World Journal of *Gastroenterology*

World J Gastroenterol 2013 March 7; 19(9): 1333-1504

**EDITORIAL**

1333 Chronic mesenteric ischemia: Time to remember open revascularization
Keese M, Schmitz-Rixen T, Schmandra T

1338 Challenges in diagnosing mesenteric ischemia
van den Heijkant TC, Aerts BAC, Teijink JA, Buurman WA, Luyer MDP

TOPIC HIGHLIGHT

1342 Hepatitis B and inflammatory bowel disease: Role of antiviral prophylaxis
López-Serrano P, Pérez-Calle JL, Sánchez-Tembleque MD

1349 Efficacy of the vaccination in inflammatory bowel disease
Carrera E, Manzano R, Garrido E

1354 Vaccines and recommendations for their use in inflammatory bowel disease
Sánchez-Tembleque MD, Corella C, Pérez-Calle JL

REVIEW

1359 Individualized hepatocellular carcinoma risk: The challenges for designing successful chemoprevention strategies
Della Corte C, Aghemo A, Colombo M

MINIREVIEWS

1372 Endoscopic ultrasonography guided biliary drainage: Summary of consortium meeting, May 7th, 2011, Chicago
Kahaleh M, Artifon ELA, Perez-Miranda M, Gupta K, Itoi T, Binmoeller KF, Giovannini M

1380 Hepatic regeneration and the epithelial to mesenchymal transition
Xue ZF, Wu XM, Liu M

ORIGINAL ARTICLE

1387 Pre-treatment role of inosine triphosphate pyrophosphatase polymorphism for predicting anemia in Egyptian hepatitis C virus patients
Ahmed WH, Furusyo N, Zaky S, Sharaf Eldin A, Aboalam H, Ogawa E, Murata M, Hayashi J

1396 Influence of Kupffer cells and platelets on ischemia-reperfusion injury in mild steatotic liver
Ogawa K, Kondo T, Tamura T, Matsumura H, Fukunaga K, Oda T, Ohkohchi N

- 1405 Exogenous bone morphogenetic protein-7 reduces hepatic fibrosis in *Schistosoma japonicum*-infected mice *via* transforming growth factor- β /Smad signaling
Chen BL, Peng J, Li QF, Yang M, Wang Y, Chen W

BRIEF ARTICLE

- 1416 Corticotropin-releasing factor receptor subtype 2 in human colonic mucosa: Down-regulation in ulcerative colitis
Chatzaki E, Anton PA, Million M, Lambropoulou M, Constantinidis T, Kolios G, Taché Y, Grigoriadis DE
- 1424 Endoscopic and surgical resection of T1a/T1b esophageal neoplasms: A systematic review
Sgourakis G, Gockel I, Lang H
- 1438 CD24 expression predicts distant metastasis in extrahepatic bile duct cancer
Kim K, Min HS, Chie EK, Jang JY, Kim SW, Han SW, Oh DY, Im SA, Kim TY, Bang YJ, Jang JJ, Ha SW

AIMS AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING *World Journal of Gastroenterology* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Chronic mesenteric ischemia is caused by stenosis or occlusion of one or more visceral arteries. It represents a therapeutic challenge and diagnosis and treatment require close interdisciplinary cooperation between gastroenterologist, vascular surgeon and radiologist. Although endovascular treatment modalities have been developed, the number of restenoses ultimately resulting in treatment failure is high. In patients fit for open surgery, the visceral arteries should be revascularized conventionally. These patients will then experience long term relief from the symptoms, a better quality of life and a better overall survival.

Keese M, Schmitz-Rixen T, Schmandra T. Chronic mesenteric ischemia: Time to remember open revascularization. *World J Gastroenterol* 2013; 19(9): 1333-1337 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i9/1333.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i9.1333>

VASCULAR ANATOMY

In embryogenesis segmental arteries regress until three major visceral vessels remain: the celiac artery, the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA). Hereby, frequent variants with complex anatomy may develop. In health, the visceral vascular supply is highly collateralized to ensure sufficient visceral blood supply. Retroduodenal and retropancreatic collaterals shunt blood from the coeliac artery to the SMA and vice versa^[1]. The SMA supplies the small bowel and parts of the colon. It originates only 1.5 to 2 cm below the coeliac artery, crosses the horizontal part of the duodenum and then enters the mesenteric root. At the splenic colon flexure the marginal artery of Drummond represents an important collateral which anastomoses the middle colic artery (MCA) with the left colic artery. The riolan anastomosis is another vascular arcade present in the colonic mesentery that connects the proximal MCA artery with the proximal IMA. The IMA supplies the descending colon, the sigmoid colon and the upper rectum. Here multiple collaterals are preformed with the hypogastric artery *via* the medial rectal artery^[2].

These interconnections between the celiac artery, the SMA and the IMA may easily compensate if stenotic lesions in one major visceral vessel develops. Therefore chronic mesenteric ischemia (CMI) with intestinal malperfusion is rarely seen in clinical practice but represents a serious and complex vascular disorder.

EPIDEMIOLOGY

In a population-based study, 553 healthy elderly persons underwent duplex sonography of the visceral arteries. Relevant stenosis was detected in 17.5% of the study cohort. The majority had isolated celiac disease. SMA stenosis and celiac artery occlusion demonstrated a significant and independent association with weight loss and concurrent renal artery disease^[3]. Among the patients

with relevant stenosis of visceral arteries only few develop symptoms. In a natural history study of 980 patients who received consecutive aortograms to identify significant mesenteric stenoses, eighty-two patients (8%) were found to have 50% stenosis of at least one mesenteric artery. Sixty of these patients (6%) had significant occlusions involving one, two, or all three mesenteric arteries. Mesenteric ischemia developed in only four patients (0.4%). Each of these four patients had significant three-vessel disease^[4].

CLINICAL PRESENTATION

The majority (over 70%) of CMI-patients are woman. Classically the symptoms include abdominal angina which presents as postprandial pain resulting in significant weight loss. Patients may develop a fear to eat, therefore among the differential diagnosis malignant diseases and functional disorders have to be considered. Atherosclerosis is by the most common etiology of CMI. Other etiologies causing this clinical entity include fibromuscular dysplasia, Buerger disease, and aortic dissection. In these patients atherosclerosis will often have manifested in other vascular beds by a history of myocardial infarction, stroke, or intermittent claudication. Atypical symptoms include diarrhea, constipation, vomiting and lower gastrointestinal bleeding which is associated with ischemic colitis or ischemic gastropathy. Endoscopic findings are unspecific and therefore subjective to inter observer variance. Previous research studies have suggested a possible role for tonometry, laser doppler, magnetic resonance (MR) oximetry, and MR measurement of mesenteric venous blood flow and spectroscopic oxymetric devices in the assessment of intestinal ischemia^[5]. All of these are still under investigation and their clinical usefulness has not been adequately established. In parallel to peripheral artery disease which may progress from claudication to tissue loss CMI may also progress from post-prandial pain to mesenteric infarction^[6]. Evidence of significant occlusion of two or more of these vessels is often found when classic symptoms and endoscopy suggest bowel ischemia. Single-vessel disease, usually of the SMA, has also been described as a cause of symptomatic CMI, particularly if collateral connections have been disrupted^[7].

DIAGNOSIS

Established non-invasive diagnostic means are duplex ultrasound or computed tomography (CT)- and MR-angiography. Especially duplex ultrasound is fast and readily available. Diagnosis is based on morphology and flow velocities. The largest series correlated angiograms and duplex sonography of 153 patients^[8]. Peak systolic velocity (PSV), end diastolic velocity, and SMA or colic artery/aortic PSV ratio were used to detect $\geq 50\%$ and $\geq 70\%$ stenosis. PSV threshold value for detecting $\geq 50\%$ SMA stenosis was ≥ 295 cm/s (sensitivity 87%, specificity 89% and OA 88%); and for detecting $\geq 70\%$

SMA ≥ 400 cm/s. PSV and ratio measurements were less reliable. Duplex ultrasound of the mesenteric artery requires a high level of technical expertise. It also depends on the fasting status of the patients. In ideal patients even higher sensitivity and specificity have been reported^[9]. There is also the tendency to measure higher flow velocities in stented arteries as compared to non-stented vessels. Therefore, the degree of in-stent stenosis may be overestimated^[10]. Native CT-scans without the application of a contrast agent already provide valuable information on the calcification status of the aorta. This is necessary to plan a revascularisation. In multiplanar reconstruction the complete aorta with all visceral branches can be visualized. Hereby vascular diameters, collateral formation and vascular variants can be imaged. Therefore, therapy should be planned on the basis of a 3-D reconstructed CT and on an invasive digital subtraction angiography^[11]. Magnetic resonance angiography plays no role in the diagnosis of chronic mesenteric ischemia. The digital subtraction angiography should show both lateral and frontal projections of the aorta and all major vessels. Furthermore the individual major branches should be imaged to gain information on collateralisation (*i.e.*, the patency of the Drummond artery or the arc of Riolan).

TREATMENT

With stenoses exceeding 70% in one or more visceral arteries patients may develop symptoms of mesenteric insufficiency. In these cases revascularisation is strongly recommended. While analgesia and parenteral nutrition may be used for optimal preparation of the patient for open surgery or endovascular intervention, conservative treatment will not slow disease progression. Therefore the clinical decision has to be made between endovascular treatment or conventional vascular revascularisation.

ENDOVASCULAR TREATMENT

In the majority of patients endovascular treatment of a mesenteric stenosis is feasible. The choice of vascular access depends on the patient's vascular anatomy. If the right femoral or iliac artery is heavily calcified, occluded or severely kinked the left femoral artery or the brachial artery may be used. Brachial access is also advisable in patients that show a steep angle between the SMA and the aorta. The regular transfemoral vascular access is achieved by puncture or cut down. A 7 F sheath normally allows the introduction of appropriately sized stents. *Via* sidewinder catheter the SMA is catheterized and a stiff wire with a long intervention sheath is placed into the SMA. Any wire manipulation has to be confirmed by angiography to avoid vessel injury. In the case of ostial calcifications balloon expandable stents should be used which are placed a few millimetres into the lumen of the aorta. Flexible nitinol stents may be used in the distal SMA. All patients should be heparinised to lower the risk

Figure 1 Conventional angiography of a 68 year-old patient who presented with weight loss and abdominal angina. The angiography shows an ostial stenosis of the celiac artery and a 1 cm stenosis of the superior mesenteric artery.

Figure 2 3-D reconstruction of a postoperative computed tomography. It shows the successful revascularisation of the common hepatic artery and the superior mesenteric artery by a ninfra-diaphragmatic bifurcation prosthesis.

of thromboembolism and/or stroke. Retrograde cannulation and stent placement of the SMA during laparotomy is another alternative approach which combines endovascular and open revascularisation of the occluded vessels.

CONVENTIONAL REVASCUARISATION

Open surgery requires a medial laparotomy since both the supracolic and the infracolic segments of the aorta have to be dissected. The celiac artery and the SMA are most frequently implicated in the disease process, and their involvement may result in chronic ischemia of the small intestine (Figure 1). Stenosis or occlusion of the IMA may lead to ischemic colitis. If both the celiac artery and the mesenteric arteries are involved, all arteries should be reconstructed to ensure long term prognosis^[12]. After mobilisation of the left hepatic lobe and transection of the right crus of the diaphragm the aorta may be tangentially clamped and longitudinal aortio-coeliac or aortomesenteric bypasses may be constructed using vein or prosthetic material (> 7 mm) (Figure 2). Bypass conduction to the mesenteric artery should follow a retro-pancreatic route to enter the mesenteric root. Here, a tunnel is formed left of the aorta. For a better hemodynamic approach to the SMA, bypasses are conducted curved around the left renal vein. Bypasses should be created tension free and kink-resistant. If longer clamping times are necessary, perfusion catheters may lengthen ischemic tolerance. For short ostial stenosis either transaortic endarterectomy with patch plasty or orthotopic short vein bypasses may be used.

EVIDENCE

So far no level 1 evidence governs the decision whether patients should receive endovascular or open revascularisation in chronic mesenteric ischemia. Early series showed a similar survival at 2 years between patients who received open revascularisation and patients who received a stent pta. No difference in the incidence of symptomatic or radiographic recurrence was found. However,

primary and assisted patency was significantly lower in the percutaneous transluminal angioplasty (PTA)/stent groups compared to OR^[13,14]. At the Cleveland clinics (United States) angioplasty and stenting was performed in 28 patients with chronic mesenteric ischemia. This cohort was compared to 85 patients who received open revascularisation^[15]. While no significant differences were found in terms of mortality, morbidity and restenosis rates, long term symptom recurrence was significantly higher in the endovascular group. In a large retrospective study major complications occurred in 7% of patients who underwent mesenteric artery stenting and resulted in higher mortality, morbidity, and longer hospital length of stay. The use of antiplatelet therapy reduced the risk of distal embolization or vessel thrombosis^[16].

A retrospective comparison at the Mayo clinic which involved 229 patients found a higher morbidity and longer hospital stay in patients after open surgery. Mortality was not different between the groups. Restenosis was five times more common in the endovascular group and symptom recurrence seven times more common than after open surgery^[17]. Restenosis within the stents occurs in nearly 40% of patients after stent placement in the mesenteric artery within the first 29 mo. Half of these patients require reintervention because of symptom recurrence or progression to an asymptomatic preocclusive lesion^[18]. This “in stent stenosis” is the result of intimal hyperplasia as a reaction to manipulation and trauma within the lumen of the artery. It involves apoptosis and the invasion of inflammatory cells. Vascular smooth muscle cells are recruited into the subendothelial space *via* signalling cascades involving tyrosin kinase receptors and the ras-pathway^[19]. The same pathways will be induced once more if a restenosis is treated by an endovascular approach. Furthermore endovascular interventions are associated with risk of access site and arterial complications from catheter and wire manipulation, balloon dilation, and stent placement. These risks are higher in the case of a reintervention on the SMA^[18]. In the mesenteric arteries, dissection, thrombosis, embolization, or perforation may result in bowel ischemia or bleeding,

necessitating additional “bail-out” manoeuvres, including emergency conversion to open repair. These complications can be fatal or result in significant morbidity and prolonged hospitalization if not recognized immediately. It is therefore advisable to change to open revascularisation especially in those patients in which endovascular treatment has already failed and who developed “in stent stenoses”.

CLINICAL PRACTISE

Today PTA/stent of the mesenteric artery has surpassed open bypass as the most frequently used option for mesenteric revascularisation, rendering open surgery as method of choice for these with unsuitable anatomy. Schermerhorn *et al*^[20] have reported on a 7 fold increase on mesenteric interventions. This was accompanied by a decrease in mortality from 15% with open bypass surgery to 4% with endovascular treatment. Kougiaris *et al*^[21] compared outcomes of endovascular treatment in a retrospective analysis which included 48 patients (58 vessels) in the endovascular group while open repair was performed in 96 patients (157 vessels). Endovascular treatment offered shorter hospitalization. Both groups had similar morbidity and mortality rates. Patients treated with surgical reconstruction were more likely to experience long-term symptomatic relief compared to endovascular cohorts, possibly due to higher incidence of two-vessel surgical revascularization^[21]. The enthusiasm for endovascular procedures is particularly surprising since no improvement of patency rates has been reported in the literature in the past 20 years^[22].

CONCLUSION

The durability and efficacy of open surgical repair are convincing over time. Therefore, open surgical revascularisation remains the treatment of choice for patients who are fit or whose fitness could be improved before surgery. Endovascular therapy has been proposed for patients at high risk for surgery and post surgical corrections. For these unfit patients, or those with short life expectancy, endovascular treatment is preferable owing to its minimally invasive nature and reduced postoperative mortality and morbidity. All others should be treated by conventional reconstruction especially if endovascular treatment has failed before. Randomized controlled studies or patient registries are needed to compare the long-term durability and efficacy of both procedures

Abstract

Early identification of acute mesenteric ischemia (AMI) is challenging. The wide variability in clinical presentation challenges providers to make an early accurate diagnosis. Despite major diagnostic and treatment advances over the past decades, mortality remains high. Arterial embolus and superior mesenteric artery thrombosis are common causes of AMI. Non-occlusive causes are less common, but vasculitis may be important, especially in younger people. Because of the unclear clinical presentation and non-specific laboratory findings, low clinical suspicion may lead to loss of valuable time. During this diagnostic delay, progression of ischemia to transmural bowel infarction with peritonitis and septicemia may further worsen patient outcomes. Several diagnostic modalities are used to assess possible AMI. Multi-detector row computed tomographic angiography is the current gold standard. Although computed tomographic angiography leads to an accurate diagnosis in many cases, early detection is a persistent problem. Because early diagnosis is vital to commence treatment, new diagnostic strategies are needed. A non-invasive simple biochemical test would

be ideal to increase clinical suspicion of AMI and would improve patient selection for radiographic evaluation. Thus, AMI could be diagnosed earlier with follow-up computed tomographic angiography or high spatial magnetic resonance imaging. Experimental *in vitro* and *in vivo* studies show promise for alpha glutathione S transferase and intestinal fatty acid binding protein as markers for AMI. Future research must confirm the clinical utility of these biochemical markers in the diagnosis of mesenteric ischemia.

van den Heijkant TC, Aerts BAC, Teijink JA, Buurman WA, Luyer MDP. Challenges in diagnosing mesenteric ischemia. *World J Gastroenterol* 2013; 19(9): 1338-1341 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i9/1338.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i9.1338>

INTRODUCTION

Mesenteric ischemia accounts for approximately 1% of acute abdomen hospitalizations and occurs in one in 1000 patients presenting to emergency rooms^[1,2]. Despite growing recognition of this entity and interest in preventing irreversible ischemia, identification and early diagnosis is challenging because early symptoms are non-specific^[3]. Despite major diagnostic and treatment advances over the past decades, low clinical suspicion leads to persistently high mortality rates of 40% to 70% for acute mesenteric ischemia (AMI)^[4]. Early diagnosis is necessary to commence appropriate treatment, whereas diagnostic delay contributes to poor patient outcomes. A 24-h delay decreases survival rates by 20%^[5]. Therefore, development of new diagnostic strategies is of great importance. Ideally, a highly specific and sensitive, non-invasive marker is needed to identify patients earlier.

MESENTERIC ISCHEMIA

Etiology and clinical presentation

In 70% to 80% of cases, intestinal ischemia is caused by an arterial embolus or thrombosis within the superior mesenteric artery. In cases of embolic occlusion, the absence of a well-developed collateral circulation causes earlier ischemia and transmural necrosis compared to other causes of mesenteric ischemia. Less common causes are venous thrombosis and non-thrombotic mechanical causes such as strangulated hernia^[6]. Patients with a history of arterial emboli, vasculitis, deep venous thrombosis, hypercoagulable state, or chronic postprandial pain are at increased risk^[7]. Vasculitis is a common cause of mesenteric ischemia in younger people with auto-immune disease^[8]. Finally, case reports implicate vascular anomalies as a cause of mesenteric ischemia^[9,10].

There are a wide variety of clinical presentations for mesenteric ischemic. Classically, AMI is associated with a dramatic onset of severe abdominal pain disproportionate to physical exam findings. Peritonitis and septicemia develop once the ischemia has progressed transmurally^[3]. Postprandial pain, nausea and weight loss often occur in patients with chronic mesenteric ischemia and superior mesenteric artery thrombosis^[3]. In chronic mesenteric ischemia, the association of pain with meals leads to fear of eating and subsequent weight loss^[7].

Early diagnosis is challenging because of the wide variability in clinical presentation of mesenteric ischemia.

Laboratory findings

Classically, patients with mesenteric ischemia have leukocytosis, metabolic acidosis, an elevated D-dimer and elevated serum lactate^[3]. Although profound leukocytosis with peripheral white blood cell counts exceeding $20 \times 10^9/L$ have been reported, this finding is not useful to distinguish AMI from other diagnoses^[11,12]. In a prospective clinical trial, Acosta *et al.*^[13] investigated the classically described metabolic acidosis. In their study, initial blood gas analysis showed metabolic alkalosis more frequently than metabolic acidosis; this finding results from profound vomiting during early bowel ischemia. D-dimer is also purported as an important tool in diagnosing AMI. However, D-dimer, an enzymatic degradation product of fibrin that is released during intravascular coagulation and fibrin deposition, may be present with AMI as well as several other conditions^[14]. A recent trial demonstrated that serum D-dimer detection does not differentiate patients with AMI from those with non-acute mesenteric ischemia, and that there is no difference in serum D-dimer levels between resectable and unresectable bowel necrosis lesions^[15]. L-lactate is associated with late-stage mesenteric ischemia with extensive transmural intestinal infarction, body tissue hypoperfusion, anaerobic metabolism and death^[16]. Some studies report absence of systemic plasma L-lactate elevation in cases of extensive intestinal ischemia. This absence of L-lactate is probably explained by the liver's capacity to clear large quantities of L-lactate from the porto-mesenteric circulation^[17]. A recent study

Table 1 Sensitivity, specificity and likelihood ratios for laboratory findings classically associated with mesenteric ischemia

| Marker | Sensitivity | Specificity | Positive likelihood-ratio (95%CI) | Positive likelihood-ratio (95%CI) |
|------------------------|-------------|-------------|-----------------------------------|-----------------------------------|
| WBC count ¹ | 0.80 | 0.50 | 1.57 (1.07, 2.27) | 0.41 (0.20, 0.83) |
| pH ¹ | 0.38 | 0.84 | 2.49 (0.82, 7.51) | 0.71 (0.45, 1.14) |
| D-dimer ¹ | 0.89 | 0.40 | 1.48 (1.28, 1.71) | 0.30 (0.14, 0.64) |

¹Evennett *et al.*^[19]. WBC: White blood cell.

by Thuijls *et al.*^[18] confirmed that plasma L-lactate level, base excess and leukocyte count cannot be used as markers of mesenteric ischemia. In that study, fifty consecutive patients suspected of having intestinal ischemia provided blood and urine samples. Plasma L-lactate level, base excess and leukocyte count were nondiscriminatory in determining whether patients had intestinal ischemia or other disease such as stomach perforation, pancreatitis or perforated appendicitis. Leukocyte counts in that study did not differ significantly between groups ($13.9 \times 10^9/L$ in the mesenteric ischemia group versus $12.7 \times 10^9/L$ in the control group).

Table 1 shows that classically described laboratory findings cannot be used as markers for AMI because of their insufficient likelihood ratios^[19]. These laboratory findings are not sensitive or specific enough to establish or exclude the diagnosis of AMI. Elevations in AMI serum markers usually occur only after transmural bowel infarction, and therefore, cannot be used for early diagnosis^[7].

Imaging techniques

The American Gastroenterological Association guideline (2000) states that mesenteric angiography is the gold standard for the diagnosis of mesenteric ischemia^[7]. When the clinician is aware of possible AMI, angiography is accurate and increases survival^[20]. However, catheter angiography is invasive and time consuming. Furthermore, the unavailability of this diagnostic modality at most hospitals leads to a critical delay. At the time of the 2000 guideline, computed tomography (CT)-angiography (CTA) seemed promising, but there was limited experience with this modality then. Over the last decade, however, there has been a major shift toward CTA because it is less invasive, less time- and resource-consuming, and more readily available. Today, CTA has replaced angiography as the gold standard in diagnosing mesenteric ischemia with a sensitivity and specificity of 0.96 and 0.94, respectively^[21,22]. These sensitivity and specificity results were obtained in a dedicated study with structural CT evaluation for all AMI characteristics. Generalizability of these outstanding diagnostic values is questionable because it is unlikely whether all AMI characteristics are evaluated by specialized radiologists at all practice locations.

Wiesner *et al.*^[23] described a group of 291 patients who presented with acute abdomen and underwent multidetector-row computed tomographic scans. All original computed tomographic diagnoses were made

during several radiologists' daily routines. The sensitivity and specificity of multidetector-row CTA for the diagnosis of AMI were 0.79 and 0.98, respectively. These statistical measures may better reflect daily practice. In these cases, no focused structural radiological search for characteristics of intestinal ischemia was performed. There were different examination protocols because of variation in suspected diagnosis. Arterial phase scanning was not performed regularly if there was no specific clinical indication. Based on the current evidence, CTA is acceptable and accurate in diagnosing AMI; however, early identification of patients remains a challenge. Early identification could alert the radiologist to perform structural evaluations of CT scans specific for AMI, so as to increase the sensitivity of CTA^[21].

NEW DIAGNOSTIC STRATEGIES

New diagnostic strategies aim for early identification (*e.g.*, biochemical markers) or seek to optimize accurate diagnosis using existing modalities such as contrast-enhanced magnetic resonance angiography (CE-MRA). CE-MRA of the splanchnic vessels is an evolving technology which is theoretically appealing because it is non-invasive and avoids the nephrotoxicity and allergic risks associated with iodinated contrast agents^[22]. Dynamic CE-MRA yielded a sensitivity and specificity of 0.95 and 1.00, respectively, in a clinical trial designed to diagnose severe stenosis or occlusion of the origins of the celiac axes and superior mesenteric artery^[24]. However, this modality is limited to identification of more distally located occlusions and does not have the same spatial resolution and acquisition time as CTA^[14]. If better spatial resolution becomes available in the future, CE-MRA has the potential to become the diagnostic modality of choice.

Non-contrast-enhanced 7 tesla magnetic resonance imaging (7T-MRI) is a recently developed diagnostic modality. A study using an *in vivo* rat model for mesenteric ischemia demonstrated that 7T-MRI allows for the identification of pathological findings of ischemic colitis and histopathological correlation^[25]. Further research is needed to substantiate these promising results in human clinical situations.

Biochemical markers for early detection

In AMI, ischemia starts at the mucosa and extends toward the serosa^[16]. An ideal biomarker for mesenteric ischemia should originate at the mucosa to detect ischemia at the earliest stage. According to a recent review by Evennett *et al.*^[19], intestinal fatty acid binding protein (I-FABP), alpha-glutathione S transferase (GST) and D-lactate are the most promising plasma markers for mesenteric ischemia. Fatty acid binding proteins comprise a class of low molecular weight (14-15 kDa) cytosolic proteins. I-FABP is a small cytosolic protein found in tissues involved in uptake and consumption of fatty acids. It is highly expressed in cells on the luminal side of small intestinal villi. I-FABP is released into the circulation and

renally cleared upon enterocyte membrane integrity loss. These characteristics, combined with localization at the initial site of destruction in mesenteric ischemia, make I-FABP a useful urinary and plasma marker for enterocyte damage^[26]. Urinary and plasma I-FABP levels are significantly elevated in patients with intestinal ischemia compared to healthy controls^[27]. Furthermore, I-FABP levels were increased in patients with small intestinal necrosis, but not patients without intestinal ischemia in a patient population with suspected ischemia due to small bowel obstruction^[28]. I-FABP has been reported as a specific and sensitive marker for postoperative intestinal necrosis^[25]. A recent clinical trial demonstrated a high sensitivity and specificity of 0.90 and 0.89, respectively, for urinary I-FABP^[18]. The rapid clearance of plasma FABPs (calculated half-life time of eleven minutes^[29]) into urine plus urinary FABP accumulation following intestinal damage make urinary FABP more diagnostically useful compared to plasma FABP^[26]. These findings suggest that further research is needed to confirm the diagnostic value of I-FABP in cases of mesenteric ischemia.

Other potential early markers of AMI are alpha-GSTs, a family of cytosolic enzymes involved in detoxification and released from a variety of cells following cell membrane damage^[30]. GST is involved in detoxification of a range of toxic compounds within the cell by conjugation to glutathione. Alpha-GST is known to be highly active both in the liver and the small intestine mucosa^[16]. Alpha-GST has pooled sensitivity and specificity for diagnosing AMI of 0.68 and 0.85, respectively. A limitation of alpha-GST is that hypotensive patients with multiple organ failure and hepatic ischemia may also have elevated alpha-GST levels with concomitant ASAT and ALAT abnormalities.

A third suggested marker for AMI is D-lactate, which originates from bacteria such as *Escherichia coli* in the intestinal lumen^[17]. It was hypothesized that D-lactate levels increase during mesenteric ischemia due to bacterial translocation and overgrowth following mucosal injury. However, a recent review showed a pooled sensitivity and specificity for D-lactate of only 0.82 and 0.48, respectively. Therefore, D-lactate cannot be used as a marker for AMI, given the superiority of alternatives such as I-FABP and alpha-GST.

CONCLUSION

AMI is a rare condition with a non-specific clinical presentation which makes early diagnosis challenging. Despite technical advances in imaging leading to more accurate diagnosis, AMI is often diagnosed late or even missed due to low clinical suspicion; therefore, a high mortality rate results.

A readily available, simple, highly sensitive and specific marker to identify patients with AMI early would be of great importance in selecting candidates for CTA. Future research must confirm the clinical utility of promising biochemical markers such as I-FABP and GST.

Abstract

Hepatitis B virus (HBV) is a very common infection worldwide. Its reactivation in patients receiving immunosuppression has been widely described as being associated with significant morbidity and mortality unless anti-viral prophylaxis is administered. Treatment in inflammatory bowel disease (IBD) patients has changed in recent years and immunosuppression and biological therapies are now used more frequently than before. Although current studies have reported an incidence of hepatitis B in inflammatory bowel disease patients similar to that in the general population, associated liver damage remains an important concern in this setting. Liver dysfunction may manifest in several ways, from a subtle change in serum aminotransferase levels to fulminant liver failure and death. Patients undergoing double immunosuppression are at a higher risk, and reactivation usually occurs after more than one year of treatment. As preventive measures, all IBD patients should be screened for HBV markers at diagnosis and those who are positive for the hepatitis B surface

antigen should receive antiviral prophylaxis before undergoing immunosuppression in order to avoid HBV reactivation. Tenofovir/entecavir are preferred to lamivudine as nucleos(t)ide analogues due to their better resistance profile. In patients with occult or resolved HBV, viral reactivation does not appear to be a relevant issue and regular DNA determination is recommended during immunosuppression therapy. Consensus guidelines on this topic have been published in recent years. The prevention and management of HBV infection in IBD patients is addressed in this review in order to address practical recommendations

INTRODUCTION

Approximately 3 billion people have been exposed to the hepatitis B virus (HBV), and there are an estimated 350 million chronic carriers worldwide^[1,2]. Exposure to HBV can be broadly divided into three categories according to viral load and liver biopsy^[1,3]: active HBV, inactive HBV carriers and resolved HBV (Table 1). Chronic hepatitis B (CHB) may result in cirrhosis in about 5%-25% of infected patients.

Active chronic HBV is defined as HBV DNA levels ≥ 2 IU/L and elevated alanine aminotransferase (ALT) levels, and treatment is indicated in either immunocom-

petent or immunosuppressed patients.

Inactive hepatitis B is defined by HBV DNA levels ≤ 2 IU/L and normal ALT levels, and antiviral therapy is not indicated in immunocompetent patients. However, in patients treated with immunosuppressant drugs, viral reactivation may occur regardless of DNA levels, so antiviral prophylaxis must be established.

Finally, patients with resolved HBV infection do not need antiviral therapy, but they must be monitored during immunosuppressant therapy and considered for prophylactic therapy based on the progression of anti-HBc or HBV DNA levels.

Ulcerative colitis (UC) and Crohn's disease (CD) are chronic inflammatory conditions of the gastrointestinal tract. In the last 10 years, treatment of these inflammatory bowel diseases (IBD) has been markedly changed by the use of immunosuppressants (mainly azathioprine/mercaptopurine and methotrexate) and biological therapies. There is an increasing trend towards earlier and more extensive use of these drugs for longer periods of time. As a result, concerns regarding safety related to immunosuppressive treatment are growing^[4,5] among the professionals involved in providing IBD care. One of these issues is related to the reactivation of hepatitis B; immunomodulator therapy has a clear impact on the natural history of viral hepatitis and there are many unresolved questions concerning the relationship between IBD and HBV that must be resolved. The management of IBD patients with viral hepatitis B is addressed in this review.

PREVALENCE OF HBV INFECTION IN IBD PATIENTS

The first step in addressing the problem is to identify its impact. The prevalence of patients with IBD who are at risk for hepatitis B reactivation has been clarified in a prospective cross-sectional nationwide study in Spain^[6]. In this multicentre study of 2076 IBD patients, the prevalence of biological markers of present and/or past hepatitis B was lower than reported in previous studies and similar to the Spanish general population: less than 1% of IBD patients had positive hepatitis B surface antigen (HBsAg) and less than 10% had positive hepatitis B core antibody (HBcAb), without differences between CD and UC patients (7.1% and 8% respectively). Similar results were also shown in a recent study in France^[7], where HBcAb was reported in only 2.78% and 1.59% of CD and UC patients, respectively; similar rates were observed in the general French population.

In previous studies^[8-10], the prevalence of HBV infection in IBD patients was shown to be comparatively higher. Biancone *et al*^[9] reported positive anti-HBc in 10.9% and 11.5% of CD and UC patients in Italy, respectively, compared to 5.1% in controls ($P < 0.02$). The risk of viral hepatitis in IBD patients has been associated with blood transfusions and surgery^[11,12], suggesting nosocomial transmission of the virus. The decreasing prevalence

of viral hepatitis in IBD patients in current reports from Spain and France suggests that preventative measures such as vaccination, the World Health Organization blood transfusion safety programs, single-use materials, and better aseptic perioperative rules and decontamination procedures in endoscopy^[7], have been effective and explains the diminishing risk for HBV.

EFFECT OF IMMUNOSUPPRESSIVE THERAPY ON HBV INFECTION

Reactivation of HBV infection is a well-described complication of immunosuppression in the setting of organ transplantation or cancer chemotherapy^[13]. The frequency of HBV reactivation depends on the type of immunosuppression and the state of HBV infection when chemotherapy is administered^[14-16]. Cytotoxic chemotherapy for hematologic malignancies appears to involve the greatest risk of HBV reactivation; spontaneous reactivation may occur in up to 22% of inactive HBV carriers, but this may increase up to 60% of patients in the case of cytotoxic chemotherapy for lymphoma, with a mortality rate between 4% and 60% if fulminant liver failure occurs^[17-19].

In patients undergoing treatment with biologic agents, hepatitis B reactivation represents an emerging cause of liver disease^[20]. In particular, the risk of HBV reactivation is greatly increased with the use of monoclonal antibodies such as rituximab (anti-CD20) and alemtuzumab (anti-CD52)^[21-23]. Based on the liver damage that occurs after viral reactivation, three kinds of liver disease^[4] can be distinguished: viral reactivation or replication, acute liver failure, and fulminant liver failure. For hepatitis B, reactivation is defined as a 1.5-2-fold increase in ALT compared with the baseline value plus an increase in HBV DNA levels > 2 IU/L or DNA reappearance in a previously negative patient^[24,25]. Acute liver failure is defined as sudden and severe impairment of liver function (bilirubin > 2 mg/dL, albumin < 34 g/L or prothrombin time $< 50\%$), meanwhile fulminant liver failure is a severe acute failure complicated by hepatic encephalopathy, liver transplantation, or death^[25].

Fatal viral reactivation has also been described in patients with IBD or other autoimmune diseases treated with immunosuppressant drugs^[26-29]. Tumor necrosis factor alpha (TNF- α) is important in regulating hepatitis B replication^[30], and the chimeric anti-tumour necrosis factor alpha monoclonal antibody infliximab has been involved in hepatitis B reactivation following treatment^[31-35]. However, the factors that may increase the risk are not properly defined^[36,37]. Additionally, there are no specific data on prophylaxis in IBD patients, the type and the timing of treatment, and which individuals make the most suitable candidates^[38-40].

Most of the information available comes from case reports about HBV reactivation in patients with CD or UC, both after the use of corticoids, with or without azathioprine and biologic therapy with infliximab^[41].

Table 1 Definitions of hepatitis B virus infection

| | HBsAg | HBsAb | HBcAb | HBV DNA | | ALT/AST | Liver biopsy |
|----------------------|----------|----------|----------|---------------|--------------|----------|--|
| | | | | HBeAg (+) | HBeAg (-) | | |
| Chronic HBV | Positive | Negative | Positive | > 20000 IU/mL | > 2000 IU/mL | Elevated | Chronic hepatitis with necroinflammation |
| Inactive HBV Carrier | Positive | Negative | Positive | < 20000 IU/mL | < 2000 IU/mL | Normal | No significant hepatitis |
| Resolved HBV | Negative | Positive | Positive | Undetectable | Undetectable | Normal | No significant hepatitis |

HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; HBsAb: Hepatitis B surface antibody; HBcAb: Hepatitis B core antibody; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

In 2004, Esteve *et al*^[42] reported three CD patients, which were hepatitis B carriers, treated with infliximab. One of them received concomitant lamivudine therapy and experienced no variations in clinical or biochemical liver parameters. However, the other two patients suffered from viral reactivation; one patient died and the other resolved after specific treatment. Reactivation may occur as soon as after the first infusion or as late as 2 years after starting infliximab, indicating that it may develop at any time during anti-TNF therapy, however, the time between the start of TNF- α inhibitors and the occurrence of hepatitis is usually longer than one year^[43].

A relevant characteristic is that almost all cases of infliximab-associated HBV reactivation have occurred in patients receiving concomitant treatment with other immunosuppressants such as corticosteroids or thiopurines, suggesting that more profound immunosuppression may facilitate viral reactivation^[26,38-40]. In a Spanish cooperative study (REPENTINA-2) on this problem^[26], 120 patients with hepatitis B or hepatitis B and C markers who had been treated with immunosuppressive therapy during a median time of 1 year were identified. The authors retrospectively assessed the frequency and severity of liver disease in these patients based on exposure to one or more immunosuppressive drugs. Although they identified 25 HBsAg-positive patients, unfortunately only 6 of them had received antiviral treatment before immunosuppression. Nine of these 25 patients developed liver disease, six developed liver failure, and none had fulminant liver failure. Almost all cases of HBV reactivation associated with infliximab occurred in patients receiving concomitant treatment with other immunosuppressants. REPENTINA-2 also showed that no single immunosuppressant seems to be specifically involved in the development of liver failure, and the risk of hepatitis B reactivation seems to be related to the magnitude of immunosuppression.

Regarding other anti-TNF treatments, reactivation has also been reported with adalimumab or etanercept in patients with rheumatoid arthritis^[44-46], but not from IBD patients or those taking certolizumab pegol. As these are newer TNF antagonists, the risk of hepatitis B reactivation is expected to be similar due to a class effect^[4,15].

Regarding patients with resolved HBV infection, reactivation following chemotherapy has also been reported in up to 40% of patients^[17,47-49], though the risk in IBD seems to be much lower. Although there has been a

report of reactivation after treatment with infliximab in a patient with CD and occult HBV infection^[47], no cases were described in the REPENTINA-2 study. In other autoimmune diseases such as rheumatoid arthritis (RA), this issue has also been examined and reactivation rates have not been relevant^[50,51]. Tamori *et al*^[52] followed 50 patients with RA who were positive for HBcAb for a mean period of 23 mo. All were patients treated with immunosuppressive agents such as methotrexate, prednisolone, and/or TNF- α inhibitors for more than one year. HBV reactivation was observed in two out of five patients with HBsAg, compared with only one of the remaining 45 patients without it.

On the other hand, the results from a retrospective analysis of 62 psoriatic patients^[53] with occult HBV infection, treated with anti-TNF biological agents, and without signs of HBV activation after a period of 4 years, also suggest the overall safety of treatment with anti-TNF and/or immunosuppressants drugs in HBV occult carriers.

SCREENING RECOMMENDATIONS

Screening measures must be instituted in IBD patients^[4,54-56]. Recommendations are based on the potentially fatal consequences of HBV reactivation, as we have seen previously, and the availability of safe and effective anti-HBV drugs to prevent them^[57]. Current guidelines by the American Association for the Study of Liver Diseases (AASLD) recommend HBV screening for populations with an intermediate or high prevalence (> 2%) and those requiring immunosuppression, including IBD patients^[3].

Screening for HBV should be performed at the time of IBD diagnosis rather than delaying until consideration of immunomodulators or TNF antagonist medication^[3,58-60]. The hepatitis B surface antibody (HBsAb), and the HBsAg and HBcAb are recommended as screening tests. Although the utility of HBcAb is controversial, it may represent chronic HBV despite undetectable HBsAg/HBsAb in immunosuppressed patients or those co-infected with hepatitis C or human immunodeficiency virus^[3,58], but it may also be falsely elevated in a low percentage of patients.

ANTIVIRAL PROPHYLAXIS

In accordance with specific guidelines for hepatitis B

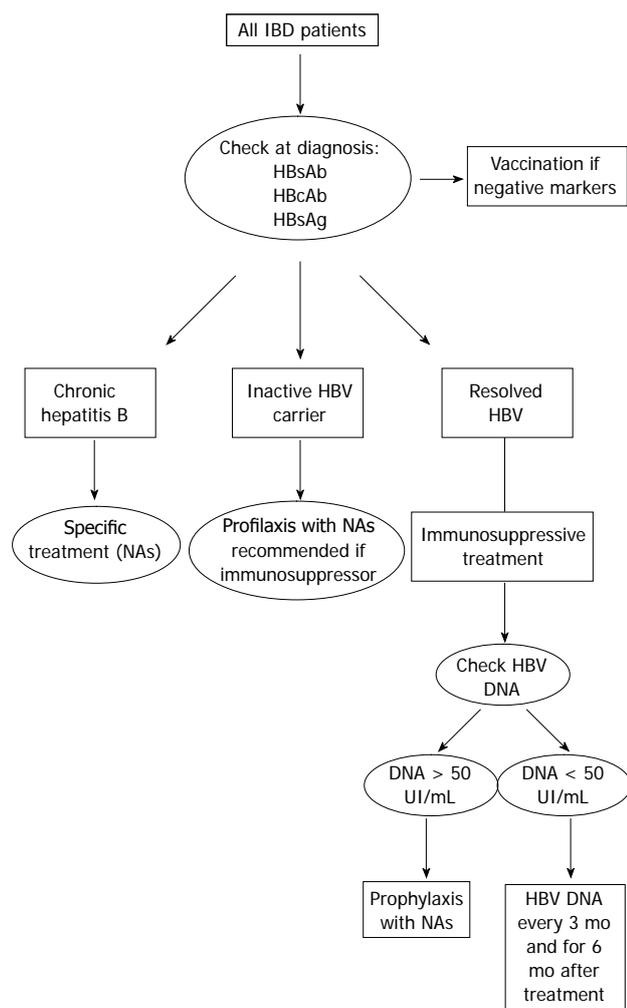

Figure 1 An algorithm for the management of patient with inflammatory bowel disease with different hepatitis B virus infection status. NAs: Nucleos(t)ide analogues; IBD: Inflammatory bowel disease; HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; HBsAb: Hepatitis B surface antibody; HBcAb: Hepatitis B core antibody.

(Figure 1)^[3], patients with high baseline HBV DNA levels (> 2 IU/L) should continue antiviral treatment until the endpoints applicable to non-immunosuppressed patients are reached.

Prophylaxis must be considered in patients with HBsAg without active viral replication prior to undergoing treatment with any immunosuppressant medication, including steroids, immunomodulators or biologicals, in order to prevent reactivation^[3,59].

While there are no data specifically for IBD, recommendations are extrapolated from randomized controlled trials in patients undergoing chemotherapy^[60-62] in which prophylaxis has been shown to be beneficial^[63,64]. Lau *et al.*^[65] randomized 30 lymphoma patients with HBV markers to lamivudine prophylaxis or no prophylaxis before chemotherapy. None of the patients receiving prophylaxis developed HBV reactivation, compared to 53% of those in the no prophylaxis group ($P = 0.002$). A recent meta-analysis^[66] of lamivudine in immunosuppressed patients included 21 studies and showed a mortality benefit

for lamivudine (OR: 0.36; 95%CI: 0.23-0.56).

The AASLD^[3] and the European Association for the Study of the Liver^[67] recommend the early introduction of nucleoside/nucleotide analogues (NAs) for all HBsAg-positive patients requiring immunosuppressive therapy. HBV prophylaxis must be introduced at least 7 d before therapy and it should be maintained for 6 mo to 1 year after completion of chemotherapy, as HBV reactivation may occur after chemotherapy is discontinued^[3,4]. The European Crohn's and Colitis Organisation^[57] also recommend an early introduction of NAs in HBsAg-positive IBD patients requiring immunosuppression, regardless of the number and type of immunosuppressants. However, it must be initiated between one and 3 wk prior to the introduction of immunosuppressive therapy and continued for 6 mo after its cessation^[11,57].

Lamivudine has been the most common drug used in this setting; however, resistance usually develops with prolonged use and has been detected in up to 30% of patients after 1 year and 70% after 5 years of treatment^[66,67]. Resistance has also been described in patients on long-term anti-TNF therapy, which is associated with viral reactivation as reported by Esteve *et al.*^[27] in a CD patient taking lamivudine for more than 5 years. Therefore, this agent may be appropriate for a short course of prophylaxis during chemotherapy but, as immunosuppressive medications for IBD may be required indefinitely, NAs with a lower propensity than lamivudine for generating drug-resistant mutations of HBV DNA must be chosen. Although alternative antiviral medications, such as tenofovir, adefovir, telbivudine and entecavir, have not been evaluated in prophylaxis for IBD patients, tenofovir and entecavir have the lowest rates of resistance with long-term use and should be preferred.

In cases in which lamivudine, adefovir or telbivudine are used, serum aminotransferase levels and HBV DNA levels must be closely followed for signs of drug resistance. Interferon- α must not be used for prophylaxis^[57].

In HBe-positive patients who are lacking HBsAg and have resolved hepatitis B, systematic use of antiviral prophylaxis in IBD patients is not recommended^[1,21,49]. This approach differs from the recommendation for patients undergoing chemotherapy and particularly for rituximab, in which anti-viral prophylaxis is desirable^[21-23,49,68]. Nevertheless, careful and constant monitoring of virological markers, including HBV DNA, is required in these patients during treatment for early recognition of viral reactivation and therapy with NAs at an early stage^[69,70] (Figure 1).

In conclusion, new therapies in IBD patients are increasing the risk for HBV reactivation. All patients should be screened for HBV markers, preferably at diagnosis.

Current guidelines recommend screening with HBsAg and anti-HBs, but anti-HBe must also be considered so as to detect occult HBV. HBsAg positive patients requiring immunosuppressive therapy should receive antiviral treatment, regardless of HBV DNA level. Prophylaxis with nucleos(t)ide analogues must be introduced at least 3 wk before, but as immunosuppressive drugs may be required

indefinitely, NA with a low rate of resistance (tenofovir or entecavir) should be preferred. Patients with positive anti-HBc without HBsAg and undetectable viral DNA should be monitored closely for reactivation.

Abstract

Inflammatory bowel disease (IBD) is associated with conditions that may predispose to infections, such as the lack of an appropriate innate immune response to infectious agents, malnutrition, surgery, and immunosuppressive and biological drugs. Some of these infections may be preventable by vaccination. Therefore, for this particular patient population, the benefits of implementing a well-established immunization protocol in daily clinical practice are potentially even greater than for the general population. In recent years international consensus guidelines have been published, but in spite of these recommendations, studies have shown that a significant number of patients with IBD remain inadequately immunized. Another important issue regarding immunization in this population is that vaccine efficacy among patients receiving immunosuppressive therapies has been variable. In a healthy population, a humoral immune response to hepatitis B vaccination (HBV) is expected in > 90%, whereas a much lower rate is achieved in the IBD patients. Immunosuppressive, anti-tumor necrosis factor therapy and disease activity have been implicated in the impaired efficacy of the

vaccination. The serological response to HBV should be confirmed and patients with an inadequate response should receive a second full series of vaccine. Modified dosing regimens, including doubling the standard antigen dose, might increase the effectiveness. Response to influenza, pneumococcal and tetanus immunization is still not clear, as there are studies that show a normal response to the vaccination while others demonstrate a lack of efficacy. We pose a series of questions on the efficacy of the different vaccinations recommended for IBD patients and attempt to answer them using scientific evidence.

INTRODUCTION

Current therapy for inflammatory bowel disease (IBD) patients often involves agents that suppress the immune system, placing them at an increased risk for developing infections. In recent years the scientific community has made an effort toward promoting preventative and prophylactic strategies against some of these infections^[1-5]. Several guidelines have been published specifically for the vaccination and immunization of patients with IBD^[6-9]. Although a consensus exists on the need to vaccinate these patients, it seems to be underused in clinical practice, and the response to immunizations in this group of patients and the factors influencing this efficacy is unknown.

ARE IBD PATIENTS CORRECTLY VACCINATED IN CLINICAL PRACTICE?

When we try to elucidate the real efficacy of vaccinations in IBD patients, the first question we have to answer is if physicians are following the immunization and vaccination recommendations provided by the guidelines. Several studies have reported on apparent knowledge deficiencies among gastroenterologists, and show that a significant number of patients remain inadequately immunized. Yeung *et al.*^[10] assessed 167 patients and 43 gastroenterologists for immunization attitudes, knowledge and practice. Only 14% of the gastroenterologists surveyed reported taking an immunization history from most of their patients, and the majority of patients felt they did not have enough information about immunizations. Similar data were highlighted in another study, where around a half of the gastroenterologists surveyed remembered asking their patients about their immunization history^[11]. Melmed *et al.*^[12] assessed risk of exposure and immunization status among patients receiving care in an IBD specialty clinic. While about 44% of patients had at least one risk factor for hepatitis B, only 28% had been vaccinated against the infection. Only 45% of the patients in this study recalled receiving a tetanus immunization within the past 10 years, 28% reported regular flu shots and 9% reported having received the pneumococcal vaccine. A Spanish multicenter study detected vaccination against hepatitis B in only 12% of IBD patients^[13].

About 20% of the gastroenterologists surveyed reported that they did not know how important it was for their IBD patients to be up to date on specific immunizations before starting immunomodulating or biological therapy^[10].

In summary, the lack of awareness of vaccination recommendations puts IBD patients at risk of infections which might easily be avoided through a more intensive vaccination program^[14].

HOW EFFECTIVE ARE VACCINATIONS IN IBD PATIENTS?

Vaccine efficacy is defined as percent risk reduction for clinically significant infection in a vaccinated group versus a control group^[15].

Vaccination is a proven and well-established strategy for preventing infectious diseases in the general population. However, immunosuppressive illnesses in general are associated with reduced immunogenicity following vaccination^[16,17]. Moreover, patients receiving immunosuppressive therapy may have a suboptimal serological response after a variety of vaccinations^[18-22].

Hepatitis B virus

A standard 3-dose hepatitis B virus (HBV) vaccination induces protective antibody concentrations in approximately 95% of healthy individuals^[16,23,24]. However the response rate to HBV is lower in patients with IBD, es-

pecially in those receiving immunosuppressive or biological therapies. In a study published by Vida *et al.*^[25], where 43% were on immunosuppressive therapy, only 36% of patients achieved adequate hepatitis B surface antibody (HBsAb) levels (defined as > 10 IU/L). Melmed *et al.*^[12] report similar data in a study where only 33% of the subgroup of patients who were immunized had detectable antibodies to hepatitis B surface antigen (anti-HBs) titers.

According to the World Health Organization, an HBsAb concentration ≥ 10 IU/L is considered a reliable marker of protection against infection^[23,24,26-28].

As time passes, HBsAb titers frequently diminish and become undetectable^[29]. Among immunocompromised patients who respond to the vaccine, clinical HBV infection has been documented in those who do not maintain a HBsAb concentration of ≥ 10 IU/L. Based on this evidence, in the United Kingdom seroprotection against hepatitis B was redefined at ≥ 100 IU/mL, especially in those with chronic diseases or with immunosuppressive therapies^[16,28,30,31]. A recent study published by Altunöz *et al.*^[30] defined the effective immune response as an antibody level > 100 IU/L after comparing the efficacy of the standard 3-dose vaccine in a group of IBD patients and comparing it to a control group. The effective immune response was significantly higher in the control group compared to the IBD group (89% *vs* 53%).

The response rate to the HBV vaccine seems to be quite low in IBD patients. Modified dosing regimens, including doubling the standard antigen dose, might increase response rates in immunocompromised patients^[28,32-35]. Chaparro *et al.*^[36] assessed the efficacy of the HBV vaccine at a double dosage (0, 1 and 2 mo) in IBD patients and found that 60% of the IBD patients had adequate HBsAb titers (≥ 10 IU/mL), but only 34% achieved adequate immunity (≥ 100 IU/mL).

Influenza

Since influenza infection may result in serious illness in immunocompromised individuals, the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention recommends influenza vaccination for all immunosuppressed patients^[37]. Several studies have concluded that the influenza vaccine is safe and effective in both children and adults with various chronic diseases^[38-41]. However, the immune response in immunocompromised patients varies. Most studies attempting to identify the efficacy of the influenza vaccine in IBD patients have been carried out in the pediatric population. Mamula *et al.*^[42] compared response to influenza vaccine in children with IBD and observed that the IBD group mounted less effective responses to one-third of antigens compared to controls, while patients on a combination of biologics and immunomodulators had an impaired response to two-thirds of antigens. In contrast, Lu *et al.*^[43] assessed the response rates to influenza vaccinations in IBD children and reported similar responses among IBD patients, regardless of their immunosuppressive status. A recent study performed in adults came to

similar conclusions and demonstrated that IBD patients on immunosuppressive treatment are able to mount an effective immune response^[44].

Pneumococcal

Melmed *et al*^[45] assessed response to pneumococcal vaccine in IBD adults compared to controls. Patients treated with a combination of biologics and immunosuppressants presented with an impaired response to the pneumococcal vaccine compared to controls and patients not receiving immunosuppressive therapy. Dotan *et al*^[44] reported contradictory results in a recent study where they concluded that IBD patients do not have an intrinsic immunodeficiency and display a significant increase in titers for all pneumococcal serotypes.

Tetanus

Response to tetanus immunization in IBD patients is not clear, as there are studies^[44,46] that demonstrate that IBD patients have a normal response to the tetanus vaccine, while others^[47] suggest an impaired anti-tetanus response.

WHAT ARE THE FACTORS THAT AFFECT THE EFFICACY OF VACCINATION IN IBD PATIENTS?

In healthy individuals, several risk factors for non-response to hepatitis B vaccination have been described, such as smoking, older age, male gender and a high body mass index^[24]. Influenza immunization may be less effective for those in the general population with certain medical conditions, such as systemic lupus erythematosus^[48] or patients receiving immunosuppressive treatments^[49].

The lack of response to vaccines by IBD patients may be due to associated immunosuppressive and anti-tumor necrosis factor (TNF) treatments rather than IBD *per se*. In this sense, some authors have demonstrated a suboptimal response to pneumococcal vaccination in patients with IBD under combination therapy with anti-TNF drugs and immunosuppressants^[42], while IBD patients who received non-immunosuppressive therapy exhibited a good response to the vaccine^[45].

Patients on anti-TNF agents have demonstrated a decreased immune response to influenza vaccine in IBD and non-IBD populations^[22,42,43]. HBV vaccination is also influenced by the medication administered. In a study by Chaparro *et al*^[36], 40% of patients had an adequate response to immunization (> 100 IU/L), while the response was much lower in patients undergoing biological therapy (10%), although this difference did not achieve statistical significance, probably due to the small size sample. Altunoz *et al*^[30] assessed immune response to HBV vaccination, and demonstrated in their subgroup analysis that the group of patients not under immunosuppressive treatment achieved an adequate immune response (> 10 IU/L) in 91% and an effective immune response (> 100 IU/L) in 73%, whereas only 61% and 29% of

patients under immunosuppressive therapy, respectively, acquired an adequate and effective immune response. There are contradictory results by Vida *et al*^[25] that could not demonstrate the effect of immunomodulators on the efficacy of the HBV vaccine. The small sample size and corresponding low statistical power may explain the lack of statistically significant differences. In fact, a tendency towards a lower rate of response to vaccine was found in the immunosuppressed group^[28].

Disease activity has also been implicated in impaired responses to vaccination. In this respect, a subanalysis in the study by Altunoz *et al*^[30] concluded that active IBD patients achieved a significantly lower response to vaccination compared to patients in remission (41% *vs* 63%). Thus, these authors recommend HBV vaccination during remission periods.

In summary, patients receiving anti-TNF therapy, immunosuppressants, or with active disease, are at risk of developing an inadequate serologic response. Future studies should attempt to determine if booster immunizations are needed in this group of patients^[43]. Further studies should determine if other factors such as genetics, gender or age could affect the response to immunization in IBD patients.

WHAT CAN WE DO IF REGULAR VACCINATION IS NOT EFFECTIVE?

Although routine serology testing for immunity is not recommended after HBV vaccination in adults, post-vaccination serology is advisable for high-risk individuals such as the immunocompromised, including IBD patients^[16,24,28,50]. Recommended seroprotection against HBV in immunosuppressed patients is defined as HBsAb \geq 100 IU/mL^[16]. In HBV immunization studies, 25%-50% of the patients that do not respond to a primary three-dose vaccine responded to an additional dose, and 44%-100% respond to a second three-dose course. Therefore, those patients that do not achieve an adequate immune response after the primary immunization should be revaccinated with three additional doses^[51]. Moreover, revaccination with a three-dose regimen using a double dose has also been suggested^[52].

Mamula *et al*^[42] propose a second booster dose of influenza vaccine in IBD patients with concomitant immunomodulatory and anti-TNF treatment. There are no other recommendations for the remaining vaccinations.

In conclusion, IBD patients are considered to be at risk for several infections and should therefore be immunized. Response to immunization in this group of patients is still a controversial issue. Further studies are necessary in order to clarify the true efficacy of these vaccinations and to provide recommendations on specific situations such as failure to respond. In spite of the aforementioned recommendations, several studies demonstrate that vaccines are under-prescribed and that intensive educational efforts are required in order to ensure correct adherence to the set guidelines by gastroenterolo-

gists and primary care physicians.

Abstract

The patient with inflammatory bowel disease will be predisposed to numerous infections due their immune status. It is therefore important to understand the immune and serologic status at diagnosis and to put the patient into an adapted vaccination program. This program would be applied differently according to two patient groups: the immunocompromised and the non-immunocompromised. In general, the first group would avoid the use of live-virus vaccines, and in all cases, inflammatory bowel disease treatment would take precedence over vaccine risk. It is important to individualize vaccination schedules according to the type of patient, the treatment used and the disease pattern. In addition, patient with inflammatory bowel disease should be considered for the following vaccines: varicella vaccine, human papilloma virus, influenza, pneumococcal polysaccharide vaccine and hepatitis B vaccine.

INTRODUCTION

Inflammatory bowel disease (IBD) is associated with a greater predisposition to infections, many of which are preventable with vaccines^[1]. Many studies show a low rate of seroprotection and adherence to vaccination programs in these patients^[1-4]. Given that at some point in the progression of the disease, 80% of patients will require treatment with corticosteroids, 40% with thiopurines and around 20% with biological drugs, it is important to consider the number of patients who will be at risk for acquiring infections due solely to the medication they receive^[5].

The vaccination plan will be made after thorough study of immunocompetence at the time of diagnosis and prior to any immunomodulating treatment and/or treatment with biological agents^[3]. After immunocompetence has been assessed, we consider the vaccine schedule, serological studies for certain infections and each patient's personal risk in order to adjust the proper vaccination regimen for each case^[2].

IS OUR PATIENT IMMUNOCOMPETENT?

Evaluation of the patient's immunocompetence is essential prior to starting any immunosuppressant treatment or putting the patient in a vaccination program^[5-7]. An IBD patient is considered to be immunocompromised when they meet any of the following criteria: first, pa-

tients on corticosteroid treatment at dosages equal to or greater than 20 mg of prednisone for more than two wk, patients on immunomodulators (azathioprine, mercaptopurine and/or methotrexate), calcineurin inhibitors (cyclosporine, tacrolimus) or anti-tumor necrosis factor (TNF) (infliximab, adalimumab or others); malnourished patients and patients with any associated immunocompromise condition [hyposplenism, asplenia, human immunodeficiency virus (HIV), *etc.*]^[5,6].

STUDIES PRIOR TO VACCINATION

Study of the patient with IBD should be individualized based on age, particular risk factors and previously-administered vaccinations prior to inclusion in a vaccination program.

The medical history should be directed towards both their bacterial (especially urinary tract infections), viral [hepatitis A vaccine, hepatitis B vaccine (HBV), herpes zoster vaccine, herpes simplex virus, HIV, varicella], fungal and tuberculosis infectious disease history. Regarding tuberculosis (TB), study should include possible current or previous contacts with tuberculosis patients as well as a history of travel to endemic areas, both in the past and in the foreseeable future^[5,6]. Careful evaluations for latent TB before the use of anti-TNF therapy is mandatory^[8]. We suspect a latent TB when there is a history of recent exposure to the disease and positive initial tuberculin skin-test (TST) or positive booster TST and no radiological evidence of active TB. Another chapter delves more on this topic^[5].

Laboratory studies will include a hemogram, C-reactive protein, urine analysis (if there is a history of urinary tract infections), the viral serologies mentioned above and a stool culture. The patient's vaccination history will always be useful if the patient has it, as will a study of group risk due to household members or occupational risk (such as teachers or healthcare workers)^[5].

VACCINATION PROGRAM

Ideal vaccination is that which is performed at diagnosis of the disease and/or prior to starting immunosuppressor therapy. In general, all patients should be vaccinated for the following: tetanus, diphtheria and polio, varicella, human papillomavirus, influenza, pneumococcus, HBV, measles, mumps and rubella^[5]. Confirmation of immunization against infections preventable by live-attenuated viruses is recommended since they are contraindicated in cases of immunosuppression, which may apply to the patient if their immune status changes over the course of the disease (Table 1).

Below we mention each of the vaccines used in these patients and the considerations to be taken into account before, during and after their administration.

Flu vaccine and pneumococcal vaccine

Flu is one of the most common vaccine-preventable

Table 1 General vaccination and contraindicated live vaccines in inflammatory bowel disease patients

| |
|--|
| IBD patients |
| General vaccination |
| VZV varicella vaccine |
| Human papilloma virus |
| Influenza (trivalent inactivated vaccine) |
| Pneumococcal polysaccharide vaccine |
| Hepatitis B vaccine in all HBV seronegative patients |
| Contraindicated live vaccines |
| Anthrax vaccine |
| Intranasal influenza |
| Measles-Mumps-rebella |
| Polio live oral vaccine |
| Smallpox vaccine |
| Tuberculosis BCG vaccine |
| Typhoid live oral vaccine |
| Varicella yellow fever |

IBD: Inflammatory bowel disease; HBV: Hepatitis B virus; BCG: Bacille calmette guerin.; VZV: Varicella zoster virus

diseases in adults^[9]. The European Crohn's and Colitis Organisation (ECCO) guidelines recommend the inactivated trivalent vaccine on an annual basis in all patients with IBD with or without immunocompromise^[5]. However, it has been confirmed that the two most common reasons for not receiving the flu vaccine were the patient's lack of awareness (49%) and fear of side effects (18%). Several studies have shown that the inactive trivalent vaccine does not affect IBD activity and caution is only recommended in those patients who have previously had adverse reactions to the vaccine^[9,10]. The Mamula study observed that among patients who received infliximab and immunomodulator treatment, response to two of the vaccine's antigens may be reduced, with significantly lower antibody titers^[11]. Later it was shown that seroconversion after the flu vaccine is not reduced by corticosteroids, methotrexate or anti-TNF treatment^[5,9,12]. However, seroconversion was not guaranteed with combined use of these agents. Thiopurines and cyclosporine did reduce the rate of seroconversion^[13-15].

The polyvalent pneumococcal vaccine is recommended in immune-compromised patients, as is revaccination at 5 years from the first vaccination if immunosuppression persists^[16]. Treatment with methotrexate is associated with a lower seroconversion rate^[5,6].

Hepatitis B vaccine

The prevalence of HBV infection in IBD is similar to the general population. The HBV vaccine is recommended in all seronegative patients^[17]. Patients with IBD may have an increased risk of developing hepatitis B^[18]. Invasive procedures such endoscopies and surgery might be some of the reasons for this. Moreover, the use of immunosuppressors may reactive a latent infection^[19-21]. Effective vaccination is only present in 12% of IBD patients although it is indicated in all with or without immunosuppression. It was observed that the only factor associated with higher efficacy of the vaccine was younger age

and the number of immunomodulators that the patient takes. The use of high antigen doses or administration of a fourth dose is sometimes needed in order to improve response to the vaccine. The response rate in the general population is related to reaching surface antibody levels (HBsAb) that are equal to or greater than 10 mU/mL. The immunological memory conferred by the vaccine produces an anamnestic immune response upon contact with the wild virus that quashes the infection or at least leads to an unapparent infection^[17,18]. Only patients who do not respond to this vaccine should be subjected to intense vaccination schedules such as administration of a fourth dose, complete revaccination and/or the use of high dosages (40 µg) of HBV surface antigen. The conventional HBV vaccination regimen requires three doses at 0, 1 and 6 mo. If faster vaccination is required, the first two doses can be administered at a three or four-week interval (0, 1 and 2 mo)^[18-20]. In another chapter will be explained in more detail the performance against HBV.

Confirmation of HBsAb seroconversion is recommended one or two months after the last dose of the vaccine^[22]. The efficacy of the vaccine is affected by the type and number of immunomodulators, with anti-TNF being the slowest. Several authors suggest that the HBsAb concentration in these patients should be greater, with titers greater than 100 mU/mL considered protective. Annual measurement of HBsAb titers is recommended and administration of a booster is recommended when these patients are older than 10, especially in patients with IBD and immunosuppressor treatment^[5].

Measles, mumps and rubella vaccine

Because this is a live attenuated virus, it is important for the patient to receive it prior to converting to an immunocompromised state^[6,23]. Previous review of the documented medical record or serology at diagnosis and protection of the seronegative group are recommended. In patients with stable IBD who are high risk of contagion, vaccination will be evaluated after discontinuing immunosuppressor therapy for at least 3 mo prior to vaccination^[23,24].

Varicella vaccine

ECCO recommends ensuring immunization against this virus in patients with IBD before their immune status changes^[5,24]. Immunization is performed at diagnosis, at least three weeks before starting immunomodulator therapy or at least 3 mo after discontinuing the immunosuppressor, if the IBD situation permits. Because this is a live attenuated virus vaccine, vaccination is not recommended in patients on immunosuppressor therapy except for seronegative patients who are at a very high risk of contagion (healthcare personnel or teachers) who are on monotherapy with thiopurine drugs. In patients in whom it is decided not to vaccinate, group protection is recommended by adequate household vaccination^[25]. The seroconversion rate in adults and adolescents is less than in children (78% *vs* 97%), so a second dose of the

vaccine is recommended 6-8 mo after the first dose. The Advisory Committee of Immunization Practices of the Centers for Disease Control and Prevention recommends discontinuing 5-aminosalicylic acid (5-ASA) until 6 mo after administering the varicella vaccine. The effects of 5-ASA may theoretically increase the risk of Reye syndrome associated with the use of live virus vaccines such as varicella^[6,23,26].

For patients with increased risk of occupational exposure to varicella (for example, an early childhood teacher or healthcare worker) without prior immunity, careful consideration of the risks of acquiring the infection need to be weighed against the potential risks and benefits of vaccination^[23,24,27]. In cases of active varicella exposure in these patients, postexposure prophylaxis with varicella zoster immunoglobulin is recommended.

Human papillomavirus vaccine

The human papilloma virus (HPV) vaccine is a quadrivalent vaccine that targets the 4 HPV serotypes associated with highest risk of progression to cervical dysplasia and cancer^[28,29]. This vaccine is indicated in all women between 11 and 14 years of age, in addition to strict cytological monitoring, according to the guidelines of each country^[30-32]. There are no studies that defend the use of this vaccine on a routine basis in women over 26 years of age. Because this is not a live virus vaccine, it can be administered to immunocompromised patients with IBD. Interruption of immunomodulator treatment should be considered in patients with extensive cutaneous warts and/or condyloma. However, past HPV infection is not a contraindication for immunomodulator therapy^[10,23].

Other vaccines

Universal administration of the tetanus and diphtheria vaccine and the inactivated polio vaccine is recommended in patients with IBD, including immunocompromised patients^[33,34].

The hepatitis A vaccine is indicated in travelers to medium or highly-endemic areas, groups at high occupational or behavioral risk and immunocompromised individuals^[35,36].

Patients with IBD who wish to travel abroad should consult their physician 4 to 6 mo prior to traveling. There are three types of vaccines in travel guidelines: systematic, recommended and required^[4]. The option of administering live virus vaccines should be considered in all IBD patients based on their immunocompromise status. Infections caused by enteropathogens can cause reactivation of quiescent IBD. The oral cholera vaccine will be indicated in all travelers to highly endemic areas. The oral typhoid vaccine should not be prescribed to patients who have undergone colectomy due to the loss of colonic bacterial colonization, though the parenteral vaccine can be administered^[5,37-40]. Patients who take immunomodulators should be discouraged from traveling to South America or Sub-Saharan Africa where yellow fever is endemic and vaccination with live virus vaccines is

required. Other vaccine-preventable diseases in travelers that should be considered are the following: Japanese encephalitis (inactivated virus), meningococcal meningitis, tick-borne encephalitis, malaria, travelers' diarrhea, tuberculosis and insect-borne diseases^[35,40].

The majority of childhood vaccinations occur in the first two years of life^[34]. The use of live virus vaccines is contraindicated in pediatric patients who receive biological treatment. In addition, children who have been exposed to biological treatment *in utero* should not receive live virus vaccines while the biological agents are still detectable in their blood, generally for the first 6 mo of life^[10,37,41]. Booster immunizations are recommended in the second decade of life at the onset of IBD. Booster recommendations include hepatitis B, diphtheria, polio, tetanus, measles, mumps, rubella and varicella^[6]. The ability to mount an effective immune response will depend on the presence of immunosuppression in the 2 wk after immunization. Adequate immune response is recovered between 3 mo and one year after discontinuing the immunosuppressor^[4,5].

In conclusion, all patients who are recently diagnosed with IBD should have their vaccine serology and immunocompromise status studied thoroughly. If the patient is immunocompromised, they will receive the following vaccines: diphtheria, tetanus, inactivated polio, pertussis, hepatitis B, pneumococcus, human papillomavirus, hepatitis A and flu, among others. If the patient is not immunocompromised, live virus vaccines will be added based on the vaccination schedule in each country and based on the patients behavioral and professional risk. This measure will prevent infectious problems over the course of their disease and reduce morbidity. The patient's disease and its treatment may vary over the course of the disease, which is why we must take prophylactic measures in order to avoid problems in the future when immunocompromise may hinder treatment. The use of immunosuppressants such as immunomodulators and/or biological agents in IBD is becoming more intense and frequent, making it necessary to take prophylactic measures such as the use of vaccines.

Abstract

Hepatocellular carcinoma (HCC) develops in the context of environmental risk factors like chronic viral hepatitis, diabetes and alcohol exposure, often associated to an increased risk of cirrhosis. Antiviral treatments that are effective to counteract hepatitis B and C may also attenuate the risk of tumor development. However, since hepatitis B-related carcinogenesis is promoted independently of the onset of cirrhosis, such antiviral treatments as nucleo(t)side analogs can promote regression of cirrhosis, prevent clinical decompensation and variceal bleeding but not HCC. This means that in successfully treated patients with cirrhosis, HCC is often the consequence of their extended survival. In hepatitis C patients, a sustained virological response to interferon-based therapies can reduce the rate of HCC development, even in patients with cirrhosis who experience histological regression of their liver disease. Future therapies aimed at this endpoint in at risk populations should take into consideration pretreatment patient stratification for host, viral and environmental risk factors. In this context the recent discovery of single nucleotide polymorphisms involved in the immune

system function and tumorigenesis, might permit enrollment of populations of patients enriched with HCC risk factors for targeted chemopreventive therapies. This could finally pave the way to personalized algorithms, as already seen in the diagnosis and treatment schemes for chemoprevention.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer in men and seventh in women, accounting for 7% of all cancers, and the third most common cause of cancer related death, worldwide^[1]. HCC is characterized by peculiar biological and clinical features that may be relevant to primary and secondary prevention strategies. Indeed, up to 95% of all HCCs occur in the context of known and preventable risk factors, such as chronic viral hepatitis, alcohol abuse and cirrhosis (Table 1). Secondly HCC is one of the few cancers that can be diagnosed by radiological techniques, hence avoiding invasive diagnostic methods. Lastly, HCC is the only cancer that does not contraindicate patients to organ transplantation but actually benefits from liver transplantation in accurately selected patients. These rather unique features of HCC, in theory, could be used to implement therapeutic

and diagnostic measures to reduce or prevent the rate of HCC development in patients at risk, enforce surveillance programs in at risk patients aimed at early diagnosis and individualize treatment options based upon patient and tumor characteristics once the tumor has developed. Some of these points have been thoroughly investigated by clinical research studies and have led to significant advances in clinical practice that include the development of specific guidelines on surveillance protocols and on individualized treatment algorithms for HCC. Less successful have been attempts to design primary prophylaxis studies in at risk populations, such as those with hepatitis B virus (HBV) or hepatitis C virus (HCV), a fact that is especially worrisome as HCC arising in these patients still represents the core of the HCC epidemic in most countries. Indeed, chronic HBV and HCV infection affect roughly 400 and 200 million people, respectively, worldwide, and are the current leading causes of liver-related death and the main indication for liver transplantation in developed countries^[2].

HCC RISK FACTORS

Hepatic disease status

HCC almost invariably occurs in a histologically abnormal liver, the mere existence of chronic liver disease representing a potential risk for the development of this tumor. Indeed, on the top of specific virus mechanisms that may be directly carcinogenetic to the liver, chronic necro-inflammation and accumulation of reactive oxygen species contribute to carcinogenesis through chromosomal injury^[3]. Cirrhosis, the end stage consequence of hepatic inflammation resulting in nodular transformation of the liver, is considered a premalignant condition, independently of etiology. Whether the association of cirrhosis with HCC reflects a long lasting exposure to carcinogenetic agents capable of causing liver cell inflammation or a carcinogenetic effect of disrupted lobular organization, is a matter of debate^[4].

The prevalence of cirrhosis in persons with HCC is about 80%-90% in autopsied series worldwide, whereas approximately only 10%-20% of HCCs may be encountered in non-cirrhotic patients^[5]. However, only a few non-cirrhotic patients with HCC have absolutely normal liver histology, as the majority show fibrosis stages that range from no fibrosis (F0) to septal (F2) and bridging fibrosis (F3) with necroinflammation, steatosis, and liver cell dysplasia^[6-8].

In a detailed study from Japan involving 490 untreated patients with chronic hepatitis C, the HCC incidence per 100 person years increased with the stage of fibrosis at diagnosis, from 0.4 among patients with stage F0 or F1 to 1.5, 5.1 and 6.9 among those with fibrosis stages F2, F3 and F4, respectively^[9]. The presence of large cell change^[10], irregular regeneration of hepatocytes and macroregenerative nodules have been evaluated as morphologic predictors of HCC in cirrhosis independently of baseline disease^[10-14].

Table 1 Risk factors for hepatocellular carcinoma

| Viral | Environmental | Host related |
|-------|--------------------|--------------|
| HIV | Alcohol exposure | Age |
| HBV | Metabolic syndrome | Male sex |
| HCV | | Genetics |

HIV: Human immunodeficiency virus; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

Cirrhosis is not only driven by viral hepatitis but can also be the consequence of other conditions like hemochromatosis, Wilson's disease, antitrypsin deficiency, primary biliary cirrhosis, and autoimmune hepatitis^[5]. Patients with cirrhosis stemming from genetic hemochromatosis have a 20-fold relative risk of developing HCC, compared to the general population, with an annual incidence of about 3%-4%^[15]. In general, the risk of HCC in patients with cirrhosis increases in parallel to ageing, male gender, disease activity, degree of liver cell proliferation, presence of hepatobiliary phenotype on liver cells and serum level of alfa-fetoprotein. Patients with more advanced Child-Pugh scores are at higher risk of liver cancer, Child-Pugh class B/C patients having a 3-fold increased risk compared to Child Pugh A patients^[16,17].

Viral factors

HBV: The annual incidence of HCC in patients with chronic hepatitis B, ranges from 2% to 5%, in strict correlation with the histological stage of the underlying liver disease, serologic status and geographic area^[18]. Chronic HBV infection is commonly considered a primary risk factor for the development of HCC, exerting its pro-oncogenic properties through both indirect and direct mechanisms^[19-23]. The indirect mechanisms are related to its propensity to induce continuous or recurrent phases of liver necroinflammation and to promote the progression of chronic hepatitis to cirrhosis, often preceding the development of HCC^[24]. Most cases of HBV-related HCC (70%-90%) occur in patients with cirrhosis secondary to chronic necroinflammation, but HBV itself can cause HCC in the absence of cirrhosis through direct carcinogenic mechanisms that have been related to the capacity of HBV to integrate into the host's genome and to produce proteins (X protein and truncated pre-S protein) with potential transforming properties^[25].

In Europe, HBV-related HCC is associated with cirrhosis in the majority of patients^[26,27], whereas this is not true in Asia and Africa where the tumor is common also among carriers with mild hepatic fibrosis, likely as a consequence of long standing infection that is often acquired perinatally^[28-30].

HCC risk may be modulated by viral load^[31-35], even when this predictor is measured years before tumor diagnosis, and can be modified also by serum hepatitis B e antigen (HBeAg) persistence and hepatitis B surface antigen (HBsAg) status^[31,36-38].

Recently, it has been demonstrated that HCC may

also develop in Asian carriers with inactive hepatitis (*i.e.*, persistently normal alanine transaminase and serum HBV DNA < 2000 IU/mL)^[26,27,31,39] and HCC was also found to develop in a significant number of patients from 1 year to more than 10 years following spontaneous clearance of serum HBsAg, with a higher risk among patients who had HBsAg seroclearance after 50 years of age^[40]. Other studies with sensitive amplification assays have shown that HBV DNA persists in serum or liver as an occult HBV infection, even following spontaneous serologic recovery from transient HBV infection (HBsAg-negative status)^[41].

The estimated incidence rates of HCC in subjects with chronic HBV infection in East Asian countries is 0.2 per 100 person-years in inactive carriers, 0.6 per 100 person-years for those with chronic HBV infection without cirrhosis, and 3.7 per 100 person-years for those with compensated cirrhosis; while in Europe/North America the HCC incidence rate was 0.02 per 100 person-years in inactive carriers, 0.3 per 100 person-years in subjects with chronic HBV without cirrhosis, and 2.2 per 100 person-years in subjects with compensated cirrhosis^[42].

Male sex, positive family history and African origins are added risk factors for HCC development in HBV positive patients^[28-30]. Genotype B of the HBV seems to be associated with lower rates of HCC development compared to genotype C of HBV^[43-48], since it is characterized by anticipated HBeAg seroconversion, higher rates of sustained remission after HBeAg seroconversion, less active hepatic necroinflammation and slower progression to cirrhosis. Genotype A infections have a generally more favorable outcome than genotype D infections which predominate in the Mediterranean basin^[49,50].

HCV: Chronic infection with HCV affects more than 170 million individuals, representing a major cause of morbidity and anticipated liver-related death in western countries and Japan. HCC is the dominant, first to appear complication of patients with long standing infection complicated by cirrhosis, which in fact is considered the main risk factor for HCC in patients with HCV infection, as only a minority of HCC cases develop in patients with mild-to-moderate HCV disease. Malignant transformation of hepatocytes occurs through a pathway of increased liver cell turnover, induced by chronic liver injury and regeneration in a context of inflammation and oxidative DNA damage^[51] which facilitates the occurrence of genetic and epigenetic alterations that over decades can lead to the development of HCC. Still there are lines of evidence that support a direct role for HCV in cancer promotion^[52]. Clinically this is supported by the incidence of HCC in HCV-related cirrhosis being higher than that reported in cirrhosis resulting from other liver diseases such as autoimmune hepatitis or metabolic syndrome^[53]. Whether HCV genotype 1b produces a higher risk of HCC development compared to other HCV genotypes, is debatable, yet *de facto* reinforces the concept that HCV itself may promote HCC^[54].

The HCV genome consists of a single stranded positive sense RNA of approximately 9.6 kb in length, that encodes a 327 kDa polyprotein that is processed into 10 mature structural and non structural viral proteins^[55]. HCV proteins have been shown to impact on cell signaling, transcriptional modulation, transformation, apoptosis, membrane rearrangements, vesicular trafficking and translational regulation^[52]. Four of the HCV gene products (core, NS3, NS4B and NS5A) show transformation potential in cell culture systems. Transgenic mouse models support HCV induced carcinogenesis, with transgenic lineages with high level liver specific expression of the core protein and transgenic mice for the two envelop proteins E1 and E2 developing HCC even in the absence of hepatic inflammation^[56,57]. HCV can also induce endoplasmic reticulum (ER) stress, a homeostatic mechanism that regulates cellular metabolism and protein synthesis in response to perturbations in protein folding and biosynthesis^[58]. Persistent ER stress may result in intra- and extra-cellular accumulation of DNA-damaging factors known to predispose cells to mutagenesis.

Human immunodeficiency virus: Human immunodeficiency virus (HIV) infection significantly increases the risk of liver-related morbidity and mortality, primarily because during the highly active antiretroviral therapy (HAART) era an important reduction in HIV-related complications has occurred, leading to the emergence of co-infection with HBV (6%-14%) and HCV (25%-30%) as hepatotoxic factors in addition to excessive alcohol consumption, non-alcoholic fatty liver disease and drug-induced liver injury^[59].

While the MORTAVIC study in 2001 indicated HCC to be responsible for 25% of all liver deaths in HIV patients, in the HAART era there are studies showing HCC developing in co-infected patients to be more aggressive, to present at an earlier age and to less frequently be curable compared to HCC developing in HCV mono-infected patients. A direct oncogenic effect of the virus has therefore been hypothesized by some^[60,61].

Environmental risk factors

Alcohol: Chronic consumption of more than 80 g of ethanol per day for more than 10 years increases the risk of HCC by approximately 5-fold; in women even smaller quantities of alcohol consumption (10 g/d) are associated with a significant (24%) increase of HCC risk^[62]. Alcohol abuse in patients with chronic hepatitis C doubles the risk for HCC, due to a synergism between alcohol and hepatitis C in anticipating HCC onset or causing more severe histological tumor patterns. In a HCC cohort in Austria, alcoholic liver disease was the likely cause of HCC in 35% of subjects^[63], whereas in the United States, the hospitalization rate for HCC related to alcoholic cirrhosis is (8-9)/100 000 people per year compared to about 7/100 000 people per year for hepatitis C^[64]. Heavy alcohol consumption can lead to liver damage by direct liver cell injury and generation of toxic metabolites, thereby

transforming the liver in a mitogenic and mutagenic environment. This not only causes development of liver fibrosis and cirrhosis^[65,66], but also increases conversion of pro-carcinogens to carcinogens through oxidation and metabolism of ethanol in the liver^[67]. Acetaldehyde and oxygen free radicals deriving from ethanol metabolism may also directly induce cell damage by initiating peroxidation of membrane lipids, through oxidative stress^[68].

Metabolic syndrome: Diabetes is an independent risk factor for HCC; a recent surveillance epidemiology and end results based re-analysis has shown a 2-3-fold increase in the risk of HCC, regardless of the presence of other major risk factors^[69]. Further evidence that obesity and diabetes are either jointly or independently associated with an increased risk of HCC is provided by an Italian case control study and by several large-scale epidemiological studies, that have associated the overweight and obesity pandemic in the general population with an increase in HCC risk^[70].

In a cohort of 900 000 American adults, the risk of dying from liver cancer was 4.5 times higher in men with a body mass index of 35 kg/m² or above compared to men with a normal body mass index (18.5-24.9 kg/m²)^[71]. A meta-analysis of case control and cohort studies concluded that the relative risk of liver cancer was 1.17 for overweight subjects and 1.89 for obese patients^[72]. These and other studies contribute to the increased recognition of non-alcoholic steatohepatitis (NASH) as a cause of cirrhosis and HCC, with many patients progressing to liver cancer without histological evidence of advanced fibrosis or cirrhosis^[73,74].

A yearly cumulative incidence of HCC in 2.6% of patients with NASH compared to 4.0% of those with HCV over a median follow-up time of 3.2 years was also demonstrated in patients referred for liver transplant evaluation at Cleveland Clinic in Ohio^[75]. Interestingly, in this cohort of patients, older age at diagnosis of cirrhosis and any alcohol consumption were independently associated with the development of HCC in a NASH-cirrhosis population, suggesting that alcohol intake, even in socially accepted amounts, may potentially increase the risk of HCC development both in NASH- and HCV-cirrhotic patients.

The precise mechanisms through which metabolic factors drive HCC development are complex and beyond the scope of this article; however, major systemic and liver specific molecular mechanisms like insulin resistance, hyperinsulinemia, increased expression of tumor necrosis factor signaling pathways and direct lipotoxicity are major players in the development of HCC.

Host-related risk factors

Age and sex: Among host factors, older age and male sex have consistently been found in longitudinal studies to be associated with an increased risk of HCC among persons with cirrhosis of different etiologies, with the caveat, however, that age might reflect longer duration of

hepatic disease^[76-79].

In patients with cirrhosis, there is a striking gender imbalance in HCC incidence, with a predominance for males independently from geographic area, etiologic factors and ethnicity with a male to female ratio between 2:1 to > 4:1 being reported across studies^[80]. While male preponderance could just reflect the greater incidence of viral hepatitis and alcohol-related disease in males, it could also be related to hormonal diversity. High serum levels of testosterone have been associated with increased HCC risk in nested case-control studies of HBV carriers in Taiwan and Shanghai^[81], while a cross-sectional study in male veterans with chronic HCV in the United States associated higher total serum levels of testosterone with risk of advanced hepatic fibrosis and inflammatory activity, without examining the association with HCC^[82].

Among the complex molecular mechanisms behind gender disparities in HCC, estrogens may play a role in increasing interleukin-6 (IL-6) production and modulation of gene expression through FOXA transcription factors that have been shown to prevent HCC development in experimental models. However, more data are still needed to define the implication of sexual hormones in the molecular pathogenesis of HCC^[83].

Single nucleotide polymorphisms associated with HCC

Genetic host factors play an important role in HCC development. The most common form of genetic variation between individuals is single nucleotide polymorphisms (SNPs) which are a variation in a DNA base at a particular nucleotide locus. A common SNP is defined by having a minor allele frequency of at least 5%. In studies designed with a “candidate gene approach”, a limited number of biologically plausible SNPs were tested. The starting hypothesis is that a given variant in a specific gene involved in a pathway that influences HCC development can sufficiently alter either protein function or expression, and result in the modulation of cancer risk. Another approach to study genetic factors is through “genome wide association studies” (GWAS). These studies are by definition “hypothesis free”, and compare allele/genotype frequency of common variants between cases and unaffected controls and test 100 000 of tag SNPs reflecting common genetic variations across the entire human genome. To reach GWAS significance (P value = 0.05/number of SNPs tested) a P value in the order of $< 10^{-8}$ is typically required^[84].

To identify susceptible genetic variants for HCV- and HBV-related HCC many genetic association studies have been conducted; unfortunately most publications suffer from major methodological drawbacks because of their case-control, retrospective and single center design, mainly involving selected Asian populations. This minimizes the potential importance of ethnic diversity, calling for external validation in populations of different ancestry before effectively translating results to clinical practice. Prospective cohort studies conducted in large homogeneous populations with sufficient number of events

Table 2 Genetic associations with hepatocellular carcinoma at genome wide association studies level

| Study | Patients | n | SNP locus | Strength | Comment |
|--|------------------------|------|-----------|----------------------|---|
| Kumar <i>et al</i> ^[85] | CHC | 1730 | MICA | OR 1.3 | This study considers HCV-negative individuals as the controls, hence it isn't useful in distinguishing HCC high risk population among HCV-related cirrhotic patients |
| | HCV neg | 8376 | | | |
| | CHC-HCC | 2115 | | | |
| Miki <i>et al</i> ^[86] | CHC | 2390 | DEPDC5 | OR 2.2 | Given the relatively small number of cases in the GWAS phase, the statistical power to detect an effect caused by this SNP was only 50%, compared to the 80% recommended to detect an association of the expected effect size |
| | CHC-HCC | 922 | | | |

¹89% HBV or HCV viral infection; ²76% HBV or HCV viral infection; ³Not known viral status. CHC: Chronic hepatitis C; CHB: Chronic hepatitis B; GWAS: Genome-wide association study; HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; SNP: Single nucleotide polymorphism.

during follow-up require a long time to be conducted and therefore are still scarce.

The genetic regions found to have a significant statistical association with HCC at a GWAS level in chronic hepatitis C patients are the 5' flanking region of *MICA* (the MHC class I polypeptide-related sequence A gene, on chromosome 6p21.33) which is essential for direct immune system functions^[85] and isoform1 of the *DEPDC5* locus on chromosome, where deletion of the region containing DEPDC has been reported in malignant brain glioblastomas^[86]. Also the MHC class II locus presenting antigen to CD4 p (helper) T cells contains three variants strongly associated with HCC, probably related to altered MHC class II proteins that result in an ineffective T-cell response^[87]. *KIF1B* was identified as a new susceptibility locus for HCC in chronic HBV carriers; the loss of heterozygosity on this locus is a common genetic lesion in a broad range of human cancers^[88]. Variations at chromosome 8p12 may also promote HCC in patients with HBV and risk-associated 8p12 SNPs or haplotypes might have an interacting effect on the DLC1 locus (Deleted in Liver Cancer 1), which becomes more susceptible to deletion or chromosomal loss^[89] (Table 2).

In the HALT-C study cohort a significant association between a polymorphism on epidermal growth factor gene and HCC was detected in a retrospective case-control study, by the use of a candidate gene approach^[90]. With this same approach in HBV patients many other genes involved in immune and tumorigenesis processes were found to be significantly associated with HCC development, among these cytotoxic T-lymphocyte antigen 4 gene^[91], the promoter region of *MCM7* gene and the enhancer II (Enh II)^[92], basal core promoter, and precore regions of HBV^[93].

Still the SNPs identified so far only partly explain the overall variability in HCC susceptibility as they carry a rather low risk ratio for HCC development, have been mostly assessed in well selected patients where HCC tissue was obtained following surgical resection and

therefore at this moment do not permit prediction at the individual and population level. Whole genome sequencing analysis of HCCs nodules are promising approaches; recently Fujimoto *et al*^[94] have identified etiological diverse specific mutation patterns and several mutation of chromatin regulators in 27 HCCs.

In 2008 the International Cancer Genome Consortium was launched with the purpose to coordinate large-scale cancer genome studies in tumors from 50 cancer types and/or subtypes that are of main importance across the globe, including HCC. Systematic studies of more than 25 000 cancer genomes at the genomic, epigenomic and transcriptomic levels are needed to reveal the repertoire of oncogenic mutations, uncover traces of the mutagenic influences, define clinically relevant subtypes for prognosis and therapeutic management, and enable the development of new cancer therapies. Hopefully in the not so distant future, partial or full cancer genomes will routinely be sequenced as part of the clinical evaluation of cancer patients and as part of their on-going clinical management^[95].

CHEMOPREVENTION

Although all host related HCC risk factors are unmodifiable and at this moment do not call for any preventive measures, environmental and viral factors can either be prevented, suppressed or in some cases cured by effective treatments^[96]. For viral hepatitis B and C and for HIV infection the question is whether the effective antiviral treatments that have been developed in the last decade to treat patients with virus induced liver disease can be considered chemopreventive approaches for HCC in parallel.

HBV

Prevention of HCC in patients with a sustained suppression of HBV following interferon or NUC therapy is far from being convincingly demonstrated, especially since this dramatic and life threatening complication in most

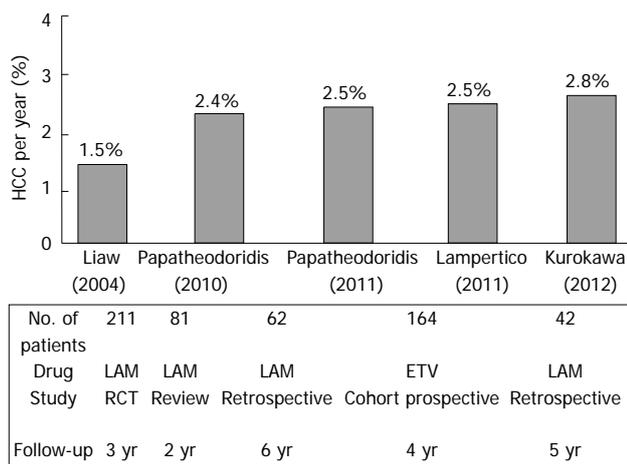

Figure 1 Hepatocellular carcinoma rates in nucleos(t)ide analogs-naive cirrhotic patients with long-term response. Several studies have shown that hepatitis B virus patients who achieve a virological response to lamivudine in some cases still develop hepatocellular carcinoma (HCC) as the only complication. LAM: Lamivudine; ETV: Entecavir; RCT: Randomized controlled trial.

patients occurs many decades after viral infection and many years after diagnosis of hepatitis.

The benefits of a virological suppression in patients with cirrhosis are easier to evaluate as these patients are the closest to developing hepatitis-related complications. Several studies have shown that HBV patients who achieve a virological response to lamivudine are protected against HCC during the precirrhotic phase of infection, in fact this is the only complication arising in virological responders with preexisting cirrhosis^[97-101] (Figure 1). In a systematic review of studies of nucleos(t)ide analog treatment of patients with HBV it was clearly shown that HCC was prevented in patients with chronic hepatitis but not in those with cirrhosis, and in general in patients that could not achieve complete virological suppression^[98]. This was confirmed by a recent cohort study from Greece where long-term cirrhotic patients responding to lamivudine remained at risk of developing liver cancer^[99]. All these studies enrolled patients treated with lamivudine or rescued with adefovir, *i.e.*, regimens characterized by limited potency and low to moderate genetic barrier, which are not recommended any more by International guidelines for treatment of patients with chronic hepatitis B in general, and especially in patients with compensated cirrhosis. This raised the hope that more potent anti-HBV drugs, like entecavir and tenofovir, might confer an advantage in terms of HCC prevention in responders with cirrhosis, however with disappointing results. A multicenter study in Italy conducted in patients with compensated cirrhosis who achieved persistently undetectable serum HBV DNA during 4 years of entecavir monotherapy, showed an annual rate of neoplastic transformation of the liver of approximately 2.5%, that mimics the HCC rates in untreated HBeAg negative patients in Europe^[100]. The reasons for these negative results may be many fold: it should be recalled that development of HCC in successfully treated patients with cirrhosis is often the conse-

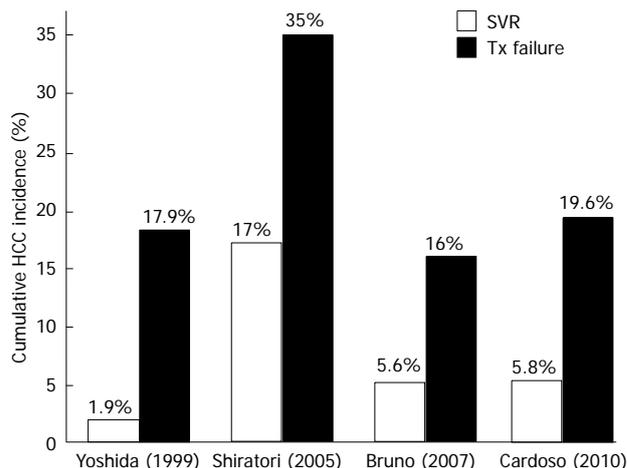

Figure 2 Cumulative incidence of hepatocellular carcinoma in patients with cirrhosis stratified by sustained virological response. Studies in Caucasian patients as well as in patients from Asia have repeatedly shown that a sustained virological response (SVR) following interferon-based therapies can reduce the rate of hepatocellular carcinoma development in hepatitis C virus related cirrhosis. HCC: Hepatocellular carcinoma.

quence of an extended survival provided by nucleot(s)ide analogues (NUCs) preventing clinical decompensation, as it was the case in the Italian multicenter study. Another explanation is that HBV related liver carcinogenesis is likely to be promoted by cellular events that are established early during chronic infection with HBV, independently on the onset of cirrhosis. This would explain why NUCs can determine regression of cirrhosis, protection from clinical decompensation and variceal bleeding but not from HCC development^[102-104].

HCV

With regards to HCV there is conclusive evidence that an sustained virological response (SVR) following interferon (IFN) based therapies can reduce the rate of HCC development, independently of fibrosis stage^[9,105-108]. This has been repeatedly shown both by studies in Caucasian patients as well as in patients from Asia (Figure 2). Interestingly an SVR does not completely negate the risk of HCC, as a small group of patients will still develop HCC in the long term follow-up period, although the annual rate is extremely low and reduced compared to non responders or untreated patients. In an Italian study on 920 patients with compensated cirrhosis who received IFN monotherapy and who were followed-up for a median period of 96 mo after treatment completion, Bruno *et al*^[109] found that SVR patients had significantly lower rates of HCC (0.66 *vs* 2.10 per 100 person-years) and liver-related death (0.19 *vs* 1.44 per 100 person-years, *P* < 0.001) compared to those with treatment failure. Similar findings were also reported by Cardoso *et al*^[110] in a study that analyzed 307 patients with bridging fibrosis or cirrhosis followed-up for 3.5 years after the end of treatment. The authors found significantly lower incidence rates per 100 person-years of liver-related complications, liver-related deaths, and HCC in SVR than in non-SVR patients (0.62

vs 4.16, 0.61 *vs* 3.76 and 1.24 *vs* 5.85, respectively; $P < 0.001$ for all comparisons). A study from France analyzing a cohort of HCV cirrhotics subjected to repeated liver biopsies following an SVR, has linked the protective effect of an SVR on HCC development on regression of cirrhosis^[111]. Indeed the 44% of patients who showed cirrhosis regression had 0% occurrence of HCC during a 118 mo follow-up period, while in the 22 patients without cirrhosis regression 3 patients developed HCC.

Unfortunately the clinical significance of the protective effect of an SVR on HCC development in HCV patients with cirrhosis is limited as the vast majority of HCV cirrhotics fail to achieve a SVR to IFN plus ribavirin therapy. In fact cirrhosis is one of the main factors associated with treatment failure to any regimen based on IFN, hence most of HCV cirrhotics even if treated remain at high risk of HCC. In this context it is important to understand the role played by other clinical and demographic factors in determining treatment outcome to PegIFN plus ribavirin and their interplay with the presence of cirrhosis^[112,113]. Not all cirrhotics show reduced rates of SVR, since the presence of a treatment favorable HCV genotype, HCV-2 and in part HCV-3, or a protective SNP in the IL-28B coding region in HCV-1 and HCV-4 patients can lead to SVR rates in the 70% range^[114-116]. IL-28B has been shown by several studies to be the strongest baseline predictor of treatment outcome; however its clinical utility in terms of individualized chemoprevention strategies is limited by its relatively low negative predictive power that should never lead to treatment deferral, especially considering the significant advantages obtained by an SVR in patients with advanced fibrosis/cirrhosis^[117].

Given that IFN also exerts several important indirect effects in the virus-infected liver that might result in tumor prevention, including immunostimulation and expression of HLA class 1 MC, and inhibition of mutagenic factor beta-UGF, three randomized controlled studies were designed to assess if a long term course of low dose PegIFN therapy could reduce the rate of liver related complications in patients with advanced fibrosis/cirrhosis who did not achieve an SVR to a full course of PegIFN plus ribavirin therapy^[116-120]. Although the three studies are hardly comparable due to differences in the patients characteristics and in the assigned treatment regimens, still they unanimously failed to demonstrate any positive impact of PegIFN maintenance therapy on HCC incidence rates^[121]. A recent extended analysis of the original HALT-C study, performed by Lok *et al.*^[122] and focused on the development of HCC, has partially contradicted these findings as long-term PegIFN maintenance therapy was associated with reduced HCC rates in patients with pre-treatment cirrhosis. The cumulative incidence of HCC at 3, 5 and 7 years was 2.6%, 5.1% and 7.8% in the PegIFN group and 4.0%, 11.1% and 24.2% in the untreated group (log-rank test, $P = 0.009$).

These results are hard to interpret and require caution before suggesting PegIFN maintenance therapy as an ef-

fective chemoprevention strategy in HCV cirrhotics; still they provide important clues and directions for future studies. Indeed, it shows patients enrolled in chemoprevention studies need to be stratified for risk factors at baseline; in this particular case enrolling patients with different disease severity stage might have precluded observation of a protective effect of low dose PegIFN on HCC development. Secondly it suggests that conducting studies on high risk rather than medium risk patients might provide more clinically meaningful data.

HIV

Although a detailed discussion about the effect of antiviral therapy in HIV positive patients on HCC development is beyond the purpose of this study, convincing evidence has been provided that HCC incidence is rising amongst the HIV positive population receiving HAART, almost exclusively in patients with concomitant HCV or HBV infection. The main explanation behind these findings is probably the increased longevity obtained by effective antiviral treatment in this population of patients. An investigation of the Swiss HIV cohort assessed that latest CD4 β cell count and CD4 β cell count percentage were significantly associated with HCC, but no association between HAART use and HCC risk was detected^[123]. Similarly, Sulkowski *et al.*^[124] reported that HCC occurred in many patients despite the use of effective HAART for a median of more than 7 years.

Thus, antiretroviral therapy is unlikely to modify the risk of HCC in HCV-infected patients in whom the risk of cancer is driven by HCV-related cirrhosis and where antiretroviral therapy is also known to have some direct hepatotoxic effects which are worsened by co-infection with HBV or HCV, raising the possibility that HAART *per se* might hasten the progression to cirrhosis and hence HCC^[125]. However the role of HAART on HCC development is controversial because its ability to preserve immune system functions could in theory provide a putatively more active anti-tumor response, since once HCC has developed, chronically low CD4+ and CD8+ lymphocyte counts may result in more rapid growth and spread of disease.

CONCLUSION

HCC develops in the context of readily identifiable environmental risk factors, first of all HBV and HCV, a fact that in theory should enable for successful primary prophylaxis. There are solid treatment endpoints that allow hepatologists to determine the efficacy of an antiviral regimen and its ability to positively modify both the natural course of the disease as well as to reduce the risk of HCC development.

Unfortunately in patients with chronic HBV and HCV infection tumor prevention is an end point quite difficult to assess in patients with early, mild hepatitis whereas it can only partially be achieved in patients with established cirrhosis given they are at higher risk of liver cancer.

In these patients there is increasing need to improve diagnosis rate, ensure equal access to antiviral therapies and develop well tolerated therapies that will finally allow most, if not all, patients with viral hepatitis to benefit from effective antiviral treatment. In fact it is estimated that as few as 35% of patients with chronic HBV and only 25% of HCV patients are aware of their disease in developed countries, with this number obviously shrinking even more in developing countries^[126]. Moreover in Europe and the United States, even if patients are diagnosed correctly only 1%-16% of HBV and HCV patients are estimated to receive treatment^[127-129].

This highlights that one of the key issues for therapies aimed at HCC chemoprevention is to broaden access to therapies by containing costs and increasing disease awareness, or eventually concentrate treatment in those more at risk of HCC development. Performing prospective studies where patients are stratified according to complex models of "genomic risk prediction" that incorporate various panels of specific SNPs, is undoubtedly a bold and possibly unreachable goal, but still it could lead to individualized chemoprevention strategies in the future, while reducing the number of patients needed to be enrolled into chemoprevention studies to assess efficacy of a treatment regimen. Until this is reached, secondary prevention through surveillance of risk populations aiming at early diagnosis is the only approach to improve treatment and survival of patients with HCC.

patients with advanced malignancy, seeking minimally invasive interventions and improved quality of life. With the advent of biliary drainage *via* endoscopic ultrasound (EUS) guidance, EUS guided biliary drainage has been used more frequently within the last decade in different countries. As with any novel advanced endoscopic procedure that encompasses various approaches, advanced endoscopists all over the world have innovated and adopted diverse EUS guided biliary and pancreatic drainage techniques. This diversity has resulted in variations and improvements in EUS Guided biliary and pancreatic drainage; and over the years has led to an extensive nomenclature. The diversity of techniques, nomenclature and recent progress in our instrumentation has led to a dedicated meeting on May 7th, 2011 during Digestive Disease Week 2011. More than 40 advanced endoscopists from United States, Brazil, Mexico, Venezuela, Colombia, Italy, France, Austria, Germany, Spain, Japan, China, South Korea and India attended this pivotal meeting. The meeting covered improved EUS guided biliary access and drainage procedures, terminology, nomenclature, training and credentialing; as well as emerging devices for EUS guided biliary drainage. This paper summarizes the meeting's agenda and the conclusions generated by the creation of this consortium group.

Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) has become the preferred procedure for biliary or pancreatic drainage in various pancreatobiliary disorders. With a success rate of more than 90%, ERCP may not achieve biliary or pancreatic drainage in cases with altered anatomy or with tumors obstructing access to the duodenum. In the past those failures were typically managed exclusively by percutaneous approaches by interventional radiologists or surgical intervention. The morbidity associated was significant especially in those

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is the procedure of choice for biliary drainage in obstructive jaundice resulting from pancreatobiliary cancer. Although this is successful in more than 90% of the times biliary drainage cannot be achieved *via* ERCP in certain cases^[1,2]. This is usually related to a difficult anatomy from prior surgical interventions or due to locally advanced tumors obstructing access to the duodenum^[3-5]. Traditionally, such patients underwent percutaneous transhepatic cholangiography^[6-8]. However, this method carries a high complication rate and could be associated with fistula formation and recurrent infection^[9]. In 1996, Wiersema used endoscopic ultrasound (EUS)-guided cholangiography to define the biliary anatomy, guiding repeat ERCP^[10]. The initial report of biliary drainage using EUS guidance was published by Giovannini *et al.*^[11], and described a bilio-duodenal anastomosis guided by EUS using a single 10 French plastic stent. Shortly after, the same author published a left hepatico-gastrostomy under EUS-Guidance. A self-expandable metal stent (SEMS) was then placed across the fistula created^[12]. Later a “rendez-vous” technique was demonstrated in a series by Kahaleh *et al.*^[13], describing a total of 13 cases undergoing trans-gastric puncture of the left biliary system. With the combination of techniques increasingly available it became obvious that this technique was destined to grow further. Since then many more papers have been published regarding this technique.

TECHNIQUES APPROACHES IN EUS-GUIDED BILIARY DRAINAGE

EUS-guided biliary drainage (EUS-BD) are divided by access route into EUS-guided intrahepatic bile duct drainage, where the intrahepatic bile duct is punctured from a transesophageal, transgastric or transjejunal approach, and EUS-guided extrahepatic bile duct drainage, where the common bile duct (CBD) is punctured from a transduodenal or transgastric approach (usually from the distal antrum). The overall rationale for performing EUS-BD is threefold: (1) logistic advantage (it can be performed in the same session as the originally failed ERCP without further delay); (2) physiologic advantage (it provides immediate internal biliary drainage without the need for external drains); and (3) anatomic advantage (it can be tailored to the individual patient’s anatomy; the precise imaging provided by EUS resulting in a potentially less invasive procedure than percutaneous transhepatic biliary drainage).

Extrahepatic approach

In addition to the underlying common rationale for EUS-BD, the extrahepatic approach has its own limitation and advantage. In case of obstruction the common bile duct or common hepatic duct are more easily imaged under EUS than the intrahepatic bile ducts, in contrast to what happens under transabdominal ultrasound. It can there-

fore potentially be accessed under EUS with minimal risks. The retroperitoneal location of the CBD makes it also an attractive access site for patients with ascites, in whom fluid around the liver makes transhepatic access (whether percutaneous or transgastric under EUS) more difficult and hazardous.

As explained in more detail, antegrade stent insertion from an extrahepatic access site is challenging and has only been reported in a few series^[14,15]. The real choice between transmural and transpapillary drainage after extrahepatic bile duct access under EUS therefore lies between EUS-guided choledochoduodenostomy (EUS-CDS) and rendezvous. Proponents of rendezvous argue that it may be less invasive than EUS-CDS, since transmural intervention is usually limited to puncture and guidewire passage, then drainage is accomplished in a retrograde fashion *via* ERCP without the need for puncture tract dilation^[16]. However, EUS-BD can fail - even in expert centers - because guidewire passage across the stricture and the papilla can be unsuccessful. The needle does not permit manipulation of the guidewire, across a stricture in the same way as it can be done during ERCP using flexible catheters. EUS-BD by needle-rendezvous may require repeat punctures with different angles often resulting in a prolonged, labor-intensive procedure with the risk of shearing the wire or biliary leakage. The second part of the rendezvous involves exchange of the echoendoscope for a duodenoscope and guidewire retrieval through the duodenoscope. This is also cumbersome and plagued with difficulties. EUS-CDS despite being perhaps more invasive, appears to be a more reproducible approach over transpapillary rendezvous. Nonetheless, both EUS-BD variant approaches can be considered complementary. As we will discuss below, some indications are better suited for one technique versus another. Similarly, even if rendezvous is the intended drainage technique, EUS-CDS can be used as a second line approach to salvage the significant proportion of failed rendezvous cases^[17,18]. This open-ended approach to EUS-BD (*i.e.*, inclusive of both rendezvous and EUS-CDS) results in comparatively higher success rates than that of EUS-BD series limiting their approach to just rendezvous^[16]. Obviously, future prospective studies comparing EUS-BD with PTBD or surgery are necessary.

TERMINOLOGY

Diagnostic and therapeutic ESCP

EUS-guided access to bile and pancreatic ducts under fluoroscopy in order to obtain diagnostic ductograms was termed “endosonography-guided cholangiopancreatography” and acronymized EGCP in 1996. The alternative acronym ESCP stands for the same name. Within ten years, therapeutic procedures building on the ESCP paradigm were reported in 39 patients to attempt duct drainage (26 biliary and 13 pancreatic). Despite seeming differences in technique and a confusing plethora of terms, the 13 reports originating from 9 different institutions which

¹18 out of 19 retrograde transpapillary endosonographic cholangiopancrea-tography (ESCP) were carried out via rendezvous; ²None of these four antegrade transpapillary ESCP were “pure” antegrade. Kahaleh *et al*^[23] used a single stent bridging both the papilla and the puncture tract, whereas Püspök *et al*^[14] used dual stenting: a transmural stent together with a transpapillary stent; ³Retrograde cannulation of spontaneous bilio-duodenal fistula developing in the setting of postoperative duct injury, after intrahepatic bile duct injection. Similar to the methylene-blue approach, but using contrast material.

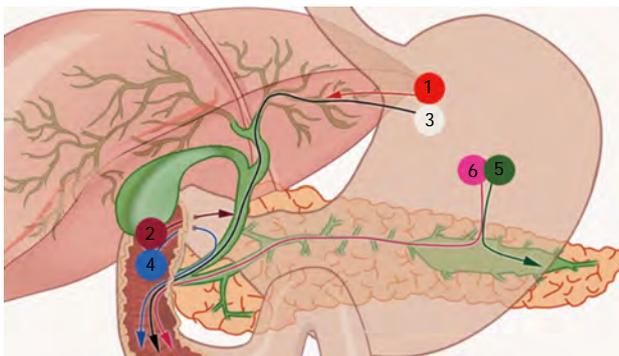

Figure 1 Therapeutic endosonographic cholangiopancreatography: Variant approaches. 1: Transmural drainage, intrahepatic access (hepaticogastrostomy); 2: Transmural drainage, extrahepatic access (choledochoduodenostomy); 3: Transpapillary drainage, intrahepatic access; 4: Transpapillary drainage, extrahepatic access; 5: Transmural drainage, pancreatic access (pancreaticogastrostomy); 6: Transpapillary drainage, pancreatic access. (Reprinted from Perez-Miranda *et al*^[11] with permission).

detail these 39 procedures are strikingly consistent (Table 1)^[2,14,19-28]. In all of them fluoroscopy-guided intervention through ERCP-based techniques was used to provide drainage following EUS-guided ductal access in complex cases not amenable to ERCP. The substantial anatomic variation in this highly selected patient cohort led to different procedural options, which can be classified into 9 subgroups (3 pancreatic and 6 biliary) based on just two variables, access route and drainage route (Figure 1). Access route can be intrahepatic biliary, extrahepatic biliary or pancreatic, whereas drainage route can be either transmural or transpapillary. Transpapillary drainage can be accomplished either antegradely - most commonly by direct stent insertion across the EUS puncture tract into the duct, the stricture and then the papilla, or retrogradely - most commonly *via* rendezvous ERCP.

Nomenclature problem

Determining the essential elements of a given procedure - the common ground to all its potential variant approaches - and the key variables defining those variant approaches, is of critical relevance to successfully name it. An example of a successful name encapsulating the essence of a complex procedure is ERCP. The acronym ERCP has withstood the test of time over four decades, as the procedure itself metamorphosed from diagnostic to therapeutic, branching out to encompass an ever growing range of interventions. The opposite is true for EUS-guided ductal access and drainage interventions. Not a single one of the 13 early reports replicates the name ESCP. It is significant that 5 of them fail to reference it at all when describing their individual variants of ESCP. However, it is even more significant that most will mention it as just one of the many then developing applications of EUS, overall or on the pancreas. A parent role for ESCP is acknowledged only implicitly and occasionally. This tendency to focus on the uniqueness of each novel variation, losing touch with the prior common ground, has worsened in subsequent reports. With a few hundred cases published, over 120 names and 30 different acronyms have been put in circulation to refer to essentially the same procedure or any of its major variants. Table 2 lists the 22 names and 8 different acronyms proposed for an all-variant encompassing procedure. Further name lists could be produced for just biliary overall ($n = 19$), pancreatic ($n = 14$), transmural overall ($n = 22$), transmural biliary ($n = 24$) or transpapillary ($n = 22$) variants.

Key name descriptors

Semantic analysis of names listed in Table 2 under the heading “diagnosis” reveals that descriptors incorporated into the final name include EUS (or endosonography),

Table 2 List of endosonographic cholangiopancreatography names (biliary and panc, *n* = 22)

| | Name | Acronym |
|--|---|----------|

EUS: Endoscopic ultrasound; FNA: Fine needle aspiration.

the ductal component (allowing differentiation between ESCP and related procedures such as EUS-guided pseudocyst drainage), and the presence of fluoroscopy (expressed in the suffix “-graphy”). Names in Table 2 under the heading “therapy” usually omit the critical element of fluoroscopy and often as well the ductal nature of the target pursued under EUS (which, in turn, is what gives fluoroscopy more prominence in ESCP than in, for example, a pseudocyst drainage procedure). The therapeutic intent is variably described, resulting in exceedingly long names. Inconsistent modifiers such as “guided” or “assisted” (sometimes also “directed”) introduce another source of variability without much added meaning. A simple way to solve the terminology conundrum would be to follow the ERCP paradigm with ESCP, where the latter refers not only to the ductograms it literally designates but also to therapeutic intervention under fluoroscopy to provide bile and/or pancreatic duct drainage. “Endoscopic” and “retrograde” qualify the way ducts are accessed, as would “endosonographic”.

A parent procedure with two major branches

The acronym ESCP could accommodate the term “endosonography-guided cholangiopancreatography” if it proves too ingrained as well as the shorter more specific versions of ESC and ESP, just like ERCP does with ERC and ERP, to designate one ductal system only. ESCP

as a manageable acronym would help frame a unifying concept for a procedure distinct from other EUS-guided interventions and from combined EUS-ERCP arrangements, despite the manifold ways in which it can be carried out. Consistently used terms describing individual ESCP approaches, such as hepaticogastrostomy, choledochoduodenostomy or rendezvous, would be bound by a specific umbrella concept and name rather than standing independently among the growing list of EUS-guided interventions.

Dr. Binmoeller proposed the alternative term “EACP”:

Endoscopic (or EUS-guided) antegrade cholangiopancreatography. He argued that EACP highlights the antegrade route of duct access (relative to the ampulla) in contrast to the retrograde of ERCP, and therefore should be the key distinguishing feature. He noted that “ERCP” does not specify use of a specific imaging modality, in contrast to ESCP. To withstand the test of time, the acronym should be open to imaging modalities that may be used in the future. Choosing an acronym that is familiar will be more likely to achieve adoption, and EACP mirrors ERCP as the antegrade option. Like ERCP, EACP broadly covers a range of diagnostic and therapeutic bilio-pancreatic interventions that will eventually be used under this name. A vote was taken during the conference and the majority favored “ESCP” over “EACP”, however, adequate presentation time was not allowed to discuss the pros and cons of the acronyms. It is important to consider the acceptance of this name worldwide and further discourse is planned.

TRAINING IN JAPAN AND IN THE WORLD: DOES ONE SIZE FIT ALL?

Interventional EUS has become popular. In order to perform EUS-guided pancreatico-biliary drainage, experience of not only endosonographer but also ERCP endoscopist is required.

Current situation of EUS instrument in Japan and in the world

Diagnostic EUS using radial model began in 1980s in Japan. Since then, basically radial EUS has been popular in Japan. In contrast, in United States and Europe, although at first radial EUS was performed, EUS-guided fine needle aspiration (EUS-FNA) showed a rapid increase. The ratio of curved linear array (CLA) echoendoscopes to all EUS scopes is 12% in Japan and 40% in United States and Europe^{29,30}. One of the reasons is the reimbursement of EUS-FNA procedure. The cost of EUS-FNA in Japan is about less than 200 United States dollars.

Current situation of EUS centers in Japan and in the world

There is no dedicated center for interventional EUS using linear EUS since endosonographers usually perform both radial and linear EUS not only for pancreaticobili-

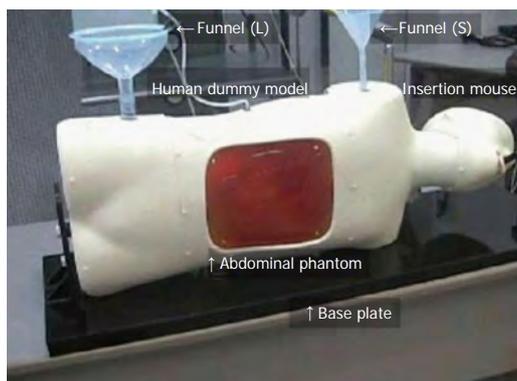

Figure 2 Pancreaticobiliary phantom model (Olympus Medical Systems).

ary diseases but also for gastrointestinal tract diseases, like esophageal or rectal lesions. Most high volume EUS centers have tutorial courses or EUS seminars for endoscopists who want to learn diagnostic EUS, namely EUS imaging including fundamental mode, contrast-enhanced mode and elastography, and EUS-FNA^[31].

In Japan, there are more than 30 EUS centers in which conventional therapeutic EUS including pancreatic pseudocyst drainage and celiac plexus neurolysis are performed. Of these centers, only in about 5 EUS centers, EUS-guided biliary drainage and/or pancreatic duct drainage are performed (more than 20 cases). In United States, there are more than 40 therapeutic EUS centers. In Australia, endosonographers perform interventional EUS in more than 17 centers. In South America, therapeutic EUS is performed in more than 10 EUS centers. In Asia including Japan, there are more than 70 EUS centers. In Europe, around 30 EUS centers provide interventional EUS services.

Current status of EUS training

As many endosonographers described, there is no well designed EUS training system. In terms of United States and Europe, the American Society for Gastrointestinal Endoscopy (ASGE) and the European Society of Gastrointestinal Endoscopy sponsored hands-on EUS workshops using a porcine model is regularly held. We can perform not only diagnostic EUS (imaging) but also EUS-FNA (including cyst puncture). Because EUS training on a swine model is recognized to be the more expensive way for EUS teaching, not all trainees in every country can use the model. In contrast, computer-based simulator (EUS mentor; Symbionix, Tel Hashomer, Israel) has been developed for repeat training and shortening the learning phase of EUS. This model is relatively similar to normal anatomy, but it is also expensive. Recently, Olympus Medical Systems made the pancreaticobiliary phantom for both radial and linear EUS training (Figure 2). It includes not only the parenchymal organs but also middle to large vessels. Training system using this kind of phantom and porcine model will probably become mandatory to establish skills in therapeutic EUS.

EMERGING DEVICES FOR EUS-BD

The technique entails three basic steps using various “off-the-shelf” tools in conjunction with a therapeutic CLA echoendoscope.

EUS-guided ductal puncture

Most cases described in the literature use conventional FNA needle (usually 19-gauge to enable passage of a 0.035 inch wire). The continuous stainless steel needle lends excellent visibility on sonographic and fluoroscopic imaging, as well as excellent transfer of force. Drawbacks of the FNA needle are its relative stiffness, which results in a very tangential angle of puncture. An alternative instrument for access is a diathermic needle knife with removable inner needle. Pure cutting current is applied during puncture to penetrate tissue. The advantage of the needle knife is the ability to immediately exchange the inner needle for a guidewire. The outer catheter can then be easily steered in the bile duct, off-axis from the angle that the duct was punctured. The main drawback of the needle knife is the poor visibility of the needle, limited to the catheter tip, on ultrasound and fluoroscopy. A further drawback is the risk of diathermy trauma to tissue, a particular concern should the needle veer off course during puncture. Whereas a continuous stainless steel needle will maintain the predicted trajectory path as it is advanced, the more flexible needle knife catheter may veer off-axis into a neighboring structure, which may be a major vessel.

Dilation of the bilio-enterostomy tract

Tract dilation is required prior to stenting. As in ERCP, graduated bougies and non compliant balloon catheters can be used. Each has pros and cons. Bougies have the advantage of excellent operator control of the dilation force, as the operator can gauge the amount of resistance encountered during advancement of the bougie. However, the dilation force is axial, which can lead to a separation of tissue planes during bougie advancement. Balloons have the advantage that they can be inserted in a compressed state, thereby minimizing the delivery catheter size to around 5 Fr. The dilation force is radial. However, balloons dilate to a fixed diameter in an “all-or-nothing” fashion which increases the risk of perforation, leakage, and bleeding.

If passage of a balloon or bougie across the bowel wall fails after guidewire access, tract dilation can be facilitated with diathermy using a double lumen needle knife catheter. Alternatively, a catheter with a diathermic ring at the tip can be used. Endoscopists in Europe have used a 6 Fr diathermic ring device, (Endoflex, Voerde, Germany). In the United States, only a 10 Fr diathermic ring device (Cystotome CST10; Cook Medical) is Food and Drug Administration cleared. Due to the large size, the Cystotome is a rigid device that is difficult to advance across the oblique exit of the working channel of the therapeutic CLA echoendoscope.

Stent drainage

Again, as in ERCP, a variety of plastic and metal stents can be used. Pigtail stents are a logical choice to minimize the risk of stent migration (especially into the duct), but the pigtail end makes coaxial stent insertion more difficult. An advantage of a straight stent is the ability to retrieve or exchange the stent over the wire without loss of ductal access. Covered SEMS have been used for transenteric drainage, but may migrate, particularly with shortening^[32]. The covering may block drainage of a secondary duct (*e.g.*, cystic duct or intrahepatic branch). Uncovered SEMS are unsuited for transenteric drainage due to leakage between the struts. However, an uncovered SEMS can be placed in exchange for a temporary plastic stent after the fistula tract has matured^[11].

Current technical challenges

There are three main limitations using current “off-the-shelf” tools. The first is the “step-off” between the wire and device. The device tends to “buckle” where tissue resistance is encountered and may not advance over the wire. The second is the need to exchange multiple devices over-the-wire. This can result in leakage of bile into the periductal space, or leakage of enteric contents into the extraintestinal space. Device exchanges are cumbersome and time consuming, and guidewire access to the bile duct can be lost. The third limitation relates to tubular stents, which are designed for luminal drainage. Whether plastic or metal, tubular stents do not impart the necessary apposition of two nonadherent lumens to prevent leakage. Lacking anchorage, the stent may move or dislocate. The ends of tubular stents may also cause tissue injury.

Compression magnet anastomosis

Jamidar *et al.*^[33] reported on a novel hinged metalloplastic anastomotic device to create a choledochoduodenostomy. The device resembles a 7 Fr stent, but has a central ferrous metallic component. The devices were inserted into the bile duct of pigs using standard ERCP technique over a 0.035-inch guidewire. A magnet was then endoscopically positioned in the duodenum to mate with the bile duct magnet and exert compressive ischemic force. Anastomoses ranging from 5 to 10 mm were successfully accomplished in all survival animals.

Compression coil anastomosis

Chang *et al.*^[34] reported on a novel EUS-guided coil technique using a modified compression coil device with “fin-coil” configuration in dogs. The coil delivery device consisted of a 19 gauge needle pre-loaded with stretched coil in the lumen. EUS-guided needle puncture into the CBD was followed by deployment of 50% of the coil into CBD, and remaining 50% stayed within the duodenal bulb to hold the CBD and duodenum walls together with its compressive force. Immediate drainage was successful in 3/4 animals with overall drainage (normalization of bilirubin) successful in 4/4. Creation of a chronic fistula between CBD and duodenum was achieved in all 4 dogs

and there was no evidence of bile leak or perforation. All coils dislodged successfully into the duodenum.

Exchange-free lumen-apposing device

Binmoeller *et al.*^[35] reported on a catheter-based system (AXT System, Xlumena, Mountain View, CA) that delivers multiple tools in a co-axial fashion without the need for device exchange to secure bile duct access, tract dilation and immediate stent placement for drainage. The AXT device locks to the echoendoscope and is designed for single operator - single hand deployment. The exchange-free system is composed of a unique anchor needle that punctures the walls of the gastrointestinal tract and bile duct and maintains continuous apposition of the two lumens to prevent leakage of contents during instrumentation. A fully covered lumen-apposing metal stent (AXIOS, Xlumena), previously evaluated in porcine studies^[36], is pre-loaded into the AXT System and deployed directly over the anchor needle to maintain tissue apposition and create a tract for drainage. Chronic porcine survival studies were conducted on 3 animals with technical success in creation of a cholecystgastrostomy in all.

CERTIFICATION AND CREDENTIALING

EUS guided biliary drainage is becoming more widely accepted as an alternative to failed ERCP^[13,28,37]. Like any other evolving technology in its developing stages, currently there are no defined guidelines as to who should be performing ESCP and what should be the criteria for credentialing someone to perform this procedure. The limitation of this technique resides in its infrequent use with limited number of cases performed and hence formal training dedicated to this specific procedure can be difficult. Further, having a fixed minimum number of cases required as part of training can be even more challenging. Currently ESCP is also limited by the tools available, which are not dedicated for this type of procedure.

National and International organizations also do not have any recommendations or required criteria for training. ASGE has recommendations for number of procedures required for EUS and ERCP credentialing. ASGE recommends 75 mucosal and pancreatico-biliary exams and 50 EUS with FNA^[38]. For ERCP the number required is 180 with half being therapeutic^[39]. Even these numbers seem suboptimal for comfort of these procedures based on surveys of trainees in advanced training. Definitely the numbers for EUS guided biliary drainage will be much higher based on the significant technical complexity involved. Different variations of the technique with different complexity, are further complicating the credentialing process.

Based on these complexities, in this recent consortium meeting of experts, recommendations on who should be doing ESCP include: (1) Endoscopists routinely performing pancreatico-biliary EUS and FNA; (2) Endoscopists with large ERCP and EUS experience for nearly 4-5 years (at least 200-300 EUS and ERCP each year); (3) Endosco-

pists with 95%-98% success rate for standard ERCP with normal anatomy; and (4) Location into a center with IR and/or pancreatico-biliary surgery back up.

CODING AND REIMBURSEMENT

Optimal reimbursement of a procedure is dependent on appropriate coding. When developing a code for a procedure, components, which are looked at, are: physician work, practice expense and malpractice expense.

Currently no specific codes exist for ESCP. They are billed with combination of EUS codes and ERCP codes. Some of the interventions done don't fall in the realm of either EUS or ERCP and then surrogate codes are used which is not optimal. Some of the interventions performed, which are unique to ESCP are EUS guided contrast injection, guidewire placement, dilation of the transgastric and transduodenal tracts (balloon/bougie or needle knife) and transmural stent placement^[13,37]. CPT specifically states that one should not simply "approximate" coding by using codes that may seem "close enough" but do not accurately describe a service.

The different approaches and drainage routes used make this even more complex. In situations where EUS is used as a mode to access the bile duct (extrahepatic or intrahepatic) and subsequent rendezvous transpapillary ERCP is performed is the simplest situation to code. One can combine EUS with FNA with standard ERCP codes. Even in this case, as there is no specific code for passage of guidewire through the EUS needle, part of the procedure is not clearly defined with currently available codes. Hence the procedure should also be coded with additional *code for unlisted procedure* and *procedure explained in detail*.

The most optimal way for coding these EUS guided bile duct procedures will be to use standard codes for very obvious interventions and along with that use the code for unlisted procedure^[40]. Using *code for unlisted procedure* requires additional work. Supporting documentation with each claim has to be submitted separately which should describe the nature, extent and need for the procedure. Time effort and equipment necessary along with complexity of symptoms, final diagnosis, and patient findings are to be described as well. Manual review by payor on case-by-case review is done and many times individual payor has to be contacted to discuss the procedure.

In conclusion, EUS-guided biliary drainage is a novel procedure destined to be incorporated into our therapeutic arsenal. The ability to offer a tailored minimally invasive solution for patients in whom ERCP fails or is not feasible due to various reasons; led to the creation of a dedicated consortium. This consortium aims to create a registry to catalogue the growing number of ESCP techniques and tools, as well as indications. Ultimately, technical advancements will be driven by dedicated research protocols, while nomenclature, training and credentialing will be formalized. Only this will allow to establish EUS-BD as a standard procedure.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Monica Gaidhane for helping organize the consortium meeting, and for helping write this paper.

Abstract

Liver injuries are repaired by fibrosis and regeneration. The core stage is the repair response and fibrosis formation as a scar. The cause of overly-responsive scar formation and diminished regeneration, especially in liver fibrosis and cirrhosis, is still unknown. The epithelial to mesenchymal transition (EMT), a previously discovered mechanism, plays an important role in liver fibrosis and tumor metastasis. Recently, EMT has been found to be associated with liver and bile duct cell fibrosis. Analyzing the established models and chronic disease processes, we propose that EMT liver cells may also lose their regenerative capability due to phenotype changes and that the remaining liver cells may quickly lose their regenerative capability in liver fibrosis or cirrhosis. Recognizing these phenotype changes or transition cells may play an important role in targeting therapy to reverse fibrosis not only by disrupting the transition that is necessary to produce the extracellular

matrix but also by restoring the regenerative capacity of EMT-like cells.

INTRODUCTION

Wound injury and repair is one of the most common pathophysiological processes during human life. In all organ systems, the normal mammalian response to injury occurs in three overlapping but distinct stages: inflammation, new tissue formation, and tissue remodeling^[1]. Therefore, injured organs, such as lung, kidney, liver or skin, will first respond with inflammation when insults, such as those caused by microorganisms and toxins, occur. Then next critical step is repair and regeneration, but during the repair or remodeling process, excessive deposition of extracellular matrix (ECM) collagen 1 and collagen 3 leads to hypertrophic scars, which results in tissue dysfunction^[1]. Fibrosis is an excessive, uncontrolled injury response that occurs in organs, such as the lungs, kidneys, heart or skin, and is described by a persistent deposition of ECM. Fibrosis has been as a leading cause of morbidity and mortality^[2]. There are more similarities between liver and skin regeneration due to the sustained regenerative capabilities of epidermal cells and hepatocytes after injury. Additionally, epidermal cells can be regenerated by

remnant stem cells in hair follicles, and hepatocytes can be regenerated by cells in the canals of Hering, such as oval stem cells or other progenitors^[1]. The core stage for injuries is the repair response and scar formation. As a protective response to insults, regeneration follows injury; therefore, the fibrogenetic source and the mechanism impeding regeneration are essential. In this review, we will explore recent evidence of liver fibrogenesis and possible regenerative capacities, especially in pathways that have been newly targeted to reverse fibrogenesis.

LIVER REGENERATION IN PHYSIOLOGICAL AND PATHOLOGICAL CONDITIONS

Unlike liver regeneration by Prometheus in Greek mythology, we have considered “regeneration” to be a hyperplastic response rather than the actual regeneration of the remnant liver^[3-5]. After a 2/3 partial hepatectomy, most hepatic cells rapidly enter the cell cycle and undergo an average of approximately 1.6 cycles of replication per cell to completely restore the original liver mass^[5,6]. The classic transplantation experiments using fumarylacetoacetate hydrolase (FAH)-deficient mice (FAH knockout mice) and urokinase-type plasminogen activator transgenic mice demonstrated that hepatocytes can replicate at least 69 times^[7,8]. Interestingly, hepatocytes can differentiate into cholangiocytes and form mature bile ducts after bile duct ligation and toxic biliary injury and may even behave as stem cells under select circumstances^[9,10]. However, under physiological conditions, hepatic regeneration only occurs to replace individual, aged hepatocytes—typically those in zone 1 (periportal)^[11]. The regenerative components required for the process may be categorized into three networks: cytokine, growth factor and metabolic^[12]. The innate immune system and cytokines, such as interleukin-6 (IL-6), tumor necrosis factor (TNF), hepatocyte growth factor (HGF) and complement, have been identified and recognized as playing important roles in regenerating the liver^[12-14]. TNF binds its type I receptor, leading to nuclear factor kappa B activation in Kupffer cells, which produce IL-6 and TNF; IL-6 is subsequently released into the serum and binds to its receptor to activate the STAT-3 signaling pathway to initiate hepatocyte regeneration^[12]. Transforming growth factor-beta (TGF- β) is released by the stellate cells, leading to Smad2 and Smad3 phosphorylation. Smad complexes translocate into the nucleus to transactivate target genes to induce epithelial to mesenchymal transition (EMT) and inhibit proliferation^[15]. TGF- β may be an essential factor in liver fibrosis.

Activation of intrahepatic stem cells, such as hepatocyte progenitor cells and oval stem cells, and bone marrow stem cells are the main sources of exceptional regenerative capacity^[16]. The properties of the liver generally allow for complete reconstitution following acute, moderate injuries.

After partial hepatectomy or CCl₄-induced injury, liver regeneration is replicated by remanent hepatocytes. In rare

cases, in the regeneration of the liver that injures induced by other toxins, such as galactosamine, activation of a progenitor cell compartment to replicate and differentiate^[12].

However, the liver does not heal as effectively in response to chronic liver diseases such as liver fibrosis and cirrhosis.

LIVER FIBROSIS AND REGENERATION

Liver fibrosis is an excessive scar response leading to cirrhosis, which is characterized by the formation of regenerative nodules in the liver parenchyma separated by fibrotic septa. Three major mechanisms are involved in the generation of cirrhosis: cell death, aberrant extracellular matrix deposition (fibrosis), and vascular reorganization^[17]. Liver fibrosis mainly represents quantitative and qualitative changes in the ECM, including the deposition of collagens, elastin, and tenascin, which can increase 3-5 fold^[18]. The excessive deposition is accompanied by a shift in the type of ECM in the subendothelial space from the normal low-density, membrane-like, basement matrix to an interstitial-type matrix containing fibril-forming collagens^[18]. Liver fibrosis accelerates to end-stage cirrhosis and shifts from reversible to irreversible. Therefore, most efforts should focus on treating liver fibrosis and understanding early fibrogenesis to control its progression. Activated fibroblasts or myofibroblasts are the key mediators of liver fibrosis^[17,19,20]. Stellate cells, which are located in the subendothelium and constitute approximately 5% of the liver parenchyma, had been considered to represent the entire population of activated fibroblast cells; however, stellate cells have recently been found to possess more multifaceted functions in liver fibrosis, and we now know they are not the sole cause of fibrosis^[19,21]. Such activated fibroblasts can be derived via the activation and proliferation of resident fibroblasts [hepatocyte stellate cells (HSCs) and portal fibroblasts], circulating fibrocytes, bone marrow stem or progenitor cells and epithelium-mesenchymal transition cells^[2,19,22].

The underlying causes of diminished liver regeneration in liver fibrosis and cirrhosis are still a mystery. Using the proliferating cell nuclear antigen to assess proliferation, a cirrhotic liver has more DNA synthesis than a normal liver but also has great variability in the pseudodubules^[23,24]. However, the high proliferation index does not reflect the actual cell division rates. The cell cycle is impaired by anaphase bridges, aberrant mitosis, and arrest in G₂/M, which has been shown in mTR^{-/-} transgenic mice^[25]. Telomere shortening delays liver regeneration and can be restored by telomerase treatment, which has been shown to improve albumin levels in mTR^{-/-} transgenic CCl₄-cirrhosis models. Telomere shortening is thought to be proof that the replicative activity of hepatocytes is diminished in advanced cirrhosis and chronic liver injury in humans^[26-28]. Telomere delivery inhibits the progression of cirrhosis in mice^[25] and leads to a state of “replicative senescence”^[29]. As with wound repair, the

majority of hepatocytes are believed to undergo necrosis or apoptosis, providing space for proliferating cells during chronic insults, such as viral infections, that exhaust the regenerative capability of the liver. Telomere shortening is evidence of these processes. However, there is no direct evidence to support the loss of regenerative capability during chronic insults is entirely due to continuous regeneration and impairments. Therefore, we investigated possible regenerative mechanisms in fibrosis.

HEPATOCTE EMT AND FIBROSIS

The most distinct difference in the injury response is the liver's powerful regenerative capability compared to the kidneys, lungs and others organs. Another difference is the rapid progression in fibrosis due to acute processes, such as hepatitis C virus infection^[30] or drug injury, or a chronic process, such as chronic hepatitis B virus (HBV) infection. Therefore, liver fibrosis is a more complex process relative to many other processes. The EMT is believed to play an important role in fibrosis, which may be reversed or attenuated by antagonizing essential cytokines and growth factors^[31]. Undergoing an EMT refers to the loss of apicobasal polarity in epithelial cells; intercellular adhesion complexes undergo dramatic phenotypic changes, causing them to become nonpolar and thus allowing these cells to move through the ECM like mesenchymal cells^[32-34]. Organ fibrosis can be classified as a type 2 EMT, which is associated with tissue repair and involves secondary epithelial or endothelial cells transitioning to resident tissue fibroblasts in response to persistent inflammation^[33,34]. A type 2 EMT can continue to respond to ongoing inflammation and lead to the expression of mesenchymal markers on cells, which can advance to various extents through an EMT, namely, a partial EMT. The partial EMT refers to an intermediate phenotype as cell transition, with progressive loss of epithelial markers (E-cadherin, ZO-1) and gain mesenchymal markers (vimentin, alpha smooth muscle actin, FSP1 and β -catenin)^[33]. If the cells ultimately shed all of their epithelial markers and gain a complete fibroblastic phenotype, the cells have undergone a complete EMT^[33]. The accumulating evidence has suggested that the EMT contributes to liver fibrosis, similar to processes that occur in other organs, such as the lungs, kidneys, and intestines^[33].

An EMT can be found in response to growth factors, such as epidermal growth factor (EGF) or TGF- β , and dimethyl sulfoxide in rat fetal liver cells^[35,36]. In normal mouse and adult livers, stroma cells can express both mesenchymal (vimentin, collagen I and alpha smooth muscle actin) and epithelial markers (cytokeratins, albumin and E-cadherin) during the hematopoietic but not the nonhematopoietic liver by the end of gestation, indicating that liver stroma cells may be EMT cells that support hematopoiesis^[37]. Chronically damaged livers, as in cirrhosis, in which there are a large number of epithelial progenitors and myofibroblastic HSCs, have cells that undergo an EMT similar to the transition that occurs in

the kidneys under pathological conditions^[38,39]. Indirect evidence of EMT has been observed in HSC culture *in vitro*, in which HSCs were shown to coexpress mesenchymal and epithelial markers^[38]. The primary HSC express stable mRNA levels of two epithelial markers, Mpk (an oval cell marker) and CK-19 (a marker of immature and mature biliary epithelial cells)^[38]. Convincing evidence has shown that TGF- β can induce an EMT in mouse hepatocytes *in vitro*. The mechanism was demonstrated to be the result of TGF- β -induced activation of the Snail transcription factor, which is a key molecule in the EMT, and repression of epithelial markers, such as E-cadherin^[32,40,41]. Further evidence has demonstrated, using AlbCre. R26R-stoplacZ double transgenic mice *in vivo*, that hepatocytes can undergo EMT. Avoiding the double transgenic mice phenotype changes, using lineage-tracing experiments, hepatocytes can transdifferentiate into mesenchymal-like cells that have lost albumin and still have an activated *Laz* gene. After CCl₄-induced liver fibrosis, up to 45% of FSP1-positive fibroblasts were found to be *Laz*(+), which drives the EMT, similar to processes that occur in the kidneys^[39,42]. Undoubtedly, these transition cells have lost their hepatic markers, such as albumin, thus losing its main secreting function. Using collagen I and transferrin costaining demonstrated that half the resident hepatocytes had undergone an EMT phenotype in a TGF- β transgenic mouse model and in samples from patients with HBV, and the key transcription factor Snail was also found in the damaged regions^[43]. Hepatitis C viral protein NS5A also induces hepatic dysplastic alterations of cell morphology with EMT phenotype and participates in oncogenic transformation of primary hepatocyte precursors^[44]. TGF- β induces Snail, activates the Smad2/3 pathway and, finally, mediates the transition to the EMT phenotype^[15]. The Snail-positive cells also consisted of 50% of the remaining hepatocytes in the damaged regions^[43]. The mesenchymal markers vimentin and α -SMA were detected in fibrotic human and rat livers around the fibrotic septa, which indicates the presence of transition hepatocytes and EMT^[45]. EMTs also occur in cirrhotic liver cells derived from murine CCl₄-induced models^[46]. Interestingly, the EMT-like cells express albumin and the mesenchymal marker vimentin and also gain collagen I secretory functions. Cell isolates from cirrhotic livers can exhibit anti-apoptosis effects in contrast to normal hepatocytes under TGF- β treatment^[46]. While untreated normal liver-derived hepatocytes have been shown not to display features of an EMT, they did respond to TGF- β with increased vimentin expression and EMT characteristics^[46]. Therefore, accumulated evidence has shown that EMT-like cells, even EMT cells, exist during chronic liver injury with a partial loss of functions such as albumin and transferrin secretion and a gain of mesenchymal features.

Recently, an EMT was also found in bile ducts in animal models and patients, especially in bile duct ligation, primary biliary cirrhosis and nonalcoholic fat liver diseases, due to hedgehog (Hh) signaling activation^[47-49]. Hedge-

hog signaling is low in the normal adult liver but plays an important role in liver development^[50]. Injured cholangiocytes activate hedgehog signaling through the patched receptor (Ptc) to release glioblastoma (Gli) family transcription factors to Hh-target genes. In Patched-deficient, Patched haplo-insufficient [Ptc(+/-)] and PtcLacZ mouse models, the bile ducts exhibit more EMTs, myofibroblast accumulation and fibrosis^[48,49,51]. Hh activation in bile ducts can contribute to biliary fibrosis and cirrhosis. Different mesenchymal markers, such as vimentin, α -smooth muscle actin and S100A4, are located in the fibrous septa and extend around the nodules of liver parenchyma, which contain transition hepatocytes that have gained the ability to secrete ECM^[43,46,48,49]. Based on the recent discoveries, these transition hepatocytes and cholangiocytes can be remodeled into other fibroblast-like phenotypes upon exposure to different insults and thus can be divided into two stages: partial-EMT or EMT-like and true, or complete, EMT. The partial-EMT can exist in the three stages of wound repair: inflammation, new tissue formation, and remodeling. Inflammation and necrosis can release different cytokines that initiate the clearance of the necrosis area and regeneration. The recognized cells contain EGF, IL-6, HGF, TNF and the important negative regulator TGF- β , especially in liver regeneration^[1,12]. Until now, TGF- β , EGF and others through the TGF- β , Smad or hedgehog pathways initiate the EMT in different liver diseases and liver fibrosis in animal models^[43,46,48-50]. Therefore, various cytokines and growth factors, released by necrotic cells, infiltrating inflammatory cells, HSCs and activated fibroblasts from different sources, can initiate the EMT as an early event during liver fibrosis.

However, these studies have been recently questioned because the use of transgenic-animal models allows for *in vivo* lineage-specific tracking using EMT-specific markers. These studies use a cross between an alpha-fetoprotein (AFP) cre mouse and a ROSA26YFP or ROSA26- β -gal stop mouse to trace cell fate through the expression of AFP^[52,53]. None of the resulting fibrosis cells originated from the genetically marked hepatic and biliary epithelial cells. The challenging EMT results were repeated after inducing liver fibrosis by bile duct ligation (BDL), CCl₄, or 3,5-diethoxycarbonyl-1,4-dihydrocollidine. However, the critical concerns originate from these EMT markers and the absence of such evidence in clinical patients.

FSP1 and Snail are popular markers for detecting the transition. FSP1 was not expressed by HSCs or type I collagen-producing fibroblasts in liver sections from FSP-GFP reporter mice BDL or CCl₄-treated mice. FSP-1 is expressed in inflammatory macrophages, thus FSP1 is not a marker for myofibroblasts or their precursors^[54]. Another important EMT marker, Snail, plays a key role in liver fibrosis progression *in vivo* in a CCl₄ model by triggering the proximal genetic programs that control multiple aspects of fibrogenesis in the Snail transgenic CKO mouse, which promotes growth factor expression and extracellular matrix biosynthesis to the ensuing chronic inflammatory responses in liver fibrosis^[55]. These Snail-

positive cells also lose transferrin expression in the damaged regions, which is a specific liver marker in a complete epithelial to mesenchymal transition. The partially trans-differentiated hepatocytes comprised 50% of the remaining hepatocytes in the damaged regions, although they cannot be distinguished from other immune cells^[43].

Although there is no current evidence that myofibroblasts originate from liver cells, more experimental and clinical liver fibrosis were reported. These models may not reflect the pathophysiology in chronic human liver disease and in the TGF- β mouse model, which requires further study. Clearly, such studies have offered important evidence for the further study of EMT programs in liver fibrosis. Nevertheless, liver fibrosis may be independent of the hepatocyte EMT program and may instead be affected by important factors, such as Snail.

TARGETS OF LIVER FIBROSIS AND RECOVERING THE REGENERATIVE CAPACITY

Stellate cells can be found within the progenitor cell niche in normal and regenerating livers, near the intrahepatic bile ducts, which was recognized as one of the central sources of fibrogenesis^[21]. Recent studies have shown more important roles for immunity in promoting liver fibrogenesis^[19]. Various cytokines and growth factors can affect stellate cells from inflammatory infiltrates and necrotic tissue. Stellate cells can also produce different cytokines or growth factors by paracrine or autocrine transmission to influence the adjacent hepatocytes. TGF- β , a key regulator of fibrogenesis and EMT, can be observed in acute or chronic liver injury in HSCs^[13,56,57]. TGF- β can directly activate adjacent hepatocytes through Smad signaling, induce EMTs, and induce ECM and fibrogenesis. Hedgehog signaling may also be a key regulator in the promotion of EMT and fibrogenesis in bile duct diseases. Blocking these signaling pathways is an important therapeutic target for mediating regeneration (Figure 1).

TGF- β exerts its effects by binding to the TGF- β type II receptor, which causes recruitment and phosphorylation of receptor type I and formation of a complex. The activated receptor type I subsequently recruiting Smad2/3 and Smad4, which are known intracellular mediators of TGF- β . Once phosphorylated by the activated TGF- β receptor, Smad2 and/or Smad3 bind Smad4 and translocate to the nucleus, where they regulate TGF- β target genes^[57]. Smad7, a feedback regulator of TGF- β , can prevent liver fibrosis and HSC activation in rat BDL- and CCl₄-induced liver fibrosis models^[13,58]. Using Smad transgenic mice also attenuates TGF- β signaling and EMTs, thus improving CCl₄-provoked liver damage and fibrosis^[43]. The complex formation of BMP-7 and TGF- β with different types of ALK receptors is mediated by Smad proteins. In renal tubular epithelial cells and mammary ductal epithelial cells, BMP7 has been shown to reverse the TGF- β 1-induced EMT, given that NTN

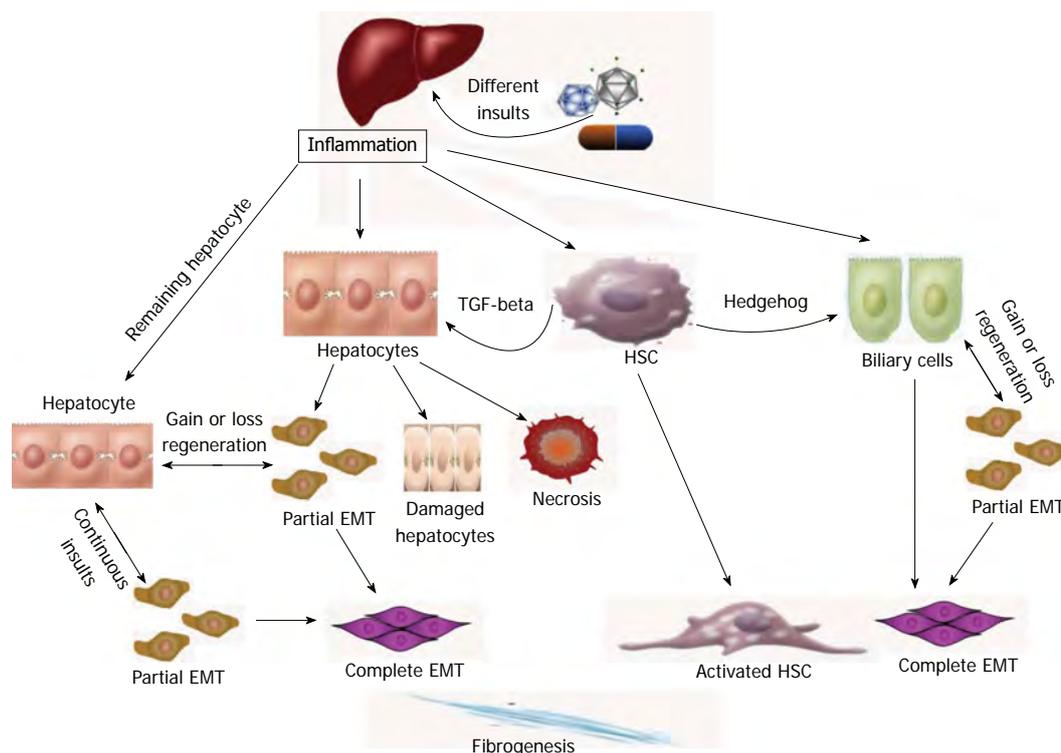

Figure 1 Liver regeneration and the epithelial to mesenchymal transition. The diagram shows the fibrogenesis *via* epithelial to mesenchymal transition (EMT) in the liver. Different insults initiate inflammation and then cause hepatocyte stellate cells (HSCs) activation and hepatocyte and biliary cell damage, necrosis and EMT. Except for the necrotic and damaged cells, the remaining “normal” liver cells can be divided into 2 groups: normal and EMT-like hepatocytes. Continuous insults will shift those EMT-like cells to complete EMT cells and finally myofibroblasts, the main producer of extracellular matrix, which may be one of the main causes of an early loss of regenerative capacity. A similar process also occurs in biliary cells. HSCs play an important role in secreting key cytokines, such as transforming growth factor-beta (TGF-beta) and hedgehog, to affect the adjacent cells and promote EMTs.

mice (nephrotoxic serum nephritis; a chronic nephritis model) treated with recombinant human BMP can re-induce E-cadherin^[59].

The Hh signaling that was observed in bile duct fibrosis and EMTs has provided us with a new mechanism and new therapeutic targets^[47,51]. Hh ligands that interact with the Hh receptor Patched (Ptc) liberate the coreceptor Smoothed, which activates Gli family transcription factors and Hh-target genes^[50]. The Hh pathway can be activated in the liver after BDL and Roux-en-Y hepaticojejunostomy to relieve biliary obstructions. Hh signaling decreased as the duct populations and concomitant fibrosis were observed^[48,60]. The role of the Hh pathway was observed in nonalcoholic fatty liver disease and verified in Ptc transgenic mouse bile duct cells. The Hh inhibitor cyclopamine and the Hh-neutralizing antibody have been shown to reverse the EMT and fibrosis in mouse models and *in vitro* co-culture with cholangiocytes and MF-HSCs and also to reduce TGF-β expression^[48,49].

Similar to TGF-β, activated HSCs can produce an Hh ligand by paracrine and autocrine signaling^[48,61,62]. Therefore, HSC can produce TGF-β and the Hh ligand to affect the adjacent hepatocytes and cholangiocytes to induce EMT and fibrosis. Inhibiting the Hh pathway may reduce TGF-β expression, which may indicate a commu-

nication between them^[49].

If the remaining “normal” liver cells had 40%-50% EMTs, as mentioned above, and continuously were damaged, the hepatocytes capable of regeneration may actually be less than 50%, excluding the damaged or necrotic hepatocytes, which would lose their normal functions and exhaust their regenerative capacity earlier than expected. The remaining hepatocytes, including the newly identified partial EMT or EMT-like cells, have diminished regenerative capacity potentially due to elevated rates of apoptosis followed by repeated regeneration and damage according to the traditional theory^[13]. The newly regenerated hepatocytes and the remaining hepatocytes can continuously transition to mesenchymal cells during fibrosis (Figure 1). Recognizing whether these phenotype changes or the transition cells have a more important role in targeting therapy for controlling the transition phenotype can not only disrupt the transition to produce ECM but can also help to recover the regenerative capacity of the EMT-like cells.

As mentioned above, EMT-targeted therapy can reverse partial EMT cells, not only during fibrosis but also during regeneration. These phenotype changes or transition cells may provide us a new insight in identifying the regenerative capacity of these partial EMT or complete EMT cells and also for targeting new therapies.

METHODS: The human genomic DNA of all patients was extracted from peripheral blood cells in order to determine the single nucleotide polymorphism (SNP) of *ITPA* (rs1127354). SNP genotyping was performed by real time polymerase chain reaction (PCR, ABI TaqMan allelic discrimination kit) for 102 treatment-naive Egyptian patients with chronic HCV. All patients had no evidence of cardiovascular or renal diseases. They received a combination treatment of pegylated interferon α (PEG-IFN α) as a weekly subcutaneous dose plus an oral weight-adjusted dose of ribavirin (RBV). The majority received PEG-IFN α 2a (70.6%) while 29.4% received PEG-IFN α 2b. The planned duration of treatment was 24-48 wk according to the viral kinetics throughout the course of treatment. Pre-treatment liver biopsy was done for each patient for evaluation of fibrosis stage and liver disease activity. The basal viral load level was detected quantitatively by real time PCR while viral load throughout the treatment course was performed qualitatively by COBAS TaqMan assay.

RESULTS: Ninety-three patients (91.2%) had *ITPA* SNP CC genotype and 9 (8.8%) had non-CC genotype (CA and AA). The percentage of hemoglobin (Hb) decline was higher for CC patients than for non-CC patients, particularly at weeks 4 and 8 ($P = 0.047$ and 0.034 , respectively). During the first 12 wk of treatment, CC patients had significantly more Hb decline > 3 g/dL than non-CC patients: 64.5% vs 22.2% at weeks 8 and 12, respectively, ($P = 0.024$ and 0.038). Reduction of the amount of the planned RBV dose was significantly higher for CC patients than non-CC patients during the first 12 wk ($18\% \pm 12.1\%$ vs $8.5\% \pm 10.2\%$, $P = 0.021$). The percentage of CC patients with RBV dose reduction was significantly greater than that of non-CC patients (77.4% vs 44.4% , $P = 0.044$). Multivariate analysis identified only the percentage of RBV dose as a predictor for Hb decline. Platelet decline

Abstract

AIM: To investigate and clarify, for the first time, the role of inosine triphosphate pyrophosphatase (*ITPA*) polymorphism in Egyptian chronic hepatitis C virus (HCV) patients.

was significantly higher in non-CC patients than CC patients at weeks 12, 24 and 48 ($P = 0.018, 0.009$ and 0.026 , respectively).

CONCLUSION: Rs1127354 *ITPA* polymorphism plays a decisive role in protecting against treatment-induced anemia and the need for RBV dose reduction in Egyptian HCV patients.

Pre-treatment role of inosine triphosphate pyrophosphatase polymorphism for predicting anemia in Egyptian hepatitis C virus patients. *World J Gastroenterol* 2013; 19(9): 1387-1395 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i9/1387.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i9.1387>

INTRODUCTION

Hepatitis C virus (HCV) infection is considered one of the most horrifying diseases. It affects approximately 3% of the world's total population, more than 170 million people worldwide. It can range in severity from a mild illness lasting a few weeks to a serious lifelong disease that may end with cirrhosis and hepatocellular carcinoma^[1,2]. The prevalence of HCV infection shows considerable differences between countries; the lowest prevalence rate has been estimated in European countries. Parenteral anti-schistosomal treatment that was used in the 1960s and 1970s played a major role in the spread of HCV throughout Egypt^[3,4]. Egypt has been reported as having the highest prevalence rate of HCV worldwide, with HCV antibodies estimated at 10% and 20% of Egyptian adults in urban and rural areas, respectively^[5].

The standard treatment for HCV treatment worldwide, including Egypt, is pegylated interferon α (PEG-IFN α), which acts as an antiviral and an immunomodulatory cytokine, and ribavirin (RBV), a guanosine analogue that interrupts the viral RNA metabolism^[6,7]. Anemia is a well-known, serious side effect associated with the PEG-IFN plus RBV combination treatment that has been reported to occur in 54% of patients during the course of treatment^[8]. It leads to the necessity of dose reduction or premature discontinuation of treatment by 10%-14% of the patients^[6]. Anemia is mainly due to a RBV hemolytic effect on red blood cells (RBCs) or by IFN through either its suppressive effect on bone marrow or an auto-immune hemolytic reaction from excessive apoptosis of erythroid cells^[9-11]. Pretreatment screening of biomarkers is essential for evaluating both the risks and benefits of the available treatment regimen. In the last few years, some genome wide association studies have discussed the impact of host genetic factors on the treatment of hepa-

titis C. Some of these studies targeted the single nucleotide polymorphism (SNP) in the inosine triphosphate pyrophosphatase (*ITPA*) gene of patients mono-infected with HCV^[12-14]. Domingo *et al*^[15] reported a strong association between this polymorphism and induction of anemia in HCV/human immunodeficiency virus (HIV) co-infected patients. This gene is located on chromosome 20, and the SNP occurs at nucleotide 94 in exon 2 of the *ITPA* gene and leads to substitution of proline residue at position 32 to threonine (P32T, 94C \rightarrow A)^[16]. Although HCV is widespread in Egypt, it has not been spotlighted from the standpoint of host genetic studies. Our motivation to carry out this study was to clarify for the first time in Egyptian patients the association between the variants of the *ITPA* gene (encoding ITPase enzyme) and anemia induced during PEG-IFN α and RBV combination treatment, regardless of the impact on treatment outcome.

MATERIALS AND METHODS

Patients

The data of this study were collected from 102 Egyptian chronic hepatitis C patients. All were positive for HCV RNA for more than 6 mo and negative for any other viral infection. The pretreatment demographic data are displayed in Table 1. All patients were mono-infected with chronic hepatitis C with no evidence of HIV or hepatitis B infection. All participants were treatment-naive patients with no evidence of the presence of any associated liver diseases other than chronic viral hepatitis C. Patients with cardiovascular problems or renal impairment were not eligible for the study. They received standard doses of the combination treatment of PEG-IFN α and RBV in the Assiut National Center for the Treatment of Chronic Hepatitis under the supervision of the Egyptian Ministry of Health.

In the first week of treatment, all patients were given the fully recommended dosages of RBV. At week 2 and throughout the course of treatment, the dose of RBV was modified according to the hemoglobin (Hb) level. In the current study, we calculated the values of Hb at weeks 2 and 4, then every 4 wk throughout the treatment course. Informed consent was obtained from all participants for the collection and storage of blood samples for *ITPA* polymorphism testing. The study protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki.

Clinical endpoints

In relation to the polymorphism of *ITPA* genotyping, we had some clinical endpoints, including the absolute and percentage decline of Hb during the first 12 wk, RBV dose reduction following anemia, and the percentage of platelet (plt) count change.

Treatment regimen

The protocol specified a treatment duration of 24-48 wk depending on viral genotype and the response of patients

Table 1 Basal demographic and biochemistry criteria of all patients (mean \pm SD)

| Criteria | Total |
|------------------------------------|--|
| Number | 102 |
| Age (yr) | 32.5 \pm 7.3 |
| Sex (male/female) | 90/12 |
| BMI | 25.6 \pm 2.7 |
| Baseline Hb (g/dL) | 14.07 \pm 1.1 |
| plt ($\times 10^3/\mu\text{L}$) | 238.5 \pm 62.7 |
| WBCs ($\times 10^3/\mu\text{L}$) | 6.3 \pm 1.4 |
| ALT > ULN, n (%) | 78 (76.5) |
| Creatinine level (mg/dL) | 0.91 \pm 0.44 |
| Baseline HCV RNA (log IU/mL) | 5.4 \pm 0.7 |
| Metavir fibrosis stage, n (%) | |
| F1 | 69 (67.7) |
| F2 | 30 (29.4) |
| F3 | 3 (2.9) |
| Grade of inflammation, n (%) | |
| A1 | 64 (62.7) |
| A2 | 33 (29.4) |
| A3 | 5 (5.4) |
| PEG IFN, n (%) (dose) | |
| $\alpha 2a$ | 72 (70.6) (180 $\mu\text{g}/\text{wk}$) |
| $\alpha 2b$ | 30 (29.4) (1.5 $\mu\text{g}/\text{kg}$ per week) |
| Ribavirin dose (mg/kg per day) | 12.5 (10-15) |
| HCV genotype (G), n (%) | G4, 62 (60.8); G1, 40 (39.2) |

during the treatment course. An additional 24 wk of follow-up was done for evaluation of efficacy. The majority of patients (70.6%) received PEG-IFN $\alpha 2a$ (Pegasys) at a dose of 180 μg per week and 29.4% received PEG-IFN $\alpha 2b$ (Peginteron) at a dose of 1.5 $\mu\text{g}/\text{kg}$ per week, given as a subcutaneous injection. All patients received a 15 mg/kg daily oral dose of RBV (Rebetol).

The study had a planned treatment duration of 48 wk. However, the study was designed with a futility-stopping rule that would halt the trial if there was < 2 log₁₀ HCV RNA decline at week 12 or persistent viremia at week 24. The treatment duration was prolonged to 72 wk only for patients who had detectable HCV RNA at week 12 but undetectable at week 24. All patients were followed for 24 wk after cessation of treatment.

HCV RNA measurement and HCV genotyping

The pre-treatment HCV RNA level was detected by quantitative real time polymerase chain reaction (PCR) technique with a lower limit of detection of 12 IU/mL. Qualitative PCR by COBAS TaqMan assay^[17] was used for detection of viral load at weeks 12, 24 and 48. All patients underwent a pretreatment liver biopsy from which the liver disease activity and fibrosis stage were scored by the Metavir scoring system^[18]. HCV genotype determination was by sequence determination in the 5'-nonstructural region of the HCV genome followed by phylogenetic analysis^[7].

SNP genotyping of ITPA

Human genomic DNA was extracted from peripheral

Table 2 Clinical and laboratory data according to rs1127354 inosine triphosphate pyrophosphatase genotypes (mean \pm SD)

| Criteria | CC | CA + AA | P value |
|------------------------------------|------------------|------------------|---------|
| Number, n (%) | 93 (91.2) | 9 (8.8) | |
| Age (yr) | 32.3 \pm 7.3 | 34.4 \pm 7.7 | 0.457 |
| Sex (male/female) | 82/11 | 8/1 | |
| BMI | 25.4 \pm 2.8 | 26.8 \pm 1.6 | 0.046 |

| plt ($\times 10^3/\mu\text{L}$) | 233.2 \pm 62.1 | 292.2 \pm 74.3 | 0.046 |
| WBCs ($\times 10^3/\mu\text{L}$) | 6.2 \pm 1.5 | 6.8 \pm 1.1 | 0.172 |
| ALT > ULN, n (%) | 71 (76.3) | 7 (77.7) | > 0.99 |
| Creatinine level (mg/dL) | 0.9 \pm 0.46 | 0.98 \pm 0.22 | 0.349 |
| Baseline HCV RNA (log IU/mL) | 5.46 \pm 0.7 | 5.4 \pm 0.8 | > 0.99 |

Hb: Hemoglobin; BMI: Body mass index; plt: Platelet; WBCs: White blood cells; ALT: Alanine aminotransferase; ULN: Upper limit of normal of ALT = 12 IU/L; HCV: Hepatitis C virus.

blood. Genotyping of the *ITPA* SNP (rs1127354) was performed using the ABI TaqMan allelic discrimination kit (7500 Real Time PCR System; Applied Biosystems, Carlsbad, CA, United States). Patients were genotyped as CC, CA, or AA at the polymorphic site rs1127354.

Statistical analysis

The statistical analysis of comparisons of the categorical variables of the groups was performed by two tailed Fischer's exact probability test calculated on 2 \times 2 contingency tables. Data are shown as mean \pm SD. Student *t* test was used to compare the direct continuous variables between groups with a significant *P* value of less than 0.05. Odds ratios (OR) for the relative risk and 95%CI in the univariate analysis were estimated by binary logistic regression (program written by Pezzullo JC and Sullivan KM, version 05.07.20). The multivariate regression analysis for the identification of the predictors of Hb decline more than 3 g/dL were performed by JMP software (JMP IN, Version 9.0.2, SAS Institute Inc., Cary, NC, United States).

RESULTS

Baseline characteristics

Baseline demographic and biochemistry criteria for all 102 patients are reported in Table 1. Comparison of the *ITPA* genotyping groups (CC and non-CC) and their relationships to the baseline data are shown in Table 2. Baseline plt count and body mass index were the only significant baseline characters, and both were higher for non-CC than for CC patients (both *P* < 0.05). Hb data were missing for 6 patients from week 16 till end of treatment. Eleven patients stopped the treatment at week 24 due to continuous positivity of HCV RNA, with 91 receiving the complete course of 48 wk.

Distribution of rs1127354 SNP

Rs1127354 SNP genotyping of all participants was successful, and the distribution is as follows: 93 (91.2%) patients were identified as CC and 9 as non-CC (8 with the CA and one with the AA genotype) (8.8%). The minor

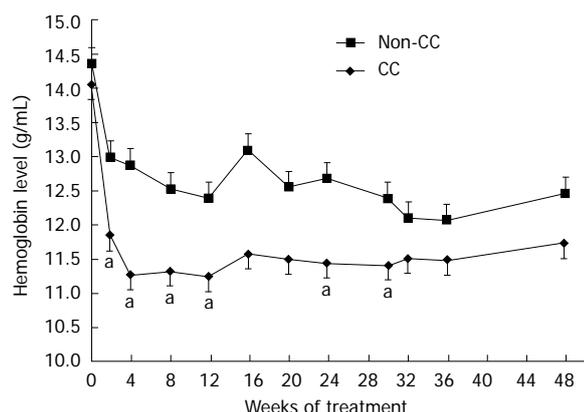

Figure 1 The hemoglobin decline in CC and non-CC inosine triphosphate pyrophosphatase genotypes. The hemoglobin (Hb) levels of the CC group show greater decline than those of the non-CC treatment groups during the course of treatment, with significance at weeks 2, 4, 8, 12, 24 and 30. $P < 0.05$ vs non-CC. The error bars indicate SE of the mean Hb level.

Table 3 Logistic regression analysis during the first 12 wk of combination therapy

| Variable | Univariate | | Multivariate | |
|---------------------------|-------------------|---------|------------------|---------|
| | OR (95%CI) | P value | OR (95%CI) | P value |
| Sex (female) | 0.49 (0.1-2.4) | 0.386 | 4.7 (0.9-26.4) | 0.123 |
| Age (≥ 40 yr) | 0.66 (0.24-1.8) | 0.421 | 1.02 (0.9-1.1) | 0.462 |
| BMI (≤ 24) | 2.03 (0.82-5.01) | 0.124 | 1.2 (1-1.5) | 0.068 |
| Baseline Hb (< 15) | 0.14 (0.04-0.49) | 0.002 | 0.8 (0.5-1.2) | 0.610 |
| Baseline plt (< 200) | 0.26 (0.1-0.65) | 0.004 | 0.9 (0.9-1) | 0.073 |
| <i>ITPA</i> genotype (CC) | 6.36 (1.24-32.41) | 0.025 | 0.4 (0.04-4.08) | 0.671 |
| RBV dose $\geq 80\%$ | 0.08 (0.01-0.3) | 0.0009 | 0.87 (0.82-0.92) | 0.00002 |

OR: Odds ratio; BMI: Body mass index; Hb: Hemoglobin; plt: Platelet; *ITPA*: Inosine triphosphate pyrophosphatase; RBV: Ribavirin.

allele frequency of rs1127354 was 0.04, which means the chance of (A) allele occurring was 4%; the distribution here is consistent with Hardy Weinberg Equilibrium ($P = 0.108$).

Hb decline according to *ITPA* genotypes

In the present study, anemia was defined as an Hb level decreased by > 3 g/dL and severe anemia was reported when Hb level declined to less than 10 g/dL. Figure 1 shows the difference in Hb level between the CC and non-CC groups throughout the treatment course. It was significantly different at weeks 2, 4, 8, 12, 24 and 30 ($P = 0.019, 0.016, 0.015, 0.013, 0.036$ and 0.047 , respectively). Hb decline > 3 g/dL during the first 12 wk was faster and more vigorous in the anemia-susceptible group CC than in the protective non-CC group at weeks 4 and 8 ($P = 0.047$ and 0.034 , respectively). By week 16, Hb had settled in the CC group with no further decrease, in contrast to the non-CC genotype group that showed a sudden increase in Hb followed by a continuous slow decrease until the end of treatment (Figure 1). The Hb decline > 3 g/dL was significantly higher among CC patients than non-CC patients at week 8 [36 of 93 (38.7%) vs none of 9 (0%), $P = 0.024$] and week 12 [60 of 93 (64.5%) vs 2

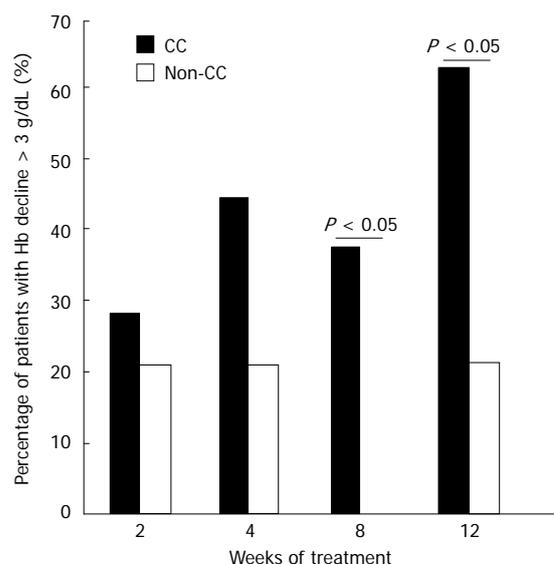

Figure 2 Patients with hemoglobin decline more than 3 g/dL. The percentage of CC and non-CC group patients who had hemoglobin (Hb) decline of more than 3 g/dL during the first 12 wk.

of 9 (22.2%), $P = 0.038$] (Figure 2). This indicated a protective advantage for patients with the minor allele A of rs1127354 SNP of *ITPA* gene against early onset anemia during combination treatment for Egyptian patients with chronic hepatitis C. During the first 12 wk, severe anemia with an Hb level less than 10 g/dL was identified in 29% of the CC patients compared with 11.1% of the non-CC patients ($P = 0.438$). Interestingly, the only patient in this study harboring a homozygous variant for the minor allele (AA) did not suffer anemia at any time during the treatment. In an attempt to identify factors predictive of the incidence of Hb decline more than 3 g/dL during the first 12 wk, we performed both univariate and multivariate regression analyses (Table 3). The univariate logistic regression analysis detected four factors as independent variables: *ITPA* genotype, percentage of received RBV dose and the baseline Hb and plt levels. On the other hand, the percentage of the received RBV dose ($\geq 80\%$ of total dose), was the only significant independent variable in the multivariate analysis.

Adjustment of RBV dose during combination treatment

The dose of RBV was modified according to the presence of treatment side effects. During the first 12 wk, the total number of patients needing an RBV dose reduction was 76 of 102 (74.5%). The percentage of RBV dose reduction was higher for the CC than for the non-CC patients ($18\% \pm 12.1\%$ vs $8.5\% \pm 10.2\%$ of the recommended dose, $P = 0.021$). The percentage of CC patients requiring an RBV dose reduction was greater than that of non-CC patients (77.4% vs 44.4%, respectively, $P = 0.044$) (Figure 3). Calculation of the time-point of reduction showed a significant difference between CC and non-CC patients at week 4, at which time none of the non-CC patients required an RBV dose reduction compared to 35 CC patients having a high reduction of RBV ($P =$

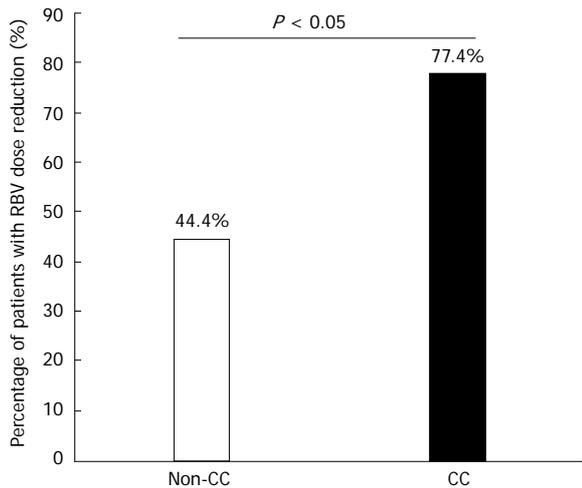

Figure 3 Patients with ribavirin dose reduction. Percentage of patients who had ribavirin (RBV) dose reduction during the first 12 wk of the combination treatment: It was significantly higher in the CC than in the non-CC genotype groups.

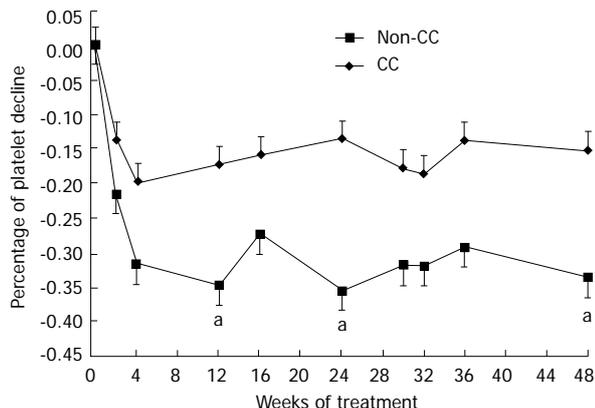

Figure 4 Decline of platelets of patients with different inosine triphosphate pyrophosphatase genotypes. The percentages of platelet decline of CC and non-CC group patients throughout the 48 wk of combination treatment. It indicates a greater decline of platelet count in the non-CC than CC variants. ^a*P* < 0.05 at weeks 12, 24 and 48. Error bars indicate standard error.

0.025). Although the reduction of RBV started earlier for patients with the CC than with the non-CC genotype (6.1 ± 5.3 wk *vs* 10 ± 8.5 wk, respectively), this did not reach statistical significance (*P* = 0.325). After the first 12 wk, 11 CC patients stopped the treatment due to non-responsiveness, whereas all non-CC patients completed the full course of treatment. Table 4 shows a comparison of the average RBV dose during the first 12 wk with the following 36 wk of treatment course between CC and non-CC patients. A significant difference was found (*P* = 0.035 and 0.029, respectively).

Protocol of RBV dose reduction

Almost all of the patients in this study had an RBV dose reduction in the first 12 wk of treatment, with 200 mg the initial reduction when Hb declined by more than 3 g/dL. Patients with severe anemia had a higher reduction when their Hb reached less than 10 g/dL. Usually, dis-

RBV: Ribavirin.

continuation of treatment is considered when the Hb declines to less than 8.5 g/dL; however, in this study, none of the patients had treatment discontinued due to this cause. During the first 12 wk, 74.2% of the CC patients (69 of 93) received 80% or more of the initially recommended dosage of RBV, whereas all non-CC patients received more than 80% of the dosage (*P* = 0.112).

Impact of ITPA polymorphism on platelet count change

Calculation of plt count change throughout the 48 wk of treatment showed a difference in the percentage of plt reduction between the CC and non-CC patients (Figure 4). Significant differences were found at weeks 12, 24 and 48 (*P* = 0.018, 0.009 and 0.026, respectively). Although CC patients had a lower baseline median plt count than non-CC patients (233.2 *vs* 292.2, respectively), they had a lower percentage of plt reduction during the early weeks of treatment (17.4% *vs* 28.5%, respectively). Figure 5 shows the difference between *ITPA* genotypes according to three levels of maximum plt reduction at week 4 (plt reduction more than $70 \times 10^9/L$, $(50-70) \times 10^9/L$, and less than $50 \times 10^9/L$). The percentage of patients was significantly different among those with plt reduction more than $70 \times 10^9/L$: 87.5% of non-CC *vs* 46.4% of CC (*P* =

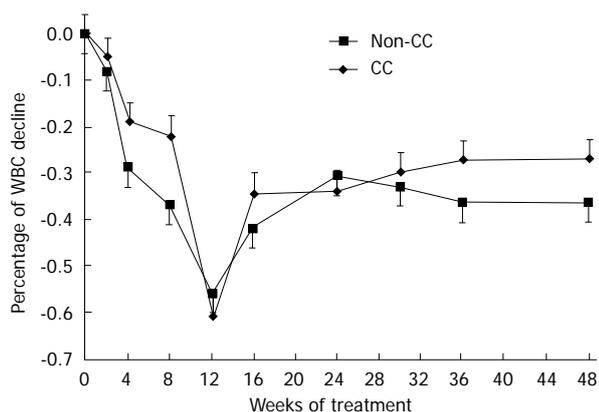

Figure 6 White blood cell decline of both inosine triphosphate pyrophosphatase genotypes. The change in white blood cells (WBCs) in the CC and non-CC inosine triphosphate pyrophosphatase genotype groups during the 48 wk of combination treatment: No significant difference between the 2 groups was found. Error bars indicate standard error.

0.029). This result indicates that the anemia-susceptible patients of group CC are less likely to develop a higher degree of plt reduction than non-CC patients. Notably, the percentage of the relative reactive increase in the plt count during weeks 1-4 was higher for CC patients than for non-CC patients but did not reach statistical significance (34.4% *vs* 11%, respectively, $P = 0.264$). However, the reactive plt increase of the CC and non-CC patients did not correlate with either an Hb reduction > 3 g/dL or with the baseline plt count of weeks 1-4.

No significant difference in the white blood cells was found between the CC and non-CC patients during the early weeks of treatment ($P > 0.05$) (Figure 6). Also, there was no significant association between *ITPA* genotype and early virological response at week 12.

DISCUSSION

To our knowledge, this is the first study to assess the impact of the rs1127354 *ITPA* genotype on the anemia of Egyptian patients infected with chronic hepatitis C, regardless of the outcome of treatment. Marsh *et al.*^[19] and Cao *et al.*^[20] reported the distribution of *ITPA* genotypes in multiple populations, which reached the highest rate among Asians (11%-19%) and lowest in Central/South Americans (1%-2%), while in Caucasian and African populations the distributions were constant (5%-7%). In our study, the minor allele distribution of *ITPA* polymorphism was 4%, which is almost comparable with previous reports. Previous studies have demonstrated the protective benefit of the minor allele A of the rs1127354 *ITPA* SNP against RBV-induced anemia during the first 12 wk of combination treatment^[14,15,21-23]. Similarly, Hb decline > 3 g/dL was detected in about 64.5% of the anemia-susceptible group CC, which means that about 35.5% did not develop anemia.

The difference of Hb decline between the CC and non-CC groups throughout the treatment is comparable with previous studies^[14,15,21,24]. Hb decline in the first 4

wk has been reported to be an independent predictor of development of anemia at some time in the course of treatment^[25-29]. This indicates the value of early monitoring of Hb and the consequence of RBV dose adjustment to obviate further hazards of anemia. Anemia is a major cause of RBV dose reduction and premature withdrawal from treatment by 10%-14% of HCV-infected patients in the first 12 wk^[6]. RBV dose reduction was obviously more necessary for patients in the CC group than for those in the protective non-CC group in the early weeks of treatment, which may explain the relative stability of the Hb level by week 16 in the CC group in comparison with the non-CC group. Since the mean age of all participants in this study was 35.5 years (range 21-50), their mean baseline Hb was 14 ± 1.1 g/dL and almost of them showed mild liver disease, thus there was no need for pretreatment reduction of the RBV dose. There are two explanations for the lack of statistical significance for the *ITPA* genotypes in multivariate analysis. First, the RBV dose in the univariate analysis showed higher significance than the *ITPA* genotype (0.0009 *vs* 0.025, respectively). Second, the colinearity between RBV dose reduction and hemoglobin decline makes the variable of RBV dose reduction strong enough to prevent the impact of *ITPA* genotypes in the multivariate analysis. This interpretation was previously confirmed by Domingo *et al.*^[15]. In previous studies^[12-14,21-23], the *ITPA* genotypes were statistically significant in their multivariate analysis; this may be due to the different ethnic cohorts and the greater number of patients included in their studies. Accumulation of the RBV metabolite (triphosphorylated RBV) in RBCs causes a relative deficiency of ATP, and hence antioxidative damage of the cells with erythrophagocytosis^[30]. Additionally, the phosphorylation of RBV is reversible in nucleated cells, and the half-life of RBV elimination from RBCs has been reported to be greater than from plasma, 40 d *vs* only 24 h respectively^[2,11], which in turn enhances the destructive effect on RBCs. Recently, it has been reported that the accumulated ITP in RBCs starts to substitute guanosine triphosphate, which has already been depleted by RBV, for biosynthesis of ATP^[31]. According to the classification of predicted ITPase deficiency by Thompson *et al.*^[14], we can classify our results of rs1127354 *ITPA* genotypes into -, ++, +++ (CC, CA, and AA, respectively). The wild type CC usually shows no deficiency (-) with 100% ITPase activity, while the heterozygous genotype CA was predicted to have 25% of ITPase activity. The mutant homozygous AA genotype represents 0% activity (the highest level of deficiency +++). This deficiency in turn leads to accumulation of ITP inside RBCs, instead of RBV triphosphate^[32].

There is a robust point in this study; we demonstrated the association between *ITPA* polymorphism (rs1127354) and RBV-induced anemia without resorting to checking the other SNP, rs7270101, of the same gene (a splice altering single-nucleotide polymorphism in intron 2). This was previously confirmed by Suzuki *et al.*^[33]. In our study, the difference in plt change of CC and non-CC genotype

patients supported, to some extent, the previous results of Tanaka *et al.*^[34]; however, it was different than those reported by Thompson *et al.*^[14]. Tanaka *et al.*^[34] identified a significant difference in their population at a maximum plt reduction of $< 30 \times 10^9/L$, but in the present study a significant difference was determined at plt count reduction of $> 70 \times 10^9/L$. In the current study, we did not find a direct association between the *ITPA* genotype and plt count change. On the other hand, the association is thought to be indirect through the role of endogenous erythropoietin (EPO), which may increase to confront the reduction of Hb during treatment^[25,34,36]. The later study showed sequence homology between EPO and thrombopoietin^[36], which may lead to similarity in their action. Actually, the effect of EPO on the plt count is controversial. In the current study, EPO was not prescribed for any patient. Although EPO prescription is not stated in the established protocol of the Egyptian Ministry of Health for the treatment of hepatitis C in Egypt, some cases may require the addition of EPO in other studies.

There are some limitations in the present study: (1) the small number of female participants did not enable us to evaluate possible associations with gender; (2) the impact of the *ITPA* polymorphism on the treatment outcome has not been assessed. This may be attributed to the lower distribution rate of the *ITPA* protective minor allele among populations, which reflects its lack of significance to change the treatment outcome^[12,14]; and (3) the unavailability of data to evaluate the endogenous serum level of EPO to determine if there was any association between it and the reactive increase in the plt count among the two *ITPA* groups.

Further research is needed to cover the following points: First, efficacy of the clinical use of this approach and the elucidation of its cost effectiveness. This may enable the physician to take precautions before starting therapy of those patients who are likely to develop anemia during therapy (*ITPA* CC genotype). These precautions may include pretreatment initial doses of EPO, initial reduction of RBV doses or even postponement of combined treatment in susceptible patients with no or mild liver disease. Second, verification is needed of the correlation between *ITPA* genotypes and RBV-induced hemolytic anemia by use of the new Specifically Targeted Antiviral Therapy for hepatitis C among Egyptian HCV patients. Third, the impact of *ITPA* polymorphism should be determined in targeted cohorts of Egyptian HCV patients, including old age populations and those suffering from advanced liver disease or chronic kidney disease. Finally, the association between *ITPA* variants and the plasma concentration of RBV in Egyptian patients should be investigated.

In summary, the minor allele in *ITPA* rs1127354 variants (CA/AA) plays a decisive role in protection against treatment-induced anemia and RBV dose reduction of Egyptian HCV patients. Additionally, pretreatment clinical decisions regarding RBV dose adjustment can be bolstered by identifying such polymorphisms.

ACKNOWLEDGMENTS

We would like to thank all of the doctors of the Assiut Center for the Treatment of Chronic Hepatitis, Egypt for sample gathering. We thank Mr. Hisham Galal, the Technician in the Department of Microbiology and Immunology, Egypt, for sample analysis. We appreciate the effort of Mr. Yoshitaka Etoh for his lab work on *ITPA* SNP genotyping.

COMMENTS

Background

Hepatitis C infection is a widespread disease caused by hepatitis C virus (HCV). It infects the liver, mainly causing acute disease developing to chronic if left without treatment. Its current standard therapy is a combination therapy of pegylated interferon injection plus oral ribavirin drug. The treatment is effective in more than half of patients but has moderate to severe side effects. Anemia is a common side effect which may be a leading cause of decreasing the doses of therapy or even premature withdrawal of the treatment. Herein, the authors reported a correlation between host genetic polymorphisms and pre-treatment prediction of anemia in Egyptian HCV patients.

Research frontiers

Due to the multiple side effects associated with the therapy of hepatitis C disease, many researchers are focusing on studying the pretreatment predictors of these side effects. This will help in obviating the dose reduction and the premature withdrawal of therapy. Although Egypt has the highest rate of HCV infection, no research has been done on its HCV patients in that field. Therefore, the authors of this study targeted this cohort.

Innovations and breakthroughs

The authors reported, for the first time, the implication of inosine triphosphate pyrophosphatase (*ITPA*) single nucleotide polymorphism (SNP) genotypes in predicting the incidence of anemia in Egyptian HCV patients during the combination therapy. The mutant genotype of this polymorphism has a crucial role in protection against treatment-induced anemia and ribavirin (RBV) dose reduction in Egyptian HCV patients. Further studies are needed to elucidate the cost effectiveness of this approach.

Applications

ITPA genotyping is a promising pretreatment predictor of treatment-induced anemia before starting the combination therapy of HCV disease. This will enhance the pretreatment decision of early adjustment of RBV dose in patients with the unfavorable genotype.

Terminology

SNP is the most common type of genetic variation of the human DNA. There are millions of human SNPs. They occur when a single nucleotide in a genome differs among members of the same species. This difference is due to substitution, insertion or deletion of one nucleotide within the genetic structural unit of human DNA. Many studies have found a robust correlation between SNPs and different diseases.

Peer review

The present study provides interesting results and novelty to genetic factors related to ribavirin-induced anemia during HCV therapy in an Egyptian HCV cohort. The manuscript is well written and the conclusion drawn in the data is appropriate.

Abstract

AIM: To investigate the effect of mild steatotic liver on ischemia-reperfusion injury by focusing on Kupffer cells (KCs) and platelets.

METHODS: Wistar rats were divided into a normal liver group (N group) and a mild steatotic liver group (S group) induced by feeding a choline-deficient diet for 2 wk. Both groups were subjected to 20 min of warm ischemia followed by 120 min of reperfusion. The number of labeled KCs and platelets in sinusoids and the blood perfusion in sinusoids were observed by intravital microscopy (IVM), which was performed at 30, 60 and 120 min after reperfusion. To evaluate serum alanine aminotransferase as a marker of liver deterioration, blood samples were taken at the same time as IVM.

RESULTS: In the S group, the number of platelets adhering to KCs decreased significantly compared with the N group (120 after reperfusion; 2.9 ± 1.1 cells/acinus vs 4.8 ± 1.2 cells/acinus, $P < 0.01$). The number of KCs in sinusoids was significantly less in the S group than in the N group throughout the observation periods (before ischemia, 19.6 ± 3.3 cells/acinus vs 28.2 ± 4.1 cells/acinus, $P < 0.01$ and 120 min after reperfusion, 29.0 ± 4.3 cells/acinus vs 40.2 ± 3.3 cells/acinus, $P < 0.01$). The blood perfusion of sinusoids 120 min after reperfusion was maintained in the S group more than in the N group. Furthermore, elevation of serum alanine aminotransferase was lower in the S group than in the N group 120 min after reperfusion (99.7 ± 19.8 IU/L vs 166.3 ± 61.1 IU/L, $P = 0.041$), and histological impairment of hepatocyte structure was prevented in the S group.

CONCLUSION: Ischemia-reperfusion injury in mild steatotic liver was attenuated compared with normal liver due to the decreased number of KCs and the reduction of the KC-platelet interaction.

INTRODUCTION

It is widely accepted that the steatotic liver is more sus-

ceptible to hepatic ischemia-reperfusion (IR) injury. Increased microcirculatory deterioration is suggested as a reason for this increased liver damage in the steatotic liver^[1-3]. Morphologically, the steatotic liver is characterized by a demonstrable deposition of large, macronodular fatty droplets in liver parenchymal cells^[4]. In addition, narrow and distorted lumens of sinusoids, resulting from the swelling of hepatic parenchymal cells due to accumulated lipid, cause a decrease in sinusoidal perfusion^[2]. These changes to microcirculation are exacerbated by leukocytes, either mechanically trapped in the narrowed sinusoids or adhering to activated Kupffer cells (KCs) with the release of cytokines, in addition to free radicals^[2,5].

Thirty percent of the population in Japan and Western countries suffers from steatotic liver, and the percentage is still increasing^[3,6]. Most of these patients have been diagnosed by abdominal ultrasonography screening, even though elevation of serum liver enzyme levels was detected in a lesser percentage^[6]. Steatosis of the liver is classified clinically into three grades according to the proportion of hepatocytes with fatty droplets: mild (< 30%), moderate (30%-60%) and massive (> 60%)^[7]. Fishbein *et al.*^[8] reported that liver enzyme levels were not elevated in the steatotic liver in which the proportion of hepatocytes with fat deposition was less than 18%. Steatotic liver even in a mild degree is a risk factor for complication after liver resection^[9]. Most of the reports describing IR injury of the steatotic liver were investigations of moderate and severe steatosis. It is unclear whether the intensity of the hepatic IR injury depends on the degree of fatty change.

Previously, we reported that liver ischemia induced the adhesion of platelets to KCs in the early period after reperfusion, and that interaction between KCs and platelets played a key role in reperfusion injury of the liver^[10,11]. In this study, we have focused on the interaction between KCs and platelets in the mild steatotic liver with intravital microscopy (IVM). We hypothesized that tolerance to hepatic IR injury differs according to the degree of steatosis. The aim of this study was to clarify the hepatic dysfunction after IR in the mild steatotic liver compared with the normal liver.

MATERIALS AND METHODS

Animals

Male Wistar rats were obtained from CLEA Japan, Inc. (Tokyo, Japan). We prepared two model types, normal liver and mild steatotic liver. In the normal liver model, rats weighting 250 g to 300 g were used. In the steatotic model, the rats' weights were adjusted to the same weight range after they were fed a choline-deficient diet (CDD) (Oriental Bio Service Kanto Inc., Ibaraki, Japan) for 2 wk. Animal experiments were carried out in a humane manner after receiving approval from the Institutional University Experiment Committee of the University of Tsukuba, and in accordance with the Regulation for Animal Experiments in our university and the Fundamental Guideline for Proper Conduct of Animal Experiment

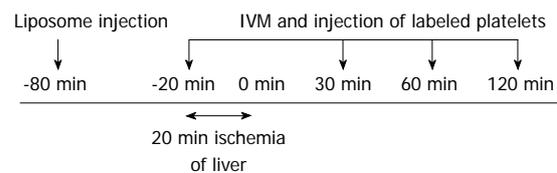

Figure 1 Experimental design. In all groups, total warm hepatic ischemia was induced for 20 min by clamping the portal triad. A total of 1×10^8 fluorescence-labeled platelets, approximately 1% of all circulating platelets in the recipient rat, were injected *via* the left carotid artery 5 min before intravital microscopy (IVM).

and Related Activities in Academic Research Institutions under the jurisdiction of the Japanese Ministry of Education, Culture, Sports, Science, and Technology.

Experimental design

Animals were divided into two groups as follows: (1) the normal liver group (N group; $n = 6$); and (2) the mild steatotic liver group (S group; $n = 6$). In both groups, total normothermic hepatic ischemia was induced for 20 min by clamping the portal triad. The hepatic microcirculation and dynamics of platelets and KCs were observed just before ischemia and at 30, 60 and 120 min after reperfusion (Figure 1).

Surgical procedure

Under anesthesia using isoflurane, the animals were tracheotomized. To reduce spontaneous breathing, animals were ventilated mechanically (MK-V100; Muromachi Kikai Co. Ltd, Tokyo, Japan). The animals were placed in a supine position on a heated pad to maintain the rectal temperature at 37 °C. To monitor arterial blood pressure and allow continuous infusion of Ringer's solution, polyethylene catheters (PE-50, 0.58/0.96mm internal/external diameter; Becton Dickinson, Sparks, MD) were inserted into the left carotid artery and left jugular vein, respectively. After performing laparotomy *via* a transverse incision, the ligaments around the liver were dissected to mobilize the left lobe. At the same time, the hepatoduodenal ligament was taped for clamping later. The left hepatic lobe was exteriorized on a plate specially designed to minimize movements caused by respiration and covered with cover glass. Surgical procedures were performed using sterile techniques. After 60 min of normal saline continuous infusion, IVM was performed as a pre ischemia study. Then, hepatic ischemia was induced by clamping the portal triad (the hepatic artery, portal vein, and bile duct) with a microclip (B. Braun Aesculap Japan Co., Ltd, Tokyo, Japan) for 20 min. IVM was performed at 30, 60 and 120 min after reperfusion. Blood samples were taken for analysis of enzyme activities from a catheter placed in the left carotid artery at the same time as IVM. Alanine aminotransferase (ALT) was evaluated as one of the liver enzyme. At 120 min of reperfusion, total body blood was taken for euthanasia. At the end of the experiments, liver tissue was taken for histological examination.

Platelet preparation

Platelets were isolated from whole blood samples of syngeneic rats and labeled with rhodamine-6G (50 μ L/mL whole blood: R-4127; Sigma, St. Louis, MO, United States), as described by Massberg *et al.*^[12]. Briefly, the collected blood was diluted with buffer after the addition of prostaglandin E1 and rhodamine 6G. After two-cycle centrifugation, fluorescent platelets were resuspended in phosphate-buffered saline. In this study, a total of 1×10^8 fluorescence-labeled platelets, approximately 1% of all circulating platelets in the recipient rat, were injected through the left carotid artery at 5 min before IVM.

Liposome entrapment method (fluorescence labeling of KCs)

Fluorescently labeled phosphatidylcholine (PC) was incorporated into liposomes, as described by Watanabe *et al.*^[13]. The fluorescent pigment used was 2-(12-(7-nitrobenz-2-oxa 1,3-diazol-4-yl) amino) dodecanoyl-1-hexadecanoly-*sn*-glycero-3-phosphocholine (NBD-C₁₂-HPC; Molecular Probes; Eugene, United States). After intra-arterial injection, KCs in the rat livers were stained and were clearly delineated under the fluorescence image in the IVM. Phagocytic activity of KCs after the administration of liposomes was reported by measuring the amount of hepatic uptake of intravenously administered fluorescent microspheres; no detrimental influence of the liposomes on the phagocytic activity was observed. Additionally, no histopathological changes were found in the livers from liposome-treated rats^[13]. Sixty minutes before hepatic ischemia, liposome-encapsulated fluorescent liposomes (4 mL/kg) were administered *via* the carotid artery catheter.

Intravital microscopy

IVM was performed using a modified microscope (BX30 FLA-SP; Olympus Co., Tokyo, Japan) with a 100 W mercury lamp attached to a filter block. The hepatic microcirculation was recorded by means of a CCD camera (C5810; Hamamatsu Photonics, Hamamatsu, Japan) and a digital video recorder (GV-HD700/1; Sony, Tokyo, Japan) for offline analysis. Using objective lenses (10 \times 0.3 to 20 \times 0.7; Olympus Co., Tokyo, Japan), a final magnification from x325 to x650 was achieved on the video screen. To assess sinusoidal perfusion, sodium fluorescein (2×10^{-3} M/kg, F-6377; Sigma, St. Louis, MO, United States) was injected *via* the jugular catheter. Rhodamine-6G labeled platelets were infused intra-arterially just before ischemia and at 30, 60 and 120 min after reperfusion, and 10 randomly chosen acini were visualized. Quantitative assessment of the microcirculatory parameters was performed offline using WinROOF imaging software (version 5.0; Mitani Shoji, Tokyo, Japan).

Microcirculatory analysis

The following parameters were analyzed: (1) the number of adherent platelets, *i.e.*, platelets firmly attached to the sinusoidal endothelium for longer than 20 s [the number of adherent platelets in the scanned acini was counted

and results were expressed as the number of adherent platelets per field (1 field = approximately 0.2 mm²); (2) the number of adherent platelets adhering to KCs; (3) the number of KCs; and (4) the sinusoidal perfusion failure rate (%) as an index of microcirculatory disturbance, calculated as the ratio of non-perfused sinusoids among the sinusoids observed in one acinus after 120 min of reperfusion.

Immunohistochemical study of KCs

We immunohistochemically assessed the number of KCs in the acini. To compare the differences between the normal liver group and the mild steatotic liver group before ischemia and after reperfusion, liver tissues were obtained from each group both before ischemia and at the end of the surgical procedure, and from another animal before ischemia. The tissues were fixed in 10% formalin and embedded in paraffin and cut into 4 μ m-thick sections. It was immersed in 0.03% hydrogen peroxidase to block endogenous peroxidase activity, and then blocked with 2% bovine serum albumin to reduce background staining. To specifically recognize KCs, mouse anti-rat ED2 antibody (Santa Cruz Biotechnology, Santa Cruz, CA, United States) was used as the primary antibody. The sections were incubated with primary diluted antibodies (1:50) at room temperature for 60 min. Primary antibody reactions were enhanced using horseradish peroxidase EnVision (Dako Japan, Tokyo, Japan). The immunoreaction was visualized with 0.05% 3,3-diaminobenzidine solution. After washing in distilled water, specimens were counterstained with hematoxylin then mounted. The number of ED2-positive cells per acinus was counted in five randomly chosen acini.

Biochemical assays

As a marker of liver deterioration, serum ALT levels were measured using a Drychem 7000V autoanalyzer (Fuji Film, Tokyo, Japan). Serum was stored at -80 $^{\circ}$ C until use for cytokine determination. Levels of interleukin (IL)-6 were measured using commercial enzyme-linked immunosorbent assay kits (R and D Systems, Minneapolis, MN, United States).

Histological analysis

Liver tissue was obtained before ischemia from the S group to assess the degree of steatosis and after 120 min of reperfusion from each group to assess the histological changes due to IR. The samples were fixed with 10% formalin, and embedded in paraffin. Thin sections (4 μ m) were prepared and stained with hematoxylin and eosin (HE). Tissue damage was evaluated in 5 randomly selected high-power fields (\times 200).

Statistical analysis

All data are expressed as mean \pm SD. The Mann-Whitney *U* test and analysis of variance were used, followed by Scheffe's test. *P* values < 0.05 were considered statistically significant.

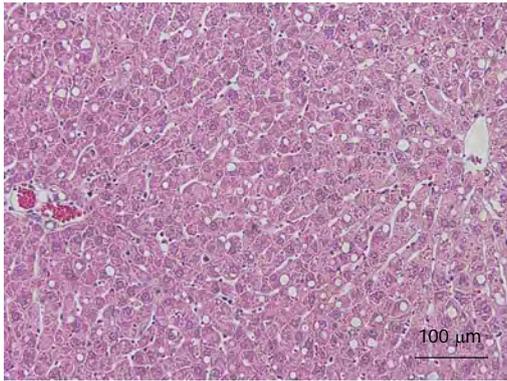

Figure 2 Mild steatotic liver model. Hematoxylin and eosin staining of liver specimens after 2 wk of a choline deficient diet demonstrated that between 10% and 20% of hepatocytes had deposition of microvesicular lipid droplets.

RESULTS

Mild steatotic liver model

Mild steatosis of the liver was induced by feeding a CDD. The CDD-induced steatotic liver is an established experimental model, in which morphological and functional features are very similar to those of the clinical steatotic liver^[14]. The rats fed on CDD for 2 wk developed mild steatotic livers. They were characterized by microvesicular lipid droplet filtration in 10% to 20% of hepatocytes (HE stain) (Figure 2). These findings were identified as a mild degree of steatosis of the liver. We preoperatively confirmed similar findings by liver biopsy in several animals.

Number of adherent platelets in acini

The number of adherent platelets in sinusoids increased along with the reperfusion time both in the N group and in the S group (Figure 3A). In the S group, the number of adherent platelets adhering to KCs was significantly less than in the N group at 30 min after reperfusion and concomitant with the reperfusion period (Figure 3B and C). In addition, there was no significant difference between the two groups in the number of blood platelets (data not shown).

Number of KCs in acini

The mild steatotic change in the liver significantly decreased the number of KCs in sinusoids compared with the normal liver at any point in time before and after ischemia reperfusion with IVM study (Figure 4A). In the IVM observation, the counted KCs represented only KCs labeled by liposome entrapment methods. In addition, the number of KCs was verified immunohistochemically. In immunohistochemical staining, the numbers of ED2-positive cells were lower in the S group than in the N group already at the time before ischemia and after 120 min of reperfusion (Figure 4B).

Sinusoidal perfusion failure rate

Vollmar *et al.*^[15] reported that the sinusoidal perfusion rate was one of the indexes of reperfusion injury. After 120 min of reperfusion, the rate of sinusoidal perfusion

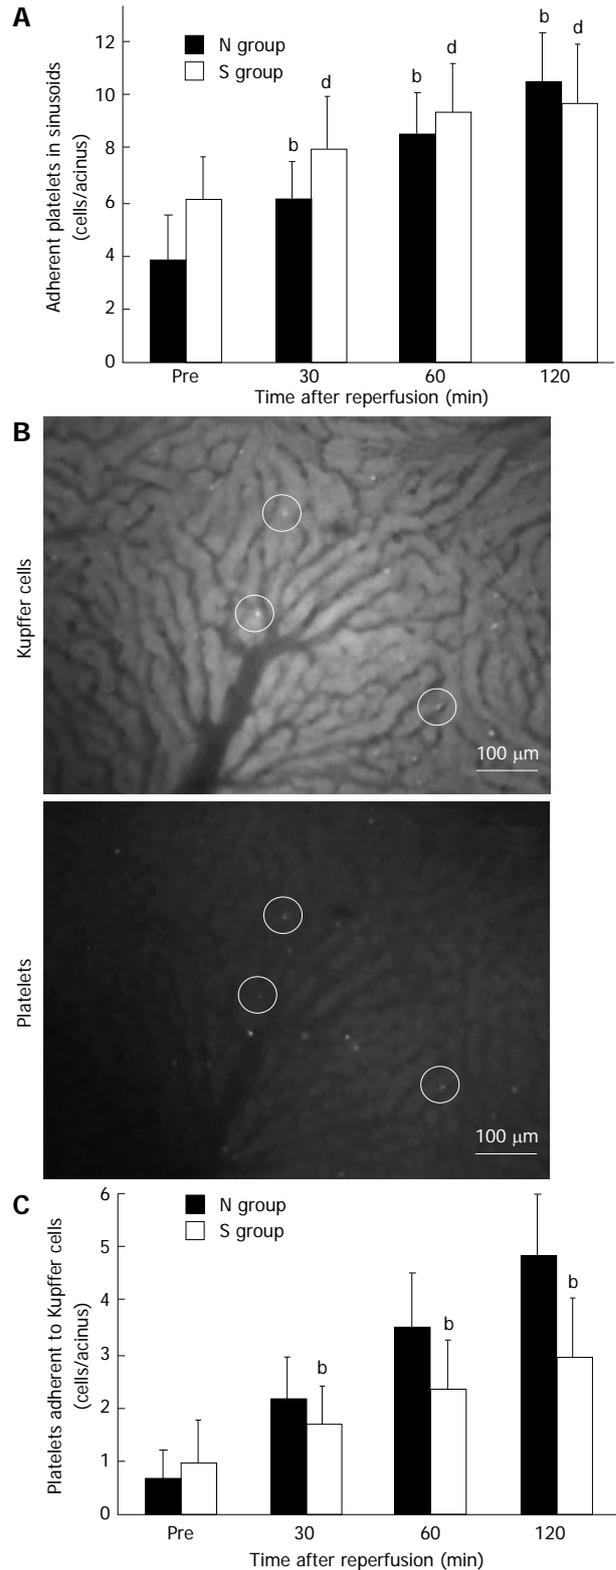

Figure 3 Platelets and Kupffer cell dynamics in sinusoids. A: The number of adherent platelets in sinusoids increased along with the reperfusion time in both groups. Shown as mean ± SD; $n = 6$. ^b $P < 0.01$ vs pre-ischemia in the normal liver (N) group, ^d $P < 0.01$ vs pre-ischemia in the mild steatotic liver (S) group; B: Video images of Kupffer cells (KCs) and platelets in acini 30 min after reperfusion. The field is approximately 0.2 mm². The upper figure shows the acini of fluorescently stained KCs, and in the lower figure, the acini of fluorescently stained platelets. White circles indicate adhesion to KCs and platelets in the same place; C: In the S group, the number of adherent platelets adhering to KCs was significantly less than in the N group at 30 min after reperfusion and concomitant with the duration of reperfusion. Shown as mean ± SD; $n = 6$. ^b $P < 0.01$ vs the N group.

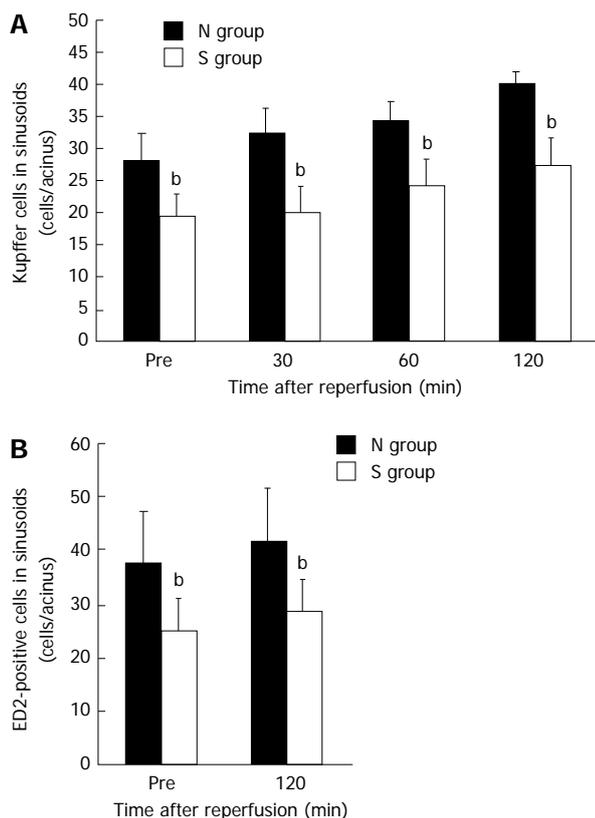

Figure 4 The number of Kupffer cells in sinusoids (mean ± SD). A: The number of Kupffer cells in sinusoids observed in the intravital microscopy system was decreased significantly in the mild steatotic liver (S) group compared to the normal liver (N) group at any point in time before and after ischemia reperfusion. $n = 6$. ^a $P < 0.01$ vs the N group; B: In immunohistochemical staining, the number of ED2-positive cells was significantly less in the S group than in the N group. $n = 6$. ^b $P < 0.01$ vs the N group.

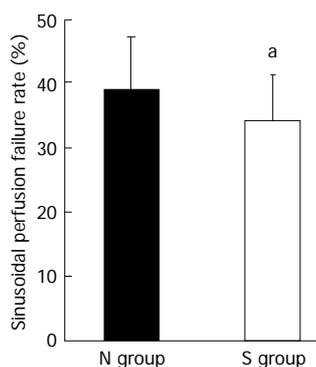

Figure 5 Sinusoidal perfusion failure rate (mean ± SD). The sinusoidal perfusion failure rate after 120 min of reperfusion was lower in the mild steatotic liver (S) group than in the normal liver (N) group. $n = 6$. ^a $P < 0.05$ vs the N group.

failure was significantly higher in the N group than in the S group (Figure 5). The perfusion of sinusoids in which KCs and platelets adhered had a failure rate of about 50% in both groups (data not shown). In contrast, the perfusion failure rate of sinusoids in which KCs adhering to platelets was not observed remained at approximately 30% in both groups (data not shown). This indicated that

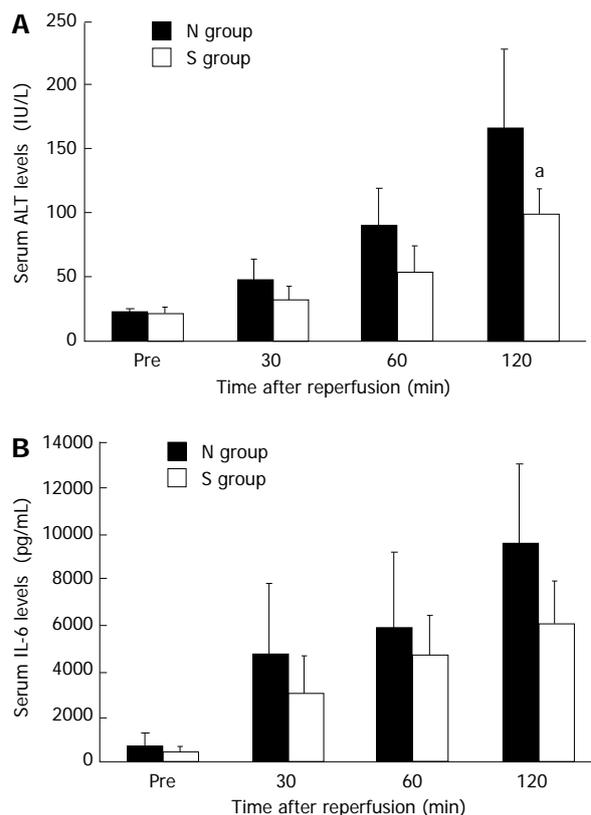

Figure 6 Serum alanine aminotransferase and interleukin-6 levels (mean ± SD). A: Serum alanine aminotransferase (ALT) levels were significantly lower in the mild steatotic liver (S) group than in the normal liver (N) group at 120 min after reperfusion. $n = 6$. ^a $P < 0.05$ vs the N group; B: The concentration of serum interleukin-6 (IL-6) tended to be lower in the S group compared with in the N group but there was no significant difference (after 120 min of reperfusion, $P = 0.09$ vs the N group). $n = 6$.

the interaction between KCs and platelets was associated with sinusoidal perfusion failure.

Serum ALT and interleukin-6 levels

Serum ALT level as a measure of hepatic parenchymal impairment was significantly lower in the S group compared with the N group after 120 min of reperfusion (Figure 6A). The concentration of serum IL-6 had a tendency to be lower in the S group than in the N group, but there was no significant difference (Figure 6B).

Histological findings

In the S group, histological damage to the liver, such as disturbance of the sinusoidal structure and sinusoidal narrowing, was slightly greater than in the N group. Necrotic changes were not observed in either group (Figure 7).

DISCUSSION

Steatosis of the liver is a common disorder with several different etiologies. This disorder is one of the most common obstacles in liver surgery, since steatotic livers are susceptible to some stressful loads, especially IR injury^[1,16]. With the increase in steatotic liver patients in the

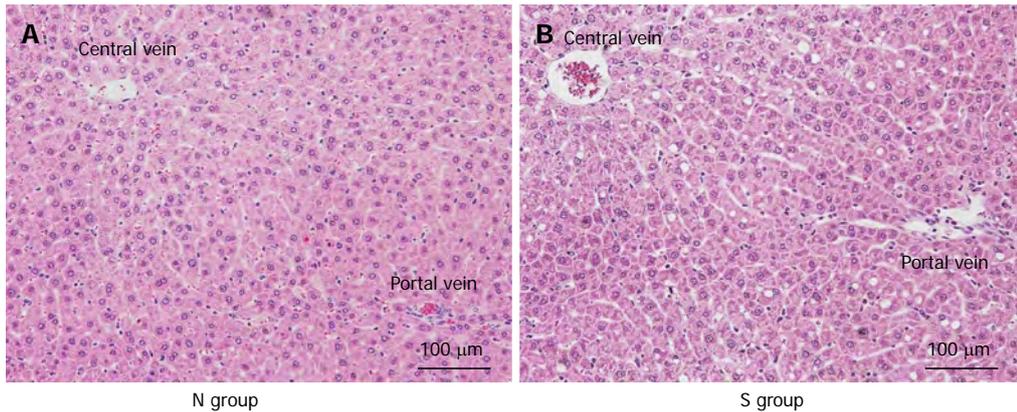

Figure 7 Histological findings after 120 min of reperfusion. In the normal liver (N) group, hepatocyte structure was strongly impaired compared with the mild steatotic liver (S) group, and sinusoidal narrowing was observed.

world, the number of mild steatotic liver cases is also increasing^[17]. A recent analysis of liver transplants, in which the graft liver suffered from cold ischemia, reported that the degree of liver graft steatosis is an important determinant of IR injury and correlated with the rate of postoperative complications and mortality^[18,19]. In warm ischemia, however, the influence of the degree of hepatic steatosis on liver dysfunction is unclear. In this study, we demonstrated that IR injury in mild steatotic liver was attenuated compared with that in normal liver, and that it resulted from the reduction in the interaction between KCs and platelets due to the decreased number of KCs.

It was reported that there are two distinct periods of liver injury after warm IR^[20,21]. The early period of IR injury, which occurs within 120 min after reperfusion, is characterized by KC-induced reactive oxygen species (ROS)^[21,22]. KC production and the release of ROS result in acute hepatocellular injury. In addition, in response to the exposure to activated KCs, neutrophils accumulate in the post-ischemic liver. In the late period of IR injury, inflammatory responses from accumulating neutrophils induce hepatocyte injury, which appears more than 6 h after reperfusion^[22,23]. Elevated liver enzymes and apoptosis of hepatocytes and sinusoidal endothelial cells (SECs) can already be observed in the early period^[10,24]. A reduction in the early period of IR injury, for instance KC depletion, also leads to inhibition of injury in the late period^[25]. Recently, some studies have focused on the function of platelets in hepatic IR injury^[26,27]. Sindram *et al.*^[24] reported that platelets caused SEC apoptosis and significantly contributed to IR injury. Khandoga *et al.*^[28] have shown that warm hepatic IR induced rolling and adhesion of platelets to SECs as well as accumulation of platelets in sinusoids. We previously reported that platelet-SEC interactions occur earlier than leukocyte responses after reperfusion, and that adhesion of platelets requires the presence of activated KCs^[11]. In addition, based on our study using the IVM system and electron microscopy, we also reported that platelet-KC interaction as well as platelet-SEC interaction contributes to early-period hepatic

IR injury^[10,24,28]. Most of the events that determine the extent of IR injury, such as KC activation, platelet adhesion to KCs or SECs, and neutrophil accumulation, occur in the early period of IR injury. Therefore, we focused on observation until 120 min after reperfusion. In this study, we demonstrated that the adherence of platelets to KCs decreased and reperfusion injury was reduced in the mild steatotic liver. The number of adherent platelets in sinusoids increased along with the reperfusion time both in the normal liver group and in the mild steatotic liver group. This suggests that the adherent ability of platelets was not reduced in the mild steatotic liver group. Therefore, we considered that the reduction in KC-platelet interaction was a result of the decreased number of KCs in the mild steatotic liver.

KCs are more likely to be activated in the steatotic liver^[5,29]. In addition, hepatic IR activates KCs^[30]. However, it is unknown whether KC activation after IR increases in steatotic liver more than in normal liver. After IR, KCs secrete pro-inflammatory cytokines including IL-6^[31,32]. Moreover, as described above, activated KCs cause adhesion of platelets to KCs, and lead to later leukocyte accumulation^[11]. We consider that serum IL-6 levels reflect the degree of the interaction between KCs and platelets according to the activity of KCs. In the present study, elevation of serum IL-6 levels after IR was less in mild steatotic liver than in normal liver. Our results indicated that in the mild steatotic liver, IL-6 secretion was suppressed because of the decreased number of KCs, even if KCs were activated after IR.

In our present study, we demonstrated that there were fewer KCs in the sinusoids in our mild steatotic liver than in the normal liver. The results were confirmed by both the IVM study and immunohistochemical examination. Several studies reported on the change in the number of KCs in steatotic liver models. Shono *et al.*^[33] reported that the number of KCs in a particular subgroup could change, for example, the proportion of CD68 positive KCs decreased in their steatotic model induced by a high-fat diet and a high-cholesterol diet. Veteläinen *et al.*^[34]

investigated the difference between a methionine-choline deficient diet (MCD) model and a CDD model in their effect on the number of KCs, and reported that the number of KCs increased in the MCD model, but did not change in the CDD model. The degree of steatosis was moderate in their CDD model, and severe in their MCD model. These investigators indicated that the difference in the method of inducing steatosis of the liver resulted in a change in the number of KCs in the sinusoids. In addition, Guo *et al.*^[35] reported that the number of KCs was reduced in their steatotic liver model induced by palmitoleate, a monounsaturated fatty acid. Thus, differences in nutrient factors may influence the number of KCs in the steatotic liver. We supposed that a change in nutrient conditions induced by CDD might lead to a decrease in KCs as well as mild steatosis of the liver. The relationship between KCs and steatotic liver has not been well established yet. Further research using various steatotic liver models and various degrees of steatosis will be necessary to elucidate the impact of steatotic liver on KCs.

Steatotic liver patients in the clinical setting of hepatic surgery have tended to increase^[17]. IR injury is closely involved with complications in the steatotic liver after hepatic resection^[36]. It is known that the steatotic liver is a risk factor for postoperative complications^[9,36]. Some investigators reported that patients with a steatotic liver who received a major hepatectomy were more likely to suffer from infective, wound-related, hepatobiliary and gastrointestinal postoperative complications^[37]. The decreased tolerance of steatotic liver to IR injury is a result of impaired microcirculation due to hepatocytes with fat deposition^[38]. Between the mild and severe steatotic liver, there are differences in microcirculatory disturbances due to differences in the degree of fat deposition. A recent meta-analysis revealed a significant association between the degree of steatosis and increased risk of postoperative complications and mortality^[9]. Several investigators reported that postoperative complications, especially infectious complications, and mortality increased in patients with severe steatotic liver compared with those with mild steatotic liver^[9,37]. It will be necessary to evaluate IR injury in the moderate to severe steatotic liver in a similar experimental model in the future.

On the other hand, there is a report that postoperative liver failure was slight in the mild steatotic liver, and so mild steatotic liver can be an indication for hepatic surgery^[39]. Moreover, mild to moderate steatotic livers have been accepted as a marginal graft in transplantation^[18,19]. Our study suggested that IR injury does not depend on the degree of fat deposition. In addition, our results provide some evidence that postoperative outcomes after liver resection or transplantation are not aggravated in mild steatotic liver.

In conclusion, in mild steatosis liver induced by CDD, hepatic IR injury was attenuated compared with the normal liver. The small number of KCs in the sinusoids decreased the number of KCs adhering to platelets, and re-

sulted in decreased interaction between KCs and platelets.

COMMENTS

Background

The steatotic liver is well known to be sensitive to ischemia-reperfusion (IR) injury. Increased microcirculatory deterioration is suggested as a reason for this increased liver damage in the steatotic liver. However, it is unclear whether IR injury increases in the mild steatotic liver. Previously, authors reported that the interaction between Kupffer cells (KCs) and platelets played a key role in hepatic IR injury. This study investigated the effect of mild steatotic liver on IR injury, focusing on Kupffer cells and platelets.

Research frontiers

KC activation plays a pivotal role in hepatic IR injury. Upon activation by hepatic ischemia, KCs release reactive oxygen species and inflammatory mediators, such as cytokines and chemokines. In addition, KC activation leads to platelet and neutrophil accumulation in hepatic sinusoids. On the other hand, KCs are more likely to be activated in the steatotic liver.

Innovations and breakthroughs

This is the first study focusing on KCs and platelets in IR injury in the mild steatotic liver. The authors demonstrated that hepatic IR injury in the mild steatotic liver was attenuated compared with normal liver. The small number of KCs in the sinusoids decreased the number of KCs adhering to platelets, and resulted in decreased interaction between KCs and platelets.

Applications

The authors suggest that IR injury in the steatotic liver does not depend on the degree of fat deposition. The results of this study provide some evidence that the postoperative outcomes after liver resection or transplantation are not aggravated in the mild steatotic liver.

Terminology

Intravital fluorescence microscopy (IVM) of the rat liver is a high-resolution real-time technique that allows authors visualize hepatic sinusoidal perfusion. The availability of an enormous number of different fluorescent markers for *ex vivo* and *in vivo* staining has extended the possibilities of IVM from purely morphological analysis to the study of complex physiological and pathological events.

Peer review

The manuscript demonstrated a decrease in IR injury in mild steatotic liver in Wistar rats by feeding with a choline-deficient diet compared to normal rats. In addition, the results also showed that the attenuation of IR injury was associated with a decrease in KC number and platelet-KC adhesion in acini. The study is well designed and the results are interesting and conceivable.

Abstract

AIM: To investigate the antifibrotic effects of bone morphogenetic protein-7 (BMP-7) on *Schistosoma japonicum* (*S. japonicum*)-induced hepatic fibrosis in BALB/C mice.

METHODS: Sixty BALB/C mice were randomly divided into three groups, including a control group (group A, $n = 20$), model group (group B, $n = 20$) and BMP-7 treated group (group C, $n = 20$). The mice in group B and group C were abdominally infected with *S. japonicum* cercariae to induce a schistosomal hepatic fibrosis model. The mice in group C were administered human recombinant BMP-7. Liver samples were extracted from mice sacrificed at 9 and 15 wk after modeling. Hepatic histopathological changes were assessed using Masson's staining. Transforming growth factor-beta 1 (TGF- β 1), alpha-smooth muscle actin (α -SMA), phosphorylated

Smad2/3 (pSmad2/3) and Smad7 protein levels and localization were measured by Western blotting and immunohistochemistry, respectively, and their mRNA expressions were detected by reverse transcription-polymerase chain reaction (RT-PCR).

RESULTS: The schistosomal hepatic fibrosis mouse model was successfully established, as the livers of mice in group B and group C showed varying degrees of typical schistosomal hepatopathologic changes such as egg granuloma and collagen deposition. The degree of collagen deposition in group C was higher than that in group A (week 9: 22.95 ± 6.66 vs 2.02 ± 0.76 ; week 15: 12.84 ± 4.36 vs 1.74 ± 0.80 ; $P < 0.05$), but significantly lower than that in group B (week 9: 22.95 ± 6.66 vs 34.43 ± 6.96 ; week 15: 12.84 ± 4.36 vs 18.90 ± 5.07 ; $P < 0.05$) at both time points. According to immunohistochemistry data, the expressions of α -SMA, TGF- β 1 and pSmad2/3 protein in group C were higher than those in group A (α -SMA: week 9: 21.24 ± 5.73 vs 0.33 ± 0.20 ; week 15: 12.42 ± 4.88 vs 0.34 ± 0.27 ; TGF- β 1: week 9: 37.00 ± 13.74 vs 3.73 ± 2.14 ; week 15: 16.71 ± 9.80 vs 3.08 ± 2.35 ; pSmad2/3: week 9: 12.92 ± 4.81 vs 0.83 ± 0.48 ; week 15: 7.87 ± 4.09 vs 0.90 ± 0.45 ; $P < 0.05$), but significantly lower than those in group B (α -SMA: week 9: 21.24 ± 5.73 vs 34.39 ± 5.74 ; week 15: 12.42 ± 4.88 vs 25.90 ± 7.01 ; TGF- β 1: week 9: 37.00 ± 13.74 vs 55.66 ± 14.88 ; week 15: 16.71 ± 9.80 vs 37.10 ± 12.51 ; pSmad2/3: week 9: 12.92 ± 4.81 vs 19.41 ± 6.87 ; week 15: 7.87 ± 4.09 vs 13.00 ± 4.98 ; $P < 0.05$) at both time points; the expression of Smad7 protein in group B was higher than that in group A and group C at week 9 (8.46 ± 3.95 vs 1.00 ± 0.40 and 8.46 ± 3.95 vs 0.77 ± 0.42 ; $P < 0.05$), while there were no differences in Smad7 expression between the three groups at week 15 (1.09 ± 0.38 vs 0.97 ± 0.42 vs 0.89 ± 0.39 ; $P > 0.05$). Although minor discrepancies were observed, the results of RT-PCR and Western blotting were mainly consistent

with the immunohistochemical results.

CONCLUSION: Exogenous BMP-7 significantly decreased the degree of hepatic fibrosis in both the acute and chronic stages of hepato-schistosomiasis, and the regulatory mechanism may involve the TGF- β /Smad signaling pathway.

INTRODUCTION

Schistosomiasis japonica, a chronic and debilitating disease caused by the trematode *Schistosoma japonicum* (*S. japonicum*), is one of the major public health problems in China and other tropical countries such as the Philippines and Indonesia. It seriously impacts the health of residents within endemic areas as well as social and economic development^[1-3]. Human immune response to schistosome eggs deposited in the liver and the granulomatous inflammation they evoke are the initial factors of hepato-schistosomiasis, while the subsequent hepatic fibrosis represents a wound-healing response to previous liver damage^[4-8]. The primary cell type involved in schistosomal hepatic fibrosis is the hepatic stellate cell (HSC); HSCs are activated in response to inflammatory injury and converted from vitamin A-storing cells into myofibroblast-like cells, characterized by the expression of alpha-smooth muscle actin (α -SMA), the secretion of excessive collagens and other extracellular matrix components, and the production of various pro-fibrosis cytokines such as transforming growth factor-beta (TGF- β)^[9-11]. TGF- β not only maintains the progressive activation of myofibroblasts, but also activates other silent HSCs^[12,13]. This positive feedback cascade reaction always causes continuous schistosomal hepatic fibrosis even when timely and effective anti-helminthic treatment has been given. In addition, praziquantel resistance has become common because of a long term dependence on this single anthelmintic^[14,15]. As etiological therapy alone is not enough to treat hepatic fibrosis, finding other strategies that can block the activation of HSCs and suppress the progression of collagen deposition is important. Considering the dominant role of the cytokine system in hepatic fibrosis, research on cytokine regulators (antagonist or promoter) has become a new focus and has very promising value.

Among the numerous cytokines and growth factors that are involved in hepatic fibrosis, TGF- β , especially

TGF- β 1, is an acknowledged critical fibrogenic stimulus to HSCs^[16,17]. TGF- β performs its functional role mostly *via* the TGF- β /Smad signaling pathway, which is implicated in a wide range of physiological and pathological events, including embryogenesis, inflammation and fibrosis. In this pathway, phosphorylated Smad2/3 (pSmad2/3) proteins act as pivotal downstream effectors of TGF- β which convey signals from TGF- β receptors to the nucleus, while Smad7 seems to be antagonistic to TGF- β as a negative feedback mediator^[18-21]. Bone morphogenetic protein-7 (BMP-7), a member of the TGF- β superfamily, has been studied extensively due to its essential roles during morphogen formation and cell differentiation^[22,23]. Recently, its therapeutic potential in the regulation of fibrosis was recognized based on the counteractive effect of BMP-7 against the TGF- β /Smad signaling pathways. For instance, Zeisberg *et al.*^[24] demonstrated the Smad-dependent reversal of TGF- β 1-induced epithelial-to-mesenchymal transition (EMT) by BMP-7 to renal tubular epithelial cells, while EMT is recognized as an important event in fibrogenesis. Moreover, varying degrees of inhibition of thioacetamide- and CCL₄-induced liver fibrosis by BMP-7 has been respectively observed in recent research^[25]. These limited findings led us to hypothesize that BMP-7 may have a similar effect on schistosomal hepatic fibrosis. Therefore, in the current study, we set TGF- β 1 and Smads as our intervention targets to investigate the potential therapeutic effect of BMP-7 in a mouse model of schistosomal hepatic fibrosis.

MATERIALS AND METHODS

Animals and parasite

Six-week-old SPF BALB/C female mice, weighing 12-16 g, were obtained from the Experimental Animal Center, Central South University, Changsha, China. All animal experiments were performed under the control of the Animal Care Committee of Central South University in accordance with the Guidelines on Animal Experiments in Central South University. *Oncomelania hupensis* harboring *S. japonicum* cercariae were purchased from the Institute of Schistosomiasis Control Center (Yueyang, Hunan, China) and the vitality of cercariae was confirmed by microscopy.

Animal treatment

Sixty BALB/C mice were randomly divided into three groups, including a control group (group A), model group (group B) and BMP-7 treated group (group C) ($n = 20$ in each group). All animals were maintained under specific pathogen-free conditions, kept at 20 °C-25 °C in a 12-h light/12-h dark cycle and had free access to standard laboratory water and chow. The mice in group B and group C were percutaneously infected with *S. japonicum* by placing a coverslip carrying 15 ± 1 cercariae in non-chlorine water on their abdomen for 30 min. The mice in group A were treated with non-chlorine water containing no cercariae. Six weeks after infection, the initial phase of hepatic schistosomiasis where, according to our previous

studies^[26], schistosome eggs reached the liver, the mice in group C were administered recombinant human BMP-7 (Peprotech, United States, Catalog Number: 120-03), 300 pg/g intraperitoneally, every other day for a period of four weeks. At 9 wk and 15 wk after infection, which are the extreme and stationary phases of schistosomal hepatic fibrosis according to our previous studies^[26], 10 mice from each group were randomly selected and sacrificed. Liver tissues were obtained and divided into two parts: the left lobes were fixed in a 4% paraformaldehyde solution for 12 h and the remainder was preserved at -80 °C until use.

Histological examination

After a graded alcohol series, dehydration and xylene treatment, the liver specimens were embedded in paraffin blocks and cut into 5- μ m thick sections. The degree of collagen deposition was assessed using Masson's staining according to standard procedures. A pathologist who was blinded to the research design checked all the sections and described the pathological changes mainly concerning hepatic fibrosis. In addition, a medical color image analysis system (Image-Pro Plus 6.0) was used to scan and sum the collagen deposition areas then calculate the percentage of collagen, a relative objective index to assess the degree of hepatic fibrosis, expressed as the ratio of the fibrotic area to the whole area. The field examined at 100 \times magnification contained at least a granuloma, portal area, or a centrilobular vein, and the results are presented as the mean of ten different fields in each section.

Immunohistochemistry

Immunohistochemical staining was performed with an HRP-Polymer anti-Mouse/Rabbit IHC Kit (MAIXIN-BIO, China, Catalog Number: KIT-5020). The sections were dewaxed, dehydrated, washed in phosphate-buffered saline (PBS, 0.01 mol/L, pH 7.2) 3 \times 5 min, heated at 100 °C in a microwave oven 6 \times 2 min, incubated in 3% H₂O₂ in deionized water for 10 min to block endogenous peroxidases activity, and washed 3 \times 5 min with PBS. The sections were then incubated overnight at 4 °C with primary antibodies (rabbit TGF- β 1 antibody, sc-146, Santa Cruz Biotechnology, Inc., 1:500; goat p-Smad2/3 antibody, sc-11769, Santa Cruz Biotechnology, Inc., 1:300; mouse Smad7 antibody, sc-365846, Santa Cruz Biotechnology, Inc., 1:300; rabbit α -SMA antibody, ab5694, Abcam, Inc., 1:400). After washing 3 \times 5 min with PBS, the appropriate HRP-polymer anti-mouse/rabbit immunoglobulin G (IgG) was added to the sections and incubated at 37 °C for 20 min. The sections were then washed 3 \times 5 min with PBS, and the color was developed with DAB for 3-5 min. The nuclei were lightly counterstained with hematoxylin. Negative controls were incubated with PBS without the primary antibody. The integral optical density (IOD) of the target protein was measured with Image-Pro Plus 6.0, and the result was determined as the sum of five different fields (one in the center and four in the periphery) of each section. IOD was defined as the sum of the optical densities of all the positive pixels in the image,

which represents the quantity of the targeted protein.

Reverse transcription-polymerase chain reaction

Total RNA was extracted from preserved liver tissue with TRIZOL Reagent (Invitrogen, United States) then reverse-transcribed into cDNA by polymerase chain reaction (PCR). Mix Reagent kits (Fermentas, Canada) were used according to the manufacturer's protocol. The housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH), was used as an internal control to calculate relative quantification of target gene expression. The primer sequences were as follows: TGF- β 1 (168 bp) forward 5'-AGGGCTACCATGCCAACTTC-3' and reverse 5'-CCACGTAGTAGACGATGGGC-3'; Smad2 (148 bp) forward 5'-CTGTGACGCATGGAAGGTCT-3' and reverse 5'-CCACGTAGTAGACGATGGGC-3'; Smad3 (135 bp) forward 5'-CAGCGAGTTGGGGAGACATT-3' and reverse 5'-TGTAAGTTCCACGGCTGCAT-3'; Smad7 (230 bp) forward 5'-GCACTCGGTGCTCAAGAAAC-3' and reverse 5'-CCGAGGAATGCCTGAGATCC-3'; α -SMA (300 bp) forward 5'-AAGAGCATCCGACACTGCTG-3' and reverse 5'-AATAGCCACGCTCAGTCAGG-3'; GAPDH (132 bp) forward 5'-AATTTGGCATTGTGGAAGG-3' and reverse 5'-GGATGCAGGGATGATGTTCT-3'. In the RT step, a 20 μ L reaction volume contained the following components: 1 μ L RNA sample (1 μ g/ μ L), 1 μ L Oligo (dT) (10 pmol/ μ L), 10 μ L DEPC-water, 4 μ L 5 \times buffer, 2 μ L dNTP mixture (10 mmol/L), 1 μ L RNase inhibitor (10 U/ μ L) and 1 μ L ReverTra Ace. The reaction was performed at 25 °C for 5 min, followed by 42 °C for 60 min, 70 °C for 5 min, and 4 °C for 5 min. In the PCR step, a 25 μ L reaction volume contained the following components: 12.5 μ L 2 \times Master Mix, 10.5 μ L nuclease-free water, 1 μ L primer, and 1 μ L cDNA. The PCR protocol was as follows: denaturation at 94 °C for 3 min; 35 cycles of denaturation at 94 °C for 30 s, annealing at 59 °C (TGF- β 1, Smad2, Smad3 and GAPDH)/58 °C (Smad7 and α -SMA) for 30 s, and elongation at 72 °C for 45 s; and final elongation at 72 °C for 5 min. The amplified products were separated by electrophoresis on 1.5% agarose gels (volume: 8 μ L samples plus 2 μ L buffer; voltage: 100 V), visualized with ethidium bromide staining and photographed using an ultraviolet imaging system (Kodak, United States). We used gel analysis software (Gel-Pro 4.0) to scan and calculate the IOD of strips. The relative mRNA expression of the target gene was represented as the ratio of target gene IOD and GAPDH IOD.

Western blotting

Liver tissues (0.5 g) were homogenized on ice in 1 mL lysis buffer prepared from a Total Protein Extraction kit (ProMab, United States) for about 20 min and then ultrasonicated for 3 \times 3 s. The homogenates were centrifuged at 9000 \times g for 10 min at 4 °C and the supernatants were then extracted to obtain the gel sample by mixing it with sampling buffer. Following heat denaturation at 100 °C for 3 min, the samples (20 μ g protein each lane) were separated by sodium dodecyl sulfate-polyacrylamide

gel electrophoresis in running buffer and subsequently transferred to nitrocellulose membrane (Pierce, United States) in precooled transfer buffer at 300 mA constant current for 70 min. Non-specific binding site sealing was performed by incubating in PBS containing 5% non-fat milk for 2 h at room temperature. The primary antibodies (rabbit TGF- β 1 antibody, sc-146, Santa Cruz Biotechnology, Inc., 1:400; goat p-Smad2/3 antibody, sc-11769, Santa Cruz Biotechnology, Inc., 1:500; mouse Smad7 antibody, sc-365846, Santa Cruz Biotechnology, Inc., 1:800; rabbit α -SMA antibody, ab5694, Abcam, Inc., 1:500; mouse GAPDH antibody, SC-365062, Santa Cruz Biotechnology, Inc., 1:800) were incubated with the membrane overnight at 4 °C. After being washed 5 \times 4 min with PBS-Tween 20 (PBST), the secondary antibody (goat anti-rabbit IgG HRP for TGF- β 1 and α -SMA, 1:40 000; rabbit anti-goat IgG HRP for p-Smad2/3, 1:40 000; goat anti-mouse IgG HRP for Smad7 and GAPDH 1:80 000) was incubated with these membranes for 1 h at room temperature. After being washed 5 \times 4 min with PBST, enhanced chemiluminescence detection of the target protein was performed. The film was scanned and the image was analyzed with Gel-Pro 4.0. The relative expression of target protein was represented by the ratio of target protein IOD and GAPDH IOD.

Statistical analysis

Statistical analysis was performed using SPSS 13.0 software. Comparisons between groups were performed using one-way analysis of variance (homogeneity of variance: S-N-K; heterogeneity of variance: Dunnett's T3). Comparisons between time points were performed using independent-samples *t* test. *P* values less than 0.05 were considered statistically significant.

RESULTS

Schistosomal hepatopathology

Typical schistosomal hepatopathological characteristics include mainly egg granuloma and collagen deposition and were observed using Masson's staining in group B and group C at both time points (Figure 1C-F), while group A showed normal hepatocyte morphology (Figure 1A and B). At week 9, in group B, a dense mass of collagen fibers surrounded the egg granulomas, and spread to the space around them, or extended to neighboring lobules (Figure 1C); in group C, there were still numerous collagen fibers around the granulomas, but these were fewer (Figure 1E). At week 15, compared to week 9, a reduction in collagen deposition in group B was observed (Figure 1D), while there were only a few collagen fibers wrapped around disintegrated granulomas in group C (Figure 1F). Data of the percentage of collagen fibers in the different groups and at the two time points are expressed as the mean \pm SD and are shown in Figure 1G.

Expression of TGF- β 1, α -SMA, pSmad2/3 and Smad7 (immunohistochemistry)

Wispy traces of TGF- β 1 positive staining were sparsely

distributed in sections of group A (Figure 2A and D). At week 9, in group B, densely TGF- β 1-stained cells which could be distinguished by their yellow, brownish-yellow or snuff color surrounded and infiltrated the granulomas, and accumulated in fibrotic lesions or stretched along the fibrous septum (Figure 2B); in group C, the quantity and intensity of positive traces were reduced compared to group B (Figure 2C) (*P* < 0.05). At week 15, in group B, there were still some TGF- β 1-stained cells wrapped around the fibrotic granulomas or scattered around them (Figure 2E); however, only a few dispersed yellow traces were seen in group C (Figure 2F) (*P* < 0.05). The variation in α -SMA and pSmad2/3 expressions between the time points and groups were similar to TGF- β 1, although discrepancies were observed (Figure 2G-L and Figure 3A-F). It is worth mentioning that pSmad2/3 was mainly located in the nuclei not only in fibrocytes and inflammatory cells, but also in normal hepatocytes (Figure 3A-F). The expression of Smad7 in the three groups was different, and was only observed at week 9 in group B. At this point, brownish-yellow traces were distributed around the granulomas and scattered in the surrounding normal hepatic tissue (Figure 3H), but no positive staining was observed in other cells (Figure 3G and I-L). Figure 2M and N, Figure 3M and N show the IODs of each target protein in the different groups and time points. These results are expressed as IOD ($\times 10^2$ or $\times 10^3$) and as the mean \pm SD.

Expression of TGF- β 1, α -SMA, pSmad2/3 and Smad7 mRNA (RT-PCR) and protein (Western blotting)

The experimental data on target mRNAs (RT-PCR) and proteins (Western blotting) were all roughly consistent with the immunohistochemical results (Figures 4 and 5). In summary, the expressions of TGF- β 1, pSmad2/3 and α -SMA mRNA and protein in group C were higher than or similar to those in group A, but significantly decreased compared to group B at both time points. With regard to the expressions of Smad7 mRNA and protein, there were no significant differences between group A and group C at both time points or group B at week 15, but they were all lower than those in group B at week 9. All data are shown in Figures 6 and 7.

DISCUSSION

The molecular components and regulatory mechanism of the TGF- β /Smad signaling pathway are more or less diverse under different pathologic processes and environmental conditions^[27-30]. During acute liver injury, especially in toxicopathic hepatitis, the principal components and the canonical progression of this signaling are as follows: catalytically active TGF- β type I receptor phosphorylates Smad2 and the highly similar protein Smad3 to create their phosphorylated (p) isoforms, then TGF- β promotes collagen synthesis in activated HSCs *via* pSmad2/3 pathways^[31]. In the recovery stage of acute liver injury, to avoid excessive collagen deposition, TGF- β also initiates the expression of antagonistic Smad7 which functions in a negative-feedback loop to reduce the fibro-

genic strength of the signal^[32,33]. However, the negative regulation of TGF- β /Smad signaling is insufficient and

transitory; when liver injury and fibrosis enter the chronic phase, the induction of Smad7 gradually ceases, while

the TGF-β superfamily due to their shared morphological characteristics, it has an almost contrary biological function compared to TGF-β. An increasing number of reports indicate that BMP-7 may be a new antagonist of organ fibrosis because of its counteractive effect on the TGF-β/Smad signaling pathway; however, the role of BMP-7 in schistosomal hepatic fibrosis and the underlying regulatory mechanism remains a mystery. The pathogenic progression and prognosis of hepatic fibrosis induced by *S. japonicum* infection are different to other types of hepatic fibrosis, and correlative studies are necessary.

In the present study, we administered recombinant human BMP-7 at the initiation of hepatic schistosomiasis and extended the treatment period to 3 wk to ensure an adequate biological effect. The data showed that both the acute and chronic phases of liver injury and collagen deposition in the model group were accompanied by high expressions of protein and mRNA of TGF-β1, pSmad2/3 and α-SMA compared to the normal group, indicating that the “TGF-β1 active HSCs *via* pSmad2/3” classic pathway is still active in *S. japonicum*-induced hepatic fibrosis. Following treatment with BMP-7, the degree

of collagen deposition significantly reduced at both time points as well as the expressions of TGF-β1, pSmad2/3 and α-SMA, indicating that BMP-7 had an inhibitory effect on schistosomal hepatic fibrosis, at least partly *via* down regulation of the expressions of TGF-β1 and pSmad2/3 and then suppression of HSC activation. Although Smad2 and Smad3 are activated only in response to TGF-β, there are still other Smads through which BMP-7 can promote fibrosis without TGF-β. For instance, Kinoshita found that BMP-7 utilized Smad1/5/8 as signaling intermediates and decreased the expression of type I collagen and α-SMA in primary cultured HSCs independent of the presence of TGF-β^[35]. Whether the above cytokines act in schistosomal hepatic fibrosis requires further research.

Smad7, known as a negative feedback regulator to profibrotic TGF-β1, seems only to act in the acute phase of schistosomal liver injury. In this stage, hepatic damage caused by schistosome eggs induces severe inflammation; to prevent further acute injury, reparative fibrosis starts and numerous collagen fibers are secreted. We speculate that the upregulation of Smad7 is decided by the inten-

sity of hepatic fibrosis, that is, only an extremely high degree of TGF- β 1 activity and collagen secretion can initiate the negative feedback effect of Smad7. This assumption is based on the following two reasons: firstly, at 15 wk after infection in the model group, hepatic fibrosis was present, but at a lower degree than previously, however, the expression of Smad7 was almost down to normal levels; secondly, after the administration of BMP-7, the degree of hepatic fibrosis at 9 wk after infection was markedly alleviated, accompanied by a lack of Smad7 induction. Interestingly, a previous report on an animal model of CCl₄-induced liver fibrosis showed that Smad7 levels (both mRNA and protein) were up-regulated in the model group in a time-dependent manner which lasted 12 wk after modeling compared to the control group, and at week 12 Smad7 was significantly lower in the BMP-7 treatment group than in the model group and control group^[36]. Thus, our speculation regarding the expression pattern of BMP-7 remains controversial and needs further verification.

In conclusion, the role of BMP-7 as an antagonist to the TGF- β 1/Smads signaling pathway and its antifibrotic effect during both the extreme and stationary phases of schistosomal hepatic fibrosis were confirmed in this study. This provides a new research strategy and offers therapeutic potential in the treatment of hepatic schistosomiasis, although the detailed intervention mechanism still requires more research. In addition, the preparatory work for the clinical application of BMP-7 is a long, arduous task.

COMMENTS

Background

There are currently few effective therapies for schistosomal hepatic fibrosis due to a lack of appropriate intervention targets. Research on antagonists which counteract key pro-fibrosis cytokines or signaling pathways has become a new attractive focus.

Research frontiers

The therapeutic potential of bone morphogenetic protein-7 (BMP-7) as an antagonist target of transforming growth factor-beta (TGF- β)/Smad signaling has been recognized recently based on research on renal fibrosis and thioacetamide/CCl₄-induced liver fibrosis. However, its role in schistosomal hepatic fibrosis is still unclear and urgently needs to be explored, as the global epidemic of this disease is becoming more serious.

Innovations and breakthroughs

This study firstly observed the role of BMP-7 as an antagonist to TGF- β 1/Smads signaling in schistosomal hepatic fibrosis, and then confirmed the antifibrotic effect of exogenous BMP-7 during both the extreme and stationary phase of this pathological process.

Applications

This study indicates the therapeutic potential of BMP-7 in the treatment of schistosomal hepatic fibrosis and provides a new research strategy related to cytokine regulators.

Peer review

The authors are to be congratulated for confirming that BMP-7 has an inhibitory effect during both the extreme and stationary phase of schistosomal hepatic fibrosis, "at least partly" *via* down regulating the expressions of TGF- β 1 and pSmad2/3 then suppressing the activation of hepatic stellate cell. This study provides a new research strategy and offers therapeutically potential for the treatment of hepatic schistosomiasis.

patients with ulcerative colitis (UC).

METHODS: We examined CRF₂ gene and protein expression in the distal/sigmoid colonic mucosal biopsies from healthy subjects and patients with UC (active or disease in remission), human immunodeficiency virus (HIV) and functional bowel disease (FBD) by reverse transcription-polymerase chain reaction and immunofluorescence.

RESULTS: Gene expression of CRF₂ was demonstrated in the normal human colonic biopsies, but not in the human colorectal adenocarcinoma cell line Caco2. Receptor protein localization showed immunoreactive CRF₂ receptors in the lamina propria and in the epithelial cells of the distal/sigmoid biopsy samples. Interestingly, CRF₂ immunoreactivity was no longer observed in epithelial cells of patients with mild-moderately active UC and disease in remission, while receptor protein expression did not change in the lamina propria. No differences in CRF₂ expression profile were observed in distal/sigmoid intestinal biopsies from HIV infection and FBD patients, showing no signs of inflammation.

CONCLUSION: The down-regulation of the CRF₂ receptor in the distal/sigmoid biopsies of UC patients is indicative of change in CRF₂ signalling associated with the process of inflammation.

Abstract

AIM: To assess corticotropin-releasing factor receptor 2 (CRF₂) expression in the colon of healthy subjects and

INTRODUCTION

Ulcerative colitis (UC) is one of the main inflammatory bowel diseases (IBD) which affect primarily the colonic segment of the gut. Inflammation is continuous and limited to the mucosa, accompanied by ulceration, pseudopolyps, oedema, crypt abscesses and spontaneous haemorrhage. Patients present urgent diarrhoea with blood and mucus, abdominal pain, fever, continual tiredness, anaemia, weight loss and potentially serious complications, such as megacolon toxicum. Symptoms often require steroid therapy and are characterised by alternating acute and remission periods. Although its etiology is unknown, its development and acute exacerbation have been related to both physical and mental stress^[1-9].

It is well established that corticotropin-releasing factor (CRF) and its homologue peptides urocortin 1, 2 and 3, are the key mediators of the endocrine, behavioural, autonomic and visceral responses to stress^[10-12]. These neuropeptides exert their multiple actions through activation of two distinct receptor types, CRF₁ and CRF₂, both belonging to the class B G-protein coupled receptor superfamily^[13,14]. CRF₁ is expressed primarily in the brain and the pituitary^[15-17] whereas expression of CRF₂ has been reported in the central nervous system but also in various peripheral tissues such as heart, skeletal muscle, gut and testis^[18-22]. CRF and urocortin 1 display equal affinity for the CRF₁ receptor while urocortin 1 is 40 times more potent than CRF in binding CRF₂^[23]. In contrast, urocortins 2 and 3 bind selectively to CRF₂ and have been established as the endogenous ligands for this receptor subtype^[13].

The gastrointestinal tract is one of the primary peripheral systems affected by stress and there is accumulating evidence that the CRF signalling pathways are responsible for mediating these effects *via* both central and peripheral routes^[24-26]. Previous reports indicate that CRF, urocortin 1 and urocortin 2 are elevated in the colonic mucosa of patients with active UC^[27,28] and are involved in the pathogenesis of this disease, participating in the regulation of motility and/or inflammatory process *via* autocrine/paracrine actions^[29-31]. Local expression of CRF receptors is a prerequisite for mediation of these effects and understanding their histological distribution would provide anatomical support to the physiological and pathophysiological condition/phenomena. Furthermore, they could provide targets for new strategies of pharmacotherapy^[32-34].

We have recently reported that CRF₁ is up-regulated in the colonic mucosa of UC patients, particularly in macrophages supporting its involvement in the immune/inflammatory process^[35]. However, recent studies in a rat model of chemically induced colitis showed that CRF₂ rather than CRF₁ is pivotal for macroscopic spread of colitis and resolution of edema^[36]. Here, we investigated the expression pattern of CRF₂ in the distal/sigmoid colonic mucosal biopsies of healthy human subjects and compared it to inflamed colonic tissues from patients with UC or with human immunodeficiency virus (HIV)

infection and functional bowel diseases (FBD), without signs of inflammation.

MATERIALS AND METHODS

Tissues

All sigmoid colonic mucosal biopsy specimens were obtained from the Mucosal Immunology Core (UCLA AIDS Institute Center for AIDS Research). Approval to conduct the study was obtained from the UCLA Human Subjects Protection Committee. All participants provided written consent at the time they presented for scheduled screening endoscopy. Sigmoid colonic biopsies were collected by flexible sigmoidoscopy, 10-20 cm from the anal verge, from 6 healthy controls (33-65 years; 1 male, 5 females) and 10 UC patients (32-83 years; 6 males and 4 females). Patients had UC for > 10 years, based on history, endoscopic and pathology reports over the years. Four patients had active clinical disease presentation and met the criteria for mild-moderately active disease (grade as 2-3) and 6 UC patients met the criteria for minimal to no active inflammation with markers of quiescent disease (grade as 1-2). Grades were based on Matts UC classifications as used in other studies^[35]. No participants were taking steroids and one was taking a low dose of the immunosuppressive agent, 6-mercaptopurine (25 mg/d). All were treated with 5-aminosalicylate except one patient who was taking only omega-3 fatty acid gel caps. The mucosal biopsies of patients with HIV (*n* = 4) or with IBD (*n* = 7) revealed no inflammation at pathological examination. All biopsies were fixed in formalin, embedded in paraffin and stored at room temperature until further use.

Cell line

The human colorectal adenocarcinoma cell line Caco2 was obtained by the American Type Culture Collection (ATCC HTB-37, Manassas, VA, United States). Cells were maintained in ATCC-formulated Eagle's Minimum Essential Medium (Invitrogen, Grand Island, NY, United States), supplemented with 1% antibiotic-antimycotic solution and 20% fetal bovine serum (Invitrogen) in tissue culture flasks (Nunclon, Rochester, NY) at 37 °C in 5% CO₂. Cell culture medium was replaced every 2-3 d and cells were passaged when subconfluent.

Reverse transcription polymerase chain reaction

Universal reference total RNAs from normal human colon and from whole human brain were purchased from Clontech (Mountain View, CA, United States). RNA from Caco2 cells was extracted using Trizol Reagent, according to the manufacturer's instructions. Reverse transcription (RT) was performed using the SuperScript Preamplification System (Invitrogen, Paisley, United Kingdom) and random hexamers in a total volume of 20 µL. Two microliter of the RT product was used as a template, amplified by polymerase chain reaction (PCR) using 2 mol/L MgCl₂, PCR buffer, 0.2 mol/L of sense and antisense

primers, 0.2 mol/L dNTPs and 2.5 U Taq polymerase (Invitrogen) in a final reaction volume of 50 μ L. PCR was performed in a Perkin-Elmer DNA Thermal Cycler with the following cycling parameters: a pre-amplification cycle (denaturation for 5 min at 96 °C), 35 cycles of amplification (denaturation for 30 s at 96 °C, annealing for 40 s at 56 °C and extension for 50 s at 72 °C) and a final extension step for 7 min at 72 °C. The primers were designed to amplify specifically the human CRF₂ (sense AAGCTTGCCATGGACGCGGCACTGCTC antisense AAGGGCGATGCGGTAGTGC, in the area of the gene encoding the transmembrane part of the receptor and thus targeting all splice variants) according to the GenBank published sequences. The size of the amplified products was expected to be 308 bp. Negative control samples where no RT enzyme was added in a total brain RNA sample (no RT) or without DNA template (no DNA) were included in every assay in order to exclude the possibility of genomic or other DNA contamination. RT-PCR for β -actin, with expected PCR product size of 175 bp, was also performed for every sample in order to assure RNA quality. The amplified PCR products were fractionated by 1.5% agarose gel electrophoresis and detected by ethidium bromide staining under UV.

Indirect immunofluorescence

Immunofluorescence was conducted as previously described^[37]. Briefly, four-micron distal/sigmoid colonic tissue sections (4 μ m) were cut, deparaffinized, and rehydrated by standard procedures. Sections were then incubated with Antigen Retrieval Solution (Dako, Glostrup, Denmark) for 15 min, pre-blocked in 1% normal goat serum (Vector Laboratories, Burlingame, CA, United States) in phosphate buffered saline (PBS). They were then incubated with the primary antisera 4392a-CRF_{1and2} (1:2000) (raised against a synthetic peptide corresponding to amino acids 381-415 of the human/rat CRF_{1/2} C-terminus) and 2064a-CRF₂ (1:500) (raised against a synthetic peptide corresponding to amino acids 404 to 438 of the human/rat CRF₂ C-terminus)^[38,39], diluted in 1% normal goat serum in PBS for 45 min at room temperature in a humid chamber, in parallel with negative controls using normal rabbit IgG instead of the primary antiserum. Following washing in PBS, secondary antibody conjugated to a fluorescent dye, goat anti-rabbit AlexaFluor594 (Molecular Probes, Eugene, OR, United States; 1:500 or 4 μ g/mL) was added for 30 min at room temperature. Slides were subsequently mounted in anti-fade mounting media (Molecular Probes) and visualized by standard fluorescence microscopy. Replacement of the antisera by non-specific rabbit IgG (negative) was used as negative control. The number of immunoreactive cells were counted and quantified in an average number of 5 fields (340 μ m \times 260 μ m/field) from each specimen in a blinded fashion such that the information on the clinical, endoscopic and pathological findings were unknown until all counting was completed.

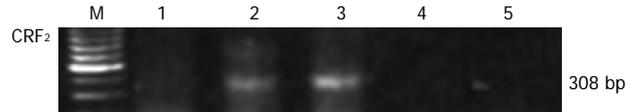

Figure 1 Reverse transcription polymerase chain reaction for corticotropin-releasing factor 2 receptor gene expression in total RNA isolated from the human colon cancer cell line Caco2 (1), human colon (2), and human brain (3) from healthy subjects. The predicted size products (308 bp) were amplified in the human colon and brain samples. Negative controls in the absence of reverse transcription enzyme (4) or DNA template (5) are also presented. CRF: Corticotropin-releasing factor; M: Marker.

Statistical analysis

Statistical significance was assessed by Fisher's exact method for small samples using the SPSS 17.0 statistical software (SPSS Inc. Chicago, Illinois, United States). Significance was set at a *P* value < 0.05.

RESULTS

CRF₂ receptor gene expression in the distal/sigmoid colon of healthy human subjects and cell lines

The expression of CRF₂ receptor gene was investigated by RT-PCR in total RNA preparations from normal human distal/sigmoid colon tissue or whole cellular extract isolated from the human colon cancer cell line Caco2. A unique RT-PCR product was amplified in RNA preparations from human distal/sigmoid colon tissue but not from the Caco2 cells (Figure 1). The size of the product was as the expected size for CRF₂ transcripts and was identical to that amplified from human brain mRNA extracts. No PCR product was amplified in the human mRNA sample when reverse transcriptase enzyme was not added in the RT reaction, or when PCR was performed in the absence of DNA template, excluding the possibility of genomic or other DNA contamination.

CRF₂ receptor protein expression in the distal/sigmoid colon biopsies of healthy human subjects

Serial tissue sections from 10 human colonic biopsies from healthy subjects were stained by immunofluorescence for CRF₂ receptor protein, using two specific polyclonal antisera (Figure 2), one of them selective for the CRF₂ receptor type. Both antibodies revealed membranous staining and similar patterns. CRF₂ positive cells were localized in the lamina propria of the colonic mucosal and in the epithelial cells of the intestinal crypts. Replacement of the antisera by non-specific rabbit IgG abolished all specific staining (although there is still some background due to non-specific absorption of secondary antibody). There were no significant differences on the pattern of distribution of receptor expression in the serial sections of the colon biopsy samples examined.

Intestinal CRF₂ receptor protein expression in distal/sigmoid colonic biopsies of patients with ulcerative colitis, HIV and FBD

CRF₂ receptor protein expression was compared in tissue

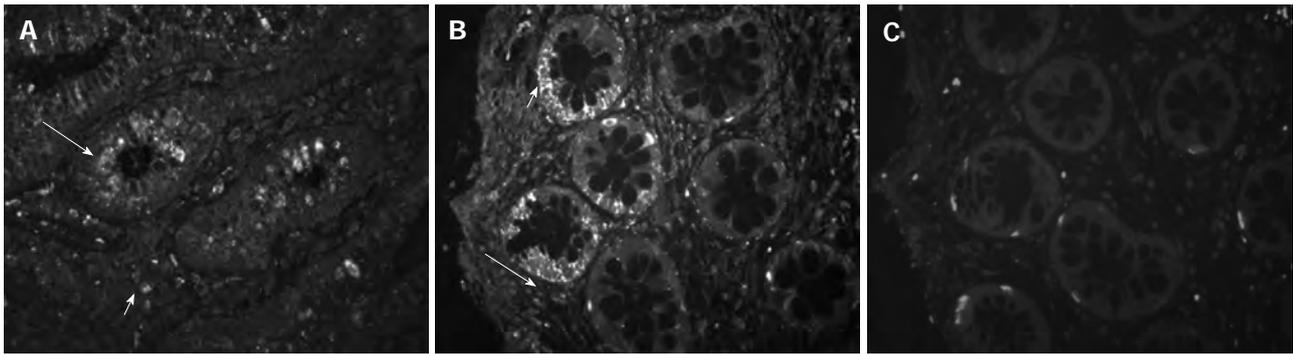

Figure 2 Mapping of corticotropin-releasing factor 2 receptor protein expression in distal/sigmoid colon biopsies of healthy human subjects. Tissue sections from normal mucosal biopsies were stained by immunofluorescence using specific antisera against corticotropin-releasing factor 2 (CRF₂) (A, 2064a-CRF₂) and both CRF₁ and CRF₂ (B, 4392a-CRF₁ and 2). Immunoreactivity was localized in isolated structures of the lamina propria (long arrows) and in the epithelial cells of the intestinal crypts (short arrows). Replacement of the antiserum by non-specific rabbit IgG (C, negative) abolished all specific staining. Original magnification 100 \times .

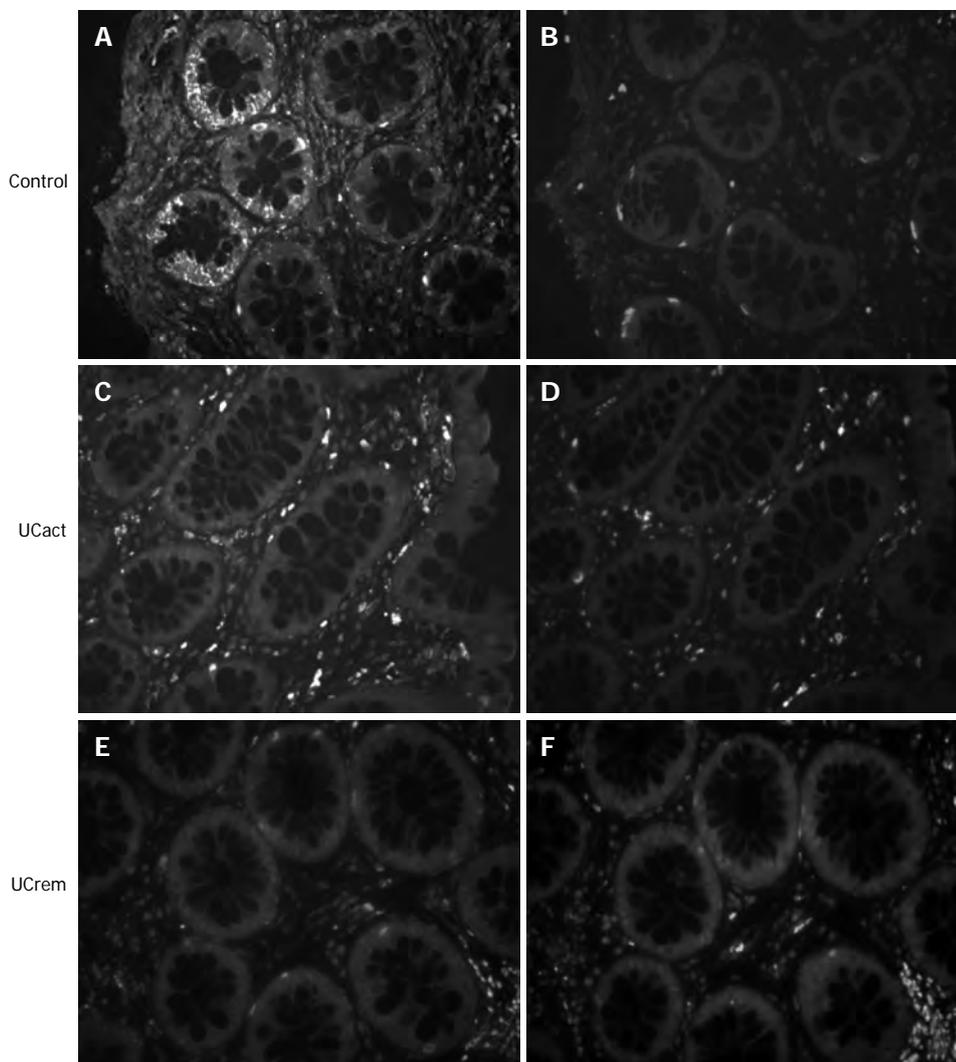

Figure 3 Comparison of corticotropin-releasing factor 2 receptor immunoreactivity in distal/sigmoid biopsies from healthy human subjects and patients with moderate ulcerative colitis and patients in remission. Tissue sections from mucosal biopsies were stained by immunofluorescence using specific antisera 2064a-corticotropin-releasing factor 2 (CRF₂) (A, C, E). Immunoreactivity for CRF₂ observed in the epithelial cells of the intestinal crypts in the control group, was not found in the UCact and UCrem groups. Replacement of the antiserum by non-specific rabbit IgG (B, D, F) abolished all specific staining. Original magnification 100 \times .

sections from five groups: A: healthy subjects (control, $n = 10$), B: UCact ($n = 4$), C: UCrem ($n = 6$), D: HIV ($n = 4$), and E: FBD ($n = 4$). The results are presented in Figures 3 and 4. CRF₂ expression in the colonic epithelial cells was down regulated in both UC patient groups, those with moderately active UC and those with disease in remission. In particular, CRF₂ immunoreactivity was

detected in the epithelial cells of the crypts in 6/10 (60%) of healthy subjects, 2/4 (50%) in the HIV group and 3/4 (75%) in the FBD group, but in none of the UCact (0/5, 0%) and UCrem group (0/6, 0%) and these differences were statistically significant ($P < 0.05$). Positive CRF₂ staining in the lamina propria was seen in all the tissues examined.

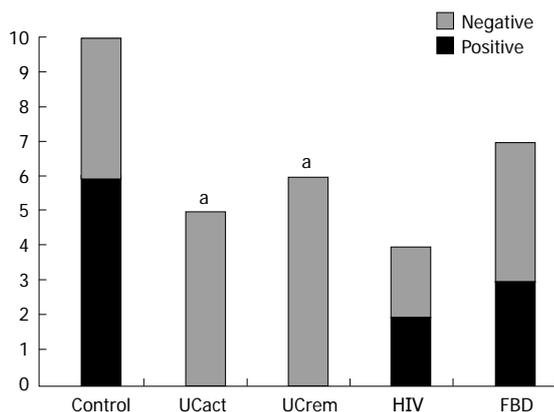

Figure 4 Corticotropin-releasing factor 2 receptor protein expression in epithelial cells in distal/sigmoid biopsies from five groups: Healthy subjects, patients with moderately active ulcerative colitis, patients with ulcerative colitis in remission, patients with human immunodeficiency virus and functional bowel disease. UCact: Active ulcerative colitis; UCrem: Ulcerative colitis in remission; HIV: Human immunodeficiency virus; FBD: Functional bowel disease. ^a*P* < 0.05 vs control group.

DISCUSSION

In the present study, we describe the expression pattern of CRF₂ in the distal/sigmoid colonic mucosa of patients with colonic inflammation (UC) or disease without inflammation (HIV infection and FBD) and compare it to healthy control subjects. Receptor protein was prominent in both the lamina propria and in epithelial cells of the intestinal crypts in tissues from healthy subjects. Interestingly, in patients with UC either moderately active or with disease in remission, expression was limited only to the lamina propria of the mucosa, whereas in the intestinal crypts it was found to be down regulated. No such difference was observed in tissues from the HIV and FBD patients.

Gene expression was confirmed by RT-PCR in total RNA preparations from full thickness intestinal tissues in healthy human subjects. Previous studies also showed CRF₂ gene expression in isolated lamina propria mononuclear cells and lower levels in the epithelial cells fraction isolated macroscopically from normal colorectal biopsies of patients undergoing surgery for non-obstructive colorectal cancer.^[28,40] More recently Wallon *et al*^[41] also found CRF₂ in subepithelial cells of human sigmoid biopsies, proven to be mast cells by colocalization with tryptase. In experimental studies, CRF₂ receptors have also been localized in the colonic enteric plexus^[38,42,43], the endothelium and vascular smooth muscle, and closely resemble human colonic expression patterns of urocortin 1 and urocortin 3^[44]. These results complement our present findings on the receptor protein histological localization, showing the respective/predicted expression pattern. By contrast, we found that the human colorectal adenocarcinoma cell line Caco2 did not express any receptor gene. These data seem specific to this cell line since previous studies showed that adenocarcinoma HT-29 cells expressed mRNA for CRF_{2x}^[45] and the non-transformed human, NCM460 colonocyte^[46] also express CRF_{2x} al-

though at a low level^[45].

Saruta *et al*^[28] showed CRF₂ mRNA expression in the lamina propria macrophages of UC patients without glucocorticoid treatment, along with an upregulation of urocortin 1 within the same cells in proportion to the severity of inflammation. We could also confirm these findings, observing an increase in urocortin 1 immunoreactivity in the colonic mucosa of UC patients (moderately active or in remission) although not a thorough quantification was performed (results not shown). Another report indicates that there is an increased gene expression of both urocortin 2 and CRF₂ in biopsies from UC patients with moderately active disease undergoing colonoscopy^[30]. The differential up-regulation of CRF₂ mRNA levels previously reported in UC and the decreased CRF₂ immunoreactivity in colonic biopsies of UC patients (present study) is not clear at the present time and may reflect alterations in CRF₂ transcription under UC conditions. However experimental studies in a rat model of chemically-induced colitis showed increased urocortin 2 accompanied by down-regulation of CRF₂ expression. CRF was also enhanced in the colonic mucosa of UC patients, in both inflammatory (namely macrophages and eosinophils) and epithelial cells^[27,47]. It is possible that the increase of peptide ligands related to the local inflammatory process, accounts for the down regulation of CRF₂ receptor protein expression reported here (being either a cause or a resultant effect). Regulation of G-protein receptor expression by its ligands is a frequent homeostatic mechanism observed in many endocrine/paracrine pathways^[48].

The down regulation of CRF₂ protein expression in the sigmoid observed in the UC patients seems to be specific to UC. This notion is enforced by our findings from a small number of two more patient groups, with HIV infection or FBD, where CRF₂ protein expression in colonic mucosa was not down-regulated. Thus, we could conclude that CRF₂ down-regulation is specific to acute or chronic inflammation of UC patients with moderately active disease and persist in colitis in remission (also inflamed) in patients receiving conventional, non-steroid therapy.

Data from experimental animal models point to a prominent role for CRF₂ in colitis-related inflammation. In a 2,4,6-trinitrobenzenesulfonic acid-induced colitis model in rats, CRF₂ expression, present on myenteric neurons and macrophages, decreased in the early phase (day 1-3) of inflammation^[49]. However a study by Moss *et al*^[30] performed on a graft of human fetal small intestinal and colonic tissues in immunodeficient mice and in which inflammation is induced by *C. difficile* toxin A 12 wk later, demonstrated increased mucosal urocortin 2 mRNA expression and up-regulation of mucosal CRF₂ expression (after 6 h), as was also the case in the murine toxin A model^[50]. Taken together, while the experimental and clinical studies provide convergent data showing an up regulation of CRF ligands including CRF, urocortin 1 and urocortin 2 under conditions of colonic inflamma-

tion or UC, this can be associated with either up or down regulation of CRF₂ receptor.

A number of studies involve the expression of the CRF system (ligands and receptors) in the regulation of local inflammation in many different tissues. In particular, local expression of urocortin 1 has been reported to act as a proinflammatory factor in rheumatoid arthritis^[29,51] or having anti-inflammatory actions in *Helicobacter pylori*-related gastritis^[52]. It seems likely that the two receptor types CRF₁ and CRF₂, being distributed in different cellular types, could mediate distinct, even opposite effects in the process of local inflammatory phenomena. Opposite signalling of the two receptor types and CRF neuropeptides has been previously reported^[53-55]. This is further supported by our data showing increased CRF₁ positive macrophages in the colonic mucosa of UC patients.

In conclusion, we report the expression of CRF₂ in the mucosal epithelium of normal human colon at gene and protein levels, and its histological mapping in the colonic mucosal and lamina propria cells. Moreover, we show down regulation of the CRF₂ protein receptor in tissues from UC patients either with moderately active disease or in remission that were not treated with glucocorticoids. These findings along with our recent studies showing the upregulation of CRF₁ receptor protein expression in macrophages of the lamina propria from sigmoid biopsies in UC patients suggest the involvement of CRF receptors in the modulation of colonic mucosa inflammation which needs further investigation. These results along with existing evidence^[32] point to the potential therapeutic use of drugs targeting CRF signaling systems to interfere with UC pathophysiology.

COMMENTS

Background

An established etiological factor for the development of ulcerative colitis (UC) is stress acting *via* initial nervous disturbance and subsequent immune dysfunction through brain-gut interactions. Activation of corticotropin-releasing factor (CRF) receptors is the principal mediator of the neuroendocrine stress responses.

Research frontiers

Previous reports indicate that CRF neuropeptides are elevated in the colonic mucosa of patients with active UC and are involved in the pathogenesis of this disease. Local expression of CRF receptors is a prerequisite for mediation of these effects and understanding their histological distribution would provide anatomical support to the physiological and pathophysiological condition/phenomena. Furthermore, they could provide targets for new strategies of pharmacotherapy.

Innovations and breakthroughs

The authors have recently reported that CRF₁ is up-regulated in the colonic mucosa of UC patients, particularly in macrophages supporting its involvement in the immune-inflammatory process. However, recent studies in a rat model of chemically induced colitis showed that CRF₂ rather than CRF₁ is pivotal for macroscopic spread of colitis and resolution of edema. In order to elucidate the molecular mechanism underlying the stress-related activation of UC symptomatology, here, we investigated the expression pattern of CRF₂ in the distal/sigmoid colonic mucosal biopsies of healthy human subjects and compared it to inflamed colonic tissues from patients with UC or with human immunodeficiency virus infection and functional bowel diseases, without signs of inflammation.

Applications

The results suggest an involvement of CRF₂ receptor in the process of inflammation in the colon and that alterations in CRF receptor expression might

participate in the pathophysiology of UC, by arresting direct stress effects on the colonic tissue. These findings could be exploited for the development of effective drugs against colitis.

Terminology

UC is one of the main inflammatory bowel diseases which affect primarily the colonic segment of the gut. Although its aetiology is unknown, its development and acute exacerbation have been related to both physical and mental stress. The hypothalamic neuropeptide CRF and its homologues urocortin 1, 2 and 3, are the key mediators of the endocrine, behavioural, autonomic and visceral responses to stress, acting *via* 2 G-protein coupled receptors, CRF₁ and CRF₂.

Peer review

The work is well written. Authors should better specify the expression of CRF₂ in response to therapy and how it changes in activity or remission state of disease.

Abstract

AIM: To investigate potential therapeutic recommendations for endoscopic and surgical resection of T1a/T1b esophageal neoplasms.

METHODS: A thorough search of electronic databases MEDLINE, Embase, Pubmed and Cochrane Library, from 1997 up to January 2011 was performed. An analysis was carried out, pooling the effects of outcomes of 4241 patients enrolled in 80 retrospective studies. For comparisons across studies, each reporting on only one endoscopic method, we used a random effects meta-regression of the log-odds of the outcome of treatment in each study. "Neural networks" as a data mining technique was employed in order to establish a prediction model of lymph node status in superficial submucosal esophageal carcinoma. Another data mining technique, the "feature selection and root cause analysis", was used to identify the most impor-

tant predictors of local recurrence and metachronous cancer development in endoscopically resected patients, and lymph node positivity in squamous carcinoma (SCC) and adenocarcinoma (ADC) separately in surgically resected patients.

RESULTS: Endoscopically resected patients: Low grade dysplasia was observed in 4% of patients, high grade dysplasia in 14.6%, carcinoma *in situ* in 19%, mucosal cancer in 54%, and submucosal cancer in 16% of patients. There were no significant differences between endoscopic mucosal resection and endoscopic submucosal dissection (ESD) for the following parameters: complications, patients submitted to surgery, positive margins, lymph node positivity, local recurrence and metachronous cancer. With regard to piecemeal resection, ESD performed better since the number of cases was significantly less [coefficient: -7.709438, 95%CI: (-11.03803, -4.380844), $P < 0.001$]; hence local recurrence rates were significantly lower [coefficient: -4.033528, 95%CI: (-6.151498, -1.915559), $P < 0.01$]. A higher rate of esophageal stenosis was observed following ESD [coefficient: 7.322266, 95%CI: (3.810146, 10.83439), $P < 0.001$]. A significantly greater number of SCC patients were submitted to surgery (log-odds, ADC: -2.1206 ± 0.6249 vs SCC: 4.1356 ± 0.4038, $P < 0.05$). The odds for re-classification of tumor stage after endoscopic resection were 53% and 39% for ADC and SCC, respectively. Local tumor recurrence was best predicted by grade 3 differentiation and piecemeal resection, metachronous cancer development by the carcinoma *in situ* component, and lymph node positivity by lymphovascular invasion. With regard to surgically resected patients: Significant differences in patients with positive lymph nodes were observed between ADC and SCC [coefficient: 1.889569, 95%CI: (0.3945146, 3.384624), $P < 0.01$]. In contrast, lymphovascular and microvascular invasion and grade 3 patients between histologic types were comparable, the respective rank order of the predictors of lymph node positivity was: Grade 3, lymphovascular invasion (L+), microvascular

invasion (V+), submucosal (Sm) 3 invasion, Sm2 invasion and Sm1 invasion. Histologic type (ADC/SCC) was not included in the model. The best predictors for SCC lymph node positivity were Sm3 invasion and (V+). For ADC, the most important predictor was (L+).

CONCLUSION: Local tumor recurrence is predicted by grade 3, metachronous cancer by the carcinoma in-situ component, and lymph node positivity by L+. T1b cancer should be treated with surgical resection.

Sgourakis G, Gockel I, Lang H. Endoscopic and surgical resection of T1a/T1b esophageal neoplasms: A systematic review. *World J Gastroenterol* 2013; 19(9): 1424-1437 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i9/1424.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i9.1424>

INTRODUCTION

Endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD), in addition to local ablation techniques, are now more extensively employed for the management of early adenocarcinoma (ADC) or squamous cell carcinoma (SCC) of the esophagus. The aim of endoscopic resection is to maintain the integrity of the esophagus and avoid the considerable morbidity and mortality of esophagectomy^[1].

Several cohort studies^[2-5] suggest the use of EMR or ESD for T1a esophageal neoplasia (including high grade dysplasia, adenocarcinoma, or squamous-cell carcinoma) confined to the superficial mucosa and not extending into the muscularis mucosa. Other studies contemplate endoscopic resection, even in muscularis mucosa invasion and in selected cases where upper third submucosal involvement is present^[6]. T1b disease may be treated by esophagectomy.

At present, there are no reliable pre-excision molecular, biological or immunohistochemical predictive markers of lymph node metastasis in T1 esophageal cancer. Moreover, the current diagnostic workup has a low diagnostic performance for N1-disease which is considered the most influential predictor of long term prognosis^[7].

The pros and cons of each endoscopic resection method have yet to be established, and level I evidence of their safety and efficacy is missing from the literature. Predictive markers of lymph node metastasis in mucosal and

submucosal esophageal cancer are also an unsolved issue.

Answers to the aforementioned issues might enable researchers to formulate curative treatment strategies and considerations for neoadjuvant referral in early esophageal carcinoma cases.

The objectives of this study were: (1) to compare the safety and efficacy of EMR and ESD in the management of early esophageal neoplasia; (2) to investigate their role as part of the diagnostic workup; (3) to establish predictors of lymph node status, local recurrence and metachronous cancer development in superficial esophageal carcinoma; and (4) to investigate potential therapeutic recommendations.

MATERIALS AND METHODS

Literature search

Medline, Embase, Pub Med and the Cochrane Library databases were searched for articles in the English language from 1997 up to 2011. The following search terms were used: Early esophageal cancer, esophageal dysplasia, high grade dysplasia, low grade dysplasia, intraepithelial neoplasia, Barrett's esophagus, superficial esophageal cancer, mucosal esophageal cancer, submucosal esophageal cancer, intramucosal/submucosal carcinoma of the esophagus, esophageal adenocarcinoma, esophageal squamous cell carcinoma, adjuvant treatment, T1a, T1b, T1m and T1sm. Terms were combined with "and/or" and asterisks. References from included studies were examined for additional studies. The main reasons for initial exclusion included animal studies, non-English literature, case reports, reviews and double publications. Figure 1 shows the process and stages throughout the review of the studies included.

Inclusion and exclusion criteria for the endoscopic database

Inclusion: (1) Application of EMR and/or ESD for early esophageal cancer; (2) Low-grade dysplasia or high grade dysplasia (HGD) in the setting of Barrett's esophagus as well as early esophageal cancer; and (3) Siewert I and II tumors.

Exclusion: (1) Studies involving previously untreated patients (no neoadjuvant therapy); (2) Studies including patients with Siewert type III, and with metastatic disease; and (3) Studies including patients with tumors other than ADC/SCC.

Inclusion and exclusion criteria for the surgically resected patients' database

Inclusion: (1) Information from the pathology reports after esophagectomy for submucosal carcinoma with curative intent; (2) Studies including patients with esophago-gastric junction carcinoma were eligible for analysis; and (3) Studies providing separate data for SCC and ADC.

Exclusion: (1) Studies administering neo-adjuvant treatment; (2) Studies involving patients with distant metastasis.

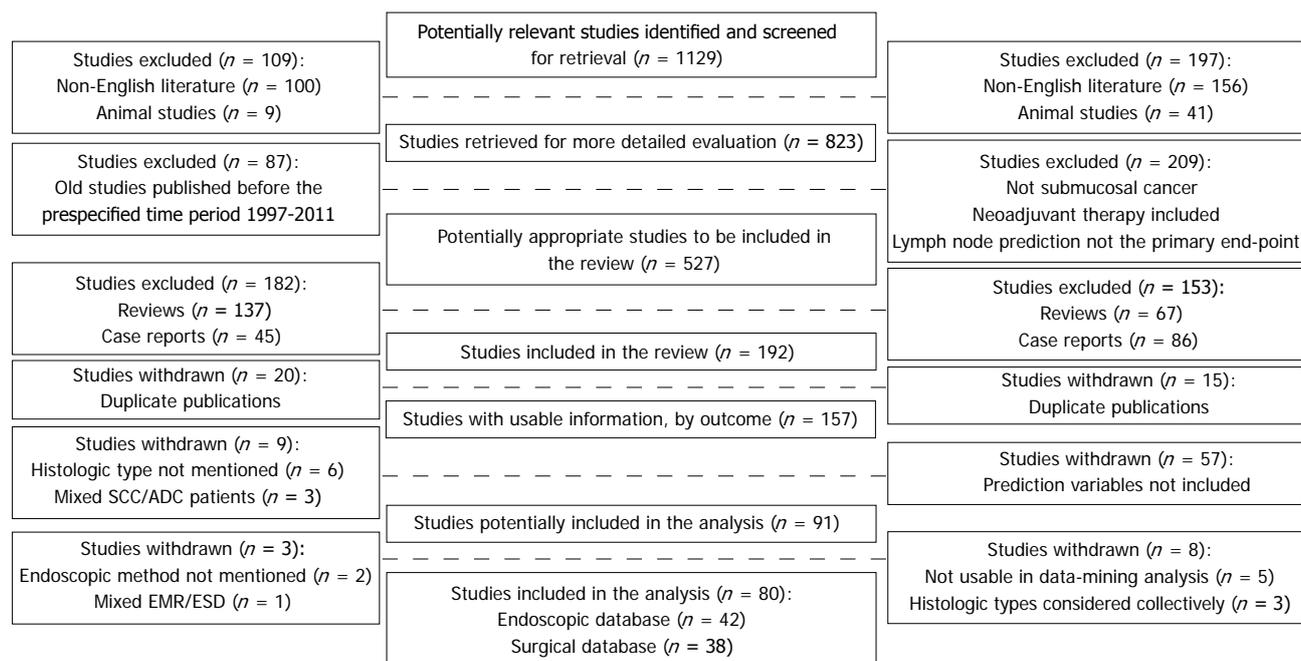

Figure 1 Progress through the stages of study review included. SCC: Squamous cell carcinoma; ADC: Adenocarcinoma; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection.

sis; (3) Case reports; (4) Mixed data for SCC and ADC; and (5) Mixed data for T1a and T1b tumors and/or surveillance of patients with dysplasia.

Data extraction

The two authors independently selected studies for inclusion and exclusion and reached a consensus when there was initial disagreement. The parameters ascertained included authors, journal and year of publication, total number of patients, type of estrogen receptor (ER) involved, final pathology results, histological type, tumor diameter, tumor location, pattern of growth, degree of differentiation, depth of tumor invasion, lymph node status, presence of lymphatic or venous invasion, as well as positive resection margins on the pathology specimen, number of patients with local recurrence, presence of metachronous lesions, and additional therapies necessary beyond ER, including surgery.

Definitions

Submucosal lesions were classified as Sm1 for tumors invading the more superficial layer of the submucosa (corresponding to one-third of its thickness), Sm2 for those invading the middle third, and Sm3 for those invading the deeper submucosal layer^[8].

Statistical analysis

For comparisons across studies, each reporting on only one treatment/histologic type, we used a random effects meta-regression of the log-odds of the outcome of treatment in each study. In this case, we estimated the variance of each study-specific log-odds as the sum of the reciprocals of the number of successes and failures. Counts of 0 were replaced by 0.5.

Statistical analysis for comparisons across studies was performed using the “metareg command” of STATA/SE 11. To address multiple testing (calculate *P* values for covariates) the “permute option” based on a Monte Carlo permutation test of STATA/SE 11 was used.

“Neural networks” as a data mining technique^[9] was employed in order to establish a prediction model of lymph node status in superficial submucosal esophageal carcinoma and find a simple model to fit the data better. The definition of a linear network was followed by training of the network. The data set was divided into three subsets: training, selection, and test cases in the proportions 3:1:1 between the training, selection, and test subsets.

Another data mining technique, the “feature selection and root cause analysis”, was used to identify the most important predictors of local recurrence and metachronous cancer development in endoscopically resected patients, and lymph node positivity in SCC and ADC separately in surgically resected patients.

In brief, this test provides extremely useful shortcuts for identifying root causes for the values observed in the outcome variables under investigation (*e.g.*, an indicator of quality or process yield); final selections of predictors are not biased in favor of any particular model (fitted to the data for the selected predictors).

The statistical programs used were: STATA/SE 11 (Statacorp LP 4905 Lakeway Drive College Station TX 77845, United States), the NCSS 2007 and GESS 2006 version 07.1.13, (Kaysville, Utah, United States) and Statistica release 7 (Stat Soft Inc., Tulsa, United States).

Table 1 Forty-two studies were included in the analysis of endoscopically resected patients

EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; SCC: Squamous carcinoma; ADC: Adenocarcinoma; APC: Argon plasma coagulation; PDT: Photodynamic therapy; CRT: Chemoradiation therapy; RFA: Radiofrequency ablation; RT: Radiology; CHEMO: Chemotherapy.

RESULTS

Endoscopically resected patients

Forty-two studies^[6,10-50] were selected (Table 1) which included a total of 2092 patients. Low grade dysplasia was observed in 4% of patients, high grade dysplasia in 14.6%, carcinoma *in situ* in 19%, mucosal cancer in 54%,

and submucosal cancer in 16% of patients. Histologic types were SCC in 23 studies and ADC in 19 studies.

EMR was employed in 29 studies and ESD in 6 studies. Both EMR and ESD were used in 7 studies. Lymphovascular invasion was found to range from 0%-30%, microvascular invasion was observed in 0%-33% of patients, and 7.4% of patients were poorly differentiated.

Table 2 Meta-regression analysis of the methods of endoscopic resection according to the published studies (the random effects model was used)

| EMR <i>vs</i> ESD | Coefficient | 95%CI | P value | Favors |
|----------------------------------|-------------|----------------------|---------|--------|
| Patients submitted to surgery | 0.401 | -2.912964, 3.714436 | 0.806 | None |
| Positive margins | -0.741 | -3.362995, 1.881024 | 0.558 | None |
| Local recurrence | -1.713 | -4.420582, 0.9937198 | 0.201 | None |
| Lymph node metastasis | 0.905 | -5.762587, 7.573427 | 0.762 | None |
| Metachronous cancer | -1.804 | -4.350273, 0.7420371 | 0.143 | None |
| Procedural complications | 1.397 | -1.264597, 4.058631 | 0.289 | None |
| Stenosis | 7.322 | 3.810146, 10.83439 | < 0.001 | EMR |
| Piecemeal resection ¹ | | | | |
| Number of cases | -7.709 | -11.03803, -4.380844 | < 0.001 | ESD |
| Local recurrence | -4.034 | -6.151498, -1.915559 | < 0.01 | ESD |
| Resection margins | 0.837 | -3.725993, 5.39999 | 0.678 | None |

¹Data available only for squamous cell carcinoma studies. EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection.

Argon plasma coagulation (APC) as the only modality was used in 3 studies^[6,37,42]. In addition to APC, 2 studies^[15,24] also utilized photodynamic therapy (PDT) and 3 studies added chemoradiation therapy (CRT)^[20,27,46]. Adjuvant only CRT was administered in 6 studies^[19,22,31,32,34,35], radiotherapy only in 2^[29,49], radiotherapy and CRT in 2^[33,47], PDT only in 3^[10,25,30], chemotherapy only in 2^[13,23], and PDT/chemotherapy in one study^[4]. Radiofrequency ablation was used in 2 studies^[18,50]. Mean follow-up time varied from 12 to 62 mo and median follow-up time ranged from 7 to 39 mo.

Lymph node metastasis

Eleven studies^[4,20,25,26,28,31,34,35,38,40,51] provided data on lymph node metastasis. Thirty-one patients out of 371 were node-positive. The overall increase in the odds was 5% for ADC and approximately 1% for SCC. No significant differences were observed between either ADC *vs* SCC or EMR *vs* ESD patients (Tables 2 and 3). Lymphovascular invasion was found to be the only predictor of lymph node metastasis (*F* value: 416.45, *P* < 0.001).

Differences between pre- and post-endoscopic resection tumor staging

Eighteen studies^[10,12,14-16,24-28,30,31,33,37,38,44,52,53] including 685 patients reported differences between pre- and post-endoscopic resection tumor staging in 235 cases. These differences were mainly due to either the histological assessment (HGD *vs* carcinoma) and/or tumor depth of invasion (Table 3). Patients treated with both endoscopic methods and subsequently submitted to surgery due to unfavorable tumor characteristics did not differ significantly (Figure 2A), although SCC patients were statistically more likely to be referred for surgery. The combined odds were 53% and 39% for ADC and SCC, respectively.

Piecemeal resection

Piecemeal resection was accomplished in 48% (732/1516)

of cases. Ten studies^[11,13,17,23,29,32-34,46,51] reporting piecemeal resection cases (*n* = 412) additionally provided the number of lesions (*n* = 466) per patient, number of patients with positive margins (*n* = 36) and local recurrence rates (*n* = 20 patients). All the aforementioned 10 studies enrolled SCC patients. Piecemeal resection and local recurrence rates were statistically significantly lower when performing ESD (Tables 2 and 3; Figure 2B). In contrast, positive margins did not differ significantly between the two endoscopic methods.

Resection margins

Eighteen studies^[10,11,13,17,20,23,25,26,28,29,33-35,38,46,50,51,54] reported outcomes concerning specimen margin status. Thirty-three per cent (294/880) of cases demonstrated positive margins. Positive margin data were from primary endoscopic resection. The overall increase in the odds was 9% for ADC and approximately 7% for SCC. No significant differences on positive resection margins were observed between either ADC *vs* SCC or EMR *vs* ESD patients (Tables 2 and 3; Figure 2C).

Monte Carlo permutation adjusted testing for meta-regression disclosed that local recurrence in patients with positive resection margins was independent of endoscopic resection modality (EMR/ESD, *P* = 1.000), histologic type (ADC/SCC, *P* = 0.972) and type of adjuvant therapy (chemo/CRT/APC/RT/PDT, *P* = 0.899). Data mining showed that grade 3 was an independent predictor of local recurrence in cases with positive margins (*P* < 0.001).

Local recurrence

Local recurrence among 30 studies^[3,6,11-15,17,20,22-24,26,27,29,30,32-35,37,42,46-48,50,51] which provided relevant data ranged from 0-17%. The combined odds were 0.8% and 1% for ADC and SCC, respectively. No significant differences were observed between either ADC *vs* SCC or EMR *vs* ESD patients (Tables 2 and 3; Figure 2D). Data mining showed that grade 3 was an independent predictor of local recurrence (*F* value: 16.2, *P* < 0.05). In cases of piecemeal resection, local recurrence was significantly higher when performing EMR (*F* value: 5.39, *P* < 0.01).

Development of metachronous lesions

Development of metachronous lesions ranged from 2%-14% in 10 studies^[6,13-15,17,20,27,34,42,50,51]. The combined odds were 6% and 1% for ADC and SCC, respectively. No significant differences were observed between either ADC *vs* SCC or EMR *vs* ESD patients (Tables 2 and 3; Figure 2E). Data mining showed that the presence of carcinoma *in situ* was an independent predictor of metachronous lesion development (*F* value: 62.5, *P* < 0.01).

Procedural and late morbidity

Twenty-five studies^[10-17,23,24,26-31,33-35,41,43-46,51] provided satisfactory data on procedural morbidity and late complications. Procedural morbidity included bleeding managed conservatively in 5.8%, bleeding requiring intervention in 0.6%, perforation 1.8% and pain in 4.2% of patients.

Table 3 Meta-regression analysis of the outcomes of endoscopic resection according to the histologic type of early esophageal cancer (the random effects model was used)

| Outcome | Histologic type | Log-odds ratio | SE | 95.0% lower confidence limit | 95.0% upper confidence limit | Odds | Favors |
|-------------------------------------|-----------------|----------------|--------|------------------------------|------------------------------|-------|------------|
| Patients submitted to surgery | ADC | -2.1206 | 0.6249 | -3.3454 | -0.8958 | 12% | ADC |
| | SCC | 4.1356 | 0.4038 | -4.9271 | -3.3440 | 37% | $P < 0.05$ |
| Positive margins | ADC | -2.3761 | 1.0181 | -4.3716 | -0.3806 | 9% | None |
| | SCC | -2.5689 | 0.6973 | -3.9357 | -1.2022 | 7% | |
| Local recurrence | ADC | -4.8189 | 0.1469 | -5.1068 | -4.5309 | 0.80% | None |
| | SCC | -4.3347 | 0.2792 | -4.8819 | -3.7874 | 1% | |
| Lymph node metastasis | ADC | -3.0565 | 0.7714 | -4.5685 | -1.5445 | 5% | None |
| | SCC | -4.7682 | 0.4413 | -5.6332 | -3.9032 | 0.90% | |
| Metachronous cancer | ADC | -2.8017 | 0.2384 | -3.2690 | -2.3344 | 6% | None |
| | SCC | -4.6030 | 0.6059 | -5.7905 | -3.4155 | 1% | |
| Pre- vs post-endoscopic tumor stage | ADC | -0.5449 | 0.4316 | -1.3909 | 0.3011 | 53% | - |
| | SCC | -0.8267 | 0.3324 | -1.4782 | -0.1752 | 39% | |

SCC: Squamous cell carcinoma; ADC: Adenocarcinoma.

Esophageal stenosis was experienced by 12.2% of patients. No significant differences in procedural complications were observed between EMR vs ESD patients. In contrast, esophageal stenosis was statistically more prevalent among patients managed with ESD ($P < 0.001$) (Tables 2 and 3; Figure 2F).

Surgically resected patients

Of 677 screened studies, 38 studies comprising a total of 2149 participants were finally included^[20,31,40,55-86].

The magnitude of kappa (0.86) reflected adequate agreement between the two reviewers. All 38 studies provided data on lymph node metastasis. The histological parameters of patients are presented in Table 4. Eight-hundred and eighty-eight (888) patients among 2149 were node-positive. Significant differences in patients with positive lymph nodes were observed between ADC and SCC ($P < 0.01$). In contrast, lymphovascular and microvascular invasion and grade 3 patients between histologic types were comparable (Table 5). Grade 3 patients were seen in 24% (158/663) with SCC and in 49% (267/541) with ADC.

Setting up a model for prediction of lymph node metastasis

In an endeavor to set up a model to predict lymph node metastasis, we applied Neural Networks as a data mining technique. All included studies provided sufficient information on depth of tumor invasion (Sm1, Sm2, Sm3), lymphatic invasion, vascular invasion, histologic differentiation, and histologic type (SCC, ADC) (Table 6).

The number of patients with positive lymph nodes was set as the dependent variable, while the respective number of patients with Sm1, Sm2, Sm3 invasion, lymphatic invasion, vascular invasion, and poor differentiation were used as continuous independent variables. The histologic type of esophageal cancer was set as a categorical variable. The linear model 5:5-1:1 emerged as the best neural network model according to its regression statistics, with the smallest error: data standard deviation ratio (0.07506; an SD ratio closer to 0.1 generally indicates very

good regression performance). This was also true for the close correlation between the prediction of the independent and dependent variables (0.99774). Its format was $\langle \text{type} = \text{Linear} \rangle \langle \text{inputs} = 5 \rangle : \langle \text{layer 1} = 5 \rangle - \langle \text{layer 2} = 1 \rangle : \langle \text{outputs} = 1 \rangle$, with two layers. Missing values were patched using the mean variable value.

The rank order of importance of the predictors of lymph node positivity was: Grade 3, Sm3 invasion, L(+), V(+), Sm2 invasion and Sm1 invasion, respectively. Histologic type (ADC/SCC) had a ratio network error ≤ 1 , and thus should not be considered as a predictor.

Validation of the model

The data set was divided into three subsets: the training, selection, and test cases (3:1:1 in our model) in order to preclude the predictive performance of the linear model being attributed to a data over-fitting phenomenon. The predicted number of patients in various studies with positive lymph nodes by the linear model was almost identical to that observed by the authors.

Predictors of lymph node metastasis in SCC and ADC

Considering only the predictors of lymph node metastasis defined by the aforementioned linear model in each of the two histological entities (SCC, ADC), we applied another data mining technique (Feature selection and root cause analysis).

The best predictors of lymph node positivity in SCC were Sm3 invasion ($P < 0.001$) and microvascular invasion ($P < 0.01$). In relation to ADC, the most important predictor was lymphovascular invasion ($P < 0.05$).

DISCUSSION

According to NCCN guidelines version 1.2011 for esophageal and esophagogastric junction cancers, in the absence of evidence of lymph node metastases, lymphovascular invasion or poor differentiation grade, T1a disease can be treated with full EMR. In cases of unfavorable characteristics, the choice lies between EMR plus ablation or esophagectomy. T1b disease may be treated by esophagectomy.

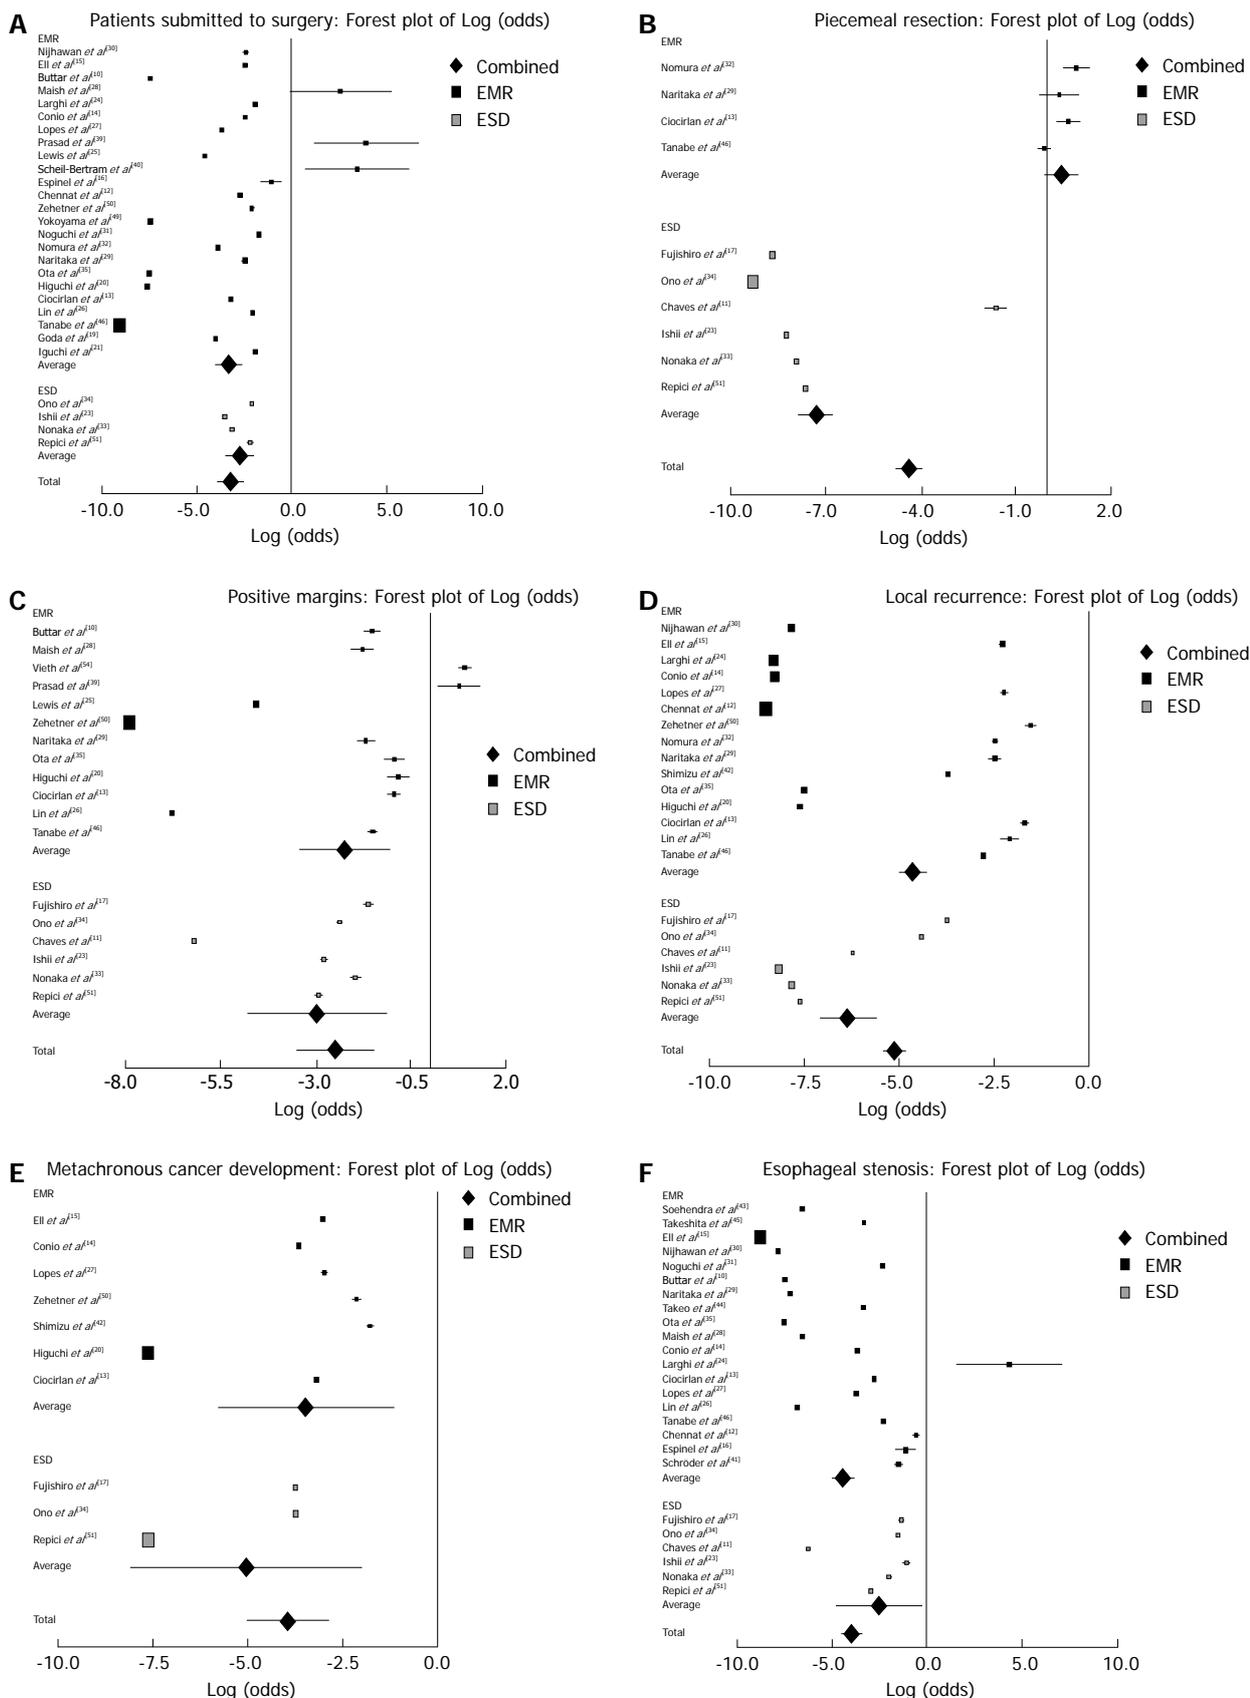

Figure 2 Forest plot of log-odds in both groups (endoscopic mucosal resection and endoscopic submucosal dissection): No statistically significant differences were observed. A: Forest plot of log-odds patients submitted to surgery; B: Forest plot of log-odds of piecemeal resected patients; C: Forest plot of log-odds of positive resection margins patients; D: Forest plot of log-odds of local recurrence in both groups [endoscopic mucosal resection and endoscopic submucosal dissection (EMR-ESD)]; No statistically significant differences were observed, with the exception of piecemeal resected patients. In this last instance ESD was more efficient; E: Forest plot of log-odds of metachronous cancer development; F: Forest plot of log-odds of esophageal stenosis in both groups (EMR-ESD): EMR was less destructive.

imaging) that obviate the need for neoadjuvant or peri-operative therapy. To our knowledge, level I evidence related to these issues is missing from the literature. The only published meta-analysis based on retrospective studies (seven full-text and eight abstracts) compares EMR *vs* ESD for esophageal, gastric, and colorectal neoplasms jointly^[87].

In addition to a variety of local ablation techniques, EMR and ESD are now extensively used for the treatment of stage Tis (high-grade dysplasia) and T1a ADC or SCC, aiming to reduce the considerable morbidity and mortality associated with esophagectomy.

The possibility of lymph node metastases, completeness of endoscopic resectability, early and late complications, local recurrence and development of a metachronous cancer, are concerns that should be measured when deciding whether to proceed with EMR, ESD or surgery.

According to our pooled analysis there were no significant differences between EMR and ESD for the following parameters: procedural complications, number of patients submitted to surgery, positive specimen margins, lymph node positivity, local recurrence rates and metachronous cancer development. In instances of piecemeal tumor resection, in particular, ESD performed better since the number of cases was significantly less ($P < 0.001$); hence, local recurrence rates were significantly lower ($P < 0.01$). An important point that should be kept in mind is the higher rate of esophageal stenosis observed following ESD ($P < 0.001$). Data on circumferential spread and tumor size were scarce among the studies.

There were no considerable differences in the appli-

cation of endoscopic methods to each of the main histologic types of early esophageal cancer, other than the fact that a significantly greater number of SCC patients were submitted for surgery ($P < 0.05$).

Another significant finding was the high percentage of patient restaging after endoscopic intervention. EUS staging prior to proceeding with mucosal resection in the setting of carcinoma is recommended. In a recent meta-analysis^[7], the pooled sensitivity (95%CI) and specificity (95%CI) for regional lymph node metastases was 0.764 (0.741-0.785) and 0.724 (0.693-0.753), respectively. The pooled diagnostic odds ratio (95%CI) was 8.001 (6.369-10.051). Although EUS has a better diagnostic performance compared to computed tomography (CT) scanning and positron emission tomography CT, the question of regional lymph node detection has yet to be satisfactorily addressed.

With regard to preoperative staging, endoscopic resection after endoscopic biopsy plays a key role. The odds for re-classification of tumor stage after endoscopic resection were 53% and 39% for ADC and SCC, respectively. This was possibly due to biopsy sampling failure, lack of adequate specimen and pathologist misinterpretation of the muscular anatomy. This obviates the need to optimize pre-treatment diagnostics and reconsider treatment strategies. The introduction of endoscopic resection in selected cases as part of the diagnostic workup should be strongly taken into consideration. This particular issue is supported by our data mining analysis: local tumor recurrence was best predicted by grade 3 differentiation and piecemeal resection, metachronous cancer development by the car-

cinoma *in situ* component and lymph node positivity by lymphovascular invasion. All the aforementioned predictors/histologic features can easily be retrieved from the EMR/ESD sample.

However, ESD is a technically demanding procedure that is not widely available. Although we were not able to perform a direct comparison of the outcomes of ESD *vs* surgery due to lack of relevant data, the likelihood of lymph node metastases and endoscopic resectability being factors that should be considered in deciding whether to pursue ESD or surgery is high, as stated by some authors^[17]. According to our results, the presence of grade 3, piecemeal resection, the carcinoma *in situ* component and lymphovascular invasion would prompt surgical resection.

Available evidence from our esophagectomy series with radical lymph node dissection database suggests that the frequency of lymph node metastasis increases in proportion with tumor depth.

The diagnostic performance of sentinel lymph node biopsy for esophageal and gastric cardia cancer provides sensitivity between 75%-100% and accuracy between 78%-100%. Albeit applied in only a small number of patients, CT-lymphography seems to be the most promising method^[7].

Considering the low incidence of lymph node metastasis (the odds are 5% for ADC and approximately 1% for SCC) and the absence of lymphovascular invasion in neoplasms limited to the mucosa, endoscopic resection is oncologically adequate for well-differentiated cancers, resected completely and lacking *in situ* foci. With regard to Barrett's patients in particular, close endoscopic surveillance should be life-long and requires the commitment of both the patient and the physician since according to our results, the odds for lymph node metastasis are 5% and for metachronous cancer development 6%.

When endoscopic therapy for early esophageal cancer is considered, EMR or ESD should be applied first prior to the use of ablative techniques. According to our analysis, the application of ablative techniques has not gained significance as an independent predictor of local recurrence or metachronous cancer development.

Considering studies including surgically resected patients, lymph node positivity was statistically greater in SCC, while lymphovascular and microvascular invasion and grade 3 percentages were comparable between ADC and SCC patients. In rank order of importance, the predictors of lymph node metastasis in the prediction model were: Grade 3, Sm3 invasion, lymphovascular invasion, microvascular invasion, Sm2 invasion and Sm1 invasion, respectively. The best predictors of lymph node positivity in SCC were Sm3 invasion and microvascular invasion. For ADC, the most important predictor was lymphovascular invasion. According to the above, the present study supports the surgical rather than the endoscopic resection of T1b esophageal cancer, since even Sm1 invasion was included in our model. In consequence, Sm1 lesions should not be removed endoscopically. Interestingly, the presence of specific histologic features should prompt

consideration of a more aggressive management, such as the use of neoadjuvant or perioperative treatment. This perception also poses the question as to the endorsement of EMR/ESD as part of the diagnostic workup.

Since there is a lack of apposite molecular-biological markers that can predict lymphatic spread in T1a and T1b-esophageal carcinoma with high diagnostic yield and the inconsistent success of the diagnostic work-up, the predictors found in our data mining analysis would possibly be of relevance in clinical decision making.

The analysis of surgically only resected patients is an updated version of an already published study by our group^[88]. Although more studies have been included, the results were identical.

The current work is not without its limitations: (1) The report included studies of retrospective case series; thus, a formal meta-analysis could not be applied; (2) Parameters, such as dysplasia grade, segment length of Barrett's and small areas of intestinal metaplasia hidden underneath neosquamous mucosa, the so-called "buried Barrett's", could not be analyzed due to paucity of data; (3) Overall patient survival and disease-free survival could not be assessed due to data inconsistency; (4) the type of resection (*en-bloc*, transhiatal, Ivor Lewis, minimally invasive) and differences according to the location of the tumor, with regard to lymph node, L and V invasion, may have influenced, to a degree, the prevalence of node positivity; and (5) in some studies, the stratification of data for distribution of the lymphovascular involvement according to the depth of tumor infiltration, and similar stratification for nodal involvement (m1, m2, m3, sm1, sm2 and sm3), were not available.

The value of patient data mining has already been established by The Medical Quality Improvement Consortium^[89]. This large clinical data warehouse contains patient data including their problem lists, test results, procedures and medication lists, all of which help identify valid associations.

Currently, the National Comprehensive Cancer Network recommends an esophagectomy over endoscopic therapy for fit patients with T1b cancer. This study suggests the option of neoadjuvant treatment for those patients with unfavorable histological characteristics in terms of tumor histologic entity, aiming at a R0 resection.

In summary, according to this study, there were no significant differences between EMR and ESD concerning procedural complications, number of patients submitted to surgery, positive specimen margins, lymph node positivity, local recurrence rates and metachronous cancer development. In instances of a predicted piecemeal tumor resection, ESD performed better since the number of cases was significantly less and local recurrence rates were therefore significantly lower. A higher rate of esophageal stenosis was observed following ESD.

Local tumor recurrence after endoscopic resection was best predicted by grade 3 differentiation, metachronous cancer development by the carcinoma *in situ* component, and lymph node positivity by lymphovascular

invasion.

T1b esophageal cancer should be managed with surgical resection and systematic lymphadenectomy since even Sm1 invasion was in the constructed model, while the histologic type and presence of specific predictors could likely alter the surgeon's policy and perspective of multimodality management. The best predictors of lymph node positivity in SCC were Sm3 invasion and microvascular invasion. For ADC, the most important predictor was lymphovascular invasion. Prospective studies, or preferably randomized controlled trials, are needed in order to validate the refinements for patient selection made by this study.

COMMENTS

Background

Endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) are frequently used to treat early esophageal cancer. Esophagectomy remains the standard of treatment especially in submucosal invasion. However, there is controversy between surgeons and endoscopists as to which is the best treatment option. The literature lacks a satisfactory level of evidence with respect to T1a and T1b esophageal cancer management.

Research frontiers

The present meta-analysis: (1) Investigated the particular role of each of the two endoscopic modalities in the treatment of early esophageal cancer; (2) Analyzed the issue of local recurrence and metachronous cancer development in patients treated endoscopically; and (3) Analyzed for potential tumor lymph node positivity.

Innovations and breakthroughs

Level I evidence related to the endoscopic management of early esophageal cancer is missing from the literature. The only published meta-analysis based on retrospective studies (seven full-text and eight abstracts) compares EMR vs ESD for esophageal, gastric, and colorectal neoplasms jointly.

Applications

Potential unfavorable tumor characteristics as documented in this systematic review and meta-analysis (besides those found by imaging) may obviate the need for neoadjuvant or perioperative therapy.

Terminology

Meta-regression is a tool used in meta-analysis to examine the impact of moderator variables on study effect size using regression-based techniques. Meta-regression is more effective at this task than standard regression techniques. The random or mixed effects model allows for within study variation and between study variation and is therefore the most appropriate model to choose. A neural network is a system of programs and data structures that approximates the operation of the human brain. A neural network generally involves a large number of processors operating in parallel, each with its own small sphere of knowledge and access to data in its local memory. Typically, a neural network is initially "trained" or fed large amounts of data and rules about data relationships.

Peer review

The authors reviewed endoscopic and surgical resection of superficial esophageal neoplasms. The review was well conducted in the topic is very interesting in order to identify selection of treatment implicated in the superficial esophageal cancer.

Abstract

AIM: To evaluate the prognostic significance of CD24 expression in patients undergoing adjuvant chemoradiotherapy for extrahepatic bile duct (EHBD) cancer.

METHODS: Eighty-four patients with EHBD cancer who underwent curative resection followed by adjuvant chemoradiotherapy were enrolled in this study. Postoperative radiotherapy was delivered to the tumor bed and regional lymph nodes up to a median of 40

Gy (range: 40-56 Gy). All patients also received fluoropyrimidine chemotherapy for radiosensitization during radiotherapy. CD24 expression was assessed with immunohistochemical staining on tissue microarray. Clinicopathologic factors as well as CD24 expression were evaluated in multivariate analysis for clinical outcomes including loco-regional recurrence, distant metastasis-free and overall survival.

RESULTS: CD24 was expressed in 36 patients (42.9%). CD24 expression was associated with distant metastasis, but not with loco-regional recurrence nor with overall survival. The 5-year distant metastasis-free survival rates were 55.1% and 29.0% in patients with negative and positive expression, respectively ($P = 0.0100$). On multivariate analysis incorporating N stage, histologic differentiation and CD24 expression, N stage was the only significant factor predicting distant metastasis-free survival ($P = 0.0089$), while CD24 expression had borderline significance ($P = 0.0733$). In subgroup analysis, CD24 expression was significantly associated with 5-year distant metastasis-free survival in node-positive patients (38.4% with negative expression *vs* 0% with positive expression, $P = 0.0110$), but not in node-negative patients (62.0% with negative expression *vs* 64.0% with positive expression, $P = 0.8599$).

CONCLUSION: CD24 expression was a significant predictor of distant metastasis for patients undergoing curative resection followed by adjuvant chemoradiotherapy especially for node-positive EHBD cancer.

predicts distant metastasis in extrahepatic bile duct cancer. *World J Gastroenterol* 2013; 19(9): 1438-1443 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i9/1438.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i9.1438>

INTRODUCTION

Extrahepatic bile duct (EHBD) cancer is a rare malignancy with a poor prognosis^[1]. Surgical resection is considered as the only curative modality in the management of EHBD cancer, but a significant number of patients have loco-regional recurrences after curative resection alone^[2-4]. Therefore, adjuvant radiotherapy with or without chemotherapy has been used for these patients, resulting in the improved loco-regional control and survival^[5-9]. As a result of the increased loco-regional control, however, the distant metastasis rate has increased^[5,6,10]. In our previous report, only 11.6% of patients had isolated loco-regional recurrences, whereas 44.2% of patients had distant metastases with or without loco-regional failure^[10]. Likewise, further technical advances in the delivery of radiotherapy may further increase the proportion of distant metastasis^[11].

Recently, metastasis-associated protein CD24 has been reported to be associated with shorter survival in various malignancies^[12-20]. As for bile duct cancer, Agrawal *et al*^[21] noted that CD24 expression was predictive of poor survival and possibly poor response to chemotherapy or radiotherapy. However, the patient number was small and the treatment details were heterogeneous.

In this study, we evaluated CD24 expression as a potential prognostic factor for predicting distant metastasis in patients undergoing curative surgery followed by adjuvant chemoradiotherapy for EHBD cancer.

MATERIALS AND METHODS

Study population

Between January 2000 and August 2006, 108 patients underwent adjuvant radiotherapy after curative resection for EHBD cancer. Of these, 6 patients who did not receive concomitant chemotherapy and 18 patients whose paraffin-embedded tissue was unavailable were excluded from the analysis. Therefore, 84 patients were the subjects of this study. This study was approved by Institutional Review Board, and all patients gave informed consent prior to treatment.

Adjuvant chemoradiotherapy

All patients underwent adjuvant chemoradiotherapy. In 69 patients, a total dose of 40 Gy was delivered using 2 Gy/fraction, 5 d/wk with 2 wk of planned rest after 20 Gy. Concomitant 5-fluorouracil (5-FU, 500 mg/m² per day *iv* bolus) was administered for the first 3 d of each 2 wk course of radiotherapy. Fifteen patients received a continuous course of radiotherapy, and the total dose ranged from 50 to 56 Gy in conventional fractionation. Of 15 patients, 13 patients received concomitant 5-FU

(500 mg/m² per day *iv* bolus for 3 d) on weeks 1 and 5 of radiotherapy. Capecitabine was prescribed for the 2 remaining patients during radiotherapy.

Fluoropyrimidine-based maintenance chemotherapy was administered to 68 patients after the completion of concurrent chemoradiotherapy. The scheduled duration of maintenance chemotherapy was 6-12 mo.

Tissue microarray and immunohistochemistry

All 84 cases diagnosed as adenocarcinoma of EHBD were retrieved from the archives in Seoul National University Hospital, which contained enough paraffin-embedded tissue for the study. All the hematoxylin and eosin-stained slides were reviewed and confirmed as adenocarcinoma. Representative paraffin blocks were selected and the tissue microarray of 4 mm core was produced. Immunohistochemical staining was done on all 84 cases using antibody to CD24 (clone SN3b, Thermo Scientific, Fremont, CA, United States; 1:200) automatically, according to the manufacturer's protocol based on the conventional streptavidin-biotin-peroxidase method. For statistical analysis, CD24 expression was scored in 4 tiers: 0, no staining; 1, staining in less than 20% of the cells; 2, staining in 20%-50% of the cells; and 3, staining in more than 50% of the cells.

Statistical analysis

Survival was calculated from the date of surgical resection. Statistical analysis was performed using SPSS software (release 12.0.1. SPSS Inc. Chicago, IL, United States). Differences in categorical variables between the parameters were compared with the standard χ^2 test or Fisher's exact test. The actuarial survival rates were calculated using the Kaplan-Meier method, and statistical significance between the actuarial survival rates was evaluated by the log-rank test. The Cox proportional hazard model was used for multivariate analysis.

RESULTS

Patient characteristics

There were 62 males and 22 females. The median age of all patients was 62 years (range: 36-86 years). Sixty-two patients had no residuum (R0), whereas 22 patients had microscopic residual disease (R1). As for the location of the tumor, 59 patients had hilar or proximal tumors, and 22 patients had intrapancreatic (distal) tumors. Three patients had tumors extending from the proximal to the distal EHBD. Stage was determined according to the American Joint Committee on Cancer staging system, 6th edition^[22]. For T classification, 3 patients had T1, 30 patients had T2, 40 patients had T3, and 11 patients had T4 disease. Thirty-three patients had lymph node involvement, whereas 48 patients did not. Lymph node dissection was not performed in 3 patients. The degree of histologic differentiation was as follows; well differentiated in 15, moderately differentiated in 59, and poorly differentiated in 8 patients. Histologic differentiation in-

¹3 patients with tumor extending from the proximal to distal bile duct were excluded; ²In 3 patients, lymph node dissection was not performed; ³In 2 patients, the information on histologic differentiation was unavailable. R0: No microscopic residual disease; R1: Microscopic residual disease; W/D: Well differentiated; M/D: Moderately differentiated; P/D: Poorly differentiated.

formation was missing for 2 patients.

CD24 immunohistochemical staining

CD24 was expressed in 36 patients (42.9%) and not in 48 patients (score = 0, 57.1%) (Figure 1). The percentage of positive cells was variable and the staining intensity was more than intermediate in most cases. Twenty-nine cases expressed CD24 in less than 20% of the tumor cells (score = 1, 80.6%), 6 cases expressed in 20%-50% of the tumor cells (score = 2, 16.7%) and only one case was diffusely

positive for CD24 (score = 3, 2.8%).

Correlation between CD24 expression and other variables

Patients with CD24 expression were more likely to have node-positive tumors ($P = 0.0360$), and less likely to have well differentiated tumors ($P = 0.0405$). Also, patients with CD24 expression tended to have proximal tumors, but the correlation was statistically marginal ($P = 0.0770$, Table 1). As for a treatment-related factor, there was no association between CD24 expression and the use of maintenance chemotherapy.

Prognostic factors

CD24 expression had a significant impact on the 5-year distant metastasis-free survival (29.0% with positive expression *vs* 55.1% with negative expression, $P = 0.0100$, Figure 2A), but not on loco-regional recurrence-free or overall survival. N stage and histologic differentiation were also significantly correlated with distant metastasis-free survival ($P = 0.0003$ and 0.0394 , respectively), while tumor location had marginal significance ($P = 0.0623$, Table 2). On multivariate analysis incorporating N stage, histologic differentiation, and CD24 expression, N stage was the only significant prognostic factor predicting distant metastasis-free survival ($P = 0.0089$, Figure 2B), while CD24 expression had borderline significance ($P = 0.0733$). When the use of maintenance chemotherapy was added in this model, the statistical significance of N stage and CD24 expression was similarly maintained ($P = 0.0100$ and 0.0683 , respectively).

In the subgroup analysis according to nodal involvement, CD24 expression was significantly associated with 5-year distant metastasis-free survival in node-positive patients (38.4% with negative expression *vs* 0% with positive expression, $P = 0.0110$), but not in node-negative patients (62.0% with negative expression *vs* 64.0% with positive expression, $P = 0.8599$, Figure 2C).

As for loco-regional relapse-free survival, residual disease status was the only significant prognostic factor on univariate analysis ($P = 0.0356$). Tumor location ($P =$

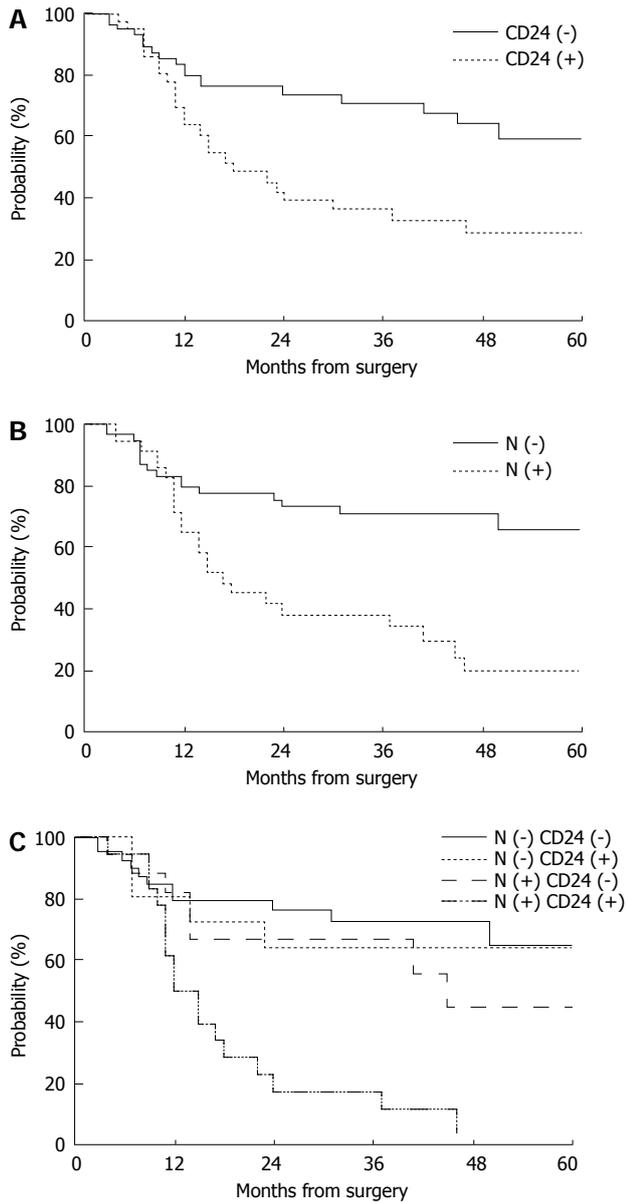

Figure 2 Distant metastasis-free survival curves. A: CD24 expression; B: Nodal involvement; C: Nodal involvement and CD24 expression.

0.0288) and N stage ($P = 0.0514$) were correlated with overall survival on univariate analysis.

DISCUSSION

This study indicates that CD24 expression is associated with poorer distant metastasis-free survival in patients undergoing curative surgery followed by adjuvant chemoradiotherapy for node-positive EHBD cancer.

CD24 is reported to be expressed in various malignancies including tumors of the ovary, lung, breast, *etc.* Because CD24 is known to be a ligand for P-selectin, which is expressed on platelets and endothelial cells, CD24-positive tumor cells can attach more easily to activated platelets and endothelial cells, and are involved in cell adhesion and metastatic tumor spread. The prognos-

tic value of CD24 has also been evaluated in the aforementioned tumors, and CD24 expression was demonstrated to be associated with poor survival^[12-20].

As for cholangiocarcinoma, Riener *et al.*^[23] reported that CD24 expression was observed in 21% of intrahepatic cholangiocarcinoma, 58% of extrahepatic cholangiocarcinoma, and 42% of gallbladder carcinoma. Regarding the prognostic value of CD24, Agrawal *et al.*^[21] evaluated CD24 expression in 22 patients with cholangiocarcinoma by immunohistochemical staining, but information on the tumor, such as location, was not described in detail. CD24 was expressed in 81.8% of patients, and the median survival times of patients with low and high CD24 expression were 36 and 8 mo, respectively ($P = 0.02$). They also tried to correlate CD24 expression with the response to chemotherapy or radiotherapy. Better survival was observed in patients with low CD24 expression in the subgroup analyses, which included patients treated with either chemotherapy or radiotherapy. However, the patient number was small, and the treatment details were heterogeneous. Moreover, the patterns of failure were not given, and therefore the prognostic value of CD24 as a metastasis-associated protein could not be fully evaluated. Su *et al.*^[24] also reported that CD24

was expressed in 36 of 70 patients (51%) with resected intrahepatic cholangiocarcinoma, and that the median survival times of patients with CD24 positive and negative tumors were 8.1 and 17.2 mo, respectively ($P = 0.028$). However, the association between CD24 expression and distant metastasis was also not reported in their study.

In the current study, CD24 expression was observed in 42.9% of patients, and the 5-year distant metastasis-free survival rate was significantly inferior in patients with CD24 positive tumors. CD24 expression was correlated with nodal involvement and histologic differentiation, all of which are known to be predictive of distant metastasis^[10,25]. On multivariate analysis incorporating these risk factors as well as CD24 expression, however, CD24 expression still showed a borderline significance. Keeratichamroen *et al*^[26] observed similar findings in 34 patients with resected cholangiocarcinoma, that is, less nodal involvement and more well differentiated tumors in patients with low CD24 expression. Multivariate analysis in the aforementioned study showed that CD24 expression was the only independent risk factor for survival. However, details on adjuvant treatment were unavailable. In the present study, CD24 expression was not associated with maintenance chemotherapy, and moreover, the statistical significance of CD24 expression remained even after the use of maintenance chemotherapy was added in the multivariate analysis. Therefore, the correlation between CD24 expression and distant metastasis was not confounded by maintenance chemotherapy.

Several strengths of our study are the relatively large sample size including only EHBD cancer patients ($n = 84$), the relatively homogeneous treatment (curative resection followed by adjuvant chemoradiotherapy), and the relevant endpoint (distant metastasis). As previously mentioned, the reported proportion of distant metastasis was increased in resected EHBD cancer as the result of increased loco-regional control with the use of adjuvant chemoradiotherapy^[5,6,10]. In addition to nodal involvement, CD24 expression can be used as a relevant predictor of distant metastasis in these populations. A distinct finding of our study is that the prognostic significance of CD24 was limited to those patients with nodal involvement. There was no difference in 5-year distant metastasis-free survival between CD24 positive and negative expression in node-negative patients. Therefore, those patients with higher risk of distant metastasis, that is, nodal involvement and CD24 expression, should be considered as potential candidates for more intensive systemic therapy.

However, due to the retrospective nature of our study, conclusions drawn from this study are limited and need further validation through another patient cohort, and possibly, through a prospective trial. In addition, it is unknown why the prognostic significance of CD24 was limited to those patients with nodal involvement. Further studies are needed to confirm and elucidate this observation.

In conclusion, CD24 expression was a relevant predictor of distant metastasis in patients undergoing curative resection followed by adjuvant chemoradiotherapy

for node-positive EHBD cancer. CD24 expression may be used as an additional index for selecting patients with higher risk of distant metastasis in future trials.

COMMENTS

Background

Extrahepatic bile duct (EHBD) cancer is a rare malignancy with a poor prognosis. The major pattern of failure after surgical resection has been shifted from loco-regional recurrence to distant metastasis as a result of increased loco-regional control with the use of adjuvant chemoradiotherapy. Given these observations, a prognostic factor predicting distant metastasis needs to be evaluated to select patients who need more intensive systemic therapy.

Research frontiers

There are a number of studies demonstrating that CD24 was associated with shorter survival in various malignancies, but only a few for EHBD cancer. In the current study, the prognostic significance of CD24 expression in EHBD cancer patients who underwent adjuvant chemoradiotherapy after curative resection was evaluated.

Innovations and breakthroughs

There were a few reports on the prognostic value of CD24 in patients with cholangiocarcinoma. However, patient numbers were small and tumor location and treatment details were heterogeneous. Moreover, the patterns of failure were not given, and therefore the prognostic value of CD24 as a metastasis-associated protein could not be fully evaluated. Several strengths of the present study are the relatively large sample size including only EHBD cancer patients, relatively homogeneous treatment, and a relevant endpoint, that is, distant metastasis. The authors found that CD24 expression was associated with poorer distant metastasis-free survival in node-positive EHBD cancer patients who underwent adjuvant chemoradiotherapy after curative resection.

Applications

From these results, CD24 expression along with nodal involvement can be used as a relevant predictor of distant metastasis and as a potential indicator for more intensive systemic therapy.

Terminology

CD24, metastasis-associated protein, is reported to be expressed in various malignancies including tumors of ovary, lung and breast. Because CD24 is known to be a ligand for P-selectin, which is expressed on platelets and endothelial cells, CD24-positive tumor cells can attach more easily to activated platelets and endothelial cells and are involved in cell adhesion and metastatic tumor spread.

Peer review

The topic and the results are interesting, well presented and of great clinical importance. The number of involved patients is also notable considering the observed type of cancer. The main conclusion of the study, namely that the timorous CD24 expression is a useful predictor of distant metastasis in patients undergoing curative resection followed by adjuvant chemoradiotherapy, especially for node-positive cases, is important both clinically and therapeutically, as CD24 immunohistochemistry (IHC) may provide a basis for patient selection for perioperative bile duct cancer treatment. The methodology is clear, tissue microarray analysis scores are relevant, and the IHC figures are representative.

Abstract

AIM: To evaluate the effect of thienorphine on small intestinal transit *in vivo* and on guinea-pig ileum (GPI) contraction *in vitro*.

METHODS: The effects of thienorphine on intestinal transit were examined in mice and in isolated GPI. Buprenorphine and morphine served as controls. The distance traveled by the head of the charchol and the total length of the intestine were measured *in vivo*. Gastrointestinal transit was expressed as a percentage of the distance traveled by the head of the marker relative to the total length of the small intestine. The isolated GPI preparations were connected to an isotonic force transducer and equilibrated for at least 1 h before exposure to drugs. Acetylcholine was used for muscle stimulation.

RESULTS: Thienorphine (0.005-1.0 mg/kg, *ig*) or bu-

prenorphine (0.005-1.0 mg/kg, *sc*) dose-dependently significantly inhibited gut transit compared with saline. Thienorphine inhibited gut transit less than buprenorphine. The maximum inhibition by thienorphine on the intestinal transit was 50%-60%, whereas the maximum inhibition by morphine on gut transit was about 100%. Thienorphine also exhibited less inhibition on acetylcholine-induced contraction of GPI, with a maximum inhibition of 65%, compared with 93% inhibition by buprenorphine and 100% inhibition by morphine. Thienorphine induced a concentration-dependent decrease in the basal tonus of spontaneous movement of the GPI, the effect of which was weaker than that with buprenorphine. The duration of the effect of thienorphine on the GPI was longer than that with buprenorphine.

CONCLUSION: Thienorphine had less influence, but a longer duration of action on GPI contraction and moderately inhibited intestinal transit.

INTRODUCTION

Opioids have a wide range of effects on the body, the most important of which is the treatment of moderate-to-severe pain. However, the utility of opioid agonists is limited by a number of well-known side effects, including tolerance, physical dependence, respiratory depres-

sion and gastrointestinal effects. In order to avoid addiction and other side effects, researchers have focused on the modification of oripavine. Buprenorphine, a semi-synthetic opioid derived from the opium alkaloid, thebaine, has been widely used for the treatment of opioid dependence. However, buprenorphine can only be administered sublingually in the clinic^[1,2] due to its low oral bioavailability^[3]. Thienorphine, N-Cyclopropylmethyl-7-[1-(R)-1-hydroxy-1-methyl-3-(thien-2-yl) propyl]-6,14-endo-ethanotetrahydro-oripavine (Figure 1), is a new oripavine derivative designed by our institute through structural modification of buprenorphine^[4]. Thienorphine exhibits higher oral bioavailability and has a stronger antinociceptive effect than buprenorphine, which is considered to be mediated by μ -opioid receptor agonism^[5]. Furthermore, thienorphine has been proved to be a long-acting κ -opioid receptor agonist^[6]. Although its efficacy in a rhesus monkey analgesic model was low, the antinociceptive effect of thienorphine (0.32 mg/kg) lasted for a week in monkeys^[6] and the protective effect of thienorphine on morphine-induced lethality was as long as 15 d in mice^[5]. Thienorphine also inhibited morphine-induced behavioral sensitization in mice^[7] and has been used for the prevention of psychological dependence induced by morphine. Therefore, thienorphine, the new analog of buprenorphine, has several advantages over buprenorphine and may have wider application in the treatment of pain and opioid dependence.

Opiates can influence the autonomic outflow to the gut through their effect on the central nervous system^[8] and have a direct effect on the bowel^[9], and therefore induce changes in gastrointestinal motility and propulsion, leading to adverse effects on gastrointestinal function. To evaluate the effect of thienorphine on the intestinal tract, *in vivo* small intestinal transit in mice and *in vitro* guinea-pig ileum (GPI) assays were performed in the present study. Hopefully these assays may provide further evidence to understand the peripheral action and the possible adverse effects of thienorphine.

MATERIALS AND METHODS

Animals

Male guinea-pigs (300-400 g) and male Kunming mice (18-22 g) were obtained from Beijing Animal Center (Beijing, China). Animals were housed in a temperature-controlled room (25 °C \pm 1 °C) and maintained on a 12-h/12-h light/dark cycle. Animals had free access to food and water. Animal care and procedures were strictly in accordance with the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health, and this study was approved by the Animal Care Committee of Beijing Institute of Pharmacology and Toxicology.

Chemicals

Thienorphine HCl and buprenorphine HCl were synthesized in our institute^[4]. Naloxone and acetylcholine (Ach) were purchased from Sigma (St. Louis, MO, United States). NaCl, KCl, CaCl₂, KH₂PO₄, NaHCO₃, MgSO₄,

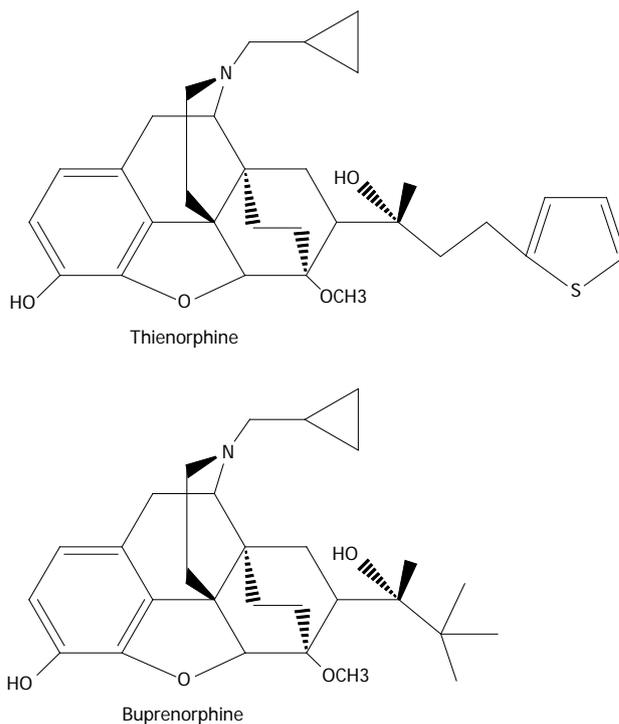

Figure 1 Chemical structure of thienorphine and buprenorphine.

glucose and charcoal were provided by Beijing Chemical Plant. Morphine was produced by Qinghai Pharmaceutical Factory (Xining, China).

Effect of thienorphine on gastrointestinal transit

Mice were randomly divided into 29 groups with 10 animals in each group. The groups were treated with saline, thienorphine (0.005, 0.05, 0.5, 1.0, 2.5, 5.0, 10 and 20 mg/kg, *ig*), buprenorphine (0.005, 0.05, 0.5, 1.0, 2.5, 5.0, 10 and 20 mg/kg, *sc*), morphine (0.5, 1.0, 2.5, 5.0, 10 and 20 mg/kg, *sc*), and naloxone (0.1, 0.5, 1.0, 5.0, 10 and 20 mg/kg, *sc*), respectively. Charcoal, used as a marker, was administered orally to mice at 0.3 mL (5 g of charcoal in 100 mL of 0.5% methylcellulose). The mice were subcutaneously treated with saline (10 mL/kg), a single dose of buprenorphine, morphine or naloxone 15 min before administration of the marker. Thienorphine was administered intragastrically 30 min before the marker. At 15 min after charcoal administration, the mice were sacrificed by cervical dislocation, the abdomen was dissected and the intestine removed from the pyloric junction to the cecal end. The distance traveled by the head of the marker and the total length of the intestine were measured. Gastrointestinal transit was expressed as a percentage of the distance traveled by the head of the marker relative to the total length of the small intestine.

Effect of naloxone on the inhibition of gastrointestinal transit by thienorphine

To determine the effects of an opioid receptor antagonist on the inhibition of intestinal transit by thienorphine (0.5 mg/kg), buprenorphine (0.5 mg/kg) and morphine (10 mg/kg), the animals were pretreated with the non-

selective opioid antagonist, naloxone (10 mg/kg, *sc*), 15 min prior to the administration of these chemicals.

Effect of thienorphine on isolated GPI contraction

All experiments were performed on isolated ileum from male guinea-pigs weighing 300-400 g. The animals were stunned and decapitated, and the ileum was quickly isolated about 10 cm from the ileo-cecal junction. The myenteric plexus-longitudinal muscle (MPLM) was prepared using the method of Rang^[10]. A glass rod was inserted into the lumen of an intestinal segment and the MPLM was removed by rubbing with a cotton swab soaked in Krebs' solution. The preparations (2.0-2.5 cm length) were suspended under 1.0 g tension in a 10 mL organ bath containing Krebs' solution (KCl 4.69 mmol/L, CaCl₂ 2.52 mmol/L, KH₂PO₄ 1.18 mmol/L, MgSO₄ 1.22 mmol/L, NaHCO₃ 25.0 mmol/L, NaCl 118.06 mmol/L, Glucose 10.0 mmol/L, pH = 7.4), at 37 °C and bubbled with 95% O₂ and 5% CO₂. The preparations were connected to an isotonic force transducer linked to eight channel organ baths (Medlab6, Meiyi Ltd., Nanjing, China). All the tissues were stimulated by Ach^[11,12]. Only the tissue preparations which responded to Ach (1 μmol/L) and produced contractions of more than 1.5 g tension were used. Preparations were equilibrated for at least 1 h with washes every 15 min before exposure to drugs. At the start of each experiment, a maximum response to Ach (1 μmol/L) was obtained in each tissue to confirm its suitability. After washing the preparation, the opioid agonists or antagonist were added to the organ bath for 10 min after which the second contraction with Ach was obtained. Maximal phasic responses were calculated as a percentage of the primary Ach-induced contraction, which was taken as 100% in each experiment. Each experiment was repeated with at least four separate tissue preparations obtained from different animals.

Effect of thienorphine on morphine-induced GPI contraction

To determine the effects of naloxone, thienorphine or buprenorphine on the inhibition by morphine on MPLM preparations of GPI, the MPLM preparations were treated with morphine (2.4 mmol/L) for 10 min, and then washed twice with Krebs' solution within 30 min. Before the second morphine (2.4 mmol/L) application, the preparations were treated with naloxone (0.5 mmol/L), thienorphine (32 μmol/L) or buprenorphine (32 μmol/L) for 10 min in the organ baths.

Recovery of GPI contraction after thienorphine treatment

To study the influence of thienorphine on the recovery of GPI contraction, thienorphine (0.1 mmol/L), morphine (3.2 mmol/L), buprenorphine (0.1 mmol/L) or naloxone (1.0 mmol/L) were added to the organ baths containing the tissue preparations. After 10 min treatment, the preparations were washed with Krebs' solution. The recovery of GPI contraction was evaluated based on stimulation with Ach (1 μmol/L) at different times during the pro-

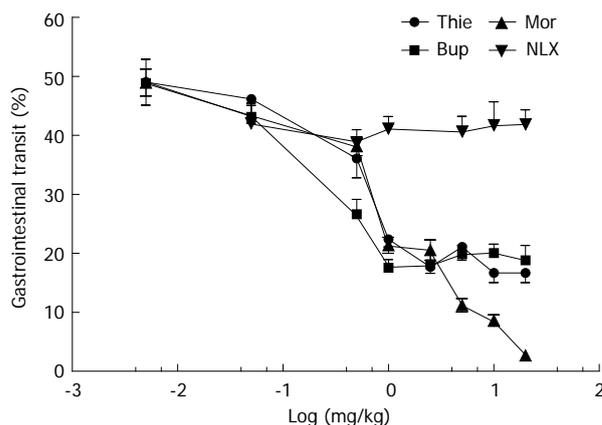

Figure 2 Effects of thienorphine, buprenorphine, morphine and naloxone on gastrointestinal propulsive activity in Kunming mice. Gastrointestinal transit was expressed as % of the distance traveled by an orally administered marker relative to the total length of the small intestine over 15 min after marker administration. Each column and vertical bar represent the mean \pm SE of 9-10 mice. Thie: Thienorphine; Bup: Buprenorphine; Mor: Morphine; NLX: Naloxone.

longed washing process, and the recovery time-course curves were generated based on GPI contraction.

Statistical analysis

Statistical and curve-fitting analysis were performed using PRISM 5.0 (GraphPad Software Inc., La Jolla, CA, United States). The data were expressed as mean \pm SE. Student's *t* test was used to compare single treatment means with control means. Analysis of variance followed by Newman-Keuls *post hoc* test was used for analysis of multiple treatment means. *P* < 0.05 was considered statistically significant.

RESULTS

Effect of thienorphine on gastrointestinal transit

Charcoal (0.3 mL, charcoal in 100 mL 0.5% methylcellulose) did not induce diarrhea in the mice. Stools colored by the marker were of the same form as normal stools, but could easily be distinguished by their black color. Gastrointestinal transit over 15 min was approximately 50% in the saline treated mice. Morphine (0.05-20.0 mg/kg, *sc*) significantly inhibited gut transit (Figure 2). Thienorphine (0.005-1.0 mg/kg, *ig*) dose-dependently inhibited gut transit, however, the inhibitory effect was not as strong as that of buprenorphine (0.005-1.0 mg/kg, *sc*). At higher doses, both thienorphine (1.0-20.0 mg/kg, *ig*) and buprenorphine (1.0-20.0 mg/kg, *sc*) inhibited intestinal transit by about 50%-60%. Naloxone (0.5-20.0 mg/kg, *sc*) had no effect on gut transit compared with the saline treated group. However, naloxone (10.0 mg/kg, *sc*) antagonized the inhibitory effect of thienorphine (0.5 mg/kg, *ig*), buprenorphine (0.5 mg/kg, *sc*) and morphine (10.0 mg/kg, *sc*) on gastrointestinal transit when it was administered 15 min prior to these chemicals (Figure 3).

Effect of thienorphine on GPI contraction

The GPI displayed regular spontaneous rhythmic contrac-

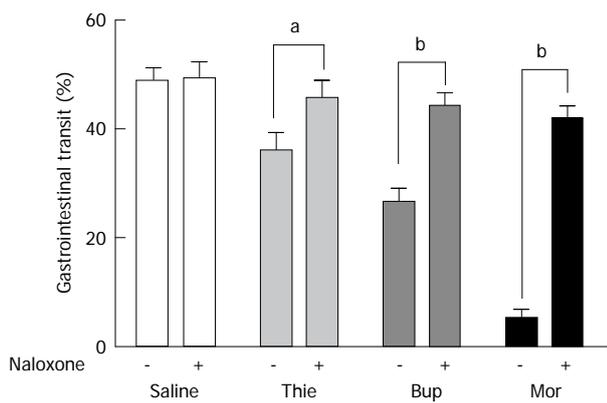

Figure 3 Effects of naloxone on the gastrointestinal propulsive activity in Kunming mice treated with thienorphine (0.5 mg/kg), buprenorphine (0.5 mg/kg), or morphine (10 mg/kg). Gastrointestinal transit was expressed as % of the distance traveled by an orally administered marker relative to the total length of the small intestine over 15 min after marker administration. Each column and vertical bar represent the mean \pm SE of 9-10 mice. ^a $P < 0.05$, ^b $P < 0.001$ vs intestinal transit without naloxone treatment. Thie: Thienorphine; Bup: Buprenorphine; Mor: Morphine.

tions following the equilibration period of 45-60 min. A contraction lasted without fading for up to several hours in the control state (Figure 4A). Thienorphine (0.32-32.0 $\mu\text{mol/L}$) or buprenorphine (0.32-32.0 $\mu\text{mol/L}$) decreased the basal tonus of GPI contraction in a concentration-dependent manner. The basal tonus of GPI was decreased by 10.0 $\mu\text{mol/L}$ of thienorphine or buprenorphine (Figure 4B and C). The maximum decrease in the basal tonus was 0.02 g by thienorphine (32.0 $\mu\text{mol/L}$) and 0.03 g by buprenorphine (32.0 $\mu\text{mol/L}$), with no difference between thienorphine and buprenorphine (Figure 5A). In comparison, morphine (0.4-3.2 mmol/L) concentration-dependently increased the basal tonus and spontaneous movement of GPI, and the maximum increase in basal tonus was about 0.65 g at 2.4 mmol/L (Figure 5B). The basal tonus and spontaneous movement of GPI was increased after the application of morphine 1.6 mmol/L (Figure 4E). Naloxone did not influence the basal contractile tonus, but increased the spontaneous movement of GPI at higher concentrations (Figure 4D).

Morphine (2.4 mmol/L) increased the basal tonus of GPI from 0.60-0.75 g (Figure 5C). After a 30 min resting period in Krebs' solution, naloxone (0.5 mmol/L), thienorphine (32.0 $\mu\text{mol/L}$) or buprenorphine (32.0 $\mu\text{mol/L}$) was added to the organ baths, the increases in basal tonus following the second addition of morphine (2.4 mmol/L) were all significantly inhibited by about 50%-60% (Figure 5C). Therefore, thienorphine, as well as buprenorphine, showed a potent antagonizing effect against morphine.

Effect of thienorphine on Ach-induced GPI contraction

The effects of thienorphine, buprenorphine, morphine and naloxone on GPI contraction are shown in Figure 6. All three drugs inhibited ileal muscle contraction induced by Ach (1 $\mu\text{mol/L}$) in a concentration-dependent manner. Thienorphine exhibited a moderate inhibition of

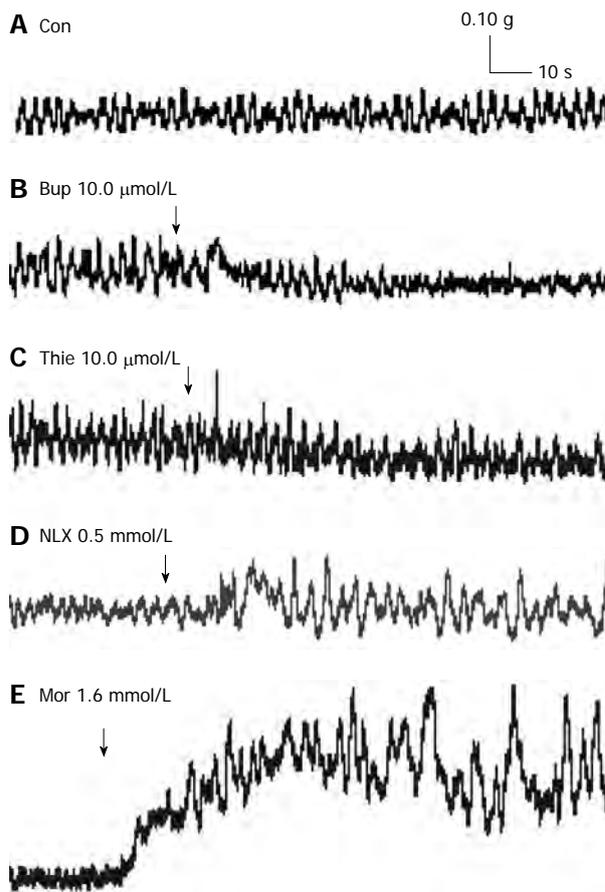

Figure 4 Typical trace of thienorphine, buprenorphine, naloxone and morphine on guinea-pig ileum. A: Spontaneous movement of the guinea-pig ileum without chemical; B: The basal tonus decreased after buprenorphine (10.0 $\mu\text{mol/L}$) treatment; C: The basal tonus decreased after thienorphine (10.0 $\mu\text{mol/L}$) treatment; D: Spontaneous movement increased after naloxone (0.5 mmol/L) treatment; E: The basal tonus and spontaneous movement increased after morphine (1.6 mmol/L) treatment. The arrow indicates the addition of chemicals. Con: Control; Thie: Thienorphine; Bup: Buprenorphine; Mor: Morphine; NLX: Naloxone.

65% ($P < 0.01$) at the highest concentration (100 $\mu\text{mol/L}$). However, buprenorphine exhibited a highly significant inhibition rate of 93% ($P < 0.01$) at 100 $\mu\text{mol/L}$. Morphine also showed a significant inhibition rate of 100% ($P < 0.01$) at the highest dose of 6.4 mmol/L. Naloxone exhibited an inhibition rate of 70% ($P < 0.01$) at the highest concentration of 1.0 mmol/L.

Recovery of GPI contraction after thienorphine treatment

When GPI was treated with a single concentration of thienorphine 100 $\mu\text{mol/L}$, buprenorphine 100 $\mu\text{mol/L}$, morphine 3.2 mmol/L or naloxone 1.0 mmol/L, the contractile amplitude response to Ach (1 $\mu\text{mol/L}$) was 27.53% \pm 4.21%, 9.60% \pm 2.43%, 21.78% \pm 4.78% and 31.75% \pm 5.08% with respect to the amplitude before treatment, respectively. The ileal muscle strip was washed with Krebs' solution. During the washing process, the ileal muscle contractile activity response to Ach (1 $\mu\text{mol/L}$) recovered more slowly in the thienorphine treated group than in the buprenorphine treated group. In the morphine and naloxone treated groups, the response of

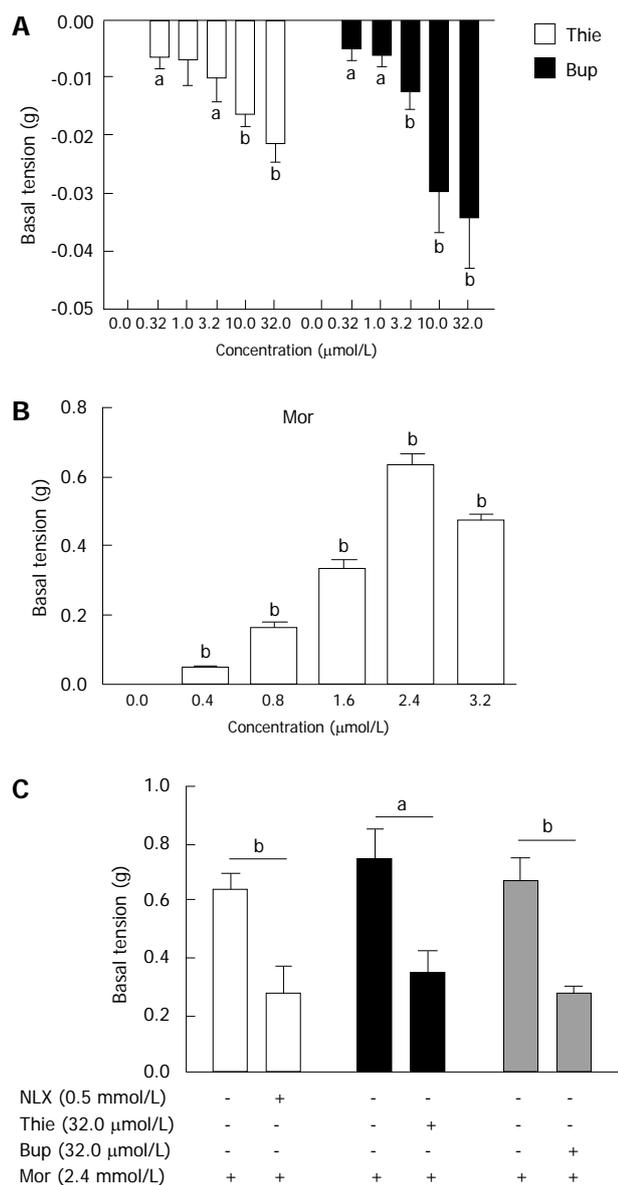

Figure 5 Effects of thienorphine, buprenorphine and morphine on the basal tonus of spontaneous movement of the guinea-pig ileum. Each point represents the mean ± SE (*n* = 5 or 6 preparations). A: Thienorphine (Thie) or buprenorphine (Bup) concentration-dependently decreased the basal tonus of guinea-pig ileum (GPI); B: Morphine (Mor) concentration-dependently increased the basal tonus of GPI; C: Naloxone (NLX, 0.50 mmol/L), Thie (32.0 μmol/L) or Bup (32.0 μmol/L) antagonized the elevation of basal tonus of GPI induced by Mor (2.4 mmol/L). ^a*P* < 0.05, ^b*P* < 0.001 vs the basal tonus before chemical application.

ileal muscle to Ach (1 μmol/L) recovered completely within 15 min. These results suggested that the effects of thienorphine on GPI lasted longer than those of the other opioids. At 60 min after the washout, the contractile amplitude of the ileal muscle after buprenorphine application recovered to 92.85% ± 3.89% with respect to the amplitude before treatment, whereas in the thienorphine treated preparation, the contractile amplitude remained at 51.25% ± 10.81%, which was significantly lower than that of the buprenorphine treated groups (*P* < 0.01). At 180 min after the washout, the response to Ach (1 μmol/L) of ileal muscle treated with thienorphine recovered to

85.25% ± 9.97% (Figure 7).

DISCUSSION

This study examined the effects of thienorphine on intestinal transit in mice and isolated GPI. The results indicated that thienorphine had a moderate inhibitory effect on intestinal transit in mice through the activation of opioid receptors. Compared with buprenorphine, thienorphine exhibited less inhibition, but the inhibitory effect on the contractility of GPI by direct or indirect activation of opioid receptors lasted longer. Therefore, thienorphine may have fewer adverse gastrointestinal effects when used for the treatment of opioid dependence.

The effects of opioids on gastrointestinal motility and transit have been attributed to the blockade of intestinal propulsion, resulting in slower elimination of the intestinal contents^[13]. Similar to buprenorphine, thienorphine seemed to be a partial μ-opioid receptor agonist, and had

weaker inhibition than morphine in the *in vivo* intestinal transit test. The present study showed 26.5% inhibition of gut transit by 0.5 mg/kg thienorphine and 6.1% inhibition by 0.05 mg/kg thienorphine. The K_i values of morphine for μ -, κ - and δ -opioid receptors were about 100-1000 times that of thienorphine. In the [35 S]-GTP γ S binding assay, the EC_{50} value for the stimulatory effects of thienorphine and morphine on μ -opioid receptors was 0.009 nmol/L and 18.24 nmol/L, and the maximum stimulatory values were 62.42% and 100%, respectively^[5]. In the present study, the maximum inhibition by thienorphine on intestinal transit was 50%-60%, whereas the maximum inhibition by morphine on gut transit was approximately 100%. The *in vivo* results of thienorphine were in accordance with the [35 S]-GTP γ S binding assay, which indicated that the adverse gastrointestinal effects of thienorphine would not be as serious as those of morphine.

Furthermore, the inhibition by thienorphine or morphine on intestinal transit was antagonized by naloxone (10.0 mg/kg). The inhibitory effects of morphine on small intestinal transit in mice were associated with the contractile effects on circular muscle in the ileum through binding to μ -opioid receptors, resulting in the inhibition of descending peristalsis relaxation^[14]. It was reported that few μ -opioid receptors were expressed in the mouse ileum, where δ - and κ -opioid receptors are dominant, and electrically induced contractions could be inhibited by δ - and κ -opioid receptor agonists, but not morphine^[15]. Thienorphine displayed high affinities for both μ -, κ - and δ -opioid receptors and produced a maximum stimulation of 74.5% on κ -opioid receptors (in comparison with U69, 593), and 19.3% on μ -opioid receptors (in comparison with DAMGO)^[6]. As a partial agonist of μ - and κ -opioid receptors, thienorphine also inhibited intestinal transit, but the effect was not as strong as that of morphine.

The MPLM from the GPI contains opioid peptide innervation, and enteric neurons modulate the release of enteric neurotransmitters^[16], therefore, MPLM has been used to investigate the effects of opioids on intestinal motility. Stimulation of the ileum or the MPLM preparation caused rapid contractions which were abolished by atropine, suggesting the participation of cholinergic neurons. Morphine can decrease the spontaneous release of Ach from the GPI and inhibit the electric-evoked contraction of MPLM from the GPI^[17]. Buprenorphine was approximately 100-fold more potent in inhibiting the electric-evoked contraction of MPLM than morphine, and the inhibition produced by buprenorphine was not eliminated by naloxone^[18]. In addition, naloxone itself inhibited these contractions^[18]. These results suggest that the effect of opioids on GPI contraction involves both a direct opioid receptor mechanism and indirect non-opioid receptor mechanisms. In the present study, MPLM preparations were stimulated by Ach instead of electrical stimulation. The inhibition of opioids on the release of Ach from the MPLM preparation could be ignored due to the application of Ach (1 μ mol/L). Through activation of M2 and M3 acetylcholine receptors, Ach induced voltage-dependent and voltage-independent Ca^{2+} entry

and intracellular Ca^{2+} release, leading to the contraction of intestinal smooth muscle^[19]. Thienorphine and buprenorphine (0.01-100 μ mol/L) induced the relaxation of contractile GPI under Ach stimulation in a concentration-dependent manner, which was similar to morphine and naloxone. Thienorphine was approximately 100-fold more potent than morphine, and the inhibition was not eliminated by naloxone. These results further proved the participation of indirect non-opioid receptors mechanisms. Activation of μ -opioid receptors led to an outward potassium conductance, and therefore produced membrane hyper-polarization and an increase in conductance, plus indirect inhibition of calcium entry^[20]; voltage-clamp studies showed that a κ opioid receptor agonist directly reduced calcium currents in mouse DRG cells^[21,22]; acute opioid exposure decreases calcium fluxes in neurons^[23,24]; loperamide, a peripheral agonist of μ opioid receptors, was found to induce intestinal relaxation by opening K_{ATP} channels *via* the cAMP-PKA pathway^[25] which further induced hyper-polarization of the cell membrane leading to relaxation of smooth muscle. Based on these studies, the inhibition by opioids on Ach-induced GPI contraction at higher concentrations further suggested the participation of other indirect non-opioid receptors or channels.

Thienorphine or buprenorphine induced a concentration-dependent decrease in the basal tonus and spontaneous movement of MPLM, whereas morphine concentration-dependently increased the basal tonus and spontaneous contraction of MPLM. The effect of thienorphine and buprenorphine was not antagonized by naloxone, while morphine-induced contraction was partially inhibited by naloxone or thienorphine. Similar results for morphine on the isolated circular muscle of mouse ileum have also been reported^[14]. Therefore, the effect of thienorphine on the MPLM simulates neither naloxone nor morphine, the mechanisms of which still require further study.

In our previous study, the contractile activity of uterine strips after thienorphine treatment recovered more slowly than after buprenorphine treatment during the washing process. In the present study, the contractile activity of isolated guinea-pig ileum also recovered more slowly after thienorphine treatment compared with buprenorphine or morphine treatment. Therefore, in the *in vitro* isolated tissue assay, the effects of thienorphine lasted longer, which was consistent with its *in vivo* effects.

In this study, we demonstrated that thienorphine, a new derivative of buprenorphine, moderately inhibited intestinal transit, showed less inhibition on contractile amplitude and a longer duration of action on guinea-pig isolated ileum.

COMMENTS

Background

Thienorphine, the new analog of buprenorphine, had several advantages over buprenorphine and may have wider application in the treatment of pain and opioid dependence. However, the utility of opioids is limited by a number of well-known side effects, including tolerance, physical dependence, respiratory depression and gastrointestinal effects.

Research frontiers

Opioids exhibit their effects through μ , κ and δ receptors both in the central and peripheral nervous system. Opiates can influence the autonomic outflow to the gut through their effects on the nervous system and have a direct effect on the bowel, and therefore induce changes in gastrointestinal motility and propulsion.

Innovations and breakthroughs

Thienorphine has several advantages over buprenorphine, such as stronger antinociceptive effects, potent rate-decreasing effects and better oral bio-availability than buprenorphine. Therefore, thienorphine, the new analog of buprenorphine, may have wider application in the treatment of pain and opioid dependence. This study reported on thienorphine, a new partial agonist of opioid receptors, which has fewer effects on intestinal transit and isolated guinea-pig ileum contraction.

Applications

Thienorphine has less influence and a longer duration of action on intestinal motility, and may be a new candidate for the treatment of pain and opioid dependence.

Terminology

In vivo intestinal transit tests and isolated guinea-pig ileum assays are well reported methods used to study the effects of chemicals on smooth muscle contraction.

Peer review

This is an interesting and important paper, which used well known tests for studying the effect of a new drug on motility. Thienorphine had moderate inhibition on intestinal transit, less inhibition on the contractile amplitude and longer duration of action on the guinea-pig isolated ileum. Thienorphine has less influence and longer duration on motility which may be a new useful candidate for the treatment of pain and opioid dependence.

Abstract

AIM: To identify a practical approach for preoperative decision-making in patients with intraductal papillary mucinous neoplasms (IPMNs) of the pancreas.

METHODS: Between March 1999 and November 2006, the clinical characteristics, pathological data and computed tomography/magnetic resonance imaging (CT/MRI) of 54 IPMNs cases were retrieved and analyzed. The relationships between the above data and decision-making for pancreatic resection were analyzed using SPSS 13.0 software. Univariate analysis of risk factors for malignant or invasive IPMNs was performed with regard to the following variables: carcinoembryonic antigen, carbohydrate antigen 19-9 (CA19-9) and the characteristics from CT/MRI images. Receiver operating characteristic (ROC) curve analysis for pancreatic

resection was performed using significant factors from the univariate analysis.

RESULTS: CT/MRI images, including main and mixed duct IPMNs, tumor size > 30 mm or a solid component appearance in the lesion, and preoperative serum CA19-9 > 37 U/mL had good predictive value for determining pancreatic resection ($P < 0.05$), but with limitations. Combining the above factors (CT/MRI images and CA19-9) improved the accuracy and sensitivity for determining pancreatic resection in IPMNs. Using ROC analysis, the area under the curve reached 0.893 ($P < 0.01$, 95%CI: 0.763-1.023), with a sensitivity, specificity, positive predictive value and negative predictive value of 95.2%, 83.3%, 95.2% and 83.3%, respectively.

CONCLUSION: Combining preoperative CT/MRI images and CA19-9 level may provide useful information for surgical decision-making in IPMNs.

INTRODUCTION

There is a controversy between pancreatic resection and close follow-up for the treatment of intraductal papillary mucinous neoplasms (IPMNs). The prognosis of non-invasive IPMNs is better than that of invasive IPMNs.

The overall prognosis of IPMNs is better than that of pancreatic adenocarcinomas^[1,2]. When noninvasive IPMNs transform into invasive IPMNs, the prognosis of this disease is as poor as that of pancreatic ductal adenocarcinomas^[3,4]. There is no good way of monitoring this malignant transformation. Considering the nature of potential malignant transformation, some surgeons think that all IPMNs should be resected. However, for patients with benign lesions, close follow-up may be reasonable, as pancreatectomy may have severe adverse consequences due to its high mortality (15% at immature clinics) and high rate of postoperative complications (49%)^[5]. It is increasingly clear that not all IPMNs should be resected immediately^[6,7]. Wang *et al*^[8] reported that there was no significant difference in the 5-year survival rate between resected IPMNs and non-resected IPMNs. He also suggested that resection is not justified in elderly patients with high surgical risks, especially in asymptomatic and aged patients. A prospective study on the management of 109 asymptomatic patients also indicated that careful non-operative management seemed to be safe and effective^[9]. Therefore, it is crucial to establish a protocol to determine which IPMNs should be resected.

According to the Sendai consensus guidelines^[10], all main duct IPMNs, symptomatic branch duct IPMNs and IPMNs > 3 cm in size accompanying mural nodules should be resected. The presence of mural nodules is a very reliable malignant predictor in IPMNs. However, there is controversy regarding lesion size > 3 cm as a reliable indicator^[11]. The Sendai Criteria also showed that more data are needed to determine whether all branch duct IPMNs > 30 mm in size should be resected immediately^[10]. The Sendai criteria have a very high negative predictive value (NPV) and low positive predictive value (PPV)^[12], which may miss some malignant cases^[12]. Moreover, the management of some asymptomatic branch duct IPMNs < 30 mm in size is not clear using these criteria^[10]. Therefore, preoperative guidelines for surgical decision-making in IPMN patients need to be investigated^[13].

However, much work have been done to clarify the characteristics of malignant or invasive IPMNs. Both computed tomography (CT) and magnetic resonance imaging (MRI) examinations have good predictive value for invasive IPMNs. They have similar functions in pancreatic diagnosis^[14], evaluating the extent of tumor invasion and judging the resectability of pancreatic tumors^[15]. In addition, a high serum carbohydrate antigen 19-9 (CA19-9) level is associated with malignant pancreatic disease^[16-19]. Because not all lesions predicted to be malignant or invasive are suitable for surgery (*e.g.*, advanced malignancy or those wrongly predicted to be malignant), and some lesions predicted to be benign may require surgery (*e.g.*, borderline tumors or those wrongly predicted to be benign), there are differences between the prediction for malignant or invasive IPMNs and the prediction for surgical decision-making. A pragmatic approach for pancreatic resection decision-making in IPMN patients is

lacking. Serum CA19-9 and CT/MRI scans are useful in predicting malignant/invasive IPMNs, but their function in surgical decision-making for IPMNs is still unclear. Moreover, the value of the combination of preoperative serum CA19-9 and dynamic enhanced thin-slice CT/MRI scanning in operative decision-making is also unknown. Therefore, in this study, the above problems were investigated and a simple and pragmatic approach for surgical decision-making in IPMNs was designed.

MATERIALS AND METHODS

Clinical data

Fifty-four patients with IPMNs of the pancreas observed from March 1999 to November 2006 were retrospectively reviewed. Clinical data and tumor marker levels, including carcinoembryonic antigen and CA19-9, were collected. All patients underwent surgery and had a confirmed pathological diagnosis. Dynamic enhanced thin-slice CT/MRI images were objectively reevaluated by two radiologists and the final decision was made by consensus. The parameters of CT/MRI images included the type of tumor, the morphology of the lesion, the size of the lesion, the diameter of the main pancreatic duct, the diameter of the common bile duct, the septum appearance of the lesion, the solid component appearance in the lesion, and the papulous intraductal papilla.

Premise and hypothesis: Gold standard for pancreatic resection in IPMNs

IPMNs include adenomas, borderline tumors, adenocarcinoma *in situ*, and invasive IPMNs. Malignant IPMNs include adenocarcinoma *in situ* and invasive IPMNs. Benign IPMNs include adenomas and borderline tumors. By analyzing the postoperative pathological diagnosis and the clinicopathological stage, we found that some of the 54 patients required surgery, while other patients with benign diseases or more advanced stages were not suitable for pancreatic resection. Because borderline tumors have a high potential to change to malignant tumors, borderline tumors or malignant tumors with stage 0, I and II (UICC 6th edition, 2002) at pathological diagnosis were the gold standard (criterion-G) for surgical resection of IPMNs. According to criterion-G, the 54 cases were divided into two groups: the operative group who required surgical resection and the observational group who required close follow-up. The predictive value of preoperative serum CA19-9 level, CT/MRI scan, or their combination for determining surgical resection were then investigated.

Statistical analysis

Statistical analysis was carried out using SPSS 13.0 for Windows. All continuous data were presented as mean \pm SD. Categorical variables were compared by the χ^2 test or Fisher's exact test. The independent-samples *t* test were used to compare the means of the two groups. Logistic regression analysis was performed to identify independent risk factors; receiver operating characteristic (ROC)

curve analysis was used to observe predictive values. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical and pathological results

There were 36 male and 18 female patients in this study. The average age was 61.43 ± 8.24 years (range, 43-81 years). Conventional pancreatoduodenectomy was performed in 40 patients, total pancreatectomy was performed in 4 cases, distal pancreatectomy with splenectomy was performed in 5 cases, and distal pancreatectomy without splenectomy was performed in 1 case. Biopsy was carried out in 4 cases due to superior mesenteric artery (SMA) invasion, celiac trunk invasion or liver metastasis. The perioperative mortality rate was zero. Postoperative pathological diagnosis of IPMNs showed that there were 8 cases of adenoma, 8 cases of borderline tumors, 2 cases of adenocarcinoma *in situ*, and 36 cases of invasive IPMNs. There were 6 IPMN cases with a positive margin status, including 5 cases with pancreatic intraepithelial neoplasia 1 (PanIN-1) and 1 case with PanIN-3. According to the stage of pancreatic malignant tumor (UICC, 6th edition), there were 2 Stage 0, 3 Stage I A, 4 Stage I B, 20 Stage II A, 5 Stage II B, 3 Stage III and 1 Stage IV in 38 malignant IPMNs.

Decision-making for pancreatic resection by CT/MRI scans

In 54 patients, 42 patients required surgery according to

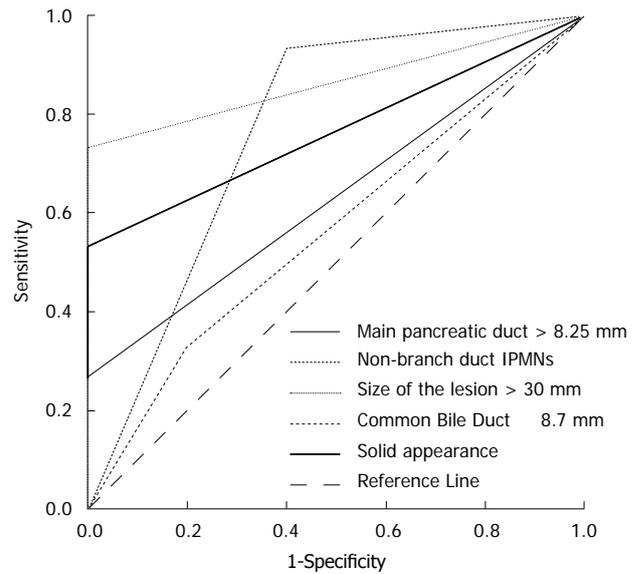

Figure 1 Characteristics of computed tomography/magnetic resonance imaging. Receiver operating characteristic analysis showed that non-branch duct intraductal papillary mucinous neoplasms (IPMNs), lesion size > 30 mm and a solid component appearance in the lesion had great significance for predicting pancreatic resection, and the area under the curve reached 0.76 ($P = 0.012$, 95%CI: 0.569-0.964), 0.867 ($P = 0.001$, 95%CI: 0.758-0.976) and 0.76 ($P < 0.01$, 95%CI: 0.623-0.910), respectively.

criterion-G. Following univariate analysis, non-branch duct IPMNs (main-duct and mixed IPMNs), lesions > 30 mm, the cystic and solid appearance of the lesion, the extended main pancreatic duct > 8.25 mm, the dilated common bile duct > 8.7 mm and the solid component appearance in the lesion from CT/MRI images were associated with pathologic findings for invasive IPMNs (Table 1). These features which were considered invasive characteristics from CT/MRI images were then further evaluated to predict surgical decision-making in IPMNs using ROC analysis. This evaluation showed that lesions > 30 mm, non-branch duct IPMNs and the solid component appearance in the lesion were good predictors for determining surgical resection (Figure 1). The patulous intraductal papilla was not analyzed due to a limited number of cases. However, all five cases with patulous intraductal papilla (3 malignant and 2 borderline tumors) harbored malignant potential, and many previous studies have indicated that patulous intraductal papilla is highly associated with invasive IPMNs. Thus, patulous intraductal papilla was also regarded as one of the invasive characteristics in IPMNs in our study. Next, our hypothesis (criterion-CT/MRI) was examined: pancreatic resection would be performed if the patient had any of the following factors on CT/MRI images: lesion size > 30 mm, non-branch duct IPMNs (main-duct and mixed), a solid component appearance in the lesion or patulous intraductal papilla, but no involvement of crucial vessels, such as SMA or celiac trunk, and definitive distant metastasis. According to criterion-CT/MRI, 95% of patients were correctly judged as requiring surgery. Using Fisher's exact test, it was confirmed that criterion-CT/MRI had good predictive value for determining pancreatic resec-

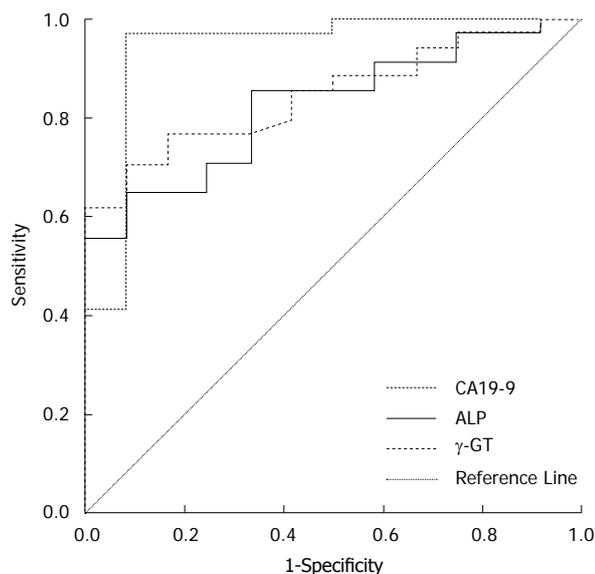

Figure 2 The predictors of malignant intraductal papillary mucinous neoplasms. Receiver operating characteristic analysis showed that γ -GT > 50 U/L, alkaline phosphatase (ALP) > 115 U/L or carbohydrate antigen 19-9 (CA19-9) > 37 U/mL effectively predicted malignant intraductal papillary mucinous neoplasms. However, the area under the curve for CA19-9 > 37 U/mL was the largest among the three indices and reached 0.939 ($P < 0.01$, 95%CI: 0.843-1.035).

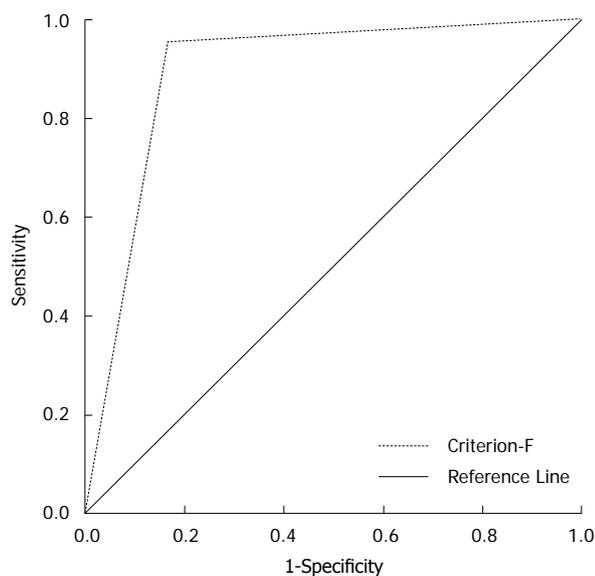

Figure 3 The predictive value of the combination of carbohydrate antigen 19-9 and computed tomography/magnetic resonance imaging (criterion-F). The area under the curve by receiver operating characteristic analysis reached 0.893 ($P < 0.01$, 95%CI: 0.763-1.023).

tion in IPMNs ($P < 0.05$). The sensitivity of criterion-CT/MRI was 95% and the specificity was 50%. The PPV and NPV were 91.3% and 100%, respectively.

Decision-making for pancreatic resection by preoperative serum CA19-9 levels

Thirty-eight cases were malignant and 16 cases were non-malignant IPMNs. Following univariate analysis, jaundice, direct bilirubin > 6.0 μ mol/L, γ -GT > 50 U/L,

Table 2 Univariate predictors of malignant intraductal papillary mucinous neoplasms

| > 5 | 1 | 5 | 0.54 | 0.65 |

ALP: Alkaline phosphatase; CEA: Carcinoembryonic antigen; CA19-9: Carbohydrate antigen 19-9.

alkaline phosphatase > 115 U/L and CA19-9 > 37 U/mL were significantly associated with malignancy (Table 2). Using multivariate analysis, only CA19-9 > 37 U/mL was identified as an independent predictor of malignant IPMNs. The ROC curve also showed that CA19-9 had much better predictive potential for malignant IPMNs than the other factors (Figure 2). The relationship between the high level of serum CA19-9 and surgical decision-making was investigated. The higher the level of serum CA19-9, the higher the possibility of surgery for IPMNs ($P = 0.013$). The sensitivity of CA19-9 > 37 U/mL for determining surgery was 57% and the specificity was 84%. The PPV and NPV were 100% and 33%, respectively.

Operative decision-making by the combination of serum CA19-9 and CT/MRI scans

Serum CA19-9 alone had a low sensitivity and NPV for predicting surgical decision-making for pancreatic resections. CT/MRI scans alone had a low specificity. High sensitivity, specificity, PPV and NPV are necessary for pancreatic resection decision-making. Therefore, the predictive value of combining CA19-9 level and CT/MRI scan images was evaluated. Our final approach (criterion-F) was as follows: patients with negative criterion-CT/MRI and serum CA19-9 \leq 37 U/mL would be watched, and the remaining patients would undergo pancreatic resection. The value of criterion-F was analyzed by ROC curve analysis (Figure 3). The area under the curve was

0.893 (95%CI: 0.763-1.023), and its sensitivity was 95.2%, specificity was 83.3%, PPV was 95.2% and NPV was 83.3%.

DISCUSSION

Pancreatic resection is necessary for invasive IPMNs, while close follow-up is also feasible for definitive benign IPMNs^[20,21]. Until now, it has not been possible to effectively identify the nature of IPMNs preoperatively, therefore, it is difficult to accurately judge which IPMNs should be resected. Cytological biopsy from ERCP or fine needle aspiration has a high specificity for differentiation between benign and malignant IPMNs, however, their sensitivity is very low^[22] and are less feasible and convenient than serum CA19-9 or CT/MRI scans. The value of CT/MRI scans in pancreatic diseases has been demonstrated^[23]. Moreover, many predictive factors of malignant or invasive IPMNs were reported, including serum CA19-9^[19,24], jaundice^[25], tumor size > 3 cm^[21], dilatation of the main pancreatic duct^[26], and the presence of patulous papilla^[27,28]. Predictors of malignant or invasive IPMNs may help surgical decision-making. However, their value in pancreatic resection decision-making for IPMNs, especially the value of combining preoperative serum CA19-9 and CT/MRI scans, have not been evaluated.

According to criterion-G, 54 patients were divided into the operative group (42 cases) and the watched group (13 cases). In the univariate analysis, main and mixed duct IPMNs, tumor size > 30 mm, an extended main pancreatic duct > 8.25 mm, common bile duct > 8.7 mm and the solid component appearance in the tumor from CT/MRI images were associated with pathologic findings of invasive IPMNs. However, only three parameters had good predictive value for surgical decision-making: main and mixed duct IPMNs, tumor size > 30 mm and the solid component appearance in the lesion. The patulous intraductal papilla has been reported to be a malignant sign in IPMNs by many researchers^[7,29] and our all IPMN patients with patulous intraductal papilla required pancreatic resections, thus we combined it with the above three parameters to form criterion-CT/MRI.

Our data showed that criterion-CT/MRI or CA19-9 > 37 U/mL alone showed good predictive value for determining pancreatic resection in IPMNs ($P < 0.05$), however, they both had limitations. The specificity of criterion-CT/MRI was only 50%. The sensitivity of CA19-9 > 37 U/mL was just 57% and the NPV of CA19-9 > 37 U/mL was just 33%. Thus, CA19-9 level and criterion-CT/MRI were combined to improve the accuracy and sensitivity. This led to our final approach (criterion-F): patients with negative criterion-CT/MRI and normal CA19-9 level (≤ 37 U/mL) would be observed; while the remaining patients would undergo pancreatic resection. Criterion-F had higher accuracy for pancreatic resection decision-making in IPMNs, with acceptable sensitivity, specificity, PPV and NPV (95.2%, 83.3%, 95.2% and 83.3%, respectively).

The Sendai criteria^[10] have a high NPV, but PPV is low (14%-22%)^[30]. Moreover, the management of some IPMNs, such as lesions > 3 cm without main pancreatic duct dilation or mural nodules, is not very clear using the Sendai criteria. The management of some asymptomatic branch duct IPMNs < 30 mm in size is also not clear using the Sendai criteria^[10]. Our criterion-F can be applied in all patients, including the patients mentioned above. According to our criterion-F, a very small number of patients would be misjudged. This small number may be less than 3% of all patients, which is acceptable considering the high risk of mortality due to pancreatic resection (3%-15%)^[5]. For elderly patients, there is controversy over operative therapy. The implementation of our criterion-F should be appropriately adjusted, especially for noninvasive IPMNs, because the time required for the noninvasive type to develop into the invasive type might be longer than an elderly patient's life expectancy^[31].

In conclusion, a combination of serum CA19-9 and CT/MRI findings may be necessary for surgical decision-making in IPMNs. Criterion-F is effective for making the correct surgical decision, and can be used in all IPMNs. Of course, this study has limitations due to its retrospective design and relatively small sample size. Our findings should be further audited and improved by prospective large-scale clinical trials.

COMMENTS

Background

Due to the potential of malignant transformation from benign intraductal papillary mucinous neoplasms (IPMNs), all patients with IPMNs were previously recommended to undergo pancreatic surgery. There is currently more data available to support non-operative management of some benign IPMNs which is reasonable and feasible. However, it is difficult for surgeons to distinguish between benign and malignant IPMNs preoperatively and make decisions regarding pancreatic resection for IPMNs.

Research frontiers

Although there have been several articles on the malignant or invasive predictive factors for IPMNs, accurate preoperative criteria have not been available to determine pancreatic resection in IPMNs. Surgical decision-making for individual patients with IPMNs is still difficult. It is important to identify a practical approach for preoperative decision-making in IPMNs.

Innovations and breakthroughs

The combined strategy of serum carbohydrate antigen 19-9 level and computed tomography/magnetic resonance imaging provided useful information for preoperative surgical decision-making in IPMNs, with acceptable sensitivity, specificity, positive predictive value and negative predictive value of 95.2%, 83.3%, 95.2% and 83.3%, respectively.

Applications

It would be helpful for surgeons to determine which IPMNs should be resected.

Terminology

IPMN: This is a type of neoplasm which grows within the pancreatic ducts (intraductal) and is characterized by the production of thick fluid by the tumor cells.

Peer review

The paper provides a practical approach for preoperative surgical decision-making for IPMNs. The topic is very interesting, the results are applicable and the conclusions are valuable.

Abstract

AIM: To study the feasibility and safety of middle segmental pancreatectomy (MSP) compared with pancreaticoduodenectomy (PD) and extended distal pancreatectomy (EDP).

METHODS: We studied retrospectively 36 cases that underwent MSP, 44 patients who underwent PD, and 26 who underwent EDP with benign or low-grade malignant lesions in the mid-portion of the pancreas, between April 2003 and December 2009 in Ruijin Hospital. The perioperative outcomes and long-term outcomes of MSP were compared with those of EDP and PD. Periop-

erative outcomes included operative time, intraoperative hemorrhage, transfusion, pancreatic fistula, intra-abdominal abscess/infection, postoperative bleeding, reoperation, mortality, and postoperative hospital time. Long-term outcomes, including tumor recurrence, new-onset diabetes mellitus (DM), and pancreatic exocrine insufficiency, were evaluated.

RESULTS: Intraoperative hemorrhage was 316.1 ± 309.6 , 852.2 ± 877.8 and 526.9 ± 414.5 mL for the MSP, PD and EDP groups, respectively ($P < 0.05$). The mean postoperative daily fasting blood glucose level was significantly lower in the MSP group than in the EDP group (6.3 ± 1.5 mmol/L vs 7.3 ± 1.5 mmol/L, $P < 0.05$). The rate of pancreatic fistula was higher in the MSP group than in the PD group (42% vs 20.5%, $P = 0.039$), all of the fistulas after MSP corresponded to grade A (9/15) or B (6/15) and were sealed following conservative treatment. There was no significant difference in the mean postoperative hospital stay between the MSP group and the other two groups. After a mean follow-up of 44 mo, no tumor recurrences were found, only one patient (2.8%) in the MSP group vs five (21.7%) in the EDP group developed new-onset insulin-dependent DM postoperatively ($P = 0.029$). Moreover, significantly fewer patients in the MSP group than in the PD (0% vs 33.3%, $P < 0.001$) and EDP (0% vs 21.7%, $P = 0.007$) required enzyme substitution.

CONCLUSION: MSP is a safe and organ-preserving option for benign or low-grade malignant lesions in the neck and proximal body of the pancreas.

INTRODUCTION

Clinically, surgical treatment for benign or low-grade malignant lesions of the pancreatic neck and body is often performed using “traditional” procedures such as pancreaticoduodenectomy (PD) or extended distal pancreatectomy (EDP). However, these approaches result in a significant and unnecessary loss of normal pancreatic parenchyma, with subsequent impairment of exocrine and endocrine functions, and the loss of the upper gastrointestinal and biliary anatomy in PD, and the spleen in EDP. In addition, tumor enucleation is only suitable for small and superficial lesions that do not involve the main pancreatic duct. Furthermore, enucleation is associated with high risk for major complications, including pancreatic leakage, and tumor recurrence cannot be ignored because of incomplete removal. Therefore, preventing unnecessary loss of pancreatic tissue and avoiding further deteriorations in the endocrine and exocrine pancreatic functions are huge challenges for surgeons managing benign and low-grade malignant lesions in the neck or the proximal body of the pancreas that cannot be managed by enucleation. Furthermore, it would be beneficial for the patient if PD or DP could be avoided.

Since it was first reported by Guillemin *et al*^[1], middle segmental pancreatectomy (MSP) has increasingly been applied for some lesions, including chronic pancreatitis, traumatic injury, and benign and borderline lesions localized at the neck and body of pancreas^[2-10]. Several recent reports have compared the morbidity, quality of life, and other outcomes in patients with chronic pancreatitis, benign, and low-grade malignant pancreatic tumors after MSP or traditional surgical procedures^[5,11-18]. The purpose of our study was to compare the perioperative safety and the long-term effects, including the preservation of pancreatic endocrine and exocrine function, following MSP, PD or EDP in patients with benign, borderline or low-grade malignant lesions.

MATERIALS AND METHODS

Ethics

The Ethics Committee of Ruijin Hospital Shanghai Jiao-tong University School of Medicine approved the study. All patients provided informed written consent.

Patient tissue

One hundred and six patients with benign or low-grade malignant tumors (without chronic pancreatitis) in the neck or proximal body of pancreas underwent MSP (n

= 36), PD ($n = 44$) or EDP ($n = 26$) between April 2003 and December 2009 in Department of General Surgery, Ruijin Hospital (affiliated to Shanghai Jiao Tong University School of Medicine). The same surgeons performed all the surgical procedures. All patients received computed tomography (CT) scans and abdominal ultrasonography before surgery to determine the location of the lesion and its relationship with mesenteric vessels. The indication for MSP was a lesion localized in the neck or proximal body of the pancreas without evidence of high-grade malignancy. Intraoperative frozen tissue sections were analyzed in all patients to exclude pancreatic adenocarcinoma and to ensure that the resection margins were clear, which was subsequently confirmed by histopathological examination.

Patient characteristics retrieved from medical records included their age, sex, presence of diabetes mellitus (DM) and mean preoperative blood glucose levels. DM was diagnosed based on abnormal fasting blood glucose levels or positive results following an oral glucose tolerance test. Tumor variables included tumor size, pathology and specific position. The location of the tumor was divided into four categories: head-neck, neck, neck-body, and body of the pancreas (Figure 1).

We compared the perioperative survival state and long-term changes in exocrine and endocrine function between MSP patients and patients with PD or EDP using matched-pairs analyses. Patients were matched for age, sex, preoperative DM, as well as tumor histopathology, size, and position (Table 1).

Surgical procedures for MSP

After making a bilateral subcostal incision with an upper midline extension to the xiphoid, the gastrocolic ligament was divided to open the lesser sac and expose the pancreas. The posterior peritoneum along the inferior and superior margins of the gland was dissected and the superior mesenteric vein was identified under the neck of the pancreas. The splenic vein was carefully divided away from the pancreas and all of the small branches of the pancreas draining into the splenic vein were ligated. The involved pancreatic segment was mobilized on both cephalic and caudal sides. The pancreas was then sectioned with an electroscalpel with a gap of at least 1-cm away from the tumor, while the limits for the cephalic and caudal sides were the gastroduodenal artery and a ≥ 5 cm gap from the distal pancreas, respectively. The two resection margins were frozen and prepared for imaging to confirm tumor-free resection. Hemostasis of the cephalic and caudal stumps of pancreas was performed with interrupted 4-0 non-absorbable stitches, and the cephalic pancreatic cut surface was closed by Endo-GIA™ 60-2.5 auto sutures (Johnson Medical Ltd., China) or continuous suture using 4-0 prolene (Figure 2). A small catheter was inserted to maintain the patency of the pancreatic duct on the distal side. The distal side stump was reconstructed by Roux-en-Y pancreaticojejunostomy (PJ, $n = 22$) or pancreaticogastrostomy (PG, $n = 14$) (Figure 3). Two

drainage tubes were placed close to the closed cephalic stump and the region of the pancreatic anastomosis. The drains were not removed until the drainage fluid volume was < 10 mL/d and the amylase value was < 300 U/L.

Perioperative outcomes

Perioperative outcomes included operative time, intraoperative hemorrhage, transfusion, pancreatic fistula, intra-abdominal abscess/infection, postoperative bleeding,

reoperation, mortality, and postoperative hospital time. Pancreatic fistulae were graded based on the International Study Group for Pancreatic Fistula (ISGPF) criteria^[19]. Pre- and postoperative nutritional status (total protein, albumin, and hemoglobin) was evaluated using the formula: (discharge numerical value - preoperative numerical value)/preoperative numerical value × 100 (%). Nutritional parameters were measured on the day of admission and the seventh postoperative day.

For postoperative glycemic control, the following approach was used in all patients. First, insulin was added to the glucose solution (1 U insulin/4-6 g glucose). Second, blood glucose was monitored every 6 h and additional insulin was given if blood glucose exceeded 10 mmol/L. Third, long-acting insulin was given when blood sugar was not well controlled using the above method. Glycemic control was determined as the mean daily fasting blood glucose.

Long-term outcomes

All patients were evaluated after a median follow-up of 44 mo (range 4-72 mo). Our aim was to evaluate the long-term changes in endocrine and exocrine functions, body weight change, and tumor recurrence, based on radiological, clinical and laboratory assessments. New-onset DM was diagnosed according to the criteria of the World Health Organization^[20]. Pancreatic exocrine insufficiency was defined as diarrhea and steatorrhea, and was treated by daily enzyme administration.

Statistical analysis

SPSS software (SPSS Inc., Chicago, IL, United States) was used for all statistical analysis. Continuous variables were summarized as mean ± SD and categorical variables as frequency and percentage. Two-sample *t* tests and Pearson's χ^2 test or Fisher's exact test were used to com-

pare continuous and categorical variables, respectively. The Wilcoxon rank sum test was used to compare body weight change. *P* values < 0.05 were considered statistically significant.

RESULTS

Perioperative outcomes

The perioperative outcomes are shown in Table 2. No in-hospital death occurred after the operation in any group. A statistically significant difference in operation time was found between the PD and MSP groups (333.5 ± 97 min vs 222.1 ± 62.1 min, respectively; *P* < 0.001). Intraoperative hemorrhage was 316.1 ± 309.6, 852.2 ± 877.8 and 526.9 ± 414.5 mL for the MSP, PD and EDP groups, respectively (*P* < 0.05). The splenic artery and vein, as well as the spleen, were preserved in all patients treated with MSP and PD; however, these were removed in all patients who underwent EDP. There were no differences in postoperative hospital time between the MSP group and the PD and EDP groups. The duration of gastrointestinal recovery was shorter in the MSP group than in the PD group (*P* < 0.05). The rate of pancreatic fistula was higher in the MSP group than in the other groups, reaching statistical significance between the MSP and PD groups (*P* < 0.05). However, the pancreatic fistulas in the MSP group corresponded to ISGPF Grade A (*n* = 9/15) or B (*n* = 6/15), and there was no significant difference in the pancreatic fistulas rate between PJ (9/22) and PG (6/14) reconstruction methods in MSP group (*P* > 0.05). All of the fistulas after MSP were sealed following conservative treatment. Two patients in the PD group underwent reoperation, one because of postoperative bleeding and the other as a result of intra-abdominal infection.

There were no differences in preoperative mean blood glucose levels between the MSP group and the PD and

IPH: Intraoperative hemorrhage; PT: Postoperative time; DGR: Duration of gastrointestinal recovery; TP: Total protein; Alb: Albumin; Hb: Hemoglobin; MSP: Middle segmental pancreatectomy; PD: Pancreaticoduodenectomy; EDP: Extended distal pancreatectomy; NS: Not significant.

EDP groups. However, the mean postoperative daily fasting blood glucose level was significantly lower in the MSP group than in the EDP group (*P* < 0.05). Serum protein is an important clinical and biochemical marker of the patients' nutritional status. Serum total protein and albumin levels were significantly higher in the MSP group than in the EDP group (*P* < 0.01 and *P* < 0.05, respectively).

Long-term outcomes

The long-term outcomes of patients were assessed by telephone interview until March 2010. The median follow-up time was 44 mo (range 4-72 mo). Two and three patients were lost to follow-up in the PD and EDP groups, respectively. The long-term outcomes are shown in Table 3. No tumor recurrence occurred in any of the patients. There was no significant difference in body-weight change between groups MSP and PD (*P* = 0.701), or MSP and EDP (*P* = 0.568). Only one patient (2.8%) in the MSP group *vs* five (21.7%) in the EDP group developed new-onset insulin-dependent DM postoperatively, which was statistically significant (*P* < 0.05). Moreover, significantly fewer patients (0%) in the MSP group than in the PD (33.3%, *P* < 0.001) and EDP (21.7%, *P* < 0.01) required enzyme substitution, indicating superior preservation of the pancreatic exocrine function with MSP than with other approaches.

DISCUSSION

In recent years, benign and borderline pancreatic lesions have been diagnosed more frequently because of the increased use of high-resolution cross-sectional imaging modalities, such as CT and magnetic resonance imaging^[21,22]. As many of these lesions are noninvasive at the time of discovery, parenchymal-sparing techniques may be beneficial to preserve endocrine and exocrine pan-

creatic function^[23-25]. Enucleation is generally appropriate for small lesions that do not involve the main pancreatic duct^[26,27]. However, it is associated with a high incidence of pancreatic fistula and pseudocyst formation^[28]. Therefore, traditional resection methods (*e.g.*, PD and EDP) are still used to treat lesions in the pancreatic neck or proximal body. These resection methods sacrifice a considerable portion of the normal pancreatic tissue, leading to marked postoperative deteriorations in exocrine and endocrine pancreatic functions^[29-31]. Moreover, the loss of the duodenum alters the natural passage of food, leading to an abnormal digestive process. Similarly, bilio-digestive anastomosis increases the risk of ascending cholangitis and subsequently intrahepatic abscesses in PD^[32]. Surgeons performing EDP often remove a large amount of normal pancreatic tissue and sometimes the spleen. Splenectomy carries some risks, including portal vein thrombosis, postsplenectomy sepsis, and reduced immune function^[3-5,33,34]. MSP avoids extensive loss of normal pancreatic tissue as compared with PD and EDP. Theoretically, MSP also preserves digestive tract continuity, as well as the spleen, potentially reducing postoperative morbidity as compared with PD or EDP. However, MSP appears to be associated with a higher incidence of pancreatic fistula compared with both PD and EDP^[11-14,16,35]. This is possibly caused by the need to manage two pancreatic remnants by anastomosis or closure. In this study, the perioperative survival and long-term outcomes were examined in patients with lesions in the neck and proximal body of the pancreas treated by PD, EDP or MSP.

In this study, we found that total blood loss during surgery was less in the MSP group than in the PD and EDP groups. The greater blood loss in the PD group may be caused by the large volume of tissue removed and the complexity of the surgical procedure. Similarly, EDP may be complicated in patients where the surgeon experiences

difficulties in exposing and isolating the spleen, which may result in injury to the spleen parenchyma or splenic vein and artery, leading to significant blood loss. Blind suturing and electric coagulation can also lead to potentially serious consequences. In such cases, the spleen must also be removed. Notably, we found that MSP was easier to perform compared with PD and EDP, because of the smaller volume of tissue to be removed, excellent exposure, and ease of handling the splenic artery and vein branches. Reconstruction *via* Roux-en-Y PJ or PG should not increase the risk of bleeding when performed by experienced surgeons. A further advantage of MSP was its shorter operation time compared with PD. Interestingly, operation time was not different between MSP and EDP, even though PJ or PG was necessary with MSP.

Compared with PD and EDP, MSP was not associated with increased mortality, but was associated with greater postoperative morbidity, notably a higher frequency of pancreatic fistula noted in previous studies^[5,11-18]. Similar to these reports, the fistula rate after MSP in our study was 42% (15/36), higher than that after PD (20.5%), but was not significantly different to that after EDP (31%). There was no significant difference in pancreatic fistulas rate between PJ (9/22) and PG (6/14) reconstruction methods in MSP group. However, all of the pancreatic fistulae in our series corresponded to ISGPF grade A or B, and were sealed by conservative measures. This may explain why the postoperative hospital time was not extended following MSP as compared with PD or EDP. Based on these data, we believe that MSP is a safe operation with morbidity and mortality rates comparable with those of PD or EDP.

PD and EDP result in marked deteriorations in pancreatic exocrine and endocrine functions. For example, Shikano *et al*^[17] reported that the incidence of DM ranged from 10% to 24% after PD and from 8% to 60% after EDP in patients with normal pancreatic parenchyma. However, in patients with chronic pancreatitis, the inci-

dence of DM increases to 40% and 85% after PD and DP, respectively. Meanwhile, the incidence of impaired pancreatic exocrine function ranged from 30% to 60%, even in the absence of chronic pancreatitis. However, the major advantage of MSP is the potential to retain more pancreatic exocrine and endocrine function than with PD and EDP. In their literature review, Allendorf *et al*^[6] reported no cases of impaired exocrine function and only two cases of abnormal endocrine function among 26 patients who underwent MSP. In another literature review, the rate of exocrine insufficiency was 5% and the rate of endocrine insufficiency was 4% among 100 patients who underwent MSP^[10]. In the current series, one of 36 patients developed new-onset DM following MSP, *vs* 21.7% of patients (5/23) after EDP and 14.3% of patients (6/42) after PD. Moreover, none of the patients in the MSP group required pancreatic enzyme substitution, *vs* 33.3% (14/42) and 21.7% (5/23) of patients after PD and EDP, respectively. Matched-pairs analysis comparing MSP with PD or EDP confirmed the superiority of this organ-preserving procedure. Furthermore, long-term exocrine and endocrine pancreatic function was significantly better preserved after MSP than after PD or EDP.

It is important to consider that MSP provides inadequate tissue resection for cancers because of incomplete dissection of soft tissue and nodes. Furthermore, it does not remove the putative lymphatic and venous drainage bed along the distal pancreas and at the splenic hilum from which many malignant pancreatic tumors are thought to spread. Therefore, MSP is contraindicated for invasive pancreatic tumors and is currently limited to benign and low-malignant potential conditions, such as intraductal papillary mucinous neoplasms, mucinous cystic neoplasms, serous cystadenomas, solid pseudopapillary neoplasms, endocrine tumors and other less frequent benign lesions. We have performed this procedure in two patients with ductal adenocarcinoma who could not tolerate a long surgical procedure, and the tumor recurred

3 and 6 mo after surgery in these patients. However, no recurrence was observed in our current series of patients with benign and low malignant potential lesions. Similarly, Adham *et al*^[9] reported no recurrence in 50 patients with non-invasive lesions who underwent MSP. The highest frequency of tumor recurrence was found in Sauvanet *et al*^[7] review in which four of 53 patients developed recurrence. We believe that providing an adequate tumor-free margin is necessary to avoid recurrence, even in benign and low malignant potential lesions.

In conclusion, MSP is a safe and organ-preserving option for benign or low-grade malignant lesions in the neck and proximal body of the pancreas. MSP offers naturally better long-term preservation of pancreatic exocrine and endocrine functions.

COMMENTS

Background

Whether patients with focal pancreatic lesions of benign or low-grade malignant pathology should be treated by middle segmental pancreatectomy (MSP) rather than by classic procedures, such as pancreaticoduodenectomy (PD) and extended distal pancreatectomy (EDP), is controversial. This study evaluated the feasibility and safety of MSP compared with PD and EDP.

Research frontiers

Clinically, surgical treatment for benign or low-grade malignant lesions of the pancreatic neck and body is often performed using 'traditional' procedures such as PD or EDP. However, these approaches result in a significant and unnecessary loss of normal pancreatic parenchyma with subsequent impairment of exocrine and endocrine functions. In the surgical treatment for benign or low-grade malignant lesions of the pancreatic neck and body, the research hotspot is how to ensure the perioperative safety and improve the long-term effects, including the preservation of pancreatic endocrine and exocrine function.

Innovations and breakthroughs

MSP has increasingly been applied for some lesions, including chronic pancreatitis, and benign and borderline lesions localized at the neck and body of pancreas. Several recent reports have compared the morbidity and quality of life in patients with chronic pancreatitis, and benign and low-grade malignant pancreatic tumors after MSP or traditional surgical procedures. The study focuses not only on the long-term effects, but also on the perioperative safety and the early postoperative patients' nutritional status after MSP. Compared with PD or EDP, MSP provided better nutritional status and postoperative preservation of pancreatic exocrine and endocrine functions.

Applications

MSP is a safe and organ-preserving option for benign or low-grade malignant lesions in the neck and proximal body of the pancreas.

Terminology

MSP: The head and tail of the pancreas were preserved, only the middle pancreas was removed when the lesions were located in the neck and proximal body of the pancreas.

Peer review

This is an interesting study that evaluated the feasibility and safety of MSP compared with PD and EDP. The results suggest that MSP is a safe and organ-preserving option for appropriate lesions in the neck and proximal body of the pancreas. MSP also provided better postoperative preservation of pancreatic exocrine and endocrine functions.

Abstract

AIM: To determine the mortality associated with functional bowel disorders (FBDs) and their possible relationship with organic bowel disease.

METHODS: Patients who satisfied the Rome III criteria for FBD (retrospective diagnosis) were followed up by telephone interview and/or outpatient review at 5 years after their first attendance. The patients were divided into the following groups: irritable bowel syndrome, functional abdominal bloating, functional constipation, functional diarrhea and unspecified FBD. The survival of the FBD patients overall and of those with each FBD were compared with data obtained from the Guangzhou population in 2005. The incidences of colonic cancer overall and for each FBD were compared with data from

the Chinese population obtained from 56 cancer registries in 19 provinces of the country in 2008.

RESULTS: Two hundred and sixty-three patients were followed-up. Five patients died, which was not significantly different from the expected survival rate. No differences in mortality among the FBDs were found. There were nine cases of organic bowel disease: three colonic cancers and six colonic polyps. The incidence of colonic cancer in FBD patients was higher than that in the general Chinese population (0.23% vs 0.03%, $P < 0.05$). There were significant differences in the incidence of colonic cancer among the FBDs (0/134, 0/24, 2/29, 1/66, 0/10, respectively, $P < 0.05$); functional constipation was the most common. The incidence of colonic polyps was similar among the FBDs. The baseline age of patients who died was greater than that of those who survived (66.60 ± 6.84 years vs 45.14 ± 10.34 years, $P < 0.05$). The baseline age of patients who had colonic cancer or polyps during follow-up was greater than that of those without colonic cancer or polyps (60.33 ± 1.53 years vs 45.38 ± 10.62 years; 54.50 ± 6.47 years vs 45.34 ± 10.68 years, $P < 0.05$).

CONCLUSION: FBDs do not increase the risk of death. The incidence of colonic cancer in patients with FBDs may be increased, especially in those with functional constipation and in the elderly.

INTRODUCTION

Functional gastrointestinal disorders (FGIDs) are common in populations of various ethnicities and can seriously affect patients' quality of life^[1,2]. Functional bowel disorders (FBDs) are the most common FGIDs and include irritable bowel syndrome (IBS), functional abdominal bloating, functional constipation, functional diarrhea and unspecified functional bowel disorder^[3,4]. FBDs are common in the Chinese population. Epidemiological investigations have found the prevalence of IBS to be 5.7% and 10.5% in Guangzhou and Beijing, respectively^[5,6], IBS patients account for 11.3% of gastroenterology department outpatients^[7], and the prevalence of functional constipation is about 3.0% in Guangzhou residents^[8]. The extent and outcomes of FBD in the Chinese population are a cause of widespread concern.

FBDs are defined by symptom-based diagnostic criteria that combine chronic or recurrent symptoms attributable to the gastrointestinal (GI) tract in the absence of other, pathologically based disorders according to the Rome III criteria^[3]. In recent years, technological advances and new research have revealed pathophysiologic changes in FBDs, including bowel motility disorder, visceral hypersensitivity, changes in the intestinal flora and psychologic abnormalities^[9-13]. It has been thought that these do not affect patient survival, and a recent study reported that functional dyspepsia was not associated with increased mortality in the community, though the data for any effect of IBS on survival were less clear^[14]. Research from Europe and the United States suggest that FBDs are closely related to certain organic bowel diseases; for example, functional constipation and colorectal cancer, or IBS and inflammatory bowel disease (IBD)^[15-18]. However, such views are controversial.

No study has shown whether FBDs increase the risk of death or whether there is a link between FBDs and organic bowel disease in the Chinese population. In the present study, we followed up 263 outpatients with FBDs for 5 years to determine their survival and incidence of organic bowel disease.

MATERIALS AND METHODS

Subjects

As shown in Figure 1, data were collected from outpatients who attended the Department of Gastroenterology at Nanjing Jiangbei People's Hospital between January, 2005 and December, 2006 and reported mainly bowel symptoms, such as abdominal pain or discomfort, bloating, swelling or abnormal bowel movements. Patients retrospectively diagnosed with FBD according to the Rome III criteria^[3] and who agreed to follow-up were included in the study. All patients underwent routine blood, urine and stool hemocult tests, stool form examination and endoscopy of the GI tract. Patients younger than 18 years or with a structural bowel disease or a history of abdominal surgery were excluded. Pregnant patients were not included. All patients included in the study were fol-

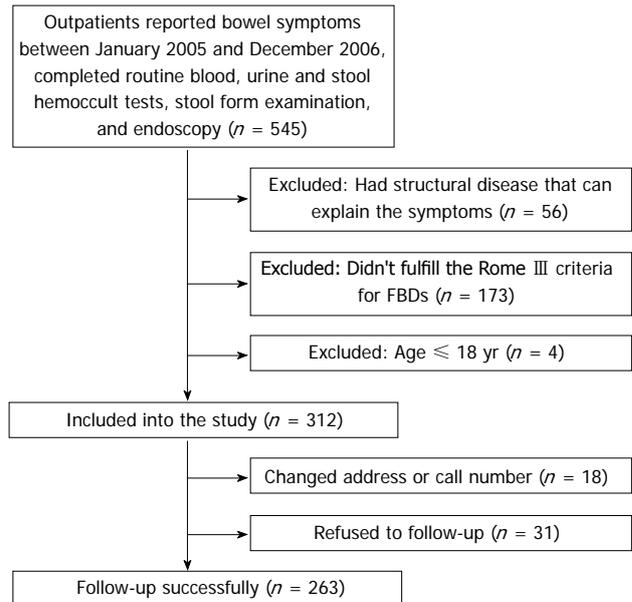

Figure 1 Patient status. FBD: Functional bowel disorder.

lowed up in June, 2012.

Measures

Two hundred and sixty-three patients with FBDs were followed up for more than 5 years and their survival and incidence of organic bowel disease recorded.

Patient groups: Based on the Rome III diagnostic criteria, the patients were divided into the following groups: IBS, functional abdominal bloating, functional constipation, functional diarrhea and unspecified FBD^[3].

Baseline data obtained: Baseline data for each subject were obtained from outpatient medical records, including age, gender, place of residence, and the duration and nature of symptoms.

Follow-up methods and content: All patients were followed up by telephone to ascertain: (1) survival (in the case of patients who had died, details of the cause and date of death were obtained); and (2) the presence of organic bowel disease and date of diagnosis. All surviving patients were asked to undergo review routine blood, urine and stool hemocult tests, stool form examination, and endoscopy or radiographic examination of the GI tract.

Statistical analysis

All data were analyzed using SPSS version 19.0. Statistical significance was set at $P < 0.05$. Categorical data were analyzed using the χ^2 test. All measurement data were reported as the mean \pm SD and analyzed using the t test (between two groups) or one-way analysis of variance (among more than two groups). Kaplan-Meier estimates of overall survival observed *vs* expected for the whole cohort. Expected survival was based on the whole cohort using survival characteristics of the Guangzhou popula-

Table 1 Baseline clinic data for each functional bowel disorder

| FBD | n (%) | Age (yr) (mean ± SD) | Gender (F/M) | Residence (urban/rural) | Duration of FBD |
|-------------------------------|------------|-------------------------|-----------------|----------------------------|--------------------|
| IBS | 134 (47.1) | 45.44 ± 10.32 | 63/71 | 68/66 | 6 mo-20 yr |
| Functional abdominal bloating | 24 (9.1) | 43.17 ± 11.86 | 10/14 | 13/11 | 6 mo-17 yr |
| Functional constipation | 29 (11.0) | 46.59 ± 13.22 | 10/19 | 12/17 | 6 mo-20 yr |
| Functional diarrhea | 66 (25.1) | 46.56 ± 9.34 | 41/25 | 34/32 | 6 mo-20 yr |
| Unspecified FBD | 10 (3.8) | 41.90 ± 13.40 | 4/6 | 4/6 | 6 mo-10 yr |

No differences were found in age, gender, place of residence (urban or rural) or duration of functional bowel disorder (FBD) among groups (all $P > 0.05$). F: Female; M: Male; IBS: Irritable bowel syndrome.

Table 2 Details of patient deaths during follow-up

| Details | n/N (%) |

tion from 2005^[19]. The incidence of colonic cancer in FBD patients was compared with data from the Chinese population obtained from 56 cancer registries in 19 provinces of the country in 2008^[20], using Fisher's exact test. Survival and the incidence of colonic cancer and polyps in different age, gender and residence groups and in each FBD group were compared using Fisher's exact test.

RESULTS

Baseline data

As shown in Figure 1, 312 patients were included in the study and 263 FBD patients were followed up; a drop-out rate of 15.71%. At baseline, these patients were aged 20-74 years (45.55 ± 10.68 years) and comprised 128 (48.66%) males and 135 (51.33%) females. The duration of FBD ranged from 6 mo to 20 years, with a median du-

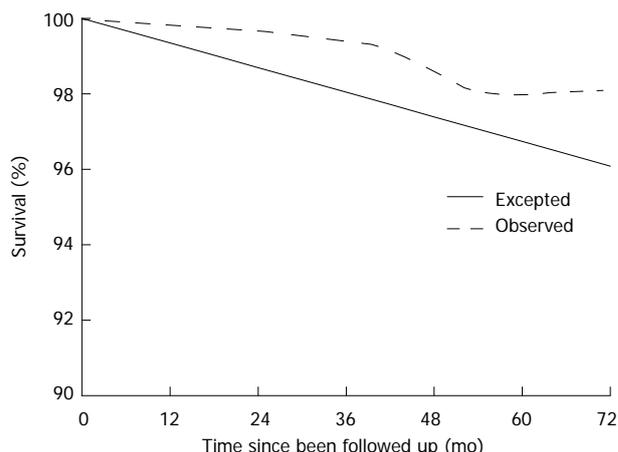

Figure 2 Observed vs expected survival for all functional bowel disease patients. There was no significant difference between the observed and expected survival ($P > 0.05$).

ration of 1 year.

Clinical data for each FBD group are shown in Table 1. IBS was the most common FBD in these patients, followed by functional diarrhea, functional constipation, functional abdominal bloating and unspecified FBD. There were no differences in age, gender, place of residence (urban or rural) or duration of FBD between groups (all $P > 0.05$).

Follow-up data

Survival: Five (1.90%) deaths had been reported in the cohort by the time of the last follow-up interview in June, 2012. Table 2 provides details of the deaths. The average age of the patients who died was greater at baseline than that of those who survived (66.60 ± 6.84 years vs 45.14 ± 10.34 years, $t = 4.617$, $P < 0.01$). There were no differences in mortality between genders or with place of residence (both $P > 0.05$). No differences of mortality in the various FBDs were found ($P > 0.05$). Expected survival was based on the whole cohort using survival characteristics of the Guangzhou population from 2005^[19]. Overall observed vs expected survival for the whole set of respondents is illustrated in Figure 2; the data suggest there was no significant difference between observed and expected ($P > 0.05$).

Detection of organic bowel disease: Organic bowel disease was detected in nine cases (3.42%): colonic cancer in three (1.14%) and colonic polyps in six (2.28%). Table 3 gives the details of the organic bowel diseases observed. The average age of patients with colonic cancer or colonic polyps was greater at baseline than that of the other patients (60.33 ± 1.53 years vs 45.38 ± 10.62 years, $t = 13.582$, $P < 0.01$; 54.50 ± 6.47 years vs 45.34 ± 10.68 years, $t = 2.089$, $P < 0.05$). There were no differences in the incidence of colonic cancer or polyps between genders or with place of residence (all $P > 0.05$). There were significant differences in the incidence of colonic cancer between the various FBDs ($P < 0.05$, Fisher's exact test); the incidence was highest in the functional constipation

^b $P < 0.01$ vs baseline in patients without colonic cancer; ^c $P < 0.05$ vs baseline in patients without colonic polyps; ^e $P < 0.05$ vs IBS but not other FBD groups; no differences in the incidence of colonic cancer or polyps were found between genders and places of residence and no differences in the incidence of colonic polyps were found among FBD groups (all $P > 0.05$). FBD: Functional bowel disorder; IBS: Irritable bowel syndrome.

group, being significantly higher than in the IBS group ($P < 0.05$, Fisher's exact test), though not significantly different from the incidence in the other FBD groups ($P > 0.05$). The incidence of colonic polyps was similar between the various FBDs ($P > 0.05$). Compared with data from the general Chinese population obtained from 56 cancer registries in 19 provinces of the country, the incidence of colonic cancer was significantly increased in patients with FBDs ($P < 0.01$, Fisher's exact test; Figure 3).

DISCUSSION

FBDs have long been considered a group of functional diseases in patients without any pathologically based disorder^[3] that do not affect survival and are not associated with organic disease. Recent research from Europe and the United States, however, suggests that FBDs are closely related to certain organic bowel diseases - for example, functional constipation and colorectal cancer, or IBS and IBD^[15-18] - and do have an effect on survival. No

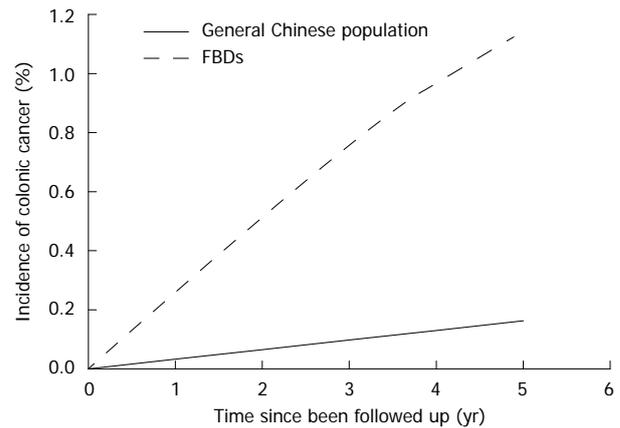

Figure 3 Incidence of colonic cancer in functional bowel disorder patients and in the general Chinese population. Compared with data from the general Chinese population obtained from 56 cancer registries in 19 provinces of the country, the incidence of colonic cancer was significantly increased in patients with functional bowel disorders (FBDs) ($P < 0.01$, Fisher's exact test).

study has investigated the association between FBDs and organic bowel disease, or whether FBDs increase the risk of death, in the Chinese population. In the present study, we followed up 263 outpatients with FBDs for 5 years, revealing new information.

The mortality of the FBD patients was 1.90% over the 5-year follow-up period, equivalent to an average annual mortality of approximately 0.38%. A death spectrum and potential life lost investigation found a crude death rate of 652.3/100 000 (approximately 0.65%) in the Guangzhou population in 2005^[19]. Compared with this population, our FBD patients showed no trend towards increased mortality. We can conclude that FBD does not increase the risk of death in Chinese patients. We found no differences in mortality among the various FBDs.

Data from 56 cancer registries in 19 provinces of China from 2008 shows the incidence of colorectal cancer to be 31.39/100 000 (approximately 0.03%) in the Chinese population^[20]. In this study, three cases (1.14%) of colonic cancer were detected, equivalent to an average annual mortality of approximately 0.23%. The incidence of colonic cancer in patients with FBDs was thus significantly increased.

Significant differences in the incidence of colonic cancer were found between the FBDs; that of functional constipation was up to 6.70%, equivalent to an average annual incidence of approximately 1.34%. This was significantly higher than in the other FBDs, and also higher than in the general Chinese population (approximately 0.03%). A study based on the Japanese population suggests that the number of bowel movements is closely related to the incidence of colorectal cancer^[21]. However, European and American studies have shown that constipation itself does not induce colorectal cancer, but use of cathartics (especially anthraquinones or phenolphthalein) may increase the incidence of both colorectal adenomas and colorectal cancer^[22,23].

During the 5 years of follow-up in the present study,

six cases (2.28%) of colonic polyps were observed. Several studies have reported the detection rate of colonic polyps in outpatients under colonoscopy, but no data are available regarding the annual incidence of colonic polyps in the Chinese population. Thus, we are unable to assess the risk of colon polyps in FBDs.

There were no differences in mortality or in the incidence of colonic polyps or cancer between genders or with place of residence. The average age at baseline of the patients who died during follow-up or who were found to have colonic cancer and polyps was greater than the average age at baseline of the patients who survived or did not have colonic cancer or polyps. We therefore suggest that the possibility of organic bowel disease should be considered in FBD patients over the age of 50 years, and that repeated review by colonoscopy is necessary after the diagnosis of FBD is established.

In conclusion, FBDs did not in general increase the risk of death assessed over 5 years in a Chinese population. Compared with the general population, the incidence of colonic cancer may be increased in FBD patients, especially those with functional constipation. These conclusions are based on the follow-up investigation of a small sample of FBD patients. A larger sample needs to be observed, control data should be collected from the general population over the same period, and a rigorous prospective study must be designed to verify our results.

COMMENTS

Background

Functional gastrointestinal disorders (FGIDs) are common in populations of various ethnicities and can severely affect patients' quality of life. Functional bowel disorders (FBDs) are the most common FGIDs and are common in the Chinese population. The extent and outcomes of FBD in the Chinese population are a cause of widespread concern.

Research frontiers

In recent years, research from Europe and the United States suggests that FBDs are closely related to certain organic bowel diseases; for example, functional constipation and colorectal cancer, or irritable bowel syndrome and inflammatory bowel disease. Whether FBDs increase the risk of death is controversial.

Innovations and breakthroughs

No study has shown whether FBDs increase the risk of death or whether there is a link between FBDs and organic bowel disease in the Chinese population. In the present study, authors followed up 263 outpatients with FBDs over 5 years to determine their survival and the incidence of organic bowel disease.

Applications

The study results suggest FBDs did not increase the risk of death over 5 years, though the incidence of colonic cancer in patients with FBDs may be increased, especially in those with functional constipation. The authors therefore suggest that the possibility of organic bowel disease should be considered in FBDs, especially in functional constipation, and repeated review by colonoscopy is necessary after the diagnosis of FBD is established.

Terminology

FBDs are defined by symptom-based diagnostic criteria that combine chronic or recurrent symptoms attributable to the gastrointestinal tract in the absence of other, pathologically based disorders according to the Rome III criteria. FBDs are the most common functional gastrointestinal disorders and include irritable bowel syndrome, functional abdominal bloating, functional constipation, functional diarrhea and unspecified functional bowel disorder.

Peer review

This is an interesting and well written manuscript examining the morbidity and

mortality of FBDs in China. This has not really been examined before and is important to the extent that certain patients with FBDs may benefit from improved cancer surveillance. This manuscript describes a small, preliminary epidemiologic study of mortality and the development of organic bowel disease in Chinese patients diagnosed with functional bowel disorders over 5 years.

Abstract

AIM: To investigate the normal hepatic magnetic resonance spectroscopy findings choline/lipid2 (Cho/Lip2) associated with age and body mass index (BMI).

METHODS: A total of 58 single-voxel proton spectra of the liver were acquired at 3.0 T using the eight-channel phased array abdominal coil as the receiver coil. Consecutive stacks of breath-hold spectra were acquired using the point resolved spectroscopy technique at a short echo time of 30 ms and a repetition time of 1500 ms. The spectra were processed with the SAGE software package. Areas and heights for metabolite resonance were obtained. Student's *t* test for unpaired data was used for comparisons of shimming, Cho/Lip2, and lipid content.

RESULTS: There were significant negative correlations between the Cho/Lip2 peak height ratios and BMI ($r = -0.615$) and age ($r = -0.398$) (all $P < 0.01$). Compared with the high-BMI group, the low-BMI group was younger (39.1 ± 13.0 years vs 47.6 ± 8.5 years, $t = -2.954$, $P = 0.005$); had better water suppression ($93.4\% \pm 1.4\%$ vs $85.6\% \pm 11.6\%$, $t = 2.741$, $P = 0.014$); had higher Cho/Lip2 peak heights ratio (0.2 ± 0.14 vs 0.05 ± 0.04 , $t = 6.033$, $P < 0.000$); and had lower lipid content (0.03 ± 0.08 vs 0.29 ± 0.31 , $t = -3.309$, $P = 0.004$). Compared with the older group, the younger group had better shimming effects (17.1 ± 3.6 Hz vs 22.0 ± 6.8 Hz, $t = -2.919$, $P = 0.008$); higher Cho/Lip2 peak heights ratios (0.03 ± 0.05 vs 0.09 ± 0.12 , $t = 2.4$, $P = 0.020$); and lower lipid content (0.05 ± 0.11 vs 0.23 ± 0.32 , $t = -2.337$, $P = 0.031$). Compared with the low-choline peak group, the high-choline peak group had lower lipid content (0.005 ± 0.002 vs 0.13 ± 0.23 , $t = -3.796$, $P < 0.000$); lower BMI (19.6 ± 2.4 vs 23.9 ± 3.0 , $t = -4.410$, $P < 0.000$); and younger age (34.7 ± 10.0 years vs 43.2 ± 12.5 years, $t = -2.088$, $P = 0.041$).

CONCLUSION: Lipid accumulation could result from the increased fat in the body depending on age and BMI. Lipid can mask the resonance signal of choline.

INTRODUCTION

Magnetic resonance spectroscopy (MRS) is a non-invasive technique that is being increasingly applied to describe biochemical changes in the liver^[1-5]. The recent installation of higher field strength (3 T) clinical magnets with multicoil arrays offers new opportunities for performing whole-body MRS. The improved signal-to-noise ratio (SNR) can reduce acquisition times, and the higher field strength also provides better separation of resonances^[6,7].

Choline is a precursor of acetylcholine and a component of the phospholipid metabolism of cell membranes. It is known that MRS may be used to diagnose malignancy; usually by measuring the choline peak. Absolute quantification of hepatic metabolite concentrations offers several advantages for the evaluation of *in vivo* MRS data. Unfortunately, absolute quantification of choline-containing compounds is impractical for most clinical applications. A few studies of *in vivo* MRS have reported an increase in choline-containing compounds relative to lipids within tumors such as hepatocellular carcinoma, and a reduction in the lipid-to-choline ratio after transarterial embolization for hepatocellular carcinoma. However, the ability to distinguish reliably benign and malignant tumors from normal liver parenchyma has yet to be established. A major limitation is the observation that relatively large amounts of choline-containing compounds may occur even in normal liver^[8-13].

Knowledge of the normal findings associated with age and body mass index (BMI) is valuable. Therefore, the central questions of our study were: (1) does choline/lipid2 (Cho/Lip2) have a relationship with BMI? and (2) does Cho/Lip2 have a relationship with age? Finally, we try to explain why no observable choline peak was detected on liver MRS in obese and elderly individuals.

Patients

The study was approved by our institutional review board, and written informed consent was obtained from all patients. We evaluated non-hepatic disease and fatty liver in 58 patients (29 men, 29 women; age range, 19-65 years; median age, 42 years) with no history of liver disease and with normal liver function test results. The mean height of the cohort was 164.4 ± 7.4 cm (range, 150-178 cm), mean body weight was 62.7 ± 11.3 kg (range, 39-93 kg), and mean BMI was 23.1 ± 3.3 (range, 16.9-30.4).

MRS protocol

MRS was performed using a GE Signa 3.0 T whole-body

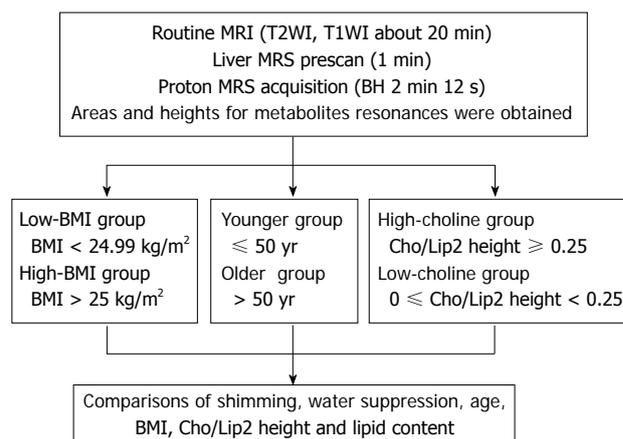

Figure 1 Detailed scanning protocols and statistical analysis. BMI: Body mass index; MRS: Magnetic resonance spectroscopy; Cho/Lip2: Choline/lipid2; MRI: Magnetic resonance imaging.

system (GE Signa Excite HD; GE Medical Systems, Milwaukee, WI, United States) with the standard proton MRS acquisition software provided by the manufacturer. The body coil was used as the transmitter, and a torso phased-array coil (eight coils, four anterior and four posterior coils; Waukesha, WI, United States) was used as the receiver. Single-volume spin-echo point-resolved spectroscopy was used with parameters of 1500/30/64 [repetition time (TR)/echo time (TE)/excitations] in all patients. The patients entered the magnetic field in the supine position with their feet first. The total acquisition time (2 min 12 s per scan) was split into consecutive blocks to match the length of a breath-hold period of about 15-40 s, while data acquisition was performed at end expiration. Volume of interest of 2 cm × 2 cm × 2 cm was localized in the middle portion of the right hepatic lobe, on the basis of T2-weighted single-shot fast spin-echo pictures in the transverse planes with a TR of 935 ms, TE of 83 ms, a matrix of 288 × 192, field of view of 40 cm, section thickness of 8 mm, an intersection gap of 1.5 mm, and a number of excitations of 0.62. The voxel was localized in such a way as to avoid large vessels, bile ducts, and fatty tissue (Figure 1).

After acquisition, data were processed by using the MR spectroscopic analysis package provided by the manufacturer (SAGE 7.1; GE Medical Systems). The raw data were zero-filled once, apodized with a 5-Hz Gaussian filter, Fourier transformed, and phase and baseline corrected. Marquardt curve fitting was performed by using a Gaussian line shape to calculate the area under the peak. MR spectroscopic data were analyzed by a single medical physicist (Xu L) with > 7 years experience in MRS analysis. For each MRS measurement of unsuppressed water, we normalized the amplitude of the lipid signal to the sum of the lipid plus water signals to obtain the percentage lipid within the liver.

For all data acquisition, water suppression was performed using a series of three chemical-shift-selective pulses with predefined flip angles to leave a significant amount of residual water in the spectrum, and high-order

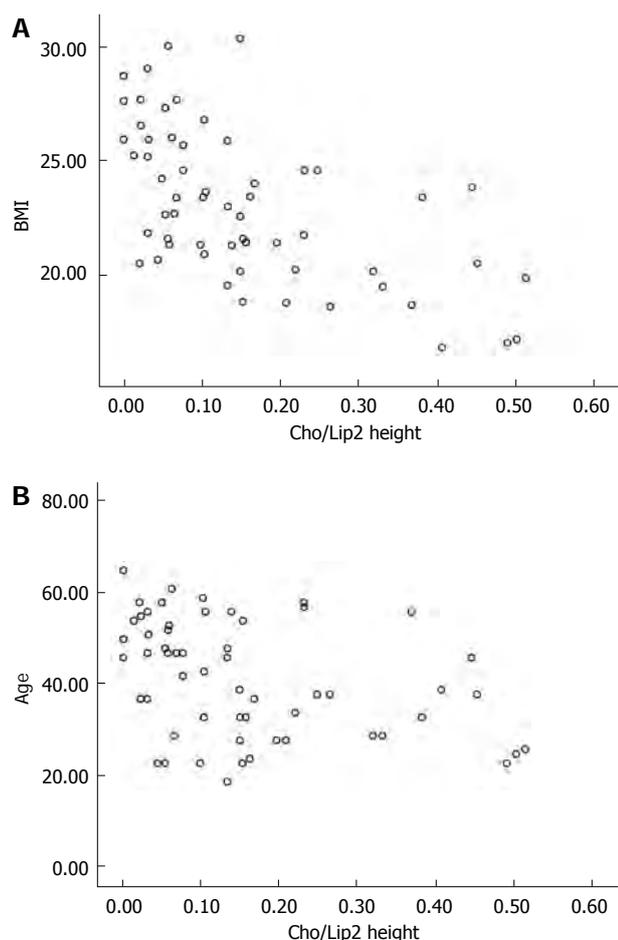

Figure 2 Scatter plots of relationships. A: Between choline/lipid2 (Cho/Lip2) and body mass index (BMI), a good inverse correlation was observed; B: Between Cho/Lip2 and age, a moderate inverse correlation was observed.

shimming followed by automatic local shimming adjustment was used. Line widths (full-width half-maximum) and water suppression were obtained.

Statistical analysis

The study group was divided into two subgroups: low BMI (< 24.99 kg/m²) and high BMI group (> 25 kg/m²). The participants were divided into two subgroups according to age: younger (≤ 50 years) and older (> 50 years). The participants were divided into two subgroups based on the Cho/Lip2 ratio: high choline (Cho/Lip2 ≥ 0.25) and low/non-choline (0 ≤ Cho/Lip2 < 0.25) (Figure 1).

For all tests, *P* < 0.05 was considered to indicate statistically significant differences. Statistical analysis was performed using SPSS version 10.0.1 (SPSS, Chicago, IL, United States). Using Spearman's correlation, we determined the relationship between Cho/Lip2 and BMI, and between Cho/Lip2 and age.

Student's *t* test for unpaired data was used for comparison of shimming, Cho/Lip2 and lipid content between the low-BMI and high-BMI groups, and between the younger and older groups. Student's *t* test for unpaired data was also used for comparison of shimming,

BMI and age between the high-choline and non-choline groups.

RESULTS

Scatter plots and Spearman's correlations

The scatter plots were used to reveal the relationships between the variables (Figure 2). There were significant negative correlations between the Cho/Lip2 peak heights ratios and BMI (*r* = -0.615, *P* < 0.000), and age (*r* = -0.398, *P* = 0.002).

Comparison between low-BMI and high-BMI group

Compared with the high-BMI group, the low-BMI group was younger (39.1 ± 13.0 years *vs* 47.6 ± 8.5 years, *t* = -2.954, *P* = 0.005); had better water suppression (93.4% ± 1.4% *vs* 85.6% ± 11.6%, *t* = 2.741, *P* = 0.014); had higher Cho/Lip2 peak heights ratios (0.20 ± 0.14 *vs* 0.05 ± 0.04, *t* = 6.033, *P* < 0.000); and had lower lipid content (0.03 ± 0.08 *vs* 0.29 ± 0.31, *t* = -3.309, *P* = 0.004) (Figure 3).

Comparison between younger and older groups

Compared with the older group, the younger group had better shimming effects (17.1 ± 3.6 Hz *vs* 22.0 ± 6.8 Hz, *t* = -2.919, *P* = 0.008); higher Cho/Lip2 peak heights ratios (0.03 ± 0.05 *vs* 0.09 ± 0.12, *t* = 2.4, *P* = 0.020); and lower lipid content (0.05 ± 0.11 *vs* 0.23 ± 0.32, *t* = -2.337, *P* = 0.031) (Figure 3).

Comparison between high-choline and low-choline groups

Compared with the low-choline group, the high-choline group had lower lipid content (0.005 ± 0.002 *vs* 0.13 ± 0.23, *t* = -3.796, *P* < 0.000); lower BMI (19.6 ± 2.4 *vs* 23.9 ± 3.0, *t* = -4.410, *P* < 0.000); and younger age (34.7 ± 10.0 years *vs* 43.2 ± 12.5 years, *t* = -2.088, *P* = 0.041) (Figure 4).

DISCUSSION

MRS at 3.0 T provides improved SNR and spectral resolution compared with 1.5 T MRI scanners, therefore, it is expected to yield more reliable measurements of metabolite concentrations^[6,8,14]. The principal metabolite that has been targeted in focal liver disease is choline. In general, choline is elevated in tumors, because choline is a cell membrane component and increased cell turnover is associated with malignancy. *In vivo* ¹H MRS has proved valuable in the diagnosis of tumors in the brain, prostate, breast, and uterine cervix. ¹H MRS is also useful for evaluation of treatment responses in malignant tumors of the head and neck, as well as in breast cancer^[1,13,15-17].

However, the ability to distinguish reliably benign and malignant tumors from normal liver parenchyma has yet to be established. According to the data from our study, the lipid content in liver parenchyma increased with both age and BMI; there were significant negative correlations between Cho/Lip2 and age; and there was no observ-

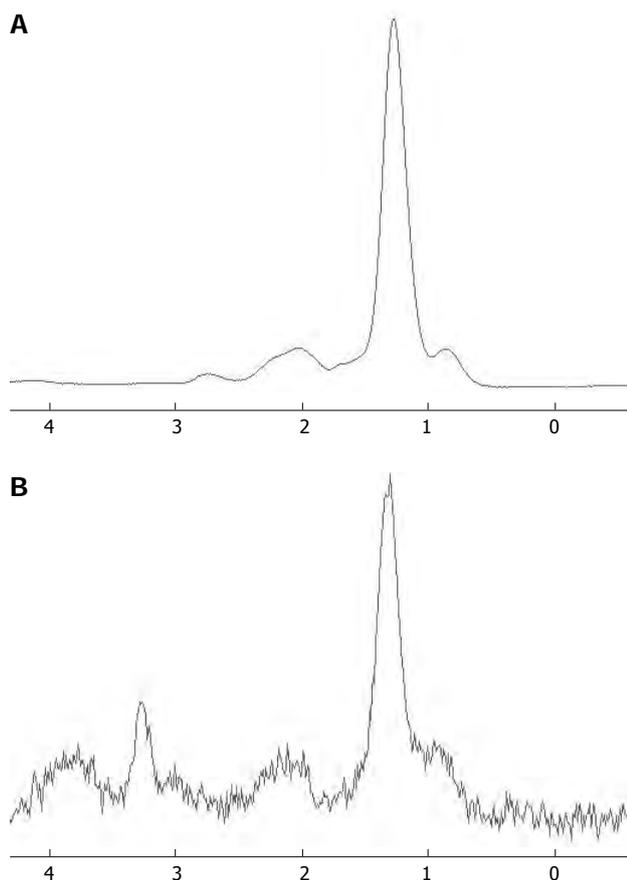

Figure 3 Point resolved spectroscopy-localized single voxel ¹H magnetic resonance spectrum. A: Originating from liver parenchyma of an obese and elderly (body mass index = 30.04, 52 years) volunteer. No observable choline peak was detected at 3.2 ppm; B: Originating from liver parenchyma of a lean and young volunteer (body mass index = 18.87, 23 years). High-choline peak was detected at 3.2 ppm.

able choline peak in obese and elderly individuals. Possible reasons for the above conclusions include: (1) the lipid content in liver parenchyma increased with both age and BMI; and (2) the choline level in liver parenchyma changed with both age and BMI.

The signals of the corresponding lipid groups can be observed at 1.3 ppm for (-CH₂)_n and 0.9 ppm for (-CH₃), and between 2.0 and 2.3 ppm for (-CH=CH-CH₂-), with signals of markedly lower intensity. In this study, the analysis of the spectra only focused on the concentrations of (-CH₂)_n. The lipid content in liver parenchyma increased with both age and BMI. This conclusion has been confirmed by Müller *et al.*^[1] and Fischbach *et al.*^[18]. Assuming that all of the metabolites that contribute to the choline peak remain constant, when the lipid volume fraction is high, the choline fraction should decrease in signal intensity. In other words, the hydrogen found in lipid can produce very strong resonance signals that can mask the resonance signal of lower concentration compounds of interest, usually metabolites such as choline^[18-23].

Choline is a nutrient essential for normal function of all cells. It is a precursor not only for acetylcholine but also for phospholipids that are found in intracellular

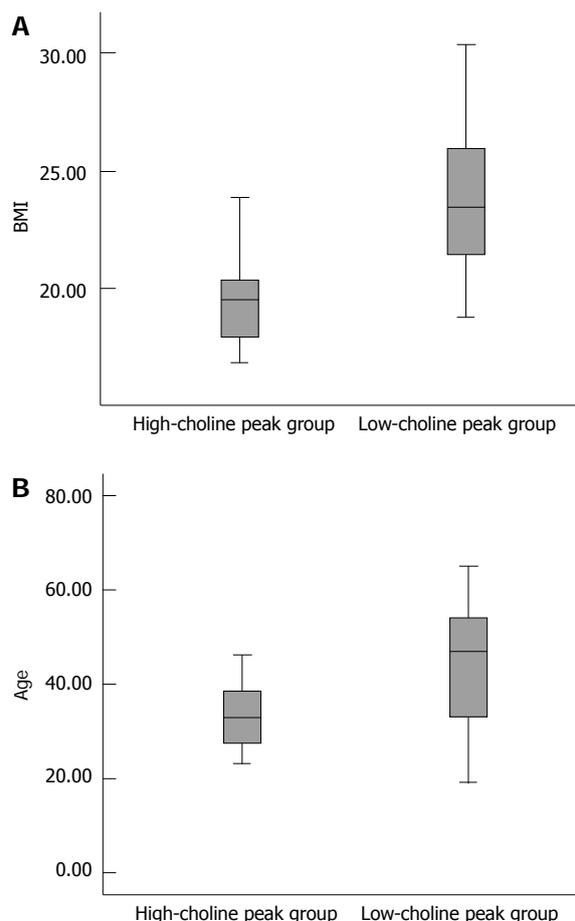

Figure 4 High-choline peak group. A: Had lower body mass index than the low-choline group; B: Was younger than the low-choline group. BMI: Body mass index.

membranes and in the cell membrane. The liver parenchyma already contains large choline metabolite pools. Although catabolic and anabolic reactions are predominant in the liver, leading to elevated choline-containing compounds (CCC) levels. Aging and high BMI may decrease hepatic metabolism, resulting in lower choline concentration. Unfortunately, this conclusion has not been confirmed by previous studies. Fischbach *et al.*^[18] have acquired 113 spectra in normal-appearing parenchyma. The mean \pm SD of the normalized measurements of CCC for the younger group (≤ 40 years) and the older group (> 40 years) was 8.14 ± 6.0 and 7.20 ± 4.32 , respectively. The researchers found that no significant differences were observed.

The presence of a large lipid peak should in principle not influence the fitting of the choline peak. It is known that the concentration of lipid in human liver is 10-1000 times greater than that of most tissue metabolites such as choline. Consequently, the signal of lipid is dominant in ¹H-MRS in some cases. Experimental evidence suggests that spectroscopic data, or metabolic measurements, may be affected by a dominant lipid peak, which makes visualization of the metabolites of interest difficult. This is because the large lipid peak overlaps with adjacent small peaks, and scaling the signal intensity is difficult. This is

the reason why no observable choline peak was detected on liver MRS in obese and elderly individuals. To compensate, fat-suppression techniques are recommended for hepatic MRS to distinguish benign and malignant tumors from normal liver parenchyma^[23-26].

This technique has its limitations in methodology. Although we used a 3.0 T MR imager and shorter TE to increase SNR, spectra containing only noise without any identifiable choline metabolite peaks still existed in a few cases. High-field MRI equipment and/or advanced techniques, such as nuclear Overhauser effect enhancement and proton decoupling, may demonstrate improved SNRs and spectral resolution between MRS peaks. The application of those new techniques may be necessary to answer this question.

In conclusion, Lipid accumulation in the liver could result from increased fat in the body, depending on age and BMI. Hydrogen found in subjects with lipid accumulation can produce very strong resonance signals that can mask the resonance signal of lower concentration compounds such as choline. This is the reason why no observable choline peak was detected on liver MRS in obese and elderly individuals. Fat suppression techniques are recommended for hepatic MRS to distinguish benign and malignant tumors from normal liver parenchyma.

COMMENTS

Background

It is known that magnetic resonance spectroscopy (MRS) can be used to diagnose malignancy; usually by measuring the choline peak. A major limitation is the observation that relatively large amounts of choline-containing compounds may occur even in normal liver. Knowledge of the normal findings associated with age and body mass index (BMI) is valuable.

Research frontiers

A few studies of *in vivo* MRS have reported an increase in choline-containing compounds relative to lipids within tumors such as hepatocellular carcinoma, and a reduction in the lipid-to-choline ratio after transarterial embolization for hepatocellular carcinoma. However, the ability to distinguish reliably benign and malignant tumors from normal liver parenchyma has yet to be established.

Innovations and breakthroughs

The ability to distinguish reliably benign and malignant tumors from normal liver parenchyma has yet to be established. According to the data from this study, the lipid content in liver parenchyma increased with both age and BMI, there was a significant negative correlation between choline/lipid2 (Cho/Lip2) and age, and there was no observable choline peak in obese and elderly individuals.

Applications

Fat suppression techniques are recommended for hepatic MRS to distinguish benign and malignant tumors from normal liver parenchyma.

Terminology

Breathholding either eliminated or markedly reduced phase and frequency shifts and outer voxel contamination that were associated with the motion of the abdomen during breathing.

Peer review

The authors investigated the normal hepatic MRS findings (Cho/Lip2) associated with age and BMI. The study was well designed, and this paper is important and interesting.

Abstract

Collagenous gastritis (CG) is characterized by patchy subepithelial collagen bands. Effective treatment and the clinical and histological outcome of CG in children are poorly defined. The aim of this study is to summarize the published literature on the clinical outcome and response to therapy of pediatric CG including two new cases. We performed a search in Pubmed, OVID for related terms; articles including management and clinical and/or endo-histologic follow up information were included and abstracted. Reported findings were pooled in a dedicated database including the corresponding data extracted from chart review in our patients with CG. Twenty-four patients were included (17 females) with a mean age of 11.7 years. The clinical presentation included iron deficiency anemia and

dyspepsia. The reported duration of follow up (in 18 patients) ranged between 0.2-14 years. Despite most subjects presenting with anemia including one requiring blood transfusion, oral iron therapy was only documented in 12 patients. Other treatment modalities were antisecretory measures in 13 patients; proton pump inhibitors (12), or histamine-2 blockers (3), sucralfate (5), prednisolone (6), oral budesonide in 3 patients where one received it in fish oil and triple therapy (3). Three (13%) patients showed no clinical improvement despite therapy; conversely 19 out of 22 were reported with improved symptoms including 8 with complete symptom resolution. Spontaneous clinical resolution without antisecretory, anti-inflammatory or gastroprotective agents was noted in 5 patients (4 received only supplemental iron). Follow up endo-histopathologic data (17 patients) included persistent collagen band and stable Mononuclear cell infiltrate in 12 patients with histopathologic improvement in 5 patients. Neither collagen band thickness nor mononuclear cell infiltrate correlated with clinical course. Intestinal metaplasia and endocrine cell hyperplasia were reported (1) raising the concern of long term malignant transformation. In summary, CG in children is a chronic disease, typically with a variable clinical response and an indolent course that is distinct from the adult phenotype. Long term therapy usually included iron supplementation but cannot be standardized, given the chronicity of the disease, variability of response and potential for adverse events.

INTRODUCTION

Collagenous gastritis (CG) is a rare idiopathic disorder characterized by the distinctive endoscopic-histopathologic finding of a thickened ($> 10 \mu\text{m}$) gastric subepithelial collagen layer in association with inflammatory cell infiltrate in the lamina propria^[1]. Collagenous gastritis was first described in a 15 years old by Colletti *et al*^[2] subsequent reports helped define the two distinct phenotypes of the disease in children and adult patients^[1,3]. The classic pattern in children centers around upper gastrointestinal symptoms including abdominal pain and severe anemia^[1,4-6]. In contrast to the adult phenotype, inflammatory changes and collagenous band deposition is usually limited to stomach and CG has a variable clinical and histopathological response to therapy^[6,7]. Adult type CG is associated with several autoimmune processes and celiac disease^[8] which is unusual in the childhood form. Concomitant collagenous colitis may be present and gastrointestinal symptoms include abdominal pain, malabsorptive symptoms and, protein losing enteropathy^[3,9]. Adult CG is characterized by the simultaneous occurrence of collagenous colitis and duodenitis, and absence of nodularity in the mucosa of the colon and duodenum. The histological appearance of adult onset CG is also characterized by extensive inflammation of the entire gastrointestinal tract.

The pathophysiology of collagenous gastritis is poorly understood; one hypothesis includes a primary vascular abnormality with increased vascular permeability resulting in deposition of extruded protein and collagen deposition. Alternatively a primary inflammatory process results in a secondary fibrotic scarring process in susceptible individuals. This is supported by the earlier observation of intraepithelial lymphocytic infiltrate and over expression of human leukocyte antigen DR and CD25^[2] suggesting an immune mediated inflammatory process.

Effective treatment of CG in either age group remains elusive and poorly defined; treatment strategies have revolved around the etiopathologic observations suggesting an inflammatory process and the association with celiac disease. Both anti-inflammatory and anti-secretory measures as well as gluten free diet have been tried but there has been, to date, no comprehensive review of treatment strategies and outcomes in this population.

The purpose of this study is to synthesize the published experience for the clinical course and outcome following different treatment modalities in children with CG including two additional cases with one patient responsive to a combination of oral budesonide in fish oil.

CASE REPORT

We performed a comprehensive chart review of the two cases of pediatric Collagenous Gastritis presenting to our institution from 2009 to 2012, and accrued through query of our institutional dedicated pediatric endoscopic database. Relevant historic, clinical, endoscopic-histologic findings and treatment modalities were summarized and

pooled with the cases reported in the literature.

Pooled literature analysis

We performed a literature search of Pubmed and Ovid for terms: collagenous gastritis, lymphocytic gastritis and Collagenous colitis. Accrued publications were filtered for inclusion of pediatric subjects. Related articles for relevant publications were also reviewed. Articles including pediatric subjects were accrued. We identified sixty peer reviewed publications from Pubmed and an additional 30 publications from Ovid. We excluded duplicate patient reports when identifiable and series where individual therapy and outcome pairs could not be determined.

We abstracted relevant demographic, clinical, endoscopic-histopathologic findings at presentation and upon follow up whenever available and all therapeutic interventions whenever reported. Reports defining therapeutic modalities and clinical or endoscopic-histopathologic outcome were included with our two cases above.

Case 1

An 11 year old boy presented with profound, symptomatic iron deficiency anemia (hemoglobin 4.7 g/dL, mean corpuscular volume 52, serum iron 10 mg/dL, serum ferritin $< 1.5 \text{ ng/dL}$), thrombocytosis (platelets were $540\,000/\mu\text{L}$). Celiac serology was negative. Upper endoscopy and colonoscopy with biopsy showed marked inflammatory changes and nodularity in the gastric body mucosa but otherwise normal findings. The corresponding gastric biopsies showed a mixed mucosal lymphocytic - neutrophilic infiltration and a prominent subepithelial collagen band ($> 10 \mu\text{m}$) that stained positive with Masson Trichrome. Wireless capsule endoscopy was also negative. The patient was treated with oral iron supplements, then standard dose omeprazole with continued periodic treatment with oral iron. Upon repeat esophago-gastroduodenoscopy at 16 years of age biopsies showed marked interval improvement in gastritis, the development of multiple gastric (fundic gland) polyps and resolution of the collagenous band. He is asymptomatic and has been weaned off omeprazole and is being monitored for iron deficiency.

Case 2

A 7 years old girl presented with chronic, mild, diffuse abdominal pain and pallor. Laboratory investigations confirmed iron deficiency anemia (hemoglobin 4.6 g/dL, mean cell volume 59.7, serum ferritin $< 1.5 \text{ ng/dL}$) with platelets count of $435\,000/\mu\text{L}$ normal inflammatory indices (erythrocyte sedimentation rate and C-reactive protein), and negative celiac serology. Upon upper endoscopy and colonoscopy with biopsy moderate to severe hemorrhagic gastropathy was noted and the corresponding biopsies were reported showing a thick Masson Trichrome staining subepithelial hyaline band partly enveloping some of the superficial glands and moderate superficial chronic inflammatory infiltrate (Figure 1). The rest of the upper intestinal biopsies as well biopsies and

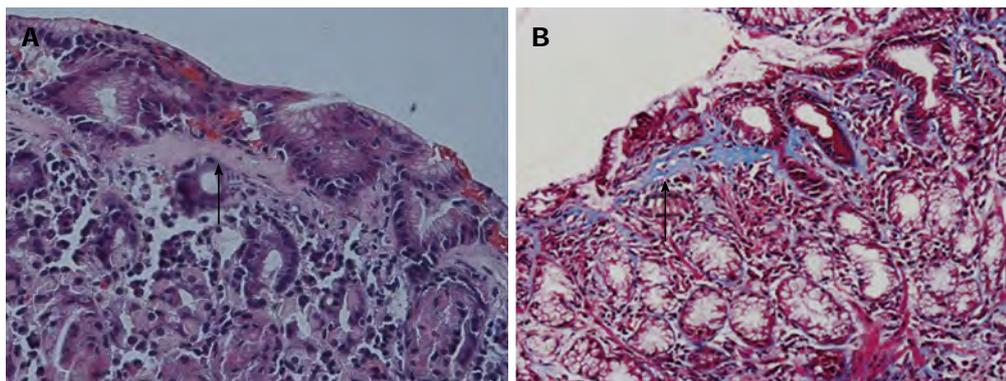

Figure 1 Gastric body surface epithelium showing marked thickening of subepithelial collagen in hematoxylin and eosin stain $\times 200$ (arrow in A) or in masson trichrome $\times 200$ stain (arrow in B) with many intraepithelial lymphocytes.

endoscopic findings on complete simultaneous colonoscopy were normal.

The patient received standard dose esomeprazole approximately 1 mg/kg per day and oral iron supplementation (sodium ferredetate) for 6 mo but upon follow up was reporting episodic, postprandial abdominal pain with corresponding epigastric tenderness on exam. Repeat endoscopy showed unchanged gross and histopathologic findings.

The treatment was escalated in view of refractory disease to include budesonide capsules (6 mg) crushed and suspended in 5 mL of fish oil given orally, daily and continuing esomeprazole and iron supplementation. Upon follow up, in 6 mo she was noted to have improved symptoms, mild constipation and was weaned off supplemental iron. Repeat endoscopy showed grossly improved gastritis (minimal diffuse antral nodularity), interval decreased inflammatory infiltrate but persistent collagen band on most biopsies. The patient was continued on the same medical treatment regimen and on follow up after a further 6 mo was noted to be asymptomatic, with stable hematologic indices.

Our search identified 16 publications and 22 pediatric cases with CG; their clinical presentation showed that anemia was predominantly observed in 17 cases (71%), Abdominal pain in 10 (41%), vomiting in 4 (17%), diarrhea in 4 (17%) and other presentations in 4 (17%) such as failure to thrive and hemocult blood, hememesis and chest pain. their demographic data, therapeutic modalities duration of follow up and outcomes were pooled with our two cases and summarized in Table 1^[1,2,4,6,9-20]. The majority of patients (17) were female, the mean age at presentation was 11.7 years (SD 4.5 years) and similar for both genders.

Gross endoscopic findings were abnormal in all reported cases, several showed gastric mucosal nodularity (11/24). Other reported finding were erythema, erosions, ulceration and hemorrhages in the gastric body, fundus and to a lesser extent in antrum.

Simultaneous colonoscopic findings were reported in 12 patients including 8 patients with gross and histological normal findings; in 3 patients there was collagenous

colitis. In addition, an infantile case showed diffuse atrophic mucosa and increased subcutaneous collagen throughout gastrointestinal (GI) tract sections^[10,11].

When reported (18 patients), the duration of follow up ranged (mean) between 0.2-14 (4) years. Duration of follow up did not significantly correlate with a consistent change in either outcome measure or disease phenotype. This is reflected by the reports by Winslow *et al.*^[13] and Kamimura *et al.*^[15], wherein follow up of 12 and 14 years respectively, and therefore into adulthood did not report features of adult onset type CG.

Despite most subjects presenting with anemia, with one patient requiring blood transfusion, oral iron therapy was only documented in 12 patients. Other treatment modalities were antisecretory measures in 13 patients; Proton pump inhibitors (12), or histamine-2 blockers (3). This includes 3 patients who received triple therapy for *Helicobacter pylori* (*H. pylori*) gastropathy in relation to the findings of CG. Sucralfate was used either alone or combined with other therapy in 5 patients.

Oral steroids were trialed in 9 patients either as systemic steroids (6) or oral budesonide (3) or were not specified (1). Steroids were used after other therapeutic modalities were ineffective. There were no cases reported in which steroids were able to eradicate the symptoms alone; in 6 cases intermittent response was noted; this included improved hematological indices or normalization of growth while recurrence of symptoms occurred in 3 cases after discontinuation of therapy^[1,10,17]. The use of topical steroids produced variable success in 3 cases^[10,12] and case 2. Our case used budesonide in fish oil and showed clinical and hematological improvement that led to eventual weaning of steroids.

In 6 individuals with CG treated with steroids and who underwent repeat endoscopy, histopathology was reported showing unchanged mononuclear (MN) cell infiltrate and collagen band in 3 patients increase in MN cells infiltrate in 2 patients and resolution of MN cells with decreased thickness of collagen in one case.

Additional measures included isolated patients treated with misoprostol, furazolidone, metronidazole and bismuth subsalicylate, hypoallergenic diet, gluten free

Table 1 Demographic outline, treatment modalities, clinical course and outcome pooled cases of collagenous gastritis in children

| Study | Age/gender | Treatment modalities | F/U | Histologic outcome | Clinical outcome |

F/U: Duration of follow up (yr); IEL: Intraepithelial lymphocytosis; MN: Mononuclear; N/R: Not reported; TPN: Total parenteral nutrition; F: Female; M: Male; CG: Collagenous gastritis; PPI: Proton-pump inhibitor.

diet and parenteral nutrition. Mesalamine was prescribed in 3 cases that were reported with concomitant collagenous colitis.

The clinical outcome was reported in 22 patients, repeat endoscopy and therefore histologic follow up was reported only in 17 patients. Three out of 22 patients showed no clinical improvement despite therapy; conversely, 19 out of 24 were reported with improved symptoms including 8 patients with complete symptom resolution. Spontaneous clinical resolution without anti-secretory, anti-inflammatory or gastroprotective agents was noted in 5 patients (4 received only supplemental oral iron).

Complete resolution of symptoms was also reported after the use of oral prednisone in a patient with concomitant CC whereas another three patients with concomitant CC treated with mesalamine were reported with variable response.

In the patients with repeat endoscopy-histopathology reported; persistent histopathologic abnormalities were reported in 12 cases including persistent collagen band and stable mononuclear cell infiltrate. Histopathologic improvement was shown in 5 cases, 3 of them with decreased mononuclear cell infiltrate and decreased/resolved collagen bands in 2 patients on repeated endoscopy. In contrast, mononuclear cell infiltrate was increased in 2 patients^[3,13]. Neither MN cell infiltration nor the collagen band changes correlated with the clinical course. Intestinal metaplasia and endocrine cell hyperplasia were reported in one case raising the concern of long term malignant transformation^[13].

DISCUSSION

Collagenous gastritis is a rare diagnosis in children; its pathophysiology is unknown and is complicated by overlap with lymphocytic gastritis and celiac disease^[8,12]. Pediatric CG is more common in girls and tends to present with severe anemia. In some cases pediatric CG coexists with collagenous sprue and collagenous colitis. The adult phenotype of collagenous gastritis is, in turn, associated with autoimmune disorders. The natural history, treatment modalities and long term outcome of pediatric CG are unknown. Herein, in addition to reporting two new cases of CG and a novel approach to treatment, we have reported on the most comprehensive review to date on the treatment modalities, response and outcome in children with CG described in the peer-reviewed literature.

The demographic outline and clinical presentation of our filtered dataset of treated children with CG and with described clinical and, or endoscopic-histopathologic outcomes reported appears representative of the whole population of pediatric cases reported in the literature. Our subset of cases includes a predominance of females, the mean age at diagnosis is 11.7 years and the duration of reported follow up (4 years) attests to the chronicity of the disease.

The presenting symptoms in our study; abdominal

pain and iron deficiency anemia are identical to those reported elsewhere^[9]. Although the pathophysiology of the iron deficiency remains unclear, most reports include the use of enteral iron supplementation and we have not come across any reference to parenteral iron supplementation alone, suggesting that blood loss rather than malabsorption, is thought to be the cause of iron deficiency.

Half the patients included in this series had undergone colonoscopy; four (16%) had collagenous colitis and three of them were treated with anti-inflammatory measures including mesalamine^[11,17,18]. It was unclear whether lower gastrointestinal symptoms were present in the patients undergoing colonoscopy; it is likely that, as in our patients, this was mandated by suspicion of GI hemorrhage at the time of presentation. The collagen deposition of the entire gastrointestinal tract described in these cases was similar to those described in adult phenotype in their presentation. Although the reported subepithelial deposit in collagenous colitis tends to spread diffusely and continuously, collagen deposition and inflammatory infiltrate in collagenous gastritis tend to vary and are often irregular. The theory behind involvement of colon in some of these patients is that collagen bands arise from panenteric insult through the same pathological process in susceptible individuals, generally more severe in the colon in adulthood compared to children^[9]. Anti-inflammatory drugs including corticosteroids have variable effect on collagenous colitis although relapses can occur, and diarrhea may resolve with or without treatment.

In our pooled analysis, coexistent collagenous colitis did not correlate with a worse prognosis. It is reasonable however to recommend colonoscopy in all patients with CG at the time of initial diagnosis in view of a potential response to therapy if coexistent CC is diagnosed.

A proven therapeutic paradigm does not exist for CG and our review failed to define a consistent response to the therapeutic strategies that were reported in the literature. It appears that the consensus approach to the treatment of isolated CG includes oral supplementation to address iron deficiency as discussed above; anti-secretory strategies, especially proton-pump inhibitors, and anti-inflammatory measures including systemic and, as in our case topically active steroids. In 3 of the patients, concomitant *H. pylori* infections were noted and warranted triple therapy^[6,14]. Measures to detect *H. pylori* on endoscopy are therefore indicated when CG is diagnosed or suspected. This also raises interesting speculation of the possible association of *H. pylori* in the causation of CG.

A therapeutic strategy that includes long term anti-secretory and anti-inflammatory measures has its limitations, central to which, given the chronicity of the disease, is adverse events from long-term treatment. This is especially true given that our analysis is the first to suggest that pediatric CG is, in the most part an indolent, benign process. Adverse effects include systemic steroid side effects are exhaustively described elsewhere^[21]. There are other potential adverse events, for example, the association of proton-pump inhibitor (PPI) use with neu-

roendocrine tumors as suggested by Winslow *et al*^[13] in one patient in our pooled reports. PPI are also reported to interfere with iron absorption^[22]. It therefore follows that, in addition to a clear explanation of our limited understanding of the efficacy of our treatment modalities, aside from oral iron supplementation, parents should also be offered treatments with the least adverse effects and for the shortest possible duration. Histamine-2-receptor Antagonists may be as suitable as PPI but entail less concern with long term use. Steroids may be considered a bridging therapy to achieve clinical and hematological response although there is a significant risk of recurrence of symptoms with discontinuation of therapy. Budesonide may be as efficacious as, and entail less potential for toxicity as systemic steroids.

There seems to be very limited evidence of restriction diet or gluten free diet improving CG. One patient was reported to respond to total parenteral nutrition but this seems an isolated case^[10]. Several other treatment modalities (*e.g.*, furazolidone) were also reported but with limited success.

This report highlights the disconnect between the endoscopic-histopathologic abnormalities that, in the large part, persisted in those patients with follow up endoscopy and the clinical outcome that was typically benign. This is especially true of the reported thickness of the pathognomonic sup epithelial collagen band that remained unchanged in most of the patients. This observation contrasts with the conclusions drawn by Leung *et al*^[12] who suggested that collagen thickness may correlate with severity of disease. In addition, mononuclear cell infiltrate did not correlate with collagen band thickness or clinical outcome.

In two reported cases, long term follow up over 12 years and into adulthood did not; however show a reversion to the adult-phenotype of the disease. This includes a 35-year-old woman presenting with a nodular pattern on Barium X-ray screening study 14 years after her initial presentation^[15]. In this patient the endoscopic and histological findings of this disease were shown to progress gradually in absence of therapy. Endoscopically, the nodular appearance became more conspicuous, in addition to a thicker collagen band evident on biopsy in the context, however, of resolved clinical symptoms. In contrast, Winslow *et al*^[13] reported on collagenous gastritis in a single patient who received multiple therapies including anti-inflammatory treatment during a 12-year period. The patient's biopsy specimens showed a significant corpus endocrine cell hyperplasia, leading to speculation on an increased risk of endocrine neoplasia with gradual progression in disease severity, and unchanged collagen band over the 12-year period. In both cases no colonic involvement as described in adult phenotype reported after this long period. These reports suggest that the pediatric and adult disease phenotypes are different and that the pediatric form does not evolve in the adult form.

This study has several limitations; it is an attempt at a review of case reports and case series that were not, in

the large part focused on therapy, response or long term outcome. There is potentially significant heterogeneity in the accuracy of reporting follow up duration, therapeutic modalities, histopathological and clinical response. Our sample size is a further significant limitation that impacts on the conclusions that can be drawn. Further studies with a more consistent method of qualifying endoscopic-histologic abnormalities are needed.

In conclusion, collagenous gastritis in children tends to be an isolated process that follows a generally benign course with limited long-term morbidity and no increased mortality reported to date. Initial investigation in children with CG needs to include investigation for *H. pylori* and colonoscopy to rule out collagenous colitis. Routine extensive investigation for autoimmune disorders appears unjustified. Response to medication is variable and needs to be individualized with the proviso that anecdotal evidence synthesized in this paper supports the use of oral iron supplementation and the judicious use of anti-secretory and anti-inflammatory agents for the shortest time feasible.

Abstract

Choroidal or cutaneous metastasis of gastric cancer is rare. Gastrointestinal cancer was found in only 4% in patients with uveal metastasis. Choroidal metastasis from gastric cancer was reported in two cases in earlier literature. The frequency of gastric cancer as a primary lesion was 6% in cutaneous metastasis of men, and cutaneous metastasis occurs in 0.8% of all gastric cancers. We report a patient with gastric adenocarcinoma who presented with visual disorder in his left eye and skin pain on his head as his initial symptoms. These symptoms were diagnosed to be caused by choroidal and cutaneous metastasis of gastric adenocarcinoma. Two cycles of chemotherapy consisted of oral S-1 and intravenous cisplatin (SPIRITS regimen); this was markedly effective to reduce the primary gastric

lesion and almost all the metastatic lesions.

INTRODUCTION

Gastric adenocarcinoma is one of the most common causes of death from cancer worldwide and more than half of the world's gastric adenocarcinoma cases arise in Asia^[1]. Gastric adenocarcinoma usually develops slowly but eventually grows to show multiple sites of metastasis. Choroidal metastasis of gastric cancer is, however, extremely rare. The uvea consists of the iris, ciliary body, and choroid. Uveal metastasis was reported in 4% of the patients who had a primary cancer in the gastrointestinal tract. Metastasis was found in the iris in 90 (9%), ciliary body in 22 (2%), and choroid in 838 (88%) of the 950 metastatic foci in the uvea^[2]. Cutaneous metastasis of gastric cancer is also relatively rare^[3,4]. We report a patient with gastric adenocarcinoma who presented with a visual disorder in his left eye and skin pain on his head as his initial symptoms.

CASE REPORT

A 75-year-old man visited our hospital in February 2011

Figure 1 Cutaneous metastasis lesion in the head. A: One of the two cutaneous nodules on his head at first visit; B: The size of the cutaneous tumor was rapidly enlarged at 1 mo after the first visit.

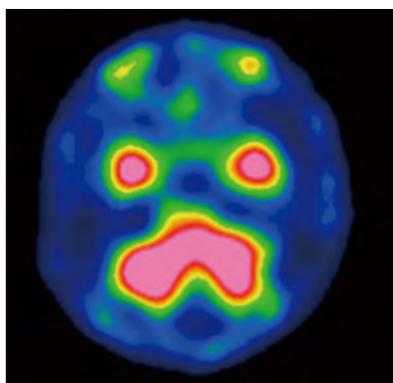

Figure 3 N-isopropyl-p-(123I) iodoamphetamine single photon emission computed tomography findings. 123I iodoamphetamine single photon emission computed tomography showed no accumulation in bilateral eyes.

because of a visual disorder in his left eye and skin pain on his head. He had two cutaneous nodules on his head. One of the cutaneous nodules grew rapidly one month after the first visit (Figure 1A and B). To evaluate the cause of the visual disorder, fundoscopic examination (Figure 2A), optical coherence tomographic examination (Figure 2B), and magnetic resonance imaging (MRI) (Figure 2C and D) were performed and an elevated choroidal neoplasm was detected. Uveal melanoma is known as the most common primary intraocular malignant tumor^[5]. The diagnostic efficacy of N-isopropyl-*p*-(¹²³I) iodoamphetamine single photon emission computed tomog-

raphy (¹²³I-IMP SPECT) for uveal melanoma has been established^[6]. We performed ¹²³I-IMP SPECT to evaluate the elevated choroidal neoplasm. It, however, showed no accumulation in bilateral eyes that is not specific for melanoma (Figure 3). We diagnosed his choroidal tumor as metastatic tumor, not melanoma.

To detect the primary malignancy, we performed 18F-fluorodeoxyglucose-positron emission tomography/computed tomography (18-FDG-PET/CT) and it showed multiple uptake in the stomach, the bilateral adrenal glands, the abdominal lymph nodes, the right pubis, the femur, and one of the head nodules, but there was no abnormal uptake in his left eye. He underwent esophagogastroduodenoscopy because of the gastric hot spot in the 18-FDG-PET/CT. Endoscopic finding revealed an advanced gastric cancer on the lesser curvature of the stomach (Figure 4A). Gastric biopsy specimens showed moderately differentiated adenocarcinoma (Figure 4B). Pathologic examination of the biopsy specimens of the cutaneous nodule also revealed poorly differentiated adenocarcinoma. Carcinoembryonic antigen (CEA) and alpha fetoprotein (AFP) were elevated to 82 ng/mL and 21 ng/mL, respectively. Abdominal contrast-enhanced CT showed multiple liver metastases, in addition to the known lesions. Thus, we made a final diagnosis of stage IV gastric cancer with multiple metastases; cutaneous, choroid, bilateral adrenal glands, lymph nodes, and liver, right pubis, femur (T4N2M1).

We started chemotherapy with oral S-1 (40 mg/m², twice a day, on days 1-21) and intravenous cisplatin (60 mg/m², on day 8), every 5 wk (SPIRITS regimen)^[7]. Chemotherapy was effective at shrinking a primary gastric

lesion (Figure 5A), an elevated choroidal lesion (Figure 5B and C), and other metastatic tumors, and improving skin pain relief on his head after 2 cycles, but was not effective in treating the larger cutaneous lesion of the head. The larger cutaneous nodule of the head increased from 25 mm to 32 mm (Figure 5D). Serum levels of CEA and AFP decreased to 8 ng/mL and 8 ng/mL, respectively.

DISCUSSION

Gastric adenocarcinoma shows multiple sites of metastasis. The most common metastatic sites from gastric cancer are liver, peritoneum, and non-regional or distant lymph nodes. Choroidal metastasis is extremely rare, and cutaneous metastasis is also relatively rare. In our case, the initial symptoms related to an advanced gastric cancer showed a visual disorder in his left eye and skin pain on his head. Therefore we reported this case as a remarkably rare case because of both metastases occurring concurrently.

Choroidal metastasis has been increasing due to the improvement of ophthalmic diagnosis techniques. A previous report showed choroidal metastasis mostly comes from breast and lung cancers. In a survey, gastrointestinal cancer was found in only 4% of 420 patients with uveal metastasis^[2]. Choroidal metastasis from gastric cancer was reported in two cases in earlier literature^[8,9], and these cases were found to be recurrent cases of gastric cancer. To the best of our knowledge, this is the first case in which a

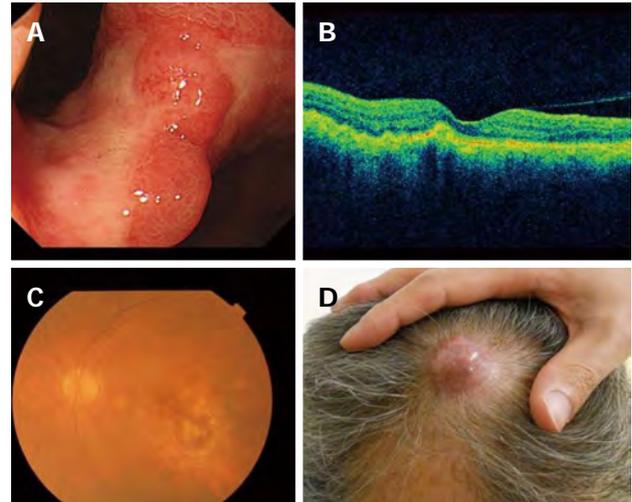

Figure 5 Response to chemotherapy. A: The primary gastric lesion was markedly reduced after 2 cycles of chemotherapy; B, C: The choroidal metastatic tumor was also markedly reduced; D: The larger cutaneous nodule of head enlarged from 25 mm to 32 mm, and headache vanished.

choroidal tumor was found because of a visual disorder as the first symptom before gastric cancer was diagnosed.

In this case, we could not pathologically diagnose the choroidal tumor of this patient as a metastatic tumor. Generally, melanoma and metastatic tumors are the most common malignant choroid tumors^[5]. Therefore we needed to differentiate melanoma and metastatic tumor. Normally, ^{123}I -IMP SPECT is clinically useful for the differential diagnosis of these conditions^[6]. In this case ^{123}I -IMP SPECT showed no accumulation in bilateral eyes. In addition, MRI of the orbits demonstrated a well-circumscribed subretinal mass, where the T1-weighted image was isointense and the T2-weighted image was hypointense. MRI findings were also compatible with a metastatic tumor, not a melanoma^[10]. Chemotherapy for the gastric adenocarcinoma was effective in treating the choroidal tumor. In general, malignant melanoma is resistant to chemotherapy and its treatment regimen is quite different from gastric adenocarcinoma^[11,12]. In our case, the choroidal tumor was markedly reduced in size after chemotherapy for gastric adenocarcinoma (consisting of S-1 and cisplatin). Based on these reasons, it would be appropriate to diagnose this choroidal tumor as a metastatic tumor, not a melanoma.

The frequency of cutaneous metastasis is relatively low, and varies with gender according to the type of underlying malignancies. The most common origins of cutaneous metastasis were reported in lung cancer, colon cancer, melanoma, squamous cell carcinoma of the oral cavity, and renal cell carcinoma in men^[3]. On the other hand, the most common origins in women were breast cancer, colon cancer, melanoma, ovarian cancer, and lung cancer^[3]. The frequency of gastric cancer as a primary lesion was 6% in cutaneous metastasis of men^[3], and cutaneous metastasis occurs in 0.8% of all gastric cancers^[13]. In addition, the cutaneous metastasis was reported to

be close to the site of the primary tumor, therefore the abdomen was the most frequent site in gastric cancer^[14]. Our patient, however, had cutaneous metastasis only on his head and we could make a pathological diagnosis based on pathological findings.

In summary, choroidal or cutaneous metastasis of gastric cancer is rare. We report a patient with gastric adenocarcinoma who presented with both choroidal and cutaneous metastasis of the gastric cancer as initial symptoms.

Abstract

A 36-year-old male was admitted with right lower abdominal pain and diarrhea for more than 3 mo. Colonoscopy and a barium enema study revealed a submucosal tumor over the cecum, but computed tomography showed an ileal lipoma. There was no definitive diagnosis preoperatively, but ileocolic intussusception was noted during surgery. Single port laparoscopic radical right hemicolectomy was performed because intra-operative reduction failed. The histological diagnosis of the resected tumor was lipoma. Single port laparoscopic surgery has recently been proven to be safe and feasible. There are advantages compared with conventional laparoscopic surgery, such as smaller incision wounds, fewer port site complications, and easier conversion. However, there are some drawbacks which need to be overcome, such as difficulties in triangulation and instrument clashing. If there are no contraindications to laparoscopy, single port laparoscopic surgery can be performed safely and should be considered for diagnosis and treatment of intussusception in adults. Here, we report the first case of ileocolic intussusception successfully treated by single port

INTRODUCTION

Intussusception is primarily a childhood disease. It is uncommon in adults and about 70%-90% of adult intussusception cases have a leading cause^[1,2]. Lipoma, which frequently arises in the terminal ileum, is the second most common benign tumor of the small intestine, and it tends to cause intussusception^[3]. As adult patients are at high risk of malignancy, surgical intervention is recommended in cases of intussusception. In recent years, laparoscopic surgery has been able to confirm the diagnosis and to resect the tumor causing intussusception of the small intestine in adults^[4]. Furthermore, single port laparoscopic surgery has been used for various abdominal procedures with safety and feasibility^[5]. We report the first case of ileocolic intussusception successfully treated by single port laparoscopic radical right hemicolectomy.

CASE REPORT

A 36-year-old male was admitted because of right lower abdominal pain and diarrhea for more than 3 mo. Colonoscopy disclosed a submucosal tumor over the cecum. The mass was a ball-like form with an eroded surface

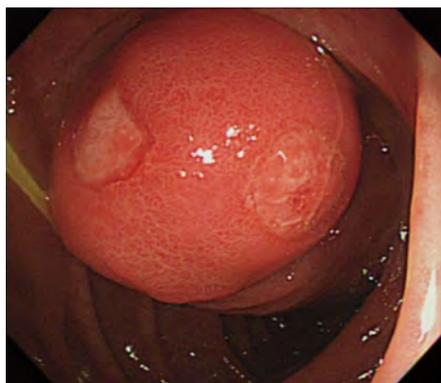

Figure 1 Colonoscopy disclosed a submucosal tumor over the cecum. The mass was a ball-like form with eroded surface.

Figure 3 Barium enema study showed a bulging lesion over the cecum.

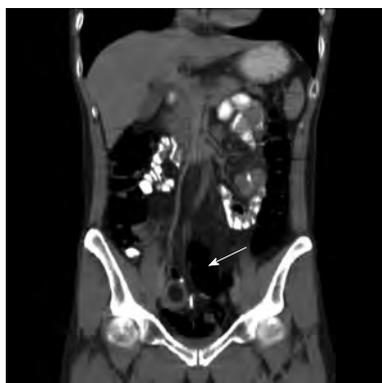

Figure 2 Computed tomography scan showing a round and low density mass about 2.5 cm in the right pelvic region.

Figure 4 The terminal ileum had invaginated through the ileocecal valve and ileocolic intussusception was observed.

(Figure 1). The tumor was initially diagnosed as an ulcer and confirmed by biopsy.

On physical examination, no palpable mass was noted in the abdomen. There was no swelling of superficial lymph nodes. He had no specific past history or family history. Laboratory studies on admission yielded normal blood hematology and chemistry results. The levels of carcinoembryonic antigen and carbohydrate antigen 19-9 were within normal limits. An X-ray of the abdomen was normal. An abdominal computed tomography scan showed a round and low density mass about 2.5 cm in the right pelvic region (Figure 2). A barium enema study showed a bulging lesion over the cecum (Figure 3).

The diagnosis was a cecal submucosal tumor or ileal lipoma. His symptoms were not remarkable. Thus, elective single port laparoscopic right hemicolectomy or single port laparoscopic enterotomy with lipoma resection was scheduled. Through inspection of the abdomen *via* the single port, the terminal ileum was found to be invaginated through the ileocecal valve, and ileocolic intussusception was observed (Figure 4). Initially, we tried manipulation and reduction of the intussusception, but failed. Then we performed single port radical right hemicolectomy because of the high risk of a malignant cause.

For the single-port laparoscopic approach (Figure 5), a vertical incision was created through the umbilicus ap-

proximately 3 cm in length to accommodate the single-port access device. The SILS Port from Covidien Inc. (Mansfield, MA, United States) was used as the single-port access device. This included an insufflation attachment and 3 access ports with associated minitrochars. A rigid 10-mm, 30° laparoscope was used for viewing and 5-mm instruments were used for manipulation of tissues and dissection. In general, a lateral to medial approach was used. The hepatic flexure and lateral peritoneal reflection was mobilized from superior to inferior. The ileocolic pedicle was elevated to allow dissection beneath the ileocolic vessels with identification of the origin of the right colic artery and then the duodenum. The right colon and proximal transverse colon were then lifted off the retroperitoneum. The ileocolic vascular pedicle underwent ligation with the use of a high energy device. The portion of the omentum attached to the specimen was then divided proximally. The right branch of the middle colon was divided. After placement of a wound protector, the tumor was exteriorized *via* the umbilical incision. After resection of the tumor, ileocolic end-to-end anastomosis was performed. The bowel was returned to the abdomen, and then reexamined *in situ*. The fascial incision was closed with a Vicryl suture. Care was taken to maintain oncologic principles, with tight vascular ligation and minimal tumor manipulation. The total surgical time was 3 h and blood loss was about 30 mL.

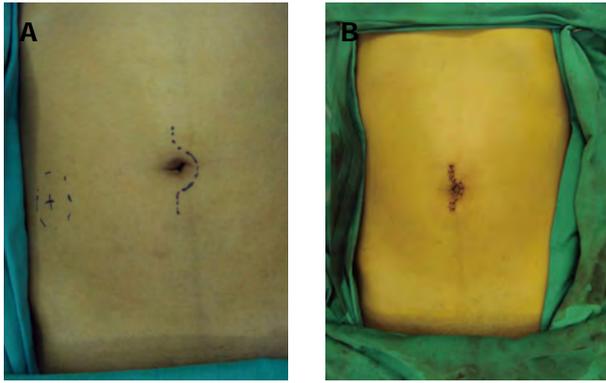

Figure 5 Single-port laparoscopic approach. A: A vertical incision was created through the umbilicus approximately 3 cm in length which accommodated the single-port access device; B: Postoperative suture wound.

The diagnosis was ileocolic intussusception caused by lipoma in the ileal region. Macroscopically, the tumor measured 2.5 cm × 2.5 cm × 2.0 cm, and was located 15 cm from the ileocecal valve (Figure 6). The tumor was ball-like with an irregular surface and soft consistency. The cut surface was yellowish-white, and histopathologic examination revealed fat cells proliferating in the submucosal layer. These characteristics confirmed a diagnosis of lipoma of the ileum.

Postoperative recovery was good and the patient was discharged on the 7th postoperative day. At present, 3 mo after surgery, he is free of symptoms and continues an uneventful course.

DISCUSSION

Single port laparoscopic surgery has been performed for the resection of benign and malignant gastrointestinal tumors in recent years; however, its safety and feasibility is still controversial. Waters *et al*^[6] reported that single port laparoscopic right hemicolectomy is a safe and effective technique for cases of colonic malignant and benign lesions. There are also several reports of benign ileocolic intussusception successfully treated by laparoscopy^[7]. Here, we successfully resected an ileal lipoma causing intussusception using single port laparoscopic radical right hemicolectomy, and to date, no report has described an ileocolic intussusception caused by ileal lipoma which was resected *via* single port laparoscopy.

In 1956, Dean *et al*^[8] classified adult intussusception as enteric; colocolic; ileocecal, with the ileocecal valve as lead point; and ileocolic, with the ileum through the ileocecal valve. The most common type is enteric, occurring in 43% of patients^[9] and our patient had the ileocolic type with ileal lipoma as the leading cause.

Adult intussusception is an uncommon clinical entity encountered by surgeons. The exact mechanism is unknown. However, it is believed that any lesion in the bowel wall or irritant within the lumen that alters normal peristaltic activity is able to initiate an invagination^[2,10]. Ingested food and subsequent peristaltic activity of the

Figure 6 The round tumor measured 2.5 cm × 2.5 cm × 2.0 cm in size and was 15 cm from the ileocecal valve.

bowel produce an area of constriction above the stimulus and relaxation below, thus telescoping the lead point (intussusceptum) through the distal bowel lumen (intussusciptiens)^[1,2,10]. The most common locations are at the junctions between freely moving segments and retroperitoneally or adhesively fixed segments^[11].

The signs and symptoms of pediatric intussusception include a classic triad of a palpable mass, current jelly stools, and pain, and occur infrequently in adults. Adult intussusception commonly presents with nonspecific signs and symptoms similar to a bowel obstruction, such as colicky pain or cramps, nausea and vomiting, palpable abdominal mass, fever, hematochezia, and diarrhea^[9]. The most common symptom is abdominal pain and the less common one is diarrhea. Our patient presented with chronic symptoms of abdominal pain and diarrhea. Because the symptoms often are nonspecific, correct preoperative diagnosis of intussusception is difficult. Eisen *et al*^[12] reported a preoperative diagnosis rate of 40.7%. Similarly, our patient was not diagnosed with intussusception preoperatively. However, laparoscopy is able to evaluate the entire small and large bowel and is another diagnostic tool, too. Although we could not reduce the intussusception *via* single port laparoscopic surgery in our patient, we think that this new technique may provide a better way than conventional laparoscopic surgery to manipulate and reduce intussusceptions.

Symptoms could be acute or chronic. The duration was reported as less than 7 d in 34% of patients and between 7 d and 3 mo in 48%^[13-15]. Gupta *et al*^[13] and Stubenbord *et al*^[14] reported that 22% experienced symptoms of more than 3 mo' duration, while some patients have reported symptoms lasting up to 1 year^[1]. Our patient presented with chronic symptoms for more than 3 mo. We found that the intussusception in our patient was dynamic, changing preoperatively from the colonoscopy and imaging studies. Spontaneous reduction of the intussusception may present in symptomatic or asymptomatic children and occurs more commonly than previously reported. These intussusceptions are usually short-segment, small-bowel intussusceptions with no recognizable leading cause^[16]. Only a few case reports presented a spontaneous

reduction of the intussusception in adults^[17,18]. We postulated that spontaneous reduction of the intussusception in our patient led to obstruction and chronic symptoms, and made preoperative diagnosis more difficult.

A precipitating lesion is found in 90% of adult intussusception cases, but in only 10% of pediatric patients. In most infants and young children, reduction of the intussusception may be tried using barium enema or surgery. However, in adults, definitive surgical resection remains the recommended treatment in nearly all cases because of its nonspecific nature, varying duration of symptoms, the large proportion of structural anomalies, and the relatively high incidence of malignancy^[2,19,20]. Although most authors agree that laparotomy is mandatory, the optimal surgical management of intussusception remains controversial. A reduction at surgery before resection may theoretically permit a more limited resection; however, the risks include intraluminal tumor seeding, a reduction in the externally viable bowel despite mucosal necrosis, venous embolization of malignant cells, spillage of fecal matter through inadvertent perforation, and anastomotic complications in cases of an edematous and weakened bowel^[19]. The main problem is to distinguish benign from malignant lesions before reduction. The cause of intussusception in adults varied by location. Large bowel causative lesions were more frequently malignant than small bowel lesions. The incidence of either primary or metastatic malignancy in the small bowel was 31% compared with 70% in colon lesions^[9]. Benign lesions, including lipomas that cause intussusception were predominantly found in the cecum and terminal ileum^[1,21]. The most common benign lesions of the colon causing intussusception were lipomas^[21].

In our patient, a cecal submucosal tumor or ileal lipoma was suspected preoperatively, but ileocolic intussusception was diagnosed during surgery. Because a benign lesion was highly suspected as the cause, we intended to reduce the intussusception initially, but in vain. Then we decided to perform radical right hemicolectomy.

Laparoscopic surgery has been a standard strategy for a variety of gastrointestinal diseases. The use of laparoscopic surgery for benign bowel tumors and ileocolic intussusception is increasing^[4,7,9]. Single port laparoscopic surgery is a development in the field of minimally invasive surgery. Potential advantages of single port laparoscopic surgery over conventional laparoscopic surgery are thought to be related to improvement in cosmesis and incisional pain and avoidance of port site-related complications. Other aspects, namely operative time, patient selection, patient outcomes, and surgeon efficiency, showed no difference between the two procedures in the existing literature. The conversion rate between the two procedures showed no significant difference, but it is easier for single port laparoscopic surgery to convert to open surgery. Furthermore, we think that a single port can provide access for intussusception diagnosis, manipulation, and reduction.

Although single port laparoscopic surgery can be performed with a conventional rigid laparoscope and

straight instruments, the crowding over the access port usually leads to clashing of instruments. In addition, the handling of both straight instruments in parallel with the laparoscope through a small single incision decreases the freedom of motion for the surgeon and hinders handling of a laparoscope for the assistant. Furthermore, lack of tissue triangulation significantly increases difficulties in exposure and dissection of the lesion. Some of the steps must be performed using the cross-hand maneuver, which is generally avoided in conventional laparoscopy surgery. In attempts to improve surgical exposure, most surgeons use 30° laparoscopes and some used articulating or curved instruments. Some investigators recommended using longer laparoscopes to avoid cluttering of instruments.

In conclusion, we think that single port laparoscopic surgery can be performed safely for ileocolic intussusception caused by ileal lipoma in adults, and should be considered if contraindications are not present.

Abstract

Intestinal hemolymphangioma is a rare vascular and lymphatic malformation and is manifested as anaemia and recurrent alimentary tract hemorrhage. Few cases of hemolymphangioma occurring in small intestine, spleen, esophagus and other organs have been reported. We herein report a case of a 37-year-old man with severe rectal bleeding. Digital examination revealed nodular mucosa. No rectal mass was palpated, but bleeding in the ampulla was detected. Colonoscopy revealed an extensive hypervascular submucosal lesion arising from the rectosigmoid junction colon to the distal edge of the anus. Endoscopic ultrasonography demonstrated an extensive anechoic mass with clear edge. Magnetic resonance imaging (MRI) showed a significant thickness of the rectal wall, extending to the distal edge of the anus, with a narrowing lumen. A sphincter-saving rectal surgery was performed. Due to a lack of knowledge of the clinical, endoscopic and radiological features, preoperative recognition of hemolymphangioma is not easy. Computed tomography and MRI are helpful in confirming the diagnosis, and defining the

extent and invasion of the lesion. For the low malignant potential tumors, a sphincter-saving rectal surgery is recommended after a full evaluation of the tumor.

INTRODUCTION

Hemolymphangioma is very rare, and few cases occurring in the small intestine, spleen, esophagus, chest wall, mediastinum, adrenal gland have been reported^[1-6]. Hemolymphangioma occurs predominately in young patients, especially in newborns and infants, and often arises from congenital malformation of vascular and lymphatic system. It is believed that hemolymphangioma is a benign disease without invasive ability. This report describes the first case of a diffuse hemolymphangioma of the rectum.

CASE REPORT

A 37-year-old man was admitted to a local hospital because of massive rectal bleeding in November 2010. He was managed with emergency care, such as blood transfusion. Upon admission, the patient's hemoglobin was 69 g/L. He had no medical history of abdominal trauma or operation. His major symptoms were rectal bleeding and tenesmus. Because it was hard to distinguish the rectal lesions from haemorrhoids by digital examination, he started on conservative treatments such as local hemostasis. Due to recurrent bleeding, colonoscopy was

Figure 1 Colonoscopy and endoscopic ultrasonography results. A, B: Colonoscopy showed an extensive hypervascular submucosal lesion, with tortuous submucosal veins and nodular mucosa; C: Endoscopic ultrasonography revealed an extensive anechoic mass with clear demarcation.

performed, which showed an extensive hypervascular submucosal lesion arising from the rectosigmoid junction colon to the distal edge of the anus, and exhibiting tortuous submucosal veins and nodular mucosa. Biopsy was not performed to avoid the secondary severe hemorrhage. The endoscopic ultrasonography indicated an extensive anechoic mass with clear edge (Figure 1). He was transferred to our hospital with the diagnosis of a tumor at the rectum by computed tomography (CT) scan in December 2010. Physical examination revealed mild tenderness on the left lower quadrant. Rectal examination revealed nodular mucosa and red blood in the ampulla, but no obvious mass was found. No other abnormalities were found except for anemia shown in laboratory data including tumor markers such as carcino-embryonic antigen. Magnetic resonance imaging (MRI) showed significant a thickness of the rectal wall, extending to the distal edge of the anus, with a narrow lumen (Figure 2).

Based on the clinical and imaging evidence, preoperative diagnosis of the lesions was cavernous rectal haemangioma. Laparotomy showed diffuse colorectal proliferative lesions arising from sigmoid colon to anus with no ascites or peritoneal dissemination. A frozen-section

examination of the rectal mass indicated a vascular tumor. Subsequently, a sphincter-saving procedure, *i.e.*, low anterior resection of the rectosigmoid colon with hand-sewn transanal colo-anal anastomosis, was performed. The rectal mass weighed 840 g and measured 20 cm × 8 cm × 8 cm (Figures 3 and 4). Gross examination showed a cavernous, soft and compressible tumor. Microscopic examination revealed a tumor which was composed of blood and lymphatic vessels mainly located in submucosa, occupied the entire intestinal wall, and extended into the surrounding fatty tissues (Figure 5). The definitive histological diagnosis was hemolymphangioma of the rectum. No evidence of malignancy was found. The postoperative course was uneventful. The patient was discharged 12 d after surgery. After one year of follow-up, there were no complaints or signs of recurrence.

DISCUSSION

Hemolymphangioma is a very rare and benign tumor. Its incidence varies from 1.2 to 2.8 per 1000 newborns, and both genders are equally affected^[1]. In a literature review until January 2013 (PubMed), no report of hemolymph-

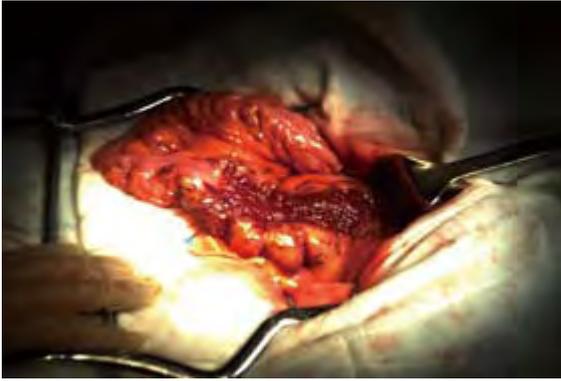

Figure 3 Diffuse colorectal proliferative lesions with no ascites or peritoneal dissemination were found during the operation.

Figure 4 The rectal mass weighed 840 g and measured 20 cm × 8 cm × 8 cm, presenting as a cavernous, soft and compressible tumor.

angioma in the rectum has been published. The primary hemolymphangioma is considered a congenital malformation of the vascular system. The formation of this tumor may be explained by obstruction of the veno-lymphatic communication between dysembryoplastic vascular tissue and the systemic circulation^[1]. Secondary hemolymphangioma is usually caused by the injury of lymphatic vessels in trauma or operation, which induces inadequate lymph fluid drainage. Hemolymphangioma often presents as a cystic or cavernous lesion. Microscopically, the tumor consists of abnormal blood and lymphatic vessels with polycystic spaces. These cysts have connective septa covered by endothelium^[7,8]. When hemolymphangioma of the intestine exists, the submucosal vascular and lymphatic network is affected, with many dilated, thin-walled and irregular blood and lymph fluid filled spaces, mainly located within the mucosa and submucosa^[1]. This tumor could also invade the adjacent structures^[8].

Hemolymphangioma of intestine is manifested clinically as recurrent, acute or chronic painless alimentary tract hemorrhage^[1]. Differential diagnoses include adenomatous polyps, tumors and hemorrhoids. Clinical examination might show mild tenderness, and nodular mucosa, however, no obvious mass could be detected. Complications like massive rectal bleeding, severe anemia, vessel compression or even pelvic organ infiltration could

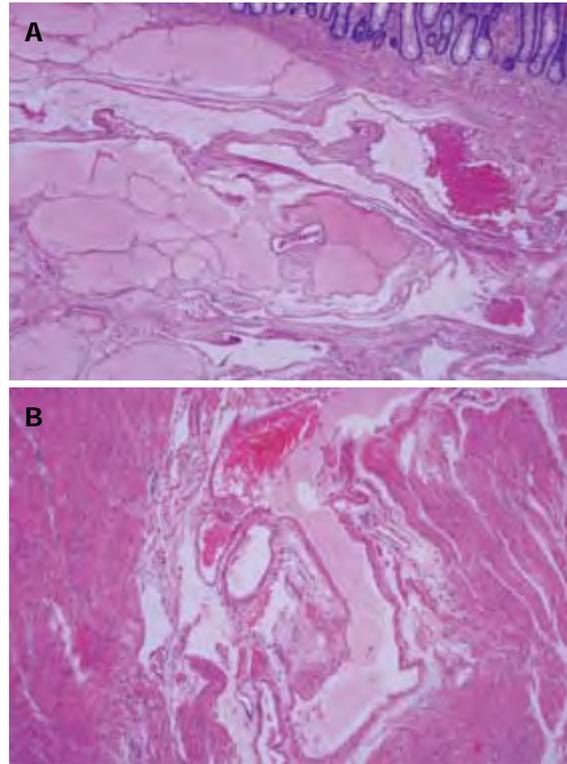

Figure 5 The tumor was composed of lymphatic and blood vessels mainly at the submucosa, occupied the entire wall (A), and extending into the surrounding fatty tissues (B).

sometimes occur.

Colonoscopy should be performed to rule out a malignancy or other problems. Elevated blue nodular lesions or dilated vessels are characteristic findings in the colon wall. Biopsy should not be performed because of the high risk of massive bleeding. The endoscopic ultrasonography is recommended because of its characteristic findings and anechoic mass with clear edge. CT and MRI are useful in defining the extent and the invasion of the mass, and planning the surgical strategy^[9]. It is very important and crucial for radiologists to recognize these lesions and establish an accurate diagnosis so as to avoid a biopsy which could cause severe hemorrhage. However, accurate diagnosis could not usually be established preoperatively.

Elective treatment should be performed and complete surgical resection of the hemolymphangioma is considered the most effective treatment. A thorough exploration of the abdominal cavity should be performed because of the potential invasion to the surrounding organs. Other options of treatment include sclerotherapy, electrocautery, radium implantation, cryosurgery and laser therapy, but these are non-surgical techniques and may only result in temporary clinical outcomes^[10,11]. Angiography and embolization can be applied in cases of acute bleeding, but rebleeding may occur. For the low malignant potential tumors, a sphincter-saving surgery is recommended after a full evaluation of the tumor, followed by sufficient follow-up^[12].

In summary, hemolymphangioma of the rectum is an uncommon vascular and lymphatic lesion, presenting

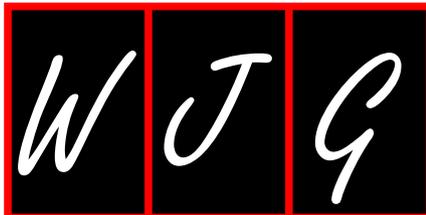

with recurrent and painless rectal bleeding. Preoperative imaging examinations such as endoscopic ultrasonography, CT and MRI are helpful in confirming the diagnosis, and in planning the surgical strategy, and a sphincter-saving surgery is recommended after a full evaluation of the tumor.

Abstract

Multiple primary carcinoma (MPC) is defined as two or more carcinomas without subordinate relationship detected in the same or other organs of an individual patient. The diagnosis of MPC must comply with the following standards: each of the tumors must present a definite picture of malignancy, each tumor must be histologically distinct, and the probability of one being a metastasis of the other must be excluded. MPC often occurs in the digestive system, but its pathogenesis remains unclear involving genetic susceptibility, tumor immunity and iatrogenic factors, including radiotherapy and chemotherapy. Most MPC patients are double primary malignancy; the occurrence of quadruple primary malignancy is below 0.1%. Here we present a rare case of quadruple primary malignancy involving the small intestine, descending colon, renal pelvis and pancreas. Due to its rarity, the relevant literature is also reviewed. In general, the incidence of MPC is rising, so prevention, early diagnosis and treatment will become necessary and important. Therefore, further research should focus on the etiology and mechanism of MPC.

INTRODUCTION

Multiple primary carcinoma (MPC) is an infrequently occurring disease that is defined as two or more carcinomas without subordinate relationship detected in the same or other organs of an individual patient. It is also called multiple primary malignant neoplasms or multiplicity cancer. The current criteria for the diagnosis of MPC were first presented by Warren *et al*^[1] in 1932: Each of the tumors must present a definite picture of malignancy, each tumor must be histologically distinct and the probability of one being a metastasis of the other must be excluded. MPC could be classified into two categories depending on the diagnosis time of each malignancy. Synchronous MPC refers to the malignancies occurring at the same time or within an interval of six months, while metachronous MPC refers to malignancies following in sequence and more than six months apart^[2]. MPC often occurs in the digestive system. Of all the MPC patients, most are double primary malignancy; the occurrence of quadruple primary malignancy has been reported to be below 0.1%^[3]. Here we present a rare case of quadruple primary malignancy involving the small intestine, descending colon, renal pelvis and pancreas. Considering its rarity, we also reviewed relevant literature.

CASE REPORT

Our patient, a 64-year-old man from Shanghai, China, is

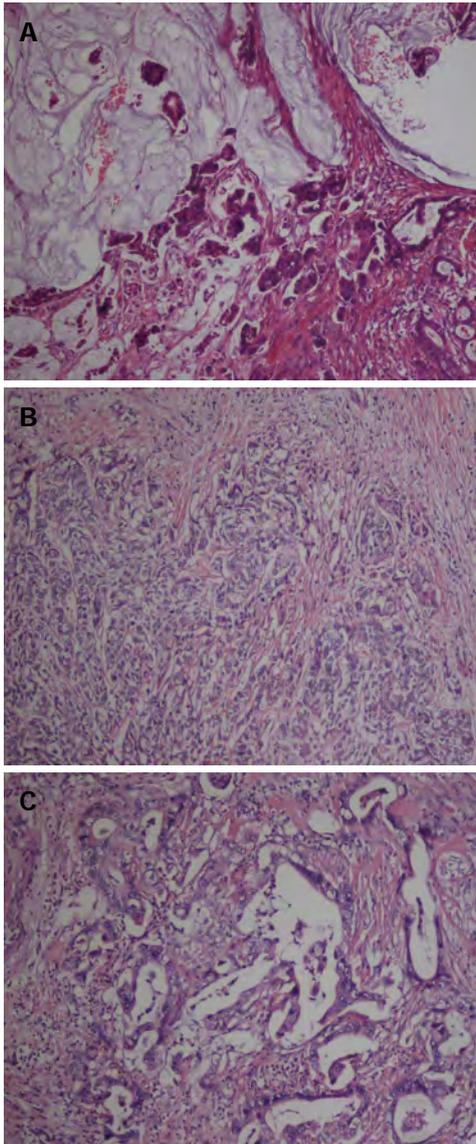

Figure 1 Pathological findings. A: Mucinous adenocarcinoma in the descending colon; B: High-grade invasive urothelial carcinoma of the pelvis; C: Grade II-III adenocarcinoma in the body and tail of the pancreas (hematoxylin and eosin staining, $\times 100$).

still alive and healthy now. He has undergone five surgeries, four for primary malignancies, and one for chronic cholecystitis and cholelithiasis. His mother died of hepatic carcinoma at the age of 81 years, and other members (his wife, daughter and younger brother) in the family have no history of malignancy. He has been suffering from hypertension for 30 years and diabetes for 20 years, and being treated with telmisartan and insulin for each disease, respectively. In addition, he is allergic to penicillin and sulfa drugs. He smokes one pack of cigarettes per day and drinks beer temperately. Other history of trauma and surgery are denied. The following are the detailed records of his medical history.

The first primary malignancy was small intestine adenocarcinoma, which was detected in 1992. According to the description of the patient, the initial symptom was mild pain in the upper abdomen. Considering his good

physical condition, he did not pay much attention to it. The pains worsened over time, and he eventually visited Shanghai Wujing Hospital. Strangely, all of the related examination results were negative, so an exploratory laparotomy was performed immediately. Exposure of the surgical site showed that the small intestine was infected and its contents poured into the peritoneal cavity. A small intestine resection surgery was necessary. The postoperative pathology result revealed small intestine adenocarcinoma. Unfortunately, we no longer have access to the surgery records or the record of the adenocarcinoma because too much time has passed. Owing to anemia caused by long-term absorption disorder after the operation, the patient underwent a blood transfusion that led to hepatitis C infection. Aside from the anemia and transfusion complications, the postoperative recovery of the patient was near perfect and he was scheduled for regular follow-up appointments.

In March 2000, the patient was sent to the Shanghai Liqun Hospital because of a six-month abdominal dull pain and a two-week mucus bloody stool. Colonoscopy performed in the outpatient department showed a tumor in the descending colon. He then underwent a surgical resection after hospitalization. The postoperative histological examination report showed an ulcerated mucinous adenocarcinoma (Figure 1A). All the surgical margins and peripheral lymph nodes were negative. The patient's postoperative recovery was excellent. He was treated with ten cycles of adjuvant chemotherapy after the operation, but the detailed regimen is not available now. All these medical treatment procedure were uneventful and he was scheduled for regular follow-up appointments.

In 2010, the patient was admitted to the department of urology of Ruijing Hospital due to observing gross hematuria symptoms for 20 d. No sign of urinary frequency, urgency, or dysuria were observed, and all physical examinations were normal except the left lumbar. B ultrasonic examination revealed the left renal pelvis was occupied by a solid mass and the ureter was expanded with hydronephrosis. In addition, an ensured abdominal computed tomography (CT) scan revealed left renal carcinoma with hydronephrosis and multiple cysts in both kidneys. Taken together, he was diagnosed as renal pelvic malignancies. Then a radical resection of the left kidney was performed. The postoperative histological examination results revealed high-level invasive urothelial carcinoma of the pelvis (Figure 1B) and vascular tumor thrombus. All surgical margins, perirenal adipose tissue and the left ureter were negative. After the operation, he underwent urinary bladder irrigation, but the detailed regimen is not available now. The patient was again scheduled for regular follow-up appointments.

At the end of 2011, he again complained of upper abdominal pain. A laboratory investigation showed that his CA 19-9 level was 1175.7 IU/mL, much higher than normal. Subsequently, an abdominal CT scan revealed a 2.86 cm \times 3.81 cm mass in the tail of pancreas. As a result of comprehensive examinations above, he was diagnosed with pancreatic cancer. Subsequently, he was im-

mediately transferred to Ruijin Hospital, where he underwent distal pancreatectomy, splenectomy and enterolysis. During the operation, a 4 cm cystic mass that infringed the retroperitoneal space was found. The postoperative histological examination reported grade II-III adenocarcinoma in the body and tail of the pancreas (Figure 1C), and positive peripancreatic lymph nodes (1/1). No tumor cells were found in the resection margins and the spleen. The postoperative recovery was uneventful and the patient was given postoperative adjuvant chemotherapy by using Xeloda. The patient is currently attending regular follow-up appointments and periodically goes to the department of general surgery for his chemotherapy.

DISCUSSION

MPC was proposed in 1889 by Billroth *et al*^[4] in the form of case report. Though there have been an increasing amount of reports on this subject since then, cases of MPC were still considered to be medical curiosities until 1932 when Warren *et al*^[1] gave an extremely detailed compilation study of 1259 cases. More importantly, they established the diagnostic criteria for MPC in their report, which is still used today. Despite its low incidence, the association of two malignancies in a single patient has been widely reported in the literature^[5-7], while only a few cases of quadruple malignancies have been described^[8]. Our patient presents a case of quadruple primary malignancy involving the small intestine, descending colon, pelvis and pancreas. All the malignancies were confirmed by surgery and postoperative pathology results, fulfilling the diagnostic criteria of MPC. Cases of quadruple primary malignancies are very rare, but what is even more astounding is the fact that this patient is still alive today, 20 years after his initial diagnosis. Further, his state of mind and physical condition are excellent, so much so that he cares for himself. Therefore we do think that this is a useful case worthy of our report.

MPC is still quite rare, but the occurrence is on the rise and differs by region and time. Age, diagnostic technique improvements, and longer life spans are all contributing factors. As is widely known and broadly accepted, age is a risk factor for many diseases, and MPC is a no exception. Spratt *et al*^[9] concluded that persons living to an extreme age were expected to have MPC with greater frequency. Another study showed that tumor survivors had a 14% higher risk of developing a new malignancy than would have been expected in the general population^[10]. Based on these findings, we speculate that countries with aging populations will begin to see more and more patients with MPC. Individual genetic susceptibility and other factors, such as hormonal stimulation, iatrogenic factors, environmental degradation and immunologic defects may be involved in the carcinogenesis and progression of MPC. However, nearly all the studies on MPC are descriptive, and detailed studies exploring the molecular mechanisms of MPC are urgently needed. Many hypotheses have been proposed to explain the

pathogenesis of MPC. Iioka *et al*^[11] observed that patients with MPC had a high frequency of microsatellite instability (MSI), arguing that MSI affected the pathogenesis of some MPC cases. Field cancerization is another possible mechanism, which suggests that when an organ is exposed to carcinogens, other nearby organs are also exposed to the carcinogens and carry a high risk of cancer^[12]. Lauchlan *et al*^[13] suggested that cancers developing in other sites originate from histologically similar epithelium. Travis *et al*^[14] discovered that radiotherapy, a kind of iatrogenic factor, following the treatment of a primary cancer lead to a second malignancy. The detailed etiology and mechanism for MPC formation still need further clarification.

Our research group has two hypotheses relating to the prevalence of MPC. The first is genetic susceptibility. All the members of a family share the similar living environment, why one does not get cancer, another may develop single primary cancer (SPC), while others may have multiple primary cancer? Maybe genetic susceptibility is a very important factor. The second is tumor immunity. The survival time of metachronous MPC patients is longer than synchronous MPC patients and metastatic SPC patients on average. A most interesting phenomenon is that the longer the interval between the malignancies, the better the prognosis of the patients (our unpublished data). Immunity abnormality is thought to exist in these patients. We speculate that the immunity of an organism is first impaired, but then is triggered and becomes strengthened by cytokines and growth factors secreted by tumor and other cells, and finally exhausted. This triggered and strengthened immunity is likely to contribute to the longer survival time of the metachronous MPC patients. Although our group has been doing relevant work and has yielded important information, both of these hypotheses still need further study and verification. In conclusion, MPC occurs rarely but is increasing in prevalence. Prevention, early diagnosis, and treatment are important factors in treating MPC. The etiology and its mechanism remain controversial, and thus further research should focus on this distinctive group - MPC patients.

Abstract

Subcapsular hepatic haematoma is a rare complication of endoscopic retrograde cholangiopancrea-tography (ERCP), and there are few reports about this unusual complication worldwide. The primary symptom of most cases reported in the literature is abdominal pain. We report an unusual case with the primary symptom of fever. A 56-year-old man who had a six-month history of recurrent episodes of upper abdominal pain was diagnosed with a common bile duct stone by magnetic resonance cholangiopancrea-tography. Endoscopic biliary sphincterotomy was performed, and stones from the common bile duct were successfully extracted with a basket. The patient had a persistent fever after ERCP, and treatment with intravenous antibiotics was unsuccessful. Computed tomography showed a 13 cm × 6 cm subcapsular hepatic haematoma filled with air and liquid on the surface of the right hepatic lobe. The patient was successfully treated with peritoneal drainage under B-ultra guidance. Subcapsular liver haematoma should be considered when hard-to- explain symptoms persist in the early period after ERCP. Percutaneous drainage is an effective treatment.

INTRODUCTION

Endoscopic retrograde cholangiopancrea-tography (ERCP) is a minimally invasive procedure for the diagnosis and treatment of biliary and pancreatic disease. Even for an expert, serious complications from therapeutic ERCP occur in 2.5%-8% of cases, with mortality ranging from 0.5%-1.0%^[1]. Pancreatitis, cholangitis, perforation, and bleeding as a result of papillotomy are the most frequently described complications^[2-6]. Subcapsular hepatic haematoma is a rare complication of ERCP, and there are few reports about this unusual complication worldwide^[7-9]. We report an unusual case of subcapsular hepatic haematoma post-ERCP with fever as the primary symptom. By contrast, the primary symptom in most cases reported in the literature is abdominal pain.

CASE REPORT

A 56-year-old man with a six-month history of recurrent episodes of upper abdominal pain was diagnosed with a common bile duct stone by magnetic resonance cholangiopancrea-tography. He was admitted for ERCP. A physical examination was unremarkable, and his laboratory tests were normal. Endoscopic biliary sphincterotomy was performed over a 0.035-inch diameter guide wire. Stones from the common bile duct were successfully extracted with a basket.

Two hours post-procedure, the patient developed a

fever (approximately 38.9 °C) without any chills. No other symptoms or findings were observed during physical examination. Laboratory tests revealed a white blood cell count of $13.3 \times 10^9/L$ [normal limit $(4-10) \times 10^9/L$] and serum C-reactive protein of 91 mg/L (normal limit < 5 mg/L). Serum amylase was elevated to 240 U/L (normal limit 30-110 U/L). We considered the cause to be cholangitis after ERCP and administered intravenous antibiotics. On the third day after ERCP, the patient complained of sudden-onset abdominal pain that disappeared after 20 min. At this time, serum amylase was normal. On the following day, the patient felt mild pain in the right upper quadrant of the abdomen without tenderness or signs of peritonism. On the 6 d post-ERCP, his laboratory data demonstrated white blood cell count of $12.3 \times 10^9/L$, neutrophils of 88.4%, and haemoglobin of 9.6 g/dL (normal 12-16 g/dL). His serum biochemistry was within normal limits. The patient had a persistent fever, and his highest body temperature was 39.4 °C. Computed tomography (CT) was performed, and demonstrated a 13 cm \times 6 cm subcapsular hepatic haematoma filled with air and liquid on the surface of the right hepatic lobe (Figure 1).

The patient was haemodynamically stable and treated with peritoneal drainage under B-ultra guidance. His body temperature returned to normal after 1 wk of drainage, and the patient gradually recovered. The drainage catheter was withdrawn after four weeks. During the following week, a follow-up CT scan showed resolution of the haematoma.

DISCUSSION

Subcapsular hepatic haematoma after ERCP is a rare complication, with few cases reported in the literature. It may be explained by an accidental puncture of the intrahepatic biliary tree by the guide wire and rupture of a small calibre intrahepatic vessel^[10].

The occurrence of persistent abdominal pain or hypotension after ERCP should raise the suspicion of subcapsular hepatic haematoma. In this case, the patient only presented with a fever within 2 d after ERCP and had no abdominal pain or hypotension. His body temperature was not controlled after the administration with intravenous antibiotics. The existence of air and liquid inside the haematoma revealed local infection, which explained of persistent fever. Therefore, persistent fever after ERCP suggests that certain precautions should be taken. Laboratory tests did not provide major indicators of the development of a subcapsular hepatic haematoma, except for a decrease in the haemoglobin level. Imaging modalities (ultrasound, CT, and magnetic resonance imaging) are the methods of choice for the diagnosis and surveillance of this complication^[11,12].

Most patients are managed conservatively. Surgical management should be considered when the general condition deteriorates, haemodynamic instability and signs of peritoneal irritation develop, and abdominal CT demonstrates free fluid. In the previously reported cases,

Figure 1 Computed tomography scan of the upper abdomen showing a 13 cm \times 6 cm subcapsular haematoma on the surface of the right lobe of the liver.

two cases^[11,13] were treated surgically and three cases^[14-16] were treated with percutaneous drainage. In this case, the patient's condition didn't improve after the administration of broad-spectrum antibiotics. Adequate percutaneous drainage was effective, suggesting that removing the liquid from within the haematoma is important.

In conclusion, subcapsular liver haematoma is a rare complication and should be kept in mind considered when hard-to-explain symptoms persist in the early period after ERCP. Conservative treatment will be sufficient in most cases. Percutaneous drainage is an effective treatment.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access (OA) journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

Aims and scope

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

WJG is published by Baishideng Publishing Group (BPG) in both electronic and online forms. All *WJG* articles are published in *WJG* website and PubMed Central. The major advantages of OA journals are faster release and delivery, no page or graph restrictions, and increased visibility, usage and impact. Full-text PDF articles and electronic/online versions are freely available to global readers. After the paper is published, the author(s) can obtain high-quality PDF files, which contain the journal cover, a list of editorial board members, table of contents, text, and back cover of the journal. BPG has a strong professional editorial team composed of editorial board members, editors-in-chief, science editors, language editors, and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15 471 editorial board members or peer reviewers, and is a world first-class publisher.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future re-

search directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers); (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, etc.; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in gastroenterology and hepatology; (12) Brief

Instructions to authors

Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (13) Meta-Analysis: To evaluate the clinical effectiveness in gastroenterology and hepatology by using data from two or more randomised control trials; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they

might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted

manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Instructions to authors

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomerybissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/..."), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Core tip

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in

Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list,

e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

Instructions to authors

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

Examples for paper writing

All types of articles' writing style and requirement will be found in the link: <http://www.wjgnet.com/esps/Navigation-Info.aspx?id=15>.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for

revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm

Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

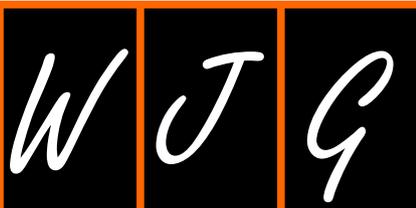

Publication fee

WJG is an international, peer-reviewed, open access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non-commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 1365 USD per article. All invited articles are published free of charge.

Abstract

The role of alcohol in causing or aggravating the pathogenesis of inflammatory bowel disease is unclear. For finding a conclusive answer for this valuable question we conducted this review. Only two studies were identified that successfully fulfilled our inclusive criteria. Usual consumption of alcohol reduced the risk compared with less frequent use (odds ratio = 0.57, 95%CI: 0.37-0.86). Light alcoholic drinking has protective effects against development of ulcerative colitis. But this inverse association disappeared when smoking was included.

INTRODUCTION

Alcohol is widely consumed in the Western part of the globe where inflammatory bowel diseases are prevalent.

However, the role of alcohol in the pathogenesis of inflammatory bowel diseases is not clear. The question is "what the role of alcohol in the pathogenesis of inflammatory bowel disease is?"

METHODOLOGY

For finding this (these) answer (s), we conducted search throughout Medline, EMBASE, Current content, CINAHL, DARE, the Cochrane Central Register, the Cochrane Database of Systematic Reviews, Joanna Briggs Institute's website, the Campbell Collaboration, the Centre for Evidence-Based Medicine, the NHS Centre for Reviews and Dissemination, ISI web of knowledge, TRIP database, INTUTE and Bandolier were searched from inception to July 2009. The search terms: alcohol (use, drinking, utilize, consume, consumption, ingestion and intake), and beverages were matched against Crohn's disease, ulcerative colitis and inflammatory bowel disease for identifying all published articles. Also, the search included reviewing the published abstracts in online journals for unpublished reports. References from relevant articles were checked as well.

Our criteria for selection were: (1) the study should be of good quality: A. the hypothesis/aim/objective of the study should be clearly described; B. a case-definition and the sources for patients and controls should be clearly described and both cases and controls were representative of their entire population; C. the selected cases should fulfill Leonard-Jones criteria (the diagnosis was confirmed by at least two investigations of these three: Barium studies, colonoscopy and/or biopsy); D. the selected controls should have no family background of inflammatory bowel diseases (Crohn's disease and ulcerative colitis). This is the minimum safest way to ensure that the selected controls had not conducted inflammatory bowel disease by excluding a hereditary genetic factor; E. clear definitions of different "alcohol drinking" categories should be plainly mentioned in the article; F. the main findings of the study should be clearly described; G. the published studies in non-English language would be excluded; (2) the study should be unbiased; (3) patients and controls should be

randomly selected and were recruited from the same population and over the same period of time; (4) the studies should not be based on long term historical recalls; (5) the statistical tests used for assessing the main outcomes should be appropriate; (6) the outcome measures should be clearly described; and (7) the outcome measures should have sufficient statistical power.

FINDINGS

Only nine studies examining the association between alcohol intake and inflammatory bowel diseases were identified. The nine studies were published in six peer review journals^[1-9] (*Z Gastroenterology*, *American Journal of Gastroenterology*, *American Journal of Epidemiology*, *Journal of Clinical Gastroenterology*, *Nippon Eisegaku Zasshi* and *Gut*). Three of them were excluded because they were written in non-English language (Brandes *et al*^[1], Katschinski *et al*^[3] and Higashi *et al*^[9]). Another two were excluded because of lack of controls (Jowett *et al*^[6] and Zutshi *et al*^[8]). A further study was excluded because the authors did not examine the association before the onset of the disease (Samuelsson *et al*^[10]). The study of Boyko *et al*^[2] was also excluded because of the lack of addressing the family background of the selected controls and the types of their diseases were not explained in the article. Therefore, only two of the nine articles fulfilled our inclusion criteria. The validated studies came from Asia with none from Europe and United States. An association between Crohn's disease and alcohol intake was not examined in either of the two studies (Table 1).

Study design

Nakamura *et al*^[4] study: A. It was a case-control study; B. Patients selection (inclusion criteria): patients were residents of areas covered by 93 selected public health centers. Patients who had begun to receive financial aid for treatment of ulcerative colitis during the period of the study were asked to participate in this survey. Three hundreds and eighty-four out of the 490 randomly selected patients with ulcerative colitis (78.4%) agreed to participate in the study; and C. Controls were healthy fit volunteers who were pair matched by age and sex to patients. They were selected randomly among those included in the schedules of health checkup programs.

Jiang *et al*^[7] study: Patients selection (inclusion criteria): 177 inpatients with ulcerative colitis were recruited prospectively from 5 major hospitals in a specified city in central China. Controls were healthy volunteers who were randomly selected among those who were neighbors and colleagues to patients. Patients and controls were matched by sex and age.

Instrument for data collection

Two studies used questionnaires for data collection. It was a self-administered questionnaire in the study by Nakamura *et al*^[4]; and the participants were interviewed to complete a detailed questionnaire in the study by Jiang *et al*^[7].

Details of alcohol consumption

(1) No indication of the level of alcohol consumption among participants in their samples was provided in either of the two studies; (2) In the study of Nakamura *et al*^[4], alcohol consumption was categorized by three levels of drinking frequency: daily alcohol drinkers: "who drank alcoholic beverages 5 d or more a week"; moderate alcohol drinkers: "who drank alcoholic beverages 1-4 d a week"; and non-drinkers: "who had drunk alcoholic beverages less than a day per week". This classification was also used in the former drinkers; and (3) But in the study by Jiang *et al*^[7], 4 categories were determined. Frequent drinking was defined as "alcoholic drinking 3 d or more per week for continuous 6 mo before the diagnosis of ulcerative colitis"; light drinking was defined as "drinking alcoholic beverages less than 3 d a week"; non drinking was defined as "never or rarely drinking"; and former drinking was defined as "patients who had quit drinking for more than 6 mo before the diagnosis of ulcerative colitis". No information was provided about either the duration of alcohol drinking or the type of alcoholic beverage.

Outcome measures

Alcohol consumption and time to onset of the disease:

Onset of the disease was defined as "the time when the related symptoms first appeared". This timing was used to discriminate between pre- and post-illness in the two acknowledged studies. No specified period before the first appearance of symptoms was determined in either.

Alcohol consumption and probability of ulcerative colitis:

Nakamura *et al*^[4] demonstrated that usual consumption of alcohol reduced the risk of developing the disease compared with less frequent use (odds ratio = 0.57, 95%CI: 0.37-0.86). But there was no significant association between ulcerative colitis and alcohol use was found by Jiang *et al*^[7].

Identification and adjustment for confounding factors:

Cigarette smoking was considered as a confounding factor by the two studies. Jiang *et al*^[7] revealed that light alcoholic drinking had protective effect against development of ulcerative colitis. But this inverse association disappeared when smoking was included.

DISCUSSION

Thousands of reports examining possible role of environmental factors in the development of inflammatory bowel disease were published. However, the outcome was trivial. It was just smoking was beneficial in patients with ulcerative colitis but was aggressive in subjects with Crohn's disease. But no reason was given. It is likely due to the use of the time of diagnosis for differentiating between pre- and post illness. But in the case of inflammatory bowel diseases as in other chronic-non-infectious diseases, the time interval between onset of the disease (conduction of the disease without symptomatic presentation) and time of diagnosis (symptomatic presentation) may be ten years

Table 1 The outcome of the study

| The study | The outcome |
|--------------------------------------|--|
| Nakamura <i>et al</i> ^[4] | Regular consumption of alcohol reduced the risk of ulcerative colitis compared with less frequent use (odds ratio = 0.57, 95%CI: 0.37-0.86) |
| Jiang <i>et al</i> ^[7] | Light alcoholic drinking had protective effect against ulcerative colitis and this effect disappeared when smoking associated with the light drinking of alcohol |

or more. Therefore, it is likely that the majority of these studies compared between two conditions of post-illness. Yet it is still possible by following this policy to assess the effect of different environmental factors on the progress of the disease.

As it can be seen from the above results, a correlation between the progress of ulcerative colitis and consumption of alcohol was investigated in only two studies. However, it was not possible to mix the results of the two studies up due to the existence of heterogeneity (different definitions on the consumption of alcohol). It is also noticeable that Nakamura *et al*^[4] failed to include light (mild) drinking in their categorization. This error was avoided by Jiang *et al*^[7]. This is likely the reason for achieving this constructive conclusion about the protective effect of light drinking in subjects with ulcerative colitis.

The reason for this beneficial effect is likely due the existence of different phenols (rich in antioxidants) in alcoholic beverages^[11]. Antioxidants have inhibitory effect against the production and function of pro-inflammatory cytokines^[12].

Yet, this beneficial action is contradicted by the activity of other contents in alcohol. Ethanol and its metabolite, "the acetaldehyde", both stimulate the production of reactive species^[13,14]. This destructive activity is dose and strength related. This may explain the reason for discovering the useful activity in only light alcohol consumers. However, it is interesting to observe that despite of the fact that both of smoking^[15] and light drinking could solely have protective effects in subjects with ulcerative colitis this advantage disappeared when both combined together. This evidently proves that the pathogenesis of inflammatory bowel disease is quite complex and the conduction of experimental studies on animal models and linking the outcome to the pathogenesis of inflammatory bowel diseases do not do any useful help but it might hurt.

OUTCOME AND IMPLICATIONS OF THE REVIEW FOR PRACTICE AND RESEARCH

People who drink regularly were at less risk for developing ulcerative colitis. Light drinking had protective effect but this effect could be abolished by smoking. Further

research studies are needed for confirming these conclusions and to assess the existence of possible correlation between different concentrations of alcohol and severity of the disease.

Abstract

Hepatocellular carcinoma (HCC) is one of the leading causes of cancer deaths worldwide, primarily affecting populations in the developing countries. Aflatoxin, a food contaminant produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, is a known human carcinogen that has been shown to be a causative agent in the pathogenesis of HCC. Aflatoxin can affect a wide range of food commodities including corns, oilseeds, spices, and tree nuts as well as milk, meat, and dried fruit. Many factors affect the growth of *Aspergillus* fungi and the level of aflatoxin contamination in food. Drought stress is one of the factors that increase susceptibility of plants to *Aspergillus* and thus aflatoxin contamination. A recent drought is thought to be responsible for finding of trace amounts of aflatoxin in some of the corn harvested in the United States. Although it's too soon to know whether aflatoxin will be a significant problem, since United States is the world's largest corn producer and exporter, this has raised alarm bells. Strict regulations and testing of finished foods and feeds in the United States should prevent a major health scare, and prevent human exposure to deleterious levels of aflatoxin. Unfortunately, such

INTRODUCTION

On August 30, 2012, Reuters reported high alert in United States grain sector because of finding of trace amounts of aflatoxin in some of the corn harvested in the United States^[1]. Since strict regulations in the United States prohibit sale of aflatoxin contaminated crops, the alert was mainly because of potential economic consequences for United States farmers. Aflatoxins are one of the most important of the environmental toxins especially in the regions of the world where dietary foodstuffs are highly contaminated. Aflatoxins are primarily produced by fungal species *Aspergillus flavus*, *Aspergillus parasiticus*, and *Aspergillus nomius*, which colonize a wide variety of food commodities including maize, oilseeds, spices, groundnuts, tree nuts, milk and dried fruit^[2]. There are several different types of aflatoxins and nearly all of them can cause illness in human beings and animals. Aflatoxin B1 is the most abundant and toxic member of the family. It is also the most potent hepatocarcinogen known. Aflatoxin B1 has been classified by the World Health Organization as a "group A" carcinogen because of its proven contribution to the pathogenesis of hepatocellular carcinoma (HCC)^[3,4].

HCC is a leading cause of cancer related death and a major public health problem worldwide^[5,6]. Annual mortality associated with HCC is virtually identical to its incidence throughout the world, underscoring the high case fatality rate of this cancer type^[7].

The incidence of HCC varies greatly according to geographic region. The distribution of HCC also differs among different ethnic groups and regions within the same country. In parts of Asia and Africa, HCC accounts for nearly 70% of cancer deaths^[8]. In China, HCC is the third leading cause of cancer mortality accounting for at least 250 000 deaths per year and with an incidence rate in some counties approaching 100 cases per 100 000 individuals per year^[9].

The differences in distribution of HCC are thought to be because of different levels of exposure to HCC risk factors. In developing countries the major risk factors for HCC are chronic infection with hepatitis B virus and exposure to aflatoxins, while in developed countries the major risk factor is cirrhosis of the liver due to hepatitis C virus infection and alcohol abuse. In developed countries the majority of HCCs occur in older patients with long-standing chronic liver disease. In regions with high frequency of hepatitis B virus carriers and aflatoxin exposure, like sub-Saharan Africa, the mean age of presentation of HCC is decades earlier than in Western countries, often decreased to as low as 33 years^[10,11].

TOXICOLOGY

Aflatoxins are associated with both toxicity and carcinogenicity in human and animal populations^[12]. Acute aflatoxicosis results in death, whereas chronic aflatoxicosis results in more prolonged pathologic changes, including cancer and immunosuppression^[12]. The liver is the primary target organ, and liver damage has been documented in rodents, poultry, and nonhuman primates following ingestion of aflatoxin B1. Acute aflatoxicosis has been manifested in humans as an acute hepatitis^[12]. In India in 1974, an outbreak of hepatitis occurred in which 100 people died following consumption of maize that was heavily contaminated with aflatoxin. Aflatoxin B1 was detected in high concentration in the livers of those individuals who died^[13,14].

It has been hypothesized that kwashiorkor, a severe malnutrition disease, and Reye syndrome, marked by encephalopathy and fatty degeneration of the viscera, represent forms of pediatric aflatoxicosis. Although aflatoxins have been found in the livers of children with kwashiorkor and in Reye syndrome patients, a strong cause-and-effect relationship between aflatoxin exposure and these disease states has not been established^[12].

Chronic low-level exposure to aflatoxins in the diet is a risk factor for the development of HCC. Such exposure has been shown experimentally to produce cancer in many animal species and several epidemiologic investigations have shown that increased aflatoxin ingestion correlates with increased risk of HCC in humans^[12].

The mechanism of aflatoxin-induced carcinogenesis is thought to involve tumor promotion or progression. There is evidence that aflatoxin is involved in the activation of proto-oncogenes and mutations in the tumor suppressor gene p53. Aflatoxin exposure and p53 mutations have been tightly linked in epidemiologic studies in Africa and China. Specifically, aflatoxin has been linked to a p53 mutation whereby there occurs a G-to-T transversion at codon 249^[15,16]. This biomarker has been used in epidemiologic studies to establish the link between aflatoxins and hepatic cancer and also to show that co-factors such as infection with hepatitis B virus increase the risk of HCC substantially. It has also been suggested that aflatoxin induces various chromosomal aberrations, unscheduled DNA synthesis and chromosomal strand breaks in human cells. Another suggested mechanism for aflatoxin-mediated carcinogenesis is production of mutagenic substances as a result of metabolism of Aflatoxin by hepatic cytochrome p450.

ENVIRONMENTAL RISKS

Aflatoxins can affect a wide range of commodities including cereals, oilseeds, spices, and tree nuts as well as milk, meat, and dried fruit. The major sources of exposure are maize and groundnuts as these are the foods that are most susceptible to contamination and consumed in the greatest amounts. Developing countries located in the tropical regions, are at greatest risk given their reliance on these commodities as their staple food source^[2]. Food insufficiency and lack of food diversity substantially increases the risk of exposure to aflatoxins among individuals who live in these regions.

Many factors affect the growth of *Aspergillus fungi* and the level of aflatoxin contamination in food. Contamination can occur at any stage of food production from pre-harvest to storage^[2,17]. Factors that affect aflatoxin contamination include the climate of the region, the genotype of the crop planted, soil type, minimum and maximum daily temperatures, and daily net evaporation^[2]. Aflatoxin contamination is also promoted by stress or damage to the crop due to drought prior to harvest, insect activity, poor timing of harvest, heavy rains at harvest and post-harvest, and inadequate drying of the crop before storage. Humidity, temperature, and aeration during drying and storage are also important factors^[2].

VULNERABLE POPULATIONS

Children

Children differ from adults in many ways that have relevance to environmental health^[18,19]. Due to smaller body weights, doses that might not affect adults may induce illness in children. They have more immature neurologic and immune systems and so are more prone to develop complications. Children's developmental state may have a disproportionate impact on their reaction to different environmental toxins.

It is well established that dietary aflatoxins reduce the rate of growth and other measures of productivity in animals. To assess the effects of aflatoxin exposure on growth in humans, Gong *et al.*^[20,21] conducted two separate epidemiologic studies in West Africa. Those studies revealed a striking association between exposure to aflatoxin in children and both stunting (a reflection of chronic malnutrition) and being underweight (an indicator of acute malnutrition). Aflatoxin exposure has also been shown to be a factor in modulating the rate of recovery from kwashiorkor in children^[22,23]. The exact mechanisms underlying these effects of aflatoxins have not been elucidated.

Individuals with viral hepatitis infection

The risk of liver cancer in individuals exposed to chronic hepatitis B virus infection and aflatoxin is up to 30 times greater than the risk in individuals exposed to aflatoxin alone^[24,25]. These two HCC risk factors, aflatoxin and hepatitis B virus, are prevalent in poor nations worldwide. Within these nations, there is often a significant urban-rural difference in aflatoxin exposure and hepatitis B virus prevalence, with both these risk factors typically affecting rural populations more strongly^[25,26].

Aflatoxin also appears to have a synergistic effect on hepatitis C virus-induced liver cancer, although the quantitative relationship is not as well established as that for aflatoxin and hepatitis B virus in inducing HCC^[25,27-29]. Studies have also shown that the genetic characteristics of the virus, and the age and sex of the infected person may play a role in increasing the risk of aflatoxin induced HCC^[27].

PREVENTIVE MEASURES AND INTERVENTION STRATEGIES

Role of politics

The political will at a national level to address the issue of aflatoxin exposure is probably the most important factor in reducing the health hazards associated with aflatoxins in poor countries. As signatories to Codex Alimentarius (World Health Organization and Food and Agricultural Organization documents that deal with food quality) aflatoxin regulatory programs are already in place in most countries^[30]. On the export side these regulatory programs are strictly enforced to protect the export market of agricultural commodities, otherwise the importing countries would reject the commodities resulting in a loss of valuable foreign exchange earnings. On the other hand, domestic regulatory measures on aflatoxins have received very little attention and are rarely enforced, with no incentives given for the aflatoxin free produce and no heavy penalty on the violators of aflatoxin regulations.

Information dissemination

Considerable information has been gathered concerning the health hazards of aflatoxin exposure and conditions that lead to mold growth and aflatoxin contamination

during growing, harvesting and storage of crops. Steps that can be followed to avoid or minimize contamination have been developed. Information is also available on safe storage, handling and transportation practices of agricultural commodities. However, this information is rarely communicated to farmers, traders and all those who need to be informed. Much could be done if the value of different interventions is communicated and the information is disseminated in an appropriate and accessible manner^[31]. As an example, during an outbreak in Kenya in 2005, individuals who received information on maize drying and storage had lower serum aflatoxin levels than those who did not receive this information^[2].

Agricultural strategies

Agricultural interventions are methods or technologies that can be applied either in the field (“pre-harvest”) or in drying, storage, and transportation (“post harvest”) to reduce aflatoxin levels in food^[32].

The presence and growth of *Aspergillus* on pre-harvested crops is dependent on the environment. Agricultural practices including proper irrigation and pest management can reduce aflatoxin contamination^[2]. Pre-harvest interventions include choosing crops with resistance to drought, disease, and pests and choosing strains of that crop which are genetically more resistant to the growth of the fungus and the production of aflatoxins^[2]. Elimination of inoculum sources such as infected debris from the previous harvest may prevent infection of the crop^[2].

Before storage, crops should be properly dried to prevent the development of aflatoxins. Sorting and disposing of visibly moldy or damaged kernels before storage has proven to be an effective method for reducing the development of aflatoxins^[2,33,34]. During storage, moisture, insect, and rodent control can prevent damage to the crop and reduce aflatoxin development. Aflatoxin contamination of maize is influenced by the facilities used for storage, storage time, and the form of maize stored^[2,35]. A community-based intervention study in Africa showed that simple and inexpensive measures such as thorough drying and proper storage of groundnuts can have a significant impact on aflatoxin levels^[34].

Vaccination against hepatitis B virus

Hepatitis B virus infection increases the risk of HCC in individuals exposed to aflatoxins exponentially. Vaccination against hepatitis B virus in infancy is an effective approach to prevent HCC, particularly in developing countries where both incidence of hepatitis B virus and exposure to aflatoxins are high^[26,36,37]. Although the vaccine itself has no impact on actual aflatoxin levels in diets, it reduces aflatoxin-induced HCC by lowering hepatitis B virus risk, thereby preventing the synergistic impact of hepatitis B virus and aflatoxin in inducing liver cancer^[38]. Those who already have chronic hepatitis B virus infection would not benefit from the vaccine, which is why vaccination should be offered in infancy^[38]. Hepatitis B vaccination in infancy has been shown to be safe and effective^[26,39].

RESEARCH PROBLEMS AND NEEDS

Better funding

Aflatoxin research programs need adequate resources in terms of qualified personnel, capital investment, and analytical and technical facilities. Improved funding for aflatoxin research is in dire need, especially in countries with high rate of aflatoxin food contamination. Currently, on a global basis, there is an imbalance between the extent of aflatoxin problem and the funds that have been allocated to its research.

Promotion of a multidisciplinary approach

Aflatoxin contamination of food and feed is a problem that affects multiple disciplines such as agriculture, toxicology, medicine, biology, microbiology, veterinary medicine and other related fields. Hence, a multidisciplinary research approach to the problem should be encouraged and promoted.

Better sampling methods

Determination of aflatoxin levels in food or feed is done via sampling. Sampling of lots of food or feed for aflatoxin analysis is an important step in exposure prevention. Current sampling methods for aflatoxin are not considered totally reliable. Furthermore, sampling techniques have not been standardized and various trade bodies have their own sampling procedure and technique^[40]. Research is needed to identify better and cheaper sampling methods which can in turn lead to standardization of sampling procedures.

Development of resistant cultivars

One of the possible ways to reduce aflatoxin contamination of food commodities is the use of cultivars resistant to seed invasion by aflatoxin-producing fungi^[41]. Breeding for resistance to aflatoxin producing *Aspergillus* species can play a significant role in preventing aflatoxin contamination of food.

Development of competitive and antagonistic microorganisms

Theoretically, competitive and antagonistic native microorganisms that can reduce the populations of aflatoxin producing fungal strains present in the soil have the potential to reduce infection of the plants^[42]. Research is needed to develop such microorganisms and also to make sure that they do not pose any dangers to humans, animals or environment by their own.

Identification of modulators of aflatoxin toxicity

Whereas it is highly desirable that food is not contaminated, the reality is that in parts of the world food contamination with aflatoxins is unavoidable. Identification of substances that can be incorporated into the human diet to reduce or prevent aflatoxin toxicity would have a great potential in reducing the incidence of aflatoxin induced HCC in endemic areas.

Determination of in utero and early childhood exposure effects

In endemic areas, pregnant women are often exposed to aflatoxin contaminated food. There is lack of knowledge about the effects of aflatoxin exposure in utero and early childhood. Research is needed to better understand these effects. This knowledge is fundamental in identification and design of preventive strategies.

CONCLUSION

The purpose of this editorial is to summarize the current knowledge on association of aflatoxin and HCC, encourage future research and draw attention to this global public health issue.

Abstract

While antimicrobials are clinically effective in preventing post-operative recurrence, the role for antibiotics in primary therapy for Crohn's disease (CD) remains unclear. The recent multicenter phase 2 trial by Prantera *et al* received wide attention because it demonstrated an increase in the week 12 remission rate in patients with moderately active CD treated with rifaximin and renewed interest in microbial manipulation as primary therapy for CD. In this commentary, we discuss aspects of durability, immune cell polarization, and safety of microbial manipulation as primary therapy for CD.

Longman RS, Swaminath A. Microbial manipulation as primary therapy for Crohn's disease. *World J Gastroenterol* 2013; 19(10): 1513-1516 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1513.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1513>

COMMENTARY ON HOT TOPICS

Inflammatory bowel disease (IBD) results from a dysregulated immune response to environmental and microbial antigens in a genetically susceptible host. Although we cannot readily manipulate the host genotypes of our patients, numerous clinical studies have attempted to modulate the inflammatory immune response with prebiotic, probiotic, and antimicrobial therapy. The results of randomized controlled trials of antibiotics, however, have been mixed (Table 1). While antimicrobials have gained traction in preventing post-operative recurrence, the role for antibiotics in primary therapy for Crohn's disease (CD) remains unclear. *Post-hoc* analysis of these studies has suggested that antibiotics may be more appropriate in patients with large bowel involvement, but this remains unproven in a randomized controlled trial. Furthermore, despite statistically significant differences in reduction in Crohn's disease activity index (CDAI) in several studies, the lack of effect on true disease remission (CDAI < 150), the concern for medication side effects, and the increasing rate of antibiotic associated *Clostridium difficile* (*C. difficile*) in the IBD population has limited its use in practice.

Given these mixed results, the recent multicenter phase 2 trial by Prantera *et al*^[1] received wide attention because it demonstrated an increase in the week 12 remission rate in patients with moderately active CD treated with 800 mg rifaximin extended release (ER) twice per day (*bid*) (62% vs 43%, $P = 0.005$) and renewed interest in microbial manipulation as primary therapy for CD. As we evaluate the implications of this work, several questions arise: What is the durability of this effect both clinically and microbially? How do we select the patients who will derive the most benefit from antimicrobial therapy? Are these therapies safe?

Durability of response is crucial in coordinating medical therapy and prognosticating clinical course. Evidence of mucosal healing in addition to clinical indicators of disease activity represented in the CDAI define a "deep

Table 1 Randomized controlled trials of antibiotic therapy in inflammatory bowel disease

| Ref. | Antibiotic therapy | Patients (n) | Primary outcome | Results |
|---|--|--------------|---------------------|--------------------------------|
| Afdhal <i>et al</i> ^[12] | Clofazimine | 49 | DAS < 5 | 64% (vs 50% placebo, NS) |
| Sutherland <i>et al</i> ^[13] | Metronidazole | 105 | ↓CDAI (16 wk) | 81 (vs -1 placebo, P = 0.001) |
| Prantera <i>et al</i> ^[14] | Ethambutol, rifampicin, clofazimine, dapsone | 45 | Relapse (9 mo) | Likelihood ratio: 4.6 |
| Steinhart <i>et al</i> ^[15] | Ciprofloxacin, metronidazole | 130 | Remission (8 wk) | 33% (vs 38% placebo, NS) |
| Arnold <i>et al</i> ^[16] | Ciprofloxacin | 47 | ↓CDAI (6 mo) | 75 (vs 25 placebo, P < 0.001) |
| Prantera <i>et al</i> ^[17] | Rifaximin | 83 | ↓CDAI < 150 (12 wk) | 52% (vs 33% placebo, NS) |

DAS: Disease Activity Score; CDAI: Crohn's disease activity index; NS: Not significant.

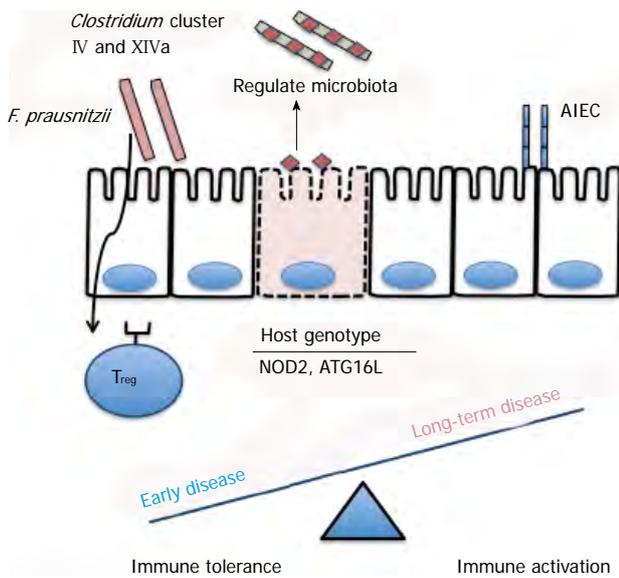

Figure 1 Microbiota regulate immune tolerance and activation in inflammatory bowel disease. *Clostridium* cluster IV and XIVa can induce regulatory T cell (T_{reg}) polarization in the lamina propria^[7]. One member of this cluster, *Fecalibacterium prausnitzii* (*F. prausnitzii*), correlates with reduced post-operative recurrence in Crohn's disease (CD)^[6]. Adherent invasive *Escherichia coli* (AIEC) are found with greater frequency in ileal CD^[11]. Interaction with microbial species may differentially modulate the immune response in early inflammatory disease compared to long-term fibrotic disease^[8]. Host genotype may regulate luminal microbial species. NOD2: Nucleotide-binding ligomerization domain-containing protein 2; ATG16L: Autophagy-related protein 16-1^[9].

remission” associated with a durable response. While the CDAI data generated by Prantera *et al*^[1] are encouraging, remission and response depended solely on clinical indicators, some of which are subjective and not necessarily reflective of systemic inflammation. Objective endoscopic and serologic endpoints to define local and systemic control of inflammation will be crucial in follow up studies of antibiotics as primary therapy.

The second aspect of durability is the effect of rifaximin on the intestinal microbiome. The intestinal “microbiome” refers to the totality of intestinal bacteria and the collection of genetic data that it encodes is called a metagenome. Advances in sequencing technology over the last decade have enabled broader analysis of the types of bacteria that are present in the intestine. Pioneering work defining the full spectrum of intestinal microbiota

in patients with IBD by 16S ribosomal RNA sequence (instead of conventional culture methods)^[2] led to the characterization of an IBD microbiome, reflecting a general reduction in bacterial diversity, a decrease in the clostridial family *Lachnospiraceae*, and an expansion of proteobacteria. More specific characterization of clinical phenotype [ileal Crohn's disease (ICD), colonic CD, ulcerative colitis] in a cohort of Swedish twins revealed the particular prevalence of *Escherichia coli* (*E. coli*) species in ICD with a unique contribution of *Ruminococcus gnavus*^[3]. One interesting finding by Scarpignato *et al*^[4] is that clinical remission was maintained in 63% of the patients in the treatment group up to 12 wk after finishing rifaximin therapy. Prior studies have shown return of pretreatment levels of microbiota within 1-2 wk after discontinuing rifaximin, so it remains unclear whether the durability of this treatment is secondary to a permanent change in the intestinal microbiota or a suppression of a specific pathogenic species. While this analysis is beyond the scope of the study offered by Prantera *et al*^[1], future studies will need to incorporate microbial analysis as well as metatranscriptomic analysis (*e.g.*, what the bacteria are doing) in order to recognize the full diagnostic and therapeutic potential of antimicrobial therapy.

Given rifaximin's broad spectrum of activity against anaerobic and aerobic gram-negative and gram-positive organisms, it is possible that rifaximin treatment eliminates a particular pathogenic or group of pathogenic bacteria that was unaffected by the antibiotics used in previous investigations. If so, does this explain the lack of a dose response in the study? In contrast to previous studies, Prantera *et al*^[1] show no benefit to colonic location of disease [odds ratio (OR) 0.5, P = 0.004]. Does this mean that a suspected pathogen isn't restricted to the colon or that colonic localization is not required? Given the distribution of CD throughout the gastrointestinal tract, this may be a reasonable conclusion.

Microbial analysis suggests several candidate bacteria may be involved in the pathophysiology of CD. Notably, adherent-invasive *E. coli* (AIEC) have been described to be attached to the ileal mucosa of patients with ICD^[5]. These invasive bacteria may sustain inflammation in genetically susceptible individuals and generate systemic immune responses (reflected by serologies) (Figure 1). While *E. coli* are sensitive to rifaximin *in vitro*, the effect

of rifaximin on AIEC populations *in vivo* has not been clearly defined, but could be studied in this cohort. In addition to AIEC, analysis of a post-operative ICD cohort revealed the correlation of the clostridial species, *Faecalibacterium prausnitzii* (*F. prausnitzii*), with a decreased incidence of post-operative recurrence^[6]. *Clostridium* species IV and XIVa (which include *F. prausnitzii*) have been shown in mouse models to induce the accumulation of regulatory T cells in the colon^[7] (Figure 1). Further microbial analysis of primary antimicrobial therapy for CD may offer deeper insight into the mechanism of rifaximin therapy.

If the efficacy of rifaximin depends on microbial mediated disease, perhaps there are clinical or diagnostic parameters that may highlight patients that will derive maximal benefit from antimicrobial therapy? Subgroup analysis by Prantera *et al*^[1] revealed maximal benefit in patients with “early disease”, defined as < 3 years at time of entry into the study (OR 1.7, *P* = 0.02). Recent data in mice showed that the timing of introduction of microbiota into “germ-free” animals regulates the influx of immune cells into intestinal tissue by modulating the expression of genes involved in recruiting these cells^[8]. Perhaps “early disease” maintains immunologic plasticity whereas long-standing disease has already been programmed to support inflammation. Further characterization may reveal distinct microbial components of their cohort. Finally, it would be interesting to know if disease susceptibility alleles correlate with antimicrobial response. A recent study of microbiota in patients with IBD revealed that genetic susceptibility alleles for nucleotide-binding oligomerization domain-containing protein 2 and autophagy-related protein 16-1 correlate with alterations in the microbiome^[9]. These clinical and genotypic parameters may improve the targeted use of antibiotic therapy for CD.

The safety of widespread and long-term antibiotics also remains an issue of concern. Rifaximin has minimal systemic absorption. As such, rifaximin does not have notable systemic side effects or interactions associated with imidazole or fluoroquinolone antibiotics. *C. difficile* remains a major problem in the clinical management of IBD with rising rates of CDI associated with morbidity, mortality and need for colectomy^[10]. Although rifaximin may help treat *C. difficile*, one case of *C. difficile* was seen in the 800 mg ER *bid* group. Further studies will be needed to determine the strength of this association. Rifaximin resistance has evolved in AIEC and should be evaluated before widespread use is adopted^[11].

In summary, this study by Prantera *et al*^[1] offers important results and safety data for the use of rifaximin and supports the role for this anti-microbial in improving remission rates in mild to moderate CD. Hard endpoints including mucosal healing and measurements of systemic inflammation will enable crucial evaluation of the efficacy of rifaximin in phase 3 trials. Further analysis of the microbial alterations during rifaximin therapy are important in not only understanding the biology of the microbiome in IBD, but also in designing rational therapeutic strate-

gies for microbial manipulation. Disease location, systemic inflammatory markers, host genotype, and intestinal microbial signatures will ultimately guide a personalized medical approach to the clinical use of directed antimicrobial and/or bacteriotherapy. Although many questions of mechanism and durability remain, Prantera *et al*^[1] offer an important step forward in the role for microbial manipulation in the clinical management of IBD.

Abstract

Quality colonoscopy is defined by the detection of adenomatous polyps at least 25% of the time in men and 15% of the time in women. Recent studies highlight the importance of key aspects of high quality colonoscopy. These include the amount of time spent examining the mucosa or withdrawal time, the quality of withdrawal technique and new technologies which seek to maximize the detection of colonic neoplasia. This review summarizes the latest evidence regarding the role of time, technique and technology in shaping the quality of colonoscopy.

COMMENTARY ON HOT TOPICS

Colonoscopy is widely considered to be the most effective

tool for colorectal cancer (CRC) screening. However, recent studies suggest that discrepancies in the quality of colonoscopy are the cause of uneven outcomes in CRC detection and prevention. As a result, clinical researchers, professional societies, and governmental policy-makers have sought to identify benchmarks for quality colonoscopy. The recent article by Filip *et al*^[1] represents an important contribution to this ongoing effort to delineate the key aspects of high quality colonoscopic examination. Furthermore, it brings into focus the salient questions which define the current debate about quality improvement in screening colonoscopy.

What is quality colonoscopy?

To address this question, the American College of Gastroenterology and the American Society for Gastrointestinal Endoscopy in 2006 developed guidelines establishing quality indicators for colonoscopy. Outlining intra-procedural standards for colonoscopy, these guidelines establish a withdrawal time (WT) ≥ 6 min, and a cecal intubation rate of $\geq 95\%$ as quality indicators^[2]. However, the most important benchmark is an adenoma detection rate (ADR) of $\geq 25\%$ in men and $\geq 15\%$ in women for average risk screening colonoscopy^[3]. European guidelines concur with this observation and outline a goal ADR of 20% for average-risk colorectal screening in patients over the age of 50^[4]. ADR was chosen as the primary quality indicator because the main benefit of colonoscopy, the detection and removal of neoplastic lesions has been estimated to prevent 76%-90% of CRCs^[5-7]. While more recent studies suggest that the polyp detection rate (PDR) which includes the detection of non-adenomatous polyps (hyperplastic polyps) can be used as a surrogate for ADR, ADR remains the principal quality indicator for colonoscopy^[4,8,9].

Do we perform quality colonoscopy?

Over the last decade, colonoscopy has been increasingly utilized as the primary modality for CRC screening in the United States, with a 14% increase in use among Medicare recipients from 2000-2003^[10]. However, recent evi-

dence suggests that the increase in colonoscopy utilization has not uniformly resulted in a concomitant reduction in CRC-related morbidity and mortality. In a case control study, Baxter *et al*^[11] demonstrated that screening colonoscopy decreased overall CRC-related mortality [odds ratio (OR) 0.69, 95%CI: 0.63-0.74] and left-sided CRC-related mortality (OR 0.69, 95%CI: 0.28-0.39). However, alarmingly, the study found that colonoscopy did not significantly decrease the risk of death from right-sided CRC (OR 0.99, 95%CI: 0.86-1.14)^[11]. This finding was remarkable given that it questioned the long-standing presumption that colonoscopy was superior to other CRC screening modalities primarily through its ability to detect right-sided neoplasms.

The relationship between the use of colonoscopy and its variable impact on CRC prevention is further elucidated by data on missed CRCs from the Manitoba cancer registry^[12]. Defining a missed cancer as a CRC occurring within 6-36 mo of colonoscopy, the investigators found that nearly 1 in 13 CRCs were likely missed on initial colonoscopic examination^[12]. Furthermore, risk factors for missed CRCs included colonoscopy with polypectomy, and proximal location, thus potentially implicating failed cecal intubation and the incomplete resection of polyps as potential causes^[12].

The importance of missed proximal colonic polyps is highlighted by the emerging recognition of sessile serrated adenomas (SSA) as distinct colonic neoplasia with malignant potential. Histologically marked by disorganized and distorted crypt patterns, SSA tend to be proximal in location and to appear as flat or depressed lesions that are easily missed without careful examination^[13]. The potential association between missed CRCs and these lesions is significant in that SSA have been found to carry an increased risk of proximal CRC (OR 4.79, 95%CI: 2.16-5.03)^[14].

The most compelling evidence linking the quality of colonoscopy to CRC prevention outcomes comes from a study by Kaminski *et al*^[15] which examined endoscopists' ADR and the risk for interval CRC after colonoscopy. In comparing endoscopists with mean ADR of < 11% *vs* those with ADR of > 20%, the investigators found a cumulative hazard rate for the development of interval CRC of 10.94 (95%CI: 1.37-87.01)^[15]. In a Cox proportional hazards regression model, endoscopists' ADR along with the patients' age were the only independent predictors of interval CRC^[15]. This study, along with the others previously discussed, strongly suggests that quality colonoscopy is not uniformly performed. Furthermore, it highlights the potential adverse impact of poor quality colonoscopy when it comes to CRC prevention.

Are endoscopists to blame for poor quality colonoscopy?

While factors such as poor bowel preparation, and patients' genetic predisposition for colorectal neoplasia have been implicated in missed neoplasia and the development of CRC between colonoscopies, the preponderance of evidence points to the role of the endoscopist

in determining the quality of colonoscopy^[16]. In a study of over 10 000 colonoscopies, Chen *et al*^[17] found a high degree of variability in mean ADR ranging from 14% to 34.6% among 9 endoscopists. In a multi-variable analysis, the identity of the endoscopist was found to have a similar impact on ADR as patient age and gender^[17]. In a separate study involving missed polyps found on tandem colonoscopy (back-to-back colonoscopies performed to assess for missed lesions), Rex *et al*^[18] found similar variability among participating endoscopists with adenoma miss rates ranging from 17% to 48%. Other factors related to the identity of the endoscopist such as medical specialty (gastroenterologist *vs* non-gastroenterologist), and training level have also been implicated as having an impact on ADR^[12,19,20]. Consequently, it is clear that factors related to the individual endoscopist have a large impact on the quality of colonoscopy.

Is quality colonoscopy a matter of time?

The debate over quality colonoscopy has largely centered on the issue of colonoscopy WT or the amount of time inspecting the colonic mucosa for neoplastic lesions. This is largely due to the landmark paper by Barclay *et al*^[21] which compared ADR among endoscopists with varying WT. Defining WT as the time from cecal identification to withdrawal of the scope from the anus, the investigators found that endoscopists with WT \geq 6 min had higher ADR compared to those with WT < 6 min (28.3% *vs* 11.8%, $P < 0.001$)^[21]. In a similar retrospective study of over 10 000 colonoscopies, Simmons *et al*^[22] found that prolonged WT was associated with higher PDRs ($r = 0.76$, $P < 0.001$) and that overall median polyp detection corresponded to a WT of > 6.7 min.

However, since the publishing of these initial studies, efforts at quality improvement by simply mandating a minimal WT have largely proven to be unsuccessful in significantly improving ADR. In a study by Sawhney *et al*^[23] the establishment of a mandatory WT of \geq 7 min produced a significant increase in the compliance rate for WT from 65% to 100%. However, in spite of this, there was no concomitant increase in the PDR (slope 0.0006, $P = 0.45$)^[23]. Similar studies involving continuous feedback regarding mean WT to endoscopists have also been disappointing in producing significant increases in ADR^[24].

One potential explanation for these findings is the possibility that there may be a ceiling to the degree of improvement in ADR that can be achieved by simply prolonging WT. This was well illustrated by retrospective data from the VA cooperative study where the mean WT was well above 12 min^[25]. While mean WT was associated with initial adenoma detection, it did not correlate with the probability of finding interval neoplasia on surveillance colonoscopy ($P = 0.61$)^[25]. A similar finding was found in a German study where WT did not correlate with variability in ADR when the mean WT ranged from 6-11 min^[26]. Given these observations, there is clear cut evidence that while WT is certainly an important perfor-

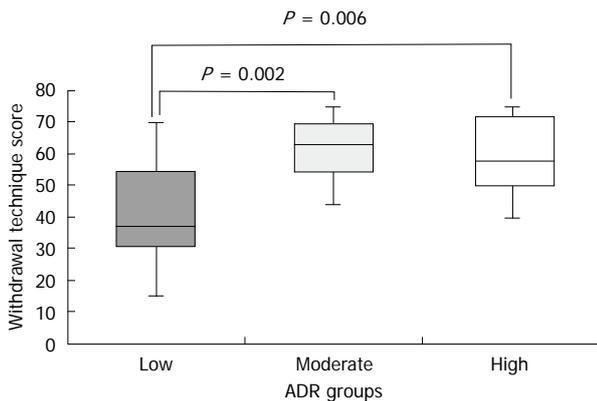

Figure 1 Withdrawal technique scores among endoscopists with low, moderate and high adenoma detection rates. ADR: Adenoma detection rate.

mance parameter, it may not necessarily be the deciding factor in determining the overall quality of colonoscopy.

Is colonoscopy a matter of technique?

Along with the speed of withdrawal, recent attention has focused upon the technique that is used to examine the colonic mucosa for neoplasia. The first study to examine this by Rex *et al*^[27] compared two endoscopists with markedly different adenoma miss rates found in a separate tandem colonoscopy study. Using video-recordings of colonoscopy withdrawals and a 5 point scale to grade the quality of withdrawal technique, the investigators found that the endoscopist with the lower adenoma miss rate (17%) had higher scores for all aspects of withdrawal (distension, cleansing, time spent viewing, examination of proximal aspects of folds) compared to the endoscopist with the highest adenoma miss rate (48%)^[27].

Our research team recently further elucidated the potential relationship between WT and withdrawal technique among a broader set of endoscopists from varying institutions (11 endoscopists from 2 Veterans Affairs Hospitals and 3 University Hospitals)^[28]. A video-recording protocol and grading system was utilized to characterize withdrawal technique and WT of endoscopists with low (11.8% ± 3.4%), moderate (34.1% ± 2.6%) and high ADR (49.0% ± 3.7%)^[28]. Withdrawal technique was assessed using a scale adapted from Rex *et al*^[27] that assigned points (0-5) for three specific dimensions: (1) fold examination (0 = not looking behind folds, 5 = look behind all folds); (2) distension (0 = not cleaning pools, 5 = cleaning all pools); and (3) cleansing (0 = not distended or in spasm, 5 = good distension). Scores for each dimension were assigned for 5 areas of the colon (cecum, ascending, transverse, descending, sigmoid). Only colonoscopies performed for average-risk CRC screening in which cecal intubation was achieved were evaluated. Using this scoring system, we found that High and Moderate ADR endoscopists had higher withdrawal technique scores compared to low ADR endoscopists (Figure 1)^[28]. Furthermore, when the highest and lowest ADR endoscopists were compared, we did not find a significant difference in WT (6.6 ± 1.7 min *vs* 7.4 ± 1.7 min) ($P =$

0.36), but did find a nearly 2-fold difference in technique score (36.2 ± 9 *vs* 61 ± 9.9, $P = 0.0001$)^[28]. One potential explanation for this was the possibility that low ADR endoscopists purposely slowed down the speed of withdrawal to meet the 6 min goal but nonetheless failed to perform a high level of quality withdrawal technique.

The importance of withdrawal technique was also recently highlighted by a quality improvement study by Barclay *et al*^[29]. Unlike the Sawhney study^[23] which solely focused upon a minimal WT, the quality improvement protocol utilized by Barclay *et al*^[29] included both a WT mandate and an institution-wide meeting among endoscopists that established guidelines on optimal withdrawal technique. Following this two-pronged approach, the investigators demonstrated an improvement in ADR (37.8% post-intervention *vs* 23.5% pre-intervention, $P < 0.0001$) and a higher number of advanced neoplasia per patient screened^[29].

The development of newer techniques for mucosal inspection also holds great promise for efforts to enhance the quality of colonoscopy. East *et al*^[30] recently showed that the use of dynamic changes in patient position during withdrawal resulted in a mean ADR of 52% compared with an ADR of 34% ($P < 0.001$) in cases where withdrawal was only performed while the patient was in the left lateral decubitus position. The use of large volume water immersion during colonoscopy along with water exchange to remove residual stool may improve mucosal visualization, with a recent meta-analysis showing an increased detection of right-sided adenomas when using this technique^[31]. Finally, utilizing the concept of the Hawthorne effect, which describes the phenomenon in which individuals often will perform better when they know that they are being monitored, Rex *et al*^[32] have demonstrated that the simple act of video-recording the procedure results in improved WT and withdrawal technique.

Is quality colonoscopy a matter of technology?

Innovations in endoscope development and imaging have shifted the focus towards finding a technological solution to the task of ensuring quality colonoscopy. One of the earliest methods to be applied to the goal of maximizing adenoma detection is chromoendoscopy. Using a spray catheter to coat the lining of the colonic mucosa with either methylene blue or indigo carmine dyes, this approach enhances colonic pit patterns and demarcates the border between normal and abnormal mucosa. Because of its ability to differentiate flat adenomas, a recent meta-analysis has demonstrated that chromoendoscopy is associated with a higher ADR (OR 1.67, 95%CI: 1.29-2.15) and a higher detection rate for ≥ 3 neoplastic lesions (OR 2.55, 95%CI: 1.49-4.36) compared to white-light endoscopy (WLE)^[33]. Furthermore, Stoffel *et al*^[34] conducted a study where patients underwent either chromoendoscopy or WLE as the second part of a tandem colonoscopy study. Here, they found that chromoendoscopy detected a higher percentage of missed adenomas (44% *vs* 17%,

$P = 0.04$) even when controlled for WT^[34]. Given these results, the investigators conclude that the higher ADR seen with chromoendoscopy is due to the method itself rather than as a consequence of the endoscopist having to take a longer time in inspecting the colon^[34].

While current evidence suggests that chromoendoscopy does result in higher ADR, the method is time-consuming and requires additional equipment. Consequently, modalities that rely upon imaging that is built into the processor of the colonoscope have been examined as a means of maximizing ADR. Narrow band imaging (NBI) is the most widely available technology utilizing short wave-length light that is primarily absorbed by hemoglobin in the superficial mucosa^[35,36]. Highlighting mucosal pit patterns and vascularity, NBI offers the ability to potentially differentiate abnormal from normal mucosa with the simple press of a button on the colonoscope. However, a systematic review of both observational and clinical trials recently demonstrated that NBI did not result in higher ADR compared with WLE (OR 1.19, 95%CI: 0.86-1.64). Furthermore, NBI did not yield a higher number of adenomas per patient (relative ratio of means 1.23, 95%CI: 0.93-1.61)^[37]. While other evidence suggests that NBI has sufficient sensitivity and specificity in differentiating adenomatous from non-adenomatous tissue to potentially give rise to a resect and discard strategy for colonic polyps, current data does not support its use as a means of enhancing ADR^[37].

Another potential imaging modality that has been proposed to increase ADR is auto-fluorescence imaging (AFI). AFI relies upon the observation that the colonic mucosa emits auto fluorescent light in response to illumination by ultraviolet light^[38]. Furthermore, the wavelength of the auto fluorescent light is dependent on architecture, light-absorptive properties and the metabolic status of the tissue that is being illuminated^[38]. Exploiting this capability, AFI has been characterized as a potential “red-flag” technology that would warn the endoscopist to carefully inspect an area where a flat neoplastic lesion is located.

Preliminary studies which have examined the relationship between AFI and adenoma detection have thus far proven to be disappointing. In a head to head study of AFI *vs* high resolution endoscopy (HRE), van den Broek *et al*^[39] found no significant differences in adenoma miss rates (29% *vs* 20%, $P = 0.35$). In a study examining the use of tri-modal imaging (AFI plus NBI plus HRE), Kuiper *et al*^[40] found an ADR that was virtually the same as that seen with standard WLE (34% *vs* 37%, $P = 0.61$).

Other technologies on the horizon which hold promise include the third-eye retroscope (Avantis Medical Systems, Sunnyvale, California) which allows for the retrograde visualization of neoplastic lesions behind mucosal folds. In a tandem colonoscopy study, Siersema *et al*^[41] recently showed that the Third Eye system resulted in a lower adenoma miss rate when compared with WLE. While these results are promising, the broad preponderance of the evidence regarding new technologies sug-

gests that technology by itself cannot guarantee quality in colonoscopy.

The way forward for quality colonoscopy

Given the world-wide economic challenges surrounding health care delivery, governments and third party payers are placing a renewed focus on policies that provide the most cost-effective approach towards disease prevention. As part of this trend, quality benchmarks for colonoscopy stand as obvious targets for Pay-For-Performance measures that seek to reward patient-oriented outcomes in CRC screening. Faced with this imperative, the endoscopic community will need to find innovative approaches to measuring and improving the quality of colonoscopy.

The review conducted in this paper illustrates that there probably is not just one solution to the dilemma of ensuring quality in colonoscopy. While recent studies have clearly demonstrated that the amount of time spent examining the mucosa is a vital component, evidence from quality improvement programs suggest that there is likely a ceiling effect to WT. Furthermore, while withdrawal technique does have a definitive impact on ADR, measuring the quality of technique is time-consuming, burdensome and not easily performed. Finally, given the mixed results of technological solutions for enhancing ADR, it is clear that further work must be done to integrate these advances into everyday practice.

The quest to preserve colonoscopy as the primary tool for quality CRC screening demands a multi-pronged approach using research and innovation to enhance all three aspects of colonoscopy. By providing a potential means for easily quantifying the quality of withdrawal technique, the paper by Filip *et al*^[1] stands as an important contribution to this process. Similar research endeavors are clearly required to achieve the goal of ensuring quality in colonoscopy.

Abstract

Atrophic gastritis and intestinal metaplasia (IM) of the stomach are common and are associated with an increased risk for gastric cancer. In the absence of guidelines, a pragmatic management has been performed in Western countries in patients with these premalignant conditions. Recently, formal European guidelines have been delivered on this topic. Basically, it has been recommended that patients with extensive atrophic gastritis (AG) and/or extensive IM should be offered endoscopic surveillance every 3 years. On the contrary, no scheduled endoscopic/histological control has been advised for those patients with precancerous conditions confined to the antrum. In this commentary, we highlighted some potential weaknesses in the management formally recommended by the new guidelines. In detail, we discussed that AG and IM patients do not share the same gastric cancer risk, at least in Western countries, deserving a different approach. Some factors significantly associated with gastric cancer risk, such as IM type, first-degree family history of gastric cancer, and smoking habit have not been considered in

COMMENTARY ON HOT TOPICS

We read with great interest the recent article by Dinis-Ribeiro *et al*^[1] reporting the first European Guidelines on management of precancerous conditions and lesions in the stomach (MAPS), and strongly recommend it to readers. Despite gastric cancer incidence is decreasing, such a neoplasia remains the fourth most prevalent tumor and second most frequent cause of cancer-related mortality in the world^[2]. The endoscopic-based screening programs performed in a few Asian countries^[3], where the gastric cancer incidence is extremely high, are not feasible in other countries due to a distinctly lower frequency of such a neoplasia. Therefore, in the Western countries, surveillance of precancerous conditions [gastric atrophy and intestinal metaplasia (IM)] and lesions (dysplasia) is the only reliable procedure able either to reduce gastric cancer onset - *i.e.*, by removing dysplasia areas at endoscopy or to diagnose an already-developed cancer in an early stage, so that patient survival is distinctly improved^[4,5]. However, the American Society for Gastrointestinal Endoscopy Guideline recommended against the surveillance

for patients with IM^[6]. Until few months ago, no European guidelines were available on the management of these precancerous lesions, leaving both gastroenterologists and general practitioners (GP) to empirically manage these patients without any actual reference standard. For this reason, Dinis-Ribeiro *et al*^[1] should be commended for having organized a workshop involving a vast panel of experts, in order to deliver the first European guideline on such a topic.

According to these new guidelines, it has been recommended that patients with extensive atrophy gastritis (AG) and/or extensive IM - *i.e.*, involving both antral and gastric body mucosa - should be offered endoscopic surveillance (evidence level 2++, recommendation grade B) every 3 years (evidence level 4, recommendation grade D). On the contrary, no scheduled endoscopic/histological control has been advised for those patients with precancerous conditions confined to the antrum. Therefore, both gastroenterologists and GPs have now a “road map” to systematically schedule the surveillance in patients with either AG or IM.

Although any guideline is better than no guideline, we would further discuss some potential flaws entailed in the management recently recommended. First, it might appear questionable that the same endoscopic follow-up has been advised for both AG and IM patients. In a nationwide study^[7], the 10-year gastric cancer incidence was estimated to be 0.8% and 1.8% in 22 365 AG and 61 707 IM patients, respectively, corresponding to an adjusted yearly incidence of 0.055% and 0.1%^[8]. Given the two-fold different gastric cancer risk, perhaps a differently scheduled endoscopic surveillance should be proposed for AG and IM patients. Differently from IM^[9], a strict follow-up in AG patients may be not cost-effective in Western countries^[10].

Secondly, appropriateness of the suggested interval for endoscopic follow-up is not well documented. The 3-year interval selected for patients with extensive AG or IM does not appear to be corroborated by any prospective study. Indeed, the panel of experts downgraded this statement as level 4, grade D. However, at least two studies demonstrated that only 36% and 38% of detected gastric cancers were in an early stage (*i.e.*, stage I disease), when scheduling the endoscopic surveillance interval at 1- or 2-years, respectively^[11,12]. Therefore, despite patients underwent a more intensive follow-up than the 3-year interval now officially recommended^[1], gastric cancer was diagnosed in an advanced stage in as many as 62%-64% of the cases. Based on these observations, an even worse scenario cannot be excluded when a 3-year interval follow-up is to be implemented in clinical practice. The dismal prognosis of gastric cancer diagnosed in an advanced stage poses ethical concerns about recommending a 3-year surveillance interval for IM patients. On the other hand, it is also unquestionable that an appropriate use of endoscopic procedures is essential to the rational use of finite resources. To dissipate economic resources in

performing yearly endoscopic controls in all IM patients - most of which would never develop gastric cancer - would also be unethical. A possible solution could be represented by a patient-tailored approach. Similarly to the extensive spreading of AG or IM in the stomach - the only risk factor considered in the MAPS guidelines^[1] - several studies demonstrated that other factors increased gastric cancer risk, including IM type, first-degree family history of gastric cancer, and smoking habit. Presence of incomplete type IM significantly increased the hazard ratio of gastric cancer as compared to complete IM (hazard ratio: 11.3, 95%CI: 3.8-33.9)^[13]. A first-degree family history of gastric cancer also increases such risk by 2.6-3.5 times, with a calculated attributable risk of 8%^[14,15]. Indeed, the gastric carcinogenetic cascade in these subjects seems to start earlier than in controls^[16]. A meta-analysis, considering 14 442 cases and 73 918 controls, found that smoking significantly increased gastric cancer risk, with an overall odds ratio (OR) of 1.48 (95%CI: 1.28-1.71), and an OR of 1.69 (95%CI: 1.35-2.11) for current smoker status in comparison to never smokers^[17].

Therefore, IM patients with at least 1 of these risk factors (incomplete IM, family history, smoking habit) - information easily available in clinical practice - would appear at a further increased risk of gastric cancer and may probably benefit of a more intensive endoscopic surveillance, rather than the 3-year follow-up uniformly suggested for all patients^[1]. We recently proposed a patient individualized follow-up with an yearly endoscopic control in those patients with adjunctive risk factors, and a less intensive (2-3 years) follow-up in the remaining IM patients^[18]. For instance, a patient with incomplete IM confined to the antral mucosa would not appear to be at lower gastric cancer risk as compared to a patient with extensive, complete IM. Similarly, a smoker patient with complete IM in the antrum or with a family history of gastric cancer likely deserves endoscopic surveillance, contrary to what recommended by the MAPS. However, further studies on this topic are needed.

Finally, the gastric biopsy sampling proposed in the MAPS includes ≥ 2 biopsies in the antrum and ≥ 2 biopsies in the gastric body. However, in the updated Sydney System, 5 biopsies were recommended, including 1 additional specimen on the *incisura angularis*^[19]. The need of this additional biopsy was based on the evidence that IM prevalence is higher in this gastric site as compared to any other part of the stomach^[20]. Indeed, IM generally initiates in the *incisura angularis*, subsequently spreading in both antrum and gastric body^[21]. Despite it could be argued that IM only located in the angulus does not increase gastric cancer risk, it is also true that IM would presumably spread to both antrum and body in the majority of patients^[21]. Therefore, by simply taking 1 biopsy on the angulus it is possible to early detect IM - that is a generally irreversible, precancerous lesion^[22]. Taking 1 further biopsy on the angulus is a simple and rapid procedure, without any additional patient discomfort and cost.

Indeed, as suggested in the Operative Link for Gastritis Assessment (OLGA) system, the additional biopsy specimens taken on the angulus should be pushed in the same vial of antral biopsies^[23]. The MAPS guideline did not include angulus biopsy among the recommendations^[1]. However, the guideline suggested that biopsies should be histologically assessed according to the OLGA/OLGIM system^[23,24], for which 5 biopsies (1 on the angulus) are required. Therefore, it would appear reasonable to include *incisura angularis* in the biopsy sampling.

In conclusion, while waiting for large prospective, randomized, multicenter studies comparing different follow-up strategies, it would appear reasonable to take into account some additional risk factors for gastric cancer in the follow-up strategy for management of gastric precancerous lesions. A simple, patient-tailored surveillance may be probably more appropriate than a single schedule proposed for all patients. Despite MAPS represents a good start, a more patient-orientated road-map(s) could be also considered.

Abstract

It is our contention that the concept of a probiotic as a living bacterium providing unspecified health benefits is inhibiting the development and establishment of an evidence base for the growing field of pharmacobiotics. We believe this is due in part to the current regulatory framework, lack of a clear definition of a probiotic, the ease with which currently defined probiotics can be positioned in the market place, and the enormous profits earned for minimum investment in research. To avoid this, we believe the following two actions are mandatory: international guidelines by a forum of stakeholders made available to scientists and clinicians, patient organizations, and governments; public

research funds made available to the scientific community for performing independent rigorous studies both at the preclinical and clinical levels.

Actual concept of "probiotics": Is it more functional to science or business? *World J Gastroenterol* 2013; 19(10): 1527-1540 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1527.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1527>

INTRODUCTION

Probiotics are generally defined as live microorganisms, preferentially of human origin, that upon ingestion in specific and sufficient numbers confer unspecified health benefits to the host. During the last twenty years the therapeutic potential of probiotic bacteria has been evaluated in a large number of basic, experimental and clinical studies^[1-3] and their use in different clinical conditions has received considerable scientific and commercial attention.

Today probiotics represent a very big business. The global functional food market has been recently estimated at up to \$50 billion annual share^[4], while the world probiotic market is estimated at \$15 billion. Today, this market is growing at a pace of 5%-30% depending on the country and product type^[5]. The marketing agency Frost and Sullivan believes that the possibility to use salutistic indications on the label of the products containing probiotics, as permitted according to CE 1924/2006 rules, can further increase the consumer interest. Proper communication paired with effective marketing strategies will prove to be useful to this aim. Consumer acceptance varies greatly across Europe, with the most developed

market in Northern European and Scandinavian countries, having a long traditional consumption of probiotic products^[5]. The existing consumer confusion over the different probiotic strains as well as skepticism about their efficacy do not seem sufficient to counteract the salutistic propaganda of the media advertisements.

The regulatory status for probiotic products is not well established at international level yet. The United States Food and Drug Administration apply a conceptual distinction among “medical foods”, “dietary supplements”, “drugs” and “biological products” to probiotic products. The regulatory consequences that accompany a probiotic product that is categorized as a dietary supplement obviously dramatically differ from those that accompany a probiotic product categorized as a drug. If the probiotic product meets the definition of dietary supplement, the manufacturers may place the probiotic product on the market without any pre-market approval and may market the product with claims concerning the effect that the product has on the structure or function of the body. The European Commission has recognized probiotic bacteria as having the status of nutrients; in addition probiotics in powder, capsule or tablet form are in most European countries regarded as “food supplements” but with important differences: according to Bianca Herr of the Leatherhead Food International, in Italy and in Hungary probiotic products are widely accepted as food supplements, in Germany these products are accepted as food supplements in some cases but their acceptance as drugs depends on their concentration, while in Spain there is no specific legislation or guidance for probiotic products. Thus, in most cases, these products reach the market without being tested in the expensive three phases required for approval of a new drug. For these reasons not only big pharma and manufacturers of probiotics but also national pharmaceutical industries and even family farms are involved in this market. Also, the work of the European Food Safety Authority regarding claims made on food labeling and advertising concerning nutrition and health provides an important but very partial solution to the problem.

One would expect that the available scientific evidence is comparable to the size of this market; however, this is certainly not the case. Food And Agriculture Organization and World Health Organization defined the following characteristics of probiotic microorganisms: (1) probiotics should be taxonomically classified and deposited in an internationally recognized culture collection; (2) they have to remain viable and stable after culture, manipulation, and storage before consumption; (3) they have to survive to gastric acid and biliary and pancreatic digestion; (4) they have to induce a host response once ingested by adhering to gut epithelium or by other mechanisms; (5) they have to yield a functional or clinical benefit to the host when consumed; and (6) finally they have to be safe, not only regarding the assessment of side effects, but also in relation to antibiotic resistance patterns. In fact beneficial bacterial populations may play

a role in the transfer of antibiotic resistance to pathogenic and opportunistic bacteria. These general rules are certainly meaningful but not sufficient as guidelines for this field. Although there are few international organizations that purport to be independent of industry, such as International Scientific Association for Probiotics and Prebiotics (ISAPP), whose mission is to engender and disseminate information on high quality, multidisciplinary, scientific investigation in the field of probiotics, in actual fact there is no organization, agency or scientific network able to (1) reduce the incredible confusion related to every aspect of probiotics; (2) direct the rudder of basic and experimental research on probiotics and, in the future, on pharmacobiotics (a fundamental goal is to move away from the restrictive and perhaps outdated term “probiotics” and over to the more inclusive term “pharmacobiotic or pharmabiotic”); and (3) propose well accepted guidelines for evaluating these products in controlled clinical trials. To date variability is the keyword and includes every aspect of probiotics: strain, dose, route of administration, trial methodology, endpoints and outcomes. A very large number of probiotic strains have been used in clinical studies for the treatment of the same clinical condition, and the same strain of probiotics has been used to treat very different disease states. In addition an incredible large range of doses [from 4.5×10^2 colony-forming units (CFUs) to 3.6×10^{12} CFUs] of probiotics has been assayed in clinical trials. Furthermore, in different studies probiotics were administered in a great variety of ways: capsules, powders, tablets, drops or yogurts. An equally great variability exists in methodology, endpoints and outcomes of clinical trials carried out so far, even limiting the analysis to a single clinical condition. As an example we summarized in Tables 1-3 the number of patients, duration of treatment, probiotic strains used, dose used and outcomes of clinical trials carried out on three adult clinical conditions in which probiotics have widely tested: irritable bowel syndrome, ulcerative colitis and Crohn's disease. The tables end with the indication of published meta-analyses. Despite the existence of guidance^[6] and recommendations^[7] for probiotic use in these intestinal diseases, it seems clear from the tables that the lack of homogeneity of the published studies does not allow to draw final conclusions and to generate, through an evidence-based approach, true guidelines useful for adult patients. This is corroborated by meta-analysis studies that recognize the variety of species, strains and doses of probiotic used associated to an evident heterogeneity of study methodologies as main limitations in the field.

This would not be accepted in clinical pharmacology. No drug can be approved for the market with a defined clinical indication without sufficient knowledge of its mode of action, pharmacokinetic parameters, toxicological features, tolerability and effectiveness. In addition this knowledge will be substantially increased by post-marketing surveillance. By contrast, probiotics are commonly commercialized and prescribed for spe-

CFU: Colony-forming unit; IBS: Irritable bowel syndrome.

cific clinical indications in the absence of any conclusive proof concerning their putative pharmacological properties. Finally, it should be remembered that the safety of probiotics should not be considered a foregone datum: in abdominal surgery, translocation of bacteria from the gastrointestinal tract through the mucosa could occur^[8], and probiotic treatment has been associated with increased mortality in patients with acute pancreatitis^[9].

Only a few cases based on studies regarding pediatric population formal meta-analyses have been used to generate clinical guidelines. These studies demonstrated ben-

eficial effects of probiotics in acute diarrhea of children. These effects are strain- and dose-dependent, being generally greater with doses > 10¹⁰ CFUs, highly significant for watery diarrhea and viral gastroenteritis but less so for invasive bacterial diarrhea, more evident when the treatment is started early in the course of disease, and more evident in children living in developed than in developing countries^[10]. In May 2008, probiotics were for the first time included in a guideline document named “the guidelines for the management of acute gastroenteritis” and produced by a Committee of the European

Society for Pediatric Infectious Diseases^[11]; this guideline document was developed through an evidence based systematic review approach that incorporates tables of evidence with their grading. The guidelines state that only the use of probiotic strains with proven efficacy and in appropriate doses is suggested for the management of acute diarrhea in European children as an adjunct to rehydration therapy. The evidence of efficacy regards only two strains: *Lactobacillus rhamnosus GG* was rated as 1A and *Saccharomyces boulardii* was rated as 2B,

corresponding to the level of evidence based respectively on meta-analysis of randomised controlled trials (RCTs) and properly designed RCTs of appropriate size. This evidence is actually confined only to the prevention/treatment of childhood acute gastroenteritis and of antibiotic-associated diarrhea. In the few conditions in which selected probiotic bacteria have shown a proven efficacy competitive mechanisms or mechanisms of restoration of bacteria flora seem to be involved. No final evidence is available in other conditions or diseases in

which probiotic agents are largely used. It appears evident that the tremendous dichotomy between the huge market of probiotic products and the insufficient knowledge of probiotic-based therapies. This would be unacceptable for any other pharmacological treatment.

We believe that some important fields of research exist that should be encouraged due to the possibility of getting information of incommensurate value in the near future. These fields of investigation will possibly permit development of a new concept of “probiotic agents”^[12,13], and should be adequately investigated.

A NEW CONCEPT OF “PROBIOTICS”

The relationship between probiotic agents and innate immune system

In recent years there have been tremendous advances in our understanding of the structure and function of signal receptors, and the pivotal role of pattern recognition receptors (PRRs) and cells of the innate immune system in processing bacterial and food components is now well established^[14-17]. PRRs include trans-membrane Toll-like receptors (TLRs) and Dectin- I; endosomal PRRs (TLR 3, 7/8 and 9); and cytosolic nucleotide oligomerization domain (NOD)-like receptors: (NOD1 and NOD2), Rig-1-like RNA helicase receptor (retinoic acid-inducible gene-1 and iron-regulated surface determinant sensors). The cells involved are dendritic cells (DC), intraepithelial lymphocytes, macrophages, neutrophils and enterocytes. At this level microorganisms are recognized only as microorganism-associated molecular patterns (MAMPs). MAMPs are first recognized by a PRR, and activation of the receptor by binding of the MAMP sequentially activates intracellular molecules such as the cytoplasmic adapter molecule MyD88, leading to the activation of transcription factors including nuclear factor- κ B (NF κ B) and activator protein-1 (AP-1), which are required for gene transcription and cytokine synthesis. The different receptors of the innate immune system are obviously only able to process specific molecular components of microorganisms and foods, whereas the recognition of a whole bacterium or food does not appear possible although simultaneous activation of several PRR's may be characteristic of a specific organism or food and lead to a different outcome than activation by single PRR. For example, studies on host mucosal gene expression following exposure to different whole bacteria have demonstrated up-regulation of different gene networks for each organism. Networks stimulated by these probiotic bacteria included cell proliferation, Th-1/Th2 balance, control of blood pressure, tissue development, water and ion regulation and wound healing. Major host differences were noted in the stimulated transcriptome. The pathways stimulated by the whole organism corresponded to pathways stimulated by known pharmacological preparations. However, the specific molecules of the bacteria that caused these effects are currently unknown^[18]. Further, whether the bacterium is alive or

dead does not seem relevant for the recognition of a molecular pattern by specific PRRs. The accessibility of MAMPs for PRRs and the presence of other microbial effector molecules, such as toxins produced by pathogens, have a pivotal role in the modulation of host immune response. Other important factors determining the host response are host-derived direct or indirect negative regulators of PRR signaling.

To date pathogenic, probiotic and commensal bacteria are considered to induce different levels of immune response: a strong host response stimulated by pathogens, an intermediate response induced by probiotics and finally a homeostatic control of the response is triggered by commensal bacteria. An important exception to this concerns a restricted number of commensal bacteria, the prototype of which is the segmented *Filamentous Bacteria* (SFB), which could largely recapitulate and orchestrate a broad spectrum of B and T cell responses^[19,20]. SFB colonized mice had low levels of ATP, suggesting that host sensing of SFB does not involve TLR or NOD receptors^[21]. We have recently showed that the progressive penetration of the holdfast segments of these bacteria within the specialized epithelial cells of the terminal ileum could permit an impressive presentation of bacterial antigens directly to the lymphocytes contained in the lymphoid packets characteristic of the M cells and to antigen presenting cells^[22].

It should also to be remembered that interactions between PRR and ligands are not as specific as those between antigens and antibodies, and ligands for PRR such as TLRs are generally present in repetitive structures to increase avidity.

Therefore, some very important and specific questions concerning immune-mediated probiotic activity are: (1) Are whole live bacteria essential to promote biological effects on the immune system? (2) Can the concept of probiotics be extended to include bacterial-derived molecular bioactive components? (3) Moreover, can probiotic molecules be also produced by non-probiotic bacteria? and (4) Finally, can probiotics be genetically manipulated to synthesize specific bioactive molecules?

Probiotic molecules

Bacterial DNA: Bacterial genomic DNA of probiotics in VSL-3TM induced a remarkable strain-specific immune response in humans as evaluated by the release of interleukin (IL)-1 β , IL-6 and IL-10. Total bacterial DNA from faeces increased the Th-1 cytokine IL-1 β more than IL-10 compared to DNA from the probiotic bacteria which had the reverse effect. However, total DNA from faeces, after being given a course of the probiotic bacteria, produced a greater stimulation of IL-10 compared to IL-1^[23]. Notably, the respective role of IL-1 β and IL-6 in the beginning and maintenance of a Th17 response is well known^[24,25]. An important and provocative study^[26] showed that in a mouse irritable bowel disease model the protective effects of probiotics contained in VSL-3 are mediated by their DNA rather than by their ability

Table 4 Reference studies concerning the probiotic role of bacterial DNA

| Ref. | Outcomes |

IL: Interleukin; IBD: Irritable bowel disease; TLR: Toll-like receptor.

to colonize the gut mucosa. TLR 9 signaling is essential in mediating the anti-inflammatory effects of probiotics. TLR-9 is an endosomal TLR which is known to interact with bacterial DNA upon bacterial lysis. The authors suggested that DNA-TLR9 signaling resulted in the differentiation of naive cluster of differentiation-4 (CD4) T lymphocytes into regulatory T cells, mediating the protective action. Another example of the immunomodulatory capacity of probiotic DNA is represented by DNA of *Lactobacillus rhamnosus* GG that induces B-cell proliferation and activates DCs^[27]. More recently, the effects on the Th1/Th2 balance by genomic DNA of different probiotic bacteria (*Lactobacillus rhamnosus* GG, *Lactobacillus gasseri*, *Bifidobacterium bifidum*, *Bifidobacterium longum*) were compared with the effects of live bacteria by using peripheral blood mononuclear cells from healthy subjects and from patients with an allergy against the house dust mite^[28]. Compared with live *Lactobacilli*, bacterial DNA inhibited IL-4 and IL-5 secretion in a similar way, and based on the maximal effects achieved with *Lactobacilli* and their DNA, more than 50% of these effects seem to be due to their DNA (Table 4).

The immunomodulatory activity of DNA is characterized by unmethylated CpG motifs which can activate innate immune responses through binding to TLR9 and triggers the translocation of NF κ B and AP-1 from the cytoplasm to the nucleus thereby up-regulating gene expression pathways. Stimulatory oligodeoxynucleosides contain the CpG within a flanking region to give a motif of Pur-p-Pur-p-CpG-p-Pyr-p-Pyr. Typically more than one CpG is present in the immunostimulatory oligodeoxynucleoside and maximal effect occurs if they are separated by 1-2 base pairs. A 5' TpC and pyrimidine rich 3' ends also increases the immunostimulatory effects. In terms of a potential therapeutic, the *in-vivo* degradation can be decreased by synthesizing a phosphorothioate backbone which increases the stimulatory activity of the motif^[29]. A very recent study based on entire genome sequences from five bifidobacterial strains^[30] showed that *Bifidobacterium* genomes contained several CpG motifs and biologically active sequences previously identified in

Lactobacilli. These bioactive sequences induced the production of monocyte chemotactic protein-1 and tumor necrosis factor- α (TNF- α) through a pattern of TLR-9 stimulation of macrophages. An inter- and intra-species investigation of 71 strains of *Bifidobacteria* of various origins showed that these bioactive DNA sequences were highly conserved in the genus. The results of these studies clearly suggest the necessity of further investigation.

MOLECULAR PRESENT AT THE BACTERIAL SURFACE

Bacterial cells wall molecules are potential probiotic ligands that can interact with PRRs and induce signaling pathways resulting in probiotic effects (Table 5).

The immune system is able of recognizing any biological polymer constituting the bacterial cell wall and presenting it to T cells. Most probiotics are typically *Gram-positive bacteria*, in which the cell wall is composed of a thick peptidoglycan layer with proteins, teichoic acids and polysaccharides^[31]. However few *Gram-negative probiotics* exist, such as *Escherichia coli* strain Nissle 1917; in this case the cell wall is composed of a thin peptidoglycan layer and an outer membrane which contains lipopolysaccharides (LPS) that is further decorated with the proteins and polysaccharides^[32].

Although adaptive immune responses have been considered the territory of antigenic proteins or glycoproteins, whereas carbohydrates were considered as not recognized by the adaptive immune system, recent studies have revolutionized this assumption. Bacterial wall polysaccharides and glycolipids are now considered perhaps the more attractive targets in the research for immunomodulatory molecules. Interestingly, the bacterial capsular polysaccharide A (PSA), the most immunodominant among the zwitterionic polysaccharides elaborated by *Bacteroides*

fragilis, a commensal *Gram-negative anaerobe* that colonizes the mammalian lower gastrointestinal tract, has been demonstrated to be the archetypal bacterial molecule capable of mediating development of the host immune system^[33]. PSA presented by intestinal DCs activates CD4+ T cells and elicits appropriate cytokine production. *Bacteroides* species are among the earliest colonizing and most represented microorganisms of the gut microbiota^[34], and they are not considered probiotic species. More recently Mazmanian *et al*^[35] showed that the *Bacteroides fragilis*-produced PSA protects mice from experimental colitis induced by *Helicobacter hepaticus*: purified PSA is required to suppress pro-inflammatory IL-17 production by intestinal T cells, and it also protects from inflammatory disease by induction of IL-10-producing CD4+ T cells. Therefore, although bacteria may have developed polysaccharide capsules known to be not recognized by the immune system, it may be that the host not only tolerates but also has evolved to require cooperation by commensal bacteria for its health. Strikingly, the finding that PSA from *Bacteroides fragilis* is a natural anti-inflammatory molecule that promotes health, so clearly performing important probiotic activities, is not produced by a probiotic bacteria, provides a fundamental platform for the discovery of new biomolecules having important probiotic effects independently from their bacterial derivation.

Polysaccharides synthesized extracellularly (exopolysaccharides, EPSO) also represent attractive candidates as probiotic effector molecules interacting with PRRs. EPSO are produced by both probiotic and symbiotic bacteria, and also potentially pathogenic bacteria, but they have not yet been studied in detail.

On the other hand, lipoteichoic acid (LTA) is considered the major immunostimulating component of the cell wall of *Gram-positive bacteria* via TLR 2 (most of the known probiotics, *Lactobacilli* and *Bifidobacteria*, are *Gram-positive bacteria*), in the same way as LPS is the major immunostimulating component in the cell wall of *Gram-negative bacteria* via TLR 4. Two important concepts concerning LTA have emerged in recent years: the first concerns the much lower potency in the stimulation of TLR 2 pathway to induce pro-inflammatory molecules by using purified LTA from a probiotic strains of *Lactobacillus plantarum* in comparison with a pathogenic strain of *Staphylococcus aureus*^[36]; the second very important concept is related to the possible modification of LTA molecules to induce a substantial reduction in *D*-alanine content with a marked increase in glucose substitutions^[37]. These modified LTA may be candidates as probiotic effector molecules able to induce secretion of anti-inflammatory IL-10.

On the other hand, LPS synthesized by *Gram-negative bacteria* of the gut microbiota have been recently involved in the development of inflammation, obesity and type 2 diabetes induced by a high fat diet^[38]. If confirmed, these findings open up a new possible role in this field not only for a direct bacterial competition by live probi-

otics, but also for research into non-immunostimulating molecules competing with LPS for the TLR 4 pathway.

Finally, both lipoproteins and glycoproteins present at the cell surface are also attractive candidates as probiotic molecules for their interactions with TLR 2 receptors, but to date their role is unexplored even in pathogenic bacteria^[39]. However flagellins of the *Escherichia coli* Nissle 1917 induce the expression of human β -defensin 2, an inducible antimicrobial peptide^[40].

Recombinant probiotics: Colonizing (*e.g.*, *Streptococcus gondii*, *Lactobacillus plantarum*, *Lactobacillus paracasei*, *Lactobacillus casei*, *Lactobacillus acidophilus*) as well as non-colonizing (*e.g.*, *Lactobacillus lactis*) bacterial species have been investigated both as live vaccine vehicles (acting as carriers for protective antigens) and as active producers of molecules with known pharmacological properties.

In respect to the use of these microorganisms as carriers for antigens, the most complete studies have been carried out with the 50 kDa carboxy-terminal fragment of tetanus toxin^[41]; this approach has now been extended to additional antigens eg the B subunit of cholera toxin^[1-3].

Transfected bacteria have also been used to deliver cytokines, but this technique was recently used to investigate other biological properties. Steidler *et al*^[42] chose to construct recombinant *Lactobacillus lactis* strains secreting murine IL-10. These authors demonstrated that these recombinant strains were able to prevent and treat inflammation in two murine models of colitis. Significantly, the same effects were obtained with much lower doses of IL-10 than those required when IL-10 itself was used as a drug. The same authors further constructed a safe (no antibiotic resistance markers and a chromosomally integrated transgene) strain of *Lactobacillus lactis* secreting IL-10 of human origin^[43]. Authorization by a local ethical committee to carry out a phase 1 clinical study on voluntary patients has been obtained in the Netherlands^[44]. In this study, Crohn's disease patients were treated with recombinant *Lactobacillus lactis* (LL-THY 12) in which the thymidylate synthase gene was replaced with a synthetic sequence encoding mature human IL-10. The oral administration of this strain was safe and a decrease in disease activity was observed. The authors concluded that the use of genetically modified bacteria for mucosal delivery of therapeutic proteins is a feasible strategy in human beings. This strategy avoids systemic side effects and appears suitable as maintenance treatment for chronic intestinal diseases. Novel therapeutic strategies for acute and chronic colitis based on recombinant probiotics were also assessed by the generation and *in vivo* evaluation of *Lactobacillus lactis* strains secreting bioactive murine trefoil factors (TFF)^[45]. The authors demonstrated that intragastric administration of this bacterial strain, but not of purified TFF, led to prevention and healing in the acute dextran sodium sulfate (DSS)-induced murine model of colitis, and was similarly effective in reducing established chronic DSS colitis. It has also to be remem-

bered that production and mucosal delivery of different bioactive molecules such as allergens, digestive enzymes and single-chain Fw antibodies have been achieved using lactic acid bacteria^[3]. Targeted diseases included vaginal candidiasis^[46], dental caries^[47], allergies^[48-50], autoimmune diseases^[51,52], human papillomaviruses-induced tumors^[53] and pancreatic insufficiency^[54]. More recently, Rosberg-Cody *et al.*^[55] investigated whether a recombinant strain of *Lactobacillus paracasei*, previously isolated from the human gastrointestinal tract, expressing conjugated linoleic acid (CLA) isomerase from *Propionibacterium acnes*, could influence the fatty acid composition of different tissues in the mouse. Ingestion of the *Lactobacillus paracasei* strain expressing CLA isomerase was associated with a 4-fold increase ($P > 0.001$) in t10c12 CLA in adipose tissues of the mice when compared with animals that received the non-CLA producing isogenic strain. These data show that a single gene encoding CLA isomerase expressed by an intestinal bacterium can influence the fatty acid composition of the host adipose tissue. This t10c12 CLA isomer is also associated with decreased body fat and increased lean body mass in various animal species^[56-60] and, to some extents, human beings^[61-65]. It is also well known that t10c12 CLA isomer is the most potent isomer in terms of potential to prevent cell proliferation and induce apoptosis in cancer cells^[66-69]; notably, when the microbially derived t10c12 CLA was incubated with SW480 colon cancer cells for 5 d, cell viability was decreased by 92%^[70], and it is possible that a CLA-producing probiotic will be able to keep colon cancer cells in check. Although commensal *Bifidobacterium* and *Lactobacillus* species from the gastrointestinal tract have been shown to produce CLA *in vitro*^[71-73], the majority of these studies have demonstrated the production of c9t11 CLA from linoleic acid, while only a few bacteria such as *Propionibacterium acnes*^[74], the rumen bacterium *Megasphaera elsdenii*^[75], and the human derived *Lactobacillus rhamnosus* PL60 and *Lactobacillus plantarum* PL62^[76,77] have been reported to produce t10c12 CLA. Modulation of fatty acid production by bacteria may represent very important probiotic activity and recombinant probiotics may become useful for this in the near future.

Recombinant probiotics may be linked not only to the addition of one or more genes but also to the deletion of one or more genes. In fact, to study the molecular mechanisms involved in the induction and repression of intestinal inflammation, Mohamadzadeh *et al.*^[78] have recently deleted the phosphoglycerol transferase gene that plays a key role in LTA biosynthesis in *Lactobacillus acidophilus* NCK 56.

The results of these authors show that the *Lactobacillus acidophilus* LTA⁻ not only down regulated IL-12 and TNF- α , which are known pro-inflammatory cytokines, but also significantly enhanced IL-10 production by DC and controlled the regulation of co-stimulatory DC functions, resulting in their inability to induce CD 4+ T cell activation. The treatment of mice with *Lactobacillus acidophilus* LTA⁻, compared with *Lactobacillus acidophilus* LTA⁺, signifi-

cantly counteracted DSS-induced colitis. These authors concluded that directed alteration of cell-surface components of *Lactobacillus acidophilus* represents a potential new strategy for the treatment of inflammatory intestinal disorders.

Moreover, efforts have been devoted to improve the efficacy of probiotic bacteria as delivery systems; in this context cell wall mutants of *Lactobacillus plantarum* and *Lactobacillus lactis* defective in alanine racemase (*alr* gene) were constructed^[79,80]: each of these mutants behaved as a substantially improved antigen delivery system compared with its wild-type counterpart^[81]. The potency of the *Lactobacillus plantarum* Alr⁻ mutant was further confirmed using a weak immunogen, such as *Helicobacter pylori* urease B, as a protective antigen; a significant reduction of the *Helicobacter pylori* load in the mouse stomach was achieved after immunization with the recombinant mutant *Lactobacillus plantarum* strain in contrast to results obtained with its wild-type counterpart^[82].

Any gene coding for an active molecule, potentially useful for human health, may be used to generate recombinant probiotic bacteria; in this context, an impressive number of options are available to be investigated in *in vitro* and *in vivo* studies. It is worthy of note, however, that several gene products need glycosylation, phosphorylation or other more complex chemical changes; these may require the enzymatic machinery of eukaryotic cells. Thus, although current available genomic information should greatly facilitate the generation of useful recombinant probiotics, several technical issues and biologically limiting factors have to be taken attentively in consideration. In any case, the use of rapidly evolving genomic technology will surely help to evolve this intriguing and fascinating field and we can expect that from the present pioneering status we will soon progress to the generation of innovative therapeutic tools.

CONCLUSION

We are convinced that, even if as mentioned above there is a very large amount of work to be performed in this field, the available evidence is already enough to move from the actual concept of probiotics to novel and very promising pharmacobiotic strategies. In fact, probiotic molecules and recombinant probiotics may represent an unlimited resource for innovative therapeutics. The following questions arise from the present analysis of available knowledge: (1) Why the therapeutic potential of probiotic molecules and recombinant probiotics has been neglected so far? (2) Why important studies showing that whole live bacteria are not needed for probiotic activity have not received adequate attention by the scientific community? (3) Why molecules such as polysaccharide-peptidoglycan (PSPG)- I from *Lactobacillus shirota*, which have demonstrated to be able to suppress inflammation in chronic intestinal inflammatory disorders *via* inhibition of IL-6, have not been extensively investigated yet? IL-6 plays a pivotal role both in activation and sustainment

of Th 17 response as well as a crucial role as a proinflammatory IL in Th 17 and Th1 cell responses. Thus the dose dependent pharmacological inhibition of IL-6 levels could have a crucial clinical impact, as suggested by animal studies^[83]. Based on these considerations, (4) Why, after identification of adequate drug delivery strategies (in fact, there may be major challenges with formulation and delivery in single cases), the clinical effectiveness of PSPG- I has not been assessed yet? and (5) Why has only a phase I study has been performed with recombinant probiotics? These are crucial questions with important implications. Thus these questions should be discussed at international level by a forum involving different players including, basic researchers, clinicians (gastroenterologists, pediatricians, allergologists, pneumologists, *etc.*), lawgivers and regulatory agencies, and probiotics pharma. Although there are already international organizations that declare to be independent of the industry, such as the aforementioned ISAPP, which tackle these issues, these have within them industry advisory committee members and have not been able until now to pull the current outdated concept of probiotics to the more inclusive concept of pharmabiotics.

Although guidelines and recommendations substantiating the evidence for beneficial effects of probiotics in different clinical conditions of adult patients have been published^[6,7,84-87], the only clinical conditions in which strains of whole live probiotics have been shown to be effective thus far are acute gastroenteritis and antibiotic-associated diarrhoea. It seems therefore that live probiotics can exert a competitive action and can have a role in restoration of intestinal flora. However, a specific role in the cure of chronic and/or autoimmune diseases has not been conclusively demonstrated. Despite this, an entire world involving probiotic molecules and recombinant probiotics is ready to be investigated. In any case, if specific live probiotic strains have been or will be found effective in specific concentrations for specific disease conditions should they still categorized as food supplements? To what extent does the market influence the national regulatory laws in this area? We think that gut microbiota and probiotic bacteria represent an inexhaustible mine from which countless molecules of potential value for human health can be obtained and investigated. If this does not happen, we risk going on discussing whether a live strain is better than another without ever reaching any definitive conclusion for many years. Even if single RCTs demonstrate a level of evidence 1a, but the findings are not confirmed by other authors in order to remove any doubt about the therapeutic role of that strain in the given clinical condition at that specific doses and route of administration, it does not solve the problem and continues to maintain doubts about the role of probiotic therapy. In addition, it should be underlined that clinical studies are almost always sponsored by companies and results of rigorous RCTs are restricted to the strains of company interest. Who needs to maintain the “status quo” without moving the research to a plot of

real pharmacobiotic strategies? Is the huge market based on “easy” trade of live microorganisms involved? We do not want to be unpleasant to anybody, but we think that opening an international forum on this important issue would be of great benefit to both physicians and patients. If to tell the story of salutistic products through well-made advertisements in the media induces big gains without big expenses, we fear that hardly anyone will decide to invest in this area. This way the birth of the pharmacobiotic era will turn away more and more. The resources that are available to us are often sacrificed by humans on the altar of interests and market strategies: among the chief concerns of the scientific community is the need to denounce all those situations in which scientific rigor is sacrificed to commercial interests. To avoid this, the following two actions are mandatory: (1) international guidelines by the forum of players made available to scientists and clinicians, patient organizations, and lawgivers; and (2) public research funds made available to the scientific community for performing independent rigorous studies both at preclinical and clinical levels.

Abstract

Metagenomics which combines the power of genomics, bioinformatics, and systems biology, provide new access to the microbial world. Metagenomics permit the genetic analysis of complex microbial populations without requiring prior cultivation. Through the conceptual innovations in metagenomics and the improvements in DNA high-throughput sequencing and bioinformatics analysis technology, gastrointestinal microbiology has entered the metagenomics era and become a hot topic worldwide. Human microbiome research is underway, however, most studies in this area have focused on the composition and function of the intestinal microbiota and the relationship between intestinal microbiota and metabolic diseases (obesity, diabetes, metabolic syndrome, *etc.*) and intestinal disorders [inflammatory bowel disease, colorectal cancer, irritable bowel syndrome (IBS), *etc.*]. Few investigations on microbiota have been conducted within the upper gastrointestinal tract (esophagus, stomach and duodenum). The upper gastrointestinal microbiota is essential for several gastrointestinal illnesses, including esophagitis, Barrett's esophagus, and esophageal carcinoma, gastritis and gastric cancer, small intestinal bacterial overgrowth, IBS and celiac disease. However, the constitution and diversity of the microbiota in different sections of the upper gastrointestinal tract under health and various

disease states, as well as the function of microbiota in the pathogenesis of various digestive diseases are still undefined. The current article provides an overview of the recent findings regarding the relationship between upper gastrointestinal microbiota and gastrointestinal diseases; and discusses the study limitations and future directions of upper gastrointestinal microbiota research.

INTRODUCTION

Microbes associated with the human body include bacteria, archaea, fungi, and viruses. The vast majority of studies on microbiota have focused on bacteria. A large number of micro-organisms colonize on the surface of and within the human body and can reach counts of 10^{12} - 10^{14} , 10 times that of the cells of the human body, while the number of genes in these micro-organisms, approximately 3.30 million, is 150 times higher than that in the human body^[1]. Humans are a type of super organism composed of the human body and symbiotic micro-organisms^[2], therefore, researching human diseases from only the human body point of view reveals only a partial view of a condition; thus, the role of commensal microbiota in human health and disease must be considered. Micro-organisms and their metabolites play important roles in human energy metabolism^[3], the absorption of nutrients^[4], immune function^[5] and other important physiological activities^[6]. In fact, a variety of human diseases will be induced when commensalism between the

host and the microorganisms is disrupted.

Microbiota composition has classically been analyzed using cost-effective and reproducible culture techniques that use differential media to select for specific bacterial populations. Early microbiological studies relied mainly on traditional culture-based methods. However, the overall microbial community structure, spatial distribution and dynamics could not be fully demonstrated using traditional culture-based methods due to the fact that 99% of such micro-organisms are uncultured^[1]. As the gene sequence of 16S rRNA has a combination of highly conserved and variable sequences in a relatively short portion of the bacterial chromosome^[7], it is increasingly used to characterize the diversity of the complex microbial communities that can be sampled from different sites of the body in both healthy individuals and patients with diverse pathological conditions^[8-12]. Many bacterial 16S rRNA gene-dependent methods, including terminal restriction fragment length polymorphism (TRFLP)^[13], denaturing and temperature gradient gel electrophoresis (DGGE and TGGE)^[14], ribosomal intergenic spacer analysis (RISA)^[15], DNA microarray^[16] and fluorescence *in situ* hybridization (FISH)^[17], have emerged as molecular biology techniques; however, the information obtained by the above methods has been very limited, thus, ongoing studies cover only a small portion of this field.

Recent microbiological studies are firmly supported technically along with the introduction of the concept of metagenomics^[18], the development of high-throughput DNA sequencing and bioinformatics technology. Metagenomics mainly include two strategies: first, the high-throughput sequencing of 16S rDNA hypervariable regions, which can provide diversity and abundance information on microbial communities, while not supplying the functional genes of microbiota and that is mainly used in the classification, identification and comparison of microbiota^[8,9]; second, metagenomic sequencing of whole community DNA, not only provides information on microbiota structure and abundance, but can also be used in the functional annotation and building of metabolic networks, and favors the in-depth investigation and screening of functional genes^[11,19,20]. Over the past 3-5 years, sequencing cost and time have been greatly reduced; thus, the feasibility of comprehensive and detailed studies of the microbiota has increased significantly.

The United States National Institutes of Health launched the Human Microbiome Project (HMP) in 2007^[20]. The European Commission also initiated the metagenomics of the human intestinal tract funded by the 7th Framework Program of the European Union in 2008. Scholars from various countries established the International Human Microbiome Consortium in 2009, an international cooperative effort aiming to explore the relationship between microbiota and human health and disease. The editors of *Science* had predicted that human microbe research may become a new hot topic worldwide^[2]; in fact, studies of microbiota in human health and disease based on high-throughput sequencing and bioinformatics

technology have already been initiated. Not long ago, the HMP Consortium investigated the human microbiome based on healthy adults sampled from five body regions including the feces, oral cavity, airway, skin and vagina, which generated 5177 microbial taxonomic profiles from 16S ribosomal RNA genes and > 3.5 terabases of metagenomic sequence to date^[19]. However, the mucosa-associated microbiota of the gastrointestinal tract was not evaluated in this study. Most researches today have focused on intestinal microbiota and the relationship between intestinal microbiota and metabolic diseases (obesity, diabetes, metabolic syndrome, *etc.*)^[11,21-23] and intestinal disorders [inflammatory bowel disease (IBD), colorectal cancer (CRC), irritable bowel syndrome (IBS), *etc.*]^[1,24-26], and rarely examined upper gastrointestinal tract microbiota. Here we review the evidence for a microbiota concept in upper gastrointestinal diseases and highlight recent studies that have enhanced our appreciation of the relationship between microbiota and human health and disease.

MICROBIOTA AND THE ESOPHAGUS

The esophagus, unlike the oral cavity, stomach and colon, does not retain food contents. Studies using culturing methods have suggested that the esophagus is either sterile or contains only a few transient microbes originating from the oropharynx by swallowing or from the stomach by gastroesophageal reflux^[27]. Moreover, under certain disease conditions, several pathogenic microorganisms, such as *Candida albicans*, *Cryptococcus* or *Herpesvirus*, can infect the esophagus^[28-31]. Whether an imbalance of esophageal microbiota is responsible for esophageal disorders remains unclear; in fact, investigations of esophageal microbiota remain limited^[27,32-38].

Culture-based studies mainly used luminal washes of esophageal contents^[27,36] and their results were not convincing. Gagliardi *et al.*^[27] demonstrated that *Streptococcus viridans* (*S. viridians*) may be the most numerous microorganism in both the normal esophagus and the oropharynx. Norder Grusell *et al.*^[36] also reported that *S. viridians* was the most common bacterium using both brush samples and biopsies; and this study confirmed that the human esophagus could be colonized with a resident flora of its own, although it was similar to the flora present in the oral cavity.

Culture-independent methods have recently been used more frequently to characterize the diversity of the microbiota in the esophagus^[33,37,38]. Pei *et al.*^[33] investigated the composition of microbiota in the normal distal esophagus using broad-range 16S rDNA polymerase chain reaction (PCR). They confirmed that the majority of esophageal microbiota were known and cultivable; and found that *Streptococcus*, *Prevotella* and *Veillonellaceae* were the most prevalent genera in esophageal biopsies. Yang *et al.*^[37] characterized the diversity of the microbiota of the distal esophagus in individuals with normal esophagus and in patients with esophagitis and Barrett's esophagus using

16S rDNA sequencing. They classified the esophageal microbiota into two types: *Streptococcus*-dominated in the normal esophagus and *Gram-negative anaerobes* in Barrett's esophagus and esophagitis^[37]. However, this study could not answer the question of how the microbiota participates in the pathogenesis of esophageal inflammation.

Gastroesophageal reflux impairs the mucosal barrier in the distal esophagus, allowing chronic exposure of the epithelial cells to diverse microbiota and inducing chronic inflammation. Chronic inflammation may play a critical role in the progression from reflux-related intestinal metaplasia or Barrett's esophagus to esophageal carcinoma^[39]. Until now, there has been no research on the diversity of esophageal microbiota in patients suffering from esophageal squamous or adenocarcinoma.

Interestingly, Fillon *et al.*^[40] sampled the microbiome in normal histological esophageal mucosa using a novel device, the Enterotest™ capsule, and found that the microbiota phylum-level diversity was similar in samples from the esophageal mucosa biopsy, esophageal string test, oral string and nasal swab as identified using 454 pyrosequencing; moreover, at the genera level, the most common three genera, *Streptococcus*, *Prevotella*, and *Veillonella*, were similar in the esophageal string test and mucosal biopsy samples, a finding that was consistent with the findings of Pei *et al.*^[33]. In fact, this novel instrument could be used for future research on the microbiota within the human esophagus. However, this study did not eliminate the effect of proton pump inhibitors (PPI)^[41,42], steroids^[43] or restricted diet on esophageal microbiota. It is also evident that PPI could have an effect on gastrointestinal microbiota^[41], and long-term PPI treatment is very common in reflux esophagitis, therefore, it may be meaningful to estimate the effect of long-term PPI treatment on esophageal microbiota.

In addition, Chagas' megaesophageal disease caused by *Trypanosoma americanum* infection is usually associated with esophageal bacterial overgrowth, recurrent pulmonary infections and esophageal neoplasia^[32]. Pajecski *et al.*^[32] showed that patients with megaesophageal disease could present with a wide variety of microbiomes, mainly aerobic *Gram-positive* and *anaerobic bacteria*. The imbalance of esophageal microbiota could play a causal role, and high-throughput sequencing technology could be used to understand esophageal bacterial overgrowth in Chagas' megaesophageal disease.

MICROBIOTA AND THE STOMACH

The stomach is a special area in the gastrointestinal microecosystem. Its unique ecological environment and characteristic microbial community are due to gastric acid secretion. Because the stomach connects the esophagus and oral cavity on the upper side and the duodenum on the lower side, bacteria from the mouth, pharynx, nose, respiratory tract, esophagus and small intestine can enter the stomach. It was once believed that gastric acid could kill the bacteria entering the stomach and that the

stomach environment was not suitable for bacterial colonization; however, some studies using traditional culture methods confirmed that large numbers of acid-resistant bacterial strains exist in the stomach and are mainly derived from the transient flora in the mouth and food, including *Streptococcus*, *Neisseria* and *Lactobacillus*, while the content was generally $< 10^3$ colony-forming unit/mL (CFU/mL)^[44].

In 1984, Marshall *et al.*^[45] isolated *Helicobacter pylori* (*H. pylori*) from the stomach, thus starting a new era of *H. pylori* and digestive diseases research, and won the Nobel Prize in medicine. With the development of molecular biology and bacterial 16S rDNA identification techniques, the composition of the stomach flora was gradually investigated using new molecular biological methods. Using bacterial 16S rDNA PCR and TGGE, Monstein *et al.*^[46] demonstrated that some other microbes, including *Enterococcus*, *Pseudomonas*, *Staphylococcus* and *Stomatococcus*, exist within the gastric mucosa.

The identification of stomach flora has increased dramatically with the development of metagenomics and high-throughput sequencing technology. Bik *et al.*^[47] performed a 16S rDNA sequencing analysis of the stomach flora of 23 patients with gastric diseases, identified 128 kinds of phylotypes belonging to eight classes, and obtained 1056 non-*H. pylori* clones. Li *et al.*^[48] performed a 16S rDNA high-throughput sequencing analysis of the gastric mucosa-associated flora in *H. pylori*-negative patients with gastritis who had never used non-steroidal anti-inflammatory drugs and obtained a total of 1223 non-*H. pylori* clones that could be classified into 133 kinds of phylotypes belonging to eight bacterial classes. Although the above two studies were conducted in populations within different regions and ethnic groups, the stomach flora composition was very similar among those populations. The two studies identified approximately 130 phylotypes belonging to 7-8 classes, and 77.4% and 79.8% of clone fragments separately for each study were homogeneous. The two species with the highest abundance, *Streptococcus* and *Prevotella*, were the same. Anderson *et al.*^[49] conducted pyrosequencing analyses of gastric mucosa-associated flora in six healthy subjects and obtained 262 phylotypes belonging to 13 classes, including strains that had not been confirmed by other studies such as *Chlamydia* and *Cyanobacteria*. Stearns *et al.*^[50] performed high-throughput 16S rDNA sequencing analysis of the oral, stomach, duodena and colon mucosa-associated flora as well as feces-related flora in four healthy subjects. The obtained stomach flora constitution was more detailed than that obtained by Bik *et al.*^[47] due to the higher sequencing depth. The high-throughput 16S rDNA sequencing techniques based on the metagenomics strategy were adopted in the above studies; thus, the obtained stomach flora information was detailed and showed that huge numbers of bacteria other than *H. pylori* exist in the stomach.

Gastrointestinal microbiota distribution is spatially specific. The gastric juice-associated microbiota is easily

affected by diet and other factors; thus, they are variable. In contrast, the gastric mucosa-associated microbiota is relatively stable and less affected by interference factors. Furthermore, gastric mucosa-associated flora can affect the host more directly and are more closely related to the pathogenesis of gastric disease. Li *et al.*^[48] thoroughly washed gastric mucosal biopsy samples, but found no change in the constitution of gastric mucosa-associated flora; thus, the gastric flora proved to be closely associated with gastric mucosa and could not be readily washed away. Although some microbes such as *Streptococcus* genus have a high abundance in both the oral cavity and stomach^[47,48,51], the study by Li *et al.*^[48] indicated that many non-*H. pylori* microbes could be resident flora in the human stomach, and not just transient flora from the oral cavity.

The use of feces has been widely adopted in the study of the relationship between intestinal microbiota and diseases as it is easily sampled and reflects the overall constitution of the intestinal flora. It is worth noting that feces-associated flora are less interfered with by host DNA; thus, they can be sequenced for whole communities of DNA or for 16S rDNA hypervariable regions. Gastrointestinal mucosa-associated flora are usually interfered with by host DNA; thus, they are commonly investigated using 16S rDNA sequencing.

Stomach flora and *H. pylori*

H. pylori is a Gram-negative bacillus that colonizes the stomachs of approximately 50% of individuals worldwide. *H. pylori* has been investigated more deeply than any other stomach pathogen. Although *H. pylori* is the major pathogenic factor of chronic gastritis and peptic ulcer and is one of the risk factors for gastric adenocarcinoma and mucosa-associated lymphoid tissue lymphoma^[52,53], the relationship between *H. pylori* infection and gastric diseases remains unclear. Stomach colonization was negative even after several weeks of oral implantation of *H. pylori* in specific pathogen-free animal models; however, it was usually positive in germ-free animal models^[54], suggesting that other stomach flora affected the intragastric colonization of *H. pylori* and its activity in gastric diseases.

In vivo and *in vitro* studies based on animal models have found that some probiotics including *Lactobacillus*, *Bifidobacterium* and *Saccharomyces* can prevent the adhesion, colonization and growth of *H. pylori* in gastric mucosa. Zaman *et al.*^[55] confirmed that some *Lactobacillus* species prevented the colonization of *H. pylori* in the stomachs of Mongolian gerbils, while *Eubacterium limosum* promoted the colonization of *H. pylori*. Yin *et al.*^[56] found that long-term intragastric colonization of *H. pylori* could affect the distribution and number of flora in the stomach and duodenum. For example, the propagation of *Lactobacilli* was inhibited, while *Enterococcus*, *Staphylococcus aureus*, *Bifidobacterium* and *Bacteroides* were rarely affected. Sun *et al.*^[57] believed that some *Lactobacillus* species were dominant strains in the stomachs of Mongolian gerbils that were not affected by *H. pylori* infection; *Lactobacillus gasseri* and

Lactobacillus reuteri existed in the gerbils' stomachs and suppressed the colonization and growth of *H. pylori*.

A small number of studies based on the human body also confirmed that *H. pylori* interacted with other gastric flora. Using traditional culture methods, Garcia *et al.*^[58] analyzed the gastric mucosa-associated flora and showed that some *Lactobacillus* species competed with *H. pylori* for colonization resources. Hu *et al.*^[59] conducted bacterial cultures using gastric mucosal biopsy samples and found that the dominant species, including *Streptococcus*, *Neisseria*, *Rothia* and *Staphylococcus*, were primarily sourced from the upper respiratory tract. They believed that *H. pylori* infection was usually accompanied by the colonization of non-*H. pylori* bacteria; they noted that these non-*H. pylori* bacteria played certain roles in gastric diseases. Sanduleanu *et al.*^[60] thought that non-*H. pylori* bacteria and their products could persist in the stomach as antigenic stimulators that enhance the immune response caused by *H. pylori* infection and that their co-infection could promote the development of atrophic gastritis. Clinical trials have initially confirmed that probiotics treatment can reduce the gastric colonization density of *H. pylori*^[61]. Probiotics can increase the eradication rate, decrease the relapse rate and reduce antibiotic side effects; thus, they may be used as an effective supplement in *H. pylori* eradication therapy.

The above results suggested that the *in vivo* colonization of *H. pylori* was closely related with other stomach flora; however, most of the above studies were based on animal models and limited by their methods. As such, composition of the human stomach flora and which stomach flora can inhibit or promote the intragastric colonization of *H. pylori* have not been or cannot be comprehensively understood.

Stomach flora and gastric cancer

Gastric cancer is one of the most common malignancies worldwide. The pathogenesis of gastric cancer is a process of multiple stages and steps affected by multiple factors that involve a huge number of molecules and complex regulation networks. The cause of gastric cancer is still not clear despite deep decades-long studies. It is generally believed that environmental, dietary, *H. pylori* infection and genetic factors participate in the pathogenesis of gastric cancer. Furthermore, *H. pylori* is closely related with gastric cancer, although whether other intragastric flora facilitate or inhibit the effect of *H. pylori* in gastric cancer development remains unknown and very few studies have examined this issue.

The pathogenesis of CRC may be the result of interactions among the intestinal flora, intestinal mucosal immunity and host genetic susceptibility^[62]. Intestinal flora interfere with the signal mechanisms of pro-inflammatory reactions in the intestinal mucosa and results in excessive repair of mucosal injury and ultimately induces tumorigenesis and canceration^[63]. Some intestinal microbes and their metabolites have direct or indirect cytotoxic effects on intestinal mucosal epithelial cells, and incomplete repair of damaged intestinal mucosal epithelium may result

in neoplastic transformation^[63]. Animal studies have also confirmed that permanent and normal intestinal flora are necessary for intestinal tumorigenesis^[64]. Studies on the relationship between intestinal flora and CRC indicated that the permanent and normal intragastric flora and their composition might participate in the pathogenesis of gastric cancer. However, few studies have focused on the issue of whether new ways of enabling early warning and early diagnoses of gastric cancer can be established using in-depth analysis and studies of gastric flora composition. The primary reason for this is that due to the large and complex flora network, comprehensive and detailed information on flora constitution could not be obtained by studies using culture-based methods; thus, the microecological study of the relationship between other stomach flora and gastric cancer pathogenesis could not be conducted. Dicksved *et al.*^[65] recently analyzed the stomach flora constitution of patients with gastric cancer and found no significant differences in the stomach flora of patients with gastric cancer and those of patients with dyspepsia and normal gastric mucosa. However, there were many limitations in that research, including the small size of the included samples and the fact that a new generation of high-throughput sequencing technology was not used; thus, the results remain to be confirmed since the stomach flora were not comprehensively and deeply studied. To date, no study on the relationship between stomach flora and gastric cancer using high-throughput sequencing technology based on the metagenomics strategy has been performed.

Stomach flora and gastric polyp

Gastric polyps are focal elevated lesions within the gastric epithelium mucosa. The current limited systematic studies of gastric polyps focus mainly on the relationship between gastric polyps and cancer as well as the role of *H. pylori* in the pathogenesis. The possible pathogenesis related to the development of gastric polyps include hereditary factors, bile reflux, *H. pylori* infection, etc., while none have been directly proved. As such, the etiology and biological characteristics of gastric polyps and its long-term effects on the human body are not yet clear. Studies of gastric polyps are far less detailed than those of colonic polyps. The intestinal flora are involved in the pathogenesis of colonic polyps^[24,25], while no study focusing on the relationship between stomach flora constitution and gastric polyps pathogenesis from the perspective of gastric microbiota using bacterial 16S rDNA sequencing has been reported.

Overall, the constitution and diversity of stomach flora under various disease states, the interactions between *H. pylori* and other stomach flora and their underlying mechanisms as well as the effect of stomach flora in the pathogenesis of various stomach diseases are expected to be uncovered more deeply from the perspective of intestinal microbiota using high-throughput bacterial 16S rDNA sequencing technology based on the metagenomics strategy.

MICROBIOTA AND THE DUODENUM

Much less is known about the microbes that are present within the duodenum, particularly because collecting samples for such microbial ecology studies is much more challenging. However, continued efforts in this regard are needed, especially in light of the growing recognition of the composition of the duodenal microbiota and the association with health and gastrointestinal disorders as revealed in recent studies. Duodenal microbiota studies have focused predominantly on small intestinal bacterial overgrowth (SIBO), IBS, and celiac disease (CD).

Duodenal flora and SIBO

Some risk factors, such as demographics (older age), anatomic abnormalities (*e.g.*, small intestinal diverticula and gastric resection), motility disorders (*e.g.*, CD, diabetic neuropathy and scleroderma), organ system dysfunction (*e.g.*, cirrhosis, chronic pancreatitis and end-stage renal disease), and medications (*e.g.*, recurrent antibiotics and gastric acid inhibitors), are closely associated with SIBO^[66].

SIBO has been traditionally defined according to the number and type of culturable bacteria within duodenal or jejunal aspirates: 10^5 CFU/mL of colonic-type bacteria has been commonly used^[67]. Although some studies have diagnosed SIBO using a direct test—that is, bacterial cultures of aspirate from the small bowel^[68], the majority of gastrointestinal microbiota could not be cultured, the culture-based method can not reveal the real changes in microbiota in the small intestine in various disease conditions. The lactulose/glucose breath tests have also recently been used for the diagnosis of SIBO^[69,70], however, these are indirect tests with poor sensitivity and specificity^[71,72]. In the future, high-throughput bacterial 16S rDNA sequencing may be used to determine the composition of microbiota in the small intestine in some disorders which could lead to SIBO, and contribute to new diagnostic criteria for SIBO.

Duodenal flora and IBS

IBS is a common disorder characterized by abdominal pain or discomfort associated with disturbed bowel function such as constipation and/or diarrhea^[73]. Epidemiological and clinical data support the new bacterial concept of IBS^[74]. Altered intestinal microbiota composition^[75-79] and gut flora metabolites (*e.g.*, short-chain fatty acids butyrate, acetate, and propionate; CH₄ and H₂ gases)^[79,80] were observed in patients with IBS. An etiological role of gastrointestinal infection in the development of IBS has been confirmed^[81]. The final and most promising area is that of alterations in small intestinal microbiota in a subset of patients with IBS^[74,82]. Several probiotics^[83,84] and antibiotics^[85] might play a potential therapeutic role in IBS.

Most studies in this area have investigated the changes in fecal microbiota in patients with IBS^[86,87], however, corresponding investigations of the microbial composi-

tion of the small intestine, the duodenum in particular, in patients with IBS are rare^[88,89]. A recent specific real-time PCR-based investigation using duodenal mucosa brush samples noted that the percentage of *Bifidobacterium* corresponding to the species *Bifidobacterium catenulatum* was significantly lower in patients with IBS than in healthy subjects^[88]. The same group showed higher levels of *Pseudomonas aeruginosa* in the upper small intestine of patients with IBS than in healthy subjects^[88]. Although further investigation is required, these findings suggest that therapies involving modulation of the small intestinal microbiota merit consideration. The relationship between SIBO and IBS is highly inconsistent among studies, and there is no evidence of SIBO being absent before IBS symptoms are evident and present after IBS emerges^[56].

Duodenal flora and CD

CD typically presents in early childhood with chronic inflammation of the small intestinal mucosa and permanent intolerance to dietary gluten. Several studies have confirmed that other factors such as abnormalities in the small intestinal microbiota might be associated with this disorder^[90-93]. Nadal *et al*^[91] conducted bacteriological analyses of duodenal biopsy specimens based on pediatric patients with CD. Their results showed that patients with active CD had significantly higher numbers of total bacteria, especially Gram-negative bacteria, compared with asymptomatic patients and healthy subjects^[91]. The ratio of *Lactobacillus-Bifidobacterium* to *Bacteroides-Escherichia coli* was lower in patients with CD. Nistal *et al*^[92] analyzed the bacterial *16S rRNA* gene sequencing of DNA extracted from duodenal biopsies and showed that the diversity of duodenal microbiota was significantly different between treated and untreated adults with CD due to treatment with a gluten-free diet. Furthermore, Di *et al*^[93] found that a gluten-free diet lasting two or more years could not completely restore the microbiota. Undoubtedly, the fecal-associated microbiota composition and related metabolites could also be disturbed in patients with CD^[94,95]. Disruption of the duodenal microbiota in patients with CD was linked overall to the symptomatic presentation and could favor the pathogenesis of CD.

The composition of the microbiota within the small intestine has not been analyzed comprehensively using a high-throughput *16S rRNA* gene or metagenomic sequencing method, either in healthy individuals or in patients with gastrointestinal conditions. The study of specimens from the small intestine (especially the distal duodenum, jejunum, and proximal ileum) collected from organ donations and transplantation could be a good way of understanding the abundance and variety of normal microbiota within the small intestine.

STUDY LIMITATIONS AND FUTURE OF HUMAN MICROBIOTA RESEARCH

It is evident that gastrointestinal microbiota contribute to human health and disease. The composition and function

of microbiota within the human gastrointestinal tract have been sought for decades, but efforts have been hampered by the following factors: the complexity of gastrointestinal microbiota, especially with regard to the abundance and diversity of commensal fungi and viruses within the human gastrointestinal tract^[96,97]; the heterogeneity and multifactorial pathophysiology of gastrointestinal diseases; the impact of the variability of host genotype, diet^[98,99], age^[100,101], race^[98], geographic location^[98], drug treatment^[102], and medical intervention^[103] on gastrointestinal microbiota; inherent limitations in the methodologies used to assess the composition and function of gastrointestinal microbiota; and a lack of suitable animal models (similar to human microecology) for studying the pathogenesis of various disorders. High-throughput sequencing and bioinformatics analyses are evolving rapidly and providing us with fascinating insight into the microbiota present within the human gastrointestinal tract. We are in the midst of a revolutionary period with respect to investigation of the gastrointestinal microbiota. There have been remarkable advances with respect to establishing which microbes are altered in healthy subjects^[19] vs those in individuals suffering from IBD^[1], obesity^[1], and type 2 diabetes^[23]. However, these studies mainly focused on the fecal-associated microbiota, because the gut microbiota has a major impact on human health and disease and is the best-studied ecosystem; and fecal samples are easy to collect and suitable for the metagenomic sequencing of whole community DNA.

At present, there are more study limitations for the microbiota in the upper gastrointestinal tract, especially the choice of representative human specimens and the application of a reliable analytical method. Endoscopic biopsy specimens, aspirate samples, mucosa brush samples, and surgical specimens from the esophagus, stomach and upper duodenum could be used for microbiota analysis. However, sample collection from the distal duodenum, jejunum, and proximal ileum is still difficult; the surgical and aspirate samples, especially the specimens from organ donations and transplantation may be suitable for analysis. In addition, contamination by the oral microflora and the microbiota from other sections of the upper gastrointestinal tract, and contamination with human host DNA could represent major and permanent methodical problems. Microbiota studies are subject to the restriction of missing distinction between transient and resident microflora in the esophagus, stomach and small intestine, thus, the collection and handling of specimens are of great importance.

A number of culture-based techniques and PCR-based molecular approaches including TRFLP, DGGE and TGGE, RISA, DNA microarray and FISH, have been applied to analyze the human microbiota. Furthermore, the next-generation high-throughput DNA sequencing techniques based on 454 pyrosequencing or Illumina (Solexa) sequencing platforms are the most powerful to investigate the composition, abundance and function of the gastrointestinal microbiota. The analytical method

selected for the assessment of upper gastrointestinal microbiota will depend on the expected target as well as the time and cost-effectiveness associated with the research. Currently, the high-throughput sequencing of 16S rDNA, but not the metagenomics sequencing of the whole microbial community DNA, may be the best molecular method for upper gastrointestinal microbiota. However, it is difficult to distinguish DNA coming from dead or live microbes, when using extracted DNA in the PCR-based molecular analysis. At present, both molecular and culture-based methods should be used to investigate the microbiota composition in the human gastrointestinal tract. Although it could be an arduous task, it is essential for scientific researchers to sequence and characterize the microbiota within the upper gastrointestinal tract. In the future, the use of metagenomics combined with human genome-wide association studies, as well as metabonomics and metaproteomics, may be an ideal approach to understand the microbiota-host interaction and unravel the significance of specific microbiota to determine which microbiota are causative and which are present merely as a consequence of disease. Perhaps one day specific microbes and microbiota-based biomarkers will be developed for diagnostic and therapeutic purposes.

CONCLUSION

In summary, the upper gastrointestinal microbiota is implicated in several gastrointestinal illnesses. There are many study limitations for the upper gastrointestinal microbiota, which could be prevented or mitigated. Through the conceptual innovations in metagenomics and the improvements in DNA high-throughput sequencing and bioinformatics analysis technology, it is now possible to explore the genetic nature of the microbiome in the esophagus, stomach, and small intestine, and the interactions between the host and the residing microbial community.

Abstract

AIM: To evaluate the inhibitory effects of *Scolopendra subspinipes mutilans* (SSM) on cerulein-induced acute pancreatitis (AP) in a mouse model.

METHODS: SSM water extract (0.1, 0.5, or 1 g/kg) was administrated intraperitoneally 1 h prior to the first injection of cerulein. Once AP developed, the stable cholecystokinin analogue, cerulein was injected hourly, over a 6 h period. Blood samples were taken 6 h later to determine serum amylase, lipase, and cytokine levels. The pancreas and lungs were rapidly removed for

morphological examination, myeloperoxidase assay, and real-time reverse transcription polymerase chain reaction. To specify the role of SSM in pancreatitis, the pancreatic acinar cells were isolated using collagenase method. Then the cells were pre-treated with SSM, then stimulated with cerulein. The cell viability, cytokine productions and high-mobility group box protein-1 (HMGB-1) were measured. Furthermore, the regulating mechanisms of SSM action were evaluated.

RESULTS: The administration of SSM significantly attenuated the severity of pancreatitis and pancreatitis associated lung injury, as was shown by the reduction in pancreatic edema, neutrophil infiltration, vacuolization and necrosis. SSM treatment also reduced pancreatic weight/body weight ratio, serum amylase, lipase and cytokine levels, and mRNA expression of multiple inflammatory mediators such as tumor necrosis factor- α and interleukin-1 β . In addition, treatment with SSM inhibited HMGB-1 expression in the pancreas during AP. In accordance with *in vivo* data, SSM inhibited the cerulein-induced acinar cell death, cytokine, and HMGB-1 release. SSM also inhibited the activation of c-Jun NH2-terminal kinase, p38 and nuclear factor (NF)- κ B.

CONCLUSION: These results suggest that SSM plays a protective role during the development of AP and pancreatitis associated lung injury *via* deactivating c-Jun NH2-terminal kinase, p38 and NF- κ B.

Jo IJ, Bae GS, Park KC, Choi SB, Jung WS, Jung SY, Cho JH, Choi MO, Song HJ, Park SJ. *Scolopendra subspinipes mutilans* protected the cerulein-induced acute pancreatitis by inhibiting

high-mobility group box protein-1. *World J Gastroenterol* 2013; 19(10): 1551-1562 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1551.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1551>

INTRODUCTION

The annual incidence of acute pancreatitis (AP) is in the range of 300 or more patients per million^[1,2]. The mortality rate for severe AP is approximately 30%, whereas that for moderate pancreatitis is about 3%. The main causes of death are circulatory shock renal, respiratory, and hepatic failure. Thus, many patients with AP develop multiple organ failure (MOF)^[3]. Generally, AP is characterized by activation of pancreatic digestive enzyme production, widespread inflammatory cell infiltration, leukocyte activation, and release of various pro-inflammatory mediators such as tumor necrosis factor (TNF)- α and interleukin (IL)^[4-6]. Although numerous approaches have attempted to identify the pathogenesis of AP^[7-9], the detailed mechanism remains unclear.

Recent studies have shown that high-mobility group box protein-1 (HMGB-1) is a late activator in the inflammatory cascade, when released into the extracellular space^[10]. Neutralization of HMGB-1 has been shown to protect against systemic inflammatory responses such as in sepsis and MOF as HMGB-1 acts as a downstream cytokine of early inflammatory factors such as TNF and ILs^[11-13]. In addition, HMGB-1 has been speculated to be a target for treating AP^[14].

Scolopendra subspinipes mutilans (SSM) is a venomous arthropod, which can be found throughout the world. SSM and its venom have been reported to exhibit many biochemical and physiological effects^[15,16]. The water soluble fractions from SSM have antimicrobial and anti-inflammatory activity and hemolytic action of the toxins^[17,18]. In addition, SSM has been prescribed for the treatment of cardiovascular diseases in South Korea, China, and other Far Eastern Asian countries for several hundred years^[16]. However, the protective activities of SSM in cerulein-induced AP have not been examined to date. Our study was designed to assess the protective effect of SSM in cerulein-induced AP.

Here, we investigated the *in vivo* and *in vitro* activities of SSM using a murine model of experimental pancreatitis. To examine the role of SSM in AP, we examined pancreatic and lung histology, myeloperoxidase (MPO) activity, pancreatic weight (PW)/body weight (BW) ratio, levels of serum amylase, lipase, and cytokines such as TNF- α and IL-1 β as well as expression levels of HMGB-1. Furthermore, we examined mitogen activated protein kinases (MAPKs) and nuclear factor (NF)- κ B to find out the inhibitory mechanisms of SSM in AP.

MATERIALS AND METHODS

Chemicals and reagents

Avidin-peroxidase, cerulein, hexadecyltrimethylammo-

nium bromide, Triton X-100, and tetramethylbenzidine were purchased from Sigma-Aldrich (St. Louis, MO, United States). Anti-mouse TNF- α and IL-1 β antibodies, and recombinant TNF- α and IL-1 were purchased from R-D Systems (Minneapolis, MN, United States).

Preparation of SSM

SSM was purchased from a standard commercial source (Omni Herb, Seoul, South Korea). The identity of the SSM was confirmed by Professor Seung-Heon Hong from Wonkwang University. SSM was prepared by decocting the dried prescription of SSM (100 g) with boiling distilled water (1 L). The decoction time was about 2 h. The water extract was frozen at -80 °C and then freeze-dried to produce a powder form (20.4 g). The yield of extract was 20.4%. The powder was extracted with distilled water and filtered. The filtrates were stored at 4 °C until use.

Animal model

All experiments were performed according to protocols approved by the Animal Care Committee of Wonkwang University. C57BL/6 mice (age 6-8 wk; weight 15-20 g) were purchased from Orient Bio (Sungnam, KyungKiDo, South Korea). All animals were bred and housed in standard shoebox cages in a climate-controlled environment with an ambient temperature of 23 \pm 2 °C and a 12-h light-dark cycle for 7 d. The animals were fed standard laboratory chow, given water, and were randomly assigned to the control or experimental groups. The mice were fasted for 18 h before the induction of AP. Six mice were included in each experimental group.

Experimental design

AP was induced by intraperitoneal injection of supra-maximal concentrations of the stable cholecystokinin analog cerulein (50 μ g/kg) or saline; injections were performed hourly for 6 h. To verify the prophylactic effects of SSM, SSM (0.1, 0.5, or 1 g/kg) was injected 1 h before the first cerulein injection. Mice were sacrificed 6 h after the last cerulein injection. Blood samples were taken to determine serum amylase, lipase, and cytokine levels. For histological examination and scoring, the entire pancreas and lungs were rapidly removed from each mouse and fixed in formalin. To measure tissue MPO activity, as an indicator of neutrophil sequestration, and to perform real-time reverse transcriptase-polymerase chain reaction (RT-PCR) examinations, 3 portions of both pancreas and lungs were stored at -80 °C.

Histological analysis

The entire pancreas of at least 6 mice from each treatment group were examined and semi-quantitatively assessed for levels of necrosis, vacuolization, inflammation, and edema. The entire section, representing a minimum of 100 fields, was examined for each sample and scored on a scale of 0-3 (0 being normal and 3 being severe) on the basis of the number of necrotic acinar cells and the presence of vacuolization, interstitial edema, and inflam-

matory cells infiltration. These characteristics include the presence of acinar-cell ghosts, vacuolization and swelling of the acinar cells, and/or the destruction of the histo-architecture of whole or parts of the acini. For scoring the lungs, the sections were examined for the presence of interstitial inflammation and edema.

Measurement of serum amylase and lipase levels

Blood samples, for the determination of serum amylase and lipase levels, were obtained 6 h after induction of pancreatitis. Mice were anesthetized with an intraperitoneal injection of ketamine (80 mg/kg) and xylazine (4 mg/kg). After anesthetization, blood was withdrawn from the heart of each mouse into a syringe. The levels of serum amylase and lipase were measured using an assay kit (BioAssay Systems, Hayward, CA, United States).

RT-PCR

RT-PCR was performed to measure mRNA transcript levels in the mouse pancreatic tissues and pancreatic acinar cells. Total RNA was isolated from the mouse pancreas using TRIzol (Invitrogen, Carlsbad, CA, United States) and was subjected to reverse transcription using SuperScript II RT (Invitrogen, Carlsbad, CA, United States). TaqMan quantitative RT-PCR using the Light-Cycler 2.0 detection system was performed according to the instructions of the manufacturer (Roche, Basel, Switzerland). For each sample, triplicate test reactions and a control reaction without reverse transcription were analyzed for expression of the gene of interest, and the results were normalized to those of the “housekeeping” hypoxanthine-guanine phosphoribosyl transferase (HPRT) mRNA. Arbitrary expression units were calculated by dividing the expression level for the gene of interest by the ribosomal protein HPRT mRNA expression level. The sequences of forward, reverse, and probe oligonucleotide primers for multiplex real-time TaqMan PCR were as follows: for mouse TNF- α (forward, 5'-TCTCTTCAAGGGACAAGGCTG-3'; reverse, 5'-ATAGCAAATCGGCTGACGGT-3'; probe, 5'-CCC-GACTACGTGCTCCTCACCCA-3'), for mouse IL-1 β (forward, 5'-TTGACGGACCCAAAAGAT-3'; reverse, 5'-GAAGCTGGATGCTCTCATCTG-3'; universal probe, M15131.1-Roche Applied Science).

Enzyme-linked immunosorbent assay

Enzyme-linked immunosorbent assays (ELISAs) for TNF- α and IL-1 β were carried out in duplicate in 96-well plates (Nunc, Roskilde, Denmark), which had been incubated with 100 L aliquots of either anti-mouse TNF- α or anti-mouse IL-1 β monoclonal antibodies (1.0 μ g/mL in phosphate-buffered saline (PBS) at pH 7.4) overnight. The plates were washed in PBS containing 0.05% Tween-20 and blocked with PBS containing 10% fetal bovine serum for 2 h. After additional washes, the standards and the serum, pancreatic homogenates and pancreatic acinar cell supernatants were added to the plates and incubated at room temperature for 3 h. To obtain pancreatic homog-

enates, the pancreas were thawed and then homogenized in PBS. After washing the wells, 0.2 μ g/mL of biotinylated anti-mouse TNF- α or IL-1 β were added to each well. Incubation was continued at room temperature for 1 h. The wells were washed, avidin-peroxidase was added, and plates were incubated for 30 min at room temperature. Wells were washed again, and 3, 3', 5, 5'-tetramethylbenzidine substrate was added. Color development was measured at 450 nm using an automated microplate ELISA reader. Standard curves were obtained for each sample by using serial dilutions of recombinant TNF- α and IL-1 β .

MPO activity estimation

Neutrophil sequestration in the pancreas was quantified by measuring the tissue MPO activity. Tissue samples were thawed, homogenized in 20 mmol/L phosphate buffer (pH 7.4), and centrifuged (15 000 revolution/min, 10 min), and the resulting pellet was resuspended in 50 mmol/L phosphate buffer (pH 6.0) containing 0.5% hexadecyltrimethylammonium bromide. The sample was then centrifuged (15 000 revolution/min, 5 min), and the supernatant used for the MPO assay. The reaction mixture consisted of the supernatant, 1.6 mmol/L tetramethylbenzidine, 80 mmol/L sodium phosphate buffer (pH 5.4), and 0.3 mmol/L hydrogen peroxide. The mixture was incubated at 37 °C for 110 s, the reaction was terminated with 2 mol/L of H₂SO₄, and the absorbance was measured at 450 nm. This absorbance was then corrected for the DNA content of the tissue sample.

Histological and immunohistochemical analysis

Fixed pancreatic tissues were embedded in paraffin, cut into 4-mm sections, and stained with hematoxylin-eosin for standard histological examination. Immunohistochemical (IHC) staining for HMGB-1 was performed using a DAB IHC kit (DAKO, Cytomation, Denmark). The relative intensity was measured using the Leica microscopy software (Wetzlar, Germany).

Acinar cell isolation

Pancreatic acini were isolated from C57BL/6 mice using collagenase digestion. All experiments were performed according to protocols approved by the Animal Care Committee of Wonkwang University. Briefly, pancreatic tissue was minced with scissors and digested for 15 min in solution Q (120 mmol NaCl, 20 mmol HEPES, 5 mmol KCl, 1 mmol MgCl₂, 1 mmol CaCl₂, 10 mmol sodium pyruvate, 10 mmol ascorbate, 10 mmol glucose, 0.1% bovine serum albumin, 0.01% soybean trypsinogen inhibitor, and 150 units of collagenase/mL). Cells were continuously shaken and gassed with 100% O₂ in a 37 °C water bath and subsequently washed in fresh isolation medium. After collagenase digestion, the tissue was gently pipetted. Dispersed acini were filtered through a 150- μ m nylon mesh, centrifuged 3 times (each for 90 s at 720 rpm), resuspended in Waymouth medium (Invitrogen, Gibco, CA) and incubated with 95% O₂ and 5% CO₂ for 4 h.

Table 1 Effect of *Scolopendra subspinipes mutilans* water extract on pancreatic histological scoring during acute pancreatitis (mean \pm SE, $n = 6$)

| Group | Edema | Inflammation | Vacuolization | Necrosis |
|--------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|
| Saline | 0.1 \pm 0.02 | 0.3 \pm 0.05 | 0.1 \pm 0.03 | 0.2 \pm 0.02 |
| AP | 2.6 \pm 0.03 ^a | 2.8 \pm 0.04 ^a | 2.4 \pm 0.02 ^a | 2.5 \pm 0.05 ^a |

Cell viability assay

Cell viability was assayed using a modified colorimetric technique that is based on the ability of live cells to convert the tetrazolium compound 3-(4,5-dimethylthiazol)-2,5-diphenyltetrazolium bromide (MTT) into purple formazan crystals. MTT (5 mg/mL) was dissolved in Krebs-Henseleit buffer (115 mmol NaCl, 3.6 mmol KCl, 1.3 mmol KH₂PO₄, 25 mmol NaHCO₃, 1 mol CaCl₂, and 1 mol MgCl₂), and 50 μ L was added to each well. After incubating for 30 min at 37 $^{\circ}$ C, the suspension was removed, and the formazan crystals formed were dissolved in 200 μ L dimethyl sulfoxide. Aliquots from each well were seeded in the wells of a 96-well plate in duplicate and assayed at 540 nm using a microplate ELISA reader. The number of viable cells was expressed as a percentage of the control.

Western blotting

Pancreatic tissues and pancreatic acini were homogenized, following which the lysates were boiled in a sample buffer [62.5 mmol Tris-HCl, pH 6.8, 2% sodium dodecyl sulfate (SDS), 20% glycerol, and 10% 2-mercaptoethanol]. Proteins in the cell lysates were then separated using 10% SDS-polyacrylamide gel electrophoresis and transferred to a nitrocellulose membrane. Then, the membrane was blocked with 5% skim milk in PBS-Tween-20 for 2 h at RT and then incubated with primary antibodies overnight. After washing 3 times, each blot was incubated with peroxidase-conjugated secondary antibody for 1 h, and antibody-specific proteins were visualized using an enhanced chemiluminescence detection system (Amersham, Piscataway, NJ) according to the manufacturer's recommended protocol.

High-performance liquid chromatography sample preparation and conditions

An aliquot of 5.0 mg extract powder was dissolved with 1.0 mL of methanol and then filtered through a 0.45 μ m filter membrane before use. A volume of 20 μ L was injected into the high-performance liquid chromatography (HPLC) sample injector system. Chromatographic experiments were performed on a SYKAM series HPLC instrument equipped with sample injector and diode-array UV/Vis detector. For all experiments a SHISEIDO

CAPCELL PACK C-18 column (4.6 mm \times 250 mm; 5 μ m) was used as stationary phase and injection volume were set 20 μ L, respectively. The mobile phase composed of water (A) and acetonitrile (B), applying gradient program starting from 10 %B to 40 %B in 40 min. The column cleaned with 10 %B for 20 min, and then the system was equilibrated for 20 min with the starting conditions. Flow rate was 0.7 mL/min, and the detection wavelength adjusted to 210 nm. The quantifications of peak are 91% (1st), 4% (2nd), 0.5% (3rd), 4.5% (4th) to total.

Statistical analysis

The results were expressed as mean \pm SE. The significance of change was evaluated using the one-way analysis of variance (ANOVA). Differences between the experimental groups were evaluated by performing ANOVA. P values < 0.05 were considered statistically significant.

RESULTS

Effect of SSM on pancreatic histology during cerulein-induced AP

In saline-treated mice, the histological features of the pancreas showed typically normal architecture. Mice treated with intraperitoneal injections of cerulein developed AP. Histological examination of the pancreas (6 h after the final injection of cerulein) revealed tissue damage characterized by mild interstitial edema, inflammatory cell infiltration, vacuolization, and acinar cell necrosis. Compared to saline pre-treatment, SSM pre-treatment resulted in a significant reduction in pancreatic injury as shown by reduced edema, inflammation, vacuolization, and necrosis, in a dose-dependent manner (Figure 1A, B and Table 1).

Effect of on the MPO activity in cerulein-induced AP

As an additional quantitative assessment of the severity of the inflammatory response, we measured MPO activity as an indicator of neutrophil sequestration in the pancreas, following the induction of AP. MPO activity in the pancreas of the SSM pre-treated AP mice was lesser than that in the pancreas of the saline pre-treated AP mice (Figure 1C).

Effect of SSM on PW/BW and serum amylase and lipase levels in cerulein-induced AP

In order to assess the effect of SSM on pancreatic edema, the PW/BW was measured. As shown in Figure 2A, the PW/BW was increased in saline-treated mice with AP. SSM treatment, however, inhibited the AP-induced PW/BW ratio increase compared with the saline treated group (Figure 2A). Serum amylase and lipase levels are most commonly used biochemical markers of pancreatic disease, particularly in AP^[19-21]. Therefore, we examined serum amylase and lipase levels during cerulein-induced AP. The administration of SSM significantly reduced the serum amylase and lipase levels (Figure 2B and C).

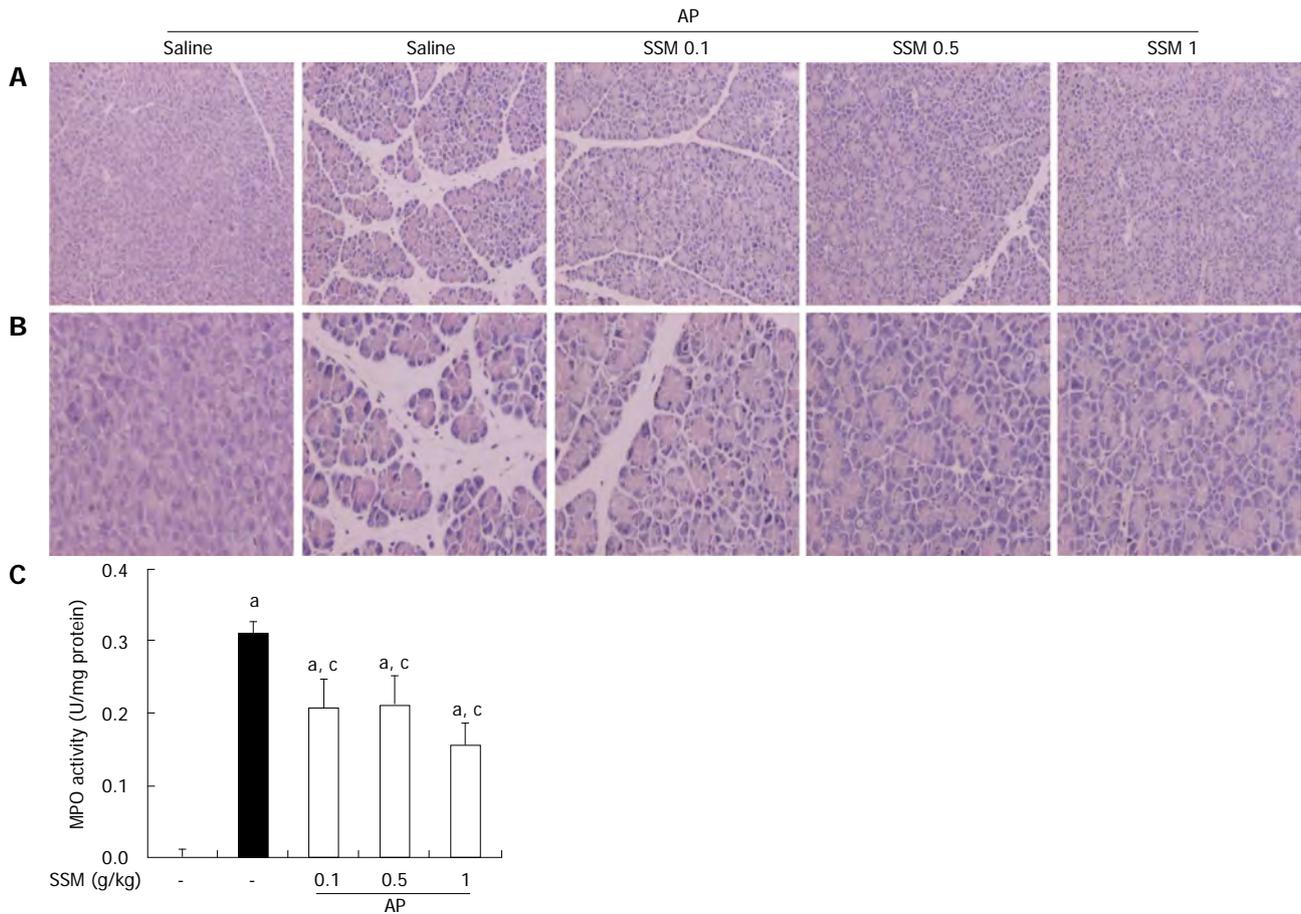

Figure 1 Effects of *Scolopendra subspinipes mutilans* on inflammation in the pancreas following pancreatitis. A, B: 200 × (A) and 400 × (B) magnification of representative hematoxylin and eosin stained pancreatic sections of control mice and mice pretreated with *Scolopendra subspinipes mutilans* (SSM) (0.1, 0.5 or 1 g/kg) 1 h before the cerulein (50 μg/kg)-mediated induction of acute pancreatitis (AP); C: Myeloperoxidase (MPO) activity was measured in the pancreas 6 h after completion of the cerulein injections. Data are expressed as U/mg protein. Data are represented as mean ± SE (n = 6 in each group). The results were similar in 3 further experiments. ^aP < 0.05 vs control group, ^cP < 0.05 vs cerulein treatment alone.

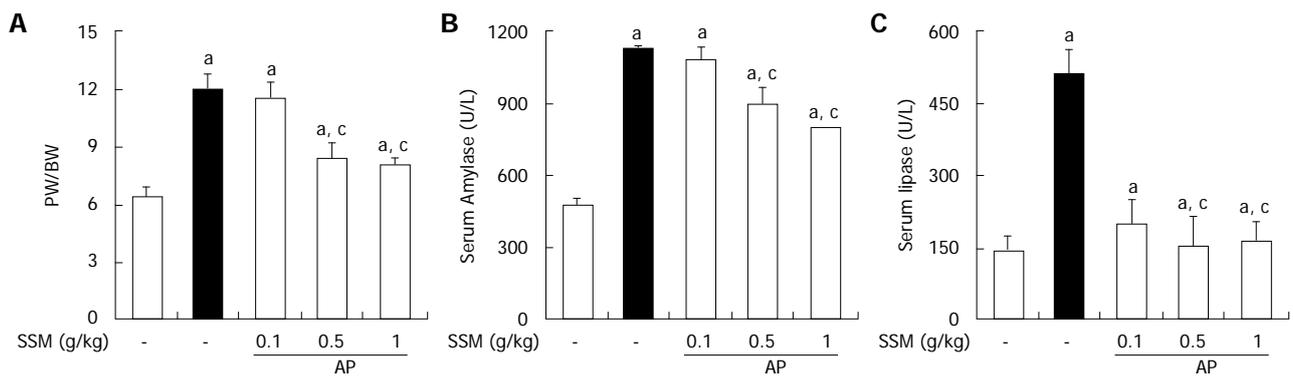

Figure 2 Effects of *Scolopendra subspinipes mutilans* pretreatment on the pancreatic weight/body weight ratio and the production of digestive enzymes such as serum amylase and serum lipase during cerulein-induced acute pancreatitis. Mice pretreated with *Scolopendra subspinipes mutilans* (SSM) (0.1, 0.5 or 1 g/kg) were challenged with intraperitoneal injections of cerulein (50 μg/kg). Mice were sacrificed 6 h after the last cerulein injection. Serum and pancreas were harvested and the pancreatic weight (PW)/body weight (BW) (A) and levels of digestive enzymes such as amylase (B) and lipase (C) were measured as indicated in the experimental protocol. Data are represented as mean ± SE (n = 6 in each group). The results were similar in 3 further experiments. ^aP < 0.05 vs control group, ^cP < 0.05 vs cerulein treatment alone. AP: Acute pancreatitis.

Effect of SSM on TNF-α and IL-1β production in cerulein-induced AP

Several inflammatory mediators have been shown to increase during AP^[22]. Therefore, to examine the effect of SSM on the occurrence of a systemic inflammatory

response during cerulein-induced AP, we measured the level of TNF-α and IL-1β induction. Compared to control mice, mice with AP showed a significant increase in the levels of these inflammatory mediators in the pancreatic tissue and serum (Figure 3). However, SSM pre-

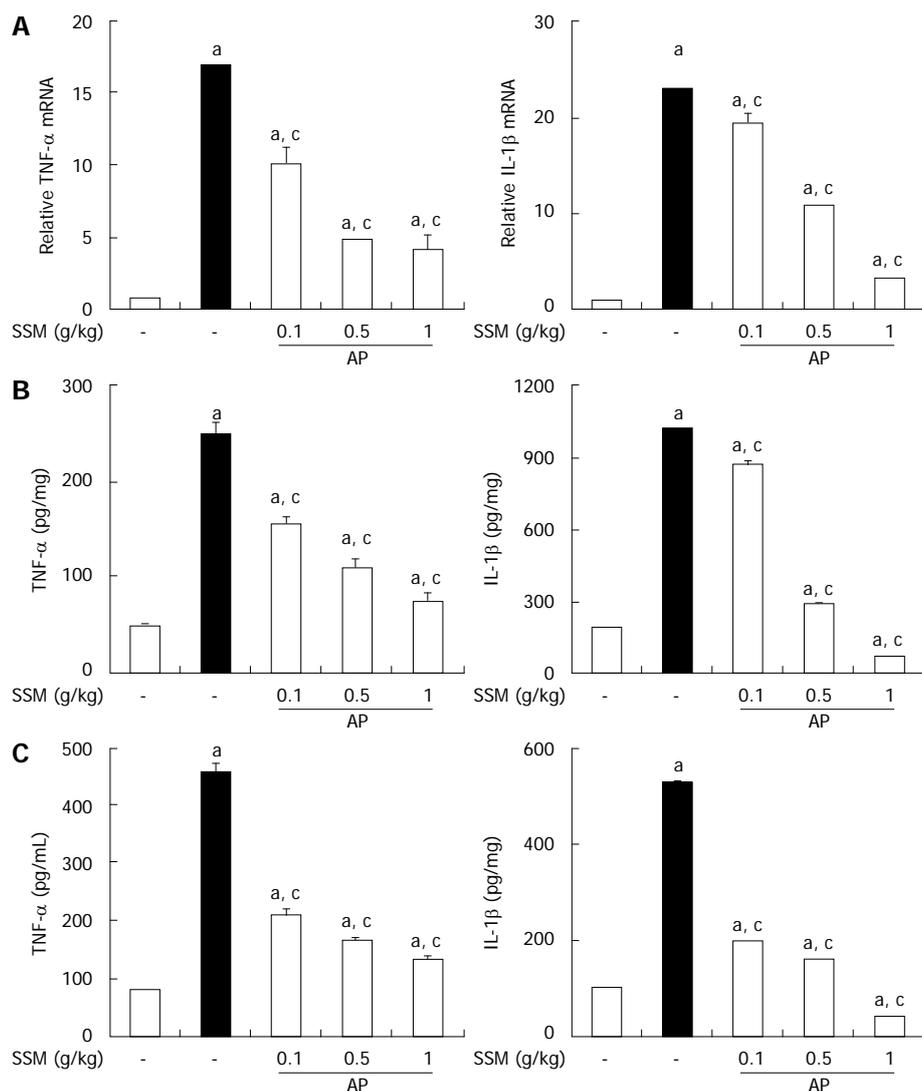

Figure 3 Effect of *Scolopendra subspinipes mutilans* on tumor necrosis factor- α and interleukins-1 β during cerulein-induced acute pancreatitis. Mice pretreated with *Scolopendra subspinipes mutilans* (SSM) (0.1, 0.5, or 1 g/kg) were challenged with intraperitoneal injections of cerulein at a supramaximal dose (50 μ g/kg). Mice were sacrificed 6 h after the last cerulein injection. A-C: Levels of pancreatic tumor necrosis factor (TNF)- α and interleukin (IL)-1 β mRNA were quantified by real-time reverse transcriptase-polymerase chain reaction (A) and the corresponding protein levels were measured in the pancreatic tissue (B) and serum by enzyme-linked immunosorbent assay (C). Data are represented as mean \pm SE ($n = 6$ in each group). The results were similar in 3 further experiments. ^a $P < 0.05$ vs control group, ^c $P < 0.05$ vs cerulein treatment alone. AP: Acute pancreatitis.

treatment reduced the cytokine levels in both pancreatic tissue (Figure 3A and B) and serum (Figure 3C).

Effect of SSM on lung histological changes during cerulein-induced AP

The lung is typically affected in cases of pancreatitis^[23-25]. Lung injury, characterized by edema and inflammation, commonly develops early in AP^[26]. Lungs from cerulein-induced AP show alveolar thickening and inflammatory cell infiltration^[26]. However, these changes were significantly reduced in lungs from the SSM pre-treated group, and this effect was dose-dependent (Figure 4A, B and Table 2).

Effect of SSM on HMGB-1 expression in cerulein-induced AP

To measure the HMGB-1 expression, an IHC method

was used. IHC analysis showed that HMGB-1 expression was detected in the pancreas by the presence of a brown color. As shown in Figure 5, HMGB-1 was slightly expressed in control mice, but strongly expressed in AP mice. However, compared to the saline pre-treated AP mice, SSM pre-treated AP mice showed a significant reduction in HMGB-1 expression in the pancreatic tissue (Figure 5).

Effect of SSM on inflammatory responses in the isolated pancreatic acinar cells

The local inflammation caused in pancreatic acinar cells results in acinar cells death and organ destruction^[8]. Thus, acinar cells death can be a hallmark of AP. To assess whether SSM water extract inhibits acinar cells death, we evaluated cell viability by using the MTT assay. At 1 h after SSM pretreatment, cerulein was added for 6 h into

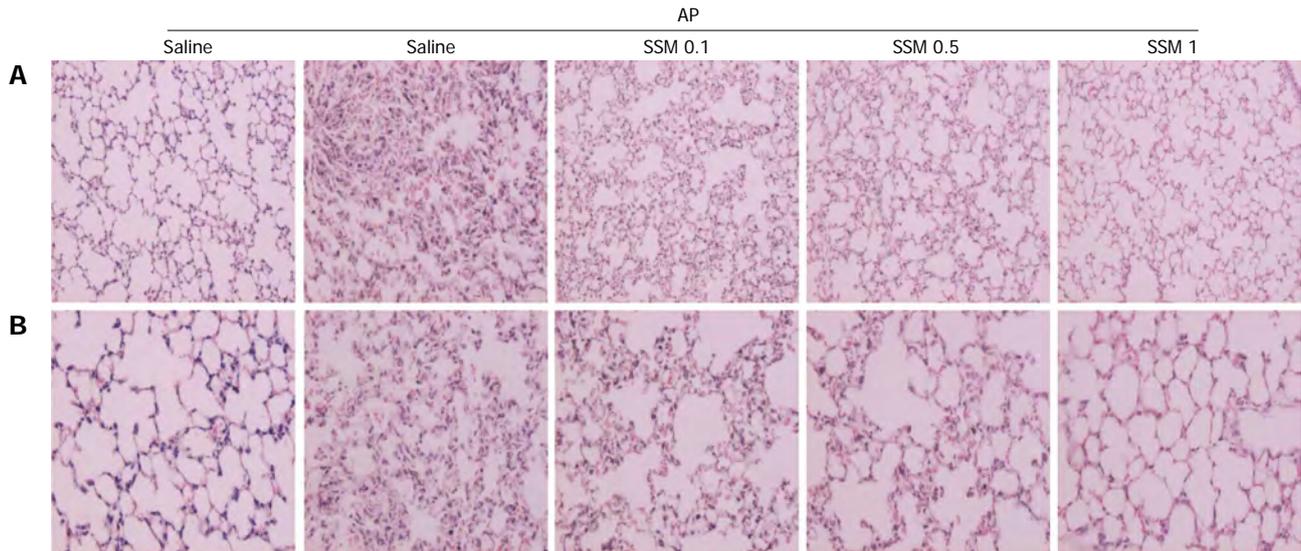

Figure 4 Effects of *Scolopendra subspinipes mutilans* on acute pancreatitis-associated lung injury. A, B: 200 × (A) and 400 × (B) magnification of representative hematoxylin and eosin-stained lung sections of control mice and mice pretreated with *Scolopendra subspinipes mutilans* (0.1, 0.5, or 1 g/kg) 1 h before the cerulein (50 μg/kg)-mediated induction of acute pancreatitis. Data are represented as mean ± SE (n = 6 in each group). The results were similar in 3 additional experiments.

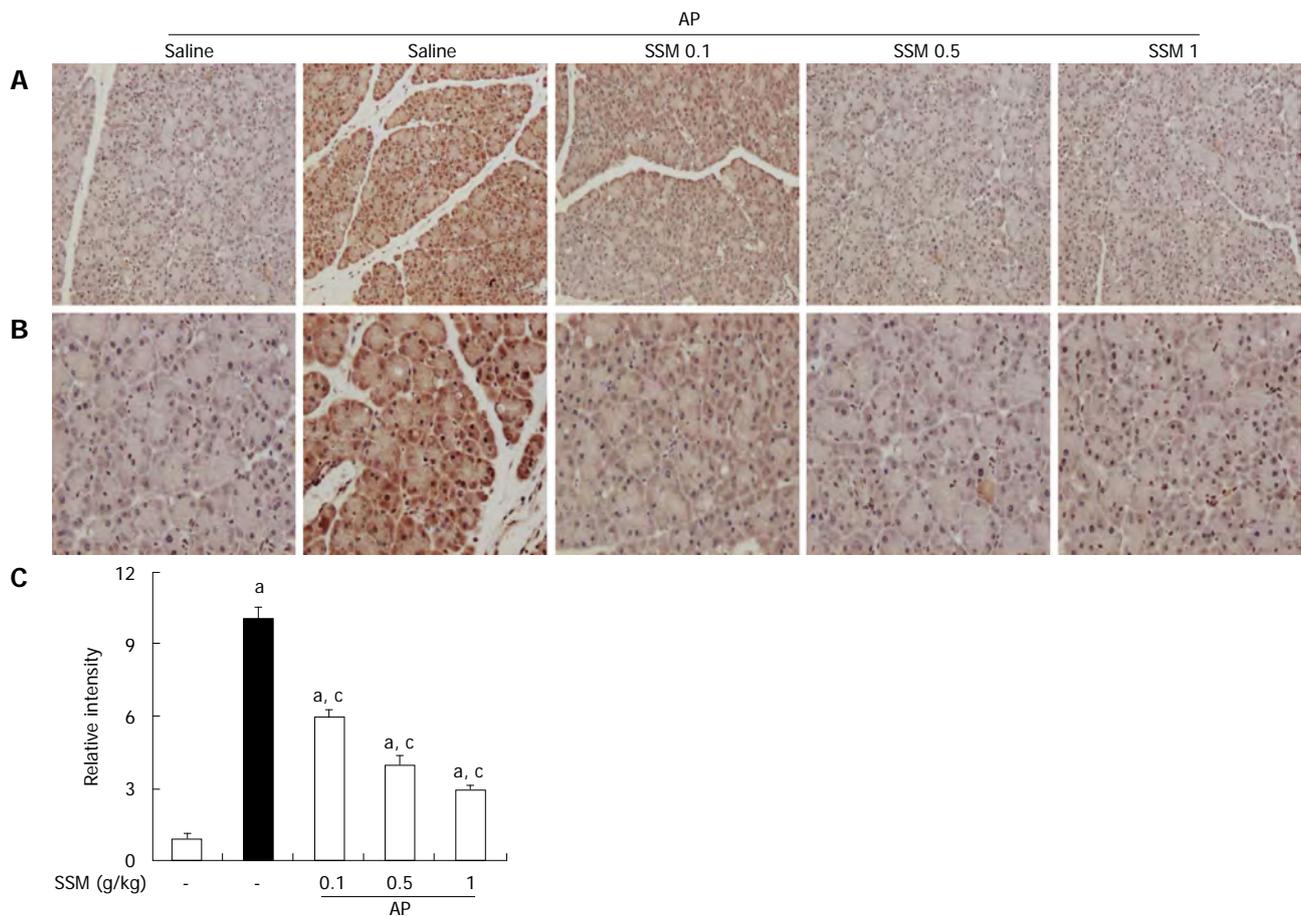

Figure 5 Effects of *Scolopendra subspinipes mutilans* on pancreatic high-mobility group box protein-1 expression in cerulein-induced acute pancreatitis. A, B: 200 × (A) and 400 × (B) magnification of representative immunohistochemical data, detecting high-mobility group box protein-1 (HMGB-1) expression in pancreatic tissue sections of control mice and mice pretreated with *Scolopendra subspinipes mutilans* (SSM) (0.1, 0.5, or 1 g/kg) 1 h before the cerulein (50 μg/kg)-mediated induction of acute pancreatitis (AP). Mice were sacrificed 6 h after the last cerulein injection; C: Relative intensity of HMGB-1 staining was scored as described in Materials and Methods. Data are represented as mean ± SE (n = 6 in each group). The results were similar in 3 further experiments. ^aP < 0.05 vs control group, ^cP < 0.05 vs cerulein treatment alone.

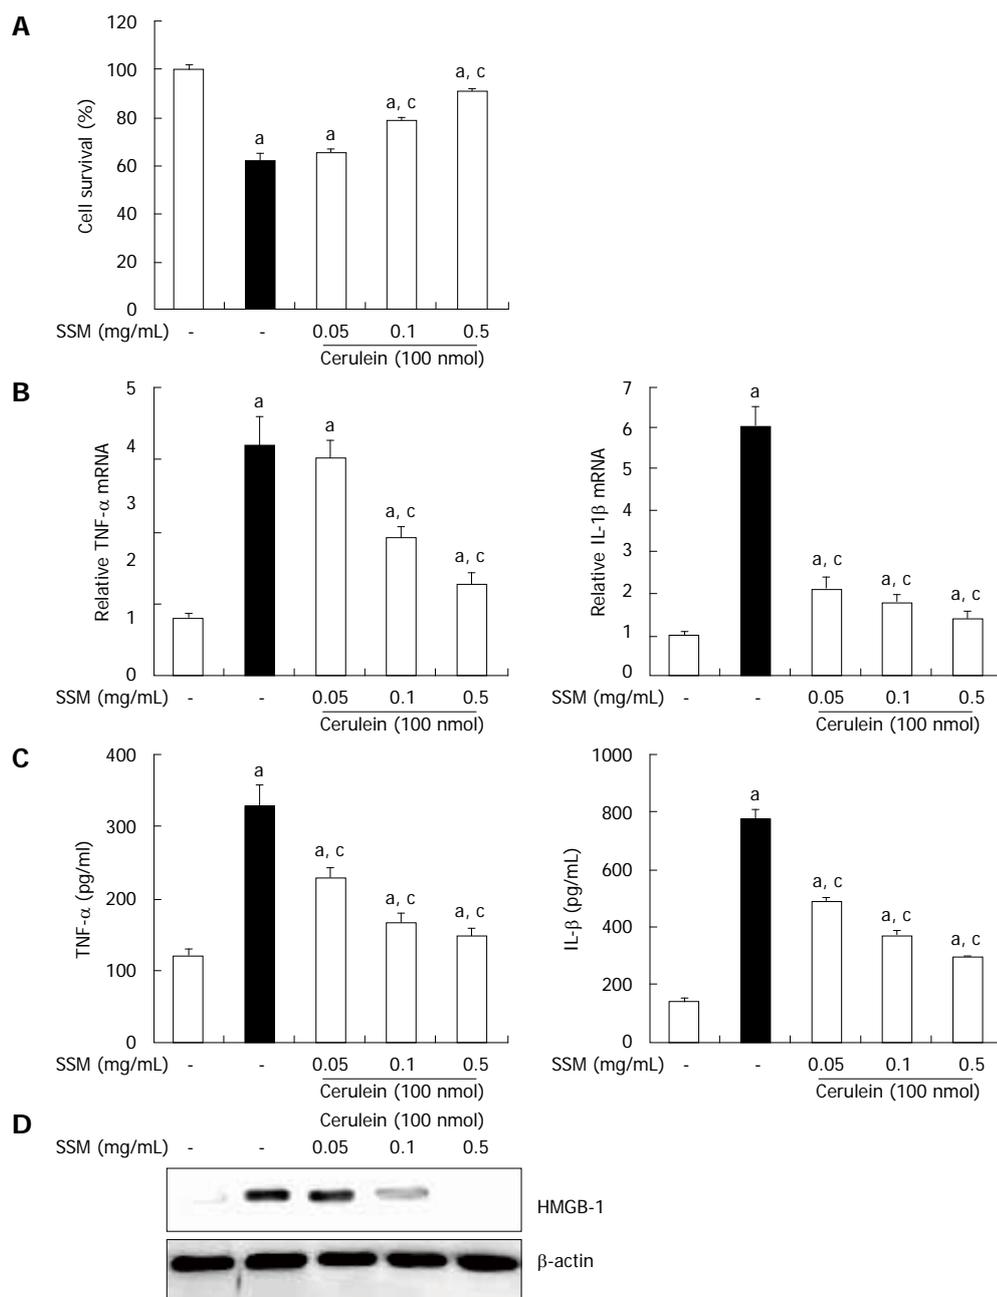

Figure 6 Effect of *Scolopendra subspinipes mutilans* on cerulein-induced acinar cell death and the production of inflammatory mediators. The acinar cells were pretreated with *Scolopendra subspinipes mutilans* (SSM) for 1 h at indicated doses. A: 6 h after cerulein stimulation, the cell viability was measured; B, C: After 24 h of cerulein stimulation, cytokine levels in isolated pancreatic acinar cells were examined using enzyme-linked immunosorbent assay (B) and real-time reverse transcription polymerase chain reaction (C); D: And also the high-mobility group box protein-1 (HMGB-1) levels were measured by western blot. Data are represented as mean \pm SE ($n = 6$ in each group). The results were similar in 3 further experiments. ^a $P < 0.05$ vs control group, ^c $P < 0.05$ vs cerulein treatment alone. TNF: Tumor necrosis factor; IL: Interleukins.

cultured acinar cells. As shown in Figure 6A, the number of cerulein-induced acinar cells death was significantly reduced by SSM (Figure 6A). Next, we also examined cytokine production in isolated pancreatic acinar cells. Pretreatment with SSM inhibited the production of cytokines, such as TNF- α and IL-1 β in a dose dependant (Figure 6C and D). In addition, SSM inhibited the cerulein-induced HMGB-1 expression, which means SSM protected the acinar cells necrosis (Figure 6E).

Further, to examine the inhibitory mechanism(s) against cerulein-induced responses in acinar cells, the activa-

tion of MAPKs and NF- κ B were examined. We assessed the activation of MAPKs and NF- κ B *via* phosphorylation and I κ -B α degradation, respectively. Cerulein treatment resulted in the phosphorylation of MAPKs and degradation of I κ -B α . However, SSM treatment inhibited the activation of c-Jun NH₂-terminal kinase (JNK), p38, and the degradation of I κ -B α but not ERK1/2 (Figure 7A). To clarify whether down-regulation of the molecules in JNK, p38 and NF- κ B by SSM is responsible for the reduced inflammatory responses, JNK inhibitor (SP600125), p38 inhibitor (SB239063) and NF- κ B inhibitor (n-acetyl

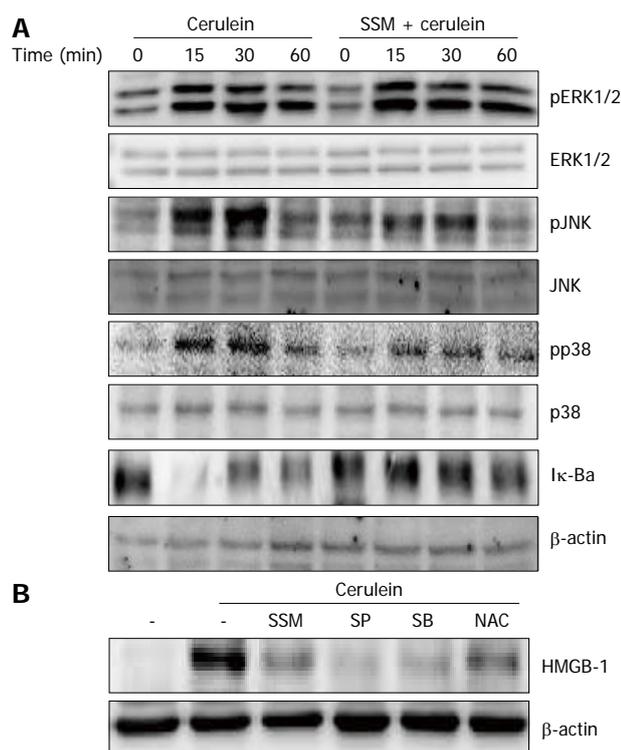

Figure 7 Effect of *Scolopendra subspinipes mutilans* on activation of mitogen activated protein kinases and nuclear factor- κ B. A: Isolated pancreatic acinar cells were pretreated with *Scolopendra subspinipes mutilans* (SSM) for 1 h and then stimulated with cerulein for indicated times. The expression of phosphospecific mitogen activated protein kinases and degradation of I κ -B α in pancreatic acini was examined *via* western blot; B: The acinar cells were pretreated with c-Jun NH $_2$ -terminal kinase (JNK) inhibitor (SP600125 50 μ mol), p38 inhibitor (SB239063 20 μ mol), nuclear factor- κ B inhibitor (N-acetyl cystein, NAC, 10 mmol) or SSM (0.5 mg/mL) for 1 h. Then cerulein was added into isolated pancreatic acinar cells and incubated for 24 h. High-mobility group box protein-1 (HMGB-1) expression was measured *via* western blot. The results were similar in 3 further experiments. ERK: Extracellular signal-related kinase.

cystein; NAC) were used. The inhibition of JNK, p38 and NF- κ B resulted in the reduction of HMGB-1 expression (Figure 7B).

Characterization of the principal component of SSM

SSM was analyzed by HPLC to characterize its main component. A chromatogram of SSM is shown in Figure 8. The peaks of the principal components of SSM have not yet been identified. Further studies to evaluate the principal components of SSM would be needed.

DISCUSSION

In this study, we have provided evidence that SSM water extract attenuated the development of cerulein-induced AP and AP-associated lung injury. Pre-treatment of mice with SSM significantly inhibited serum amylase and lipase production, TNF- α and IL-1 β expression, and MPO activity. In addition, SSM pre-treatment inhibited HMGB-1 expression in the pancreas. In accordance with *in vivo* experiments, SSM inhibited the acinar cell death, cytokine productions, and HMGB-1 production. Furthermore, SSM inhibited the activation of JNK, p38 and NF- κ B.

These findings suggested that SSM protected the AP *via* JNK, p38 and NF- κ B deactivation.

Recently, many studies have reported the anti-inflammatory activity of SSM. Wang *et al.*^[27] showed the protective effects of SSM on acute renal failure and multiple focal neuropathy, and Ren *et al.*^[28] reported the anti-inflammatory effects of SSM in Alzheimer's disease. Therefore, to further investigate the anti-inflammatory activities of SSM, we selected to examine the effects of SSM in a cerulein-induced AP model, which has not previously been assessed. As we expected, SSM water extract significantly inhibited pancreatic and lung inflammation in a dose-dependent manner (Figures 1 and 4). We supposed that the anti-inflammatory effects of SSM on AP would be due to anti-microbial effects of SSM. Ren *et al.*^[17] reported that water soluble fraction of SSM could remove the all type of bacteria such as gram-positive, gram-negative bacteria and fungi. Because one of the main causes of AP would be bacterial infection^[29,30], the removal ability of SSM would be helpful to protect AP. Thus, the anti-microbial ability of SSM might contribute to inhibition of pancreatic inflammation.

Amylase and lipase levels are used alone, or in combination, to diagnose patients with AP^[31]. An increased level of serum amylase, at least 3 times over the normal limit, indicates AP. Amylase activity rises quickly during the early phase after the onset of symptoms and returns to normal quickly^[31]. Serum amylase activities could reflect the exocrine pancreatic insufficiency, thus resulting in mal-digestion^[32]. In comparison with serum amylase activity, serum lipase activity remains increased (up to 16-28 fold) for longer, thereby giving greater opportunity in patients with a delayed presentation. Pancreatic lipase activities are less likely to be affected by other environmental factors^[33]. Thus, the serum amylase and lipase activities play a key role in determining the severity of AP. In this experiment, cerulein stimulation resulted in significant elevation in serum amylase and lipase levels. This increase was inhibited by SSM pre-treatment, suggesting that SSM is effective against the induction of AP (Figure 2).

The activation of inflammatory cells that release cytokines such as TNF- α and IL-1 β is an important cascade in the pathogenesis of AP^[34-36]. TNF- α and IL-1 β are derived predominantly from activated macrophages and

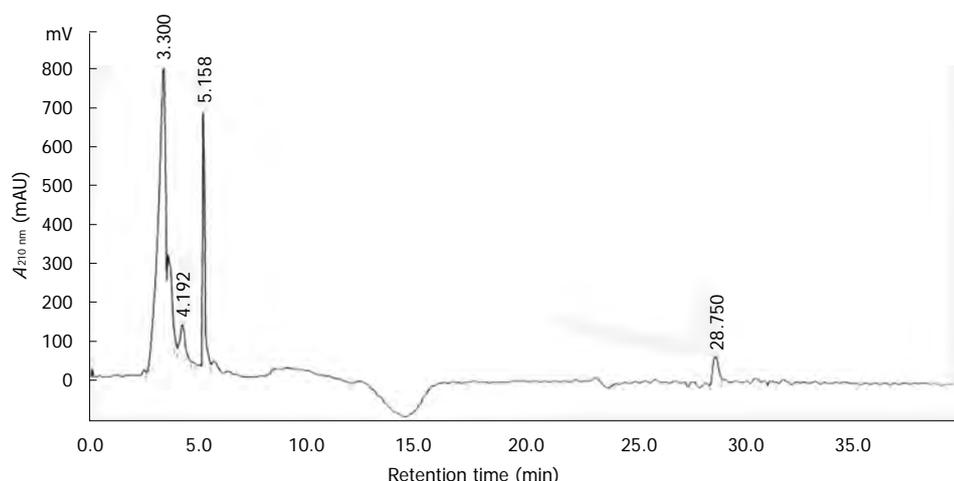

Figure 8 High-performance liquid chromatography chromatogram of the *Scolopendra subspinipes mutilans* at the length of 210 nm.

act *via* specific cell membrane-bound receptors. Levels of both these pro-inflammatory mediators are elevated on initiation of and during AP^[37,38]. Intrapancreatic TNF- α and IL-1 β can be detected 1 h after induction of AP, and the levels of these cytokines increase rapidly over the next 6 h^[37,38]. Recently, many studies have reported that both TNF- α and IL-1 β play an important role in AP^[7,39]. In our experimental model of pancreatitis, the serum levels of TNF- α and IL-1 β were elevated during AP. However, when mice were pre-treated with SSM water extract, this elevation of TNF- α and IL-1 β was inhibited (Figures 3 and 6).

In this study, we examined the role of HMGB-1 as a late inflammatory mediator in AP. Generally, HMGB-1, a DNA-binding intranuclear protein, is known to be a late activator in the inflammatory cascade^[10]. HMGB-1 has the capacity to induce cytokines and activate inflammatory cells when applied extracellularly^[10]. This implicates that HMGB-1 is a pro-inflammatory mediator. Recent investigations reported that serum HMGB-1 levels increase in patients with sepsis/endotoxemia^[40], hemorrhagic shock^[41], acute lung injury^[42], rheumatoid arthritis^[43], and disseminated intravascular coagulation^[44]. Similarly, many studies have shown the pivotal role of HMGB-1 plays in the development of pancreatic inflammation in AP^[45-48]. In this study, compared to saline pre-treatment, SSM pre-treatment significantly inhibited AP-induced HMGB-1 expression (Figures 5A and 6).

Oxidative stress and pro-inflammatory cytokines trigger common signal transduction pathways involved in the inflammatory cascade, particularly through activation of MAPK^[49]. We previously reported that the inhibition of MAPKs could inhibit the cytokine productions^[7,8]. In the present study, acinar cells with cerulein showed increased TNF- α and IL-1 β release *via* MAPKs and NF- κ B activation. However, SSM treatment inhibited activation of JNK, p38 and NF- κ B but not ERK1/2, consequently inhibiting cytokine release and HMGB-1 (Figures 6 and 7). In addition, we have shown here that cerulein-induced HMGB-1 expression was inhibited in pancreatic acinar cells by inhibition of JNK, p38 and NF- κ B activation

(Figure 7). These data suggest that SSM inhibits expression of HMGB-1 *via* inhibition of JNK, p38 and NF- κ B activation.

In conclusion, this study shows that SSM attenuates the severity of cerulein-induced AP and pancreatitis-associated lung injury through the inhibition of tissue injury, pro-inflammatory cytokine production, and HMGB-1 expression. Therefore, SSM exerts potent anti-inflammatory effects in AP and could be a beneficial agent in the AP and its pulmonary complications.

COMMENTS

Background

Acute pancreatitis (AP) is a serious, unpredictable clinical problem, whose pathophysiology remains poorly understood. Therefore, drugs and therapies need to be developed.

Research frontiers

Scolopendra subspinipes mutilans (SSM) is a venomous arthropod, which can be found throughout the world. SSM and its venom have been reported to exhibit many biochemical and physiological effects. In addition, SSM has been prescribed for the treatment of cardiovascular diseases in South Korea, China, and other Far Eastern Asian countries for several hundred years. However, the protective activities of SSM in cerulein-induced AP have not been examined to date. This study aimed to assess the protective effect of SSM in cerulein-induced AP.

Innovations and breakthroughs

Many studies have been tried to explore the possible candidate for treatment of acute pancreatitis (AP), but failed to find out. Nowad, the drug of AP is limited in protease inhibitors, and also the pathogenesis is not well-studied. In this paper, the authors studied the possible candidate to develop drug for AP, in line with their previous report. Also the authors provided the regulating mechanisms in AP. This finding could strengthen up the further studies of AP. Furthermore, this *in vivo* and *in vitro* studies would suggest that SSM could protect cerulein-induced AP *via* inhibiting high mobility group box chromosomal protein-1 release.

Applications

By understanding how SSM is effective in AP, these results could provide the clinical basis for development of drug or compound to treat AP and/or other inflammatory diseases.

Terminology

AP is a sudden inflammation of the pancreas. It can have severe complications and high mortality despite treatment. While mild cases are often successfully treated with conservative measures and aggressive intravenous fluid rehydration, severe cases may require admission to the intensive care unit or even surgery to deal with complications of the disease process.

Peer review

The role of SSM is mainly deleterious and also anti-inflammatory and antimicrobial, what in literature has support about the protective effect of SSM in AP. The study is designed reasonably and the methods and the results seem mostly proper to show interesting protective effect of SSM on AP.

Abstract

AIM: To evaluate the role of multi-detector row computed tomography (MDCT) angiography for assessing the therapeutic effects of percutaneous transhepatic variceal embolization (PTVE) for esophageal varices (EVs).

METHODS: The subjects of this prospective study were 156 patients who underwent PTVE with cyanoacrylate for EVs. Patients were divided into three groups according to the filling range of cyanoacrylate in EVs and their feeding vessels: (1) group A, complete obliteration, with at least 3 cm of the lower EVs and peri-/EVs, as well as the adventitial plexus of the gastric cardia and fundus filled with cyanoacrylate; (2) group B, partial obliteration of varices surrounding the gastric cardia and fundus, with their feeding vessels being obliterated with cyanoacrylate, but without reaching lower EVs; and (3) group C, trunk obliteration, with

the main branch of the left gastric vein being filled with cyanoacrylate, but without reaching varices surrounding the gastric cardia or fundus. We performed chart reviews and a prospective follow-up using MDCT images, angiography, and gastrointestinal endoscopy.

RESULTS: The median follow-up period was 34 mo. The rate of eradication of varices for all patients was 56.4% (88/156) and the rate of relapse was 31.3% (41/131). The rates of variceal eradication at 1, 3, and 5 years after PTVE were 90.2%, 84.1% and 81.7%, respectively, for the complete group; 61.2%, 49% and 42.9%, respectively, for the partial group; with no varices disappearing in the trunk group. The relapse-free rates at 1, 3 and 5 years after PTVE were 91.5%, 86.6% and 81.7%, respectively, for the complete group; 71.1%, 55.6% and 51.1%, respectively, for the partial group; and all EVs recurred in the trunk group. Kaplan-Meier analysis showed *P* values of 0.000 and 0.000, and odds ratios of 3.824 and 3.603 for the rates of variceal eradication and relapse free rates, respectively. Cyanoacrylate in EVs disappeared with time, but those in the EVs and other feeding vessels remained permanently in the vessels without a decrease with time, which is important for the continued obliteration of the feeding vessels and prevention of EV relapse.

CONCLUSION: MDCT provides excellent visualization of cyanoacrylate obliteration in EV and their feeding veins after PTVE. It confirms that PTVE is effective for treating EVs.

INTRODUCTION

Percutaneous transhepatic variceal embolization (PTVE) was introduced in the 1970s to manage esophageal varices (EVs)^[1,2], but this approach has not attained widespread clinical acceptance because of the associated high rebleeding rate^[3-5]. PTVE with cyanoacrylate is a modified procedure for conventional percutaneous transhepatic obliteration^[6-12]. Since both the varices and their feeding vessels are sufficiently and permanently obliterated by cyanoacrylate, this modified PTVE technique has been confirmed as an effective and safe method for preventing EV rebleeding^[11,12]. Multi-detector row computed tomography (MDCT) angiography has significantly improved our understanding of the complex vascular structural changes that occur during portal hypertension^[13-18], along with their clinical and prognostic significance^[19-24]. This technique enables the noninvasive study of the hemodynamic changes in the portal venous system^[14] and plays an important role in the treatment and follow-up of esophageal and gastric varices^[19,24].

The purpose of this study was to assess the relationship between hemodynamic changes in portosystemic collaterals and the long-term results of modified PTVE with cyanoacrylate for patients with EVs using multiplanar reformatted image MDCT imaging.

MATERIALS AND METHODS

Patients

This was a retrospective-prospective follow-up study to evaluate the long-term results of modified PTVE with cyanoacrylate for treating variceal bleeding. Patients with cirrhosis who had a history of EVs bleeding within 6 mo between January 2005 and December 2011 and who underwent PTVE were selected. A chart review of all patients was performed. We recorded demographic and clinical information, including type of underlying liver disease, liver function tests, and renal function prior to and after PTVE. Liver function was classified according to the Child-Pugh classification. PTVE was performed as a rescue maneuver in all patients, including patients who had uncontrolled severe bleeding during endoscopic therapy or those who had recurrent bleeding episodes from EVs during or after band ligation. All patients underwent diagnostic endoscopy before the intervention to confirm the presence of EV as the bleeding source. This study was approved by the local ethics committee and informed written consent was obtained from each patient.

The inclusion criteria were as follows: (1) cirrhosis confirmed by laboratory and imaging examinations; (2) preoperative gastroscopy showing mild to severe EVs and gastric fundal varices; (3) acute bleeding because of ruptured varices or a history of rupture and bleeding

within the last 3 mo; (4) surgery not indicated or preferred; and (5) the patient and their family agreeing to complete preoperative examinations and postoperative follow-ups.

The exclusion criteria were as follows: (1) concomitant liver cancer or other cancers; (2) concomitant widespread portal vein embolism or severe portal vein cavernous transformation; (3) phase II or higher hepatic encephalopathy; (4) obvious jaundice with total bilirubin levels three times higher than normal; (5) obvious bleeding tendency with a prothrombin time > 25 s; (6) severe hypertension, coronary heart disease, or cardiopulmonary insufficiency; and (7) concomitant hepatorenal syndrome or chronic renal insufficiency.

Computed tomography scanning and three-dimensional computed tomography portogram

MDCT images were used to evaluate EVs and their feeding vessels before and after the procedures. Computed tomography (CT) was performed *via* a 64-MDCT scanner (Sensation, Siemens Healthcare, Erlangen, Germany) during the unenhanced, arterial, and portal venous phases. A bolus-tracking technique was applied with a trigger threshold at the upper abdominal aorta of 150 Hounsfield units, with a delay time of 10 s for the arterial phase and an additional 30 s after the first acquisition for the portal venous phase. Iohexol 350 (100-150 mL) was administered at a dose calculated according to patient weight at a rate of 3 mL/s. MDCT was performed with Virtual Place Advance (AZE Ltd., Irvine CA, United States). Three reformatting techniques were used for image reconstruction in this study.

Image analysis evaluation of EVs and portosystemic collaterals

Imaging studies were independently reviewed by two abdominal imaging specialists with fellowship-level training and 5 years of experience as attending radiologists. Said reviewers were blinded to all other clinical and imaging information. EVs and peri-/para-EVs, as well as the adventitial plexus of the gastric cardia and fundus, could be detected by cross-sectional CT scanning during the unenhanced and portal venous phases. After PTVE, the varices adequately embolized with cyanoacrylate to show hyperdensity without enhancement on post-procedural images, whereas isodensity was observed on pre-contrast images in patients with inadequate eradication of the vessels, and with no enhancement being shown on post-contrast images. Portosystemic collaterals were independently assessed on MDCT images before and after PTVE with cyanoacrylate. The supplying vessels, including the left gastric vein (LGV), posterior gastric vein (PGV), and paraesophageal vein were identified on the three-dimensional CT portogram.

According to the findings of CT images, patients were divided into three groups on the basis of the filling range of cyanoacrylate in EVs and their feeding vessels: (1) group A, complete obliteration, with at least 3 cm of

Table 1 Clinical characteristics of patients included in the study

| Characteristics | Value (n = 156) |
|--|-----------------------|
| Gender: Male/female | 91/65 |

the lower EVs and peri-/para-EVs, as well as the adventitial plexus of the gastric cardia and fundus filled with cyanoacrylate; (2) group B, partial obliteration, with the varices surrounding the gastric cardia, fundus, and their feeding vessels being obliterated with cyanoacrylate, but without reaching the lower EVs; and (3) group C, trunk obliteration, with the main branch of the LGV being filled with cyanoacrylate, but without reaching the varices surrounding the gastric cardia or fundus.

Follow-up study

All subjects included in this study were followed up at regular intervals of 1, 3 and 6 mo after the procedures, and then every 6-12 mo in a specialized clinic under coordination by a research nurse. Patients underwent a brief recording of medical history at each visit, including possible gastrointestinal bleeding, alcohol intake, concurrent medications, and patient complaints. A brief physical examination, including estimation of ascites and HE by routine neurological examination and laboratory profiling, was performed. Gastrointestinal endoscopy and CT portal venography were performed every 6-12 mo to evaluate EVs and their feeding veins.

Relapse after PTVE was assessed by endoscopy. Follow-up endoscopy was performed at 6 mo intervals after treatment. EVs were evaluated independently during endoscopy by two experienced endoscopists. The endoscopic EVs findings were evaluated according to the classification system of the Japanese Society for Portal Hypertension and EVs^[25]. A final decision regarding the endoscopic findings was reached by consensus. The appearance of the localized red color sign F1 or bleeding on follow-up endoscopy was regarded as a relapse of EVs. In this prospective study, we defined relapse of EVs as the primary endpoint, and survival as the secondary endpoint. The relationship between the cyanoac-

rylate filling range in the vessels and prognosis of PTVE for EVs was determined by the MDCT imaging results.

Modified PTVE procedure

The PTVE procedure was performed under radiological guidance as described previously. In brief, after transhepatic puncture of the intrahepatic portal vein branch under ultrasonographic or fluoroscopic guidance, a 5F Cobra catheter was introduced into the splenic vein, and splenoportography was performed to evaluate the index varices as well as the feeding vessels and draining veins. The main feeding vessel (*e.g.*, left, short or PGV) was selected with the 5F cobra catheter, and cyanoacrylate was injected into all varices in the lower esophagus and gastric fundus, as well as into all feeding vessels. Next, splenoportography was repeated to assess the extent of varix obliteration. If other feeding vessels were detected, the procedure was repeated until blood flow in the varices completely ceased. The lower EVs, peri-EVs, and/or the gastric cardiac submucosal and perforating vessels were sufficiently obliterated with cyanoacrylate. Finally, the 5F sheath system was withdrawn, and the puncture tract was embolized with microcoils.

Statistical analysis

All data are expressed as mean \pm SD or median values. The cumulative relapse-free rate and cumulative survival rate among the groups based on the reduction rate after treatment were determined using the Kaplan-Meier method and JMP version 5 statistical software (SAS Institute, Tokyo, Japan). Significance was tested using the generalized Wilcoxon signed-rank test and Student's *t*-test. A *P* value < 0.05 was regarded as significant.

RESULTS

Demographics

A total of 181 patients underwent PTVE during the study period. Fifteen patients with hepatocellular carcinoma and five cases of technical failures were excluded. Five cases were lost in follow-up. Thus, the final study population consisted of 156 patients (Figure 1). The clinical characteristics of the patients in the groups, including age, gender, etiology of cirrhosis, severity of liver disease, and size of EVs, are shown in Table 1.

CT detection of EVs and their feeding vessels

(1) All EVs were detected in all patients by MDCT angiography during the portal venous phase, and ninety-seven of the 156 patients had paraesophageal varices. According to the MDCT angiography findings before PTVE, 86 of the patients had a LGV alone (Figure 2A), 46 had a LGV plus a PGV (Figure 2B), and 37 patients had a LGV plus a PGV and a short gastric vein (SGV) (Figure 2C). The supplying portosystemic collaterals were further confirmed according to the findings on DSA following the PTVE procedures; and (2) MDCT scanning and angiography during the portal venous phase were

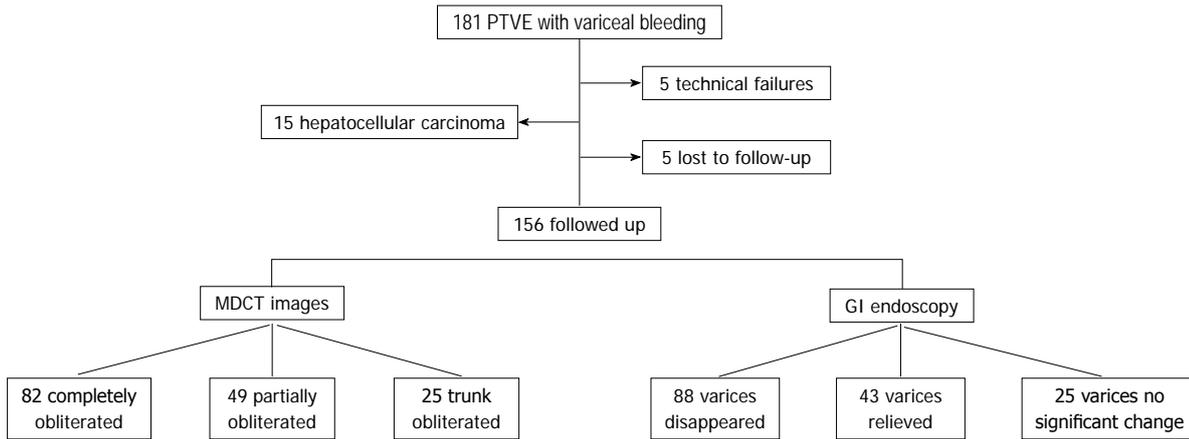

Figure 1 Study flow chart. PTVE: Percutaneous transhepatic variceal embolization; MDCT: Multi-detector row computed tomography; GI: Gastrointestinal.

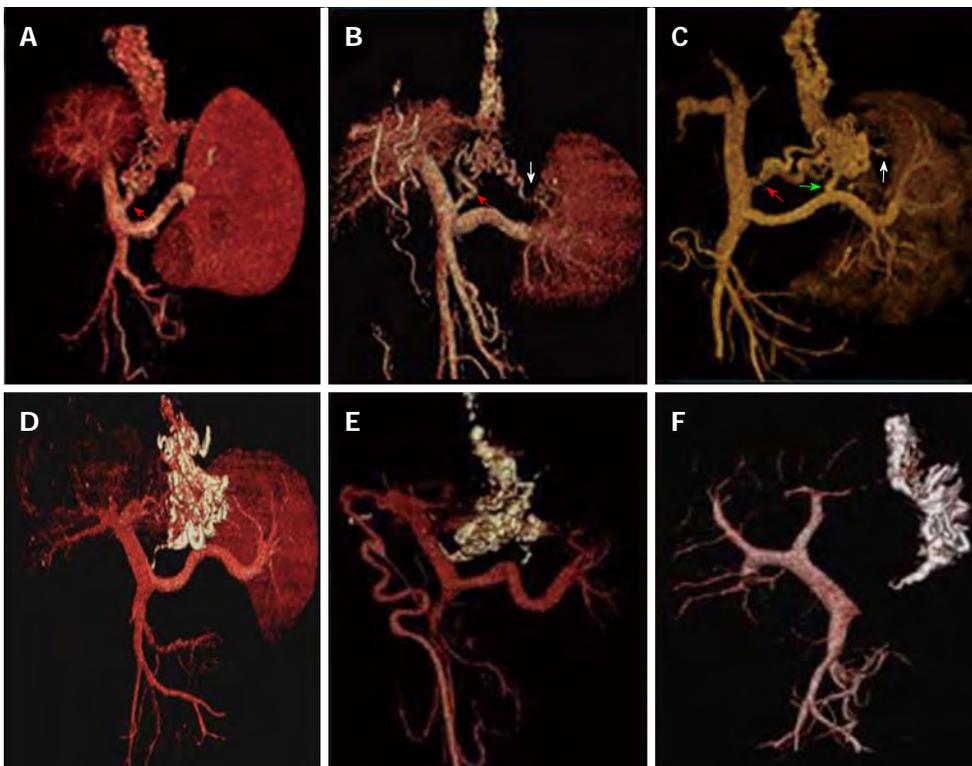

Figure 2 Volume rendering of the multi-detector row computed tomography angiography data set during the portal venous phase demonstrated the esophageal-gastric varices and their afferent vessels before and after percutaneous transhepatic variceal embolization. A-C: Volume rendering of multi-detector row computed tomography angiography data set during the portal venous phase demonstrates the esophageal-gastric varices and their afferent vessels (left gastric vein (LGV) only for A, LGV and short gastric vein (SGV) for B, LGV, posterior gastric vein and SGV for C); D-F: All varices and their feeding vessels are completely filled with cyanoacrylate (arrows) after percutaneous transhepatic variceal embolization; no flow signals were revealed in any of the cases.

used to evaluate EVs and their collaterals after the procedures. Figures 2 and 3 show the three typical groups of obliteration with cyanoacrylate according to coronal thin slab maximum intensity projection of MDCT angiography follow-up. Group A: complete obliteration, the lower EVs and peri-/para-EVs, as well as the adventitial plexus of the gastric cardia and fundus, were completely filled with cyanoacrylate; Group B: partial obliteration, the varices surrounding the gastric cardia and fundus and their feeding vessels were obliterated with cyanoacrylate, but cyanoacrylate did not obliterate the lower EVs; Group

C: trunk obliteration, the main branch of the LGV was filled with cyanoacrylate, but it did not reach the varices surrounding the gastric cardia or fundus. Volume rendering of the MDCT angiography data set during the portal venous phase demonstrated that the esophageal-gastric varices and afferent vessels were completely filled with cyanoacrylate, but without flow signal in the varices (Figure 2D-F). Of the 156 patients, 82 achieved complete obliteration, 49 achieved partial obliteration, and 25 achieved trunk obliteration.

During the follow-up, CT images revealed dynamic

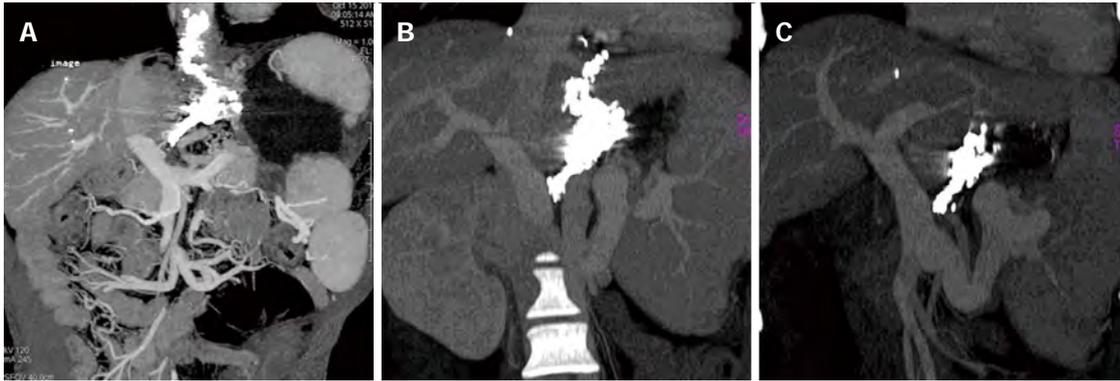

Figure 3 Coronal thin-slab maximum intensity projection of multi-detector row computed tomography angiography during the portal venous phase demonstrates the three different obliteration types of cyanoacrylate. A: Complete obliteration: with the lower esophageal varices (EVs) and peri-/para-EVs, as well as the adventitial plexus of the gastric cardia and fundus, filled with cyanoacrylate; B: Partial obliteration: along with the left gastric vein (LGV) and its main branches being obliterated with cyanoacrylate, the varices surrounding the gastric cardia and fundus are also obliterated, but without reaching the lower EVs; C: Trunk obliteration: cyanoacrylate mainly obliterates the LGV and its main branches outside of the gastric wall.

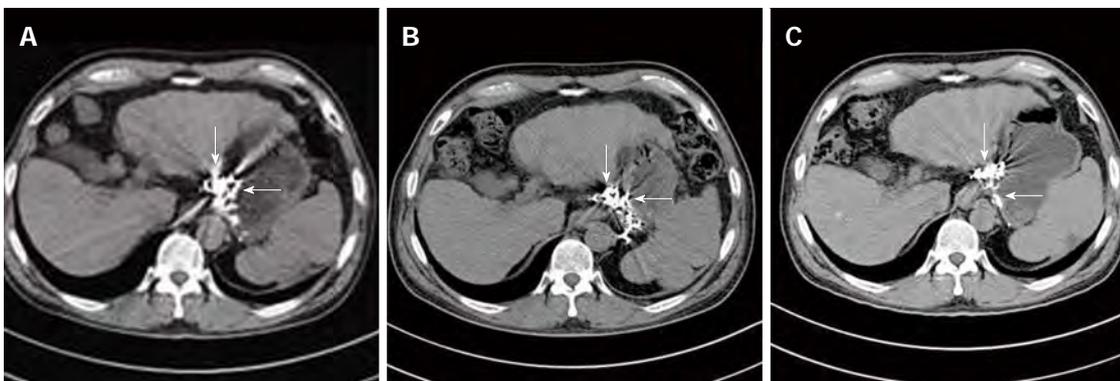

Figure 4 Computed tomography image follow-up revealed the different outcome of cyanoacrylate in the different veins: cyanoacrylate in submucosal varices (within the wall of the fundus, large arrow) disappeared with time, but those in the para- and peri-gastric varices (outside the wall of the fundus, small arrow) remained permanently in the vessels without a time-dependent decrease. A: The cyanoacrylate in both the gastric varices and peri- and para-gastric varices stayed full at 3 mo after percutaneous transhepatic variceal embolization (PTVE); B: The cyanoacrylate in the gastric varices was reduced at 6 mo after PTVE; C: The cyanoacrylate in the gastric varices nearly disappeared at 12 mo after PTVE, but the cyanoacrylate in the peri- and para-gastric vessels retained the same as before.

changes and outcome of cyanoacrylate injection in different veins. Cyanoacrylate in esophageal and gastric varices gradually reduced with time, but that in the para- and peri-varices was retained permanently in the vessels without a time-dependent decrease, which is important to continue the obliteration of the feeding vessels and prevent the relapse of esophageal-gastric varices (Figure 4).

Cumulative relapse-free rates

The median follow-up period was 34 mo, ranged from 6 mo to 71 mo. The rate of eradication of varices for all patients was 56.4% (88/156), and the rate of relapse was 31.3% (41/131). The rates of variceal eradication at 1, 3, and 5 years after PTVE were 90.2%, 84.1% and 81.7%, respectively, for the complete group; 61.2%, 49% and 42.9%, respectively, for the partial group; and with no varices disappearing in the trunk group (Figure 5A). The relapse free rates at 1, 3 and 5 years after PTVE were 91.5%, 86.6% and 81.7%, respectively, for the complete group; 71.1%, 55.6% and 51.1%, respectively, for the par-

tial group; and all EVs recurring in the trunk group (Figure 5B). Kaplan-Meier analysis showed a $P = 0.000$ and 0.000 and odds ratios (OR) = 3.824 and 3.603 for rates of variceal eradication and relapse free rates, respectively (Tables 2 and 3).

Rebleeding

Thirty-six of the 156 patients experienced upper gastrointestinal rebleeding during the follow-up period. The overall bleeding rate was 23.1% (36/156). Seven patients (8.5%, 7/82) in the complete obliteration group, 11 patients (22.4%, 11/49) in the partial obliteration group, and 18 patients (72%, 18/25) in the trunk obliteration group experienced rebleeding. The different rebleeding rates among the groups was statistically significant (Kaplan-Meier values: $P = 0.000$; OR, 3.560; Figure 5A). Portal hypertensive gastropathy was the main cause of bleeding in the complete obliteration group (six cases, the remaining one was bleeding from a peptic ulcer). Esophagogastric variceal rupture was the main cause of bleeding in the trunk obliteration group (12 cases,

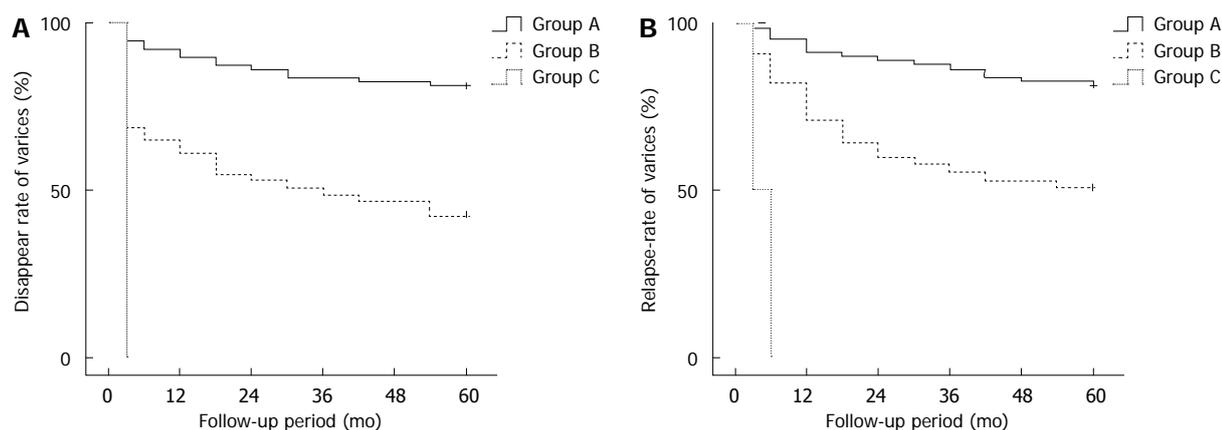

Figure 5 Kaplan-Meier analysis of the disappearance rate (A) and non-relapse rate (B) of varices shown at gastroscopy during the follow-up. Group A: Complete obliteration; Group B: Partial obliteration; Group C: Trunk obliteration.

tial obliteration group died. Of these, four died of gastrointestinal tract bleeding, six from hepatic failure, and two from primary liver cancer. Nineteen patients (76%, 19/25) in the trunk obliteration group died. Of these, 10 died of gastrointestinal tract bleeding, five from hepatic failure, and four from primary liver cancer. The overall 5-year mortality rate after the operation was 30.8% (48/156). The differences in the mortality rates among the groups were statistically significant (Kaplan-Meier values, $P = 0.02$; OR, 2.822; Figure 6B). A Cox regression analysis was performed for factors that might influence the rebleeding and survival rates after the operation

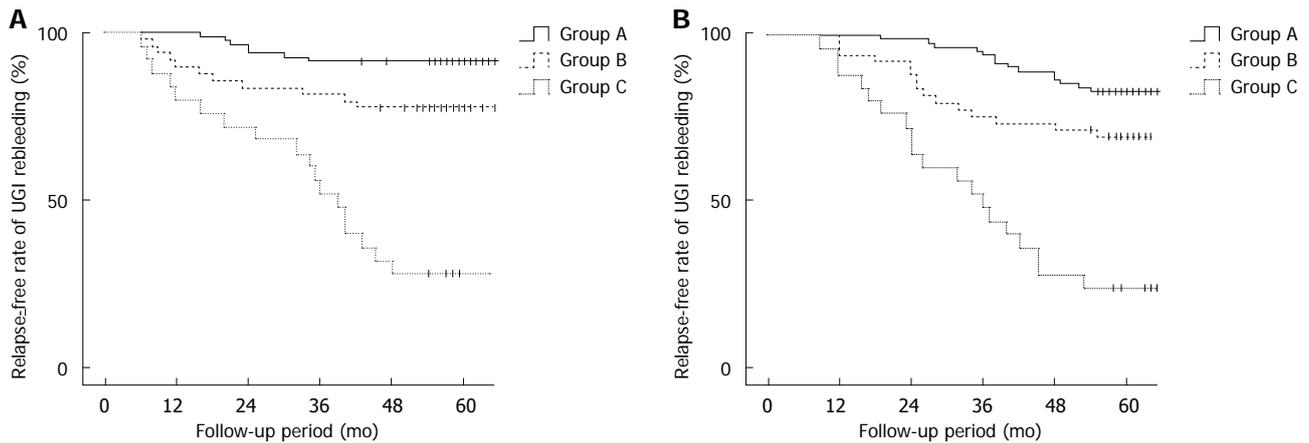

Figure 6 Kaplan-Meier analysis of non-bleeding (A) and survival rates (B) among the different obliteration types after modified percutaneous transhepatic variceal embolization. Group A: Complete obliteration; Group B: Partial obliteration; Group C: trunk obliteration.

(type of obliteration, gender, age, Child-Pugh classification, cause of cirrhosis, severity of varices, hepatic encephalopathy, ascites, and laboratory data) and showed that the range of obliteration and Child-Pugh grade were independent predictors of rebleeding and survival rates after the embolism operation (Tables 2 and 3).

DISCUSSION

MDCT has recently become more useful for examining EVs and the entire portosystemic shunt^[14,26]. MDCT allows for visualization of abnormal vessels of the intrinsic circulation, such as peri-EVs that are attached to the muscularis externa of the esophagus and para-EVs localized to the surrounding tissue^[14,27]. MDCT also allows for the detection of perigastric and paragastric varices^[23,28].

EVs are located within the wall of the lower esophagus, whereas para-esophageal veins are situated outside the wall of the lower esophagus. These vessels are supplied primarily by the LGV, which divides into anterior and posterior branches. The anterior branch supplies EVs, and the posterior branch forms the paraesophageal veins. EVs are usually connected with para-EVs in the distal esophagus^[29-31]. Previous studies have shown that large paraesophageal collateral veins (> 5 mm) are associated with high rates of variceal recurrence and rebleeding after banding^[32-34], and the increased risk of bleeding also seems to be associated with large perforating veins^[29,35].

With regard to the vascular anatomy of the lower esophagus and upper stomach in patients with EVs, it is important to achieve not only obliteration of EVs, but also embolization of the feeding vessels supplied by the portal venous system. We have a long-lasting interest in applying PTVE with cyanoacrylate to sufficiently obliterate the entire lower esophageal and peri-/para-EVs, and the adventitial plexus of the gastric cardia and fundus, to achieve this purpose^[11,12].

In this study we used multi-slice helical CT and three-dimensional portography to evaluate the hemodynamic

changes in EVs and their collaterals after PTVE with cyanoacrylate. Patients were divided into three groups on the basis of the filling range of cyanoacrylate filling in EVs and their feeding vessels: (1) Group A, complete obliteration: at least 3 cm lower than EVs and peri-/para-EVs, with the adventitial plexus of the gastric cardia and fundus being filled with cyanoacrylate; (2) Group B, partial obliteration: the varices surrounding the gastric cardia and fundus and their feeding vessels being obliterated with cyanoacrylate, but not reaching the lower EVs; and (3) Group C, trunk obliteration: the tissue adhesive filling the main branch of the LGV, but not reaching the varices surrounding the gastric cardia or fundus.

Our results demonstrated the relationship between MDCT image-based embolization range and the prognosis of patients with EVs after PTVE. Of the 156 patients who underwent PTVE with cyanoacrylate for EVs, 82 had their varices completely obliterated; relapse and rebleeding of varices were very low in this group [13.4% (11/82) and 8.5% (7/82), respectively]. However, the relapse rate and rebleeding rate of varices was significantly higher in patients with inadequate embolization of the varices and the feeding vessels than in those with adequate embolization. Multivariate analyses showed that the cyanoacrylate embolization range was an independent risk factor for rebleeding and the relapse of EVs. Thus, a close relationship was observed between the range of EV obstruction, their feeding veins, and the recurrence of EVs. These results demonstrate that it is important to achieve not only obliteration of the feeding vessels, but also embolization of EVs. This result may also explain why conventional PTVE does not achieve long-term prevention of variceal rebleeding, as it focuses mainly on the embolization of feeding veins using a coil or gelatin sponge.

In this study, we first reported the different changes and regression of cyanoacrylate in different veins. Cyanoacrylate in esophageal and gastric varices (vessels within the wall) gradually reduced with time, but the cyanoacrylate in the para- and peri- varices (vessels outside the wall) was permanently retained in the vessels without

a time-dependent decrease. This is important in order to continue obliterating the feeding vessels and prevent the relapse of esophageal-gastric varices, as the para- and peri- varices (vessels outside the wall) are the feeding vessels for EVs.

In summary, standard liver MDCT has significantly improved our understanding of the complex vascular structural changes that occur during portal hypertension, and MDCT provides excellent visualization of glue obliteration in EVs and their feeding veins. The results of our study emphasize the importance of sufficient eradication of EVs and their feeding vessels.

COMMENTS

Background

Bleeding from esophageal varices (EVs) is a serious complication of portal hypertension and a leading cause of death in patients with liver cirrhosis. Recurrent variceal bleeding is a challenging problem in patients with advanced cirrhosis.

Research frontiers

Percutaneous transhepatic variceal embolization (PTVE) with cyanoacrylate, a modified procedure for conventional percutaneous transhepatic obliteration, has been confirmed as an effective and safe method for preventing EVs rebleeding. Multi-detector row computed tomography (MDCT) has recently become more useful for examining EVs and the entire portosystemic shunt.

Innovations and breakthroughs

PTVE is effective for treating EVs, and the sufficient eradication of EVs and their feeding vessels is important in treating varices. MDCT has significantly improved our understanding of the complex vascular structural changes that occur during portal hypertension, and provides excellent visualization of cyanoacrylate obliteration in EVs and their feeding veins.

Applications

With the extensive and permanent obliteration of both EVs and their feeding veins, PTVE with cyanoacrylate is a prospective modality for the treatment of esophageal varices. MDCT is effective in evaluating the range of cyanoacrylate obliteration in EV and their feeding veins after PTVE.

Peer review

In the present study, instead of using EV embolization, PTVE for the eradication of varices feeding veins was instead attempted. The outcomes are encouraging: with clear data showing that PTVE could be an effective method. The MDCT images verified the importance of sufficient eradication of the feeding vessels for the long-term effect of PTVE with cyanoacrylate. The application of this modified technique in the presented cohort with EVs provides sufficient evidence for drawing conclusions. These findings were interesting, and contributed new data to the various effective EV treatment modalities.

Abstract

AIM: To investigate the effects of mitofusin-2 (MFN2) on insulin sensitivity and its potential targets in the liver of rats fed with a high-fat diet (HFD).

METHODS: Rats were fed with a control or HFD for 4 or 8 wk, and were then infected with a control or an MFN2 expressing adenovirus once a week for 3 wk starting from the 9th wk. Blood glucose (BG), plasma insulin and insulin sensitivity of rats were determined at end of the 4th and 8th wk, and after treatment with different amounts of MFN2 expressing adenovirus (10^8 , 10^9 or 10^{10} vp/kg body weight). BG levels were measured by Accu-chek Active Meter. Plasma insulin levels were analyzed by using a Rat insulin enzyme-

linked immunosorbent assay kit. Insulin resistance was evaluated by measuring the glucose infusion rate (GIR) using a hyperinsulinemic euglycemic clamp technique. The expression or phosphorylation levels of MFN2 and essential molecules in the insulin signaling pathway, such as insulin receptor (INSR), insulin receptor substrate 2 (IRS2), phosphoinositide-3-kinase (PI3K), protein kinase beta (AKT2) and glucose transporter type 2 (GLUT2) was assayed by quantitative real-time polymerase chain reaction and Western-blotting.

RESULTS: After the end of 8 wk, the body weight of rats receiving the normal control diet (ND) and the HFD was not significantly different ($P > 0.05$). Compared with the ND group, GIR in the HFD group was significantly decreased ($P < 0.01$), while the levels of BG, triglycerides (TG), total cholesterol (TC) and insulin in the HFD group were significantly higher than those in the ND group ($P < 0.05$). Expression of MFN2 mRNA and protein in liver of rats was significantly down-regulated in the HFD group ($P < 0.01$) after 8 wk of HFD feeding. The expression of INSR, IRS2 and GLUT2 were down-regulated markedly ($P < 0.01$). Although there were no changes in PI3K-P85 and AKT2 expression, their phosphorylation levels were decreased significantly ($P < 0.01$). After intervention with MFN2 expressing adenovirus for 3 wk, the expression of MFN2 mRNA and protein levels were up-regulated ($P < 0.01$). There was no difference in body weight of rats between the groups. The levels of BG, TG, TC and insulin in rats were lower than those in the Ad group ($P < 0.05$), but GIR in rats infected with Ad-MFN2 was significantly increased ($P < 0.01$), compared with the Ad group. The expression of INSR, IRS2 and GLUT2 was increased, while phosphorylation levels of PI3K-P85 and AKT2 were increased ($P < 0.01$), compared with the Ad group.

CONCLUSION: HFDs induce insulin resistance, and this can be reversed by MFN2 over-expression targeting the insulin signaling pathway.

Mitofusin-2 ameliorates high-fat diet-induced insulin resistance in liver of rats. *World J Gastroenterol* 2013; 19(10): 1572-1581 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1572.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1572>

INTRODUCTION

With obesity and diabetes reaching epidemic proportions worldwide, the role of insulin resistance and its consequences are attracting much attention. Insulin resistance is a critical mechanism of type 2 diabetes mellitus (T2DM) and of predisposing conditions for T2DM such as obesity and metabolic syndrome^[1]. Chronic excess energy consumption has been shown to contribute to hyperinsulinemia and insulin resistance. The liver plays a critical role in energy metabolism and is a major insulin target organ responsible for glucose homeostasis^[2]. In the liver, insulin acts through a complex signaling network and functions as an important regulator of carbohydrate and lipid homeostasis. Deficiency in insulin signaling may cause insulin resistance and subsequently lead to systemic insulin resistance and T2DM^[3,4]. Specific members of the suppressor of cytokine signaling (SOCS) family of proteins are now thought to play a role in the development of insulin resistance owing to their ability to inhibit insulin signaling pathways. Work with hepatocyte-specific suppressor of cytokine signaling 3 (SOCS3)-deficient (L-SOCS3 cKO) mice, reveals that hepatic SOCS3 is a mediator of insulin resistance in the liver^[5]. Therefore, it is of significance to identify the mechanism of insulin resistance and improve the function of the insulin signaling network for the cure of insulin resistance.

Mitochondria generate energy and play central roles in cell energy metabolism^[6]. Studies have shown that insulin resistance states such as T2DM or obesity were correlated with a decrease in mitochondria number and function^[7,8]. Fusion of mitochondria constitutes an important step in the regulation of mitochondrial morphology and function^[9,10]. Mitofusin-2 (MFN2) encodes a mitochondrial membrane GTPase which participates in mitochondrial fusion and contributes to the maintenance and operation of the mitochondrial network^[11]. MFN2 plays a central role in mitochondrial metabolism and may be associated with metabolic diseases such as obesity and T2DM^[12-14].

Previous studies revealed that a high-fat diet (HFD) induced insulin resistance^[15] and MFN2 could play a important role in development of insulin resistance^[12,16,17]. However, the role of MFN2, a key factor for mitochondrial function and energy metabolism, in liver insulin resistance and the insulin signaling pathway should be further elucidated. In this study, we established an HFD-in-

duced insulin resistance model in rats and used an MFN2 expressing adenovirus to investigate the mechanism by which MFN2 ameliorates HFD-induced insulin resistance.

MATERIALS AND METHODS

Animal care and grouping

Male Wistar rats about 60-80 g (4 wk old) were housed in wire bottom cages to prevent coprophagia. The environment was controlled in terms of light (12:12-h light-dark cycle starting at 6:00 AM), humidity, and room temperature (20-23 °C). Except for pretest overnight fasting and the immediate postoperative period, animals had free access to water and chow. The experimental protocols were approved by the Institutional Animal Care and Use Committee of the Centre for Gerontology and Geriatrics of Hebei Province in China.

Seven days after their arrival, rats were randomly divided into 9 groups ($n = 6$), as is schematically represented in Figure 1. In brief, rats were fed with a normal control diet (ND) or an HFD for 4 or 8 wk, and then some groups were infected with Ad-MFN2 or empty Ad adenovirus or PBS control once a week, for 3 wk. The HFD consisted of 59.8% fat, 20.1% protein, and 20.1% carbohydrate (kcal). The normal rodent chow diet contained 10.3% fat, 24.2% protein, and 65.5% carbohydrate (kcal). The MFN2 expressing adenovirus Ad-MFN2 and the empty control adenovirus Ad were obtained from Dr. Zhang, Hebei Medical University^[18].

Blood samples were collected from the abdominal aorta. Blood glucose (BG) levels were measured by Accu-chek Active Meter (ACCU-CHEK® Active; Roche, Germany) and insulin levels were analyzed using a rat insulin enzyme-linked immunosorbent assay kit (Crystal Chem. Inc, United States). The liver tissue samples of rats were taken immediately and kept at -80 °C after being quickly frozen in liquid nitrogen.

Euglycemic hyperinsulinemic clamp

Hyperinsulinemic clamp studies were performed as previously described^[19]. Rats were under general anesthesia (3% pelltobarbitalum natricum, 60 mg/kg, intraperitoneally), and catheters were inserted into the right jugular vein and the thoracic aorta of rats and exteriorized from the back of the neck subcutaneously. At the end, the catheters were flushed with isotonic saline containing heparin (50 U/mL). Rats were allowed to fully recover for a minimum of 3 d and only those that had lost less than 5% of their preoperative weights were used. Euglycemic-hyperinsulinemic clamp tests were performed on fasted, awake, and unrestrained animals. Insulin was infused at 4 mU/(kg min) through the jugular vein catheter for 0-90 min. Glucose concentrations were clamped at euglycemic levels by a variable rate infusion of 30% glucose. BG levels were monitored with a glucometer (ACCU-CHEK® Active; Roche), and glucose infusion rates (GIR) were adjusted every 5-10 min as needed. A stable GIR was obtained within about 60 min after in-

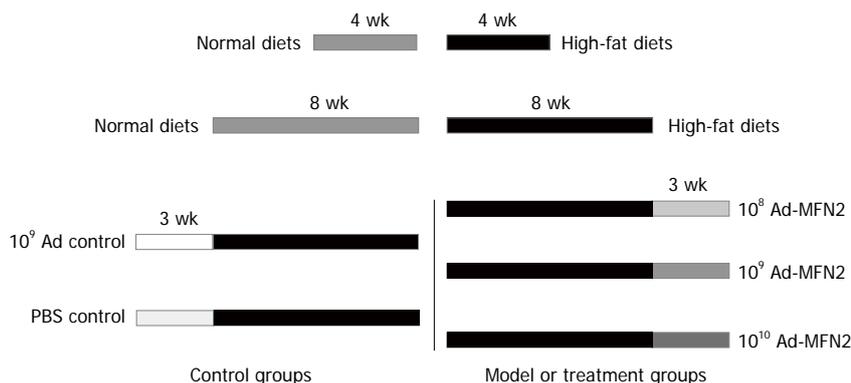

Figure 1 Schematic presentation of rat groups. Rats were fed with control or high-fat diets for 4 or 8 wk, and then some groups were infected with Ad-mitofusin 2 (MFN2) or empty Ad adenovirus or phosphate-buffered saline (PBS) control once a week for 3 wk.

GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; MFN2: Mitofusin-2; INSR: Insulin receptor; IRS2: Insulin receptor substrate 2; PI3K: Phosphoinositide-3-kinase; AKT2: Protein kinase beta; GLUT2: Glucose transporter type 2; SOCS3: Suppressor of cytokine signaling 3.

sulin infusion and maintained thereafter. At steady state, mean GIR was normalized to body weight.

Real-time polymerase chain reaction analysis

Total RNA was isolated from liver tissue using TRIzol reagent (Invitrogen, United States) according to the manufacturer’s instructions. Equal amounts of RNA were used to synthesize first strand cDNA (Promega, United States), and quantitative real-time polymerase chain reaction (RT-PCR) was performed on an ABI PRISM 7300 PCR System (Applied Biosystems, United States) using Syber Green I GoTaq[®] qPCR Master Mix (Promega, United States). PCR was performed as: one cycle at 95 °C for 5 min, followed by 40 cycles of 95 °C for 15 s, 58 °C for 20 s and 72 °C for 30 s. Then PCR products were analyzed by melting curve to confirm the specificity of amplification. The PCR primer sequences are shown in Table 1. mRNA expression of target genes was normalized to the internal reference gene glyceraldehyde 3-phosphate dehydrogenase. The relative expression of target genes was obtained using SDS v1.3.2 software linked with the PCR machine.

Western blotting

Protein samples were prepared with lysis buffer (10 mL/L Triton X-100, 150 mmol/L NaCl, 10 mmol/L Tris-HCl, pH 7.4, 1 mmol/L EDTA, 1 mmol/L EGTA, pH 8.0, 0.2 mmol/L Na₃VO₄, 0.2 mmol/L phenylmethyl-

sulfonyl fluoride, and 5 mL/L NP-40). Equal amounts of protein were separated by 10% SDS-PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis), and electrotransferred to polyvinylidene difluoride membranes, and were then blocked with 5 g/L bovine serum albumin for 2 h at room temperature. Membranes were incubated with appropriate diluted primary antibodies of MFN2, insulin receptor (INSR), insulin receptor substrate 2 (IRS2), phosphoinositide-3-kinase (PI3K-P85), p-PI3K-P85, AKT2, p-AKT2, glucose transporter type 2 (GLUT2) or β-actin (all from Santa Cruz or Cell Signaling Technology, United states) respectively overnight at 4 °C, and then with the respective secondary antibody for 2 h. Proteins were detected with the enhanced chemiluminescence detection system. β-actin served as an internal control protein. The experiments were replicated three times.

Statistical analysis

Data were shown as mean ± SD. One-way analysis of variance was used to determine statistically significant differences between groups. P < 0.05 was considered statistically significant.

RESULTS

HFD decreased insulin sensitivity in rats

As shown in Figure 2, fasting BG and plasma insulin lev-

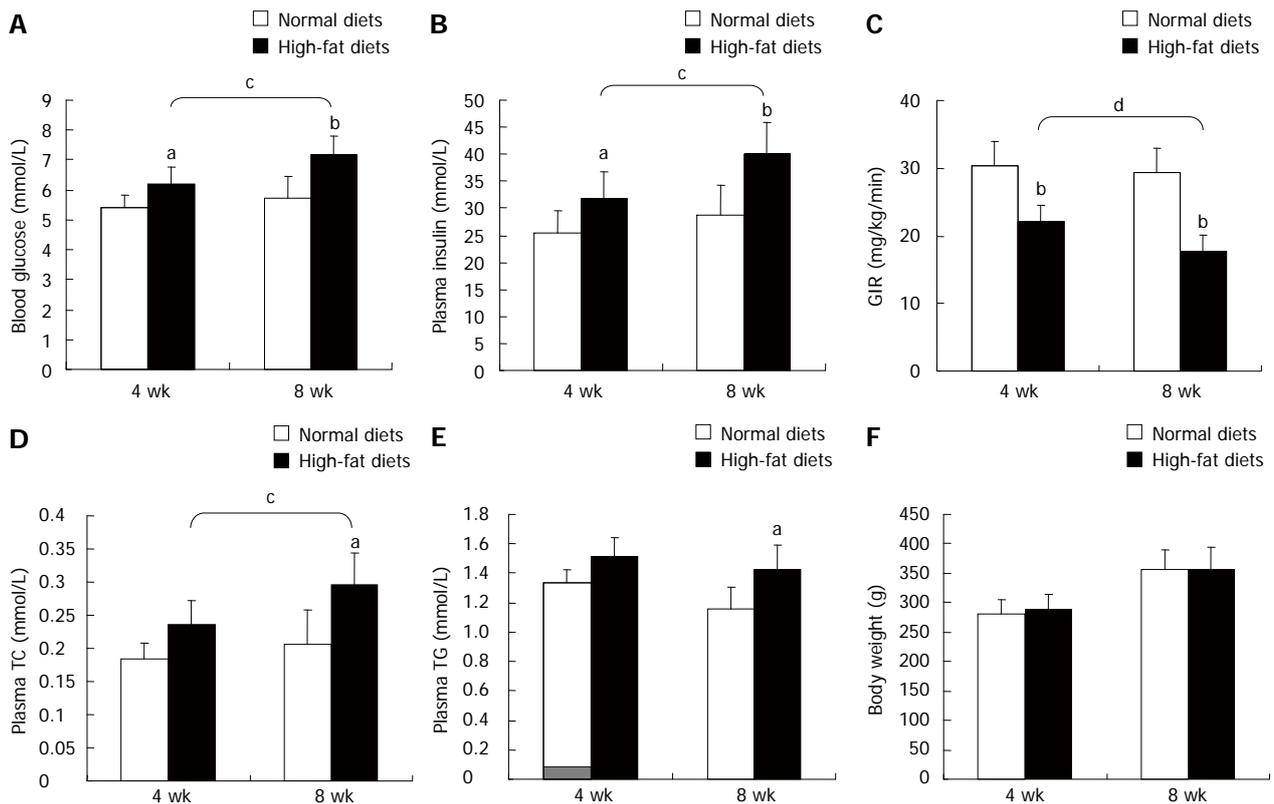

Figure 2 High-fat diets resulted in insulin resistance in rats ($n = 6$). Rats were fed with high-fat diets or normal control diets for 4 wk or 8 wk. A: The level of blood glucose; B: The level of plasma insulin. C: The values of glucose infusion rate (GIR) were used to assess insulin sensitivity of rats assayed by hyperinsulinemic euglycemic clamping; D: The level of plasma total cholesterol (TC); E: The level of plasma triglyceride (TG); F: The body weight. ^a $P < 0.05$, ^b $P < 0.01$ vs normal diets; ^c $P < 0.05$, ^d $P < 0.01$ vs 4 wk.

els of rats increased after 4 or 8 wk HFD feeding, while GIR, a more sensitive indicator for insulin sensitivity, decreased markedly. The levels of plasma total cholesterol (TC) and triglycerides (TG) were higher than those in the ND group at 4 and 8 wk. Greater changes in these values were seen at 8 wk than 4 wk, while the body weights of rats in each group were not significantly different at 4 or 8 wk.

HFD inhibited the expression of MFN2 and insulin signaling pathway factors and their phosphorylation levels

MFN2 is a key factor for energy metabolism, while the IRS2/PI3K cascade is the main insulin signaling pathway in hepatocytes, so we detected the expression of MFN2 and the IRS2/PI3K cascade pathway. As shown in Figure 3, the expression of MFN2, INSR, IRS2 and GLUT2 was down-regulated markedly by HFD both at 4 and 8 wk. While the mRNA and total protein expression of PI3K-P85 and AKT2 were not significantly changed (Figure 3A and B), their protein phosphorylation levels decreased markedly (Figure 3B). However, HFD seemed to have no effects on the expression of IRS1, PI3K-P110 and AKT1 or their phosphorylation (data not shown).

Over-expression of MFN2 ameliorated HFD induced insulin resistance in rats

In order to know the effect of MFN2 on insulin sensitiv-

ity, rats were fed with an HFD for 8 wk, and then were infected with different amounts of Ad-MFN2 (10^8 , 10^9 or 10^{10} vp/kg body weight) or empty Ad adenovirus or PBS control for 3 wk. The results showed that MFN2 expression in the liver of rats increased dramatically after Ad-MFN2 infection (Figure 4A-C). At the same time, fasting BG, plasma insulin, TC and TG levels decreased (Figure 4D-G), while GIR increased (Figure 4H) markedly after infection with different amounts of Ad-MFN2. The body weight of rats in the two groups showed no significant difference (Figure 4I). The results indicated that MFN2 over-expression could neutralize the effects of HFD on insulin sensitivity.

Over-expression of MFN2 neutralized the inhibition of the insulin pathway by HFD in rats

Based on MFN2 over-expression in liver of rats, we detected changes in the insulin pathway by quantitative RT-PCR and Western-blot assays. The results showed that both mRNA and protein levels of INSR, IRS2 and GLUT2 were up-regulated markedly (Figure 5A and B). Though there were no changes in PI3K-P85 and AKT2 expression, their phosphorylation levels increased significantly (Figure 5B). After treated with MFN2 expressing adenovirus, the expression of SOCS3 was decreased (Figure 5C and D). The results suggested that MFN2-induced improvement in insulin sensitivity may be correlated with the promotion of the insulin signaling pathway.

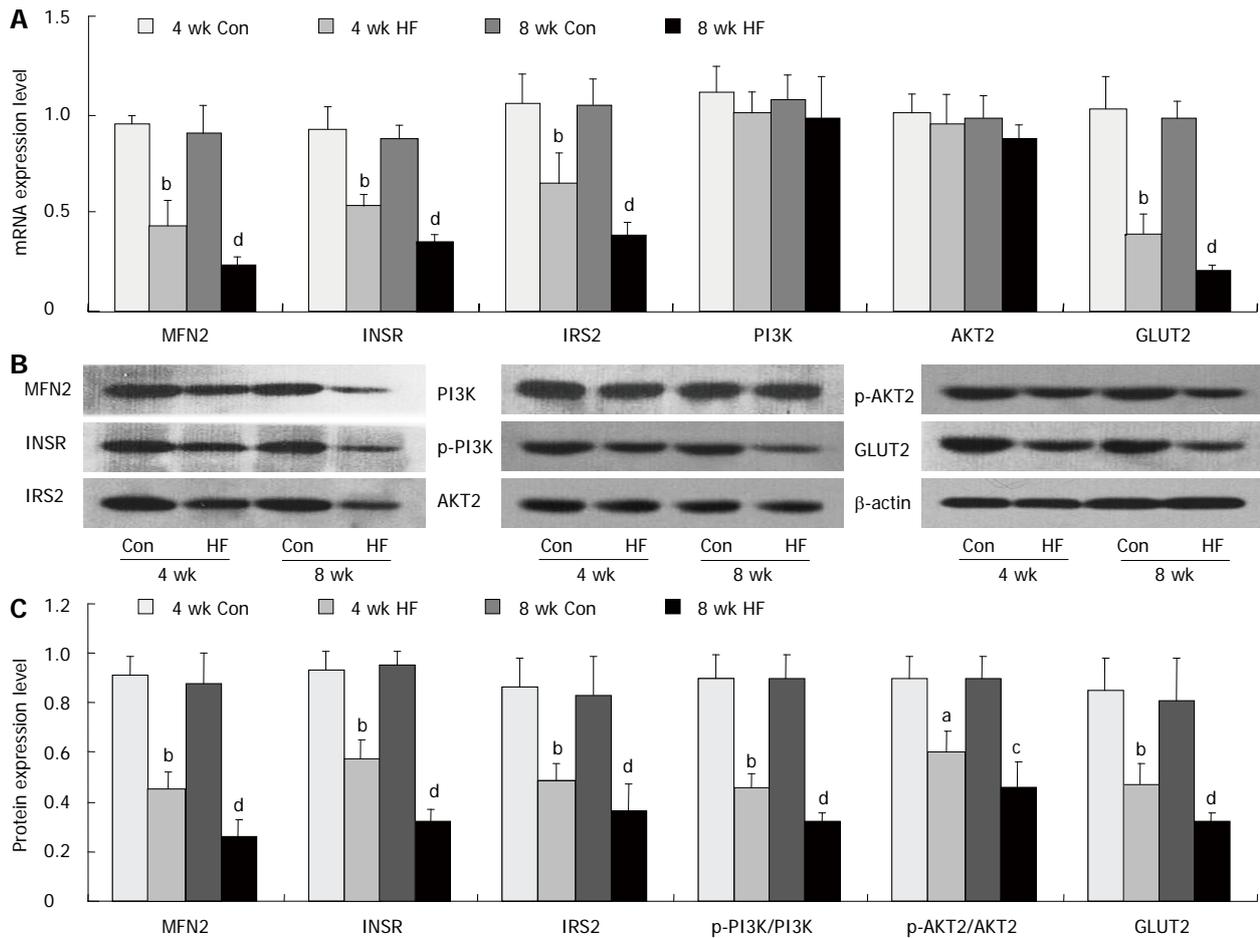

Figure 3 High-fat diets inhibited insulin pathway in liver of rats. Rats were fed with high-fat diets (HF) or normal control diets (Con) for 4 or 8 wk. A: The mRNA expression levels of mitofusin 2 (MFN2), insulin receptor (INSR), insulin receptor substrate 2 (IRS2), phosphoinositide-3-kinase (PI3K), AKT2 and glucose transporter type 2 (GLUT2) were examined by quantitative real-time-polymerase chain reaction; B and C: The protein levels were detected by Western-blotting. ^b*P* < 0.01 vs normal diets for 4 wk; ^d*P* < 0.01 vs normal diets for 8 wk.

Over-expression of MFN2 alleviated hepatic steatosis

All of the tissue sections in the control and Ad groups exhibited diffuse hepatic steatosis under a light microscope. Hepatic steatosis was most obvious around the portal area and was accompanied by inflammatory cell infiltration. The liver HE staining of rats infected with Ad-MFN2 showed a lower cell volume and fat droplet accumulation (Figure 6).

DISCUSSION

HFDs induce dysfunction of energy metabolism and impaired insulin sensitivity^[20]. Insulin resistance is not only the most important pathophysiological feature in many pre-diabetic states, but is also a key component of the metabolic syndrome, in which target cells fail to respond to normal levels of circulating insulin^[21]. The liver is a vital organ for lipid metabolism and glycometabolism, and therefore one of the main organs in which insulin resistance occurs. Mitochondria are the power centres, and also the energy metabolism centres in cells, so mitochondrial dysfunction is the main reason for insulin resistance and is involved in the pathogenesis of T2DM^[22]. The

MFN2 gene plays a central role in mitochondrial metabolism^[23]; however, the role of MFN2 in insulin resistance and the insulin signaling pathway remains uncertain. Our study suggested that MFN2 expression and insulin sensitivity were inhibited by an HFD, while recovery of MFN2 expression could recover impaired insulin sensitivity, and may be associated with improvements of the insulin signaling pathway in liver.

An HFD enriched with lard, a significant contributor to the development of obesity and insulin resistance, has been widely used to induce an animal model of obesity with insulin resistance^[24]. Previous studies have reported a long-term HFD could cause a marked increase in body weight. In this study, we confirmed that an HFD, for only 4 wk, could result in insulin resistance, which progressed further after 8 wk in the absence of major changes in total body weight. It may be because an HFD produces altered fat distribution, leading to the accumulation of visceral fat^[25,26]. At the same time, MFN2 expression was down-regulated dramatically, and the insulin signaling pathway was inhibited markedly in the liver of rats.

MFN proteins have been shown to regulate the biogenesis and maintenance of the mitochondrial network

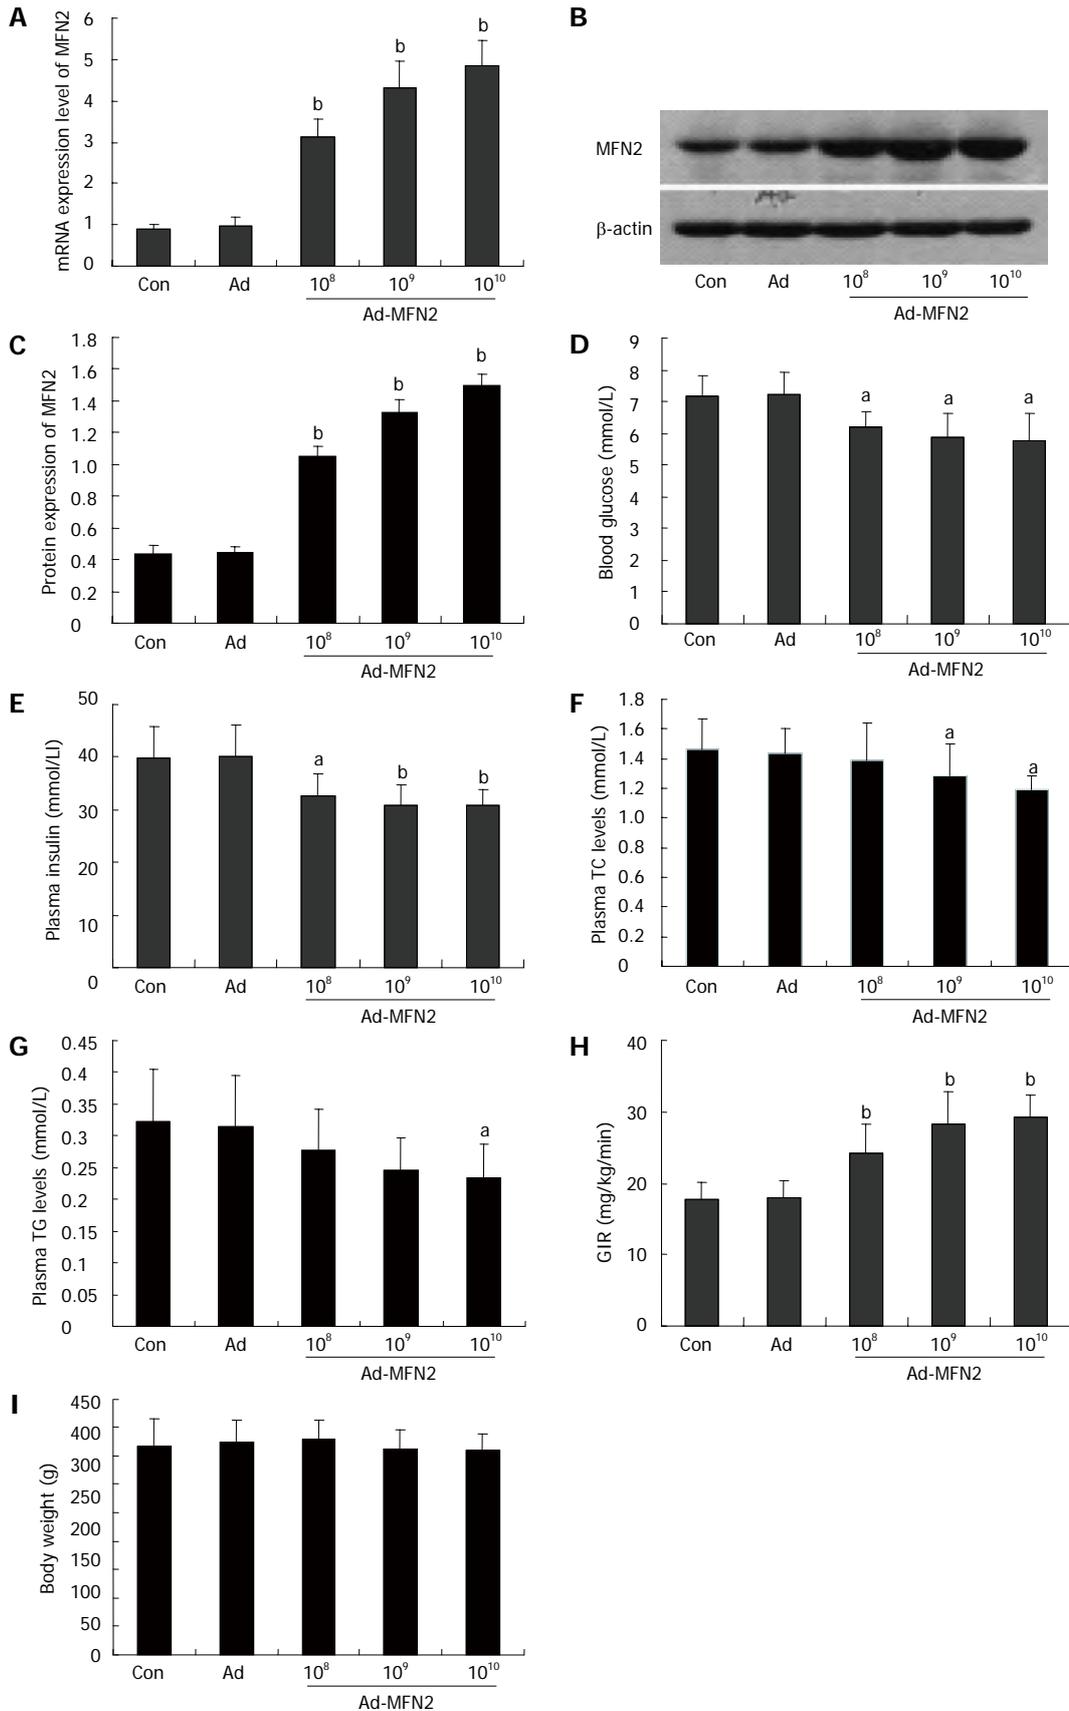

Figure 4 Mitofusin-2 over-expression improved insulin sensitivity of rats ($n = 6$). Rats were fed with high-fat diets for 8 wk, and then were infected with different amount of Ad-mitofusin-2 (MFN2) (10^8 , 10^9 or 10^{10} vp/kg body weight) or empty Ad adenovirus or phosphate-buffered saline (PBS) control for 3 wk. MFN2 over-expression in liver of rats was confirmed by quantitative real-time-polymerase chain reaction (A) and Western-blotting (B and C). The levels of blood glucose (D), plasma insulin (E), triglycerides (TG) (G) plasma total cholesterol (TC) (F) and insulin sensitivity (H) levels were examined, respectively. The body weight of rats was measured (I). ^a $P < 0.05$, ^b $P < 0.01$ vs Ad. GIR: Glucose infusion rate.

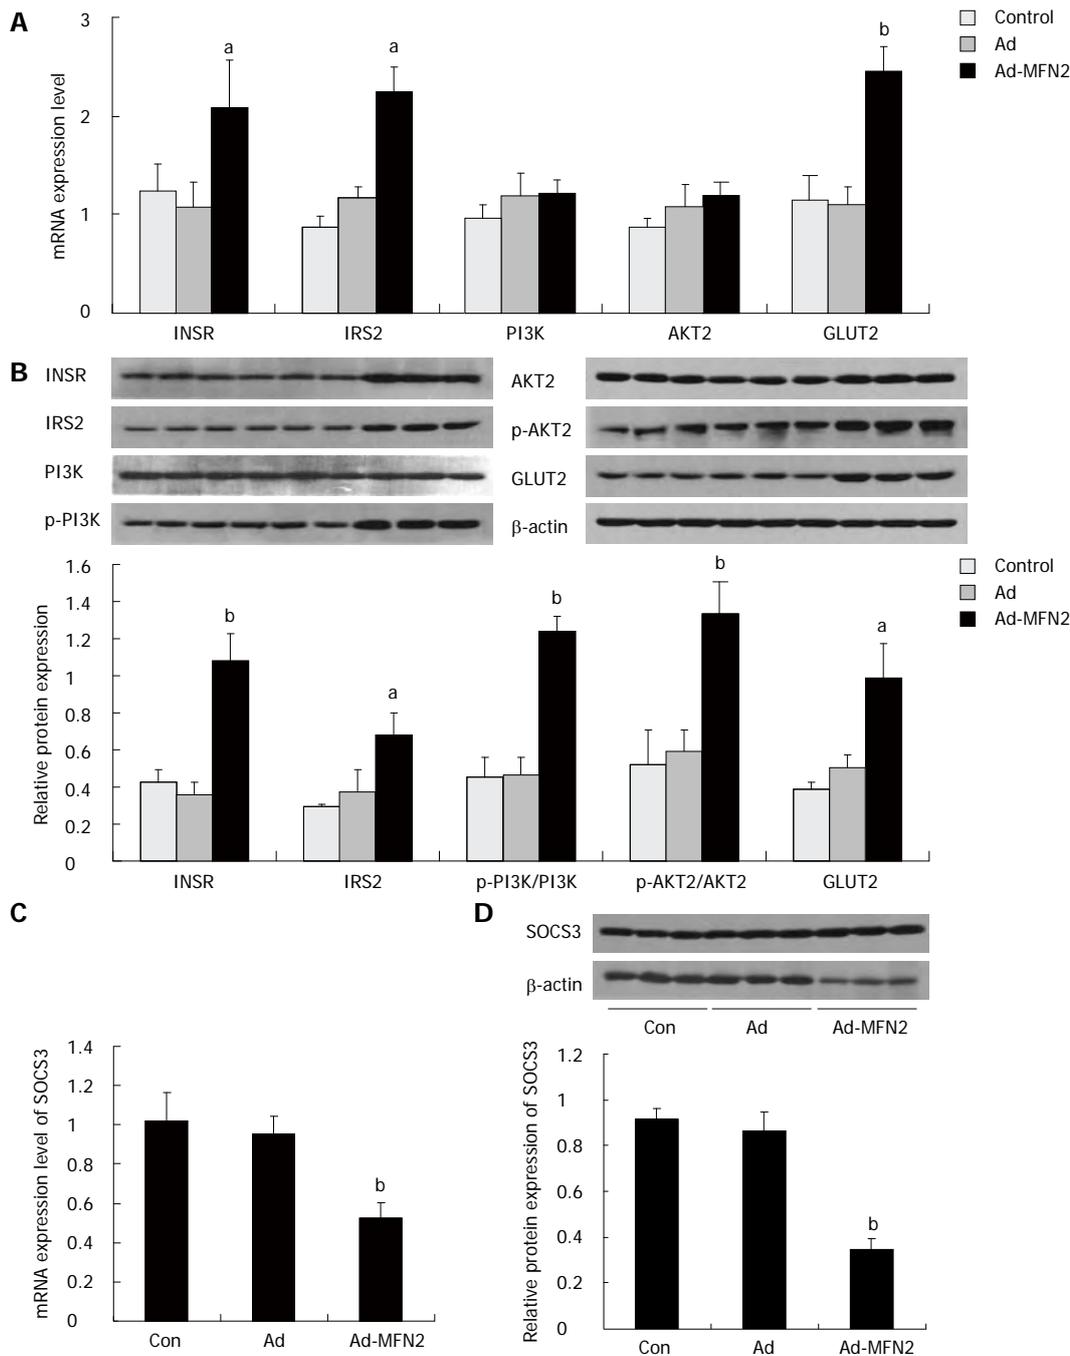

Figure 5 Mitofusin-2 over-expression up-regulated the expression of insulin pathway related genes in liver of rats. Rats were fed with high-fat diets for 8 wk, and then were infected with Ad-mitofusin-2 (MFN2) or empty Ad adenovirus or phosphate-buffered saline (PBS) control for 3 wk. The expression levels of insulin receptor (INSR), insulin receptor substrate 2 (IRS2), phosphoinositide-3-kinase (PI3K), AKT2 and glucose transporter type 2 (GLUT2) were determined by quantitative real-time-polymerase chain reaction (RT-PCR) (A) and Western-blot (B). The phosphorylation levels of PI3K and AKT2 were assayed by Western-blotting (B). The expression level of suppressor of cytokine signaling 3 (SOCS3) was determined by quantitative RT-PCR (C) and Western-blot (D). ^a*P* < 0.05, ^b*P* < 0.01 vs Ad.

rk^[27]. MFN protein deficiency could cause a failure in the mitochondrial architecture and decreases in oxidative capacity and glucose oxidation. MFN2 is a proliferation-inhibiting gene encoding a mitochondrial fusion protein that participates in the maintenance of the mitochondrial morphology and regulates mitochondrial metabolism and intracellular signaling^[6]. A recent study found that liver MFN2 protein was significantly decreased, and fasting BG concentrations were increased in mice after

interference with MFN2 protein expression^[28]. Our data demonstrate that over-expression of MFN2 significantly restored insulin sensitivity and reduced the levels of BG and plasma insulin in rats, suggesting MFN2 as a potential therapeutic target in insulin resistance.

Most metabolic processes are regulated by insulin in muscle, adipocytes, and liver. A recent study indicated that mitochondrial protein down-regulation contributes to defects in insulin signaling in insulin resistance^[29]. Insu-

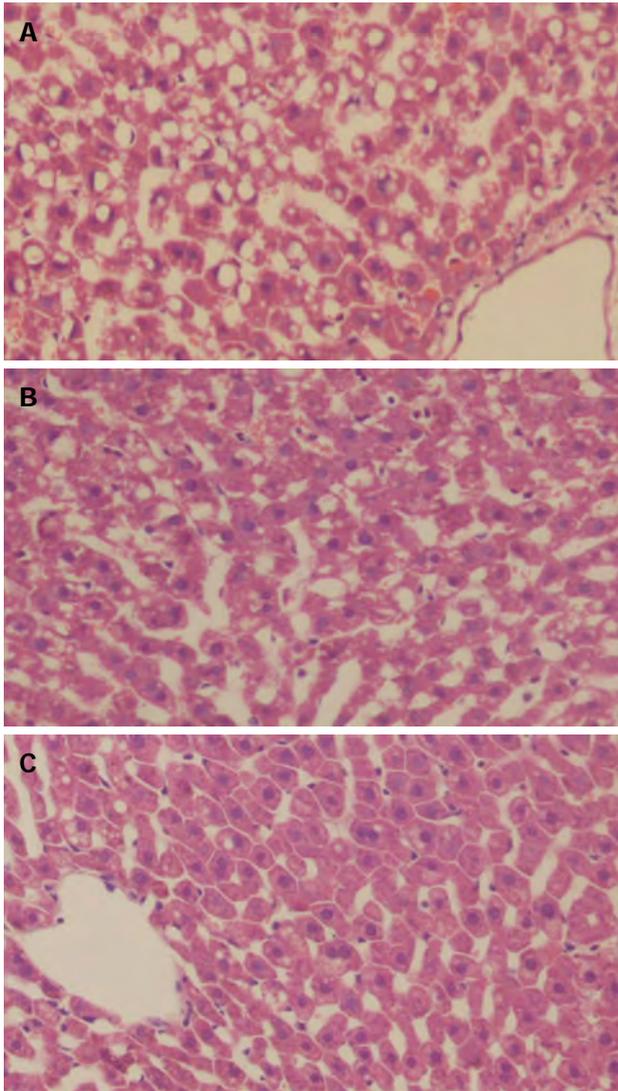

Figure 6 Over-expression of mitofusin-2 improves high-fat diets induced hepatic steatosis. Histological analysis of liver sections from rats fed with high-fat diets infected with phosphate-buffered saline control (A), empty Ad adenovirus (B) or Ad-mitofusin 2 (C) for 3 wk (HE, $\times 200$).

lin acts through a complex signaling network including alternative or complementary pathways, with multiple molecular systems involved^[30]. Abnormalities in the early stages of insulin signaling have been considered as an important component of many insulin-resistant states^[31,32]. Our results showed that the expression of INRS, IRS2 and GLUT2 decreased; the phosphorylation of PI3K-P85 and AKT2 was also inhibited by HFD, but was restored markedly by recovery of MFN2 expression.

Hepatic expression of SOCS3 has been reported to be elevated in rodent models of obesity and insulin resistance^[33,34]. SOCS3 was found to bind to phosphotyrosine 960 of the insulin receptor and prevent STAT5b activation by insulin^[35]. In COS-7 cells, SOCS3 reduced IRS-2 phosphorylation and its subsequent association with p85, the regulatory subunit of PI3K^[36]. In multiple cell lines, SOCS3 has been shown to bind IRS-2 and promote its ubiquitination and subsequent degradation^[34,37]. The inhi-

bition of SOCS3 expression restores IRS-1 and IRS-2 tyrosine phosphorylation, and IRS-1 and IRS-2 association with p85-PI3K and [Ser473] phosphorylation of Akt^[38]. In our study, expression of SOCS3 in the liver of rats treated with MFN2 expressing adenovirus was decreased. MFN2 expression may improve insulin resistance by regulating the expression of SOCS3 in the liver of rats.

In conclusion, MFN2 could ameliorate insulin resistance induced by HFD by improvement of the insulin signaling pathway, and this may be a potential target for the treatment of insulin resistance and metabolic syndrome.

COMMENTS

Background

Insulin resistance is associated with numerous modern health problems, such as obesity, metabolic syndrome and type 2 diabetes mellitus. Mitofusin 2 (MFN2) regulates mitochondrial morphology and signaling, and is involved in the pathogenesis of insulin resistance and development of diabetes, but the exact mechanism is unclear.

Research frontiers

MFN2, a large transmembrane GTPase located in the outer mitochondrial membrane, promotes membrane fusion and is involved in the maintenance of the morphology of mitochondria. Recent studies show that *MFN2* gene expression is positively correlated with insulin resistance. Some metabolic diseases, such as type 2 diabetes show impaired MFN2 expression. MFN2 deficiency impairs insulin signaling in the liver and muscle. The research hotspot is the mechanism of MFN2 in improving insulin sensitivity.

Innovations and breakthroughs

MFN2, a large transmembrane GTPase located in the outer mitochondrial membrane, promotes membrane fusion and is involved in the maintenance of the morphology of mitochondria. Recent studies show that *MFN2* gene expression is positively correlated with insulin resistance and that MFN2 deficiency impairs insulin signaling in the liver and muscle.

Applications

The study results suggest that MFN2 over-expression improves insulin sensitivity, and may be used for preventing the development of diabetes in future.

Terminology

MFN2 encodes a mitochondrial membrane protein that participates in mitochondrial fusion and contributes to the maintenance and operation of the mitochondrial network. This protein is involved in the regulation of vascular smooth muscle cell proliferation, and it may play a role in the pathophysiology of obesity. Mutations in this gene cause Charcot-Marie-Tooth disease type 2A2, and hereditary motor and sensory neuropathy VI, which are both disorders of the peripheral nervous system. Defects in this gene have also been associated with early-onset stroke.

Peer review

The authors examined the expression of insulin signaling pathways and suppressor of cytokine signaling 3 (SOCS3) after infection with an MFN2 expressing adenovirus. It revealed that expression of insulin signaling pathways were increased and SOCS3 was inhibited in the liver of insulin resistant rats. Expression of MFN2 improves the insulin signaling pathway through the inhibition of SOCS3 expression. The results are interesting and may represent a molecular mechanism of MFN2 amelioration of insulin resistance.

Abstract

AIM: To investigate the effects of ginsenoside Rh2 on the human pancreatic cancer cell line Bxpc-3.

METHODS: The human pancreatic cancer cell line Bxpc-3 was cultured *in vitro* and treated with or without ginsenoside Rh2. Growth rates for Bxpc-3 cells were assessed by methyl thiazolyl tetrazolium (MTT) and colony formation assays. Cell cycle changes were analyzed by flow cytometry. Apoptosis was measured by flow cytometry and Hoechst 33258 fluorescence staining. A scratch assay and a Matrigel invasion assay were used to detect cell migration and invasion. Expression of Bax, Bcl-2, survivin, cyclin D1, matrix metalloproteinase (MMP)-2, MMP-9, cleaved caspase-3, caspase-8, and caspase-9 mRNA were determined by reverse transcriptase-polymerase chain reaction (RT-PCR). Bax, Bcl-2, survivin, cyclin D1, cleaved caspase-3, caspase-8 and caspase-9 protein levels were examined by western blotting. Expression of MMP-2 and MMP-9 proteins

in culture supernatants were determined by enzyme-linked immunosorbent assay (ELISA).

RESULTS: Rh2 significantly inhibited Bxpc-3 cell proliferation in a dose- and time-dependent manner, as evaluated by the MTT ($P < 0.05$) and colony formation assays ($P < 0.05$). Compared to the control group, Rh2 significantly increased the percentage of Bxpc-3 cells in the G₀/G₁ phase from 43.32% \pm 2.17% to 71.32% \pm 1.16%, which was accompanied by a decrease in S phase (from 50.86% \pm 1.29% to 28.48% \pm 1.18%) and G₂/M phase (from 5.81% \pm 1.19% to 0.20% \pm 0.05%) in a dose-dependent manner ($P < 0.05$), suggesting that Rh2 arrested cell cycle progression at the G₀/G₁ phase, as measured by flow cytometry. Compared to the control group, cells treated with Rh2 showed significantly higher apoptosis ratios in a dose-dependent manner (percentage of early apoptotic cells: from 5.29% \pm 2.28% to 38.90% \pm 3.42% ($F = 56.20$, $P < 0.05$); percentage of late apoptotic cells: from 4.58% \pm 1.42% to 36.32% \pm 2.73% ($F = 86.70$, $P < 0.05$). Rh2 inhibited Bxpc-3 cell migration and invasion, as detected by scratch wound healing assay and Matrigel invasion assay [percentages of scratch wound healing for 12 h, 24 h and 48 h (control *vs* experimental group): 37.3% \pm 4.8% *vs* 18.30% \pm 1.65%, 58.7% \pm 3.5% *vs* 38.00% \pm 4.09% and 93.83% \pm 4.65% *vs* 65.50% \pm 4.09%, respectively; $t = 6.489$, $t = 6.656$ and $t = 7.926$, respectively, $P < 0.05$; the number of cells invading at various concentrations (0 μ mol/L, 35 μ mol/L, 45 μ mol/L and 55 μ mol/L): 81.10 \pm 9.55, 46.40 \pm 6.95, 24.70 \pm 6.88 and 8.70 \pm 3.34, respectively ($F = 502.713$, $P < 0.05$)]. RT-PCR, western blotting or ELISA showed that mRNA and protein expression of Bax, cleaved caspase-3 and caspase-9 were upregulated ($P < 0.05$), while mRNA and protein expression of Bcl-2, survivin, cyclin D1, MMP-2 and MMP-9 were downregulated ($P < 0.05$).

CONCLUSION: Ginsenoside Rh2 inhibits proliferation, migration and invasion and induces apoptosis of the human pancreatic cancer cell line Bxpc-3.

INTRODUCTION

Pancreatic cancer (PC) is a disease with a high mortality rate and the 1-year survival rate is < 10%^[1]. The successful surgical resection rate for PC is not high and current chemotherapy is not effective. Thus, there is an urgent need to develop novel treatment modalities. Ginseng is a traditional herbal medicine that is well known for its wide spectrum of pharmacological effects^[2]. Ginsenoside is the main effective component of ginseng and has been widely used in oriental countries for thousands of years^[3,4]. Recently, some experiments have demonstrated that ginsenoside has a wide variety of biological activities including immunomodulatory effects and anti-inflammatory and antitumor activity^[5-7]. Ginsenoside Rh2 is a pure compound extracted from ginsenosides. Recently, researchers have found that ginsenoside Rh2 could inhibit growth of many kinds of cancer cells, including breast cancer, prostate cancer, hepatoma, gastric cancer and colon carcinoma^[8-13]. Rh2 may play an antitumor role through the following mechanisms: (1) regulating tumor cells through the signaling pathway system, including the signaling pathway of protein kinase C, insulin-like growth factors, caspase family and Bcl-2 family; (2) affecting the activity of cell telomerase; (3) blocking anabolism and metabolism of important components in tumor cells; and (4) reversing abnormal differentiation and resistance of tumor cells.

However, to date, little is known about the role of ginsenoside Rh2 in PC. The purpose of this study was to investigate the effects of ginsenoside Rh2 on proliferation, apoptosis and migration of the human pancreatic cancer cell line Bxpc-3, and to explore the potential mechanisms of the effects.

MATERIALS AND METHODS

Materials

The human pancreatic cancer cell line Bxpc-3 was obtained from the Cell Resource Center, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences. RPMI 1640 medium and fetal bovine serum were purchased from Gibco BRL (Gaithersburg, MD, United States). Ginsenoside Rh2 was obtained from the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). The drug was dissolved

in dimethyl sulfoxide (DMSO) with a stock concentration of 40 mmol/L. The following materials were used: monoclonal antibodies to Bcl-2, Bax, survivin, cyclin D1, cleaved caspase-3, caspase-8 and caspase-9 (Santa Cruz Biotechnology, Santa Cruz, CA, United States), enzyme-linked immunosorbent assay (ELISA) kits for matrix metalloproteinase (MMP)-2 and MMP-9 (Boster Bioengineering Co., Wuhan, China), Annexin V-FITC Apoptosis Detection Kit and Cell Cycle Detection Kit (KeyGEN Biotech Co., Nanjin, Jiangsu, China), Hoechst 33258 staining kit (Beyotime Biotechnology Co., Jiangsu, China), Matrigel (BD Biosciences, United States) and 24-well invasion chambers (Corning-Costar, New York, United States).

Cell culture

Bxpc-3 cells were maintained in RPMI 1640 medium supplemented with 10% heat-inactivated fetal bovine serum, 100 U/mL penicillin and 100 µg/mL streptomycin at 37 °C in a 5% CO₂ atmosphere.

Methyl thiazolyl tetrazolium assay

Cells were seeded on 96-well plates in triplicate. Following 24 h culture at 37 °C, the medium was replaced with fresh medium containing increasing concentrations of ginsenoside Rh2 (0 µmol/L, 10 µmol/L, 20 µmol/L, 35 µmol/L, 45 µmol/L, 55 µmol/L and 60 µmol/L) in a final volume of 200 µL. Cells were incubated at 37 °C for 24 h, 48 h and 72 h. Methyl thiazolyl tetrazolium (MTT) [20 µL, 2 mg/mL in phosphate-buffered saline (PBS)] was added and cells were incubated for a further 4 h. The medium was removed and 150 µL DMSO was added to each well. It was shaken mechanically for 10 min and the optical density was measured at 570 nm. The experiment was repeated three times.

Colony formation assay

Cells were plated in six-well plates at a density of 100 cells/well for 48 h, prior to the addition of various concentrations of Rh2 (0 µmol/L, 35 µmol/L, 45 µmol/L and 55 µmol/L). After 48 h treatment, the drug-containing medium was removed and replaced with complete growth medium. The medium was changed every 3 d for 14 d until visible colonies formed. Colonies were simultaneously fixed and stained with 0.5% crystal violet in methanol, and were manually counted. Individually stained colonies in each well were counted and the colony formation fraction was calculated as following: colony number/(number of cells seeded × plating efficiency), where plating efficiency was equivalent to the colony number divided by the number of cells seeded in the drug-free medium. The experiment was repeated three times.

Flow cytometry

Bxpc-3 cells seeded in six-well plates were treated with different concentration (0 µmol/L, 35 µmol/L, 45 µmol/L and 55 µmol/L) Rh2 for 48 h at a cell density of 1.5

$\times 10^5$ cells/mL. Cells were processed using the following assay. (1) Cells were resuspended by adding 500 μ L binding buffer, followed by adding 5 μ L annexin V-FITC and 5 μ L propidium iodide (PI) dye. After mixing at room temperature in the dark for 5-15 min, flow cytometry analysis was performed. Annexin V-FITC-positive and PI-negative cells were considered as apoptotic cells; (2) Cells were resuspended by adding 100 μ L RNase A H₂O and incubated in water at 37 °C for 30 min. After adding 400 μ L PI and mixing at 4 °C for 30 min in the dark, flow cytometry analysis was performed. The G₀/G₁, S and G₂/M stages were compared. The experiment was repeated three times.

Reverse transcriptase-polymerase chain reaction

Bxpc-3 cells (1.5×10^4 /mL) were seeded in six-well plates. After 48 h culture, cells were treated with Rh2 (0 μ mol/L and 45 μ mol/L) for 48 h. Total RNA was extracted using TRIzol reagent. cDNA synthesis was performed using an RNA PCR kit. Samples were separated on 20 g/L agarose gels. The band intensity was determined by a gel image analysis system (Bio-Rad, Hercules, CA, United States) and normalized with β -actin. The PCR primers and regimen were as follows: 5'-AGGATCGAGCAGGGC-GAATG-3', 5'-GCTCCCGGAGGAAGTCCAAT-3' for Bax (345 bp); 5'-GATGGCAAATGACCAGCAGA-3', 5'-GCAGGATAGCAGCACAGGAT- 3' for Bcl-2 (346 bp); 5'-TGCCAGGATGATAAGTTCTT-3', 5'-ATCAAAGGCAGAAGGTTTGTGT-3' for cyclin D1 (316 bp); 5'-CCTCCTCAGCATCTTATCCG-3', 5'-CA-CAAACACCCACCTCAAA-3' for survivin (206 bp); 5'-CCGTGCCCCATCATCAAGTTCC-3', 5'-GCACGA GCAAAGGCATCATCCA-3' for MMP-2 (350 bp); 5'-CTTCCCTGGAGACCTGAGAAC-3', 5'-CCAAACT-GGATGACGATGTCT-3' for MMP-9 (423 bp); and 5'-TgacgTGGACATCCGCAAAG-3', 5'-CTGGAAGGT-GGACAGCGAGG-3' for β -actin (205 bp). The PCR conditions were denaturation at 94 °C for 5 min, annealing at 54 °C (Bax), 58 °C (Bcl-2) and 60 °C (cyclin D1, survivin, MMP-2, MMP-9) for 30 s \times 35 cycles, and extension at 72 °C for 7 min.

Western blotting

Bxpc-3 cells were treated with 0 μ mol/L, 35 μ mol/L, 45 μ mol/L and 55 μ mol/L Rh2 for 48 h, and collected by centrifugation, washed twice with cold PBS, and resuspended in 200 μ L protein lysate. Cells were centrifuged at 4 °C at 12 000 *g* for 5 min and the supernatant was stored at -20 °C. The protein concentration was determined by the bicinchoninic acid method (Beyotime Biotechnology Co., Jiangsu, China), and 40 μ g protein was loaded onto 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis gels. After electrophoresis, proteins were transferred onto polyvinylidene difluoride membranes at 4 °C for 4 h. Membranes were blocked in 5% non-fat milk for 1 h followed by incubation with primary antibodies of Bax, Bcl-2, survivin, cyclin D1, cleaved caspase-3, caspase-8 and caspase-9, overnight at 4 °C with shaking. Af-

ter washing in Tris-buffered saline with Tween 20 (TBST), membranes were incubated with peroxidase-linked IgG conjugates for 2 h at room temperature, washed again in TBST, and detected by an enhanced chemiluminescence reagent kit (Beyotime Biotechnology). The band intensity was determined by a gel image analysis system (Bio-Rad) and normalized with β -actin.

Hoechst 33258 assay for apoptosis

Bxpc-3 cells were treated with 0 μ mol/L, 35 μ mol/L, 45 μ mol/L and 55 μ mol/L Rh2 for 48 h and rinsed with PBS twice, followed by incubation with 10 μ g/mL Hoechst 33258 reagent at 37 °C in the dark for 15 min. Cells were fixed in 0.5 mL 4% paraform for 10 min and rinsed with PBS twice. The stained cells were examined and immediately photographed under a fluorescence microscope (Olympus, Shinjuku-ku, Tokyo, Japan) at an excitation wavelength of 330-380 nm. Apoptotic cells were identified on the basis of morphological changes in their nuclear assembly by observing chromatin condensation and fragment staining with Hoechst 33258. In each group, 10 microscopic fields were randomly selected and counted.

Invasion assay

Transwell chambers (Corning-Costar) were used to examine the ability of cells to invade through a Matrigel-coated filter following the manufacturer's instructions. RPMI 1640 medium was added to the upper chambers and allowed to hydrate for 2 h at 37 °C with 5% CO₂. Next, 5×10^4 Bxpc-3 cells treated with various concentrations of Rh2 (0 μ mol/L, 35 μ mol/L, 45 μ mol/L and 55 μ mol/L) were added to the upper chamber and grown in medium containing 2% fetal bovine serum on 8.0 μ m porous polycarbonate membranes, which were coated with diluted Matrigel basement membrane matrix. The lower chambers were filled with RPMI 1640 medium containing 10% fetal bovine serum. After 24 h incubation, the cells remaining on the upper surface of the filter were removed using cotton tips, and the cells that invaded to the underside of the membrane were fixed with 4% paraform and stained with crystal violet. Cells in 10 random fields of view at 400 \times magnification were counted and expressed as the average number of cells/field of view.

Migration assay

We scribed five paralleled lines on the bottom of six-well plates using a marker pen and seeded cells at a density of 4.0×10^5 cells per well in triplicate for 48 h. A perpendicular scratch wound was generated by scratching with a pipette tip. After rinsing with PBS to remove the detached cells, medium containing different concentrations of Rh2 (0 μ mol/L, 35 μ mol/L, 45 μ mol/L and 55 μ mol/L) was added. Photographic images were taken from each well at 0 h, 12 h, 24 h and 48 h. The distance that cells migrated through the area created by scratching was determined by measuring the wound width at the above times and subtracting it from the wound width at the start. The values

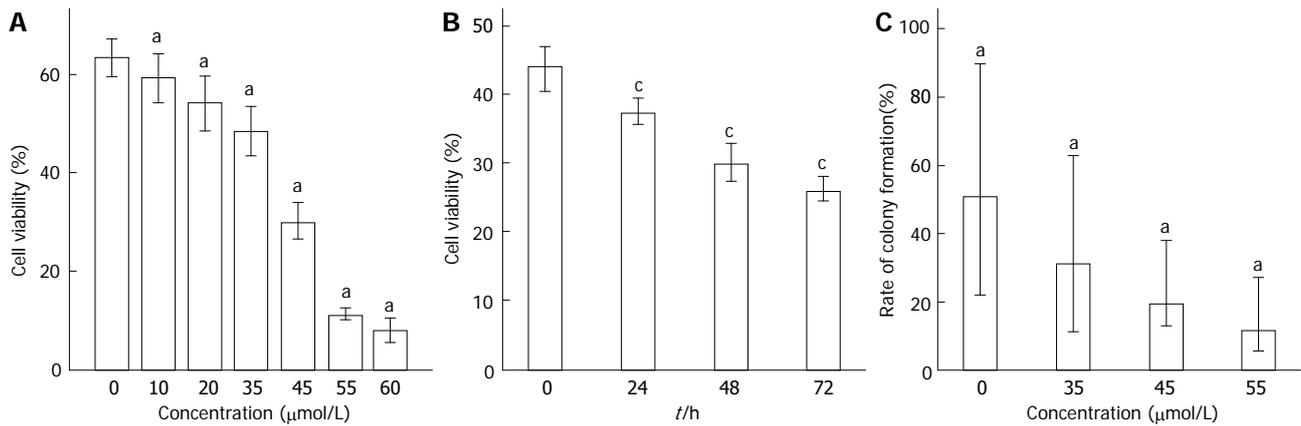

Figure 1 Effect of Rh2 on viability of Bxpc-3 cells. A and B: Methyl thiazolyl tetrazolium assay showed that the inhibitory effects of Rh2 on the viability of BxPc-3 cells were observed in both a dose- and time-dependent manner; C: A colony formation assay was used to examine the growth of BxPc-3 cells, ^a $P < 0.05$ vs 0 µmol/L group; ^a $P < 0.05$ vs 0 h group.

obtained were then expressed as the rate of wound healing. The experiment was repeated three times.

ELISA

Cells were cultured in six-well plates with RPMI 1640 containing different concentrations of Rh2 (0 µmol/L, 35 µmol/L, 45 µmol/L and 55 µmol/L) for 48 h. Supernatants were collected and stored at -80 °C. The protein concentrations of MMP-2 and MMP-9 in culture supernatants were determined using an ELISA kit according to the manufacturer's instructions.

Statistical analysis

The data were analyzed with single factor analysis of variance and a Student's *t* test using SPSS 13.0 software. Data were represented as mean ± SD. $P < 0.05$ was considered statistically significant.

RESULTS

Rh2 inhibiting Bxpc-3 cell viability

The inhibitory effect of Rh2 on the growth of Bxpc-3 cells was assessed by MTT and colony formation assays. The MTT assay showed that the various concentrations of Rh2 inhibited the viability of Bxpc-3 cells in a dose- and a time-dependent manner. The viable Bxpc-3 cells consistently decreased with higher concentrations of Rh2 for 48 h, as shown in Figure 1A (0 µmol/L, 10 µmol/L, 20 µmol/L, 35 µmol/L, 45 µmol/L, 55 µmol/L and 60 µmol/L: 63.867% ± 2.675%, 59.883% ± 3.16%, 54.917% ± 3.553%, 48.850% ± 3.316%, 29.900% ± 2.134%, 10.917% ± 0.671% and 8.267% ± 1.191%, respectively, $F = 477.542$, $P < 0.05$, Figure 1A). When cells were treated with 45 µmol/L Rh2 for 24 h, 48 h or 72 h, the cell viability declined significantly compared to 0 h (24 h, 48 h and 72 h: 37.417% ± 1.710%, 29.900% ± 2.134% and 25.917% ± 1.447%, respectively, $F = 81.633$, $P < 0.05$; Figure 1B). The clonogenic assay showed that Rh2 treatment resulted in significant inhibition of colony formation of Bxpc-3 cells compared with controls in

a dose-dependent manner (0 µmol/L, 35 µmol/L, 45 µmol/L and 55 µmol/L): 50.667% ± 13.204%, 31.000% ± 10.149%, 19.333% ± 5.132% and 10.667% ± 4.041%, respectively, $F = 11.229$, $P < 0.05$; Figure 1C).

Rh2 altering Bxpc-3 cell cycle distribution

The cell cycle distribution of Bxpc-3 cells treated with various concentrations of Rh2 (0 µmol/L, 35 µmol/L, 45 µmol/L and 55 µmol/L) for 48 h is shown in Figure 2A and 2B. The various concentrations of Rh2 altered cell cycle progression. Rh2 significantly increased the percentage of Bxpc-3 cells in the G₀/G₁ phase in a dose-dependent manner (0 µmol/L, 35 µmol/L, 45 µmol/L and 55 µmol/L: 43.32% ± 2.17%, 56.76% ± 1.33%, 67.40% ± 1.12% and 71.32% ± 1.16%, respectively, $F = 208.37$, $P < 0.001$), accompanied by a decrease in the percentage in S phase (50.86% ± 1.29%, 38.29% ± 1.40%, 32.08% ± 0.96% and 28.48% ± 1.18%, respectively, $F = 32.45$, $P < 0.001$) and G₂/M phase (5.81% ± 1.19%, 4.95% ± 0.81%, 1.32% ± 0.83% and 0.20% ± 0.05%, respectively, $F = 214.80$, $P < 0.001$). This suggested that the cell cycle was arrested at the G₀/G₁ phase by Rh2. Western blotting and reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of molecular marker, cyclin D1, which was related to G₁ phase arrest, showed significant downregulation [Figure 2C and D, ratio of cyclin D1/glyceraldehyde-3-phosphate dehydrogenase (GADPH): 1.896 ± 0.104, 1.443 ± 0.074, 1.084 ± 0.162 and 0.225 ± 0.074, respectively, $F = 251.18$, $P < 0.05$; Figure 2E and F, ratio of cyclin D1/β-actin: 0.885 ± 0.083 and 0.687 ± 0.096, respectively, $F = 3.818$, $P < 0.05$]. The western blotting and RT-PCR data were consistent with the G₁ arrest phenomenon observed in flow cytometry analysis.

Rh2 inducing Bxpc-3 cell apoptosis

Rh2-induced apoptotic cell death was found using Annexin V-FITC/PI double stained flow cytometry. Annexin V-FITC-positive and PI-negative cells, which were considered as apoptotic cells, increased in a dose-dependent manner compared to the control group (Figure

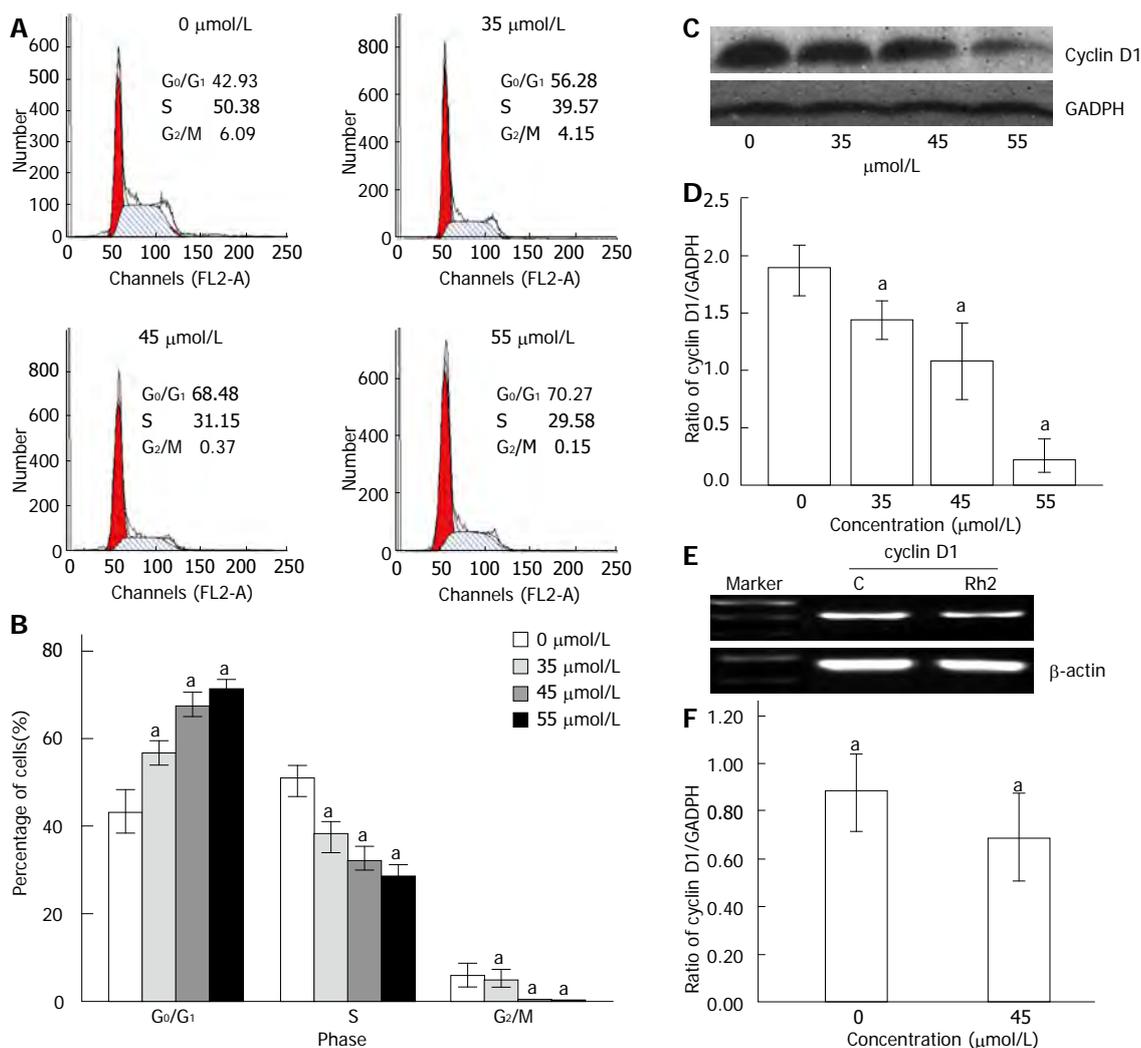

Figure 2 Rh2 induces G₀/G₁ arrest in Bxpc-3 cells treated for 48 h. **A, B:** Cell cycle distribution was assessed by flow cytometry. The results showed that the cell cycle was arrested at the G₀/G₁ phase when treated with Rh2; **C, D:** Western blotting was used to examine protein expression of cyclin D1; **E, F:** Reverse transcriptase-polymerase chain reaction was used to examine the expression of cyclin D1 mRNA. The results indicated that Rh2 downregulated protein and mRNA expression of cyclin D1 in Bxpc-3 cells. ^a*P* < 0.05 vs 0 μmol/L group. GADPH: Glyceraldehyde-3-phosphate dehydrogenase.

3A and B). The percentages of early apoptotic cells (0 μmol/L, 35 μmol/L, 45 μmol/L and 55 μmol/L) were 5.29% ± 2.28%, 12.15% ± 3.58%, 23.88% ± 4.07% and 38.9% ± 3.42%, respectively (*F* = 56.20, *P* < 0.05). The percentages of late apoptotic cells (0 μmol/L, 35 μmol/L, 45 μmol/L and 55 μmol/L) were 4.58% ± 1.42%, 9.9% ± 2.2%, 25.67% ± 3.87% and 36.32% ± 2.73%, respectively (*F* = 86.70, *P* < 0.05).

We also detected morphological changes in apoptotic cells by Hoechst 33258 staining (Figure 3C and D). In the untreated Bxpc-3 cells, the nuclei were stained weak homogeneous blue, while in the group treated with Rh2, bright chromatin condensation and nuclear fragmentation were observed. Furthermore, the rates of bright chromatin condensation and nuclear fragmentation increased in a dose-dependent manner. The percentages of apoptotic cells (0 μmol/L, 35 μmol/L, 45 μmol/L and 55 μmol/L) were 0.40% ± 0.05%, 16.4% ± 2.7%, 39.20% ± 2.28% and 50.4% ± 2.7%, respectively (*F* = 502.71, *P* < 0.05).

In order to investigate the mechanisms for Rh2 induc-

ing Bxpc-3 cell apoptosis, western blotting and RT-PCR analysis of related apoptotic proteins and mRNA were used, including Bax, Bcl-2, survivin, cleaved caspase-3, caspase-8 and caspase-9. The results revealed significant downregulation of Bcl-2 and survivin, and upregulation of Bax, cleaved caspase-3 and caspase-9 (*P* < 0.05), but no change in cleaved caspase-8 (*P* > 0.05; Figure 4). The ratios of Bax/GADPH (0 μmol/L, 35 μmol/L, 45 μmol/L and 55 μmol/L) were the following: 0.815 ± 0.147, 1.169 ± 0.127, 2.226 ± 0.398 and 12.580 ± 2.592, respectively (*F* = 109.651, *P* < 0.05). The ratios of Bcl-2/GADPH were 1.964 ± 0.221, 1.407 ± 0.163, 1.020 ± 0.141 and 0.726 ± 0.136, respectively (*F* = 60.424, *P* < 0.05). The ratios of survivin/GADPH were 2.959 ± 0.296, 1.406 ± 0.118, 1.004 ± 0.169 and 0.473 ± 0.129, respectively (*F* = 187.58, *P* < 0.05). The ratios of cleaved caspase-3/GADPH were 0.257 ± 0.095, 0.460 ± 0.097, 1.439 ± 0.111 and 1.805 ± 0.076, respectively (*F* = 367.81, *P* < 0.05). The ratios of cleaved caspase-9/GADPH were 1.096 ± 0.105, 1.457 ± 0.079, 1.900 ± 0.097 and 2.420 ±

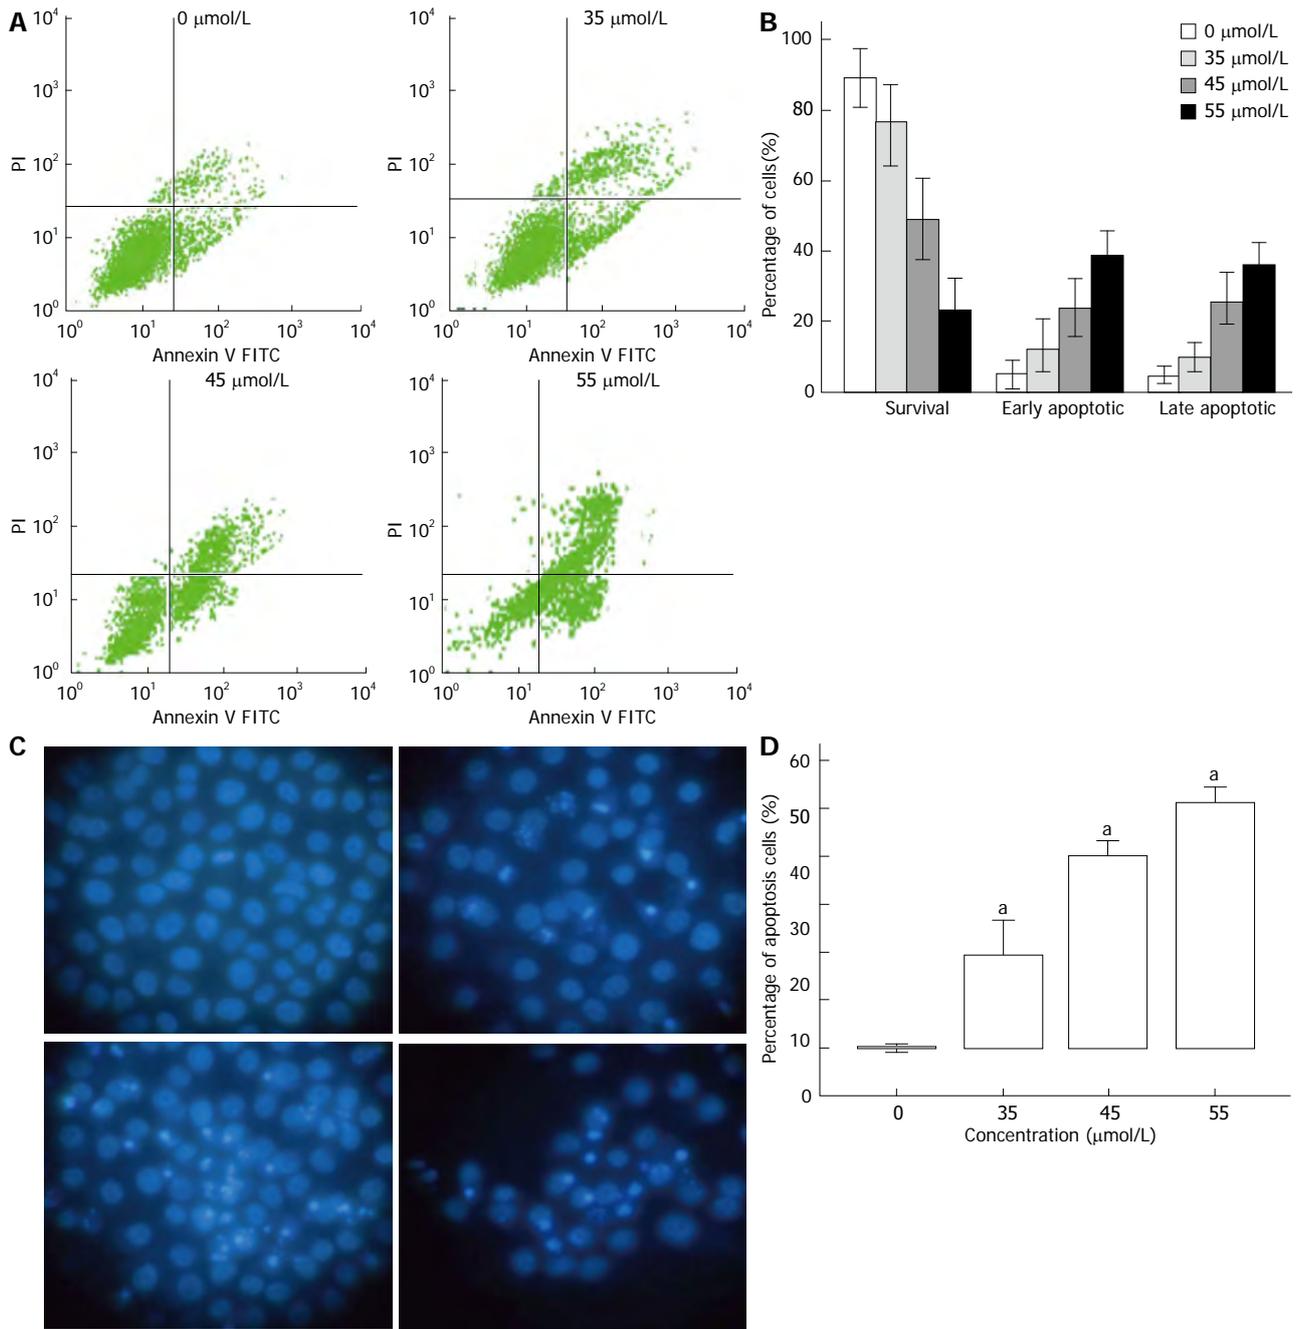

Figure 3 Rh2 induces Bxpc-3 cells apoptosis. A, B: An apoptosis assay was carried out using flow cytometry after Annexin V-FITC/PI staining. Viable cells are in the lower left quadrant, early apoptotic cells are in the lower right quadrant, late apoptotic or necrotic cells are in the upper right quadrant, and nonviable necrotic cells are in the upper left quadrant. The data showed that Rh2 increased the percentages of early and late apoptotic cells; C, D: An apoptosis assay was also carried out using Hoechst 33 258 staining. Nuclei were stained weak homogeneous blue in the normal cells, and bright chromatin condensation and nuclear fragmentation were found in the apoptosis cells. The percentages of apoptosis cells treated with Rh2 were increased, ^a*P* < 0.05 vs 0 μmol/L group.

0.238, respectively (*F* = 93.925, *P* < 0.05). The ratios of cleaved caspase-8/GADPH were 0.464 ± 0.095, 0.469 ± 0.106, 0.507 ± 0.112 and 0.468 ± 0.066, respectively (*F* = 0.255, *P* = 0.857). The ratios of Bax, Bcl-2, and survivin/β-actin (0 μmol/L and 45 μmol/L) were 1.148 ± 0.007 vs 1.361 ± 0.098 (*t* = -4.34, *P* < 0.05), 1.482 ± 0.120 vs 1.149 ± 0.143 (*t* = 4.358, *P* < 0.05) and 1.053 ± 0.144 vs 0.654 ± 0.120, respectively (*t* = 5.235, *P* < 0.05).

Rh2 inhibiting Bxpc-3 cells invasion and migration

We first examined the effect of Rh2 on the migration of

Bxpc-3 cells. For the migration assay, a scratch wound healing assay was used. In the scratch wound healing assay, treatment with Rh2 of 45 μmol/L for 12 h, 24 h and 48 h significantly inhibited the migration of Bxpc-3 cells compared to the control group (Figure 5A and B). Compared to the control group, the rates of scratch wound healing for 12 h, 24 h and 48 h were the following (control vs trial group): 37.3% ± 4.8% vs 18.3% ± 1.65% (*t* = 6.489, *P* < 0.05), 58.7% ± 3.5% vs 38.00% ± 4.09% (*t* = 6.656, *P* < 0.05) and 93.83% ± 4.65% vs 65.50% ± 4.09% (*t* = 7.926, *P* < 0.05), respectively.

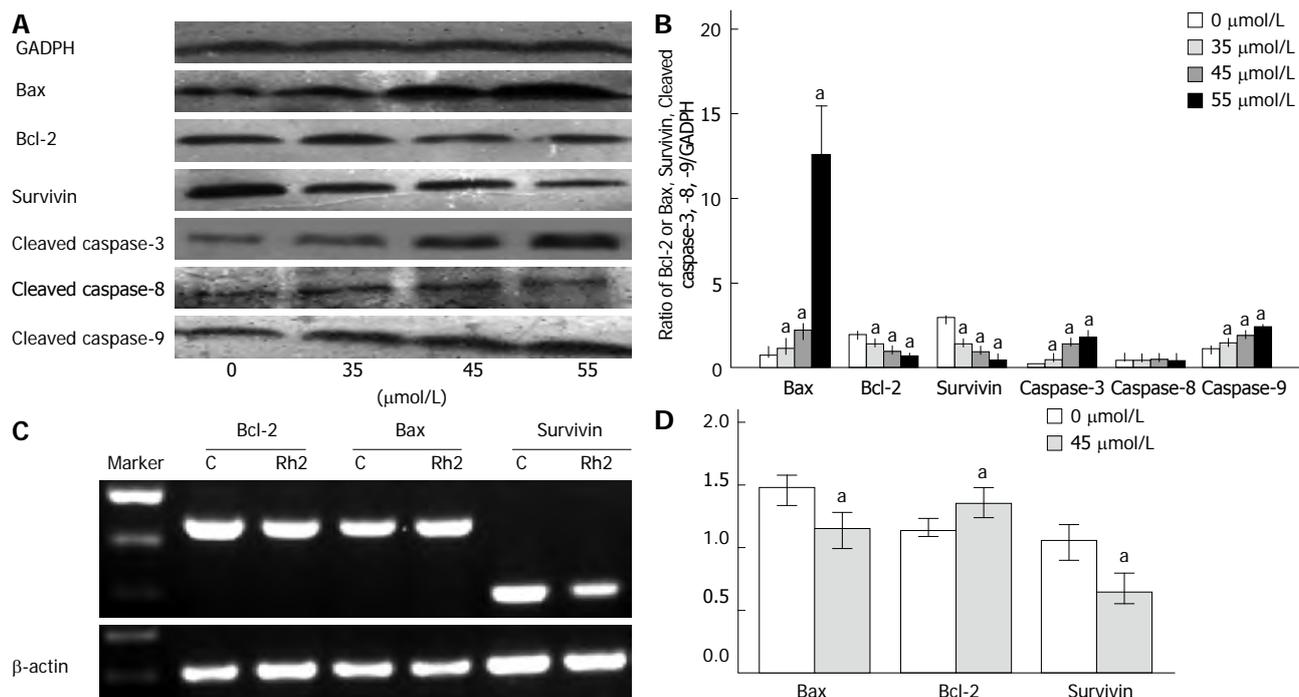

Figure 4 Effects of Rh2 on proteins and mRNA expression of Bax, Bcl-2, survivin, cleaved caspase-3, caspase-8, caspase-9 in Bxpc-3 cells. A, B: Western blotting was used to examine protein expression of Bax, Bcl-2, survivin, cleaved caspase-3, caspase-8 and caspase-9. Rh2 upregulated protein expression of Bax, cleaved caspase-3 and caspase-9 in a dose-dependent manner and downregulated protein expression of Bcl-2 and survivin in a dose-dependent manner. However, Rh2 had no effect on protein expression of cleaved caspase-8; C, D: Reverse transcriptase-polymerase chain reaction was used to examine the expression of Bax, Bcl-2 and survivin mRNA. Rh2 (45 $\mu\text{mol/L}$) upregulated mRNA expression of Bax, and downregulated mRNA expression of Bcl-2 and survivin, $^aP < 0.05$ vs 0 $\mu\text{mol/L}$ group.

We next examined the effect of Rh2 on Bxpc-3 cell invasion using the Matrigel invasion assay. Compared to the control group, Rh2 inhibited cell invasion in a concentration-dependent manner. Even the lowest concentration of Rh2 (35 $\mu\text{mol/L}$) significantly inhibited cell invasion (Figure 5C and D). The numbers of cells invading through Matrigel and filters into the lower surface in the control group and the group treated with Rh2 in various concentrations were as follows (0 $\mu\text{mol/L}$, 35 $\mu\text{mol/L}$, 45 $\mu\text{mol/L}$ and 55 $\mu\text{mol/L}$): 81.10 ± 9.55 , 46.40 ± 6.95 , 24.70 ± 6.88 and 8.70 ± 3.34 , respectively ($F = 502.713$, $P < 0.05$).

We also used RT-PCR and ELISA to detect the expression of factors related to migration: that is, MMP-2 and MMP-9. Compared to the control group, Rh2 downregulated expression of MMP-2 and MMP-9 mRNA and protein in a dose-dependent manner (Figure 6). The ratios of MMP-2/ β -actin (0 $\mu\text{mol/L}$ and 45 $\mu\text{mol/L}$) were 0.644 ± 0.074 vs 0.424 ± 0.063 ($t = 5.543$, $P < 0.05$). The ratios of MMP-9/ β -actin (0 $\mu\text{mol/L}$ and 45 $\mu\text{mol/L}$) were 0.995 ± 0.105 vs 0.408 ± 0.105 ($t = 9.679$, $P < 0.05$). Protein expression levels of MMP-2 (0 $\mu\text{mol/L}$, 35 $\mu\text{mol/L}$, 45 $\mu\text{mol/L}$ and 55 $\mu\text{mol/L}$) were 126.128 ± 9.132 , 86.681 ± 8.134 , 62.033 ± 6.979 and 37.672 ± 6.671 , respectively ($F = 140.802$, $P < 0.05$). Protein expression levels of MMP-9 (0 $\mu\text{mol/L}$, 35 $\mu\text{mol/L}$, 45 $\mu\text{mol/L}$ and 55 $\mu\text{mol/L}$) were 127.652 ± 6.792 , 94.235 ± 7.427 , 67.704 ± 6.731 and 44.195 ± 6.705 , respectively ($F = 161.173$, $P < 0.05$).

DISCUSSION

Ginsenosides are the major pharmacologically active components of ginseng and they exhibit various biological effects such as anti-inflammatory and anticancer effects^[14]. Ginsenoside Rh2 is one of the main bioactive components in ginseng extracts and has been reported in both *in vitro* and *in vivo* studies to possess potent antitumor activity, including inhibition of cell growth and induction of apoptosis in various tumor cells. However, there are no relevant reports about the effects of ginsenoside Rh2 on pancreatic cancer. In this study, we investigated the effects of Rh2 on apoptosis, proliferation, invasion and migration of the human pancreatic cancer cell line Bxpc-3.

The typical characteristics of the abnormal proliferation of tumors are out-of-control cell reproduction and strong growth. Therefore, inhibiting tumor cell proliferation is the key to controlling tumor development. Studies have shown that Rh2 can inhibit cell viability by inducing cell cycle arrest in human breast cancer cells^[15]. In the cell cycle, cyclin D1 regulates cell proliferation by encoding a key regulator of the cell cycle transition from the G₁ to S phase. We demonstrated that the expression of cyclin D1 was depressed in Bxpc-3 cells treated with Rh2. This result is consistent with MTT, clonogenic assay and flow cytometry results. Flow cytometry showed that Rh2 arrested Bxpc-3 cells in G₁ phase. The data suggested that Rh2 may downregulate cyclin D1 and regulate cell cycle transition, thereby suppressing cancer cell proliferation.

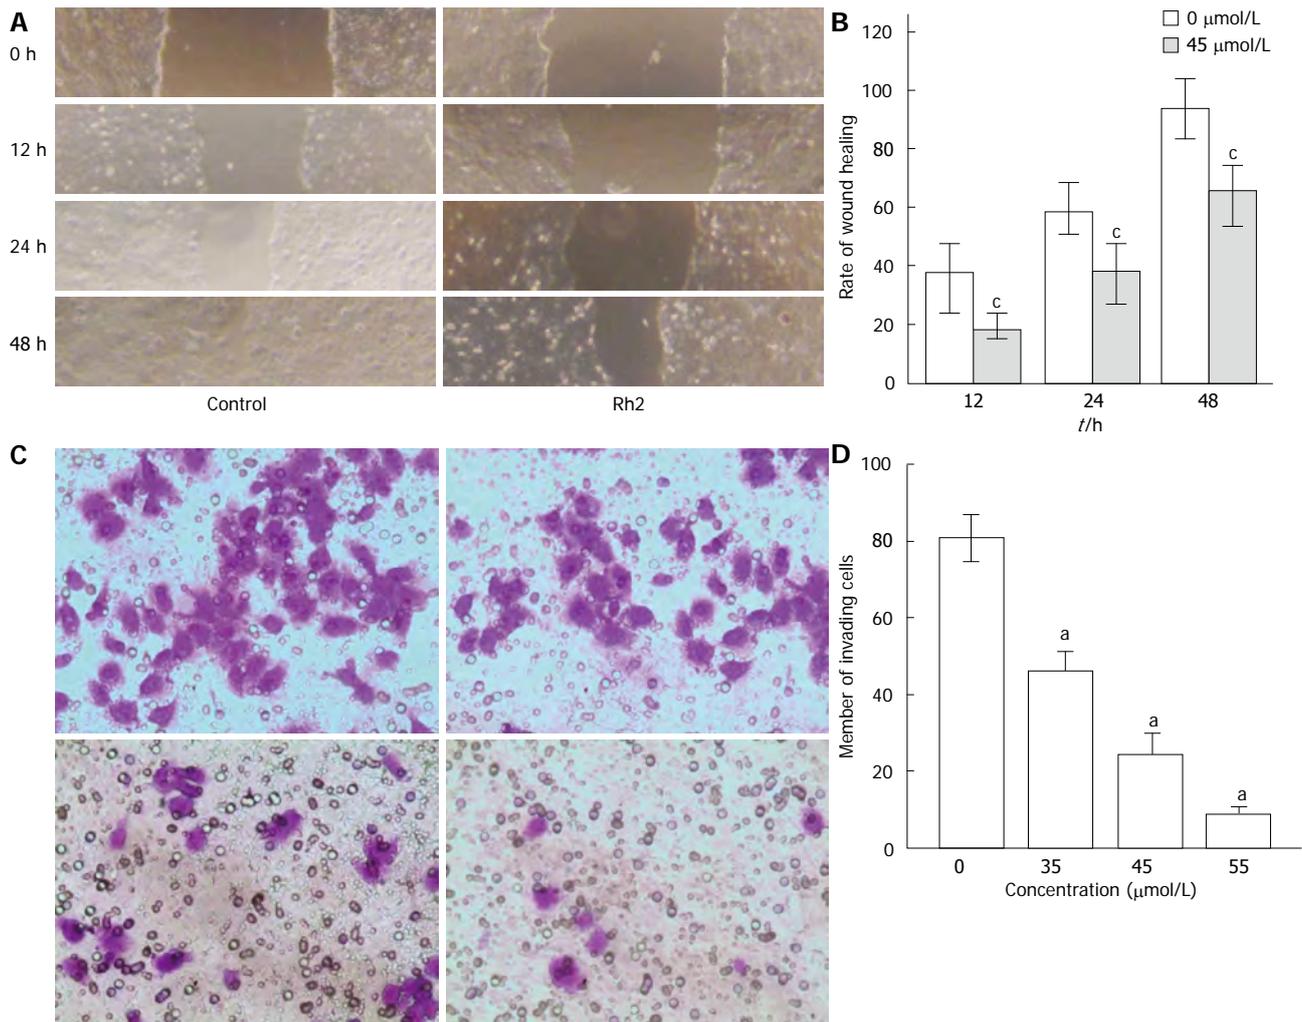

Figure 5 Rh2 inhibits Bxpc-3 cell invasion and migration. A, B: Viability of cell migration was assessed with a scratch wound healing assay and expressed by a wound healing area. Rh2 decreased the rate of scratch wound healing; C, D: Viability of cell invasion was assessed by Matrigel invasion assay and expressed by the number of invading cells. Rh2 decreased the number of invading cells, ^a $P < 0.05$ vs 0 $\mu\text{mol/L}$ group; ^c $P < 0.05$ vs control group.

Except for cell proliferation, we investigated apoptosis in Bxpc-3 cells treated with Rh2. We examined cell apoptosis rates through flow cytometry and Hoechst 33258 fluorescence staining. Our experiments showed that Rh2 could induce Bxpc-3 cell apoptosis in a concentration-dependent manner. What is the mechanism of apoptosis induced by Rh2? Recent reports have shown that Rh2 induces two types of cell death (caspase-dependent apoptosis and caspase-independent paraptosis-like cell death) in colorectal cancer cells through the activation of p53^[16], and Rh2 inhibits cell viability by inducing Bcl-2 family protein-mediated apoptosis in human breast cancer cells^[17]. Therefore, we investigated several apoptosis-related proteins, including Bcl-2, Bax, survivin, cleaved caspase-3, caspase-8 and caspase-9. The Bcl-2 and caspase families are considered to be the most important proteins regulating apoptosis, which can be divided into two types: antiapoptotic and proapoptotic proteins^[18]. Dominant in the two families, Bcl-2 is an antiapoptotic protein, however, Bax, cleaved caspase-3, caspase-8 and caspase-9 are proapoptotic proteins. The activation pathway of

apoptotic protein is divided into the endogenous and exogenous pathways. In the endogenous pathway, caspase-3 is activated, which initiates the apoptotic program^[19]. The other above-mentioned apoptotic proteins, except for caspase-8, belong to the endogenous pathway. Activation of endogenous and exogenous apoptosis-related proteins regulates the expression of cleaved caspase-3, which plays a different apoptotic role. Another important apoptosis inhibiting factor, survivin, is an important member of the inhibitors of apoptosis family and promotes many tumor cells including pancreatic cancer cell survival by regulating the G₁ checkpoint and G₂/M phase of the cell cycle and directly inhibiting caspase-3 and caspase-7 activation^[20-22]. Survivin has attracted growing attention as a potential target for cancer treatment because its expression has been found in primary and cultured tumor cells and its overexpression is associated with poor prognosis^[23]. Our results showed that Rh2 downregulated Bcl-2 and survivin, and upregulated Bax, cleaved caspase-3 and caspase-9. However, it had no effect on cleaved caspase-8. This indicated that Rh2 could induce apoptosis of Bxpc-3 cells mainly

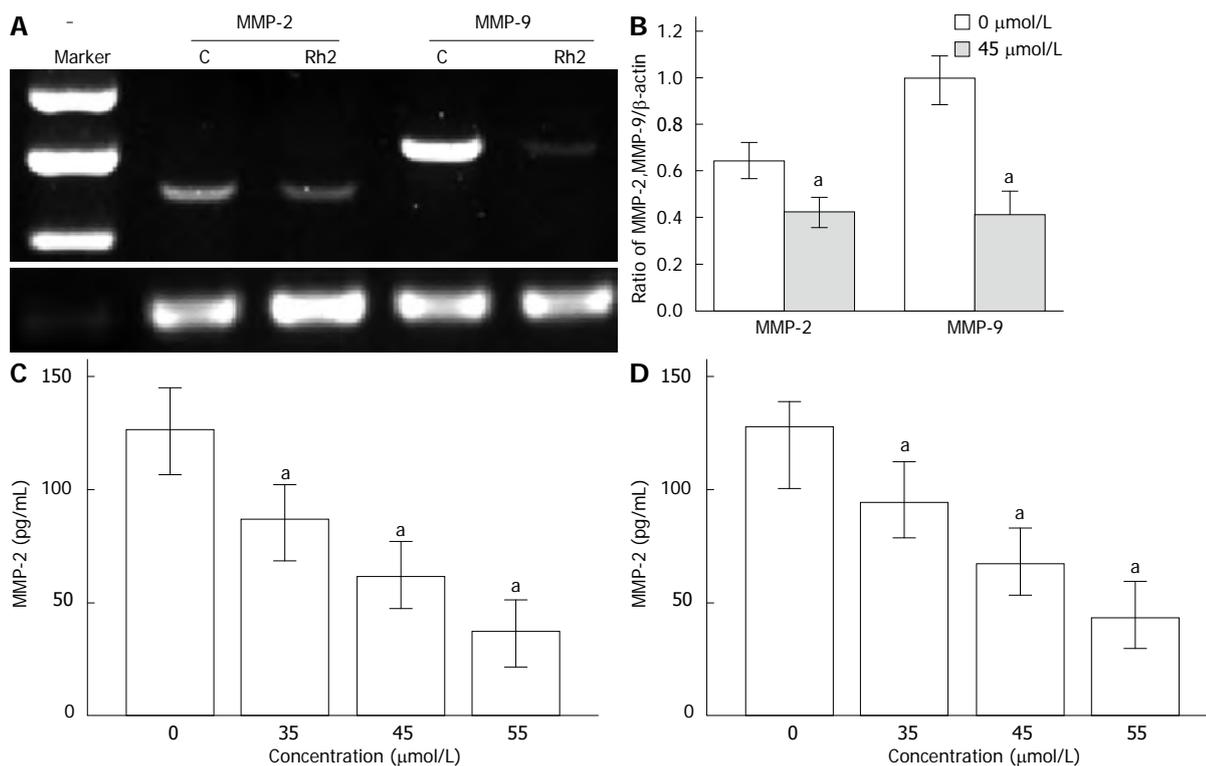

Figure 6 Effects of Rh2 on protein and mRNA expression of matrix metalloproteinase-2 and matrix metalloproteinase-9 in Bxpc-3 cells. A, B: Reverse transcriptase-polymerase chain reaction was used to examine the expression of matrix metalloproteinase (MMP)-2 and MMP-9 mRNA. Rh2 (45 $\mu\text{mol/L}$) downregulated expression of MMP-2 and MMP-9 mRNA; C, D: Enzyme-linked immunosorbent assay was used to examine protein expression of MMP-2 and MMP-9. Rh2 downregulated protein expression of MMP-2 and MMP-9 in supernatants of Bxpc-3 cells in a dose-dependent manner, ^a $P < 0.05$ vs 0 $\mu\text{mol/L}$ group.

through initiating the endogenous apoptotic pathway. However, it remains unclear how Rh2 induced apoptosis of Bxpc-3 cells by initiating the endogenous apoptotic pathway instead of the exogenous pathway. This mechanism merits further investigation in the future.

Another typical characteristic of pancreatic cancer is aggressive metastasis^[24], including local invasion of adjacent structures and metastasis to lymph nodes and liver in the very early stages. Therefore, efforts must be focused on not only targeting the primary tumor but also controlling metastases of pancreatic cancer. Therefore, we examined the effect of Rh2 on invasion and migration of Bxpc-3 cells by using a Matrigel invasion assay and a scratch wound healing assay. Our results showed that Rh2 significantly inhibited cell invasion and migration in a concentration-dependent manner. What is the mechanism of Rh2 in inhibiting Bxpc-3 cell invasion and migration? In invasion and metastasis of tumors, cataplasia of the extracellular matrix is an important component. In such processes, MMPs, as a family of endopeptidases, play a major role and can induce extracellular matrix degradation related to cancer cell invasion and metastasis. Among all members of the MMP gene family, MMP-2 and MMP-9 are considered to be especially important in the degradation of the extracellular matrix that is associated with malignant behavior in a variety of tumor cells^[25-30], including pancreatic cancer^[31]. We therefore examined the expression of MMP-2 and MMP-9, and found that Rh2 significantly downregulated MMP-2 and MMP-9. This

suggested that Rh2 prevented Bxpc-3 cells from invasion and migrating through downregulating MMP-2 and MMP-9.

In summary, we demonstrated the effects of Rh2 on Bxpc-3 pancreatic cancer cells for the first time: (1) Rh2 inhibits cell proliferation by downregulating cyclin D1 and arresting cells in G₁ phases; (2) Rh2 induces cell apoptosis mainly through initiating the endogenous apoptotic pathway; and (3) Rh2 prevents cells from invading and migrating through downregulating MMP-2 and MMP-9. Our study shows that Rh2 can inhibit the proliferation and invasion and induce apoptosis of Bxpc-3 pancreatic cancer cells. As a natural and safe medicine, Rh2 may have future utility in clinical applications for treating pancreatic cancer. Our study will provide a new experimental basis for the clinical application of Rh2 in pancreatic cancer treatments.

COMMENTS

Background

Several studies have revealed that ginsenoside Rh2 could inhibit the growth of many kinds of cancer cells, including breast cancer, prostate cancer, hepatoma, gastric cancer and colon carcinoma. However, little is known about the role of ginsenoside Rh2 in pancreatic cancer. In this study, the authors investigated the effects of ginsenoside Rh2 on the proliferation, apoptosis and migration of cells in the human pancreatic cancer cell line Bxpc-3, and the potential mechanisms were explored.

Research frontiers

This is the first report on ginsenoside Rh2 relevant to pancreatic cancer cells.

Innovations and breakthroughs

By studying the growth-inhibiting, apoptosis-inducing and migration-inhibiting effects of ginsenoside Rh2 on the human pancreatic cancer cell line Bxpc-3, the authors concluded that Rh2 could induce apoptosis and inhibit the growth and migration of cells in the human pancreatic cancer cell line Bxpc-3.

Applications

As a natural and safe medicine, Rh2 may have future utility in clinical applications for treating pancreatic cancer. This study will provide a new experimental basis for the clinical application of Rh2 in pancreatic cancer treatments.

Terminology

Ginsenoside is the main effective component of ginseng, which has been widely used in oriental countries for thousands of years. Ginsenoside Rh2 is a pure compound extracted from ginsenosides.

Peer review

The authors present new findings that constitute the first evidence that this compound may have potential in pancreatic cancer treatment. The data are consistent and provide a solid foundation for future work. The data presented by the authors are interesting. The experiments were well controlled and executed.

Abstract

AIM: To assess effects of heme on messenger RNA (mRNA) and microRNA (miRNA) profiles of liver cells derived from humans.

METHODS: We exposed human hepatoma cell line Huh-7 cells to excess iron protoporphyrin (heme) (10 $\mu\text{mol/L}$) or induced heme deficiency by addition of 4, 6-dioxoheptanoic acid (500 $\mu\text{mol/L}$), a potent inhibitor of aminolevulinic acid dehydratase, for 6 h or 24 h. We harvested total RNA from the cells and performed both mRNA and miRNA array analyses, with use of Affymetrix chips, reagents, and instruments (human genome U133 plus 2.0 and miRNA 2.0 arrays). We assessed

changes and their significance and interrelationships with Target Scan, Pathway Studios, and Ingenuity software.

RESULTS: Changes in mRNA levels were most numerous and striking at 6 h after heme treatment but were similar and still numerous at 24 h. After 6 h of heme exposure, the increase in heme oxygenase 1 gene expression was 60-fold by mRNA and 88-fold by quantitative reverse transcription-polymerase chain reaction. We found striking changes, especially up-regulation by heme of nuclear erythroid-2 related factor-mediated oxidative stress responses, protein ubiquitination, glucocorticoid signaling, P53 signaling, and changes in RNAs that regulate intermediary metabolism. Fewer mRNAs were down-regulated by heme, and the fold decreases were less exuberant than were the increases. Notable decreases after 24 h of heme exposure were patatin-like phospholipase domain-containing protein 3 (-6.5-fold), neuronal PAS domain protein 2 (-1.93-fold), and protoporphyrinogen oxidase (-1.7-fold).

CONCLUSION: Heme excess exhibits several toxic effects on liver and kidney, which deserve study in humans and in animal models of the human porphyrias or other disorders.

INTRODUCTION

Iron protoporphyrin (heme) is a primordial macrocycle upon which nearly all life on earth depends. It has manifold known functions and diverse properties, but there remains much about its roles and functions that is unknown. The importance of a normal pathway and regulation of heme metabolism is underscored by the seriousness of diseases in which there are defects in heme homeostasis. For example, the porphyrias are a group of diseases in which there are defects in normal heme synthesis, due mainly to inborn errors of metabolism that produce deficient activities of the enzymes of normal porphyrin and heme synthesis^[1-4]. Genes and their products of particular importance in heme metabolism are delta-aminolevulinic acid (ALA) synthase 1 (ALAS1) and heme oxygenase 1 (HMOX1), respectively, the rate-controlling enzymes of heme synthesis and catabolism. Regulation of expression of these genes and proteins is complex, but we and others have shown that heme is a major regulator of both, albeit exerting opposite effects. Specifically, heme is a negative regulator of ALAS1 by virtue of decreasing gene transcription, decreasing stability of the messenger RNA (mRNA), decreasing its uptake into mitochondria, where it carries out the synthesis of ALA, and by decreasing the half-life of the mature mitochondrial protein^[2,5-7]. In contrast, heme produces rapid and profound up-regulation of the gene for HMOX1, acting to increase gene transcription by virtue of destabilizing repressive dimers of basic leucine zipper transcription factor 1 (BACH1) and small musculo-aponeurotic factor (maf) proteins and increasing nuclear erythroid-2 related factor (Nrf2)-maf dimers^[8-11].

HMOX1 has emerged as an important anti-inflammatory and cytoprotective principle, and its up-regulation has been associated with several beneficial effects in diverse systems^[2,12]. It is believed to function chiefly by increasing levels of carbon monoxide and biliverdin, which are important signaling and anti-oxidant molecules, respectively. In most mammals, biliverdin is rapidly reduced to the more lipophilic bilirubin, which also has potent anti-oxidant properties and which more readily passes through and dissolves in biological membranes, where it can exert its anti-oxidant and protective functions^[13,14]. In addition, HMOX1 will decrease high levels of heme, which itself is a potential strong pro-oxidant, leading to formation of carbon monoxide CO, biliverdin, and iron. The importance of HMOX1 is underlined by the severe pathology of mice or humans with severe HMOX1 deficiencies^[15-18].

Intravenous (IV) heme was first used as a therapeutic agent more than 40 years ago, for treatment of acute porphyrias in relapse^[19], based upon the understanding that uncontrolled up-regulation of hepatic ALAS1 was a hallmark of acute porphyric attacks and that this enzyme could be dramatically and rapidly down-regulated by administration of heme intravenously. This treatment has stood the test of time, and IV heme continues to be the treatment of choice for all but mild, self-limited attacks

of acute porphyria^[1,3,4,20,21]. Recently, IV heme, in the form of hematin, was reported to also be of benefit in the treatment of acute pancreatitis in mice^[22].

Small, non-coding RNAs, such as microRNAs (miRNAs), have emerged as important modulators of gene expression. They bind to complementary sequences (called “seed sequences”) of mRNAs, especially in 3'-untranslated regions, and alter their stability and their translation into proteins. Recently, we reported important novel effects of miRNAs-122, -196, and -let 7 on expression of HMOX1 and its key repressor BACH1^[17,23], and we recently discovered new and heretofore unexpected roles of proteasomal and other protease pathways that regulate levels of ALAS1, BACH1, and HMOX1^[17,24].

Because of the several effects of heme on hepatic pathways and because of its role as a therapeutic agent, in this work we set out to characterize more nearly completely the comparative effects of heme excess *vs* heme deficiency in human hepatocytes. We performed detailed studies of mRNA and miRNA profiles under these conditions, and we have found evidence for increased oxidative stress and several other changes in metabolic and signaling pathways by heme.

MATERIALS AND METHODS

Chemicals and reagents

Fe protoporphyrin (heme) was purchased from Frontier Scientific (Logan, UT). 4,6-dioxoheptanoic acid (DHA) was from Sigma-Aldrich (St. Louis, MO). Dimethyl sulfoxide (DMSO) was purchased from Fisher Biotech (Fair Lawn, NJ). Fetal bovine serum (FBS), Dulbecco's modified Eagle's medium (DMEM), trypsin and TRIzol reagent were from Invitrogen Inc. (Carlsbad, CA).

Cell culture and treatments

Human hepatoma cell line, Huh-7 (Japan Health Research Resources Bank, Osaka, Japan) was cultured with DMEM supplemented with 100 units/mL penicillin, 100 mg/L streptomycin, and 10% (v/v) FBS. All cells were maintained in a humidified atmosphere of 95% room air and 50 mL/L CO₂ at 37 °C. Freshly prepared heme (dissolved in DMSO) or DHA (dissolved in water) was added to final concentrations of 10 μmol/L or 500 μmol/L, respectively. After 6 h or 24 h at 37 °C in 50 mL/L CO₂/950 mL/L room air, cells were harvested and washed with ice cold phosphate buffered saline once, and lysed directly with TRIzol reagent (Invitrogen, Carlsbad, CA). Total RNA was extracted according to the manufacturer's instructions and stored at -80 °C until mRNA and miRNA microarrays were performed.

cDNA microarray profiling

Total RNA samples were reverse transcribed, amplified and labeled using GeneChip® 3' IVT Express Kit (Affymetrix Inc., Santa Clara, CA). The resultant labeled cRNA (complementary RNA) was then purified and fragmented as per the manufacturer's instructions. The cRNA samples together with probe array controls were

Listing of all messenger RNAs with ≥ 1.5 fold differences in expression at 6 h, 24 h after treatment of Huh-7 cells with heme (10 $\mu\text{mol/L}$) vs DHA (500 $\mu\text{mol/L}$). Cells were cultured, treated, harvested and total RNA prepared and assays as described in Materials and Methods. qRT-PCR: Quantitative real time polymerase chain reaction; *HMOX1*: Heme oxygenase 1; *IL-8*: Interleukin-8; *ANXA1*: Annexin A1; *BACH*: Basic leucine zipper transcription factor; *HSPB8*: Heat shock 22kDa protein 8; *PNPLA3*: Patatin-like phospholipase domain-containing protein 3.

hybridized onto Affymetrix GeneChip[®] Human Genome U133 Plus 2.0 arrays. Hybridization controls were spiked into the cRNA samples in order to monitor and troubleshoot the hybridization process. Probes for housekeeping genes were used to assess sample integrity. Hybridization, washing, staining and scanning were performed using Affymetrix GeneChip[®] system instruments and protocols.

miRNA microarray profiling

The total RNA was Poly (A) tailed and ligated to biotinylated signal molecules using the FlashTag[™] Biotin RNA labeling Kit (Genisphere, Llc in Hatfield, PA, United States). An enzyme linked oligosorbent assay quantitative-competitive assay was performed to verify labeling prior to array hybridization to GeneChip[®] miRNA 2.0 microarrays (Affymetrix, Santa Clara, CA, United States). Hybridization, washing, staining and scanning were performed using Affymetrix GeneChip[®] system instruments and protocols.

Real-time fluorescent reverse transcription-polymerase chain reaction for quantification of mRNAs

First-strand complementary DNA was synthesized using iScript[™] cDNA synthesis kit (Bio-Rad, Hercules, CA, United States). The reverse transcription reaction was incubated at 42 °C for 30 min and stopped by heating to 85 °C for 5 min. 50 ng of final product was used as template for polymerase chain reaction (PCR). Quantitative reverse transcriptase (qRT)-PCR was performed using TaqMan[®] Probe-Based Detection (Applied Biosystems,

Foster City, CA, United States) per manufacturer's instructions with an ABI Prism 7500 Fast Real-Time PCR System, using Taqman[®] gene expression assays and Taqman[®] Gene expression master mix (Applied Biosystems). Template was amplified by 40 cycles of denaturation at 95 °C for 15 s, annealing of primers and probe together with extension at 60 °C for 1 min in triplicate reactions. Fluorescence data were acquired during a combined anneal/extension step. RT negative reactions were run on each plate to confirm the absence of DNA contamination. Fold change values were calculated using comparative Ct analysis and normalized to those of glyceraldehyde phosphate dehydrogenase, which was an invariant control^[25].

Statistical analysis

Affymetrix GeneChip[®] Command Console Software version 3.0.1 was used to analyze microarray image data and to compute intensity values. Affymetrix files containing raw, probe-level signal intensities were analyzed using Partek Genomics Suite (Partek, St. Louis, MO, United States). Robust multichip averaging was used for background correction, quantile normalization, and probe set summarization with median polish^[26]. Statistical differences were assessed by two-way analysis of variance analysis with false discovery rate. Partek miRNA workflow was used to access TargetScan^[27] target prediction databases to perform miRNA-mRNA target integration. Pathway analysis was performed using Ariadne Pathway Studios (Ariadne Genomics, Rockville, MD, United States). The core analysis function in Ingenuity Pathway Analysis (Ingenuity Systems, Redwood City, CA, United States) was used for canonical and toxicity pathway analyses. Cluster and Treeview software were used to perform miRNA hierarchical cluster analysis and visualization.

RESULTS

Heme excess, compared to control or to heme deficiency, produced by DHA, produced a number of striking changes, particularly up-regulation of mRNAs in Huh-7 cells, as shown in Figure 1A and B. The changes were most numerous and striking at 6 h after heme treatment (Figure 1A), but also were similar and numerous at 24 h (Figure 1C). After 6 h of heme exposure, the increase in *HMOX1* gene expression was 60-fold ($P = 9.97 \times 10^{-9}$) by mRNA array and 88-fold by qRT-PCR (Table 1). *HMOX1* is also known as heat shock protein (HSP)-32. Several other stress-response/heat shock-responsive genes also were markedly up-regulated, including interleukin-8 (*IL-8*), sestrin 2 (*SESN2*), heat shock 22kDa protein 8 (*HSPB8*), stanniocalcin 2, *MAFF*, and annexin A1 (*ANXA1*). mRNAs for lipoprotein receptor and *BACH1*, the latter a major repressor of *HMOX1*, were increased 3.9 and 3.0-fold, respectively Table 1 provides a summary list of some of the more striking changes in mRNA levels at 6 h. It also shows results for the more quantitative method of qRT-PCR. Note that, for the genes studied, the fold

P values are for comparison of results following treatment with iron protoporphyrin (heme) vs 4, 6-dioxoheptanoic acid (DHA). Listing of all microRNAs with ≥ 1.5 fold differences in expression at 6 h after treatment of Huh-7 cells with heme (10 $\mu\text{mol/L}$) vs DHA (500 $\mu\text{mol/L}$). Cells were cultured, treated, harvested and total RNA prepared and assays as described in Materials and Methods. FXR/RXR: Farnesoid X receptor/retinoic X receptor; Nrf2: Nuclear erythroid-2 related factor.

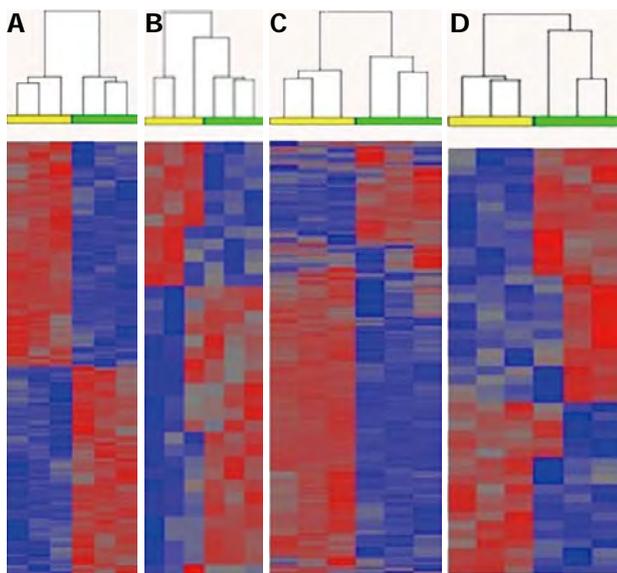

Figure 1 Heat maps with hierarchical clustering of mRNAs (A, C) and microRNAs (B, D) in Huh-7 cells exposed to heme, 10 $\mu\text{mol/L}$ (yellow bars, left side of each panel) or 4, 6-dioxoheptanoic acid, 500 $\mu\text{mol/L}$ (green bars, right side of each panel). A and B: The duration of exposure to heme or DHA was 6 h; C and D: The duration of exposure was 24 h. Cells were cultured, treated, harvested, and RNA arrays performed and analyzed as described in Materials and Methods. Blue color indicates decreased expression; red color indicates increased expression.

differences in expression of mRNAs, comparing heme to DHA treatment, were generally similar by the two methods. The directions of the differences (+ or -) produced by heme vs DHA were always the same (because of limited funds and limited amounts of RNA we were able to directly compare results of mRNA arrays and qRT-PCR for only 4-5 genes).

Fewer mRNA levels were lower with heme excess, and the fold decreases were much less exuberant than were the fold increases. After 24 h of exposure, the greatest fold increase by mRNA array was that of *HSPB8* (77-fold), followed by *ANSA1*, *IL-8*, *HMOX1*, *HSPA1A*, and *SESN2* (46 to 11-fold). At 24 h, there was a notable increase in expression of the *BACH1* gene both by mRNA array (4.5-fold increase by heme) and by qRT-PCT (22.6-fold increase by heme). Notable decreases after 24 h of heme exposure were observed for patatin-like phospholipase domain-containing protein 3 (-6.5-fold), neuronal PAS domain protein 2 (-1.93-fold), and protoporphyrinogen oxidase, the penultimate enzyme of the heme biosynthetic pathway (-1.7-fold). Results of some of the striking differences after 24 h of heme excess vs heme deficiency are summarized in Table 1, which also again shows generally good agreement between results by mRNA array vs qRT-PCR. There also were several changes in miRNA profiles, as shown in Figure 1B and D.

Next, we subjected the mRNA array profiles to analysis by Ingenuity Pathway algorithms. We found striking and highly statistically significant effects at 6 h in Nrf2-mediated oxidative stress response genes, in protein ubiquitination pathway genes, in aldosterone signaling genes in epithelial cells, and in glucocorticoid receptor signaling genes (Table 1). At 24 h, the NRF2-mediated oxidative stress response and the protein ubiquitin pathways continued to show highly significant differences ($P = 1.6 \times 10^{-9}$ and 3.3×10^{-8} , respectively), and pathways involved in biosynthesis of steroids and in propanoate and urea and amino acid metabolism were also significantly affected. Other notable and major effects of heme excess occurred in pathways involved in toxicity, including those that mediate renal necrosis, hepatic necrosis, and

Table 3 Summary of analysis with ingenuity pathway analytical tools

| Glomerular | 3.57×10^{-2} - 5.17×10^{-1} | 2 | | |
| Renal tubule injury | | | 4.27×10^{-5} - 1.63×10^{-1} | 30 |
| Renal proliferation | | | 2.17×10^{-3} - 4.83×10^{-1} | 24 |

P values for the comparison of iron protoporphyrin (heme) *vs* 4, 6-dioxoheptanoic acid (DHA) are shown. Listing of all microRNAs with ≥ 1.5 fold differences in expression at 24 h after treatment of Huh-7 cells with heme (10 $\mu\text{mol/L}$) *vs* DHA (500 $\mu\text{mol/L}$). Cells were cultured, treated, harvested and total RNA prepared and assays as described in Materials and Methods.

those involved in P53 signaling, liver proliferation, cholesterol biosynthesis, and nuclear receptor (farnesoid X receptor, retinoic X receptor) dependent activation (Table 2).

We examined the pathways of hepatotoxicity and nephrotoxicity in greater detail (Table 3). At 6 h after heme or DHA treatment, 12 molecules involved in liver proliferation, 15 in liver cell damage/necrosis, and 12 in liver damage pathways were markedly affected, whereas, at 24 h, 32 involved in cholestasis, 54 in hepatocellular carcinoma, 34 in hepatic steatosis, and 19 in hepatic fibrosis were increased by heme (Table 3). With respect to molecules involved in pathways of renal damage, many involved in renal cell damage, renal failure, tubular injury and proliferation were up-regulated following heme exposure (Table 2).

Changes in miRNA levels are shown as heat maps in Figure 1B and D. Note that miR-181c, -296-5p, -513a-5p, and -637, were significantly affected by heme, compared with DHA. All were up-regulated by heme, with the exception of miR-513a-5p, which was down-regulated -3.84 fold ($P = 0.034$) at 24 h post-treatment.

Figure 1C and D provides a summary of the major pathways affected by heme excess (*vs* heme deficiency, induced by DHA) in human Huh-7 cells. Note the striking effects on HSPs, on *HMOX1*, on *BACH1* and *BACH2*, and on *FOXP3*, *CEBP*, *JUN*, *MYC*, *ATF3*, *GCLO*, *GDF*, *IRS2*, *EGR1*, and lesser but wide-spread up-regulation of expression of *CYP* genes, including *CYP2E1*, *CY1*, *3A4*, *CYP2B6*, *CYP2C9*, *CYP1A2*.

DISCUSSION

The major findings of this work are as follows: (1) heme

excess *vs* heme deficiency, produced by exposure of cells to DHA for 6 or 24 h, leads to marked changes in global gene expression in the Huh-7 line of cells derived from a human hepatocellular carcinoma; (2) a large number of genes that are activated by stressful conditions (stress response genes), including several HSPs, Nrf2 and NQO1 are markedly up-regulated by heme; (3) several important transcription factors, including FOS, JUN, MYC, ATF, BACH1, BACH2, SMADs, CEBP, are up-regulated by heme excess; (4) marked up-regulation of NRF2-mediated, protein ubiquitination, steroid signaling, P53 signaling, and renal and liver cell necrosis pathways is produced by heme excess; and (5) heme excess also produces changes in miRNA profiles, which likely contribute to the modulation of mRNA expressions observed (Figure 1).

A deficiency of hepatic heme is well-known to be associated with disease phenotypes, especially the acute porphyrias in relapse, in which there are partial defects in genes and enzymes of heme synthesis, which, with other genetic and environmental factors, lead to a critical deficiency in the regulatory heme pool of hepatocytes and hence to uncontrolled and marked up-regulation of hepatic ALS synthase-1, which normally is the rate-controlling enzyme of heme synthesis^[1-4]. Acute attacks of porphyria cause much morbidity loss of productivity, hospitalization, and occasionally acute mortality.

Realization of this cascade of effects led one of us (Bonkovsky HL) to develop heme as a potential therapy for acute porphyria in relapse^[19]. This therapy has withstood the test of time and still today. The prompt administration of heme intravenously is the treatment of choice for acute porphyria attacks^[1,20,21]. It also has benefits in other diseases in which there are defects in normal heme synthesis or excesses of ALA production,

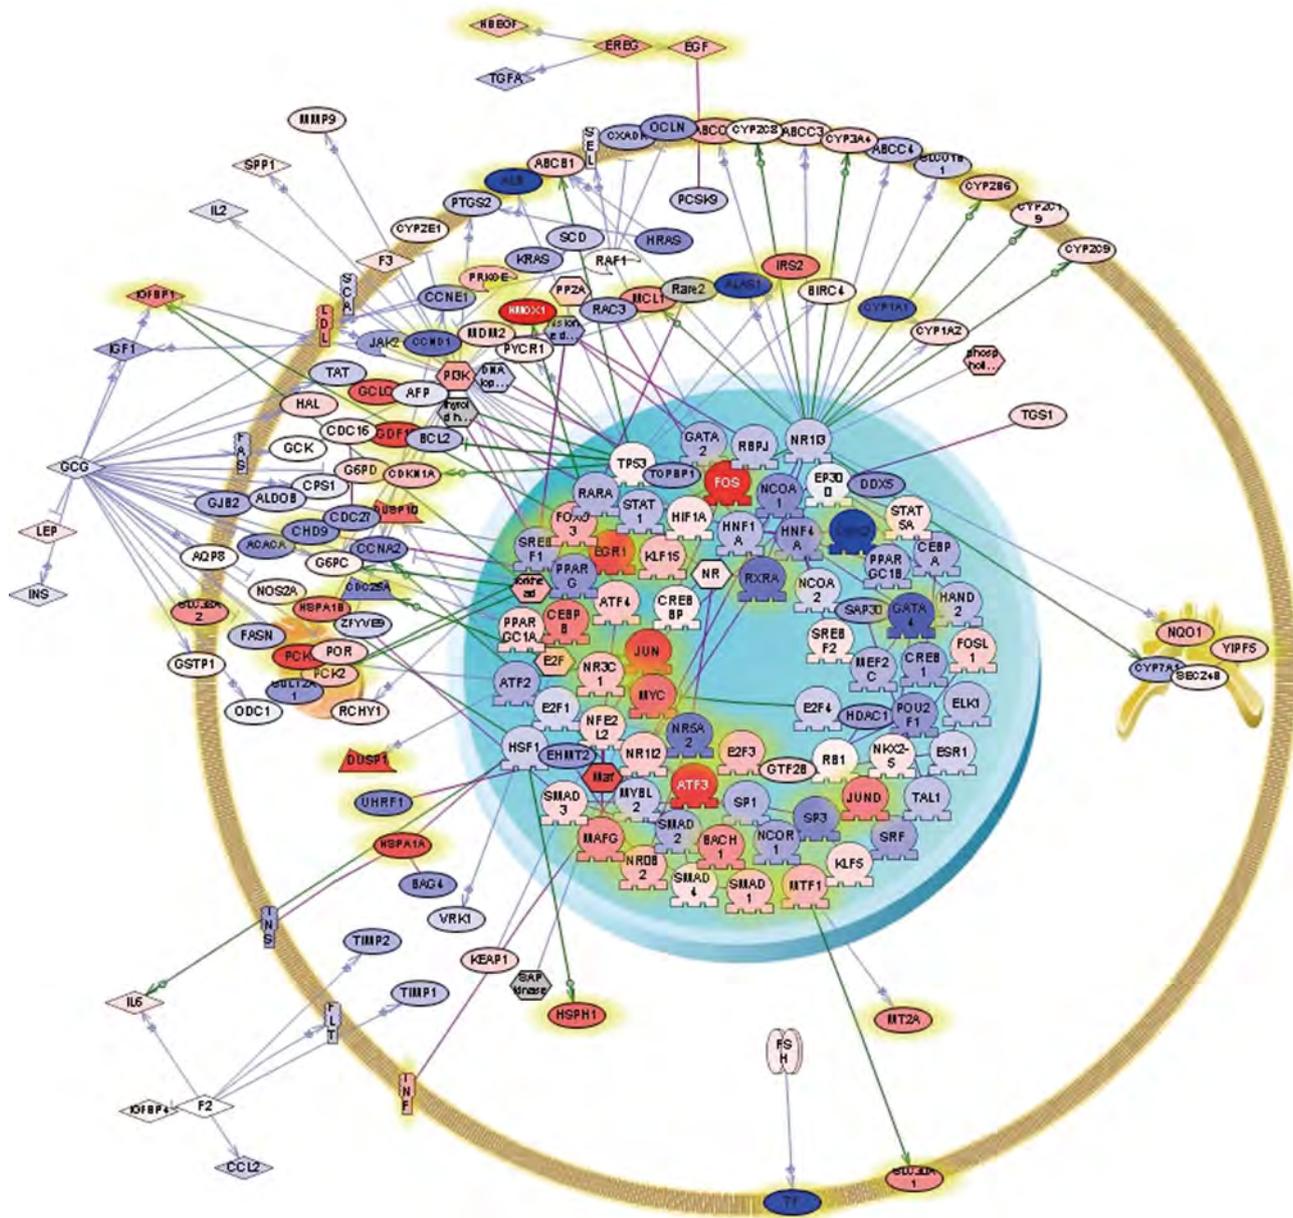

Figure 2 Pathway analysis illustrating differential gene expression in iron protoporphyrin- vs 4, 6-dioxioheptanoic acid- treated Huh-7 cells. Cells were cultured and exposed to iron protoporphyrin (10 μmol/L) or 4, 6-dioxioheptanoic acid (500 μmol/L) for 6 h, after which they were harvested and total RNA isolated using TRIzol. Pathway analysis was performed using Ariadne Pathway Studio by defining sub-networks of genes selected using gene set enrichment analysis ($P \leq 0.01$). The resulting sub-networks were combined. Entities satisfying the filtering criteria are depicted. The intensity of red or blue of the entities themselves indicates the corresponding degree of up- or down-regulation, respectively. Differing shapes are used to represent the entity types and the relationships among them.

which likely is neurotoxic^[28]. In addition, heme has been of benefit in managing other forms of porphyria, especially congenital erythropoietic (uro)porphyria^[29-31] and erythropoietic protoporphyria^[32-34].

In addition, as shown previously by us^[5,9,12,35,36] and others^[37], and as confirmed in this work (Figure 1A and B; Table 1), heme is a potent inducer of the *HMOX1* gene. *HMOX1* is a key cytoprotective and anti-oxidant gene, exerting a myriad of beneficial effects on diverse tissues and in diverse conditions, especially oxidative stress (for reviews see^[2,12,38-40]). Indeed, heme has recently been shown to ameliorate experimental pancreatitis in mice^[22,41], and similar effects seem likely for other inflammatory diseases, based upon the emerging anti-inflammatory and immuno-

suppressive effects of carbon monoxide, biliverdin, and bilirubin, the products of the HMOX-catalyzed breakdown of heme^[21,42]. Heme has also shown promise for blocking the replication of the hepatitis C virus^[23,24,36], at least in part by virtue of its effects BACH1 and HMOX1. The results of this work introduce a note of caution into the therapeutic uses of heme. It may be that heme itself is acting as a pro-oxidant and is increasing oxidative stress and reactive oxygen species, leading to up-regulation of several cytoprotective genes. Thus, heme itself may also be toxic, especially if the doses are too high or if HMOX is deficient^[15-17].

The current findings also lend greater weight to the possible usefulness of other means of inducing HMOX1,

such as by cobalt protoporphyrin, which we^[9,35] and others^[43-45] have shown is a potent and long-acting inducer and which, unlike heme, does not increase oxidative stress nor undergo catabolism by HMOX. Thus, its effects may be achieved with lower doses and for longer times than for heme.

We recognize that our results have limitations: We have performed arrays only of mRNA's and miRNAs, and we have not yet confirmed all major changes and results with qRT-PCR. However, it is reassuring that the qRT-PCR data generally are well correlated with the array data (Table 1). In addition, we have not yet performed detailed proteomic analyses or heme-excess *vs* heme-deficient hepatocytes. However, in a preliminary proteomics study, we have found several changes consistent with our findings. Specifically, at 18 h of heme treatment (10 μ mol/L) *vs* the vehicle, DMSO, we found sixty-six proteins differentially expressed to a highly significant degree. Among these, a total of 24 were decreased, whereas 42 were increased in expression, in keeping with the greater up-regulation of mRNAs by heme, noted above. Among those most strongly increased in expression were HMOX1, ubiquitin and ribosome protein S27a precursor, retinal dehydrogenase, HSP70, ferritin light chain, and ferritin heavy chain. In a similar comparison of DHA (500 μ mol/L *vs* DMSO), 5 proteins were significantly decreased in expression, namely, ATIC, CCT8, GANAB, ENO1, and XP07. Thus, there are similarities in the mRNA and protein results, notably HMOX1 and other HSPs. The increases in ferritin light and heavy chain peptides, but not mRNAs, are in keeping with the known post-transcriptional up-regulatory effects of iron on ferritin chain synthesis^[46,47]. One expects that heme treatment will lead to increases in free iron in hepatocytes, as a result of the action of HMOX^[11,12]. This will be the subject of a later manuscript in this series (Figure 2).

In summary, heme excess in a human hepatocyte line produces manifold changes in mRNA and miRNA profiling, including especially effects on oxidative/stress response, protein ubiquitination, steroid signaling (aldosterone, glucocorticoids), cholesterol, propanoate, urea, and amino acid metabolism. These findings emphasize that additional and more in-depth studies of effects of heme on the transcriptome and proteome are needed and that heme should be used with due caution as a treatment of human disease.

ACKNOWLEDGMENTS

We thank Cecilia Hurtado Vaca, Melanie McDermid, and Kay Snider for excellent help with preparation of the manuscript.

COMMENTS

Background

Heme is used as therapy for acute porphyria in relapse and for other conditions of iron protoporphyrin (heme) deficiency. Because it is a potent inducer of heme oxygenase-1, a major cytoprotective enzyme, heme is proposed as a drug that

may benefit a variety of acute or chronic inflammatory conditions. Heme has also been found recently to bind to and influence levels and activities of several proteins involved in circadian rhythms and intermediary metabolism of carbohydrates and lipids.

Research frontiers

Although heme is a primordial molecule upon which aerobic life as the authors know it depends, the myriad effects of heme on gene and protein expression and metabolic and circadian pathways remain imperfectly understood.

Innovations and breakthroughs

In this work, authors have carried out detailed analyses of alterations caused by heme excess *vs* heme deficiency on messenger RNA and microRNA profiles in the Huh-7 liver cell line derived from a human subject. They also have performed exploratory measures of effects of heme on the proteome of these cells.

Applications

Their results have important implications especially for cautions regarding the use of heme as a therapeutic agent in humans.

Terminology

Heme is one of the class of metalloporphyrins, which include cobalt protoporphyrin, tin- and zinc porphyrins, an others. The circadian rhythm proteins are proteins that influence the normal daily sleep-wake and other 24 h cycles upon which life on earth depends.

Peer review

The data highlight significant heme-dependent alterations in biochemical pathways, which could contribute in understanding aspects of pharmacological heme toxicity. The findings are appropriately discussed and potential limitations are acknowledged. The study is relatively well-done and the results of the microarray approach are convincing.

Abstract

AIM: To determine the rates and impact of hepatitis B virus (HBV) and hepatitis C virus (HCV) infections on response to long-term highly active antiretroviral

therapy (HAART) in a large human immunodeficiency virus (HIV) population in Nigeria.

METHODS: HBV and HCV as well as HIV infections are endemic in sub Saharan Africa. This was a retrospective cohort study of 19 408 adults who were recruited between June 2004 and December 2010 in the AIDS Prevention Initiative in Nigeria in Nigeria programme at Jos University Teaching Hospital. Serological assays, including HBV surface antigen (HBsAg) and hepatitis C antibody were used to categorise hepatitis status of the patients. HBsAg was determined using enzyme immunoassay (EIA) (Monolisa HBsAg Ultra3; Bio-Rad). HCV antibody was tested using third generation EIA (DIA.PRO Diagnostic, Bioprobes srl, Milan, Italy). HIV RNA levels were measured using Roche COBAS AmpliCor HIV-1 monitor test version 1.5 (Roche Diagnostics, GmbH, Mannheim, Germany) with a detection limit of 400 copies/mL. Flow cytometry was used to determine CD4+ cell count (Partec, GmbH Munster, Germany). Comparison of categorical and continuous variables were achieved using Pearson's χ^2 and Kruskal Wallis tests respectively, on MedCalc for Windows, version 9.5.0.0 (MedCalc Software, Mariakerke, Belgium).

RESULTS: With an overall hepatitis screening rate of over 90% for each virus; HBV, HCV and HBV/HCV were detected in 3162 (17.8%), 1983 (11.3%) and 453 (2.5%) HIV infected adults respectively. The rate of liver disease was low, but highest among HIV mono-infected patients (29, 0.11%), followed by HBV co-infected patients (15, 0.08%). Patients with HBV co-infection and triple infection had higher \log_{10} HIV RNA loads (HBV: 4.6 copies/mL vs HIV only: 4.5 copies/mL, $P < 0.0001$) and more severe immune suppression (HBV: 645, 55.4%; HBV/HCV: 97, 56.7%) prior to initiation of HAART compared to HIV mono-infected patients (1852, 48.6%) ($P < 0.0001$). Of 3025 patients who were 4.4 years on HAART and whose CD4 cell counts results at baseline and end of follow up were

available for analyses, CD4 increase was significantly lower in those with HBV co-infection (HBV: 144 cells/mm³; HBV/HCV: 105 cells/mm³) than in those with HCV co-infection (165 cells/mm³) and HIV mono-infection (150 cells/mm³) ($P = 0.0008$).

CONCLUSION: High rates of HBV and HCV infections were found in this HIV cohort. CD4 recovery was significantly diminished in patients with HBV co-infection.

Rates and impact of hepatitis on human immunodeficiency virus infection in a large African cohort. *World J Gastroenterol* 2013; 19(10): 1602-1610 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1602.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1602>

INTRODUCTION

Studies of the prevalence of hepatitis in human immunodeficiency virus (HIV) infected individuals confirm that the rates of hepatitis B virus (HBV) in HIV-infected patients vary widely with tendency towards higher values compared to HBV prevalence in the general population^[1,2]. In the north central region of Nigeria, the prevalence of HBV and hepatitis C virus (HCV) in HIV infected people were 27.8% and 18.3% respectively, and triple infection (HBV/HCV/HIV) was found in 7.2% of 180 HIV infected patients^[3]. HBV prevalence in the Nigeria general population ranges between 10% and 20%^[4].

Although it is widely recommended that HIV infected patients be screened for hepatitis before antiretroviral therapy (ART), no data are accessible to ascertain adherence to this guideline in Nigeria. Reports from Thailand confirm that compliance to hepatitis screening in HIV patients prior to initiating antiretrovirals (ARVs) was poor (55%-69%)^[5,6]. Inadequate epidemiological information on hepatitis in HIV patients may underpin one reason for national health schemes in many developing countries not offering integrated hepatitis services in HIV infected persons. As a consequence, patients co-infected with HBV and HCV are being ignored in regards to timing of antiretroviral therapy, screening for cirrhosis of the liver and hepatocellular carcinoma (HCC), as well as in the choice of ARV regimens that have the potential to optimise their care.

Rising trends in the prevalence of HBV and HCV among HIV-infected individuals during the last decade have been reported in a United States study. That study, involving about 30 000 HIV-infected patients recorded a low, but significantly increasing proportion of patients

being screened for hepatitis; from 20% in 1998 to 60% in 2004^[7]. The researchers found that the rate of HBV and HCV increased from 7% to 8.5% and 9% to 24% respectively. To date, no report of trends in the rate of hepatitis in patients infected with HIV from sub Saharan countries has been published.

The choice of ART regimen can be critical in achieving good treatment outcomes; and knowledge of hepatitis co-infection is vital in this regard. Lamivudine resistance in HIV/HBV co-infected patients on ART has been described in some studies within the West African sub region^[8,9]. A French study has recently demonstrated the advantage of treating HBV-HIV co-infected patients with Tenofovir-containing ARV regimen, particularly for wild type precore mutant and lamivudine-resistant HBV^[10]. Guidelines for the choice of ART regimens generally recommend screening for hepatitis, but this is not routinely undertaken and/or largely depends on availability of resources. Even where screening for hepatitis takes place, a large number of HIV physicians base the choice of ART on available drugs rather than on informed co-morbid conditions. However, changes in treatment guidelines have advocated administration of HBV active ART to co-infected patients in Nigeria.

The importance of well-designed research to answer these questions cannot be overemphasised in order to inform adequate provision of resources for the optimisation of care for HIV/hepatitis co-infected individuals in Africa. We thus aimed to determine the rate of hepatitis screening in HIV infected patients, magnitude of hepatitis co-infection in this large cohort, impact of hepatitis co-infection on baseline HIV parameters, HIV suppression and CD4+ cell increase following HAART.

MATERIALS AND METHODS

Study population

The AIDS Prevention Initiative in Nigeria (APIN) and Harvard School of Public Health HIV program, supported by a grant from the United States President's Emergency Plan for AIDS Relief have been providing ART, at no cost to patients in Nigeria from 2004 till date. This programme is run on a community-based model (although the major sites in Nigeria are located within tertiary health centres), in which integrated community prevention outreaches, on-site HIV screening, counselling, provision of medications, follow up, monitoring and evaluation of all activities are embarked upon. Jos University Teaching Hospital (JUTH) site is one of several centres in Nigeria, with latest HIV prevalence of 4.4%^[11]. JUTH has a specialised centre of care for HIV infection where patients are seen at the outpatient facility at planned intervals of 4-12 wk.

The initial first line ARVs in this population included Stavudine/Zidovudine, Lamivudine and Efavirenz/Nevirapine. However, from 2006, Truvada® (Tenofovir plus Emtricitabine) started to be administered to HIV patients initiating ART in the programme. From June 2004 to December 2010, approximately 19 408 HIV-infected

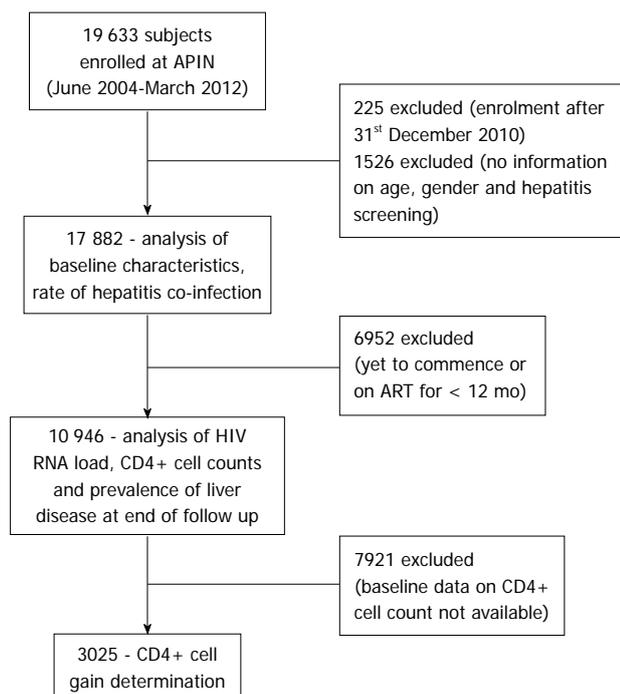

Figure 1 Schematic representation of analyses carried out on recruited human immunodeficiency virus infected individuals at Jos University Teaching Hospital, Nigeria. HIV: Human immunodeficiency virus; ART: Antiretroviral therapies; APIN: Acquired immunodeficiency syndrome prevention initiative in Nigeria.

individuals had been recruited in the JUTH/APIN/Harvard programme and were initiated on ARVs and anti-tuberculosis drugs if indicated.

For the first part of the study, we included all the subjects whose HIV status was confirmed by Western blot assay and enrolled in the programme between 2004 and 2010. Information on age, gender, educational attainment, status of HBV and HCV were obtained. HIV RNA levels and CD4+ cell counts at baseline and most recent assays were also included as were information on the last day of follow up, death or discontinuation of therapy.

Subjects were defined as having HBV and HCV infection if they tested positive for HBV surface antigen (HBsAg) and hepatitis C antibody (HCV Ab) respectively on baseline blood samples. HIV RNA levels and CD4+ cell count were determined at baseline for patients and at 3 monthly intervals until the end point of the study. Hepatotoxicity was defined as alanine aminotransferase (ALT) values ≥ 5 folds over upper limit of normal (ULN) (41 IU/mL for JUTH) or if ≥ 3.5 folds over ULN if baseline ALT was above ULN.

Recruited patients gave written informed consents approved by the ethical committee at JUTH and the institutional review board at the Harvard School of Public Health. For the present work, we obtained a further approval for secondary use of data to study liver-related morbidities in this cohort.

Study design

This was a retrospective cohort study. The pro-forma

utilised in the analyses is summarised in Figure 1. The number of HIV infected individuals that were screened for HBV and HCV were divided by the total number of patients recruited to ascertain the proportion of hepatitis screening. We then calculated the prevalence of HBV and HCV from the numbers that underwent serological testing. We categorised all patients who had hepatotoxicity, liver cirrhosis and hepatocellular carcinoma to a single group (liver disease). As there was overlap of the morbidities, we categorised the cumulative rates of liver related morbidities.

Case-controlled studies of the impact of hepatitis co-infections on baseline HIV viral load and CD4+ cell counts were also embarked upon. HBV, identified by HBsAg, HCV (anti-HCV) and both infections (triple infection) were categorised as cases; which were compared to HIV-only (controls).

Laboratory testing

Before recruitment into the APIN programme, subjects were screened for HIV, using enzyme linked immunoassay and subsequently confirmed by Western blot assay. HBsAg was determined using enzyme immunoassay (EIA) (Monolisa HBsAg Ultra3; Bio-Rad). HCV antibody was tested using third generation EIA (DIA.PRO Diagnostic, Bioprobes srl, Milan, Italy). HIV RNA levels were measured using Roche COBAS Amplicor HIV-1 monitor test version 1.5 (Roche Diagnostics, GmbH, Mannheim, Germany) with a detection limit of 400 copies/mL (Figure 1). Flow cytometry was used to determine CD4+ cell count (Partec, GmbH Munster, Germany).

Statistical analysis

As the diagnoses of HBV, HCV and liver diseases were likely to overlap, we calculated the cumulative prevalence of liver morbidities by overlapping diagnoses; categorised into HBV only, HCV only, HBV/HCV, liver disease only and liver disease with any of HBV, HCV and HBV/HCV. We determined relationships in the demographics of the patients and liver morbidities as well as baseline HIV parameters. The obtained characteristics of HBV, HCV, HBV/HCV and HIV only subjects were compared against each other at baseline using Spearman's chi square and Kruskal Wallis tests for categorical and continuous variables respectively. Analyses were accomplished using MedCalc for Windows, version 9.5.0.0 (MedCalc Software, Mariakerke, Belgium). *P* values of < 0.05 were considered statistically significant.

RESULTS

Between June 2004 and December 2010, 19 408 HIV individuals were enrolled and followed for a median of 53 mo (interquartile range: 31-72 mo). Table 1 presents a summary of the main characteristics of the cohort at baseline. Subjects diagnosed with HBV were more likely to be young (median age: 32 years; $P < 0.001$), male and to have had high HIV RNA loads and CD4+ cell count below 200/mm³. HCV co-infected individuals were more

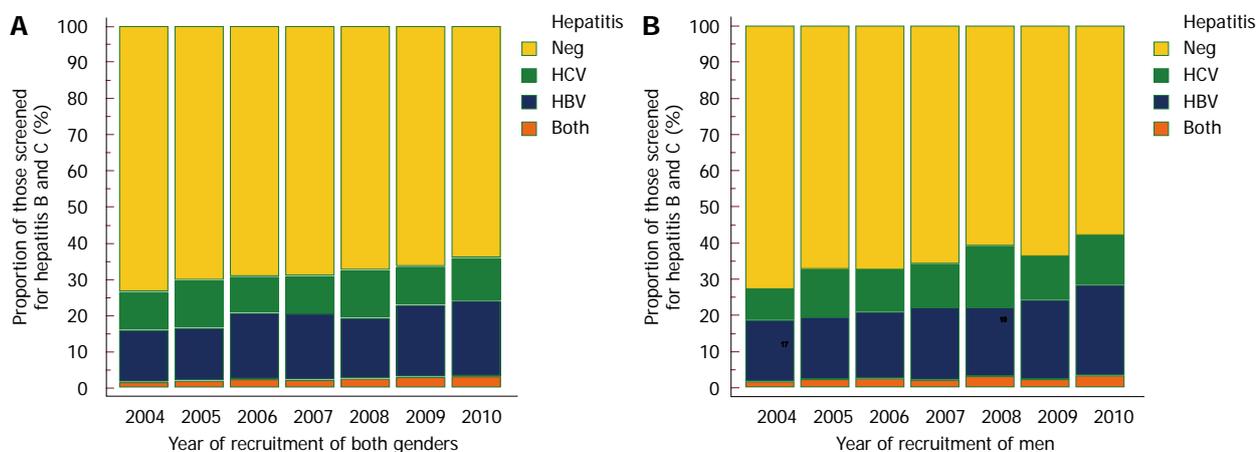

Figure 2 Rates of hepatitis co-infection of human immunodeficiency virus infected individuals in both genders (A) and men (B) among acquired immunodeficiency syndrome prevention initiative in Nigeria cohort, Jos University Teaching Hospital; 2004-2010. HBV: Hepatitis B virus; HCV: Hepatitis C virus.

likely to be males, older (median age: 36 years), have had low level of education and high HIV RNA in their plasma.

Hepatitis screening and prevalence of co-infections

At the beginning of the study period, 99.3% and 99.5% of recruited HIV infected individuals underwent HBV and HCV screening respectively. There has been a significant decline in the rates of screening for HBV and HCV during approximately 7 year study period to 73.0% and 87.6% respectively in 2010 ($P < 0.001$, Figure 2). Overall, the prevalence of HBsAg was 20.7%. A significant increase in the rate of HBV from 14.4% in 2004 to

21.0% in 2010 was observed ($P < 0.001$) and although, fluctuating rates of HCV Ab was recorded among those that were screened, an increasing pattern was noted. The prevalence of HCV Ab was 10.6% in 2004, increasing to 11.7% in 2010. Higher rates of HBV infection was found in men than women rising from 17% in 2004 to 25% in 2010.

Overlapping diagnosis

Cumulatively, 3185 (17.8%) patients were positive to HBsAg and 2014 (11.3%) patients had HCV Ab. 453 (2.5%) patients had evidence of combined HBV and HCV infections (Figure 3). Liver disease was diagnosed

^b*P* < 0.01 vs human immunodeficiency virus (HIV) only. HBV: Hepatitis B virus; HCV: Hepatitis C virus.

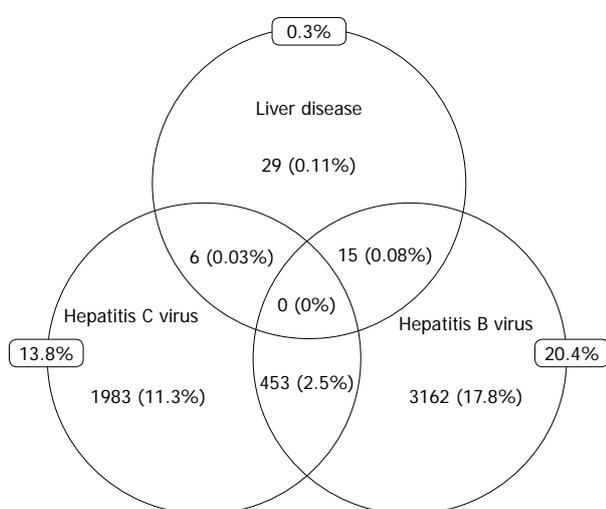

Figure 3 Prevalence of hepatitis B, hepatitis C, hepatitis B and C and liver disease diagnoses among human immunodeficiency virus infected individuals at Jos University Teaching Hospital, 2004-2010.

in 50 (0.3%) patients. Of these, 15 had HBV, 6 had HCV and 29 had no evidence of hepatitis co-infection. None of those with triple infection had a diagnosis of liver disease. Diagnoses of liver disease were achieved via conventional means, including: assessment of sequential liver enzymes, liver ultrasound, and alpha fetoprotein.

Impact of hepatitis co-infection on outcome of ARTs

Higher proportion of HBV (645, 55.4%) and HBV/HCV (97, 56.7%) co-infected patients had CD4+ cell counts below 200 cells/mm³ at baseline compared with HCV (343, 52.5%) and HIV (1852, 48.6%) patients (*P* < 0.0001) (Table 2). The median HIV RNA at baseline was Log₁₀ 4.6 copies/mL each for HBV and HCV patients; and 4.5 copies/mL for HIV mono-infected patients (*P* < 0.0001) (Figure 4). At the end of follow up on ART [median duration: 4.4 years (interquartile range: 2.6-6 years)], no significant difference in HIV RNA load suppression was observed in all study groups. However, there was a significantly lower CD4+ cell increase among those individuals co-infected by HBV/HCV (105 cells/mm³) and HBV (144 cells/mm³) than in HCV (165 cells/mm³)

and HIV-only (150 cells/mm³) patient groups (*P* = 0.008, Figure 5).

DISCUSSION

In this large cohort of HIV infected sub-Saharan African patients, we found that whereas chronic HBV and HCV were frequent diagnoses, liver disease was not common; although investigated only when there were overt clinical symptoms. Overall, one out of every five patients had HBV and more than a tenth had HCV. Almost every patient that was recruited at the beginning of study was screened for HBV and HCV. This is rather remarkable for a resource limited setting and much higher than obtainable in some cohorts in Thailand^[5,6]. The fact that our study site benefited from grants for research and involved the services of specialists may explain the high hepatitis screening rate. However, this initial enthusiasm was not sustained, as there has been a significant decline in the rates of screening for hepatitis during the study period. Interestingly, diagnoses of HBV and HCV showed significant rising trends. We note that there may be a selection bias in this regard as people tend to go to tertiary care centres to seek treatment.

Our findings corroborate the reports of other researchers who had observed higher prevalence of HBV and HCV infection among HIV-infected patients than in the general population^[12]. Studies of prevalence of HBV in the general population of people living within the study area during the period between 2002 and 2007 had found rates of between 10.3% and 15.1%^[13-16]. These confirm that the rates of hepatitis are higher in the HIV patients than in the general population of Nigeria. The fact that HIV and hepatitis viruses share the same routes of transmission supports this explanation. However, it remains unknown whether hepatitis occurs at the same time as HIV infection or predates it.

The precise modes of transmission of HBV and HCV in our cohort are not known. However, it has been reported that transmission of HBV most commonly occurs in early childhood among African populations^[17], compared to high transmission rates among adults in industrialised countries^[18]. Whereas intravenous drug use

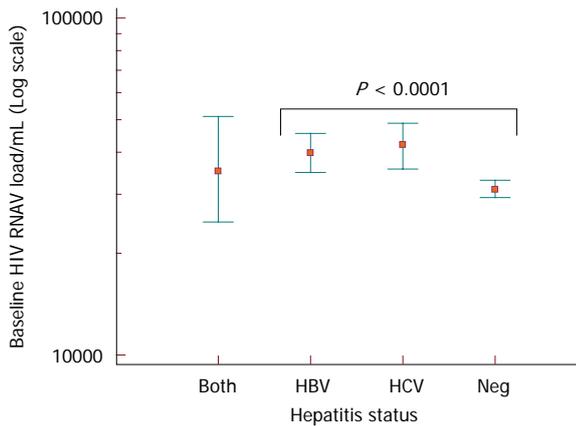

Figure 4 Baseline HIV viral load by hepatitis status among HIV infected patients at AIDS Prevention Initiative in Nigeria, Jos University Teaching Hospital, 2004-2010. HBV: Hepatitis B virus; HCV: hepatitis C virus.

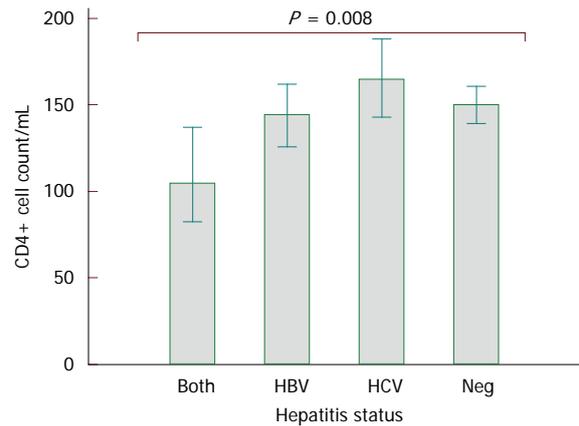

Figure 5 Median CD4 increase by hepatitis status following antiretroviral therapies at Jos University Teaching Hospital, 2004-2010. HBV: Hepatitis B virus; HCV: hepatitis C virus.

is the major route of transmission of HIV and indeed hepatitis viruses in western industrialised countries, heterosexual and horizontal routes, as well as indiscriminate injections (unsterile needles) are thought to be the prevalent modes of transmission of these viral infections in African communities^[19]. Many patients may have iatrogenic transmission from poor sterilisation during routine medical, obstetric, dental and surgical procedures. Most HIV/hepatitis co-infected patients in Nigeria are postulated to have become infected by hepatitis viruses before HIV^[17]. Longitudinal studies will be required to appropriately determine patients that may have acquired hepatitis before, at the same time or after HIV infection. Such a study has the advantage of providing additional information for reinforcing prevention methods, for example HBV vaccination not only for the present cohort but for HIV infected patients in HBV endemic regions.

The incidence of liver disease in the present study was not assiduously documented, although observed to be common. Only 11 patients were documented to have had primary liver cancer in the present study. Eight of these patients were screened for hepatitis. While four were HBsAg positive, 4 were negative to both HBV and HCV. As population-based cancer registries are not routinely available and/or reliable in Nigeria owing to poor registration of diseases and deaths, we did not compare the incidence of primary liver cancer in the present cohort with those from the general population. However, studies in United States have confirmed that primary liver cancer occurs about 6 times more commonly in HIV infected individuals than in the general population^[20,21]. With such a high rate of HBV and HCV infection in this African cohort, there is a chance that a large number of primary liver cancer cases were missed or will yet manifest. It should be noted that prior to free provision of ART to HIV patients in Nigeria from 2004, the cost of these medications was prohibitive and the incidence of HIV mirrored its mortality^[22]. It is thus likely that most patients would have died earlier than they could present with HCC. Furthermore, with prolonged ART, many

of these patients will survive longer and HCC could become more frequently diagnosed.

Unfortunately, the study design did not allow for prospective evaluation of hepatitis status. In addition, the patients were treated with ARVs (*e.g.*, Truvada) that in some cases may have been both active on hepatitis and HIV infection. The baseline evaluation and hepatitis status seems to indicate that other non-infectious causes of hepatic disease may need to be considered. It will be anticipated that HIV hepatitis co-infected patients would have higher incidence of liver disease. This would have been the case if we restricted the definition of liver disease to end stage liver disease (fibrosis, cirrhosis and liver cancer). However, we included hepatotoxicity of ARVs in the definition. This would explain, in part the higher incidence of liver disease in HIV mono-infected patients. Chronic liver disease was small in the cohort, perhaps due to under reporting, or perhaps a high threshold for recording cases in the database. Reasons for the apparent rarity of liver disease in HIV/hepatitis co-infected patients and higher cases of liver disease in HIV mono-infected than hepatitis co-infected patients require further studies.

At baseline, patients with hepatitis co-infection had higher HIV RNA than patients with HIV mono-infection. Correspondingly, a higher proportion of patients co-infected with HBV had CD4+ cell counts below 200/mL compared to HIV mono-infected individuals. The finding of higher HIV RNA at baseline corroborates earlier findings in a study of a small number of patients (1564) from the same study site^[23], as well as another study from China^[24]. Following HAART, the gain in CD4+ cell count was significantly diminished in those patients who had HBV co-infection compared to those with HIV mono-infection. In contrast to our findings, two studies that assessed the impact of HBV on response to HAART found no difference in CD4+ cell gain^[25,26]. Reasons for the differential outcomes are not obvious. Differences in environment are unlikely, as our findings contrast the observation of a study of South African patients^[27]. We

note however, that whereas the South Africa study had a shorter duration of follow up (1.5 years), the present cohort was followed for a longer duration on ART (4.4 years). Nevertheless, results of HBV and long-term HIV outcomes (7 years) in the US found no difference in the HIV load suppression and CD4+ cell gain. Be that as it may, as the natural history of HBV is likely to differ between US and African populations, owing to differential age at acquisition of hepatitis infections, studies comparing African patients on long-term ART would provide a better assessment.

Our findings suggest that CD4+ cell loss by HIV is accentuated by HBV, despite on-going HIV treatment. A few studies have highlighted that active HBV infection is associated with T-lymphocyte exhaustion^[28,29]. This has been further strengthened by the fact that inhibition of HBV DNA replication using anti-HBV drugs resulted in immune restoration^[30,31]. One would expect such an effect to be universal. However, variable outcomes of HAART in regards to HIV load suppression and/or increases in CD4+ cell count in HBV co-infected versus HIV mono-infected patients have been reported. While some studies found no differences between HBV and HIV mono-infected groups^[27,32], others found non-sustained differences in CD4+ cell increases^[25,33]. Studies of HIV treatment outcomes of HBV co-infected and HIV mono-infected African patients comparing HBV suppressive agents versus regimens that are non HBV suppressing will be required to adequately characterise the importance of HBV in the era of HAART.

Our study was not without limitations. First, the use of HBsAg positivity as the sole indicator of chronic HBV infection may be misleading. Definition of chronic HBV would require a positive HBsAg assay consecutively carried out at least 6 mo apart. As single HBsAg was utilised to define cases of HBV in this current study, cases of misclassification might have occurred. Also, delineating HBV cases by their HBV DNA loads and HBeAg status would have provided more meaningful analyses. However, as it is generally known that HBV infection in Africans occur more commonly in childhood, the chance of falsely misclassifying HBV is low. For want of resources, we could not perform HBeAg and HBV DNA. Another issue that could have led to misclassification to hepatitis status is reliance on HCV Ab result to define active HCV infection. Earlier data (unpublished) from a sub group of the current cohort had found HCV viraemia of 33% in those that were HCV Ab positive. It is thus possible that of the patients that were classified “HCV”; only a third may actually be HCV viraemic. More studies with better characterisation of HCV status in this cohort would be required. Missing data was another issue we encountered. In some of the patients, HBsAg and HCV Ab and baseline CD4+ data results were unavailable. Also, we relied on diagnosis of liver diseases (hepatotoxicity, cirrhosis and primary liver cancer) on clinical notes of the patients, where available. As a result of these, we only analysed the rates of hepatitis among those that had hepatitis results. Also, CD4

cell gain was analysed for 3012 patients for whom there were baseline and follow up results and who were on HAART.

In conclusion, high and increasing rates of HBV, HCV and HBV/HCV co-infections were found in this large HIV infected cohort of Africans. The prevalence of liver disease, particularly liver cancer was low; mostly reported among HBV/HIV and HIV-only individuals. HBV co-infection was associated with high HIV RNA load and decreased CD4+ cell counts at baseline and attenuated immunological recovery after a median follow up duration on HAART of 4.4 years. Our findings underscore the urgent need to maintain a strict hepatitis screening policy among HIV infected patients undergoing HAART as well as inclusion of ART regimens with potent anti-HBV activities in HBV endemic regions of the world. Longitudinal studies in African patients to ascertain super-infection of HIV by hepatitis, assessments of impact of HBV-suppressive versus HBV non-suppressive HAART regimens and predictive value of hepatitis on the mortality of the present cohort will form a significant contribution to future research.

ACKNOWLEDGMENTS

The authors acknowledge the unwavering contribution of all the clinic staff of APIN, JUTH; particularly members of the Hepatitis co-infection group, Hope Support group and the Tracking Team as well as the patients without which there would be no manuscript.

COMMENTS

Background

Owing to shared routes of transmission, co-infection of human immunodeficiency virus (HIV) by hepatitis B (HBV) and hepatitis C viruses (HCV) is common. National guidelines recommend that commencement of antiretroviral therapy be preceded by hepatitis screening. Until the writing of this paper, no data is accessible from Africa to ascertain adherence to this guideline. Perhaps, more interesting is the fact that the impact of HBV (most prevalent hepatitis infection in Africa) on HIV therapy is yet to be determined in a large HIV infected population.

Research frontiers

Studies from Asia have reported a modest hepatitis screening rate among HIV patients. A landmark study in France led to the recommendation of Tenofovir-based antiretroviral regimen for HBV/HIV co-infected patients going on treatment. It will be helpful to lay a foundational study in African patients to ascertain whether the effects of such treatment will be the same; especially as the mode and natural history of chronic viral hepatitis vary between developed and developing countries.

Innovations and breakthroughs

In the present study, the authors characterised the patients based on hepatitis status, comparing them with HIV mono-infected cohort and have shown that HBV in particular was associated with decreased CD4 cell increase following long-term highly active antiretroviral therapy. Additionally, the fact that hepatitis screening rate was about 90% in this Nigeria cohort suggests that the recommendation of pre-highly active antiretroviral therapy (HAART) screening for hepatitis is achievable in resource-limited healthcare settings.

Applications

This study suggests that HBV/HCV infection among HIV population is higher than in the general population of Nigeria and portends considerations for HBV preventive programmes, including vaccination. As HBV co-infection negatively impacted CD4 increase during HAART, individualised treatment algorithms,

which had been advocated by international specialists needs to be followed assiduously in order to reduce morbidity in HIV patients.

Peer review

This article delves into a topic that we have few data, coming from sub-Saharan Africa grappling the scourge of hepatitis and HIV and looks on the impact of the former on HIV care. However, it fails to address the impact of the latter on the course of hepatitis. The surprising revelation is the rarity of liver disease in those with co-infection; this is deserving of further studies.

sive symptoms in adolescents with inflammatory bowel disease (IBD).

METHODS: A neuropsychological test battery, including subtests of the Wechsler Adult Intelligence Scale-Revised and III, Wechsler Memory Scale-Revised, California Verbal Learning Test (CVLT), Stroop Color-Word Test, and Trail Making Test, which assessed verbal and visual short- and long-term memory, processing speed, logical reasoning, verbal intelligence, attention, and executive functioning, was administered to 13- to 19-year-old patients with IBD ($n = 34$; active disease $n = 20$). Depressive symptoms were measured with the Beck Depression Inventory. The findings were compared with peers with non-acute juvenile idiopathic arthritis (JIA; $n = 23$). Patients with coexisting psychiatric disorders were excluded.

RESULTS: The IBD group, especially patients in the acute phase, made more perseverative errors in the CVLT test that assessed verbal memory than the JIA group (6.0 ± 4.3 vs 3.3 ± 2.9 , $P < 0.01$), but no other differences between the IBD and JIA groups were observed in the neuropsychological tests. The difference was close to statistical significance, even when glucocorticoid medication was controlled for ($P < 0.052$). The IBD group had more depressive symptoms than the JIA group (7.9 ± 7.6 vs 4.0 ± 4.0 , $P < 0.05$). Approximately one third of the IBD group had at least mild depressive symptoms, and those with acute illness had the highest scores. However, depressive symptoms were not related to the difference in the verbal memory test (perseverative errors in the CVLT) between the IBD and JIA groups.

CONCLUSION: Adolescents with acute IBD may have mild verbal memory problems but no major cognitive deficits compared to peers with JIA.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic life-long disease comprising Crohn's disease, ulcerative colitis and unclassified colitis that may appear at any age. The incidence of IBD among adolescents is increasing^[1-3], and thus, it is important to study the possible burden of the disease on the everyday life of the patients. According to parent reports, adolescents with IBD have more emotional, social, and thought problems and lower competence than their healthy peers^[4]. The disease affects the quality of life of adolescents^[5-7], may have negative consequences on education and school functioning^[8,9], and may cause higher unemployment later in life^[10-13]. Furthermore, adolescents with severe IBD have disturbed sleep and are overtired more often than their healthy peers^[14]. However, research on cognitive dysfunction, which refers to deficits in cognitive information processing, is scarce in patients suffering from IBD.

Two prior studies^[15,16] on adults found some cognitive difficulties among patients with IBD. Attree and co-authors^[15] reported poorer performance in a test measuring verbal functioning in adults with IBD compared to healthy controls. There were, however, no differences in tests assessing attention and mental speed. The other study^[16] also showed that adults with IBD had a decrease in verbal functioning compared with healthy controls and that this was unlikely to be due to premorbid levels of intellectual functioning. Thus, like many other chronic illnesses, IBD seems to be accompanied by some cognitive deficits among adults. However, there are no studies on cognitive functioning among adolescent patients with IBD. In addition, it is not known whether the phase of the illness is associated with cognitive functioning. Given that this disorder often begins in adolescence, it is important to examine whether the illness has an impact on cognitive development and, consequently, the performance of young patients at school.

Depressive symptoms are common among adults^[17] and adolescents with IBD^[18-20]. Depression may also be associated with cognitive impairments^[21,22]. In particular, early-onset depression may be related to deficits in attention, memory, and executive functioning^[23,24]. Depressive symptoms in adolescence might be associated with serious and long-lasting psychosocial difficulties, such as problems in education and work^[25], and cognitive impairments in adolescence and early adulthood may also

complicate school performance and affect successful psychosocial development. Therefore, adolescence is a key period for both the recognition and treatment of mental health and cognitive problems associated with somatic illnesses to avoid long-term sequelae in several areas of psychosocial functioning. Taken together, more studies are needed on illness-related psychosocial and cognitive correlates to improve the care and assessment of young IBD patients.

The main aim of the present study was to examine cognitive functioning among adolescent patients with IBD and investigate whether disease activity or depressive symptoms were associated with cognitive functioning. As a clinical comparison group, an adolescent patient group with minor symptoms of a chronic disease, juvenile idiopathic arthritis (JIA) in the non-acute phase, was included. It was hypothesized that IBD would be related to difficulties in cognitive functioning, especially in verbal functions and that these difficulties would be more pronounced in the acute phase of the disorder.

MATERIALS AND METHODS

Participants

The study groups were enrolled during May 2008-March 2009 at the Hospital for Children and Adolescents, Helsinki, Finland. Consecutive IBD patients aged 13 years or older were invited to participate in the study along with their routine outpatient visits. Likewise, consecutive non-acute JIA patients of the same age group, followed-up at the same outpatient facilities, were invited to participate to represent a control group with non-acute chronic illness (identical recruitment procedure). Patients with coexisting psychiatric, neurological, or developmental disorders (based on hospital case records and information from the patients and their parents) were excluded. All patients were native Finnish speakers and attended regular school, and none had particularly poor school performance (based on self-reports). There were 17 decliners (IBD $n = 8$, JIA $n = 9$). The decliners did not differ from those who participated in age, gender, or severity of the disorder, and the reason for refusal was mainly lack of time. One participant underwent the procedure but was excluded later because of previously diagnosed neuropsychological difficulties and special education at school. None of the included patients had major learning disabilities, but one patient with IBD self-reported as being diagnosed with minor dyslexia in secondary school, with the problems overcome. The final study sample consisted of 34 IBD patients aged 13 to 19 years (ulcerative colitis $n = 16$, Crohn's disease $n = 17$, and unclassified colitis $n = 1$) and 23 JIA patients aged 14-19 years (Table 1). Most patients were full-time students, and only two persons were employees. Current medication included 5-aminosalicylic acid ($n = 26$), azathioprine ($n = 11$), glucocorticoids ($n = 17$), and antibiotics ($n = 3$) in the IBD group and methotrexate ($n = 11$), anti-tumor necrosis factor- α agent ($n = 4$), chloroquine ($n = 4$), and hydroxychloroquine ($n = 4$) in the JIA group.

Table 1 Background data of the study groups

| | IBD (<i>n</i> = 34) | | JIA (<i>n</i> = 23) | |
|-------------------------------------|----------------------|-----------|----------------------|-----------|
| Age (yr) | 16.3 ± 1.7 | 13.6-19.7 | 15.5 ± 1.2 | 14.0-18.6 |
| Age at receiving the diagnosis (yr) | 12.7 ± 3.5 | 2.0-16.7 | 9.0 ± 4.6 | 1.3-15.0 |
| Gender (female) | 15 (44) | | 14 (61) | |
| Socioeconomic status ¹ | | | | |
| Class I | 10 (32) | | 11 (50) | |
| Class II | 9 (29) | | 3 (14) | |
| Class III | 12 (39) | | 7 (32) | |
| Class IV | 0 (0) | | 1 (5) | |
| State (acute) | 20 (59) | | 0 (0) | |
| Disease duration | | | | |
| Less than one year | 6 (18) | | 2 (9) | |
| One to two years | 10 (29) | | 1 (4) | |
| More than two years | 18 (53) | | 20 (87) | |

¹Data missing for three inflammatory bowel disease (IBD) and one juvenile idiopathic arthritis (JIA) patients. Data are expressed as absolute *n* (%) or mean ± SD.

= 1), leflunomide (*n* = 1), and sulfasalazine (*n* = 1) in the JIA group. Three patients with Crohn's disease had undergone surgery more than six months prior to the neuropsychological examination. None of the patients had current psychotropic medication or ongoing psychiatric treatments. The study was approved by the Ethics Committee of the Hospital District of Helsinki and Uusimaa, and it conformed to the provisions of the Declaration of Helsinki and its amendments. Written informed consent was obtained after a complete description of the study from each examined patient or a parent when the examinee was under 18 years of age.

Socioeconomic status

The socioeconomic status of the adolescent's family was classified according to Helsinki City socioeconomic statistics: class I included persons with an academic degree, business managers, and professionals (*e.g.*, engineers); class II included administrative personnel, owners of small businesses, and minor professionals (*e.g.*, graduate nurse); class III included skilled manual employees (*e.g.*, laboratory assistant); and class IV included unskilled employees (*e.g.*, domestic maid). This grading is adapted nationally and comparable to international classification^[26]. The higher socioeconomic class of the parents was considered to be the socioeconomic class of the family (Table 1).

Clinical evaluation

The activity of IBD was based on the clinical evaluation of experienced clinicians (Physician's Global Assessment) and inflammatory markers [erythrocyte sedimentation rate (ESR), C-reactive protein, and fecal calprotectin, with values < 100 µg/g of stool considered normal and values >1000 µg/g considered exceedingly high]^[27]. The disease activity in JIA was based on the child health assessment questionnaire and clinical evaluation by a pediatric rheumatologist.

On the day of the neuropsychological assessment,

patients also completed a questionnaire in the Finnish language gathering information on depressive symptoms and background factors. Depressive symptoms were measured with the Beck Depression Inventory (BDI)^[28]. The BDI is a 21-item questionnaire in which the items are answered using a 4-point rating scale ranging from 0 to 3. High scores indicate a high level of depressive symptoms. The total score was calculated and used in the statistical analyses. Additionally, the BDI total score was categorized into four classes by classifying scores from 0 to 9 as no symptoms, 10 to 18 as mild symptoms, 19 to 29 as moderate symptoms, and 30 to 63 as severe symptoms. Five patients had one missing value in the BDI, which was replaced by their individual item mean scores of the BDI. The patients also completed an in-house questionnaire with questions on school performance, subjective view of learning difficulties, sick leave, employment, and parental professions.

Neuropsychological examination

The neuropsychological examination was conducted individually by a psychologist blinded to the presence of diagnosis or disease activity prior to the examination. The examination took place in one session of approximately one hour. The neuropsychological test battery, including Finnish versions of internationally used, validated test methods administered in a fixed order, was selected to allow for the comparison of verbal and visual short-term memory, verbal long-term memory and learning, attention, logical reasoning and social insight, psychomotor processing speed, and executive functioning between the study samples. Because the cognitive functioning of adolescents with IBD has not been previously investigated, the tests were chosen to evaluate a wide range of neuropsychological functions instead of focusing on only some specific functions. Tests were scored according to standardized procedures by the examiner.

Auditory attention and verbal working memory were assessed with the Digit Span Forward and Backward subtests, respectively, of the Wechsler Memory Scale, Revised^[29] (WMS-R). Visual attention and working memory were measured with the Visual Span Forward and Backward subtests, respectively, of the WMS-R^[29]. Visuo-motor performance and processing speed were assessed with the Digit Symbol subtest of the Wechsler Adult Intelligence Scale, Revised^[30] (WAIS-R). General verbal intelligence was estimated with the Vocabulary subtest of the WAIS-R^[30], and logical reasoning and social insight were assessed with the Picture Arrangement subtest of the WAIS-III^[31]. The Stroop Color-Word Test^[32] (Golden), given in three parts, was administered to evaluate executive functioning, and the interference score was calculated and used in the analysis. The Trail Making Test^[33] (TMT), given in two parts, was administered to evaluate attentive and executive functioning. Part A measures visuo-spatial attention and performance speed, whereas Part B requires mental flexibility, ability to shift attention,

and strategy. Possible errors made by the examinee were not corrected by the examiner. The time to complete Parts A and B and the difference in score between B and A (the executive aspect of the task when the speed component is removed) were used in the statistical analysis. The California Verbal Learning Test^[34] (CVLT), in which the examinee is required to learn a 16-item word list over five trials and recall and/or recognize it after short and long delays, was used to measure various aspects of verbal learning and memory. The following variables of the CVLT were included in the statistical analyses: Total Recall from trials 1-5 (learning performance), Short-Delay Free Recall (short delay memory performance), Long-Delay Free Recall (long delay memory performance), Discriminability (recognition memory taking into account both hits and false positives), Perseverative Repetition Errors, Intrusion Errors, Semantic Clustering (the use of an active learning strategy of reorganizing target words into categorical groups), and Learning Slope (the increase in recalled words per trial over trials 1-5). Higher scores indicate better performance in all tests, except in the Stroop test, TMT and Perseverative and Intrusive Errors of the CVLT.

Three IBD patients had missing values in neuropsychological tests: the Stroop test performance of two patients was excluded due to red-green color blindness. One patient had distractions during the testing situation, and therefore, the results of the Picture Arrangement and the Stroop test were considered invalid in this case.

Statistical analysis

Pearson's χ^2 test was used to compare differences in gender, a one-way analysis of variance (ANOVA) was used to compare differences in age, and a two-tailed Mann-Whitney test was used to compare differences in the socioeconomic status of the adolescent's family between the study groups.

Neuropsychological test scores were compared between the IBD and JIA groups with a univariate ANOVA. The main group comparisons were performed separately for each test score as a dependent variable, with group membership as an independent variable and gender as an additional independent variable to adjust for gender effects. Neuropsychological test performance was also compared between subgroups of active and non-active IBD groups and the JIA group with Bonferroni's *post hoc* test. To adjust for the effects of glucocorticoids, group comparisons of neuropsychological functioning were conducted when this medication (yes *vs* no) was treated as an additional independent variable.

Depressive symptoms were compared between the groups with ANOVA. ANOVAs with *post hoc* tests, corrected for multiple testing with the Bonferroni correction, were also used to compare depressive symptoms between the subgroups of active and non-active IBD patients and the JIA group. Linear regression models were used to predict depression score by age or gender. In addition, to adjust for the effects of depressive symptoms

on neuropsychological test performance, these group comparisons were also conducted with the continuous BDI score as an additional covariate factor.

All analyses were conducted with SPSS 16.0 software, and a *P* value < 0.05 was defined as indicating a statistically significant result throughout the study. Raw test scores were used. Scores that were not normally distributed were log (TMT: A, B, B-A; CVLT: Perseverations, Intrusions) or cube (CVLT: Discriminability) transformed.

RESULTS

The IBD and JIA groups did not differ in age ($F = 3.210$, $\nu = 1, 55$, $P = 0.079$), gender ($\chi^2 = 1.540$, $\nu = 1$, $P = 0.215$), or socioeconomic status of the family ($U = 304.500$, $P = 0.483$). Among IBD patients with the acute state ($n = 20$), the median ESR was 19 mm/h (range from 3 to 53 mm/h), fecal calprotectin was 870 $\mu\text{g/g}$ (range from 101 to 3130 $\mu\text{g/g}$), and 14 of the 20 patients were on glucocorticoids. The respective figures for IBD patients with quiescent disease ($n = 14$) were 4 mm/h for ESR (from 1 to 28 mm/h), 183 $\mu\text{g/g}$ for fecal calprotectin (from 150 to 505 $\mu\text{g/g}$) and three on low-dose glucocorticoids.

The only statistically significant difference in the neuropsychological test performance between the groups appeared in Perseverative Repetition Errors of the CVLT, with the IBD group performing poorer than the JIA group (Table 2). When the subgroups of active and non-active IBD patients were compared with each other and the JIA group, the only difference was again in Perseveration Errors ($F = 5.150$, $\nu = 2, 51$, $P = 0.009$), with the acute IBD group performing poorer than the JIA group ($P = 0.027$; other data not shown). When glucocorticoid medication was treated as an additional independent variable, the difference in Perseveration Errors was close to the level of statistical significance ($F = 3.948$, $\nu = 1, 51$, $P = 0.052$; other data not shown).

The IBD group had scores suggesting more depressive symptoms than the JIA group (mean \pm SD, IBD: 7.9 ± 7.6 , JIA: 4.0 ± 4.0 ; $F = 5.046$, $\nu = 1, 55$, $P = 0.029$), especially IBD patients in the active disease phase ($F = 3.966$, $\nu = 2, 54$, $P = 0.025$; active IBD *vs* JIA $P = 0.022$). In the IBD group, 24% had scores suggesting mild depressive symptoms (half of the patients were in the active and half in the non-active state), and 9% had scores suggesting moderate or severe depressive symptoms (all in the active state). In the JIA group, 9% had scores for mild depressive symptoms, while none had moderate or severe symptoms. None of the patients reported suicidal ideation or suicidal behavior in the BDI. The depression score was not predicted by age ($\beta = 0.247$, $\nu = 1, 55$, $P = 0.064$) or gender ($F = 2.766$, $\nu = 1, 55$, $P = 0.102$).

When the BDI score was set as a covariate in the group comparisons of the neuropsychological data, the difference in Perseveration Errors remained significant between the study groups ($F = 4.591$, $\nu = 1, 52$, $P = 0.004$), and no other differences between the groups emerged (data not shown).

Table 2 Neuropsychological test results (row scores) in the study groups

| | IBD (<i>n</i> = 34) | JIA (<i>n</i> = 23) | IBD vs JIA | | |

DISCUSSION

To our knowledge, this is the first study that describes cognitive functioning in adolescent patients with IBD. We found only minor impairments in the verbal memory test, in which IBD patients, particularly in the acute phase, produced more perseverative errors than patients with non-acute JIA. Perseveration in the CVLT test may be related to a momentary loss of alertness in the tiresome and long verbal memory test. However, no other differences in cognitive functioning between the study groups were detected. These findings indicate that adolescents with active IBD may have some mild problems in verbal memory but no major cognitive deficits. The two prior studies in adults with IBD found deficits, particularly in verbal functioning^[15,16], suggesting that in the clinical evaluation of young patients with IBD, it may be relevant to pay attention to even minor cognitive problems that may be aggravated in the process of growing up.

Depressive symptoms were measured using the BDI on the same day as the neuropsychological examination. Adolescents with IBD, especially those in the acute phase of the illness, may more commonly have depressive symptoms compared with peers with mild disease or non-acute JIA. Approximately one third of the IBD patients had scores indicative of at least mild depres-

sive symptoms, and some of those with acute illness scored for moderate or severe symptoms. This finding is noteworthy, as in non-acute JIA, no patients reported moderate or severe depressive symptoms, and less than one out of ten reported mild symptoms. In line with our results, previous studies have described depressive symptoms among young patients with IBD^[18-20]. Although the minor impairment in the verbal memory test in IBD patients was not explained by the severity of depressive symptoms, depressed mood may have other severe and long-lasting consequences for the psychosocial functioning of these patients.

One limitation of the present study is the lack of a healthy control group, which potentially weakens the generalization of the findings. The patient control group was chosen to represent adolescents with similar life surroundings (chronic disorder with inflammatory pathology) but with less severe health problems that have not been found to be related to cognitive deficits^[35]. The strength of the present study is that the JIA patients underwent exactly the same procedure as the IBD group in the outpatient clinic of the same hospital during the same time period and with the same examiners, who were blinded to patient data. Furthermore, the patient groups did not differ in age or gender. There was no major attrition of participants that could limit the interpretation of the results; however, the sample

sizes were still relatively small. Another limitation is that there may be some potential confounders, such as sleep disturbances or acute stressful life events, *e.g.*, divorce of parents, that should be taken into account. In the IBD group, the majority (70%) of the patients in the acute state were on glucocorticoids, which may affect cognitive functioning^[36]. Unfortunately, the total exposure time of glucocorticoids was not available. However, it is unlikely that the only reason for the minor problem in the verbal memory test was glucocorticoids because the group difference between the IBD and JIA patients remained close to the level of statistical significance when glucocorticoid medication was adjusted for in the statistical analyses. Furthermore, in active IBD, patients need either glucocorticoids or other immunosuppressive therapy, and it would be unethical to decline these medications for study purposes. Thus, studying treatment-naïve patients with active IBD is challenging.

Taken together, this is the first study that investigates cognitive functioning in adolescents with IBD. The results indicate that young patients with IBD, especially in the acute state of the disease, may have some problems in verbal memory, particularly when assessed with a test requiring alertness in a tiresome context. However, no major cognitive deficits among young patients with IBD were found compared to peers with JIA. The clinical significance of this finding and its possible impact on school performance, is unclear, warranting further studies. Likewise, the relation of cognitive functioning to medication and disease-related factors, such as sleep disturbances or depression, needs to be assessed in larger study samples. In particular, longitudinal studies on disease activity and cognitive functioning related to psychosocial functioning are warranted in adolescents with IBD.

ACKNOWLEDGMENTS

The authors thank all study participants, Anne Nikkonen RN for recruiting the patients, and MPsych Hannamari Heino for assisting in the neuropsychological data collection.

COMMENTS

Background

The incidence of inflammatory bowel disease (IBD) among adolescents is increasing, and therefore, it is important to study its possible burden on patients' everyday life. However, research on cognitive functioning has been scarce in IBD, especially among adolescents.

Research frontiers

It is important to examine whether IBD has an impact on cognitive development and possibly consequently on the performance of young patients at school and everyday life.

Innovations and breakthroughs

Cognitive functioning in IBD has previously been investigated in only two studies, which both found some cognitive deficits relating to IBD, but both studies were conducted in adults. There are no studies investigating cognitive functioning in adolescents with IBD. This study shows that adolescents with acute IBD may have mild verbal memory problems but no major cognitive deficits.

Applications

In the clinical evaluation of young patients with IBD, it may be relevant to pay attention to even minor cognitive problems that may be aggravated in the process of growing up and affect school performance.

Terminology

Cognitive functioning refers to functions of cognitive information processing, such as memory, attention, concentration, processing speed, and executive functions.

Peer review

The present study includes an interesting research question with an original design. The authors utilize numerous neuropsychological tests to assess cognition from various perspectives.

Abstract

AIM: To investigate the influence of percutaneous local therapy on gastric myoelectrical activity in patients with hepatocellular carcinomas.

METHODS: Forty-four patients with hepatocellular carcinoma (HCC) [27 males and 17 females, ranging in age from 49 to 81 years old (69.7 ± 8.01 years)] who were admitted for percutaneous local therapy were enrolled in this study. We examined clinical abdominal symptoms using the Gastrointestinal Symptom Rating Scale (GSRS) before and 3 d after percutaneous local therapy. We also measured cutaneous fasting and

postprandial electrogastrography (EGG) recordings before and 3 d after percutaneous local therapy.

RESULTS: We found that the percentage of normogastria in the fasting period was lower in the Child B group than in the Child A group ($66.8\% \pm 8.6\%$ vs $84.0\% \pm 3.8\%$). After percutaneous local therapy for HCC, the percentages of normogastria in the fasting period were significantly decreased ($81.6\% \pm 3.5\%$ vs $75.2\% \pm 4.5\%$). None of the postprandial EGG parameters changed significantly after percutaneous local therapy for HCC. Percutaneous local therapy for HCC reduced the power ratio (PR). In particular, the PR of tachygastria was significantly decreased after therapy ($P < 0.01$). However, no significant differences were found in the postprandial EGG parameters. Likewise, no significant differences were found in the calculated GSRS scores obtained from the questionnaire before and after therapy.

CONCLUSION: Gastric slow-wave dysrhythmias were induced by percutaneous local therapy in HCC patients, even though the GSRS scores obtained from the questionnaire did not change significantly.

Influence of percutaneous local therapy for hepatocellular carcinoma on gastric function. *World J Gastroenterol* 2013; 19(10): 1618-1624 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1618.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1618>

INTRODUCTION

In treating hepatocellular carcinoma (HCC), various percutaneous local therapies, such as percutaneous ethanol injection (PEI), microwave coagulation, and radio frequency ablation (RFA), are frequently used because of their demonstrated effectiveness. Although these treatment modalities can induce coagulated tumor necrosis effectively, they are also known to cause adverse effects on extrahepatic abdominal organs^[1]. There are, however, few published reports on the influence of percutaneous local therapy on gastric myenteric activity. Therefore, it is unclear whether gastric function is affected by percutaneous local therapy.

Gastric myoelectrical activity is regulated by electrical pacemaker activity known as slow waves. Gastric slow waves originating from pacemaker cells on the major curvature of the stomach can be measured noninvasively by using a cutaneous electrogastrography (EGG) recorder and placing electrodes on the abdominal skin. In this study, to clarify the influence of percutaneous local therapy for HCC on gastric function, we continuously recorded gastric myoelectric activity by EGG and estimated the influence of percutaneous local therapy on HCC gastric function. In addition, we investigated whether gastric slow-wave dysrhythmias were associated with clinical abdominal symptoms occurring after therapy.

MATERIALS AND METHODS

Patient population

Forty-four patients with HCC [27 males and 17 females, ranging in age from 49 to 81 years old (69.7 ± 8.01 years)] were enrolled in the present study. Patients with diseases known to affect gastric myoelectrical activity, such as diabetes mellitus, who had received a partial or total gastrectomy or who were taking medication known to alter gastrointestinal electrical activity were excluded from this study. After being provided with a careful explanation regarding the goals of the investigation, all patients provided informed consent. The study was conducted in accordance with the local ethical guidelines and the recommendations of the Declaration of Helsinki. HCC was diagnosed by its characteristic appearance on ultrasonography, computed tomographic scan, angiography, serum α -fetoprotein assays, and serum protein induced by vitamin K absence or antagonist-2 assays.

We have developed several novel percutaneous local therapies for HCC. The first of these therapies is the combination of PEI and RFA (PEI-RFA). In this treatment modality, RFA is performed immediately after PEI. The second therapy is percutaneous ethanol-lipiodol injection (PELI). In this modality, a 10:1 mixture of pure ethanol and lipiodol, a lipid-based contrast medium, is injected percutaneously into the HCC. The third therapy is the combination of PELI and RFA (PELI-RFA). The final therapy is RFA alone. The relative usefulness of each of these new treatment modalities has been reported elsewhere^[2-6]. In the present study, 18 patients with

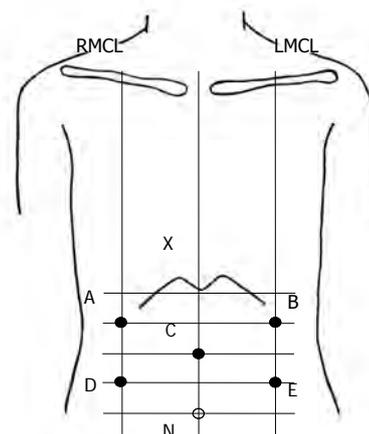

Figure 1 Positions of electrodes for electrogastrography recording. X: Xyphoid process; N: Navel; A: Channel 1 placed on the intersecting point between the right mid-clavicular line (RMCL) and the vertical bisectrix of the line XC; B: Channel 2 placed on the intersecting point between left mid-clavicular line (LMCL) the avertical bisectrix of the line XC; C: Central terminal electrode placed on the patient's ventral midline approximately halfway between the umbilicus and the xyphoid process; D: Channel 3 placed on the intersecting point between RMCL and the avertical bisectrix of the line NC; E: Channel 4 placed on the intersecting point between LMCL and a vertical bisectrix of the line NC.

HCC underwent PEI-RFA, 7 patients underwent PELI, 6 patients underwent PELI-RFA, and 13 patients underwent RFA.

Assessment of abdominal symptoms after therapy

We examined clinical abdominal symptoms using the questionnaire developed by Svedlund *et al.*^[9] (Gastrointestinal Symptom Rating Scale, GSRS), which was translated into Japanese. The GSRS consists of 15 items that assess symptoms of the digestive tract on an interview-based rating scale. Items on the GSRS are scored using a seven-point scale, where a score of 1 represents the absence of any troublesome symptoms and a score of 7 represents very troublesome symptoms. The 15 items on the GSRS evaluate the following 5 symptom categories: reflux (heartburn and regurgitation), abdominal pain (abdominal pain, hunger pains, and nausea), diarrhea (diarrhea, loose stools, and an urgent need to defecate), indigestion (borborygmus, abdominal distension, eructation, and increased flatus), and constipation (constipation, hard stools, and a feeling of incomplete evacuation).

Electrogastrography

We recorded an EGG before therapy began and on the third day after therapy and compared the results. The EGGs were recorded with a portable electrogastrographic recorder (NIPRO, EGG, A and D, Tokyo, Japan). The central terminal electrode for the EGG recorder was placed at the midpoint between the processus xiphoideus and the navel, and 4 other electrodes were placed above, below, and to the left and right of the stomach (Figure 1). The recordings of the EGGs were stable because of the tenth filter sampling at 1-s cycles. Data recording was performed at 13 bits and at a frequency between 2.1 and 6.0 cycles/min. Electrogastrography was performed

Table 1 Clinical characteristics of the subjects

with the patients in a dorsal position. Patients were asked to remain as still as possible to reduce motion artifacts. Electrogastrograms were recorded for 30 min during a fasting period and again during a postprandial period.

EKG analysis

The EKG data were downloaded to a personal computer via an RS-232C port, and a frequency analysis (fast Fourier transformation; FFT analysis) was performed on 512 points and analyzed using EGS2 Ver.1.31 software (Gram, Japan). Using an FFT analysis, we evaluated the percentages of bradycardia (< 2.4 cycles/min), normogastria (2.4-3.6 cycles/min), and tachycardia (> 3.6 cycles/min), as well as the dominant frequency and the postprandial-to-fasting power ratio (PR).

Statistical analysis

Measured values are expressed as the mean \pm SE. Comparisons before and after therapy were performed by the paired Student *t* test, and $P < 0.05$ was accepted as indicating a significant difference. A regression analysis was performed to examine the relationship between decreases in the percentage of normogastria (%normogastria) after treatment and clinical factors. A P value < 0.05 was considered statistically significant. The software package used for the statistical analysis was SPSS (SPSS statistics 20 IBM Corporation, New York, United States).

RESULTS

According to the Child-Pugh classification of liver disease severity, there were 33 patients in stage A and 11 patients in stage B (Table 1), and the conditions of their Child-Pugh classifications remained the same during the administration of percutaneous local therapy. The causes of liver dysfunction in the HCC patients were as follows: chronic hepatitis B virus infection in 5 cases, chronic hepatitis C virus infection in 30 cases, negative for both hepatitis B surface antigen and hepatitis C antibody in 5

Table 2 Clinical characteristics of Child A and B patients

| | Child A group | Child B group |
|----------------------------|----------------|----------------|
| Sex (male/female) | 23/10 | 4/7 |
| Age (yr) | 69.4 \pm 8.0 | 70.6 \pm 8.8 |

| HBV | 4 | 1 |
| HCV | 23 | 7 |
| Alcoholic | 2 | 1 |
| PBC | 0 | 1 |
| NBNC | 4 | 1 |

PBC: Primary biliary cirrhosis; NBNC: Negative for both hepatitis C virus (HCV) and hepatitis B virus (HBV).

cases, alcoholism in 3 cases, and primary biliary cirrhosis in 1 case.

No major complications occurred during or after treatment. All the subjects tolerated the electrogastrographic examination well, and no gastrointestinal complaints were reported by the patients during the EGG recording. First, we examined the gastric myenteric activity among the liver cirrhosis subgroups before the treatment. The clinical characteristics of the patients in the Child A and Child B group are shown in Table 2, and the pretreatment EGG data are shown in Table 3.

We found that the percentage of normogastria in the fasting period was lower in the Child B group than in the Child A group. However, no significant differences were found in the calculated GSRS scores obtained from the questionnaire. Furthermore, no differences in symptom categories were significant (Table 4).

Next, we examined the change in EGG associated with treatment. The EGG results are summarized in Table 3. Examples of the raw EGG signals before and after therapy are shown in Figure 2.

After percutaneous local therapy for HCC, the percentages of normogastria in the fasting period were significantly decreased ($P < 0.05$). Although the ratio of bradycardia increased, the change was not significant ($P = 0.967$). None of the postprandial EGG parameters changed significantly after percutaneous local therapy for HCC. Therapy reduced the PR of bradycardia, normogastria, and tachycardia. In particular, the PR of tachycardia was significantly decreased after therapy ($P < 0.01$).

Conversely, no significant differences were found in the calculated GSRS scores changes within any symptom category (Table 4). A single regression analysis was performed to examine the relationship between decreases in the percentage of normogastria (%normogastria) after treatment and the following factors: patient sex, patient age, ethanol injection, location of the treated hepatoma (right or left lobe), tumor size (diameter), use of RFA, and the Child-Pugh score. The results revealed that the decreases in %normogastria were positively correlated with patient age ($P = 0.037$). Moreover, the decreases in %normogastria were significantly larger in the group with ethanol consumption than in the group without ethanol consumption ($P = 0.018$). A multiple regression

analysis revealed, however, that none of the independent variables were significantly related to the decreases in %normogastria. In assessing the effect of the independent variables based on P value, tumor size appeared to have the strongest influence on the changes in %normogastria (Table 5).

DISCUSSION

We previously reported the influence of percutaneous local therapy for HCC on gastric myenteric activity^[10].

This is the first formal report with additional cases.

The first electrogastrogram measurement in humans was performed by Alvarez, who found that ECG waves recorded on the body surface of a middle-aged woman occurred at a rate of three cycles per minute.

This method can be used to noninvasively assess the electrical activity generated by gastric smooth muscles^[11].

Although the role of EGG in clinical gastroenterology has not yet been clearly defined and the cause of gastric dysrhythmias at the cellular level is unknown, EGGs are believed to reflect the electrical control activity and gastric motility regulated by pacemakers. In humans, these EGG waves originate from the pacemaker area along the major curvature of the stomach and propagate aborally with increasing velocity at intervals of approximately 20 s. EGGs have been shown to provide useful information for clinical diagnoses.

Abnormal gastric slow-wave frequencies have been described in disorders of gastric emptying, nausea and vomiting in pregnancy^[12], motion sickness^[13], anorexia nervosa^[14], functional dyspepsia^[15-18], and diabetic gastroparesis^[19-21].

Patients with cirrhosis of the liver frequently present with many gastrointestinal complaints that are most likely due to abnormal gastrointestinal motility.

Table 5 Clinical factors associated with decreases in the %normogastric after treatment using regression analysis

| | Regression coefficient | 95%CI | | P value | Partial regression coefficient | 95%CI | | P value |
|----------------------------|------------------------|--------|-------|---------|--------------------------------|--------|-------|---------|
| Sex (M) | -10.77 | -27.34 | 5.79 | 0.196 | -11.58 | -29.4 | 6.25 | 0.196 |
| Age(yr) | 1.05 | 0.07 | 2.04 | 0.037 | 0.73 | -0.45 | 1.91 | 0.22 |
| Ethanol (use) | 20.6 | 3.75 | 37.46 | 0.018 | 13.99 | -3.88 | 31.87 | 0.121 |
| Tumor location (left lobe) | -12.26 | -32.3 | 7.78 | 0.224 | -11.83 | -32.05 | 8.39 | 0.243 |
| Tumor size (cm) | -5.78 | -14.32 | 2.77 | 0.18 | -6.6 | -14.89 | 1.68 | 0.115 |
| RFA (use) | -0.54 | -23.04 | 21.96 | 0.962 | -5.74 | -27.61 | 16.13 | 0.598 |
| Child-Pugh (score) | -4.52 | -11.96 | 2.92 | 0.227 | -8.05 | -15.3 | -0.8 | 0.031 |

Regression analysis was performed to examine the relationship between decreases in the percentage of normogastric after treatment and the following factors: patient sex, patient age, ethanol injection, location of the treated hepatoma (right or left lobe), tumor size (diameter), use of radio frequency ablation (RFA), and the Child-Pugh score.

However, reports on the gastric myoelectrical activity in liver diseases are surprisingly scarce, with only a few papers. Caras *et al*^[22] demonstrated an abnormal electro-gastrogram in 8 of 14 (57%) patients with end-stage liver disease awaiting liver transplants. Usami *et al*^[23] found a decreased share of the power within the normogastric range relative to the total power of the entire frequency band considered in a study group comprising 32 patients with liver cirrhosis of various etiologies and stages.

Their study also confirmed that the results of EGG became less favorable as the severity of liver damage increased.

Gastrointestinal hormones may increase in liver cirrhosis owing to reduced hepatic metabolism and portosystemic shunting. Metabolic abnormalities of these peptides have been reported in patients with liver cirrhosis.

In some studies, the levels of plasma vasoactive peptides with liver cirrhosis have been shown to be higher compared with the normal population^[24,25].

It has been shown that transcatheter arterial chemo-embolization affects gastric myenteric activity and that overproduction of endogenous prostaglandin is related to dysrhythmia of the gastric myenteric activity, suggesting that prostaglandin is related to the activation of the inflammatory response, production of pain, and fever^[26].

Pain and stress may affect the stomach's electrical and mechanical activities. Therefore, it is useful to know whether the abdominal pain induced by percutaneous local therapy produces changes in gastric myoelectric activity.

In this study, multiple regression analysis revealed that tumor size was the strongest and has strong adverse effects on gastric motility.

The pathophysiology of gastric dysrhythmias induced by percutaneous local therapy in HCC patients is poorly understood.

In this study, we demonstrated that gastric myenteric activity was affected by percutaneous local therapy for HCC, even though abdominal symptoms were not apparent and the GSRS scores obtained from the questionnaire did not change significantly after therapy. Delayed gastric transit is a significant clinical matter that may

occur after percutaneous therapy for HCC. Because patients with HCC have reportedly tended to have gastrointestinal dysfunction^[27], we must monitor gastrointestinal dysfunction after percutaneous local therapy for HCC even when there no clinical symptoms are present.

We found that the percentage of normogastric during fasting was decreased after therapy, suggesting that therapy may have an adverse effect on the interdigestive migrating contractions (IMCs) of the fasting period.

IMCs occur approximately every two hours in humans. The physiological role of IMCs is thought to be the housekeeping of the gastrointestinal tract by transferring food residues and detached epithelium toward the rectum through intense contractions that migrate from the stomach to the end of the ileum^[28]. IMCs have four phases, as described by Szurszewski^[29], and there are two types of IMCs. IMCs originating in the stomach are called gastrointestinal IMCs (GI-IMCs), and those originating in the duodenum or lower tract are called intestinal IMCs (I-IMCs). Motilin, which is secreted by the duodenum and upper intestinal mucosa, triggers GI-IMC but is not involved in I-IMCs^[30]. In recent years, ghrelin and serotonin in the digestive tract have been of interest as mediators of IMCs^[31-33].

Normal gastrointestinal movement is also involved in immunity. The secretion of immunoglobulin A peaks during IMCs in the intestinal tract^[34], and a lack of housekeeping by IMCs induces bacterial overgrowth (BO)^[35]. Patients with hepatic cirrhosis are known to have prolonged oro-cecal transit times and are likely to suffer from small intestine BO^[36]. As shown in animal models, aggravated BO may allow bacterial translocation and the development of sepsis. Thus, maintaining normal gastrointestinal movement is of clinical significance in patients with hepatic cirrhosis who are susceptible to infection.

In conclusion, gastric slow-wave dysrhythmias were induced by percutaneous local therapy in HCC patients, but no significant differences were found in the calculated GSRS scores obtained from patient questionnaires collected before and after therapy. The mechanisms underlying the effect of percutaneous local therapy for HCC on extrahepatic abdominal organs require further exploration.

COMMENTS

Background

In the treatment of hepatocellular carcinoma (HCC), various percutaneous local therapies are frequently used, but they are also known to cause adverse effects on extrahepatic abdominal organs. However, the influence of percutaneous local therapy on gastric myenteric activity has not been well investigated.

Research frontiers

Because patients with HCC tend to have gastrointestinal dysfunction, we must monitor gastrointestinal dysfunction after percutaneous local therapy for HCC. In this study, the authors continuously recorded the gastric myoelectric activity by electrogastrography (EGG) and estimated the influence of percutaneous local therapy on HCC gastric function to clarify the influence of percutaneous local therapy for HCC on gastric function.

Innovations and breakthroughs

There are few published reports on the influence of percutaneous local therapy on gastric myenteric activity. To the best of the authors' knowledge, the present study was the most detailed and systematic study investigating the influence of percutaneous local therapy on gastric myoelectrical activity in patients with HCC.

Applications

Gastric slow-wave dysrhythmias were induced by percutaneous local therapy in HCC patients, even though abdominal symptoms were not apparent and the Gastrointestinal Symptom Rating Scale scores obtained from the questionnaire did not change significantly after therapy.

Terminology

EGG is a method that enables gastric electrical activity to be recorded using abdominal surface electrodes. The method has the advantages of being noninvasive, convenient, and providing considerable functional information.

Peer review

This is a very well organized and well conducted study. The results are clearly described, and the discussion and conclusions do not overstate the results.

Abstract

AIM: To investigate the therapeutic efficacy and safety of continuous autotransfusion system (CATS) during liver transplantation of hepatocellular carcinoma patients.

METHODS: Eighty-three hepatocellular carcinoma (HCC) patients who underwent liver transplantation with intraoperative CATS ($n = 24$, CATS group) and without ($n = 59$, non-CATS group) between April 2006 and November 2011 at the Liver Transplant Institute of Inonu University were analyzed retrospectively. Post-operative HCC recurrence was monitored by measuring alpha-fetoprotein (AFP) levels at 3-mo intervals and performing imaging analysis by thoracoabdominal multidetector computed tomography at 6-month intervals. Inter-group differences in recurrence and correlations

between demographic, clinical, and pathological data were assessed by ANOVA and χ^2 tests. Overall and disease-free survivals were calculated by the univariate Kaplan-Meier method.

RESULTS: Of the 83 liver transplanted HCC patients, 89.2% were male and the overall mean age was 51.3 ± 8.9 years (range: 18-69 years). The CATS and non-CATS groups showed no statistically significant differences in age, sex ratio, body mass index, underlying disease, donor type, graft-to-recipient weight ratio, Child-Pugh and Model for End-Stage Liver Disease scores, number of tumors, tumor size, AFP level, Milan and University of California San Francisco selection criteria, tumor differentiation, macrovascular invasion, median hospital stay, recurrence rate, recurrence site, or mortality rate. The mean follow-up time of the non-CATS group was 17.9 ± 12.8 mo, during which systemic metastasis and/or locoregional recurrence developed in 25.4% of the patients. The mean follow-up time for the CATS group was 25.8 ± 15.1 mo, during which systemic metastasis and/or locoregional recurrence was detected in 29.2% of the patients. There was no significant difference between the CATS and non-CATS groups in recurrence rate or site. Additionally, no significant differences existed between the groups in overall or disease-free survival.

CONCLUSION: CATS is a safe procedure and may decrease the risk of tumor recurrence in HCC patients.

INTRODUCTION

Since the first report of a successful human liver transplantation (LT) in 1963, this procedure has become the gold standard treatment for end-stage liver diseases, including acute liver failure, some metabolic liver diseases, primary liver cancers [such as hepatocellular carcinoma (HCC)], and some metastatic liver tumors^[1-3]. Despite its widespread application, intraoperative hemorrhaging remains a significant limitation of the procedure^[1,4]. The liver is directly connected to three different vascular systems, all of which may be weakened by the underlying disease's pathogenic processes. Serious collateral circulation damage can accompany chronic liver disease and parallel severity of the disease status, increasing the risk of hemorrhage during LT surgery.

Clinical studies have identified the most important factors influencing development of major hemorrhage during surgery as adhesions between cirrhotic liver and surrounding structures, impaired clotting factor synthesis, inherent hemorrhage tendency of some liver diseases, retransplantation, portal vein thrombosis, and the experience level of the involved hepatobiliary surgical team^[3,5-7]. Moreover, the extent of any hemorrhage that develops during surgery has been defined as one of the most significant factors affecting patient morbidity and mortality^[6,8]. Suitable and balanced blood replacement is vital for patients undergoing major surgery. Unfortunately, the exogenous blood transfusion methods remain inadequate for resolving major blood loss that occurs during surgery. Various intraoperative blood salvage autotransfusion systems have been developed to overcome this clinical challenge, and are based upon re-use of the patient's own blood that has accumulated at the surgical site^[4,9].

Intraoperative blood salvage autotransfusion (IBSA) systems have emerged as cost-effective intraoperative tools that reduce the blood requirement by up to 60%^[5]. However, some studies have indicated that the IBSA systems may cause cancer cell dissemination when used during cancer surgery^[5], thereby increasing a patient's risk for metastasis or recurrence. These results have not been upheld by other studies^[4] and the therapeutic efficacy and safety of IBSA systems remain to be definitely established. The IBSA system employed in our health-care institute is the continuous autotransfusion system (CATS) manufactured by Fresenius Kabi AG (Bad Homburg, Germany). To gain a better understanding of the therapeutic efficacy and safety of CATS during LT, this research study was designed to retrospectively analyze groups of HCC patients who underwent LT with and without CATS to determine postoperative rates of tumor recurrence and survival.

MATERIALS AND METHODS

Between April 2006 and November 2011, a total of 702 LTs were performed for 664 patients at the Liver Transplant Institute of Inonu University. Histopathological evaluation of the resected hepatectomy specimens revealed HCC foci of varying sizes and numbers for 17.1% (114/702) of the LT recipients. Of those, 28.1% (32/114) were considered ineligible for this study based upon insufficient follow-up data (< 3 mo; *n* = 2) and other-cause mortality within 3 mo after the LT (*n* = 29). From the remaining cohort of LT HCC patients, only those receiving primary liver transplants were selected for study inclusion. These 83 patients were then divided into two groups according to use of CATS during the LT surgery: CATS group, *n* = 24; non-CATS group, *n* = 59. The study participant selection process is outlined in Figure 1.

The following data were recorded for comparative analysis between the CATS and non-CATS groups: age, sex, body mass index (BMI; in kg/m²), underlying disease [hepatitis B virus (HBV) infection, hepatitis C virus (HCV) infection, or primary HCC], donor type (living/deceased), graft-to-recipient weight ratio (GRWR), Child-Pugh score, model for end-stage liver disease (MELD) score, number of tumors (< 10 or > 10), mean tumor size (in cm), Milan selection criteria (within/beyond), University of California San Francisco (UCSF) selection criteria (within/beyond), preoperative alpha-fetoprotein (AFP) levels (< 200 or > 200 ng/mL)^[10], tumor differentiation (good/average/poor), macrovascular invasion (positive/negative), systemic metastasis and locoregional recurrence (positive/negative), recurrence site (hepatic and/or extrahepatic), current status (alive/died), and duration of follow-up (in mo).

The LT patients had been classified according to the Milan and UCSF criteria, both of which consider the diameter and number of HCC lesions observed by pathological examination to identify individuals likely to benefit from and survive the LT procedure. Specifically, patients with a single lesion of ≤ 5 cm diameter or with three or less lesions for which the largest was ≤ 3 cm were defined as 'within' Milan criteria, whereas patients with a single lesion of ≤ 6.5 cm or with three or less nodules for which the largest was ≤ 4.5 cm and the total tumor diameter was ≤ 8 cm were defined as 'within' UCSF criteria^[2,11]. Donor type (deceased or living) was based on recommendations of the Milan group and the criteria accepted by the United Network of Organ Sharing. HCC cases within the Milan criteria (*n* = 30) were first given the chance of deceased-donor liver transplantation (DDLT; *n* = 3), whereas HCC cases beyond the Milan criteria were given living-donor liver transplantation (LDLT; *n* = 80).

In the LDLT procedure, venous drainage was facilitated by creating a wide-orifice venous drainage model using a saphenous vein graft followed by a wide-aperture anastomosis created between the wide-orifice hepatic vein and inferior vena cava. In the DDLT procedure, a hepato-caval anastomosis was created by using the standard piggyback technique. Anastomoses of other vascular

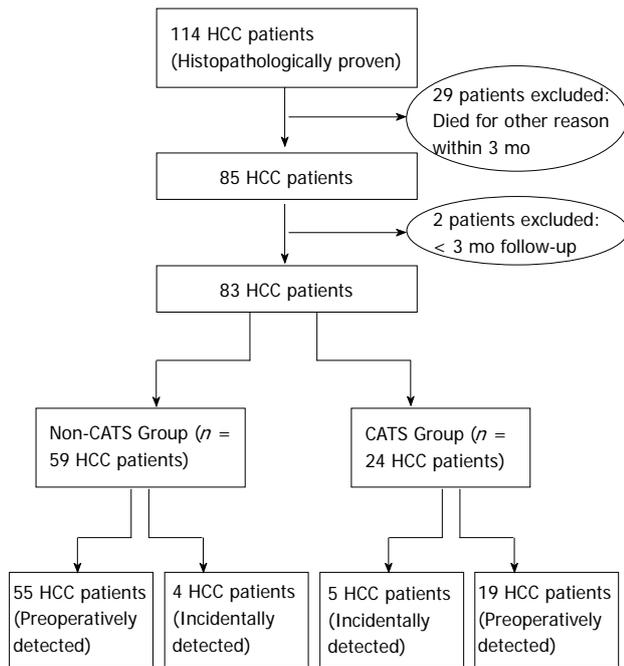

Figure 1 Flow chart showing the study selection methodology for hepatocellular carcinoma patients. HCC: Hepatocellular carcinoma; CATS: Continuous autotransfusion system.

structures and the biliary tract were created by standard techniques.

In the early postoperative period, all known HCC cases were given the immunosuppressive regimen of low-dose sirolimus, steroids, and mycophenolate mofetil. The postoperative pharmaceutical regimen for non-HCC patients who received LT for end-stage liver disease included the calcineurin inhibitor; however, nine of those patients were subsequently diagnosed with HCC by pathology and were immediately switched to sirolimus treatment.

All patients were followed-up with measurement of AFP levels at 3-mo intervals and thoracoabdominal multidetector computed tomography (MDCT) imaging at 6-mo intervals. Suspicion of tumor recurrence led to shorter interval monitoring. Sixty-nine patients with chronic liver disease showed enhanced AFP values during follow-up and were monitored by dynamic MDCT. Five additional cases of primary HCC showed enhanced AFP levels by other tests carried out for symptoms unrelated to clinical liver disease and were then monitored by dynamic MDCT. HCC recurrence was indicated when dynamic MDCT scan images showed heterogeneous contrast with the arterial phase, evidenced by hypodense or isodense regions in the normal liver parenchyma of the portal phase, and contrast enhancement extending to the capsule in the late phase. In cases of suspected HCC, ultrasonography or CT-guided biopsy was performed, depending on mass location. A total of 74 patients were diagnosed with HCC during follow-up.

HCC recurrence was diagnosed by enhanced blood AFP levels, MDCT tumor detection, and/or biopsy-detected cancer of the same cell type as the originally re-

sected HCC. Recurrence was categorized as either systemic metastasis (in a different organ system with no other identifiable cause) or locoregional (within the transplanted liver and/or perihepatic lymph node chain). Overall survival was defined as the time interval from LT to death from any cause, or to the last outpatient clinical follow-up for censored patients. Disease-free survival was defined as the time from LT to HCC recurrence or death from any cause.

Statistical analysis

Statistical analyses were performed by the SPSS software package (version 13.0; SPSS, Chicago, IL, United States). Categorical data were analyzed by the χ^2 test. Continuous data were analyzed by the ANOVA test. Overall and disease-free survivals were calculated by the univariate Kaplan-Meier method. Statistical significance was indicated by $P < 0.05$. Data are expressed as mean \pm SD errors of the mean (SEM).

RESULTS

Eighty-three HCC patients who underwent LT were analyzed. The male:female ratio was strongly biased (74:9). The mean age was 51.3 ± 8.9 years (range: 18-69). The CATS procedure was used in only 28.9% of the LT patients (CATS group, $n = 4$; non-CATS group, $n = 59$). No significant differences were identified between the two groups in terms of age, sex, BMI, underlying disease, donor type, GRWR, Child-Pugh score, MELD score, tumor count, tumor size, AFP levels, Milan criteria, UCSF criteria, tumor differentiation, macrovascular invasion, presence of recurrence, recurrence site, mortality rate, or duration of hospital stay. Clinical and demographic data of both groups are shown in Table 1. The tumor characteristics of all patients are shown in Table 2. There was no difference between the groups for disease-free ($P = 0.9$) or overall ($P = 0.06$) survival (Figure 2).

The mean follow-up time for the CATS group was 25.8 ± 15.1 mo (range: 4-53), during which systemic metastasis and/or locoregional recurrence was detected in 29.2% (7/24) of the patients. Four of these patients experienced locoregional recurrence together with distant organ metastasis. One patient developed distant organ metastasis only, and the remaining two patients developed locoregional recurrence only. The mean follow-up time of the non-CATS group was 17.9 ± 12.8 mo (range: 4-56 mo), during which systemic metastasis and/or locoregional recurrence developed in 25.4% (15/59) of the patients. Ten patients experienced locoregional recurrence together with distant organ metastasis. Two patients developed distant organ metastasis only, and the remaining three patients developed locoregional recurrence only. There was no significant difference between the CATS and non-CATS groups in recurrence rate ($P < 0.7$) or site ($P < 0.8$) (Table 2).

DISCUSSION

IBSA collects a patient's own blood accumulated at a

surgical site for re-use after aspiration, washing, filtration, and reinfusion^[9,12-15]. Following the first description of an IBSA system, the Bentley autotransfusion device, the Haemonetics Co. manufactured an IBSA-based device for washing and concentrating of erythrocytes; known as the Cell Saver (Haemonetics, Braintree, MA, United States), this system became commercially available in 1974. Nearly two decades later, the CATS was produced by the Fresenius Kabi Co. and has since been successfully applied in clinical practice.

Correlations of IBSA with postoperative complications, tumor recurrence, and mortality of patients receiving either homologous (allogenic) or autologous blood transfusion have been extensively studied, but the results have been inconsistent^[16]. Some studies have shown increased infection rates, delayed wound healing, and increased mortality, depending on the amount of blood used following homologous transfusion. Similarly, increased rates of tumor recurrence and mortality were reported for patients who underwent homologous transfusion. Further study has suggested this situation is associated with suppression of natural killer cells and cytotoxic T-cells, and activation of T-suppressor cells^[7,13,16-18]. Some studies have also demonstrated that the infectious and

non-infectious complications associated with homologous blood transfusion occur less frequently with autologous blood transfusion^[13,15,17]. The autologous transfusion strategy boasts other advantages as well, including: lower volume requirement for exogenous blood, which increases cost-effectiveness; higher oxygen-carrying capacity, which accelerates wound healing; an immunostimulant effect, which reduces tumor recurrence and increases patient survival rates^[5,7,13-15,18,19].

Although positive results have been obtained with autologous transfusion in patients undergoing tumor surgery, the possibility that tumor dissemination may be caused by the IBSA transfusion method remains a significant concern^[17,20]. This potential risk was first reported by Yaw *et al.*^[15], who demonstrated the ability of tumor cells to pass through the filter of the Bentley autotransfusion device. Subsequently, the American Medical Association designated IBSA systems as unsuitable for use in cancer surgery^[13,17]. However, this restriction was later modified by the National Institute of Clinical Excellence, which indicated that IBSA systems could be used in cancer surgery when combined with leukocyte depletion filters (LDFs)^[13,19]. Since then, the Association of Anaesthetists of Great Britain and Ireland, Obstetric Anaesthetists As-

sociation, American College of Obstetricians and Gynecologists, and British Confidential Enquiry of Maternal and Child Health, have confirmed the clinical utility and safety of various IBSA systems alone or integrated with LDF in cancer surgery.

The most comprehensive study of IBSA systems in cancer surgery was conducted as a meta-analysis of 10 published studies of 2326 prostate, liver, cervical, and gastrointestinal cancer patients^[12]. The results showed that IBSA did not constitute a risk in terms of tumor recurrence and metastasis. Yet, it has been shown in many studies that 91%-100% of tumor cells passing through the IBSA system filter reach the reinfusion bag^[1,9,13,14,16,17,19,21]; therefore, LDF should be integrated into the IBSA systems.

Catling *et al*^[17] showed that the Cell Saver filter failed to remove 91.2% of tumor cells but that integration of LDF resolved this completely. Another study of patients undergoing LT for HCC showed that the Cell Saver filter system alone removed only 25% of tumor cells, but 93.3% of tumor cells when integrated with an LDF^[1]. However, the IBSA CATS system used in our study was not integrated with LDF and was not associated with increased tumor recurrence. This difference may reflect the pore diameters of the different IBSA systems' filters; for example, the pore diameter range of the Cell Saver's filter is 20-150 μm , whereas the CATS machine's filter is 40-120 μm . The different cancer cells types examined in the different studies may also influence the finding. Cervical cancer cells generally range from 25-65 μm diameter, whereas HCC cells range from 41-55 μm . Thus, certain cancers may require different filters and IBSA systems, integrated or unintegrated, should be applied accordingly.

Most studies of IBSA systems in gastrointestinal surgery have involved the liver and emergency situations^[17]. The complicated vascular structure of the liver and the frequency of severely cirrhotic conditions necessitate highly expert surgeons to lessen the high risk of hemorrhage. Nonetheless, massive blood loss remains a common occurrence in liver tumor surgeries involving major resection, and particularly in LT^[17]. Two studies have investigated the survival rates associated with IBSA systems in patients undergoing liver resection for HCC. Fujimoto *et al*^[22] found equal cumulative overall and disease-free survival rates for patients treated with and without IBSA, and showed that the IBSA system was superior in its requirement for a lower volume of transfused blood. Hirano *et al*^[7] reported better 10-year overall and disease-free survival rates for patients treated with IBSA. These authors also showed that the overall and disease-free survival rates were better for early-stage HCC cases treated with IBSA, but no significant advantage was found when used in advanced-stage HCC cases.

A few studies have reported on IBSA systems in LT. One study by Philips *et al*^[23], in which HCC and sepsis cases had been excluded, use of the Cell Saver during LT reduced the requirement for homologous blood transfusion and was cost-effective. Similarly, Sankarankutty *et al*^[8] showed that use of the Cell Saver during LT reduced the requirement for homologous blood transfusion and lowered the risk of infection. In a study of CATS during LT performed by Massicote *et al*^[24], in which patients with preoperative infection had been excluded, the procedure reduced the requirement for homologous blood transfusion. Finally, Liang *et al*^[3] showed that the Cell Saver integrated with LDF reduced bacterial contamination rates by 90.3%. Thus, IBSA systems exhibit a reduced requirement for homologous blood transfusion, are cost-effective, and have less risk of microbiological contamination.

According to our knowledge, only three studies have investigated the effect on tumor recurrence of IBSA systems used during LC in HCC patients^[1,4,5]. Foltys *et al*^[5] reported use of the Cell Saver in 40 of 136 HCC patients

undergoing LT showed no influence on recurrence rate, overall survival, or disease-free survival during a mean follow-up period of 1015 d. In another study of the Cell Saver autotransfusion system in 31 of 47 HCC patients undergoing LT, Muscari *et al*^[4] reported no influence on recurrence rates during a mean 34-month follow-up period. Liang *et al*^[1] reported that 15 samples of blood collected in the re-infusion bag by the Cell Saver from the surgical sites of 20 HCC patients undergoing LT contained tumor cells; however, when a two-stage LDF system was used with the Cell Saver process, 14 of those samples were tumor-cell negative. In these studies, cases that were beyond the Milan and UCSF criteria and developed tumor perforation due to manipulation during surgery, the Cell Saver system was shown to be insufficient. It is, thus, presumed that the cell-holding capacity of the filters decreases due to the combined tumor load in the surgical area and that resulting from the IBSA device.

Studies in our laboratory have attempted to determine whether the IBSA system-displaced tumor cells enter systemic circulation and, if so, to what extent and whether their presence promotes metastasis. It is well established that the surgical procedure itself can passage tumor cells into the patient's systemic circulation. However, once in circulation, these tumor cells have a 0.000 001%-0.01% chance of causing metastasis^[9,17,19,20]. Therefore, cells passing into the circulation via the IBSA system are expected to have a less-than-absolute potential to cause metastases. In the current study, there was no difference in postoperative metastasis between the CATS group and the non-CATS group. This finding may reflect the fact that > 50% of the CATS group was beyond the Milan and UCSF criteria. Thus, our results indicate that cancer cells passing into the circulation did not cause metastasis.

This study has some important limitations that may have influenced the results. First, some patients' records were missing blood transfusion data, making it impossible to determine how much CATS reduced the need for homologous blood transfusion. Second, the retrospective design of the study restricted the data available for analysis. A future study of prospective design may allow for quantitative detection of tumor cells or AFP using a genetic-based procedure, such as polymerase chain reaction; in this way, blood collected from surgical sites and in the re-infusion bag can be compared to a preoperative peripheral blood sample to more directly determine whether the CATS procedure contributed to recurrence, as opposed to preexisting tumor cells in circulation.

In conclusion, our findings suggest that the use of IBSA systems during LT of HCC patients has no effect on tumor recurrence and survival.

such as liver transplantation. However, tumor cell dissemination may be caused by autotransfusion systems when used during cancer surgery.

Research frontiers

The authors examined whether the use of CATS during liver transplantation to treat hepatocellular carcinoma (HCC) affected tumor recurrence and mortality rates by retrospectively analyzing tumor development and overall and disease-free survival in 83 HCC patients who underwent liver transplantation with ($n = 24$) and without ($n = 59$) CATS.

Applications

Kaplan-Meier analysis was used to compare disease-free and overall survival associated with the CATS procedure during liver transplantation to treat HCC. There was no difference observed between the CATS and non-CATS groups in terms of disease-free or overall survival.

Terminology

Systemic metastasis was defined as metastatic cancer of the same cell type in a different organ system with no other identifiable cause. Locoregional recurrence was defined as recurrent cancer within the transplanted liver or perihepatic lymph node chain, or both. Overall survival was defined as the time interval from liver transplantation to death from any cause or to the last outpatient clinic follow-up visit in censored patients. Disease-free survival was defined as the time from liver transplantation until recurrence of tumor or death from any cause

Peer review

This article has retrogradely investigated the effects of Intraoperative blood salvage autotransfusion (IBSA) on the survival, recurrence and metastasis of hepatocellular carcinoma patients who underwent liver transplantation. Generally, the study is of interest and useful for evaluating IBSA on liver transplantation of HCC patients.

Abstract

AIM: To investigate long-term outcome in obscure gastrointestinal bleeding (OGIB) after negative capsule endoscopy (CE) and identify risk factors for rebleeding.

METHODS: A total of 113 consecutive patients underwent CE for OGIB from May 2003 to June 2010 at Seoul National University Hospital. Ninety-five patients (84.1%) with a subsequent follow-up after CE of at least 6 mo were enrolled in this study. Follow-up data were obtained from the patients' medical records. The CE images were reviewed by two board-certified gastroenterologists and consensus diagnosis was used in all cases. The primary outcome measure was the detection of rebleeding after CE, and factors associated with rebleeding were evaluated using multivariate analysis.

RESULTS: Of the 95 enrolled patients (median age 61 years, range 17-85 years), 62 patients (65.3%) were male. The median duration of follow-up was 23.7 mo (range 6.0-89.4 mo). Seventy-three patients (76.8%) underwent CE for obscure-overt bleeding. Complete examination of the small bowel was achieved in 77 cases (81.1%). Significant lesions were found in 38 patients (40.0%). The overall rebleeding rate was 28.4%. The rebleeding rate was higher in patients with positive CE (36.8%) than in those with negative CE (22.8%). However, there was no significant difference in cumulative rebleeding rates between the two groups (log rank test; $P = 0.205$). Anticoagulation after CE examination was an independent risk factor for rebleeding (hazard ratio, 5.019; 95%CI, 1.560-16.145; $P = 0.007$), regardless of CE results.

CONCLUSION: Patients with OGIB and negative CE have a potential risk of rebleeding. Therefore, close observation is required and alternative modalities should be considered in suspicious cases.

Long-term outcome in patients with obscure gastrointestinal bleeding after negative capsule endoscopy. *World J Gastroenterol* 2013; 19(10): 1632-1638 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1632.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1632>

INTRODUCTION

Obscure gastrointestinal bleeding (OGIB) represent about 5% of all gastrointestinal (GI) hemorrhage and is defined

as recurrent or persistent bleeding or iron-deficiency anemia originating from the GI tract, with negative results from upper and lower endoscopy^[1,2]. It has been reported that small-bowel hemorrhage is the most common cause for OGIB^[3]. However, the difficulty in establishing a diagnosis in patients suspected of having small-bowel hemorrhage has made assessment of OGIB problematic, and diagnosis is often delayed. Recently, there have been advances in the identification of small-bowel hemorrhage using capsule endoscopy (CE) or balloon-assisted endoscopy.

CE is useful in the detection of the cause of small-bowel hemorrhage, and CE has a higher diagnostic yield than other diagnostic modalities^[4-7]. In addition, CE has advantages over balloon-assisted endoscopy, in that CE allows observation of the whole small bowel and identification of the bleeding foci^[8]. Furthermore, CE allows non-invasive viewing of the whole small-bowel mucosa. Most investigators, therefore, agree that CE should be the initial form of investigation for OGIB^[3].

Several studies have evaluated the clinical implications of negative CE results over the long-term. However, there are contradictory findings regarding long-term outcome in patients with OGIB and negative CE results^[9-11]. In addition, most of these studies comprise small numbers of patients and have short-term follow-up. Furthermore, it has been reported that significant small-bowel pathology may be missed during CE examinations, but can be subsequently diagnosed using alternative diagnostic tools including double-balloon enteroscopy (DBE)^[12,13]. On the basis of these results, establishment of long-term clinical outcomes in patients with OGIB and negative CE remains unknown.

The aim of this study was to investigate the long-term outcomes in patients with OGIB and negative CE results and to identify the risk factors that are associated with rebleeding.

MATERIALS AND METHODS

Patients and study design

Between May 2003 and June 2010, a total of 113 consecutive patients at Seoul National University Hospital that had OGIB underwent CE to identify the cause of bleeding. Among those, long-term follow-up (> 6 mo) data were available for 95 (84.1%) patients. OGIB was defined as either obscure-overt (presented as melena or hematochezia) or obscure-occult (iron-deficiency anemia with or without positive fecal occult blood) GI bleeding. Patient enrollment required one or more non-diagnostic esophagogastroduodenoscopy and colonoscopy examinations prior to CE. Clinical information and follow-up data were obtained from the patients' medical records. The data included age, sex, comorbidity, anticoagulant use, aspirin use, nonsteroidal anti-inflammatory drugs (NSAIDs) use, hemoglobin level, and type of treatment for bleeding. This study was approved by the Institutional Review Board of Seoul National University Hospital.

CE and outcome measurement

CE was performed with the PillCam SB (Given Imaging, Yoqneam, Israel) or MiroCam (IntroMedic, Seoul, South Korea) CE system. After 12 h fasting, the capsule was taken by the patients. According to our unit's protocol, bowel preparation was not performed. Patients were allowed to drink water 2 h after swallowing the capsule and to have a light meal 4 h later. The recorder was stopped at about 8 h or 12 h after swallowing the PillCam SB or MiroCam. Patients were advised to keep away from magnetic exposure until capsule excretion.

The CE images were reviewed by two board-certified gastroenterologists; consensus diagnosis was used in all cases. Inter-observer agreement was > 95%. The videos were read at a speed of 15 frames/s.

According to standard practice guidelines, CE findings were categorized into three types: lesions considered to have a high potential for OGIB (P2); lesions with uncertain bleeding potential (P1); and lesions with no bleeding potential (P0)^[14,15]. Positive studies were defined as examinations that identified one or more P2 lesions, whereas those that identified only P1 or no abnormal lesions were regarded as negative results. Further evaluations such as abdominal computed tomography (CT), small-bowel follow-through, bleeding scan, or conventional angiography were performed in patients with persistent overt GI bleeding. However, because it was only introduced in our institution in September 2009, balloon-assisted endoscopy was only performed in four patients who had positive CE findings. Patients who showed minor OGIB without recurrence were carefully observed without further evaluation.

Each patient's subsequent management was decided according to their CE results and clinical conditions. Specific treatment was performed in patients with identifiable causes on CE or with persistent overt bleeding, which included endoscopic, angiographic or surgical hemostasis; discontinuation of anticoagulants, nonsteroidal anti-inflammatory drugs, aspirin, or other antiplatelet agents; steroids for patients with Crohn's disease; and anti-tuberculosis medication for patients with tuberculosis enterocolitis. Red blood cell (RBC) transfusion, iron supplementation, or watchful waiting, which were classified as non-specific treatments, were performed in patients with negative CE after minor OGIB.

The primary outcome measure was the detection of rebleeding after CE. Rebleeding was defined as evidence of GI bleeding at least 30 d after the initial bleeding. Evidence of GI bleeding was defined as overt bleeding (melena or hematochezia) or a fall in hemoglobin value of ≥ 2 g/dL compared with the baseline value, and in the absence of other causes of decline in hemoglobin level^[10]. Secondary outcome measures were the rate of transfusion and subsequent hospitalization after CE.

Statistical analysis

Univariate analyses were performed using Student's *t* test for continuous variables and the χ^2 or Fisher's exact tests

Table 1 Clinical characteristics of patients with obscure gastrointestinal bleeding *n* (%)

| Characteristics | Total (<i>n</i> = 95) |
|---|------------------------|
| Age (yr), median (range) | 61.0 (17-85) |
| Male | 62 (65.3) |
| Obscure-overt bleeding | 73 (76.8) |
| Complete small-bowel visualization | 77 (81.1) |
| Comorbidity | 43 (45.3) |
| Hemoglobin concentration at the time of the procedure (g/dL), mean \pm SD | 8.3 \pm 2.0 |
| Need for transfusion before capsule endoscopy | 50 (52.6) |
| Diagnostic yield | 38 (40.0) |
| Follow-up duration (mo), median (range) | 23.7 (6.0-89.4) |
| > 12 mo follow-up | 73 (76.8) |
| Aspirin use | 23 (24.2) |
| Other antiplatelet agent | 13 (13.7) |
| Anticoagulation | 8 (8.4) |
| Nonsteroidal anti-inflammatory drugs | 10 (10.5) |

for categorical variables. A Kaplan-Meier curve with a log rank test was used to analyze the cumulative rebleeding rates. Multivariate analysis was done by using the Cox proportional hazards model to identify the risk factors associated with rebleeding. Statistical significance was determined using a *P* value < 0.05. All analyses were carried out using SPSS for Windows version 12.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Patient characteristics

Ninety-five patients who had undergone CE, with subsequent follow-up of > 6 mo within the defined period were studied. The baseline characteristics of the patients are summarized in Table 1. The median age was 61.0 years (range 17-85 years) and 62 patients (65.3%) were men. Seventy-three (76.8%) underwent CE for obscure-overt GI bleeding. Complete small-bowel visualization was achieved in 77 patients (81.1%). The median follow-up period was 23.7 (range 6.0-89.4) mo after CE. The majority of patients had undergone additional diagnostic workup, which included abdominal CT (61.1%, 58/95), small-bowel follow-through (21.1%, 20/95), RBC scan (14.7%, 14/95), and conventional angiography (9.5%, 9/95).

CE findings

The CE results are summarized in Table 2. Thirty-eight (40.0%) patients had a significant abnormality that showed as one or more P2 lesions. These included erosion or ulcer (21.1%, 8/38), angiodysplasia (26.3%, 10/38), inflammatory bowel disease (IBD) including tuberculosis enteritis (23.7%, 9/38), small-bowel tumors (5.3%, 2/38), and active bleeding of unknown origin (23.7%, 9/38). There was no significant difference in the prevalence of positive findings according to the initial manifestation (*P* = 0.921), with 29 of 73 patients with overt GI bleeding showing a positive CE result (39.7%), compared to 9 of

Table 2 Capsule endoscopy results of patients with obscure gastrointestinal bleeding and rebleeding rates *n* (%)

| Findings | Total (<i>n</i> = 95) | Specific treatment | Re-bleeding |
|--------------------------------------|------------------------|--------------------|-------------|
| P2 lesion | 38 | 24 (63.2) | 14 (36.8) |
| Ulcer or erosion | 8 | 6 (75.0) | 3 (37.5) |
| Tumor | 2 | 2 (100) | 0 (0) |
| Angiodysplasia | 10 | 3 (30.0) | 4 (40.0) |

IBD: Inflammatory bowel disease.

22 patients with occult bleeding showing a positive CE result (40.5%).

Clinical course and management after CE

Of the 38 patients with positive CE results, 24 received specific treatments. Conservative management such as iron replacement, watchful waiting, or blood transfusion was performed in 14 patients. Of the 10 patients with angiodysplasia, argon plasma coagulation (APC) was performed in three. The rebleeding rate was higher in patients treated with APC (66.7%, 2/3) than in those undergoing conservative management (28.6%, 2/7). In eight patients with small-bowel ulcer or erosion, one patient with multiple ulcers was considered to have involvement of myeloproliferative disease, which was treated with systemic chemotherapy. Five patients discontinued NSAID use. Two patients with small-bowel tumor underwent surgical resection; their tumors were histologically diagnosed as GI stromal tumor and an inflammatory fibroid polyp, respectively. Of the nine patients classified in the IBD group, including Crohn's disease and tuberculosis enterocolitis, all were treated with steroids or anti-tuberculosis medication. Of the four patients who had active bleeding without identifiable cause, one was treated with explorative laparotomy and diagnosed with radiation enterocolitis. One patient was confirmed with Crohn's disease after performing balloon-assisted endoscopy. One patient was also confirmed with early stage Crohn's disease that involved the terminal ileum and cecum, after performing colonoscopy and biopsy. Finally, one patient was diagnosed with angiodysplasia of the duodenum and treated with APC.

Of the 51 patients with negative CE, rebleeding was identified in 12, and nine of these patients underwent additional evaluation for recurrent overt GI bleeding. The evaluation included abdominal CT, small-bowel follow-through, RBC scan, Meckel's scan, and explorative laparotomy. Despite these examinations, the focus of significant bleeding was not detected in six patients. However,

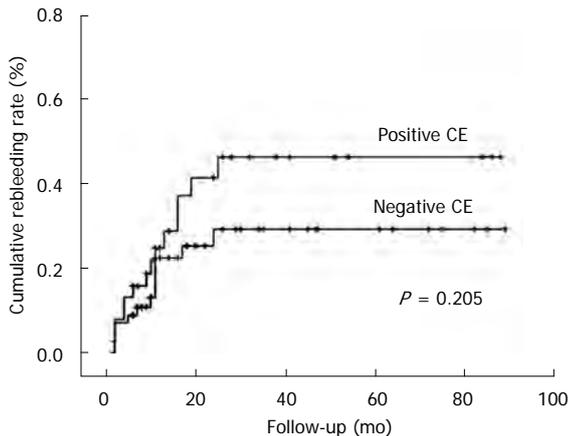

Figure 1 Cumulative rebleeding rates according to the initial capsule endoscopy results. CE: Capsule endoscopy.

significant small-bowel lesions were detected in three patients. In one of these, a bleeding diverticulum arising from distal ileum was identified on CT angiography and treated with angiographic embolization. In another, an ulcer was identified in the distal ileum using small-bowel follow-through. That lesion was confirmed with extranodal marginal zone lymphoma after explorative laparotomy. In the last case, jejunal angiodysplasia was identified as the focus of the recurrent bleeding through explorative laparotomy with intraoperative enteroscopy. The remaining three patients who showed recurrent occult bleeding and had negative CE results received symptomatic treatment including iron replacement.

Subsequent risk for rebleeding and long-term outcome in patients with OGIB

The rebleeding rates in the CE results are summarized in Table 2. Of the 95 patients, 27 (28.4%) showed one or more rebleeding events during follow-up. The median time to rebleeding was 10.0 mo (range 1.0-25.0 mo). The rebleeding rate in patients with positive and negative CE was 36.8% and 22.8%, respectively. There was no significant difference in rebleeding between these two groups ($P = 0.205$, log rank test; Figure 1). In addition, there was no significant difference in the cumulative rebleeding rates between P1 and P0 lesion groups ($P = 0.711$, log rank test). Subsequent hospitalization for bleeding was required in five patients (13.2%) in the CE-positive group compared to seven (12.3%) in the CE-negative group ($P = 1.000$). Subsequent blood transfusions were given in three (7.9%) *vs* six (10.5%) patients, respectively ($P = 1.000$).

On the basis of multivariable analysis *via* the Cox proportional hazards analysis, anticoagulation therapy was independently associated with an increased risk of rebleeding [hazard ratio (HR), 5.019; 95%CI, 1.560-16.145; $P = 0.007$]. However, negative CE and specific treatment were not associated with a decreased risk of rebleeding (Table 3). To identify the risk factors for rebleeding in patients with negative CE, we performed subgroup analysis.

Anticoagulation therapy was identified as an independent risk factor for rebleeding in patients with negative CE (HR, 7.069; 95% CI: 1.942-29.809; $P = 0.004$).

DISCUSSION

CE is a safe and effective tool in evaluating small-bowel disease. It is generally accepted as the first diagnostic choice for patients with OGIB^[3]. It provides a higher diagnostic yield compared to other modalities because of its improved visualization. However, there are several limitations of CE reported in evaluations of small-bowel pathology. These include a limited visual field of the bowel lumen, poor bowel preparation, inadequate luminal distension, rapid passage around the proximal small bowel, and incomplete study of the cecum^[16,17]. Therefore, it is plausible that CE can miss significant lesions; a risk which could translate into poor prognosis in patients with OGIB in the long term. Although there have been many reports determining the clinical impact of negative CE, the long-term risk of recurrent bleeding in patients with OGIB after negative CE remains controversial. According to a prospective analysis comparing CE with intraoperative endoscopy as the standard of reference, the negative predictive value (NPV) for CE was 86%^[18]. Delvaux *et al*^[19], in a 12-mo follow-up study, reported that the NPV was 100% in patients with normal findings on CE. In addition, several studies have reported that patients with OGIB and negative CE results have very low rebleeding rates^[9,10,20,21]. Therefore, it has been generally accepted that a negative CE result predicts a favorable prognosis in patients with OGIB. However, a well-designed prospective study reported that the rebleeding rate during 1-year follow-up was 33% in patients with normal CE findings^[22]. Moreover, a retrospective study demonstrated that there was no significant difference in the cumulative rebleeding rates between patients with positive CE and those with negative CE^[11]. The present study demonstrated that the overall rebleeding rates in patients with positive and negative CE results during the minimum 6 mo follow-up period were 36.8% and 22.8%, respectively. There was no significant difference in the cumulative rebleeding rates between these two groups. In addition, multivariate analysis showed that CE results were not associated with a risk of rebleeding. Therefore, our results indicate that the risk for recurrent bleeding is considerable, even if patients with OGIB have negative CE results.

According to the current recommendations for OGIB from the American Gastroenterological Association, subsequent intervention directed by CE findings is recommended in patients with positive CE results. Moreover, further diagnostic testing can be deferred in patients with negative CE, and balloon-assisted endoscopy is considered only in patients with a high suspicion of small-bowel pathology. However, little information is available on the duration of follow-up. The duration of follow-up in previous studies, which found very low rebleeding rates,

Table 3 Risk factors for rebleeding in patients with obscure gastrointestinal bleeding

| Variables | Hazard ratio | 95%CI | P value |
|------------------------|--------------|--------------|---------|
| Male | 2.082 | 0.882-4.910 | 0.094 |
| Age > 50 yr | 0.980 | 0.328-2.922 | 0.971 |
| Hb < 8 g/dL | 0.861 | 0.365-2.029 | 0.732 |
| Transfusion before CE | 1.719 | 0.674-4.382 | 0.257 |
| Comorbidity | 1.619 | 0.661-3.969 | 0.292 |
| Aspirin use | 1.020 | 0.357-2.914 | 0.970 |
| Anticoagulation use | 5.019 | 1.560-16.145 | 0.007 |
| NSAIDs use | 1.153 | 0.314-4.232 | 0.830 |
| Obscure-overt bleeding | 1.143 | 0.382-3.416 | 0.811 |
| Specific treatment | 1.123 | 0.368-3.422 | 0.839 |
| Positive CE | 1.564 | 0.561-4.355 | 0.392 |

NSAIDs: Nonsteroidal anti-inflammatory drugs; CE: Capsule endoscopy.

was only 12 mo^[19,21]. However, increased rebleeding rates have been reported with longer follow-up periods in recent studies^[9,10]. In the present study, approximately 50% of the patients showed a first rebleeding episode > 1 year after the initial bleeding, while the maximum time to rebleeding was 24 mo after a negative CE result. Moreover, Park *et al*^[11] reported a rebleeding rate of 35.7% during 32 mo follow-up. On the basis of these results, a close follow-up duration of at least 2 years is needed in patients with OGIB, even if patients have negative CE findings (Table 4).

CE can improve the diagnostic yield in patients with OGIB, but it remains uncertain whether CE improves clinical outcomes. A recent, prospective, randomized control trial demonstrated that a substantial improvement in diagnostic yield with the use of CE did not lead to improved outcome in patients with OGIB^[22]. In addition, a recent study showed that positive CE results are not predictive of a favorable outcome in patients with iron-deficiency anemia^[23]. On that basis, treatment directed by CE may not improve long-term outcome in patients with OGIB. In contrast, Park *et al*^[11] demonstrated that specific treatments decrease long-term rebleeding after CE, suggesting that vigorous investigation to detect the bleeding focus could definitely reduce the rebleeding. In addition to this, Delvaux *et al*^[19] also showed that only one among 18 patients who were treated directed by CE relapsed during 1 year follow-up. In the present study, a significant proportion (63.2%) of patients with positive CE results had specific treatment. Higher rebleeding rate was found in patients with angiodysplasia and IBD, while patients with tumors exhibited no rebleeding after surgical intervention. There was no significant difference in the cumulative rebleeding rates regardless of specific treatment. In addition, multivariate analysis showed that specific treatment did not reduce the risk of rebleeding. These results suggest that CE plays a limited role in clinical outcome among patients with OGIB. However, these results should be interpreted with caution because our data were retrospectively obtained from a single tertiary referral hospital. Outcomes in patients with OGIB

Table 4 Follow-up duration and rebleeding rates in patients with obscure gastrointestinal bleeding after negative capsule endoscopy

| Study | No. of enrolled cases | Follow-up duration (mo) | Rebleeding rates after negative capsule endoscopy |
|--|-----------------------|-------------------------|---|
| Lai <i>et al</i> ^[9] | 49 | 12 | 6% |
| Macdonald <i>et al</i> ^[10] | 49 | 17 | 11% |
| Park <i>et al</i> ^[11] | 51 | 32 | 36% |
| Delvaux <i>et al</i> ^[19] | 44 | 12 | 0% |
| Lorenceanu-Savale <i>et al</i> ^[21] | 35 | 12 | 0% |
| Current study | 51 | 23 | 23% |

are likely attributable to various etiologies and to the severity of initial presentation. Moreover, the natural history of etiology such as angiodysplasia remains unclear. Therefore, prospective, well-designed, long-term follow-up studies that include the various etiologies of OGIB are required to determine whether diagnostic testing with CE will translate into a significant improvement in the management and outcome in patients with OGIB.

There are no clear guidelines for evaluating patients with initially negative CE results. The management of these patients with OGIB remains elusive. However, patients with evidence of ongoing or recurrent OGIB need further investigation. The options include repeat upper and lower endoscopy, CE, DBE, radiology or nuclear medicine, and intraoperative enteroscopy^[24]. In a recent study, patients with initial negative CE results benefited from a second-look CE if the bleeding presentation changed from occult to overt, or if hemoglobin decreased by ≥ 4 g/dL^[25]. In addition to this, DBE could be useful in evaluating patients with negative CE results because it has a diagnostic yield similar to that of CE^[26]. Furthermore, it has great advantages in providing histological confirmation and simultaneous treatment^[27]. Therefore, well-designed prospective studies are required to improve the management in OGIB patients with a nondiagnostic CE test.

Our study had a few limitations. First, the data were obtained from a single tertiary referral hospital and the study was of retrospective design. Second, balloon-assisted endoscopy was not performed in most of the patients. Therefore, the possibility exists that a less-invasive approach might have led to higher rebleeding rates in both groups. Finally, it is possible that some lesions may have been missed because our data included incomplete CE results.

In conclusion, patients with OGIB and negative CE have a potential risk of rebleeding. Therefore, close observation is needed even in patients with negative CE and alternative modalities should be considered in clinically suspicious cases.

COMMENTS

Background

Obscure gastrointestinal bleeding (OGIB) represent about 5% of all gastrointestinal hemorrhage and is defined as recurrent or persistent bleeding or iron-deficiency anemia originating from the gastrointestinal tract, with negative results from upper and lower endoscopy. Capsule endoscopy (CE) is useful for detection of the cause of small-bowel hemorrhage, and has a higher diagnostic yield than other diagnostic modalities.

Research frontiers

Wireless CE is considered a first-line investigation in patients with OGIB. However, a significant proportion of patients with OGIB have nondiagnostic CE results. Although many studies have investigated the diagnostic yield of CE, little information is available about long-term outcome in patients after negative CE. In addition, it remains uncertain whether treatment directed by CE improves long-term outcome in patients with OGIB.

Innovations and breakthroughs

This study showed that the rebleeding rate in patients with OGIB after negative CE results was substantial. Treatment directed by CE did not reduce the risk of rebleeding.

Applications

The study showed that negative CE did not predict a favorable outcome, which suggests that close observation for rebleeding is warranted.

Peer review

The authors have reported that patients with OGIB and negative CE have a potential risk of rebleeding. Treatments directed by CE were not associated with a decreased risk of rebleeding. The data provided in this study contribute to understanding the long-term outcome in patients with OGIB.

Abstract

AIM: To evaluate long-term outcomes and prognostic factors for esophageal squamous cell carcinoma (SCC) treated with three dimensional conformal radiotherapy (3D-CRT).

METHODS: Between January 2005 and December 2006, 153 patients (120 males, 33 females) with pathologically confirmed esophageal SCC and treated with 3D-CRT in Cancer Hospital of Shantou University were included in this retrospective analysis. Median age was 60 years (range: 37-84 years). The proportion of tumor location was as follows: upper thorax (including the cervical region), 73 (48%); middle thorax, 73 (48%); lower thorax, 7 (5%), respectively. The median radiation dose was 64 Gy (range: 50-74 Gy). Fifty four cases (35%) received cisplatin-based concurrent chemotherapy. Univariate and multivariate analysis were performed to determine the association between the correlative factors and prognosis.

RESULTS: The five-year overall survival rate was 26.3%, with a median follow-up of 49 mo (range: 3-66 mo) for patients who were still alive. On univariate analysis, lesion location, lesion length by barium esophagogram, computed tomography imaging characteristics including Y diameter (anterior-posterior, AP, extent of tumor), gross tumor volume of primary lesion (GTV-E), volume of positive lymph nodes (GTV-LN), and the total target volume (GTV-T = GTV-E + GTV-LN) were prognostic for overall survival. By multivariate analysis, only the Y diameter [hazard ratio (HR) 2.219, 95%CI 1.141-4.316, $P = 0.019$] and the GTV-T (HR 1.372, 95%CI 1.044-1.803, $P = 0.023$) were independent prognostic factors for survival.

CONCLUSION: The overall survival of esophageal carcinoma patients undergoing 3D-CRT was promising. The best predictors for survival were GTV-T and Y diameter.

Long-term outcomes and prognostic factors for patients with esophageal cancer following radiotherapy. *World J Gastroenterol* 2013; 19(10): 1639-1644 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1639.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1639>

INTRODUCTION

In the Radiation Therapy and Oncology Group (RTOG) 85-01 trial, patients with locally advanced, unresectable esophageal carcinoma (EC) were randomized to receive either chemoradiation or radiation alone. Those patients

receiving chemoradiotherapy had a 26% 5-year survival rate compared with 0% in those treated with radiotherapy alone^[1]. Since the results of this study were reported, concurrent chemoradiotherapy has become a widely accepted standard treatment for patients with EC who are treated with non-surgical methods. However, not all the patients are good candidates for chemoradiotherapy due to the presence of multiple co-morbid medical conditions. The outcomes and factors that predict overall survival in patients treated with radiotherapy alone should also be considered in the management of esophageal cancer. The development of three-dimensional conformal radiotherapy (3D-CRT) and other advanced radiotherapy techniques has allowed clinicians to treat patients with increased accuracy and normal tissue sparing capabilities. These advantages may allow for the safe delivery of higher radiation doses compared with historic radiotherapy approaches^[2-5].

To our knowledge, this study was the largest single institution experience to report the long-term survival for esophageal squamous cell carcinoma (SCC) in patients treated with 3D-CRT with or without chemotherapy in English.

MATERIALS AND METHODS

Patient selection

Patients with non-metastatic and pathologically confirmed SCC who received definitive 3D-CRT, with or without chemotherapy, in the Department of Radiation Oncology, Cancer Hospital of Shantou University Medical College (SUMC) between Jan 2005 and December 2006 were enrolled in the study. Patients were treated with definitive chemoradiotherapy because the disease was not amenable to resection, patients had multiple medical co-morbidities that would preclude surgery, or the patient declined surgery. Patients were treated with radiotherapy alone if other co-morbid medical conditions precluded them from receiving concurrent chemotherapy or the patient declined chemotherapy.

Treatment

The gross tumor volume (GTV) was identified using both diagnostic and radiotherapy planning computed tomography (CT) images and barium swallow examination. The clinical target volume (CTV) was then expanded from the GTV with a margin of 1.0 cm laterally and a 2 cm margin in the superior and inferior dimensions. An additional 0.5 cm margin expansion around the CTV was included for the planning target volume. For treatment planning purposes, lung V_{20} 30%-35% and spinal cord maximum dose < 45 Gy were used as dose constraints. All 153 patients were treated using 3D-CRT to a median dose 64 Gy (range: 50-74 Gy) in 25 to 37 fractions. Of these, 137 patients received conventionally fractionated radiotherapy at 2 Gy per fraction, five times a week throughout the treatment course, while 16 patients received an accelerated course of treatment in which the

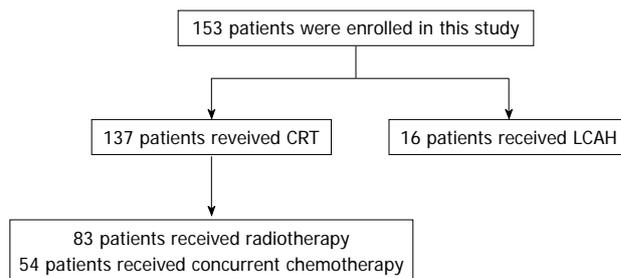

Figure 1 Patient flow chart of treatment allocation. CRT: Conventionally fractionated radiotherapy; LCAH: Late course accelerated hyperfractionated radiotherapy.

first 40 Gy was conventionally fractionated and the latter course was treated with accelerated hyperfractionated radiotherapy consisting of 24 Gy given 1.5 Gy *bid*, to a total dose of 64 Gy. All fractions were delivered at least 6 h apart. Fifty four patients (35.3%) received cisplatin-based concurrent chemotherapy. The treatment allocation was showed in a patient flow chart (Figure 1).

Clinical variables for prognostic analysis

General clinical features included gender, age, lesion location, late course accelerated hyperfractionation, chemotherapy and radiation dose. Imaging parameters included the lesion length, as defined by esophageal barium swallow; and lesion characteristics on CT imaging, such as the largest diameter, X diameter (maximum lateral extent of tumor) and Y diameter (anterior-posterior, AP, extent of tumor); esophageal wall thickness (maximum thickness of esophageal wall if the esophageal lumen is visible or half of the largest diameter with invisible esophageal lumen); lesion length; invasion to adjacent structures (including thoracic aorta, bronchus, trachea, pericardia); supraclavicular lymph nodes metastasis; number of positive lymph nodes; volume of the primary lesion (GTV-E); the volume of positive lymph nodes (GTV-LN); and the total gross tumor volume ($GTV-T = GTV-E + GTV-LN$).

Statistical analysis

Survival curves were generated using the Kaplan-Meier method with mortality data being estimated from first day of radiotherapy until date of death or date of last follow-up. The log-rank test was used to compare the survival curves. A univariate analysis was performed to identify factors for the multivariable model. A multivariate Cox-regression analysis was then performed incorporating significant univariate factors to determine the relevant prognostic factors. Results were reported using hazard ratios (HRs) and 95% CIs. All analyses were performed with SPSS (version 19.0; Chicago, IL). All reported *P* values were 2-sided with a value < 0.05 considered statistically significant.

RESULTS

Between January 2005 and December 2006, there were

Table 1 Radiographic tumor characteristics

| Characteristic | mean \pm SD | Range |
|--|-----------------|-----------|
| Length of lesion in barium esophagogram (cm) | 5.8 \pm 2.3 | 1.6-12.8 |
| Largest diameter (cm) | 3.4 \pm 1.0 | 1.5-6.0 |
| X dimension (cm) | 3.2 \pm 1.0 | 1.2-5.9 |
| Y dimension (cm) | 2.5 \pm 0.6 | 1.2-4.4 |
| Esophageal wall thickness (cm) | 1.5 \pm 0.6 | 0.5-4.2 |
| Length of lesion in CT (cm) | 6.6 \pm 2.2 | 2.4-16.0 |
| GTV-E (cm ³) | 31.8 \pm 20.7 | 3.4-114.3 |
| GTV-LN (cm ³) | 4.3 \pm 10.6 | 0-78.8 |
| GTV-T (cm ³) | 36.1 \pm 23.8 | 3.4-124.0 |

GTV-E: Gross tumor volume of primary lesion; GTV-LN: Volume of positive lymph nodes; GTV-T: Total gross tumor volume.

637 patients with EC that were prospectively registered in the Department of Radiation Oncology, Cancer Hospital of SUMC. One hundred and fifty three of these patients met the enrollment criteria. There were 120 males and 33 females, with a median age of 60 years (range: 37-84 years). The number of patients with primary tumor location in upper (including neck), middle and lower thorax was 73 (48%), 73 (48%) and 7 (5%), respectively. Of these patients, 57.5% had invasion to adjacent structures and 64.1% were found with positive regional lymph nodes metastases. Table 1 summarized the radiographic tumor characteristic of 153 patients.

Survival

For the 153 patients included in this study, the median follow up time was 49 mo (range: 3-66 mo) for the 47 living patients. The 1-, 3- and 5-year overall survival (OS) rates were 72.5%, 34.7% and 26.3%, respectively. The 1-, 3- and 5-year OS rates for the 99 patients that were treated with radiotherapy alone were 69.9%, 34.3% and 26.5%, respectively, and for the 54 patients treated with chemoradiotherapy, the 1-, 3-, and 5-year OS rates were 79.2%, 35.8% and 25.5%, respectively.

Predictors of overall survival

We performed an analysis to identify factors that predicted for OS for patients with EC. The results of univariate analysis and multivariate analysis are shown in Table 2. By univariate analysis, lesion location ($P = 0.011$); lesion length by barium esophagogram ($P = 0.003$); lesion characteristics by CT imaging such as the largest diameter ($P = 0.002$), X diameter ($P = 0.006$) and Y diameter of lesion ($P = 0.001$); thickness of esophageal wall ($P = 0.016$); length of lesion ($P = 0.024$); invasion to adjacent structure ($P = 0.007$); invasion of bronchus ($P = 0.046$); number of metastatic lymph nodes ($P = 0.008$); GTV-LN ($P = 0.010$); GTV-E ($P = 0.007$); and GTV-T ($P = 0.002$) were significant prognostic factors. By multivariate analysis, only the Y diameter (HR 2.219, 95%CI 1.141-4.316, $P = 0.019$) and GTV-T (HR 1.372, 95%CI 1.044-1.803, $P = 0.023$) were independent prognostic factors for survival. The survival curves with different Y diameters and GTV-T are shown in Figure 2.

Table 2 Univariate analysis for survival of patients

| Feature | Cases | Median survival (mo) | 5-yr OS | χ^2 value | P value |
|--|----------------------|----------------------|---------|----------------|--------------|
| Gender | Male | 120 | 19.2 | 24.2% | 0.896 0.344 |

DISCUSSION

EC is an uncommon malignancy in the United States and adenocarcinoma accounts for nearly 60%^[6,7]. In China, EC is endemic and the majority of cases are SCC. We retrospectively analyzed 153 cases of esophageal SCC that were treated with 3D-CRT during 2005 to 2006. The radiation was delivered by 3D-CRT in this patient cohort, which should be contrasted with the 2D conventional radiotherapy technique reported in RTOG 85-01 trial. The 1- 3- and 5-year OS rates were 72.5%, 34.7% and 26.3% respectively, which compares favorably to the results of RTOG 85-01. For the 99 patients who received 3D-CRT alone, the median survival and the 5-year OS rates were 18.4 mo and 26.5%, respectively, which was similar to previous reports from patients receiving chemoradiotherapy^[8-12].

Although the RTOG 85-01 trial reported no 5 year survivors in those patients receiving radiation alone, in this current retrospective review, a 5-year OS rate of 26.5% in those patients receiving 3D-CRT alone was observed. We hypothesize that the improvement in outcome may be a function of increased dose conformity and improved tumor targeting. These advances in 3D-CRT likely lead to decreased treatment related toxicities and reduced the potential for “marginal misses”^[2-4]. Furthermore, 35.3% of patients received chemotherapy in this study, but no significant difference in survival was found between patients with or without chemotherapy ($\chi^2 = 0.438, P = 0.508$). However, due to the limitations of this retrospective study, it is difficult to define the precise role of chemotherapy in EC treated with 3D-CRT.

Tumor length was replaced by depth of esophageal wall invasion as a staging factor in the 1987 version of the American Joint Committee on Cancer (AJCC) tumor node metastasis (TNM) staging system based on the EC registration database of Japan between 1969 and 1980, which demonstrated that depth of tumor invasion was a better predictor for 10-year survival of EC patients than the superficial extent of tumor^[13,14]. In the newly published edition of the AJCC TNM staging system, histological grading and tumor location, as well as depth

of esophageal wall invasion, are regarded as prognostic factors for both adenocarcinoma and SCC^[15,16]. Nevertheless, several previously published results proposed that tumor length was still an independent staging factor for EC other than previously mentioned prognostic factors^[17-20]. However, most, if not all of these results were based on surgery patients, which may be quite different from the outcome of non-surgical cases. Meanwhile, there were few English publications about the prognosis of EC treated with non-surgical approaches.

Many potential prognostic tumor factors achieving significance in univariate analysis were identified in our study. However, only the AP dimension (Y diameter) and GTV-T maintained significance for OS on multivariate analysis. Deep anterior-posterior invasion or large tumor size indicated poor prognosis.

Wang *et al*^[21] reported a Cox model analysis on 100 cases of EC treated with 3D-CRT which also showed similar results as our study, indicating that the GTV-T was an independent predictor for OS. Generally, larger GTV-T means heavier tumor load, increasing numbers of radioresistant hypoxic tumor cells and clonogenic cells and greater limitation of relevant organs at risk that lead to poor survival, which has been regarded as an important predictive factor for cancer in other sites such as lung, breast and head and neck.

Tumor cells tend to invade through the mucosa of the esophagus or spread longitudinally as it is a hollow tube structure. Therefore, deeper invasion through a transverse direction generally means more advanced status. Indeed, the AJCC staging system for EC classifies T staging based upon the depth of tumor invasion^[15,16]. However, transverse diameters are more reasonable predictors of the invasion of tumor especially for non-surgical patients due to the imprecise measurement of thickness of esophageal wall in CT images. Y diameter was the only independent prognostic factor in our study. Concerning the adjacent structures, trachea, bronchus and pericardia are anterior and aorta and vertebrae are posterior to the esophagus. The esophageal tumor tends to grow in other directions than anterior or posterior due to the limitation of these adjacent structures. We found Y diameter was much sma-

ller than the other two diameters (2.5 cm vs 3.2 cm or 3.4 cm). This may explain why the Y diameter becomes the most sensitive predictor to the invasion of esophageal cancer, the bigger Y diameter, the lower OS.

In addition to tumor invasion, the AJCC TNM staging system also incorporates the number of metastatic lymph nodes as an independent staging factor for EC^[15,16]. Several prior studies have confirmed the prognostic significance of lymph nodes^[22-25]. In these studies, lymph node metastases were determined pathologically while in the current study of patients treated by nonsurgical approaches, the lymph node status was determined by CT imaging. Clinical staging is never as accurate as surgical staging which likely explains why lymph node involvement in our study lost significance on multivariate analysis.

In conclusion, 3D-CRT with or without chemotherapy should be considered as a definitive treatment option for patients with inoperable esophageal SCC. Big anterior-posterior tumor dimension (Y diameter) or large tumor size predicted for worse survival which may provide additional prognostic information to the non-surgical staging system and clinical decision making for esophageal SCC.

COMMENTS

Background

Esophageal cancer is the eighth most common cancer worldwide. The incidence of this disease in the United States is relatively low and adenocarcinoma accounts for nearly 60%, while in China, esophageal cancer is endemic and the majority of cases are squamous cell cancer (SCC). Radiation therapy is the most commonly used treatment method for patients with this disease under the following conditions: (1) unresectable disease; (2) resectable disease, but with medical co-morbidities that would preclude surgery; (3) patients declined surgery. Since the report of the results of Radiation Therapy and Oncology Group (RTOG) 85-01 trial in 1999, concurrent chemoradiotherapy has become a widely accepted standard treatment for patients with esophageal carcinoma (EC) who are treated with non-surgical methods.

Research frontiers

In the RTOG 85-01 trial, patients with locally advanced, unresectable EC were randomized to receive either chemoradiation or radiation alone. Those patients receiving chemoradiotherapy had a 26% 5-year survival rate compared with 0% in those treated with radiotherapy alone. However, not all patients are good candidates for chemoradiotherapy due to the presence of multiple co-morbid medical conditions. The outcomes and factors that predict overall survival in patients treated with radiotherapy alone should also be considered in the management of esophageal cancer. Furthermore, the technique used in this report was a conventional method, whereas the development of three-dimensional conformal radiotherapy (3D-CRT) and other advanced radiotherapy techniques has allowed clinicians to treat patients with increased accuracy and normal tissue sparing capabilities. Therefore, it is meaningful to explore the outcomes and predict outcome factors of patients with the advent of modern radiation techniques.

Innovations and breakthroughs

Patients with esophageal cancer in the previous reports were mostly treated with conventional radiation techniques. This study was the largest single institution experience to report the long-term survival for SCC in patients treated with 3D-CRT with or without chemotherapy in English. The tumor node metastasis (TNM) staging system has long been used to predict the outcomes of patients with esophageal cancer after treatment. However, the current TNM staging category of esophageal cancer is wholly based on pathological findings from surgery. Hence it is inapplicable in patients treated with a non-surgical method, especially radiation therapy. Factors other than pathological findings are desperately needed to help predict outcomes or make clinical decisions. In this study, we enrolled general clinical features (including gender, age, lesion location, late course accelerated hyperfractionation, chemotherapy, radiation dose)

and imaging parameters (including the lesion length as defined by esophageal barium swallow and lesion characteristics on computed tomography imaging), (in total 22 factors) in the prediction analysis. These factors could be attained easily through general clinical examinations without surgical approaches.

Applications

The study results suggest that 3D-CRT with or without chemotherapy should be considered as a definitive treatment option for patients with inoperable esophageal SCC. Big anterior-posterior tumor dimension (Y diameter) or large tumor size predict for worse survival which may provide additional prognostic information to the non-surgical staging system and clinical decision making for esophageal SCC.

Terminology

3D-CRT is a type of modern radiation technique, in which the profile of each radiation beam is shaped to fit the profile of the target from a beam's eye view using multileaf collimator (or lead block) and a variable number of beams. This technique has allowed clinicians to treat patients with increased accuracy and normal tissue sparing capabilities and deliver a higher dose of radiation to the tumor than conventional techniques would allow. Since the start of this century, 3D-CRT has been gradually implemented in the radiation treatment of esophageal cancer.

Peer review

This is a good study in which authors evaluate long-term outcomes and prognostic factors for esophageal SCC treated with 3D-CRT. The results are interesting and suggest that the overall survival of EC patients undergoing 3D-CRT is promising.

Abstract

AIM: To investigate the performance and diagnostic accuracy of interferon-gamma (IFN- γ) for tuberculous peritonitis (TBP) by meta-analysis.

METHODS: A systematic search of English language studies was performed. We searched the following electronic databases: MEDLINE, EMBASE, Web of Science, BIOSIS, LILACS and the Cochrane Library. The Standards for Reporting Diagnostic Accuracy initiative and Quality Assessment for Studies of Diagnostic Accuracy tool were used to assess the methodological quality of the studies. Sensitivity, specificity, and other measures of the accuracy of IFN- γ concentration in the diagnosis of peritoneal effusion were pooled using random-effects models. Receiver operating characteristic (ROC) curves were applied to summarize overall test performance. Two reviewers independently judged study eligibility while screening the citations.

RESULTS: Six studies met the inclusion criteria. The

average inter-rater agreement between the two reviewers for items in the quality checklist was 0.92. Analysis of IFN- γ level for TBP diagnosis yielded a summary estimate: sensitivity, 0.93 (95%CI, 0.87-0.97); specificity, 0.99 (95%CI, 0.97-1.00); positive likelihood ratio (PLR), 41.49 (95%CI, 18.80-91.55); negative likelihood ratio (NLR), 0.11 (95%CI, 0.06-0.19); and diagnostic odds ratio (DOR), 678.02 (95%CI, 209.91-2190.09). χ^2 values of the sensitivity, specificity, PLR, NLR and DOR were 5.66 ($P = 0.3407$), 6.37 ($P = 0.2715$), 1.38 ($P = 0.9265$), 5.46 ($P = 0.3621$) and 1.42 ($P = 0.9220$), respectively. The summary receiver ROC curve was positioned near the desirable upper left corner and the maximum joint sensitivity and specificity was 0.97. The area under the curve was 0.99. The evaluation of publication bias was not significant ($P = 0.922$).

CONCLUSION: IFN- γ may be a sensitive and specific marker for the accurate diagnosis of TBP. The level of IFN- γ may contribute to the accurate differentiation of tuberculosis (TB) ascites from non-TB ascites.

Assessment by meta-analysis of interferon-gamma for the diagnosis of tuberculous peritonitis. *World J Gastroenterol* 2013; 19(10): 1645-1651 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1645.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1645>

INTRODUCTION

Tuberculous peritonitis (TBP) is a manifestation of tuberculosis (TB), which constitutes about 3% of extrapulmonary tuberculosis (EPTB) cases, and EPTB constitutes

about 15%-20% of all cases of TB in immunocompetent patients and accounts for more than 50% of cases in human immunodeficiency virus-positive individuals^[1]. TBP is one of the most common forms of EPTB and cases of TBP are expected to increase with the increasing incidence of TB worldwide^[2,3]. Early diagnosis of TBP is beneficial for anti-TB treatment, the prevention of complications, and reduction of mortality rate^[4]. However, current clinical diagnostic techniques for TBP are time-consuming and inefficient. The definitive diagnosis requires histological confirmation of caseous granulomas. As ascites is one of the clinical signs of TBP, bacteriologic confirmation can be performed using ascitic fluid-derived acid-fast bacilli smears as well as cultures for *Mycobacterium tuberculosis* (*M. tuberculosis*). However, four weeks are required for the cultivation of *M. tuberculosis*, and acid-fast bacilli smears are too insensitive to meet the current diagnostic demand^[5]. Laparoscopy-guided biopsy is advantageous for rapid TBP diagnosis, but has complications related to anesthesia and potential injury and bleeding^[6]. An evaluation of existing techniques is urgently required as is the development of new methods with high sensitivity and specificity for early and accurate TBP diagnosis.

M. tuberculosis infection initiates an immunologic cascade involving the secretion of various cytokines and recruitment of Th1 lymphocytes. With abundant cell recruitment at the morbid site, the levels of various cytokines are markedly elevated. Interferon-gamma (IFN- γ) is an important cytokine following infection with *M. tuberculosis*^[7,8]. Studies assessing the level of IFN- γ have been reported. Several studies from different parts of the world have demonstrated the efficacy of IFN- γ for the diagnosis of TB pleural and pericardial effusions^[9,10], and its diagnostic efficacy has been compared with that of adenosine deaminase (ADA) in terms of cost-effectiveness^[11]. Some studies have also evaluated the role of IFN- γ in the diagnosis of TB ascites^[12-14]. However, whether IFN- γ detection contributes to accurate TBP diagnosis remains controversial. In the present study, we systematically analyzed and assessed the overall efficacy of IFN- γ in the diagnosis of TBP *via* meta-analysis techniques.

MATERIALS AND METHODS

Search strategy and study selection

We searched the following electronic databases: MEDLINE (1980-2011); EMBASE (1980-2011); Web of Science (1990-2011); BIOSIS (1993-2011) and LILACS (1980-2011). We also reviewed the Cochrane Library to identify relevant studies. Updated searches were carried out in December 2011. The following search terms were used: "tuberculosis" "*Mycobacterium tuberculosis*" "peritonitis" "peritoneal effusion/peritoneal fluid/abdominal effusion/ascitic fluid/ascites" "interferon/IFN" "sensitivity and specificity" and "accuracy". We contacted experts in the specialty and searched the reference lists of primary and review articles. Although no language restrictions

were imposed initially, our resources only permitted the review of articles published in the English language for the full text review and final analysis. Conference abstracts and letters were excluded due to unavailable data.

A study was included when it provided both the sensitivity (true-positive rate) and specificity (false-positive rate) of IFN- γ for TBP diagnosis, or provided IFN- γ values in a dot-plot form that allowed results to be extracted for individual study subjects. Patients of any age diagnosed with TBP underwent smear or culture of *M. tuberculosis* and/or histologic observation of peritoneal tissue, as well as clinical diagnosis, such as response to anti-TB therapy. In addition, we selected studies including at least 10 TBP specimens which were eligible for inclusion in order to reduce selection bias due to a small number of participants. Two reviewers (Su SB and Jiang HX) independently judged study eligibility while screening the citations. Disagreements were resolved by consensus.

Data extraction and quality assessment

Two reviewers (Su SB and Jiang HX) checked and extracted data independently. The reviewers were blinded to publication details, and disagreements were resolved by consensus. Data retrieved from the reports included participant characteristics, assay methods, sensitivity and specificity data, cutoff values, year of publication, and methodological quality. Peritonitis IFN- γ values provided in dot plots were measured by placing scalar grids over the plots, and were analyzed by a receiver operating characteristic (ROC) curve for each study (SPSS; Chicago, IL, United States). A summary of each study, including the numbers of true-positive, false-positive, false-negative and true-negative findings, is displayed in Table 1.

We assessed the methodological quality of studies using guidelines established by the Standards for Reporting Diagnostic Accuracy (STARD)^[15] initiative and the Quality Assessment for Studies of Diagnostic Accuracy (QUADAS) tool^[16]. In addition, the following study design characteristics were retrieved: (1) cross-sectional design *vs* case-control design; (2) consecutive or random sampling of patients; (3) blind (single or double) interpretation of determination and reference standard results; and (4) prospective data collection. If primary studies did not show data that met the above criteria, we requested them from the authors. The "unknown" items were then treated as "no" if the authors did not respond.

Statistical analysis

We used standard methods recommended for meta-analyses of diagnostic test evaluations^[17]. Analyses were performed using a professional statistical software program (Meta-DiSc for Windows; XI Cochrane Colloquium; Barcelona, Spain). The following measures of test accuracy were analyzed for each study: sensitivity, specificity, positive likelihood ratio (PLR), negative likelihood ratio (NLR) and diagnostic odds ratio (DOR).

The analysis was based on a summary ROC (SROC) curve^[17]. Sensitivity and specificity as a single test thresh-

old identified for each study were used to plot an SROC curve^[18]. A random-effects model was adopted to calculate the average sensitivity, specificity, and other measures across studies^[19,20].

The term heterogeneity refers to the degree of variability in results across studies, which was used in relation to meta-analyses. We detected statistically significant heterogeneity with the χ^2 test (Fisher exact tests). To assess the effects of STARD and QUADAS scores on the diagnostic ability of IFN- γ , we included them as covariates in univariate meta-regression analysis (inverse variance weighted). We also analyzed the effects of other covariates on DOR, such as cross-sectional design, consecutive or random sampling of patients, single or double interpretation of determination, reference standard results, and prospective data collection. The relative DOR (RDOR) was calculated according to standard methods to analyze the change in diagnostic precision in the study per unit increase in the covariate^[21,22]. Since publication bias is of concern for meta-analyses of diagnostic studies, we tested for the potential presence of this bias with funnel plots and the Egger test^[23].

RESULTS

Selection and summary of studies

Eleven out of 25 publications dealing with peritonitis IFN- γ concentration for TBP diagnosis were considered to be eligible for inclusion in the meta-analysis^[10,12-14,24-30]. Among these publications, five studies^[10,24-27] were excluded because IFN- γ was detected only in peritoneal dialysis patients^[27], there was no detailed data^[25] and the

number of participants was 10 or less^[10,24,26] (Figure 1). Finally, 6 studies^[12-14,28-30] including 131 TBP patients and 309 non-TBP patients were available for analysis, and the clinical characteristics of these studies, along with QUADAS scores, are outlined in Table 1.

Quality of reporting and study characteristics

The average inter-rater agreement between the two reviewers for items in the quality checklist was 0.92. All studies (100%) were collected from consecutive patients. The average sample size was 69 (range, 41-119) in the included studies. In four studies^[12,13,28,30], a small proportion of the patients received the diagnosis according to clinical presentation, peritoneal effusion analysis, radiology findings and responsiveness of the patient to anti-TB chemotherapy. However, the diagnosis of peritoneal TB was confirmed in most of the TBP patients based on the conventional "gold standard" which was a smear or a positive *M. tuberculosis* culture which was taken from ascitic fluid and/or histology showing a caseating granuloma. In two studies^[14,29], all patients were diagnosed with TBP based on a smear or culture that was positive for *M. tuberculosis* and had been taken from ascitic fluid and/or histology showing a caseating granuloma. All studies (100%) which reported that the study design was prospective could be identified (Table 2). Two studies (33.3%) reported blinded interpretation of the IFN- γ assay independent of the reference standard.

Diagnostic accuracy

The sensitivity and specificity of 6 IFN- γ assays for the diagnosis of TBP are shown in the forest plot (Figure 2).

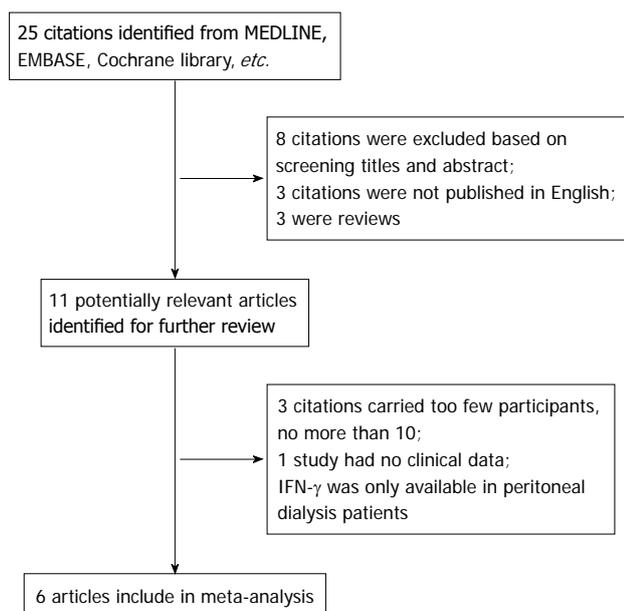

Figure 1 Flowchart of study selection. IFN- γ : Interferon-gamma.

Sensitivity of IFN- γ for TBP diagnosis ranged from 0.54 to 1.00 (mean, 0.93; 95%CI, 0.87-0.97), while specificity ranged from 0.87 to 1.00 (mean, 0.99; 95%CI, 0.97-1.00). We also noted that PLR was 41.49 (95%CI, 18.80-91.55), NLR was 0.11 (95%CI, 0.06-0.19) and DOR was 678.02 (95%CI, 209.91 to 2190.09). χ^2 values of sensitivity, specificity, PLR, NLR and DOR were 5.66 ($P = 0.3407$), 6.37 ($P = 0.2715$), 1.38 ($P = 0.9265$), 5.46 ($P = 0.3621$) and 1.42 ($P = 0.9220$), respectively, indicating no significant heterogeneity for sensitivity, specificity, PLR, NLR and DOR between studies.

The SROC plot is different from the traditional ROC plot and explores the effect of varying thresholds on sensitivity and specificity in a single study. In a SROC plot, any of the data points represent a separate study. The SROC curve represents a global summary of test performance and shows the tradeoff between sensitivity and specificity. A graph of the SROC curve for IFN- γ determination showing true-positive rates and false-positive rates from individual studies is shown in Figure 3. As a global measure of test efficacy, we used the Q -value, the intersection point of the SROC curve with a diagonal line from the left upper corner to the right lower corner of the ROC space, which corresponds to the highest common value of sensitivity and specificity for the test. This point represents an overall measure of the discriminatory power of a test. Our data showed that the SROC curve was positioned near the desirable upper left corner and that the maximum joint sensitivity and specificity was 0.97. The area under the curve (AUC) was 0.99. This indicated a high level of overall accuracy.

Multiple regression analysis and publication bias

By using the STARD guidelines^[15], a quality score for each study was compiled on the basis of title and introduction, methods, results and discussion (Table 1). Qual-

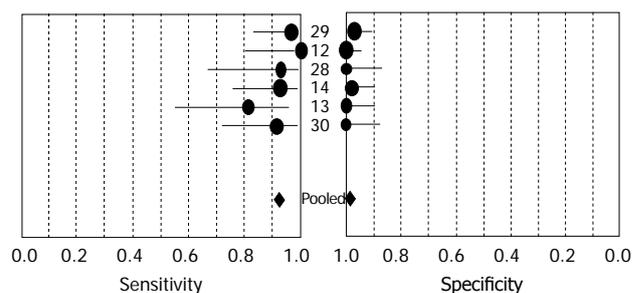

Figure 2 Forest plot showing the sensitivity and specificity of interferon-gamma in the diagnosis of tuberculous peritonitis. Forest plot shows the sensitivity and specificity of interferon-gamma (IFN- γ) for tuberculous peritonitis diagnosis. The point estimates of sensitivity and specificity from each study are shown as solid circles. Error bars indicated 95%CI. Numbers indicate the studies included in the meta-analysis, as cited in the reference list. Pooled estimates for IFN- γ assay were as follows: sensitivity, 0.93 (95%CI, 0.87 to 0.97), specificity, 0.99 (95%CI, 0.97 to 1.00).

ity scoring was also carried out using QUADAS^[16], in which a score of 1 indicated a fulfilled criterion, 0 if an unclear criterion, and -1 if criterion not achieved. These scores were used in the meta-regression analysis to assess the effect of study quality on the RDOR of IFN- γ in the diagnosis of TBP. As shown in Table 3, studies with higher quality (STARD score, ≥ 13 ; QUADAS score, ≥ 10) produced RDOR values that were not significantly higher than those studies with lower quality. We also noted that differences for studies with or without blinded, cross-sectional, consecutive/random and prospective designs did not reach statistical significance, indicating that the study design did not substantially affect the diagnostic accuracy.

The evaluation of publication bias showed that the results from the Egger test were not significant ($P = 0.922$). These results indicated little potential for publication bias.

DISCUSSION

The diagnosis of extrapulmonary mycobacterial infection is often difficult to establish since it has a nonspecific clinical presentation. Conventional diagnostic tests such as microscopic examination of peritonitis fluid by Ziehl-Neelsen staining, culture of mycobacteria from peritoneal effusion and peritonitis pathological examinations, are not always helpful in making the diagnosis because of their limitations. Invasive procedures, such as peritoneoscopy, laparotomy and peritoneal biopsy, which require appropriate and adequate clinical specimens are complex and sometimes risky^[6,14]. A negative smear for acid-fast bacilli, a lack of granulomas on histopathology, and failure to culture *M. tuberculosis* do not exclude the diagnosis^[5,31-33]. Furthermore, the culture of *M. tuberculosis* takes 4 wk, and acid-fast bacilli smears are too insensitive to meet current needs^[5,34].

The most popular biomarkers which have been proposed for TBP diagnosis are ADA and INF- γ . The levels of both were significantly higher in TBP patients than in

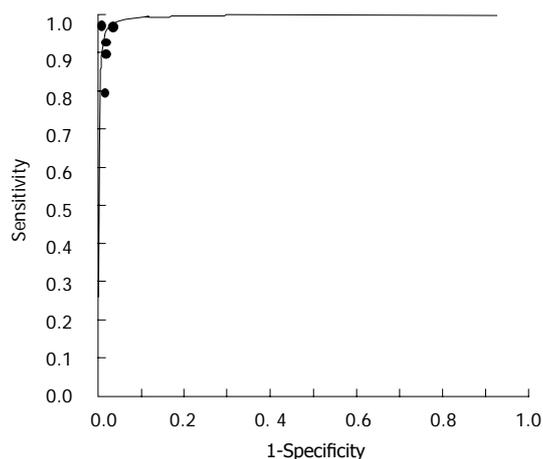

Figure 3 Summary receiver operating characteristic curves for interferon-gamma assays. Solid circles represent each study included in the meta-analysis. The size of each study is indicated by the size of the solid circle. Summary receiver operating characteristic curves summarize the overall diagnostic accuracy.

non-TBP patients. Both showed relatively high sensitivity and specificity in diagnosing TBP^[12,14,24,26,28,29]. However, there are also other methods for TBP diagnosis, such as the molecular rapid amplification-based tests [for example polymerase chain reaction (PCR)] which detect specific DNA or RNA fragments of *M. tuberculosis*. Many reports suggest that various PCR tests have good performance with sensitivity reaching up to 95% in smear-positive patients. However, Ziehl-Neelsen staining in patients with TB peritonitis is positive in only 3% of cases, and PCR sensitivity would be similarly very low^[35]. At present, the ADA assay has been recommended not only in the TB peritonitis diagnostic test^[36], but also as a tool for the differential diagnosis of different forms of EPTB, such as pleuritis, synovitis, and meningitis, infections of the female genital system and peripheral lymph nodes, and uveitis^[37]. Liang *et al.*^[38] and his colleagues have completed a meta-analysis (including 63 studies) to estimate ADA in the diagnosis of tuberculous pleurisy. The meta-analysis showed that the mean sensitivity of the ADA assays was 0.92, while the mean specificity was 0.90, the maximum joint sensitivity and specificity was 0.91, while AUC was 0.96, indicating a relatively high level of overall accuracy. However, the present meta-analysis showed that the mean sensitivity of the IFN- γ assay was 0.93, while the mean specificity was 0.99, and that the maximum joint sensitivity and specificity was 0.97, while the AUC was 0.99, indicating a higher level of overall accuracy.

The DOR is a single indicator of test accuracy^[39] that combines the data from sensitivity and specificity into a single number. The DOR of a test is the ratio of the odds of positive test results in the patient with disease relative to the odds of positive test results in the patient without disease. The value of DOR ranges from 0 to infinity, the higher values indicate better discriminatory test performance (higher accuracy). A DOR of 1.0 indicates that a test does not discriminate between patients with

Table 3 Weighted meta-regression of the effects of study design methods and methodological quality on diagnostic accuracy of interferon-gamma assays

| Covariate | Studies | Coefficient | RDOR (95%CI) | P |
|------------------------|---------|-------------|----------------------|-------|
| Consecutive or random | 6 | - | - | - |
| Prospective | 6 | - | - | - |
| Cross-sectional design | 1 | -1.763 | 0.17 (0.00, 2053.55) | 0.593 |
| Blinded design | 2 | -0.649 | 0.52 (0.01, 31.46) | 0.649 |
| Methods | | | | |
| RIA | 2 | -0.815 | 0.44 (0.01, 26.58) | 0.571 |
| ELISA | 4 | | | |
| QUADAS ≥ 10 | 5 | -2.137 | 0.12 (0.00, 98.54) | 0.387 |
| STARD ≥ 13 | 5 | -2.137 | 0.12 (0.00, 98.55) | 0.387 |

ELISA: Enzyme-linked immunosorbent assay; RIA: Radioimmunoassay; STARD: Standards for Reporting Diagnostic Accuracy, maximum score 25, guidelines that aim to improve the quality of reporting in diagnostic studies; QUADAS: Quality Assessment for Studies of Diagnostic Accuracy, appraisal by use of empirical evidence, maximum score 14, expert opinion and formal consensus to assess the quality of primary studies of diagnostic accuracy; RDOR: Relative diagnostic odds ratio.

and those without disease. In the present meta-analysis, we found that the mean DOR was 678.02, also indicating a high level of overall accuracy.

Since the SROC curve and the DOR are not easy to interpret or use in clinical practice^[40], and likelihood ratios are considered to be more clinically meaningful^[40], we also presented both PLR and NLR as our measures of diagnostic accuracy. Likelihood ratios of > 10 or < 0.1 generate large and often conclusive shifts from pre-test to posttest probability (indicating high accuracy). A PLR value of 41.49 suggests that patients with TBP have an approximately 41-fold higher chance of being IFN- γ assay-positive compared with patients without TBP. This high probability would be considered high enough to begin or to continue anti-TB treatment of TBP patients, especially in the absence of any evidence of malignancy. On the other hand, NLR was found to be 0.11 in the present meta-analysis. If the IFN- γ assay result was negative, the probability that this patient has TBP is approximately 10%, which is not low enough to rule out TBP. These data suggest that a negative IFN- γ assay result should not be used alone as a justification to deny or to discontinue anti-TB therapy. The choice of therapeutic strategy should be based on the results of microscopic examination of smear or culture of *M. tuberculosis* and/or histologic observation of peritoneal tissue, as well as other clinical data, such as response to anti-TB therapy.

An exploration of the reasons for heterogeneity rather than computation of a single summary measure is an important goal of meta-analysis^[41]. In our meta-analysis, both STARD and QUADAS scores were used in the meta-regression analysis to assess the effect of study quality on RDOR. Most of the studies were of high quality (STARD score of ≥ 13 or QUADAS score of ≥ 10), with the exception of one study^[12] which was assessed to be of low quality (STARD score of 11 and QUADAS score of 9). We found that there was no statis-

tical heterogeneity for sensitivity, specificity, PLR, NLR, and DOR among the studies, which indicated that the differences for studies with or without a blinded, cross-sectional, consecutive/random and prospective design did not reach statistical significance, and the study design did not substantially affect diagnostic accuracy.

It should be emphasized that a definite TBP diagnosis is achieved when *M. tuberculosis* is demonstrated in peritonitis specimens, or when caseating granulomas are found in peritonitis biopsy specimens. As mentioned above, *M. tuberculosis* requires 4 wk of culture, and acid-fast bacilli smears are too insensitive to meet current needs^[15,34]. Where diagnostic difficulty exists, measuring the levels of several biomarkers, such as ADA and IFN- γ , in ascitic fluid is useful, and clinicians can embark on empirical anti-TB therapy while awaiting culture results, especially in young patients from areas with a high prevalence of TB. One criticism of the use of biomarkers rather than cultures for TBP diagnosis is that culture results are not available to guide anti-TB therapy. In short, none of the biomarkers, including IFN- γ , provide culture and sensitivity data. Culture results are particularly useful if drug resistant TB is prevalent^[42].

Our meta-analysis had several limitations. Firstly, the exclusion of conference abstracts, letters to the editor, and non-English-language studies might have led to publication bias, which was not found in the present review. However, a review of these abstracts and letters suggested that the overall results were similar to the results in the English language studies included. Secondly, misclassification bias may occur. TBP is not always diagnosed by either histologic or microbiological examination. Actually, some patients were diagnosed with TBP infection based just on the clinical course. This issue regarding accuracy of diagnosis could cause nonrandom misclassification, leading to biased results. Finally, the number of studies that met the inclusion criteria was not large enough. Multi-center and large blinded randomized controlled trials with IFN- γ assays using peritoneal effusion for TBP diagnosis should be conducted.

Based on this study, IFN- γ may play a potential role in accurate TBP diagnosis. This may be helpful in clinical findings and conventional tests including microbiological examination and peritoneal biopsy. Numerous studies are required to further establish the role of IFN- γ for early and accurate TBP diagnosis.

ACKNOWLEDGMENTS

We are grateful to Professor Shi HZ for his great assistance in the statistical analysis and translating foreign language articles.

COMMENTS

Background

Tuberculous peritonitis (TBP) is a manifestation of tuberculosis. Its diagnosis is still challenging and of great importance. Early and accurate diagnosis contributes to effective therapy and good survival rates. However, current clinical

diagnostic techniques for TBP are time-consuming and inefficient. Interferon-gamma (IFN- γ) in peritoneal effusion has been shown to be a marker for the diagnosis of TBP.

Research frontiers

How does IFN- γ in ascitic fluid testing relate to blood interferon- γ release assay (IGRA) tests? The blood IGRA test is an established test for latent tuberculous (TB) infection, however, there is little information on the difference between IFN- γ and IGRA tests in clinical diagnosis. Multi-center and large blinded randomized controlled trials using both these tests for TB diagnosis should be conducted in the future.

Innovations and breakthroughs

Authors assessed IFN- γ for TBP diagnosis by meta-analysis, and the clinical findings may greatly facilitate the diagnosis and differential diagnosis of TBP.

Applications

IFN- γ may play a potential role in the accurate diagnosis of TBP. This may be helpful in clinical findings and conventional tests including microbiological examination and peritoneal biopsy. The level of IFN- γ may contribute to the accurate differentiation of tuberculosis ascites from non-tuberculosis ascites.

Peer review

This systematic review and meta-analysis of IFN- γ testing for TBP was generally of good quality, and adhered to relevant guidelines for systematic review and quality assessment.

Abstract

Lichen planus is a fairly common chronic idiopathic disorder of the skin, nails and mucosal surfaces. Esophageal involvement of this disease on the other hand is rare and only about 50 cases have been reported in literature. Given its rarity, it can be difficult to diagnose and may be easily misdiagnosed as reflux esophagitis. Currently, there are no clear recommendations on the optimal management of this disease and little is known about the best treatment approach. Systemic steroids are usually the first line treatment and offer a favorable response. In this report, we would like to present a novel approach in the management of esophageal lichen planus in a middle-aged woman treated successfully with swallowed fluticasone propionate 220 mcg twice a day for 6 wk, as evidenced by objective clinical findings. Based on our review of related literature and experience in this patient, we feel that a trial of swallowed fluticasone may be a prudent approach in the management of these patients since it has a more favorable side effect profile than systemic treatment.

INTRODUCTION

Lichen planus is a well-recognized chronic idiopathic disorder involving the skin, nails and mucosal surfaces including the mouth, pharynx and perineum^[1]. It affects less than 1% of the general population^[2]. Mucosal surface involvement is found in about 30%-70% of patients diagnosed with lichen planus^[3]. Esophageal involvement, on the other hand, is considered to be rare with its true prevalence unknown. The study by Dickens *et al*^[4] demonstrated esophageal lichen planus in 26% of patients with mucocutaneous lesions while a larger study by Eisen^[5] found esophageal lesions in only 1% of patients. Here we describe a case of esophageal lichen planus who was treated with swallowed fluticasone with good response and present a review of this topic.

CASE REPORT

A 63-year-old female with history of gastric bypass surgery, coronary artery disease, and hyperlipidemia reported having intermittent solid food dysphagia for the past 3 years. She also had symptoms of gastroesophageal reflux disease that was initially controlled with omeprazole 20 mg daily. Later on, she developed multiple episodes of breakthrough and nocturnal reflux symptoms accompanied by occasional difficulty in swallowing large pills that happened 2-3 times a week. She denied food regurgitation, odynophagia, nausea, vomiting or weight loss. For further evaluation of her dysphagia, a barium swallow

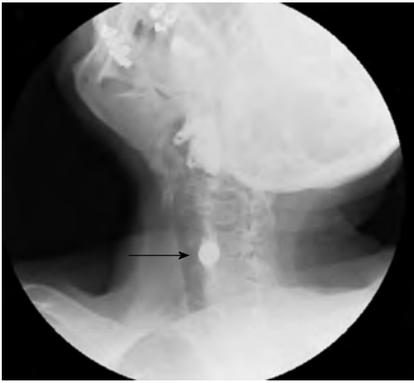

Figure 1 Barium swallow showing barium pill (arrow) trapped in C6-C7.

Figure 2 Endoscopy image showing friable mucosa and dried blood in upper esophagus with a mild to moderate stricture at upper and mid-esophageal junction.

Figure 4 Endoscopy image showing resolution of lesions in the upper esophagus post treatment.

was performed. During the procedure, the barium pill briefly got trapped in the upper esophagus at the level of C6-C7. This location correlated with the reported site of dysphagia (Figure 1). The rest of the exam was uneventful and no mass or stricture was noted except for a small sliding hiatal hernia. She subsequently underwent an upper endoscopy which showed areas of friable mucosa and dried blood in the upper esophagus with a mild to moderate stricture at the upper and mid-esophageal junction (Figure 2). Esophageal biopsies were obtained which showed hyperkeratosis, parakeratosis and spongiosis of the lower third of the epithelium with focal dys-

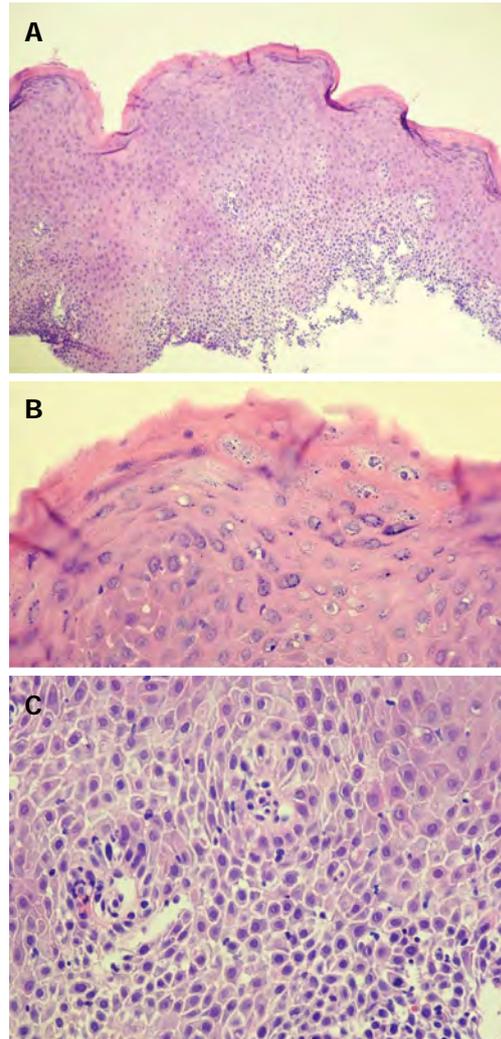

Figure 3 Chronic inflammatory cell infiltration of the epithelium was also present and was mainly composed of lymphocytes. A: Low power view of upper esophagus shows extensive severe keratinization, organizational disarray of cell arrangement and spongiosis of lower layer associated with inflammatory infiltration. (E, $\times 40$); B: High power of parakeratotic cells and accumulation of keratohyaline granules in the cytoplasm of the mature keratinocytes. In this zone keratinization is mild. (HE, $\times 400$); C: High power view of spongiosis of lower layers of squamous epithelium associated with sprinkling of lymphocytes typical of longstanding chronic inflammation. (HE, $\times 400$).

keratosis. Chronic inflammatory cell infiltration of the epithelium was also present and was mainly composed of lymphocytes (Figure 3). Submucosa was not present for evaluation of lichenoid inflammation. Nonetheless, in the presence of the clinical history, the findings were interpreted to be consistent with lichen planus. On further questioning, patient reported having an oral lesion diagnosed to be lichen planus in 2009. Due to her history of previous lichen planus and endoscopy findings, patient was diagnosed with esophageal lichen planus and was started on swallowed fluticasone propionate 220 mcg twice daily for 6 wk. At her 4th wk follow-up she noted resolution of her symptoms. On follow-up endoscopy at 15 wk, only small light pink plaques were noted in the mid-esophagus while the rest of the esophagus showed normal looking mucosa (Figure 4). Pathology

Table 1 Differentiation between types of lichen planus

| | Cutaneous | Oral | Esophageal |
|-----------------------------|---|---|---|
| Age and gender distribution | No gender preference | No gender preference | Generally middle aged females ¹ |
| Clinical findings | Eruptions of violaceous, scaling, pruritic plaques ^[7] | Atrophic lesions, erosions, lace-like reticulated plaques ^[2] | Elevated lacy white papules, esophageal webs, pseudomembranes, desquamation, and superficial pinpoint erosions with and without stenosis ^[4,5,15,22-25] |
| Duration of illness | Self-limited with spontaneous regression in 1-2 yr ^[21] | Propensity for chronicity ^[7] | Propensity for chronicity ^[7] |
| Histologic findings | Hypergranulosis, hyperorthokeratosis, acanthosis and "saw-tooth" elongation of the rete pegs ^[21] Typical band-like inflammatory infiltrate with a predominance of mature T cells and basal layer degeneration including characteristic Civatte bodies (<i>i.e.</i> , apoptotic basal keratinocytes) ^[21] | Oral lesions closely resemble esophageal lesions Typical band-like inflammatory infiltrate with a predominance of mature T cells and basal layer degeneration including characteristic Civatte bodies (<i>i.e.</i> , apoptotic basal keratinocytes) ^[21] | Parakeratosis, atrophic epithelium, lacks hypergranulosis, variable thinning or acanthosis ^[21] Typical band-like inflammatory infiltrate with a predominance of mature T cells and basal layer degeneration including characteristic Civatte bodies (<i>i.e.</i> , apoptotic basal keratinocytes) ^[21] |
| Risk of malignancy | No increased risk of malignant transformation | Increased risk of oral malignancy; Associated with hepatitis C | Some case reports have shown malignancy associated with esophageal lichen planus |

¹One report by Chryssostalis *et al*^[10] showed esophageal lichen planus in a 22-yr-old male patient.

showed normal to atrophic squamous mucosa with mild non-specific inflammation including rare eosinophils and no evidence of interface band-like lymphocytic infiltrate which was compatible with lichen planus post-therapy.

DISCUSSION

Lichen planus is a common disorder of squamous epithelium^[2]. The exact cause of this disease is unknown; however infectious (viral), neurologic, genetic and immunologic causes have been proposed^[6]. Lichen planus appears to be mediated by cytotoxic CD8+ T cells that attack an antigen in the basal epithelium in a manner resembling graft-versus-host disease^[2]. There are no detailed studies published to specifically address the pathogenesis of esophageal lichen planus. Chandan *et al*^[7] suggests that the pathogenesis may be similar to oral lichen planus. It has been suggested that oral lichen planus is due to an immune response to an exogenous or endogenous antigen found in the basal keratinocytes. This activates the Langerhans cells which then present the antigen to the CD4+ T lymphocytes migrating to the oral mucosa lamina propria. Keratinocytes respond to the injury by producing cytokines that promote CD8+ T lymphocyte stimulation. These CD8+ cytotoxic cells will distribute near the epithelium and destroy it^[8]. Table 1 summarizes the differences between esophageal *vs* oral and cutaneous lichen planus.

Esophageal lichen planus is considered to be a rare disease with only about 50 cases reported in English literature. Retrospectively, Eisen^[5] suggests a prevalence of less than 1% among patients with oral lichen planus but because of subtle clinical findings and lack of characteristic histologic features, the true prevalence is hard to determine^[9]. All reported patients are usually middle-aged females except in the study by Chryssostalis *et al*^[10] that

reported a case of a 22-year-old male with esophageal involvement. Esophageal lichen planus is often present in patients with extraesophageal involvement, but it may also be present in patients without dermal or oropharyngeal manifestations^[11]. In a case series of esophageal lichen planus, the initial site of involvement was esophagus in 48% of patients^[12]. Symptoms can range from asymptomatic to odynophagia and dysphagia^[4]. The proximal or mid-esophagus is the most common site of involvement^[7], although the entire esophagus can also be affected with sparing of the gastroesophageal junction^[13]. Different types of lesions have been reported and can range from elevated lacy white papules, esophageal webs, pseudomembranes, desquamation, and superficial pinpoint erosions with and without stenosis. Most case reports mention the characteristic finding of peeling of the mucosa away from the esophagus leaving a friable, inflamed surface that bleeds on contact^[11]. Strictures are also common in these patients and may represent progression from inflammation to ulceration, fibrosis with subsequent stricture formation^[14].

Esophageal lichen planus may be misdiagnosed as reflux esophagitis which further compounds the situation. In our patient, esophageal lichen planus was favored over reflux esophagitis due to the extensive degree of hyperkeratosis and focal parakeratosis with accumulation of keratohyaline granules which are unlikely in reflux related injury. The presence of spongiosis in the lower third of the epithelium was also more consistent with esophageal lichen planus. The spongiosis in reflux diseases tend to occur in the upper third of the epithelium where acid is in contact with the mucosa. The other factor that can help to differentiate these 2 entities is the site of involvement in the esophagus. While reflux disease is usually more severe in the distal esophagus, lichen planus affects the middle and upper esophagus in most cases.

The most characteristic histologic finding in esophageal lichen planus is a bandlike or lichenoid lymphocytic infiltrate involving the superficial lamina propria and basal epithelium^[7]. A predominance of mature T cells is present within this infiltrate. These are associated with basal keratinocyte degeneration which often include Civatte bodies (necrotic keratinocytes with anucleate remnants)^[7]. Lymphocytic infiltration of the mucosa is not pathognomonic of this disease and medications such as gold, thiazide, and anti-malarials can induce lichen planus-like lesions and need to be excluded clinically^[15].

No clear guidelines are present for the treatment of esophageal lichen planus and there is no specific way to treat this entity. Historically, systemic corticosteroids have been used as first-line treatment with a response rate of up to 74% based on multiple reports. However, relapse rate can be as high as 85% with steroid withdrawal^[11]. Treatment response was also reported with adrenocorticotrophic hormone injection, etretinate, topical tacrolimus, intralesional corticosteroids and cyclosporine^[2,16]. Esophageal dilation is commonly used to treat strictures, although intralesional steroid injections and/or oral tacrolimus may decrease the frequency of required dilations. It is important to note that koebner phenomenon which is defined as development of new lesions along the lines of trauma, can occur with dilatation.

Although effective, systemic corticosteroid treatment can be associated with serious side effects and therefore there is a need for a safer alternative. In our review of literature, we have come upon case reports and a recent case series where treatment with swallowed fluticasone propionate has resulted in symptomatic improvement as well as endoscopic improvement in 4 out of 6 treated patients^[14,17]. Because of these promising results, we decided to try this novel approach for our patient which proved to be successful.

Oral lichen planus has a 1%-3% risk of malignant transformation to squamous cell carcinoma^[3]. It is unknown however if the same is true for esophageal lichen planus. To date, 3 case reports have described squamous cell carcinoma and 1 described a verrucous carcinoma arising from these lesions^[10,18,19]. In these reports, squamous cell carcinoma developed more than 20 years after the diagnosis of esophageal lichen planus^[18]. Due to this risk, some advocated surveillance endoscopies in patients with esophageal lichen planus to detect early malignancy. In the study by Quispel *et al.*^[20], high magnification indigo carmine chromoendoscopy was used to establish the prevalence of endoscopic and histopathologic esophageal abnormalities consistent with lichen planus and dysplasia in a cohort of patients with lichen planus. It was found that up to 50% of patients with orocutaneous lichen planus had esophageal involvement but no dysplasia was found. The authors of this study proposed to set a low threshold for performing endoscopy in patients with lichen planus and symptoms suggestive of esophageal involvement but recommended against routine screening^[20]. Based on these data, we recommend that the frequency

of screening by endoscopy be individualized, but the possibility of malignancy be kept in mind while evaluating these patients with a low threshold for further evaluation in patients with symptoms suggestive for esophageal cancer.

In conclusion, esophageal lichen planus should be suspected in middle-aged female patients who present with symptoms of dysphagia and odynophagia and found to have mucosal abnormalities involving the upper third of the esophagus. Once the diagnosis of esophageal lichen planus is made, these patients should be considered for treatment with swallowed fluticasone before other systemic and more toxic therapies. It is important to keep in mind that secondary to the risk for malignant transformation, these patients should be followed closely.

Abstract

A 23-year-old male presented with a three-week-history of crampy abdominal pain and melaena. Colonoscopy revealed a friable mass filling the entire lumen of the cecum; histologically, it was classified as perivascular epithelioid cell tumor (PEComa). An magnetic resonance imaging scan showed, in addition to the primary tumor, two large mesenteric lymph node metastases and four metastatic lesions in the liver. The patient underwent right hemicolectomy and left hemihepatectomy combined with wedge resections of metastases in the right lobe of the liver, the resection status was R0. Subsequently, the patient was treated with sirolimus. After 4 mo of adjuvant mammalian target of rapamycin inhibition he developed two new liver metastases and a local pelvic recurrence. The visible tumor formations

were again excised surgically, this time the resection status was R2 with regard to the pelvic recurrence. The patient was treated with 12 cycles of doxorubicin and ifosfamide under which the disease was stable for 9 mo. The clinical course was then determined by rapid tumor growth in the pelvic cavity. Second line chemotherapy with gemcitabine and docetaxel was ineffective, and the patient died 23 mo after the onset of disease. This case report adds evidence that, in malignant PEComa, the mainstay of treatment is curative surgery. If not achievable, the effects of adjuvant or palliative chemotherapy are unpredictable.

INTRODUCTION

Perivascular epithelioid cell tumor (PEComa) are rare mesenchymal neoplasms for which, according to a World Health Organization classification, histologically and immunohistochemically distinctive perivascular epithelioid cells are diagnostic^[1]. Clinical courses are highly variable from benign behaviour to aggressive local tumor growth and seeding of metastases^[2]. In this case report, a highly malignant type of PEComa in a 23-year-old male and its response to multimodal therapies is described.

CASE REPORT

A 23-year-old male was admitted to the hospital because of crampy abdominal pain and melaena for three weeks. Colonoscopy revealed a 5.5 cm mass lesion in the cecum surrounding the ileocecal valve (Figure 1). At biopsy, the friable tumor tissue was bleeding easily. An magnetic resonance imaging (MRI) scan showed, in addition to the primary tumor, two mesenteric lymph node metastases (each 5 cm in diameter) and 4 metastatic lesions in the liver (1-2 cm in diameter, segments 1, 2, 4a and 6) (Figure 2). Additional staging procedures at the time of primary diagnosis [abdominal and chest computed tomography (CT), positron emission tomography] revealed no further tumor manifestations.

In a two-stage procedure, the patient underwent right hemicolectomy and, after recovery, left hemihepatectomy combined with atypical wedge resections of hepatic segments 1 and 6 (resection status R0). On the basis of biopsy and resection material, a diagnosis of malignant PEComa was made (see below).

Owing to the aggressive nature of the tumor, both clinically and histologically, the patient received adjuvant treatment with the mammalian target of rapamycin (mTOR) inhibitor sirolimus (2 mg/d). However, after 4 mo the drug had to be discontinued due to two new liver metastases in segments 7 and 8 which were removed by atypical wedge resection. Simultaneously, a local pelvic recurrence of 13 cm × 12 cm × 8 cm with bilateral ureteral obstruction and rectal impression was diagnosed. A debulking operation was performed which resulted in Hartmann's situation (resection status R2); additionally, splints were inserted into both ureters.

Palliative chemotherapy with doxorubicin (75 mg/m²) and ifosfamide (5000 mg/m²) every 3 wk was started. This regime was well tolerated until cycle 7 when the dose had to be reduced due to hematotoxicity. Altogether, the patient received 12 cycles of doxorubicin/ifosfamide under which the disease was stable for 9 mo as evaluated by CT scans every 8-12 wk.

Afterwards renewed tumor growth in the pelvic cavity was observed, aggravated by malignant ascites. Three cycles of second line chemotherapy (gemcitabine 900 mg/m² on days 1 and 8 combined with docetaxel 100 mg/m² on day 8 every 21 d) were administered without measurable effect. The patient died 23 mo after the onset of disease.

Pathology

The specimen obtained at hemicolectomy showed a 5.5 cm measuring mass in the cecum with metastases in 2 of 18 regional lymph nodes, each measuring 5 cm in diameter. The tumor was located in the bowel wall, with broad ulceration of the overlying mucosa. Histology (Figure 3) revealed a tumor of low to moderate cellularity, with a vague nodular pattern, an epithelioid and solid arrangement of the tumor cells and a sinusoidal vascular pattern without stromal desmoplasia. The tumor cells had a broad clear to granular eosinophilic cytoplasm,

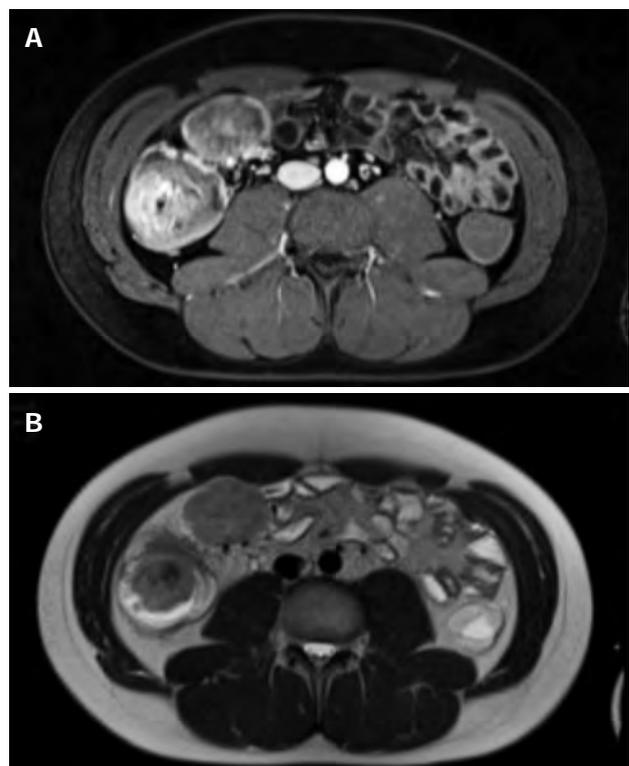

Figure 2 Magnetic resonance imaging of cecal perivascular epithelioid cell tumor and mesenteric lymph node metastasis. A: T2-weighted image; B: T1-weighted image after iv administration of contrast medium.

with moderate PAS positivity. The distinct cellular membranes exhibited some wrinkling. Most tumor nuclei showed moderate nuclear pleomorphism, but there were some highly pleomorphic hyperchromatic tumor cell nuclei. Sixty percent of the tumor area was necrotic. The mitotic rate was 12 per 10 high-power field (HPF). In some areas, the tumor was well demarcated, but there were other areas with a more infiltrative pattern of invasion.

Immunohistochemistry revealed positivity for HMB45 and negativity for melanoma antigen recognized by T cells 1 and microphthalmia-associated transcription factor. There was a weak expression of pankeratin markers (AE1/3, KL1) and CD56 in few tumor cells. Other mark-

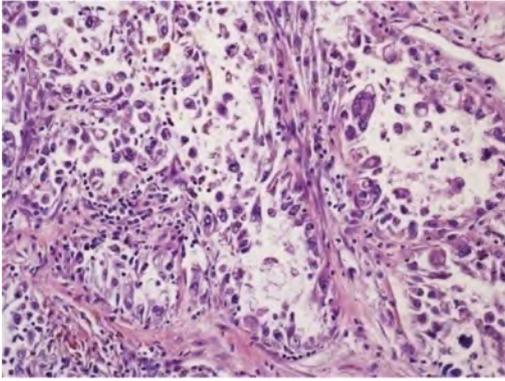

Figure 3 Histologic section of the primary tumor in the cecum. A representative part of the tumor shows epithelioid tumor cells. The cytoplasm exhibits both clear and granular eosinophilic parts. The tumor cells are arranged in large nodules with necrotic debris in the central parts. In the lower left corner, a cytoplasmic brown pigment is seen that upon ultrastructural evaluation turned out to be melanin pigment and melanosomes. There are narrow stalks of collagen-rich stroma with a scant lymphocytic infiltrate (Hematoxylin and eosin, magnification 200 ×).

ers (Synaptophysin, Chromogranin, PanLeu, CD34, CD31, S100, CD117, DOG1, Myogenin, MyoD1, EMA, Actin, Caldesmon, Desmin, CD30) were absent. Ki67 labeled 50%-60% of the tumor cells. PCR analysis of fresh frozen tumor material was negative for translocations suggestive of clear cell sarcoma [t(12;22)], synovial sarcoma [t(X;18)], myxoid liposarcoma [t(12;16)] and alveolar rhabdomyosarcoma [t(2;13)].

The diagnosis of PEComa was suggested in the biopsies obtained at endoscopy. Because of the rarity of this tumor and the missing expression of smooth muscle markers usually found in PEComas, the tissue was sent to a reference pathologist (Fletcher CDM, Boston, MA, United States) who confirmed the diagnosis of PEComa. From the surgical material, a tumor area with brown cytoplasmic pigment (with negativity in the Prussian blue and PAS stains) was selected for electron microscopy; in this sample typical melanosomes could be demonstrated.

The tumor material obtained at the resection of liver metastases did not differ histologically from that of the primary tumor. However, following chemotherapy with doxorubicin/ifosfamide, there was a tremendous increase in nuclear pleomorphism with many extremely large hyperchromatic bizarre tumor nuclei, many tumor cells with nuclear fragmentation and micronuclei, and a decrease in the amount of mitotic figures. These morphologic alterations resemble regressive tumor changes following chemotherapy. However, the area of necrotic tumor cells was 20% at this time point, i.e. most of the tumor contained still viable cells.

DISCUSSION

This report of malignant PEComa has to be seen in the context of other single case descriptions or small case series on an extremely rare tumor entity. Predictors of prognosis in PEComa have been described in a clinicopathologic study on 26 cases by Folpe *et al*³¹. A

significant association between tumor size > 5 cm, infiltrative growth pattern, high nuclear grade and cellularity, mitotic rate $\geq 1/50$ HPF, necrosis, vascular invasion and subsequent aggressive clinical behaviour has been seen. In a more recent review article⁴¹ on the basis of 234 PEComas the only pathologic factors of recurrence after surgical resection were primary tumor size ≥ 5 cm and a high mitotic rate of > 1/50 HPF. All of these “worrisome” pathologic features were present in the 23-year-old patient of the actual case. Additionally, the presence at initial diagnosis of two large metastases in mesenteric lymph nodes (each measuring 5 cm in diameter) and of 4 hepatic metastases had to be considered as clinical indicators of poor prognosis.

PEComas arise from various organs such as uterus and vagina, kidney, digestive tract, retroperitoneum, bone, skin and eye. Intestinal origins include stomach, colon and rectum, peritoneal cavity and falciform ligament. Considering only PEComas of the colon and rectum, there are 4 reports on 7 patients^{5-8]} in whom the clinical course was benign (5 × operation only, 2 × operation and adjuvant chemotherapy, no evidence of disease at the end of follow-up). These findings are in contrast with the actual case when mesenteric and hepatic metastases were present at the time of diagnosis. The organ of origin, therefore, does not seem to be a predictor of prognosis.

Concerning treatment strategies, Bleeker *et al*⁴¹ stated that cytotoxic chemotherapy and radiation had shown little benefit in malignant PEComa. According to the authors, the emerging role of mTOR inhibitors would raise enthusiasm in the therapy of these rare tumors. The clinical course reported herein reflects the opposite impression: After R0 resection of the primary tumor and mesenteric/hepatic metastases, adjuvant mTOR inhibition with sirolimus given for 4 mo at a dose of 2 mg/d (suitable for liver transplant recipients) failed to prevent a local recurrence and new liver metastases. On the contrary, cytotoxic chemotherapy (doxorubicin/ifosfamide) considered first choice in soft tissue sarcomas was associated with stable disease for 9 mo. Thus, the combination of repetitive surgery with conventional chemotherapy may still be a choice in the palliative therapy of malignant PEComa. The benefit of mTOR inhibition (sirolimus, temsirolimus, everolimus), although theoretically attractive, is at present unpredictable^{9,10]}. Many other therapies have been tried to control unresectable PEComa, *e.g.*, dacarbazine, epirubicin, paclitaxel, gemcitabine, oxaliplatin, imatinib, α -interferon, thalidomide, alone or in combinations. However, clinical outcomes have been extremely variable and a standard treatment is not in sight.

Some PEComas are associated with phakomatosis and hamartomatous diseases, *e.g.*, the tuberous sclerosis complex (TSC). In these conditions the mTOR signalling pathway is activated which may thus be targeted by sirolimus and related compounds^{11]}. In the present case of the 23-year-old patient there was no indication of TSC. Due to the paucity of data it is unknown if the presence or absence of TSC can be used as a predictor of susceptibility to sirolimus therapy.

Given the extreme rarity and heterogeneity of PEComas, a comparative study with a focus on optimal treatment will unlikely be performed. Instead, a PEComa registry based at a sarcoma center would be a reasonable option. Well documented clinical courses, histological features and empirical therapies could thus be accumulated and best practice procedures deduced.

ACKNOWLEDGMENTS

The support of Fletcher CDM, MD, Surgical Pathology, Brigham and Women's Hospital, Boston, in confirming the histological diagnosis and discussing therapeutic options is gratefully acknowledged. The authors thank Kuesters W, MD, Department of Radiology, Juliuspital Wuerzburg, for providing the MRI of Figure 2.

Abstract

We present the case of a 29-year-old patient with a history of abdominal pain and vomiting. Based on wireless video capsule findings he was previously diagnosed with ileal Crohn's disease at a different institution, although the clinical and radiological picture was not typical and the response to corticosteroids was poor. We performed a single-balloon enteroscopy showing a short, ulcerous stenosis 50 cm proximal from Bauhin's valve. The endoscopic and clinical histopathological findings were compatible with cryptogenic multifocal ulcerous stenosing enteritis (CMUSE). High dose corticosteroids were again started, without effect. The monoclonal tumor necrosis factor- α (TNF- α) antibody infliximab was added to the medical therapy. After induction therapy, both clinical and endoscopic amelioration was obtained. Larger case studies are needed to confirm the efficacy of TNF- α inhibition in steroid refractory CMUSE.

Key words: Cryptogenic multifocal ulcerous stenosing enteritis; Infliximab; Stenosis; Intestinal ulceration; Inflammatory bowel disease

Infliximab induces remission in cryptogenic multifocal ulcerous stenosing enteritis: First case. *World J Gastroenterol* 2013; 19(10): 1661-1664 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1661.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1661>

INTRODUCTION

Ulceration of the small intestine poses a rather limited but difficult differential diagnosis. The most common causes are Crohn's disease, nonsteroidal anti-inflammatory drug (NSAID) associated enteritis, lymphoma, tuberculous enteritis and (mainly in immunocompromised patients) cytomegalovirus (CMV) enteritis. Less frequent etiologies should be kept in mind however. A recently described differential diagnosis is cryptogenic multifocal ulcerous stenosing enteritis (CMUSE), which may be difficult to treat.

CASE REPORT

A 29-year-old male patient presented at our department in April 2011 for a second opinion. He suffered from aspecific abdominal complaints since 2003. Initially, a diagnosis of irritable bowel syndrome was put forth. In 2008, an ileocolonoscopy was performed in a different institution which showed several small ulcerations in the terminal ileum in the presence of a normal colon. Gastroduodenoscopy was normal. A wireless video capsule examination was performed showing multiple small ulcerations in the ileum. A tentative diagnosis of Crohn's disease was made. The patient was started on corticosteroids in January 2009 (prednisolone 40 mg/d), azathioprine was associated as a maintenance therapy but not

Figure 1 Computed tomography showing the location of a potential short stricture (arrow) in the preterminal ileum with mild pre- and poststenotic dilatation. This stricture was identified only after second reading of the computed tomography images and based upon the enteroscopic findings. A: Transverse plane; B: Coronal plane; C: Parasagittal plane.

After infliximab induction therapy, the ulceration almost completely disappeared and only a short hyperemic and less pronounced stenosis remained. A: Before infliximab; B: After infliximab.

tolerated due to intractable nausea. The steroids were slowly tapered over 8 mo, after which the correctness of the diagnosis of Crohn's disease was questioned for unspecified reasons and all treatment stopped. The patient consulted our department for a second opinion.

When we first met this patient in April 2011, diffuse abdominal cramping pain was still the chief complaint. The pain was worse postprandially leading to sitophobia. There was frequent vomiting and a 15 kg weight loss over the past 5 years was noted. Stools tended to be loose with the occasional presence of bloody slimes, the frequency was approximately once daily. There was no fever. His medical history was unremarkable apart from the presumed inflammatory bowel disease. There was no familial history of digestive disease. He smoked 20 cigarettes per week and used marijuana on a daily basis for medicinal purposes. There was no other substance (ab) use mentioned nor detected upon repeated urine toxicology. The use of NSAIDs was systematically denied. Blood work showed normal hemoglobin and red blood cell count and no leucocytosis or C-reactive protein elevation. Antinuclear antibodies and anti-neutrophil cytoplasmic antibodies titers were not elevated.

Since all previous examinations only mentioned small intestinal involvement, a computed tomography (CT) en-

terography was performed to guide subsequent endoscopy but failed to show intestinal inflammation or sequelae of inflammation such as strictures. We subsequently performed a retrograde single-balloon enteroscopy in May 2011 showing the presence of multiple circular but short ileal ulcerations over a distance of 20 cm, starting at the ileocaecal valve. Based upon these findings the CT enterography was consequently reviewed with the radiologist. After a careful second reading, a very short segment in the preterminal ileum was identified which could represent a small intestinal stricture although differentiation with a segmental contraction could not be made (Figure 1). Reconsidering the possibility of a mild form of Crohn's disease, the patient was again started on corticosteroids (budesonide tapered over 3 mo).

In November 2011 a repeat enteroscopy was performed, which showed a small ulceration 20 cm proximally from the ileocaecal valve and a short but circular and stenosing ulceration 30 cm more proximally (Figure 2). The microscopic examination showed superficial ulceration in the ileal mucosa, without associated signs of Crohn's disease in the surrounding, preserved mucosa (Figure 3A).

Based upon the clinical course and the characteristic endoscopic image, CMUSE was diagnosed. Considering the lack of endoscopic or clinical response to treatment

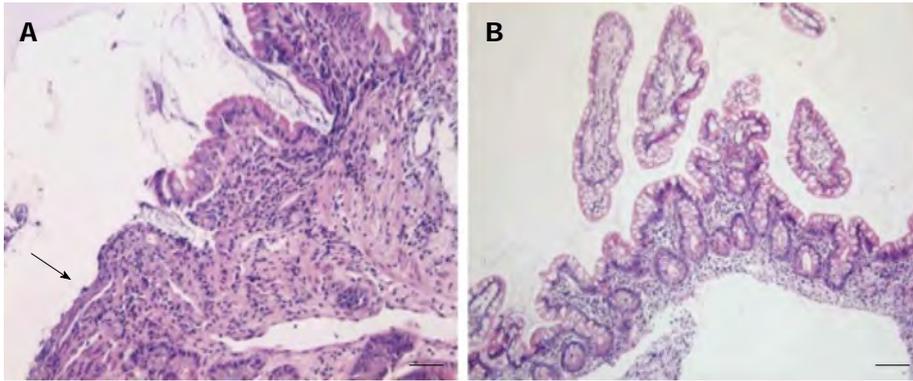

Figure 3 Ileal biopsy before and after infliximab treatment. A: Superficial ulceration of the mucosa (arrow), with an acute inflammatory infiltrate in the lamina propria (HE stained paraffin section, bar: 100 μ m); B: Ileal biopsy after treatment with infliximab, showing restoration of the villus architecture and only slight, non-specific inflammatory changes (bar: 200 μ m).

with budesonide so far, the patient was switched to high dose prednisolone (40 mg daily) in December 2011. After two months, no clinical improvement was noticed, in contrast, the patient almost completely stopped oral food intake because of postprandial cramping and was started on continuous nasogastric tube feeding. In addition, a third enteroscopy confirmed that the endoscopic image was unaltered. To avoid surgery, the ethical committee of our institution was consulted to consider our patient for a compassionate use treatment with the monoclonal tumor necrosis factor- α (TNF- α) antibody infliximab. A standard induction scheme was started in March 2012 (intravenous infliximab at a dose of 5 mg/kg on weeks 0, 2 and 6), followed by maintenance treatment (intravenous infliximab at a dose of 5 mg/kg every 8 wk). After administration of the induction scheme, significant clinical improvement occurred with a reduction in abdominal pain and significant amelioration of sitophobia, leading to cessation of nasogastric tube feeding and prednisolone treatment. A fourth enteroscopy was performed, showing disappearance of the ileal circular ulceration (Figure 2A). A nonsignificant and probably irreversible stenosis remained. Histological examination showed only minor, non-specific inflammatory changes and a restoration of the villus architecture in the ileal biopsies (Figure 3B).

Infliximab treatment is currently still ongoing, clinical remission is maintained up till 6 mo after starting treatment.

DISCUSSION

Small intestinal ulceration is a less frequent cause of abdominal pain. Its differential diagnosis includes lymphoma, Crohn's disease, tuberculous enteritis, CMV enteritis, NSAID related enteritis, oral potassium chloride toxicity, severe celiac disease (ulcerative jejunoileitis), systemic vasculitis and CMUSE. Small intestinal strictures are seen in chronic NSAID, ischemic enteritis, abdominal irradiation, Crohn's disease and CMUSE^[1].

CMUSE is an independent entity showing characteristics of inflammatory bowel disease and ischemic enteritis.

The etiology is unclear but angiography studies suggest that in at least a subset of patients, CMUSE may involve vasculitis and even represent a visceral variant of polyarteritis nodosa. It seems likely that CMUSE incorporates chronic nonspecific ulcers of the small intestine (CNSU), a disease reported solely in the Japanese population^[2]. CNSU does not respond to corticosteroid administration, and can therefore be seen as steroid-refractory CMUSE.

CMUSE patients always report intestinal symptoms such as abdominal pain, diarrhea and vomiting related to intestinal (sub)obstruction. In 70% of cases, extraintestinal complaints are mentioned: 50% of patients lose weight, 20% develop fever and 10% complain of joint aches. The relatively frequent presence of extraintestinal signs such as oral aphthae, Raynaud's phenomenon, sicca syndrome and pulmonary disease suggests that CMUSE may be part of a more systemic disorder.

Diagnostic criteria for CMUSE were proposed by Perlemuter *et al.*^[3,4], who published the 2 largest collections of patients (totaling 28 patients): unexplained small intestinal strictures found in adolescents and in middle-aged subjects, superficial ulceration restricted to the mucosa and submucosa, a chronic or relapsing clinical course (even after surgery), no biological signs of systemic inflammatory reaction and a typically (initially) beneficial effect produced by steroids. These criteria can be distilled from the clinical history and (balloon assisted) enteroscopy, the latter providing the histological material necessary to confirm the diagnosis. Histopathology shows an inflammatory response and ulcerative damage restricted to the mucosa and submucosa, different from the transmural involvement typical from Crohn's disease. Blood analysis is needed to detect anemia, to exclude systemic inflammation and may show hypoproteinemia due to protein-losing enteropathy. Medical imaging has its own role in diagnosing small intestinal ulceration/stenosis. A simple contrast follow-through fluoroscopy can dynamically show the presence of intestinal stenosis, but provides no specificity. As mesenteric vascular changes only occur in a subset of patients, performing a diagnostic angiography will not *per se* guide the diagnosis nor the therapy, and should be reserved for selected cases. Our case shows that

CT enterography may lack the sensitivity to capture the often short and circular stenoses that are characteristic for CMUSE, in contrast to the often longer and more complex strictures seen in Crohn's disease.

Differential diagnosis was mentioned earlier and should at least and most importantly include Crohn's disease and NSAID-related enteropathy^[5].

Current medical therapy consists of corticosteroid induction and maintenance with slow tapering of daily dosage, although no randomized clinical trials or guidelines are available to defend this strategy. Corticosteroids may prevent surgical intervention but often lead to steroid-dependence. Steroid-refractory CMUSE has recently been reported in one patient^[6]. The use of other immune suppressive medication such as azathioprine or anti TNF- α inhibition is not reported in current literature. The mainstay of treatment of CMUSE stenosis is surgery, although recurrence is frequent (symptoms and strictures recur in 50% of patients). Endoscopic balloon dilatation can be used as a bridge to surgery, in order to prevent extensive resections of the small intestine and the threat of a short bowel syndrome.

Our patient fits the Perlemuter criteria for CMUSE (although we have no proof that the inflammation does not extend to the submucosa, as the latter can only be confirmed on a resection specimen). He evidently was refractory to steroid treatment, confirming an earlier anecdotal report^[6]. To avoid surgical resection and the high risk of disease recurrence it implies, we opted to treat our patient with the standard of care treatment in inflammatory bowel disease, *i.e.*, the monoclonal TNF- α antibody infliximab. In a small series of patients, this immunosuppressive drug was able to induce disease remission for symptomatic enteric Crohn's strictures^[7], providing a rationale for our treatment trial. Moreover, infliximab has shown its worth in treating rheumatoid arthritis and several forms of vasculitis (although the data for the latter are less extensive)^[8].

After the infliximab induction regimen, clinical remission was immediately noted. Enteroscopy showed near

complete endoscopic remission as well. To our knowledge, this is the first report to describe the beneficial effect of TNF- α blockade in steroid-refractory CMUSE. Evidently, larger series are necessary to confirm this observation.

Abstract

Colonic metastasis from other organs is very rare. Here we report the case of a 62-year-old man with a history of pancreatoduodenectomy for stage IIB pancreatic head cancer performed seven years back. He presented with abdominal distension and pain. Under the preoperative diagnosis of bowel obstruction, surgical treatment was performed, and a circumferential lesion causing bowel obstruction of the ascending colon was detected. A right hemicolectomy with lymph node dissection was performed. The specimen showed a 5-cm wall thickening with a cobble-stone like appearance of the ascending colon, which morphologically appeared scirrhous. Histological examination revealed cancer nests invading from the subserosa to the muscular and submucosal layers of the colon. Immunohistochemical analysis of the tumor cells demonstrated positive staining for cytokeratin 7, but negative for cytokeratin 20, which was the same as the previous pancreatic cancer specimen. These pathological and immunohistochemical features strongly supported the diagnosis of colonic metastasis from the pancreas. Thereafter, the patient

INTRODUCTION

Primary colon cancer is the most common malignancy in the Western part of the world^[1], but colonic metastasis from other solid organs such as the pancreas is extremely rare. Only two cases of colonic metastasis from the pancreas have been previously reported in the English literature^[2,3]. Here we report a case of metachronous colonic metastasis from pancreatic cancer, seven years post-pancreatoduodenectomy, marked by bowel obstruction.

CASE REPORT

A 62-year-old man underwent a pancreatoduodenectomy in May 2001 for pancreatic head cancer. The pathological diagnosis was a well-differentiated adenocarcinoma with strong fibrosis, which was defined as a scirrhous type. There was invasion into the pancreatic duct and lymph node metastases. The stage of pancreatic cancer was T2N1M0 stage II B, as per the American Joint Committee on Cancer staging system 7th edition^[4]. Follow-

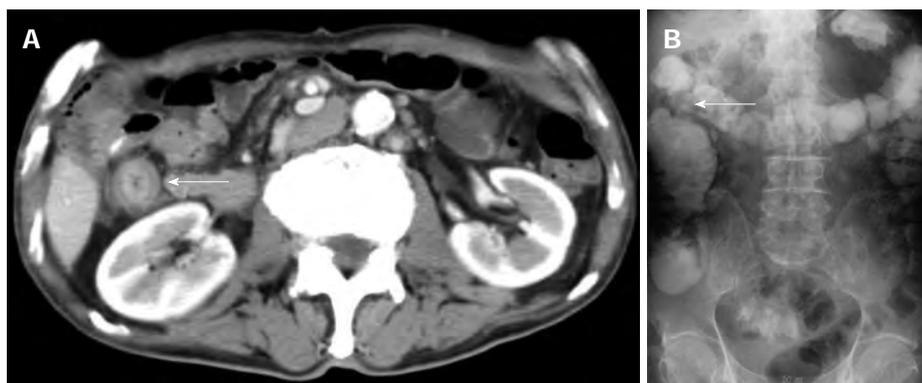

Figure 1 Examinations at seven years after pancreatoduodenectomy. A: An abdominal computed tomography showing thickening of the ascending colon wall with enhancement and luminal narrowing (arrow); B: A contrast examination showing a 5-cm stricture of the ascending colon (arrow).

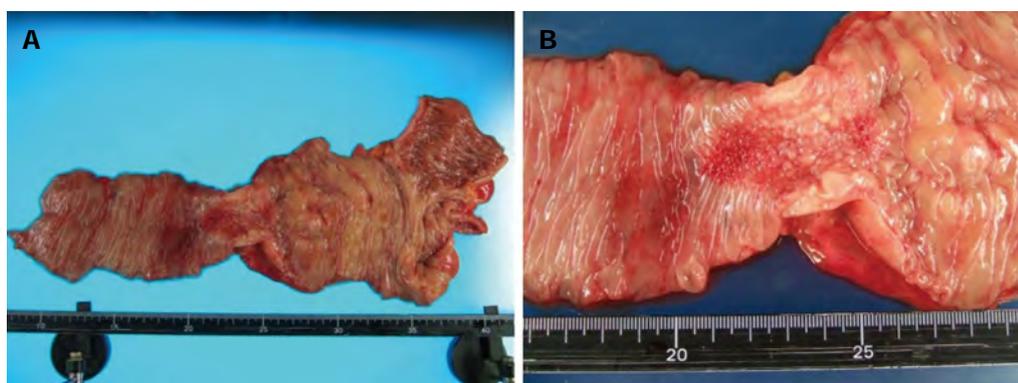

Figure 2 A pathological specimen showing a 5-cm wall thickening and a cobblestone-like appearance of the ascending colon.

up regimen of pancreatic cancer was examinations of computed tomography (CT), ultrasonography and the biological marker every 6 mo. During the seven years of follow-up, he showed no signs of recurrence. In July 2008, he began complaining of abdominal distension and pain. A CT of his abdomen revealed ascending colon wall thickening with luminal narrowing (Figure 1A). There were no other obvious signs of recurrence of pancreatic cancer or ascites. Both chest CT and abdominal ultrasonography also revealed no obvious sign of recurrence. In addition, a contrast examination of the patient's alimentary tract revealed stricture of the ascending colon (Figure 1B). The levels of the biological marker carbohydrate antigen 19-9 (CA19-9) were within the normal range for seven years post-pancreatoduodenectomy; this time, the levels were elevated to 1886.6 U/mL. The carcinoembryonic antigen levels were normal. At this time, a colonoscopy was not performed because of fear of precipitating an overt obstruction. Conservative therapy did not improve the bowel obstruction, thus surgical treatment was performed in August 2008, under the presumptive diagnosis of either an adhesive intestinal obstruction or colon cancer. Intraoperative findings revealed a 5-cm mass in his ascending colon, which was causing the bowel obstruction. Neither peritoneal dissemination nor any other lesions could be observed in the abdomen, including the residual pancreas

or liver. With an intraoperative diagnosis of a tumor in the ascending colon, a right hemicolectomy with adjacent lymphadenectomy was performed. The specimen revealed a 5-cm wall thickening with a cobblestone-like appearance of the ascending colon (Figure 2). The tumor was morphologically scirrhous and infiltrated the colon wall, as seen in gastric linitis plastica. Histological examination revealed cancer nests with glandular structures from the subserosa invading into the muscular and submucosal layers of the colon (Figure 3).

Immunohistochemical staining of the colon tumor as well as the previously resected pancreatic tumor was positive for cytokeratin 7 and negative for cytokeratin 20 (Figure 4). These pathological and immunohistochemical features strongly supported the diagnosis of a tumor in the ascending colon originating from the pancreas and was not a primary adenocarcinoma of the colon. In addition, infiltration of the lymphatic vessels and metastases were observed in two of the 28 dissected lymph nodes. However, the patient had an uneventful postoperative course and was discharged on the 12th post-surgical day. The CA19-9 levels decreased to 840 U/mL after surgery; however, the levels elevated to 8200 U/mL two months later. He was treated with seven cycles of gemcitabine (1000 mg/m²) after pancreatoduodenectomy; nevertheless, his condition deteriorated and he died 14 mo after surgery.

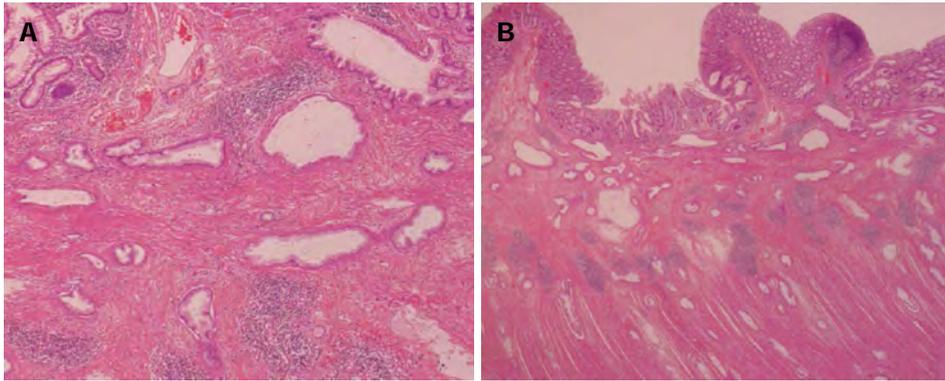

Figure 3 Histological findings revealed the cancer nests invading from the subserosa to the muscular and submucosal layers of the colon. A: $\times 4$; B: $\times 10$.

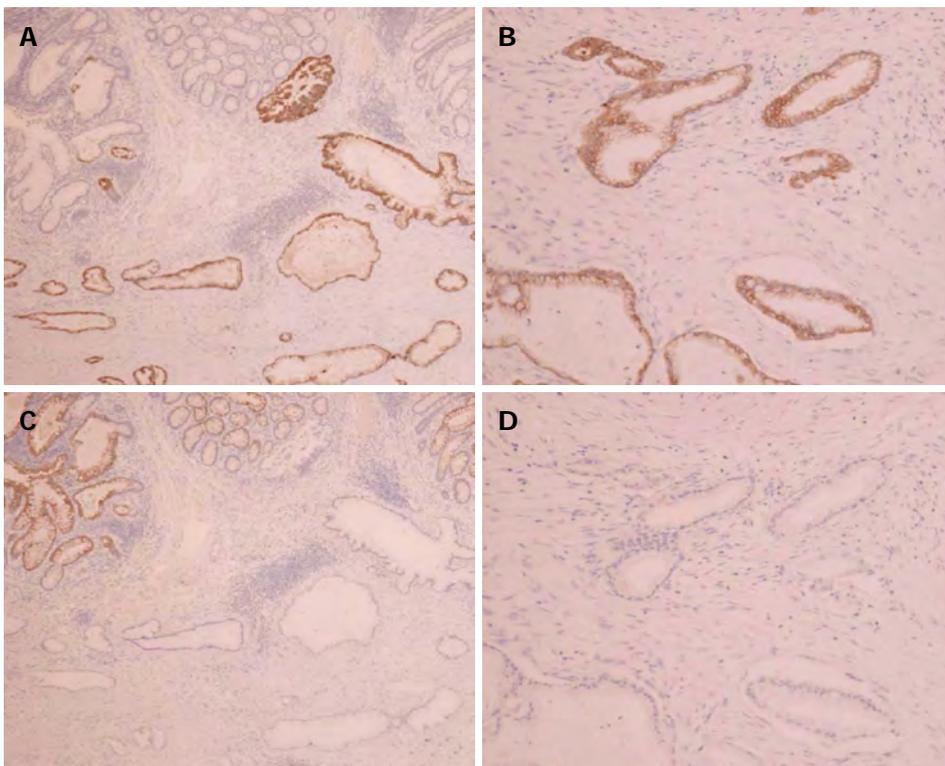

Figure 4 Photomicrographs ($\times 10$). A: Immunostaining showing cytokeratin 7 positivity in colonic metastasis; B: Immunostaining showing cytokeratin 20 negativity in colonic metastasis; C: Immunostaining showing cytokeratin 7 positivity in primary pancreatic cancer; D: Immunostaining showing cytokeratin 20 negativity in primary pancreatic cancer.

DISCUSSION

Pancreatic cancers are very aggressive. Less than 10%-15% of cases present with tumors those are localized to the pancreas at the time of diagnosis. The overall survival rate of advanced pancreatic cancer cases is $< 5\%$ at five years with most patients dying within the first year^[5]. Pancreatic cancer commonly spreads to the liver, lungs, abdomen, regional lymph nodes and peritoneum. Postoperative colonic metastasis from pancreatic cancer is extremely rare, as only two cases have been reported previously in the English literature^[2,3].

Colonic metastases from other organs are rare. However, with regard to treatment and prognosis, a correct diagnosis is very important. Colonic metastases from

other organs typically present scirrhous morphology^[6] and the tumors infiltrate the colon wall in a manner similar to gastric linitis plastica. Specific immunohistochemical staining is useful to diagnose primary tumor sites. Cytokeratin is an intermediate filament protein; cytokeratin 7 is expressed in epithelial cells of the kidney, prostate, pancreas, ovary, lung, and breast, but not in the colon or gastrointestinal tract. However, cytokeratin 20 is expressed in all cases of colorectal carcinomas, 62% of pancreatic carcinoma cases, and 50% of gastric adenocarcinomas^[7]. Thus, a combination of cytokeratins 7 and 20 is very useful to distinguish metastatic colon cancer from ovarian^[8], breast^[9], and primary colon cancers. In two cases, cytokeratin 7 positivity and cytokeratin 20 negativity strongly indicated metastases.

However, in the present case, it was unclear as to how the pancreatic cancer metastasized to the colon. Invasive cancer nests in the muscular layer were conspicuous and the lymph vessels were filled with tumor cells. Only 2 of 28 lymph nodes were positive for metastatic carcinoma. On the basis of these observations, not lymphatic spread but peritoneal (drop-down) metastasis from the pancreas to the colon was assumed as the most likely pathway.

In conclusion, the present report describes a case of colonic metastasis from pancreatic cancer after a pancreatoduodenectomy. Immunohistochemical staining by cytokeratins 7 and 20 were very useful to distinguish metastatic tumors from primary tumors. To our knowledge, this is the third report documenting pancreatic adenocarcinoma metastasizing to the colon by probable lymphatic spread.

Abstract

This is a response letter to Verna E's comments regarding our previous manuscript published last year in the *World Journal of Gastroenterology* entitled "Relationship between *LYVE-1*, *VEGFR-3* and *CD44* gene expressions and lymphatic metastasis in gastric cancer", which evaluated the relationship between these expression levels and clinicopathological parameters (Ozmen F *et al*, *World J Gastroenterology* 2011; 17: 3220-3228). The mean values for lymphatic vessel endothelial hyaluronan receptor-1, CD44 and vascular endothelial growth factor receptor-3 expression (represented as $2^{-\Delta\Delta Ct}$) were 1.13, 1.24 and 1.17, respectively, suggesting an increase in gene expression in tumor tissue compared to normal tissue. Despite the increase in gene expression in the cancer tissues ($2^{-\Delta\Delta Ct} > 1$), only some of the results reached statistical significance, which was thoroughly discussed in our paper. In the present letter, we report that his comments are flawed and result in confusion. Therefore, we herein provide more explanation regarding gene expression in gastric cancer. We hope that this letter will address Verna E's misunderstandings.

Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i10/1669.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i10.1669>

TO THE EDITOR

I recently noticed that a Letter to the Editor written by Verna E, regarding our paper (Ozmen F *et al*, *World J Gastroenterol* 2011; 17: 3220-3228), had been published in the June issue of the Journal this year (Verna E, *World J Gastroenterol* 2012; 18: 3181-3182)^[1,2].

Although I would like to thank Dr. Verna for his interest and for providing us with this opportunity to address his concerns, I have to stress that it is very important to understand the paper in its entirety before coming to certain conclusions: (1) Our study investigated the expression levels of the lymphatic vessel endothelial hyaluronan receptor-1 (*LYVE-1*), vascular endothelial growth factor receptor-3 (*VEGFR-3*), and *CD44* genes in human tissues with or without a tumor using real-time polymerase chain reaction (RT-PCR) and evaluated the relationship in gastric cancer between these expression levels and clinicopathological parameters that included tumor type, stage, differentiation, and the presence of lymph node metastasis, vascular invasion, and neural/perineural invasion^[1]; (2) Relative expression levels were calculated using the PCR cycle threshold (Ct) number for each tissue and control sample using the formula $2^{-\Delta(Ct_{\text{sample}} - \Delta Ct_{\text{control}})}$. ΔCt represents the difference in Ct values between the target and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) transcripts. RT-PCR was performed in duplicate for each sample, and average Ct values were calculated according to the previous papers from Pfaffl^[3] and Livak *et al*^[4], which are references he cited in his letter; (3) It is not clear why he required an explanation of the interpretation of the gene expression data because everyone involved in this type of study is familiar with

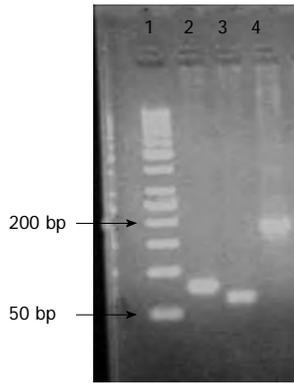

Figure 1 Polymerase chain reaction products of the *CD44*, vascular endothelial growth factor receptor-3, and lymphatic vessel endothelial hyaluronan receptor-1 genes. Lane 1: Ladder (50 bp); Lane 2: *CD44* (80 bp); Lane 3: Vascular endothelial growth factor receptor-3 (63 bp); Lane 4: Lymphatic vessel endothelial hyaluronan receptor-1 (184 bp).

the analysis. As previously explained by Livak *et al*^[4], the choice of the calibrator for the $2^{-\Delta\Delta C_t}$ method depends on the type of gene expression experiment that one has planned. The simplest design is to use the untreated control (in our study, the patient's own normal tissue) as the calibrator and GAPDH as an internal control. Using the $2^{-\Delta\Delta C_t}$ method, the data are presented as the fold change in gene expression normalized to an endogenous reference gene and relative to the normal control. For the control sample, $\Delta\Delta C_t$ equals zero, and 2^0 equals one; as a result, the fold change in gene expression relative to the untreated control equals one, by definition. For the treated samples (tumor tissue), an evaluation of $2^{-\Delta\Delta C_t}$ indicates the fold change in gene expression relative to the untreated control. The gene expression levels in tumor tissues represent the difference from normal controls in our study, and all values were shown in Fig. 2^[1]. There were some values over 1, representing increased expression, and there were also values less than 1, representing decreased expression; (4) The mean values for *LYVE1*, *CD44* and *VEGFR3* expression (represented as $2^{-\Delta\Delta C_t}$ and shown in Fig. 2) were 1.13, 1.24 and 1.17, respectively, suggest-

ing increased gene expression in tumor tissues compared to normal tissue. Therefore, we believe it is natural to conclude from these results that the expression levels were increased. Despite the increase in gene expression in the cancer tissues ($2^{-\Delta\Delta C_t} > 1$), only some of the results reached statistical significance, which was thoroughly discussed in our paper^[1]; (5) In our study, we did not only report the gene expression data, but also presented data obtained using immunohistochemistry, pathology, and other clinical features of the tumors. Although we are commenting on our results, we used all of these data to reach a logical conclusion. As shown in Fig. 3, 4 and 5, gene expression was increased ($2^{-\Delta\Delta C_t} > 1$) with increased T-stage, a PLN/TLN ratio > 0.4 and the presence of perineural invasion^[1]; and (6) In our manuscript, we used Figure 1 to show the PCR products of the genes. Dr. Verna is correct to note that there are some non-specific amplicons of the *VEGFR-3* gene in that Figure. However, we optimized both the conventional PCR and real-time PCR reactions for the *VEGFR-3* gene and also all others, as shown in the lower part of Figure 1. It is easy to note that no nonspecific band is present in this reaction for *VEGFR-3*.

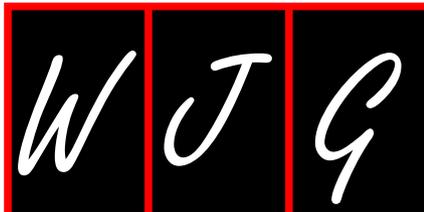

Once again, I would like to thank Dr. Verna for his interest in our study and hope that this letter will resolve any misunderstandings.

Abstract

The selection of antiviral drugs for chronic hepatitis B (CHB) treatment in pregnancy is very difficult since none of the drugs have been approved for use in pregnancy. Transmission from mother to newborn remains the most frequent route of infection in mothers with high viral load and positive hepatitis B e antigen status, even with the use of appropriate prophylaxis with hepatitis B virus (HBV) immunoglobulin and HBV vaccination. We read from the article written by Yi *et al* that lamivudine treatment in early pregnancy was safe and effective. However, we could not understand why adefovir dipivoxil (ADV) was used in three pregnancy cases, since ADV has been classified as pregnancy category C. In pregnancy, telbivudine or tenofovir should be selected when the treatment of CHB is necessary, since these drugs have been classified as Food and Drug Administration pregnancy risk category B.

TO THE EDITOR

We read the article entitled “Safety of lamivudine treatment for chronic hepatitis B in early pregnancy”, with great interest. The management of chronic hepatitis B (CHB) in pregnancy is complex. Especially in endemic areas, vertical transmission from mother to newborn remains the most frequent route of infection and this situation often leads to chronic disease. Moreover, even with the use of appropriate prophylaxis with hepatitis B virus (HBV) immunoglobulin and HBV vaccination, a significant risk of vertical transmission remains, particularly in mothers with high viral loads and positive hepatitis B e antigen status^[1].

Without a doubt, the article by Yi *et al*^[2] sheds very important light on CHB treatment in pregnancy. They reported that lamivudine treatment in early pregnancy was safe and effective. In addition they stated that adefovir dipivoxil (ADV) was given in three cases who had HBV DNA above 10⁶ copies/mL, from week 28 of pregnancy. However, we know that ADV is classified as pregnancy category C and there are no adequate and well controlled studies on the use of adefovir during pregnancy^[3]. On the other hand, we have two drugs, tenofovir and telbivudine, which are classified as Food and Drug Administration pregnancy risk category B^[4]. Tenofovir received this classification based on data collected from human exposure, and in addition, Han *et al*^[5] study in pregnant women supports the “B” rating of telbivudine^[1]. In patients treated with ADV or entecavir, these drugs should be switched to safer drugs, if a woman becomes pregnant^[1]. For the sake of clarity for readers, it would be helpful if the authors explained why they selected ADV instead of tenofovir or telbivudine for pregnant women with CHB.

Abstract

Low-dose aspirin (LDA) is clinically used for the prevention of cardiovascular and cerebrovascular events with the advent of an aging society. On the other hand, a very low dose of aspirin (10 mg daily) decreases the gastric mucosal prostaglandin levels and causes significant gastric mucosal damage. The incidence of LDA-induced gastrointestinal mucosal injury and bleeding has increased. It has been noticed that the incidence of LDA-induced gastrointestinal hemorrhage has increased more than that of non-aspirin non-steroidal anti-inflammatory drug (NSAID)-induced lesions. The pathogenesis related to inhibition of cyclooxygenase (COX)-1 includes reduced mucosal flow, reduced mucus and bicarbonate secretion, and impaired platelet aggregation. The pathogenesis related to inhibition of COX-2 involves reduced angiogenesis and increased leukocyte adherence. The pathogenic mechanisms related to direct epithelial damage are acid back diffusion and impaired platelet aggregation. The factors associated with an increased risk of upper gastrointestinal (GI) complications in subjects taking LDA are aspirin dose, history of ulcer or upper GI bleeding, age > 70 years, concomitant use of non-aspirin NSAIDs including COX-2-selective NSAIDs, and *Helicobacter pylori* (*H. pylori*) infection. Moreover, no significant differences have been found

between ulcer and non-ulcer groups in the frequency and severity of symptoms such as nausea, acid regurgitation, heartburn, and bloating. It has been shown that the ratios of ulcers located in the body, fundus and cardia are significantly higher in bleeding patients than the ratio of gastroduodenal ulcers in patients taking LDA. Proton pump inhibitors reduce the risk of developing gastric and duodenal ulcers. In contrast to NSAID-induced gastrointestinal ulcers, a well-tolerated histamine H₂-receptor antagonist is reportedly effective in prevention of LDA-induced gastrointestinal ulcers. The eradication of *H. pylori* is equivalent to treatment with omeprazole in preventing recurrent bleeding. Continuous aspirin therapy for patients with gastrointestinal bleeding may increase the risk of recurrent bleeding but potentially reduces the mortality rates, as stopping aspirin therapy is associated with higher mortality rates. It is very important to prevent LDA-induced gastroduodenal ulcer complications including bleeding, and every effort should be exercised to prevent the bleeding complications.

INTRODUCTION

Low-dose aspirin (LDA) is clinically used for the prevention of cardiovascular and cerebrovascular events with

the advent of an aging society^[1-6]. Worldwide trials of antiplatelet therapy have demonstrated that an antiplatelet regimen (such as aspirin 75-325 mg/d) offers worthwhile protection against myocardial infarction, stroke, and death.

On the other hand, a very low dose of aspirin (10 mg daily) decreases the gastric mucosal prostaglandin levels and causes significant gastric mucosal damage^[7]. The incidence of LDA-induced gastrointestinal (GI) mucosal injury has increased^[8-11]. This review focuses on the clinical characteristics of LDA-induced GI ulcer or erosion and bleeding, including incidence, mechanism, risk of bleeding, clinical manifestations, risk factors, endoscopic features, prevention, and treatment.

CLINICAL FEATURES OF LDA-INDUCED GI INJURY

Incidence of LDA-induced GI ulcer and bleeding

The incidence of upper GI damage in patients taking long-term LDA has been investigated. In a multicenter investigation, Yeomans *et al*^[12] found that the prevalence rates of ulcer and erosion were 10.7% and 63.1%, respectively, in 187 patients taking long-term LDA, and that the incidence rates of ulcer and erosion in 113 patients followed up for 3 mo were 7.1% and 60.2%, respectively, indicating that GI ulcers develop in one in 10 patients taking LDA.

The annual incidence of serious upper GI ulcer bleeding among Japanese patients taking LDA or non-aspirin non-steroidal anti-inflammatory drugs (NSAID) was investigated. The pooled incidence rate of bleeding was 2.65% (range: 2.56%-2.74%) and 1.29% (range: 1.27%-1.31%) per 1000 patient years for LDA and non-aspirin NSAID users, respectively^[13]. Niv *et al*^[14] have investigated, using esophagogastroduodenoscopy, 46 asymptomatic patients taking LDA and they detected ulcer or erosions in 22 patients, erosive gastroduodenitis in 13, gastric ulcer in 14, duodenal ulcer in 2, and gastric and duodenal ulcers in 2, suggesting that esophagogastroduodenoscopy is important for LDA users, even the asymptomatic patients. The incidence and factors influencing the occurrence of upper GI bleeding in 903 consecutive patients taking LDA were analyzed. The results revealed that 4.5% of patients presented with upper GI bleeding requiring hospitalization during follow-up, and the incidence of upper GI bleeding was 1.2 per 100 patient years^[9]. The incidence rates of upper GI bleeding in 27 694 users of LDA were analyzed, and a total of 207 exclusive users of LDA experienced a first episode of upper GI bleeding. The standardized incidence rate of upper GI bleeding among LDA users was 2.6% (range: 2.2%-2.9%), and the standardized incidence rate for combined use of LDA and other NSAIDs was 5.6% (range: 4.4%-7.0%)^[10].

The frequency of gastroduodenal injuries associated with LDA use for prevention of cardiovascular and cerebrovascular events were investigated. The results

showed that mucosal injuries occurred in 61.4% and gastroduodenal ulcers in 18.8% of 101 LDA users with ischemic heart disease who were not receiving antiulcer treatment^[15]. In another investigation, screening upper endoscopic examinations were prospectively performed on 236 patients with ischemic heart disease, and mucosal defects were found in 92 of 190 (48.4%) users of LDA and in 6 of 46 (13.0%) non-users^[16].

Taha *et al*^[17] have investigated the efficacy of famotidine in prevention of peptic ulcers and erosive esophagitis in patients receiving LDA. They showed that gastric ulcers had developed in 3.4% of patients treated with famotidine and in 15.0% of patients on placebo, while duodenal ulcers had developed in 0.5% and 8.5%, respectively. Other previous reports have examined the efficacy of esomeprazole as compared with placebo in prevention of peptic ulcers in patients who were at risk for ulcer development taking low-dose acetylsalicylic acid (ASA). These studies have shown that esomeprazole significantly reduced the cumulative proportion of patients with peptic ulcers, and that 7.4% of placebo recipients developed peptic ulcers^[18]. These studies have revealed not only the efficacy of famotidine or esomeprazole but also the incidence of gastroduodenal ulcer in patients taking long-term LDA without anti-ulcer drugs.

A clinical investigation examined the efficacy of low-dose lansoprazole in the secondary prevention of LDA-associated gastric or duodenal ulcers, and showed that the cumulative incidence of gastric or duodenal ulcers was 3.7% in the lansoprazole group and 31.7% in the placebo group. This investigation indicated that the incidence of gastric or duodenal ulcers was 31.7% in patients with a definite history of gastric or duodenal ulcers who required long-term LDA therapy^[19].

The incidence rates of upper GI events in LDA users are summarized in Table 1.

Mechanism of LDA-induced gastroduodenal mucosal damage

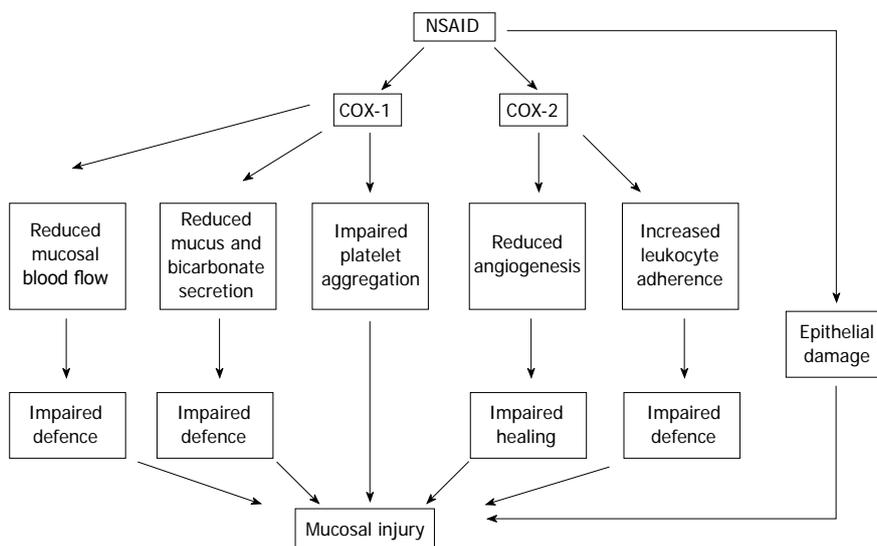

The mechanism of action of NSAIDs or LDA can be subdivided into local action and systemic action, and several mechanisms have been reported in a previous review^[20] (Figure 1). The pathogenesis related to inhibition of cyclooxygenase (COX)-1 includes reduced mucosal flow, reduced mucus and bicarbonate secretion, and impaired platelet aggregation. The pathogenic mechanisms involved in inhibition of COX-2 are reduced angiogenesis and increased leukocyte adherence. The pathogenesis related to direct epithelial damage involves acid back diffusion and impaired platelet aggregation. Aspirin is a more potent inhibitor of COX-1 than of COX-2^[20] (Figure 1).

Both the direct effect of aspirin on the GI mucosa and the systemic effect related to reduction of prostaglandin level are suggested to contribute in the pathogenesis of LDA-induced GI mucosal damage^[7]. Some researchers have suggested that reduction in the ability of the gastric mucosa to synthesize prostaglandin E2 and

Table 1 Incidence of upper gastrointestinal events in low-dose aspirin users

| Ref. | Subjects | GI event | Incidence rate |
|---------------------------------------|-----------------------------|---------------------------------|--|
| Yeomans <i>et al</i> ^[12] | 187 | Gastroduodenal | 10.7% |
| | | Gastroduodenal | 63.1% |
| Ishikawa <i>et al</i> ^[13] | 1657 | Gastroduodenal | 2.65 (95%CI: 2.56-2.74) per 1000 patient years |

GI: Gastrointestinal.

**Figure 1** Pathogenesis of non-steroidal anti-inflammatory drug-induced gastric injury. Non-steroidal anti-inflammatory (NSAID) drugs induce injury *via* three key pathways: inhibition of cyclooxygenase (COX)-1 activity, inhibition of COX-2 activity, and direct cytotoxic effects on the epithelium. Aspirin is a more potent inhibitor of COX-1 than of COX-2^[20].

the consequent side effects result in injury of the gastric mucosa following aspirin use^[21].

Gastric damage in rats induced by a selective COX-1 inhibitor (SC-560) and a selective COX-2 inhibitor (celecoxib) were investigated. SC-560 alone or celecoxib alone did not cause gastric damage, whereas the combination of SC-560 and celecoxib invariably caused hemorrhagic erosion. This study suggested that inhibition of both COX-1 and COX-2 is required for NSAID-induced gastric injury in the rat^[22].

Another study demonstrated that COX-1-deficient mice survived well and had no gastric pathology, indicating that inhibition of both COX-1 and COX-2 was required for NSAID-induced gastric injury^[23].

A previous review has suggested a mechanism of LDA-induced gastroduodenal mucosal injury, claiming that ion trapping and back diffusion of hydrogen ions lead to gastric erosion and bleeding; this is known as the hypothesis of NSAIDs' dual insult on the stomach^[24].

It has been suggested that NSAID-induced neu-

trophil adherence is associated with NSAID-induced GI mucosal damage. The neutrophil adherence to the vascular endothelium could lead to obstruction in the capillaries with consequent reduction of blood flow in the gastric mucosa. The increased production of oxygen-derived free radicals and the liberation of proteases are also associated with NSAID-induced mucosal damage^[25].

Risk of upper GI injury and bleeding associated with long-term use of LDA

A previous investigation has evaluated the long-term effects of individual doses of aspirin (10 mg, 81 mg, or 325 mg daily for 3 mo) on the GI tract, and revealed that a very low dose of aspirin (10 mg daily) decreased the gastric mucosal prostaglandin levels and caused significant gastric mucosal damage^[7].

Other researchers studied the characteristics of patients with acute upper GI hemorrhage at 3 time points over a 6-year follow-up period, and revealed that the incidence of hemorrhage in patients taking LDA increased

from 15 per 100 000 of the population per annum to 18 and 27, and that the respective incidence rates in patients taking other anti-thrombotic drugs were 4, 8, and 12, respectively. On the other hand, no significant change was found in NSAID users. This study has suggested that the rate of LDA-induced GI hemorrhage is higher than that of non-aspirin NSAID-induced lesions^[26]. A previous case-control study demonstrated that the percentages of regular users of aspirin regimens (300 mg daily or less) among patients with gastric or duodenal ulcer bleeding, hospital and community controls were 12.8%, 9.0%, and 7.8%, respectively, concluding that the regular users of aspirin regimens were at risk for gastric or duodenal ulcer bleeding^[27].

A case-control study in Japan has shown that the odds ratio (OR) of upper GI bleeding was 5.5 for aspirin and 6.1 for non-aspirin NSAIDs, indicating that the risk of upper GI bleeding in the cases taking LDA is almost similar to the risk in the cases taking non-aspirin NSAIDs^[28].

A meta-analysis of 24 randomized controlled trials has evaluated the incidence of GI hemorrhage associated with long-term aspirin therapy to determine the effect of dose reduction and formulation on the incidence of hemorrhage. This meta-analysis revealed that GI hemorrhage occurred in 2.47% of patients taking aspirin as compared with 1.42% taking placebo. This study suggested that long-term therapy with aspirin is associated with a significant increase in the incidence of GI hemorrhage, and no evidence was found supporting the proposal that reducing the dose or using modified release formulations would reduce the incidence of GI hemorrhage^[29]. Another meta-analysis of 6 trials investigated the benefits and GI risk of aspirin use for secondary prevention of cerebrovascular and cardiovascular diseases. It was shown that aspirin reduced all-cause mortality by 18%, the number of strokes by 20%, myocardial infarctions by 30%, and other vascular events by 30%. It was further demonstrated that patients who took aspirin were 2.5 times more likely than those in the placebo group to have GI tract bleeding, concluding that aspirin use for secondary prevention of thromboembolic events has a favorable benefit-to-risk profile^[30].

A previous investigation has demonstrated that following percutaneous coronary intervention, long-term (one year) clopidogrel therapy significantly reduced the risk of adverse ischemic events, indicating the efficacy of clopidogrel therapy in such cases^[31].

The risk of major upper gastrointestinal bleeding associated with various antiplatelet drugs has been examined, and the results revealed that the individual risks of upper GI bleeding were 4.0% (range: 3.2%-4.9%) with acetylsalicylic acid, 2.3% (range: 0.9%-6.0%) with clopidogrel, 0.9% (range: 0.4%-2.0%) with dipyridamole, and 3.1% with ticlopidine (range: 1.8%-5.1%), suggesting that not only acetylsalicylic acid but also the other various antiplatelet drugs have some risk for upper GI bleeding^[32].

The risk of upper GI bleeding following the combined use of LDA and other antithrombotic drugs has

been investigated. Hallas *et al.*^[33] have assessed the risk of serious upper GI bleeding in patients taking LDA alone or in combination with other antithrombotic drugs. This investigation demonstrated that the adjusted odds ratios associating drug use with upper GI bleeding were 1.8 (range: 1.5-2.1) for LDA, 1.1 (range: 0.6-2.1) for clopidogrel, 1.9 (range: 1.3-2.8) for dipyridamole, and 1.8 (range: 1.3-2.4) for vitamin K antagonists. Furthermore, they have shown that the adjusted odds ratios associated with combined use were 7.4 (range: 3.5-15) for clopidogrel and aspirin, 5.3 (range: 2.9-9.5) for vitamin K antagonists and aspirin, and 2.3 (range: 1.7-3.3) for dipyridamole and aspirin^[33]. The higher risk of upper GI bleeding in patients receiving LDA and other antithrombotic drugs was revealed.

Risk factors for LDA-induced GI damage and bleeding

A previous investigation demonstrated that at doses below 163 mg/d, GI hemorrhage occurred in 2.30% of patients taking aspirin as compared with 1.45% taking placebo, and that with modified release formulations of aspirin, the odds ratio was 1.93, indicating that reducing the dose or using modified release formulations would not reduce the incidence of GI hemorrhage^[29].

Another report examined the association between taking LDA and the risk of symptomatic ulcer. The authors demonstrated that the relative risk was 2.9 (range: 2.3-3.6) for aspirin (75 mg) users as compared with non-users, and that the relative risk was similar for doses up to 300 mg daily^[34].

On the other hand, a multivariate analysis examined the risk factors for LDA-related upper GI bleeding, and showed that higher doses of aspirin increased the risk of upper GI bleeding, suggesting a dose-dependent risk for aspirin^[9].

A multicenter case-control study investigated 550 incident cases of upper GI bleeding admitted into hospital with melena or hematemesis and confirmed by endoscopy, in comparison with 1202 controls identified from population census lists about the use of aspirin. This study demonstrated that the relative risks of upper GI bleeding for plain, enteric-coated, and buffered aspirin at average daily doses of 325 mg or less were 2.6, 2.7, and 3.1, respectively, and at doses greater than 325 mg, the relative risk was 5.8 for plain and 7.0 for buffered aspirin^[35]. Another investigation disclosed that the risk of upper GI bleeding was similar among users of non-coated LDA and coated LDA^[10]. It was also suggested in another study that the risk of gastroduodenal ulcer was similarly elevated for both regular and enteric-coated preparations of LDA^[34]. These clinical reports revealed no important differences in risk among the three aspirin forms.

Some studies have been designed to identify patients who are most likely to have adverse events of NSAID therapy. The established risk factors for development of NSAID-associated gastroduodenal ulcers were reportedly advanced age, history of ulcer, concomitant use of corticosteroids, higher dose of NSAID including the use of

more than one NSAID, concomitant administration of anticoagulants, and serious systemic disorders, while possible risk factors were reportedly concomitant infection with *Helicobacter pylori* (*H. pylori*), cigarette smoking, and consumption of alcohol^[36].

The risk factors for upper GI bleeding or peptic ulcer in patients taking LDA have been suggested in a previous investigation. A clinical study evaluated the risk predictors of gastroduodenal ulcers during treatment with vascular protective doses of aspirin, and suggested that older age and *H. pylori* infection increased the risk of gastroduodenal ulcers^[12].

A multivariate analysis examined the risk factors for LDA-related upper GI bleeding, and showed that a history of peptic ulcer or upper GI bleeding correlated with higher risk of upper GI bleeding. On the other hand, antisecretory and nitro-vasodilator drugs correlated with a decreased risk^[9]. It has been suggested that the factors associated with an increased risk of upper GI complications in subjects taking LDA are aspirin dose, history of ulcer or upper GI bleeding, age > 70 years, concomitant use of non-aspirin NSAIDs including COX-2-selective NSAIDs, and *H. pylori* infection^[8].

A previous cohort study investigated the incidence rates of upper GI bleeding in 27 694 users of LDA as compared with the incidence rates in the general population. This study disclosed that the standardized incidence rate ratio was 2.6 (range: 2.2-2.9), and the standardized incidence rate ratio for combined use of LDA and other NSAIDs was 5.6 (range: 4.4-7.0), indicating the higher risk of combined use of LDA and other NSAIDs^[10].

Many investigators have reported the relationship between *H. pylori* infection and use of NSAIDs in the pathogenesis of gastroduodenal ulcer, and this is still controversial. A meta-analysis of 25 studies has shown that both *H. pylori* infection and use of NSAIDs independently and significantly increase the risk of peptic ulcer and ulcer bleeding, concluding that there is synergism for the development of peptic ulcer and ulcer bleeding between *H. pylori* infection and NSAID use^[37]. Another previous study investigated whether *H. pylori* increases the risk of upper GI bleeding in patients taking LDA, evaluating the role of *H. pylori* infection and other clinical factors. The results revealed that *H. pylori* infection was an independent risk factor of upper GI bleeding in this population (OR: 4.7, range: 2.0-10.9)^[38]. On the other hand, another previous report has demonstrated that *H. pylori*-infected patients were less likely to have any gastric erosion than the non-infected, indicating that *H. pylori* infection may partially protect against LDA-induced gastric erosion^[39].

A previous case-control study investigated the risk of peptic ulcer and upper GI bleeding associated with the use of coxibs, traditional NSAIDs, aspirin, or combinations of these drugs. This study demonstrated that the risk associated with coxib use for upper GI bleeding was less than that of non-selective NSAIDs. This report revealed that with combined use of LDA, the lower risk

of coxibs tended to disappear^[40]. The Celecoxib Long-term Arthritis Safety Study has shown that for patients not taking aspirin, the annual incidence rates of upper GI ulcer complications alone and combined with symptomatic ulcers for celecoxib were 0.44% and 1.40%, respectively, and for patients taking aspirin, the corresponding rates were 2.01% and 4.70%, respectively. These results suggested that celecoxib was associated with a lower incidence of GI toxicity, but that the risk increased with concomitant use of LDA^[41].

Although coxibs tend to present a lower risk of upper GI complications than NSAIDs overall, aspirin is a strong effect modifier, abolishing completely the GI safety advantage of coxibs over NSAIDs, suggesting that concomitant use of COX-2 inhibitor and LDA increases the risk of upper GI complications^[42].

Clinical manifestations of LDA-induced gastroduodenal injury

Previous studies have demonstrated a correlation between clinical manifestations and ulcers in patients taking LDA. In a multicenter investigation, Yeomans *et al*^[12] demonstrated that the ulcer prevalence was 10.7% in 187 patients taking long-term LDA, and that only 20% had dyspeptic symptoms, which was not significantly different from the patients without ulcer. This study revealed no significant differences between the ulcer groups and non-ulcer groups in the frequency and severity of symptoms such as nausea, acid regurgitation, heartburn, and bloating^[12]. Another previous report stated that some patients on aspirin complained of symptoms whereas the others remained completely asymptomatic, indicating that the patients remaining free of symptoms seemed to characteristically have a higher gastric sensory threshold^[43]. Niv *et al*^[14] have investigated 46 asymptomatic patients taking mini-dose aspirin for more than 3 mo. Ulcer or erosions developed in 22 of those patients taking mini-dose aspirin, erosive gastroduodenitis in 13, gastric ulcer in 14, duodenal ulcer in 2, and gastric and duodenal ulcers in 2, indicating a high prevalence of ulcerations of the stomach and duodenum in asymptomatic LDA users^[14].

The mechanism of asymptomatic ulceration in aspirin users has been investigated, and it was suggested that subjects on aspirin remaining free of symptoms appear to characteristically have higher gastric sensory thresholds^[43].

Endoscopic features of LDA-induced gastroduodenal mucosal damage

A recent investigation has examined the chronological changes of the GI mucosa with LDA use in 20 healthy *H. pylori*-negative subjects. These patients were divided into those receiving 100 mg aspirin with placebo, and those receiving 100 mg aspirin + 300 mg rebamipide daily for 7 d, and they were examined for mucosal damage at 0, 2, 6, and 24 h on the first day, and then on the third and seventh days. The results revealed that ulcers developed in the duodenum at 24 h and in the antrum at 72 h, and

that erosions mainly developed in the duodenum in the subjects receiving 100 mg aspirin, concluding that damage occurred in the duodenum most frequently and that almost all damage improved gradually in spite of continuous aspirin^[44]. A prospective study on 238 patients with bleeding peptic ulcers demonstrated the endoscopic characteristics of LDA-induced hemorrhagic ulcer. Non-NSAID-induced ulcers were significantly higher in the gastric body than the LDA-induced ulcers, and non-aspirin NSAID-induced ulcers and most of the LDA-induced ulcers were found in the gastric body, angular notch, and duodenum. The number of ulcers was investigated in 18 non-aspirin NSAID-induced ulcers, and the ulcer was single in 44.4% and multiple in 55.6%^[11]. In our previous investigation, the ratios of ulcers located in the antrum of patients taking LDA and non-aspirin NSAIDs were significantly higher than those of patients not taking NSAIDs (the bleeding patients and the whole gastroduodenal ulcer patient population). It also has been shown that the ratios of ulcers located in the body, fundus, and cardia were significantly higher in the bleeding patients than in the whole gastroduodenal ulcer patient population taking LDA^[45]. Shiotani *et al*^[46] investigated 305 patients taking 100 mg aspirin for cardiovascular diseases. They found that 38 patients (12.4%) had ulcer lesions (34 gastric ulcer, 2 duodenal ulcer, and 2 with gastroduodenal ulcer). Of the 34 gastric ulcers, 18 were single and 16 were multiple, and 58.8% of the gastric ulcers were in the gastric body while the maximum ulcer size was 25 mm^[46].

Some investigators analyzed the size of LDA-induced ulcers, and demonstrated that gastric ulcers were more frequent than duodenal ulcers in both *H. pylori*-negative and -positive patients; the gastric ulcers and duodenal ulcers were most commonly 5-10 mm in size^[47]. In a study on 674 upper GI bleeders, erosive esophagitis was detected in 150 cases, suggesting that erosive esophagitis is common in patients with upper GI bleeding taking LDA or antithrombotic agents^[48].

PREVENTION AND TREATMENT OF LDA-INDUCED GASTRODUODENAL MUCOSAL DAMAGE

Prevention of LDA-induced gastroduodenal mucosal damage and bleeding

The primary prevention of LDA-induced gastroduodenal damage has been investigated. It was demonstrated that famotidine is effective in prevention of gastric and duodenal ulcers, as well as erosive esophagitis, in patients taking LDA^[17]. In contrast to NSAID-induced GI ulcers, a well-tolerated histamine H2-receptor antagonist is effective in preventing the development of LDA-induced GI ulcers.

A previous study investigated the efficacy of esomeprazole in reducing the risk of gastric and duodenal ulcers in patients receiving continuous LDA therapy. The results revealed that 5.4% in the placebo group developed

a gastric or duodenal ulcer during the 26-wk treatment as compared with 1.6% in the esomeprazole group, suggesting that esomeprazole (20 mg once daily) reduces the risk of developing gastric and duodenal ulcers^[47]. Another clinical trial revealed that treatment with esomeprazole (40 mg or 20 mg once daily) reduces the occurrence of peptic ulcers in LDA-taking patients who are at risk for ulcer development^[18].

The secondary prevention of LDA-induced gastroduodenal damage has been investigated. A case-control study demonstrated that proton pump inhibitors, H2-receptor antagonists, and nitrates reduced upper GI bleeding risk, suggesting that antisecretory agents or nitrate treatment results in reduced relative risks of upper GI bleeding in patients taking NSAIDs or aspirin^[49]. A clinical trial involving 160 patients with aspirin-related peptic ulcers/erosions compared the efficacy of H2-receptor antagonists (famotidine group) and proton pump inhibitors (pantoprazole group). This trial demonstrated that GI bleeding was significantly more frequent in the famotidine group than in the pantoprazole group^[50]. A clinical investigation in Japan examined the efficacy of low-dose lansoprazole (15 mg once daily) in the secondary prevention of LDA-associated gastric or duodenal ulcers. The patients were randomized to receive lansoprazole 15 mg daily ($n = 226$) or gefarnate 50 mg twice daily ($n = 235$) for 12 mo or longer. The results disclosed that the cumulative incidence of gastric or duodenal ulcers was 3.7% in the lansoprazole group and 31.7% in the placebo group, indicating that lansoprazole was superior to gefarnate for the secondary prevention of LDA-associated gastric or duodenal ulcers^[19]. After the ulcers had healed, the patients who were negative for *H. pylori* were randomly assigned to receive either 75 mg of clopidogrel daily plus placebo or 80 mg of aspirin daily plus 20 mg of esomeprazole twice daily for 12 mo. The results showed that recurrent ulcer bleeding occurred in 13 patients receiving clopidogrel and in 1 receiving aspirin plus esomeprazole. This study concluded that among patients with a history of aspirin-induced ulcer bleeding, aspirin plus esomeprazole was superior to clopidogrel in the prevention of recurrent ulcer bleeding in *H. pylori*-negative patients^[51]. The studied co-treatments for prevention of LDA-induced gastroduodenal events are displayed in Table 2.

Treatment of LDA-induced gastroduodenal injury and bleeding

It has been reported that ranitidine with NSAID discontinuation is effective in the treatment of NSAID-induced gastroduodenal ulcer^[52]. If it is not possible to stop NSAID treatment, rabeprazole should be used as its efficacy for NSAID-induced ulcer under continuous NSAID administration has been confirmed^[53].

Many investigations have studied the efficacy of proton pump inhibitors in the healing of NSAID-induced gastroduodenal ulcer in comparison with the efficacy of H2-receptor antagonists. Most of the reports stated that

Table 2 Prevention of low-dose aspirin-induced gastroduodenal events

| Ref. | Co-treatment | GI event | Incidence rate |
|---------------------------------------|---|---------------------------------------|-------------------------------|
| Taha <i>et al</i> ^[17] | Famotidine 40 mg vs placebo | Gastric ulcers/duodenal ulcers | 3.4% vs 15.0% 0.5% vs 8.5% |
| Scheiman <i>et al</i> ^[18] | Esomeprazole 40 mg vs 20 mg vs placebo | Gastroduodenal ulcers | 1.5% vs 1.1% vs 7.4% |
| Sugano <i>et al</i> ^[19] | Lansoprazole 15 mg vs placebo | Gastroduodenal ulcers | 3.7% vs 31.7% |
| Yeomans <i>et al</i> ^[47] | Esomeprazole 20 mg vs placebo | Gastroduodenal ulcers | 1.6% vs 5.4% |
| Ng <i>et al</i> ^[50] | Famotidine 40 mg vs pantoprazole 20 mg | Dyspeptic or bleeding ulcers/erosions | 20% vs 0% |
| Chan <i>et al</i> ^[67] | Omeprazole 20 mg vs <i>H. pylori</i> eradication | Gastroduodenal bleeding | 0.9% vs 1.9% |
| Lai <i>et al</i> ^[68] | <i>H. pylori</i> eradication + lansoprazole 15 mg vs <i>H. pylori</i> eradication | Gastroduodenal ulcers | 1.6% vs 14.8% |

GI: Gastrointestinal; *H. pylori*: *Helicobacter pylori*.

the proton pump inhibitors healed and prevented ulcers more effectively than H₂-receptor antagonists^[54-56]. An animal experiment revealed that lansoprazole protection against NSAID-induced gastric damage depends on a reduction in mucosal oxidative injury, which is also responsible for an increase in sulfhydryl radical bioavailability^[57].

Another previous report stated that the differences between the efficacy of proton pump inhibitors and H₂-receptor antagonists in the treatment of NSAID-induced ulcer were not statistically significant^[58].

In patients with LDA-induced upper GI bleeding, the risk involved in stopping the LDA was higher than that of non-aspirin NSAID. A previous study compared the therapeutic effects of proton pump inhibitors and H₂-receptor antagonists on the healing rate of gastroduodenal ulcers during continuous use of LDA, and no significant differences were found. The results indicated that not only proton pump inhibitors but also H₂-receptor antagonists are effective in the treatment of gastroduodenal ulcers during continuous use of LDA^[59,60].

Previous research has also revealed that misoprostol is effective for the treatment of gastroduodenal injury in patients taking NSAIDs or LDA^[61-63].

It is a clinical problem whether aspirin therapy should be continued or discontinued in patients who develop peptic ulcer bleeding while receiving LDA. A clinical trial examined whether discontinuation of aspirin therapy is a risk factor for ischemic stroke and compared the frequency of aspirin therapy discontinuation during four weeks before an ischemic cerebral event in patients and four weeks before interview in controls. This trial suggested the importance of continuous aspirin therapy and clarified the risk associated with discontinuation of aspirin therapy in patients at risk for ischemic stroke^[64]. A recent clinical investigation has analyzed the recurrent ulcer bleeding and mortality rates attributable to cardiovas-

cular and cerebrovascular events in 78 patients receiving aspirin and 78 taking placebo for 8 wk immediately after endoscopic therapy. It was demonstrated that recurrent ulcer bleeding rate within 30 d was 10.3% in the aspirin group and 5.4% in the placebo group. The patients who received aspirin had lower all-cause mortality rates than the patients who received placebo (1.3% vs 12.9%), while the patients in the aspirin group had lower mortality rates attributable to cardiovascular, cerebrovascular, or GI complications than the patients in the placebo group (1.3% vs 10.3%). This study suggested that continuous aspirin therapy may increase the risk of recurrent bleeding but potentially reduces the mortality rates, indicating that continuous aspirin therapy had lower mortality rates^[65].

Our previous study has revealed that the ratios of patients taking LDA who required additional endoscopic treatment on the next day following the first procedure were higher than those of non-aspirin NSAID and non-NSAID patients. The duration of hospitalization of the patients taking LDA was significantly longer than that of the patients taking non-aspirin NSAIDs and non-NSAIDs. These results suggested the possibility that the treatment of LDA-induced hemorrhagic gastroduodenal ulcers is more difficult than treatment of those induced by non-aspirin NSAIDs or non-NSAIDs, indicating that every effort should be exercised to prevent bleeding complications in patients receiving LDA^[45]. Endoscopic high-frequency soft coagulation has been recently developed in Japan, and the efficacy of hemostasis with soft coagulation for bleeding gastric ulcer patients (including aspirin users) has been investigated by comparing it with hemoclips. The results demonstrated that 85% of patients in the endoscopic hemostasis with soft coagulation group and 79% patients in the endoscopic hemoclip group were successfully treated^[65]. Another clinical investigation involved 39 cases where hemostasis was attempted with bipolar forceps to deal with non-variceal upper GI bleeding. This study revealed that the technique of bipolar forceps (a new technique of endoscopic hemostasis) is simple, safe and unlikely to induce complications^[66]. Although standard endoscopic hemostasis is reportedly difficult for upper GI bleeding in aspirin users, this new technique of endoscopic hemostasis is potentially effective in such cases^[45,65,66].

Eradication of *H. pylori* in treatment of LDA-induced gastroduodenal damage

A meta-analysis has investigated the prevalence of *H. pylori* infection and NSAID use in patients with peptic ulcer bleeding, and revealed that *H. pylori* infection increased the risk (3.53-fold) of peptic ulcer disease in NSAID takers, in addition to the risk associated with NSAID use, concluding that both *H. pylori* infection and NSAID use independently and significantly increase the risk of peptic ulcer and ulcer bleeding^[37].

A previous report demonstrated that among those taking aspirin, the probability of recurrent bleeding during a 6-mo period was 1.9% for patients who received

eradication therapy and 0.9% for patients who received omeprazole, indicating that eradication of *H. pylori* is equivalent to treatment with omeprazole in preventing recurrent bleeding. On the other hand, omeprazole is superior to eradication of *H. pylori* in preventing recurrent bleeding in patients who are taking non-aspirin NSAIDs^[67].

However, in another study, after the ulcers had healed and the *H. pylori* infection was eradicated, the patients were randomly assigned to treatment with 30 mg of lansoprazole daily or placebo, in addition to 100 mg of aspirin daily, for 12 mo. The results revealed that the treatment with lansoprazole in addition to eradication of *H. pylori* infection significantly reduced the rate of recurrence of ulcer complications^[68].

CONCLUSION

Worldwide trials of antiplatelet therapy have demonstrated that an antiplatelet regimen (75-325 mg/d) offers worthwhile protection against myocardial infarction, stroke, and death. On the other hand, the rate of low-dose aspirin-induced GI hemorrhage has increased more than that of non-aspirin NSAID-induced lesions. Continuous aspirin therapy in the case of GI bleeding may increase the risk for recurrent bleeding but potentially reduces mortality rates. Although the size of gastroduodenal ulcers in patients taking LDA is smaller than that of patients taking non-aspirin NSAIDs, more cases need additional endoscopic treatment on the next day after the first procedure as compared with patients taking non-aspirin NSAIDs. Previous clinical investigation has suggested that co-treatment with proton pump inhibitors is effective in preventing the development of LDA-induced GI ulcer. These results indicate that it is very important to prevent LDA-induced gastroduodenal ulcer complications including bleeding, and that every effort should be exercised to prevent bleeding complications.

Abstract

Ischemia reperfusion injury is a major obstacle in liver resection and liver transplantation surgery. Understanding the mechanisms of liver ischemia reperfusion injury (IRI) and developing strategies to counteract this injury will therefore reduce acute complications in hepatic resection and transplantation, as well as expanding the potential pool of usable donor grafts. The initial liver injury is initiated by reactive oxygen species which cause direct cellular injury and also activate a cascade of molecular mediators leading to microvascular changes, increased apoptosis and acute inflammatory changes with increased hepatocyte necrosis. Some adaptive pathways are activated during reperfusion that reduce the reperfusion injury. IRI involves a complex interplay between neutrophils, natural killer T-cells cells, CD4+ T cell subtypes, cytokines, nitric oxide synthases, haem oxygenase-1, survival kinases such as the signal transducer and activator of transcription, Phosphatidylinositol 3-kinases/Akt and nuclear factor κ B pathways. Transgenic animals, particularly genetic knockout models, have become a powerful tool at elucidating mechanisms of liver ischaemia reperfusion injury and are

complementary to pharmacological studies. Targeted disruption of the protein at the genetic level is more specific and maintained than pharmacological inhibitors or stimulants of the same protein. This article reviews the evidence from knockout models of liver IRI about the cellular and molecular mechanisms underlying liver IRI.

Molecular mechanisms of liver ischemia reperfusion injury: Insights from transgenic knockout models. *World J Gastroenterol* 2013; 19(11): 1683-1698 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1683.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1683>

INTRODUCTION

Ischemia reperfusion injury is a major cause of morbidity and mortality in liver resection and liver transplantation surgery. Prolonged organ ischemia is characterised reduced tissue oxygenation resulting in tissue adenosine triphosphate (ATP) depletion with a transition to activation of anaerobic metabolic pathways which cannot maintain cellular function for prolonged periods ultimately leading to cell death. Restoration of blood flow is necessary to restore cellular function, but paradoxically reperfusion can initiate a cascade of pathways that cause further cellular injury after prolonged ischaemia. Understanding the mechanisms of liver ischemia reperfusion injury (IRI) and developing strategies to counteract this injury will reduce acute complications in hepatic resection and transplantation, as well as expanding the potential pool of usable donor grafts.

The initial liver injury is initiated by reactive oxygen species (ROS) which cause direct cellular injury and also activate a cascade of mediators leading to microvascular changes, increased apoptosis and acute inflammatory changes with increased necrosis. Not all pathways activated are injurious and some adaptive pathways are activated during reperfusion that dampen the reperfusion injury. Classically two phases of liver injury have been described, an early (< 6 h) and late (> 12 h) phase of injury. In reality, this is a somewhat artificial distinction, as liver injury occurs as a continuum during reperfusion where pathways are activated at various often overlapping time-points.

The extent of liver injury in IRI is normally measured by raised levels of serum liver enzymes, most commonly aspartate transaminase, alanine transaminase (ALT), lactate dehydrogenase and/or serum glutamic-oxaloacetic transaminase, and by histological assessment with the Suzuki classification, with or without modifications, being most widely used in liver IRI^[1]. In this classification sinusoidal congestion, hepatocyte necrosis and ballooning degeneration are graded 0 to 5. No necrosis, congestion/centrilobular ballooning is given a score of 0 whereas severe congestion/ballooning degeneration, as well as > 60% lobular necrosis is given a score of 5 (Table 1).

Transgenic animals, particularly genetic knockout models, have become a powerful tool at elucidating mechanisms of liver ischaemia reperfusion injury and are complementary to pharmacological studies^[2-9]. The mechanistic insights derived from transgenic knockout models of liver ischaemia reperfusion injury will be reviewed. Knockout models provide a very specific targeted disruption of a particular protein at the genetic level which is more informative than the use of “specific” pharmacological inhibitors or stimulants of the same protein are used.

REACTIVE OXYGEN SPECIES

Depletion of intracellular and extracellular ATP during ischaemia results in increased ATP degradation products, including adenosine, hypoxanthine and xanthine and a shift towards anaerobic metabolism. On reperfusion, initially the increase in oxygen delivery exceeds the rate at which cellular metabolism returns to aerobic pathways, which generates damaging free radicals. A wide variety of ROS are generated, the most widely implicated being superoxide, hydrogen peroxide and reactive nitrogen species, such as peroxynitrite.

There are thought to be three main pathways for the generation of ROS: conversion of xanthine dehydrogenase to xanthine oxidase during ischaemia, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activation and uncoupling of the mitochondrial electron transport chain^[10,11]. Although hepatocytes can directly produce ROS, physiologically Kupffer cells are thought to be the main source of ROS in the early stages of liver IRI with natural killer T-cells (NKT) cells generating ROS

Table 1 Suzuki classification of liver ischaemia reperfusion injury

| Numerical assessment | Sinusoidal congestion | Vacuolisation/ballooning | Necrosis |
|----------------------|-----------------------|--------------------------|-------------|
| 0 | None | None | None |
| 1 | Minimal | Minimal | Single cell |
| 2 | Mild | Mild | < 30% |
| 3 | Moderate | Moderate | 30%-60% |
| 4 | Severe | Severe | > 60% |

later and neutrophils being the main source in the very later stages^[10,11]. The role of these various cells, NADPH oxidase and mitochondrial depolarisation have been supported by knockout animal models^[12-15]. There are no xanthine oxidase knockout on liver IRI. These mice only survive up to 6 wk and are runted.

MICROCIRCULATORY DYSFUNCTION

Microcirculatory changes play an important part in hepatic IRI. Reduction in sinusoidal diameter and blood flow are among the earliest changes in reperfusion injury. This results from a combination of direct damage to sinusoidal endothelial cells (SECs), vasoconstriction and expression of adhesion molecules with accumulation of platelets and leucocytes.

Two of the key vasoactive substances that maintain sinusoidal vascular tone are endothelin-1 (ET-1), a vasoconstrictor, and nitric oxide (NO), a vasodilator and inhibitor of platelet aggregation. There appears to be a relative excess of ET-1 in the early stages of liver IRI.

Liver transplantation in pigs has provided evidence that after reperfusion Kupffer cell activation leads to increased release of ET-1 which binds to SEC and hepatocyte endothelin A (ETA) receptor, thereby reducing hepatic micro and macro-perfusion resulting in increased liver injury^[16,17]. The activation of this pathway is associated with increased expression of tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6) and endothelial NOS (eNOS)^[16,17]. Knockout models for ETA receptor or heterozygote knockout for endothelin-1 have not been studied in liver ischaemia reperfusion injury. Double knockouts of ET-1, ET-2 and ETA receptor are lethal pre- or perinatally. It has become apparent products of heme oxygenase, namely carbon monoxide (CO) and biliverdin, and NO from nitric oxide synthase, which are all vasodilators, are likely play a role in reducing the severity of liver IRI *in vivo*.

CELL INJURY AND DEATH

Hepatocytes and SECs are the two main cell types that are injured in IRI. Hepatocytes are more sensitive to warm ischaemic injury (37 °C), while SECs are more sensitive to cold ischaemia (4 °C) found in cold preservation of donor liver grafts before transplantation. Physiologically, exclusive injury of one cell type is not found and

there is evidence that both cell types have been injured directly in both cold and warm IRI.

There has been debate about what the primary mode of cell death is in liver IRI: apoptosis or necrosis. Apoptosis is an energy dependent process, so in theory when there is greater depletion of ATP, necrosis should dominate. Also, necrosis takes longer to become apparent, normally more than 3 h. This is challenging to show experimentally *in vivo*, as tissue ATP before and after reperfusion would need to be measured as well as the change in metabolic state of the cell. Many of the same initiators and pathways are involved for both types of cell death, so there is much overlap. Some authors refer to the process as neuroapoptosis.

Different assays have been used to implicate apoptosis, including activation of various genes such as caspase-3 which is thought to be a specific indicator of apoptosis, and Bax. One isolated *ex vivo* perfused liver model using knockout of Bax showed reduced liver IRI (Table 2), apoptosis and caspase-3 activation in the knockouts compared to the normal wild type livers^[18]. The TUNEL assay has been used to indicate apoptosis, but it now appears that it does not specifically distinguish between apoptosis and necrosis. Varying degrees of necrosis and apoptosis have been shown in the literature for different ischaemia reperfusion protocols, but these conclusions on the different levels of necrosis versus apoptosis need to be interpreted with caution as the assays for apoptosis are relatively nonspecific.

ADHESION MOLECULES

The adhesion to the hepatic sinusoidal endothelial cells and transmigration into liver tissue require sequential steps in which many molecules are involved. The selectin family (P-, E- and L-selectin) of adhesion molecules are expressed by SECs early in reperfusion. They mediate loose or rolling adhesion of platelets and leucocytes. Knockout models indicate that there is an initial peak of P-selectin expression 20 to 30 min after reperfusion which is required for early IRI^[19,20]. Functionally, some groups have found that E-selectin expression, and not P-selectin, is required for IRI to occur^[21]. This is followed by firmer adhesion of leucocytes on SECs by upregulation of integrins, such as anti-CD11a and anti-CD11b, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecules (ICAM-1), respectively (Table 2).

PLATELETS

Platelets and leucocytes begin to adhere to SECs within 5 min of reperfusion (Table 2). Khandoga *et al.*^[22] used an ICAM-1 knockout model of early liver IRI and showed reduced IRI in the knockouts. Although ICAM-1 deficiency attenuated postischemic adherence of both platelets and leucocytes, the application of an anti fibrinogen antibody selectively reduced the number of adherent

platelets but did not influence leucocyte adhesion, which significantly reduced liver IRI. The study concluded that the very early phase of IRI is characterised by increased lipid peroxidation, apoptosis and reduced sinusoidal perfusion, depends on platelet rather than leucocyte adhesion on SECs and that this is mediated by fibrinogen deposited on the adhesion molecules: E-selectin, VCAM-1 and ICAM-1.

NEUTROPHILS

Neutrophils are important cellular mediators of liver IRI after 6 h of reperfusion as demonstrated using partial hepatic ischemia reperfusion (IR) models with histology and MPO assay of liver samples (myeloperoxidase, an enzyme expressed most abundantly in neutrophils) as endpoints^[23,24]. The neutrophil oxidative burst is the main source of reactive oxygen species in the later stages of IRI and contributes directly to hepatocellular injury. This has been supported by immunologically deficient knockout models of liver IRI using nude (nu/nu) mice which lack a thymus so cannot generate mature T lymphocytes and a knockout for gp91 phox, the glycosylated subunit of the heterodimer phagocyte NADPH oxidase(-/-). The knockouts have shown reduced liver IRI, reduced neutrophil infiltration and reduced oxidative burst (Table 2)^[13,25].

Leucocyte transmigration across endothelial and extracellular matrix (ECM) barriers is a complex process. Leucocyte migration across ECM proteins is dependent on matrix degradation, not only by increasing matrix permeability, but also for generating ECM-derived fragments, which are highly chemotactic for leucocytes. Matrix metalloproteinase (MMP)-9 is one of two major gelatinases in the MMP family responsible for the turnover and degradation of several ECM proteins, including fibronectin, a key ECM protein expressed by SECs in the early phase of IRI.

An MMP-9-/- knockout model of liver IRI showed reduced liver damage compared to normal mice and that neutrophil transmigration within liver sinusoids occurs over fibronectin in an MMP-9 dependent manner^[26]. These conclusions were based on correlations between assays of MMP-9 activity and liver histology from *in vivo* experiments and *in vitro* but not *in vivo* studies of neutrophil transmigration induced by fibronectin. The limitations of this study are that it did not assess other ECM proteins and that the conclusions are based on *in vitro* studies which may not reflect the *in vivo* mechanism of neutrophil transmigration. For instance, the role of SECs in leucocyte migration was not considered in this knockout model of IRI. SEC activation and injury has an important role in liver IRI as discussed earlier, by contributing to microcirculatory dysfunction. Neutrophil recruitment is mediated, at least in part, by macrophage inflammatory protein-2 (MIP-2) binding to the chemokine receptor (CXCR2) on neutrophils, supported by a study using a CXCR2 knockout model which showed reduced

Table 2 Summary of knockout models of liver ischemia reperfusion injury pertaining to reactive oxygen species, cellular metabolism/adenosine and cells involved in the injurious mechanisms

| Ref. | Knockout model | IR protocol | Outcome measure | Agent | Adaptive responses | Injurious responses |
|--|--|--|--|---|---|---|
| Kuboki <i>et al</i> ^[24] | OTII; TCRd deficient | 70% I 90 min/R 4, 8 h | Histology; serum ALT; MPO | AntiCD1d Ab; anti NK1.1 Ab; anti CD25+ Ab | | Antigen dependent CD4+ T cell activation <i>via</i> TCR and NKT cell activation increase IRI; GD T cell recruit PMN but not affect IRI |
| Evans <i>et al</i> ^[2] | ob/ob or double knockout of leptin and UCP2 | Total hepatic ischaemia 15 min/R 1, 24 h | Histology (Neil and Hubscher scoring); serum ALT; WB; liver ATP assay; lipid peroxidation; 24 h survival | | | In steatotic livers of ob/ob mice only, UCP-2 depletes liver ATP which increases IRI 1 h onwards |
| Hanschen <i>et al</i> ^[12] | IL6 (-/-); CD4 (-/-); TNFR1 (-/-) | Left lobe I 90 min/R 30 min, 2, 3, 4 h | Kupffer cell activity (fluorescent latex beads and intravital microscopy, IVM); IH; serum AST and ALT | GdCl ₃ or glutathione to wild types (WT) only | | Kupffer cells activation, ROS, IL6 and TNF- α increase SEC VAP-1 expression and CD4+ T cell sinusoidal recruitment which increase IRI; CD4+ T cells inhibit Kupffer cell phagocytic activity |
| Kim <i>et al</i> | Adenosine A1 receptor (A1AR) (-/-) | 70% I 1 h/R 24 h | Histology; serum ALT; IH; semiquantitative PCR; WB; TUNEL | CCPA (A1AR agonist); DPCPX (A1AR antagonist) | Endogenous adenosine <i>via</i> A1AR reduces IRI | Exogenous adenosine increase IRI most likely <i>via</i> a different adenosine receptor subtype to A1AR |
| Ben-Ari <i>et al</i> ^[18] | Bax (-/-); Bax (+/-) | Isolated liver perfused in environmental chamber: Global I 90 min/R 1 or 15 min | Histology (apoptosis features); serum ALT, AST, LDH; TUNEL and caspase-3 assay; WB | | | Bax activation after 15 min reperfusion activates caspase-3 which increases liver apoptosis |
| Lapps <i>et al</i> ^[30] | Rag1 (-/-), i.e., lack mature lymphocytes A2AR (-/-); IFN γ (-/-) | 70% I 72 min/R 2, 24 h | Histology; serum ALT; intracellular IFN γ | <i>ip</i> ATL146 (A2AR agonist); PK136 (NK1.1 depletion); CD1d Ab (inhibit NKT cell); NKT cell adoptive transfer from WT, A2AR and IFN γ KO to Rag1 KO | Exogenous and endogenous adenosine acts through AZAR to reduce NKT cell recruitment | NKT cell recruitment increases IRI through release of IFN γ from at least 2 h reperfusion onwards and increased neutrophil recruitment from at least 24 h after reperfusion |
| Shimamura <i>et al</i> ^[25] | Cd1d (-/-); nu/nu (no NKT cell, normal NK cells); perforin (-/-); gld/gld (Fas ligand deficient) | Total hepatic ischaemia 30 min/R 2, 6, 12, 24, 48 h | Serum ALT; peroxide assay; cytotoxic assay; IH; ELISA | Anti-NK and anti-NKT Ab | | NKT cell activation 1 to 24 h after reperfusion releases IFN γ and PMN activation 6 to 12 h after reperfusion with increased oxidative burst lead to increased apoptosis and necrosis in IRI |
| Caldwell <i>et al</i> ^[26] | CD4 (-/-); B cell (-/-) | 70% I 90 min/R 1, 2, 4, 8 h | Histology; serum ALT; MPO | Adoptive transfer CD4+ T cell to CD4(-/-); anti-IL17 Ab | CD4+ T cell only 1-4 h after reperfusion secrete IL17 releasing MIP-2 increasing neutrophil infiltration, but inhibiting their oxidative burst, and reducing necrosis 8 h reperfusion onwards | |
| Baskin-Bey <i>et al</i> | Cathepsin B (-/-) | Two weeks fed methionine choline deficient (MCD) diet to induce steatosis; liver stored 24 h 4 °C UWS then perfused in isolated apparatus at 37 °C for 1 h | Histology; electron microscopy (EM); TUNEL; IH; liver tissue ALT and LDH | R-3032 <i>ip</i> 2 h preop (cathepsin B inhibitor) | | Reduced lysosomal integrity more pronounced in steatotic livers with increased cathepsin B release into cytosol associated with increased apoptosis and necrosis |

| | | | | | |
|--|---|--|--|---|---|
| Khandoga <i>et al.</i> ^[21] | ICAM (-/-) | Left lobe I 90 min/R 20 min | Serum AST and ALT; IH; caspase-3 assay; lipid peroxidation assay; IVM | Anti-fibronectin Ab | Platelets bind fibronectin deposited on ICAM-1 expressed on SECs, associated with reduced sinusoidal perfusion, increased lipid peroxidation and apoptosis |
| Shen <i>et al.</i> ^[33] | nu/nu; CD154 (-/-) | 70% I 90 min/R 4 h | Serum ALT; histology; MPO; WB | Anti-CD154 Ab to WT; adoptive transfer spleen lymphocytes into KO or Ab treated group | CD4-CD154 T cell costimulation is associated with increased IRI |
| Wyllie <i>et al.</i> ^[69] | Natural resistance associated macrophage protein 1 (Nrampl) (-/-) | 70% I 45 min/R 30, 60 min | Plasma GOT and TNF- α ; histology; WB; Northern Blot; IH; EMSA (NF κ B) | | Macrophage activation after reperfusion increases TNF- α release and NF κ B activity which increases IRI |
| Young <i>et al.</i> ^[21] | P-selectin/ ICAM-1 double KO | 70% I 90 min/R 1.5, 3, 6 h | Serum ALT; histology | | |
| Ozaki <i>et al.</i> ^[13] | gp91 phox component of phagocyte NADPH oxidase (-/-) | 70% I 60 min/R 5, 8, 24 h +/- <i>in vivo</i> injection 3 d preop of adenovirus | Serum GOT; histology (HE); ELISA for DNA histone fragments; TUNEL; IH; WB; assays for lipid peroxidation, hydrogen peroxide and superoxide; EMSA (NF κ B) | Replication deficient adenovirus encoding Rac1 (control: Ad β gal) | P-selectin and ICAM-1 do affect the severity of IRI up to 6 h reperfusion in this model, although PMN infiltration is slightly increased in midzonal area Liver tissue releases ROS within 5 min of reperfusion and PMN from 8 h onwards, associated with increased lipid peroxidation, apoptosis and necrosis. NF κ B DNA binding is associated with increased IRI; NADPH oxidase regulated by Rac1 small GTP binding protein is a source of ROS in IRI |
| Sawaya <i>et al.</i> ^[90] | P-selectin (-/-) | Left lobe I 30 min/R 15, 30, 60, 120 min | Serum AST, ALT, LDH; histology; IVM in terminal hepatic venule (THV) | Radiolabelled anti P-selectin Ab | P selectin expression on SECs increases rolling, saltating and adherent leucocytes in THV peaking at 30 min reperfusion |
| Singh <i>et al.</i> ^[20] | P-selectin (-/-) | Left lobe I 30 min/R 20 min, 2, 5, 12, 24 h | Serum AST, ALT, LDH; histology; WB | Radiolabelled anti P-selectin Ab | P-selectin expression peaks at 20 min and 5 h after reperfusion and is associated with worse IRI |

neutrophil transmigration and hepatocellular injury in the knockout animals^[27]. These responses are coordinated by a complex mixture of substances including cytokines, chemokines and adhesion molecules produced by other leucocytes and various liver cell types. These will be discussed further.

T CELL RESPONSES IN LIVER WARM IRI

CD4+ T cells are activated and recruited into liver sinusoids in liver IRI (Figure 1). They have a dual role either contributing to injury or reducing the extent of injury depending on the CD4+ subtype and mechanism of cellular activation. The majority of CD4+ T cells can be subdivided into $\alpha\beta$ TCR (the most common subtype) expressing cells, $\gamma\delta$ TCR expressing cells, NKT cells and regulatory T cells (Tregs). B cells, CD8+ T cells^[28] and NK cells^[25,29] do not have an important role in modulating IRI.

NKT cells contribute to liver injury in the early stages from 1 h of reperfusion onwards. This has been supported by immunologically deficient knockout models, such as nu/nu, CD1d-/- (a non classical MHC that presents glycolipid and phospholipid to NKT cell TCR activating NKT cells) and RAG-1/- (recombination activation gene-1 required for the maturation of lymphocytes) knockout mice with up to 50% reduction in liver injury in the knockouts^[25,29,30]. NKT cells are also thought to contribute to neutrophil activation mediated by cytokines which NKT cells release, such as interferon gamma^[30]. A study using T cell subtype specific knockouts showed Treg cells are not in-

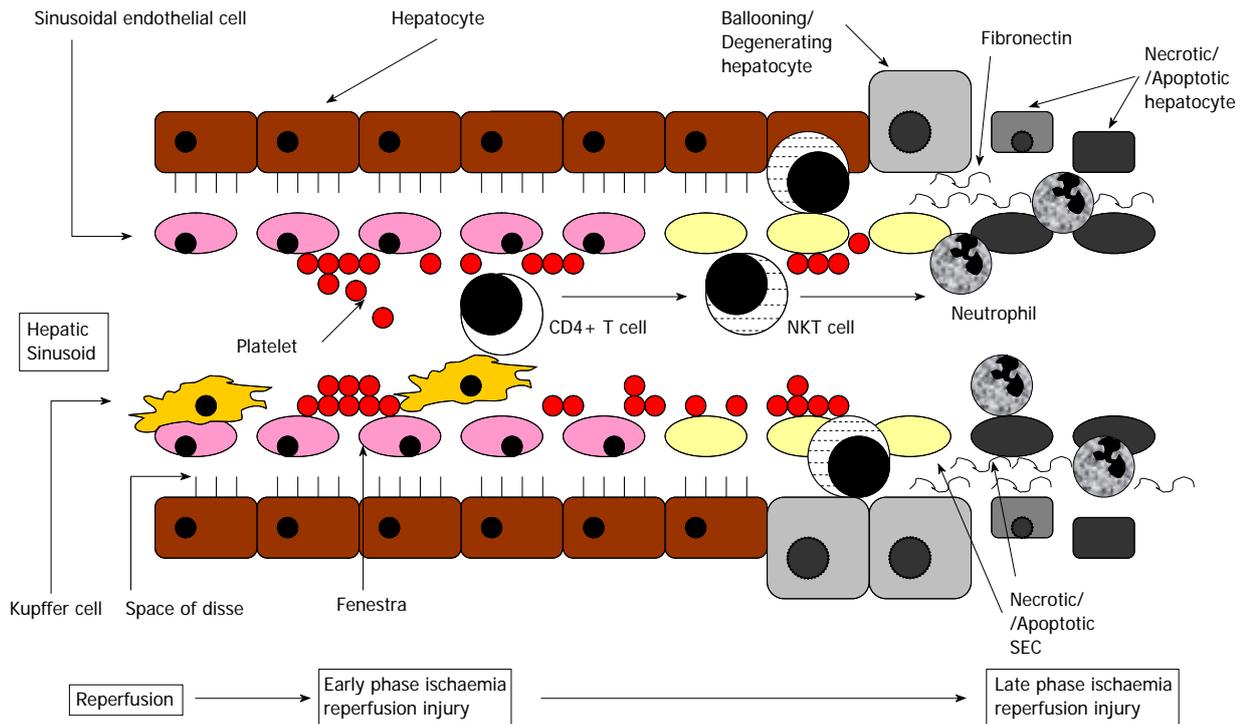

Figure 1 Schematic diagram of cellular mechanisms of liver ischaemia reperfusion injury within a liver sinusoid and the surrounding area containing hepatocytes. Initial sinusoidal perfusion failure from platelet plugging, then Kupffer cells activate CD4+ T cells that activate natural killer T (NKT) cell which cause sinusoidal endothelial cells (SEC) and hepatocyte injury, followed by neutrophil activation, adhesion and transmigration causing more cell injury.

involved in IRI. $\gamma\delta$ TCR T cells recruit neutrophils but this does not affect the severity of IRI^[29].

The CD4+ T cell activation in IRI is by an antigen independent pathway^[31]. This is supported by knockout models of the Toll-like receptor 4 (TLR 4) in which TLR 4 knockouts show reduced IRI and in normal animals the TLR 4 is activated on Kupffer cells resulting in IRI^[32].

One study on CD4+ T cell related liver IRI suggested co-stimulatory activation of the CD4 with the CD154 receptor on activated T cells^[33]. There is emerging evidence that there are also antigen dependent pathways activated in liver IRI. One partial hepatic IR (ischaemia reperfusion) model with 90 min ischaemia and 8 h reperfusion using a knockout for a TCR specific for ovalbumin self antigen showed reduced IRI in the knockout, with serum ALT reduced by 15% and reduced histological injury although this was not quantified, indicating that a small subset of T cells sensitised to self antigen contribute directly to liver IRI at least up to 8 h into reperfusion^[29].

CD4+ T cells of the $\alpha\beta$ TCR variety are recruited into liver sinusoids within 1 h of reperfusion. CD4+ T cell knockout models of liver IRI with adoptive transfer of functional CD4+ T cells into the knockout mice indicate that these cells are involved in neutrophil recruitment *via* cytokines such as interleukin 17 (IL 17) and MIP-2, these T cells inhibit the neutrophil oxidative burst. In a model of partial hepatic ischaemia for 90 min followed by reperfusion, CD4+ knockouts showed greater IRI than normal mice, with serum ALT approximately 25% higher in the knockouts and more severe histological injury in the knockouts although this was not numerically

quantified^[28]. They reduce the extent of liver IRI both indirectly *via* cytokines they release affecting other leucocytes and directly acting on hepatocytes^[28].

CYTOKINES AND CHEMOKINES

The complex interplay between cytokines and chemokines in liver IRI is not fully understood. The most extensively studied cytokines are TNF- α , interferon (IFN)- β , IFN- γ and IL-6 (Figure 2).

TNF- α is raised in serum within 30 min of reperfusion and persists for up to 8 h^[34,35]. TNF- α has ischaemic but not normal liver tissue^[36]. Release of TNF- α is stimulated by a cytokine cascade involving activation of interferon regulatory factor-1 (IRF-1), as shown using a double knockout of this factor in a partial hepatic IR (ischaemia reperfusion) model with 60 min ischaemia and 6 h reperfusion, where hepatocellular injury was 60% less in the IRF-/- knockout^[37].

There is some evidence from knockout studies that antigen independent macrophage/Kupffer cell TLR-4 activation stimulates TNF- α secretion^[32,38]. The effects of TNF- α are mediated by binding to its receptor Tumour necrosis factor receptor subtype 1 (TNFR1) leading to increased apoptosis^[39,40] and increased CD4+ T cell sinusoidal recruitment within 30 min of reperfusion^[12]. One TNFR1-/- knockout model of mouse liver transplantation with liver transplantation of either normal or TNFR1-/- livers into normal or TNFR-/- mice showed the deleterious effects of TNF- α are mediated by TNFR outside the liver, most likely infiltrating leucocytes, but

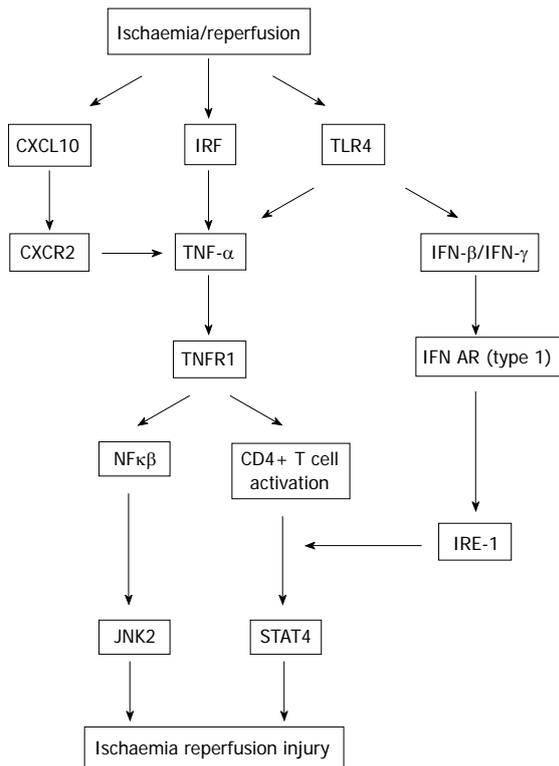

Figure 2 Cytokine and downstream signalling pathways in liver ischaemia reperfusion injury. Following liver ischaemia reperfusion, there is activation of tumor necrosis factor- α (TNF- α) by chemokine (CXCL) 10, interferon regulatory factor (IRF) and toll-like receptor (TLR) 4 in parallel. TNF- α activates downstream hepatocyte/sinusoidal endothelial cells (SEC) nuclear factor κ B (NF κ B) and CD4+ T cells separately which activate c-Jun N-terminal protein kinase-2 (JNK-2) and signal transducer activator of transcription-4 (STAT4), respectively leading to increased cell injury. A parallel pathway of cell injury occurs where TLR4 activation stimulates interferon (IFN)- β and IFN- γ expression, which acting through their receptor IFN receptor subtype (AR) activate interferon regulatory element (IRE)-1 which in turn activate CD4+ T cells. CXCR: Chemokine receptor.

TNFR on liver cells appear to reduce IRI in this model (Table 3).

IFN- β is a cytokine which is involved throughout the reperfusion period in liver IRI, a finding substantiated by work using knockout mice (Table 3). The damaging effects of IFN- β are mediated by binding to the interferon receptor subtype IFN AR (Type 1)^[41] with no hepatocellular liver injury demonstrated in IFN AR-/- knockouts (Figure 2)^[37]. Knockout models support other studies showing that IFN- γ produced by NKT cells contribute to liver IRI from early on in reperfusion^[25,27,30,32,37,42,43]. Activation of innate immune pathways *via* TLR 4 stimulate release of IFN- β and IFN- γ in liver IRI, confirmed by TLR 4 knockout models^[32].

Some cytokines released during liver IRI appear to reduce the severity of injury. The best evidence for this from knockout studies is for IL6^[34]. Camargo *et al*^[34] showed worse IRI in livers of IL6 knockout mice than wild type mice, which was restored to the wild type injury patterns by administration of recombinant IL6 to the knockout mice before ischaemia. There is evidence that IL4 and IL10 may also be protective in IRI, but knock-

outs of these cytokines have not been used in liver IRI models to substantiate this.

Chemokines (CXCL), like cytokines, are a family of locally produced factors, but chemokines are smaller molecules, which act locally forming concentration gradients that guide leucocyte chemotaxis. A CXCL 10 knockout model found that this chemokine contributed to liver IRI (Figure 2 and Table 3) from 1 h of reperfusion onwards with associated activation of neutrophils, Kupffer cells and increased TNF- α and IL 1 β release^[44]. A study using knockouts of chemokine receptor 2 (CXCR 2) showed CXCR 2 activation contributes to liver IRI and neutrophil recruitment^[26].

Plasminogen activator inhibitor type-1 (PAI-1) inhibits plasmin generation by inhibiting activation of plasminogen activators which play a role in diverse proteolysis related processes. One group used a model of liver ischemia reperfusion using wild type normal and PAI-1 knockout mice based on controlled intravenous haemorrhage maintaining MAP 25-30 mmHg for 2.5 h followed by controlled resuscitation intravenously with shed blood/Ringer's lactate maintaining MAP > 80 mmHg for 4 h. They demonstrated liver IRI in wild type animals reflected by raised serum ALT, histological periportal and pericentral injury (zone 2) and electron microscopic SEC injury with loss of fenestra. DNA microarray showed PAI-1 mRNA was most elevated after haemorrhage-resuscitation and immunohistochemistry showed PAI-1 expression was localised to SEC. PAI-1 knockouts had no liver injury following haemorrhage-resuscitation. In normal mice PAI-1 mediated IRI was associated with reduced urokinase plasminogen activator (u-PA) in zymogens of hepatocytes, reduced hepatocyte growth factor (HGF) and increased TGF- β 1, but no differences in IL6 and IL10. These changes with haemorrhage-resuscitation are associated with reduced phosphorylation activation of the ERK-1/-2 MAP kinase pathway which were reversed in PAI-1 knockouts. Based on these results, the study concluded that liver IR activates SEC PAI-1 which inhibits u-PA which reduces levels of active HGF and increases levels of TGF- β 1 that together reduce activation of downstream ERK MAP kinase pathway, mediating liver IRI. The group used a systemic model of liver IRI (systemic hypotension) rather than direct liver ischaemia and reperfusion so PAI-1 may not have the same role in liver IRI resulting from total or partial inflow occlusion. The knockout animals which showed no liver IRI with haemorrhage-resuscitation, were anaesthetised with isoflurane, while wild type animals which did show liver IRI with haemorrhage-resuscitation were anaesthetised with sodium pentobarbital. These results need to be interpreted with caution as isoflurane preconditions against liver IRI, so the protective effect may not be due to lack of PAI-1.

COMPLEMENT SYSTEM

Activation of the complement system has been shown

| Ref. | Knockout model | IR protocol | Outcome measure | Agent | Adaptive responses | Injurious responses |
|---|--|--|--|---|---|---|
| Kuboki <i>et al</i> ^[26] | CXCR2 | 70% I 90 min/R 12, 24, 48, 96 h | Histology; MPO; serum ALT, TNF- α , IL6; WB and NF- κ B activity | | CXCR2 activates STAT3 hepatocyte proliferative pathway | MIP2 activates CXCR2 which increases neutrophil recruitment and IRI. Nuclear factor (NF) κ B activity reduced in IRI |
| Zhai <i>et al</i> ^[44] | IFNAR type1 (-/-); IFNAR type 2 (-/-) | 70% I 90 min/R 6 h | Histology; quantitative PCR | | | IFN β (not IFN γ) mediates IRI by binding to IFNAR type 1 |
| Zhao <i>et al</i> | CXCL10 (-/-) | 70% I 90 min/R 1, 2, 4, 8 h | Histology; serum ALT; IH; quantitative PCR; WB | | | CXCL10 activation increases TNF- α , IL6, IL1b, iNOS, MIP-2 mRNA and PMN and Kupffer cell activation contributes to IRI |
| Fondevilla <i>et al</i> | C6 deficient rats | Donor/recipient: WT/WT, KO/WT, WT/KO, KO/KO; | Serum GOT; histology; MPO; IH; TUNEL; WB; PCR; ELISA | | | Membrane attack complex (C5b-C9) activation in this OLT model of cold/warm IRI increases apoptosis, necrosis, PMN and macrophage infiltration and TNF- α , IFN γ and IFN β expression |
| Shen <i>et al</i> ^[32] | Toll like receptor 4 (TLR4) (-/-) | OLT and organ storage 24 h 4 °C UWS Donor/recipient: WT/WT, KO/WT/WT, KO, KO/KO; OLT with dearterialisation, organ stored 24 h 4 °C UWS | Histology; IH; MPO; quantitative PCR; caspase-3 activity; WB | | TLR4 activation increases IL4 and IL10, but inhibits HO-1 | TLR4 activation increases TNF- α , IL1b, IL2, IFN γ , ICAM1, CXCL10, PMN and CD4+ T cell recruitment leading to increased liver necrosis and apoptosis |
| Conzelmann <i>et al</i> | TNFR (-/-) | Donor/recipient: WT/WT, KO/WT/WT, KO, KO/KO; organ storage 12 h 4 °C UWS; 8 h graft harvest | Histology; serum ALT; MPO; TUNEL and caspase-3 assay; IH | | TNFR within liver mediates reduced IRI | TNFR outside liver increases IRI in terms of necrosis, apoptosis and neutrophil infiltration |
| Tsung <i>et al</i> ^[37] | Interferon regulatory factor-1 (IRF-1) (-/-) | 70% I 60 min/R 1, 3, 6, 12 h | Histology; serum ALT; WB; PCR | Adenovirus IRF-1 vector | Increased IL6 | IFN γ , TNF- α , IL1b all activate IRF-1 which increase JNK (not p38 MAPK) and TNF- α and iNOS expression in IRI |
| Tian <i>et al</i> ^[40] | TNFR1 (-/-); IL6 (-/-) | Donor/recipient: WT/WT, KO/WT, WT/KO, KO/KO; OLT: 50% or small for size 30% arterialised graft | Histology; serum AST; portal flow measurement; IVM; IH; PCR; 30 d mortality | GdCl3 (ip to donor); pentoxifylline (to donor and recipient sc); recombinant IL6 to KO only | | Increased activation of Kupffer cells and TNF- α mediated activation of IFNRI from 3 h reperfusion onwards increases liver necrosis, nonperfused sinusoids, adherent leucocytes and reduces hepatocyte regeneration |
| Shen <i>et al</i> ^[38] | TLR4 (-/-); TLR2 (-/-) | 70% I 90 min/R 6 h | Histology; serum ALT; MPO; WB; PCR | Snp (inhibit HO-1); CoPP | HO-1 is expressed which inhibits TLR4 | TLR4 activation increases TNF- α expression associated with increased IRI |
| Lagoa <i>et al</i> ^[81] | PAL-1 (-/-) | MAP 25-30 mmHg for 2.5 h (2.25 mL/100 g blood withdrawn)/ Resuscitation MAP > 80 mmHg for 4 h (30 min with shed blood and crystalloid) | Serum ALT, IL6, IL10; histology; Electron microscopy; IH; zymography for plasminogen activators; DNA microarray; PCR; WB | PAL-1 to PAL-1 (-/-) mice | | PAL-1 expression in SEC contributes to IRI with periportal/pericentral injury, loss of sinusoidal fenestra and prominent SEC injury; PAL-1 inhibits u-PA which reduces formation of active HGF and increases active TGF- β 1, but no effect on IL6 or IL10; this is associated with reduced activation of ERK-1/-2 pathway. |
| Teoh <i>et al</i> ^[36] | TNF- α (-/-) | 70% I 90 min/R 2, 4, 24 h | Serum ALT; IH; serum TNF- α ; EMSA (NF- κ B); WB | Low dose or high dose TNF- α ip | | TNF- α from at least 2 h reperfusion onwards is injurious to ischaemic but not normal liver, increasing NF- κ B DNA binding |
| Inderbitzin <i>et al</i> ^[7] | CI inhibitor overexpressed | Total hepatic ischaemia 30 min/R 2 h | Endothelial permeability index (measured using radiolabelled albumin iv into inferior vena cava) of liver, lung and gut | | CI inhibitor overexpression is protective in IRI | Classical complement pathway is activated in IRI; liver ischaemia and reperfusion causes liver and gut, but not lung, IRI in this model |

| | | | | |
|--------------------------------------|-----------------------------------|--|--|--|
| Zhai <i>et al</i> | TLR4 (-/-); TLR2 (-/-) | 70% I 90 min/R 6 h | Serum ALT; histology; PCR | TLR4 activation increases expression of IRF3 which upregulates IFN β associated with increased IRI |
| Rudiger <i>et al</i> ^[69] | TNFR (-/-); Fas (-/-); FasL (-/-) | 70% I 75 min/R 3 h | Serum AST; TUNEL; caspase-3 assay; ELISA; WB | TNF- α binds to TNFR1 which increases apoptosis in IRI; Fas and FasL not involved in this model |
| Kato <i>et al</i> ^[62] | IL1R (-/-) | 70% I 90 min/R 1, 2, 4, 8, 16, 24 h | Serum ALT, IL1 β , TNF- α and MIP-2; histology (PMN score); MPO; EMSA (NF- κ B); PCR | IL1R not involved in IRI |
| Calmargo <i>et al</i> | IL6 (-/-) | Median lobe (45%) I 90 min/R 30, 60, 90, 120 min | Serum AST and ALT; histology; PCR | TNF- α expression during reperfusion is associated with protective IL6 released in IRI is worse IRI |

KO: Transgenic knockout; WT: Wild type (normal animals); IF: Immunohistochemistry; WB: Western blotting; MPO: Myeloperoxidase assay; PCR: Polymerase chain reaction; ELISA: Enzyme labelled immunosorbent assay; EMSA: Electrophoretic mobility shift assay; AST: Aspartate transaminase; ALT: Alanine transaminase; GOT: Glutamic oxaloacetic transaminase; I: Ischemia; R: Reperfusion; IR: Ischemia reperfusion injury; IVM: Intravital microscopy; IFN: Interferon; Ab: Antibody; TNF: Tumour necrosis factor; TNFR1: Tumour necrosis factor receptor (subtype 1); TUNEL: Terminal deoxynucleotidyl transferase dUTP nick end labeling (assay for cell death); IL: Interleukin; CXCR: Chemokine receptor; PAI: Plasminogen activator inhibitor; NF: Nuclear factor; C1-9: Complement protein 1 to 9; MAP: Mean arterial pressure; MIP: Major intrinsic protein.

to occur in local and remote IRI in many organs^[45]. This system consists of around 30 soluble and membrane bound proteins which are activated by one of three pathways: the antibody dependent classical pathway, the alternate pathway and the mannose binding lectin pathway. Activated complement acts both directly through the formation and deposition of membrane attack complexes (C5b-C9) and indirectly following activation by cytokines and chemokines in IRI^[46]. Knockout models have been used to consolidate the results of other studies showing activation of complement by all three pathways having direct and indirect effects on cellular reperfusion injury. The best examples of these complement knockout studies of IRI are in the gut^[47-51], kidneys^[52,53] and heart^[54]. Studies on the liver have looked at nonspecific blockade of all parts or the final common pathways of the complement system, so based on current evidence there is little understanding of the relative importance of the different pathways of complement activation in liver IRI.

Inhibition of complement formation before hepatic ischaemia in studies of liver IRI have shown a reduction in the severity of injury within an 1 h of reperfusion when cobra venom factor (to inhibit all parts of the complement system)^[11] was used, but liver IRI and polymorphonuclear cell accumulation were also reduced in the late phase of IRI 24 h following ischaemia when animals were pretreated with sCRI (a complement inhibitor derived from the family of complement regulatory glycoproteins and inhibits activation of C3, which is common to all pathways of complement activation, and so blocks the generation of both C3a and C5a and the MAC)^[11]. Scozaec *et al*^[11] found local complement activation in human liver allografts correlated to cell injury. One pharmacological *in vivo* and *in vitro* study of a warm liver IRI model in a rat showed that complement is involved in the induction of Kupffer cell-induced oxidant stress, the priming of Kupffer cells and neutrophils for enhanced reactive oxygen generation, and the continuous accumulation of neutrophils in the liver during reperfusion. In a pig whole liver to canine left liver xenotransplantation model where a control group was compared against a gadolinium chloride (GdCl₃) (which depletes Kupffer cells) and cobra venom treated group, there was less liver injury following transplantation in those with complement inhibition using the cobra venom. This provided a large animal model supporting the role of complement in activation of Kupffer cells in liver ischaemia reperfusion injury. The groups were small (3 animals each) and the conclusions would be more robust if there had been groups treated with only GdCl₃ or cobra venom^[55].

One group used wild type rats and rats deficient in C6 in all combinations of donor and recipient in a liver transplantation model to show that there was less injury in recipients of C6-/- grafts, implicating that the membrane attack complex (C5b-9) is involved in cold ischaemia related liver IRI in this model^[56]. One model of liver IRI using mice overexpressing the inhibitor of the classical complement pathway, C1 inhibitor, showed C1 inhibitor reduces liver IRI and remote IRI in the lungs and gut followed liver ischaemia and reperfusion^[57]. This would appear to indicate that the classical pathway of complement activation is the most important complement activation pathway involved in liver IRI (Table 3), although further studies using C1 inhibitor knockouts and mannose binding lectin knockouts to substantiate the relative contribution of the various activation pathways, as well as specific knockouts of other complement components to assess the significance of different complement mediated injurious pathways.

MATRIX METALLOPROTEINASE-9

MMP-9 is a zinc dependent secreted gelatinase which catalyses degradation of type IV collagen and gelatin. MMP-9 knockout models of liver IRI have shown liver IRI is reduced by up to 80% in MMP-9^{-/-} knockouts and that in normal animals increased expression of MMP-9 on macrophages and neutrophils occurs during reperfusion (Table 4) which increases neutrophil transmigration over fibronectin in liver sinusoids and increases TNF- α and interferon γ secretion and CD4⁺ T cell activation by mechanisms that remain to be elucidated^[12,27]. The mechanisms by which MMP-9 expression is increased in liver IR were not investigated in these knockout studies, but a possible pathway involves induction of MMP-9 by ROS and TNF- α .

NITRIC OXIDE SYNTHASE

NOS catalyses formation of NO from L-arginine. NO is a versatile molecule which is vasoactive, is involved in activating molecular signalling pathways in cell survival, has immunological effects as well as directly injurious effects in high levels as a free radical itself. There are three isoforms of NOS: constitutive calcium (Ca²⁺) dependent forms which are eNOS and neuronal NOS (nNOS), and an inducible calcium independent form, namely inducible NOS (iNOS). Only eNOS and iNOS are expressed in liver. Most studies agree that eNOS is upregulated in liver IRI and this reduces the severity of IRI. This is confirmed by knockout models of IRI (Table 4), where eNOS expression is related to reduced liver necrosis, apoptosis, leucocyte infiltration and increasing liver sinusoidal diameter and liver blood flow^[23,24,58,59].

The role of iNOS is more controversial (Table 4)^[58-64]. Some knockout models of iNOS show no role for iNOS in liver IRI^[24,60,61]. One knockout study of iNOS showed in the liver IRI model used that iNOS was protective which was at least partly mediated by activation of iNOS by eNOS^[23]. Yet another set of knockout studies conclude iNOS contributes to IRI^[27,37,58]. Hamada *et al.*^[27] used separate iNOS and MMP-9 knockout mice to show in their model of liver IRI that iNOS is upregulated in macrophages which increases IFN- γ release and NO which increases MMP-9 expression on the macrophages and neutrophils. This signalling cascade contributes to increased liver IRI. However, one study using the partial (70%) hepatic IR model with 45 min lobar ischaemia found increased IR injury in iNOS^{-/-} mice demonstrated by increased hepatocellular and histological injury and increased liver sinusoid neutrophil infiltration compared to wild type animals, but they found no iNOS mRNA expression in wild type livers^[24]. This led the authors to conclude that there may be genetic compensation in iNOS^{-/-} animals, although there was no reference to which genes may have been involved in this compensation. Genetic compensation is a rare phenomenon where after a gene is mutated and its function is lost, compensatory genes are upregulated, although the mechanisms for

this is unclear^[65].

Large animal studies using pigs and various inhibitors of iNOS (AG, ONO-1714) on both a warm liver ischaemia reperfusion model and an orthotopic liver transplantation model have shown that iNOS expression is stimulated by IR in Kupffer cells and neutrophils in the centrilobular region resulting in higher levels of serum nitrite/nitrate, reduced capillary perfusion with more thrombi and ultimately increased liver injury and increased mortality^[62-64].

The conflicting results of the role of iNOS in early phase liver IRI may reflect different roles of iNOS and the regulation of its function in liver IRI depending on the duration of the liver ischaemia. Partial hepatic IR models with prolonged ischaemia of 60 min or longer have found that iNOS does have a role in liver IRI^[27], while models using shorter ischaemia times of 45 min have shown no role of iNOS^[24]. Several studies that have used iNOS^{-/-} knockout animal models of hepatic IR, but there is evidence, that iNOS^{-/-} knockouts show genetic compensation^[24], so conclusions based on models of liver IR using iNOS^{-/-} animals need to be interpreted with caution.

The overall conclusions from the current literature is that eNOS and iNOS are both induced during liver IRI from 1 h reperfusion onwards (for mRNA and 2 h reperfusion onwards for protein), eNOS reduces injury and low levels of iNOS induction are probably protective while high expression of iNOS contributes to increased injury and the overall effect of iNOS physiologically depends on how ischaemia and reperfusion is produced.

HAEM OXYGENASE-1

Haem oxygenase-1 (HO-1 or heat shock protein 32, HSP 32) is the inducible isoform of HO-1, the constitutive isoform being HO-2. This enzyme catalyses the formation of CO, biliverdin and Fe²⁺ from haem degradation. HO-1 has been implicated as having a protective role in IRI^[66] through CO and biliverdin being vasodilators and reducing apoptosis and necrosis^[67]. HO-1 is typically expressed three or more h after liver reperfusion^[38,68]. The protective effects of HO-1 are supported by knockout models of liver IRI, where knockouts of HO-1 have more severe IRI than normal animals (Table 4)^[38,43]. These knockout models also provide evidence that HO-1 acts at least partly by inhibiting TLR4 (Toll-like receptor 4) activation and the resulting release of TNF- α and IFN- γ ^[38,43,69].

DOWNSTREAM PATHWAYS

A wide range of downstream pathways have been studied in liver IRI. The majority of systems which are activated in ischaemia reperfusion are effective through these pathways. Some of the key mediators TNF- α , IFN- β , IFN- γ and CXCL10 (Figure 2). In particular, the roles of the transcription factors nuclear factor $\kappa\beta$ (NF $\kappa\beta$)^[70], the survival kinases (JNK, MAPK³s, PKC, PI3K/Akt), signal

| Hines <i>et al.</i> ^[60] | iNOS (-/-) | 70% I 45 min/R 1, 3, 6 h | Serum ALT; histology; MPO | L-NIL (iNOS inhibitor) | | Reduced IRI in iNOS (-/-), but no iNOS mRNA or L-NIL effect in WT; may be genetic compensation effect in KO |
| Kawachi <i>et al.</i> ^[24] | eNOS (-/-); iNOS (-/-) | 70% I 45 min/R 5 h | Serum ALT; histology; MPO | | eNOS is activated in IRI and is protective | There is no PMN infiltration up to 5 h reperfusion and iNOS is not activated in IRI in this model |

IH: Immunohistochemistry; WB: Western blotting; MPO: Myeloperoxidase assay; RT-PCR: Reverse transcriptase polymerase chain reaction; ELISA: Enzyme labelled immunosorbent assay; EMSA: Electrophoretic mobility shift assay; AST: Aspartate transaminase; ALT: Alanine transaminase; GOT: Glutamic oxaloacetic transaminase; I: Ischemia; R: Reperfusion; IR: Ischemia reperfusion injury; iVM: Intravital microscopy; IFN: Interferon; Ab: Antibody; TNF: Tumour necrosis factor; TNFR1: Tumour necrosis factor receptor (subtype 1); TUNEL: Terminal deoxynucleotidyl transferase dUTP nick end labeling (assay for cell death); IL: Interleukin; NF: Nuclear factor; MMP: Matrix metalloproteinase; HSP: Heat shock protein; eNOS: Endothelial nitric oxide synthase; iNOS: Inducible nitric oxide synthase; HO-1: Heme oxygenase (subtype 1).

transducer and activator of transcription (STATs)^[71], poly ADP ribose polymerase (PARP), peroxisome proliferator-activated receptor (PPAR) from pharmacological studies have been supported by knockout models of liver IRI (Table 5).

Table 5 Knockouts of downstream mediators and models of liver ischemia reperfusion injury

| Ref. | Knockout model | IR protocol | Outcome measure | Agent | Adaptive responses | Injurious responses |
|---|---|--|---|---|--|--|
| Theruvath <i>et al</i> ^[61,63] | JNK (-/-) | 70% I 1 h/R 4, 8 h | Histology; serum ALT; IVM (dyes to probe mitochondrial function and cell death); survival 14 d | | | JNK2 activation leads to mitochondrial depolarization and increased necrosis only |
| Theruvath <i>et al</i> ^[61,63] | JNK (-/-) | WT or KO donor; 30 h, 4 °C, UWS preservation; WT recipient | Histology 8 h posttransplant; serum ALT, TUNEL and caspase-3 assay; IVM; IH; lipid peroxidation | | NFκB activity reduces necrosis and apoptosis, inhibits TNF-α, JNK and iNOS | JNK2 activation leads to caspase-3 activation, mitochondrial depolarisation and release of cytochrome c, lipid peroxidation which all translate into reduced survival posttransplant |
| Beraza <i>et al</i> ^[72] | Conditional hepatocyte specific NEMO knockout | 70% I 1 h (caudate lobe resected)/R 3, 6 h | TUNEL and caspase-3 assay; WB; IH; Southern blotting; EMSA (NFκB) | | | |
| Okaya <i>et al</i> ^[65] | PPARα (-/-) | 70% I 90 min/R 4, 8 h | Serum ALT; TNF-α; MIP-2; MPO; liver NO; NO ₂ ; WB; EMSA (AP-1, NFκB) | WY14643 <i>in vivo</i> (PPARα agonist) | PPARα protective in IRI | PPARα independent release of TNF-α and MIP-2 and increased NO; NO ₂ associated with IRI |
| Shen <i>et al</i> ^[78] | STAT4 (-/-); STAT6 (-/-); nu/nu | 70% I 90 min/R 6 h | Serum ALT; histology; MPO; WB; PCR | Adoptive transfer of CD4+ T cells from WT or other KO to nu/nu; SnPP <i>in vivo</i> | HO-1 expressed at very low levels after 6 h in this model, but protective in IRI | CD4+ T cell activation involving T cell STAT4 activation, but not STAT6 associated with increased IRI |
| Khandoga <i>et al</i> ^[61] | PARP (-/-) | Left lobe I 90 min/R 30 min | Serum ALT; IVM; IH; PCR | | | PARP activation in IRI upregulates E-selectin, ICAM1 and VCAM1, associated with increased platelet and leucocyte endothelial interaction and reduced sinusoidal perfusion |
| Kato <i>et al</i> ^[62] | P50 NFκB (-/-) | 70% I 90 min/R 1, 8 h | Serum ALT; histology; MPO WB; EMSA (p50 and p65 subunits of NFκB) | | | No effect of p50 subunit deletion, but increased p50/p65 heterodimer in WT and some p65 in KO, so there may be some functional redundancy of NFκB subunits |
| Kato <i>et al</i> ^[63] | STAT4 (-/-) | 70% I 90 min/R 30 min, 1, 2, 4, 8 h | Serum ALT; histology; MPO; WB | Anti IL12 Ab | | IL12 expression associated with IRI. STAT4 not activated in IRI in this model |
| Kato <i>et al</i> ^[70] | STAT6 (-/-) | 70% I 90 min/R 1, 4, 8 h | Serum ALT, TNF-α; MPO; PCR; EMSA (NFκB) | IL4 or IL13 <i>in vivo</i> | | STAT6 is not activated in IRI in this model, although STAT6 activation by <i>in vivo</i> IL4 or IL13 is protective. IRI is associated with increased NFκB DNA binding |

KO: Transgenic knockout; WT: Wild type (normal animals); IH: Immunohistochemistry; WB: Western blotting; MPO: Myeloperoxidase assay; PCR: Polymerase chain reaction; EMSA: Electrophoretic mobility shift assay; ALT: Alanine transaminase; I: Ischemia; R: Reperfusion; IR: Ischemia reperfusion injury; IVM: Intravital microscopy; IFN: Interferon; Ab: Antibody; TNF: Tumour necrosis factor; TNFR1: Tumour necrosis factor receptor (subtype 1); TUNEL: Terminal deoxynucleotidyl transferase dUTP nick end labeling (assay for cell death); IL: Interleukin; NF: Nuclear factor; STAT: Signal Transducer and Activator of Transcription; JNK: A survival kinase; PARP: Poly (ADP-ribose) polymerase.

Most studies show that NFκB DNA binding increases after liver ischemia and contributes to liver IRI^[13,36,67,70,71]. TNF-α increases NFκB activity^[36,70]. One knockout study, in contrast, showed a CXCR2 dependent fall in NFκB activity following liver reperfusion^[60], although a longer period of ischemia and reperfusion was used than other studies. Another group used a conditional NFκB knockout to study liver IRI and showed NFκB activity was protective, reducing necrosis, apoptosis, JNK expression and TNF-α expression. Unlike the other studies, the caudate lobe was resected in their protocol, which alters how IR occurs compared to a model of hepatic IR without resection. The role of NFκB, therefore, is unclear in liver IRI, but it may be that the specific way in which IR is executed modulates NFκB activity and the resulting activation of downstream sig-

nalling pathways in IRI.

Theruvath *et al.*^[14,15] used a JNK 2 knockout to show JNK 2 contributes to IRI in both a mouse liver transplantation model and warm ischaemia reperfusion model of liver IRI by increasing mitochondrial depolarisation and caspase-3 activity leading to liver injury manifested as hepatocyte cell membrane lipid peroxidation, necrosis and apoptosis. A knockout model has provided evidence that JNK activity, but not p38 MAPK contributes to liver IRI after reperfusion (Table 5)^[37].

Knockout models of PI3K and Protein kinase C (PKC) have been used in cardiac IRI, but not in the liver IRI. One group used a porcine liver transplant model using chelerythrine (a PKC inhibitor) and/or ischaemic preconditioning (IPC) of the donor liver before cold storage to show that PKC activity was not affected by IRI alone, although PKC was strongly activated by IPC reducing the severity of IRI^[73-79].

In a rat model of warm partial hepatic ischaemia reperfusion using a caspase-3 inhibitor (Z-Aspmk *in vivo* 2 min before 2 h of ischaemia) it was found that IRI was associated with reduced PI3K/Akt activity and increased hepatocyte apoptosis, with the converse pattern in the caspase-3 inhibitor treated group^[77-79]. In contrast, in another rat model of IRI, hepatocytes isolated from rats which underwent partial warm hepatic ischaemia/reperfusion or sham laparotomy cultured and treated with IL-1 β provided evidence that during IR, IL-1 β binding to IL-1 β receptor-1 increased NF κ B activity and phosphorylated Akt which acted in parallel to increase iNOS expression (mRNA and protein) with a resulting increase in NO release^[77-79].

Activation of the STAT family of transcription factors is mediated by extracellular signalling molecules such as cytokines which bind to membrane receptors which activate intracellular Janus kinases on the cytoplasmic face of the plasma membrane, which in turn activate a STAT protein which is then transported to the nucleus where they bind DNA to affect gene expression (Jak/STAT signalling pathway). STAT6 activation does not appear to be involved in liver IRI based on results from knockout models^[71,72,80]. Kato *et al.*^[72] found in their model of IRI using STAT4 knockouts that STAT4 did not affect the extent of liver injury after 8 h reperfusion. In contrast, Shen *et al.*^[80] showed STAT4 expression was related to IRI after 6 h of reperfusion, although it was specifically its expression within CD4+ T cells that mediated the liver injury (Table 5). This was demonstrated by reduced IRI in mice lacking mature lymphocytes (nu/nu mice), which was restored to normal animal IRI severity in the nu/nu mice by adoptive transfer of CD4+ T cells from spleens of normal mice but not from spleens of STAT4 knockouts. The reasons for this discrepancy between Kato *et al.*^[72] and Shen *et al.*^[80] are not clear, as both groups used a partial (70%) hepatic IR model of 90 min ischaemia and reperfusion including the same timeframe, the same endpoints and double knockouts. The transgenic knockouts had different wild type backgrounds in the two studies of

C57Bl6 or Balb/c wild types by Kato *et al.*^[72] and Shen *et al.*^[80] respectively, which may have affected the IRI results. Genetic compensation in the knockouts of either study is a possibility that may explain the discrepancy, although STAT4 protein expression was not assessed by Shen *et al.*^[80] and there is little detail on how the knockouts were generated in both studies.

A knockout of PARP has been used to show that PARP activation contributes to early liver IRI (Table 5) and activates signalling pathways increasing expression of adhesion molecules on SECs^[61]. A liver IRI model using a PPAR knockout demonstrated background PPAR activity reduces the severity of liver reperfusion injury acting *via* signalling pathways that remain to be elucidated but appear not to involve NO or TNF- α , both of which act independently of PPAR in this model^[55].

CONCLUSION

Liver IRI is a clinically relevant phenomenon in a wide range of settings including trauma surgery, hepatic resection and transplantation, affecting clinical outcome. Laboratory work using knockout models and large animal studies have provided insights into the mechanisms of liver IRI. Liver IRI occurs as a continuum beginning from the moment of reperfusion onwards for up to a week.

There is a complex interplay between cellular mediators, ROS, the complement system, cytokines/chemokines and other secreted factors that activate several parallel intracellular pathways that include transcription factors, nitric oxide synthase and haem oxygenase-1, all of which is beginning to be unravelled. Further laboratory work using knockout models and large animal studies of liver IRI will provide further mechanistic insights into this phenomenon and identify pharmacological agents that could be entered into clinical trials for reducing IRI.

Abstract

Although a great variety of new drugs have been introduced for the therapy of inflammatory bowel diseases so far, a definite cure of the disease is still out of scope. An anti-inflammatory approach to induce remission followed by maintenance therapy with immunosuppressants is still the mainstay of therapy. Thiopurines comprising azathioprine and its active metabolite mercaptopurine as well as tioguanine, are widely used in the therapy of chronic active inflammatory bowel disease (IBD). Their steroid sparing potential and efficacy in remission maintenance are out of doubt. Unfortunately, untoward adverse events are frequently observed and may preclude further administration or be life threatening. This review will focus on new aspects of thiopurine therapy in IBD, its efficacy and safety.

INTRODUCTION

The main aim in treating patients with inflammatory bowel disease (IBD) taking into account the armamentarium of available therapeutic agents is to choose the most efficient therapeutic regimen on an individual basis in order to achieve remission of disease. Two aspects have to be kept in mind to achieve this goal: first is to treat the patient with the greatest efficacy regarding disease remission and probably obtaining mucosal healing. And in second place treat with the greatest safety and minimal toxicity. One integral part of this management strategy is the use of immunosuppressants after remission induction. Most commonly used among this group are the thiopurines azathioprine (AZA) and mercaptopurine (MP). AZA and MP need to be activated by metabolism to 6-thioguanine nucleotides (6-TGN). Although these nucleotides disturb proper DNA synthesis it has not conclusively shown, that 6-TGN are the one and only molecules responsible for proper action. However, immunosuppressive function seems to be mediated in part by induction of apoptosis in lymphocytes. A correlation of therapeutic benefit and 6-TGN levels has been put into question. Although thiopurines are widely used, several safety concerns remain. Tioguanine has been proposed as an alternative to overcome such problems, as it skips the metabolic conversion to 6-methyl mercaptopurine (6-MMP) which is responsible for hepatotoxicity. This review will discuss efficacy and safety of thiopurine therapy in IBD.

PHARMACOLOGY OF THIOPURINES

Oral bioavailability is variable and inversely proportional to the oral dose (AZA 27% to 83%, MP 5% to 37%). After oral intake 88% of AZA is rapidly converted non-enzymatically to 6-MP and S-methyl-4-nitro-5-thioimidazole in erythrocytes and human cells. This process relies on sulphydryl-containing compounds such as cysteine and glutathione. Deposition and consumption of the latter is in part controlled by glutathione-S-transferase activ-

ity^[1]. 6-MP as the active metabolite undergoes a complex biotransformation into active and inactive metabolites that easily transfer membranes. At first 6-MP undergoes extensive first pass catabolism by xanthine oxidase (XO) forming 6-thiouric acid which is excreted by the kidneys. Allopurinol is a well known inhibitor of XO. In addition, 6-MP is a substrate for thiopurine methyltransferase (TPMT), the rate limiting enzyme of detoxification. Methylation results in the inactive metabolite 6-MMP. The active metabolites of 6-MP are initially formed by hypoxanthine phosphoribosyltransferase (HPRT). The first active intermediate thioinosine monophosphate is then rapidly converted to the 6-TGN which are accredited to be the paramount effectors of thiopurines. Their cytotoxic and immunosuppressive effect is attributed to their incorporation into cellular nucleic acids resulting in inhibition of lymphocyte proliferation. Beside this action, 6-TGN might play an important role in the signaling cascade of apoptosis in lymphocytes by inhibiting Rac 1 activation in T-cells^[2]. Competing with this intracellular activation is the thiol-methylation by TPMT. The individual capacity of this enzyme influences the relative proportion of intracellular active 6-TGN produced by a given individual and has important implications in predicting toxicity. TPMT polymorphism will be discussed elsewhere (see below). Pharmacology of thiopurines is comprehensively summarized in^[3,4].

USE OF THIOPURINES IN CROHN'S DISEASE

The efficacy of thiopurines has been demonstrated in several trials both for induction and maintenance of disease free remission in Crohn's disease (CD). The first study demonstrating the efficacy of MP to induce remission was reported by Present *et al*^[5]. Sixty-seven percent of the patients treated with 1.5 mg/kg MP daily responded as compared to 8% in the placebo group. The today well known delayed onset of action was additionally well described in this study with a mean time to response of 3.1 mo. The efficacy in remission maintenance was clearly shown in the landmark withdrawal trial by Candy *et al*^[6]. Several other studies reported variable responses ranging from 36%-100%^[7-11]. A major drawback of some of these studies was their short duration. Due to the thiopurines' time lag of action the therapeutic gain might have been underestimated. Despite these varying results updated meta analysis favour therapy over placebo with an odds ratio of 2.43 (95%CI: 1.62-3.64) regarding remission induction with AZA or MP^[12,13]. In case of remission maintenance the OR for AZA is 2.32 (95%CI: 1.55-3.49) with a number needed to treat (NNT) of 6 and with MP 3.32 (95%CI: 1.40-7.87) with a NNT of 4, including 7 trials^[14].

As one third of the patients become steroid dependent and 20% of the patients loose response to steroids after one year^[15], an early introduction of immunomodulators seems mandatory, at least in patients who fail to taper off steroids. An elegant study by Markowitz *et al*^[16] in

children with new onset of CD underlines the potential of early MP administration for remission maintenance. Steroid pulse therapy in combination with MP resulted in a reduction of relapse rates from 28% to 4% after 6 mo and from 47% to 9% after 18 mo compared to steroids alone. Additionally, a significant steroid sparing effect was observed. These results suggest a short term steroid use for induction of remission and thiopurines for long term steroid-free maintenance therapy.

A recent randomised controlled trial assessed steroid free remission in active CD after 26 wk of treatment with AZA, infliximab or the combination of both^[17]. While AZA was less beneficial than infliximab, the best results were obtained with combined treatment. Similar findings were reported regarding mucosal healing. The inferior performance of AZA as a single agent may be related to the defined primary aim and time point.

USE OF THIOPURINES IN ULCERATIVE COLITIS

Although thiopurines are widely used in the treatment of patients suffering from ulcerative colitis (UC) controlled data are limited^[18-21]. If thiopurines have any place in the treatment of UC it is for remission maintenance or steroid-dependence. A recent meta-analysis including 6 studies reported an OR of 2.56 in favour of thiopurines (95%CI: 1.51-4.34)^[22]. Moreover, a steroid sparing potential of thiopurines in UC is obvious^[20,21].

In patients presenting with steroid refractory disease thiopurines play a role as they enhance the beneficial effect of the rescue therapy with cyclosporine^[23]. Despite fundamental evidence, thiopurines remain a therapeutic option for UC patients failing 5-ASA monotherapy or requiring multiple steroid courses^[24]. One half of the UC patients responding to a first course of corticosteroids will require immunosuppressives mainly because of steroid-dependence^[25]. In accordance with the SONIC trial for CD, a similar study was conducted in UC^[26]. The results and drawbacks are comparable though the difference between AZA and infliximab monotherapy vanished. Thus, combination treatment was stated to be the most effective with regard to steroid-free remission and mucosal healing at 16 wk.

OPTIMAL DURATION OF TREATMENT?

An unresolved question after successful initiation of thiopurine treatment is, how to assess the optimal duration of treatment. Bouhnik *et al*^[27] reported that the beneficial effects disappear after 4 years of AZA treatment, based on a small number of patients. In a controlled study AZA withdrawal was not equivalent to continued therapy with AZA for maintenance of remission in patients with CD who had been in remission on AZA for more than 3.5 years^[26,28]. In case of UC the data are sparse. A retrospective survey reported that relapse rates were higher in UC patients with a short duration of AZA administra-

tion indicating a favourable longevity of treatment^[29]. In accordance with a large observational study in England AZA sustains remission in CD as well as UC for at least 5 years^[30].

Thus far patients should be informed about indefinite treatment especially in complicated cases and after recurrent surgery. The decision to withdraw the drug has to be made on an individual relapse-risk assumption.

MUCOSAL HEALING

The surrogate marker mucosal healing is increasingly acknowledged as a treatment goal despite the lack of prospective data to assume disease course prediction. First insight in endoscopic healing was given by D' Haens *et al*^[31] who found that the majority of AZA treated CD patients were able to achieve near to complete mucosal healing. Mantzaris *et al*^[32] found that after 1 year of maintenance therapy in clinically quiescent CD, AZA was superior to budesonide in improving endoscopic healing and histological remission. In steroid dependent UC AZA was more effective than 5-ASA in achieving clinical and endoscopic remission^[33]. More data can be extracted from the SONIC and US SUCCESS trials (endoscopic healing with AZA in CD at 26 wk 16.5%, UC at 16 wk 37%) contradicting former results^[17,26]. As shown in CD thiopurines are effective drugs to induce remission and mucosal healing and to maintain it in UC as well^[34].

SAFETY OF THIOPURINES

Adverse events during the use of thiopurines in the treatment of patients with IBD can be categorized as non-dose dependent (allergic/idiosyncratic) side effects on one hand and dose dependent ones on the other^[35-37]. In general the number needed to harm is 15.

Five percent to ten percent of the patients do not tolerate thiopurines regardless of the dose and their underlying drug metabolism. Most common reactions are flu-like illness, fever, nausea, rash, abdominal pain, pancreatitis and allergic reactions that typically occur within 2-4 wk after initiating therapy. This has not been conclusively related to TPMT polymorphisms but wildtype glutathione-S-transferase is overrepresented in those patients^[38]. About half of those patients can be successfully re-challenged with MP which lacks an imidazole ring. This switch cannot generally be recommended for patients who experienced pancreatitis. Patients with an allergic reaction should be allocated to alternative immunomodulators such as methotrexate. In the following a few severe adverse events shall be enlightened in detail.

Myelotoxicity

The most common side effect in the treatment of IBD patients with thiopurines is myelosuppression, which is mostly manifested as leucopenia and occurs in 2.2% to 15% of the patients^[37-39]. The majority of those events respond to dose reduction, but infectious complications in-

crease if the white blood cell count falls below 2000/ μ L. Therefore special care is warranted in those patients and in patients on multiple immunosuppressants. TPMT deficiency accounts for one fourth of the leukopenia in CD treated with thiopurines whereas the rest is obscure^[40]. A drop in platelets may occur in conjunction with leucopenia or as a single event. If it is not reversible after dose reduction or discontinuation of therapy patients need to be further evaluated with a special focus on hepatotoxicity.

Hepatotoxicity

The exact mechanisms of hepatotoxicity by thiopurines are not clarified^[41,42]. Some of the patients develop a mild elevation in their liver function tests and most of them respond to dose reduction. Hence, a cessation of therapy is not necessary. In those patients whose liver enzymes do not normalize over time further exploration is necessary. Potentially serious hepatic side effects occur with the development of nodular regenerative hyperplasia in patients treated with tioguanine^[43] as well as AZA^[42-44] resulting in progressive liver damage and portal hypertension. An alternative is the use of the XO-inhibitor allopurinol in combination with 1/4 of the standard dose of a thiopurine which increases 6-MP bioavailability and reduces 6-MMP formation thereby limiting the risk of hepatotoxicity but long-term prospective studies are lacking^[45-48].

Malignancy

The incidence of cancer and lymphoma in IBD and the influence of thiopurines is still a controversial topic^[49-53]. 6-Thioguanine accumulates in the DNA of thiopurine treated patients and is able to interact with UVA to generate reactive oxygen species. It has recently been shown that the UVA/DNA 6-TG interaction irreversibly inhibits transcription in cultured human cells and provokes polyubiquitylation of the major subunit of RNA polymerase II. This persistent transcription-blocking DNA lesions seem to be responsible for acute skin responses to sunlight and predispose for the development of skin cancer^[54]. Recently published data point to an increased risk for non-melanoma skin cancer (NMSC). The incidence rate ratio was higher among patients with IBD compared with controls (1.64, 95%CI: 1.51-1.78). Persistent thiopurine use (> 365 d) was even stronger associated with NMSC (adjusted OR 4.27, 95%CI: 3.08-5.92)^[55]. There is one study that contradicts these results^[56], but three others confirm the data and report an increased risk for NMSC in patients with IBD treated with thiopurines^[57-59]. To summarize, up to now these patients should be protected against UV radiation and should undergo lifelong dermatologic screening.

The issue of lymphoma is open for discussion. There is an ongoing debate if the disease itself already increases the risk for the development of lymphoma. Additionally a confounding factor should be kept in mind as patients with an aggressive course of the disease do have a greater

innate risk for lymphoma and besides a higher likelihood to receive thiopurine treatment^[60]. There are some studies finding no association between thiopurine treatment and lymphoma in IBD while others suggest an increased incidence^[61-69]. A meta-analysis of the above mentioned data revealed a relative risk of four for all lymphomas in patients on thiopurine treatment compared with those with IBD not receiving thiopurines^[70]. This increase was confirmed in a recent prospective evaluation of french IBD patients with a hazard ratio of 5.28 for ongoing thiopurine treatment^[71,72]. Of interest is the potentially overt risk in patients with double immunosuppression but the data are lacking so far. The rare variant of hepatosplenic lymphomas with fatal outcome has to be acknowledged and is related to thiopurines as well as TNF blockers.

Thiopurines have been demonstrated to be risk-neutral in the context of the development of colorectal cancer in IBD patients^[73]. And there are various studies available with regard to cervical cancer related to HPV 16 and 18 infection. So far there is no clear picture due to the paucity of data and the risk of cervical cancer seems to be comparable to the general population. Although there is no evidence for an increased risk of other solid tumors the lack of data always needs to be taken into consideration^[61].

Taken together thiopurine treatment in patients with IBD has a potential to induce or propagate neoplasia. This relative risk increase is most significant for lymphoma and NMSC in second place but the risk-benefit ratio supports the continuation of treatment in IBD.

Use in pregnancy

Women with IBD have similar rates of fertility compared to the general population. Unfortunately they have a greater rate of adverse pregnancy outcomes which are related to disease activity. Therefore an immunosuppressive treatment of patients with severe disease course is mandatory during pregnancy. Although thiopurines are rated D (positive evidence of human fetal risk, but potential benefits may warrant its use) by the Food and Drug Administration they seem to be safe and well tolerated during pregnancy^[74]. There are smaller studies that found an increased risk of congenital malformations, perinatal mortality, and preterm birth^[75,76]. Opposing results are presented by Francella *et al*^[77] in their analysis on 155 patients who conceived after IBD was diagnosed. There was no statistical difference regarding rates of spontaneous abortion, abortion as a result of a birth defect, major congenital malformations, neoplasia or increased infections after the intake of MP. This is now confirmed by the registered data from the CESAME study^[78].

OPTIMIZING SAFETY AND EFFICACY

Due to their complex metabolism and genetic polymorphisms in metabolizing enzymes there is a wide inter- and intra-patient variation in the concentrations of active and toxic metabolites. In 9%-25% of patients serious drug

toxicity leads to a cessation of therapy and therapeutic efficacy is unachievable in about 15% of patients^[79].

TPMT measurement

TPMT competes with XO and HPRT for the substrate 6-MP. The TPMT gene carries genetic polymorphisms that lead to a nearly 50-fold variation in the enzyme activity between individual patients^[80]. Hence, low TPMT activity leads to a greater conversion of 6-MP to 6-TGN (the predominant active metabolite) *via* the HPRT pathway. This is not only associated with greater therapeutic activity but also a higher likelihood of myelotoxicity. On the other hand high TPMT activity results in greater 6-MMP production at the expense of active metabolites.

A growing number of single nucleotide polymorphisms within the TPMT gene are identified, but the frequency among approximately 30 known alleles is very low except for the 3A/C alleles. There are population differences in the frequency of abnormal TPMT alleles especially in relation to the 3A and 3C genotypes, with more than 90% of the patients carrying the 1/1 wild type genotype and normal enzyme activity. 10%-11% of the patients have a reduced enzyme activity due to the heterozygous 1/3 (TPMT3A or 3C) genotype. Only 1 in 300 patients carries the homozygous 3/3 genotype with absent TPMT activity. Together this distribution in a population follows a classical trimodal pattern^[80], although very high metabolizers superimpose this view without clinical relevance. The TPMT status can be determined by measuring enzyme activity (radiochemical or HPLC) or by genotyping. Allelic frequencies in IBD may be somewhat higher^[81-83]. In patients with TPMT deficiency a tiny dose of thiopurines (1/10) can be used under careful monitoring. Patients with intermediate TPMT activity should receive half or one third of the initial dose, normal to high TPMT activity is in need of up to very high doses. Other adverse drug effects are unrelated to TPMT pheno- or genotype. However, a recent finding is the association of some type 2 adverse events (flu-like illness, rash) and inositol pyrophosphohydrolase (ITPase, ITPA) polymorphisms. This has not been implemented in the recommendations so far but warrants attention^[84]. At present determination of TPMT activity is questionable in the clinical setting although cost effectiveness has been noted. A recent position paper summarizes the recommendations of TPMT testing and monitoring of 6-TGN levels^[85].

Monitoring metabolites

Metabolite monitoring is not mandatory for patients with IBD who are treated with thiopurines. Although several trials have observed an association between high 6-TGN levels and a favourable response this has not been unequivocally reproduced (summarized in^[86]). However, monitoring is particularly useful in those patients that do not respond to a standard dose of thiopurine drugs after a meaningful duration of treatment. The combination of erythrocyte 6-TGN and 6-MMP concentrations can

be helpful to detect the reason for a lack of response. Absent 6-TGN and 6-MMP levels unmask poor compliance. If the concentration of both metabolites is low, the patient is probably under-dosed. A low 6-TGN level in conjunction with a high 6-MMP concentration identifies a patient who may respond to a rechallenge with low dose AZA in combination with allopurinol. Otherwise he has to be termed thiopurine resistant. In case of high concentrations of both metabolites the patient suffers from thiopurine refractory disease.

TIOGUANINE AS AN ALTERNATIVE TO AZA AND MP-REAL BENEFIT?

In order to overcome problems of toxicity and delayed action of thiopurines, tioguanine, originally established for treatment of leukemias mainly in children, was investigated for remission induction and maintenance in IBD. It serves as a direct precursor to 6-TGN, the proposed active metabolite of thiopurines. In one group with 37 patients with active CD tioguanine appeared to be effective with acceptable short-term toxicity^[87,88]. 6-TGN levels were far above those documented for classical thiopurines. However, neither toxicity nor efficacy increased. Recent data has shown that hepatotoxicity does not reoccur during tioguanine treatment in most IBD patients who failed conventional thiopurines due to 6-MMP associated hepatotoxicity. Hence, tioguanine appears to be a justifiable alternative in these IBD patients^[89]. Another investigation by Dubinsky *et al.*^[92] found opposing results and stated that NRH is a common finding in tioguanine treated patients with IBD. As progression or reversibility of NRH remains unknown the authors do not recommend tioguanine therapy for patients with IBD. Tioguanine related hepatotoxicity in the Dubinsky study was surprisingly frequent whereas in other studies this rate is nearly comparable to that of AZA as NRH has been described under therapy with AZA as well (see chapter hepatotoxicity). A lower dose of 10-20 mg tioguanine for remission maintenance has been proposed to be safe in the long term^[90]. Accordingly, tioguanine should not be abandoned but more surveillance data are needed.

CONCLUSION

The role of conventional thiopurines, 6-MP and AZA, still evolves in the treatment of patients with IBD. The above stated data underline the important role of thiopurines in remission maintenance. Understanding the metabolic pathways has greatly optimized treatment and lead to greater safety and efficacy. Long-term observational studies regarding the still controversial issues of hepatotoxicity, nodular regenerative hyperplasia and malignant potential of the drugs are still warranted. Tioguanine may be an effective alternative in patients who are intolerant to AZA or MP but the incidence and fate of NRH is still unresolved.

Abstract

Portal hypertension (PHT) is defined as a pathological increase in portal venous pressure and frequently accompanies cirrhosis. Portal pressure can be increased by a rise in portal blood flow, an increase in vascular resistance, or the combination. In cirrhosis, the primary factor leading to PHT is an increase in intra-hepatic resistance to blood flow. Although much of this increase is a mechanical consequence of architectural disturbances, there is a dynamic and reversible component that represents up to a third of the increased vascular resistance in cirrhosis. Many vasoactive substances contribute to the development of PHT. Among these, nitric oxide (NO) is the key mediator that paradoxically regulates the sinusoidal (intra-hepatic) and systemic/splanchnic circulations. NO deficiency in the liver leads to increased intra-hepatic resistance while increased NO in the circulation contributes to the hyperdynamic systemic/splanchnic circulation. NO mediated-angiogenesis also plays a role in splanchnic vasodilation and collateral circulation formation. NO donors reduce PHT in animals models but the key clinical challenge is the development of an NO donor or drug delivery system that selectively targets the liver.

INTRODUCTION

Portal hypertension (PHT) is a common clinical consequence of chronic liver disease that is associated with significant morbidity and mortality. PHT is classified as either pre-hepatic, intra-hepatic or post-hepatic, with intra-hepatic PHT being the form most often caused by cirrhosis, irrespective of etiology^[1]. The extent of PHT is quantified in clinical practice by measuring the hepatic portal vein pressure gradient (HPVG)^[2], representing the difference between the wedged hepatic vein pressure (a measure of pressure at the level of the hepatic sinusoid), and the free hepatic vein pressure. Thus, HPVG is often used to assess the effects of pharmacological therapy in reducing portal pressure^[3].

Based on hydromechanics, fluid pressure in a hollow tube is determined by fluid resistance and flow. In PHT, therefore, the intra-hepatic vascular resistance (IHVR) and splanchnic blood flow are the two main contributors to portal pressure^[4]. Under normal circumstances, post-prandial increases in splanchnic blood flow is always associated with an autonomous down-regulation of IHVR, leading to no alteration in portal pressure. In contrast, IHVR is significantly up-regulated by mechanical and hemodynamic factors in the setting of cirrhosis, which is further aggravated by splanchnic vasodilation^[5]. Clinically, this increase in portal pressure is the antecedent to

variceal bleeding with its associated morbidity and high mortality^[6,7].

IHVR is influenced by both hepatic fibrotic architectural distortion in cirrhosis leading to obstruction to blood flow, as well as by dynamic hepatic stellate cell (HSC) contraction around sinusoidal blood vessels. Angiogenesis, or the formation of new blood vessels, is also an important component of the pathophysiology of PHT. The resulting alterations in vascular contractility and angiogenesis contribute to PHT in both the intrahepatic and splanchnic circulation.

Endothelin 1 (ET-1), angiotensin II, norepinephrine, prostaglandin F₂, thromboxane A₂, and thrombin can trigger liver sinusoidal contraction. In contrast, substances such as acetylcholine, vasointestinal peptides, nitric oxide (NO), carbon monoxide, prostaglandin E₂, and adrenomedullin relax the sinusoidal vasculature^[8,9]. Among these agents, ET-1 and NO are the most important regulators of the sinusoidal microcirculation^[8,9]. In PHT, an insufficient release of vasodilators particularly NO from endothelial cells is critical to the genesis of the dynamic and modifiable component of increased vascular resistance^[8,9]. Consistent with this, improvements in intrahepatic NO availability is beneficial for the treatment of PHT in animals and patients^[10-14]. Hence, this review will focus on an update on the mechanisms whereby NO mediates PHT and on the potential to modulate this system to reduce portal pressure.

SYNTHESIS AND FUNCTION OF NO

NO is synthesized by nitric oxide synthase (NOS) through a series of redox reactions involving L-arginine (the main substrate), oxygen and nicotinamide adenine dinucleotide phosphate. There are 4 major isoforms of NOS: endothelial nitric oxide synthase (eNOS), inducible nitric oxide synthase (iNOS), neuronal nitric oxide synthase (nNOS) and mitochondrial nitric oxide synthase^[15]. Following synthesis by NOS, the half-life of endogenously generated NO is extremely short, about 1 s. Thus, endogenous NO production is intimately regulated by the activity of NOS.

The generated NO molecule has a large diffusion coefficient and can therefore freely penetrate cellular membranes in an autocrine or paracrine manner. Within the cell, NO stimulates the conversion of guanosine 5'-triphosphate (GTP) to cyclic guanosine 3'-5'-monophosphate (cGMP), thereby regulating calcium balance through the cGMP-dependent protein kinase pathway (Figure 1). This leads to vasodilatation^[16]. The end products of NO metabolism *in vivo* are nitrate (NO₃⁻) and nitrite (NO₂⁻) that are an indirect measure of the total NO concentration^[17].

NO is also highly reactive with other molecules including superoxide anion (O₂⁻), oxygen (O₂) and hemoproteins such as hemoglobin and myoglobin. The intermediate products of these reactions are known as reactive nitrogen species, which promotes many pathophysiologi-

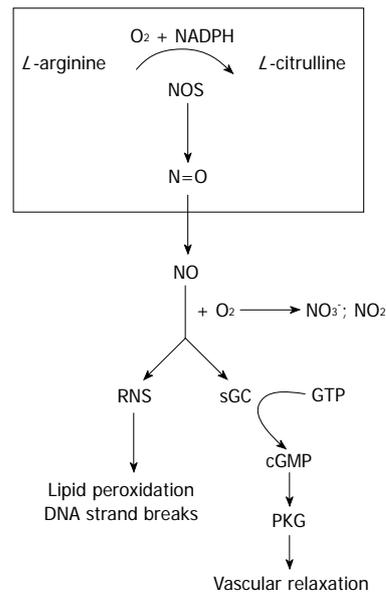

Figure 1 Nitric oxide formation and function. Nitric oxide synthase (NOS) catalyzes the biosynthesis of nitric oxide (NO) from L-arginine, nicotinamide adenine dinucleotide phosphate (NADPH) and O₂. NO freely diffuses into cells where it mediates vascular relaxation by stimulating the cyclic guanosine 3'-5'-monophosphate (cGMP)/cGMP-dependent protein kinase G (PKG) pathway. It also forms reactive nitrogen species (RNS) which leads to many damaging reactions including lipid peroxidation and DNA strand breaks. GTP: Guanosine 5'-triphosphate; sGC: Soluble guanylyl cyclase.

cally damaging reactions including lipid peroxidation, DNA strand breaks, and the generation of nitrosamines, nitrotyrosine and nitro guanosine.

MOLECULAR MECHANISMS REGULATING NOS

eNOS serves a key role in maintaining circulatory homeostasis and is expressed mainly in endothelial cells and to a lesser extent in cardiac myocytes and platelets^[15]. The enzyme localizes to small invaginations of the plasma membrane named caveolae in quiescent cells. eNOS protein is constitutively expressed in the cell and activation mostly comprises post-translational regulation and modifications in its subcellular localization^[18].

Within cells, eNOS closely associates with several proteins that impact on its function, including caveolin. Caveolin negatively regulates eNOS by directly abrogating the enzyme's activation and blocking the binding site for calmodulin^[19]. In contrast, calmodulin acts as an indispensable protein competing with caveolin for binding with, and activating eNOS^[20,21]. Other relevant proteins in relation to NO production include heat shock protein 90 and tetrahydrobiopterin (BH4) that are positive regulators of eNOS^[22-24]. Finally, eNOS interacting protein and eNOS trafficking inducer protein participate in the subcellular trafficking of eNOS when eNOS translocates from caveolae into the cytoplasm^[25-27].

Phosphorylation at key serine residues is the major post-translational modification that is required for eNOS

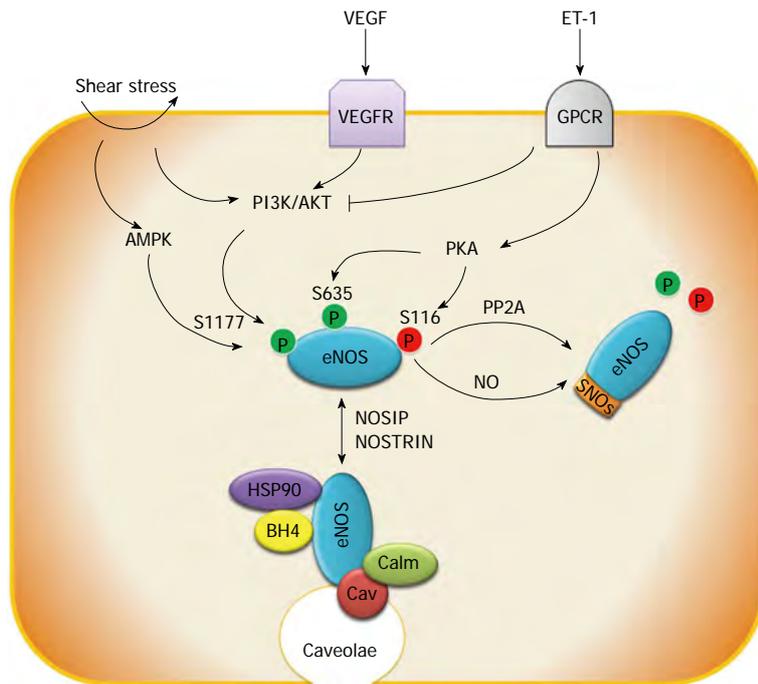

Figure 2 The molecular regulation of endothelial nitric oxide synthase activity. Endothelial nitric oxide synthase (eNOS) phosphorylation can be triggered by shear stress, vascular endothelial growth factor (VEGF), endothelin 1 (ET-1) and other factors through adenosine monophosphate-activated protein kinase (AMPK), protein kinase B (AKT) and protein kinase A (PKA) pathways, whereas protein phosphatase 2 (PP2A) de-phosphorylates eNOS. In addition, S-nitrosylation (SNOs) by eNOS-derived nitric oxide (NO) inhibits eNOS activity. Endothelial nitric oxide synthase interacting protein (NOSIP) and endothelial nitric oxide synthase trafficking inducer protein (NOSTRIN) regulate the sub-cellular location of eNOS protein between the caveolae and cytoplasm. The principal location of eNOS is in caveolae where its function is inhibited by binding to caveolin (Cav). HSP90, calmodulin (Calm) and tetrahydrobiopterin (BH4) are indispensable proteins and cofactors for catalyzing NO production. PI3K: Phosphatidylinositol-3-kinase; GPCR: G protein-coupled receptor.
