which harbors the HBV genome, and can support HBV replication and the secretion of infectious virus particles<sup>[20-23]</sup>. However, the low expression of HBV was due to the low viral genome copy number integrated in the host cell chromosome. This drawback limits the application of this cell line as an *in vitro* cell model of HBV infection, especially as an infection model for antiviral drug-resistant mutant screening and investigation of biological characteristics<sup>[24]</sup>.

Simian vacuolating virus 40 (SV40), which was first obtained from cultured rhesus monkey kidney cells<sup>[25]</sup>, belongs to the *Papovaviridae* family<sup>[26]</sup>. The transfection of

**Figure 6** Expression of hepatitis B virus 1.3-fold genome plasmids in SV40 T-antigen-immortalized mouse hepatic cells. A: 42 nm Dane particles (a) and 22 nm subviral particles (b) in the supernatant; B: Hepatitis B virus (HBV) DNA replication intermediates in HBV 1.3-fold genome plasmids (pHBV1.3)-transfected cells 24 h after transfection. rc DNA: Relaxed circular DNA; dsDNA: Double-stranded DNA; ssDNA: Single-stranded DNA.

the SV40 early gene into cells is the most common method for cell immortalization. There are different opinions regarding the mechanism by which SV40LT causes cell immortalization<sup>[27,28]</sup>. This method has been found to be useful for a variety of human cell types<sup>[29]</sup>. The use of SV40 for cell immortalization has a long history. It has been used to immortalize epithelial cells of the bronchial intrahepatic bile duct, cervical cells and other cells<sup>[30-32]</sup>. Many studies of SV40T-immortalized cell lines have shown that the transduction of the *SV40T* gene can increase the growth rate of cells, while retaining the differentiation phenotype of many original cells and keeping the biological characteristics of the original cells, with the rare expression of a non-original gene<sup>[33,34]</sup>. These characteristics make the SV40T-immortalized cells suitable for use as an *in vitro* model. In this study, the pRSV-T plasmid was used to transfect the mouse hepatic cells to establish an SV40T-immortalized mouse hepatic cell line, which was selected through 500 µg/mL G418 screening.

Our experimental results showed that there were no significant differences in morphology between primary and SV40T-immortalized mouse hepatic cells. Furthermore, the same level of expression and secretion of ALB, as well as the CK-18 activity, was observed between the primary and SV40T-immortalized mouse hepatic cells (without any tumorigenic potential). At present, the SV40T-immortalized mouse hepatic cells have been passaged to the 38<sup>th</sup> generation.

The genome of the HBV 1.3-fold genome plasmid is smaller than that of the HBV 2.0-fold plasmid, and its efficiency of replication and expression is higher than that of the 1.2- and 1.1-fold plasmids<sup>[35]</sup>. The HBV 1.3-fold genome plasmid contains HBV 5'-end Enh I, Enh II, replication-origin (DR1, DR2), the former genome transcription start site, x and pre-C promoter, and x open reading frame. Hence, the HBV 1.3-fold genome plasmid is used most frequently. After Huh7 and HepG2 cells were transfected with the recombinant plasmid pHBV1.3, the *in vitro* replication and expression of the *HBV* gene could be detected, and high levels of HBsAg/HBeAg intermediates and transcripts involved in HBV DNA replication were also found<sup>[18,36]</sup>. In this study, the pHBV1.3 plasmid was transfected into SV40T-immortalized mouse hepatic cells. After transfection, the expression of HBsAg

and HBcAg was observed in the pHBV1.3-transfected cells. Additionally, HBV DNA replication intermediates, including relaxed circular DNA, double-stranded DNA and single-stranded DNA, were also observed 72 h after transfection. Furthermore, a few 42 nm Dane particles, as well as many 22 nm subviral particles with a spherical or filamentous shape, were observed in the supernatant.

In summary, our findings suggest that the expression of the *SV40T* gene immortalized a mouse hepatic cell line, and subsequent transfection of pHBV1.3 established a new *in vitro* cell model for anti-HBV drug research.

## COMMENTS

### Background

Chronic hepatitis B (CHB) is a severe public health problem, and treatment of hepatitis B poses many challenges, such as treatment for an advanced stage of disease and the potential for drug resistance. Thus, the development of new antiviral treatments remains a major research task, and new suitable hepatitis B virus (HBV)-infected *in vitro* cell models are urgently required to evaluate new therapeutic strategies. With this in mind, this study aimed to establish a new immortalized mouse hepatic cell line induced by SV40 T-antigen (SV40T) expression, and to investigate the consequences of HBV 1.3-fold genome plasmid (pHBV1.3) expression in this SV40T-immortalized mouse hepatic cell line.

### Research frontiers

SV40LT antigen has the ability to immortalize some animal cells. The genome of the HBV 1.3-fold genome plasmid is smaller than that of the HBV 2.0-fold plasmid, and its efficiency of replication and expression is higher than that of the 1.2- and 1.1-fold plasmids. The HBV 1.3-fold genome plasmid contains HBV 5'-end Enh I, Enh II, replication-origin (DR1, DR2), the former genome transcription start site, x and pre-C promoter, and x open reading frame. Hence, the HBV 1.3-fold genome plasmid is used most frequently. The genome of the HBV 1.3-fold genome plasmid has been shown to replicate in HepG2 and Hu7 cell lines. According to the authors, there has been no report concerning the expression of the HBV 1.3-fold genome plasmid in an immortalized mouse hepatic cell line.

### Innovations and breakthroughs

The SV40LT antigen immortalized mouse hepatic cells, which was not found in previous reports. In this study, a new immortalized mouse hepatic cell line was established through the transfection of the pRSV-T plasmid into primary mouse hepatic cells. The genome of the HBV 1.3-fold genome plasmid can replicate in human hepatoma cell lines (HepG2 or HUH7 cells). The authors successfully transfected the pHBV1.3 plasmid into the immortalized mouse hepatic cell line and observed the expression of HBV. The new cell model established in this study will contribute to the research of HBV and the evaluation of anti-viral drugs *in vivo*.

### Applications

This cell model will contribute to the research of HBV and the evaluation of anti-viral drugs *in vivo*.

## Peer review

This is a good basic study in which authors transfected the pRSV-T plasmid into primary mouse hepatic cells and established a new immortalized mouse hepatic cell line. The authors transfected the pHBV1.3 plasmid into the immortalized mouse hepatic cell line and observed the expression of HBV. This cell model would contribute to the research of HBV and the evaluation of anti-viral drugs *in vivo*.

### Abstract

**AIM:** To evaluate the three-dimensional (3-D) representation performance of 4 publicly available Shape-from-Shading (SfS) algorithms in small-bowel capsule endoscopy (SBCE).

**METHODS:** SfS techniques recover the shape of objects using the gradual variation of shading. There are 4 publicly available SfS algorithms. To the best of our knowledge, no comparative study with images obtained during clinical SBCE has been performed to date. Three experienced reviewers were asked to evaluate 54 two-dimensional (2-D) images (categories: protrusion/inflammation/vascular) transformed to 3-D by the aforementioned SfS 3-D algorithms. The best algorithm was selected and inter-rater agreement was calculated.

**RESULTS:** Four publicly available SfS algorithms were compared. Tsai's SfS algorithm outperformed the rest (selected as best performing in 45/54 SBCE images), followed by Ciuti's algorithm (best performing in 7/54 images) and Torreão's (in 1/54 images). In 26/54 images; Tsai's algorithm was unanimously selected as the best performing 3-D representation SfS software. Tsai's 3-D algorithm superiority was independent of lesion category (protrusion/inflammatory/vascular;  $P = 0.678$ ) and/or CE system used to obtain the 2-D images (MiroCam®/PillCam®;  $P = 0.558$ ). Lastly, the inter-observer agreement was good ( $\kappa = 0.55$ ).

**CONCLUSION:** 3-D representation software offers a plausible alternative for 3-D representation of conventional capsule endoscopy images (until optics technology matures enough to allow hardware enabled-"real" 3-D reconstruction of the gastrointestinal tract).

**Key words:** Capsule endoscopy; Small-bowel; Three-dimensional; Software; Algorithm; Reconstruction; Technology; Advance

**Core tip:** Accurate three-dimensional (3-D) reconstruction of the gastrointestinal tract requires the use of stereo-cameras that can simulate human binocular vision. In the absence of such technology in capsule endoscopy, we rely on software approaches [such as the Shape-from-Shading (SfS) algorithms] to obtain 3-D representation of digestive tract structures. In the present study, we evaluated the use of 4 publicly available SfS in capsule endoscopy. 3 experienced/experts reviewers concluded that Tsai's approach is the best of the four available algorithms.

Evaluation of 4 three-dimensional representation algorithms in capsule endoscopy images. *World J Gastroenterol* 2013; 19(44): 8028-8033 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/8028.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.8028>

## INTRODUCTION

Capsule endoscopy (CE) has changed our diagnostic approach for small-bowel diseases<sup>[1,2]</sup>. Although more accurate and of higher diagnostic yield than other modalities<sup>[3,4]</sup>, there are still occasions where pathology is either missed or misinterpreted<sup>[5-7]</sup>. Furthermore, reports have shown that three-dimensional (3-D) reconstruction can facilitate diagnosis by enhancing textural features of mucosal structures or intestinal abnormalities<sup>[8,9]</sup>. However, accurate 3-D reconstruction of the gastrointestinal (GI) tract requires the use of stereoscopic cameras that can simulate human binocular vision<sup>[10,11]</sup>. With the current level of technological investment in CE though *i.e.*, camera size, packaging constraints and power consumption, accurate 3-D imaging of the intestinal lumen in small-bowel capsule endoscopy (SBCE) is still unfeasible<sup>[9,12]</sup>.

Therefore, software approaches that offer 3-D representation of conventional monocular two-dimensional (2-D) CE frames have been developed<sup>[13]</sup> and proposed for use in CE<sup>[14]</sup>. Such approaches *e.g.*, Shape-from-Shading (SfS) algorithms, are members of a family of shape recovery algorithms called shape-from-X techniques (Figure 1)<sup>[13]</sup>. Given a single 2-D image, these algorithms recover the shape of objects using the gradual variation of shading<sup>[13]</sup>. Essentially, surface “reconstruction” with SfS is achieved through a mathematical representation that is inverted in order to recover dense surface distance and normal information by the gradual variation of shading<sup>[13]</sup>. We were able to retrieve 4 publicly available SfS algorithms<sup>[15-18]</sup>. To the best of our knowledge, no comparative study with images obtained during clinical SBCE has been performed to date<sup>[19]</sup>. We aimed to evaluate the 3-D representation performance of 4 publicly available SfS algorithms by comparing them with their equivalent 2-D images of small-bowel structures/lesions obtained during SBCE, in order to identify the algorithm more helpful in facilitating identification and distinction between lesion and surrounding mucosa.

## MATERIALS AND METHODS

Between January 2011 and January 2012, 262 SBCE procedures were performed at the Royal Infirmary of Edinburgh (tertiary referral centre for CE for the southeast of Scotland, United Kingdom) in 249 patients (mean age:  $52.6 \pm 12.1$  years), as already described elsewhere<sup>[9]</sup>. Out of them, 140 were performed with PillCam<sup>®</sup>SB2 (Given<sup>®</sup> Imaging Ltd., Yokneam, Israel) and 122 with MiroCam<sup>®</sup> (IntroMedic<sup>®</sup>Co, Seoul, South Korea). A total of 54 were selected images (27 obtained with MiroCam<sup>®</sup> and 27

with PillCam<sup>®</sup>SB) on the basis of the overall quality *i.e.*, brightness, absence of air bubbles, debris, or opaque luminal fluid and clarity of findings (lesions or structures). Thereafter, images were classified in the following image groups: (1) vascular lesions *i.e.*, angioectasias ( $n = 16$ ); (2) inflammatory lesions *i.e.*, ulcers, erosions, aphthae, cobblestone, fold and/or villous oedema ( $n = 18$ ); and (3) protruding lesions/structures *i.e.*, polyp/mass, nodular lymphoid hyperplasia, cluster of focal lymphangiectasia, chylous cysts, and ampulla of Vater, ( $n = 20$ ).

### 3-D image representation software

All selected images were reconstructed in 3-D by means of all 4 SfS algorithms. Three reviewers (Rondonotti E, Mandelli G, Koulaouzidis A) with extensive CE experience and blinded to each other participated in this study. In order to facilitate the evaluation process, a Mathworks<sup>®</sup> Matlab program with a graphic user interface (GUI) was developed (Figure 2; a video presenting the evaluation process is provided as supplementary material *via* this link: <https://dl.dropboxusercontent.com/u/7591304/EvaluationVideo.mov>). The program consisted of two windows in which the conventional 2-D SBCE image (Figure 2, single frame at the right side/window of the GUI screen) and its corresponding 3-D represented images (four, one for each of the 4 SfS under evaluation) are presented to the reviewer (Figure 2, left side/window of the GUI screen).

The 3-D SfS representations appeared in random order. The reviewers had the ability and freedom to rotate and zoom in each of the 3-D represented images. At the bottom of the GUI screen, a single “task request”: “Choose the 3-D representation you consider most helpful in distinguishing the finding (seen in 2-D) from the surrounding mucosa” appeared. This prompted reviewers to choose one among the four 3-D ‘reconstructed’ images, each generated by a different 3-D algorithm. After selecting the best SfS representation, the reviewer had to click “next” to proceed to the next case. This process was repeated until the program reached the last case after which each separate evaluation was concluded.

### Outcome measures

Reviewers were asked to evaluate 54 images. The following subgroup analyses were performed: (1) evaluation of 3-D representation according to the type of finding (vascular *vs* inflammatory *vs* protruding); and (2) evaluation according to the system generating the 2-D image (PillCam<sup>®</sup> *vs* Mirocam<sup>®</sup>). Furthermore, inter-observer agreement was calculated.

### Ethics consideration

This study was conducted in accordance with United Kingdom research ethics guidelines. After review by the local ethics committee further specific ethical review and approval were not required, as the study was considered an evaluation of previously collected endoscopy images, using data already obtained as part of regular clinical care<sup>[20]</sup>.

**Figure 1 Shape-from-Shading function.** Capturing a surface using a camera removes depth information. Shape-from-Shading (SfS) techniques try to reproduce the missing depth information from a given two-dimensional (2-D) image.

**Figure 2** For the evaluation phase, a Mathworks® Matlab program with a graphic user interface was developed. The program consists of two windows in which the conventional two-dimensional capsule endoscopy image (single frame at the right side/window of the graphic user interface screen) and its corresponding three-dimensional represented images (four, one for each of the 4 shape-from-shading under evaluation) were presented to the reviewer.

Table 1 Results of the Shape-from-Shading method per lesion category						
SfS method	Vascular		Inflammatory		Protrusion	
	PillCam®	MiroCam®	PillCam®	MiroCam®	PillCam®	MiroCam®
Tsai	7	7	7	6	8	10
Ciuti	1	0	1	0	1	4
Torreão	0	0	1	0	0	0
Barron	0	0	0	0	0	0
None selected	0	1	0	0	0	0

SfS: Shape-from-Shading.

Statistical analysis

For numerical variables, values are presented as mean ± SD. Where necessary, the Fisher exact test was calculated. A two-tailed *P* value < 0.05 was considered statistically significant. Inter-observer agreement was calculated using an online *kappa* calculator (available from <http://justus-randolph.net/kappa/>) which provides the calculation of Randolph's free-marginal multirater *kappa*<sup>[21]</sup>, applicable

when raters are not forced to assign a certain number of cases to each category. Values of *kappa* can range from -1.0 to 1.0, with -1.0 indicating perfect disagreement below chance, 0.0 indicating agreement equal to chance, and 1.0 indicating perfect agreement above chance. More specifically, the inte is classified per *kappa* as poor < 0.20, fair 0.2-0.40, good 0.41-0.60, very good 0.61-0.80 and, excellent 0.81-1.00<sup>[22]</sup>. All other statistical analyses were performed using a statistical package, StatsDirect, Stats-Direct Ltd, Altrincham, Cheshire, United Kingdom.

RESULTS

Of the 4 SfS algorithms, Tsai's 3-D algorithm outperformed the rest (selected as best in 45/54 images), followed by Ciuti's (best performing SfS in 7/54 images) and Torreão's (in 1/54 images); there was a single image for which each reviewer selected (as best performing) a different 3-D representation algorithm. Of note, not once was Barron's 3-D algorithm selected as best performing (Table 1, Figure 3).

In 26/54 images, Tsai's algorithm was unanimously

Figure 3 Assessment results for the 4 Shape-from-Shading algorithms per lesion category.

selected as the best performing 3-D representation SfS software. Tsai's 3-D algorithm superiority was independent of lesion category (protrusion/inflammatory/vascular;  $P = 0.678$ ) and/or CE system used to obtain the 2-D images (MiroCam®/PillCam®,  $P = 0.558$ ). Lastly, the inter-observer agreement was good ( $\kappa = 0.55$ ).

## DISCUSSION

In the present study, we compared the performance of 4 publicly available 3-D “reconstruction” algorithms<sup>[15-18]</sup> (SfS software) using 54 conventional 2-D CE images. The evaluation criterion was subjective *i.e.*, perceived visualisation improvement (3-D representations offered over the corresponding conventional 2-D images) by 3 experienced CE reviewers. Based on this evaluation, Tsai's algorithm is the 3-D representation model recommended for use in CE. This outcome directly supports Tsai's SfS model theoretical advantages: (1) able to produce good results for round surfaces, which are the case for most digestive tract shapes; and (2) it behaves quite well with bright surfaces<sup>[13]</sup>.

Depth information is an important aspect of human vision; it helps human brain to analyse and comprehend the surrounding environment. Images captured with conventional (non-stereoscopic) cameras “discard” the 3<sup>rd</sup> dimension (depth) as conventional cameras can only save 2 dimensions (height and width). Therefore depth information is lost; and moreover, most imaging algorithms perform less efficiently.

To date, engineers have not been able to equip capsule endoscopes with stereoscopic cameras for the following reasons: (1) packaging/space limitations; (2) low depth resolution of stereoscopic or time-of-flight cameras<sup>[22-24]</sup>; and (3) power consumption issues. However, it is almost certain that in the foreseeable future these hardware-related limitations will be overcome<sup>[11]</sup> and eventually 3-D CE will be a commodity. Nevertheless, until hardware changes are widely implemented, several efforts have been made to convert 2-D images into 3-D images (3-D representation or “reconstruction”) through software and dedicated algorithms. There are software algorithms that

offer a fair trade-off between 2-D images and hardware-enabled 3-D images. These algorithms are part of a family of shape recovery algorithms called Shape-from-X techniques<sup>[13]</sup>. Basically a SfS algorithm recovers the shape of objects, given a single monocular image, using the gradual variation of shading<sup>[8,13]</sup>.

SfS algorithms can be divided into four groups: (1) minimization approaches<sup>[16-18]</sup>; (2) propagation approaches; (3) local approaches; and (4) linear approaches<sup>[15]</sup>. It is important to remember that each of the 4 SfS algorithms evaluated herein utilizes a different approach to recover the shape from a conventional 2-D image.

More specifically, Tsai *et al.*<sup>[15]</sup> described an repetitive update of the depth using a linear approximation of the reflectance function. Ciuti *et al.*<sup>[16]</sup> used a camera model with perspective projection and a light source close to the surface and away from the optical centre to measure depth. Torreão *et al.*<sup>[17]</sup> applied a linear-nonlinear biological model that mimics neuronal responses to estimate shape. Finally, Barron *et al.*<sup>[18]</sup> proposed a unified model for recovering shape, reflectance and optional illumination while using local smoothness, global scarcity or entropy, and the absolute colour of each pixel. Although Tsai's<sup>[14,15]</sup> method is very straightforward and to an extent simplistic, it provides satisfying results. Ciuti's *et al.*<sup>[16]</sup> algorithm, on the other hand, uses a more advanced model (incorporating a camera model with perspective projection) that makes things in the background appear further back than in Tsai's model (Figure 4).

Since for a given 2-D image, light source and surface shape are not known, these algorithms try to model how the 2-D image was created from the 3-D environment to finally produce an approximation this 3-D depth. The above modelling has a significant impact on the resulting 3-D representation. During SfS process additional constraints need to be applied on the surface shape parameters or the light conditions to find the surface characteristics.

In conclusion, we showed previously that 3-D representation software offers a plausible alternative for 3-D representation of conventional CE images (until optics technology matures enough to allow a hardware enabled-“real” 3-D reconstruction of the GI tract)<sup>[9]</sup>. In the pres-

**Figure 4** Ciuti's algorithm (left) and Tsai's method (right). Although Tsai's method is very straightforward and to an extent simplistic, it provides satisfying results. Ciuti's *et al*<sup>[18]</sup> algorithm, on the other hand, uses a more advanced model that makes things in the background appear darker than in Tsai's model.

ent study we compared 4 publicly available SfS methods. 3-D reconstruction is attracting interest in capsule endoscopy<sup>[8,9,14,25-28]</sup>, especially as newly developed and/or under development CE become available, with greater potential (due to imager and optics) for 3-D software<sup>[20]</sup>.

## COMMENTS

### Background

Over the past decade, conventional endoscope technology has advanced with the use of three-dimensional (3-D) cameras offering increased diagnostic and interventional capabilities. Unfortunately, due to hardware limitations, 3-D small-bowel capsule endoscopy (SBCE) is still an open technological challenge. It is aspired that 3-D SBCE will be able to offer similar benefits to conventional 3-D endoscopy. Therefore, information technology engineers suggested the use of software techniques (Shape-from-Shading, SfS) methods that simulate 3-D reconstruction *i.e.*, 3-D representation in SBCE images. To date, various SfS approaches have been proposed; each aims to retrieve depth information from 2-D images (shape recovery) through different mathematical transformations, hence offering different shape approximations.

### Research frontiers

The authors aimed to evaluate the 3-D representation performance of 4 publicly available SfS algorithms by comparing them with their equivalent 2-D images of small-bowel structures/lesions obtained during SBCE, in order to identify the algorithm more helpful in facilitating identification and distinction between the lesion and the surrounding mucosa.

### Innovations and breakthroughs

This study, in conjunction with further similar work in the field, is useful in the assessing the potential validity of integrating 3-D representation in capsule endoscopy reviewing software.

### Applications

Software-enabled 3-D representation is a promising approach that enables 3-D imaging at no additional cost. The authors have shown that SfS application leads to improved visualisation in SBCE and is likely to be of use in certain clinical scenarios, like the 'mass or bulge' question.

### Peer review

An interesting paper dealing with software and capsule endoscopy.

### Abstract

**AIM:** To describe and analyse factors associated with *Clostridium difficile* infection (CDI) severity in hospitalised medical intensive care unit patients.

**METHODS:** We performed a retrospective cohort study of 40 patients with CDI in a medical intensive care unit (MICU) at a French university hospital. We include patients hospitalised between January 1, 2007 and December 31, 2011. Data on demographics characteristics, past medical history, CDI description was collected. Exposure to risk factors associated with CDI within 8 wk before CDI was recorded, including previous hospitalisation, nursing home residency, antibiotics, antiseptics, and surgical procedures.

**RESULTS:** All included cases had their first episode of CDI. The mean incidence rate was 12.94 cases/1000 admitted patients, and 14.93, 8.52, 13.24, 19.70, and 8.31 respectively per 1000 admitted patients annually from 2007 to 2011. Median age was 62.9 [interquartile range (IQR) 55.4-72.40] years, and 13 (32.5%) were women. Median length of MICU stay was 14.0 d (IQR 5.0-22.8). In addition to diarrhoea, the clinical symptoms of CDI were fever ( $> 38^{\circ}\text{C}$ ) in 23 patients, abdominal pain in 15 patients, and ileus in 1 patient. The duration of diarrhoea was 13.0 (8.0-19.5) d. In addition to diarrhoea, the clinical symptoms of CDI were fever ( $> 38^{\circ}\text{C}$ ) in 23 patients, abdominal pain in 15 patients, and ileus in 1 patient. Prior to CDI, 38 patients (95.0%) were exposed to antibiotics, and 12 (30%) received at least 4 antibiotics. Fluoroquinolones, 3<sup>rd</sup> generation cephalosporins, coamoxiclav and tazocillin were prescribed most frequently (65%, 55%, 40% and 37.5%, respectively). The majority of cases were hospital-acquired ( $n = 36$ , 90%), with 5 cases (13.9%) being MICU-acquired. Fifteen patients had severe CDI. The crude mortality rate within 30 d after diagnosis was 40% ( $n = 16$ ), with 9 deaths (9 over 16; 56.3%) related to CDI. Of our 40 patients, 15 (37.5%) had severe CDI. Multivariate logistic regression showed that male gender [odds ratio (OR): 8.45; 95%CI: 1.06-67.16,  $P = 0.044$ ], rising serum C-reactive protein levels (OR = 1.11; 95%CI: 1.02-1.21,  $P = 0.021$ ), and previous exposure to fluoroquinolones (OR = 9.29; 95%CI:

1.16-74.284,  $P = 0.036$ ) were independently associated with severe CDI.

**CONCLUSION:** We report predictors of severe CDI not dependent on time of assessment. Such factors could help in the development of a quantitative score in ICU's patients.

**Key words:** *Clostridium difficile*; Health-care associated infection; Hospital-acquired infection; Intensive care unit; Nosocomial infection; Severe *Clostridium difficile* infection

**Core tip:** We reported that male gender, rising serum C-reactive protein level, and previous exposure to fluoroquinolones were independently associated with severe *Clostridium difficile* infection (CDI) in medical intensive care unit. This could help in the development of a quantitative severity score that could fuel comparative effectiveness studies and prospective trials of CDI therapy in critically-ill patients.

Predictors of *Clostridium difficile* infection severity in patients hospitalised in medical intensive care. *World J Gastroenterol* 2013; 19(44): 8034-8041 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/8034.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.8034>

## INTRODUCTION

*Clostridium difficile* (*C. difficile*) infection (CDI) has become a growing cause of nosocomial morbidity, high hospital costs and mortality in North America as well as in other areas of the world<sup>[1-6]</sup>. Hospital-acquired CDI has surpassed methicillin-resistant *Staphylococcus aureus* (*S. aureus*) in some hospitals as the leading source of healthcare-associated infections<sup>[7]</sup> and was ranked in the five most important scientific issues facing healthcare epidemiology<sup>[8]</sup>. Several mechanisms have been postulated to increase disease severity, including the emergence of specific strains with genetic polymorphisms that encode higher levels of bacterial toxins A and B as well as the production of a binary toxin<sup>[9-11]</sup>. Advanced age, severe co-morbidity, hospitalisation, antibiotic exposure, immunosuppressants and treatment with motility-influencing or acid-suppressive drugs have all been implicated as risk factors for CDI<sup>[12-17]</sup>.

The cumulative mortality attributable to CDI for all patients typically ranges from 5.5% to 6.9% but can reach 16.7% during severe outbreaks<sup>[18-24]</sup>. In the United States, *C. difficile* is now the 9<sup>th</sup> leading gastrointestinal cause of death<sup>[25]</sup>. CDI is more common in the intensive care unit (ICU) setting, with an overall incidence of roughly 4%<sup>[26]</sup>. Up to 20% of ICU patients who develop symptomatic

disease will progress to fulminant colitis with a mortality rate of nearly 60%<sup>[26]</sup>. In the United States, attributable costs range from \$2871 to \$4846 per case of primary CDI and from \$13655 to \$18067 for infection recurrence or relapse<sup>[18]</sup>, with annual expenditures in excess of \$3 billion<sup>[27]</sup>. A study of ICU patients disclosed gross costs of \$11353 for CDI compared to \$6028 without CDI<sup>[26]</sup>.

CDI among critically-ill patients usually presents as diarrhoea, abdominal pain, hypotension, electrolyte perturbations, and fever<sup>[2,3,10,21,28,29]</sup>. Several studies have examined factors related to CDI acquisition and mortality in different medical units<sup>[30,31]</sup>. To the best of our knowledge, factors associated with CDI severity in medical ICUs (MICU) are poorly documented. We undertook a one-center cohort investigation to analyse factors linked with CDI severity and to report the prognosis of CDI in hospitalised MICU patients.

## MATERIALS AND METHODS

### Study population

This retrospective cohort study was performed at an 860-bed university-affiliated public hospital in Lyon, France. All adult patients with CDI diagnosed in a MICU (15 beds) between January 1, 2007 and December 31, 2011 were included. Patients were followed up until the last point of hospital contact. Thirty-day in-patient mortality from any cause was chosen as the primary endpoint. According to French law, a study like this one does not require ethics committee approval because it is observational and derives from a surveillance database approved under national regulations (*Comité National Informatique et Liberté*)<sup>[32]</sup>. Protocol design was approved by the hospital's institutional review board.

### Data collection

After case identification, full medical files were reviewed and data collected through our institution's electronic medical database. The following data were analysed: age, sex, body weight, diagnosis on admission, co-morbidities, Glasgow coma score available on the day of ICU admission, nutritional status, parenteral nutrition administration, CDI symptoms and their duration, prior CDI history, results of microbiological tests, specific antibiotic therapy for CDI, and evolution of infection. Exposure to risk factors associated with CDI within 8 wk before CDI was recorded, including previous hospitalisation, nursing home residency, antibiotics, antisecretory drugs (proton pump inhibitors, PPI), and surgical procedures (endoscopy, percutaneous gastrostomy, nasogastric feeding, gastrointestinal surgery). Leukocyte count, C-reactive protein, and serum albumin values were collected on days -2 to +2 relative to day 0 (the day the diarrhoeal sample was tested for CDI). Patient outcomes were analysed until in-patient death or last point of hospital contact.

### Microbiological data

*C. difficile* testing was performed only on unformed stool samples from patients clinically suspected to have

CDI. Laboratory diagnosis of CDI was based on stool enzyme-linked immunosorbent assay (ELISA, Immuno-Card Toxins A and B, Meridian Biosciences, Cincinnati, OH, United States, Ref. 716060) coupled with toxigenic culture.

### Definitions

All definitions were selected as part of routine CDI surveillance. Bacteriological cases of CDI were defined as positive enzyme linked immunosorbent assay (ELISA) results and/or positive toxigenic culture. Clinical CDI severity was considered when patients met at least 1 of the following criteria: endoscopically- or histologically-proven colitis or CDI-related complications, such as toxic megacolon, intestinal perforation, colectomy, septic shock, CDI requiring admission to ICU or related death in 30 d. It should be noted, however, that there are currently no prospectively-validated severity scores for CDI. Recurrence was defined as a new episode of diarrhoea and positive toxin assay within 8 wk after a first correctly-treated episode.

According to French guidelines, a nosocomial CDI was assumed if diarrhoea onset took place more than 2 d after admission to hospital or if hospital admission occurred within 4 wk of discharge and indeterminate or unknown if the patient had been discharged from a healthcare facility within the previous 4-12 wk. Cases were defined as community-acquired if CDI signs presented in the absence of previous hospitalisation within the last 12 wk in out- or in-patients within the first 48 h of admission<sup>[33]</sup>. French health authorities currently adopt a cut-off period of 48 h post-admission to define hospital-acquired infections. We considered fever as core temperature  $> 38^{\circ}\text{C}$ , and leukocytosis as leukocyte count  $> 15 \times 10^9/\text{L}$ . Malnutrition was defined according to the national recommendations<sup>[34]</sup>. The incidence rate was calculated as the number of CDI in MICU per 1000 admitted patients.

### Statistical analysis

The data were analysed in 2 stages. First, univariate analysis identified significant differences between severe and non-severe CDI cases. Continuous variables were compared by the Mann-Whitney *U* test. The  $\chi^2$  or Fisher's exact test compared categorical variables. Second, a multivariate logistic regression model identified factors associated with CDI severity. The distribution of continuous variables was checked. All potential risk factors significant at the 0.2 level in univariate analysis were entered into the model. Multivariate analysis was performed with models that were judged a priori to be clinically sound. This was prospectively determined to be necessary to avoid producing spuriously significant results with multiple comparisons. The goodness-of-fit was assessed by the Hosmer-Lemeshow test. For all tests performed, 2-tailed *P* values  $< 0.05$  were regarded as denoting statistical significance. Statistical data were analysed with statistical package for the social sciences (version 17.0 for Windows, SPSS, Inc.,

Chicago, IL).

## RESULTS

A total of 40 adult patients suffering from CDI-related diarrhoea diagnosed in MICU from January 2007 and December 2011 were included. The mean incidence rate was 12.94 cases/1000 admitted patients, and 14.93, 8.52, 13.24, 19.70, and 8.31 respectively per 1000 admitted patients annually from 2007 to 2011 ( $P = 0.99$ ). The demographics and outcomes of these patients are summarised in Table 1. Median age was 62.9 [interquartile range (IQR) 55.4-72.40] years; 13 (32.5%) were women, and 24 (60%) were admitted directly to MICU. Median length of MICU stay was 14.0 d (IQR 5.0-22.8). Twenty-nine patients (72.5%) presented symptoms after MICU admission, and 15 patients (37.5%) developed CDI 10 d or less after MICU admission. Based on the inclusion criteria, ELISA was positive in 35 patients (87.5%), with the remaining 5 patients (12.5%) being diagnosed by toxigenic culture. Median time between onset of symptoms and microbiological diagnosis was 2 d for ELISA and 10 d for toxigenic culture. The mean interval between onset of symptoms and *C. difficile* laboratory test results was  $7.2 \pm 16.5$  d. The duration of diarrhoea was 13.0 (8.0-19.5) d. In addition to diarrhoea, the clinical symptoms of CDI were fever ( $> 38^{\circ}\text{C}$ ) in 23 patients, abdominal pain in 15 patients, and ileus in 1 patient. At the time of diagnosis, median leukocyte count was 14.4 (9.45-21.73), with leukocytosis ( $> 20 \times 10^9/\text{L}$ ) in 12 patients (30%). C-reactive protein was 117 mg/L (60-193), and albumin was 26.0 g/L (20.0-28.0). Prior to CDI, 38 patients (95.0%) were exposed to antibiotics, and 12 (30%) received at least 4 antibiotics. Fluoroquinolones, 3<sup>rd</sup> generation cephalosporins, coamoxiclav and tazocillin were prescribed most frequently (65%, 55%, 40% and 37.5%, respectively). During MICU stay, 12 patients received parenteral nutrition due to malnutrition and impossible intake. The majority of patients had hospital-acquired CDI (90%), with 5 cases (13.9%) being MICU-acquired. Metronidazole was administered as a single agent to 25 patients and vancomycin to 2 (5%). Eight patients (20%) received a combination of 2 CDI medications during the course of treatment. Five patients were given no antimicrobials against CDI.

Of our 40 patients, 15 (37.5%) had severe CDI. Table 1 shows characteristics of severe and non-severe patients. Univariate analysis showed that Glasgow coma score, gender, diabetes mellitus, previous exposure to fluoroquinolones, PPI or coamoxiclav, and C-reactive protein were statistically different between severe and non-severe patients. Multivariate analysis indicated that male gender, C-reactive protein levels, and fluoroquinolones were independently associated with severe CDI (Table 2).

The prognosis of CDI was good in 18 patients. A total of 12 patients (30%) experienced complications due to their infection with 2 cases (16.7%) of pseudomembranous colitis (PMC) and 4 cases (33.3%) of colitis. In one patient, CDI was marked by hyper-leukocytosis (53

g/L), PMC, renal failure and intestinal perforation. The patient died 56 d after CDI diagnosis.

Overall mortality was 52.5%; 12 patients expired in MICU and 9 in-hospital after MICU discharge. The mortality rate within 30 d after diagnosis was 40%; 9 deaths (56.3%) were CDI-related according to the physician in charge of the patient.

## DISCUSSION

*C. difficile* acquisition and severe CDI development are primarily associated with healthcare, although severe, community-acquired infections among persons previously thought to be at low risk have been reported<sup>[35,36]</sup>. CDI management has become more daunting over the past decade because of alarming increments in CDI incidence and severity. These increases have caused significant, concomitant escalation of the healthcare economic

burden from CDI and will likely translate into excessive ICU admissions and attributable mortality. Up to 20% of critically-ill patients may suffer from ileus without the diarrhoea typically associated with CDI<sup>[37]</sup>. The absence of diarrhoea coupled with the inability of critically-ill patients to communicate with care providers make the diagnosis of CDI extremely difficult<sup>[38]</sup>. The objectives of this study were to analyse factors associated with CDI severity and to describe the prognosis of CDI in hospitalised MICU patients.

Our investigation comprised 40 CDI patients diagnosed at a MICU between 2007 and 2011, with a mean incidence rate of 12.94 cases/1000 admitted patients. All included cases had their first episode of CDI. The majority were hospital-acquired (90%), with 5 cases (13.9%) being MICU-acquired. In this work, we compared the characteristics of a group of 15 cases of severe CDI with a group of 25 patients without severe CDI in our MICU.

**Table 2** Factors independently associated with severe *Clostridium difficile* infection among patients in medical intensive care unit

Variables	Unadjusted OR (95%CI)	P value	Adjusted OR (95%CI)	P value
Glasgow coma score	1.16 (0.99-1.36)	0.15	-	
Diabetes mellitus	4.89 (1.00-23.93)	0.04	-	
Previous PPI exposure	2.55 (0.67-9.66)	0.17	-	
Coamoxiclav (in the previous 8 wk)	2.43 (0.65-9.07)	0.18	-	
Fluoroquinolones (in the previous 8 wk)	6.0 (1.12-32.28)	0.026	9.29 (1.16-74.28)	0.036
C-reactive protein (mg/L; 10 mg/L increments)	1.10 (1.02-1.18)	0.014	1.11 (1.02-1.21)	0.021
Male gender	5.11 (0.95-27.55)	0.045	8.45 (1.06-67.16)	0.044

Exposure to fluoroquinolones, C-reactive protein level and gender were included in the multivariate model [The value of the likelihood was 34.56 with 3 df, and  $\chi^2$  test: 18.37 ( $P < 0.0001$ )]. OR: Odds ratios; PPI: Proton pump inhibitor.

In univariate analysis, gender, BMI, diabetes mellitus, fluoroquinolone use and C-reactive protein were associated with CDI severity. Multivariate logistic regression modelling showed that male gender, C-reactive protein, and previous exposure to fluoroquinolones were independently linked with severe CDI. Exposure to specific antimicrobial drugs, notably fluoroquinolones, clindamycin, and cephalosporins, has been linked to severe CDI in some studies<sup>[3,21]</sup> but not in others<sup>[14]</sup>.

Malnutrition, reported to be as high as 40%, is prevalent in ICU patients and is associated with increased morbidity and mortality<sup>[39]</sup>, but to the best of our knowledge, this observation has not been made in CDI patients. The majority of patients were not referred to a dietitian. Among patients consulting a dietitian, 87.5% required parenteral nutrition, which was not associated with 1-month survival in our study. This is consistent with the findings of a previous meta-analysis of 26 randomised trials<sup>[40]</sup>. The investigators showed that, in critically-ill patients, parenteral nutrition did not influence overall mortality.

Underlying illness is moderately associated with severe CDI<sup>[14]</sup>, an effect not observed in our study and could be related to the homogeneity of our study population. Recent investigations have disclosed a potential role of acid suppression in CDI acquisition and relapse<sup>[41,42]</sup>. Hardt *et al.*<sup>[43]</sup> noted an association between these agents and severe CDI, although their definition of severe CDI was different. Also, significant linkage has been reported in a recently-published paper<sup>[44]</sup>. This effect was not seen in our study, but may be related to our study population, and PPIs did not play a role in CDI severity in MICU. Previous works have identified few clinical characteristics that consistently predict severe CDI. Different findings, such as fever, abdominal pain, decreased albumin, and significant leukocytosis (often  $> 20$  g/L), are likely in severe colitis<sup>[45,46]</sup>. Such outcomes often precede multi-organ dysfunction and should prompt urgent consideration of CDI as a possible cause<sup>[47,48]</sup>. In our study, these variables were not different between severe and non-severe cases. Ananthakrishnan *et al.*<sup>[49]</sup> demonstrated that serum albumin  $< 3$  g/dL, haemoglobin  $< 9$  g/dL and creatinine  $> 1.5$  g/dL were independent predictors of severe CDI and may have prognostic significance in patients with inflammatory bowel disease. We also identified rising serum

C-reactive protein levels as being independently associated with severe CDI. As the distribution of C-reactive protein was normal, our multivariate result suggested that an increase by 10 mg/L lead to an increase of the risk of severe CDI by 10%. In fact, serum C-reactive protein was a far better predictor of severe CDI than white blood cell count, which has been implicated by others<sup>[43,50-52]</sup>. Perhaps more sensitive markers of inflammation, such as procalcitonin, might be especially useful in the evaluation of disease severity. Male gender was associated with severe CDI; to the best of our knowledge, this has not been found in other series. However, a similar effect was reported in a Canadian study, where women were less likely to develop severe CDI, but it was indicated by univariate analysis and was not significant<sup>[53]</sup>. Our study provides data on the initial treatment courses chosen by care providers. The majority of patients were treated with metronidazole. Only 7 (46.7%) with severe disease received vancomycin. However, information regarding antibiotherapy (duration and dosage) of CDI was not fully captured; thus, the treatment response could not be analysed in our study. Although current guidelines from the Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America urge vancomycin as first-line therapy in severe disease among adult patients<sup>[54]</sup>, a major portion of our study period predated the publication of these recommendations. In contrast, severe CDI was not associated with nursing home residency, the presence of hospital-acquired CDI or increasing age.

Our study has some limitations which need to be considered when interpreting the data. Our sample size was limited and the study was conducted in one single hospital. Therefore we would not be able to extrapolate our results to other groups. Other potential predictors of severe CDI were unable to provide complete risk scores. There was no validated definition of severe CDI; thus, we applied criteria of severe CDI without a scoring system. A larger, multi-center study would be required to validate any definition of severe CDI. Our patients were assembled from a MICU in a tertiary hospital and may not be generalisable to patients in community hospitals or outpatient settings. Our study population consisted of a significant proportion of patients with multiple co-morbidities, which may reflect tertiary care settings. However, these

centers may be ideal to investigate severe CDI, as patients at risk of severe disease are usually found in tertiary care facilities. The number of antibiotic days should be considered as a potential risk factor for severity, which was not available in our data. Nevertheless, we could not detail the antibiotic consumption. Instead we simply noted if antibiotics were used in the last 2 mo preceding CDI.

We performed this study with the aim of identifying factors that predict severe outcomes associated with CDI in MICU patients. Our results indicate that low C-reactive protein, male gender and previous use of fluoroquinolones are independent predictors of severe CDI in hospitalised MICU patients. In the majority of published studies, factors for a severity score index of CDI were assessed within 48 h after laboratory reporting of test results positive for *C. difficile*. This is problematic in terms of reproducibility in deciding the severity score index of CDI, because the time window from CDI diagnosis to the evaluation of severe CDI is variable. We reported predictors of severe CDI not dependent on the timing of their assessment except for C-reactive protein; in our study, however, values were obtained from the day of CDI diagnosis which made these results valid in clinical practice.

Identification of such factors would foster the development of a quantitative severity score that could drive comparative effectiveness investigations and prospective trials of CDI therapy in these patients. Clinicians need to maintain a high index of suspicion and must often rely on physical examinations and laboratory findings to make the diagnosis. Vancomycin is recognized as the first-line treatment of severe CDI and should be preferred in the ICU setting. Rigorous attention to infection control measures and vigorous antimicrobial stewardship are essential to prevent *C. difficile* transmission. Improved diagnostic methods and new therapeutic tools are required to help clinicians to manage severe CDI cases.

## ACKNOWLEDGMENTS

We thank Sanofi-Pasteur, France. Special thanks Mr Ovid Da Silva for editing this manuscript.

## COMMENTS

### Background

*Clostridium difficile* infection (CDI) has become a growing cause of nosocomial morbidity, high hospital costs and mortality over the world. Several mechanisms have been postulated to increase disease severity, including the emergence of hypervirulent strains. Critically-ill patients are at particularly high risk of CDI due to the prevalence of multiple risk factors in the patient population. However, factors associated with CDI severity in medical intensive care unit (MICU) are poorly documented.

### Research frontiers

Current data are dealing with many aspects related to CDI. The list of hotspots, not exhaustive in any standards, would include measures of prevention, modalities of diagnosis and treatment, and standardization of basic definitions including severity and evaluation scales. Defining a set of approved prognostic factors would help us dealing with aforementioned topics.

### Innovations and breakthroughs

The authors reported predictors of severe CDI no matter the timing of assess-

ment except for C-reactive protein. Nevertheless, values were obtained from the day of CDI diagnosis which made these results valid in clinical practice.

### Applications

Identification of some factors would foster the development of a quantitative severity score that could drive comparative effectiveness investigations and prospective trials of CDI therapy in patients hospitalised in MICU. Intensivists need to maintain a high index of suspicion and must often rely on physical examinations and laboratory findings to make the diagnosis.

### Peer review

Risk factor assessment limited due to small sample size, but a tremendous time investment into the statistical analysis of this small sample makes the manuscript interesting. The study design is simple and reasonable and statistics are excellent.

**study** We analyzed prospectively 135 consecutive patients who met criteria for definitive or probable IC according to Brandt criteria, and follow up these patients during the next five years, retrospectively. Long-term results (recurrence and mortality) were evaluated retrospectively after a median interval of 62 mo (range 54-75 mo).

**RESULTS:** Estimated IC recurrence rates were 2.9%, 5.1%, 8.1% and 9.7% at years 1, 2, 3 and 5 years, respectively. Five-year survival was 69% (93 of 135) and 24% (10 of 42 patients) died for causes related to the IC. Among these 10 patients, 8 died in their first episode at hospital (4 had gangrenous colitis and 4 fulminant colitis) and 2 due to recurrence.

**CONCLUSION:** The five-year recurrence rate of IC was low. On the other hand, mortality during follow-up was high and was not associated with ischemic colitis.

**Key words:** Colonic; Ischemic; Recurrence; Follow-up; Mortality

**Core tip:** The prognosis of patients with ischemic colitis is unknown. In this study we observed that recurrence rate of ischemic colitis was low (9.7% at 5 years). However, the mortality was high (31% at 5 years) and the only factor associated with mortality was age.

### Abstract

**AIM:** To study the prognosis (recurrence and mortality) of patients with ischemic colitis (IC).

**METHODS:** This study was conducted in four Spanish hospitals, participants in the Ischemic Colitis in Spain

Cosme A, Montoro M, Santolaria S, Sanchez-Puertolas AB, Ponce M, Durán M, Cabriada JL, Borda N, Sarasqueta C, Bujanda L. Prognosis and follow-up of 135 patients with ischemic colitis over a five-year period. *World J Gastroenterol* 2013; 19(44): 8042-8046 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/8042.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.8042>

## INTRODUCTION

Ischemic colitis (IC) has been estimated to account for approximately 3 in 1000 of all admissions to tertiary hospitals<sup>[1]</sup>. In a recent prospective study conducted in 24 Spanish hospitals, IC was the reason for 1.28 per 1000 hospital admissions<sup>[2]</sup>. According to the literature, the incidence in the general population is of 4.5-9.9 cases per 10<sup>5</sup> people/year and of 44 per 10<sup>5</sup> people/year for those above 40 years of age<sup>[3]</sup>. Many cases of IC (reversible forms) are ignored and undiagnosed.

The number of comorbid disorders ( $\geq 5$ )<sup>[4]</sup>, location in the right colon<sup>[5]</sup>, and certain clinical onset (gangrenous colitis and/or fulminant pancolitis)<sup>[2]</sup> are known to be associated with poor prognosis of the disease. However, only a few number of studies, have analysed the long-term prognosis of these patients. The objective of this study was to assess the prognosis (recurrence and mortality) of our patients with IC after first hospital admission.

## MATERIALS AND METHODS

We assessed the long-term recurrence and mortality of patients in four hospitals participating in the Ischemic Colitis in Spain (CIE) study (San Jorge Hospital in Huesca, Donostia Hospital in San Sebastian, La Fe Hospital in Valencia and Galdakao Hospital in Bizkaia). The CIE study is a prospective multicentre study which consecutively included all patients with diagnosis of IC between March 2005 and December 2006<sup>[2]</sup>.

For our study, patients follow-up was continued until June 2011. Data were obtained retrospectively from the outpatient clinic (gastroenterology and/or surgery) or by telephone using a questionnaire given to the patient and/or their families. The mean follow-up period was 62 mo (54-75 mo).

Patients were categorized as having definitive, probable, or possible IC according to the Brandt criteria<sup>[6-8]</sup>. The clinical pattern and outcome for each patient was categorised according to Brandt and Boley classification<sup>[6]</sup>: (1) reversible colopathy; (2) transient colitis; (3) chronic segmental IC; (4) gangrenous colitis; or (5) fulminant universal colitis.

The Ethics Committee of the Clinic Hospital of Barcelona approved the study protocol on 9 June 2005. All patients gave their written consent. The initial study protocol included, in all cases, a colonoscopy before the patient was released from the hospital. A second colonoscopy was not performed in asymptomatic patients and those with reversible colopathy or transient colitis, as these subclasses of disease heal spontaneously.

### Statistical analysis

To compare differences between the groups, the Fisher test was used for qualitative variables and the Student's *t*-test for quantitative variables. Differences were consid-

ered to be significant when *P* values were below 0.05.

## RESULTS

A total of 135 patients with who met IC criteria were included in the study. The diagnosis of IC was definitive in 74% and probable in 26% of these cases. The average age of our cohort was  $73 \pm 10$  years with a range of 17-90 years, and 50% of them were women. Of the 135 patients included in the study, 51 (38%) were classified with reversible colopathy; 29 (21%) transient colitis; 42 (31%) chronic segmental IC; 9 (7%) gangrenous colitis, and 4 (3%) fulminant universal colitis.

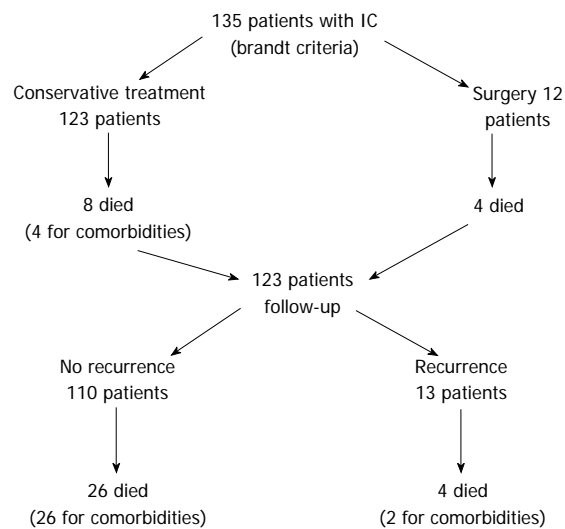

A total of 16 (12%) of the 135 patients had an unfavourable outcome namely death and/or the need for surgery. In the first episode at hospital, 12 patients (8.8%) died, 8 due to IC and 4 due to comorbidities after the acute episode had been solved (1-2 mo after) (Figure 1). Among the 8 who died from IC (3 fulminant universal colitis and 1 gangrenous colitis operated with a subtotal colectomy, and 1 fulminant universal colitis and 3 gangrenous colitis non-operated) the outcome reflected the severity of disease: gangrenous colitis (4/9, 44.4%) and fulminant pancolitis (4/4, 100%).

IC recurred during the follow-up period in 13 (9.7%) of the 123 patients (Tables 1 and 2). Patients with IC recurrence had a similar clinical onset at the first episode at hospital and at relapse. All these patients had colitis not gangrenous and had more frequently vomiting and abdominal pain in the first episode. These were non-gangrenous forms of colitis and located mainly in the left colon. Recurrence occurred in 4, 3, 4, 2 cases through the first, second, third and five year of follow-up, respectively.

Considering the course of the 123 patients, 30 (24.3%) of them died within 5 years, 28 due to comorbidities and only 2 due to recurrence and complications of the IC. The only factor that was associated increased mortality was age ( $72.5 \pm 11$  years *vs* 78.6 years;  $P < 0.001$ ). There were no differences by sex, nonsteroidal anti-inflammatory drugs (NSAIDs) intake or recurrence of colitis. Patients who died had more frequently hypertension 38.8% *vs* 22.4% ( $P = 0.06$ ). Among the 2 patients who died of recurrent IC, one, had reversible colitis, two months after stent insertion for chronic mesenteric ischemia, and the other had chronic segmental colitis, after 24 mo of mesenteric angina. The overall five-year survival was 69% (93 of 135 patients).

### Chronic segmental ischaemic colitis

The patients with chronic segmental IC were followed-up for six months with periodic colonoscopies and/or barium enemas. Of the 42 patients, 30 remained asymptomatic; 6 (14%) developed a stenosis; 3 (7%) had continuing or recurrent bloody diarrhoea and 1 (2%) suffered from persistent or chronic diarrhoea with protein-losing colopathy and serum albumin levels  $< 2.8$  g/L. After six

AUBD: Sequence of abdominal pain, urgent desire to defecate, and bloody diarrhoea.

months none of these patients reported complications.

DISCUSSION

IC is the most common form of intestinal ischemia<sup>[9]</sup>. It is predominantly observed in elderly patients with varying comorbidities, though younger individuals may also be affected. The mean incidence of autopsy-verified fatal IC has been estimated to be 1.7/10<sup>5</sup> person years, rising to 23/10<sup>5</sup> person years in octogenarians<sup>[10]</sup>. In our study, the average age was 73 years, and clinical onset of IC was observed equally frequent in both women and men.

Clinical presentation in ischemic colitis varies, depending of the severity and extent of the disease. In general, the first symptoms of IC are haematochezia and acute abdominal pain<sup>[2,11-14]</sup>. Any part of the colon may be affected in IC although the left colon is the predominant location in approximately 75%-85% of patients<sup>[12-14]</sup>. Splenic flexure is involved in nearly one-

NSAID: Nonsteroidal anti-inflammatory drug.

quarter of patients<sup>[15-17]</sup>, and isolated right colon ischemia (IRCI) in about 10%-26% of cases<sup>[6,17]</sup>. Right-sided colonic ischemia tends to be more severe: about 60% of patients require surgery (four or five times more than with colitis in other areas). In our cohort, of the 10 patients with the right colon involved, 6 (5 with gangrenous colitis) required surgery.

It has been estimated that about 20% of patients with acute IC will require surgery with an associated mortality rate of up to 60%<sup>[18-21]</sup>. In our study, 12 (9%) of the 135 patients underwent surgery, 3 with universal fulminant colitis, 6 with gangrenous colitis, 2 with chronic segmental colitis and 1 with transient colitis. The gangrenous and fulminant universal colitis are associated with poorer prognosis than non-gangrenous forms of IC. Global mortality of IC is of 8%-10%. Gangrenous forms mortality usually reaches 30% and universal colitis is near 100%.

The rate of the recurrence of IC has been reported to be 10%-16% within five years<sup>[11,22]</sup>. To assess the recurrence, we evaluated the long-term outcomes in our patients (54-75 mo). Thirteen patients had recurrent symptoms. Two of them, one presented chronic segmental colitis and another with transient colitis did not have sigmoid colon involved. There were no statistically significant differences between the clinical presentation of IC and the involvement of different segments of the left colon. The estimated cumulative recurrence rates at years, 1, 2, 3 and 4/5 were 2.9%, 5.1%, 8.1% and 9.7%, respectively.

Some authors<sup>[23,24]</sup> have recommended that the following studies should be carried out on a prospective basis to assess potential etiologic factors that may increase the likelihood of recurrence: hypercoagulability workup, tests for connective tissue disorders, echocardiogram and holter, and magnetic resonance angiography. In this way, we may be able to detect structural heart diseases, fibromuscular dysplasia and other conditions that may predispose individuals for IC or to recurrence.

The question of whether patients should receive prophylactic treatment for recurrent IC after discharge from the hospital is important. Currently, our efforts should be addressed to control those factors that may contribute to develop IC such as intake of NSAID<sup>[25,26]</sup> and vasoactive drugs and arterial hypertension.

The limitations of this study are those of a retrospective analysis but prospective follow-up patients. The data collection was made by telephone or at the outpatient clinic and colonoscopy was undertaken only if symptoms were consistent with IC.

In summary, IC is associated with age and occurrence on the right-side markedly increases the risk of severe disease that requires surgery or leads to death. The mortality rate of IC is still high and the recurrence increases with time. In our sample, mortality due to IC at the first admission was 5.9% and 7.4% five years later. The overall rates of mortality, including comorbidities were 8.8% and 31.1% respectively.

## COMMENTS

### Backgrounds

Ischemic colitis (IC) is the most common form of intestinal ischemia. IC is predominantly observed in elderly patients with varying comorbidities, although younger individuals may also be affected. IC was the reason for 1.28 per 1000 hospital admissions.

### Research frontiers

Few studies have assessed the long-term prognosis of these patients.

### Innovations and breakthroughs

IC is associated with age and occurrence on the right-side markedly increases the risk of severe disease that requires surgery or leads to death. The mortality rate of IC is still high and the recurrence increases with time. In our study, mortality due to IC at the first admission was 5.9% and 7.4% five years later. The overall rates of mortality, including comorbidities were 8.8% and 31.1% respectively.

### Applications

Patients with ischemic colitis should be monitored continuously to prevent decompensation during follow-up.

### Peer review

It is a clinical series of IC. It is well written.

### Abstract

**AIM:** To evaluate single balloon enteroscopy in diagnostic and therapeutic endoscopic retrograde cholangiography (ERC) in patients with Roux-en-Y hepaticojejunostomosis (HJA).

**METHODS:** The study took place from January 2009 to December 2011 and we retrospectively assessed 15 patients with Roux-en-Y HJA who had signs of biliary obstruction. In total, 23 ERC procedures were performed in these patients and a single balloon videoen-

teroscope (Olympus SIF Q 180) was used in all of the cases. A transparent overtube was drawn over the videoenteroscope and it freely moved on the working part of the enteroscope. Its distal end was equipped with a silicone balloon that was inflated by air from an external pump at a pressure of  $\leq 5.4$  kPa. The technical limitations or rather the parameters of the single balloon enteroscope (working length - 200 cm, diameter of the working channel - 2.8 mm, absence of Albarran bridge) showed the need for special endoscopic instrumentation.

**RESULTS:** Cannulation success was reached in diagnostic ERC in 12 of 15 patients. ERC findings were normal in 1 of 12 patients. ERC in the remaining 11 patients showed some pathological changes. One of these (cystic bile duct dilation) was subsequently resolved surgically. Endoscopic treatment was initialized in the remaining 10 patients (5 with HJA stenosis, 2 with choledocholithiasis, and 3 with both). This treatment was successful in 9 of 10 patients. The endoscopic therapeutic procedures included: balloon dilatation of HJA stenosis - 11 times (7 patients); choledocholithiasis extraction - five times (5 patients); biliary plastic stent placement - six times (4 patients); and removal of biliary stents placed by us - six times (4 patients). The mean time of performing a single ERC was 72 min. The longest procedure took 110 min and the shortest took 34 min. This shows that it is necessary to allow for more time in individual procedures. Furthermore, these procedures require the presence of an anesthesiologist. We did not observe any complications in these 15 patients.

**CONCLUSION:** This method is more demanding than standard endoscopic retrograde cholangiopancreatography due to altered postsurgical anatomy. However, it is effective, safe, and widens the possibilities of resolving biliary pathology.

© 2013 Baishideng Publishing Group Co., Limited. All rights reserved.

**Key words:** Single balloon enteroscopy; Endoscopic retrograde cholangiography; Roux-Y hepaticojejunoanastomosis; Endoscopic diagnosis; Endoscopic treatment

**Core tip:** Endoscopic retrograde cholangiopancreatography (ERCP) represents a demanding method even in a normal anatomical situation. When a surgically altered gastrointestinal or pancreatobiliary anatomy is present, ERCP becomes even more demanding. Our retrospective study assessed diagnostic and therapeutic endoscopic retrograde cholangiography (ERC) using a single balloon enteroscope in 15 patients with Roux-en-Y hepaticojejunoanastomosis. A comparatively high success rate was achieved in both diagnostic (80%) and therapeutic (90%) ERC. This method is both time-consuming and technically demanding. However, it is an effective and safe method that widens the possibilities of resolving biliary pathology in these conditions.

Single balloon enteroscopy for endoscopic retrograde cholangiography in patients with Roux-en-Y hepaticojejunoanastomosis. *World J Gastroenterol* 2013; 19(44): 8047-8055 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i44/8047.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i44.8047>

## INTRODUCTION

Hepaticojejunoanastomosis (HJA) construction is a frequent method of surgical bypass for resolution of pathological conditions of the extrahepatic bile ducts, which enables bile drainage into the small intestine. These are the main groups of indications for HJA construction: (1) benign pathological processes in the papilla of Vater (VP) and terminal common bile duct, which cannot be resolved by endoscopy or surgical resection; (2) local inoperable pathological processes in the VP and distal part of the hepatocholedoch that cannot be resolved radically in patients who are able to undergo surgery; (3) stenoses of the distal part of the hepatocholedoch during expansion of the pancreas (both malignant and benign) stenosing the common bile duct; (4) iatrogenic or traumatic damage of the hepatocholedoch (*e.g.*, after laparoscopic cholecystectomy) leading to bile leak or stenosis that cannot be resolved by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC), leaving a proximal section of the hepatic duct long enough to enable anastomosis; (5) HJA stenosis; and (6) congenital bile duct anomaly with proximal section of the extrahepatic bile ducts in good condition.

Bile duct injuries during laparoscopic and open cholecystectomy belong to the most serious iatrogenic injuries, with high morbidity and mortality. The increasing

number of laparoscopic cholecystectomies has led to an increase in the number of bile duct injuries. Early perioperative detection of these injuries serves as the basis of successful reconstruction of the bile duct where HJA on Roux loop is the gold standard<sup>[1]</sup>. This procedure is nowadays a standard way of treating injuries of the bile duct and its consequences in the form of stenoses. HJA performed using Roux-en-Y loop (less frequently using omega loop) can be used universally. In general, using this method of bile duct reconstruction for any indication does not lead to mistakes. In contrast to simple end-to-end anastomosis, HJA can be used at any time, in the case of loss-making injury of the bile duct (*e.g.*, excision of its part) or in the case of thin and fine bile duct. HJA can be used in all recent injuries to the bile duct as well as in all adjustments of its stenoses (*i.e.*, in chronic conditions)<sup>[2]</sup>. It is controversial to perform reoperations for complications of laparoscopic procedures of the bile duct. For reoperations, it is possible to use the da Vinci robotic system, which offers a wide range of visualizing possibilities (fluoroscopy) and movability of instruments (endowrist)<sup>[3-5]</sup>. The main condition necessary for long-term successful diagnostic results and results of treatment of hepatobiliary diseases is the multidisciplinary approach of surgeons, endoscopists, and interventional radiologists.

One of the serious postoperative complications of HJA is stenosis, with the possible development of cholangitis. Surgery is frequently performed in the unfavorable conditions of inflammatory changes. It is therefore clear that the percentage of restenosis in the area of HJA is comparatively high and reaches about 7% even in the best institutions<sup>[6]</sup>.

The HJA construction (mainly on Roux-en-Y or less frequently on the omega intestinal loop) causes the bile duct orifice into the small intestine to become unreachable by ERCP performed in the standard way (*i.e.*, by lateroscope). That is why biliary drainage used to be provided using the transhepatic approach (*i.e.*, PTC) or surgically.

These patients with Roux-en-Y HJA and with signs of biliary obstruction have therefore in the past been a challenge for endoscopists due to the absence of endoscopic access to enterobiliary anastomosis<sup>[7,8]</sup>.

Single balloon enteroscopy has proved to be effective for deep intubation of the small intestine. The basic technique of performing single balloon enteroscopy has been described extensively in the literature<sup>[9,10]</sup>.

The use of a balloon enteroscope (initially a double balloon and recently also a single balloon) has resulted in achievement of enteroenteroanastomosis, and then bilioenteral anastomosis at the distal end of the afferent intestinal loop<sup>[11]</sup>. ERC was performed in our group of patients with Roux-en-Y HJA by single balloon enteroscopy. Using standard ERCP, in comparison with a lateroscope, one has to take account of certain technical limitations caused by the current balloon enteroscopes: (1) extreme working length of a single balloon enteroscope -

200 cm; (2) small diameter of the working channel of the single balloon enteroscope - 2.8 mm; and (3) absence of Albarran bridge in a single balloon enteroscope. These technical limitations or parameters show the necessity to use suitable endoscopic instrumentation.

ERCP is considered to be a technically demanding procedure of digestive endoscopy and the presence of surgically altered gastrointestinal or pancreatobiliary anatomy makes it even more difficult<sup>[12,13]</sup>.

The aim of this retrospective study was to analyze and evaluate our experience in using single balloon enteroscopy in diagnostic and therapeutic ERC in patients with Roux-en-Y HJA.

## MATERIALS AND METHODS

### Patients

The study took place from January 2009 to December 2011 and we retrospectively assessed 15 patients (7 men, average age: 55 years; 8 women, average age: 53 years) with Roux-en-Y HJA, who had signs of biliary obstruction.

### ERC procedure

Altogether 23 ERC procedures were performed in these 15 patients with Roux-en-Y HJA using a single balloon videenteroscope (Olympus SIF Q 180). Its working length was 200 cm, the outer diameter was 9.2 mm, and the diameter of the working channel was 2.8 mm. A transparent overtube was drawn over a single balloon enteroscope and it freely moved on the working part of the enteroscope. The overtube was 13.2 mm in diameter and 140 cm long. The distal end was equipped with a silicon balloon that was filled with air from an external pump up to a maximum pressure of 5.4 kPa. Inflation and deflation of this silicon balloon were performed by means of the external pump control.

The examination was performed after a 12-h fast. This endoscopic procedure was both time consuming and technically demanding and required the presence of an anesthesiologist. The mean time to perform the procedure was 72 min. The longest procedure took 110 min and the shortest took 34 min.

During the procedure, the patient lay on the left side and received intravenous sedation (mainly in various combinations) with: midazolam 1-5 mg, sufentanil 5-10 µg, and propofol 20-40 mg repeatedly, to a maximum dose of 200 mg. Buscopan was used after reaching the blind end of the afferent intestinal loop when looking for the HJA orifice.

As can be seen in the schematic image with Roux-en-Y HJA (Figure 1), if an endoscopist wishes to reach the target location, that is, the orifice of the HJA, he/she needs to cover a long distance using a single balloon enteroscope - namely the esophagus, stomach, duodenum, duodenojejunal flexure, proximal jejunum, enteroenteroanastomosis, and afferent intestinal loop, where, at its distal end, 5-6 cm before the blind end of the intestinal

loop, lies the orifice of the HJA. Non-ionic iodinated contrast medium (Omnipaque 300) was used for X-ray imaging of the biliary system.

As already mentioned above, the technical limitations or parameters of the single balloon enteroscope (working length - 200 cm, diameter of the working channel - 2.8 mm, absence of Albarran bridge) necessitate the use of special endoscopic instrumentation.

First, a cannula (width 6 Fr and length 330 cm, or width 7 Fr and length 312 cm; Cook Co., Bloomington, IN, United States) was used for cannulation of the orifice of the HJA and the adjoining bile ducts. Later, a triple-lumen extraction balloon was used more frequently for cannulation of the orifice of the HJA, which enabled simultaneous application of the contrast medium and insertion of the guidewire, which made cannulation significantly more effective. This triple-lumen extraction balloon is described below, and it is used, in addition to cannulation of the orifice of the HJA, for endoscopic extraction of choledocholithiasis.

An especially long guidewire of 600 cm (width 0.035 inches; Cook) was used specifically for this type of procedure using a single balloon enteroscope. HJA stenosis was endoscopically dilated by a bougie dilator (7 Fr) and by a balloon dilator (Cook Co., dilatation balloon type QBD, diameter 10 mm, balloon length 3 cm, designated for 2.8 mm diameter working channel, total length of instrument 320 cm). This balloon dilator was used for dilation under a pressure of 3 atm for 2 min.

Choledocholithiasis was endoscopically extracted using the above mentioned triple-lumen extraction balloon (Cook, TXR- HE, width 6.6 Fr, length 275 cm). Plastic biliary drains - width 7 Fr (and in 1 patient also 8.5 Fr), length 3-5 cm (Medinet or Cook or MSA) - were inserted endoscopically. Apart from others, Cook pusher, width 7 Fr, length 320 cm, was used. In cases of biliary obstruction, these inserted biliary drains were endoscopically removed using a polypectomy loop (Olympus).

### Ethics

The study was performed in accordance with the ethical criteria of the Declaration of Helsinki. The study was reviewed and approved by the Ethics Committee of St. Anne's University Hospital Brno. Written informed consent to perform diagnostic and therapeutic ERC using a single balloon enteroscope was obtained from all the patients.

## RESULTS

In the majority of patients (12/15), HJA construction was required for iatrogenic lesions of the common bile duct after laparoscopic cholecystectomy. In the remaining three patients HJA was required: (1) after resection of the head of the pancreas for chronic pancreatitis; (2) congenital malformation of the common bile duct; and (3) after orthotopic liver transplantation (OLT) for primary sclerosing cholangitis (PSC). Our patients are described

Figure 1 Schematic image of Roux-en-Y hepaticojejunostomosis<sup>[22]</sup>.

in Table 1 and a detailed description of each patient follows below.

#### Patient 1

ERC was performed three times in patient 1 (49-year-old woman). A narrow HJA stenosis was found during the first ERC procedure. Endoscopic balloon dilation of this HJA stenosis was subsequently performed, followed by endoscopic insertion of an 8.5 Fr plastic biliary drain into the bile duct, which completely bridged the HJA stenosis. Another ERC procedure was performed under the same conditions 1 mo later. No complications occurred during this month. Initially, an 8.5 Fr biliary drain was endoscopically extracted. After that, a control ERC was performed, showing that the original HJA stenosis was less prominent. Subsequently, repeat endoscopic balloon dilation of the HJA stenosis was performed. At the end of the second ERC session, an 8.5 Fr plastic biliary drain was repeatedly inserted into the bile duct. A third ERC was performed under the same conditions 1 mo later. An 8.5 Fr biliary drain was endoscopically extracted and a control ERC was performed, which showed a smaller HJA stenosis compared with the previous ERC. Another endoscopic balloon dilation of the small HJA stenosis was performed followed by control ERC. The results were satisfactory, showing almost no HJA stenosis. The procedure was then finished. Both the diagnostic and therapeutic ERC in this patient were therefore successful. The patient had no complications after the first ERC.

#### Patient 2

ERC was performed once in patient 2 (64-year-old woman) and there was only a slight manifestation of HJA stenosis. Endoscopic balloon dilation of this HJA stenosis was subsequently performed followed by control ERC, with satisfactory results and absence of HJA stenosis. Both the diagnostic and therapeutic ERC were therefore successful.

#### Patient 3

Successful diagnostic ERC was performed once in patient 3 (26-year-old woman) and showed cystic dilation of the bile duct. The condition was primarily resolved surgically, that is, without any attempt to perform endoscopic therapy.

#### Patient 4

The orifice of the HJA was found in patient 4 (60-year-old man). However, the attempt to probe the orifice was not successful, therefore, ERC was not performed. This was a case of cannulation failure, thus, the condition had to be resolved by PTC and percutaneous transhepatic drainage (PTD).

#### Patient 5

ERC was performed once in patient 5 (67-year-old man) and it showed slight choledocholithiasis. Endoscopic extraction of the choledocholithiasis using a balloon followed. Both the diagnostic and therapeutic ERC were

**Table 1 Detailed description of 15 patients with Roux-en-Y hepaticojejunostomosis**

<i>n</i>	Age/sex	Cause of HJA	Success of diagnostic ERC	Finding on diagnostic ERC	No. of ERC	Characteristics and No. of endoscopic therapeutic procedures
1	49/F	ILC after LCE	Yes	HJA stenosis	3	BD-3x, EBD-2x
2	64/F	Condition after RHP (CHP)	Yes	HJA stenosis	1	BD-1x
3	26/F	Congenital malformation choledochus (CBD)	Yes	Cystic dilatation choledochus (CBD)	1	Surgical solution
4	60/M	ILC after LCE	No	HJA found but not probed into	1 (SBE)	Solved by PTC and PTD
5	67/M	ILC after LCE	Yes	CDL	1	ECDL-1x
6	57/F	ILC after LCE	Yes	HJA stenosis + CDL	2	BD-1x, ECDL-1x
7	52/M	ILC after LCE	Yes	HJA stenosis + CDL	2	BD-1x, ECDL-1x
8	29/M	Condition after OLT (PSC)	Yes	HJA stenosis	3	BD-2x, EBD-2x
9	64/M	ILC after LCE	Yes	Normal ERC results	1	Without endoscopic treatment
10	48/F	ILC after LCE	Yes	HJA stenosis + CDL	2	BD-1x, ECDL-1x, EBD-1x
11	56/F	ILC after LCE	Yes	too narrow HJA stenosis	1	Therapeut. ERC impossible, condition solved by PTC and PTD
12	59/F	ILC after LCE	Yes	CDL	1	ECDL-1x
13	63/F	ILC after LCE	No	HJA not found at all	1 (SBE)	Solved by PTC and PTD
14	59/M	ILC after LCE	No	HJA found but not probed into	1 (SBE)	Solved by PTC and PTD
15	54/M	ILC after LCE	Yes	HJA stenosis	2	BD-2x, EBD-1x

BD: Balloon dilation; CDL: Choledocholithiasis; CHP: Chronic pancreatitis; EBD: Endoscopic insertion of plastic biliary drains; ECDL: Extraction of choledocholithiasis; ILC after LCE: Iatrogenic lesion of the common bile duct after laparoscopic cholecystectomy; RHP: Resection of the head of the pancreas; SBE: Single balloon enteroscopy; ERC: Endoscopic retrograde cholangiography; CBD: Common bile duct; M: Male; F: Female; PTC: Percutaneous transhepatic cholangiography; PTD: Percutaneous transhepatic drainage; HJA: Hepaticojejunostomosis; PSC: Primary sclerosing cholangitis.

therefore successful.

#### Patient 6

ERC was performed twice in patient 6 (57-year-old woman) and slight HJA stenosis and choledocholithiasis were found. Endoscopic balloon dilation of the HJA stenosis was performed during the first ERC, followed by endoscopic balloon extraction of the choledocholithiasis. Control ERC showed satisfactory results for the biliary tree. Both the diagnostic and therapeutic ERC were therefore successful.

#### Patient 7

ERC was performed twice in patient 7 (52-year-old man). The first ERC showed slight HJA stenosis and choledocholithiasis. Balloon dilation of the HJA stenosis was performed first, followed by endoscopic extraction of the choledocholithiasis using an extraction balloon. Control ERC showed satisfactory results in the biliary tree. Both the diagnostic and therapeutic ERC were therefore successful.

#### Patient 8

Patient 8 (29-year-old man) underwent HJA construction for a condition that developed after OLT for PSC. ERC was performed three times. The first ERC showed a narrow HJA stenosis. Endoscopic balloon dilation of the stenosis was subsequently performed, followed by endoscopic insertion of a 7 Fr plastic biliary drain into the bile duct, which completely bridged the HJA stenosis. The second ERC was performed under the same conditions 1 mo later. No complications occurred during that month. First, a 7 Fr biliary drain was endoscopically extracted. After that, control ERC was performed, showing that the original HJA stenosis was less prominent. Repeated

endoscopic balloon dilation of the HJA stenosis was performed. At the end of the second ERC session, a 7 Fr plastic biliary drain was inserted into the bile duct. Third, control ERC was performed under the same conditions 6 wk later. A 7 Fr biliary drain was endoscopically extracted and control ERC was performed, showing significant improvement of the HJA stenosis, which was in fact unnoticeable. Both the diagnostic and therapeutic ERC in this patient were therefore successful.

#### Patient 9

Successful diagnostic ERC was performed once in patient 9 (64-year-old man) and showed normal findings.

#### Patient 10

ERC was performed twice in patient 10 (48-year-old woman). The first ERC showed HJA stenosis and slight choledocholithiasis. Balloon dilation of the HJA stenosis was performed first, followed by endoscopic extraction of the choledocholithiasis using an extraction balloon. A 7 Fr plastic biliary drain was subsequently inserted into the bile duct, completely bridging the HJA stenosis. Control ERC in 4 wk (*i.e.*, during the second ERC session) showed satisfactory findings in the bile duct. Both the diagnostic and therapeutic ERC were therefore successful.

#### Patient 11

ERC was performed once in patient 11 (56-year-old woman) and prominent HJA stenosis was found. Therapeutic ERC, that is, insertion of a balloon or biliary drain into the HJA stenosis, was not possible because the stenosis was too narrow. This led to PTC and PTD. Successful diagnostic ERC was therefore performed once in this patient.

**Table 2** Diagnostic endoscopic retrograde cholangiography in patients with Roux-en-Y hepaticojejunostomosis

Results in ERC	No. of patients
Normal results	1
Cystic dilation of the bile duct	1
HJA stenosis	5
Choledocholithiasis	2
HJA stenosis + choledocholithiasis	3
Total	12

Cannulation success was reached in 12 of 15 patients [80% diagnostic endoscopic retrograde cholangiography (ERC) success rate]. HJA: Hepaticojejunostomosis.

### Patient 12

ERC was performed once in patient 12 (59-year-old woman) and slight choledocholithiasis was found. Endoscopic extraction of the choledocholithiasis using an extraction balloon was subsequently performed. Both the diagnostic and therapeutic ERC were therefore successful.

### Patient 13

The area of the distal end of the afferent intestinal loop was reached by single balloon enteroscopy in patient 13 (63-year-old woman), nevertheless the HJA was not found. ERC was therefore not performed. This was a case of cannulation failure, thus, the condition had to be resolved by PTC and PTCD.

### Patient 14

The orifice of the HJA was found in patient 14 (59-year-old woman), nevertheless, the attempt to probe the orifice was not successful. ERC was therefore not performed. This was a case of cannulation failure, thus, the condition had to be resolved by PTC and PTCD.

### Patient 15

ERC was performed once in patient 15 (54-year-old man). The first ERC showed HJA stenosis. Endoscopic balloon dilation of the stenosis was performed, followed by endoscopic insertion of a 7 Fr plastic biliary drain into the bile duct, which completely bridged the HJA stenosis. The second ERC was performed under the same conditions 1 mo later. No complications occurred during that month. First, a 7 Fr biliary drain was endoscopically extracted. After that, control ERC was performed, showing marked improvement, with the original HJA stenosis being almost unnoticeable. In spite of that, endoscopic balloon dilation of the area of the HJA stenosis was performed. At the end of the second ERC session, control ERC was performed, showing almost normal findings, which means that the original HJA stenosis was no longer noticeable. Both the diagnostic and therapeutic ERC in this patient were therefore successful.

### Summary of results

The results clearly show that cannulation was successful

in diagnostic ERC in 12 of 15 patients (80% diagnostic success rate). The diagnostic ERC findings in these patients are shown in Table 2. Normal ERC findings were present in one of the 12 patients. ERC in the remaining 11 patients showed some pathological findings. One of these cases (cystic dilation of the bile duct) was subsequently resolved by surgery.

Endoscopic treatment was started immediately after diagnostic ERC in the remaining 10 patients (5 with HJA stenosis, 2 with choledocholithiasis, and 3 with both conditions). This treatment was successful in nine patients (90% therapeutic success rate). Therapeutic ERC was not successful in the other patient due to an extremely narrow HJA stenosis. This condition was resolved by PTC and PTCD.

Endoscopic therapeutic procedures were performed as follows. Balloon dilatation of HJA stenosis was performed a total of 11 times in seven patients; choledocholithiasis extraction was performed a total of five times in five patients; plastic biliary stent insertion was performed a total of six times in four patients; and removal of a biliary stent inserted by our team was performed a total of six times in four patients.

Some of these endoscopic procedures are presented in Figures 2 and 3.

Cannulation failure was recorded in three of 15 patients. Causes of failure were: one patient in whom HJA was not found at all; and two cases in which HJA was found but not probed. All three cases were resolved using PTC and PTCD.

There were no complications in our group of 15 patients.

### Problems with ERC

It is also important to draw attention to some of the pitfalls that we encountered and resolved when performing ERC. (1) Fixing an overtube closely in front of the anastomosis in the area of an enteroenteroanastomosis is not recommended because the overtube, in case of the entrance to the afferent intestinal tube being at an acute angle, made insertion of the enteroscope harder; (2) The afferent intestinal loop could be identified by finding its blind end, and bilioenteral anastomosis can be found a few (5-6) centimeters before this blind end; (3) We suggest using endoscopic accessory of diameter no larger than 7 Fr in the working channel of the single balloon enteroscope (2.8 cm diameter). Based on our personal experience, the use of an 8.5 Fr dilator and biliary drain, or their insertion via the working channel, was difficult. A 7 Fr dilator was much easier to use for dilation and was followed by the use of a dilation balloon. Biliary drainage was, in indicated cases, easier to perform using two 7 Fr drains; and (4) It is advised to straighten the overtube during extraction of the enteroscope from the overtube by manipulation under skiascopic control but, at the same time, it is necessary to prevent the creation of curves that are small in diameter because they tend to break after the removal of the enteroscope, and make repeated insertion complicated.

**Figure 2** Endoscopic image. A: Successful cannulation of a stenotic orifice of the hepaticojejunostomosis (HJA) (followed by successful cannulation of adjoining bile ducts); B: Dilation balloon in a deflated form successfully inserted down the guide wire into the area of the stenotic HJA; C: Last phase of a successful endoscopic insertion of a 7 Fr plastic biliary drain into the stenotic HJA and adjoining bile ducts; D: Highly satisfactory final effect of endoscopic treatment of the stenotic HJA (with inserted guide wire).

## DISCUSSION

Single or double balloon enteroscopy enables us to reach

**Figure 3** Endoscopic retrograde cholangiography performed by using single balloon enteroscopy. A: A patient with hepaticojejunostomosis (HJA) shows comparatively narrow HJA stenosis with suprastenotic dilation of bile ducts; B: The patient from Figure 3A in whom HJA stenosis was successfully bridged by endoscopic insertion of a 7 Fr plastic biliary stent.

even the more distant parts of the small intestine. It is therefore reasonable that this examination method began to be used also for reaching the orifice of the bile duct under conditions of altered anatomy after surgical procedures, when the bile ducts become unreachable by standard lateroscopy (*i.e.*, using conventional ERCP). Previously, pathological conditions (or biliary obstruction) had to be resolved surgically or using PTC<sup>[14]</sup>.

One of these most frequently resolved problems is bile duct pathology in patients with Roux-en-Y HJA (HJA stenosis, choledocholithiasis in the bile duct above the HJA, or both). If we know the type of surgical procedure, ERC using single balloon enteroscopy can be attempted in these cases<sup>[14]</sup>. Balloon enteroscopy can enable one to reach the afferent intestinal loop, identify the orifice of the HJA<sup>[15-17]</sup>, perform diagnostic ERC, and if indicated, also perform therapeutic ERC. Originally, the procedure was carried out with double balloon enteroscopy<sup>[7,18]</sup> and later also with single balloon enteroscopy<sup>[13,19-21]</sup>. There was a wide range of endoscopic therapeutic procedures performed. These procedures are also being performed in standard ERCP<sup>[11]</sup>. We used single balloon enteroscopy for diagnostic and therapeutic ERC in our group of 15 patients with Roux-en-Y HJA.

The results of diagnostic and therapeutic ERC using single balloon enteroscopy in patients with Roux-en-Y HJA in other endoscopic centers show that Dellon *et al*<sup>[20]</sup> were successful when performing ERC in three of four patients. Neumann *et al*<sup>[21]</sup> worked with 13 patients in

whom the diagnostic success rate was 62% and the therapeutic success rate 54%. The largest study to date was by Saleem *et al.*<sup>[12]</sup> who achieved a success rate of 78% (32 of 41 patients) in diagnostic ERC. Wang *et al.*<sup>[13]</sup> have recently described a group of 13 patients (16 procedures in total). Cannulation success rate was 81% (13 of 16 cases) for diagnostic ERC. Therapeutic ERC was necessary in 10 of these 13 patients and was successful in nine patients (90% therapeutic ERC success rate).

The diagnostic and therapeutic ERC success rates in our study were comparatively high and, at the same time, there were no procedure-related complications. Cannulation success was achieved in 12 of 15 patients (80% diagnostic ERC success rate). Endoscopic treatment was successful in nine of 10 patients (90% therapeutic ERC success rate). Our results in diagnostic and therapeutic ERC are comparable to those of other endoscopic centers dealing with this issue<sup>[12,13,20]</sup>.

As mentioned above, we encountered some pitfalls when performing ERC, which are not addressed in detail by other authors<sup>[7,12,19,20]</sup>. Nevertheless, they do consider the following: (1) avoidance of fixing an overtube closely in front of an enteroenteroanastomosis at the entrance of the enteroscope into the afferent loop; (2) identification of the afferent loop and the bilioenteral anastomosis; (3) using an endoscopic accessory of diameter no larger than 7 Fr in the working channel of the single balloon enteroscope (diameter 2.8 cm) - a suggestion based on our own experience; and (4) straightening the overtube during extraction of the enteroscope from the overtube, by manipulation under skiascopic control, and at the same time, preventing creation of curves that are small in diameter, because they tend to break after removal of the enteroscope and make repeated insertion complicated.

No complications, not even acute pancreatitis, appeared in our group of 15 patients. It might be that the altered anatomy of the gastrointestinal tract decreases the risk of complications associated with balloon enteroscopy<sup>[7]</sup>.
