function. Phosphorylation of Ser 1177, Ser 635 and Ser 617 activates eNOS whereas phosphorylation of Thr 495 and Ser 116 inhibits eNOS activity^[28]. Phosphorylation at Ser 1177 can be initiated by activation of several intracellular pathways including phosphatidylinositol-3-kinase (PI3K/AKT), cAMP-dependent protein kinase A (PKA), adenosine monophosphate-activated protein kinase, cGMP-dependent protein kinase G (PKG) and *Calmodulin Kinase II*-dependent pathway (CaM kinase II)^[29-32], while Ser 635 and Ser 116 is activated *via* a PKA-dependent pathway^[33,34]. Additionally, shear stress, vascular endothelial growth factor (VEGF) and high-density fatty acids can phosphorylate and activate eNOS (Figure 2)^[35]. In contrast, phosphatases like protein phosphatase 2 dephosphorylates and inactivates eNOS^[36]. S-Nitrosylation inhibits eNOS activity by modifying its steric configuration, whereas de-nitrosylation is associated with an increase in eNOS activity^[37,38].

Unlike eNOS, iNOS is more widely expressed, including in macrophages, vascular smooth muscle cells, HSCs and Kupffer cells after stimulated by lipopolysaccharide (LPS) or inflammatory cytokines. iNOS produces a relatively high level of NO compared to eNOS^[39]. In contrast to eNOS, iNOS expression is principally modulated by transcriptional mechanisms. Many transcription factors regulate the expression of iNOS including nuclear factor- κ B (NF- κ B), activator protein, signal transduction and activation of transcription 1a, specificity protein 1, CCAAT/enhancer-binding protein (C/EBP), *cAMP*

response element-binding, GATA binding transcription factor, hypoxia-inducible factor, interferon regulatory transcription factor, nuclear factor of activated T-cells, nuclear factor-interleukin 6, octamer-1 transcription factor, poly [ADP-ribose] polymerase 1, polyomavirus enhancer activator 3, tumor protein 53 and serum response factor^[40]. Among these, NF- κ B is considered the primary mediator for iNOS induction. In turn, NF- κ B can be activated by a range of stimuli including LPS, interleukin-1 β , tumor necrosis factor (TNF)- α and oxidative stress^[41,42]. iNOS can also be post-translationally regulated through mRNA stabilisation by RNA-binding proteins such as A+U rich RNA binding factor, human antigen R, K-homology splicing regulator protein, polypyrimidine tract-binding protein and tristetraprolin^[40].

nNOS is principally expressed in neurons localized to the nervous system including the brain, the autonomic nervous system and neurons around interlobular arteries. The portal vein endothelial cells also express nNOS^[43]. Like eNOS, nNOS is regulated by post-translational mechanisms and both Hsp90 and calmodulin are involved in the process of nNOS activation^[44-46].

MOLECULAR REGULATION OF NOS IN LIVER CIRRHOSIS AND PHT

Regulation of intra-hepatic eNOS

In cirrhosis and PHT, there is reduced NO production

by hepatic endothelial cells that is attributed to dysfunction of the eNOS system^[47-50]. Many factors contribute to intra-hepatic eNOS dysfunction/reduced eNOS activity. These include increases in oxidative stress, caveolin-1, RhoA, thromboxane A₂ (TXA₂), G-protein-coupled receptor kinase-2 (GRK2) and asymmetric dimethylarginine (ADMA) as well as decreased AKT and BH4 activity.

Reduced AKT activity and increased binding ability of caveolin-1 to eNOS in cirrhosis attenuates eNOS expression^[51,52]. Liu *et al.*^[51], reported that ET-1 activates G-protein-coupled receptor kinase-2 (GRK2) which directly interacts with and inhibits AKT phosphorylation. They also noted that the IHVR was significantly reduced in bile duct ligation (BDL) mice genetically deficient in GRK2^[52]. In another study of eNOS expression during BDL, Morvarid *et al.*^[53], noted that total eNOS protein was unchanged, but that functional, phosphorylated eNOS protein was decreased. Similarly, AKT expression was down-regulated in a time dependent manner. In contrast, caveolin-1 was increased^[53].

Intrahepatic oxidative stress is a key mediator of sinusoidal endothelial dysfunction and impairment of eNOS/NO expression^[54-57]. For example, Gracia *et al.*^[58], noted that increased intrahepatic oxidative stress (increased ROS and O₂⁻) was associated with reduced NO production and NO bioavailability. The authors went on to demonstrate that cyclooxygenase (COX) attenuated eNOS activation by stimulating TXA₂ which inhibits AKT phosphorylation in endothelial cells^[59]. A superoxide dismutase mimetic, Tempol significantly decreased superoxide, and increased NO in cultured hepatic endothelial cells. As expected, Tempol administration also resulted in a decline of portal pressure^[60].

ADMA, an endogenous inhibitor of NOS, causes uncoupling of NOS leading to generation of RNS, such as peroxynitrite. In BDL rats, a higher serum ADMA level was observed^[61]. Further, impaired endothelial cell-mediated relaxation in perfused livers of BDL rats was exacerbated by ADMA and was associated with a decreased rate of ADMA removal^[61,62].

BH4, a cofactor of eNOS, has been reported to be associated with dysfunction of the NO system. BH4 expression is down-regulated in liver cirrhosis and can further be oxidized and inactivated by O₂⁻. In the absence of BH4, eNOS cannot generate NO but instead produces O₂⁻, thereby leading to further decreases in NO production^[24,63]. In an *in vivo* study, Matei *et al.*, observed that in rats rendered cirrhotic after the administration of carbon tetrachloride (CCl₄), exogenous BH4 resulted in hepatic NOS and cGMP activation and a reduction in portal pressure^[64].

Rho-associated protein kinase (ROCK) is a kinase belonging to the AGC (PKA/PKG/PKC) family of serine-threonine kinases. It is mainly involved in regulating the shape and movement of cells by acting on the cytoskeleton. Rho-kinase is substantially involved in the contraction of activated HSCs^[65,66]. In BDL rats, fasudil (a potent Rho-kinase inhibitor) significantly suppressed liver

Rho-kinase activity and increased eNOS phosphorylation compared with controls^[67]. Fasudil also reduced the binding of the serine/threonine AKT to Rho-kinase and increased the binding of AKT to eNOS^[67].

Regulation of extra-hepatic vascular eNOS, iNOS and nNOS in cirrhosis

In contrast to the hypoactive SECs in the intrahepatic microcirculation, hyperactive endothelial cells with increased NO production play a critical role in modulating the vascular changes observed in the splanchnic and systemic circulation. For example, increased activity of peripheral vascular AKT signaling is noted, while constitutive AKT inhibition by an inactive mutant decreases aortic eNOS and improves systemic hemodynamics, splanchnic perfusion pressure and renal excretory function without affecting portal pressure^[68]. Other studies reported that VEGF induces NO production by activation of eNOS protein expression and activity^[69,70]. Likewise, in portal hypertensive rats, NO production is increased in response to shear stress^[71]. LPS detoxification is limited in liver with PHT thereby increasing plasma LPS. Resident macrophages in the splanchnic circulation respond to this circulating LPS with the production of proinflammatory cytokines, such as TNF- α ^[72] that then induces iNOS in extrahepatic vasculature^[73-75]. Bacteria-derived TNF- α also triggers the expression and activity of the key enzyme involved in the regulation of BH4, GTP-cyclohydrolase I, thereby increasing eNOS-derived NO in the mesenteric vasculature^[76,77]. Finally, nNOS expression is augmented in mesenteric nerves in portal hypertensive rats (portal vein ligation), an effect mediated by HSP-90^[46,78,79].

THE ROLE OF NO/NOS IN THE REGULATION OF IHVR

An increase in IHVR can be induced by reversible hemodynamic modifications to vascular tone which may represent 28%-40% of the increase in portal pressure in cirrhosis^[80-82]. Anatomic structures leading to this change include vascular smooth muscle cells surrounding branches of the portal vein, and HSCs located in the space of Disse. Both cells types have contractile properties and thus modulate IHVR^[82-84].

The role of NO in the modulation of IHVR has been well documented^[85-87]. eNOS dysfunction in sinusoidal endothelial cells and consequent reduction in NO production (or bioavailability) plays an essential role^[51]. This results in reduced vasodilation and a decreased capacity for antagonizing contractile factors such as ET-1, angiotensin II, norepinephrine, prostaglandin F₂, and thromboxane A₂^[83,88].

Recently, gene delivery techniques have been used to increase NOS (eNOS or nNOS) delivery to the liver of CCl₄ treated mice. In one study, a plasmid eukaryotic expression vector (liposome-pcDNA3/eNOS) or control vector was injected into rat portal vein, leading to increased eNOS mRNA and protein in liver. Hepatic

NO production was enhanced and IHVR and portal vein pressure (PVP) reduced^[89]. In another study, recombinant adenovirus carrying the nNOS gene (Ad.nNOS) or control vector was administered *via* the femoral vein to rats. Again, Ad.nNOS reduced IHVR and portal pressure^[90]. These data indicate that NO deficiency in cirrhotic liver contributes to the elevation in IHVR and conversely that NO delivery may play a therapeutic role^[89-92].

Activation and contraction of HSCs also contributes significantly to the dynamic and reversible component of IHVR. Indeed, activated HSCs are more susceptible to vasoconstrictor substances than quiescent cells^[83,92,93]. Under physiological conditions, NO produced by hepatic endothelial cells inhibits the growth, migration and contraction of HSCs through paracrine pathways^[94,95]. However, reduced NO production and/or impaired NO bioavailability in cirrhosis promotes HSCs activation and contraction, leading to sinusoidal remodeling and elevation of the IHVR.

iNOS has also been suggested to contribute to the hyperdynamic status seen in PHT. However, its role in mediating IHVR is unclear. In one study, liver iNOS was increased in BDL rats and reduction of portal pressure by ursodeoxycholic acid was associated with iNOS down-regulation^[96,97].

ROLE OF NO/NOS IN THE REGULATION OF SPLANCHNIC BLOOD FLOW

A hyperdynamic splanchnic circulatory state is a major accompaniment of PHT. The increase in splanchnic blood flow and the subsequent increase in portal venous inflow aggravates and perpetuates PHT. The mechanisms underlying this phenomenon are not fully understood, but overproduction of endogenous vasodilators and decreased vascular reactivity to vasoconstrictors has been suggested^[98].

Overproduction of NO in the splanchnic and systemic circulation contributes to this phenomenon as NOS inhibition effectively ameliorates splanchnic hyperemia^[99,100]. eNOS up-regulation and increased NO release by the superior mesenteric arteries endothelium occur before the development of the hyperdynamic splanchnic circulation^[101]. Juan *et al.*^[70], noted increased eNOS expression in portal-hypertensive rats with even mild increases in portal pressure. In another study, phosphorylated eNOS protein was increased, whereas caveolin-1 was decreased in the aorta of BDL rats^[52]. In contrast, in eNOS knockout mice injected with CCL4, attenuated splanchnic blood flow was observed. However, this was associated with an increase in IHVR, presumably due to the reduced NO within the liver^[102]. Taken together, these results suggest up-regulated eNOS expression during splanchnic hyperemia, contrasts with the relative eNOS deficiency in liver.

There are also several studies demonstrating the im-

portance of iNOS in the hyperdynamic circulation of cirrhosis^[64,72,73,103,104]. In cirrhosis, endotoxins, cytokines and bacterial infection promote iNOS formation and overproduction of NO^[64,105-107]. The increased splanchnic iNOS appears to reside in resident macrophages of the superior mesenteric artery^[73,108]. Supporting this concept, Ferguson *et al.*^[64], observed that a selective iNOS inhibitor, *N*-[3-(aminomethyl) benzyl]acetamide, caused peripheral vasoconstriction in patients with cirrhosis. It is interesting to note that there also exists an interaction between eNOS and iNOS in the vasculature. For example, in cirrhosis, increased and dominant expression of eNOS in large arteries results in systemic hypotension and increased blood flow. These effects could be abrogated by activated iNOS in the small vessels of the splanchnic circulation as iNOS activation inhibited eNOS expression in the small vessels^[109]. nNOS may likewise promote vasodilation of the splanchnic circulation, though its contribution is overall less significant^[110,111].

NO AND ANGIOGENESIS IN PHT

It is now established that angiogenesis is associated with the progression of PHT^[112,113]. Angiogenic factors stimulate collateral vessel formation both in the liver and in extrahepatic locations, manifesting as the reopening of pre-existing shunts^[114,115]. This pathological angiogenesis may directly participate in the development of liver fibrosis^[56,116,117].

Again, NO is an important mediator of intrahepatic microcirculatory remodeling^[114,115]. Thus, NO inhibition prevents angiogenesis and diminishes mesenteric vascular proliferation in animals with PHT^[118,119]. Shaki *et al.*^[120], found that NO-mediated angiogenesis was mediated by endothelial VEGF and VEGF receptor-1. Most recently, Huang *et al.*^[121], reported that through mesenteric eNOS and COX1 down-regulation, the cannabinoid receptor 2 agonist JWH 015, could alleviate mesenteric and intrahepatic angiogenesis, PHT, the severity of portosystemic collaterals and the extent of fibrosis in BDL cirrhotic rats.

NO-BASED PHARMACOTHERAPY

As discussed, NO is paradoxically regulated in PHT. There is excessive production of NO in the splanchnic circulation (thereby leading to vasodilation), while in the intra-hepatic microcirculation, a deficit of NO production is associated with increased IHVR. These paradoxical roles of NO initially raised concerns about the use of NO inhibitors or donors as therapy for PHT. However, inhibition of NO release has been shown in animals and humans to attenuate the hyperdynamic circulation of cirrhosis^[122-125]. No significant reduction in portal pressure was achieved^[122-125]. This is likely a consequence of reductions in portal venous inflow induced by the NO inhibitors being offset by an increase in intra-hepatic resistance.

In recent years, many animal and clinical studies have

demonstrated that NO donors result in a substantial reduction in portal pressure^[10-14]. These agents could theoretically aggravate the cirrhotic vasodilatory syndrome leading to harmful effects such as systemic hypotension and renal dysfunction^[126,127]. For these reasons, the ideal NO drug for the treatment of PHT should act to decrease IHVR without worsening splanchnic/systemic vasodilatation^[128].

NCX-1000 is a drug synthesized by adding an NO-releasing moiety to ursodeoxycholic acid. The compound is selectively metabolized by hepatocytes to release NO in the liver^[129,130]. Animal studies demonstrate that this drug alleviates IHVR and portal pressure without changes in systemic hemodynamics^[129-131]. However, human clinic trials were disappointing as NCX-1000 failed to decrease HVP, there were postprandial increases in portal pressure and systolic blood pressure was reduced in a dose-dependent manner^[132].

O₂-vinyl-1-(pyrrolidin-1-yl)diazen-1-ium-1,2-diolate (V-PYRRO/NO) was designed as a liver-selective NO-producing pro-drug activated by hepatic P450s^[133]. The drug has a short half-life and may additionally alleviate liver injury by NO-mediated protection of hepatocytes^[134-136]. Continuous administration of V-PYRRO/NO to BDL rats was shown to improve liver fibrosis and splanchnic hemodynamics without adverse systemic effects^[137]. However, in another study in mice using the CCl₄ model, V-PYRRO/NO significantly lowered mean arterial pressure making it less suitable for use in humans^[138].

AVE-9488(4-fluoro-*N*-indan-2-yl-benzamide) is a novel agent that up-regulates eNOS expression^[139]. Biecker *et al*^[139], reported that oral application of AVE 9488 ameliorated portal pressure by 24% in BDL rats, without any impact on the mean arterial pressure. Additional experiments confirmed that AVE 9488 increased hepatic eNOS protein synthesis, but not in the aortic and superior mesenteric artery^[139]. However, following 3-d use, AVE 9488 increased blood flow in the collateral circulation^[139].

Recently, an inorganic gold and silica nanoparticle mediated drug delivery system using SNAP (*S*-nitroso-*N*-acetyl-DL-penicillamine), an NO donor was reported^[140]. This system inhibited HSC proliferation and HSC tube formation, though the relevance of the latter to the situation *in vivo* is unclear. The methodology described however, does provide a novel approach to deliver NO into specific liver cell types. Whether this drug modulates PHT *in vivo* is unclear. Taken together, the data presented indicates that there are no liver-selective NO donors/drugs with demonstrated efficacy for the treatment of PHT.

CONCLUSION

NO plays a pivotal role in the pathogenesis of PHT. NO levels are differentially altered in cirrhosis, with reduced production in the intrahepatic circulation and increased NO production in the splanchnic bed. Ideally, a NO do-

nor or drug delivery system that selectively targets liver cells (HSCs or SECs) without actions on the systemic circulation is required to reduce PHT without adverse systemic effects.

Abstract

AIM: To evaluate the utility of measuring epigenetic alterations in pancreatic and biliary fluids in determining molecular markers for pancreatobiliary cancers.

METHODS: DNA was extracted from undiluted pancreatic and biliary fluids. As a surrogate for a genome-wide hypomethylation assay, levels of long interspersed nuclear element-1 (LINE-1) methylation were analyzed

using bisulfite pyrosequencing. CpG island hypermethylation of 10 tumor-associated genes, aryl-hydrocarbon receptor repressor, adenomatous polyposis coli, calcium channel, voltage dependent, T type α 1G subunit, insulin-like growth factor 2, O-6-methyl-guanine-DNA methyltransferase, neurogenin 1, CDKN2A, runt-related transcription factor 3 (RUNX3), secreted frizzled-related protein 1, and ubiquitin carboxyl-terminal esterase L1 (UCHL1), was analyzed using MethylLight. To examine the role of CpG methylation and histone deacetylation in the silencing of UCHL1, human gallbladder carcinoma cell lines and pancreatic carcinoma cell lines were treated with 2 or 5 μ mol/L 5-AZA-dC for 72 h or 100 nmol/L Trichostatin A for 24 h. After the treatment, UCHL1 expression was analyzed by real-time reverse transcription-polymerase chain reaction.

RESULTS: Pancreatobiliary cancers exhibited significantly lower LINE-1 methylation levels in pancreatic and biliary fluids than did noncancerous pancreatobiliary disease ($58.7\% \pm 4.3\%$ vs $61.7\% \pm 2.2\%$, $P = 0.027$; $53.8\% \pm 6.6\%$ vs $57.5\% \pm 1.7\%$, $P = 0.007$); however, LINE-1 hypomethylation was more evident in pancreatic cancer tissues than in pancreatic fluids ($45.4\% \pm 5.5\%$ vs $58.7\% \pm 4.3\%$, $P < 0.001$). CpG island hypermethylation of tumor-associated genes was detected at various frequencies, but it was not correlated with LINE-1 hypomethylation. Hypermethylation of the *UCHL1* gene was cancer-specific and most frequently detected in pancreatic (67%) or biliary (70%) fluids from patients with pancreatobiliary cancer. As a single marker, hypermethylation of the *UCHL1* gene in pancreatic and biliary fluids was most useful for the detection of pancreatic and pancreatobiliary cancers, respectively (100% specificity). Hypermethylation of the *UCHL1* and *RUNX3* genes in pancreatic and biliary fluids was the most useful combined marker for pancreatic (87% sensitivity and 100% specificity) and pancreatobiliary (97% sensitivity and 100% specificity) cancers. Treatment with a demethylating agent, 5-AZA-

2'-deoxycytidine, restored UCHL1 expression in pancreatobiliary cancer cell lines.

CONCLUSION: Our results suggest that hypermethylation of UCHL1 and RUNX3 in pancreatobiliary fluid might be useful for the diagnosis of pancreatobiliary cancers.

INTRODUCTION

Despite recent advances in diagnosis and treatment, the prognosis of patients with pancreatobiliary cancer is still poor. Surgical resection is possible in only a small proportion of patients^[1,2]. Consequently, elucidation of the biological characteristics of pancreatobiliary carcinomas is necessary to improve the prognosis of patients and to devise better treatment strategies. Various genetic and epigenetic alterations play a role in pancreatobiliary cancer^[3-6].

Two contradicting epigenetic alterations often coexist in cancer: global or genome-wide hypomethylation, which is mainly observed in repetitive sequences within the genome, and regional hypermethylation, which is frequently associated with CpG islands within gene promoters^[7]. Hypermethylation of CpG islands is a common feature of cancer that is associated with gene silencing^[7,8]. A number of genes are aberrantly methylated and silenced in pancreatobiliary cancer that are rarely methylated in non-neoplastic counterparts^[4-6,8], and this methylation is detectable in pancreatic and/or biliary fluids^[9-12]. The detection and/or quantification of these alterations in pancreatic and/or biliary fluids has promise for facilitating the differentiation of benign and malignant pancreatic and/or biliary strictures.

In contrast to CpG islands, repetitive DNA elements are normally heavily methylated in somatic tissues. Approximately 45% of the human genome is composed of repetitive sequences, including long interspersed nuclear elements (LINEs) and short interspersed nuclear elements^[13]. Liquid chromatography-mass spectrometry analysis has shown that levels of LINE-1 methylation strongly correlate with methyl cytosine content. This strong correlation enables LINE-1 methylation to be

used as a proxy for genome-wide methylation^[14]. Moreover, LINE-1 hypomethylation is known to occur during the development and progression of various human malignancies^[15,16]. Additionally, we recently reported that LINE-1 hypomethylation correlates significantly with the aggressiveness of gastrointestinal stromal tumors and that LINE-1 methylation could be a useful marker for risk assessment^[17]. Array comparative genomic hybridization analysis revealed a significant correlation between LINE-1 hypomethylation and chromosomal aberrations^[17]. Chromosomal gains and losses are also common in pancreatic and biliary cancers^[18,19]; their detection by fluorescence *in situ* hybridization modestly improves the prediction of cancer using biliary brushings^[20,21]. Gene hypomethylation has been reported to be a frequent epigenetic event in pancreatic cancer and is commonly associated with the overexpression of affected genes^[22]. A previous study showed that hypomethylation is more common in carcinoid tumors than in pancreatic endocrine tumors and is associated with clinicopathologic features, including lymph node metastasis, as well as genetic and epigenetic alterations in these tumors^[23].

To date, however, only a few groups have reported the methylation of LINE-1 and/or other repetitive sequences in pancreatobiliary cancer^[23,24], and there are no published studies analyzing LINE-1 methylation in pancreatic and/or biliary fluids. We found correlations between the level of LINE-1 methylation and the methylation of other repetitive sequences^[17]. In this study, we analyzed LINE-1 methylation and its relationship with hypermethylation of CpG islands in pancreatic and biliary fluids, and we investigated whether the detection and/or quantification of these epigenetic alterations can be used as markers for pancreatobiliary cancer.

MATERIALS AND METHODS

Clinical samples and cell lines

Pancreatic and biliary fluids were obtained at the time of endoscopic retrograde cholangiopancreatography (ERCP) and ERCP/percutaneous transhepatic cholangiography and drainage, respectively^[9-12]. Pancreatic and biliary fluids were collected from 30 and 48 patients, respectively. Informed consent was obtained from each subject. Tumors were classified according to the tumor-node-metastasis classification system of the International Union Against Cancer. The absence of cancer was based on clinical evaluation and follow-up of one or more years. Human gallbladder carcinoma cell lines TGBC1TKB and TGBC2TKB and pancreatic carcinoma cell lines PANC-1, PK-1, PK-45P and PK59 were purchased from Riken Cell Bank (Tsukuba, Japan). Cells were cultured in RPMI1640 or DMEM supplemented with 10% fetal bovine serum.

Extraction and bisulfite treatment of DNA

DNA was extracted from undiluted pancreatic and bili-

ary fluids using a DNeasy Tissue Kit. Extracted DNA was quantified, and 500 ng of DNA was modified with sodium bisulfite using a Methylamp™ DNA modification kit.

Bisulfite-pyrosequencing

Bisulfite-pyrosequencing analysis was performed as described previously^[17,24]. Briefly, polymerase chain reaction (PCR) was run in a 25 μ L volume containing 50 ng bisulfite-treated DNA, 1 \times MSP buffer, 1.25 mmol/L dNTP, 0.4 μ mol/L of each primer and 0.5 U of Jump-Start REDTaq DNA Polymerase. The PCR protocol for bisulfite sequencing entailed 5 min at 95 $^{\circ}$ C; 40 cycles of 1 min at 95 $^{\circ}$ C, 1 min at 60 $^{\circ}$ C and 1 min at 72 $^{\circ}$ C; and a 7 min final extension at 72 $^{\circ}$ C. The biotinylated PCR product was purified, made single-stranded and used as a template in a pyrosequencing reaction run according to the manufacturer's instructions. The PCR products were bound to Streptavidin Sepharose beads HP; then, the beads containing the immobilized PCR product were purified, washed and denatured using a 0.2 mol/L NaOH solution. After adding 0.3 μ mol/L sequencing primer to the purified PCR product, pyrosequencing was performed using a PSQ96MA system and Pyro Q-CpG software. Primer sequences for LINE-1 methylation were as previously described^[25].

MethylLight assay

The MethylLight assay was performed as previously described^[25,26]. Based on previous studies and our preliminary results, we analyzed 10 promoter CpG island loci: aryl-hydrocarbon receptor repressor, adenomatous polyposis coli, calcium channel, voltage dependent, T type α 1G subunit, insulin-like growth factor 2, O-6-methylguanine-DNA methyltransferase, neurogenin 1, CDKN2A, runt-related transcription factor 3 (RUNX3), secreted frizzled-related protein 1, and ubiquitin carboxyl-terminal esterase L1 (UCHL1). β -actin was used as the internal reference gene to quantify modified DNA levels in the samples^[26]. Primers, probes and the percentage of methylated reference (PMR, *i.e.*, the degree of methylation) were as previously described^[27-29]. We used a PMR cutoff of 4 to distinguish methylation-positive (PMR > 4) from methylation-negative (PMR \leq 4) samples based on previously validated data^[29].

5-AZA-2'-deoxycytidine and/or Trichostatin A treatment

To examine the role of CpG methylation and histone deacetylation in the silencing of UCHL1, cancer cells were treated with 2 or 5 mol/L 5-AZA-2'-deoxycytidine (5-AZA-dC) (Sigma) for 72 h or 100 nmol/L Trichostatin A (TSA) for 24 h. The cells were also treated with 2 μ mol/L 5-AZA-dC for 72 h, followed by 100 nmol/L TSA for an additional 24 h. The timing and sequencing of 5-AZA-dC and/or TSA were based on similar preliminary studies, as well as published studies^[30]. After the treatment, UCHL1 expression was analyzed by real-time RT-PCR.

Real-time quantitative PCR

Total RNA from cell lines was extracted using an extraction kit. cDNA was synthesized from 1 μ g of total RNA using SuperScript III reverse transcriptase with random hexamers. qRT-PCR was performed using the TaqMan real-time PCR system as previously described^[31]. A comparative threshold cycle (C_T) was used to determine the gene expression relative to the control (calibrator). Control reactions were performed without reverse transcriptase.

Statistical analysis

Mean methylation levels of LINE-1 were compared using *t* tests, the Welch test, or one-way ANOVA with a post hoc Games-Howell test. LINE-1 methylation levels and hypermethylation of tumor-associated genes were assessed for associations with clinicopathological parameters using *t* tests, the Welch test, the χ^2 two-tailed test, Fisher's exact test, the Mann-Whitney test, or one-way ANOVA. A *P* value < 0.05 was considered statistically significant. A *P* value between 0.05 and 0.10 was considered to indicate a trend toward an association.

RESULTS

Hypomethylation of LINE-1 in pancreatic and biliary fluids from patients with pancreatobiliary cancers

We performed bisulfite pyrosequencing to quantitatively analyze LINE-1 promoter methylation as a surrogate for genome-wide methylation (Figure 1). The mean level of LINE-1 methylation in pancreatic fluids was slightly but significantly lower in patients with pancreatic cancer than in those with noncancerous pancreatic disease (Figure 2). The mean level of LINE-1 methylation in biliary fluids was significantly lower in patients with pancreatobiliary cancer than in those with noncancerous pancreatobiliary disease. There was no correlation between LINE-1 methylation levels and clinicopathological characteristics in patients with pancreatic or pancreatobiliary cancers. The mean level of LINE-1 methylation in pancreatic cancer tissues was significantly lower than that in pancreatic fluids from the corresponding patients.

Analysis of CpG island hypermethylation of tumor-related genes

We next assessed the methylation levels of CpG islands of well-characterized tumor-suppressor and tumor-associated genes. Using MethylLight assays, we analyzed 10 genes. CpG island hypermethylation of tumor-associated genes was detected at various frequencies. The results are summarized on the basis of each individual marker (Tables 1 and 2). Methylation of several genes, such as UCHL1 and RUNX3, was cancer-specific (Figure 3). Some cancer samples showed methylation in many genes, suggesting that these cancers have a CpG island hypermethylator phenotype. We failed to find any significant correlation between the methylation of these genes and clinicopathological features or between CpG island meth-

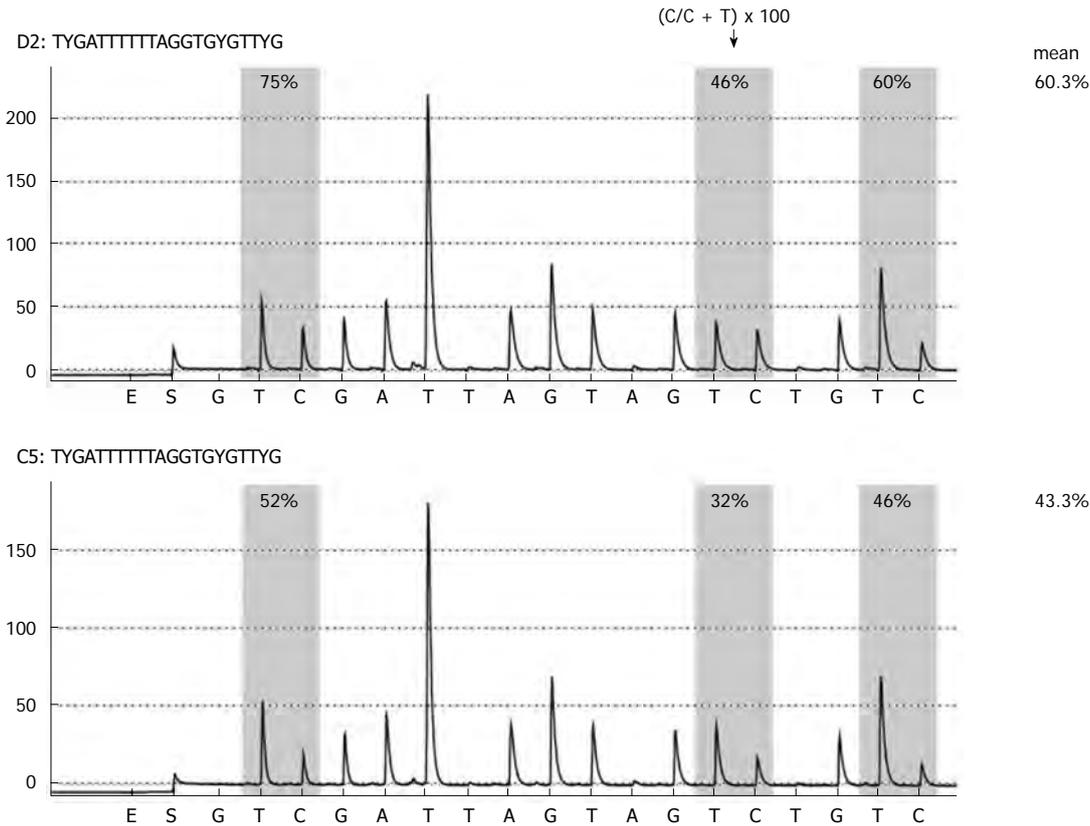

Figure 1 Representative long interspersed nuclear element-1 methylation analysis by pyrosequencing. Long interspersed nuclear element-1 methylation analysis in biliary fluids from patients with noncancerous pancreatic disease (chronic pancreatitis, upper panel) and pancreatic cancer (lower panel) is shown.

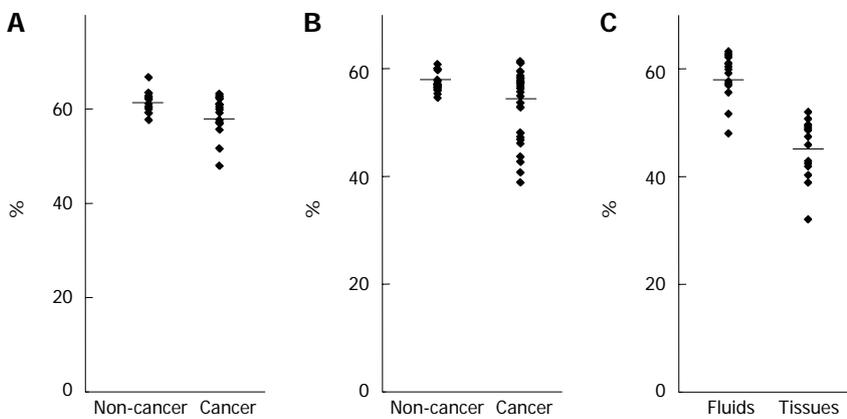

Figure 2 Analysis of long interspersed nuclear element-1 methylation levels using pancreatobiliary fluids. A: Comparison of the long interspersed nuclear element-1 (LINE-1) methylation levels in pancreatic fluids between pancreatic cancer and noncancerous pancreatic disease; B: Comparison of the LINE-1 methylation levels in biliary fluids between pancreatobiliary cancer and noncancerous pancreatobiliary disease; C: Comparison of the LINE-1 methylation levels in pancreatic cancer between pancreatic fluids and tissues.

ylation and LINE-1 methylation levels.

Among the cancer-specific hypermethylated genes in pancreatic fluids, the *UCHL1* gene was most frequently (67%) detected in pancreatic cancer and served as the most useful single marker for the detection of pancreatic cancer (Figure 3A). Hypermethylation of the *UCHL1* and *RUNX3* genes in pancreatic fluids was the most useful combined marker for the detection of pancreatic cancer.

Among the cancer-specific hypermethylated genes in biliary fluids, the *UCHL1* gene was most frequently (70%) detected in pancreatobiliary cancer and served as the most useful single marker for the detection of pancreatobiliary cancer (Figure 3C). Hypermethylation of the *UCHL1* and *RUNX3* genes in biliary fluids was the most useful combined marker for detection of pancreatobiliary cancer.

The pancreatic and biliary fluids obtained from pan-

NC: Non-cancer; IP: Intraductal papillary and mucinous pancreatic tumour; pancreatic cancer (PC) 1, PC5, PC7, PC8 and PC13 are identical in Tables 1 and 2. MP: Methylation-positive; MN: Methylation-negative.

creatic cancer patients were compared with regard to the methylation patterns of 10 tumor-associated genes ($n = 5$). The methylation patterns were similar in both the pancreatic and biliary fluids from the same patients (Tables 1 and 2). The methylation patterns of the *UCHL1* and *RUNX3* genes were identical in the pancreatic and biliary fluids from the same patients.

Reactivation of *UCHL1* expression by 5-AZA-dC/Trichostatin A treatment in pancreatobiliary cancer cell lines

To further examine the role of CpG methylation and histone deacetylation in silencing *UCHL1*, cancer cells were treated with 5-AZA-dC and/or TSA. 5-AZA-dC restored *UCHL1* expression, and combined treatment with 5-AZA-dC and TSA restored *UCHL1* expression synergistically at the mRNA level in pancreatobiliary cancer cell lines (Figure 4 and data not shown). TSA alone did not restore *UCHL1* expression in cell lines.

DISCUSSION

In the present study, we found that the levels of methylation of LINE-1 were reduced in pancreatobiliary cancers compared to those in noncancerous pancreatobiliary

disease. Genome-wide hypomethylation is known to be a common feature of human cancer, and genome-wide hypomethylation has recently been studied in various human malignancies using LINE-1 and other repetitive sequences as surrogates. Our results suggest that pancreatobiliary cancers exhibit a pattern of genome-wide hypomethylation that can be detected using pancreatic and biliary fluids.

Genome-wide hypomethylation is thought to be associated with tumor malignancy through a variety of mechanisms. For example, global hypomethylation is associated with genomic instability^[32], which may confer a poor prognosis. Hypomethylation can also lead to the activation of proto-oncogenes, endogenous retroviruses or transposable elements; such transcriptional dysregulation could affect tumor aggressiveness. Although we found correlations between the level of LINE-1 methylation and the methylation of other repetitive sequences^[17], it is possible that there are functional and/or biological differences in the regulation of repetitive DNA sequences. Further analysis is necessary to clarify the role of genome-wide hypomethylation in pancreatobiliary cancers.

The LINE-1 hypomethylation in pancreatic cancers determined using pancreatic fluids was less significant than that determined using tissue samples, although the

number of samples analyzed was limited. It is possible that some of the pancreatic fluid samples did not contain sufficient concentrations of cancer DNA^[12]. Given the relatively poor diagnostic yield of cytology in this setting, a problem that is likely to be related to the highly scirrhous nature of pancreatic ductal adenocarcinomas, sample adequacy is likely to be one of the limiting factors in the molecular analysis of these samples^[12]. Serum LINE-1 hypomethylation has been reported to be a potential prognostic marker for hepatocellular carcinoma^[33]. It would be interesting to analyze serum LINE-1 meth-

ylation levels in patients with pancreatobiliary cancers.

CpG island hypermethylation of tumor-associated genes was detected at various frequencies in pancreatobiliary cancers using pancreatobiliary fluids. Although genome-wide hypomethylation and regional hypermethylation of 5' CpG islands are common features of neoplasias, the link between the two remains controversial^[17]. In the current study, we did not find a significant correlation between 5' CpG island hypermethylation of tumor-associated genes and global hypomethylation.

Hypermethylation of the *UCHL1* gene was cancer-

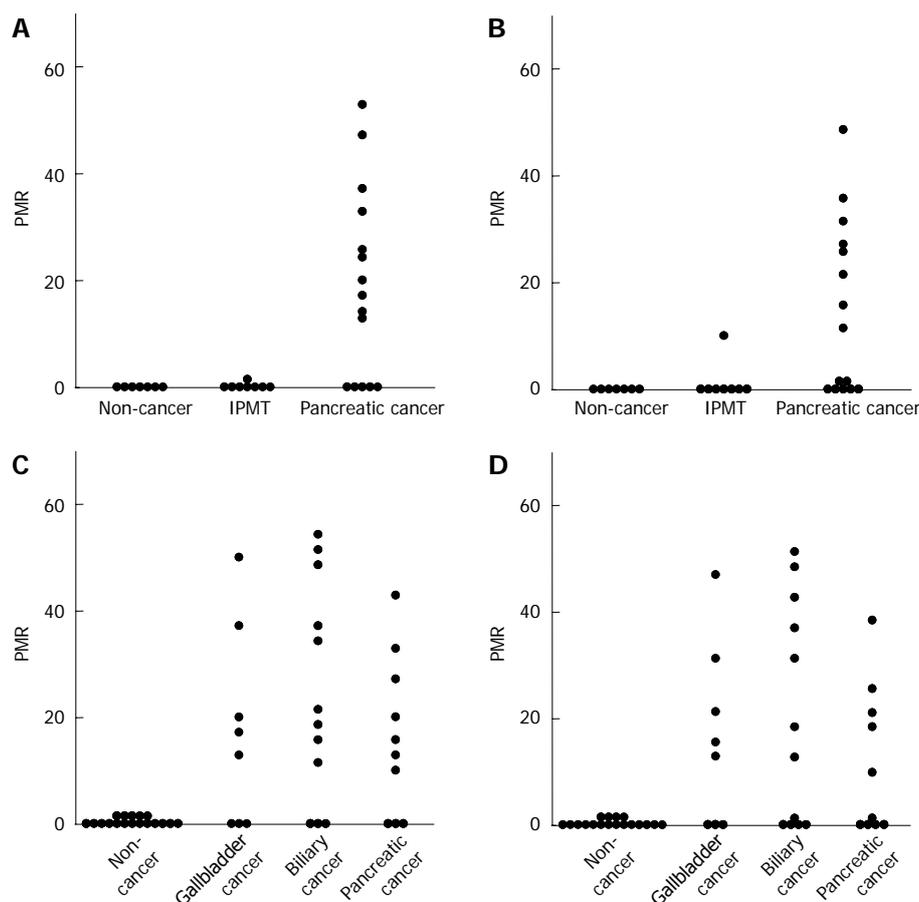

Figure 3 Analysis of methylation levels of ubiquitin carboxyl-terminal esterase L1 and runt-related transcription factor 3 using pancreatobiliary fluids. Comparison of the ubiquitin carboxyl-terminal esterase L1 (UCHL1) (A) and runt-related transcription factor 3 (RUNX3) (B) methylation levels in pancreatic fluids between pancreatic cancer and noncancerous pancreatic disease; Comparison of the UCHL1 (C) and RUNX3 (D) methylation levels in biliary fluids between pancreatobiliary cancer and noncancerous pancreatobiliary disease. PMR: Percentage of methylated reference.

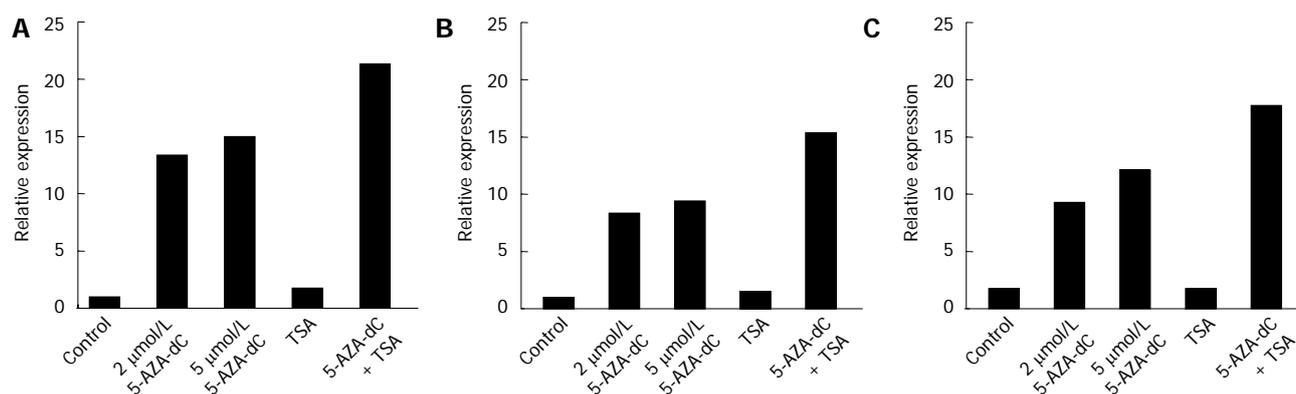

Figure 4 Reactivation of ubiquitin carboxyl-terminal esterase L1 by 5-AZA-2'-deoxycytidine and/or Trichostatin A treatment in pancreatic and biliary cancer cell lines. A: PK-1 cells; B: PK45P cells; C: TGBC1TKB cells. To examine the roles of CpG methylation and histone deacetylation in the silencing of ubiquitin carboxyl-terminal esterase L1, cancer cells were treated with 2 or 5 μmol/L 5-AZA-2'-deoxycytidine (5-AZA-dC) for 72 h or 100 nmol/L Trichostatin A (TSA) for 24 h. The cells were also treated with 2 μmol/L 5-AZA-dC for 72 h, followed by 100 nmol/L TSA for an additional 24 h.

specific and most frequently detected in pancreatobiliary cancers. Hypermethylation of the *UCHL1* gene in pancreatic and biliary fluids was the most useful single marker of pancreatic and pancreatobiliary cancers, respectively. Hypermethylation of the *UCHL1* and *RUNX3* genes in pancreatic and biliary fluids was the most useful combined marker for pancreatic and pancreatobiliary cancers,

respectively. Epigenetic inactivation of *UCHL1* has been reported in a variety of human cancers^[34]. Epigenetic inactivation of *RUNX3* is known to play an important role in the pathogenesis of pancreatobiliary cancer^[35,36].

LINE-1 and SAT2 methylation levels have been reported to be significantly lower in extrahepatic cholangiocarcinoma than in normal duct and biliary intraepithelial

neoplasias (BilINs). BilINs showed a decrease of SAT2 methylation levels, but no decrease of LINE-1 methylation levels was found compared to those in normal samples^[24]. Most of the cancer-specific CpG island hypermethylation is thought to occur in the BilIN stage, before LINE-1 hypomethylation. Our results also suggest that CpG island hypermethylation analyzed in pancreatobiliary fluids is more useful than LINE-1 methylation for the detection of pancreatobiliary cancer.

Importantly, the methylation patterns of 10 tumor-associated genes were similar in both the pancreatic and biliary fluids from the same patients with pancreatic cancer. Moreover, the methylation patterns of the *UCHL1* and *RUNX3* genes were identical in both the pancreatic and biliary fluids from the same patients. These results further support the notion that hypermethylation of *UCHL1* and *RUNX3* in pancreatobiliary fluids is a useful marker for the detection of pancreatobiliary cancer.

To confirm the role of epigenetic alterations in transcriptional repression of the *UCHL1* gene, we treated pancreatobiliary cancer cell lines, in which *UCHL1* was methylated, with 5-AZA-dC alone or in combination with TSA. Treatment with 5-AZA-dC restored the *UCHL1* expression in cancer cell lines. Moreover, combined treatment with 5-AZA-dC and TSA restored *UCHL1* expression synergistically, indicating that CpG methylation and histone deacetylation play important roles in silencing the *UCHL1* gene.

Not only the clinical utility but also the pathobiological effects of nucleic acids in circulation (nucleosomes, DNA, RNA, microRNA *etc.*) are receiving increasing attention^[37,38]. Further analysis is necessary to clarify the possible detrimental effects of nucleic acids in the tumor microenvironment, including the contribution of methylated DNA in pancreatobiliary fluids to disease progression.

In conclusion, our results suggest that hypermethylation of the *UCHL1* gene plays a key role in the pathogenesis of pancreatobiliary cancers and that detection of hypermethylation of *UCHL1* and *RUNX3* in pancreatobiliary fluids is useful for the diagnosis of these malignancies. Our MethyLight panel (*UCHL1* and *RUNX3*) is simple and accurate for differentiating between neoplastic and non-neoplastic samples and compares favorably with other quantitative MSP panels and with the identification of mutant *KRAS* or telomerase, which have been used previously to differentiate between malignant and benign pancreatic samples^[39,40]. Moreover, newer assays that can detect low concentrations of mutations in pancreatic juice^[41], as well as novel assays and technologies, are likely to improve the detection of low concentrations of mutant DNA for cancer diagnosis in the future. Although we focused on epigenetic alterations in the current study, a combination of highly specific epigenetic and genetic markers might provide the best diagnostic utility.

with pancreatobiliary cancer is still poor. Elucidation of the biological characteristics of these carcinomas has become necessary to improve the prognosis of patients and to devise better treatment strategies.

Research frontiers

Roles of epigenetic alterations in pancreatobiliary cancer are receiving increasing attention. Two contradicting epigenetic alterations often coexist in cancer: global or genome-wide hypomethylation, which is mainly observed in repetitive sequences within the genome, and regional hypermethylation, which is frequently associated with CpG islands within gene promoters. Long interspersed nuclear element-1 (LINE-1) methylation status and its relationship with the hypermethylation of CpG islands in pancreatic and biliary fluids taken from patients with pancreatobiliary cancer is not known.

Innovations and breakthroughs

This is the first study to report that pancreatobiliary cancers exhibit a pattern of genome-wide hypomethylation that can be detected using pancreatic and biliary fluids. CpG island hypermethylation of tumor-associated genes was detected at various frequencies. Hypermethylation of the ubiquitin carboxyl-terminal esterase L1 (*UCHL1*) gene may play a key role in the pathogenesis of pancreatobiliary cancers.

Applications

Hypermethylation of *UCHL1* and runt-related transcription factor 3 in pancreatobiliary fluids might be useful for the diagnosis of pancreatobiliary cancers. A combination of highly specific epigenetic and genetic markers might provide the best diagnostic utility.

Terminology

LINEs are 6-8 kb long, GC-poor sequences encoding an RNA-binding protein and a reverse transcriptase/endonuclease; these sequences constitute approximately 20% of the human genome. LINE-1 elements are most abundant, and over half a million copies of these elements are present in the human genome; *UCHL1*, which is also known as PARK5/PGP9.5, is a member of the ubiquitin carboxy terminal hydrolase family targeting the ubiquitin-dependent protein degradation pathway. With both ubiquitin hydrolase and dimerization-dependent ubiquitin ligase activities, *UCHL1* plays important roles in multiple cellular processes. *UCHL1* is a tumor-suppressor gene that is inactivated by promoter methylation or gene deletion in several types of human cancers.

Peer review

The presence of such high amounts of methylated DNA in pancreatobiliary fluid is intriguing. The study has translational significance.

Abstract

AIM: To evaluate the effectiveness of a short-type single-balloon-enteroscope (SBE) for endoscopic retrograde cholangiopancreatography (ERCP) in patients with a reconstructed intestine.

METHODS: Short-type SBE was developed to perform ERCP in postoperative patients with a reconstructed intestine. Short-type SBE is a direct-viewing endoscope with the following specifications: working length, 1520 mm; total length, 1840 mm; channel diameter, 3.2 mm. In addition, short-type SBE has a water-jet channel. The study group comprised 22 patients who underwent

31 sessions of short-type SBE-assisted ERCP from June 2011 through May 2012. Reconstruction was performed by Billroth-II (B-II) gastrectomy in 6 patients (8 sessions), Roux-en-Y (R-Y) gastrectomy in 14 patients (21 sessions), and R-Y hepaticojejunostomy in 2 patients (2 sessions). We retrospectively studied the rate of reaching the blind end (papilla of Vater or choledochojejunal anastomosis), mean time required to reach the blind end, diagnostic success rate (defined as the rate of successfully imaging the bile and pancreatic ducts), therapeutic success rate (defined as the rate of successfully completing endoscopic treatment), mean procedure time, and complications.

RESULTS: Among the 31 sessions of ERCP, the rate of reaching the blind end was 88% in B-II gastrectomy, 91% in R-Y gastrectomy, and 100% in R-Y hepaticojejunostomy. The mean time required to reach the papilla was 18.3 min in B-II gastrectomy, 21.1 min in R-Y gastrectomy, and 32.5 min in R-Y hepaticojejunostomy. The diagnostic success rates in all patients and those with an intact papilla were respectively 86% and 86% in B-II gastrectomy, 90% and 87% in R-Y gastrectomy, and 100% in R-Y hepaticojejunostomy. The therapeutic success rates in all patients and those with an intact papilla were respectively 100% and 100% in B-II gastrectomy, 94% and 92% in R-Y gastrectomy, and 100% in R-Y hepaticojejunostomy. Because the channel diameter was 3.2 mm, stone extraction could be performed with a wire-guided basket in 12 sessions, and wire-guided intraductal ultrasonography could be performed in 8 sessions. As for complications, hyperamylasemia (defined as a rise in serum amylase levels to more than 3 times the upper limit of normal) occurred in 1 patient (7 sessions) with a B-II gastrectomy and 4 patients (19 sessions) with an R-Y gastrectomy. After ERCP in patients with an R-Y gastrectomy, 2 patients (19 sessions) had pancreatitis, 1 patient (21 sessions) had

gastrointestinal perforation, and 1 patient (19 sessions) had papillary bleeding. Pancreatitis and bleeding were both mild. Gastrointestinal perforation improved after conservative treatment.

CONCLUSION: Short-type SBE is effective for ERCP in patients with a reconstructed intestine and allows most conventional ERCP devices to be used.

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is often difficult to perform in postoperative patients with a reconstructed intestine because of altered anatomical features. However, the advent of balloon enteroscopy has improved the outcome of ERCP in patients with a reconstructed intestine, and many recent studies have found this procedure to be useful^[1-20]. However, during ERCP, several problems remain to be solved. For example, these scopes do not have a lifting device, and the narrow channel diameter precludes the use of wire-guided devices. Moreover, the development of special devices is required because a single balloon enteroscope (SBE) has a long working length. Therefore, the development of a balloon endoscope with a short working length and a large working channel is eagerly anticipated^[9]. The development of short-type double balloon enteroscopy (DBE) (models EC-450B15 and EI-530B, Fujifilm, Osaka, Japan) allowed many ERCP devices to be used. However, because the channel diameter of most conventional balloon enteroscopy is 2.8 mm, wire-guided devices cannot be used. We describe our experience with 22 postoperative patients with a reconstructed intestine who underwent ERCP (31 sessions) using a short-type SBE that was specifically developed for ERCP (model SIF-Y0004; Olympus Medical Systems, Tokyo, Japan). To the best of our knowledge, this is the first report to describe ERCP performed with this SBE.

MATERIALS AND METHODS

Patients

From June 2011 to May 2012, 37 sessions of short-type SBE-assisted ERCP were performed in 28 postoperative

patients who had a reconstructed intestine in our hospital. Six patients were excluded from the study because the passage of the scope to the blind end (papilla of Vater or choledochojejunal anastomosis) was precluded by proximal narrowing or occlusion of the intestine caused by tumor invasion. The remaining 22 patients (31 sessions) were studied. Reconstruction was performed by Billroth II (B-II) gastrectomy in six patients (eight sessions), Roux-en-Y (R-Y) gastrectomy in 14 (21 sessions), and R-Y hepaticojejunostomy in two (two sessions). B-II gastrectomy was performed only in patients with a long afferent loop or Braun's anastomosis in whom a direct-viewing multipurpose endoscope could not reach the blind end. Table 1 shows the detailed demographic characteristics of the patients.

Endoscope and ERCP Instruments

The SIF-Y0004 is a direct-viewing endoscope with the following specifications: angle of view, 120°; bending section, up 180°, down 180°, right 160°, and left 160°; working length, 1520 mm; total length, 1840 mm; outer diameter of distal end, 9.2 mm; outer diameter of insertion end, 9.2 mm; and working channel diameter, 3.2 mm. The SIF-Y0004 has a water-jet channel.

A sliding tube with a working length of 880 mm was

Table 2 Specifications of two types of single-balloon endoscopes

used. The specifications of the SIF-Y0004 are compared with those of a conventional SBE (SIF-Q260; Olympus Medical Systems, Tokyo, Japan) in Table 2 and Figure 1.

For biliary cannulation and injection of contrast media, a conventional ERCP catheter (PR-4Q-1; Olympus Medical Systems, Tokyo, Japan) and a bending cannula (PR-233Q; Olympus Medical Systems) were used. If cannulation was difficult to perform with a catheter alone, a 0.035-inch guide wire (RF-GA35403; Radifocus®, Terumo Corporation, Tokyo, Japan) was used. For stent placement and insertion of guide-wire instruments, a 0.035-inch Jag-wire™ (Boston Scientific; Natick, MA, United States) and a 0.025-inch disposable Visiglide™ guide wire (G-240-2545A, Olympus Medical Systems, Japan) were mainly used.

Endoscopic papillary balloon dilation was done using a Quantum TTC® Biliary Balloon Dilator (QBD-8X3, Cook Medical, Bloomington, IN, United States) and a CRE™ Balloon Dilation Catheter (Boston Scientific), measuring 10 to 15 mm, was used to perform endoscopic papillary large balloon dilation. Lithotripsy was performed with the following retrieval baskets: models FG-V435P (Flower Basket V®, Olympus Medical Systems), FG-V436P (Tetra Catch V®, Olympus Medical Systems), and EBL-15-200 (Escort II Extraction Balloon, Cook Medical).

Intraductal ultrasonography was carried out with a miniature ultrasound probe (UM-G20-29R, Olympus Medical Systems), inserted using a guide wire. As for stents, a 7-French pigtail plastic stent (PBD-203 series, Olympus Medical Systems) and metallic WallFlex™ Biliary RX Fully Covered and RX Partially Covered Stents Systems (Boston Scientific) were used.

Methods

Many studies have reported that balloon enteroscopy-assisted ERCP is therapeutically useful; however, a system for this procedure is not commercially available. We explained to patients that treatment outcomes and the incidence of complications have not been reported, and received written informed consent from all patients. Patients were sedated with pethidine (50 mg) and midazolam

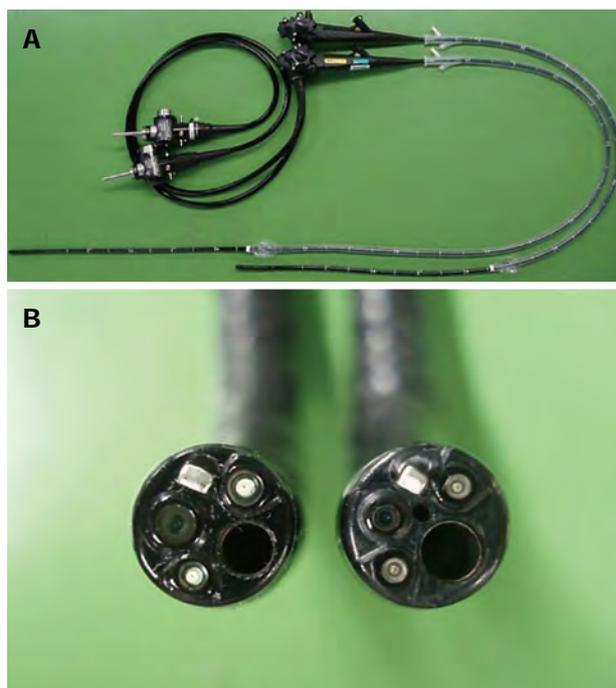

Figure 1 Comparison of two types of single-balloon endoscopes. A: Comparison of working lengths of two types of single balloon endoscopes (SBEs). Left: SIF-Q260 (working length 2000 mm); Right: SIF-Y0004 (working length 1520 mm); B: Comparison of working channel diameters of two types of SBE. (3 to 10 mg), and vital signs were intermittently monitored during all procedures. Propofol was used if necessary. The same operator performed all examinations from the time of endoscope insertion to treatment. The endoscope was inserted with the patient in the prone position, and abdominal compression was applied manually if a scope was technically difficult to insert deeply. Butylscopolamine (20 to 40 mg) or glucagon (1 to 2 mg) was administered as an antispasmodic. Three very experienced endoscopists (with experience in > 1200 sessions of ERCP) conducted the examinations. After ERCP, all patients received nafamostat mesilate (10 mg) to prevent pancreatitis, with the exception of those in whom the drug was contraindicated because of allergies or other reasons.

We retrospectively studied the rate of reaching the blind end, time required to reach the papilla, diagnostic success rate, therapeutic success rate, procedure time, and complications according to the reconstruction method. The diagnostic success rate was defined as the rate of successfully imaging of the bile and pancreatic ducts. The therapeutic success rate was defined as the rate of successfully completing the endoscopic treatment. The procedure time was defined as the interval from the start of cannulation to removal of the endoscope. Pancreatitis and bleeding occurring after ERCP were evaluated according to the 1991 Consensus Guidelines (Cotton Classification)^[21]. Hyperamylasemia was defined as a rise in serum amylase levels to more than three times the upper limit of normal. In our hospital, we routinely measure

ERCP: Endoscopic retrograde cholangiopancreatography.

serum amylase 3 h after the completion of ERCP, as well as the next morning. In patients in whom the blind end was not reached, SBE-assisted ERCP was not attempted a second time, except if the patient strongly requested to undergo the procedure again. If SBE-assisted ERCP was unsuccessful, open surgery or percutaneous cholangioscopy was performed.

RESULTS

Rate of reaching the blind end (papilla of Vater or choledochojejunal anastomosis)

The rate of reaching the blind end was 88% (7/8) in patients with a B-II gastrectomy, 91% (19/21) in those with a R-Y gastrectomy, and 100% (2/2) in those with a R-Y hepaticojejunostomy (Table 3).

Mean time required to reach the blind end

The mean time required to reach the blind end was 18.3 min (range, 5 to 37 min) in B-II gastrectomy, 21.1 min (range, 10 to 37 min) in R-Y gastrectomy, and 32.5 min (range, 32 to 33 min) in R-Y hepaticojejunostomy (Table 3).

Diagnostic success rates

The diagnostic success rate was 86% (6/7) in B-II gastrectomy, 90% (17/19) in R-Y gastrectomy, and 100% (2/2) in R-Y hepaticojejunostomy. All the patients with a B-II gastrectomy and 15 (80%) of the 19 patients with an R-Y gastrectomy had an intact papilla. The diagnostic success rate among patients with an intact papilla was 86% (6/7) in B-II gastrectomy and 87% (13/15) in R-Y gastrectomy (Table 3).

Therapeutic success rate

The therapeutic success rate was 100% (5/5) in B-II gastrectomy, 94% (15/16) in R-Y gastrectomy, and 100% (2/2) in R-Y hepaticojejunostomy. Among patients with an intact papilla, the therapeutic success rate was 100% (5/5) in B-II gastrectomy and 92% (11/12) in R-Y gastrectomy (Table 3).

Treatment procedures

The channel diameter of 3.2 mm allowed 12 sessions of stone extraction with a wire-guided basket, and eight sessions of wire-guided intraductal ultrasonography to be performed (Figures 2, 3). Residual stones could thus be confirmed, and biliary strictures evaluated. All treatment procedures are summarized in Table 4.

Mean procedure time

The mean procedure time was 35.4 min (range, 7 to 65 min) in B-II gastrectomy, 43.3 minutes (range, 12 to 125 min) in R-Y gastrectomy, and 29.5 min (range, 26 to 33 min) in R-Y hepaticojejunostomy (Table 3).

Complications

Hyperamylasemia, pancreatitis, and gastrointestinal perforation were the main complications encountered (Table 5). Pancreatitis and bleeding were both mild. Gastrointestinal perforation improved after conservative treatment.

DISCUSSION

When performing ERCP in postoperative patients with a reconstructed intestine, whether the scope can reach the papilla or choledochojejunal anastomosis is an important concern. However, recent studies have reported that the blind end is reached in more than 80% of patients^[3-5,9-15,17]. After reaching the blind end, imaging and treatment of the papilla or biliary anastomosis become the most important issues. In particular, the outcomes of ERCP in patients with an intact papilla differ substantially among hospitals and remain far from satisfactory. Shimatani *et al*^[12] reported that the diagnostic success rate of DBE-assisted ERCP exceeded 90% in patients with an intact papilla, as compared with 25% to 80% in general^[8,9,11]. In several small studies, the diagnostic success rate of SBE-assisted ERCP in patients with an intact papilla ranged from 25% to 80%^[1,4,5]. In our study, the diagnostic success rate was 86%, indicating relatively good results. As for the relative advantages and disadvantages of SBE and DBE, May *et al*^[22] reported that setting up a DBE system requires 15.2

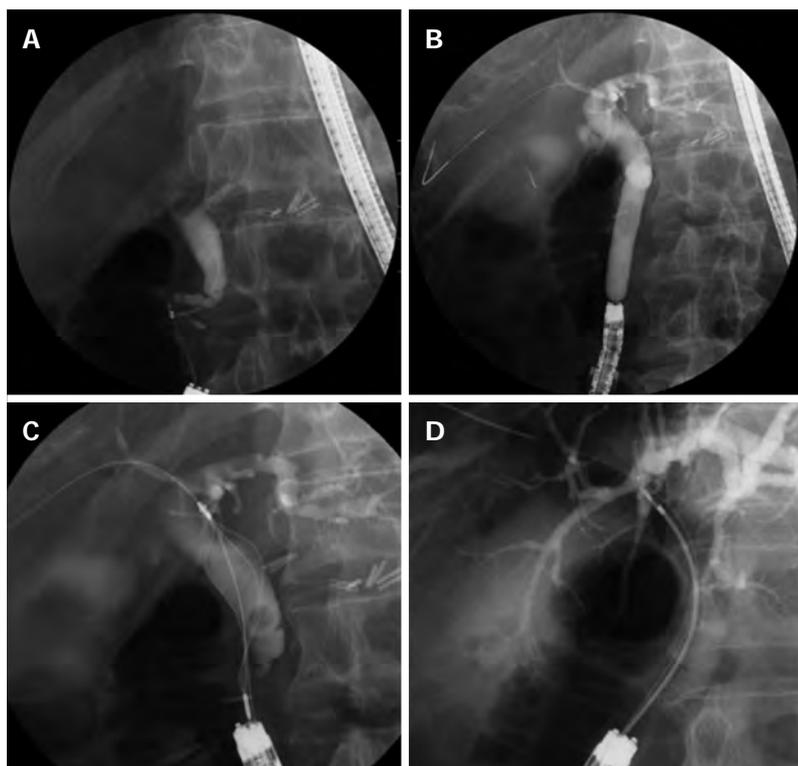

Figure 2 Therapeutic intervention. A: Cholangiogram showing a bile duct stone; B: Radiographic image showing papillary dilation using a large balloon catheter; C: Radiographic image showing wire-guided 4-wire retrieval basket; D: Radiographic image showing wire-guided intraductal ultrasonography.

min, whereas Kawamura *et al*^[23] showed that an SBE system could be set up within 5 min because it is simpler. A DBE system requires two balloons; therefore, the technique is complex, and the balloon at the distal end may interfere with passage of the scope through the intestine. However, one study reported that a DBE is easier to pass through an intestine with sharp angles than an SBE^[24].

Although several studies have compared SBE-assisted ERCP with DBE-assisted ERCP, and such a comparison would be challenging, these procedures are reported to be similarly clinically useful^[1,11,18-20].

The SIF-Q260, a conventional SBE, has a working length of 2000 mm and a channel diameter of 2.8 mm. Therefore, most conventional ERCP devices cannot be used, and the types of devices that could be used are limited. A short-type DBE has a working length of 1520 mm and a channel diameter of 2.8 mm, making passage of devices through the forceps channel difficult. Itoi *et al*^[3] replaced an SBE with a conventional forward-viewing

endoscope after reaching the papilla. We have used this technique in several patients in our hospital. However, even if the papilla is reached, some patients have severe bowel adhesion associated with complex loops that are difficult to resolve. Replacement of the scope is therefore not necessarily successful.

In this study, we used an SIF-Y0004, a new enteroscope that was developed to perform ERCP in post-operative patients with a reconstructed intestine. This enteroscope has a working length of 1520 mm and a channel diameter of 3.2 mm, allowing most conventional ERCP devices to be employed. In our hospital, the use of the SIF-Y0004 permitted the delivery of 8.5-French or smaller devices. The SIF-Y0004 also allowed the use of wire-guided devices that could not be passed through enteroscopy with a 2.8 mm channel diameter, as well as the insertion of a 7-French stent after the placement of two guide wires. A decreased rate of reaching the blind end was an important concern, because the SIF-Y0004

Table 4 Treatment procedures

has a shorter effective length than a conventional SBE. However, the rate of reaching the blind end in our study was 90%, which was similar to that of ERCP performed with a SIF-Q260 in our hospital (89%).

The SIF-Y0004 permitted the use of devices that could not be used with the SIF-Q260. Compared with a short-type DBE, more devices and diagnostic instruments could be used with SIF-Y0004. Conventional models have a channel diameter of 2.8 mm; therefore, ERCP for stone extraction requires free-hand cannulation and the use of a 4-wire retrieval basket. However, the SIF-Y0004 allowed wire-guided devices to be used for stone extraction; successfully accomplished in 12 patients in our study. In addition, this new SBE allowed wire-guided intraductal ultrasonography to be easily performed to confirm residual stones.

The incidence of complications after ERCP in patients with a reconstructed intestine has been reported to be 0% to 11% for perforation, 0% to 20% for pancreatitis, and 0% to 32% for bleeding, and differed considerably among hospitals^[1-5,8,9,12-16]. Many patients who underwent ERCP in our hospital had undergone gastrectomy and had an intact papilla; therefore, cannulation was expected to be difficult, potentially leading to a high incidence of pancreatitis. However, the incidence of pancreatitis in this study was 7.7%, which is not particularly higher compared with previous reports. Further studies of larger numbers of patients are required because our study group was small.

The patient with gastrointestinal perforation had duodenal ulcer postoperatively and had undergone abdominal surgery three times. The initial procedure was Roux-en-Y reconstruction after distal gastrectomy, and a duodenum-transverse colon fistula developed. Subsequently, abdominal surgery was performed twice to repair the fistula site. Marked adhesion was found in the horizontal portion of the duodenum. Although a defect apparently caused by a stone in the bile duct was found on endoscopic retro-

²According to Cotton's criteria. ERCP: Endoscopic retrograde cholangiopancreatography.

grade cholangiography, the scope was retracted during the examination and did not reach the blind end. The scope was inserted several times, but the results were the same. Lithotripsy was therefore not performed, and the examination was terminated. After endoscopy, the patient had abdominal pain and increased amylase levels. Post-ERCP pancreatitis was suspected. Enhanced computed tomography showed a small amount of free air around the horizontal portion of the duodenum, and perforation was diagnosed. There were no symptoms of peritoneal irritation. Computed tomography performed 5 d after surgery showed disappearance of the free air. As for the common bile duct stones, there was no dilation of the bile duct, and a percutaneous approach was precluded. We therefore recommended open surgery. However, ERCP with the SIF-Y0004 was repeated after 10 d at the strong request of the patient. Lithotripsy was successfully performed without perforation.

In the patient with papillary bleeding, melena occurred 12 h after endoscopic papillary large balloon dilatation. The hemoglobin level decreased by 2 g/dL. Bleeding from the papilla was suspected, and endoscopic examination with the SIF-Y0004 showed blood clots at and around the papilla. There was no active bleeding from the papilla. The examination was completed without any treatment. Subsequently, there was no melena or progression of anemia. Hemostasis was achieved spontaneously, with no need for blood transfusion.

The present study was small. The SIF-Y0004 has a channel diameter of 3.2 mm, currently the largest available among balloon endoscopes, and a short working length. The water-jet channel of this model helps to maintain a field of view during scope insertion and treatment. It will be particularly useful in the presence of bleeding.

Further studies in larger numbers of patients are needed to confirm our results. However, in postoperative patients with a reconstructed intestine who underwent ERCP, the rate of the reaching the blind end with the SIF-Y0004 was similar to that with the SIF-Q260. This

new model SBE permitted the use of most ERCP devices. Our results suggest that the SIF-Y0004 enables high-quality diagnosis and treatment to be provided reliably.

COMMENTS

Background

Endoscopic retrograde cholangiopancreatography (ERCP) with duodenal scope or conventional forward viewing endoscope for reconstructed intestine (Billroth-II reconstruction, Roux-en-Y reconstruction) has often been described as unsatisfactory because of altered anatomical features. Balloon enteroscopy has improved the outcomes of ERCP in patients with a reconstructed intestine.

Research frontiers

Balloon enteroscopy has improved the outcomes of ERCP in patients with a reconstructed intestine. These patients may avoid the need for surgical treatment in case of biliopancreatic problems.

Innovations and breakthroughs

Balloon-enteroscope assisted-ERCP is an important endoscopic breakthrough for the therapeutic management of the conventionally inaccessible biliopancreatic ducts. However, several problems remain to be solved. For example, wire-guided devices cannot be used because these scopes have a narrow channel diameter, 2.8 mm. In this study, the authors used a newly designed short-type single balloon enteroscope (SBE) that was developed to perform ERCP in postoperative patients with a reconstructed intestine. This short-type SBE has a working length of 1520 mm, and a channel diameter of 3.2 mm, allowing most conventional ERCP devices to be employed. Among all balloon enteroscopy, these specifications are limited to this scope. As for treatment, this scope permitted the use of devices that could not be used with conventional SBE. Compared with a short-type double balloon enteroscopy, more devices and diagnostic instruments could be used with this scope. Conventional models have a channel diameter of 2.8 mm; therefore, ERCP for stone extraction requires free-hand cannulation. However, this scope allowed wire-guided devices to be used for stone extraction. In addition, this scope allowed wire-guided intraductal ultrasonography to be easily performed to confirm residual stones.

Applications

This study suggests that short-type SBE enables high-quality diagnosis and treatment to be provided reliably.

Terminology

Billroth-II reconstruction is a surgical technique in gastrectomy. Roux-en-Y reconstruction of the small intestine is a frequently performed surgical technique in gastrointestinal surgery, hepatobiliary and pancreatic surgery. The location of the Vater's papilla and choledochojejunal anastomosis of the most patients who are underwent these operation are differed from normal position that was accessible with conventional endoscope.

Peer review

The authors investigated the efficacy of new short-type SBE for ERCP in patients with altered gastrointestinal anatomy, and concluded that short-type SBE is effective for ERCP in patients with a reconstructed intestine. This study clearly shows the efficacy of short-type SBE as a clinical trial.

Abstract

AIM: To investigate the role of endoplasmic reticulum (ER) stress in cancer radiotherapy and its molecular mechanism.

METHODS: Tunicamycin (TM) was applied to induce ER stress in human esophageal cancer cell line EC109, and the radiosensitization effects were detected by acute cell death and clonogenic survival assay. Cell cycle arrest induced by TM was determined by flow cytometric analysis after the cellular DNA content was labeled with propidium iodide. Apoptosis of EC109 cells induced by TM was detected by annexin V staining and Western blotting of caspase-3 and its substrate poly ADP-ribose polymerase. Autophagic response was determined by acridine orange (AO) staining and Western blotting of microtubule-associated protein-1 light chain-3 (LC3) and autophagy related gene 5 (ATG5).

In order to test the biological function of autophagy, specific inhibitor or Beclin-1 knockdown was used to inhibit autophagy, and its effect on cell apoptosis was thus detected. Additionally, involvement of the phosphatidylinositol-3 kinase (PI3K)/Akt/mammalian target of the rapamycin (mTOR) pathway was also detected by Western blotting. Finally, male nude mice inoculated subcutaneously with EC109 cells were used to confirm cell model observations.

RESULTS: Our results showed that TM treatment enhanced cell death and reduced the colony survival fraction induced by ionizing radiation (IR), which suggested an obvious radiosensitization effect of TM. Moreover, TM and IR combination treatment led to a significant increase of G2/M phase and apoptotic cells, compared with IR alone. We also observed an increase of AO positive cells, and the protein level of LC3-II and ATG5 was induced by TM treatment, which suggested an autophagic response in EC109 cells. However, inhibition of autophagy by using a chemical inhibitor or Beclin-1 silencing led to increased cell apoptosis and decreased cell viability, which suggested a cytoprotective role of autophagy in stressed EC109 cells. Furthermore, TM treatment also activated mTORC1, and in turn reduced Akt phosphorylation, which suggested the PI3K/Akt/mTOR signal pathway was involved in the TM-induced autophagic response in EC109 cells. Tumor xenograft results also showed synergistic retarded tumor growth by TM treatment and IR, as well as the involvement of the PI3K/Akt/mTOR pathway.

CONCLUSION: Our data showed that TM treatment sensitized human esophageal cancer cells to radiation *via* apoptosis and autophagy both *in vitro* and *in vivo*.

INTRODUCTION

Esophageal cancer, which principally consists of esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma, is one of the leading causes of cancer-related death, and its worldwide incidence is increasing annually^[1]. Historically, treatment of esophageal cancer involved radiotherapy, which was often combined with other treatments, such as surgery and chemotherapy^[2]. However, there is differential sensitivity to radiation in tumors of the same grade, which to some extent has limited the clinical application of radiotherapy. How to enhance the radiosensitivity of esophageal cancer is still an unresolved problem.

Enhancing radiosensitivity can be accomplished by increasing tumor-specific cell death induced by radiation. Following ionizing radiation (IR), many types of tumor cells primarily undergo apoptosis, which is often significant even at very low doses^[3]. Recently, however, another type of cell death, termed type II cell death or cell death with autophagy, has been observed following radiation^[4]. Induction of autophagy leads to the formation of a double membrane-bound structure called the autophagosome. The autophagosome subsequently fuses with a lysosome, creating an autolysosome, whose contents and inner membrane are degraded and recycled^[5,6]. Recent studies have reported a role for autophagy in a variety of pathophysiological conditions, including cancer, defense against infections, and as a response to radiation. Although the fundamental role of induced autophagy is controversial, the current literature appears to support the role of autophagy as a mode of radiosensitization rather than radioprotection. Radiation-induced up-regulation of autophagic responsive genes has suggested a new mechanism of cell death and a new target for cancer therapy^[7-9].

The endoplasmic reticulum (ER) is an essential intracellular organelle with multiple roles including the synthesis of nascent proteins, Ca²⁺ storage, glycosylation, and the trafficking of newly-synthesized membrane and secretory proteins. Perturbations of these processes have been demonstrated to interfere with the proper functioning of ER, thus leading to a condition defined as ER stress^[10,11]. Following ER stress, specific signaling pathways have evolved in eukaryotic cells and are collectively termed the unfolded protein response (UPR). The UPR consists of three signal transduction pathways: protein kinase RNA dependent-like ER kinase (PERK), activating transcription factor 6 (ATF6), and inositol-requiring protein-1 (IRE1). Failure to relieve ER stress can result in cellular dysfunction and disease^[12]. The end result of sustained ER stress

and the UPR is usually cell death involving apoptosis and autophagy^[13,14]. Signaling through PERK, IRE1, and ATF6 pathways can trigger pro-apoptotic signals *via* the activation of downstream molecules such as the C/EBP homologous protein (CHOP, also known as growth arrest and DNA damage 153, GADD153), Jun kinase (JNK), and members of the Bcl-2 protein family^[15,16]. Cell death for a given cell is dependent on its genetic background and the treatment given. Radiation in the absence of the pro-apoptotic Bcl-2 family members Bax and Bak results in increased autophagy and cell death. This radiosensitization response is blocked by inhibitors of autophagy such as 3-methyladenine (3-MA)^[17].

In our previous work, we found that IR-induced up-regulation of ER stress markers glucose-regulated protein 78 (GRP78) and 94 (GRP94), both at the level of protein and mRNA. PERK and IRE1 signaling pathways were also activated by radiation, which suggested that IR could induce an ER stress response^[18]. However, its biological significance remained unknown. Tunicamycin (TM) is a naturally-occurring antibiotic that induces ER stress in a range of cell contexts^[19,20]. However, whether it could sensitize esophageal cancer cells to radiation was unknown. In order to explore the role of ER stress and the molecular mechanisms invoked following radiation treatment, TM was applied to induce ER stress in the human esophageal cancer cell line EC109. Our results showed that TM treatment sensitized esophageal cancer cells to radiation *via* apoptosis and autophagy both *in vitro* and *in vivo*.

MATERIALS AND METHODS

Materials

The ER stress inducers tunicamycin and autophagy inhibitor 3-MA were obtained from Merck. The annexin V staining kit was purchased from the Beyotime Institute of Biotechnology. Acridine orange (AO) was purchased from Sigma-Aldrich. All primary antibodies except Beclin-1 (Santa Cruz Biotechnology, sc10086) were purchased from Cell Signaling Technology. Specific siRNA of Beclin-1 (BECN1-homo-358) was obtained from Shanghai GenePharma Co., Ltd. Lipofectamine 2000 was obtained from Invitrogen. DMEM cell culture media and fetal bovine serum were obtained from Thermo Scientific.

Cell culture and radiation

The human esophageal cancer cell line EC109 was obtained from Shanghai Cell Bank (<http://www.cellbank.org.cn/>), and cultured in DMEM supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin (complete media). Cells were treated with 10 Gy of gamma radiation using a ⁶⁰Co source. The medium was immediately replaced after irradiation, and the dishes were returned to the incubator for the indicated times. Cells were harvested by scraping in PBS.

Cell growth and colony forming assays

For cell growth curves, exponentially growing cells were cultivated in 96-well plates, with 5×10^3 cells in each well. Twelve hours later, cells were treated with TM at the indicated concentrations, and further cultivated. Viable cells were detected using the cell counting kit 8 (Beyotime Institute). Briefly, 10 μ L of cell counting kit-8 (CCK-8) solution (10 mg/mL) was added to the media, and cells were incubated for two more hours. Plates were read using a microplate reader (Bio-Tek Instruments) set to 450 nm (wavelength correction set to 540 nm). Relative abundance was normalized to that of the control.

For colony formation assays, cells in the logarithmic growth phase were seeded in 6-well plates at concentrations predetermined to give 25-200 colonies. Cells were then pretreated with TM (5 μ g/mL) for 24 h, and then irradiated at the indicated dose. After changing the media, cells were further cultivated for 10-14 d. Cultures were fixed and stained with 0.5% crystal violet in absolute methanol. The number of colonies with > 50 cells was counted using a dissecting microscope. The percentage of cell survival was calculated and normalized to that of the control.

Cell cycle analysis

Exponentially growing EC109 cells were cultivated and synchronized for 24 h in serum-free media. The media with or without TM (0.5 μ g/mL) was replaced with complete media before irradiation with 10 Gy. Twenty four hours later, cells were harvested by trypsinization, washed with ice-cold PBS, and fixed in 70% ethanol. Before analysis, DNA was labeled with propidium iodide (PI) in the presence of RNase (1 mg/mL) for 30 min at room temperature. Cell cycle distributions were analyzed on a FACSsort (Becton Dickinson) with Cell Quest software (version 313) for the proportions of cells in the G1, S, and G2/M phases of the cell cycle.

Apoptosis assays

Apoptosis was measured using the annexin V fluorescein isothiocyanate (FITC) Apoptosis Kit (Beyotime Institute) according to the manufacturer's instructions. Briefly, TM or TM plus radiation-treated cells were trypsinized and washed twice with cold PBS. Cells were then stained for 15 min at room temperature, and analyzed on a FACSsort (Becton Dickinson). Caspase-8 activity was measured using the human active Caspase-8 immunoassay (Beyotime Institute). Optical density (A) was detected by using the microplate reader (Bio-Tek Instruments). Enzymatic activities were expressed as arbitrary A units, and relative activity was normalized to that of control.

AO and Hoechst 33342 staining

Cells were treated with TM for the indicated times, washed with PBS, trypsinized, and then collected in PBS. Cells were then stained with AO (100 μ g/mL) for 15 min at room temperature. Green (510 to 530 nm) and red (650 nm) fluorescence emissions from 1×10^5 cells illuminat-

ed with blue (488 nm) excitation light were analyzed on a FACSsort. For Hoechst 33342 staining, EC109 cells were stained for 15 min at room temperature, and then visualized with a fluorescence microscope.

siRNA transfection

EC109 cells were transfected with siRNA against Beclin-1 (5' GGAGCCAUUUUUUGAAACUTT) or control siRNA using Lipofectamine 2000 according to the manufacturer's instructions. Cells were collected and used for Western blotting 48 h after transfection. For cell viability assays, cells were further treated with TM for a further 24 or 48 h.

RNA extraction and quantitative real-time PCR

RNA was extracted with TRIzol reagent (Invitrogen) and converted to cDNA using the reverse transcription kit (Applied Biosystems). Quantitative real-time PCR (qRT-PCR) was carried out using the ABI 5700 real-time PCR system (Applied Biosystems) using specific primers. Reactions were done in triplicate from the same cDNA reaction. The PCR conditions were: initial denaturation at 95 $^{\circ}$ C for 5 min; 40 cycles of denaturation at 95 $^{\circ}$ C for 20 s; annealing at 60 $^{\circ}$ C for 30 s; and elongation at 72 $^{\circ}$ C for 30 s. Gene expression of ATG5 and Beclin-1 was normalized to the corresponding β -actin level and the comparative CT method was used to calculate relative gene expression.

Western blotting

Total protein was resolved on SDS-PAGE and transferred onto a nitrocellulose membrane. After blocking in 3% non-fat milk (in PBS) for 30 min, membranes were incubated with antibodies against GRP78 (#3177), GRP94 (#2104), LC3 (#4108), ATG5 (#2630), PARP (#9542), cleaved Caspase-3 (#9662), and Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (#8884), followed by incubation with corresponding secondary antibodies (Zhongshan Corp.). Expression of individual proteins was normalized to that of GAPDH. Western blotting were repeated at least three times.

Tumor xenograft model

All mouse experiments were approved by the University Committee on the Use and Care of Animals of the Third Military Medical University. Male nude mice were inoculated subcutaneously with 1×10^6 human EC109 cells in the dorsal aspect of the neck. Three weeks after tumor inoculation, all mice developed a large tumor (approximately 100 mg). Mice with established 3-wk-old tumors were randomly divided into four groups: Groups 1 and 2 were injected intraperitoneally (IP) with PBS or TM (1.5 mg/kg), respectively; Group 3 was given a single dose of localized irradiation (10 Gy); and the final group were irradiated and then given an IP injection of TM. All experiments used five mice per group. Tumor volume (TV) was measured every 3 d post-irradiation (day 0), and was calculated according to the formula $TV = L \times W^2/2$,

where L and W are the length and width, respectively. Tumor tissues and other organs (liver and kidney) were removed and processed for Western blotting analysis on day 15.

Statistical analysis

The one-sample *t*-test was used to statistically analyze the differences in the expression ratios of irradiated versus non-irradiated samples. A *P*-value less than 0.05 was considered significant.

RESULTS

Radiosensitization effect of TM in EC109 cells

TM has been used to induce ER stress in various studies. We first determined that TM induced ER stress in EC109 cells. TM treatment increased protein levels of GRP78 and GRP94, hallmarks of ER stress, in a dose- and time-dependent manner. The mRNA level of these two genes also increased after TM treatment, which was consistent with the changes in protein levels. Another indicator of ER stress is the selective splicing of X-box binding protein 1 (XBP1), which can be detected by RT-PCR. TM treatment induced an additional product of XBP1, indicating that a 26-bp intron was spliced from its normal transcript. Together, these results showed that TM treatment induced an ER stress response in EC109 cells.

The effect of TM treatment on the growth of cells was determined by a CCK-8 assay. TM treatment resulted in a reduction of cell growth in a dose-dependent manner, which became apparent after 24 h of treatment. Compared with other concentrations, 5 $\mu\text{g}/\text{mL}$ of TM induced obvious growth inhibition in EC109 cells, and was used in further experiments (Figure 1A). To evaluate if TM could increase radiosensitivity, EC109 cells were treated with various concentrations of TM alone or combined with IR at a dose of 10 Gy for 24 or 48 h. Cell viability was then determined using the CCK-8 assay. Cell viability decreased significantly when IR was combined with TM (Figure 1B). Cell viability at 48 h after IR was more pronounced than at 24 h, which indicated a time-dependent effect. To further confirm radiosensitization by TM, clonogenic survival assays were performed to examine long-term survival. Compared with IR alone, cell survival was significantly decreased in cells treated with TM and IR (Figure 1C). These results indicated that TM could sensitize EC109 cells to radiation.

Cell cycle arrest induced by TM

As TM treatment decreased cell viability, we wondered whether this was due to cell cycle arrest. To void its intrinsic cytotoxic effect, we decided to use TM at 0.5 $\mu\text{g}/\text{mL}$, a concentration that was able to consistently inhibit cell growth. Flow cytometric analysis of DNA content was conducted to assess changes in the proportion of cells in each phase of the cell cycle. TM treatment for 24 h indicated no significant changes in the cell cycle compared to the control. However, IR alone induced a G2/M

arrest in EC109 cells, which was consistent with our previous observation^[21]. TM treatment combined with IR greatly enhanced G2/M arrest (Figure 2). This indicated that the radiosensitization effect of TM was associated with cell cycle arrest.

Apoptosis is enhanced by TM in irradiated cells

Both IR and prolonged ER stress can induce an apoptotic response. We therefore studied whether TM enhanced apoptosis of irradiated EC109 cells. Apoptotic signaling pathways (both extrinsic and intrinsic) lead to activation caspases, which cleave essential cell substrates such as PARP. IR and ER stress have been shown to activate executioner caspases Caspase-3 and -8. The protein levels of active (cleaved) Caspase-3 were determined by Western blotting. Levels of cleaved Caspase-3 increased after TM treatment or IR (Figure 3A). Combined TM and IR treatment induced an increase greater than that of radiation alone. Furthermore, cleaved PARP and Caspase-8 activity (Figure 3B) showed a similar pattern of increase compared to Caspase-3.

To evaluate the proportion of apoptotic cells, EC109 cells were stained with Annexin V-FITC and PI, and analyzed by FACS (Figure 3C). TM treatment increased the amount of apoptotic cells and occurred in a time-dependent manner. Combined treatment significantly increased the number of apoptotic cells compared with that of radiation alone. Hoechst 33342 staining of TM-treated cells showed a similar result (Figure 3D). These results indicated that TM treatment enhanced cell apoptosis induced by IR.

Autophagy response induced by TM

TM treatment has been reported to induce cell death with autophagy in some cell lines. Upon induction of autophagy, cytosolic LC3- I is converted into LC3- II, which decorates the autophagosome and often serves as a marker of autophagy. Simultaneously, the gene expression of ATGs, such as ATG5, ATG7, and ATG12, were up-regulated under the condition of autophagy. To determine if TM induces an autophagic response in EC109 cells, Western blotting for LC3 and ATG5 protein levels were performed. As expected, the protein levels of autophagic markers increased after TM treatment in a dose-dependent manner. Consistent with the increase in protein levels, mRNA levels of Beclin-1 and ATG5 also increased after TM treatment. In order to verify that the molecular response to TM resulted in the morphological characteristics of autophagy, EC109 cells were treated with TM and then stained with AO. TM increased the number of cells displaying red fluorescence in a dose-dependent manner (Figure 4A).

We then determined the autophagic response following radiation. EC109 cells were irradiated and the protein levels of LC3 and ATG5 were detected by Western blotting. TM treatments increased protein levels of LC3 and ATG5, and the levels of these proteins were further increased by TM and radiation combined treatment (Figure

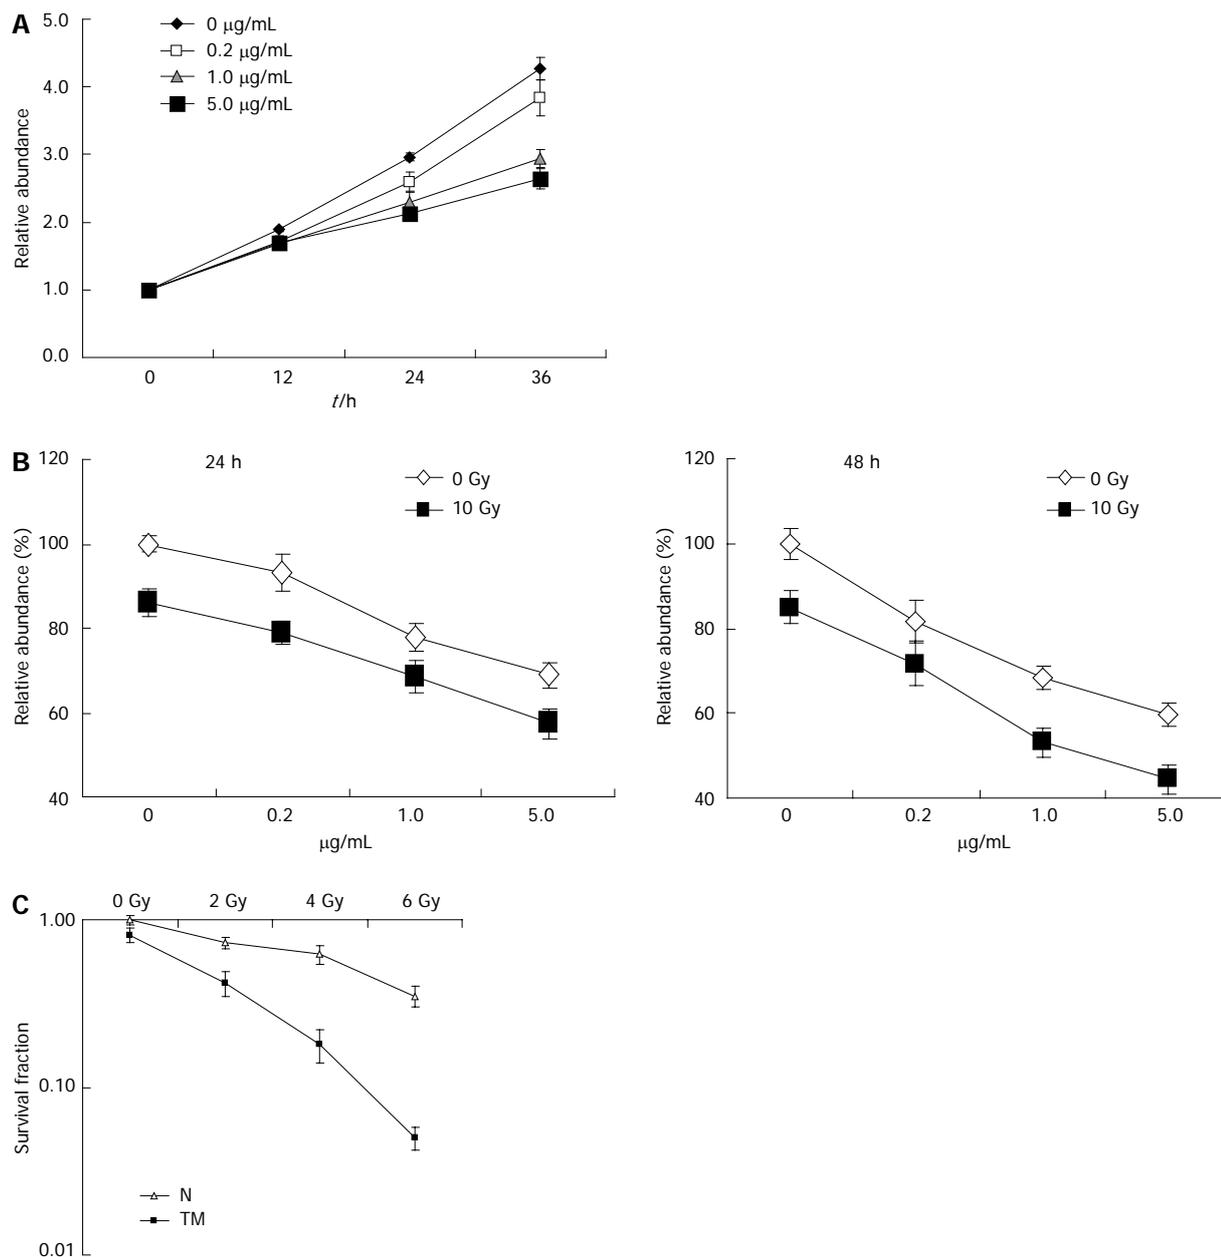

Figure 1 Radiosensitization effect of tunicamycin in EC109 cells. A: Exponentially growing EC109 cells were treated with tunicamycin (TM) at the indicated concentrations. Cell growth was determined using cell counting kit-8 (CCK-8) and relative growth rate was calculated using the absorption at 0 h as a baseline; B: EC109 cells were pretreated with or without TM (5 $\mu\text{g/mL}$), followed by a single dose of 10 Gy. 24 h (left panel) or 48 h (right panel) later, relative cell viability was measured using CCK-8; C: EC109 cells were pretreated with or without TM (5 $\mu\text{g/mL}$) for 24 h. After irradiation with 2, 4 and 6 Gy, cells were further cultivated for 10-14 d. The number of colonies with > 50 cells was counted under a dissecting microscope. N: Untreated with TM.

4B). Similarly, mRNA levels of Beclin-1 and ATG5 also increased after combined treatment, which suggested an augmented autophagic response (Figure 4C). Moreover, the percentage of AO positive cells was synergistically enhanced by radiation and TM treatment (Figure 4D).

As autophagy is thought to be involved in cell survival or cell death, we wanted to understand the significance of the autophagy response induced by TM. 3-MA, an inhibitor of autophagy, was used to specifically inhibit the autophagic response of EC109 cells to TM treatment. The addition of 3-MA resulted in an increase of LC3-II for-

mation in accordance with previously published data^[22]. Western blotting analysis revealed that the protein level of ATG5 decreased in EC109 cells after 3-MA treatment, compared with TM treatment alone (Figure 4E). This indicated that the autophagic response induced by TM treatment was inhibited by 3-MA. We then determined if 3-MA affected cell viability. As shown in Figure 4F, when cells were treated with inhibitor alone, cell viability after radiation did not change significantly. However, it decreased significantly when the cells were co-treated with TM and inhibitor. This suggested that inhibition of

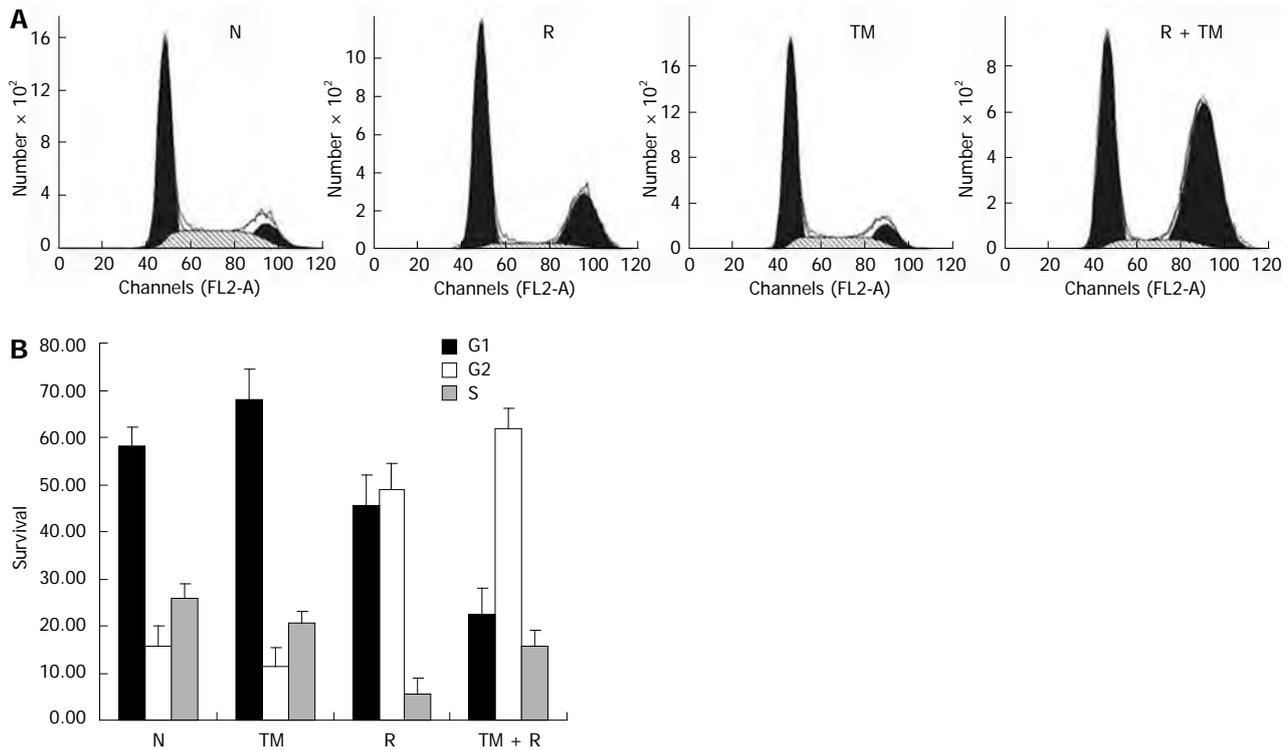

Figure 2 Cell cycle arrest induced by tunicamycin. A: EC109 cells were pretreated with or without tunicamycin (TM) (0.5 μg/mL), followed by a single dose of 10 Gy. 24 h later, cells were harvested, fixed, and labeled with propidium iodide. Cell cycle distributions were analyzed on a FACSsort; B: Data are the mean ± SD of three independent experiments. N: Sham-treated with TM; R: 10 Gy irradiation.

autophagy sensitized cells to radiation.

The effect of autophagy inhibition on apoptosis

Recent studies indicated a cross-talk between apoptosis and autophagy, yet the reciprocal relationship between them is far from clearly elucidated^[23]. Many studies have shown that blockage of autophagy with inhibitors increased apoptosis. Thus, we studied whether apoptosis of EC109 cells treated with TM would be augmented by an autophagy inhibitor.

To this end, autophagy was inhibited using 3-MA in cells treated with TM and IR, and then cells were analyzed by annexin V staining. 3-MA treatment significantly increased cell apoptosis (TM *vs* TM + 3-MA, Figure 5A). Similarly 3-MA treatment increased apoptosis in EC109 cells synergistically treated with TM and radiation. Western blotting for cleaved Caspase-3 and its substrate PARP showed that 3-MA treatment after radiation and TM induced a substantial increase in the active form of Caspase-3 and cleaved PARP (Figure 5B). Autophagy was subsequently inhibited by silencing Beclin-1, which has pivotal role in autophagy. siRNA against Beclin-1 was transfected into EC109 cells, and protein levels of Beclin-1 were detected 24 h later. Beclin-1 was significantly knocked down by the siRNA (Figure 5C). As expected, the autophagic response induced by TM treatment was attenuated when Beclin-1 was knocked down, which indicated a suppression of LC3II and ATG5 (Figure 5D). To determine the impact of Beclin siRNA on TM-induced apoptosis, Western blotting for cleaved

Caspase-3 and PARP was carried out. Similarly, increased levels of cleaved Caspase-3 and PARP were observed after silencing of Beclin-1 (Figure 5E). In addition, the levels of CHOP were also augmented. These results indicated that inhibition of autophagy increased apoptosis induced by TM.

Cell signaling pathways involved in TM response

Recent studies have shown that the PI3K/Akt/mTOR pathway is involved in ER stress-triggered apoptosis, and is also involved in the regulation of autophagy^[24,25]. Upon induction of ER stress, activation of mTORC1 reduces Akt phosphorylation, an event upstream of IRE-JNK signaling and subsequent apoptosis. We first explored whether TM treatment would activate mTORC1, using phosphorylation of p70S6K as a marker. Basal activity of mTORC1 was observed in untreated cells, and was rapidly upregulated following TM treatment in a dose- and time-dependent manner (Figure 6A). Accordingly, the protein levels of PI3K and phosphorylated Akt (p-Akt) declined. This suggested that the PI3K/Akt/mTOR signaling pathway was involved in TM treatment, which led to an autophagic response in EC109 cells. Western blotting for levels of PI3K and p-Akt were carried out to further explore the effect on this pathway after the combined treatment of TM and IR. Protein levels of PI3K and p-Akt showed a further decrease after combined treatment (Figure 6B). This suggested that this signal pathway was involved in the enhancement of radiosensitivity induced by TM treatment.

EC109 cells were pretreated with or without tunicamycin (TM) (5 $\mu\text{g}/\text{mL}$), followed by a single dose of 10 Gy. **A:** Western blotting analysis for poly ADP-ribose polymerase (PARP), Caspase-3, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH); **B:** Caspase-3 activity of treated cells; **C:** Apoptosis was determined by annexin V labeling; **D:** Representative images of cells stained with Hoechst 33343. N: Sham-treated with TM; R: 10 Gy irradiation.

In vivo studies

To determine if radiosensitization of TM *in vitro* could be recapitulated *in vivo*, nude mice with established tumor xenografts were treated with TM and local radiotherapy. To assess the effect of TM alone on ER stress markers, samples from tumor xenografts were analyzed by Western blotting. TM treatment induced an increase of GRP78 and GRP94 (Figure 7A). In addition, TM treatment increased the protein levels of ATG5 and LC3II, which indicated that TM treatment upregulated the autophagy response *in vivo* (Figure 7A). Similar results were observed in liver and kidney samples.

Simultaneously, the growth of tumors was determined. In control groups, tumors grew progressively to an average volume of 300 mm^3 , and all mice were sacrificed at day 12. The results of tumor growth curves showed that tumor growth could be retarded by radiation alone (Figure 7B, C). TM treatment also significantly inhibited the growth of tumor xenografts, compared with the control group. Moreover, the inhibition of tu-

mor xenograft growth was synergistically enhanced by combined radiation and TM treatment. Furthermore, the protein level of PI3K and p-Akt was also determined in tumor xenografts. TM treatment combined with radiation induced a significant decrease of the PI3K/Akt/mTOR signaling pathway, which showed that TM functioned similarly to that of the cell model (Figure 7D). These results suggested that TM treatment sensitized EC109 cells to radiation *in vivo*.

DISCUSSION

Here we have shown that the classic ER stress inducer TM could sensitize esophageal cancer cells to radiation *in vitro* and *in vivo*. TM causes ER stress by specifically inhibiting N-linked glycosylation of peptides in the ER, which leads to protein misfolding that exceeds the capacity of protein chaperones. Cells benefit from moderate ER stress to alleviate damage, while sustained ER stress induces cell death^[20]. In this study, we treated EC109 cells

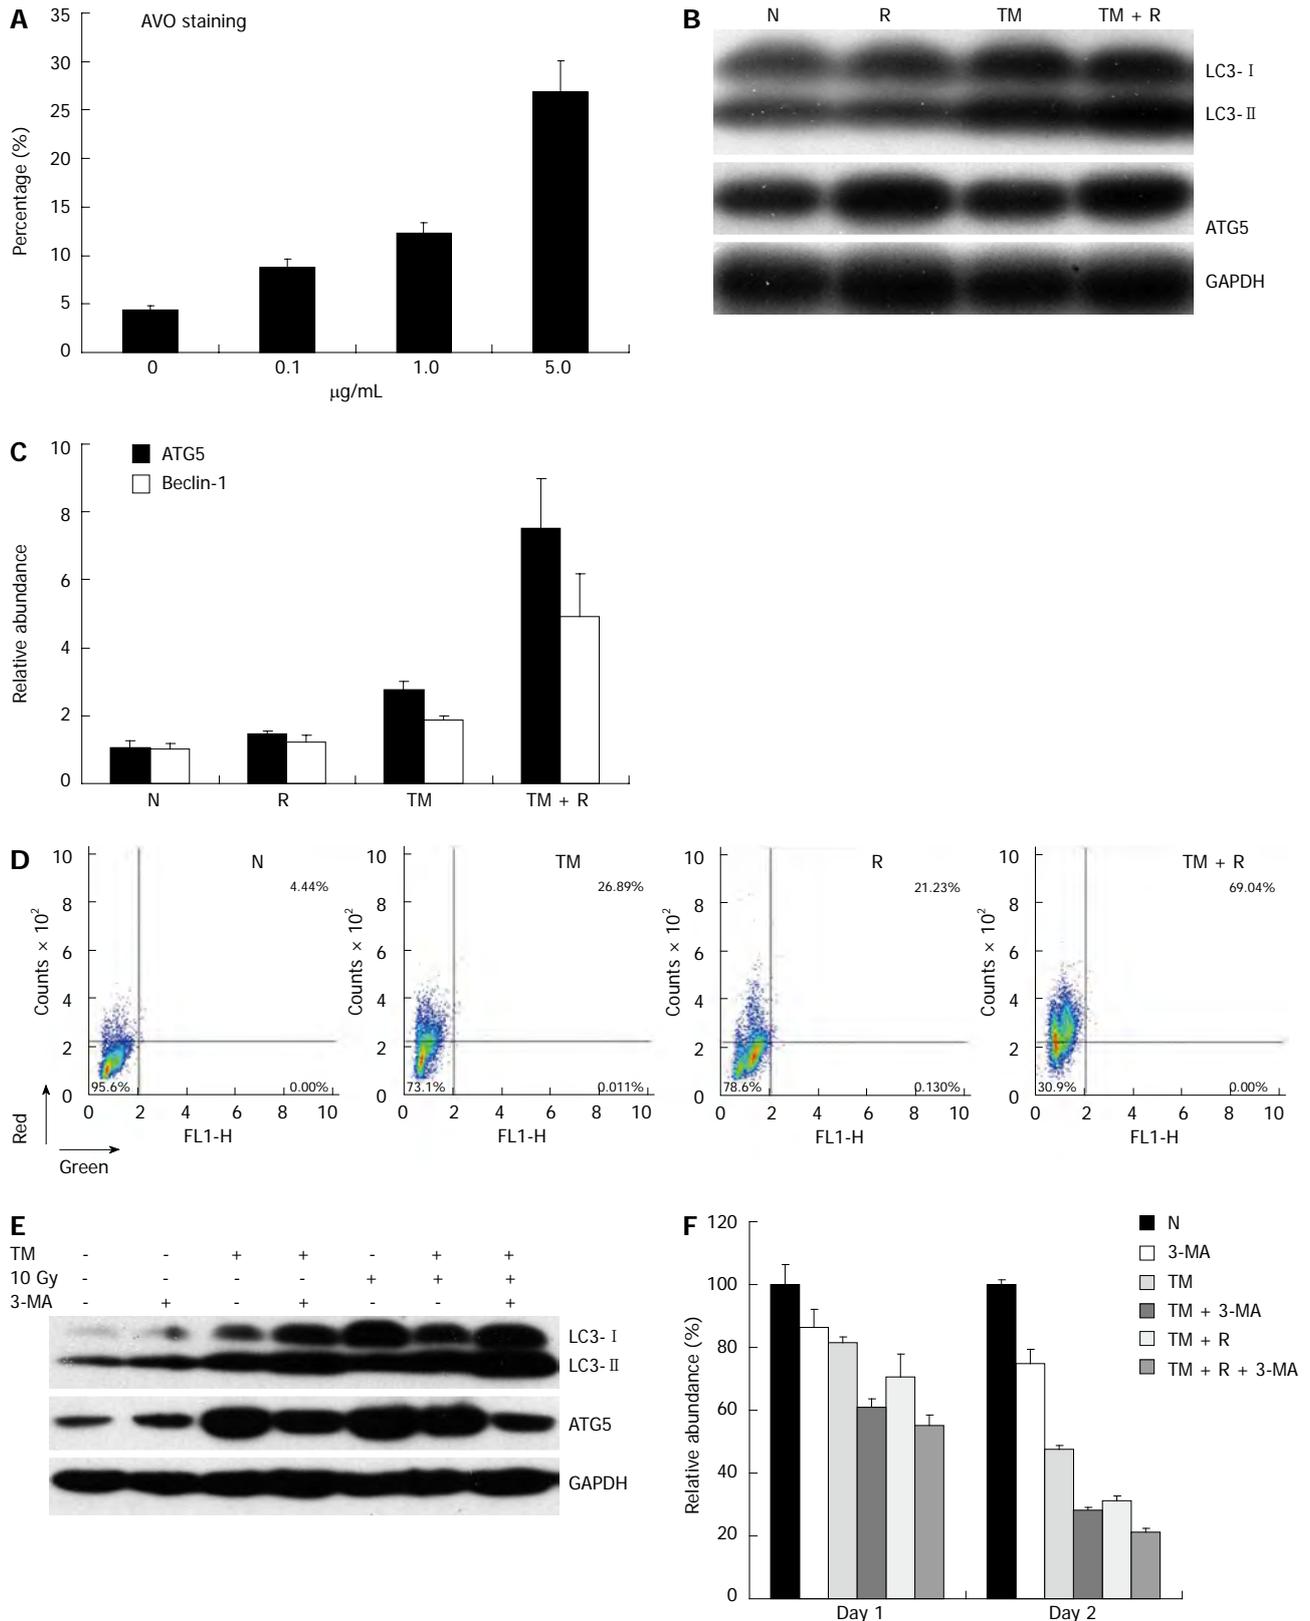

Figure 4 Autophagy response induced by tunicamycin. **A:** EC109 cells were exposed to increasing concentrations of tunicamycin (TM), and stained with acridine orange (AO); **B:** EC109 cells were pretreated with or without TM (5 µg/mL), followed by a single dose of 10 Gy and analyzed by Western blotting for LC3 and ATG5; **C:** Relative mRNA expression of Beclin-1 and ATG5 was assessed by quantitative polymerase chain reaction; **D:** After AO staining, cells were quantitatively analyzed on a FACSsort; **E:** Cells were treated as indicated, and protein levels of LC3 and ATG5 were assessed by Western blotting; **F:** Relative cell viability of cells treated with TM, radiation and autophagy inhibitor 3-MA for 24 or 48 h. with TM for 24 h, which led to sustained ER stress and induced cell death. Increased apoptosis induced by TM was observed in a time-dependent manner. Besides inducing ER stress, TM was found to induce autophagy in renal proximal tubular cells. In this work, we established that TM induced an autophagic response in esophageal cancer cells (Figures 4B, 7A). Other classic ER stress inducers, such as DTT and MG132, were also found to induce autophagy. These studies implied a causal link between ER stress and autophagy. However, the biological significance of ER stress-induced autophagy largely remained unresolved.

In our previous work, we found that radiation alone also induces moderate ER stress, which was verified by other studies^[27,28]. The ER stress induced by radiation could also be interpreted as an adaptive response, as the ER stress inhibitor salubrinal blocked 50% of apoptosis induced by X-rays in pulmonary artery endothelial cells. However, sustained ER stress leads to cell death. In this work, sustained ER stress induced by TM treatment enhanced radiation sensitivity *in vitro* and *in vivo*. This suggests a potential strategy for maximizing the efficiency of cancer radiotherapy. The mechanism underlying ER stress-induced cell death needs to be further studied. In

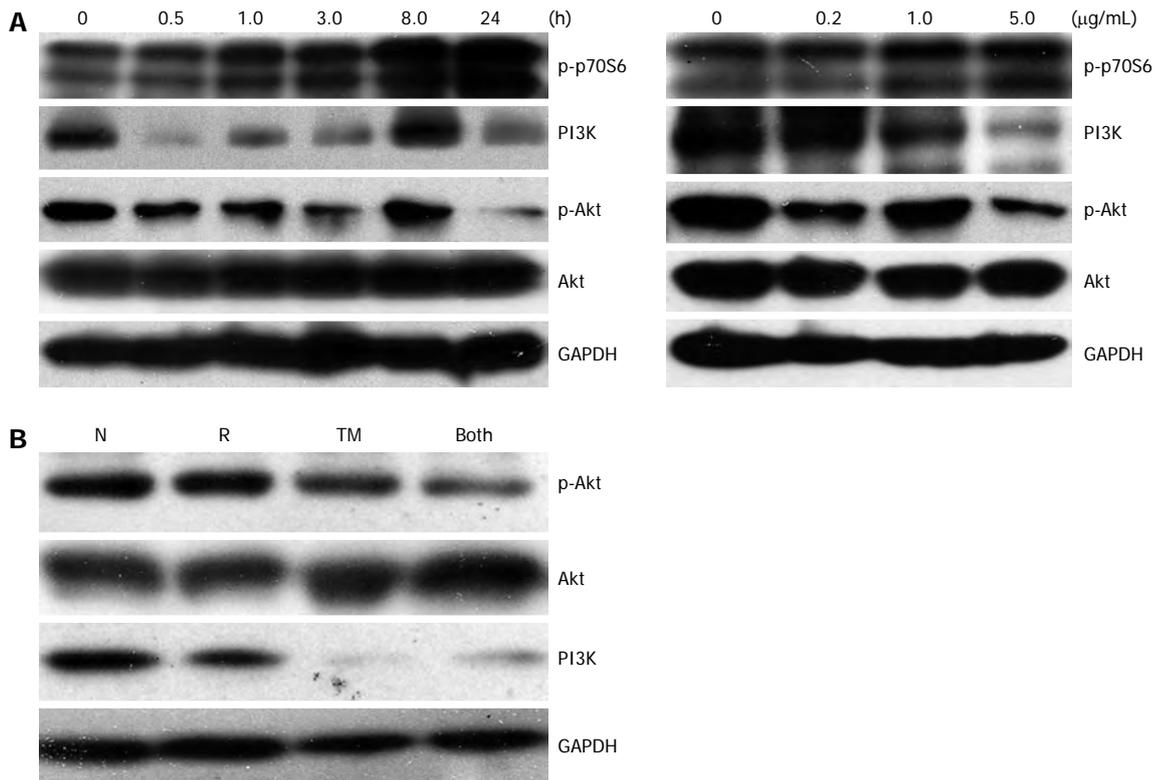

Figure 6 Cell signaling pathways associated with tunicamycin. A: EC109 cells were exposed to tunicamycin (TM) (5 µg/mL) for the indicated time periods, subjected to Western blotting analysis (left panel) or treated with TM at the indicated concentrations for 24 h, and subjected to Western blotting analysis (right panel); B: Western blotting analysis of cells pretreated with or without TM (5 µg/mL), followed by a single dose of 10 Gy. this work, we focused on autophagy and its relationship with cell apoptosis.

Induction of autophagy can be associated with cell death, and has greatly attracted researchers' interest. Initial work showed that nutrient starvation induced autophagy^[29]. Autophagy is also involved in physiological processes, such as development and differentiation. Moreover, recent studies have demonstrated a fundamental role of autophagy in a variety of pathophysiological conditions, including cancer, virus infection, heart failure, and neurodegeneration.

Many studies have found that autophagy might have a function in cancer treatment. However, contradictory findings about the role of autophagy were observed. Autophagy has been considered a mechanism by which the cell protects itself from various stresses, including nutrient starvation and chemotherapy. For example, it was reported that autophagy could protect glioma and fibrosarcoma cells from cisplatin-mediated apoptosis^[30]. But, there are also multiple examples in the literature where autophagy is the mode of cell death in tumor cells. Akar *et al.*^[31] reported that doxorubicin promoted autophagic cell death in MCF-7 cells at a clinically appropriate dose. It was also reported that autophagy was the main type of cell death in DNA-PK deficient human malignant glioma cells after radiation, while normal control cells could survive and proliferate, although a small portion of the cells underwent apoptosis^[32]. Another study reported that

autophagy (but not apoptosis) was the primary response to IR and radiosensitization induced by inhibition of NF-kappa B activation associated with autophagy^[33]. Conversely, pharmacological inhibition of autophagy using 3-MA blocked radiosensitization. Rapamycin, an inhibitor of the mTOR pathway that ordinarily induces autophagy in various types of cancer cells, increased the sensitivity of MCF-7 cells to radiation^[17]. Thus, the cytoprotective or cytotoxic role of autophagy depends on the cell context. In this work, we found that blockage of autophagy by the inhibitor 3-MA led to enhanced apoptosis, which suggested a cytoprotective role for autophagy in TM treatment. In addition, the autophagy response induced by TM treatment could be inhibited by Beclin-1 siRNA. It was reported that the inhibition of Beclin-1 diminished survival in radioresistant cancer cell lines after radiation, whereas survival in more radiosensitive carcinoma cells was enhanced^[34]. We did not assess the radiosensitivity of Beclin-1 knockdown alone. However, Beclin-1 knockdown enhanced cell apoptosis induced by TM.

Different cell signaling pathways are associated with TM treatment. The PI3K/Akt/mTOR pathway is critical for ER stress-induced apoptosis and autophagy induced by TM. Akt (also known as protein kinase B) functions as a principle mediator for many biological functions, including cell proliferation, differentiation, and survival. Dysregulation of Akt has been frequently detected in many types of cancer. The relationship between Akt and

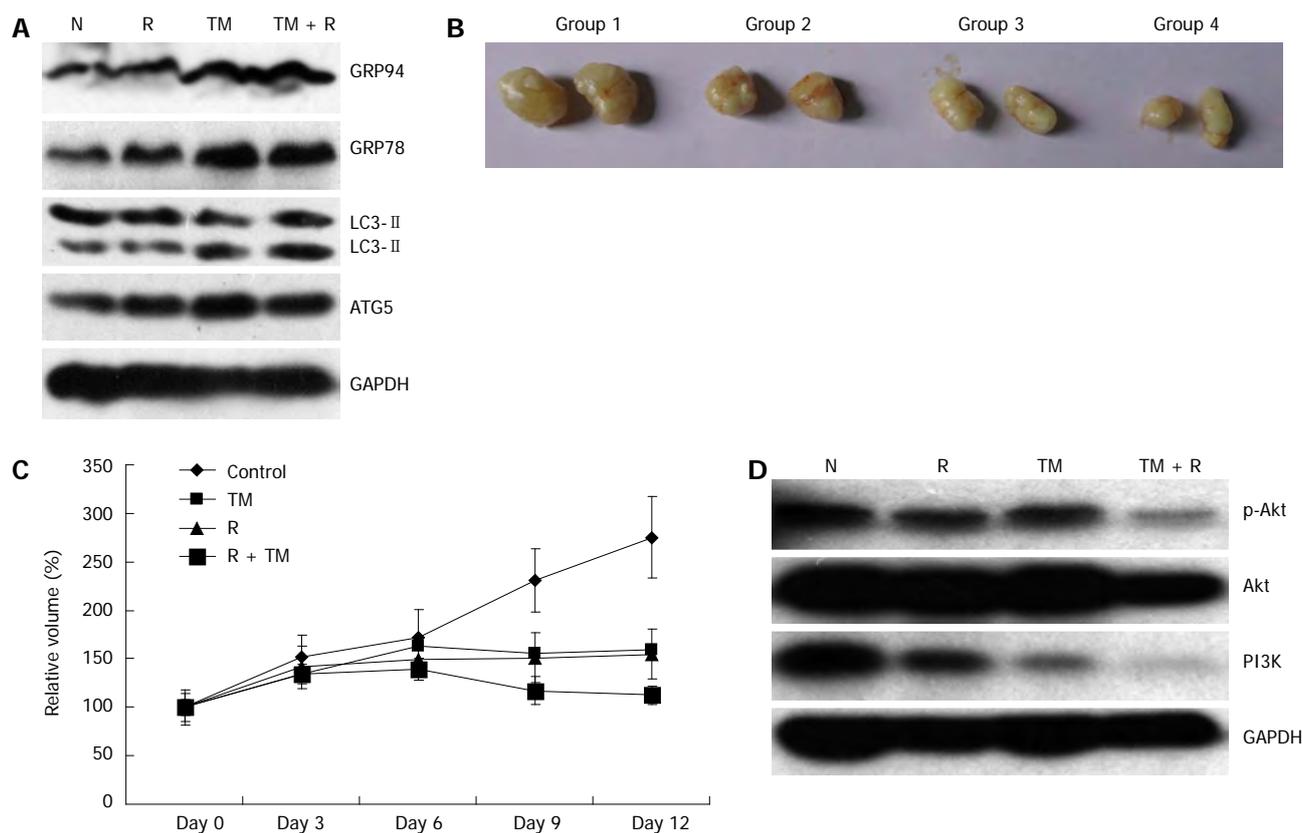

Figure 7 Radiosensitization by tunicamycin *in vivo*. A: Tumor xenografts removed from each group were subjected to Western blotting analysis for GRP78, GRP94, LC3, and ATG5; B: Examples of tumor xenografts removed from each group; C: Growth curves of tumor xenografts; D: Samples of tumor xenografts were subjected to Western blotting analysis for Akt, p-Akt, and PI3K. N: Sham-treated with tunicamycin (TM); R: 10 Gy irradiation; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

mTOR is very intricate. Akt activates mTOR through the inactivation of tuberous sclerosis complex 2 (TSC2) within the TSC1-TSC2 complex. Increased activation of mTOR triggers a negative feedback loop for the PI3K/Akt pathway, leading to suppression of Akt^[35]. TM led to a sharply decreased level of p-Akt in mouse embryonic fibroblasts, while inducing a transient and biphasic activation of p-Akt in the rat renal tubular epithelial cell line NRK-52E^[20,24]. In this study, TM treatment led to decreased levels of p-Akt, which was further diminished following radiation. This unexpected observation could be related to the different cell context of these experiments.

In summary, cellular apoptosis and autophagy were found to be associated with TM treatment in EC109 cells and tumor xenografts. TM induced sustained ER stress, which sensitized cancer cells to radiation *in vitro* and *in vivo*. Our findings help to understand the molecular mechanisms associated with TM treatment, and suggest a potential strategy to maximize the efficiency of cancer radiotherapy.

COMMENTS

Background

The endoplasmic reticulum (ER) is an essential intracellular organelle with multiple roles, including the synthesis of nascent proteins, Ca²⁺ storage, gly-

cosylation, and the trafficking of newly-synthesized membrane and secretory proteins. Perturbations of these processes have been demonstrated to interfere with the proper functioning of ER, thus leading to a condition defined as ER stress. ER stress plays an important role in many cellular processes; it can activate an adaptive response aimed at neutralizing these threats and re-establishing homeostasis, which leads to cell survival. However, if these countermeasures are unsuccessful and prolonged stress persists, the ER stress response may abandon its pro-survival efforts and initiate a pro-apoptotic program to eliminate the faulty cells. In the authors' previous work, it was found that radiation could induce ER stress, which was associated with the protein kinase RNA dependent-like ER kinase and inositol-requiring protein-1 signaling pathways. However, the biological significance of ER stress remained unknown. The ER stress induced by radiation could also be interpreted as an adaptive response, as the ER stress inhibitor salubrinal blocked cell apoptosis induced by X-rays in pulmonary artery endothelial cells. However, sustained ER stress leads to cell death.

Research frontiers

According to a recent review, ER stress can be viewed as a "yin" and "yang" principle based on its relative levels. Moderate levels of ER stress favor the pro-survival, cell-protective module ("yang") while severe levels of ER stress will abandon their protective efforts and instead will trigger cell death ("yin"). For cancer chemotherapy and radiotherapy, those approaches which block the pro-survival function and/or enhance the pro-apoptotic process will benefit the therapeutic effects. Based on this delicate sensitivity of ER function, a large number of compounds which cause ER stress are tested for cancer therapy. However, its molecular mechanisms have not been fully elucidated.

Innovations and breakthroughs

Previous studies showed tunicamycin (TM) inhibited N-Acetylglucosamine transferases, and thus prevented the formation of N-linked glycoproteins, which ultimately induced sustained ER stress in various types of cells. A number of *in vitro* studies have investigated the chemosensitizing properties of TM. However, the radiosensitizing properties of TM are less investigated, and its

molecular mechanisms remained unknown. In this study, the authors found that sustained ER stress induced by TM sensitized human esophageal cancer cells to radiation. This finding was confirmed both *in vitro* and *in vivo*. The authors also showed that the PI3K/Akt/mTOR pathway was involved in the TM-induced autophagic response, and inhibition of autophagy increased apoptosis induced by TM.

Applications

The results of this study suggest that TM induces sustained ER stress, which sensitized cancer cells to radiation *in vitro* and *in vivo*. The authors' findings help to add to the understanding of the molecular mechanisms associated with TM treatment, and suggest a potential strategy for maximizing the efficiency of cancer radiotherapy.

Peer review

This is a good descriptive study in which the authors analyzed the radiosensitizing effect of TM on human esophageal cancer cells. The results are interesting and suggest that TM might be a potential therapeutic substance that could be used for cancer radiotherapy.

Abstract

AIM: To study the effects of hypoxia-inducible factor-1 α (HIF-1 α) silencing on the proliferation of hypoxic CBRH-7919 rat hepatoma cells.

METHODS: The CBRH-7919 rat hepatoma cell line was used in this study and the hypoxic model was constructed using CoCl₂. The HIF-1 α -specific RNAi sequences were designed according to the gene coding sequence of rat HIF-1 α obtained from GeneBank. The secondary structure of the *HIF-1 α* gene sequence was analyzed using RNA draw software. The small interfering RNA (siRNA) transfection mixture was produced by mixing the siRNA and Lipofectamine2000™, and transfected into the hypoxic hepatoma cells. Real time reverse transcription-polymerase chain reaction (RT-PCR) and Western blotting assay were used to detect

the expression levels of mRNA and protein. HIF-1 α and vascular endothelial growth factor (VEGF) mRNA was determined using real time RT-PCR; the protein expression levels of AKT, p-AKT, p21 and cyclinD1 were determined using Western blotting. The proliferation of hepatoma cells was observed using the methyl thiazolyl tetrazolium (MTT) assay and the bromodeoxyuridine (BrdU) incorporation cell proliferation assay.

RESULTS: Under induced hypoxia, the viability of the hepatoma cells reached a minimum at 800 μ mol/L CoCl₂; the viability of the cells was relatively high at CoCl₂ concentrations between 100 μ mol/L and 200 μ mol/L. Under hypoxia, the mRNA and protein expression levels of HIF-1 α and VEGF were significantly higher than that of hepatoma cells that were cultured in normoxia. HIF-1 α -specific RNAi sequences were successfully transfected into hepatoma cells. The transfection of specific siRNAs significantly inhibited the mRNA and protein expression levels of HIF-1 α and VEGF, along with the protein expression levels of p-AKT and cyclinD1; the protein expression of p21 was significantly increased, and there was no significant difference in the expression of AKT. The MTT assay showed that the amount of hepatoma cells in S phase in the siRNA transfection group was obviously smaller than that in the control group; in the siRNA transfection group, the amount of hepatoma cells in G1 phase was more than that in the control group. The BrdU incorporation assay showed that the number of BrdU positive hepatoma cells in the siRNA transfection group was less than that in the control group. The data of the MTT assay and BrdU incorporation assay suggested that HIF-1 α silencing using siRNAs significantly inhibited the proliferation of hepatoma cells.

CONCLUSION: Hypoxia increases the expression of HIF-1 α , and HIF-1 α silencing significantly inhibits the proliferation of hypoxic CBRH-7919 rat hepatoma cells.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies. HCC accounts for more than 660 000 new cases of cancer arising annually all around the world^[1,2]. HCC is a highly malignant tumor and the majority of HCC patients are diagnosed at the intermediate or advanced stages of tumor growth. HCC is often accompanied by poor liver function, which makes surgical resection impossible. Liver transplantation is one treatment option for HCC patients. However, the availability of organ donors limits the application of this treatment. Currently, nonsurgical therapy has been accepted as the main treatment for HCC, and gene therapy for the treatment of HCC has begun to attract increasing attention. RNA interference is a powerful method for the knock-down of pathologically relevant genes. Small interfering RNAs (siRNAs) have been widely demonstrated as effective biomedical genetic-therapy applications for many diseases^[3,4]. siRNAs induce sequence-specific gene silencing of the target mRNAs to which they are perfectly complementary by directing the RNA-induced silencing complex to mediate site-specific cleavage, thus destroying the targeted mRNA^[5]. In view of its powerful gene-silencing properties, RNAi has been proposed as an important option to validate new therapeutic targets and to develop innovative anticancer therapies.

Intratumoral hypoxia is a common finding in human cancers and associated with an increased risk of tumor regeneration, invasion, metastasis and patient mortality^[6]. Hypoxia inducible factor-1 (HIF-1) functions as a master regulator of oxygen homeostasis in almost all nucleated mammalian cells and is composed of the constitutively expressed HIF-1 β subunit and the highly regulated HIF-1 α subunit. The HIF-1 α subunit is the functional subunit of HIF-1 and plays a critical role in cellular adaptation to change in oxygen availability^[7-9]. HIF-1 α is a central transcription factor produced by tumor cells under hypoxic conditions and is a key regulator of several genes that are important in cancer biology. Over-expression of HIF-1 α in human tumors is associated with poor prognosis and poor therapeutic outcomes, and HIF-1 α has been suggested as a significant target for cancer therapy^[10,11].

According to previous studies^[12-14], it is possible to silence HIF-1 α using siRNA interference technology. Thus, in this study we constructed specific HIF-1 α siRNA in-

terference sequences, and transfected these into hypoxic CBRH-7919 rat hepatoma cells to study the effects of HIF-1 α silencing on the activation of the phosphatidylinositol 3'-kinase(PI3K)/AKT signaling pathway and the proliferation of hepatoma cells. Consequently, we found that the HIF-1 α silencing significantly inhibits the activation of the PI3K/AKT signaling pathway and the proliferation of hypoxic CBRH-7919 rat hepatoma cells.

MATERIALS AND METHODS

Cell lines and cell culture

The CBRH-7919 rat hepatoma cell line was provided by the Central Laboratory of Sun Yat-Sen University (Guangzhou, China). The hepatoma cells were routinely grown in RPMI1640 medium, supplemented with 10% fetal bovine serum, 100 U/mL penicillin and 100 U/mL streptomycin in a 37 °C incubator with 5% CO₂. The cells were passaged every 2-3 d to maintain exponential growth.

Hypoxia model construction

Cells were plated in 60-mm dishes or 6-well plates according to the experimental requirements and were cultured at 37 °C with 5% CO₂. In preparation for the experiment, the medium was replaced with a thin layer of fresh medium which contained 10% FCS to decrease the diffusion distance of the ambient gas. Different densities of CoCl₂ (100, 150, 200 and 300 μ mol/L) were then mixed into the culture dishes, and the samples were processed for 12 and 24 h. A control sample containing 0 μ mol/L CoCl₂ was also processed.

Design of siRNA and transfection studies

siRNAs targeted against HIF-1 α were designed according to the gene coding sequence of rat HIF-1 α obtained from GeneBank. The secondary structure of the HIF-1 α gene sequence was analyzed using RNA draw software. Three potential target mRNA sequences were selected and siRNA sequences were determined using online design software (www.ambion.com/techlib/misc/siRNA_finder.htm): 1:P1:5'-AGUGACUGAUUCUG-GCAGCTT-3', P2: 5'-GCUGCCAGAAUCAGUCACUTT-3'; 2:P1: 5'-GGAUGACUUUAAGCAAGAATT-3', P2: 5'-UUCUUGCUUAAAGUCAUCCTT-3'; 3:P1: 5'-GAAACUCUCCAAGCAAUUTT-3', P2: 5'-AAU-UGCUUGGAAGAGUUUCTT-3'. Based on the process of siRNA target sequence design, the silencer siRNAs were produced according to the sequence of the selected target mRNA. Then the siRNAs transfection mixture was produced by mixing the siRNA and Lipofectamine2000TM (Invitrogen, Carlsbad, CA, United States). The mixture containing siRNA sequences was then transfected into cultured cells, according to the manufacturer's protocol. The cells were harvested 24 h after transfection for analyses. A subset of CBRH-7919 cells was treated only with Lipofectamine 2000TM reagent as a control group.

Real time reverse transcription-polymerase chain reaction

RNA was extracted directly from all samples using TRIzol reagent (Invitrogen) followed by isopropanol precipitation. An RNA polymerase chain reaction (PCR) kit (TaKaRa) was used to obtain template cDNA for real-time PCR (ABI Prism 7500, Perkin Elmer, Foster City, CA, United States) using SYBR Premix Ex Taq (TaKaRa). Specific primer sequences were designed by TaKaRa as follows: HIF-1 α : 5'-ACTGCACAGGCCACATTCAT-3' (sense) and 5'-CGAGGCTGTGTCTGACTGAGA-3' (antisense); vascular endothelial growth factor (VEGF): 5'-AGGCGAGGCAGCTTGAGTTA-3' (sense) and 5'-CTGTCTGACGGTGACGATGGT-3' (antisense); β -actin: 5'-CCTAGGCACCAGGGTGTGAT-3' (sense) and 5'-TTGGTGACAATGCCGTGTTTC-3' (antisense). The initial denaturation phase was 3 min at 95 °C followed by 39 cycles of denaturation at 95 °C for 10 s and annealing at 55 °C for 30 s. Relative quantification of PCR products was performed after normalization to β -actin.

Western blotting

Cellular proteins were extracted with RIPA lysis buffer, and protein concentrations were measured by the Bradford method. Protein samples (20 μ g/well) were separated by 10% sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis, and electrophoretically transferred to nitrocellulose membranes. The membranes were then blocked for 60 min and subsequently incubated with primary antibodies (1:3000) overnight at 4 °C prior to incubation with anti-mouse IgG conjugated to horseradish peroxidase (1:6000) for 120 min at room temperature. Finally, after developing with enhanced chemiluminescence detection reagents, the protein bands of membranes were visualized by exposure to x-ray film. Protein expression was quantified by densitometry and normalized to β -actin expression. Anti-HIF-1 α , anti-Akt/phosphorylated Akt, anti-VEGF, anti-p21, cyclinD1, and anti- β -actin, antibodies were obtained from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, United States).

Methyl thiazolyl tetrazolium cell proliferation assay

Cells were seeded into 96-well plates (Costar; Corning Inc., Corning, NY, United States) for 9 h. Following exposure to 0.5% O₂, the cells were exposed to various concentrations of cisplatin or doxorubicin for 48 h in a CO₂ incubator. Methyl thiazolyl tetrazolium (MTT) (10 μ L; 5 g/L in PBS) was added to each well followed by incubation for 4 h at 37 °C. Subsequently, the formazan crystals were solubilized with 150 μ L of 10% SDS in 0.01 mol/L HCl for 24 h. The absorbances at 500 nm relative to a reference wave length of 490 nm were determined with a microplate reader (Bio-Rad 680, Bio-Rad, United States). The absorbance values were expressed as percentages relative to the untreated controls, and the concentrations resulting in 50% inhibition of cell growth (IC₅₀ values) were calculated.

Bromodeoxyuridine incorporation assay

CBRH-7919 cells were seeded in 96-well plates and treated with various drugs as indicated in each experiment for 48 h. At the end of treatment, bromodeoxyuridine (BrdU) incorporation was assayed by incubating the cells with BrdU for 0.5-1 h using a BrdU Cell Proliferation Assay Kit (Calbiochem, San Diego, CA, United States) according to the manufacturer's instructions.

Statistical analysis

All experimental data were expressed as mean \pm SD. Comparisons between two groups were made using the Student's *t*-test. Statistical significance was determined by analysis of variance followed by Fisher's least significant difference analysis using the SPSS 19.0 software package. The statistical significance level was set at $P < 0.05$.

RESULTS

Viability of hepatoma cells under hypoxia

CBRH-7919 hepatoma cells were cultured in a hypoxia model, which was constructed using various concentrations of CoCl₂ (Figure 1). The viability of hepatoma cells under hypoxia was observed using MTT, and the results of the analysis indicated that the viability of hepatoma cells was gradually decreased as CoCl₂ concentrations increased from 100 μ mol/L to 800 μ mol/L. The viability of the hepatoma cells reached a minimum at 800 μ mol/L CoCl₂; however, the viability of the cells was relatively high at CoCl₂ concentrations between 100 μ mol/L and 200 μ mol/L (Figure 1).

Hypoxia increased the expressions of HIF-1 α and VEGF

Hepatoma cells were cultured under 0, 100, 150, 200 and 300 μ mol/L CoCl₂ using processing times of 12 and 24 h, respectively. CoCl₂ at 0 μ mol/L was the control group. The results of real-time RT-PCR assay indicated that the mRNA levels of HIF-1 α and VEGF gradually increased as the concentrations of CoCl₂ increased from 0 μ mol/L to 200 μ mol/L with a 12 h processing time and the expression levels of HIF-1 α and VEGF reached a maximum at 200 μ mol/L CoCl₂ (Figure 2). However, the expressions of HIF-1 α and VEGF were declined as the concentration of CoCl₂ reached 300 μ mol/L. When the processing time was increased to 24 h, the expression levels of HIF-1 α and VEGF were higher than those observed at 12 h. Additionally, the protein expression levels of HIF-1 α and VEGF demonstrated the same patterns as their respective mRNA expression levels (Figure 3).

Expressions of HIF-1 α and VEGF were inhibited by siRNA interference

Based on the previous phase of our study, the optimal hypoxia-mimicking condition was determined to be the concentration of 150 μ mol/L CoCl₂ with a 24 h processing time. Thus, CBRH-7919 hepatoma cells were cultured under these conditions prior to the next step of the ex-

periment. The specific siRNA sequences were designed and the hepatoma cells were transfected using three different groups of specific siRNA vectors. The protein and mRNA expression levels of HIF-1 α and VEGF were measured using real-time RT-PCR and western blot analysis, respectively. The results indicated that both the mRNA and protein expression levels of HIF-1 α and VEGF were significantly decreased after the transfection with specific siRNA sequences with a processing time of 24 h (Figures 4 and 5). However, there were no differences in the mRNA and protein expression levels of HIF-1 α and VEGF of hepatoma cells in the control group.

Effects of HIF-1 α silencing on the expressions of VEGF, AKT, p-AKT, p21 and cyclinD1

Based on the previous phases of our study, the specific siRNA sequence “Ri3” was selected for the next phase of this study. “Ri3” was transfected into the hepatoma cells cultured with 150 μ mol/L CoCl₂ with a 24 h processing time, and Western blotting analysis was performed to detect the protein expression levels of HIF-1 α , VEGF, AKT, p-AKT, p21 and cyclinD1. The results indicated that the protein expression levels of HIF-1 α , VEGF, p-AKT and cyclinD1 were significantly decreased compared with those of the control group; however, the

expression of p21 protein was significantly increased and there was no significance difference in the expression of AKT protein (Figure 6).

Effects of HIF-1 α silencing on the proliferation of hepatoma cells

In consideration of the functions of p21 and cyclinD1 in the cell cycle, the decrease in the expressions of p21 and cyclinD1 caused by HIF-1 α silencing suggested that the knockdown of HIF-1 α may suppress the proliferation of the hepatoma cells. Thus, we studied the effects of HIF-1 α -specific siRNAs on the proliferation of the CBRH-7919 hepatoma cells. HIF-1 α -specific siRNAs or controls were transfected using Lipofectamine 2000TM and the proliferation of hepatoma cells was determined using the MTT assay and the BrdU incorporation assay at 24 h after the transfection. The results of the MTT assay and BrdU incorporation assay indicated that the HIF-1 α silencing significantly inhibited the proliferation

of CBRH-7919 hepatoma cells when compared with the control group at the processing time of 24 h (Figures 7 and 8).

DISCUSSION

The hypoxia inducible transcription factors mediate the primary transcriptional responses to hypoxic stress in normal and transformed cells^[15]. HIF-1 α was firstly described by Semenza in 1992 and was shown to play a critical role in mediating O₂-dependent transcriptional responses. HIF-1 activity in tumors depends on the availability of the HIF-1 α subunit, the expression level of which is increased under hypoxic conditions and is associated with the activation of oncogenes and/or the inactivation of tumor suppressor genes. Over-expression of HIF-1 α has been correlated with increased angiogenesis, tumor progression, invasion, metastasis and poor patient prognosis, and this has led to the current interest in HIF-

1 α as a promising anticancer genetic target for anticancer therapies^[16,17].

In this study, rat CBRH-7919 hepatoma cells were cultured in a hypoxic model constructed using CoCl₂, and specific HIF-1 α siRNA sequences were designed and transfected into hypoxic hepatoma cells. Our study demonstrated that the expressions of HIF-1 α , VEGF, p-AKT and cyclinD1 were significantly decreased compared with those of the control group; however, the expression of p21 was significantly increased and there was no significant difference in the expression of AKT. This finding indicates that silencing of HIF-1 α using specific siRNA can inhibit the expressions of VEGF, p-AKT and cyclinD1 while up-regulating the expression of p21. The subsequent MTT cell proliferation and BrdU incorporation assays revealed that the proliferation of hepatoma cells was significantly inhibited by HIF-1 α silencing.

The PI3K/AKT signaling transduction pathway is

one of the most important pathways inside human cancer and plays a critical role in various cellular functions, such as proliferation, adhesion, migration, invasion, metabolism and survival^[18-20]. The activation of the PI3K/AKT signaling pathway depends on the expression of p-AKT (phosphorylated AKT). Over-expression of p-AKT is one of the most common indications of human malignancies, such as gastric cancer, liver cancer, colorectal cancer, pancreatic cancer and breast cancer^[21,22]. Additionally, p-AKT is believed to play an important role in cancer cell survival and chemotherapy resistance. In our study, although there was no significant difference in the expression of AKT, the expression of p-AKT was significantly inhibited after the specific siRNA sequences were transfected into hepatoma cells. This indicated that the silencing of HIF-1 α using specific siRNAs inhibited the activation of the PI3K/AKT signaling transduction pathway. The inhibition of the PI3K/AKT signaling pathway may be

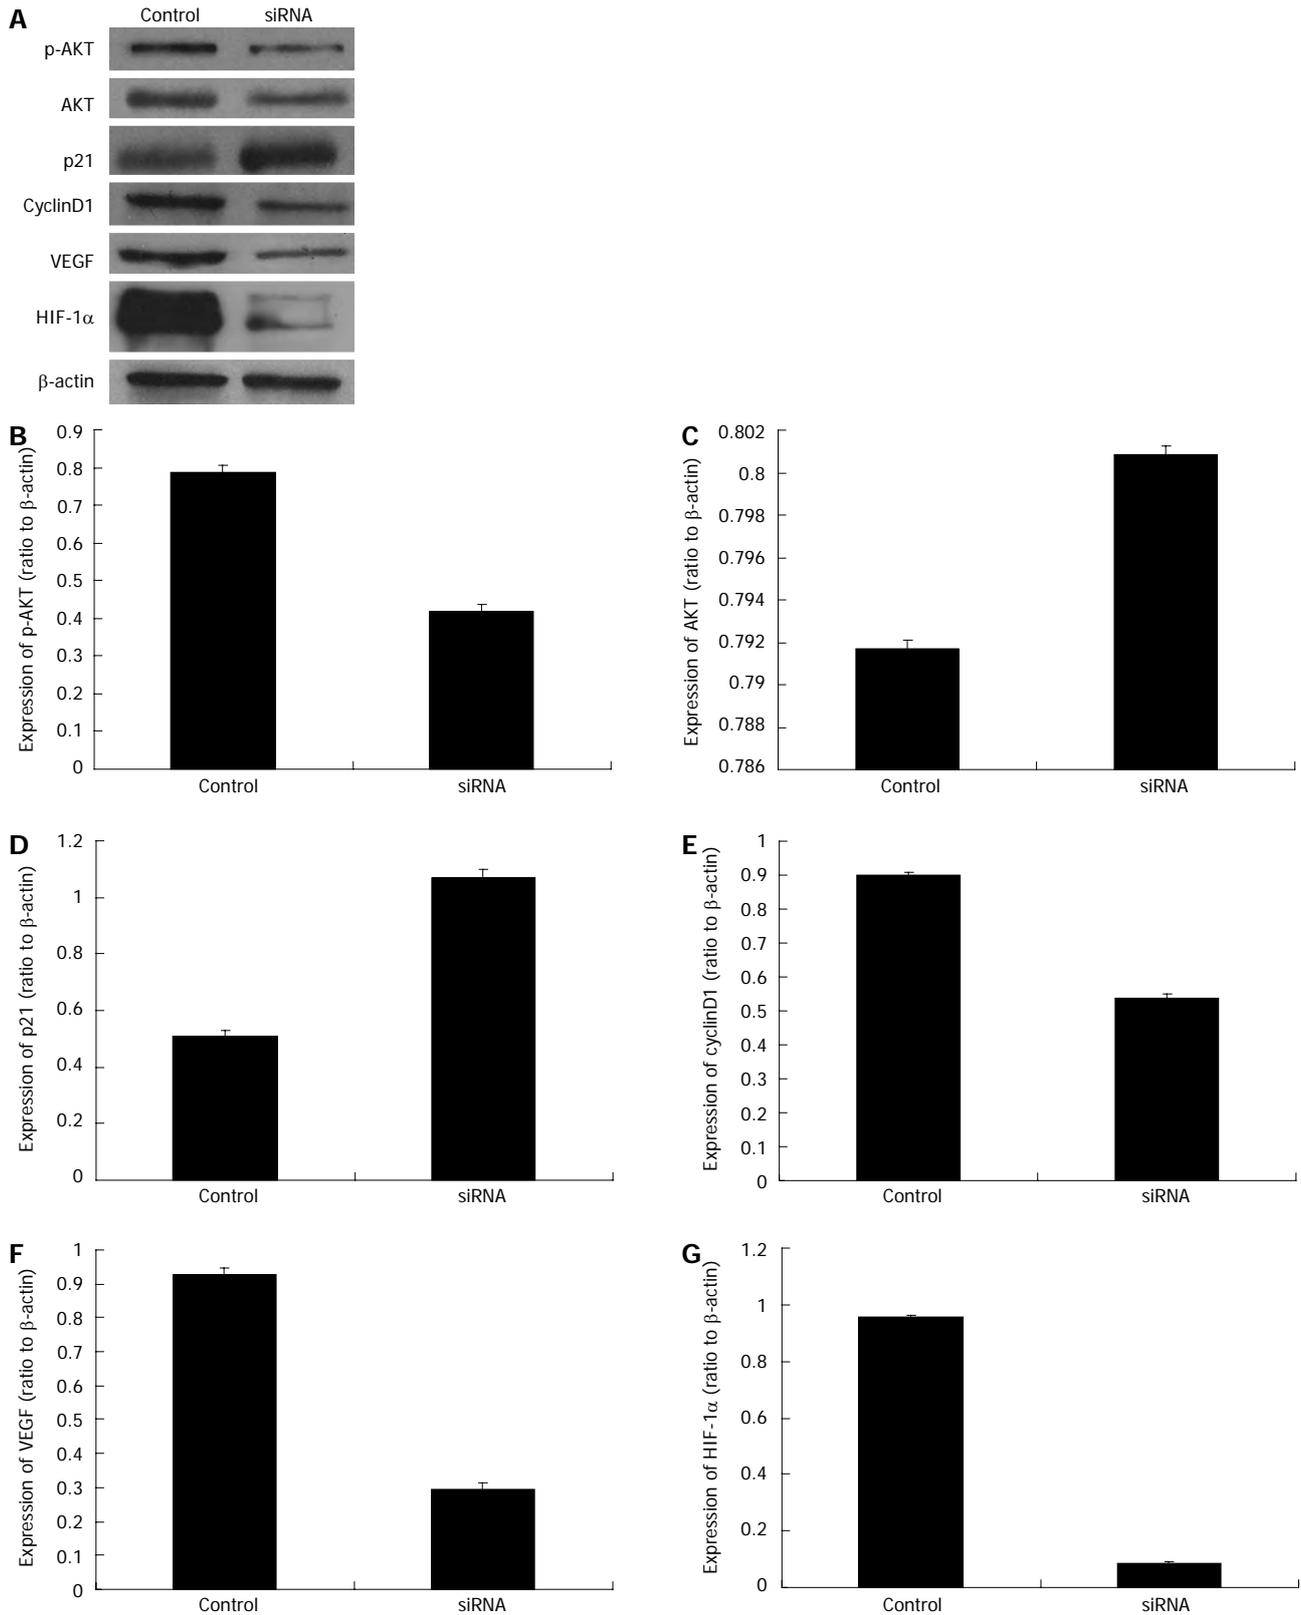

Figure 6 Protein expression levels of p-AKT, AKT, p21, cyclinD1, vascular endothelial growth factor and hypoxia-inducible factor-1 α after the transfection with specific small interfering RNAs (processing time of 24 h). A: The Western blotting analysis of protein expression levels of p-AKT, AKT, p21, cyclinD1, vascular endothelial growth factor (VEGF) and hypoxia-inducible factor-1 α (HIF-1 α) after specific small interfering RNA (siRNA) transfection; B-G: Histograms illustrating p-AKT (B), AKT (C), p21 (D), cyclinD1(E), VEGF (F) and HIF-1 α (G) protein expression after specific siRNA transfection.

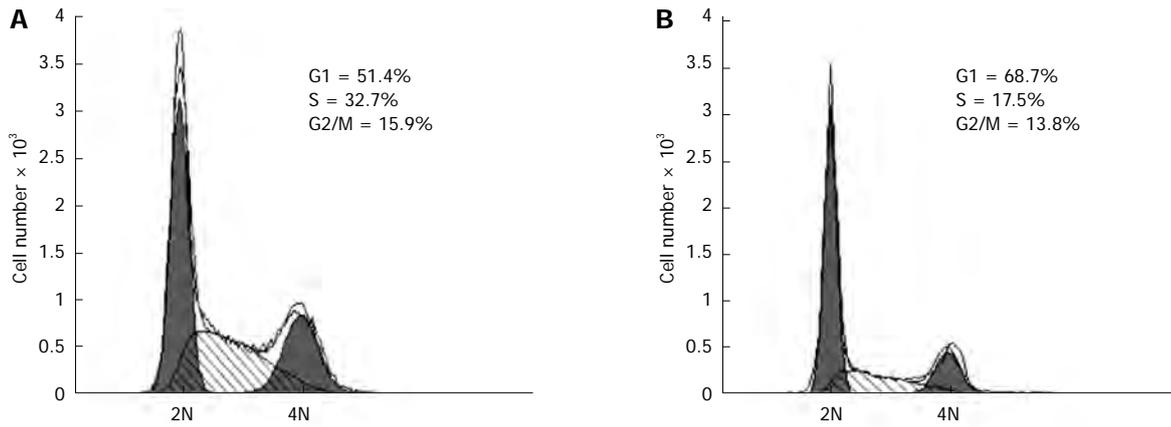

Figure 7 Methyl thiazolyl tetrazolium cell proliferation assay indicated that the hypoxia-inducible factor-1 α silencing *via* specific small interfering RNAs significantly inhibited the proliferation of CBRH-7919 hepatoma cells. A: Contro group; B: Processing time of 24 h.

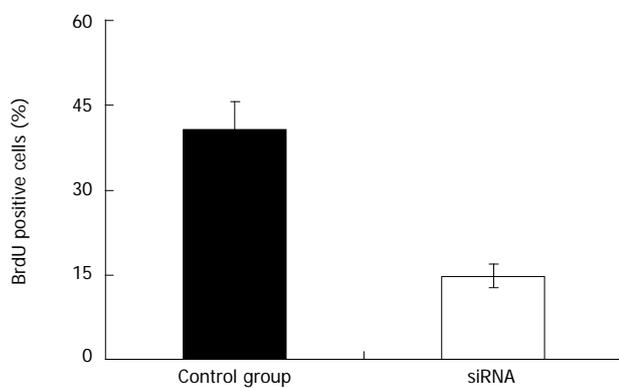

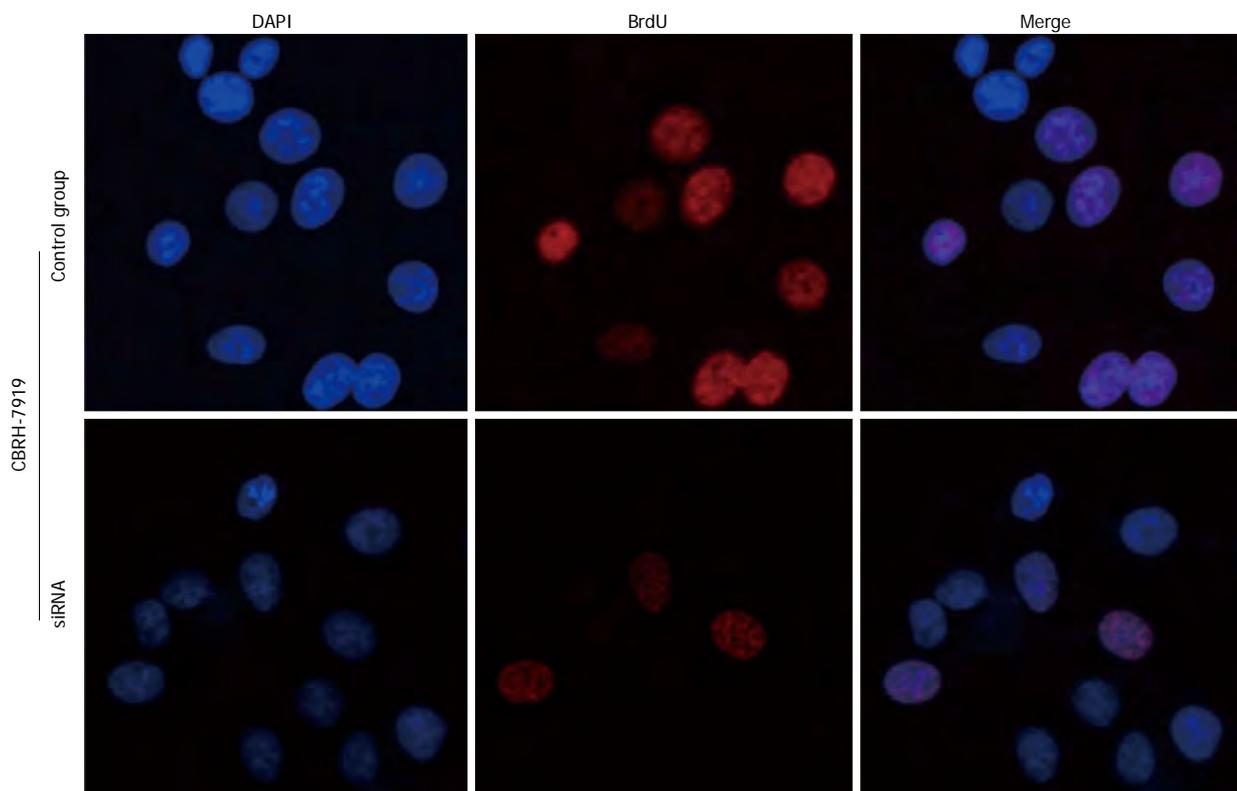

Figure 8 Proliferation of hepatoma cells detected by bromodeoxyuridine incorporation illustrates that hypoxia-inducible factor-1 α silencing *via* specific small interfering RNAs significantly inhibited the proliferation of CBRH-7919 hepatoma cells. DAPI: 4',6'-diamidino-2-phenylindole hydrochloride; BrdU: Bromo-deoxyuridine.

associated with inhibition of the activation of the PI3K-independent pathway. Under hypoxia or within tumor cells, the normal degradation of HIF-1 α is inhibited and HIF-1 α accumulates in the nucleus, which promotes the activation of downstream targeted genes and activates AKT^[23-25]. Over-expression of VEGF is also observed in various types of human cancer cells. VEGF promotes the proliferation of vessel endothelial cells, inhibits the apoptosis of vessel endothelial cells, and stimulates the formation of blood vessels. Previous studies reported that VEGF alone can activate the PI3K/AKT pathway^[26,27]. Hence, it is indicated that inhibition of the expression of VEGF by HIF-1 α silencing may affect the activation of the PI3K/AKT pathway. p21 and cyclinD1 are the downstream targets of the PI3K/AKT signaling transduction pathway and their expressions are also regulated by the pathway^[28,29]. Our data revealed that the expression of p21 was significantly increased; however, the expression of cyclinD1 was significantly decreased after HIF-1 α was silenced by specific siRNAs. The results of our study provide strong evidence to support our hypothesis that the activation of the PI3K/AKT signaling pathway can be inhibited by HIF-1 α silencing.

Considering the functions of p21 and cyclinD1 in cell cycle processing^[30-34], HIF-1 α silencing may have an effect on PI3K/AKT signaling pathway-dependent proliferation of hepatoma cells as well. In our study, the results of the MTT cell proliferation and BrdU incorporation assays indicated that the transfection of specific siRNAs effectively increased the number of cells in G0/G1 phase, and the numbers of cells in S and G2/M phases were significantly decreased compared with those of the control group. Additionally, the proportion of BrdU-positive cells in the siRNA interference group was smaller than that of the control group. Taken together, these data indicate that HIF-1 α silencing by the specific siRNAs can significantly inhibit the activation of the PI3K/AKT signaling transduction pathway and the proliferation of hepatoma cells.

HIF-1 α is currently accepted as one of the most important genetic targets for anticancer therapy. However, to our knowledge, there have only been a few studies examining the effects of HIF-1 α on the proliferation of hepatoma cells. Our study demonstrated that HIF-1 α silencing can inhibit the proliferation of hypoxic rat CBRH-7919 hepatoma cells. However, the correlation between HIF-1 α and the PI3K/AKT signaling transduction pathway is still contested^[35-38] and further research is urgently needed to provide new evidence. The evidence obtained in our study indicated that HIF-1 α can be silenced using specific siRNAs and that the silencing of HIF-1 α can significantly inhibit the activation of the PI3K/AKT signal transduction pathway.

Transcatheter arterial chemoembolization (TACE) is the most commonly used palliative treatment for HCC in clinical practice^[39-41]. However, the hypoxic microenvironment of tumor tissue after TACE often induces high expression levels of HIF-1 α and promotes tumor progres-

sion, invasion and metastasis of tumor, providing a poor prognosis for patients with HCC. Thus, the long-term results of TACE are not satisfying. The combination of TACE and siRNA interference for the treatment of HCC can be expected to down-regulate the expression of HIF-1 α after TACE. Unfortunately, it is unclear whether the effects of siRNA interference *in vivo* are the same as (or similar to) that which are observed *in vitro*. Thus, further studies are required to explore the effects of siRNA interference *in vivo*.

COMMENTS

Background

The over-expression of hypoxia-inducible factor-1 α (HIF-1 α) has been demonstrated in multiple types of malignant tumors. HIF-1 α contributes to tumor angiogenesis and metastasis and plays a critical role in mediating O₂-dependent transcriptional responses. Preliminary tests showed that it is possible to silence HIF-1 α using small interfering RNA (siRNA) interference technology.

Research frontiers

Gene therapy is a potential treatment for malignant tumors and some other diseases. siRNAs have been widely demonstrated as effective biomedical genetic-therapy applications for many diseases. In this study, the authors demonstrate that HIF-1 α silencing using siRNAs can significantly inhibit the proliferation of hepatoma cells, which could be a potential gene therapy for anti-cancer treatment.

Innovations and breakthroughs

Previous studies reported that HIF-1 α contributes to tumor angiogenesis and metastasis and plays a critical role in mediating O₂-dependent transcriptional responses. However, the relationship between HIF-1 α and the PI3K/AKT signaling pathway, and the effects of HIF-1 α on the proliferation of hepatoma cells, have not been unequivocally addressed. The results of this study showed that HIF-1 α silencing can significantly inhibit the activation of the PI3K/AKT signaling pathway and the proliferation of hepatoma cells. This study proves that HIF-1 α could be an effective and important gene target for anti-cancer treatment.

Applications

By understanding the effect of HIF-1 α silencing on the PI3K/AKT signaling pathway and the proliferation of hepatoma cells, an effective gene target has been identified for the gene treatment of hepatocellular carcinoma (HCC), providing an experimental basis for the clinical practice of gene therapies for malignant tumors.

Terminology

HIF-1 α has been correlated with increased angiogenesis, tumor progression, invasion, metastasis and poor patient prognosis. In this study, HIF-1 α was silenced using siRNA technology. It demonstrated that HIF-1 α silencing significantly inhibited the activation of the PI3K/AKT signaling pathway and the proliferation of hepatoma cells, and HIF-1 α was proved to be an effective gene target for the gene therapy of HCC.

Peer review

This paper reported that hypoxia induces HIF-1 α expression, and knocking-down HIF-1 α by siRNA inhibits the PI3K/AKT signaling pathway and the proliferation of hypoxic CBRH-7919 rat hepatoma cells. Those findings indicate HIF-1 α could be a potential drug target for cancer therapy.

Abstract

AIM: To investigate the effects of small interfering RNA (siRNA)-mediated inhibition of Class I phosphoinositide 3-kinase (Class I PI3K) signal transduction on the proliferation, apoptosis, and autophagy of gastric cancer SGC7901 and MGC803 cells.

METHODS: We constructed the recombinant replication adenovirus PI3K(I)-RNA interference (RNAi)-green fluorescent protein (GFP) and control adenovirus NC-RNAi-GFP, and infected it into human gastric cancer cells. MTT assay was used to determine the growth rate

of the gastric cancer cells. Activation of autophagy was monitored with monodansylcadaverine (MDC) staining after adenovirus PI3K(I)-RNAi-GFP and control adenovirus NC-RNAi-GFP treatment. Immunofluorescence staining was used to detect the expression of microtubule-associated protein 1 light chain 3 (LC3). Mitochondrial membrane potential was measured using the fluorescent probe JC-1. The expression of autophagy was monitored with MDC, LC3 staining, and transmission electron microscopy. Western blotting was used to detect p53, Beclin-1, Bcl-2, and LC3 protein expression in the culture supernatant.

RESULTS: The viability of gastric cancer cells was inhibited after siRNA targeting to the Class I PI3K blocked Class I PI3K signal pathway. MTT assays revealed that, after SGC7901 cancer cells were treated with adenovirus PI3K(I)-RNAi-GFP, the rate of inhibition reached 27.48% \pm 2.71% at 24 h, 41.92% \pm 2.02% at 48 h, and 50.85% \pm 0.91% at 72 h. After MGC803 cancer cells were treated with adenovirus PI3K(I)-RNAi-GFP, the rate of inhibition reached 24.39% \pm 0.93% at 24 h, 47.00% \pm 0.87% at 48 h, and 70.30% \pm 0.86% at 72 h ($P < 0.05$ compared to control group). It was determined that when 50 MOI, the transfection efficiency was 95% \pm 2.4%. Adenovirus PI3K(I)-RNAi-GFP (50 MOI) induced mitochondrial dysfunction and activated cell apoptosis in SGC7901 cells, and the results described here prove that RNAi of Class I PI3K induced apoptosis in SGC7901 cells. The results showed that adenovirus PI3K(I)-RNAi-GFP transfection induced punctate distribution of LC3 immunoreactivity, indicating increased formation of autophagosomes. The results showed that the basal level of Beclin-1 and LC3 protein in SGC7901 cells was low. After incubating with adenovirus PI3K(I)-RNAi-GFP (50 MOI), Beclin-1, LC3, and p53 protein expression was significantly increased from 24 to 72 h. We also found that Bcl-2 protein expression down-regulated with the treatment of adenovirus PI3K(I)-RNAi-GFP (50 MOI). A number of

isolated membranes, possibly derived from ribosome-free endoplasmic reticulum, were seen. These isolated membranes were elongated and curved to engulf a cytoplasmic fraction and organelles. We used transmission electron microscopy to identify ultrastructural changes in SGC7901 cells after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment. Control cells showed a round shape and contained normal-looking organelles, nucleus, and chromatin, while adenovirus PI3K(I)-RNAi-GFP (50 MOI)-treated cells exhibited the typical signs of autophagy.

CONCLUSION: After the Class I PI3K signaling pathway has been blocked by siRNA, the proliferation of cells was inhibited and the apoptosis of gastric cancer cells was enhanced.

Zhu BS, Yu LY, Zhao K, Wu YY, Cheng XL, Wu Y, Zhong FY, Gong W, Chen Q, Xing CG. Effects of small interfering RNA inhibit Class I phosphoinositide 3-kinase on human gastric cancer cells. *World J Gastroenterol* 2013; 19(11): 1760-1769 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1760.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1760>

INTRODUCTION

Gastric cancer is the fourth most common cancer and the second leading cause of cancer death worldwide^[1], with nearly a million new cases diagnosed each year. The phosphatidylinositol 3-kinases (PI3Ks) are a family of lipid kinases whose primary biochemical function is to phosphorylate the 3-hydroxyl group of phosphoinositides^[2]. Phosphorylation results in the activation of second messenger molecules, with consequent signal transduction that sets in motion a variety of physiological cellular metabolic and survival functions.

The PI3K-serine/threonine kinase (AKT)-mammalian target of the rapamycin (mTOR) pathway is an important cellular pathway involved in cell growth, tumorigenesis, cell invasion, and drug response^[3-5]. This pathway is frequently activated in many cancers, and uncontrolled PI3K-AKT-mTOR signaling may also result in poor clinical outcome in lung, cervical, ovarian, and esophageal cancers^[3,4,6-8].

PI3Ks are grouped into three Classes (I-III), with varying structure and substrate preference. The functions of Class I PI3Ks relate to glucose homeostasis, metabolism, growth, proliferation, and survival. Isoform-specific roles are described, albeit with degrees of overlap, with potential implications for toxicity and efficacy of novel inhibitors of Class I PI3Ks^[9]. A substantial body of evidence exists in support of the notion that not only does PI3K pathway activation promote cell survival and tumor

progression, but also can predict for therapeutic resistance to a broad range of anticancer therapies.

The discovery of Class I PI3K revealed a novel role for autophagy in induced cell death, and Class I PI3K is believed to be a crucial modulator in both apoptosis and autophagy. Our aim was to detect the effects of adenovirus PI3K(I)-RNA interference (RNAi)-green fluorescent protein (GFP) on the growth and apoptosis of gastric cancer cells *in vitro*. To compare transduction efficiency, biological and molecular mechanisms of adenovirus PI3K(I)-RNAi-GFP on gastric cancer cell lines will be detected.

MATERIALS AND METHODS

Reagents

SGC7901 and MGC801 gastric cancer cells were purchased from the Shanghai Institute of Cell Biology, Chinese Academy of Sciences (Shanghai, China). RPMI1640 medium was purchased from Gibco (Rockville, MD, United States). Fetal bovine serum was obtained from Hangzhou Sijiqing Biological Engineering Material Co., Ltd. (Hangzhou, China), L-glutamine and MTT were provided by Sigma (St Louis, MO, United States). Antibodies against p53, Bcl-2, Beclin-1, and LC3 were provided by Cell Signaling Technology (Beverly, MA, United States).

Adenoviral vectors and infections

RNAi sequence design against Class I PI3K and the construction of vectors expressing Class I PI3K short hairpin RNA (shRNA). The Class I PI3K-specific target sequence was chosen according to online shRNA tools of Invitrogen (<http://www.invitrogen.com/rnai>) using the Class I PI3K reference sequence (GenBank accession No. NM_006218). The target sequence was designed as follows: Class I PI3K (base 3090-3118), "5'-AGAG-GTTTCAGGAGATGTGTT ACAAG GCT-3'". shRNAs were then chemically synthesized and a lentiviral vector was constructed. The exact insertion of the specific shRNA was further confirmed by sequencing. The recombinant adenovirus vector that expresses shRNA against Class I PI3K was synthesized by Shanghai Genesil Co., Ltd. Stocks of replication-defective adenoviral vectors expressing green fluorescent protein [adenovirus PI3K(I)-RNAi-GFP and control adenovirus NC-RNAi-GFP] were stored at -80 °C. Infections were performed at 70% to 75% confluence in DMEM supplemented with 2% FCS. Cells were subsequently incubated at 37 °C for at least 4 h, followed by the addition of fresh medium. Cells were subjected to functional analyses at fixed time points following infection as described for individual experimental conditions.

Determination of optimal multiplicity of infection

1×10^4 SGC7901 and MGC803 cells/well were seeded in 96 well plates to 60%-70% cultured adherent cells. Different multiplicities of infection (MOI = 10, 20, 30,

50, 100) of the adenovirus NC-RNAi-GFP (100 μ L) and diluted infected cells were then added. Eight hours later, 10% fetal bovine serum for RPMI1640 culture medium was added, and 48 h later was counted under a fluorescence microscope to calculate the number of cells that expressed GFP.

Cell culture and viability assay

SGC7901 and MGC803 cells were maintained in RPMI1640 medium containing 10% heat-inactivated fetal bovine serum and 0.03% *L*-glutamine incubated in a 5% CO₂ atmosphere at 37 °C. Cells in a mid-log phase were used in experiments. Cell viability was assessed by MTT assay. To determine the response of SGC7901 cells to adenovirus PI3K(I)-RNAi-GFP, SGC7901 cells were plated into 96-well microplates (7×10^4 cells/well) and adenovirus PI3K(I)-RNAi-GFP was added to a culture medium and cell viability was assessed with MTT assay 24 h after adenovirus PI3K(I)-RNAi-GFP treatment. MTT (Sigma, St Louis, MO, United States) solution was added to a culture medium (500 mg/L final concentration) for 4 h before the end of treatment, and the reaction was stopped by the addition of 10% acidic SDS (100 μ L). The absorbance value (*A*) at 570 nm was read using an automatic multiwell spectrophotometer (Bio-Rad, Richmond, CA, United States). The percentage of cell proliferation was calculated as follows: cell proliferation (%) = $(1 - A \text{ of experiment well} / A \text{ of positive control well}) \times 100\%$.

Visualization of monodansylcadaverine-labeled vacuoles

Exponentially-growing cells were plated onto 24-chamber culture slides, cultured for 24 h, and then incubated with the drug in 10% FCS/RPMI 1640 for 12 and 24 h. Autophagic vacuoles were labeled with MDC^[10] (Sigma, St Louis, MO, United States) by incubating cells with 0.001 mmol/L MDC in RPMI1640 at 37 °C for 10 min. After incubation, cells were washed three times with phosphate-buffered saline (PBS) and immediately analyzed with a fluorescence microscopy (Nikon Eclipse TE 300, Japan) equipped with a filter system (V-2A excitation filter: 380-420 nm, barrier filter: 450 nm). Images were captured with a CCD camera and imported into Photo-shop.

Immunofluorescence staining LC3

MGC803 cells were seeded onto 24-chamber culture slides and treated with adenovirus PI3K(I)-RNAi-GFP (50 MOI) and adenovirus NC-RNAi-GFP. After fixation in methanol for 10 min and blocked with a buffer containing 1% bovine serum albumin (BSA) and 0.1% Triton X-100 for 1 h, cells were incubated with either the primary antibody against LC3 from Cell Signaling Technology (Beverly, MA, United States) or diluted at 1:200 with PBS containing 1% BSA at 4 °C overnight. Cells were then incubated for 1 h with 1:500 secondary fluorescence conjugated antibodies (Sigma) to visualize the binding sites of the primary antibody under a laser confocal microscope

(Leisa, Germany).

Detection of mitochondrial potential

Mitochondrial $\Delta\psi$ was determined using the KeyGEN Mitochondrial Membrane Sensor Kit (KeyGEN, Nanjing, China). The MitoSensor dye aggregates in the mitochondria of healthy cells and emits red fluorescence against green monomeric cytoplasmic background staining. However, in cells with a collapsed mitochondrial $\Delta\psi$, the dye cannot accumulate in the mitochondria and remains as monomers throughout the cells with green fluorescence^[11]. SGC7901 cells were briefly incubated with adenovirus PI3K(I)-RNAi-GFP in 24-well plates for the indicated times, then pelleted, washed with PBS, and resuspended in 0.5 mL of diluted MitoSensor reagent (1 mmol/L in incubation buffer). After incubating cells with MitoSensor reagent for 20 min, 0.2 mL of incubation buffer was added and cells were centrifuged then resuspended in 40 μ L of incubation buffer. Finally, cells were washed and resuspended in 1 mL PBS for flow cytometry analysis.

Total cell protein extraction and Western blotting analysis

For extraction of total cell proteins, cells were washed with pre-cooled PBS and subsequently lysed in pre-cooled RIPA lysis buffer (50 mmol Tris-HCl, pH 7.4, 150 mmol NaCl, 1 mmol dithiothreitol, 0.25% sodium deoxycholate, and 0.1% NP-40) containing 1 mmol/L phenylmethylsulfonyl fluoride, 50 mmol sodium pyrophosphate, 1 mmol/L Na₃VO₄, 1 mmol NaF, 5 mmol EDTA, 5 mmol EGTA, and a protease inhibitors cocktail. Cell lysis was performed on ice for 30 min. Clear protein extracts were obtained by centrifugation for 30 min at 4 °C. Protein extraction from SGC7901 gastric cancer cells was performed as previously described. Protein concentration was determined with a Bradford protein assay kit. Proteins were resolved on 8.5% polyacrylamide gels and subsequently transferred onto nitrocellulose membranes. For immunoblotting, nitrocellulose membranes were incubated with specific antibodies recognizing target proteins overnight at 4 °C. The membranes were then incubated with horseradish peroxidase-conjugated secondary antibody (1:3000) for 1 h at room temperature, and subsequently analyzed by an enhanced chemiluminescence detection system (Amersham Pharmacia Biotech) and visualized by autoradiography. Protein β -actin (1:5000; Sigma) was used as a loading control.

Transmission electron microscopic examination

Pursuant to treatment with adenovirus PI3K(I)-RNAi-GFP, cells were fixed in ice-cold 2.5% glutaraldehyde in 0.1 mol/L PBS, and preserved at 4 °C for further processing. When processing resumed, cells were post-fixed in 1% osmium tetroxide in the same buffer, dehydrated in graded alcohols, embedded in Epon 812, sectioned with an ultra-microtome, and stained with uranyl acetate and lead citrate, followed by examination with a transmission

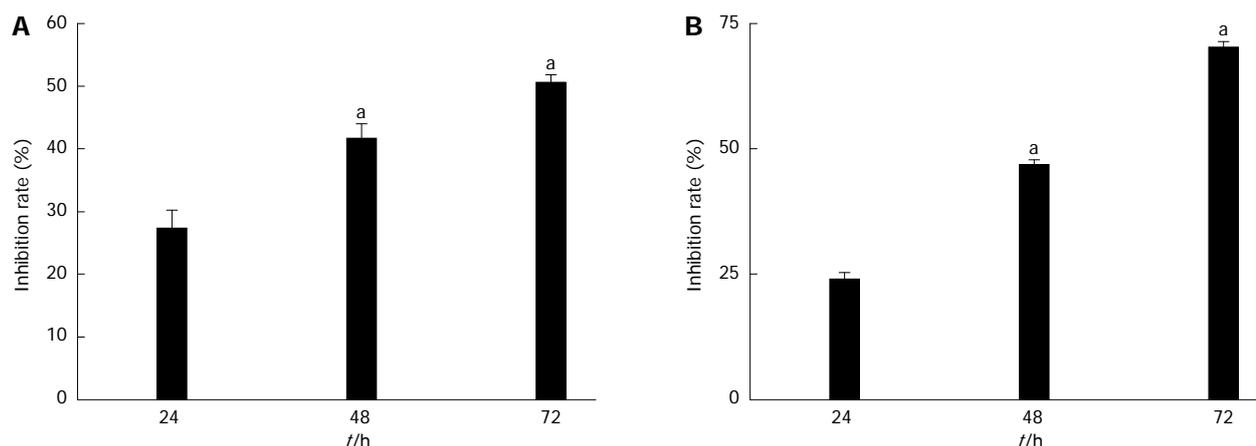

Figure 1 Reduced viability of SGC7901 and MGC803 cells after adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein treatment. A: SGC7901 cells (7×10^4 cells/mL); B: MGC803 cells (7×10^4 cells/mL) cultured with adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNA interference-green fluorescent protein (RNAi-GFP) (50 MOI) and adenovirus negative control-RNAi-GFP for 24, 48, and 72 h. Cell viability was analyzed by MTT assay. Values were given as mean \pm SD of three independent experiments. ^a $P < 0.05$ vs control group.

electron microscope (Philips CM120, Dutch).

Statistical analysis

All data were presented as mean \pm SD. Statistical analysis was carried out by ANOVA, followed by a Dennett's-test, with $P < 0.05$ being considered significant.

RESULTS

Cell viability was detected after adenovirus PI3K(I)-RNAi-GFP treatment

MTT assay showed that the inhibition rate of gastric cancer cells transfected with adenovirus PI3K(I)-RNAi-GFP was significantly higher than adenovirus NC-RNAi-GFP (50 MOI) ($P < 0.05$). Adenovirus PI3K(I)-RNAi-GFP inhibited the proliferation of SGC7901 and MGC803 cancer cell viability. MTT assays revealed that, after 24 h of treatment with adenovirus PI3K(I)-RNAi-GFP, the rate of inhibition for SGC7901 cancer cells had reached $27.48\% \pm 2.71\%$. The rate of inhibition rose when the incubation time was prolonged, reaching $41.92\% \pm 2.02\%$ at 48 h, and $50.85\% \pm 0.91\%$ at 72 h after treatment (Figure 1). It was also revealed that, after 24 h of treatment with adenovirus PI3K(I)-RNAi-GFP, the rate of inhibition for MGC803 cancer cells had reached $24.39\% \pm 0.93\%$. The rate of inhibition rose when the incubation time was prolonged, reaching $47.00\% \pm 0.87\%$ at 48 h, and $70.30\% \pm 0.86\%$ at 72 h after treatment (Figure 1).

Transfection efficiency and cell morphology were detected by fluorescence microscope

With the treatment of adenovirus PI3K(I)-RNAi-GFP (50 MOI) transfected SGC7901 and MGC803 cells after 24 h, we found that the cell body was swollen and rounded, with the cells showing further deformation after 48 h. For fragments of recombinant adenovirus containing GFP, after transfection with 72 h, SGC7901 and MGC803 cells can be counted under a fluorescence

microscope due to the green fluorescence of the tumor cells (Figure 2). It was determined that when 50 MOI, the transfection efficiency was $95\% \pm 2.4\%$.

Adenovirus PI3K(I)-RNAi-GFP transfection increased autophagic vacuoles:

The autofluorescent substance MDC has been recently shown to be a marker for late autophagic vacuoles (L-AVs), but not endosomes^[10]. The dye is trapped in acidic, membrane-rich organelles, and also exhibits increased fluorescence quantum yield in response to the compacted lipid bilayers present in L-AVs^[12]. When cells are viewed with a fluorescence microscope, AVs stained by MDC appear as distinct dot-like structures distributed within the cytoplasm or localizing in the perinuclear regions. We found that there was an increase in the number of MDC-labeled vesicles after treatment of adenovirus PI3K(I)-RNAi-GFP (50 MOI) from 24 to 72 h (Figure 3).

Adenovirus PI3K(I)-RNAi-GFP transfection increased punctate LC3:

Microtubule-associated protein 1 light chain 3 (LC3), the mammalian ontology of Atg8, targets to the autophagosomal membranes in an Atg5-dependent manner and remains there even after Atg12-Atg5 dissociates. LC3 is considered to be the only credible marker of the autophagosome in mammalian cells^[13]. We used immunofluorescence staining to detect the expression and localization of LC3. The results showed that adenovirus PI3K(I)-RNAi-GFP transfection induced punctate distribution of LC3 immunoreactivity, indicating an increased formation of autophagosomes by adenovirus PI3K(I)-RNAi-GFP (Figure 4).

Adenovirus PI3K(I)-RNAi-GFP transfection induced mitochondrial dysfunction:

In the present study, mitochondrial membrane potential was examined using the fluorescent dye JC-1. We detected a collapse in mitochondrial membrane potential ($\Delta\psi$) as early as 24 h after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment, as indicated by the increased emission of green fluorescence.

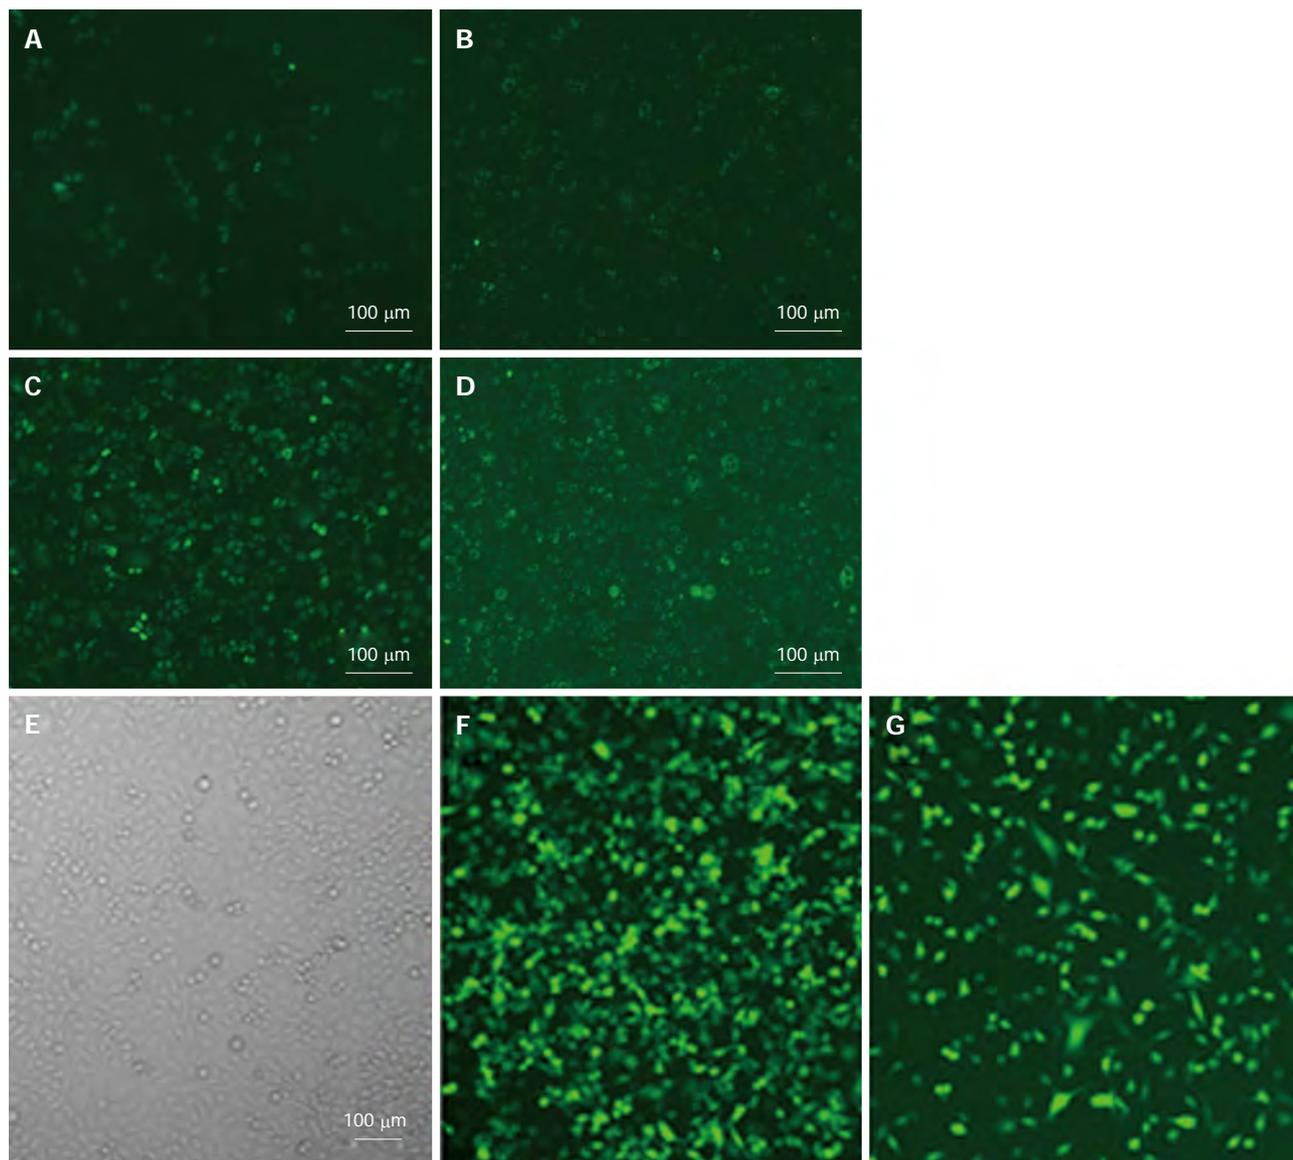

Figure 2 Transfection efficiency and cell morphology were detected by fluorescence microscope after adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein and adenovirus negative control-RNA interference-green fluorescent protein treatment. A-D: SGC7901 cells; E-G: MGC803 cells incubated with adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNA interference-green fluorescent protein (RNAi-GFP) (50 MOI) for the indicated time. A and E: Control group; B and F: 24 h after adenovirus PI3K(I)-RNAi-GFP treatment; C and G: 48 h adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment; D: 72 h after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment ($\times 200$) ($n = 3$).

This change reached its maximum at 24 h after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment (Figure 5). A collapse in mitochondrial membrane potential always indicates cell apoptosis or necrosis. Adenovirus PI3K(I)-RNAi-GFP (50 MOI) induced mitochondrial dysfunction and activated cell apoptosis in SGC7901 cells, and the results described here prove that RNAi of Class I PI3K induced apoptosis in SGC7901 cells.

Adenovirus PI3K(I)-RNAi-GFP transfection up-regulated the expression of Beclin-1 and LC3: To assay if adenovirus PI3K(I)-RNAi-GFP (50 MOI) transfection increases the expression of autophagic relative protein, Western blotting analysis was used to detect the expression of LC3 and Beclin-1. The results showed that the

basal level of Beclin-1 and LC3 protein in SGC7901 cells was low. After incubating with adenovirus PI3K(I)-RNAi-GFP(50 MOI), Beclin-1 and LC3 protein expression was significantly increased from 24 to 72 h (Figure 6).

Adenovirus PI3K(I)-RNAi-GFP transfection increased the expression of p53 and decreased the expression of Bcl-2: To assay if adenovirus PI3K(I)-RNAi-GFP (50 MOI) transfection influences the expression of apoptotic relative protein, Western blotting analysis was used to detect the expression of Bcl-2 and p53. The results showed that the basal level of p53 protein in SGC7901 cells was low. After incubating with adenovirus PI3K(I)-RNAi-GFP, p53 protein expression was significantly increased from 24 to 72 h. We found that Bcl-2 protein expression down-regulated

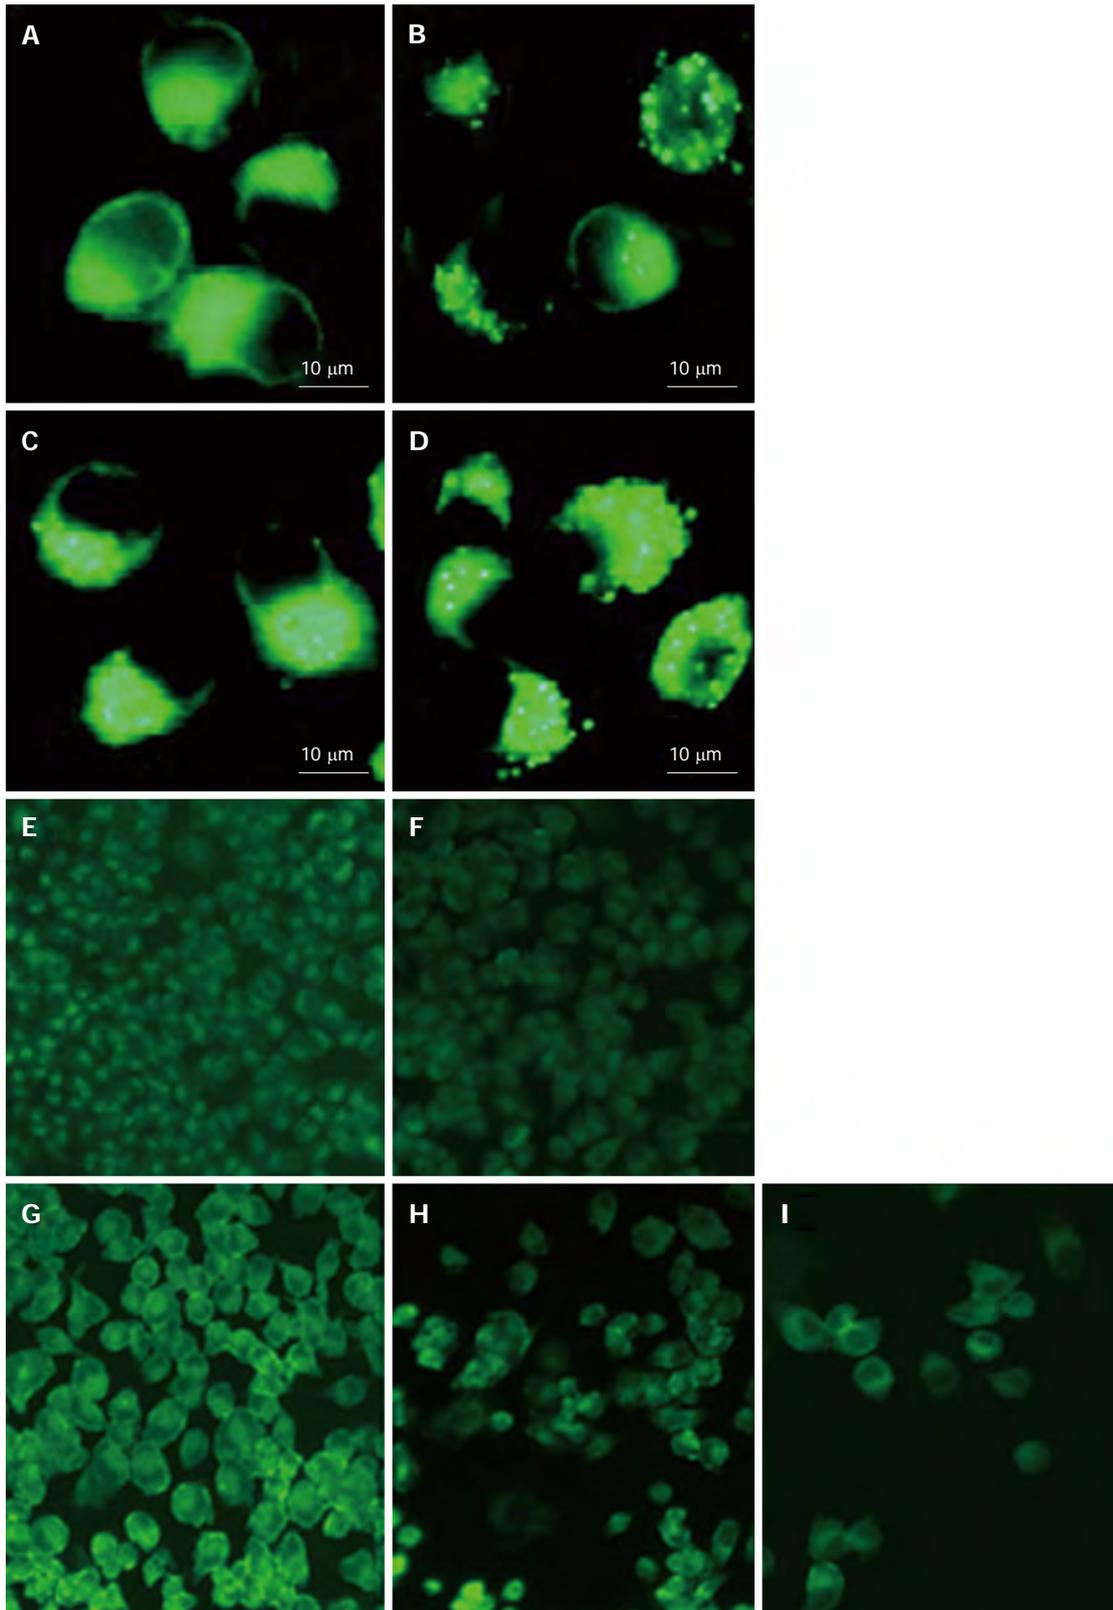

Figure 3 Monodansylcadaverine staining showed autophagy was activated after adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein (50 MOI) treatment. A-D: SGC7901 cells; E-I: MGC803 cells incubated with adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNA interference-green fluorescent protein (RNAi-GFP) (50 MOI) and adenovirus negative control (NC)-RNAi-GFP for the indicated time and stained with monodansylcadaverine (100 $\mu\text{mol/L}$). Fluorescence particles showed L-acoustic vector sensor. A and E: Control; B and F: Adenovirus NC-RNAi-GFP; C and G: 24 h after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment ($\times 200$) ($n = 3$); D and H: 48 h after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment; I: 72 h after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment ($\times 1000$) ($n = 3$).

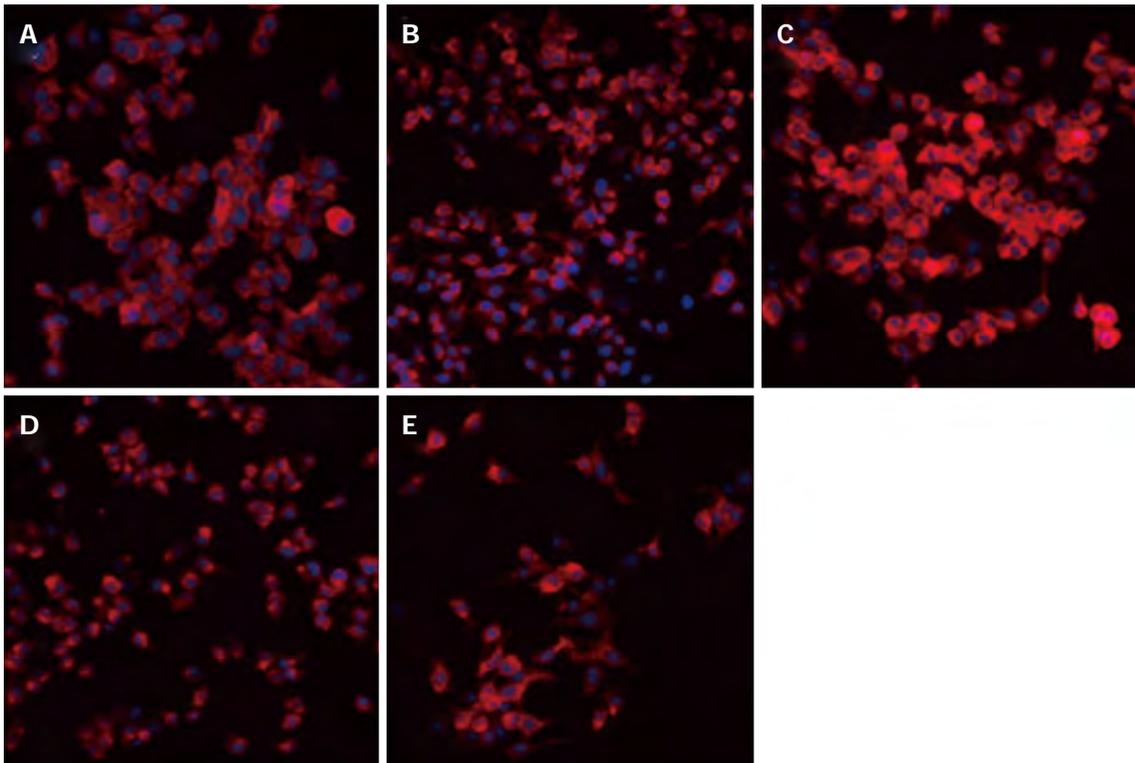

Figure 4 Microtubule-associated protein 1 light chain 3 expression and location in MGC803 cells after treatment with adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein. Cells were treated with adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNA interference-green fluorescent protein (RNAi-GFP) (50 MOI) for 24 h (C), 48 h (D), and 72 h (E), and analyzed with an immunofluorescence microscope. A: Control; B: Adenovirus negative control-RNAi-GFP ($\times 400$) ($n = 3$). Adenovirus PI3K(I)-RNAi-GFP increased the punctate distribution of light chain 3 from 24 to 72 h.

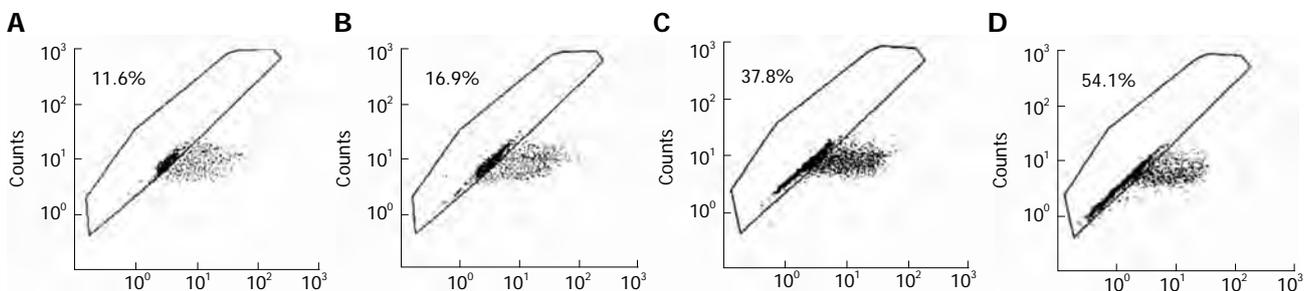

Figure 5 Flow cytometric analysis of mitochondria membrane potential in the control and adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein-treated SGC7901 cells. A: Control: adenovirus negative control RNA interference-green fluorescent protein (RNAi-GFP), cells were treated with adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNAi-GFP (50 MOI) for 24 h (B), 48 h (C) and 72 h (D), and were then stained with JC-1 (5 $\mu\text{mol/L}$) for 30 min.

with the treatment of adenovirus PI3K(I)-RNAi-GFP (50 MOI) (Figure 6).

Activation of autophagy/lysosomes and impairment of mitochondria with adenovirus PI3K(I)-RNAi-GFP treatment: We used transmission electron microscopy to identify ultrastructural changes in SGC7901 cells after adenovirus PI3K(I)-RNAi-GFP (50 MOI) treatment. Control cells showed a round shape and contained normal-looking organelles, nucleus, and chromatin (Figure 7), while adenovirus PI3K(I)-RNAi-GFP (50 MOI)-treated cells exhibited the typical signs of autophagy (Figure 4B-D). A number of isolated membranes, possibly derived from ribosome-free endoplasmic reticulum,

were seen. These isolated membranes were elongated and curved to engulf a cytoplasmic fraction and organelles (Figure 7C and D). These membrane structures formed autophagosome traits with double or multi-membranes, and then fused with lysosomes in the formation of autolysosomes. The lysosome staining darkened, indicating the activation of lysosomal enzymes (Figure 7C and D). The loss of organelles and cytoplasm vacuolization were also observed when the incubation time was prolonged (Figure 7C and D).

DISCUSSION

In the present study, we showed that the RNAi of Class I

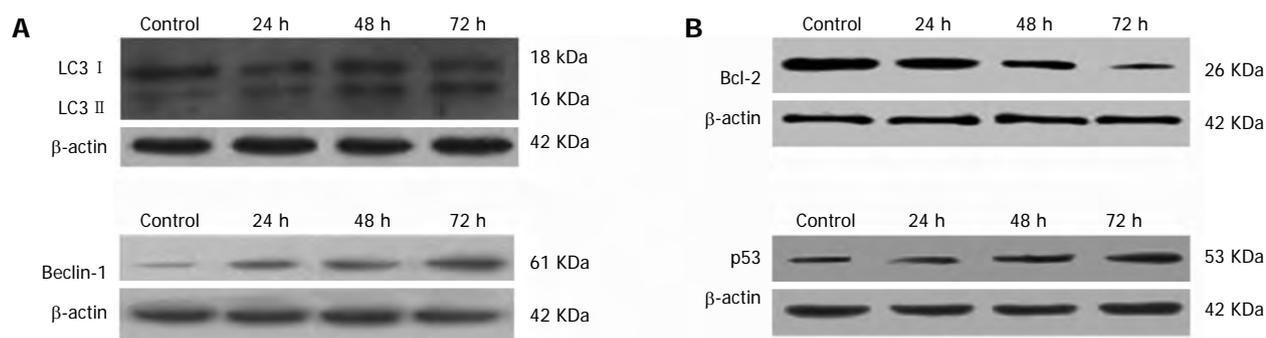

Figure 6 Effects of adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein on light chain 3 and Beclin-1 protein expression/Bcl-2 and p53 protein expression in SGC7901 cells. A: Effect of adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNA interference-green fluorescent protein (RNAi-GFP) (50 MOI) and adenovirus negative control (NC)-RNAi-GFP on light chain 3 (LC3) and Beclin-1 protein expression. Control: Adenovirus NC-RNAi-GFP. SGC7901 cells were treated with adenovirus PI3K(I)-RNAi-GFP (50 MOI) for 24 to 72 h then harvested for the extraction of total proteins. Adenovirus PI3K(I)-RNAi-GFP up-regulates the expression of LC3 and Beclin protein; B: Adenovirus PI3K(I)-RNAi-GFP (50 MOI) and adenovirus NC-RNAi-GFP on Bcl-2 and p53 protein expression. Control: Adenovirus NC-RNAi-GFP. SGC7901 cells were treated with adenovirus PI3K(I)-RNAi-GFP (50 MOI) for 24 to 72 h then harvested for the extraction of total proteins. Adenovirus PI3K(I)-RNAi-GFP up-regulates the expression of p53 and down-regulates the expression of Bcl-2 protein.

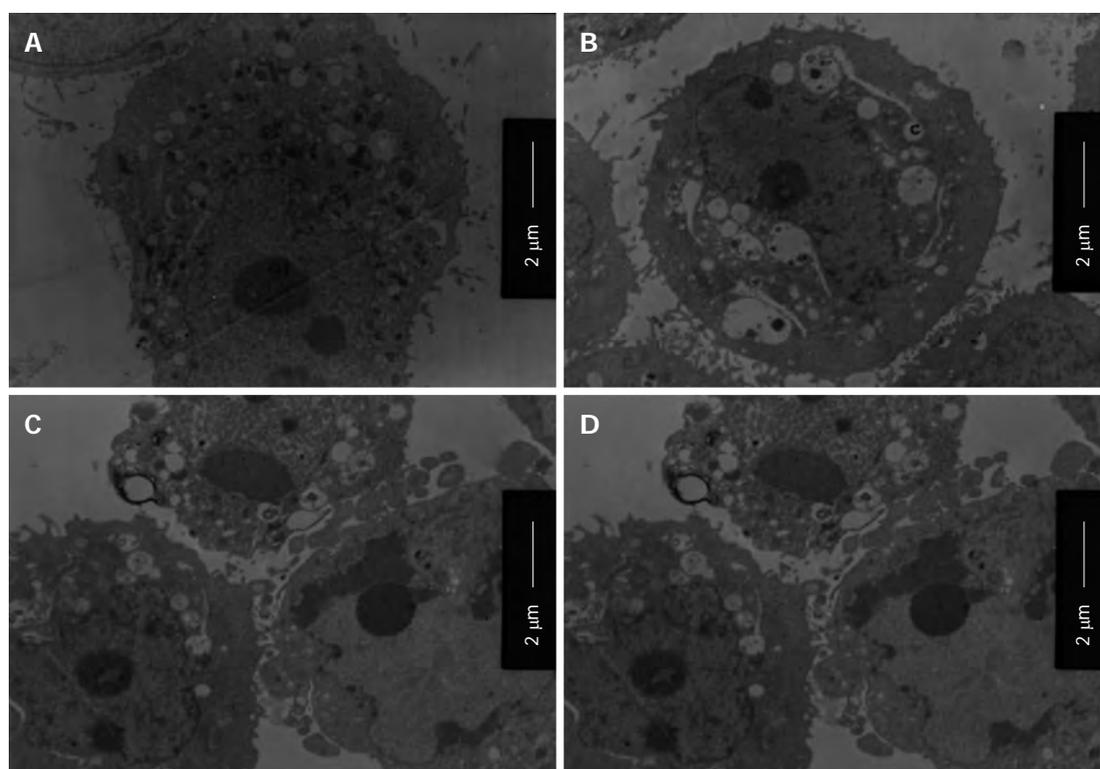

Figure 7 Ultrastructure of SGC7901 cells undergo autophagy, apoptosis and necrosis after adenovirus Class I phosphoinositide 3-kinase-RNA interference-green fluorescent protein treatment. A: Control: Adenovirus negative control RNA interference-green fluorescent protein (RNAi-GFP); B: Adenovirus Class I phosphoinositide 3-kinase [PI3K(I)]-RNAi-GFP (50 MOI)-treated (24 h); C: Adenovirus PI3K(I)-RNAi-GFP (50 MOI)-treated (48 h); D: Adenovirus PI3K(I)-RNAi-GFP (50 MOI)-treated (72 h).

PI3K reduced viability and induced apoptosis in SGC7901 and MGC803 gastric cancer cells, thus demonstrating the cytotoxic effects of adenovirus PI3K(I)-RNAi-GFP. We also showed that adenovirus PI3K(I)-RNAi-GFP increased the expression of p53, Beclin-1, and LC3, while decreasing the expression of Bcl-2. These findings suggest that RNAi of the Class I PI3K signaling pathway is a potential strategy for managing gastric cancers.

The mitochondria play critical roles in integrating cell death signals. Apoptosis is a cellular process involving the

selective degradation of membranous organelles such as the mitochondria. The mitochondrial permeability transition (MPT) represents an important event in initiating apoptosis. Thus, it is not surprising that apoptosis, and even necrosis, share a common mechanism through induction of the MPT. Observations made in the present study suggest that the mitochondrial $\Delta\psi$ collapsed after treatment of adenovirus PI3K(I)-RNAi-GFP; thus mitochondria may have initiated an apoptotic pathway.

The tumor suppressor p53 plays a central role in sensing

various genotoxic stresses. The basal levels of p53 were low in SGC7901 gastric cancer cells, and adenovirus PI3K(I)-RNAi-GFP upregulated the expression of p53. Upregulation of p53 after treatment with adenovirus PI3K(I)-RNAi-GFP induced apoptotic cell death. Moll and Zaika have proposed that the induction of apoptotic cell death by p53 occurs *via* both target gene activation and transactivation-independent mechanisms in mitochondria^[14]. In response to various forms of cellular stress, the levels of p53 increase, and a proportion of p53 rapidly localizes to the mitochondria^[15]. In the present study, the mitochondrial $\Delta\psi$ collapse after adenovirus PI3K(I)-RNAi-GFP treatment may have been caused by upregulation of p53. p53 accumulates in the nucleus, where it transactivates a number of proapoptotic target genes^[16], and induces apoptotic cell death.

Beclin-1 is monoallelically deleted in human breast and ovarian cancers, where it is expressed at reduced levels^[17,18]. The present results suggest that autophagy induced by adenovirus PI3K(I)-RNAi-GFP may contribute to anti-tumor effects. We also found that adenovirus PI3K(I)-RNAi-GFP increased the expression of Beclin-1, particularly the production of p53. Bcl-2 and Bcl-xL associate with the evolutionarily-conserved autophagy inducer Beclin-1, a haploinsufficient tumor suppressor^[19].

Inhibition may require Bcl-2 localized on the endoplasmic reticulum^[20,21]; notably, a BH3 domain within Beclin-1 mediates their association^[22]. In our research, we also found that the expression of Beclin-1 up-regulated with the treatment of adenovirus PI3K(I)-RNAi-GFP and the expression of Bcl-2 decreased. This indicated that autophagy activated and apoptosis induced after adenovirus PI3K(I)-RNAi-GFP treatment decreased the expression of Bcl-2.

All these observations suggest that autophagy and apoptosis activation may have significant contributions to adenovirus PI3K(I)-RNAi-GFP-induced death of SGC7901 and MGC803 cells. Further investigation of upstream signal regulation of autophagy and apoptosis may provide new insights into the mechanisms accommodating or contributing to autophagy and apoptosis, thereby unveiling new strategies for tumor therapy.

COMMENTS

Background

The discovery of Class I phosphoinositide 3-kinase (Class I PI3K) revealed a novel role for autophagy in induced cell death, and it is believed to be a crucial modulator in both apoptosis and autophagy. The authors predicted that activation of autophagy by blocking Class I PI3K may contribute to the anti-tumor actions of Class I PI3K inhibitors.

Research frontiers

The anti-tumor activity of Class I PI3K short hairpin RNA (shRNA) might be related to the induction of apoptosis of tumor cells, but the precise mechanism of its anti-tumor activity is not well understood.

Innovations and breakthroughs

Blocking Class I PI3K increases the expression of p53 and Beclin-1, and induces apoptotic and autophagic proteins, which contribute to the Class I PI3K inhibitor-induced apoptosis of cancer cells through both apoptotic and autophagic mechanisms. Further investigation of the relationship between autophagy activation and the anti-tumor effects of Class I PI3K inhibitors will unveil new

strategies for tumor therapy.

Applications

Blocking Class I PI3K increases the expression of p53 and Beclin-1, and induces apoptotic and autophagic proteins, which contribute to Class I PI3K shRNA-induced apoptosis of cancer cells by activating autophagic mechanisms; thereby providing new ideas for tumor treatment.

Terminology

Autophagy is a general term for the degradation of cytoplasmic components within lysosomes. There are three types of autophagy: macroautophagy, microautophagy, and chaperone-mediated autophagy. The term "autophagy" usually indicates macroautophagy.

Peer review

The authors examined the effects of Class I PI3K shRNA on the activation of apoptosis and autophagy, and the contribution of autophagy to the cytotoxic effects of Class I PI3K shRNA in gastric cancer cell line SGC7901. The results showed that shRNA Class I PI3K leads to the activation of apoptotic and autophagic pathways, and autophagy activation contributes to Class I PI3K shRNA-induced death of cancer cells.

Abstract

AIM: To investigate the role of psychological characteristics as risk factors for oesophageal adenocarcinoma (OAC), as well as the reflux-mediated precursor pathway.

METHODS: An all-Ireland population-based case-control study recruited 230 reflux oesophagitis (RO), 224 Barrett's oesophagus (BO) and 227 OAC patients and 260 controls. Each case/control group completed measures of stress, depression, self-efficacy, self-esteem, repression and social support. A comparative analysis was undertaken using polytomous logistic regression adjusted for potential confounders.

RESULTS: Compared to controls, OAC patients were almost half as likely to report high stress levels over their lifetime ($P = 0.010$, OR 0.51; 95%CI: 0.29-0.90)

and 36% less likely to report having experienced depression (OR 0.64; 95%CI: 0.42-0.98). RO patients reported significantly higher stress than controls particularly during middle- and senior-years (P for trends < 0.001). RO patients were 37% less likely to report having been highly emotionally repressed (OR 0.63; 95%CI: 0.41-0.95). All case groups (OAC, RO and BO) were more likely than controls to report having had substantial amounts of social support (OR 2.84; 95%CI: 1.63-4.97; OR 1.97; 95%CI: 1.13-3.44 and OR 1.83; 95%CI: 1.03-3.24, respectively).

CONCLUSION: The improved psychological profile of OAC patients may be explained by response shift. The role of psychological factors in the development of OAC requires further investigation.

INTRODUCTION

Gastro-oesophageal reflux comprises a series of chronic symptoms caused by abnormal reflux of gastric and intestinal digestive juice^[1] which may cause inflammation of the oesophageal mucosa reflux oesophagitis (RO)^[2] or cause a squamous to columnar cell metaplasia within the

distal oesophagus Barrett's oesophagus (BO)^[3]. Prevalence rates for gastro-oesophageal reflux disease in western countries range from 10%-20%^[4,5]. Incidence of BO in Northern Ireland is 567/100 000 of the population (unpublished data, Northern Ireland BO Registry). Although the absolute risk remains low (0.5% per patient per year)^[6], BO confers an increased risk of developing oesophageal adenocarcinoma (OAC)^[7], the incidence of which has increased by 600% in western countries in recent decades^[8]. The incidence rate for oesophageal cancer in Northern Ireland is similar to rates reported elsewhere^[9].

Previous studies have found associations between hypothesized risk factors including diet, obesity and smoking^[10-14] and the development of OAC though the demographic distribution of risk factors does not fully align with OAC incidence^[15]. Stress appears to affect the neuroendocrine and immune systems as well as the sympathetic nervous system^[16,17]. In population-based studies, job strain-related stress has been positively associated with symptomatic reflux and an increased risk of OAC^[17-19]. However, the role of psychosocial factors in the development of OAC and its precursor lesions has not been investigated.

Data from an all-Ireland population-based, case-control study (the FINBAR Study) was used to investigate the nature and extent to which different psychosocial factors (*e.g.*, stress and depressed mood) affected the development of OAC, including the influence such factors may have on the reflux-mediated precursor pathway.

MATERIALS AND METHODS

The FINBAR study was an all-Ireland population-based case-control study comprising three patient groups with (1) OAC; (2) long-segment BO; and (3) RO and a group of normal population controls. All participants were Caucasian and aged between 35-85 years. The design of the FINBAR Study has been described elsewhere^[10,20]. Briefly, OAC cases had histological confirmation of adenocarcinoma within the oesophagus. They were identified using electronic pathology records from all pathology laboratories in Northern Ireland and from the main hospitals involved in the treatment of oesophageal cancer in the Republic of Ireland. BO patients had histological confirmation of specialized intestinal metaplasia within the oesophagus and at least 3 centimeters of BO observed at endoscopy. RO patients were those diagnosed with macroscopically visible erosive oesophagitis (grades 2-4 in the Savary Miller/Hetzel-Dent classification or grades B, C or D in the Los Angeles classification) at upper gastro-intestinal (GI) endoscopy. BO and RO patients were frequency matched (within 5-year age- and sex-strata) to the distribution of OAC patients. Control subjects had no history of oesophageal or other GI cancer or BO. They were frequency matched by sex, and 5-year age bands to OAC patients.

For the psychosocial assessment patients were asked to reflect on their life as a whole when answering the

questions. Self-perceived stress or daily strain was assessed using the 4-item Reed Stress Inventory. Responses to items were scored as follows: 0, no response on one or more statements; 1, "not at all" for all four statements; 2, "not at all" for any three statements with any other response for the fourth; 3, "not at all" for any two statements with "hardly true" for the other two; 4, "not at all" for any one or two statements with any other responses for the remainder but not those for a score of 3; 5, all other response sets not specified under 0, 1, 2, 3, 4, 6, 7 or 8; 6, "moderately true" to all four statements, or "moderately true" for three statements with "exactly true" for the fourth; 7, "exactly true" for any three statements with "moderately true" or "hardly true" for the fourth; and 8, "exactly true" in response to all four statements. Scores from 1 to 8 were categorised as representing high (6-8), medium (4-5), or low (1-3) levels of stress.

A 4-part item was used to assess self-reported stress across the lifespan from: (1) childhood/teenager (up to 19 years); (2) young adulthood (20-39 years); (3) midlife (40-59 years); and (4) senior or later years in life (60-85 years). Each life period was considered a separate variable in the analyses in order to gauge approximately the extent to which any particular developmental period in an individual's life had been stressful and to assess its significance for patients compared to controls.

Depressed mood was assessed using an adapted 2-item case-finding instrument^[21]. A score of 1-2 on either question indicated a "not depressed" status while a score of 3-4 on either question indicated that the respondent was likely to be "depressed" or to have a depressed mood.

Self-efficacy and coping ability were measured using a 10-item scale designed to assess the extent to which a respondent had a self-belief that they had the capacity to overcome difficult tasks and cope with adversity. Responses on the 4-point likert scale were summed yielding a score of between 10 and 40 in the direction of increasing self-efficacy and coping ability. Self-efficacy was categorized as low (scores of 10-29), medium (30-34) and high (35-40) based on the tertile distribution of scores among the controls.

A single-item was used to measure self-esteem with a score of 1-2 indicating low self-esteem and a score of 3-4 indicating high self-esteem.

A single-item was used to assess emotional repression. A high score (3-4) indicated a tendency to share feelings and emotions relatively easily and a low score (1-2) was endorsed by respondents who were reticent or repressive in nature.

The responses to three questions on social support and loneliness were summed and categorized as indicating varying degrees of support from hardly any (scores 0-8), some (score 9), moderate (score 10) and substantial (scores 11-12) based on the quartile distribution of scores among the control group.

RO: Reflux oesophagitis; BO: Barrett's oesophagus; OAC: Oesophageal adenocarcinoma; GOR: Gastroesophageal reflux.

from the Research Ethics Committee of the Queen's University Belfast, the Clinical Research Ethics Committee of the Cork Teaching Hospitals and the Research Ethics Committee Board of St. James's Hospital, Dublin.

Statistical analysis

Group *t*-tests and Pearson χ^2 tests were used to compare cases and controls. Polytomous multivariate logistic regression was used to compare the psychosocial factors in each case group with the control group, adjusting for potential confounders including gender, age, years of full-time education, job type (manual, non-manual), Gastroesophageal reflux (GOR) symptoms (never, ever), smoking status (never, ex-smoker, current smoker), alcohol consumption (g/d) and BMI (self-reported weight 5-years before interview divided by height measured at

interview).

RESULTS

In total, 227 OAC patients, 224 BO patients, 230 RO patients and 260 controls were recruited into the study with participation rates of 64%, 82%, 69% and 42% respectively. Case groups and controls were similar regarding gender and age due to frequency matching. Other characteristics are displayed in Table 1.

There were no significant trends between reported stress levels as measured by the Reed Stress Inventory and risk of RO or BO (Table 2). However, OAC patients were half as likely to report high stress than controls (OR 0.51; 95%CI: 0.29-0.90). Stress levels were similar during childhood/teenage years for RO, BO, OAC cases and

RO: Reflux oesophagitis; BO: Barrett's oesophagus; OAC: Oesophageal adenocarcinoma; 1: Low; 2-4: Medium; 5: High; AOR: Adjusted odds ratio.

controls, respectively. Regarding young adulthood, there was a significant trend between having RO and reported stress; RO cases also reported significantly much higher stress during middle- and senior-years than controls (almost 10-fold and 6-fold more, respectively) with a significant linear trend (*P* for trend < 0.001) observed for each point on the life-span stress scale.

OAC cases were 36% less likely than controls to report depression; no significant association was observed between depression and BO or RO (Table 3). Self-efficacy levels were 3-times higher in RO patients and 2-times higher in OAC patients compared to controls. No significant association was observed for self-efficacy and BO. OAC patients were 58% more likely than controls to report high self-esteem though the association was not statistically significant (95%CI: 0.99-2.52). Self-esteem did not differ significantly between RO or BO cases respectively and controls. RO patients were 37% less likely than controls to report being repressed; significant associations were not observed between repression and BO or OAC status. RO, BO and OAC patients were more likely to report high levels of social support than controls.

DISCUSSION

This is the first study to investigate psychological characteristics of RO, BO and OAC patients as possible risk factors for the development of these conditions. OAC patients compared to controls reported significantly lower stress levels throughout their life in contrast to comparisons between RO and BO patients and controls. RO patients reported significantly higher stress levels in later life. OAC patients were also less likely than controls to report depression and to have higher (albeit non-significant) self-esteem and significantly better coping skills. All three case groups reported more social support than controls.

It has been hypothesized that psychosocial factors such as stress and social support may mediate or moderate cancer risk through, for example, influencing neuroendocrine and immune functioning^[22]. Long-term exposure to stress causes persistent activation of the hypothalamic-pituitary-adrenal axis reducing tumour suppressor capability and suppressing DNA repair functions^[23-26] through suppression of lymphocyte activity^[27] and cytotoxic T-cell

Table 3 Psychosocial factors by group status

| | Controls | RO | | BO | | OAC | |
|----------------|------------|------------|------------------|------------|------------------|------------|------------------|
| | n (%) | n (%) | AOR (95%CI) | n (%) | AOR (95%CI) | n (%) | AOR (95%CI) |
| Depression | | | | | | | |

RO: Reflux oesophagitis; BO: Barrett's oesophagus; OAC: Oesophageal adenocarcinoma; AOR: Adjusted odds ratio.

and natural killer cell activity^[28,29]. However, perceived stress over one's lifetime appeared to be significantly lower in OAC patients. Other factors such as recall bias and response shift may explain these reported lower levels of stress. Retrospective reporting may be skewed by recall bias as patients may lose their memory trace with time and their salience following a cancer diagnosis. Also, the current study identified an overall positive psychological profile among OAC patients including less depression, higher self-efficacy, higher self-esteem and more social support. The phenomenon of "response shift" may help to explain the findings in so far as a perceptual adjustment may occur in how a patient views stress or adversity and friends; and family tend to be sympathetic, caring and more likely to offer support at times of illness^[30-32]. Furthermore, a "cancer experience" has the potential to effect positive psychological change or post-traumatic growth (PTG)^[33]. For example, studies have found that PTG is inversely associated with emotional distress^[34] and positively associated with happiness^[35]. The majority of studies that have investigated the role of PTG have been conducted with patients with breast cancer, a form of cancer which has relatively high survival rates. In Europe, five and ten year survival rates of women diagnosed with breast cancer between 2000 and 2002 were 82% and 72%, respectively^[35]. In contrast, survival rates for OAC patients are much lower between 13% and 17% for males and females, respectively, in Ireland^[36]. A diagnosis of a cancer such as OAC with a poor prognosis and survival rate might be expected to result in despair, pessimism, reduce active coping and increase dependence on more an emotional-based style; and, in turn, these factors might be expected to reduce potential for PTG. In addition, OAC presents a unique symptom complex and the psychosocial issues and disabilities that arise from the treatment modalities involved with this cancer might be expected

to influence a patient's benefit finding ability and diminish their capacity for PTG. However, this study - the first to investigate PTG and response shift in OAC patients - suggests that benefit finding and positive well-being may be experienced by OAC patients despite the often hopeless prognosis. High levels of self-efficacy reported by OAC patients may serve to regulate the stress process, relieve depression and improve cancer symptoms^[37,38]. For example, OAC patients were less depressed than controls (OR 0.64; 95%CI: 0.42-0.98).

Perceived stress was higher in RO patients (particularly among older patients) in line with other studies [that demonstrate a link between psychosocial factors and gastro-oesophageal reflux disease (GORD)^[19,39]] even though RO patients were more likely than controls to report high self-efficacy. The association between GORD and somatisation disorder and depression reported elsewhere^[40] was not supported by the results of this study. The voluntary self-selection to participate in the study may have led to a form of ascertainment bias, whereby individuals with lower self-efficacy may have been less likely to participate in the study. Also, recall bias may have over-reported prior levels of self-efficacy, based on their current ability to cope with adversity.

Repression has been linked with poor health and cancer^[41-45]. However, there was no significant association found between repression and OAC. The single-item measure of repression used in this study may not have been sufficiently sensitive^[46]. RO patients were less likely than controls to report high repression. This relationship may have been moderated by social support - RO patients were more likely than controls to report that they had good social support.

This is a large, all-Ireland, population-based study, for which there was a relatively high response rate among case groups. The low control group response rate (42%),

however, merits a cautious approach to the interpretation of results (*e.g.*, representativeness of the population) though adjusted analyses were performed on potential confounders such as GOR, gender, age at interview, smoking status, alcohol consumption, occupation and BMI.

The retrospective nature of this study meant that it was susceptible to recall bias; this problem may be overcome by using a prospective study design. The resource-heavy nature, however, of these kinds of studies means that a retrospective study design, which can generate large data sets relatively quickly and efficiently, is usually more practicable. In any case, the incidence of OAC is still relatively low^[8] and the sample population is not large enough for a prospective study.

In conclusion, our results suggest that there may be a complex interaction between psychological factors regarding the development of RO, BO and OAC. Furthermore, the results presented here indicate that these conditions have significant psychological health consequences. Further research with enhanced methodological rigor is required to clarify the role of psychological factors in the development of OAC.

ACKNOWLEDGMENTS

We appreciate the contributions made by the study participants and their families. We would like to thank the clinicians who were contacted throughout the study period and their secretaries for administrative support. We acknowledge the contribution of Miss Siobhan Reynolds, Ms Majella Gallagher, Ms Carol Anderson and Mr. Martin McAnaespie and Dr. Damian McManus. Thanks to the Northern Ireland Cancer Registry and National Cancer Registry Ireland for their support and involvement in the research. The FINBAR study group members include Johnston BT, Watson RGP, McGuigan J, Ferguson HR (Belfast Health and Social Care Trust, Belfast, County Antrim, United Kingdom), Murphy SJ (Craigavon Hospital, Northern Ireland), JV Reynolds (St James' Hospital, Dublin, Ireland) and H Comber (National Cancer Registry of Ireland, Cork, Ireland).

COMMENTS

Background

Incidence of oesophageal adenocarcinoma (OAC) is rising more rapidly than that of any other form of cancer in the western world. The causes of OAC are largely unknown. Psychological factors are thought to mediate cancer risk for other forms of malignancies, but have not been investigated with regards to OAC or the conditions predisposing to it, including reflux oesophagitis (RO) and Barrett's oesophagus (BO).

Research frontiers

Several risk factors for OAC have been investigated, including diet, obesity and smoking. These factors mediate cancer risk in a variety of ways and have been shown to confer an increased risk of OAC. These risk factors, however don't fully explain the dramatic increase that has been seen over the last three decades (600% in Western countries) and psychosocial factors are thought to play a role.

Innovations and breakthroughs

Stress has been shown to mediate immune function, and subsequently cancer

risk in several forms of cancer, through the hypothalamic-pituitary-adrenal axis. Other psychosocial risk factors for cancer, such as depression, anxiety and job strain have also been investigated, but it remains unclear to what extent these factors are influencing the risk of OAC; either independently or through RO or BO.

Applications

Survival rates for OAC patients are relatively low and the comorbidities and treatment regimens for this form of cancer can greatly diminish quality of life in these patients. Identification of unambiguous risk factors for both OAC itself as well as the premalignant, reflux-mediated pathway, would provide the potential for early intervention and greatly improve survival and quality of life for RO, BO and OAC patients.

Terminology

Oesophageal adenocarcinoma is a cancer of the oesophagus that originates in the glandular tissue of the epithelium. Barrett's oesophagus is a squamous to columnar cell metaplasia within the distal oesophagus and is the main risk factor for OAC. Reflux oesophagitis is an inflammation of the oesophageal mucosa and is caused by abnormal gastro-oesophageal reflux; it also increases the risk of developing OAC.

Peer review

This is a very well written original manuscript assessing relationship between psychosocial factors and reflux esophagitis, Barrett's esophagus and esophageal adenocarcinoma.

Abstract

AIM: To evaluate the relationship among *Helicobacter pylori* (*H. pylori*) infection, *CagA* status, and dietary factors with *RUNX3* promoter hypermethylation.

METHODS: Gastric cancer tissue samples were collected from 184 South Korean patients. All patients were interviewed following a semi-quantitative food frequency questionnaire. The average frequencies of intake and portion sizes of 89 common food items were documented, and total intakes of calories, nutrients, vitamins, and minerals were calculated for each subject. DNA was extracted from gastric cancer tissue samples, and amplification of the *HSP60* gene was performed to detect *H. pylori* infection. Nested polymerase chain reaction (PCR) was used to detect the presence of the *CagA* gene. *RUNX3* gene expression was measured by reverse transcription-PCR, and *RUNX3* methylation status was evaluated by methylation-specific PCR. The odds ratios (ORs) and 95%CI associated with *RUNX3* promoter hypermethylation status were estimated for each of the food groups, lifestyle factors, and the interaction between dietary and lifestyle factors with *CagA* status of *H. pylori* infection.

RESULTS: Overall, 164 patients (89.1%) were positive for *H. pylori* DNA, with the *CagA* gene detected in 59 (36%) of these *H. pylori*-positive samples. In all, 106 (57.6%) patients with gastric cancer demonstrated CpG island hypermethylation at the *RUNX3* promoter. *RUNX3* expression was undetectable in 52 (43.7%) of the 119 gastric cancer tissues sampled. A high consumption of eggs may increase the risk of *RUNX3* methylation in gastric cancer patients, having a mean OR of 2.15 (range, 1.14-4.08). A significantly increased OR of 4.28 (range, 1.19-15.49) was observed with a high consumption of nuts in patients with *CagA*-positive *H. pylori* infection. High intakes of carbohydrate, vitamin B1, and vitamin E may decrease the risk of *RUNX3* methylation in gastric cancer tissue, particularly in *CagA*- or *H. pylori*-negative infection, with OR of 0.41 (0.19-0.90), 0.42 (0.20-0.89), and 0.29 (0.13-0.62),

respectively. A high consumption of fruits may protect against *RUNX3* methylation.

CONCLUSION: These results suggest that the *CagA* status of *H. pylori* infection may be a modifier of dietary effects on *RUNX3* methylation in gastric cancer tissue.

INTRODUCTION

The incidence of gastric cancer has declined dramatically in most countries over the past 70 years, yet it remains the second most common cause of cancer-related deaths worldwide. The estimated incidence in 2008 was 989 600, and the majority of new cases occurred in developing countries^[1]. Asian countries, including Japan, South Korea and China, have a particularly high incidence of gastric cancer; it is the second most frequently diagnosed cancer in the Korean population.

The development of gastric cancer appears to be the result of a complex interaction between environmental and genetic factors. Extensive epidemiology studies have shown that *Helicobacter pylori* (*H. pylori*) infection is a major risk factor for gastric cancer and its precursor lesions^[2]. The risk of developing gastric cancer is estimated to increase 2 to 6 times in patients with *H. pylori* infection, as determined by retrospective case-control and prospective epidemiology studies^[3]. As such, the World Health Organization and the International Agency for Research on Cancer consensus group have classified *H. pylori* as a Class I human carcinogen. More than half of the world's population is infected with *H. pylori*; its prevalence ranges from 25% in developed countries to more than 90% in developing regions^[4]. Among individuals infected with *H. pylori*, a small percentage develop gastric cancer by a process influenced by bacterial virulence. The most widely studied *H. pylori* virulence factor is the *CagA* antigen, a 96-to 138-kDa protein^[5]. The *CagA* gene, found on a genomic region called the *cag* pathogenicity island (PAI), is considered as a marker for enhanced virulence. Moreover, individuals infected with *CagA*-positive *H. pylori* strains have a higher risk of developing peptic ulcers and gastric cancer compared to those harboring *CagA*-negative *H. pylori* strains^[6].

The human runt-related transcription factors (*RUNX*) are important targets of the transforming growth factor (TGF)- β superfamily signaling pathway^[7]. Three different *RUNX* genes have been identified as human homologues of the *Drosophila* genes *runt* and *lozenge*^[8]. *RUNX1* (*AML1/CBEA2/PEBP-2aB*) is believed to be essential in hematopoiesis and is located in chromosome 21q22.3^[8]. Moreover, it is targeted for translocation or mutation in acute and chronic leukemias and in myelodysplastic syndromes^[9]. *RUNX2* (*AML3/CBEA1/PEBP2aA*), located on chromosome 6q21, is regarded as indispensable for the development of the musculoskeletal system and has been associated with the human bone disease cleidocranial dysplasia^[10]. In humans, *RUNX3* (*AML2/CBEA3/PEBP2aC*) is found at chromosomal locus 1p36 in a region that is frequently deleted in many types of cancers. This region is therefore postulated to contain an important tumor suppressor gene^[11]. The *RUNX3* protein combines with Smads and acts synergistically to regulate various target genes^[7]. Little or no expression of *RUNX3* has been observed in gastric cancer^[12] or in carcinomas of the liver, lung, breast, prostate, endometrium, and colon^[13]. Several mechanisms are thought to be responsible for downregulating *RUNX3*, including promoter hypermethylation, loss of heterozygosity, hemizygous deletion, and mutation, and these mechanisms have been linked to carcinogenesis in a wide range of human solid tumors. Recent studies have demonstrated that loss of *RUNX3* expression is causally related to the genesis and progression of gastric cancer. Approximately 45% to 60% of surgically resected gastric cancer specimens and cell lines derived from these cancers do not express *RUNX3* due to either hemizygous deletion of the gene or hypermethylation of its promoter region^[14]. Therefore, *RUNX3* is considered a tumor suppressor gene, and hypermethylation of its promoter is thought to play an important role in gastric carcinogenesis. Diets low in methyl-contributing folate, vitamins B6 and B12, and methionine and a high consumption of alcohol have been hypothesized to affect DNA methylation at CpG islands and confer an increased risk of cancer^[15]. CpG island DNA methylation is also thought to occur as a result of inflammation^[16]. Infection with *CagA*-positive *H. pylori* has been associated with higher grades of gastric mucosal inflammation as well as severe atrophic gastritis and is believed to play a role in the development of gastric carcinoma^[17].

The purpose of this study was to evaluate the associations between dietary factors and *RUNX3* promoter hypermethylation status and to assess the combined contribution of dietary factors and *H. pylori CagA* status to *RUNX3* promoter hypermethylation in patients with gastric cancer.

MATERIALS AND METHODS

Study subjects

Between September 2003 and March 2006, 184 South Korean patients with gastric cancer were enrolled in the

Table 1 Characteristics of the study subjects

| Variables | n (%) |
|--------------------------------------|----------------------------|
| All subjects | 184 |
| Age (mean ± SD), yr | 59.8 ± 11.3 (range: 23-83) |
| Gender | |
| Male | 124 (67.4) |
| Female | 60 (32.6) |
| <i>Helicobacter pylori</i> infection | |
| Negative | 20 (10.9) |

| Negative | 78 (42.4) |
| Positive | 106 (57.6) |
| <i>RUNX3</i> expression | |
| Positive | 67 (56.3) |
| Negative | 52 (43.7) |

study. All patients were diagnosed at Chungbuk National University Hospital and Eulji University Hospital, both of which are located in the middle of the South Korean peninsula. Gastric cancer tissue samples were collected from all patients with prior consent. Patient characteristics are shown in Table 1. Tissue samples were obtained during resection surgery, immediately frozen in liquid nitrogen, and stored at -80 °C until needed for DNA and RNA extraction.

Patient demographics and other potential risk factors for gastric cancer were collected during direct interviews with subjects. Trained personnel interviewed the subjects using a structured questionnaire within one month of the diagnosis of gastric cancer and other benign diseases. Control subjects were questioned while undergoing routine medical examinations during hospital visits. Dietary data were collected using a semiquantitative food frequency table that had been previously evaluated for its validity and reliability^[18]. The average frequency of intake and portion size of 89 common food items was documented. These items were classified into 21 food groups based on their ingredients: cereals; potatoes; nuts; noodles (pasta); breads and cakes; vegetables; mushrooms; fruits; red meats; eggs; fish and shellfish; stews; chicken; kimchi; soybean foods; soybean pastes; milk and dairy products; jams, honey, sweets and chocolates; coffee and tea; seaweeds; and alliums. Each food item was divided into high and low groups according to the median value of its distribution.

The amount of calories, nutrients, vitamins, and minerals consumed for each food item was estimated by multiplying the amount of the food item consumed by its nutrient value. Total intakes of calories, nutrients, vitamins, and minerals were calculated for each subject by summing the respective calories, nutrients, vitamins, and minerals for each food item^[19]. The intake amounts of these factors were adjusted for caloric intake using the method of Willett *et al.*^[20].

Polymerase chain reaction amplification of heat-shock protein 60 and *CagA* gene

DNA was extracted from gastric cancer tissue samples using a commercially available kit (Wako, Osaka, Japan). To detect *H. pylori* infection in these samples, a nested PCR protocol was developed against heat-shock protein (*HSP60*). *HSP60* was chosen due to its high degree of sequence conservation in all biota^[21].

DNA amplification of the *HSP60* gene was performed according to the nested polymerase chain reaction (PCR) method described by Varsha *et al.*^[22]. Forward and reverse oligonucleotides were derived from the conserved region located between bases 8085 and 8675 of the *HSP60* gene of *H. pylori* (ATCC 26695). Internal primers sets were derived from the region between bases 8162 and 8663 (Gene Bank Accession number NC-0091; gene ID 899089). The first amplification was performed using HSP1, the sense primer (5'-AAGGCATGCAATTGATAGAGGCT-3'), and HSP2, the antisense primer (5'-CTTTTCTCTTTCATTTCCACTT-3'), in a 25-μL reaction mixture containing 2.5 μL of 10 × PCR buffer, 5 pmol of each primer, 10 ng of DNA, 200 μmol/L aliquots of each dNTP, and 1 unit of *Taq* polymerase. This PCR resulted in a 590-base pair DNA fragment.

For the second amplification, 2 μL of the primary amplification product was used in a 15-μL reaction mixture with HSPN1, the sense primer (5'-TTGATAGAGGCTACCTCTCC-3'), and HSPN2, the antisense primer (5'-TGTCATAATCGCTTGTCGTGC-3'). Both PCR amplifications consisted of 35 cycles of denaturation at 94 °C for 30 s, annealing at 58 °C for 40 s, and elongation at 72 °C for 30 s. The final amplicon (expected size, 501 base pairs) was analyzed by electrophoresis on a 2% agarose gel.

Nested PCR was also chosen as a sensitive and specific method to detect the presence of the *CagA* gene. Forward and reverse oligonucleotides were derived from the conserved region located between bases 544680 and 545161 of the *CagA* gene of *H. pylori* (ATCC 26695). Internal primers sets were derived from the region between bases 544833 and 545131 (Gene Bank Accession number NC-00921; gene ID 899089). The first amplification was performed with *CagA* N1, the sense primer (5'-TG-GCAGTGGGTTAGTCATAGCAG-3'), and *CagA* N2, the antisense primer (5'-AGGACTCTTGCAGGCGTTGGTG-3'), in a 15-μL reaction mixture containing 1.5 μL of 10 × PCR buffer, 5 pmol of each primer, 10 ng of DNA, 200 μmol/L aliquots of each dNTP, and 1 unit of *Taq* polymerase, resulting in a 481-base pair DNA fragment. For the second amplification, 2 μL of the primary amplification product was used in a 15 μL reaction mixture with *CagA* D1, the sense primer (5'-ATAATGCTA-AATTAGACAACCTTGAGCGA-3'), and *CagA* R1, the antisense primer (5'-TTAGAATAATCAACAAACAT-CACGCCAT-3'). Both PCR amplifications consisted of 35 cycles of denaturation at 94 °C for 30 s, annealing at

55 °C for 30 s, and elongation at 72 °C for 30 s. The final amplicon (expected size, 298 base pairs) was analyzed by electrophoresis on a 2% agarose gel.

***RUNX3* hypermethylation analysis**

The methylation status of the CpG island in the promoter region of *RUNX3* was determined by bisulfite treatment of DNA (Imprint DNA Modification Kit, Sigma-Aldrich, St. Louis, MO, United States) in order to convert all unmethylated cytosines to uracils while leaving methylated cytosines unchanged, followed by methylation-specific PCR. Amplifications were carried out in a 96-well plate. DNA extracted from the leukocytes of healthy individuals and treated with *SssI* methyltransferase (New England Biolabs, Beverly, MA, United States) prior to bisulfite modification was used as a positive control for the methylated alleles. Bisulfite-modified DNA extracted from leukocytes of a healthy individual served as a positive control for the unmethylated alleles, and water was used as a negative control.

Amplification was carried out in a 20 µL reaction volume containing 10 ng of bisulfite-modified DNA and 2 µL of 10 × PCR buffer with 20 mmol/L MgCl₂, 4 µL of a GC-rich solution, 5 pmol of each primer for *RUNX3*, 200 µmol/L aliquots of each dNTP, and 1 unit of Faststart *Taq* DNA polymerase (Roche Applied Science, Mannheim, Germany). PCR was performed in a TaKaRa PCR Thermal Cycler Dice Gradient (Otsu, Japan) for methylated *RUNX3* with *RUNX3*-5M, the sense primer (5'-TTACGAGGGGCGGTCGTACGCGGG-3'), and *RUNX3*-3M, the antisense primer (5'-AAAACGACC-GACGCGAACGCCTCC-3'), using an initial denaturation at 95 °C for 5 min, followed by 35 cycles of 95 °C for 1 min, 69.1 °C for 1 min, 74 °C for 1 min and a final extension at 74 °C for 7 min. For unmethylated *RUNX3*, PCR was performed using *RUNX3*-5U, the sense primer (5'-TTATGAGGGGTGGTTGTATGTGGG-3') and *RUNX3*-3U, the antisense primer (5'-AAAACAACCAA-CACAAACACCTCC-3') following an initial denaturation at 95 °C for 5 min, followed by 35 cycles of 95 °C for 1 min, 61.8 °C for 1 min, 72 °C for 1 min and a final extension at 72 °C for 7 min. The PCR product (expected size, 218 base pairs) was separated on a 3% agarose gel. To verify the PCR product, the methylation-specific PCR amplicons from 5 samples were purified with HiYield PCR DNA Extraction Kit (Real Biotech, Banqiao, Taiwan) and subjected to direct DNA sequencing (ABI 3100, Applied Biosystems, Foster City, CA, United States).

RNA isolation and reverse transcription-PCR

Total RNA was extracted from 137 gastric cancer tissue samples using a commercially available kit (Easy-Blue, Intron, Seongnam, South Korea). All samples were assayed for *RUNX3* expression. The assay failed for 18 samples due to RNA degradation. The RT reaction was performed using 1 µg of total RNA with SuperScript III First-strand cDNA Synthesis Kit (Invitrogen, Carls-

bad, CA, United States). The following primer sets were used: 5'-TCTGCTCCGTGCTGCCCTCGCACTG-3' and 5'-AGGCATTGCGCAGCTCAGCGGAGTA-3' for *RUNX3* (151 bp) and 5'-ACCCACTCCTCACCTTTG-3' and 5'-CTCTTGTGCTCTTGCTGGG-3' for *GAPDH* (178 bp). Amplification was carried out in a 15-µL reaction volume containing 0.1 µg of cDNA and 1.5 µL of 10 × PCR buffer with 20 mmol/L MgCl₂, 3 µL of a GC-rich solution, 5 pmol of each primer, 200 µmol/L aliquots of each dNTP, and 1 unit of Faststart *Taq* DNA polymerase. PCR was performed in the TaKaRa PCR Thermal Cycler Dice Gradient with an initial denaturation at 95 °C for 5 min, followed by 30 cycles (for *RUNX3*) or 25 cycles (for *GAPDH*) of 95 °C for 1 min, 62.3 °C for 1 min, 72 °C for 1 min and a final extension at 72 °C for 7 min. The PCR product was separated on a 3% agarose gel.

Statistical analysis

The amount of calories, nutrients, vitamins and minerals for each particular food type was calculated by multiplying their respective values by the level of intake. The total intake of calories, nutrients, vitamins, and minerals was calculated as the sum of each value across all food types consumed by each individual^[19]. Each value was adjusted for caloric intake using the method of Willet *et al*^[20]. The median value calculated for each variable was used as the grouping criterion in the unmethylated *RUNX3* group.

The odds ratios (ORs) and 95% CIs associated with the *RUNX3* methylation status were estimated for each of the food groups and lifestyle factors and for the interaction between dietary and lifestyle factors with *CagA* status of *H. pylori* infection using an unconditional logistic model that controlled for age, sex and total energy intake. The homogeneities of the ORs according to the *CagA* status were evaluated using the Breslow-Day test. *P* values less than 0.05 were considered significant.

RESULTS

Overall, 164 patients (89.1%) were found to be positive for *H. pylori* DNA, with the *CagA* gene detected in 59 (36%) of the *H. pylori*-positive samples. Overall, *CagA*-positive expression was detected in 32.1% of all patients included in our study. In all, 106 (57.6%) patients with gastric cancer demonstrated CpG island hypermethylation at the *RUNX3* promoter. *RUNX3* expression was undetectable in 52 (43.7%) of the 119 gastric cancer tissues sampled.

We found a significant difference in *RUNX3* expression status between patients with and without hypermethylated *RUNX3*. *RUNX3* gene expression was detected in 71.7% of patients with unmethylated *RUNX3*. In contrast, *RUNX3* gene expression was detected in only 46.6% of patients with methylated *RUNX3* (*P* = 0.0070) (Table 2).

A high consumption of eggs was associated with a higher risk of *RUNX3* methylation, with an OR of 2.15

Table 2 Distribution of age, gender, *Helicobacter pylori* infection, *CagA* status, and *RUNX3* expression according to *RUNX3* methylation status *n* (%)

| Variables | <i>RUNX3</i> methylation (+) | <i>RUNX3</i> methylation (-) | <i>P</i> value |
|--------------------------------------|------------------------------|------------------------------|----------------|
| Age (mean ± SD), yr | 60.5 ± 11.2 | 58.7 ± 11.5 | 0.290 |
| Gender | | | 0.648 |
| Male | 70 (56.5) | 36 (67.4) | |
| Female | 54 (43.5) | 24 (40.0) | |
| <i>Helicobacter pylori</i> infection | | | 0.234 |
| Negative | 14 (13.2) | 6 (7.7) | |
| Positive | 92 (86.8) | 72 (92.3) | |
| <i>CagA</i> status | | | 0.997 |
| Negative | 72 (67.9) | 53 (68.0) | |
| Positive | 34 (32.1) | 25 (32.0) | |
| <i>RUNX3</i> expression | | | 0.007 |
| Positive | 34 (46.6) | 33 (71.7) | |
| Negative | 39 (53.4) | 13 (28.3) | |

(95%CI, 1.14-4.08). In contrast, high fruit consumption was associated with a lower risk of *RUNX3* methylation, with an OR of 0.50 (95%CI, 0.27-0.93). A large consumption of eggs or chicken increased the risk of *RUNX3* methylation in *CagA*- or *H. pylori*-negative cancer patients. A high intake of unfermented seaweeds or aliums conferred larger protective effects against *RUNX3* methylation in *CagA*-positive cancer patients compared to *CagA*-negative cancer patients. In homogeneity tests, however, the OR of high consumption of these food groups was similar between those with *CagA*-positive and *CagA*-negative status. In contrast, a high consumption of nuts was a significant risk factor for *RUNX3* methylation in *CagA*-positive patients. The OR of high nut intake in *CagA*-positive patients was 4.28 (95%CI, 1.19-15.49), and this value significantly differed from that in *CagA*-negative or *H. pylori*-negative cases (Table 3).

Large intakes of carbohydrates and vitamin E decreased the risk of *RUNX3* methylation in gastric cancer, with odd ratios of 0.48 (95%CI, 0.25-0.91) and 0.47 (95%CI, 0.26-0.88), respectively. When stratified according to the *CagA* status, high intakes of carbohydrates, vitamin B1, or vitamin E conferred a protective effect in *CagA*-negative or *H. pylori*-negative patients but not in *CagA*-positive patients, with statistically significant differences demonstrated for vitamins B1 and E (Table 4).

DISCUSSION

RUNX3, a member of the *RUNX* family, is a candidate tumor suppressor gene that is thought to play a role in the progression of gastric cancer. *RUNX3* is unique in that it is inactivated primarily by epigenetic silencing, unlike many other tumor suppressors, such as *p53*, that are inactivated mainly by deletion and mutation^[23]. Molecular epidemiology studies have investigated the relationship between DNA hypermethylation-induced inactivation of *RUNX3* and individual risk of cancer development in various organs, including the lungs, pancreas, urinary

bladder, and gastric cancers^[12,24-26].

In the present study, we found that *RUNX3* methylation was observed in 58% (106/184) of our gastric cancer patients. Consistent with our results, *RUNX3* methylation was previously observed in 52.6% (30/57) of the gastric cancer specimens in a Japanese study^[27]. Other investigators have reported the prevalence of *RUNX3* methylation in primary gastric cancers to be 71% (57/80) and 64% (48/75)^[13,28]. These differences in methylation frequency can be explained by the fact that different regions were examined within the *RUNX3* CpG island. Homma *et al*^[29] suggested that the methylation status of the regions spanning the transcription start site (No 6-8) is critical for the loss of *RUNX3* expression. In our study, we examined CpG islands within regions No 6-7 of *RUNX3* and observed levels of methylation similar to those reported by Homma *et al*^[29]. Previous studies have shown that, among primary gastric cancer samples and gastric cancer cell lines, 45%-60% showed loss of *RUNX3* expression due to hypermethylation of the CpG island located in the P2 promoter region^[12,30]. We found that *RUNX3* expression was undetectable in 43.7% of primary gastric cancer tissues. The significant association between *RUNX3* methylation status and its expression is consistent with the fact that promoter hypermethylation downregulates the expression of this gene.

H. pylori infection and *CagA* status did not reveal any significant association with *RUNX3* promoter hypermethylation or with *RUNX3* expression levels (Table 2). This finding suggests that *H. pylori* infection, regardless of *CagA* status, does not induce *RUNX3* methylation and that the ability of *RUNX3* to function as a tumor suppressor is not specific to *H. pylori*-related gastric cancer. A Japanese study reported a marginally significant association between *H. pylori* infection and *RUNX3* promoter hypermethylation; however, no significance was found between *CagA* positive *H. pylori* infection and *RUNX3* promoter hypermethylation^[27]. Our results are further supported by a German study that demonstrated that the level of *RUNX3* mRNA expression in the gastric epithelium is not influenced by *H. pylori* infection^[31]. Interestingly, it has previously been shown that *H. pylori* infection induces the ubiquitination and degradation of *RUNX3* and suppresses *RUNX3* expression in cultured gastric epithelial cells and mouse gastric epithelial cells. This discordance may be due to differences between *in vivo* and *in vitro* systems, and differences between mouse and human diseases. Furthermore, we tested the association of *H. pylori* infection with *RUNX3* promoter hypermethylation, not with *RUNX3* expression. It is possible that *H. pylori* infection suppresses the expression of *RUNX3* in gastric epithelial cells *via* pathways other than promoter hypermethylation. For example, Liu *et al*^[32] reported that *CagA* can inhibit the expression of *RUNX3* *via* Src/MEK/ERK and p38 MAPK pathways.

Several dietary factors, including folate, methionine, and vitamins B12 and B6 have been reported to be involved either directly or indirectly in DNA methylation^[15]. Re-

verse associations between these dietary factors and cancer risk, observed in epidemiological studies, have led to the hypothesis that folate, methionine, and other dietary factors confer an altered risk of gastric cancer due to their role in DNA methylation^[33]. However, few data exist to support this hypothesis. Many studies have investigated potential associations between dietary factors and DNA promoter methylation in colon cancer^[34,35]; however, these studies have failed to establish a consistent association. Methionine is considered to be an essential dietary component because it is the penultimate methyl donor for mammalian methylation reactions and it cannot be manufactured by the body. Consuming excessive quantities of methionine may affect DNA promoter CpG island methylation and thereby cause dysregulation of gene expression. In the present study, a high consumption of methionine-rich foods such as eggs and chicken increased the risk of *RUNX3* promoter methylation, and a high consumption of nuts increased the risk when combined with *CagA*-positive *H. pylori* infection.

Two major forms of *CagA* have been identified: East Asian *CagA* and Western *CagA*. In countries such as Japan, South Korea and China, most *H. pylori* infections contain East Asian *CagA*. The degree of inflammation, activity of gastritis, and atrophy are significantly higher in patients infected with East Asian *CagA*-positive strains compared to patients infected with *CagA*-negative or

Western *CagA*-positive strains^[36]. *CagA*-positive *H. pylori* infection induces progressive inflammatory changes in the gastric mucosa that ultimately lead to gastric cancer: superficial gastritis, atrophic gastritis, intestinal metaplasia, dysplasia, and carcinoma^[37]. In the present study, we observed that *CagA*-positive *H. pylori*-infected individuals who consume a large quantity of nuts may increase the risk of *RUNX3* methylation by 4-fold. The risk of *RUNX3* methylation was higher in *CagA*-positive *H. pylori*-infected subjects than in *CagA*- or *H. pylori*-negative patients of the same age.

The association of certain vitamin deficiencies and cancer is well established and is usually associated with environmental conditions that affect all tissues. High intakes of folate and vitamins B6 and B12 may protect against DNA methylation in colorectal cancer^[35]. In the present study, however, we did not find a protective effect of these vitamins. Instead, we found that high intakes of vitamin B1 and carbohydrates provide a protective effect against *RUNX3* methylation in gastric cancer, but this was not demonstrated in individuals with *CagA*-positive status. Vitamin B1 is essential for the body to utilize carbohydrates for energy and for metabolizing amino acids. The main biologically active vitamin B1 derivative is thiamine diphosphate, which is involved in universal metabolic pathways including glycolysis, the pentose phosphate pathway and the tricarboxylic acid cycle. Several studies

have reported that a high intake of carbohydrates protects against esophageal cancer and gastric cancer^[38]. Our study suggests that carbohydrates may protect against *RUNX3* promoter CpG island hypermethylation.

Vitamin E is a lipid-soluble antioxidant found in cell membranes where it prevents lipid peroxidation of polyunsaturated fatty acids. An Italian study reported that individuals with a high intake of vitamin E reduce their risk of gastric cancer by 50%^[39]. In the present study, the protective effect of high vitamin E intake on *RUNX3* methylation was observed in *CagA*-negative or *H. pylori*-negative gastric cancer patients but not in individuals with *CagA*-positive *H. pylori* infection. However, adverse effects of vitamin E have also been reported^[40]. Because vitamin E is metabolized using the same pathway as xenobiotics and may induce drug-metabolizing enzymes in rodents, it is hypothesized that high doses of vitamin E may lead to bioactivation of carcinogens within the human body^[41].

The association between high fruit consumption and protection from gastric cancer has been reported in many studies^[42,43]. The European Prospective Investigation into Cancer and Nutrition (EPIC-EURGAST) has reported similar results: fresh fruit and citrus fruit consumption may protect against diffuse and cardia gastric cancer, respectively^[44], but consistent results have yet to be achieved. Fruits contain vitamins C and E, which may protect cell membranes and DNA from oxidative damage. In our study, a protective effect of high fruit intake on *RUNX3*

methylation was observed, as well as a marginal inverse association between high vitamin C intake and *RUNX3* methylation.

We used nested PCR methods with DNA from gastric cancer tissues to detect *H. pylori* infection and *CagA* status. Nested PCR has the advantages of high sensitivity and specificity, quick results, and the ability to type bacteria without the requirement for special transport conditions. In our study, 89% of the gastric cancer patients were found to be positive for *H. pylori* DNA, and 32% were positive for *CagA* DNA. A Japanese study in which PCR methods were used to detect *H. pylori* infection and *CagA* status reported a 31.6% *CagA*-positive rate in 57 gastric cancer tissues^[27], which is very similar to our result. Several South Korean studies documented a higher prevalence of *CagA*-positive *H. pylori* infection^[45,46]. However, one study used an immunoblot method and the other included a smaller sample size. Because of the potential for false-positive immunoblot test results and the fact that individuals who had the infection in the past, irrespective of current infection, were classified as *CagA*-positive by this test, the actual *CagA* prevalence was likely lower than reported (97%). The difference between the *CagA* positive rates in our study and the previous one could be explained by the different detection methods. Moreover, a majority of the previous studies only investigated the role of *RUNX3* promoter methylation or *H. pylori* infection and *CagA* status in gastric cancer. We demonstrate, for the first time, that the interaction between *CagA*-positive

H. pylori infection and a high methionine intake contributes to *RUNX3* methylation in gastric cancer.

This study has some limitations. Because non-cancerous mucosa from gastric cancer patients or normal mucosal tissues from healthy controls were not included in this study, we were unable to determine *RUNX3* hypermethylation status or *RUNX3* expression level in those tissues. In addition, because this study is retrospective, we could not determine the temporal sequence of *H. pylori* infection and *RUNX3* promoter methylation. Finally, our sample size was not large enough to allow us to draw firm conclusions, especially regarding the effects of dietary factors on *RUNX3* promoter methylation.

In summary, a high consumption of chicken, eggs, or nuts rich in methionine may increase the risk of *RUNX3* promoter methylation in gastric cancer patients, whereas diets rich in fruits, carbohydrates, and vitamins B1 and E may decrease that risk. However, these inverse associations were observed only in patients negative for *CagA* or *H. pylori*. Moreover, a high intake of nuts combined with *CagA*-positive *H. pylori* infection significantly increased the risk of *RUNX3* promoter methylation. The *CagA* status of the *H. pylori* infection may be an important modifier of *RUNX3* methylation in gastric cancer patients.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) infection is a major risk factor for gastric cancer, and the cytotoxin-associated gene A (*CagA*) is considered a marker for enhanced *H. pylori* virulence. Individuals infected with *CagA*-positive *H. pylori* strains have a higher risk of developing gastric cancer. *RUNX3* is a candidate tumor suppressor gene, and loss of *RUNX3* expression is considered a critical step in the genesis and progression of gastric cancer.

Research frontiers

Recent epidemiological studies have investigated the relationship between inactivation of *RUNX3* and the risk of cancer development in various organs. *RUNX3* inactivation has been reported to be frequently, but not always, found in gastric cancer tissues. One of the most important mechanisms for silencing *RUNX3* expression is *via* hypermethylation of the gene promoter, but little is known regarding the causative factors of *RUNX3* promoter hypermethylation. The authors cannot rule out the possibility that other risk factors for gastric cancer, such as dietary factors and *CagA*-positive *H. pylori* infection, can induce promoter hypermethylation of the *RUNX3* gene. In this study, the authors found that *H. pylori* infection, regardless of *CagA* status, is not associated with *RUNX3* methylation and that the ability of *RUNX3* to function as a tumor suppressor is not specific to *H. pylori*-related gastric cancer. In addition, the authors identified dietary factors that, in combination with *CagA*-positive *H. pylori* infection, modify the risk of *RUNX3* promoter methylation.

Innovations and breakthroughs

The authors determined the relationship between *CagA*-positive *H. pylori* infection and certain dietary factors with *RUNX3* promoter hypermethylation positive in gastric cancer patients. The authors adopted this case-case study design to maximize comparability and statistical power. To the best of our knowledge, this is the first study of the interaction between *CagA*-positive *H. pylori* infection and *RUNX3* methylation in gastric cancer tissues.

Applications

The results of this study suggest that the *CagA* status of *H. pylori* infection may modify dietary effects on *RUNX3* promoter hypermethylation in gastric cancer tissue. Further studies are needed to determine the mechanisms by which *CagA* and dietary factors interact and influence the development of gastric cancer.

Terminology

CagA, a 120-145 kDa protein encoded on the 40 kb *Cag* pathogenicity island, is

a *Helicobacter pylori* virulence factor. *RUNX3* is a member of the runt domain-containing family of transcription factors and is encoded by the *RUNX3* gene.

Peer review

In this study, the authors evaluated associations of *Helicobacter pylori* infection, *CagA* status, and dietary factors with *RUNX3* promoter hypermethylation in 184 Korean patients with gastric cancer.

Abstract

AIM: To investigate the attenuation patterns and detectability of common bile duct (CBD) stones by multidetector computed tomography (MDCT).

METHODS: Between March 2010 and February 2012, 191 patients with suspicion of CBD stones undergoing both MDCT and endoscopic retrograde cholangiopancreatography (ERCP) were enrolled and reviewed retrospectively. The attenuation patterns of CBD stones on MDCT were classified as heavily calcified, radiopaque, less radiopaque, or undetectable. The association between the attenuation patterns of CBD stones on MDCT and stone type consisting of pure cholesterol, mixed cholesterol, brown pigment, and black pigment and the factors related to the detectability of CBD stones by MDCT were evaluated.

RESULTS: MDCT showed CBD stones in 111 of 130 patients in whom the CBD stones were demonstrated

by ERCP with 85.4% sensitivity. The attenuation patterns of CBD stones on MDCT were heavily calcified 34 (26%), radiopaque 31 (24%), less radiopaque 46 (35%), and undetectable 19 (15%). The radiopacity of CBD stones differed significantly according to stone type ($P < 0.001$). From the receiver operating characteristic curve, stone size was useful for the determination of CBD stone by MDCT (area under curve 0.779, $P < 0.001$) and appropriate cut-off stone size on MDCT was 5 mm. The factors related to detectability of CBD stones on MDCT were age, stone type, and stone size on multivariate analysis ($P < 0.05$).

CONCLUSION: The radiopacity of CBD stones on MDCT differed according to stone type. Stone type and stone size were related to the detectability by MDCT, and appropriate cut-off stone size was 5 mm.

Kim CW, Chang JH, Lim YS, Kim TH, Lee IS, Han SW. Common bile duct stones on multidetector computed tomography: Attenuation patterns and detectability. *World J Gastroenterol* 2013; 19(11): 1788-1796 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1788.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1788>

INTRODUCTION

Traditionally, endoscopic retrograde cholangiopancreatography (ERCP) was the gold standard for investigation of bile duct diseases, but its role has been limited to therapeutic use due to the invasiveness for the procedure^[1-4]. Therefore, multiple imaging tests have been used to diagnose stones in the common bile duct (CBD) instead of

ERCP. Commonly performed imaging tests are abdominal sonography, computed tomography (CT), magnetic retrograde cholangiopancreatography (MRCP), and endoscopic ultrasonography (EUS). Abdominal sonography is easy to perform, but it cannot evaluate the overall CBD. MRCP and EUS have been reported to be accurate for the diagnosis of choledocholithiasis^[5-8]. However, they both have some limitations that prevent active use on patients; metal in the body, claustrophobia, and lack of rapidity for MRCP; operator dependency for EUS; high cost and the differences of the facilities among different centers for MRCP and EUS.

CT scans are being used more frequently and performed as the initial imaging technique in patients with abnormal liver function test results or possible symptoms related to the biliary tract because it can be performed rapidly, is equipped in most centers, has relatively low cost, and gives extensive information on pancreaticobiliary structures including CBD stones. However, CT has been reported to have lower accuracy for the diagnosis of CBD stones than MRCP or EUS^[9-11], which does not make CT the imaging technique of choice for patients with clinical suspicion of choledocholithiasis. The development of multi-detector computed tomography (MDCT) has shown promise in increasing the accuracy of CT in the diagnosis of pancreaticobiliary diseases. With an almost universal use of MDCT, acquisition of images with high spatial resolution is now routine and the advent of more recent MDCT technology may further advance the use of CT for these diagnoses given its ability to acquire an isotropic data set with minimal motion artifacts^[12]. A recent study showed that MDCT was comparable with MRCP or EUS for the detection of CBD stone with 87% sensitivity, 85% specificity, and 86% accuracy^[13].

Gallstones are classified into cholesterol stones (pure cholesterol, combination, or mixed) and pigment stones (black or brown) according to the National Institutes of Health (NIH)-International Workshop on Pigment Gallstone Disease^[14] and the Gallstone Research Committee from the Japanese Society of Gastroenterology^[15]. CT can reveal the heterogeneous nature of these biliary stones in attenuation patterns ranging from being heavily calcified and radiopaque, to being slightly less radiopaque than bile due to cholesterol, to having gas attenuation due to locules of nitrogen gas^[16]. The association between the attenuation patterns of CBD stones on MDCT and the gallstone type has not been clarified. It is also not fully elucidated how the types and size of stones affect the detectability of MDCT. Therefore, we investigated the attenuation patterns and the detectability of CBD stones by MDCT according to stone type and stone size, and intended to find the factors related to the detectability of CBD stones by MDCT.

MATERIALS AND METHODS

Patients

We consecutively enrolled patients with suspicion of

choledocholithiasis undergoing both MDCT and ERCP during the period from March 2010 and February 2012 at a single institution. Hematologic and biochemical tests were performed at the time of admission. Suspected choledocholithiasis was defined as follows: recent abdominal pain, leukocytosis, and/or abnormal blood chemistry findings including total bilirubin, alanine aminotransaminase, alkaline phosphatase, or γ -glutamyl transferase levels. Exclusion criteria were as follows: CT from other institution, more than one month duration between MDCT and ERCP, failure in removing CBD stones by ERCP, and patients suspected of cystic duct stones. After MDCT, MRCP or EUS was performed for further determination of CBD stones if possible. ERCP was performed when the imaging study showed CBD stones or CBD stones were highly suspected despite negative imaging studies. Patient anonymity was preserved and the Institutional Review Board of our hospital approved this study (HC12RISI0038). This study protocol was in complete compliance with the Declaration of Helsinki, as revised in Seoul in 2008.

Multidetector computed tomography

CT studies were performed either a 64-slice MDCT scanner (Somatom Sensation 64; Siemens, Erlangen, Germany) with a detector collimation of 24 mm \times 1.2 mm, a table feed of 28.8 mm per rotation, a rotation time of 1 s, a tube current of 200 effective mAs, and a tube voltage of 120 kV or a 16-slice MDCT scanner (Somatom Sensation 16; Siemens, Erlangen, Germany) with a detector collimation of 16 mm \times 1.5 mm, a table feed of 24 mm per rotation, a rotation time of 1 s, a tube current of 200 effective mAs, and a tube voltage of 120 kV. Precontrast scan ranged from the diaphragm to the iliac crest and postcontrast scan ranged from the diaphragm to the symphysis pubis. Contrast material (Ultravist 300, Bayer, Berlin, Germany) with a volume of 120 mL and an injection rate of 2 mL/s was injected into the antecubital vein. Image acquisition was initiated after 90 s of contrast injection. Pre and post contrast axial images were reconstructed by 5 mm without overlap and postcontrast coronal images by 3 mm without overlap.

Endoscopic retrograde cholangiopancreatography

ERCP was performed with a duodenoscope (JF 240; Olympus Optical Co., Ltd., Tokyo, Japan). Two experienced gastroenterologists who had performed > 1000 ERCPs conducted the procedures. Conscious sedation was achieved with midazolam and pethidine hydrochloride. Contrast media (iopromide; 1:1 dilution with saline) was injected to obtain a cholangiogram after cannulation of the common bile duct without papillotomy. If the cholangiogram was interpreted as positive for CBD stones, endoscopic sphincterotomy was performed and the bile duct was swept with a Dormia basket and a retrieval balloon catheter to remove the calculi. Following this, the calculi were taken out for the evaluation of stone

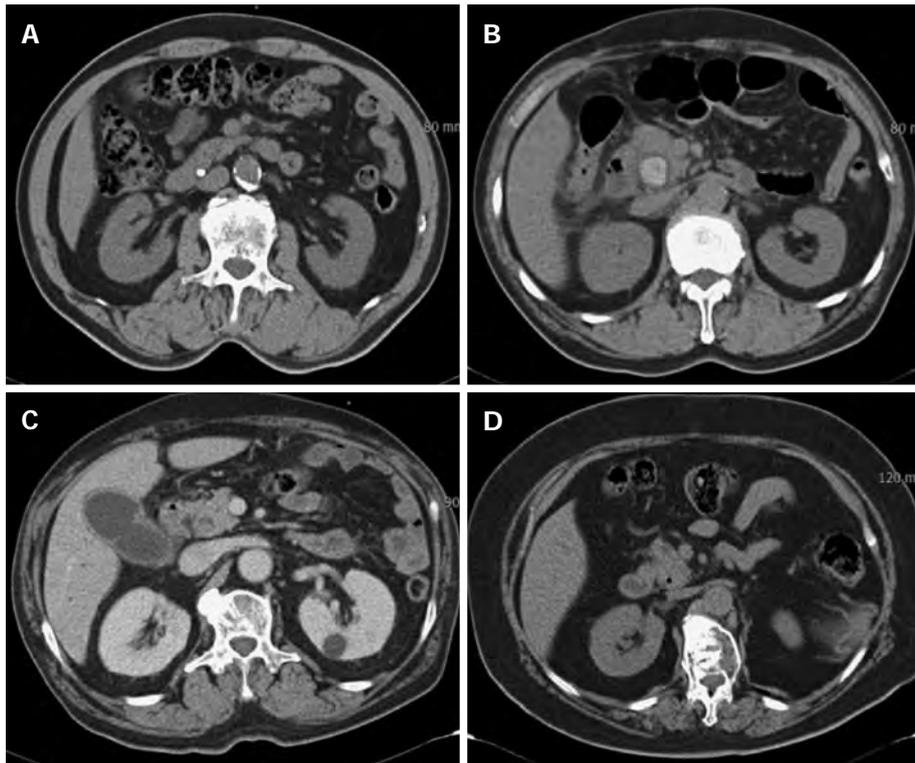

Figure 1 Attenuation patterns of common bile duct stones on multidetector computed tomography. A: Heavily calcified; B: Radiopaque; C: Less radiopaque; D: Gas attenuation in the stone.

type. If the cholangiogram was considered as negative for CBD stones, the absence of stones were confirmed again by a basket and a retrieval balloon catheter.

Analysis of images on multidetector computed tomography

CT scan data sets were transferred to picture archiving and communication system (PACS) workstations for analysis, and CT images were interpreted by one radiologist who had more than ten years of experience interpreting gastroenterological images. The radiologist received no clinical information or results of ERCP and used pre-contrast and portal venous phase images. Pre-contrast images were used for the initial detection of CBD stones. If the stones could not be discriminated in pre-contrast images, portal venous phase images served as references. The radiologist was free to use the window settings he preferred, which included narrow settings if a common duct stone was not initially identified on soft tissue window settings. The mean Hounsfield units of the stones were measured on PACS workstations. The attenuation patterns of CBD stones were classified as follows (Figure 1): (1) heavily calcified as having very high attenuation (mean Hounsfield unit > 150); (2) radiopaque as having distinctly higher attenuation than surrounding structures ($150 \geq \text{mean Hounsfield unit} > 80$); (3) less radiopaque as having slightly higher attenuation than surroundings (mean Hounsfield unit ≤ 80); and (4) gas attenuation as having a gas in or around the

stones^[16]. Common bile duct caliber was measured using the axial image of CT.

Type and size of common bile duct stones

Types of stones were classified by morphology as black pigment, brown pigment, and cholesterol stones according to the NIH-International Workshop^[14]. The color and shape on the external appearance and cross sectional shape on the internal structure were used as indexes. Cholesterol stones were subclassified into pure cholesterol stones, mixed stones, and combination stones according to the classification of the Japanese Society of Gastroenterology^[15]. To reduce the confusion in discrimination between mixed and combination stones, they both were classified as mixed stone. For measuring the stone size and number, MDCT (axial and coronal), MRCP, EUS, and/or ERCP were utilized together. The largest diameter of the stone, as the representative of size, was measured using electronic calipers on the workstation. If there were more than two stones, the largest stone was selected for the evaluation of stone type and stone size.

Statistical analysis

A Pearson's χ^2 test or Fisher's exact test was used to compare categorical data and Student's *t*-test or Mann-Whitney *U*-test was used for comparisons of continuous data to analyze the attenuation patterns and the detectability of CBD stones. A linear by linear association was used to analyze the trend between the attenuation patterns and the

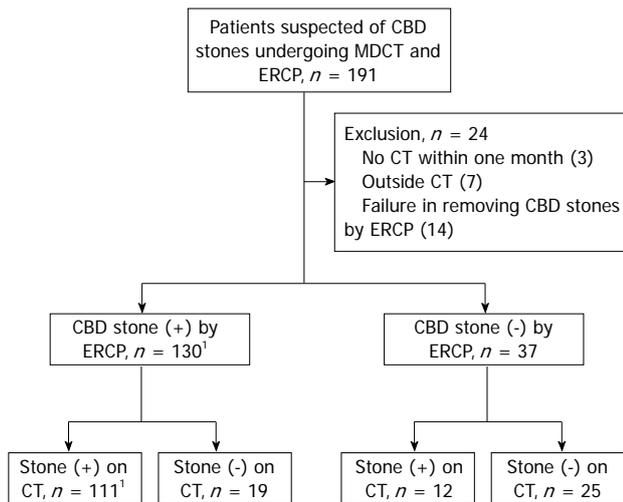

Figure 2 Flow chart of patients with suspicion of common bile duct stones undergoing multidetector computed tomography and endoscopic retrograde cholangiopancreatography. The sensitivity of multidetector computed tomography (CT) for common bile duct stones was 85.4%. ¹Two patients had recurrent common bile duct stones during the study period. CBD: Common bile duct; ERCP: Endoscopic retrograde cholangiopancreatography.

stone type. Receiver operating characteristic curve for CT detectability of CBD stone according to stone size was plotted. The area under the curve and the optimal cut-off value of stone size for CT detectability were calculated. Multivariate analysis for the related factors to the detectability of CBD stones by MDCT was performed with the significant factors identified from univariate analysis using binary logistic regression analysis (enter method). Statistical analyses were performed with SPSS, version 14 (SPSS, Inc., Chicago, IL, United States). *P*-values < 0.05 were considered significant.

RESULTS

Patients

One hundred ninety-one patients with suspicion of CBD stones undergoing MDCT and ERCP were consecutively enrolled from March 2010 and February 2012 (Figure 2). Twenty-four patients were excluded because they did not undergo CT within 1 mo (3), received CT from other institution (7), and failed to remove CBD stones by ERCP (14). This resulted in a study population of 167 patients consisting of 86 males and 81 females with a mean age of 65.7 years (SD, ± 15.9 years). The mean time between MDCT and ERCP was 2.4 d (SD, ± 4.5 d). MDCT was performed with 64-channel or 16-channel in 76% and 23%, respectively. CBD stones were demonstrated by ERCP in 130 patients. Of them, 54 (42%) patients had accompanying gallbladder stones and 31 (24%) previously received cholecystectomy. Thirteen patients (10%) underwent endoscopic sphincterotomy previously. The mean number of CBD stones was 2.0 (SD, ± 1.6). The types of stones revealed by ERCP was as follows: 23

Table 1 Correlation between the attenuation patterns of common bile duct stones on multidetector computed tomography and stone type (*n* = 111)

| Attenuation patterns | Stone type, <i>n</i> (size, mean ± SD, mm) | | | | Overall |
|------------------------------|--|-------------------|---------------|------------------|--------------|
| | Black pigment | Mixed cholesterol | Brown pigment | Pure cholesterol | |
| Heavily calcified | 15 | 14 | 5 | 0 | 34 |
| Radiopaque | (6.1 ± 3.4) | (7.0 ± 3.2) | (9.2 ± 4.1) | | (6.9 ± 3.5) |
| Less radiopaque ¹ | 3 | 12 | 16 | 0 | 31 |
| Overall | (7.0 ± 1.0) | (10.2 ± 4.3) | (13.6 ± 4.8) | | (11.6 ± 4.8) |
| Less radiopaque ¹ | 3 | 10 | 33 | 0 | 46 |
| Overall | (5.7 ± 4.0) | (7.6 ± 3.5) | (9.9 ± 5.1) | | (9.1 ± 4.8) |
| Overall | 21 | 36 | 54 | 0 | |
| | (6.2 ± 3.1) | (8.2 ± 3.6) | (10.9 ± 5.1) | | |

¹Including six less radiopaque stones with gas attenuation. *P* < 0.001.

(18%) black pigment stones, 38 (29%) mixed cholesterol stones, 60 (46%) brown pigment stones, and 9 (7%) pure cholesterol stones. The mean size of stones were 10.1 mm (SD, ± 5.4 mm), 8.0 mm (SD, ± 3.9 mm), 5.8 mm (SD, ± 3.2 mm), and 5.7 mm (SD, ± 3.8 mm) in brown pigment, mixed cholesterol, black pigment, and pure cholesterol stones, respectively. The brown pigment stones were significantly larger than other types of stones (*P* < 0.05).

Attenuation patterns of common bile duct stones

The attenuation patterns of CBD stones consisted of heavily calcified 34 (31%), radiopaque 31 (28%), and less radiopaque (41%, Table 1). The mean Hounsfield units were 421 (range, 156-1552), 104 (range, 81-141), and 59 (range, 11-80) in heavily calcified, radiopaque, and less radiopaque patterns, respectively. The radiopacity of stones differed significantly according to stone type (*P* < 0.001). An increasing trend in the radiopacity was observed among brown pigment, mixed cholesterol, and black pigment stones by analysis with a linear-by-linear association (*P* < 0.001). The mean size of heavily calcified stones, radiopaque stones, and less radiopaque stones differed significantly (*P* < 0.05). The order of mean stone size according to the radiopacity was radiopaque stones, less radiopaque stones, and heavily calcified stones. Heavily calcified and radiopaque stones were well discriminated on the pre-contrast images of MDCT. For less radiopaque stones, the images of portal venous phase were helpful in discriminating CBD stones because bile duct was well shown in that phase. The coronal reconstructed CT scan was useful in one patient. One mixed cholesterol stone with less radiopacity was ambiguous on portal venous-phase images, but the coronal reconstructed CT scan showed less radiopaque stone near the major ampulla (Figure 3). Of 46 less radiopaque stones, six stones had a pattern of gas attenuation in or around the stones which were less radiopaque or not well discriminated. All patients with gas attenuated stones had previously undergone endoscopic sphincterotomy.

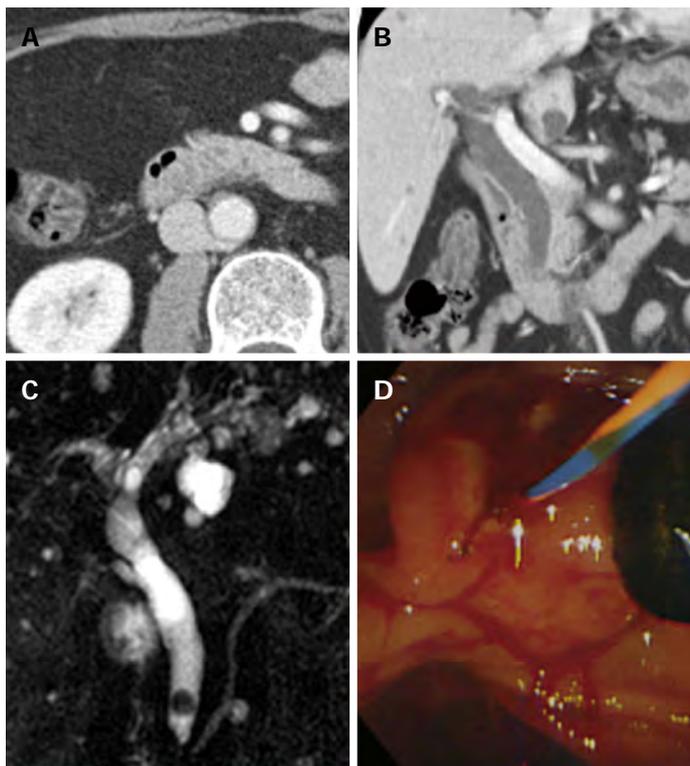

Figure 3 A case of difficult discrimination of common bile duct stone on the axial image of multidetector computed tomography. The coronal reconstructed image was helpful. A: The stone was ambiguous on the portal venous-phase axial computed tomography (CT) scan; B: The coronal reconstructed CT scan showed a less radiopaque stone near the major ampulla; C, D: Magnetic retrograde cholangiopancreatography and endoscopic retrograde cholangiopancreatography showed a six mm, mixed common bile duct stone.

Table 2 Detectability of common bile duct stones according to stone size and stone type *n* (%)

| | <i>n</i> | Detectable (<i>n</i> = 111) | Undetectable (<i>n</i> = 19) | <i>P</i> value |

Detectability of common bile duct stones

The detectability of CBD stones by MDCT increased according to stone size (Table 2). 96% of stones larger than 5 mm were detectable by MDCT, but 67% of stones smaller than 5 mm were detectable (*P* < 0.001). Three stones were not detected by MDCT despite having a size of more than 5 mm and they all were determined to be pure cholesterol stones. The detection rate of CBD stones less than 3 mm was 44% (4/9). Although this rate was less than the detection rate of CBD stones between 3-5 mm (75%, 29/40), it was not statistically significant. From the receiver operating characteristic curve, stone size was useful for the determination of

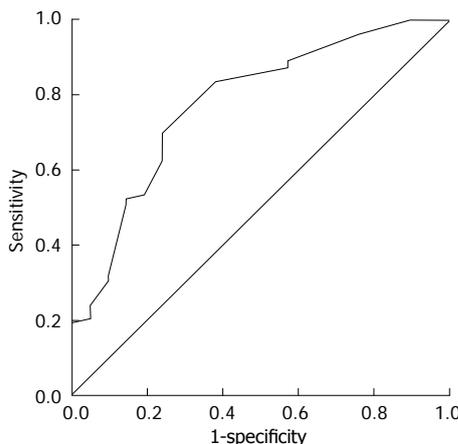

Figure 4 Receiver operating characteristic curve of the detectability of multidetector computed tomography for common bile duct stones according to stone size. The area under the curve was 0.779 and the optimal cut-off value of stone size was 5 mm.

CBD stone by MDCT (area under curve 0.779, *P* < 0.001, Figure 4). Appropriate cut-off stone size considering sensitivity and specificity was 5 mm. The detection rate of black pigment or mixed cholesterol stones (93%) was higher than that of brown pigment or pure cholesterol stones (78%, *P* = 0.023). However, the detection rate did not differ among black pigment, mixed cholesterol, and brown pigment stones. Nineteen undetected CBD stones by MDCT consisted of nine pure cholesterol stones, six brown pigment stones, two black pigment stones, and two mixed cholesterol stones. Of them, the sizes of all stones except for the pure cholesterol stones were less

Table 3 Univariate analysis of the factors related to the detectability of common bile duct stones by multidetector computed tomography *n* (%)

| Factors | Detectable (<i>n</i> = 111) | Undetectable (<i>n</i> = 19) | <i>P</i> value |
|----------------------------------|---------------------------------|----------------------------------|----------------|
| Age (yr) | 68.3 ± 14.2 | 58.0 ± 16.2 | 0.009 |
| Male sex | 58 (52) | 9 (47) | 0.966 |
| Accompanying GB stones | 43 (39) | 11 (58) | 0.117 |
| Previous cholecystectomy | 28 (25) | 3 (16) | 0.561 |
| Previous sphincterotomy | 13 (12) | 0 (0) | 0.213 |
| Black or mixed stone | 57 (51) | 4 (21) | 0.009 |
| Stone size (mm) | 9.1 ± 4.8 | 4.3 ± 2.9 | < 0.001 |
| CBD diameter (mm) | 12.4 ± 4.6 | 9.2 ± 3.5 | 0.005 |

CBD: Common bile duct; WBC: White blood cell.

than 5 mm. The size of two black pigment stones which were undetected by MDCT were as small as 1 and 3 mm.

The related factors to the detectability of CBD stones were age, stone type, stone size, and CBD diameter in univariate analysis ($P < 0.01$, Table 3). In multivariate analysis, age, stone size, and stone type were significant independent factors for CBD stone detectability by MDCT ($P < 0.05$, Table 4). Of them, stone size and stone type had large odds ratios of 8.851 (95%CI: 2.249–34.84) and 1.437 (95%CI: 1.153–1.791), respectively.

DISCUSSION

Abdominal CT has been a very popular procedure in routine clinical practice. Rapidity, relatively low cost, extensive information about the abdomen, and wide availability facilitate the use of CT. Especially in the emergency department, the utilization of CT has increased for the rapid detection of pancreato-biliary diseases. CT has been developed from conventional to helical CT. Recently, multi-detector CT was introduced and has been used in many institutions. Helical CT using MDCT technology can use thin slice images in a single breath-hold and reconstruct those slices retrospectively using a variable overlap. It reduces much of the image degradation previously experienced from motion artifacts and volume averaging^[13]. As CT technology continues to improve with the increasing use of 16-, 32-, 64-, and 256-MDCT, it is likely that the accuracy for the detection of choledocholithiasis in patients undergoing routine abdominal CT will improve^[12]. MDCT showed better results than previous studies that showed various sensitivities for the detection of choledocholithiasis by CT range

Table 4 Multivariate analysis of the factors related to the detectability of common bile duct stones by multidetector computed tomography

| Factors | <i>P</i> value | Odds ratio (95%CI) |
|---|----------------|---------------------|
| Age | 0.032 | 1.049 (1.004-1.095) |
| Stone type (black or mixed <i>vs</i> brown or pure cholesterol) | 0.002 | 8.851 (2.249-34.84) |
| Stone size | 0.001 | 1.437 (1.153-1.791) |
| CBD diameter | 0.538 | |

CBD: Common bile duct.

from 71% to 93%^[17-21], with a mean sensitivity of approximately 80%. In the present study, MDCT displayed a sensitivity of 85.4% for the detection of CBD stones. Although MDCT has a better resolution and can detect greater number of small stones, there is a theoretic limitation for the detectability of choledocholithiasis by CT due to the iso or slightly hypoattenuating nature of pure cholesterol stones relative to bile, making them difficult to detect^[13,22-24].

The detectability of CBD stones by MDCT depends on several factors. The present study showed that the factors related to the detectability of CBD stone were age, stone size, and stone type. Although the optimal size of CBD stones for MDCT detection was determined as 5 mm, 67% of CBD stones smaller than 5 mm were detectable by MDCT. This showed that MDCT had some role in the initial screening even for small CBD stones less than 5 mm. The radiopacity of stones differed significantly according to stone type. Black pigment and mixed cholesterol stones were more detectable than brown and pure cholesterol stones. However, attenuation patterns could not discriminate between specific stone types because of the overlap in CT attenuation. A previous study showed that the mean CT attenuation of cholesterol stones was lower than that of pigment gallstones, and CT attenuation measurement was not useful for the determination of gallstone composition due to the overlap of CT attenuation values^[25]. Besides the type and size of stones, the position of stones can influence the detectability. It is recognized that small stones impacted at the ampulla are difficult to identify, particularly in non-dilated biliary ducts. One patient in the present study has a CBD stone near the ampulla, and it was detected by a coronal image rather than an axial image. Unfortunately, a previous study revealed that CT coronal images did not show significant improvement of diagnosis for CBD stones^[11]. We consider that coronal images do not increase the general detectability of CBD stones, but it may become helpful in special situations such as stones near the ampulla. The phase of CT image is another factor concerning the detectability of CBD stones. It was reported that portal venous phase CT images are specific and sensitive for the detection of biliary duct narrowing and choledocholithiasis^[26]. Radiopaque stones are well demarcated on a precontrast image, but

less radiopaque stones are not easily discriminated on a precontrast image. Portal venous phase images show common bile duct clearly, so it helps discriminate CBD stones especially for less radiopaque stones. Peak voltage setting also affects the detection of gallstones. In a study to evaluate the effect of four peak voltage settings (80, 100, 120, and 140 kV) on the *in vitro* conspicuity of gallstones in an anthropomorphic phantom by CT, the sensitivity for gallstone detection was significantly higher at 140 kV^[25]. We used 120 kV for the peak voltage setting on MDCT. 140 kV would increase the sensitivity of MDCT according to a previous study. However, the danger of increasing radiation hazard cannot be neglected. In the present study, the diameter of the bile duct affected the CT detectability of CBD stones in univariate analysis, but not in multivariate analysis. This was probably because the diameter of the bile duct is related to stone size. Although age was a significant factor related to the detectability, the odds ratio of age was as small as 1.049 and the lower limit of 95% confidence interval was close to 1 (1.004). Therefore, it can be stated that age showed little clinical significance. With regard to age, it could be considered that younger patients had a tendency of small stones and cholesterol stones. However, this needs the further investigation.

Formation of pigment stones in the bile duct is a late complication of endoscopic sphincterotomy^[27]. Sphincterotomy permits chronic bacterial colonization of the bile duct that results in deconjugation of bilirubin and precipitation of pigment stones. In the present study, all six patients with gas attenuated stones had previously undergone endoscopic sphincterotomy. According to our results, if CBD stones were indistinct by CT and air attenuations were found in the CBD in patients previously undergoing endoscopic sphincterotomy, CBD stones would be strongly suspected and further studies should be performed for the confirmation of CBD stones.

Gallstones are extremely common in Western countries, where the prevalence of bile-duct stones is relatively low. In contrast, primary choledocholithiasis and hepatolithiasis appear to be more frequent in East Asian countries than in Western societies^[28,29]. Primary bile duct stones are predominantly composed of calcium bilirubinate, namely brown pigment stones. The pathogenesis of primary bile duct stones is based on bile stasis and infection, which are associated with bile duct strictures, extrahepatic anomalies, and biliary parasites. In contrast, secondary stones are considered to originate from gallbladder stones, and are commonly composed of cholesterol. In the present study, the proportion of cholesterol stones, black pigment stones, and brown pigment stones were 36%, 18%, and 46%, respectively. Tazuma^[28] reported that the proportion of cholesterol stones, black pigment stones, and brown pigment stones in the CBD were 31%, 12%, and 54%, respectively in

Japan. This was similar to our study. In a Korean population study of bile duct stones 14 years ago, the majority were brown pigment stones (76%), and the remaining were cholesterol stones (18%) and black pigment stones (4%)^[30]. The discrimination of stone type is sometimes difficult. Atypical stones with a black or brown colored surface, but with a radial fashioned surface and a high cholesterol content are not rare^[15,31,32]. These stones are frequently confused by their external appearance with black pigment stones originating from the gallbladder. We used color and shape on the external appearance and cross sectional shape on the internal structure as the indexes to reduce such confusion. Mixed and combination stones were classified as mixed stones to make a clear classification. Some investigators classify mixed or combination stone as stones of the intermediate group which are difficult to classify into either cholesterol stones or pigment stones^[15].

There were some limitations in the present study. First, this was a retrospective study. Some disparity in the interpretation of CBD stones between the original time of the examination and the time of the study can exist. The interpreter in the present study who was primed for the detection of choledocholithiasis likely led to a little improved sensitivity for detection for bile duct stones compared with real-time interpretations at the time of the examination. Second, stone composition analysis was not performed. Analysis using spectroscopy would help determine stone type more precisely. However, we exerted the greatest effort to determine stone type by using the color and shape on the external appearance and cross sectional shape on the internal structure. Third, reformation of MDCT images was not performed. Reformation process such as multiplanar reformation or minimum intensity reformation helps with the detection of gallstones^[33,34]. However, reformation needs an additional process which requires much time and effort. Most hospitals do not perform reformation as a routine procedure due to this restraint.

In conclusion, MDCT showed a moderately high sensitivity for the detection of CBD stones, and the radiopacity of CBD stones by MDCT differed according to stone type. Type and size of stones were significant factors related to the detectability of CBD stones. We expect further prospective studies with a larger cohort of patients to demonstrate the characteristics of CBD stones by MDCT.

COMMENTS

Background

Multidetector computed tomography (MDCT) can reveal the heterogeneous nature of the biliary stones in attenuation patterns ranging from being heavily calcified and radiopaque, to being slightly less radiopaque than bile due to cholesterol, to having gas attenuation due to locules of nitrogen gas. The association between the attenuation patterns of common bile duct (CBD) stones on MDCT and the gallstone type has not been clarified. It is also not fully elucidated how the types and size of stones affect the detectability of MDCT.

Research frontiers

This study demonstrated that the radiopacity of CBD stones differed significantly according to stone type. Stone size was important for the determination of CBD stone by MDCT, and appropriate cut-off stone size was 5 mm. The factors related to detectability of CBD stones on MDCT were age, stone type, and stone size.

Innovations and breakthroughs

This is the first report the radiopacity of CBD stones according to stone type. MDCT showed moderately high sensitivity for the detection of CBD stones. Although magnetic retrograde cholangiopancreatography or endoscopic ultrasonography is considered more accurate method for the detection of CBD stones, MDCT also had good sensitivity and can give information about stone type.

Applications

MDCT is useful method for detection of CBD stones, especially when CBD stones are more than 5 mm. Stone type can be estimated by the radiopacity of CBD stones on MDCT

Peer review

The author evaluated the role of MDCT in detection of CBD stones, and found a moderately high sensitivity for the detection of CBD stones, and the radiopacity of CBD stones by MDCT differed according to stone type. The article is of great significance in clinical evaluation of CBD stones by this approach.

Abstract

AIM: To investigate the 10-year results of treating low rectal cancer by a single surgeon in one institution.

METHODS: From Oct 1998 to Feb 2009, we prospectively followed a total of 62 patients with cT2-4 low rectal cancer with lower tumor margins measuring at 3 to 6 cm above the anal verge. All patients received neo-

adjuvant chemoradiation (CRT) for 6 wk. Among them, 85% of the patients received 225 mg/m²/d 5-fluorouracil using a portable infusion pump. The whole pelvis received a total dose of 45 Gy of irradiation in 25 fractions over 5 wk. The interval from CRT completion to surgical intervention was planned to be approximately 6-8 wk. Total mesorectal excision (TME) and routine defunctioning stoma construction were performed by one surgeon. The distal resection margin, circumferential resection margin, tumor regression grade (TRG) and other parameters were recorded. We used TRG to evaluate the tumor response after neoadjuvant CRT. We evaluated anal function outcomes using the Memorial Sloan-Kettering Cancer Center anal function scores after closure of the defunctioning stoma.

RESULTS: The median distance from the lower margin of rectal cancer to the anal verge was 5 cm: 6 cm in 9 patients, 5 cm in 32 patients, 4 cm in 10 patients, and 3 cm in 11 patients. Before receiving neoadjuvant CRT, 45 patients (72.6%) had a cT3-4 tumor, and 21 (33.9%) patients had a cN1-2 lymph node status. After CRT, 30 patients (48.4%) had a greater than 50% clinical reduction in tumor size. The final pathology reports revealed that 33 patients (53.2%) had a ypT3-4 tumor and 12 (19.4%) patients had ypN1-2 lymph node involvement. All patients completed the entire course of neoadjuvant CRT. Most patients developed only Grade 1-2 toxicities during CRT. Thirteen patients (21%) achieved a pathologic complete response. Few post-operative complications occurred. Nearly 90% of the defunctioning stomas were closed within 6 mo. The local recurrence rate was 3.2%. Pathologic lymph node involvement was the only prognostic factor predicting disease recurrence (36.5% vs 76.5%, $P = 0.006$). Nearly 90% of patients recovered sphincter function within 2 year after closure of the defunctioning stoma.

CONCLUSION: Neoadjuvant CRT followed by TME,

combined with routine defunctioning stoma construction and high-volume surgeon experience, can provide excellent surgical quality and good local disease control.

Lin SC, Chen PC, Lee CT, Tsai HM, Lin PC, Chen HHW, Wu YH, Lin BW, Su WP, Lee JC. Routine defunctioning stoma after chemoradiation and total mesorectal excision: A single-surgeon experience. *World J Gastroenterol* 2013; 19(11): 1797-1804 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1797.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1797>

INTRODUCTION

Since total mesorectal excision (TME) was first described by Heald in 1982, low rectal cancer treatment has experienced a revolutionary advancement. The traditional abdominoperineal resection procedure has gradually been replaced by TME and coloanal anastomosis for resectable rectal cancers. Improved overall survival and decreased local recurrence rates have been achieved with the combined progression of knowledge about surgical anatomy and technique, new chemotherapy regimens and radiotherapy technology. For locally advanced rectal cancers, randomized controlled trials have shown that neoadjuvant chemoradiation therapy (CRT) leads to a decrease in tumor size and enhances the possibilities of tumor resectability and sphincter preservation^[1,2]. Furthermore, with new chemotherapy regimens developing at a rapid pace, every new clinical trial has attempted to incorporate these new drugs into their protocols to gain better oncologic results. However, the complications related to CRT overuse can be devastating, including treatment toxicity, anastomotic leakage, or any type of postoperative complications, such as persistent fistula^[3] and subsequent permanent colostomy. These complications can adversely affect patient quality of life and even make patients abandon the treatment course before the scheduled operation. In addition, many large series have reported that chemotherapy regimens can differ between series and surgeon experience can be variable between the institutions, making a uniform comparison difficult. To avoid these problems, our team has adopted a less toxic chemotherapy regimen and routine defunctioning stoma construction after TME surgery since the initiation of the treatment protocol 10 year ago. Because surgical resection remains the only curative treatment for locally advanced rectal cancer, we believe patients will have better chance of cure if they can benefit from neoadjuvant CRT without associated complications and

proceed to surgical operations in good physical condition. The aim of this report is to present our recent 10 years' experience of 62 consecutive low rectal cancer patients undergoing neoadjuvant CRT and TME surgery at National Cheng Kung University Hospital where all operations were performed in a standard fashion by a single surgeon.

MATERIALS AND METHODS

From Oct 1998 to Feb 2009, we prospectively followed patients with locally advanced low rectal cancer who underwent a radical operation by a single surgeon, Jenq-Chang Lee. Patients with clinical tumor category cT2-4 or clinical node category cN1-2 low rectal cancer and a lower tumor margin within 3-6 cm of the anal verge were offered the choice of receiving neoadjuvant CRT and were included in the study. The exclusion criteria included other synchronous malignancies, previous chemotherapy or radiotherapy to the pelvis, contraindications to CRT and unwillingness to receive neoadjuvant CRT. All patients had a confirmed pathological diagnosis before undergoing any treatment. Among a total of 302 rectal cancers operated by Dr. Lee during this time period, 63 consecutive patients were included according to the above criteria. All but one patient received neoadjuvant CRT and then underwent a radical operation. All operations achieved R0 resection. One patient was excluded because she refused the radical operation after CRT. In the end, a total of 62 patients were included for retrospective data analysis. All of them were followed for more than 3 year.

A clinical staging evaluation was performed before neoadjuvant CRT with a digital examination and computed tomography. Magnetic resonance imaging, endorectal ultrasonography and positron emission tomography were used selectively. All patients were well informed before treatment initiation. All patients received neoadjuvant CRT for 6 wk. Among them, 85% of the patients received 225 mg/m²/d 5-fluorouracil (5-FU) using a portable infusion pump. The whole pelvis received a total dose of 45 Gy of irradiation in 25 fractions over 5 wk. The duration from CRT completion to surgical intervention was planned to be approximately 6-8 wk. The clinical staging was re-evaluated just before the operation. Each rectal cancer was reviewed and staged according to the American Joint Committee on Cancer Staging Manual^[4]. The distal resection margin (DRM), circumferential resection margin (CRM), tumor regression grade (TRG) and other parameters were recorded. We used the TRG to evaluate the tumor response to neoadjuvant CRT^[5]. The follow-up protocol was based on the National Comprehensive Cancer Network (NCCN) guidelines^[6]. We evaluated anal function outcomes using the Memorial Sloan-Kettering Cancer Center anal function scores (MSK-AF)^[7] after closure of the defunctioning stoma.

¹Evaluated by digital examination and computed tomography; ²Grade I - II;

³Grade I - III. CRT: Chemoradiation therapy.

Surgical technique

Total mesorectal excision (TME) was performed in every patient. The methods of TME^[8,9] have previously been described in detail. Low anterior resection with the double-stapling technique and straight coloanal anastomosis was attempted in every patient if feasible. If double-stapling anastomosis could not be performed for low-lying rectal cancer, intersphincteric resection was performed for patients with adequate oncological margins. Abdominoperineal resection (APR) was chosen for patients with inadequate oncological margins or by patients themselves. All patients who underwent sphincter-saving procedures underwent the routine construction of a defunctioning loop colostomy or ileostomy. The defunctioning loop colostomy construction was performed by simply pulling the transverse colon out through the right upper quadrant abdominal wall incision and was matured immediately without placing a fixation suture between the colonic serosa and abdominal wall peritoneum or fascia layer.

Post-operative adjuvant chemotherapy

Postoperative adjuvant chemotherapy was proposed to every patient. A total of five patients (8.1%) refused adjuvant chemotherapy. Forty-one patients (71.9%) received a short-term infusion of 5-FU/leucovorin. Fourteen patients (24.6%) received either the FOLFOX or FOLFIRI regimen. Two patients (3.5%) received oral capecitabine. Two patients (3.5%) did not complete adjuvant chemotherapy due to personal reasons.

Statistical analysis

The survival rates were assessed by Kaplan-Meier analysis, and survival curves were compared by the log-rank test. The analysis was performed using Prism 4 software. A *P* value < 0.05 (two tailed) was regarded as statistically significant.

Table 2 Peri-operative and pathological characteristics (n = 62) n (%)

| Variable | |

| 2-3 | 41 (66.1) |
| 4-5 | 8 (12.9) |

¹Tumor regression grade (TRG): Grade 1, no residual tumor; Grade 2, rare residual cancer; Grade 3, fibrosis outgrowing residual cancer; Grade 4, residual cancer outgrowing fibrosis; Grade 5, absence of regressive change. DRM: Distal resection margin; CRM: Circumferential resection margin; APR: Abdominoperineal resection; TME: Total mesorectal excision.

RESULTS

Patient demographics

The patient demographics are summarized in Table 1. The median distance from the lower margin of the rectal cancer to the anal verge was 5 cm: 6 cm in 9 patients, 5 cm in 32 patients, 4 cm in 10 patients, and 3 cm in 11 patients. Before neoadjuvant CRT, 45 patients (72.6%) had a cT3-4 tumor and 21 (33.9%) patients had a cN1-2 lymph node status. After CRT, 30 patients (48.4%) had a greater than 50% clinical reduction in tumor size. The final pathology reports revealed that 33 patients (53.2%) had a ypT3-4 tumor and 12 (19.4%) patients had ypN1-2 lymph node involvement. All patients completed the entire course of neoadjuvant CRT.

Toxicity associated with chemoradiation

The toxicity profiles are summarized in Table 1. Twenty-seven patients (43.5%) experienced Grade 1-2 toxicity. No Grade 4-5 toxicity was reported. Adverse events were graded according to the National Cancer Institute Common Terminology Criteria^[10].

Surgical and pathological characteristics

The peri-operative characteristics are summarized in Table 2. All patients who underwent sphincter-preserving surgery also underwent temporary defunctioning stoma construction. Among them, fifty-four patients (96.4%) underwent a loop transverse colostomy, and two patients underwent a loop ileostomy.

Table 3 Post-operative morbidity and mortality (*n* = 62) *n* (%)

| | Case number |
|--------------------------------|-------------|
| Mortality | 0 (0) |
| Early complication | |
| Anastomotic leakage | 1 (1.6) |
| Wound infection | 2 (3.2) |
| Delayed perineal wound healing | 1 (1.6) |
| Pelvic abscess | 0 (0) |
| Rebleeding | 0 (0) |
| Adhesion ileus | 1 (1.6) |
| Central venous port infection | 1 (1.6) |
| Pneumonia | 0 (0) |
| Deep vein thrombosis | 0 (0) |
| Urinary tract infection | 1 (1.6) |
| Late complication | |
| Anastomotic stenosis | 1 (1.6) |
| Fistula formation | 0 (0) |
| Incisional hernia | 1 (1.6) |
| Anal bleeding | 2 (3.2) |

Operative morbidity and mortality

The post-operative morbidity and mortality are summarized in Table 3. One patient had subclinical Grade A anastomotic leakage by the definition of the International Study Group of Rectal Cancer^[11]. No patient developed Grade B or C anastomotic leakage. One patient developed post-operative adhesion ileus and recovered after conservative treatment. Late post-operative complications occurred in three patients, including incisional hernia, anastomotic stenosis, and occasional anal bleeding related to irradiation proctitis, which were all managed uneventfully and without the necessity of creating a permanent defunctioning stoma.

Anal function outcome

Six patients received APR. Among the 56 patients who underwent a sphincter-saving procedure, 49 patients also underwent defunctioning stoma closure, and their post-operative anal functions are summarized in Table 4. We performed the defunctioning stoma closure 5-6 mo after the sphincter-saving procedure and the completion of adjuvant chemotherapy. Among the seven patients who did not undergo stoma closure, four patients had early disease recurrence and one patient had a major co-morbidity. The other two patients died from noncancerous causes. The MSK-AF scores revealed that 32 patients (65.3%) had fair or poor anal function one month immediately after stoma closure. However, the proportion of patients with fair or poor anal function decreased at 12 (24.5%) and 24 (12.2%) mo. At 12 and 24 mo after defunctioning stoma closure, the proportion of patients with excellent or good anal function improved from 75.5% to 87.8%, meaning that most patients had recovered anal function within 1 to 2 year after stoma closure.

Recurrence and survival

The median follow-up period of our patients was 58 mo. All patients were followed up for more than 3 year. One

Table 4 Post-operative anal function (*n* = 49) *n* (%)

| | 1 ² | 12 ² | 24 ² |
|--------------------------|----------------------|----------------------|----------------------|
| MSK-AF ¹ (mo) | | | |
| Excellent/good | 8/9 (16.3/18.4) | 23/14 (46.9/28.6) | 23/20 (46.9/40.8) |
| Fair/poor | 12/20 (24.5/40.8) | 10/2 (20.4/4.1) | 4/2 (8.2/4.1) |

¹Memorial Sloan-Kettering Cancer Center anal function score (MSK-AF): Excellent: 1-2 bowel movements/d and no soilage; Good: 3-4 bowel movement/d or mild soilage; Fair: More than 4 bowel movements/d or moderate soilage; Poor: More than 6 bowel movement/d or significant leakage or enema dependent; ²Periods after stoma closure.

patient (1.6%) had only local recurrence. One patient (1.6%) had both local recurrence and distant metastasis, and another thirteen patients (21%) had distant metastases. For patients with distant metastasis, the lungs were the most frequent site of metastasis (12/14, 85.7%). Seven patients with isolated lung metastasis underwent pulmonary metastasectomy, and four are still alive. For these four patients, lung metastasis occurred at 16, 17, 34 and 46 mo, respectively, after TME, and they have lived for an additional 21, 63, 41 and 20 mo, respectively, to date. Among the thirteen patients with a PCR, twelve patients (92.3%) remain disease free and one patient who refused adjuvant chemotherapy developed lung metastasis 18 mo after surgery.

Six patients (10%) died of disease recurrence. Four patients died from noncancerous causes. Nine patients (14.5%) had disease recurrence or distant metastasis but are still alive. The five-year overall survival and disease-free survival rates were 83.6% and 69.3%, respectively (Figure 1A). Our data show that, if patients achieved a pathologic complete response (PCR), a favorable disease-free survival trend could be observed in the TRG1 group, although no statistical significance was reached (Figure 1B, *P* = 0.07). Our data also demonstrate that persistent pathologic lymph node involvement after neoadjuvant CRT increases the risk of subsequent disease recurrence (Figure 1C, *P* = 0.006). However, neither TRG nor pathologic lymph node status affects overall survival.

DISCUSSION

This study investigated the treatment results of neoadjuvant CRT with protracted venous infusion of 5-FU followed by TME and routine defunctioning stoma construction in locally advanced low rectal cancer patients by a single surgeon at one institution. Beginning in 1998, we treated our locally advanced low rectal cancer patients with neoadjuvant CRT followed by TME surgery. In accordance with the NCCN guidelines, we have prescribed protracted venous infusion of 5-FU as a neoadjuvant radio-sensitizer for most patients with concurrent radiotherapy, which has resulted in less treatment toxicity and made all patients more likely to complete the entire

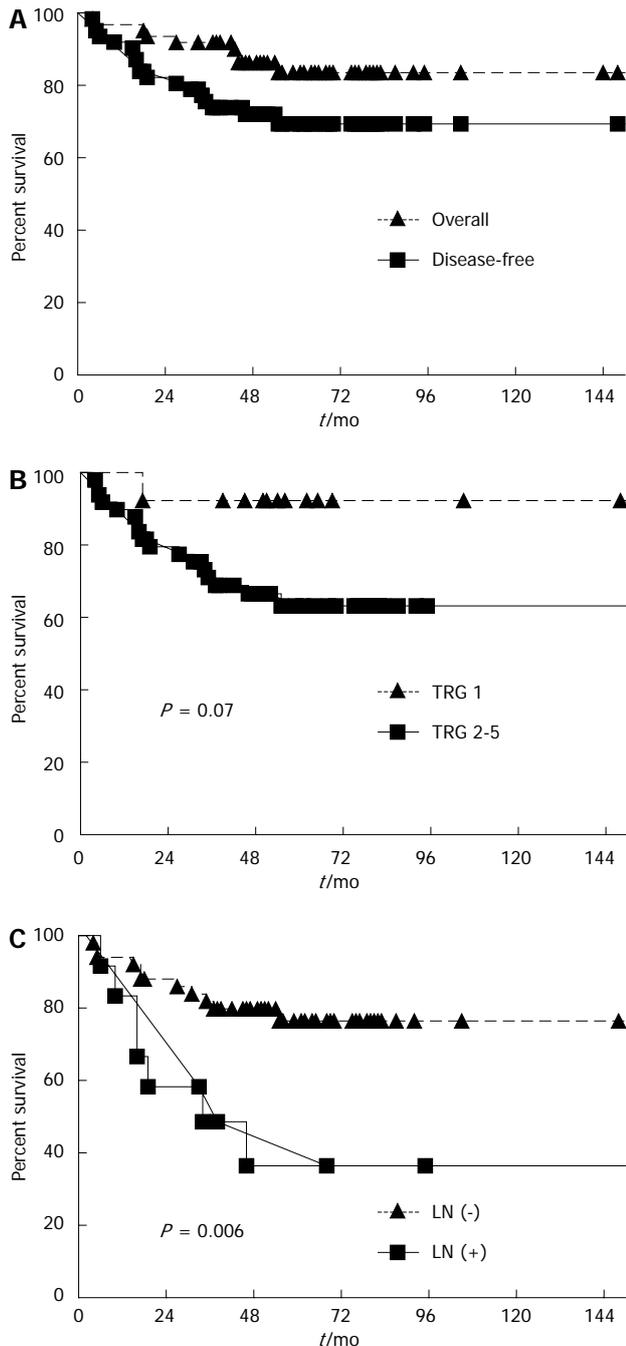

Figure 1 Five-year survival rate of the low rectal cancer patients treated with neoadjuvant chemoradiation and total mesorectal excision. A: The 5-year overall and disease-free Kaplan-Meier survival curves; B: The 5-year disease-free survival rates of patients with tumor regression grade (TRG) 1 and TRG 2-5 are 92.3% and 63.2%, respectively; C: The 5-year disease-free survival rates of patients with positive and negative lymph node (LN) involvement are 36.5% and 76.5%, respectively.

course of CRT and subsequent radical surgery after a 6-8 wk interval. Our protocol is identical to that of the Cleveland Clinic and has achieved very similar PCR and completion rates to theirs^[12]. With this neoadjuvant CRT protocol, we achieved a PCR rate of 21%, a nearly 50% decrease in preoperative tumor size, and only 1.6% associated Grade 3 toxicity, with a 100% CRT completion

rate. Long-term follow-up also demonstrated a five-year overall survival rate of 83.6%, a five-year disease-free survival rate of 69.3%, and a local recurrence rate of approximately 3%. These outcomes were comparable to other prospective trials using different neoadjuvant CRT regimens, including short-term 5-FU/leucovorin infusion and 5-FU plus oxaliplatin, cetuximab, or bevacizumab^[13]. Most of these trials reported PCR rates of 8%-20%. Very few reports using stronger regimens achieved more than 30% PCR rates^[14,15], but these also incurred more serious treatment toxicities, which could possibly make patients abandon the entire treatment protocol. Clearly, our protocol achieved lower treatment toxicity without compromising the desirable treatment effects of neoadjuvant CRT.

The DRM has been identified as one of the prognostic factors affecting local recurrence. In our series, the median DRM was 2.5 cm. All our patients achieved a DRM of more than 2 cm. However, in some studies, 1 cm was postulated to be a sufficient DRM in low rectal cancer patients receiving neoadjuvant CRT^[16]. The CRM is another important prognostic factor^[17]. Tumor involvement over the CRM has a negative impact on the five-year local recurrence, distant metastasis, and overall survival rates in patients with low rectal cancer^[18,19]. In our series, two patients (3.2%) acquired positive CRMs and developed local and distant metastases, corresponding to the negative impact on survival. In addition, recent studies have shown that a PCR is associated with favorable outcomes with regard to local control, disease-free survival and overall survival^[20-22]. In our series, we also achieved the same favorable trend.

Frequently, fewer than 12 lymph nodes can be harvested despite maintaining vigorous surgical standards in low rectal cancer patients if neoadjuvant CRT was performed^[23,24]. However, the persistence of lymph node metastasis after neoadjuvant radiotherapy is known to be associated with poorer prognosis and survival and may serve as a marker for more aggressive tumor behavior^[25]. In our series, the median number of retrieved lymph nodes was 8, which is the same as the median number of retrieved lymph nodes published in EORTC trial 22 921^[26]. Our result confirms that the persistence of lymph node metastasis after neoadjuvant CRT is a poor prognostic factor and a possible predictor of future recurrence.

Routine temporary defunctioning stoma construction after TME was, at one time, a controversial issue^[27]. However, current opinions have gradually shifted to support the routine construction of defunctioning stoma to decrease post-operative complications^[28-30]. A recent meta-analysis has also demonstrated that anastomotic leakage can have a negative impact on local recurrence and cancer-specific survival in colorectal cancers^[31]. In our series, a defunctioning loop stoma was created for every low rectal cancer patient treated with neoadjuvant CRT and a sphincter-saving procedure, achieving very

low rates of early and late surgical complications. Only one patient who underwent a sphincter-saving procedure suffered from sub-clinical anastomotic leakage. We believe that our good result was the consequence of stool diversion by the defunctioning stoma. In addition, we did not encounter major complications associated with the colostomy takedown procedure because we only trimmed the colocolic junction and closed the colonic wall directly, instead of routinely performing segmental resection. No sutures were used to attach the colon serosa to the abdominal wall fascia or peritoneum during the colostomy construction stage, and we therefore did not need to perform segmental resection of the colon at the colostomy reversal stage. Our method of colostomy construction and reversal was proven to be safe and feasible by other authors as well^[32]. Only patients dying shortly after the procedure due to early recurrence or noncancerous causes did not have their stomas closed. Based on our experience, we believe that routine defunctioning stoma construction prevents significant postoperative complications, including fistula formation due to anastomotic leakage and subsequent permanent colostomy, and guarantees a smooth and safe treatment course.

For patients undergoing TME and coloanal anastomosis, post-operative anal function recovery is crucial, and sphincter preservation without adequate function can be troublesome or even meaningless to patient quality of life. In addition, neoadjuvant radiotherapy has been reported to delay postoperative anorectal function recovery^[33]. In our series, one month after closure of the defunctioning stoma, only one third of the patients reported good to excellent sphincter function, but most recovered to good to excellent sphincter function within 2 year. Only 6 patients (12.2%) reported fair or poor anal sphincter function 2 year after closure of the defunctioning stoma. Our result was consistent with other reports noting that patients could achieve equal anal sphincter function two year after a straight coloanal anastomosis procedure to those who underwent J-Pouch coloanal anastomosis or T-coloplasty^[34].

TME is the integral part of low rectal cancer treatment in which surgeon experience plays the most critical role. However, current large series, both prospective and retrospective in nature, have to enroll a large numbers of patients and involve many surgeons with different training backgrounds and techniques. In this situation, surgeon experience is arbitrarily unified, and complications related to personal skill become difficult to evaluate. There is a paucity of evidence in the literature regarding the volume-outcome relationship in the field of rectal surgery. Two systemic reviews and a meta-analysis reveal that surgeons with more experience are associated with decreased mortality, decreased local recurrence, better overall survival, lower permanent stoma, and lower APR rates^[35,36]. The important surgical quality parameters of our team, including the DRM, CRM, retrieved lymph

node number, anastomotic leakage rate, and local recurrence rate, are in line with the current standards throughout the world. Our results can be largely attributed to the experience of the surgeon.

In conclusion, our experience demonstrates that neoadjuvant CRT with protracted venous infusion of 5-FU can minimize associated morbidities and achieve a comparable pathologic response for patients with locally advanced low rectal cancer. TME at 6-8 wk after CRT and routine defunctioning stoma construction can achieve excellent local control and better quality of life. The whole process can be safely executed in a standard fashion by experienced surgeons.

ACKNOWLEDGMENTS

The authors thank Dr. Chao-Han Lai for assistance with aspects of the statistical analysis of this manuscript.

COMMENTS

Background

Rectal cancer incidence has increased steadily year by year. Although surgical resection remains the only chance of cure, low rectal cancer surgery is still relatively difficult because the lesion is located in a confined pelvic space and is near the anal sphincters.

Research frontiers

The procedure of total mesorectal excision (TME) and pre-operative chemoradiation have gradually become a standard procedure for low rectal cancer. Clinical trials have successfully demonstrated that this procedure can decrease local recurrence rates and make tumor shrink before surgery, achieving better chance of anal sphincter preservation.

Innovations and breakthroughs

Although the procedure is popular in the western society, this is still not a common practice in the eastern society. The authors' ten-year single-surgeon experience demonstrates that this procedure can be safely performed with continuous infusion chemotherapy, routine defunctioning stoma construction and sufficient surgeon experience.

Terminology

TME is a surgical procedure involving resection of all perirectal soft tissue, which contains rectal lymphatic drainage and is the origin of local recurrence. Defunctioning stoma is a surgical procedure involving pulling out a part of bowel segment for stool diversion to protect the distal bowel anastomosis site.

Peer review

This is a paper addressing a single-surgeon's experiences regarding treatment for patients with mid-low rectal cancer. The authors emphasized the importance of routine defunctioning stoma after chemoradiation and TME. It is a reasonable paper although there are no novel points reported compared to pertinent literatures.

Abstract

AIM: To investigate the impact of esophagogastroduodenoscopy with conscious sedation on the subsequent 24-h catheter-based pH monitoring.

METHODS: Fifty patients with extra-esophageal symptoms of gastroesophageal reflux disease undergoing ambulatory dual-probe 24-h pH monitoring were enrolled from March 2010 to August 2011. All of the data were collected prospectively and analyzed retrospectively. Thirty-six patients (72%, group A) underwent pH monitoring shortly after esophagogastroduodenoscopy (EGD) with conscious sedation, and 14 patients (28%, group B) underwent pH monitoring without conscious

sedation. The 24-h pH data from two time periods were analyzed: the first 4 h (Period I) and the remaining time of the study (Period II).

RESULTS: The mean age of the patients was 49.6 ± 12.5 years; 20 patients (40%) were men. The baseline data, including age, sex, body mass index, reflux esophagitis, the Reflux Symptom Index, and the Reflux Findings Score, were comparable between the two groups. The percentage of total time with a pH < 4 and the frequency of acid reflux during Period I were not significantly different between the two groups, as measured using both pharyngeal ($0.03\% \pm 0.10\%$ vs $0.07\% \pm 0.16\%$, $P = 0.32$; and 0.07 ± 0.23 episodes/h vs 0.18 ± 0.47 episodes/h, $P = 0.33$, respectively) and esophageal probes ($0.96\% \pm 1.89\%$ vs $0.42\% \pm 0.81\%$, $P = 0.59$; and 0.74 ± 1.51 episodes/h vs 0.63 ± 0.97 episodes/h, $P = 0.49$, respectively). The percentage of total time with a pH < 4 and the frequency of acid reflux were also not significantly different between Periods I and II in group A patients, as measured using both pharyngeal ($0.03\% \pm 0.10\%$ vs $0.23\% \pm 0.85\%$, $P = 0.21$; and 0.07 ± 0.23 episodes/h vs 0.29 ± 0.98 episodes/h, $P = 0.22$, respectively) and esophageal probes ($0.96\% \pm 1.89\%$ vs $1.11\% \pm 2.57\%$, $P = 0.55$; and 0.74 ± 1.51 episodes/h vs 0.81 ± 1.76 episodes/h, $P = 0.55$, respectively).

CONCLUSION: EGD with conscious sedation does not interfere with the results of subsequent 24-h pH monitoring in patients with extra-esophageal symptoms of gastroesophageal reflux disease.

INTRODUCTION

The manifestation of gastroesophageal reflux disease (GERD) can be either esophageal or extra-esophageal^[1]. Extra-esophageal reflux, or laryngopharyngeal reflux (LPR), refers to the backflow of gastric contents into the larynx and pharynx^[1,2]. Ambulatory dual-probe 24-h pH monitoring is currently considered the gold-standard diagnostic modality for the evaluation of patients with LPR^[2-4]. This catheter-based pH measurement is performed with a pH sensor located within 2 cm above the proximal border of the upper esophageal sphincter (UES)^[5]. Prior manometry-guided localization is required to determine UES positioning relative to the nostril. The two trans-nasal procedures are usually performed without intravenous sedation. Therefore, they are unpleasant and uncomfortable tests for patients^[6,7].

Conscious sedation improves the quality of the test and increases the patient's willingness to undergo a gastrointestinal examination^[8]. Benzodiazepine administration and opiate-based sedation are the most common practices for conscious sedation^[9]. Meperidine causes a reduction in the LES pressure in animal and human studies^[10,11]. It may induce or exacerbate gastroesophageal reflux (GER), causing interference with pH studies^[11]. However, capsule-based (Bravo) wireless pH measuring system is usually performed during or shortly after an esophagogastroduodenoscopy (EGD) with conscious sedation^[12]. Therefore, it is unclear whether conscious sedation during EGD has an impact on the results of the subsequent esophageal pH test. To increase patient willingness to undergo 24-h pH monitoring, we attempted to perform a catheter-based pH study in a manner similar to the Bravo system in our patients. The aim of this study was to investigate whether EGD with conscious sedation interfered with subsequent catheter-based 24-h pH monitoring in patients with extra-esophageal symptoms of GERD.

MATERIALS AND METHODS

From March 2010 to August 2011, 53 patients with LPR-like complaints underwent ambulatory 24-h pH monitoring at the Chang Gung Memorial Hospital. These complaints included globus ($n = 27$), sore throat ($n = 13$), chronic cough ($n = 9$), hoarseness ($n = 3$), and dysphagia ($n = 1$). Three patients were excluded from the analysis because of numerous artifacts (pH out of range) on their pH records ($n = 2$) and intolerance of the procedure ($n = 1$). All of the patients were instructed to discontinue any

medications that affect gastric acid secretion and esophageal motility at least 7 d prior to the 24-h pH monitoring. This cohort study was incorporated into a prospective study (CMRPG390591) that was originally designed to evaluate the effects of different doses of proton pump inhibitors on the treatment of LPR. All of the data were collected prospectively and analyzed retrospectively. The study protocol was approved by the ethics committee at Chang Gung Memorial Hospital (IRB No: 99-3494C).

A total of 50 patients were enrolled in the current study. The mean patient age was 49.6 ± 12.5 years (range, 20-76 years). There were 20 (40%) men and 30 (60%) women. The mean body mass index (BMI) was 23.0 ± 3.2 kg/m² (range, 18.1-30.0 kg/m²). Group A included 36 patients (72%) who underwent EGD with conscious sedation 30 min prior to pH monitoring. Group B included the remaining 14 patients (28%) who did not undergo EGD or conscious sedation on the same day.

EGD with conscious sedation

All of the patients in group A underwent EGD with intravenous sedation using meperidine and midazolam on the same day prior to their 24-h pH monitoring study. The dosage of meperidine was 0.52 ± 0.10 mg/kg (range, 0.32-0.81 mg/kg), and the dosage of midazolam was 33.1 ± 7.1 g/kg (range, 16.1-53.6 g/kg). Hyoscine butylbromide was not given before or during the endoscopy in any of the participants.

Esophageal manometry and 24-h pH monitoring

All of the patients underwent esophageal manometry using a station pull-through technique to locate the UES in reference to the nostril. Subsequently, 24-h pH monitoring was performed using antimony electrodes and fitting recorders (Orion II, Medical Measurement Systems, The Netherlands). The pH catheter had two or four sensors that were 15 cm or 5 cm apart. The pH electrodes were calibrated before and after the test using reference buffer solutions with a pH of 4 or 7. The most proximal electrode (pharyngeal probe) was placed in the hypopharynx 2 cm above the manometry-defined proximal border of the UES. Each patient wore a data-logger with a sampling frequency of 1 Hz during the test period. Symptom occurrence, meal times and body positions (supine or upright) were written down in a diary and recorded in a data log. The patients were advised to eat their usual meals and engage in their usual activities on the day of the test. After a period of 24 h, they returned the data log, and the data were downloaded onto a computer using software provided by the manufacturer. The data from the diaries were extracted for interpretation.

A single pharyngeal event (pH < 4) preceded by a precipitous pH drop of the same magnitude in the esophageal probe was defined as a positive result for LPR. The most distal pH sensor in the esophagus (esophageal probe) was 15 cm away from the pharyngeal probe. Pathologic GER was defined as a percentage of total time with a pH < 4 greater than 4.2% as measured

Table 1 Comparisons of baseline data and data obtained during the first 4 h between patients in group A and group B

| Variables | Group A (n = 36) | Group B (n = 14) | P value ¹ |

by the esophageal probe^[13].

Analysis of the pH data

The elimination half-life of meperidine is 3.2-3.7 h, and the half-life of midazolam is approximately 3 h^[14,15]. To analyze the effect of conscious sedation on 24-h pH monitoring, computer software provided by MMS was used to analyze the 24-h pH data of each patient during two periods: the first 4 h (Period I) and the remaining time of the study (Period II). Meal times and sleep h were excluded from the analysis. Thus, only data recorded when the patients assumed an upright position were used for the comparisons. The mean duration of each period was 3.5 ± 0.5 h for Period I and 10.1 ± 2.1 h for Period II.

An acid reflux event was defined as an episode of pH < 4 detected on the pharyngeal or esophageal probe. Long reflux was defined as a reflux event lasting more than 5 min. The variables used for the comparisons were percentage of total time with a pH < 4, frequency of acid reflux events (episodes/h), and presence of long reflux.

Statistical analysis

Continuous variables are expressed as the mean ± SD in the text and tables. The differences in the variables between patients in group A and B were compared using a t test for age and a Mann-Whitney U test for BMI, Reflux Symptom Index (RSI), Reflux Finding Score (RFS),

percentage of total time with a pH < 4, and frequency of acid reflux. Either a χ^2 or Fisher's exact test (when χ^2 test was inappropriate) was used to analyze differences in sex, presence of heartburn and regurgitation, erosive esophagitis, LPR, pathologic GER, and long reflux. The differences in the variables between Period I and Period II in group A patients were compared using a Wilcoxon Signed Rank test for the percentage of total time with a pH < 4, frequency of symptoms, and the presence of acid reflux. A McNemar's test was used to analyze differences in the presence of long reflux. Statistical significance was defined as $P < 0.05$. The statistical analyses were performed using the SPSS version 17.0 for Windows.

RESULTS

Comparisons between patients with and without sedated EGD

The demographic, clinical, and endoscopic data from the patients in groups A and B were compared (Table 1). There were no significant differences between the two groups. Characteristic symptoms of GERD, heartburn and acid regurgitation were present in both groups (13/36 vs 7/14, $P = 0.37$). Six patients (16.7%) in group A and 2 (14.3%) in group B had erosive esophagitis (all were grade A, except one patient in group A who was grade B based on the Los Angeles classification) on the EGD ($P = 1$). The RSI is a validated patient-administered questionnaire for the diagnosis of LPR^[16]. A total score greater than 13 is regarded as a positive result. The patients in group A scored 15.9 ± 7.5, and the patients in group B score 16.8 ± 9.2 ($P = 0.62$). The RFS is an 8-item scale listing common physical findings in LPR patients^[17]. A total score of greater than 7 is regarded as a positive result. The RFS was 8.1 ± 3.7 in group A and 6.4 ± 2.4 in group B ($P = 0.19$). Twelve patients (33.3%) in group A and 5 (35.7%) in group B met the pH criteria for LPR ($P = 0.87$). There were three (8.3%) patients in group A and one (7.1%) in group B who had pathologic GER ($P = 1.00$).

The pH data obtained from Period I were compared between the two groups (Table 1). Using the pharyngeal probe, the percentage of total time with a pH < 4 was 0.03% ± 0.10% (range, 0%-0.4%) in group A and 0.07% ± 0.16% (range, 0%-0.5%) in group B ($P = 0.32$). The frequency of acid reflux events was 0.07 ± 0.23 episodes/h (range, 0-1.1 episodes/h) in group A and 0.18 ± 0.47 episodes/h (range, 0-1.7 episodes/h) in group B ($P = 0.33$). None of the patients in either group had long reflux events. Using the esophageal probe, the mean percentage of total time with a pH < 4 was 0.96% ± 1.89% (range, 0%-7%) in group A and 0.42% ± 0.81% (range, 0%-2.9%) in group B ($P = 0.59$). The frequency of acid reflux events was 0.74 ± 1.51 episodes/h (range, 0-6.3 episodes/h) in group A and 0.63 ± 0.97 episodes/h (range, 0-3.1 episodes/h) in group B ($P = 0.49$). One patient in group A and no patients in group B had long reflux ($P = 1$).

Table 2 Comparisons between Period I and Period II in group A patients (mean ± SD)

| Variables | Period I | Period II | P value ¹ |
|---------------------------------------|-------------|-------------|----------------------|
| Frequency of symptom (episodes/h) | 0.04 ± 0.10 | 0.03 ± 0.06 | 0.29 |
| Pharyngeal probe | | | |
| Total time of pH < 4 (%) | 0.03 ± 0.10 | 0.23 ± 0.85 | 0.21 |

| Mean frequency of reflux (episodes/h) | 0.74 ± 1.51 | 0.81 ± 1.76 | 0.55 |
| Patients with long reflux | 1 (2.8%) | 5 (13.9%) | 0.22 |

¹Statistical significance was defined as a *P* < 0.05.

Comparisons between different periods in patients who underwent EGD with conscious sedation

The pH data for Period I and Period II from the group A patients are shown in Table 2. The frequency of symptom occurrence was 0.04 ± 0.10 episodes/h (range, 0-0.3 episodes/h) during Period I and 0.03 ± 0.06 episodes/h (range, 0-0.3 episodes/h) during Period II (*P* = 0.29). Based on the pharyngeal probe measurements, the percentage of total time with a pH < 4 was 0.03% ± 0.10% (range, 0%-0.4%) in Period I and 0.23% ± 0.85% (range, 0%-5%) in Period II (*P* = 0.21, Figure 1A). The frequency of acid reflux was 0.07 ± 0.23 episodes/h (range, 0-1.1 episodes/h) in Period I and 0.29 ± 0.98 episodes/h (range, 0-5.7 episodes/h) in Period II (*P* = 0.22). None of the patients had a long reflux event. Based on the esophageal probe measurements, the percentage of total time with a pH < 4 was 0.96% ± 1.89% (range, 0%-7%) in Period I and 1.11% ± 2.57% (range, 0%-13.6%) in Period II (*P* = 0.55, Figure 1B). The frequency of acid reflux was 0.74 ± 1.51 episodes/h (range, 0-6.29 episodes/h) in Period I and 0.81 ± 1.76 episodes/h (range, 0-9.78 episodes/h) in Period II (*P* = 0.55). One patient had a long reflux event during Period I and five had a long reflux event during Period II (*P* = 0.22).

DISCUSSION

EGD is usually performed without conscious sedation in Taiwan. Some of our patients reported that nasally passed procedures for esophageal manometry and 24-h pH monitoring were less tolerable than EGD without conscious sedation. Because moderate conscious sedation may be helpful to facilitate gastrointestinal procedures, we performed a catheter-based pH study in a manner similar to the Bravo system in our patients^[8,12]. Our study results showed that EGD with conscious sedation does not have an immediate effect on subsequent catheter-based pH monitoring with regard to the relevant parameters assessed with pH monitoring techniques^[6,18].

The Bravo capsule is usually placed during an EGD with conscious sedation^[19-23]. The Bravo pH system allows for the measurement of esophageal acid exposure

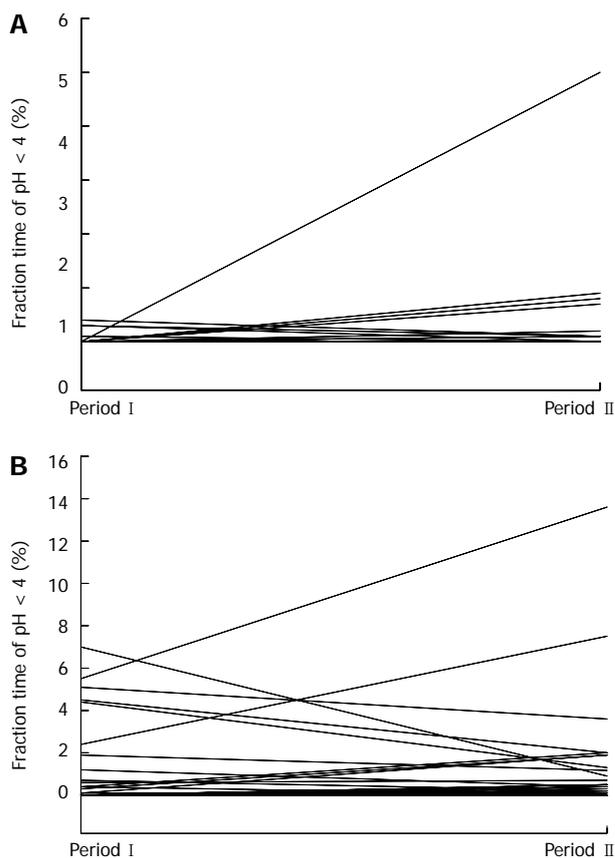

Figure 1 Individual comparison of the fraction of total time with a pH < 4 between Period I and Period II in group A patients. A: Using pharyngeal probe measurements; B: Using esophageal probe measurements.

over a 48-h period. Therefore, many studies have investigated whether there is day-to-day discrepancy during Bravo pH monitoring^[19-23]. The results are conflicting. Bechtold *et al*^[19] and Bhat *et al*^[20] reported more acid reflux events on day 1 than on day 2 using the Bravo system, suggesting that endoscopy and the associated sedatives may be responsible for the day-to-day discrepancy. Other studies showed that patients who underwent same-day EGD with intravenous sedation did not demonstrate any significant differences in reflux variables between day 1 and day 2 using Bravo pH monitoring^[21-23].

Bhat *et al*^[20] further analyzed their pH data by dividing the study period into the first 6 h and the remaining 18 h on both day 1 and day 2. They found an increase in esophageal acid exposure during the first 6 h after capsule insertion on day 1 compared to the corresponding period on day 2. There was no such difference during the remaining 18 h on day 1 and day 2. They concluded that EGD with conscious sedation interferes with subsequent capsule-based Bravo pH measurements. In this study, we divided the study period into the first 4 h and the remaining 20 h because the elimination half-life is nearly 4 h for meperidine and approximately 3 h for midazolam^[14,15]. Our results showed no interference in patients who underwent EGD with sedation. Our data further revealed that three pH variables were not significantly different between the patients with and without prior sedation (us-

ing both the pharyngeal and laryngeal probes). Ayazi *et al.* observed a similar day-to-day discrepancy in patients receiving capsule-based Bravo pH monitoring without prior EGD and conscious sedation^[24]. Their results argue for an iatrogenic effect of sedated EGD on the pH monitoring.

There are some limitations in the present study. First, the study cohort had extra-esophageal symptoms (LPR) but not esophageal symptoms (classical GERD). The mechanism of LPR may be different from that of classical GERD^[2,25]. Therefore, whether the study results can be applied to pH monitoring in patients with characteristic symptoms of GERD needs further investigation. Second, the esophageal probe was placed at a variable distance above the proximal border of the LES of participants. The results of the pH parameters obtained from the esophageal probe may be suboptimal.

In conclusion, our results suggest that EGD with conscious sedation does not interfere with the results of subsequent catheter-based pH monitoring in patients with extra-esophageal manifestations of GERD. Catheter-based 24-h pH monitoring can be performed shortly after EGD with conscious sedation, especially for those patients who are intolerable to the procedures.

COMMENTS

Background

One of the limitations of catheter-based pH monitoring is discomfort. Whether it can be performed shortly after esophagogastroduodenoscopy (EGD) with conscious sedation like the performance of Bravo pH system is unknown. Authors aimed to investigate the impact of sedated EGD on the subsequent 24-h catheter-based pH monitoring.

Research frontiers

In order to increase patients' willingness to receive 24-h pH monitoring, authors have attempted to perform the catheter-based pH study in a similar way to Bravo system in our patients.

Innovations and breakthroughs

EGD with conscious sedation does not interfere with the results of the subsequent 24-h pH monitoring in patients with extraesophageal symptoms of gastroesophageal reflux disease.

Applications

Catheter-based 24-h pH monitoring can be performed shortly after sedated EGD especially for those patients who are intolerable to the procedures.

Terminology

Laryngopharyngeal reflux is backflow of gastric content into larynx and pharynx which has been widely used by otolaryngologists, while extraesophageal reflux is commonly used by gastroenterologist.

Peer review

The paper is well composed, documented. The results are interesting and suggest that EGD with conscious sedation does not interfere with the results of subsequent 24-h pH monitoring in patients with extra-esophageal symptoms of gastroesophageal reflux disease.

Abstract

AIM: To explore the relationship between α -fetoprotein (AFP) and various clinicopathological variables and different staging system of hepatocellular carcinoma (HCC) thoroughly.

METHODS: A retrospective cohort study of consecutive patients diagnosed with HCC between January 2008 and December 2009 in West China Hospital was enrolled in our study. The association of serum AFP values with the HCC clinicopathological features was analysed by univariate and multivariate analysis, such as status of hepatitis B virus (HBV) infection, tumor size, tumor number, vascular invasion and degree of tumor differentiation. Also, patients were divided into four groups at the time of enrollment according to different cutoff values for serum value of AFP (≤ 20 $\mu\text{g/L}$, 21-400 $\mu\text{g/L}$, 401-800 $\mu\text{g/L}$, and ≥ 801 $\mu\text{g/L}$), to compare the positive rate of patient among four groups stratified by vari-

ous clinicopathological variables. And the correlation of different kinds of tumor staging systems, such as TNM, Barcelona Clinic Liver Cancer (BCLC) staging classification and China staging, were compared with the serum concentration of AFP.

RESULTS: A total of 2304 HCC patients were enrolled in this study totally; the mean serum level of AFP was 555.3 ± 546.6 $\mu\text{g/L}$. AFP levels were within the normal range (< 20 $\mu\text{g/L}$) in 27.4% ($n = 631$) of all the cases. 81.4% ($n = 1875$) patients were infected with HBV, and those patients had much higher serum AFP level compared with non-HBV infection ones (573.9 ± 547.7 $\mu\text{g/L}$ vs 398.4 ± 522.3 $\mu\text{g/L}$, $P < 0.001$). The AFP level in tumors ≥ 10 cm (808.4 ± 529.2 $\mu\text{g/L}$) was significantly higher ($P < 0.001$) than those with tumor size 5-10 cm (499.5 ± 536.4 $\mu\text{g/L}$) and with tumor size ≤ 5 cm (444.9 ± 514.2 $\mu\text{g/L}$). AFP levels increased significantly in patients with vascular invasion (694.1 ± 546.9 $\mu\text{g/L}$ vs 502.1 ± 543.1 $\mu\text{g/L}$, $P < 0.001$). Patients with low tumor cell differentiation (559.2 ± 545.7 $\mu\text{g/L}$) had the significantly ($P = 0.007$) highest AFP level compared with high differentiation (207.3 ± 420.8 $\mu\text{g/L}$) and intermediate differentiation (527.9 ± 538.4 $\mu\text{g/L}$). In the multiple variables analysis, low tumor cell differentiation [OR 6.362, 95%CI: 2.891-15.382, $P = 0.006$] and tumor size (≥ 10 cm) (OR 5.215, 95%CI: 1.426-13.151, $P = 0.012$) were independent predictors of elevated AFP concentrations (AFP > 400 $\mu\text{g/L}$). Serum AFP levels differed significantly ($P < 0.001$) in the D stage of BCLC (625.7 ± 529.8 $\mu\text{g/L}$) compared with stage A (506.2 ± 537.4 $\mu\text{g/L}$) and B (590.1 ± 551.1 $\mu\text{g/L}$).

CONCLUSION: HCC differentiation, size and vascular invasion have strong relationships with AFP, poor differentiation and HCC size ≥ 10 cm are independent predictors of elevated AFP. BCLC shows better relationship with AFP

Liu C, Xiao GQ, Yan LN, Li B, Jiang L, Wen TF, Wang WT, Xu MQ, Yang JY. Value of α -fetoprotein in association with clinicopathological features of hepatocellular carcinoma. *World J Gastroenterol* 2013; 19(11): 1811-1819 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1811.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1811>

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer and third most significant cause of cancer mortality in the world, with 5-year survival rates at a mere 7% in patients^[1-3]. When patients with obvious clinical symptoms come to the hospital for treatment, the HCC has already reached the mild to advanced stages and is usually large in size. Given the subsequent rapid growth and vascular invasion, patients have to face serious progress and poor prognosis. There is no doubt that a thorough comprehension of the pathobiological features of HCC will definitely help clinicians diagnose HCC at earlier stages, thus improving patient outcomes.

Currently, the most commonly used methods for screening and diagnosing HCC are ultrasound imaging and serum α -fetoprotein (AFP) concentration measurements. AFP has been used worldwide as the golden standard compared to other serum markers, especially in poor, remote areas. However, the diagnostic value of AFP is still controversial given that its sensitivity and specificity are unstable^[4,5]. Moreover, researchers have studied AFP-related parameters, such as AFP mRNA^[6-8] and AFP glycoforms^[9-11]. Recently, both of these AFP-related parameters have been proven to have diagnostic potential in a way, and even they are recommended as complementary tests. Nevertheless, their usage is limited due to financial and technological reasons; it is unlikely that they can replace serum AFP as the golden standard of diagnostic serum markers for hepatocellular carcinoma.

The serum AFP level also plays an important role in representing the pathobiological features of HCC identified as prognostic factors^[12-14]. Some clinicians have reported that the elevation of serum AFP levels is consistent with increased tumor sizes^[15-17] and that small tumors seem to excrete less AFP into the blood. They also report that there is no clear increasing tendency between tumor size and AFP levels^[18]. Others have reported that highly differentiated small tumors express undetectable levels of serum AFP^[14], whereas lowly differentiated tumor cells, in most cases, had AFP levels of $> 400 \mu\text{g/L}$ ^[19]. Similarly, other factors such as tumor number^[14,16] and vascular invasion^[14,20-22] have been found to be correlated with serum AFP levels to a certain extent. Nonetheless, these studies failed to research the relationship

between various variables thoroughly, and the sample size of some cohort studies was not large enough.

The objects of this study were to comprehensively evaluate the relationship between AFP and clinicopathological features of HCC, to compare the clinical practicality of different tumor staging systems, and to state the clinical importance of measuring AFP concentrations in cases of HCC in China.

MATERIALS AND METHODS

Ethics

Informed consent was obtained from all subjects for participation in the study and the usage of sera. The study protocol conformed to the ethical guidelines of the World Medical Association Declaration of Helsinki and was approved by the ethical committee of the West China Hospital, Sichuan University. All participants provided their written informed consent to participate in this study.

Patient tissue

The base population consisted of 2381 consecutive patients who received a final diagnosis of HCC at the department of liver and vascular surgery, West China Hospital, Sichuan University, between January 2008 and December 2009. Of these 2381 patients, 31 were excluded from the study because of the absence of tumor size data, and 46 were excluded due to missing serum AFP level data. Therefore, a total of 2304 HCC patients were included in this study. The final diagnosis of HCC was made in two main ways according to whether the patients had a hepatectomy or not. HCC diagnosis was made by the pathological examination of the resected specimens for the 1825 patients (79.2%) who received hepatic resection or fine needle aspiration. The remaining 479 patients (20.8%) had advanced HCC with impaired liver function, with portal vein invasion or metastasis, and thus did not undergo an invasive operation. Instead, this group of patients had their HCC confirmed by a variety of combined imaging techniques, identification of a focal lesion $> 2 \text{ cm}$ in diameter in 2 imaging modalities, such as ultrasonography (US), enhanced computed tomography (CT) image, magnetic resonance imaging (MRI), and/or angiography, and showing arterial hypervascularization in at least 1 of imaging modalities. A mass lesion within a cirrhotic liver in the presence of a serum AFP level $> 400 \mu\text{g/L}$ was also diagnostic^[23]. For lesions $< 2 \text{ cm}$ in diameter, diagnosis of HCC required hepatitis B surface antigen (HBsAg) positive and AFP $> 400 \mu\text{g/L}$. The severity of liver dysfunction was assessed *via* the Child-Pugh classification. Serum samples were collected and stored at $-70 \text{ }^\circ\text{C}$ until examined. Hepatitis B virus (HBV) infection status was determined on the basis of HBsAg, hepatitis B surface antibody, hepatitis B core antibody, hepatitis B e antigen, and hepatitis B e antibody using the electrochemiluminescence immuno-

assay (ECLIA) method, and HBsAg positive was defined as HBV infection. Background characteristics of the patients are listed in Table 1.

AFP assay and assessment

Serum samples for the detection of AFP were taken upon entry into the study before initial treatment, and AFP was determined by ECLIA, which was intended for use on Roche MODULAR ANALYTICS E170 immunoassay analyzers (Roche Diagnostics GmbH, Mannheim, Germany). The time between collecting serum samples and performing an operation or getting a CT, US, MRI and/or angiography image was less than seven days. Detected serum AFP values ranged from 0 to 1210 $\mu\text{g/L}$, and all of the AFP values more than 1210 $\mu\text{g/L}$ were recorded as 1210 $\mu\text{g/L}$ in our study. The cutoff for normal AFP levels ($< 20 \mu\text{g/L}$) was chosen on the basis of the EASL guidelines^[24] and on the data reported in the majority of previous studies^[14,25]. Four different cutoff values for serum AFP were set: $\leq 20 \mu\text{g/L}$, 21-400 $\mu\text{g/L}$, 401-800 $\mu\text{g/L}$, and $\geq 801 \mu\text{g/L}$. Thus, patients were classified into four groups based on their level of serum AFP at the time of enrollment.

Clinicopathological variables

We assessed the association of AFP values with the clinicopathological variables that have been reported as prognostic factors for HCC^[16,26]. The investigated variables are shown in Table 2. All variables were assessed either pathologically, *via* resected specimens and fine needle biopsy, or by imaging techniques. Vascular invasion was defined as the presence of portal vein invasion, venous invasion and/or biliary invasion. Tumor size was defined by the longest axis and estimated with US, CT or MRI. When multiple HCC tumors were present, the axis of the largest one was measured and taken as the representative HCC diameter. The diagnosis was histologically

¹We assessed 1843/2304 patients who had underwent hepatectomy or fine needle aspiration. ^b $P < 0.001$ vs high and low differentiation groups. ^d $P < 0.001$ vs stage A and B of BCLC. AFP: α -fetoprotein; HBV: Hepatitis B virus; TNM: Tumor-node-metastasis; BCLC: The Barcelona-Clinic Liver Cancer Group.

confirmed using resected specimens or fine needle aspiration biopsy, and the grading followed the methodology reported by Edmonson *et al*^[27] (high, intermediate, or low differentiation). Similarly, if multiple tumors had more than two grades of histological differentiation, the most dedifferentiated grade was recorded.

Among the several tumor staging systems used in the world, the tumor-node-metastasis (TNM) system is the most widely accepted^[28,29]. The American Joint Committee on Cancer (AJCC) published its 7th edition in 2009^[30], and the main difference from the 6th edition of the AJCC staging system is the separation of the T3 stage into two subgroups, T3a and T3b. The definition of the T3a stage is the presence of multiple tumors, any $> 5 \text{ cm}$, while the T3b stage is defined as having tumors of any size involving a major portal or hepatic vein. The tumor staging was also determined by the Barcelona Clinic Liver Cancer (BCLC) staging classification, which

Patients were divided into four groups according to the serum α -fetoprotein (AFP) level, they were ≤ 20 , 20-400, 401-800 and ≥ 801 $\mu\text{g/L}$, the positive rate of patients in each interval of AFP were calculated. HBV: Hepatitis B virus; TNM: Tumor-node-metastasis; BCLC: The Barcelona-Clinic Liver Cancer Group.

was updated in 2010^[31], and not involving the Cancer of the Liver Italian Program (CLIP) staging^[32] because it includes AFP as a stage criteria. We also adopted the China Staging system, which was updated in 2001^[33].

Statistical analysis

Values are presented as the mean \pm SD. Correlations between markers values were analyzed by Spearman's rank correlation. Categorical binary variables were compared by χ^2 . Associations between marker values and clinicopathological variables were analyzed by the Wilcoxon rank-sum test, and a binary logistic regression model for multiple variables analysis. *P* values of < 0.05 were accepted as statistically significant. All statistical analyses were performed using SPSS 17.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

The distribution of patients with respect to the etiology of the disease is reported in Table 1. Of the 2304 cases,

1987 patients were men and 317 patients were women (male-to-female ratio 6.27: 1). The mean serum level of AFP was 555.31 ± 546.69 $\mu\text{g/L}$. The mean patient age was 51.9 ± 12.9 years old. AFP levels were within the normal range (< 20 $\mu\text{g/L}$) in 27.4% ($n = 631$) of the cases. 81.4% ($n = 1875$) patients were infected with HBV, and those patients had much higher AFP level ($P < 0.001$) compared with non-HBV infection ones.

AFP as a marker for clinicopathological variables representatives of tumor-related features

The correlation of AFP levels with tumor-related features is depicted in Tables 2, 3 and 4. The AFP level in patients with tumor sizes ≥ 10 cm was significantly higher ($P < 0.001$) than those patients with smaller tumors (tumor size < 10 cm). There was no significant difference between patients with one or multiple tumors ($P = 0.451$). AFP levels were remarkably higher in patients with vascular invasion, such that the AFP level was clearly higher than those levels in patients without evidence of vascular invasion ($P < 0.001$). Notably, there is also a

Table 4 Binary logistic regression analysis of tumor related factors elevating the level of α -fetoprotein ($> 400 \mu\text{g/L}$)

| Variables | P value | Odds ratio (95%CI) |
|-----------------------|---------|----------------------|
| HBV infection | 0.156 | 4.162 (0.991-16.557) |
| Vascular invasion | 0.060 | 3.963 (0.529-7.384) |
| ≤ 5 | - | - |
| 5-10 | 0.341 | 0.862 (0.317-9.284) |
| ≥ 10 | 0.012 | 5.215 (1.426-13.151) |

| Tumor differentiation | | |
| High | - | - |
| Intermediate | 0.017 | 3.951 (1.501-9.917) |
| Low | 0.006 | 6.362 (2.891-15.382) |

The level status of α -fetoprotein ($> 400 \mu\text{g/L}$) was used as a dependent variable. HBV: Hepatitis B virus.

similar pattern with increasing tumor cell differentiation—patients with low tumor cell differentiation have the significantly highest AFP levels ($P = 0.007$). In the BCLC staging classification, AFP levels at various stages are significantly different ($P = 0.008$), with stage D having the highest level of AFP. No relationship or difference was found in the TNM staging and China staging classification systems.

Positive rates of patients with HCC in four AFP intervals

The positive rate of patients in four AFP intervals with and without HBV infection were quite different ($P < 0.001$), about half of the HBV infected patients with the AFP levels greater than $801 \mu\text{g/L}$. On the contrary, only one fifth of the non-HBV infection patients had AFP levels more than $801 \mu\text{g/L}$, AFP levels in half of the uninfected patients were less than $20 \mu\text{g/L}$ approximately. With respect to different tumor sizes, the positive rate of patient was significantly different ($P < 0.001$). The patients with the largest tumor size, ≥ 10 cm, accounted for most of the cases in the interval where the AFP cutoff value was more than $801 \mu\text{g/L}$ (63.75%). Patients with tumor sizes either ≤ 5 cm, 5-10 cm, or ≥ 10 cm had the lowest rate of serum AFP in the AFP interval from 401 to $800 \mu\text{g/L}$. The positive rate of serum AFP levels in different intervals was not significantly different in patients with solitary or multiple tumors ($P = 0.593$). Whether the patients with vascular invasion or not, the portion of AFP values beyond $801 \mu\text{g/L}$ accounted for the most cases (49.15% and 35.30% respectively), and the positive rate of AFP value was significantly different ($P < 0.001$). The high, intermediate, and low tumor cell differentiation had significant differences in each serum AFP interval. The low differentiation group accounted for the majority of patients in the AFP interval of more than $801 \mu\text{g/L}$ (41.12%), and the patients with high tumor cell differentiation had the highest negative rate (42.22%). The value of AFP had a statistically significant

correlation with BCLC, and the positive rate of the AFP level in the interval greater than $801 \mu\text{g/L}$ was found to be significantly different ($P < 0.001$). However, AFP levels greater than $801 \mu\text{g/L}$ tended to exist in the highest percentage of patients among all stages under the BCLC and China staging systems.

Multiple variables analysis of tumor related factors elevating the level of AFP

In the binary logistic multiple-regression models, the level status of AFP ($> 400 \mu\text{g/L}$) was used as a dependent variable. Both low tumor cell differentiation (OR 6.362, 95%CI: 2.891-15.382, $P = 0.006$) and tumor size (≥ 10 cm) (OR 5.215, 95%CI: 1.426-13.151, $P = 0.012$) were independent predictors of elevated AFP concentrations.

DISCUSSION

Serum tumor markers are useful in detecting malignant carcinoma rapidly and simply using biochemical methods. In this study, we focused on AFP, which is the most commonly used tumor marker in HCC. To date, many previous studies have evaluated the relationship between serum AFP levels and tumor-related clinicopathological factors. However, in the majority of those studies, researchers^[14,19,21,26] only took one or two clinicopathological variables into consideration, such as tumor size, tumor number, or portal venous invasion. Moreover, few of these researchers investigated these relationships in a comprehensive manner. With these facts in mind, we obtained a thorough understanding of the correlation between tumor markers and various clinicopathological variables.

It is known to all that, HBV is the major hepatocarcinogen which is responsible for up to 80% of HCC worldwide. There are over 400 million patients infected with chronic HBV globally, which equals to over 5% of the world's whole population; and it is estimated that about 20% of these infected individuals may eventually develop HCC^[34]. Just as the relationship between HBV and HCC has been clarified, AFP is found higher in HBV-related HCC than in non-HBV-related HCC^[35]. Hann *et al*^[36] conducted a clinic based longitudinal cohort study (617 cases and followed for up to 22 years) retrospectively to determine the predictive role of baseline AFP value in the prediction of the long-term risk of developing HCC in HBV patients. Their conclusion was that elevated serum AFP was significantly associated with increased risk of HCC in HBV patients and that high levels of serum AFP were associated with the higher risk of developing HCC in non-cancer HBV patients. Our result indicated that 81.4% patients was in status of HBV infection and their serum AFP level raised up at quite a high level compared with non-HBV infection patient. Mutual influence of the HCC and HBV might have effect on the level of AFP.

Our study showed that patients' serum AFP concen-

trations were progressively higher with increasing tumor sizes, which is consistent with the results of previous studies^[15-17], and the same pattern could be observed for the incidence rate of serum AFP greater than 801 µg/L. Specifically, the negative rates of serum AFP concentrations (< 20 µg/L) decreased as tumor sizes increased. This particular focus on tumor sizes and different cutoff values might be useful in suggesting criteria values for the screening and diagnosing of HCC. Moreover, it is still controversial as to whether AFP concentration has a positive correlation with tumor size worldwide^[14,26,37]. One possible reason for this difference may be that the size of HCC tumors included in other studies was relatively smaller than in our study. We divided patients into three groups according to the longest axis: ≤ 5 cm, 5-10 cm and ≥ 10 cm. Nevertheless, the conventional division manner of tumor sizes in previous studies focused on a diameter ≤ 5 cm. Another possible reason for these differences may be due to the difference in the tumor stages of the patients enrolled in these studies. As for the tumor sizes, the serum AFP level showed no tendency to increase with increasing tumor number, and the incidence of different intervals of the AFP level showed no clear correlation with tumor number as well. This result was not consistent with other studies^[12], which showed a significant relationship between AFP levels and tumor number. The main difference was that the interindividual variation of secretion ability of tumor cell played a more important role in elevating the serum AFP concentration compared with tumor cell number.

The cause of cancer recurrence in HCC patients is mainly due to tumor cells spreading *via* the portal and hepatic veins. Additionally, vascular invasion has been proven to be an adverse prognostic factor for HCC recurrence. It is important to detect vascular invasion at earlier stages of the cancer. In our study, there was a relationship between AFP concentration and the presence of indices of tumor vascular invasiveness, that is, the serum AFP value was significantly higher in patients with various vascular invasions compared to those patients without vascular invasion. Among the patients with vascular invasion, the majority of them had AFP values greater than 801 µg/L (49.15%). Some early studies have shown that high serum AFP levels are a good indication of the higher incidence of vascular invasion in patients with HCC, but the total incidence of vascular invasion was 25.61% in all of our cases, which is slightly lower than some other studies^[21,38,39]. This deviation from the literature might be due to the definition of vascular invasion in our study, which focused on the involvement of the vessels within the portal and hepatic vein and biliary ducts, not including the vessels within the fibrous tumor capsule.

Before patients underwent hepatectomy, it is impossible to exactly distinguish the degree of differentiation of the tumor cell by imaging techniques, and fine needle aspiration is not recommended because it has the risk of

the cancer seeding. Hence, a serum AFP value greater than 400 µg/L might be a useful criterion for predicting the histological tumor grade^[19]. In the present study, the serum AFP value increased according to the change of tumor cell differentiation from high to low differentiation, which strongly suggests that the tumor cell with elevated malignant potential will relatively enhance the secretion capacity. Previous studies that investigated the relationship between AFP and tumor cell differentiation, namely Kentaroh Yamamoto^[14], Koicci Oishie^[19] and Chaur-Shine Wang^[16] and Fabio Farinati^[40], reached the same conclusion. Together, these findings highlighted that during the course of the back and forth liver cell necrosis and regeneration, cell proliferation and serum AFP values are abnormally elevated. With respect to the tumor staging system, several staging systems are available, such as Okuda, CLIP, BCLC, Child-Pugh staging, TNM staging and the French classification. In terms of our study, the main function of tumor staging is presented in three main concepts: the malignant characteristics of tumor cells, the degree of liver impairment and the patients' general condition. As a result, BCLC and TNM staging are used in our study. Another staging system that was included was China staging. With our data, BCLC had the dominant advantage compared to the other two staging systems given that it showed a clear relationship with increasing AFP levels. This result may be due to BCLC integrating the Okuda and Child-Pugh staging systems, which consist of tumor features and conditions of liver functions. The serum AFP level of 400 µg/L was adopted as the cutoff value based on the Milan and Hangzhou criterion^[41] for liver transplantation. In our study, patients with AFP levels less than 400 µg/L had less vascular invasion and were at a lower tumor stage. Based on Hangzhou criteria, HCC patients with a simultaneous total tumor diameter of smaller than 8 cm, histopathology grade of I or II and a preoperative AFP level of less than or equal to 400 µg/L, can be selected for liver transplantation and have good outcomes.

The limitation of this study is that it does not include other serum tumor markers, such as AFP-L3 and des-gamma-carboxy prothrombin (DCP), to assess the correlation among them and to compare differences in their relationship with various clinicopathological variables. AFP-L3 and DCP have been proposed as complements or substitutes in the diagnosis of HCC. A high serum AFP-L3 fraction has been proven to be closely related to the poor differentiation of HCC^[42]. Research has also indicated that a high serum DCP is more useful than AFP in the differential diagnosis of HCC from other benign hematopathologist and is unique in detecting small tumors in patients^[43]. The reason we did not include AFP-L3 and DCP is that few cases have examined these markers in our hospital so far. Next, we plan to accumulate enough HCC cases with DCP and AFP-L3 data to investigate the detailed relationship with HCC and to compare them to the relationship with the serum AFP

concentration.

Although some clinical doctors regard serum AFP as 'obsolete', measuring AFP concentrations in the blood is still the easiest and preferred serum tumor marker for the current screening and diagnosing of HCC in China. Despite the promising results of these newly discovered serum tumor markers, such as DCP and AFP-L3, they are only regarded as a complementary test to the AFP value and currently cannot match the diagnostic and prognostic value of AFP. At least for the proportion of AFP seropositive patients, AFP is indeed demonstrated to be associated with larger tumor sizes, vascular invasion and low tumor differentiated grades, which confirmed the rationality of using BCLC with AFP values in our study. However, physicians should be aware that neither a positive nor a negative serum AFP result is conclusive for the final diagnosis of HCC.

ACKNOWLEDGMENTS

We give great thanks to Fang Liu for collecting the data.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common and important cancers in the world that is associated with a poor prognosis. Although imaging studies are the most important and valuable diagnostic tool for HCC, α -fetoprotein (AFP) is also indispensable for diagnosing HCC. Regarding the clinicopathological features of HCC with AFP, several investigators have reported a high frequency of vascular invasions, intrahepatic metastasis, large tumor size, low differentiation, multiple tumor number, and worse survival in HCC patients with high levels of AFP.

Research frontiers

AFP has been the most widely used tumor marker worldwide and is still the golden standard amongst diagnostic markers for HCC. However, its diagnostic value is more and more questioned, due to poor sensitivity and specificity. To date, several other tumor markers have been investigated and compared with AFP, such as plasma des-c-carboxy prothrombin, also known as protein induced by vitamin K deficiency or antagonist-II, the lens culinaris agglutinin-reactive fraction of α -fetoprotein and Golgi protein-73 have been investigated as complements for AFP, despite the promising results of these new potential markers, at this moment, they are only recommended as complementary tests to the conventionally diagnostic methods used and cannot (yet) replace serum AFP as the gold standard of tumour markers for HCC. As a result, a comprehensive investigation with large samples in regard to the relationship between clinicopathological features of HCC and AFP is needed urgently.

Innovations and breakthroughs

The authors analyzed the correlation between serum AFP levels and characteristics of the patients with HCC. Together with the sample size of the study, which is large enough to obtain statistically relevant results, this article could be useful for the physicians at the clinical practice, keeping in mind that represent a guidelines for the clinicopathological features of HCC, as long as the AFP result is accompanied by other diagnosis techniques.

Applications

The present study provides a whole description of the relationship of various clinicopathological features of HCC with serum level of AFP, these finding in the article will play an important role in clinical decision making in future.

Terminology

AFP is a glycoprotein and synthesized by the yolk sac during early foetal life and later on by the foetal liver. In adult life, AFP synthesis is repressed. Elevated serum levels of AFP are only seen in maternal serum during pregnancy, in certain tumors (gastric cancer, lung cancer, pancreatic cancer, testicular car-

cinoma and mainly in HCC) and hepatic non-tumor disease (chronic hepatitis and liver cirrhosis).

Peer review

This is a large study about the diagnostic and prognostic abilities of AFP in hepatocellular carcinoma. The series is impressive and various interesting conclusions are reached. In this sense, the article has merit and would represent a valuable contribution to the literature.

Abstract

AIM: To assess the value of double-balloon enteroscopy (DBE) for the diagnosis of gastrointestinal mesenchymal tumors (GIMTs) in the small bowel and clarify their clinical and endoscopic characteristics.

METHODS: A retrospective review in a total of 783 patients who underwent a DBE procedure from January 2003 to December 2011 was conducted. Data from patients with pathologically confirmed GIMTs were analyzed at a single tertiary center with nine years' experience. The primary outcomes assessed included characteristics of patients with GIMTs, indications for DBE, overall diagnostic yield of GIMTs, endoscopic morphology, positive biopsy, comparison of diagnosis with capsule endoscopy, and subsequent interventional management.

RESULTS: GIMTs were identified and analyzed in 77 patients. The mean age was 47.74 ± 14.14 years

(range: 20-77 years), with 63.6% being males. The majority of individuals presented with gastrointestinal bleeding, accounting for 81.8%, followed by abdominal pain, accounting for 10.4%. Small bowel pathologies were found in 71 patients, the detection rate was 92.2%. The diagnostic yield of DBE for GIMTs was 88.3%. DBE was superior to capsule endoscopy in the diagnosis of GIMTs ($P = 0.006$; McNemar's χ^2 test). Gastrointestinal stromal tumor was the most frequent and leiomyoma was the second frequent GIMT. Single and focal lesions were typical of GIMTs, and masses with smooth or unsmooth surface were the most common in the small bowel. GIMTs were removed from all the patients surgically except one patient treated with endoscopic resection.

CONCLUSION: DBE is a safe and valuable procedure for patients with suspected GIMTs, and it provides an accurate position for subsequent surgical intervention.

He Q, Bai Y, Zhi FC, Gong W, Gu HX, Xu ZM, Cai JQ, Pan DS, Jiang B. Double-balloon enteroscopy for mesenchymal tumors of small bowel: Nine years' experience. *World J Gastroenterol* 2013; 19(11): 1820-1826 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1820.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1820>

INTRODUCTION

Small bowel diseases (SBDs) are less common in the entire digestive tract^[1]. As a result of deep anatomical location of the small bowel (SB) and nonspecific clinical manifestations of SBDs, the diagnosis and management

of SBDs are frequently delayed, leading to considerable medical cost and poor prognosis^[2]. Early identification, diagnosis and intervention for SBDs become extremely important in clinical practice. With the development of capsule endoscopy (CE) and balloon-assisted enteroscopy (BAE), a new era has been created for the diagnosis of SBDs.

Gastrointestinal mesenchymal tumors (GIMTs), including myogenic tumors, neurogenic tumors and gastrointestinal stromal tumors (GISTs), account for less than 10% of gastrointestinal tumors^[5-5]. Radiological imaging, such as barium study, computed tomography and angiography, is usually performed to examine GIMTs without the advent of CE and double-balloon enteroscopy (DBE). Traditional examination by barium study is feasible for bigish intraluminal SBTs^[6,7]. CT is used to locate the lesion, assess for invasion and detect metastasis of SBTs^[8,9]. Angiography is effective for detecting SBTs with active bleeding. GIMTs are common in the SB, varying from the duodenum to the ileum^[10]. Their true incidences might be higher than those reported, as novel methods such as CE and BAE are much more sensitive and specific in diagnosing GIMTs than conventional methods^[7]. CE is performed to detect SBTs and produce a higher detection rate due to its advantage of invasiveness^[11-14].

Several studies reported DBE for the diagnosis of SBTs, indicating that DBE is a safe and effective procedure that enables accurate diagnosis of SBTs^[15-19]. To date, few studies have reported the diagnosis of GIMTs by DBE and described their clinical and endoscopic features. This study was conducted retrospectively to evaluate the usefulness and safety of DBE for the diagnosis of GIMTs and to understand their clinical and endoscopic characteristics.

MATERIALS AND METHODS

Patients

Retrospective chart review was conducted in 783 consecutive patients who were suspected to have SBDs and investigated by DBE between January 2003 and December 2011 at a single center (a university teaching hospital). The data of the patients were reviewed, including demographic data, examinations prior to DBE, indications for DBE, the locations of GIMTs, endoscopic findings, removal mode of GIMTs, histopathological findings and postoperative management.

Written informed consents were obtained from each patient and/or their guardians. The study was approved by the Institutional Review Board of Nanfang Hospital, Southern Medical University, Guangzhou, China.

DBE procedure

All DBE procedures were performed with no absolute contraindications. A low residue and liquid diet was prescribed for the patients undergoing this procedure, and colored food was avoided at least one day prior to the procedure. All the patients completed bowel cleansing

Table 1 Demographic data of patients undergoing double-balloon enteroscopy

| Characteristics | |
|--------------------------------------|---------------------------|
| Sex (M/F) | 49/28 |
| Age (mean \pm SD, range, yr) | 47.74 \pm 14.14 (20-77) |

preparation by ingesting a 1.8-2 L polyethylene-glycol solution followed by an overnight fasting, at least 6-10 h prior to the start of the procedure.

The Fujinon DBE system (Fujinon Inc, Japan) introduced in our center in 2003 was used and reported previously elsewhere^[20-22]. All procedures were carried out by experienced endoscopists. The selection of transoral or transanal approach was based on the clinical manifestations and/or suspected findings from prior examinations such as barium study, CT scan, and CE findings. The opposite routine was performed after making a positional mark by India ink if negative findings were detected by the peroral routine, and vice versa. If a lesion was detected by DBE, a positional mark was performed as well.

Statistical analysis

Statistical analysis was performed using the software SPSS Version 17.0 for Windows. Continuous data were presented as means, mean \pm SD or range, and categorical variables were expressed as frequency or percentages. The χ^2 test was used to compare differences in categorical variables examined. Agreement analysis was assessed by the Kappa statistic. A *P* value < 0.05 (two-sided) was considered statistically significant.

RESULTS

Demographics of clinical data

A total of 77 inpatients who underwent DBE were identified; their final diagnoses were confirmed as GIMTs by histopathology and/or surgery. Characteristics of all the

Table 2 Comparison of diagnosis in 31 patients evaluated by capsule endoscopy and double balloon enteroscopic investigation

| CE findings (<i>n</i> = 31) | DBE findings (<i>n</i> = 31) | | Total |

| Negative | 11 | 1 | 12 |
| Total | 29 | 2 | 31 |

Kappa = 0.036. CE: Capsule endoscopy; DBE: Double-balloon enteroscopy.

patients are shown in Table 1. The mean age was 47.74 ± 14.14 years (range: 20-77 years), with 63.6% being males. The majority of patients presented with GI bleeding, accounting for 81.8%, followed by abdominal pain, accounting for 10.4%.

All the patients underwent other medical examinations prior to DBE, including gastroduodenoscopy (73 cases), colonoscopy (66 cases), and push enteroscopy (1 case), and yielded negative or suspected diagnoses. Barium study was conducted in 10 patients, only one patient was suspected of having a SBT. Twelve patients received CT scan, SBT was found in two patients and suspected SBT was found in one patient. Two patients were found to have suspected SBT by magnetic resonance imaging, 2 by angiography, 3 by Meckel's scan and 2 by bone marrow aspiration.

Thirty-one patients underwent CE examination before DBE within an interval of two weeks. All patients successfully completed CE procedures which reached the colon. Positive diagnoses were made in 11 patients, and suspected diagnoses in 8 patients. No lesion was detected in 12 patients. No complications occurred during and after the procedure. Thirty-seven DBE procedures were performed in 31 patients, including 22 antegrade approaches, 3 retrograde approaches, and 6 combinations of the two approaches. The sensitivity of DBE and CE for the diagnosis of GIMTs was 93.5% and 61.3%, respectively. DBE for the diagnosis of GIMTs was superior to CE ($P = 0.006$, McNemar's χ^2 test) (Table 2).

Endoscopic diagnosis and management

A total of 93 DBE procedures were performed in 77 patients, including 49 antegrade DBE approaches, 12 retrograde DBE approaches and 16 combinations of the two approaches. Total enteroscopy (TE) was achieved in 3 patients. Lesions were found in the small bowel in 71 patients, the detection rate for GIMTs being 92.2%. Clear diagnosis was established in 68 patients, and the diagnostic yield of DBE for GIMTs was 88.3%. Multiple tissue samplings were made in 41 cases; positive diagnoses were obtained in 5 cases. Only one therapeutic procedure was performed in one patient, *i.e.*, a leiomyoma (8 mm) was removed by DBE. All the patients successfully completed the entire DBE procedure, without any complications occurring during and after the procedure.

Among 9 patients with unclear diagnosis by DBE,

one was found with overt, ongoing bleeding, and two were found with single ulcerative lesions in proximal small bowel, respectively. No abnormality was found in six patients, including two patients treated with the combination of the two approaches (neither completed TE), one with the antegrade approach, the other three with the retrograde approach. Patients with indefinite diagnoses underwent surgical procedures (laparotomy or laparoscopic exploration) because of persistent symptoms. Five patients had GIMTs with extraluminal growth confirmed by surgery; one patient undergoing the antegrade approach had a GIMT located in the ileum.

Endoscopic and clinical features

Endoscopic diagnosis was established in the overwhelming majority of the patients. Most GIMTs presented as a single lesion under the endoscopic view, protruding into the intra-luminal mass in the small bowel. The unsmooth surface of the tumor was seen most frequently, showing the appearance of erosion or ulcer (Figure 1). The second frequent morphology was a mass with smooth surface, indicating a tumor with sessile base in a rounded or oval shape (Figure 2). Rare GIMTs presented with irregular shapes under endoscopic view.

In this study, GIMTs with confirmed diagnoses included GIST (60 cases), leiomyoma (6 cases), lipoma (3 cases), hemangioma (3 cases), lymphangioma (3 cases), fibrous histiocytoma (1 case), and angiosarcoma (1 case). Based on the primary sites of tumors, GIMTs in our study were all primary tumors verified surgically and pathologically. Two kinds of GIMTs were detected on the basis of site, including intra- and extra-luminal tumors. Intra-luminal GIMTs were detected most frequently and verified by endoscopy and surgery (Figures 1, 2). A single lesion was most frequently examined, except in two patients who had multiple lymphangiomas. GIMTs were detected most frequently in the jejunum (60 cases), and next in the ileum (16 cases) and duodenum (1 case). No spread and metastasis was investigated and confirmed after surgical removal.

Postoperative management and follow-up

The findings of DBE changed the therapeutic plan and enabled all the patients to receive early intervention. The clinical symptoms disappeared after surgery and all the patients felt an improvement in their conditions. They received an average follow-up time of 14.5 mo after intervention, and important improvements were obtained in the patients after DBE and surgical intervention. No complication was reported.

DISCUSSION

Since the introduction of CE and DBE, the blind spot of the entire GI tract has been revealed and investigated thoroughly. Our study reported the diagnosis of GIMTs using the DBE technique and their clinical characteristics. We analyzed the data of all the subjects registered in the

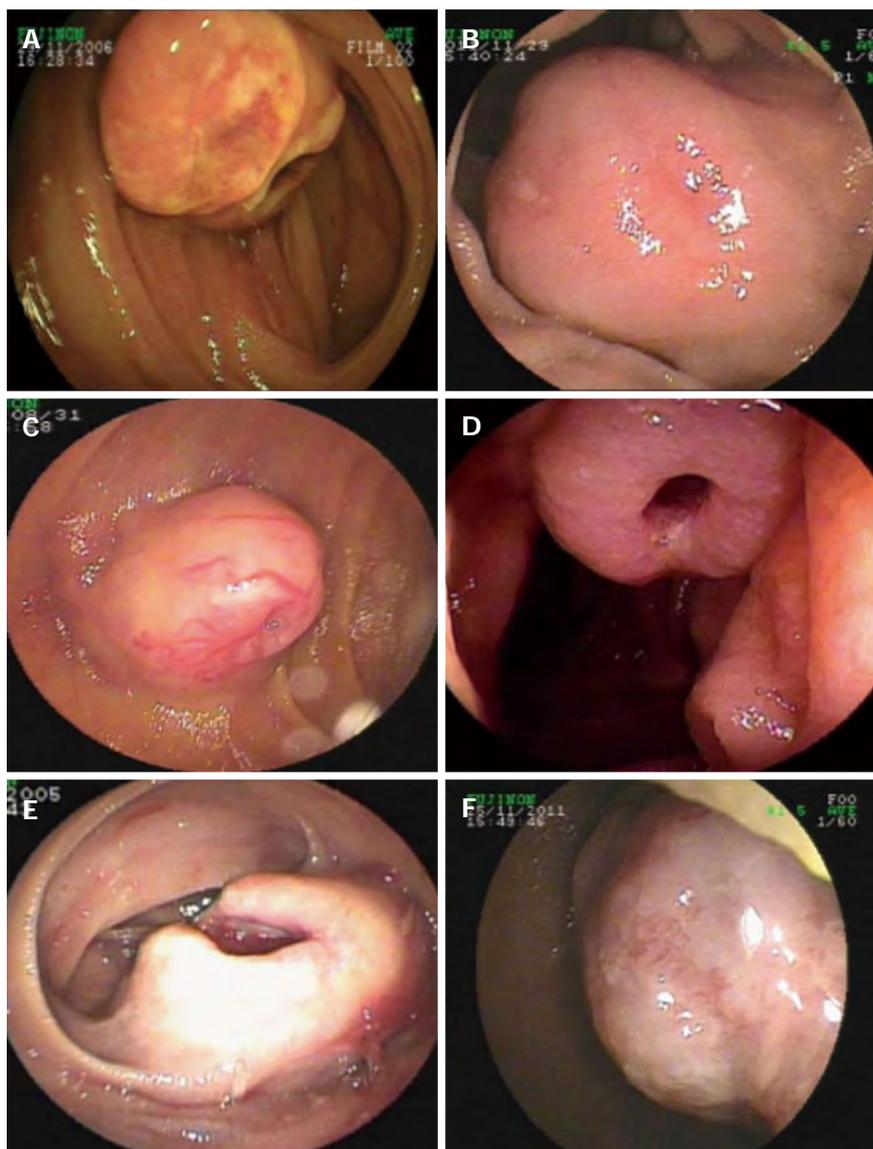

Figure 1 Unsmooth surface of verified gastrointestinal mesenchymal tumors, showing the appearance of erosion or ulcer. A, B, F: Ulcerative lesions in the surface of the tumors; C, D, E: Ulcerative and depressed pits (A-D: Gastrointestinal mesenchymal tumor; E: Leiomyoma; F: Lipoma).

DBE database in China, which represented more than 780 patients investigated by DBE for a variety of indications after the introduction of this modality. DBE produced a higher detection rate because GIMTs were diagnosed in 77 (9.8%) of 783 subjects who were suspected to have SBDs.

Other diagnostic modalities such as barium study and CT scan were used to detect SBTs prior to the introduction of CE and DBE. However, confirmative analysis is unfeasible for GIMTs. Moreover, surgical intervention should be performed cautiously in patients with indefinite diagnosis by these examinations. Small lesions are difficult to examine by these traditional examinations. DBE is performed to permit real-time visualization of the tumors and make a positional mark, which helps the surgeons to reveal the lesions. In our study, prior examinations only established clear diagnoses in a few patients. This may result in delayed interventions for GIMTs in patients

with negative diagnoses. Most GIMTs in the small bowel may be malignant and invasive. Early detection and diagnosis of GIMTs using DBE would be conducive to early intervention and improvement of prognosis. Therefore, DBE is a reliable method as a complementary tool for traditional methods (such as barium meal and CT) or as a direct means for detecting GIMTs in the small bowel.

As a noninvasive and pain-free tool for investigating the small bowel, these advantages have made CE more competitive than DBE. Previous studies have shown that using CE to diagnose SBTs produced a higher accuracy in suspected patients^[2,11,14,23]. Even though a small proportion of subjects received CE examinations before DBE, clear diagnosis for GIMTs established by CE was significantly lower than that by DBE in this study. This may be because of the nature of CE and confirmation of previous reports. CE is performed to visualize the GI tract according to bowel movement, this feature is

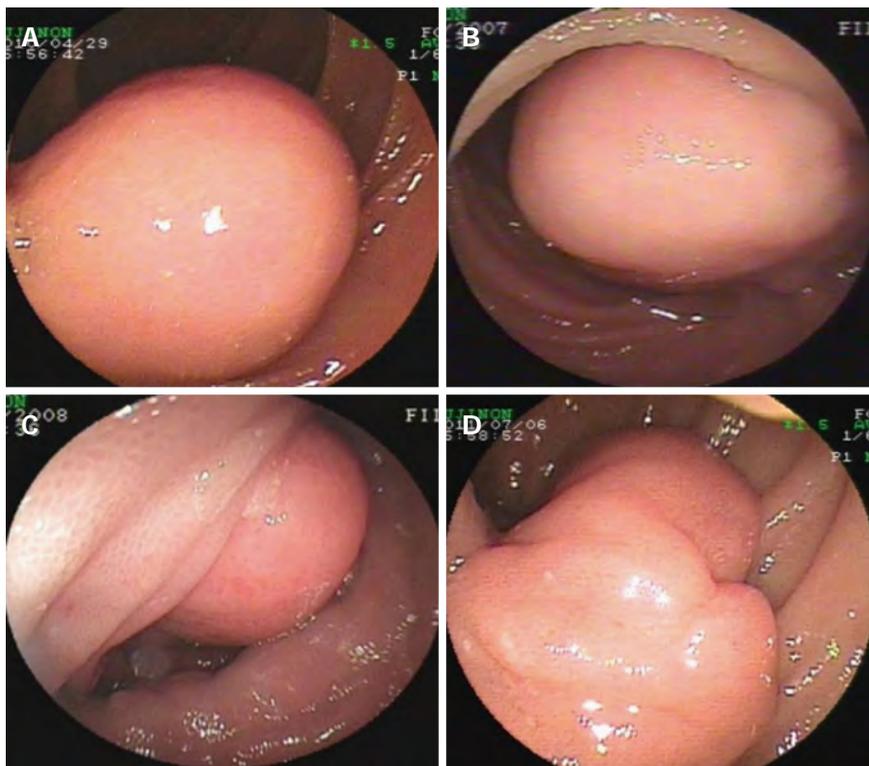

Figure 2 Morphology of verified tumors with smooth surface, indicating tumors with sessile base in round or oval shape. A-C: Single tumor with round shape and smooth surface (A, B: Gastrointestinal mesenchymal tumor; C: Lipoma; D: A polyp-like tumor with expanded tail, and hemangioma was confirmed by post-surgical pathology).

both an advantage and a disadvantage. False positive or false negative findings for SBTs are the significant limitations of CE^[24,25]. Missed diagnosis may occur during the examination because of only forward movement^[26]. An intra-luminal tumor without mucosal damage or with less protuberance into the lumen is a significant challenge for CE to establish a clear diagnosis. In diagnosis of GIMTs in this study, CE failed to detect the presence of tumors in some patients. This shortcoming can be overcome by DBE through straightening the intestinal tube, which can reduce greatly the possibility of missed tumors. Moreover, severe complications, such as intestinal obstruction or CE retention, may occur during the procedure^[27-31]. The most important aspect is that biopsy and histopathological establishment are unavailable for CE. These shortcomings of CE can be overcome by BAE.

Although previous studies have reported the diagnosis of DBE for SBTs and characterized the features of SBTs,^[15,17-19,32] there are differences in distinct types of tumors arising from different tissues. Furthermore, a few patients with confirmed GIMTs were detected in these studies. The present study exclusively focused on the diagnosis and characteristics of GIMTs investigated by DBE. In theory, tumors from mesenchymal tissues have similar clinical and endoscopic characteristics. As reported in the literature^[17-19,32], most SBTs are detected in adult patients and GI bleeding is a major indication for the DBE procedure. We found that patients with GIMTs were all adults. Males predominantly accounted for more

than half of the patients. GI hemorrhage is the most frequent symptom of GIMTs. The main site of SBTs reported in the literature is the ileum^[33]. Confirmed GIMTs from the current findings were almost exclusively located in the jejunum. Moreover, our rate of GIMTs (77/783) is higher than that previously reported^[18]. In fact, GISTs represented 77.9% of GIMTs in our series. It is reported that this type of tumor is more frequently seen in the proximal small bowel^[18,19].

We found that a single and focal lesion is typical of GIMTs, and that masses with a smooth or unsmooth surface are the most common in the small bowel. As far as GIMTs were concerned, precise diagnosis is readily concluded using the DBE procedure before histopathological analysis, which is judged by the endoscopic characteristics of GIMTs. According to our experiences and the findings of the present study, preoperative endoscopic diagnosis is consistent with the final histological diagnosis. As reported by Mitsui *et al*^[18] 40.9% of patients with GISTs were positively diagnosed by the biopsy specimen. In our series, the rate of positive diagnosis by biopsy pathology was lower in patients with GIMTs (12.2%) than that reported previously. Biopsy diagnosis for GIMTs is not as effective as postoperative pathology of the excised specimen. Therefore, endoscopic diagnosis by BAE for GIMTs is effective and significant in clinical practice.

In conclusion, DBE is a safe and valuable procedure for patients with suspected GIMTs, and provides accurate position for subsequent surgical intervention.

ACKNOWLEDGMENTS

We are grateful to our colleagues from the Department of General Surgery, Nanfang Hospital, Southern Medical University for their help with the study; and to the Department of Pathology, Nanfang Hospital, Southern Medical University for providing us the pathological images.

COMMENTS

Background

Previous studies reported that double balloon enteroscopy (DBE) is a safe and effective procedure for the diagnosis of small bowel tumors. To date, few reports have focused on the diagnosis of gastrointestinal mesenchymal tumors (GIMTs) detected by DBE and described their clinical and endoscopic features.

Research frontiers

A growing number of studies have been conducted on the diagnosis of small bowel diseases (SBDs) since the introduction of double-balloon enteroscopy. The current study exclusively focuses on the diagnosis of mesenchymal tumors in the small bowel and their clinical characteristics.

Innovations and breakthroughs

This study reported the diagnosis of GIMTs using the DBE technique and their clinical characteristics in 780 patients investigated by DBE for a variety of indications. DBE produced a higher detection rate because GIMTs were diagnosed in 77 (9.8%) out of 783 subjects who were suspected to have SBDs.

Applications

DBE is a safe and valuable procedure for patients with suspected GIMTs, and provides an accurate position for subsequent surgical intervention.

Peer review

This study is interesting, representing one of the largest DBE series ever reported and provides very good information for gastroenterologists. DBE is a very useful diagnostic tool for SBDs, particularly for the diagnosis of GIMTs for both gastroenterologists and surgeons.

Abstract

AIM: To evaluate potential risk factors in the development of ulcerative colitis (UC) in China.

METHODS: A total of 1308 patients with UC and 1308 age-matched and sex-matched controls were prospectively studied in China. The UC cases were collected from 17 hospitals in China from April 2007 to April 2010. Uniform questionnaires were designed to investigate risk factors including smoking, appendectomy, stress, socio-economic conditions, nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives, diet, breastfeeding, infections and family sanitary conditions. Group comparisons by each factor were done using simple logistic regression analysis. Conditional logistic regression was used for multivariate analysis.

RESULTS: By univariate analysis, the variables predictive of UC included feeling stress, light and heavy alcoholic drinking, spicy food, sugar consumption and infectious diarrhea, while heavy tea intake and tap water consumption were protective against UC. On multivariate analysis, the protective factor for UC was tap water consumption [odds ratios (OR) = 0.424, 95%CI: 0.302-0.594, $P < 0.001$]; while the potential risk factors for UC were heavy sugar consumption (OR = 1.632, 95%CI: 1.156-2.305, $P < 0.001$), spicy food (light intake: OR = 3.329, 95%CI: 2.282-4.857, $P < 0.001$; heavy intake: OR = 3.979, 95%CI: 2.700-5.863, $P < 0.001$), and often feeling stress (OR = 1.981, 95%CI: 1.447-2.711, $P < 0.001$). Other factors, such as smoking habit, appendectomy, breastfeeding, a history of measles, rural or urban residence, education, oral contraceptives, and NSAID use have not been found to have a significant association with the development of UC in the present study.

CONCLUSION: Our study showed tap water consumption was a protective factor for UC, while spicy food, heavy sugar consumption and often feeling stress were risk factors for UC in this Chinese population.

INTRODUCTION

The causes of inflammatory bowel diseases (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), remain unknown. IBD is thought to arise in genetically predisposed individuals who mount an aberrant immune response to gut microbiota secondary to some environmental trigger^[1]. Genetic susceptibility in the population should be relatively stable; it cannot account for the rapid rise of IBD incidence in China. Environmental factors may play an important role in the pathogenesis of IBD.

IBD has been primarily characterized as a disease of industrialized nations, emerging in the early 20th century in developed countries. In the past 20 years, incidence rates of traditionally high incidence areas such as North America and Europe have remained relatively stable or even decreased^[2], while the diseases have become more prevalent in previously low incidence areas as they have become industrialized^[3]. Recent surveys in China have

also shown that IBD, especially UC, has been increasing in China^[4-7].

A number of environmental risk factors have been explored in Western countries. There is no such epidemiologic study of large sample groups in Chinese populations. China presents an opportunity to study an environment that is evolving more to a Western-style based on changes in socioeconomics, diet habit, *etc.* The present study aims to assess the potential risk factors for the development of UC in the Chinese population by a multicenter case-control study.

MATERIALS AND METHODS

Patients and controls

A multicenter case-control study was undertaken in China during a 3-year period from April 2007 to April 2010. Patients were collected from 17 hospitals in 12 areas of China including Beijing and Dalian, which were chosen from Northern China; Shanghai, Nanjing and Hefei from Eastern China; Guangzhou from Southern China; Chengdu, Xian, Nanchong, Kunming from Western China; Wuhan and Changsha from Central China. The investigators were invited to take part in the program if their medical centers fulfilled the following requirements: (1) the medical center should be a university hospital or grade A tertiary hospital; and (2) diagnostic facilities for high-quality endoscopy, radiology and pathology should be available. The diagnosis of UC was made by clinical, laboratory, endoscopic, and histologic examinations in accordance with the suggested guidelines for the diagnosis and treatment of IBD, which were approved in China in 2007^[8].

Controls were randomly selected in the same area as friends, neighbors or colleagues of the patients and matched by sex and age during the study. The controls were healthy volunteers with no bowel disease or other severe disease.

Questionnaire survey

UC patients and controls were interviewed to complete a questionnaire. A uniform questionnaire was designed by the IBD collaborative group of the Chinese Digestive Association. The questionnaire included an exploration of dietary habits, smoking, alcohol use, oral contraceptives, nonsteroidal anti-inflammatory drugs (NSAIDs), previous appendectomy, breast-feeding in infancy, childhood measles virus infection, parasite infection, infectious gastroenteritis, education, employment, stress and family sanitary conditions (including lavatory and water conditions). Subjects were instructed to answer questions in such a way that the information reflected their behavior and characteristics prior to the appearance of disease symptoms. Participating investigators or supervised physicians were in charge of the questionnaire.

In the questionnaire, study subjects were asked about the consumption of milk, green tea, alcohol, spicy food,

Table 1 Social characteristics and household factors between ulcerative colitis and healthy controls

| Variables | UC | Control | P value | OR | 95%CI |

and sugar in the year before the appearance of symptoms. Consumption degree of each food item was assessed using the following three categories: none or rare, light (1-2 times a week) and heavy (3-6 times a week or every day for a period of at least 2 mo). Consumption of meat and vegetables was classified into the following 3 categories: vegetarian, meat-eater, and balanced diet. Vegetarian was defined as eater of fruits and vegetables, and never or hardly eats meat or any animal products. Meat-eater was defined as eater of meat and never or hardly eats fruits and vegetables. Balanced diet was defined as consumption of both meat and vegetables.

Oral contraceptive use was defined as use for at least 1 mo for any indication including birth control, hormone replacement therapy, regulation of menstrual disorders, or other reasons. NSAID use was defined as taking related drugs at least twice per week for a period of at least one month.

The questionnaire ascertained whether subjects were non-smokers, current smokers and ex-smokers. Non-smokers were defined as those who never or rarely smoked. Current smokers were those who had smoked more than 1 cigarette per day within 6 mo before the diagnosis of UC. Ex-smokers were defined as patients who quit smoking more than 6 mo before the diagnosis of UC.

The frequency of feeling stress was classified into none, occasionally (feeling stress 1-2 times a week) and often (feeling stress 3-6 times a week or every day for a period of at least one month).

Statistical analysis

Statistical analyses were performed using SPSS17.0 software. We compared the background characteristics of UC with those of control subjects by two-sample *t* tests or χ^2 tests. Group comparisons by each factor were done using simple logistic regression analysis. Multiple logistic regression analysis was performed to propose a final set of independent risk factors for UC. Odds ratios (OR) and 95%CI were calculated. Odds ratios are provided for associations that were statistically significant at a *P* value < 0.05.

RESULTS

Demographic characteristics

A total of 1308 UC patients and 1308 age-matched and sex-matched controls were enrolled. The age of the patients at diagnosis ranged from 16 to 70 years. The average age was 41.6 ± 12.3 years for UC patients and 41.4 ± 13.5 years for healthy controls. The male to female ratio was 1.23:1 both for UC patients and controls. There were no statistically significant differences between UC and the controls in age and sex ratio (*P* > 0.05).

Univariate analysis of risk factors for UC

Sociodemographic characteristics and family sanitary conditions for both UC patients and controls are shown in Table 1. Patients with UC were more likely to feel stress (22.9%) than controls (12.2%) (OR = 1.858, 95%CI: 1.440-2.398, *P* < 0.001). However, UC patients tended to be less likely to have used tap water as their primary water source compared with boiled well or tap water *vs* controls (OR = 0.210, 95%CI: 0.159-0.279, *P* < 0.001). There were no statistically significant differences between UC and the controls in living area in recent 5 years, educational status, lavatory and refrigerator details.

Dietary factors between the two groups are shown in Table 2. Compared with the group of none or rare tea intake, heavy tea intake before the diagnosis seemed to have a protective effect on the development of UC (OR = 0.738, 95%CI: 0.591-0.922, *P* = 0.007). In contrast to nonalcoholic drinkers, light and heavy alcoholic drinkers before the diagnosis were at a higher risk of developing the disease (light drinkers: OR = 1.264, 95%CI: 1.073-1.490, *P* = 0.005; heavy drinkers: OR = 1.453, 95%CI: 1.122-1.882, *P* = 0.005). Compared with the group of none or rare spicy food intake, UC patients were significantly more likely to ingest spicy food than controls (light intake: OR = 2.432, 95%CI: 1.943-3.043, *P* < 0.001; heavy intake: OR = 3.189; 95%CI: 2.513-4.046, *P* < 0.001). Compared with the group of none or rare sugar intake, subjects with UC were also significantly more likely to ingest sugar than controls (light intake: OR = 3.162, 95%CI: 2.480-4.032, *P* < 0.001; heavy intake: OR = 3.390, 95%CI: 2.921-5.288, *P* < 0.001). There were no significant differences in milk, vegetable and meat consumption between two groups. Medical histories and

| Meat-eaters | 10.4% | 9.4% | 0.421 | 0.909 | 0.720-1.147 |
| Balanced diet | 76.3% | 78.2% | 0.848 | 1.032 | 0.745-1.432 |

UC: Ulcerative colitis; OR: Odds ratio.

other issues between the two groups are shown in Table 3. As shown in Table 3, UC patients (14.1%) were more likely to report that they had ever had infectious diarrhea than controls (9.3%) (OR = 1.610, 95%CI: 1.256-2.064, $P < 0.001$). There were no significant differences in smoking status, breast feeding during infancy, appendectomy, measles and parasite infection, NSAID and oral contraceptive use between the two groups.

Multivariate analysis of risk factors for UC

The multivariate analysis by logistic regression analysis showed that consumption of tap water was a protective factor for UC (OR = 0.424, 95%CI: 0.302-0.594, $P < 0.001$); while the potential risk factors for UC were often feeling stress (OR = 1.981, 95%CI: 1.447-2.711, $P < 0.001$), spicy food consumption (light intake: OR = 3.329, 95%CI: 2.282-4.857, $P < 0.001$; heavy intake: OR = 3.979, 95%CI: 2.700-5.863, $P < 0.001$), and heavy sugar consumption (OR = 1.632, 95%CI: 1.156-2.305, $P < 0.001$).

DISCUSSION

This is the first multicenter study to investigate the risk factors of UC patients in the Chinese population. We conducted a case-control study during a 3-year period and evaluated a number of potential risk factors in a group of UC patients and a group of age-matched and sex-matched controls.

The major finding of the present study (on multivariate analysis) was to demonstrate that some dietary habits

Table 3 Smoking, breast feeding and medical history between ulcerative colitis and healthy controls

| Variables | UC | Control | P value | OR | 95%CI |
|-------------------------|-------|---------|---------|-------|-------------|
| Smoking | | | | | |
| Nonsmoker | 74.8% | 74.5% | | | |
| Current smoker | | | | | |
| < 10 cigarettes per day | 13.5% | 13.4% | 0.982 | 1.003 | 0.798-1.259 |
| > 10 cigarettes per day | 7.7% | 8.9% | 0.292 | 0.859 | 0.648-1.139 |
| Ex-smoker | 4.0% | 3.2% | 0.272 | 1.264 | 0.832-1.922 |
| Breast feeding | 46.5% | 53.5% | 0.628 | 1.080 | 0.790-1.477 |
| Infectious diarrhea | 14.1% | 9.3% | 0.000 | 1.610 | 1.256-2.064 |

UC: Ulcerative colitis; NSAIDs: Nonsteroidal anti-inflammatory drugs; OR: Odds ratio.

including sugar consumption, spicy food and tap water consumption were related to UC development.

First of all, our study confirmed that sugar consumption was related to an increased risk of UC. Previous studies have found strong positive associations between foods with a relatively high amount of sugar and CD^[9,10]. Tragnone *et al*^[11] confirmed that both UC and CD patients had a higher intake of total carbohydrate, starch, and refined sugar than did healthy controls. Russel *et al*^[12] reported consumption of cola drinks and chocolate were positively associated with developing ulcerative colitis. However, a negative relationship was found for carbohydrate consumption in a Canadian study^[13]. The possible reasons for this finding were studied in CD. Rashid *et al*^[14] report that high dietary starch intake increases the growth of intestinal microflora, among which *Klebsiella* microbes constituted an important part. Increased exposure to *Klebsiella* in the gut leads to high production of anti-*Klebsiella* antibodies as well as autoantibodies to the cross-reactive self-antigens with resultant inflammation at the pathological sites. Another study^[15] shows that translocation of *Escherichia coli* is reduced by soluble non-starch polysaccharide, but increased by the emulsifier Polysorbate-80. Although all studies above were related to CD, perhaps sugar is having the same deleterious effects in UC as it does in CD through effects on the composition of intestinal microflora or on the permeability of the gastrointestinal mucosa.

Secondly, spicy food is confirmed to be a risk factor for UC in our study. Another study from China also shows spicy food may contribute to the progress of UC^[16]. Capsaicin is the spicy component of hot peppers. Capsaicin can promote intestinal vasodilation, stimulate mucus secretion, and sometime even lead to diarrhea. Therefore, capsaicin may lead to changes in mucosal barrier function or colonic motility. Some studies also show capsaicin can modulate the lymphocyte prolifera-

tive response and induce tumor necrosis factor- α secretion^[17,18]. There is no such study about spicy food and UC. The exact effect and mechanism still needs further study.

Thirdly, our study shows consumption of tap water has a protective effect for UC. A systematic environmental factor study from the EPIMAD registry reported that the regular consumption of tap water decreased the risk of CD^[19]. Another two case-control studies revealed a more frequent hot water supply among patients presenting with CD than among controls^[20,21], but failed to find such an association with UC. Although findings are inconsistent, consumption of tap water may have the same protective effect in UC as it does in CD.

This is consistent with the hygiene hypothesis of IBD, which theorizes that a lack of exposure to enteric pathogens makes one susceptible to IBD. A possible explanation is that tap water may contain non-pathogenic bacteria which thrive in untreated water, but are absent from boiled water. This kind of bacteria may play an immunoregulatory role and reduce the risk of UC or CD by helping to establish the body's normal intestinal flora.

The data above showed that some dietary habits are related to UC development. Diet is probably the single most important factor influencing the composition and metabolic behavior of the microbiota. Some dietary habits may have a consistent impact on the gut microbiome or gastrointestinal mucosa permeability, and maybe trigger an aberrant immune response in genetically predisposed individuals.

Another finding of this study on multivariate analysis was to demonstrate that often feeling stress was a risk factor for UC. A case-control study observed an excess of life events in the 6-mo period prior to the onset of CD and UC^[22]. However, results remain controversial. The different results may be attributed to no standard method to measure stress and recall bias. Quantification and identification of stress remains a difficult task. Our study quantified "stress" by the frequency of feeling stress. As in most case-control studies, recall bias may be also a concern in this study.

In the present univariate analysis, a prior episode of infectious gastroenteritis and alcohol use were related to an increased risk of UC, while heavy tea consumption was shown to be a protective factor for UC. However, these positive associations failed to be demonstrated in the multivariate analysis.

Two large-scale case-control studies have also shown that IBD risk is higher in patients with a prior episode of infectious gastroenteritis, but specific pathogenic agents cannot be found in IBD^[23,24]. The hypothesis is that an enteric infection may trigger an initial change in the gut epithelial barrier resulting in exposure to microflora and disturbed adaptive and innate immune responses, leading to disease in a genetically susceptibility individual. Another possible reason for this finding may be related to antibiotics. Other studies^[25,26] have shown that exposure to antibiotics in childhood could hypothetically interfere

with the normal process of developing tolerance to enteric bacteria and may lead to IBD. However, we could not include this possible factor in the present study. Thus, further such studies are necessary to be done in China.

Alcohol has been shown to disrupt gut barrier function and increase intestinal permeability^[27,28]. However, another study reported an inverse relation between alcohol use and UC^[29]. Some studies also showed potential anti-inflammatory properties of green tea^[30,31]. It is likely that these factors are simply cofactors with other variables. Further studies are needed to examine these findings.

Other factors, such as smoking habit, appendectomy, breast-feeding in infancy, a history of measles, rural or urban residence, education, oral contraceptives, and NSAID use have not been found to have a significant association with the development of UC in the present study.

A main disadvantage of the study is that it is retrospective, relying on recall of childhood events and ingestions. There is a potential recall bias on some variables such as dietary ingestions. However, the recall issues should equally apply to cases with IBD and to controls. These data should be tested prospectively.

Exploring UC risk factors in China will be a great opportunity to advance our understanding of disease pathogenesis by investigating this aspect when the disease is newly emerging. Our study showed that often feeling stress, and a high intake of spicy food and sugar may enhance the risk of developing UC, while consumption of tap water may reduce the rate of presenting with UC. Smoking and appendectomy, which have been demonstrated to be associated with the development of UC in western studies, could not be confirmed in our study. These differences provide further evidence that environmental factors may influence development of UC and may give us some valuable clues to the cause of the disease. Thus, further studies are necessary to better understand the environmental determinants of IBD.

ACKNOWLEDGMENTS

The authors would like to thank all the members of the IBD collaborative group of the Chinese Digestive Association who have actively joined in the investigation.

COMMENTS

Background

Ulcerative colitis (UC) and Crohn's disease (CD) are collectively referred to as inflammatory bowel disease (IBD). The etiology of IBD has been extensively studied; however, causative factors are not yet fully understood. IBD is thought to arise in genetically predisposed individuals who mount an aberrant immune response to gut microbiota secondary to some environmental triggers. Genetic susceptibility in the population should be relatively stable, it cannot account for the rapid rise of IBD incidence in China. Environmental factors may play an important role in the pathogenesis of IBD. A number of environmental risk factors have been explored in western countries. However, there is a lack of such epidemiologic study in Chinese populations.

Research frontiers

A number of environmental risk factors of UC and CD have been explored in Western countries, including smoking, appendectomy, stress, socio-economic conditions, nonsteroidal anti-inflammatory drugs, oral contraceptives, diet, breastfeeding, infections/vaccinations, antibiotics, and childhood hygiene. However, most of these factors have demonstrated inconsistent findings.

Innovations and breakthroughs

The relationship between the risk of UC and environmental factors has been well studied, but the results are inconsistent in different racial populations. To date, there is no such epidemiologic study of large samples in Chinese populations. China presents an opportunity to study an environment that is evolving more to a Western-style based on changes in socioeconomics, diet habit, *etc.*

Applications

This study shows consumption of tap water is a protective factor for UC, while spicy food, heavy sugar consumption, and stress are risk factors for UC in Chinese populations.

Peer review

This is well done article. A great deal of work went into this study and should not be wasted. It is a clear paper with convincing results.

Abstract

Autoimmune hepatitis (AIH) is a necroinflammatory liver disease of unknown etiology. The disease is characterized histologically by interface hepatitis, biochemically by increased aspartate aminotransferase and alanine aminotransferase levels, and serologically by increased autoantibodies and immunoglobulin G levels. Here we discuss AIH in a previously healthy 37-year-old male with highly elevated serum levels of soluble interleukin-2 receptor and markedly enlarged hepatoduodenal ligament lymph nodes (HLLNs, diameter, 50 mm). Based on these observations, the differential diagnoses were AIH, lymphoma, or Castleman's disease. Liver biopsy revealed the features of interface hepatitis without bridging fibrosis along with plasma cell infiltration which

is the typical characteristics of acute AIH. Lymph node biopsy revealed lymphoid follicles with inflammatory lymphocytic infiltration; immunohistochemical examination excluded the presence of lymphoma cells. Thereafter, he was administered corticosteroid therapy: after 2 mo, the enlarged liver reached an almost normal size and the enlarged HLLNs reduced in size. We could not find AIH cases with such enlarged lymph nodes (diameter, 50 mm) in our literature review. Hence, we speculate that markedly enlarged lymph nodes observed in our patient may be caused by a highly activated, humoral immune response in AIH.

Case of autoimmune hepatitis with markedly enlarged hepatoduodenal ligament lymph nodes. *World J Gastroenterol* 2013; 19(11): 1834-1840 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1834.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1834>

INTRODUCTION

Autoimmune hepatitis (AIH) is histologically characterized by inflammatory cell infiltration (plasma cell-dominant), piecemeal necrosis in the portal area of the liver, hypergammaglobulinemia, and autoantibodies in the serum^[1,2]. The onset is frequently insidious with nonspecific symptoms; however, the clinical spectrum is wide, ranging from an asymptomatic presentation^[3,4] to an acute severe disease such as fulminant hepatitis^[5,6]. The

diagnosis is based on typical histological changes in the liver and the presence of autoantibodies in the serum after excluding other etiologies that cause liver diseases. Because there can be a wide range of presentations at onset, a prompt diagnosis is required to achieve a favorable prognosis.

Here we report the case of a previously healthy patient who developed acute hepatitis with markedly enlarged hepatoduodenal ligament lymph nodes (HLLNs).

CASE REPORT

A 37-year-old male presented to a hospital with the complaints of general fatigue, loss of appetite, and icterus for the past two weeks. He was a non-smoker and non-drinker with no relevant medical history. Until that date, blood biochemistry (including liver function) was normal. He gave no history of previous trauma, indulgence in casual sex, or illicit drug abuse. He was suffering from mild atopic dermatitis that was not treated. Laboratory examination revealed a high serum total bilirubin (T-Bil) levels of 13.8 mg/dL, aspartate aminotransferase (AST) levels of 828 IU/L, alanine aminotransferase (ALT) levels of 823 IU/L and alkaline phosphatase (ALP) levels of 1055 IU/L. In addition, the HLLNs were markedly enlarged along with elevated serum levels of the soluble interleukin-2 receptor (sIL-2R, 2167 U/mL).

Eventually, he was referred to our hospital. Upon admission, his blood pressure, pulse rate, and body temperature were normal. Neurological examination did not reveal hepatic encephalopathy; however, severe icterus was observed. The liver was palpable > 5 cm below the costal margin and was smooth and hard. Mild lymphadenopathy of the axillary lymph nodes (diameter ≤ 10 mm) was observed, which were palpable but asymptomatic.

The laboratory data collected at the time of admission are summarized in Table 1. Following were the important parameters recorded for evaluation: AST, 1068 IU/L; ALT, 696 IU/L; T-Bil, 15.6 mg/dL; prothrombin time/international normalized ratio (PT/INR), 1.2; immunoglobulin (Ig) G, 3814 mg/dL; anti-nuclear antibody (ANA) × 2560; anti-mitochondrial antibody (AMA)-negative; anti-smooth muscle antibody-negative; serum sIL-2R, 2550 U/mL.

Extensive serological screening was conducted to identify liver injury caused by viral infection. Subsequently, the following tests were negative: hepatitis A virus IgM (HA-IgM), hepatitis B surface antigen (HBsAg), anti-hepatitis B core antibody (HBcAb), hepatitis C virus (HCV) RNA, fourth-generation human immunodeficiency virus screening assay, and Epstein-barr virus viral capsid antigen IgM (EBV VCA IgM). In addition, we excluded other potential causes of acute hepatitis (drug-induced liver injury, hereditary hemochromatosis, and Wilson's disease). Cytomegalovirus IgM (CMV IgM) was positive by enzyme-linked immunosorbent assay (2.06); however, CMV IgG and pp65-antigenemia (by immunofluorescent

assay of peripheral blood leukocytes) were negative. Immunoelectrophoresis revealed increased polyclonal immunoglobulins. The following types of human leukocyte antigen were detected: A24, B7, B71, DR1 and DR4.

Ultrasonography of the abdomen revealed slightly heterogeneous liver parenchyma and hypoechoic masses around the main trunk of the portal vein. Dynamic computed tomography (CT) of the abdomen revealed an enlarged liver and markedly enlarged HLLNs (50 mm in length along the major axis). Periportal edema, hepatomegaly and thickening of the gallbladder wall were apparent, thereby suggesting acute hepatitis. These lymph nodes displayed high intensity in diffusion-weighted magnetic resonance imaging. Magnetic resonance cholangiopancreatography revealed no dilation of the biliary tract. The positron emission tomography (PET)/CT using ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) revealed mild uptake of ¹⁸F-FDG in these lymph nodes. The maximum standard-

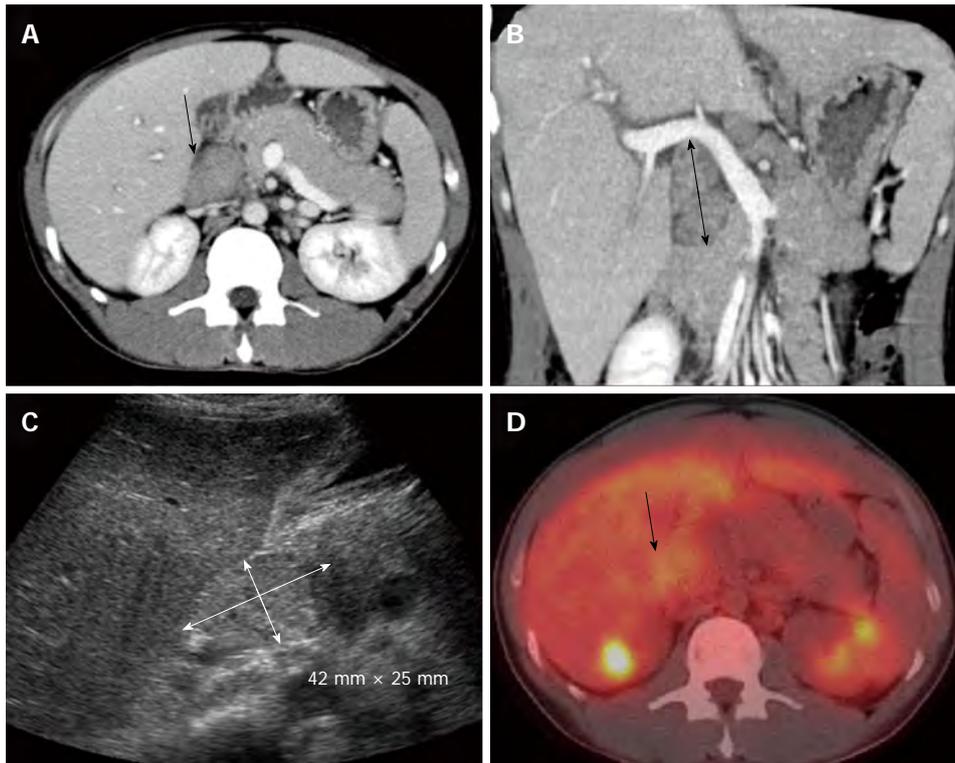

Figure 1 Imaging findings. A: Dynamic computed tomographic image (CT) of a transverse section; B: A coronal section revealing enlargement of the hepatoduodenal ligament lymph nodes (arrows); C: Ultrasonography of the abdomen revealing a large mass in the region of the hepatic portal vein (arrow); D: Positron emission tomography/CT using ^{18}F -fluorodeoxyglucose revealing mild accumulation. The maximum standardized uptake value was 3.98. The arrow shows the hepatoduodenal ligament lymph nodes.

ized uptake value was determined as 3.98 (Figure 1).

A high titer of ANA and high serum levels of IgG suggested the diagnosis of AIH; however, high serum levels of sIL-2R and markedly enlarged HLLNs prompted us to exclude the possibility of lymphoma before initiating the treatment. Biopsy of the liver and HLLNs were simultaneously performed. Liver biopsy revealed interface hepatitis and lymphocytic infiltration (plasma cell-dominant) without the formation of bridging fibrosis. Lymph node biopsy revealed lymphoid follicles with plasma cell infiltration; however, monoclonal prolifer-

ation of malignant cells was not observed by immunohistochemical staining. These observations confirmed the diagnosis of inflamed lymph nodes (Figures 2 and 3).

As per the international diagnostic criteria for AIH, our patient's score was 15^[7]. Using the simplified criteria for the diagnosis of AIH, the score was 8^[8]. These data were compatible with the final diagnosis of AIH. Moreover, the patient had a hyperbilirubinemia and a mildly reduced PT; thus, we had to consider the potential for severe acute hepatitis or fulminant hepatitis^[9]. Corticosteroid pulse therapy with 1000 mg of methylpredniso-

No evidences of granuloma or necrosis are visible; B: CD3 (T-cell marker) is positive in the interfollicular areas; C: CD10 (a marker of B-cell activation) is positive in the center of the follicles; D: CD20 (B-cell marker) is observed in the nodules; E: Kappa chain; F: Lambda chain. Neither the kappa nor the lambda chains predominate.

lone for 3 d was started followed by daily administration of 40 mg of prednisolone (per orally) with a dose reduction of 10 mg/d each week. Levels of AST, ALT and T-Bil improved gradually (Figure 4). At the time of discharge, the dose was 20 mg/d, thereafter the dose was reduced by 5 mg/d every 2 wk; subsequently, the levels of AST, ALT, T-Bil, and PT-INR improved. After 2 mo, the enlarged liver reached an almost normal size, and the markedly enlarged HLLNs reduced in size as well (Figure 5). Now, the levels of AST and ALT remain in the normal ranges with 5 mg/d of prednisolone after 8 mo and the size of HLLNs also presents normal size.

DISCUSSION

Here we present a case of AIH with markedly enlarged

HLLNs (50 mm in diameter). Liver biopsy revealed the features of acute phase AIH; lymph node biopsy revealed lymphoid follicles with inflammatory lymphocytic infiltration (plasma cell-dominant). He was successfully treated with oral prednisolone therapy. After 2 mo, the enlarged lymph nodes reduced in size and the serum AST and ALT levels lowered to normal ranges. In this case, a high serum titer of ANA and elevated IgG levels led us to a diagnosis of AIH. However, elevated serum levels of sIL-2R, markedly enlarged HLLNs, and accumulation of ^{18}F -FDG required us to exclude malignant lymphoma or Castleman's disease (CD).

A lymphoma in the abdominal cavity is not rare^[10], however, some cases of hepatic lymphoma (*e.g.*, lymphoplasmacytic lymphoma and T-cell/histiocyte-rich large B-cell lymphoma) have been reported to present as a dif-

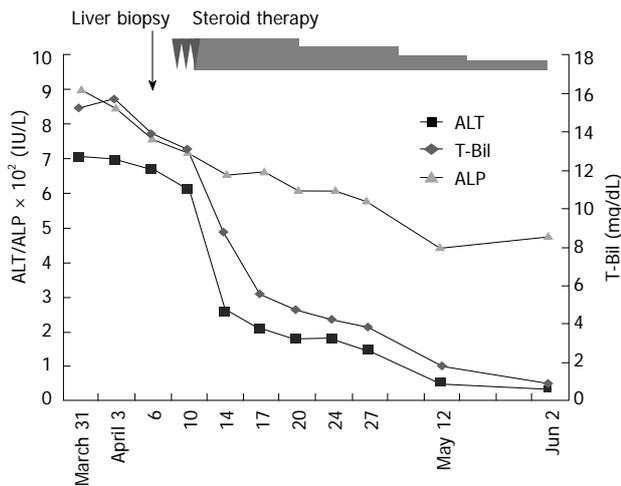

Figure 4 Clinical course. The patients showed high levels of alanine aminotransferase, alkaline phosphatase and total bilirubin. However, after the initial corticosteroid therapy, these levels improved gradually. ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; T-Bil: Total bilirubin.

fuse infiltration of the liver parenchyma without forming a discrete mass^[11]. Although the imaging findings of lymphoma vary appreciably in each case^[12,13], ¹⁸F-FDG PET/CT has become widely used in the diagnosis of malignant lymphomas. However, only 67% of marginal zone lymphomas and 40% of peripheral T-cell lymphomas can take up FDG^[14]. The blood chemistry reports and markedly enlarged HLLNs with weakly positive ¹⁸F-FDG PET indicated that a malignant lymphoma could not be excluded until biopsy.

CD (also known as angiofollicular lymph node hyperplasia) is a rare non-neoplastic lymphoproliferative disorder of unknown etiology^[15]. Two clinical presentations can be distinguished. The localized (unicentric) variant of CD is the most common form of the disease and is confined to a single lymph node chain or area; histologically, it is usually a hyaline vascular form and is often asymptomatic and curable by surgical excision. The systemic (multicentric) variant of CD is less common and more aggressive; its corresponding histological pattern is a plasma cell variant and rarely the plasmablastic type^[16]. Extremely high levels of interleukin (IL)-6^[17] could be a characteristic of the multicentric variant of CD but not of IgG4-related systemic disease or other diseases presenting with lymphadenopathy^[18]. CD is usually localized to the chest (especially in the mediastinum and neck) and rarely occurs in the abdominal cavity^[19]. A differential diagnosis was necessary between AIH and the unicentric variant of CD. However, in this case, high serum levels of liver transaminases, lymph node findings, and slightly increasing levels of IL-6^[17] did not correspond to the unicentric variant of CD. Another differential diagnosis was IgG4-related disease but serum levels of IgG4 were substantially low.

A high incidence of swelling of the intra-abdominal lymph nodes has been reported in patients with non-ma-

lignant tumors, particularly subjects with chronic hepatitis B (CHB), chronic hepatitis C (CHC) or primary biliary cirrhosis (PBC)^[20]. Swelling of the lymph nodes near the common hepatic artery has been observed in 77%-91% of patients with CHC and 96% of patients with CHB. In addition, a higher incidence of lymph node swelling in PBC (74%-100%) and AIH (13%-73%) has been reported^[21]. Furthermore, some studies have reported that lymph node size can be correlated with an index of hepatocellular injury^[22,23]. However, the correlation between lymph node size and laboratory data is controversial^[24]. We could not find cases of AIH with such enlarged lymph nodes in the literature review similar to the ones described in our case. The pathological significance of enlarged lymph nodes in liver disease is unknown; however, further studies of such cases might help in clarifying its significance.

sIL-2R is an extracellular domain of a membrane-bound IL-2 receptor that is detectable on the cell surface of lymphoid cell lines such as activated T cells and natural killer cells, monocytes, eosinophils^[25-27], and on the cell surface of some tumor cells^[28] as well. The biological function of sIL-2R is incompletely understood; however, it is thought to be a marker of T-cell activation^[28]. Some studies have demonstrated that sIL-2R levels are increased in liver diseases^[29]. Liver damage in AIH is triggered by CD4+ T lymphocytes that recognize a certain autoantigenic epitope on the hepatocytes^[30,31]. An activated immune system is deeply involved in the pathophysiology of AIH; thus, highly elevated serum levels of sIL-2R could reflect the inflammatory activity of AIH, as observed in our patient.

In summary, we reported a case of AIH with elevated serum levels of sIL-2R and markedly enlarged HLLNs. Cases with such enlarged lymph nodes (50 mm in diameter) in AIH were not found in our literature review. We speculate that markedly enlarged lymph nodes might reflect a highly activated, humoral immune response in AIH, as observed in our patient.

Abstract

Enteropathy-associated T-cell lymphoma (EATL) is an extremely rare disease, which is often related to gluten-sensitive enteropathy. It is an uncommon intestinal lymphoma with very poor prognosis and high mortality rate. In the absence of specific symptoms or radiological findings, it is difficult to diagnose early. Major complications of EATL have been known as intestinal perforation or obstruction, and only 5 cases of EATL are reported in South Korea. In this study, we report a case of 71-year-old male with symptoms of diarrhea, which later it progressed into cancer perforation of the colon. The initial colonoscopic findings were normal and computed tomography scan demonstrated a segmental

wall thickening of the distal ascending colon with non-specific multiple small lymphnodes, along the ileocolic vessels, but no signs of mass or obstruction. The histologic findings of resected specimen confirmed EATL type II. Patient expired two weeks after the operation. Therefore, we emphasize the need of random biopsy in the presence of normal mucosa appearance on colonoscopy for the early diagnosis of EATL.

INTRODUCTION

Enteropathy-associated T-cell lymphoma (EATL) is a rare gastrointestinal non-Hodgkin's lymphoma, originating from intraepithelial T lymphocyte, which is strongly related with celiac disease^[1]. Due to its scarcity, EATL is accounted for less than 1% of all non-Hodgkin's lymphomas category, which primarily involves the small bowel^[2]. EATL has generally poor prognosis with high mortality rate. World Health Organization classified two types of EATL, defined as type I EATL, which comprises 80%-90% and type II EATL, a monomorphic variant^[3]. We have experienced the first case of EATL type II involving the whole tract of the colon in South Korea that was initially misdiagnosed as enterocolitis, resulting in the fatal colon perforation.

CASE REPORT

A 71-year-old man was admitted to the hospital with persistent diarrhea and abdominal pain for the past 6 mo. At that time, his abdominal computed tomography (CT) showed segmental wall thickening of distal ascending colon with nonspecific multiple small lymph nodes along the ileocolic vessels with colonoscopic findings, which revealed normal mucosa in the entire colon (Figure 1A). He continued to have diarrhea and diffuse abdominal pain when he arrived at our institution. He had chronic ill-looking appearance with alert mental status. The initial vital signs checked were normal, with increased bowel sound and right lower quadrant area tenderness. The laboratory findings revealed white blood cell count 3840/mm³, Hb 9.3 g/dL, and Plt 134 × 10³/mm³ with peripheral blood morphology, showing normocytic normochromic anemia. In liver chemistry, aspartate aminotransferase was increased to 61 IU/L, and C-reactive protein check 6.4 mg/dL. A plain abdominal radiography showed paralytic ileus in the large-bowel with gaseous distention. With the supportive treatment, abdominal symptoms and follow-up abdominal X-ray showed gradual improvement. He was discharged after one week of admission; however, few hours after the discharge, he revisited to emergency room with sudden onset of acute abdominal pain with high fever and drowsy mental status. Patient assumed to be at septic shock condition with blood pressure measuring 60/40 mmHg, heart-rate 104/min, respiration 27/min, and body temperature 39.7 °C. Plain abdomen radiography revealed free air on the diaphragm, which indicated the perforation of the intestine. Abdomen CT scan showed large irregular masses on the right ascending colon and the hepatic flexure was seen with hydropneumoperitoneum, indicating colon cancer perforation (Figure 1B). Also, multiple enhanced enlarged lymph nodes were found in pericolic, right iliac chain, preaortic, portal hepatis and peripancreatic area, suggesting metastatic lesions. Emergent right hemi-colectomy of large bowel was performed, and post-operative gross findings from the resected tumor showed 9 cm × 7 cm × 3 cm size mass in the ascending colon extension to serosa layer, without the invasion to the adjacent area (Figure 2). Histologic findings showed tumor cells diffusely infiltrating the whole intestinal mucosa, involving the resection margins of the terminal ileum to the colon. The lymphoma cells were small to medium-sized, with round, hyperchromatic nuclei, having a stippled chromatin pattern. Immunohistochemical staining of the tumor cells expressed CD56 and positive for CD3 and CD8 intraepithelial lymphocytes, but negative for CD20 and Epstein-Barr virus. The adjacent mucosa showed heavy lymphoid infiltrate invading in all layers of the colon layer (Figure 3). The final diagnosis confirmed type II EATL.

Two weeks after the operation, the follow up colonoscopy revealed normal mucosa and several random multiple biopsies were made in the entire colon (Figure 4). Histologic findings re-confirmed type II EATL. We recommend the treatment of cyclophosphamide, doxorubi-

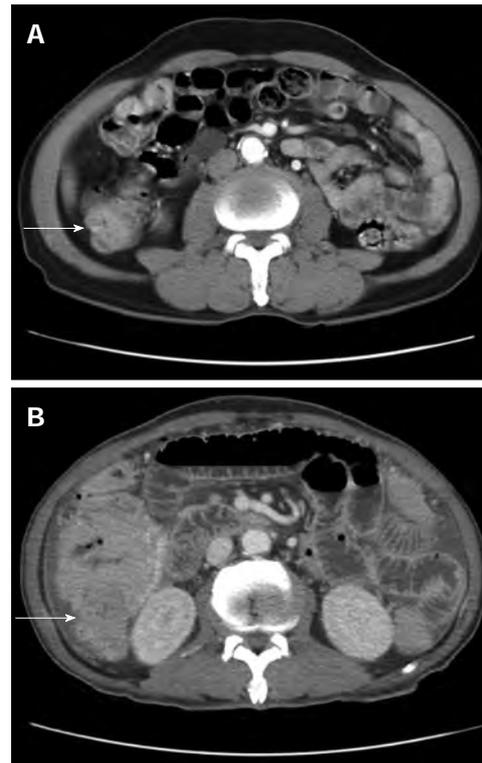

Figure 1 An abdominopelvic computed tomography shows segmental wall thickening of distal ascending with nonspecific multiple small lymph nodes along ileocolic vessels. Large irregular mass (A) in right ascending colon along hepatic flexure (B).

Figure 2 A gross specimen from the ascending colon after right hemicolectomy. In perforated site, there is an ulceroinfiltrative mass measuring 9 cm × 7 cm × 3 cm which is 13 cm away from ileocecal valve and distal resection margin, respectively. The tumor is grayish tan, fish-fresh and appears to extend to serosa.

cin, vincristine and prednisone chemotherapy to increase the chances of survival; however, he refused and wanted to go to a hospice facility near his hometown. He was transferred out and expired 3 d after the discharge from our institution.

DISCUSSION

Reports on the diffuse involvement of EATL type II are a rare finding, as described in this report. Recent ret-

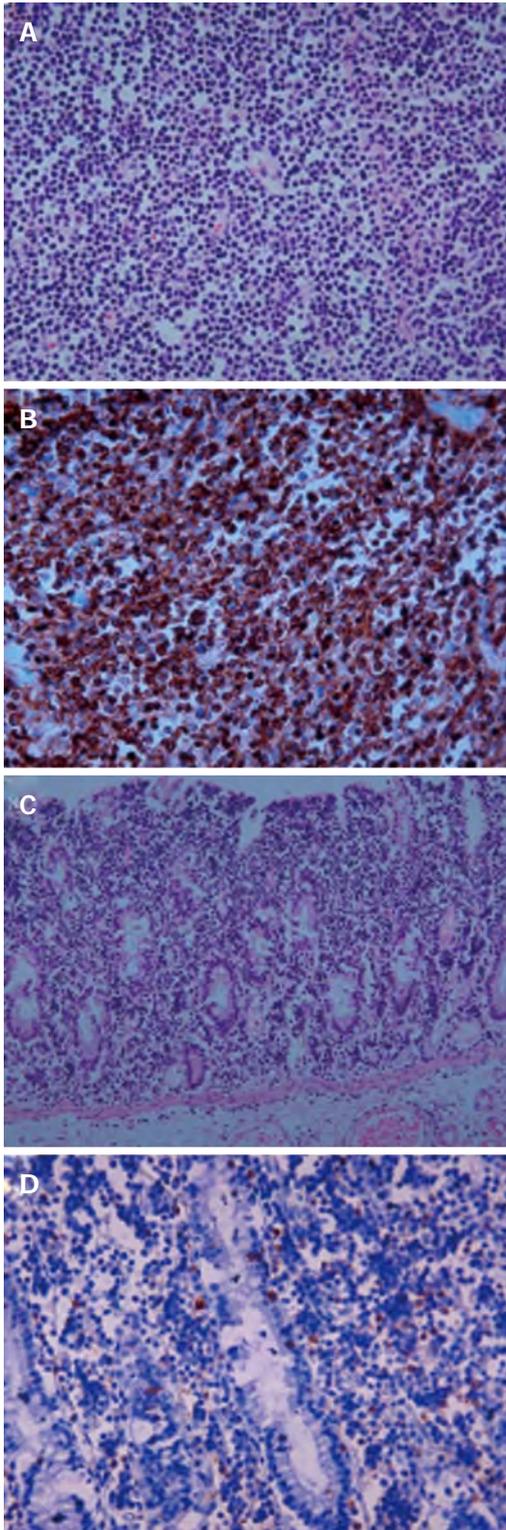

Figure 3 Histologic features in enteropathy-associated T-cell lymphoma type II. A: The lymphoma cells are small to medium-sized with round, hyperchromatic nuclei (x 400); B: The cells express CD56 (x 400); C, D: The adjacent mucosa shows heavy lymphoid infiltrate (x 200) (C) and CD8 positive intraepithelial lymphocytes (x 400) (D).

rospective study conducted by Asia Lymphoma Study Group have shown a few case series of EATL arising from an Asian population, site involving the whole colonic tract have not been reported yet. However, patho-

Figure 4 Colonoscopy revealed normal mucosa pattern in whole colonic tract.

logic features of type II EATL from Asian population were very different from those of classical EATL^[4].

Due to the absence of specific symptoms, EATL is often diagnosed after the intestinal perforation or obstruction, which makes it more difficult to give proper initial treatment. As reported in our case, the patient had an acute onset of lower abdominal pain, without other associated symptoms, and colonoscopic findings were normal with non-specific findings on radiologic studies. A similar case was reported recently on 39-year-old African-American male, who was diagnosed with EATL after emergent exploratory laparotomy^[5]. Among gastrointestinal tumors, primary gastrointestinal lymphomas comprise of 5%-10% of all non-Hodgkin's lymphoma and EATL accounts for less than 1% of all non-Hodgkin's lymphoma^[6]. The prevalence of the annual incidence of EATL is 0.5-1 per million people in Western countries^[7]. WHO classified the two types of EATL: Type I EATL more often arising in areas with the high prevalence of celiac disease, while type II EATL seen in regions where celiac disease prevalence is rare. Sharaiha *et al*^[8] reported that type I EATL is significantly increasing in the United States with close relation to celiac disease steadily rising every year. On the contrary, gluten sensitive celiac disease is rare in South Korea with very low prevalence^[9]. The immunophenotype of type II EATL show distinctive pattern, in which the tumor cells are positive in CD3, CD8+, CD56+ and TCR β + and the intraepithelial lymphocytes in the adjacent mucosa share the identical immunophenotype^[10]. The neoplastic cells have medium-sized, round, darkly staining nuclei, with a rim of a _ENREF_7 pale cytoplasm^[11]. There has been interesting case report by Okumura *et al*^[12] on the unusual type II EATL with MYC translocation in a Japanese patient, recently. As shown in our case, immunohistochemistry confirmed us to diagnose EATL and its subtype, rather than imaging study or colonoscopy. Therefore, it is crucial to require adequate biopsy and immunophenotyping to give early diagnosis and treatment to patients. With the introduction of a double balloon enteroscopy in 2003, diagnosis of celiac disease has been significantly advanced by non-surgical modalities^[13]. And a recent study on the usefulness of

diagnostic ¹⁸F-fluorodeoxyglucose-positron emission tomography (¹⁸F-FDG-PET) in distinguishing between the sites of lymphoma and refractory celiac disease over CT showed better sensitivity and specificity^[14]. Also, there was a case report using a capsule endoscopy to detect EATL involving the small bowel^[15]. As described above, double balloon enteroscopy, ¹⁸F-FDG-PET and capsule endoscopy might be all useful options to detect EATL in advanced to increase survival of patients. One-year survival rate of the intestinal T-cell non-Hodgkin's disease is 33%, and five-year survival to be 9%^[16]. The prognosis of EATL is more decimating; when treated with surgery and/or systemic chemotherapy, 80%-84% of patients die with a 5-year survival rate of 3.2%. Chemotherapy seems to be more beneficial to patients rather than surgery; however, there is no difference in the outcome between patients with type I and type II EATL^[17].

Our patient had chronic abdominal symptoms with normal colonoscopic findings. Diagnostic tools, such as plain abdominal X-ray, CT and colonoscopy findings were not effective to diagnose EATL in advance. And considering that most of colonoscopists do not perform a biopsy if mucosa shows normal pattern, this may delay from an early discovery of EATL.

In summary, we report a unique case of diffuse involvement of type II EATL of colon with perforation, who was presented with non-specific radiological findings. Therefore, we emphasize the need of a random biopsy or capsule endoscopy to diagnose EATL early. Due to the disease appearance resembling features of colitis, careful attention should be made to reveal its obscure clinical manifestations, and physicians should be aware to conduct through physical examination and adequate biopsy to rule out EATL_ENREF_10.

Abstract

We present three cases of gastrointestinal muco-submucosal elongated polyps, two located in the duodenum and one in the descending colon. All three cases had a characteristic, “worm-like” endoscopic appearance and were lined by unremarkable mucosa. The vascular component was located in the submucosa and was composed of a mixture of variably dilated blood vessels (capillaries and veins) and lymphatics. The duodenal polyps displayed lipomatous metaplasia of the submucosal stroma. The dual vascular phenotype of the vascular component was confirmed by immunohistochemistry with D2-40 and CD31.

Tan CL, Tan SH, So JBY, Petersson F. Muco-submucosal elongated polyps of the gastrointestinal tract: A case series and a review of the literature. *World J Gastroenterol* 2013; 19(11): 1845-1849 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i11/1845.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i11.1845>

INTRODUCTION

Benign gastrointestinal polyps composed of mucosa and submucosa, the latter with a prominent vascular component are relatively unusual non-neoplastic lesions with uncertain etiopathogenesis. Such polyps have mainly been studied by Japanese investigators, but are increasingly being recognized by western investigators^[1,2]. The nomenclature pertaining to these polyps has varied. In the seminal paper on this entity, Mataka *et al*^[3] chose the term “colonic muco-submucosal elongated polyp”. Most of the reported cases have been located in the large bowel^[4-7], but three polyps with identical endoscopic and histological features have also been documented in the small bowel, including the duodenum^[8-10].

Irrespective of site, muco-submucosal elongated polyps display characteristic endoscopic features, with a “worm-like” appearance which are lined by unremarkable mucosa. Histologic examination confirms the presence of a normal mucosa and reveals a submucosal component with a variably prominent mixture of blood vessels and lymphatics and absence of significant inflammation. In this paper we present the clinicopathologic features of three additional cases of this entity and review the literature on these characteristic benign gastrointestinal polyps.

CASE REPORT

Case 1

A 55 year-old previously healthy female presented with postprandial abdominal discomfort of 3 mo duration. There were no signs or symptoms of gastrointestinal bleeding or malabsorption. Gastroduodenoscopy revealed a 4 cm long, slender, “worm-like” polyp in the second part of the duodenum (Figure 1A). The polyp was

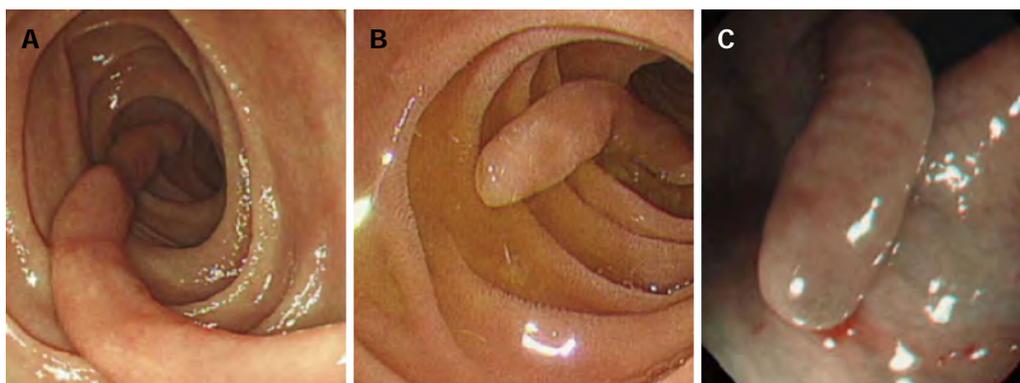

Figure 1 Endoscopic views of the polyps. A: Gastroduodenoscopy revealed a 4 cm long, slender, “worm-like” polyp in the second part of the duodenum; B: Gastroduodenoscopy showed a 2.2 cm long, slender polyp in the duodenum; C: Colonoscopy showed a 1.4 cm long, slender polyp in the descending colon.

removed endoscopically. The patient was well on follow up at 3 mo.

Case 2

A 70 year-old previously healthy man presented with reflux symptoms of unknown duration. Gastroduodenoscopy showed a 2.2 cm long, slender polyp in the duodenum (Figure 1B). The polyp was removed endoscopically.

Case 3

A 74 year-old female with a history of hypertension and iron deficiency anemia secondary to peptic ulcer disease presented with epigastric pain associated with constipation of 1 mo duration. Colonoscopy showed a 1.4 cm long, slender polyp in the descending colon (Figure 1C) and a distal rectal ulcer near the anal verge. The polyp was removed endoscopically. There was no evidence of diverticular disease. In addition, gastroduodenoscopy showed several benign gastric and duodenal ulcers (biopsies from the gastric ulcers showed mild chronic gastritis with reactive changes and no activity; no *Helicobacter pylori* were identified; the rectal biopsy showed features consistent with a solitary rectal ulcer).

The tissues were fixed in neutral formalin and both polyps were completely embedded in paraffin. 4 µm thick sections were cut and stained with hematoxylin and eosin (HE). An immunohistochemical study with commercially available antibodies (D2-40-podoplanin, CD31) using protocols according to the manufacturers’ recommendations were employed in Case 1 and 3. Immunohistochemistry with WT-1 were performed in all three cases.

Gross findings and histology

All three polyps were thin and elongated corresponding to the “worm-like” endoscopic appearance (Figure 2A). All polyps were lined by unremarkable mucosa. The submucosal components contained prominent vasculature including dilated, variably sized veins and lymphatic vessels running parallel to the long axis of the polyps and surrounded by loose collagenous stroma (Figure 2B and C). In addition, there was also focal lipomatous metaplasia in both duodenal polyps. No arterial vascular com-

ponent was identified. No vascular abnormalities were present in the mucosa. No significant inflammation was identified.

Immunohistochemistry

The endothelial cells of both vascular components in the polyps displayed immunoreactivity for CD31 throughout the lesion (Figure 3A). D2-40-podoplanin was selectively expressed by the endothelial cells of the lymphatic component (Figure 3B). In Case 1 and 2, the endothelial cells of both vascular components displayed patchy cytoplasmic positivity for WT-1 whereas Case 3 was completely negative (data not shown).

DISCUSSION

We herein report three cases of muco-submucosal elongated polyps, two in the duodenum and the other one in descending colon. This characteristic, albeit unusual entity, is not well covered in most standard textbooks in gastrointestinal pathology. Initially described by Japanese investigators, Matake *et al.*^{3,11} published two series of these polyps comprising 19 cases *in toto*. The polyps ranged in size from 1.2-16 cm (mean 2.9 cm) and displayed a characteristic appearance (elongated, slender, drumstick shaped). Histological examination revealed normal mucosa and a loose to dense submucosal layer containing a variably prominent vascular component composed of dilated blood vessels (veins and capillaries) and lymphatics. Subsequently, these polyps have been increasingly recognized and mostly documented in the large bowel (all parts) including rectum^{1,5,6,12,13}. In all 23 reported polyps from the large bowel, the size has ranged from 0.7 to 15 cm (mean 2.8 cm).

Two polyps with endoscopic and morphologic features conforming to a muco-submucosal elongated polyp have also been described in the small bowel^{9,10}.

In addition, in 2009, Kim *et al.*⁸ reported a case of a 5 cm long duodenal polyp with a “wormlike/drumstick” endoscopic appearance which they labelled as “polypoid vascular and lymphatic malformation of the duodenum”. The histologic features as described by the authors and the provided photomicrographs show, in our opinion, a

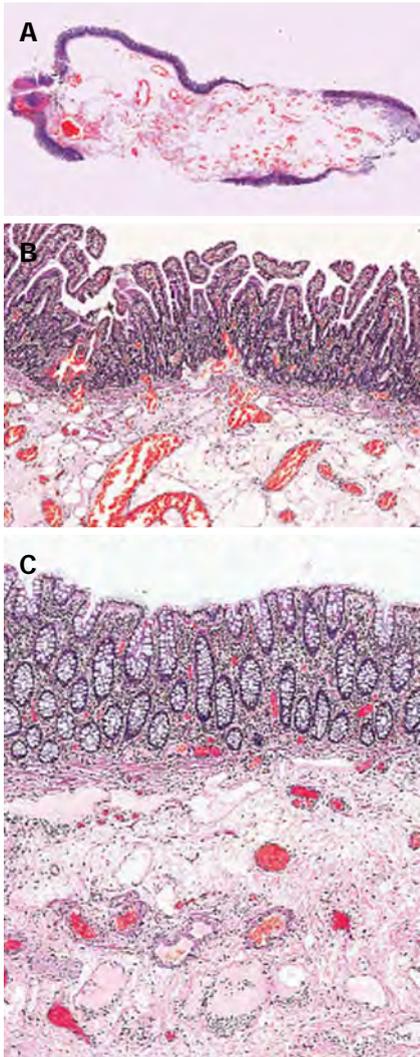

Figure 2 Histological section (hematoxylin and eosin staining). A: Case 1; B: Case 1 with normal small intestinal mucosal lining; C: Case 3 with normal large bowel mucosa overlying the submucosa which contains a prominent vascular component.

muco-submucosal elongated polyp.

Our Case 1 and 2 were of duodenal origin, which is a rare site and thus represents the third and fourth published cases of muco-submucosal elongated polyps of the small bowel.

A lesion resembling muco-submucosal elongated polyps has been described by Kelly^[14]. In this paper, the author characterized eight cases of swollen mucosal folds and broad based, ‘leaf-like’ polyps with mucosal and submucosal vascular congestion, thrombi, edema, hemorrhage and hemosiderin deposits in the sigmoid colon associated with diverticular disease in resection specimens. In addition to the submucosal component, these polypoid lesions showed mucosal prolapse-type changes. The author adequately labelled these lesions “polypoid prolapsing mucosal folds in diverticular disease” (PPMF). Interestingly, cases of muco-submucosal elongated polyps associated with diverticular disease have also been documented^[1,7]. In contrast to muco-submucosal

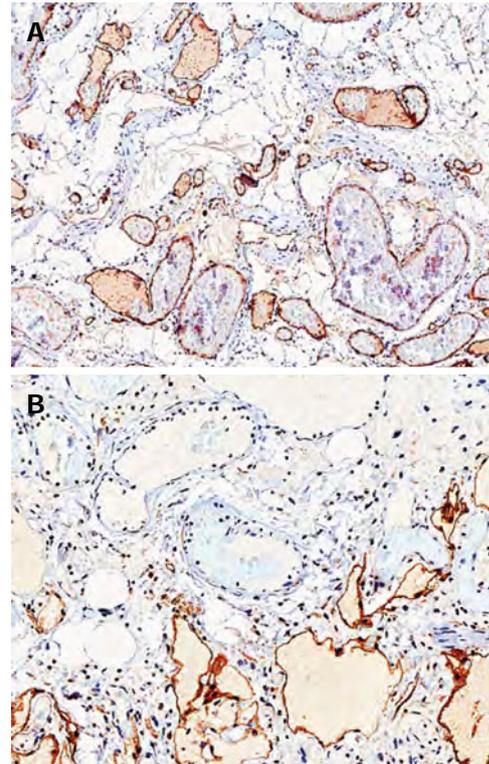

Figure 3 Immunohistochemistry. A: Positivity for CD31 in the endothelial cells of both vascular components; B: Positivity for D2-40/podoplanin selectively expressed by the endothelial cells in the lymphatic vessels.

elongated polyps, PPMFs do not display the “wormlike”, slender gross appearance with narrow attachment to the bowel mucosa. In addition, on histological examination, the mucosal component in PPMFs shows prolapse-type changes, which reportedly are absent in muco-submucosal elongated polyps, including the three cases presented herein.

Absence of significant inflammation in muco-submucosal elongated polyps also differentiate this entity from other mucosal prolapse associated polyps such as inflammatory “cap” polyps, inflammatory cloacogenic polyps and inflammatory myoglandular polyps^[15].

Filiform polyps (a subtype of inflammatory polyps) characterized by finger like projection covered by normal colonic mucosa with central core containing vessels and smooth muscle fibers can also mimic muco-submucosal elongated polyps. However, these polyps are usually multiple (“filiform polyposis”) and are associated with inflammatory bowel disease. Of note is that cases without apparent history of inflammatory bowel disease appear to exist^[16].

An inverted colonic diverticulum is a clinically important differential diagnosis. When these are large in size, they may resemble a pedunculated polyp and an endoscopic polypectomy may be performed which is associated with risk of perforation^[17]. A high index of clinical suspicion is important for these lesions and the key to its recognition is the endoscopic association with conventional diverticuli in the segment where the polyp

is located. A small biopsy from an inverted diverticulum shows non-specific features including normal to mildly inflamed mucosa and congested submucosa with variable degrees of chronic inflammation.

The residual stalk after a previously excised pedunculated adenoma or after autoamputation of any pedunculated polyp may also come into the endoscopic and histological differential diagnosis. Distinguishing, albeit non-specific features, are procedure related changes (granulation tissue and hemosiderin) and obviously, a history of previous polypectomy.

The etiology of muco-submucosal elongated polyps is unknown. It has been suggested that the gastrointestinal peristaltic movement may serve as mechanical traction for redundant mucosa, thereby making such areas of mucosa a nidus for polyp formation^[3,18]. In line with this, Alizart *et al*^[11] hypothesized that focal areas with prominent submucosal venous plexus may elevate the mucosa and serve as the leading point/nidus for the traction and hence polyp formation. A similar explanation has also been put forward by Kelly^[14] to explain the formation of PPMFs associated with diverticular disease.

We have immunohistochemically confirmed that the submucosal vascular component is composed of both blood vessels and lymphatics. Thus, we suggest that in addition to the criteria for the diagnosis of muco-submucosal elongated polyp as suggested by Alizart *et al*^[11]: (1) elongated, cylindrical shape with narrow base; (2) presence of submucosa; (3) absence of marked architectural disturbance of the overlying mucosa; and (4) absence of inflammatory infiltrate in both the mucosa and submucosa; the presence of a significant vascular submucosal component with a dual phenotype could be added to these criteria.

The endoscopic ultrasonographic features of muco-submucosal elongated polyps have been reported by Takahashi *et al*^[12] and Akahoshi *et al*^[13]. The ultrasonographic findings appear characteristic for this entity and in all lesions, elongated polypoid structures with both mucosal and submucosal layers were visualized. The “microcystic components” that the authors reported in the submucosal layer, most likely corresponds to the ectatic vascular component that is characteristically present in these lesions. The authors conclude that the distinctive ultrasonographic features allow for the diagnosis to be made and hence differentiate muco-submucosal elongated polyps from other submucosal lesions such as leiomyoma, lipoma and lymphangioma^[13]. Successful endoscopic removal of muco-submucosal elongated polyp (as in our cases) have previously been reported^[5,6,9,13].

Recently it has been suggested that endothelial cytoplasmic immunohistochemical expression of WT-1 is helpful in discriminating between cutaneous vascular neoplasms and vascular malformations. Trindade *et al*^[19] studied 117 cutaneous vascular neoplasms and 50 vascular malformations and found that all vascular neoplasms showed diffuse endothelial expression of WT-1 whereas all vascular malformations except for the arteriovenous

type were negative. The expression of WT-1 in a random manner in our first and second case and complete negativity in our third case lend support to the reactive nature of the vascular components in muco-submucosal elongated polyps. However, it is important to bear in mind that all the cases in Trindade *et al*^[19] study were of cutaneous origin and the underlying molecular mechanisms behind the development of cutaneous and intestinal vascular lesions may differ. Further studies are warranted to clarify this.

In conclusion, we report three cases of gastrointestinal muco-submucosal elongated polyps with prominent submucosal vascular components. One of these was located in the large bowel and the other two were of duodenal origin. We have determined by immunohistochemistry that the vascular component is a mixture of blood vessels and lymphatics. The endoscopic ultrasonographic appearance of these polyps appears to be characteristic allowing for a high degree of certainty in making this diagnosis by the endoscopists.

ACKNOWLEDGMENTS

We would like to thank Department of Pathology, Singapore General Hospital for performing immunohistochemistry D2-40-podoplanin on Case 1 and 3.

Abstract

Extranodal natural killer/T-cell lymphoma (ENKTL) is a distinct subtype of non-Hodgkin's lymphoma and is rare in the colon. Synchronous adenocarcinoma and ENKTL of the colon has not been reported in the literature. In the present study, we report a 63-year-old male who suffered from intermittent bloody stools for 2 mo. He did not have fever, body weight loss or night sweat. Endoscopic and imaging studies revealed a 4.5-cm ulcerative mass in the ascending colon and a 3.0-cm polypoid, easy bleeding mass in the sigmoid colon, respectively. Thought to have double carcinoma of the colon, he received simultaneous right hemicolectomy and sigmoidectomy. The pathological diagnosis was a synchronous ENKTL (ascending colon) and adenocarcinoma (sigmoid colon). The literature on synchronous adenocarcinoma and malignant lymphoma of the colon

was also reviewed.

INTRODUCTION

Malignant lymphoma of the colorectum is uncommon with an incidence of less than 0.5% of all malignant large intestinal tumors^[1], and comprises 5.8% of all gastrointestinal lymphomas^[2]. Synchronous colonic adenocarcinoma and malignant lymphoma in the same patient is rare with an estimated incidence of around 0.0002%^[3]. Synchronous colonic adenocarcinoma and extranodal natural killer/T-cell lymphoma of the colon has not been reported. Herein, we present such a rare case and review the literature.

CASE REPORT

A 63-year-old male with a 2-year history of hypertension and gout under medical control visited our outpatient department on April 25, 2012. He complained of intermittent bloody stool passage in the previous 2 mo. There was no B symptoms (fever, night sweating, body weight loss greater than 10% in the past 6 mo) noted. Dark red blood in the upper rectum was noted during

digital examination and tumor bleeding was suspected. Colonoscopy was performed one week later, which revealed an approximately 4-cm ulcerated mass coated with necrotic tissue in the proximal ascending colon near the ileocecal valve (Figure 1A). Another 3.5-cm bleeding mass was located 30 cm from the anal verge (Figure 1B). Biopsies were taken from the two masses, which showed necrotic tissue and adenocarcinoma *in situ*, respectively. After discussion, the patient was admitted for colectomy to remove the two masses. On admission, his vital signs and routine blood and biochemical studies were all within normal limits. The tumor marker, carcinoembryonic antigen, was mildly elevated at 9.4 ng/mL (normal range: 0-7 ng/mL). During preoperative evaluation, a computed tomography (CT) scan of the chest and abdomen was performed and revealed an irregular mass in the proximal ascending colon and a polypoid, protruding mass located in the sigmoid colon (Figure 1C). A tiny questionable pulmonary nodule (about 1-2 mm) of unknown nature in the left upper lung lobe was also noted at this time. Thought to have double carcinoma of the colon with sparing transverse and descending colon and for keeping well post-operative life quality, he underwent laparoscopic right hemicolectomy and sigmoidectomy with anastomosis on May 4, 2012. Grossly, the specimen from laparoscopic right hemicolectomy demonstrated an ulcerative mass, measuring 4.5 cm × 3.5 cm × 1.2 cm, in the proximal ascending colon with ileocecal valve involvement (Figure 1D). The tumor was yellow-green in color, ulcerative and necrotic. On cutting, the mass showed a yellowish fleshy cut surface and invaded serosa. Some enlarged lymph nodes, measuring up to 1.0 cm were noted. Microscopic examination revealed an ulcerative tumor composed of sheets of large pleomorphic lymphoid cells with a scattered angiocentric pattern and patchy necrosis (Figure 1E and F). The tumor had metastasized to three of the twelve right pericolic lymph nodes. On immunohistochemical study, the neoplastic lymphocytes were positively stained for CD3, CD56 (Figure 1G), T cell intracellular antigen 1 and CD30, but negatively stained for pancytokeratin, CD20, CD246 (ALK), CD4, CD8 and myeloperoxidase. An *in situ* hybridization (ISH) study revealed positive Epstein-Barr virus encoded RNA (EBER) in tumor nuclei (Figure 1H). Other parts of intestinal tissue showed no evidence of atrophic mucosa or enteropathy. The pathologic diagnosis was extranodal NK/T-cell lymphoma, nasal type, of the proximal ascending colon. The specimen from sigmoidectomy showed a red fleshy and polypoid mass, measuring 3.0 cm × 2.0 cm × 1.2 cm, taken from the central part of the sigmoid colon (Figure 1I). On cutting, the mass showed a polypoid, fleshy cut surface and invaded subserosa grossly. Microscopically, this tumor revealed marked pleomorphic tumor cells with complex glands, foci of cribriform formation, and an extensive infiltrative pattern (Figure 1J). The pathologic diagnosis was a moderately-differentiated adenocarcinoma. Four pericolic lymph nodes with no evidence of metastasis were retrieved in this specimen. An additional ISH

study of the adenocarcinoma showed negative EBER. In accordance with these findings, a synchronous adenocarcinoma of the sigmoid colon and extranodal natural killer/T-cell lymphoma (ENKTL) of the proximal ascending colon was finally diagnosed. His post-operative course was uneventful and he was discharged 10 d after surgery.

On June 14, 2012, the patient was readmitted for further tumor staging and chemotherapy. His ECOG performance score was grade 1. A tumor survey using sinuscopy showed no tumor in the upper respiratory tract. Bone marrow biopsy performed on June 16, 2012 revealed neither tumor nor granuloma. Biochemical studies showed a lactate dehydrogenase (LDH) level of 176 IU/L (normal range: 85-227 IU/L). A CT scan of the head, neck, chest and abdomen was performed and showed multiple nodules in bilateral lungs with the largest nodule being 1.2 cm in diameter in the left upper lung lobe. He then received chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP). Unfortunately, a subsequent chest CT scan revealed rapid progression of bilateral lung nodules; the largest nodule being 5.4 cm in diameter in the right upper lung lobe on September 3, 2012 (Figure 1K). It was confirmed to be metastases of ENKTL by CT-guided biopsy (Figures 1L and M). In addition, serum LDH was markedly elevated at 1079 IU/L. Due to poor response to chemotherapy, the regimen was changed to dexamethasone, methotrexate, ifosfamide, *L*-asparaginase and etoposide but this was in vain. The patient died of respiratory failure secondary to lung metastasis on September 21, 2012. The survival time after diagnosis was only 4.5 mo.

DISCUSSION

The gastrointestinal tract is the most frequently involved extranodal site in non-Hodgkin lymphoma, stomach being the most common (50%-60%) followed by the small intestine (30%)^[4]. ENKTL is an extranodal lymphoma characterized by angioinvasion and damage, prominent necrosis, cytotoxic phenotype and associated with Epstein-Barr virus (EBV). Primary ENKTL of the gastrointestinal tract is very rare and carries a poor prognosis. The large intestine is the most common site in the gut affected by ENKTL followed by the small intestine^[5]. Synchronous adenocarcinoma and malignant lymphoma of the colon in the same patient is rare and only a few cases have been reported in the literature. Furthermore, synchronous colonic adenocarcinoma and ENKTL has never been reported.

The symptoms of colonic ENKTL are related to ulcerative plaques, or shallow multiple ulcerations, due to its angioinvasive nature, and may clinically manifest as abdominal pain and bloody stools, as seen in the present case. Due to its ulcerative nature in the colon, the differential diagnosis of ENKTL includes inflammatory bowel disease, tuberculous or cytomegaloviral infection, and neoplasm. There are no characteristic features to distin-

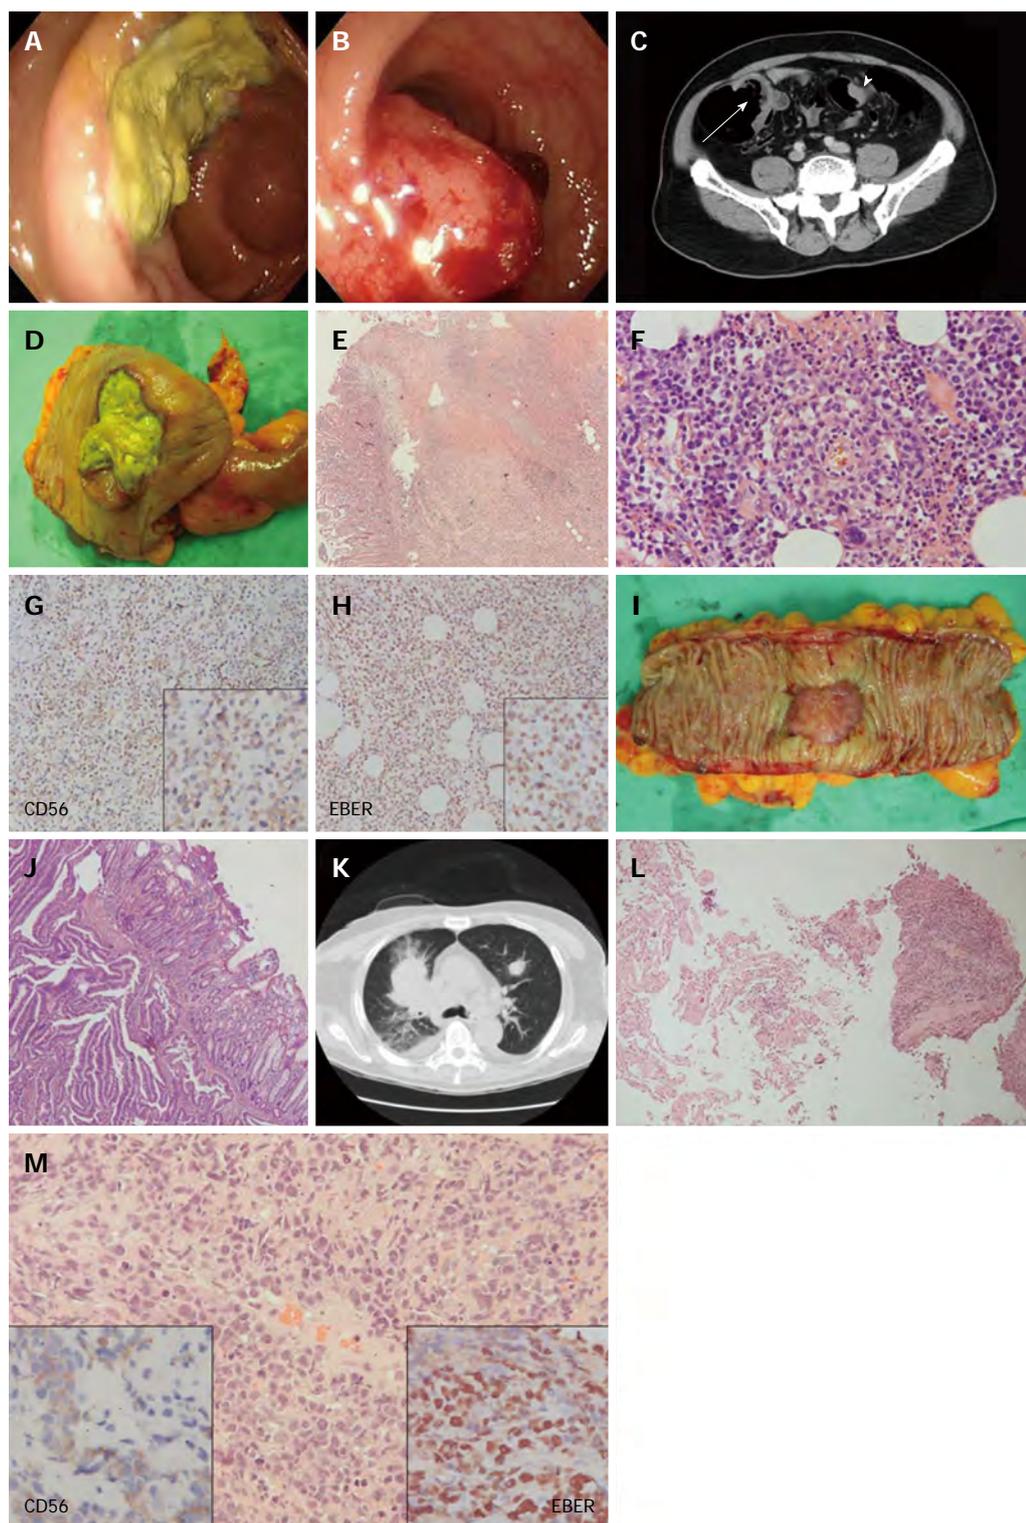

Figure 1 Clinical imaging studies and pathologic features of synchronous extranodal natural killer/T cell lymphoma and adenocarcinoma of the colon, as well as lung metastasis of the lymphoma. A: Appearance of the proximal ascending colon on colonoscopy: A marked ulcerative mass coated with necrotic tissue; B: Appearance of the sigmoid colon on colonoscopy: A polypoid bleeding mass; C: Computed tomography (CT) scan of the abdomen revealing a mass in the proximal ascending colon (arrow on the left) and another mass in the sigmoid colon (arrowhead on the right); D: Surgical specimen of the proximal ascending colon showing an ulcerative mass; E: Histologically, a section of the tumor from the proximal ascending colon showing neoplastic lymphoid cells (right lower part) infiltrating the colonic mucosa (left part) accompanied by a necrotic ulcer (upper middle part), hematoxylin and eosin (HE) stain, $\times 40$; F: Angioinvasion of the neoplastic lymphoid cells of the lymphoma, HE stain, $\times 400$; G: CD56 reactivity of the lymphoma cells, $\times 200$ (right lower inset, $\times 400$); H: Epstein-Barr virus encoded RNA (EBER) reactivity of the lymphoma cells, $\times 200$ (right lower inset, $\times 400$); I: Surgical specimen from the sigmoid colon revealing a polypoid, hemorrhagic mass; J: Histology of the sigmoid colon tumor showing adenocarcinoma with infiltrative neoplastic glands, HE stain, $\times 40$; K: Multiple lung metastases of the lymphoma on follow-up CT scan of the chest (the largest nodule on the right lung was biopsied); L: Histology of the lung biopsy showing lung parenchyma (on the left) and tumor cells (on the right), HE stain, $\times 100$; M: Histologically, a section of the lung biopsy showing the ovoid nucleated neoplastic cells with high N/C ratio, HE stain, $\times 400$, and reactivity of EBER (right lower inset, $\times 400$) and CD56 (left lower inset, $\times 400$).

Table 1 Synchronous adenocarcinoma and malignant lymphoma of colon in the literature

| Year | Age/ gender | Tumor1/tumor2 | Location1/location2 | Pre-OP Dx | OP | Die of | Survival time (mo) |

| 2012 (the current case) | 63/M | Adenoca/ENKTL | Ascending/sigmoid | Double cancer | R't hemicolectomy + sigmoidectomy | ENKTL lung metastasis | 4.5 |

Adenoca: Adenocarcinoma; Large cell L: Large cell lymphoma; ML: Malignant lymphoma; MCL: Mantle cell lymphoma; MALToma: Mucosa-associated lymphoid tissue lymphoma; FL: Follicular lymphoma; SLL: Small cell lymphoma; CLL: Chronic lymphocytic leukemia; AITL: Angioimmunoblastic T-cell lymphoma; ENKTL: Extranodal natural killer/T-cell lymphoma; Rectosigmoid: Rectosigmoid colon; Ascending: Ascending colon; Sigmoid: Sigmoid colon; R't: Right; LAR: Low anterior resection; F/U: Follow-up.

guish colonic ENKTL from carcinoma from colofibrosopic and imaging viewpoints. This makes the preoperative diagnosis of colonic ENKTL challenging.

Synchronous colonic adenocarcinoma and malignant lymphoma is rare. There are only 13 reported cases, including the present case, in the literature (Table 1)^[6-16]. All these cases, with the exception of two (14-year-old and 32-year-old) were older than 50 years with a mean age of 63.7 years. Synchronous mantle cell lymphoma and adenocarcinoma (5 cases) were the most frequent diagnoses followed by synchronous extranodal marginal zone lymphoma of mucosa associated lymphoid tissue and adenocarcinoma (3 cases). The involved sections of the colon included the cecum, ascending colon, sigmoid colon and rectum. It is intriguing that the transverse colon and descending colon were spared in the reported cases including the present case. All cases except one of the synchronized colonic lymphoma were preoperatively diagnosed as colonic adenocarcinoma. This indicates that it is a challenge to preoperatively recognize synchronous colonic adenocarcinoma and malignant lymphoma. The most frequent surgical technique in these cases was right hemicolectomy (8 cases) since the right colon was the most common section involved. The overall survival time was relatively short with a mean of 7.6 mo (range: 1-17 mo). Four patients, including the present patient, out of the 13 cases died of lymphoma. In short, synchronous adenocarcinoma and malignant lymphoma of the colon involved aging patients, spared the transverse and descending colon and had a poor prognosis and short survival time.

The etiology of synchronous adenocarcinoma and malignant lymphoma of the colon is unknown. Chance coincidence is favored^[9,14]. However, local factors such

as absent immune surveillance in the lymphoma which possibly allowed carcinoma cells to grow has also been suggested^[8]. Recently, it was reported that EBV-derived latent membrane protein-1-induced protein may have an important role as a mediator in EBV-mediated neoplasms, including ENKTL^[17]. A low incidence of adenocarcinoma was also proven to be infected with EBV^[18]. Although EBV infection in adenocarcinoma of the sigmoid colon in our patient was not determined, the role of EBV in synchronous adenocarcinoma and ENKTL requires further elucidation.

In conclusion, synchronous adenocarcinoma and malignant lymphoma is uncommon. In particular, synchronous adenocarcinoma and ENKTL is extremely rare, with the present case being the only one reported, with poor prognosis. The etiology of this synchronization is still unknown. Chance coincidence or poor immunity in patients may contribute to the etiology, and the role of EBV needs further elucidation.

AIMS AND SCOPE *World Journal of Gastroenterology (World J Gastroenterol, WJG, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748)* is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING *World Journal of Gastroenterology* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Colorectal cancer (CRC) is still one of the leading causes of cancer-related death in Western countries, despite major improvements in its treatment. The dramatically high social and economic impact of CRC on human health makes the identification of a reliable screening tool of paramount importance. Current screening methods, such as the fecal occult blood test and colonoscopy do not adequately meet the ideal requisites of a screening test because, even if they are effective, they are limited first by too low specificity and sensitivity, or second by high invasiveness, costs and risk. Nowadays extended efforts are made by researchers to look for more reliable and effective screening tests based on a systems biology approach, using biological samples easily available, such as urine, breath, serum and feces. The effectiveness and reliability of several new attempts to screen these patients by non-invasive analysis of their biological samples using genomic (genetic and epigenetic alteration), transcriptomic (miRNA), proteomic (cancer-related antigens, new antibodies against tumor-associated antigens, mutated proteins) and metabolomic (volatile organic metabolites) methods are discussed in this review. Among the most interesting new screening tools, fecal fluorescent long-DNA, fecal miRNA and metabolomic evaluation in breath and/or serum seem to be most promising.

TRADITIONAL APPROACH TO COLORECTAL CANCER SCREENING

Colorectal cancer (CRC) is the second most commonly diagnosed cancer and the second leading cause of cancer death in Europe, with an incidence of 43 600 new cases between 2007 and 2008^[1]. The dramatically high social and economic impact of CRC on human health makes the identification of a reliable screening tool of paramount importance. CRC, as a cancer actually fulfills the World Health Organization conditions required for mass screening, since it is a very common disease, with major morbidity and mortality rates and is almost always preceded by a slow progressive premalignant lesion (the adenomatous polyp) which can readily be removed leading to true cancer prevention^[2]. Screening strategies for CRC involve the separation of the population into two main categories: average risk and high risk populations. Each of these categories is targeted using a different screening program. In the first group, adults over 50 years without a personal or family history of CRC, polyps or inflammatory bowel diseases (IBD) are screened. The high risk population includes subjects with a family history of CRC, a personal history of CRC or polyps or are index cases affected by IBD. There is, however, a third category, more specifically characterized by an hereditary risk and represented by hereditary cancer syndromes such

as familial adenomatous polyposis and hereditary non-polyposis CRC^[3,4]. Such cases should be screened directly with total colonoscopy (TC). The average risk population reflects the vast majority of the population and needs to be screened by less-invasive, low-cost techniques with acceptable patient compliance^[5]. For that reason, in the last decade, there has been a great interest and research effort in developing the optimal CRC screening tool.

Clinically validated screening strategies currently available in practice include fecal occult blood testing (FOBT), TC, flexible sigmoidoscopy (FS) and radiographic imaging, such as double contrast barium enema and virtual TC. FOBT is the most commonly used method for CRC screening. In this respect, it is non-invasive, inexpensive and matches patient compliance better than other screening tools. In 2008, Hewitson *et al*^[6] published a systematic review comparing the results of four randomized controlled trials, using FOBT as a screening tool, and in approximately 320 000 patients screened, there was an overall reduction of the relative risk of dying of CRC of 16%. Despite this, FOBT has demonstrated an unacceptably low specificity rate. To improve its reliability in this regard, fecal immunohistochemistry testing (FIT), which specifically detects non-degraded human globin using anti-human hemoglobin antibodies, has replaced the older guaiac-based FOBT (which identified the heme group by pseudoperoxidase). Despite this major improvement, the search for occult blood in the feces still has severe limitations as a screening tool, mainly because of its low specificity, hence leading to a high number of unnecessary colonoscopies^[7,8]. FS has been proposed as a balance between the invasiveness of a given test (such as low invasive tests like FOBT and FIT), their accuracy and their potential complications (*e.g.*, TC), considering that about two-thirds of the screened CRCs detected are located in the rectum and sigmoid colon. It may be possible to increase the performance characteristics of FS by combining it with FOBT/FIT, however, the risk of leaving undetected CRC in other colonic sites is currently unacceptable^[9,10].

TC still remains the gold standard for the diagnosis of both colorectal polyps and malignancies. The National Polyp Study demonstrated that the incidence of CRC was reduced from 76% to 90%^[11] after polypectomy. Although very effective for diagnosis and treatment, TC has the limitations of low patient compliance, high cost, a high level of invasiveness and a moderate incidence of serious complications in specific subgroups (an incidence of 0.1%-0.3% of life-threatening complications including bleeding and perforation). TC colonography (or virtual TC) involves the use of helical TC to generate high-resolution 3D images of the abdomen and pelvis, replacing the older barium enema in providing full structural evaluation of the entire colon. A study conducted by Fenlon *et al*^[12] in a high risk population, reported a sensitivity of 71% for TC colonography, although this was strongly influenced by polyp size where only 55% of polyps between 1 and 5 mm in maximal diameter were

correctly identified. The sensitivity for virtual diagnosis was significantly higher when polyps ranged between 6 and 9 mm or were larger than 10 mm in size (82% and 91%, respectively; $P = 0.001$)^[12]. This investigation, however, had the drawbacks of considerable exposure to ionizing radiation, discomfort of the bowel preparation and the necessity to complete the procedure by TC in cases of polyp or cancer detection, as well as being expensive (with inherent derivative costs) and currently not suitable for screening purposes.

From these considerations it is clear that current screening methods do not properly meet the ideal requisites of a screening test, so that extended effort has been dedicated by researchers at looking for more reliable and effective screening tests based on the systems biology approach using biological samples easily available such as urine, breath, serum and feces. Since the human genome was completely identified in 2003, the entire set of genes and proteins expressed have been extensively studied using genomic, transcriptomic or proteomic approaches.

GENOMIC APPROACH TO CRC SCREENING

Several authors have attempted to identify cancer-related mutated DNA/RNA, mutated proteins or normal proteins abnormally synthesized [*e.g.*, carcinoembryonic antigen (CEA), cytokeratins] in different biological samples as potential biomarkers for CRC. Colorectal carcinogenesis is characterized by genetic alteration (gene mutation or gene amplification) and epigenetic alteration (gene *hypermethylation* or *chromatin* modification), which both transform normal epithelial cells into cancer cells. CRC cells are continuously shed in the feces, due to a high proliferative rate, so that mutated DNA can be readily detected in the feces of these patients. This issue is complex, where mutation in the *APC*, *K-ras* and *p53* genes were initially investigated in stool samples of CRC patients, in accordance with the Volgenstein model of CRC genesis^[13]. Other markers have also been studied by Imperiale *et al*^[14] who conducted a large population-based study comparing the fecal DNA test with FOBT, using a DNA marker panel formed by 21 mutations and demonstrated a sensitivity of 52% for invasive cancers compared with 13% for FOBT in the same population. Fecal DNA testing has been commercially available in the United States since 2003, but so far has rarely been adopted for screening despite preliminary studies showing that the use of a large pool of genetic markers results in a sensitivity of 71%-91% and a specificity of more than 93%^[15]. A recent interesting approach involves the use of fluorescent long DNA (FL-DNA) measurement, designed to identify cancer DNA fragments greater than 150-200 db pairs. Changes are noted since cancer cells do not undergo apoptosis, which in normal epithelial cells typically initiate DNA cleavage and degradation producing small measurable fragments. This FL-DNA technique has shown a performance sensitivity up to 80% in detecting CRC^[16]. Such mutated DNA can also

be demonstrated in the urine of CRC patients. Human urine has been shown to contain two types of DNA: large type, greater than 1 kb, presumably derived from cells shed into the urine from the urinary tract and small type, between 150 bp and 250 bp, derived from the circulation, which can cross the renal barrier. Sample urine collection is non-invasive and isolation of DNA from urine is easier than from others specimens, due its low extraneous protein content. The comparison of mutated *K-ras* sequences, in particular the mutation in codon 12, between tumor, blood and urine from CRC patients and healthy controls showed an 83% correspondence of mutated DNA in urine and tumor tissue in the same patients^[17]. Epigenetic changes which characterize CRC cells have only been studied in urine samples; most notably, the *hypermethylated vimentin (m-VIM)* gene. The detection of *m-VIM* in urine samples is significantly associated with CRC when compared with healthy controls^[18].

TRANSCRIPTOMIC APPROACH TO CRC SCREENING

The most recent transcriptomic approach to identify potential biomarkers for CRC involves the study of microRNAs (miRNA), short non-coding 18-22 nucleotide RNA molecules involved in regulation of gene expression through post-transcriptional processing. Their expression is deregulated in cancer cells where altered miRNA expression leads to altered expression of their target gene including a range of potential oncogenes and oncosuppressors during carcinogenesis. Chen *et al*^[19] showed that levels of miRNA in the serum are stable, reproducible and consistent in humans, concluding that they can be potential biomarkers for different diseases. Recent studies have indicated that circulating microRNAs incorporated into microvesicles and exosomes may be involved in genetic informational exchange between cells and may regulate extracellular matrix degradation, immunologic response and angiogenic factors which favor cancer cell growth and metastasis^[20]. MiR-145, miR-143, miR-135a and b, miR-17-92, miR-21 have been most studied in CRC where Ng *et al*^[21] were able to identify a significant increase of miR92 in the plasma of CRC patients compared with controls. Similar results have been reported by Huang *et al*^[22] demonstrated a significant increase in miR29a and miR92a in patients with adenomas and CRC compared with controls, supporting the hypothesis that the miR17-92 cluster could have a role in cell proliferation, tumor angiogenesis and apoptotic suppression. Altered miRNA^[23] expression has been examined in the stools of CRC patients and could represent an optimal screening tool for this cancer where colonic cancer cells exfoliate in greater quantity and their nucleic acid can be extracted and distinguished from those of bacteria. In this regard, Link *et al*^[24] compared fecal specimens of patients with CRC, patients with adenomas and normal controls, showing a specific miRNA pattern in the three groups where miR21, miR106 were over expressed in

CRC patients compared with controls, but where levels were higher in patients with adenomas and tended to decrease in cancer cases. Other researchers, however, were unable to confirm the higher expression of miR21, whilst the clusters miR17-92 and miR135 have been found to be significantly higher in the feces of CRC patients when compared with controls^[25]. Another fecal mRNA frequently investigated as a potential CRC marker in stool is the prostaglandin-synthase 2, which showed a sensitivity between 50% and 90% and a specificity of 93% or higher in the diagnosis of CRC, although the reliability of this study was limited by the small number of CRC patients evaluated^[26,27].

PROTEOMIC APPROACH TO CRC SCREENING

A further method for early detection and screening of CRC is to look at the modified “proteome” as a direct effect of mutated gene expression or as the occurrence of new antibodies against tumor-associated antigens (TAAs) identified in CRC. Hundt *et al*^[28] have published a systematic review of 19 studies, in which 52 protein markers were analyzed, using common standard procedures such as enzyme-linked immunoassay, radioimmunoassay or more recent approaches like chromatographic and mass spectrometric assays based on surface-enhanced laser desorption/ionization time-of-flight (TOF) and matrix-assisted laser desorption/ionization TOF technologies. These compounds can be divided into antigens, antibodies, cytokines and other CRC-relevant proteins. CEA is the most investigated marker. High CEA levels are derived from embryonic tissues and CRC, but they also increase in other malignancies, including gastric and pancreatic cancer, as well as in IBD and in smokers. Its role for screening is limited because CEA evaluation has been shown to have a sensitivity of only 43%-69% in detecting early CRC, whilst its reliability increases in metastatic cancer where assessment lies outside the screening purpose. Carbohydrate antigens such as CA 19-9, CA195, CA 50 or CA 72-4 have been investigated in many studies, but with comparatively disappointing results. The best performance amongst these antigens is that of CA 19-9, with a sensitivity ranging between 18% and 65% and a specificity of over 90%. Other antigens considered for screening purposes include the sialylated Lewis antigen X, CO 29.11^[29], urokinase-type plasminogen activator^[30] and small intestinal mucin antigen^[31], but none of these serological antigens have so far demonstrated an acceptable reliability in clinical testing. Recently Matsubara *et al*^[32] studying the proteome of CRC patients compared with healthy controls, using label-free quantitative mass spectrometry and protein microarray, identified the adipophilin or adipose differentiation-related protein, a protein involved in the cancer pathway and normally expressed in cancer cells but not by the normal mucosa. This protein has been investigated as a potential plasma biomarker for early CRC stages, showing high receiver

operating characteristics^[32].

Other studies have focused on the use of autoantibodies antibodies against TAAs as serological markers for cancer diagnosis, because they are absent in healthy subjects and other non-cancer conditions. Many autoantibodies against known or unknown TAAs, have been found in the sera of patients with a range of malignancies^[33-35]. Various technologies such as serologic analysis of recombinant cDNA expression libraries, first described in 1995 by Sahin *et al*^[36], and protein arrays or phage display techniques have been used in their measurement. The occurrence of several serum autoantibodies against TAAs, such as epithelial cell adhesion molecule or cytokeratin, p53, p62, CEA, HER-2/neu, Ras, topoisomerase II -alpha, histone deacetylases 3 and 5, ubiquitin C-terminal hydrolase L3, tyrosinase, tropomyosin and cyclin B1 have all been evaluated in CRC patients^[37], but were detected only in a limited proportion of patients (< 40%). Mutated or abnormal proteins have been detected also in the feces as potential biomarkers for screening, including tumor pyruvate kinase type M2, which has good sensitivity for CRC (85%), but not for adenomas (28%)^[38], S100 calcium binding protein A12 and metalloproteinase inhibitor 1. The latter showed a sensitivity for cancer of around 85% and a specificity of 95%^[39] compared with healthy controls.

METABOLOMIC APPROACH TO CRC SCREENING

More recently, the study of specific metabolomic biomarkers for cancers has developed as a new frontier in cancer screening. Metabolomics are the endpoint of the “omics” cascade and incorporate the comprehensive study of low-molecular-weight metabolites, using high-throughput technologies, such as gas chromatography-mass spectrometry, or other analytical platforms. Ikeda *et al*^[40] investigated the differences in serum metabolite profiles of esophageal, gastric and CRC patients and healthy volunteers, using the metabolomic approach to determine specific metabolomic biomarker candidates. They showed a different distribution of L-alanine, glucuronic lactone and L-glutamine in CRC patients, with a sensitivity of 54.5%-81.8% and a specificity of 6.7%-91.6%^[40]. Specific metabolomes can be identified in several types of biological samples, including feces, urine, serum, sputum and breath. In this regard, breath analysis could be considered the favored option for medical diagnostic purposes mostly because of its non-invasive nature, its low cost and its ready patient compliance^[41]. Volatile organic compounds (VOCs) in exhaled breath were first isolated by Pauling *et al*^[42] in 1971, and alteration in VOC production in cancer patients has been postulated to relate to (per)oxygenation of cell membrane-based polyunsaturated fatty acids resulting from genetic and/or protein mutations within tumor cells and the increased relative prevalence of reactive oxygen species within cancer cells^[43,44]. Urine and serum are ideal tools for metabolomic analyses. Some studies using high-throughput techniques and artificial neural

network statistics have identified some volatile organic metabolites as potential biomarkers for CRC in urine^[45], and very recently, a Japanese group has developed a CRC-prediction model based on serum metabolomic analysis and which demonstrated a high sensitivity (82.8%) as a novel potential screening test for CRC^[46]. A similar metabolomic approach was carried out by our group^[47], looking at the VOCs contained in breath. In this study, 15 of the 58 VOCs identified formed a specific pattern in CRC patients and, using a probabilistic neural network, the ability to identify CRC patients showed a sensitivity of 86%, a specificity of 83% and an accuracy of 85% (area under the receiver operating characteristics curve: 0.85) for the diagnosis of CRC.

In conclusion, despite their usefulness and effectiveness, traditional methods for CRC screening are still far from fulfilling the optimal requisites for a screening test. The FOBT/FIT both have too low a sensitivity or specificity whilst the high sensitivity of CT is counterbalanced by its invasiveness and high cost. TC colonography is still improving its technical performance but is expensive and, in cases of positivity, a traditional TC is still required to remove polyps or for biopsies. New hopes are rapidly growing in this field with the application of the systems biology approach using biological samples which are readily available. Among these, the search for fecal FL-DNA, fecal miRNA and metabolomic evaluation in the breath and/or serum seems to be the most promising.

Abstract

This article reviews the latest developments in understanding the pathogenesis, detection and treatment of small intestinal damage and bleeding caused by nonsteroidal anti-inflammatory drugs (NSAIDs). With improvements in the detection of NSAID-induced damage in the small intestine, it is now clear that this injury and the associated bleeding occurs more frequently than that occurring in the stomach and duodenum, and can also be regarded as more dangerous. However, there are no proven-effective therapies for NSAID-enteropathy, and detection remains a challenge, particularly because of the poor correlation between tissue injury and symptoms. Moreover, recent studies suggest that commonly used drugs for protecting the upper gastrointestinal tract (*i.e.*, proton pump inhibitors) can significantly worsen NSAID-induced damage in the small intestine. The pathogenesis of NSAID-enteropathy is complex, but studies in animal models are shedding light on the key factors that contribute to ulceration and bleeding, and are providing clues to the development of effective therapies and prevention

Biography

John L Wallace is a Professor in the Department of Medicine at McMaster University. He received his BSc and MSc from Queen's University (Canada) and his PhD from the University of Toronto. He completed his post-doctoral studies in the Department of Mediator Pharmacology at Wellcome Research Laboratories in London, England. That work was carried out in a group led by Sir John Vane, Sir Salvador Moncada and Dr. Brendan Whittle. In 2007, Dr. Wallace completed his MBA degree from the University of Birmingham (United Kingdom).

In 1996, he co-founded NicOX SA, based in Nice, France. He served as the Chair of the company's Scientific Advisory Board from 1996-2003, overseeing the development of nitric oxide-releasing drugs. NicOx went public on the Paris Stock Exchange in 1999, and has an ophthalmic drug in phase 3 clinical trials. In 2004, Dr. Wallace founded Antibe Therapeutics Inc., a company developing hydrogen sulfide-releasing drugs.

Dr. Wallace's research is focused on mediators of inflammation and their contribution to mucosal injury and dysfunction. He is also interested in the mechanisms of injury induced by the gastrointestinal tract by anti-inflammatory drugs, and the factors that regulate healing of ulcers. Dr. Wallace is attempting to develop gastrointestinal-sparing anti-inflammatory drugs.

He is a Fellow of the Royal Society of Canada, a member of the Brazilian Academy of Science and a Fellow of the British Pharmacological Society. He has won numerous international awards for his research, including the 2009 Premier's Summit Award (\$5 million) and the 2012 William Harvey Medal for Outstanding Contributions to Science. From 2000-2002, Dr. Wallace was President of the Canadian Association of Gastroenterology.

Dr. Wallace has published approximately 400 peer-reviewed papers 100 book chapters, and is among the top 0.5 percent of biomedical scientists in the world in terms of citations (Hirsch factor of 88, > 25 000 citations).

strategies. Novel NSAIDs that do not cause small in-

testinal damage in animal models offer hope for a solution to this serious adverse effect of one of the most widely used classes of drugs.

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the widely used prescription and over-the-counter medications. They are used to treat the symptoms of a variety of inflammatory conditions, most notably osteoarthritis, rheumatoid arthritis, ankylosing spondylitis and gout. In such conditions, NSAIDs are used chronically, and the affected patients frequently have co-morbidities such as hypertension, diabetes and obesity, as well as often also taking glucocorticoids or anti-coagulants.

By inhibiting the activity of cyclo-oxygenase (COX), NSAIDs prevent the formation of prostaglandin (PG) H₂, which is the precursor for the production of all other PG and thromboxane subtypes. Most NSAIDs inhibit COX activity in a competitive fashion, whereas aspirin is an irreversible inhibitor of the enzyme. Indeed, the ability of aspirin to irreversibly inhibit thromboxane synthesis by platelets, and the lack of capacity of platelets to synthesize more COX, underlie the utility of chronic, low-dose aspirin as an anti-thrombotic drug, reducing the incidence of several adverse cardiovascular events (*e.g.*, stroke, myocardial infarction).

Inhibition of COX is central to the major anti-inflammatory actions of NSAIDs. By inhibiting the production of PGs (particularly PGE₂ and PGI₂), NSAIDs reduce two key elements of inflammation: vasodilation and pain. By reducing blood flow to a damaged and inflamed site, NSAIDs also contribute to a reduction of edema.

Unfortunately, PGs do not only contribute to the cardinal signs of inflammation. They also play important roles in many physiological processes. In the gastrointestinal (GI) tract, PGs are very important mediators of mucosal defence and repair^[1]. Inhibition of their synthesis renders GI tissues much more susceptible to damage induced by luminal irritants (including gastric acid and bile), and less able to restore mucosal structure and function after injury^[1]. Suppression of PG synthesis is the key effect of NSAIDs that leads to gastro-duodenal ulceration and bleeding. However, several other effects of NSAIDs appear to be central to the ability of these drugs to cause damage in the small intestine.

OVERVIEW OF THE CLINICAL PROBLEM

For several decades, the ability of NSAIDs to induce significant damage to the small intestine was largely unappreciated, being over-shadowed by the attention paid to damage induced by these agents in the stomach and proximal duodenum. The prevalence and clinical significance of NSAID-enteropathy continues to be greatly under-recognized. NSAID-induced enteropathy and bleeding occur more frequently than NSAID-induced gastropathy^[2,3]. Significant small intestinal damage and bleeding can be observed in about 70% of chronic NSAID users^[4,5], and in the majority of patients the injury is sub-clinical^[6].

Unlike the case for NSAID-gastropathy, there are no proven-effective preventative therapies for NSAID-enteropathy, and the pathogenesis is poorly understood^[7]. Iron-deficient anemia is a common first presentation of NSAID-enteropathy, and serious complications can include massive bleeding, perforation and strictures, sometimes leading to death^[2,6,8].

Aspirin is the most commonly used NSAID, and it is a very frequent cause of small intestinal bleeding. In the United States and Europe, in over 50% of cases, aspirin has been identified as the precipitator of GI bleeding leading to hospital admissions^[3,9,10]. Aspirin-induced small intestinal damage appears to occur more frequently when the aspirin is enteric-coated^[8,11]. There is a lack of recognition of the frequency and potential severity of aspirin-induced lower GI injury, particularly when the aspirin is given at low doses for cardiovascular protection. In a recent clinical trial that involved over 1200 patients taking aspirin and another anti-platelet therapy for cardiovascular protection, lower GI bleeding was found to occur 3-times more frequently than upper GI bleeding^[12]. Zhu *et al*^[13] reported that only about 3.5% of patients prescribed low-dose aspirin also received a prescription for a proton pump inhibitor (PPI), histamine H₂ receptor antagonist (H₂RA) or muco-protective drug, suggesting that the prescribing physicians did not recognize the potential for GI adverse effects of low-dose aspirin. The pathogenesis of aspirin-induced small intestinal damage differs in several respects to that of the ulceration caused by other NSAIDs (discussed in more detail below).

Selective COX-2 inhibitors were introduced to the marketplace at the beginning of this century with a promise of GI safety^[14,15]. While some selective COX-2 inhibitors produce less gastroduodenal damage in some circumstances, the promise of these drugs has been largely unfulfilled^[16,17]. Selective COX-2 inhibitors cause small intestinal damage and bleeding (the latter effect is somewhat surprising given the minimal inhibitory effects these drugs of these drugs on platelet function). McCarthy^[3] noted that in the VIGOR study, the majority of the GI bleeds originated from lesions in the small intestine (distal to the ligament of Treitz): 58% of the GI bleeds in patients taking rofecoxib and 52% of the GI bleeds in patients taking naproxen^[13].

There are several reasons for the lack of recognition of the prevalence and seriousness of NSAID-enteropa-

thy. First, it is more difficult to detect small bowel damage than that induced by NSAIDs in the stomach and proximal duodenum: “The single most important reason for underestimating the clinical importance of NSAID enteropathy is the difficulty in making a diagnosis”^[2]. Second, there is a poor correlation between NSAID-induced small intestinal damage and clinical symptoms. The vast majority of NSAID-enteropathy is sub-clinical^[6], and when there are symptoms, they are largely non-specific (including iron deficiency anemia, occult blood, diarrhea, hypoalbuminemia, and malabsorption of vitamin B₁₂ and/or bile acids). Thirdly, some researchers have argued that the focus of large pharmaceutical companies on the development of “gastroprotective” drugs, such as H₂RA, PPI, and putative gastric-sparing drugs (selective COX-2 inhibitors, NSAID pro-drugs) has led to a preoccupation of physicians and researchers with the stomach and proximal duodenum, at the expense of consideration of the detrimental effects of NSAIDs in the small (and large) intestine. The fact that there are no proven-effective treatments for NSAID-enteropathy likely also contributes to the lack of recognition of this serious condition^[7].

DETECTION OF NSAID-ENTEROPATHY

Until recently, detection of NSAID-enteropathy has been very difficult, with most of the evidence for its occurrence coming from post-mortem studies or through indirect measures of intestinal bleeding^[4,18,19]. Several indirect methods for detecting and measuring the severity of NSAID-enteropathy were developed, prior to improved endoscopic techniques for viewing the small intestine becoming widely available. These included measuring small intestinal permeability with sugars^[20,21] or small molecular weight radioactive probes^[22], measuring bleeding (presumed of intestinal origin) with radiolabelled red blood cells^[23], and measuring leukocyte markers in the small intestine (radiographically)^[24] or in feces^[25]. All of these methods provide useful information, but none have become recognized as a “gold standard” for detecting and quantifying enteropathy, because of lack of specificity and/or sensitivity. However, with video capsule endoscopy (VCE) and double-balloon enteroscopy, it is now possible to directly visualize of NSAID-induced damage and bleeding throughout the small intestine. Using these methods, it has become clear that NSAID-enteropathy occurs frequently, even in low-risk subjects (healthy, young volunteers) with low-risk treatment protocols (short-term ingestion of NSAIDs, sometimes together with a “gastro-protective” agent). For example, using VCE, Graham *et al*^[5] found a high prevalence of ulcers in long-term NSAID users. More than 70% of these patients (taking NSAID for more than 3 mo) had intestinal inflammation accompanied by bleeding and protein loss. Symptoms persisted after stopping the therapy (by as long as 16 mo in some patients). Maiden *et al*^[25] reported gross damage in 68% of healthy volunteers taking diclofenac plus omeprazole for 2 wk. Even low-dose aspirin

was found to cause significant small intestinal damage with short-term administration; thus, Endo *et al*^[26] reported that 80% of patients taking low-dose aspirin for 2 wk had intestinal damage.

POLYPHARMACY CONUNDRUM: SHIFTING GI INJURY MORE DISTALLY

Animal studies of NSAID injury to the GI tract usually involve the use of healthy animals. Of course, the people most commonly taking NSAIDs on a chronic basis are those with chronic illnesses, and more often than not, they are affected by more than one disease. It is also the case that disorders such as rheumatoid arthritis, obesity and diabetes can increase the susceptibility of the patient to the GI (and other) adverse effects of NSAIDs^[27-29]. Moreover, these patients are often taking a number of different drugs, which can also affect susceptibility to NSAID-induced GI injury and bleeding. Polypharmacy is now commonplace, even in patients that do not have disorders other than the one for which NSAID therapy is indicated. Consider a disorder like osteoarthritis, which is more common in the elderly. Cardiovascular diseases are common in this group of patients, often leading to co-prescription of low-dose aspirin and sometimes of other anticoagulants. Low-dose aspirin is also frequently co-prescribed with selective COX-2 inhibitors and conventional NSAIDs because of concerns about the elevated risk of serious cardiovascular events in patients taking those drugs^[30]. Of course, co-administration of low-dose aspirin together with a selective COX-2 inhibitor essentially eliminates any advantage, in terms of upper GI safety, of the selective COX-2 inhibitor as compared to a conventional NSAID^[15,31-33]. To reduce the expected upper GI toxicity of the combination of an NSAID and low-dose aspirin, PPIs are typically prescribed as well. Indeed, there are now fixed-dose, enteric-coated, combination tablets available that contain an NSAID and a PPI^[34]. While there is strong evidence for PPIs reducing the severity of damage and bleeding in the stomach and duodenum, where the role of acid in the production of damage has been clearly demonstrated^[1,35], there is no evidence to suggest that a PPI (or other anti-secretory drug) would reduce the severity of NSAID-induced enteropathy. Indeed, antisecretory drugs have been described as “useless either in preventing or treating mucosal lesions” induced by NSAIDs in the intestine^[36]. It is worth repeating that the majority of damage and bleeding caused by NSAIDs occurs in the small intestine, distal to the ligation of Treitz^[3,13].

Using a rat model, we attempted to replicate common clinical scenarios of polypharmacy to determine the effects on the small intestine^[37]. Groups of rats were treated with combinations of anti-inflammatory doses of NSAIDs (naproxen, celecoxib or a novel hydrogen sulfide-releasing NSAID, ATB-346)^[38], a PPI (omeprazole or lansoprazole) and an anti-thrombotic dose of aspirin. In rats that received only the NSAID, the levels of small

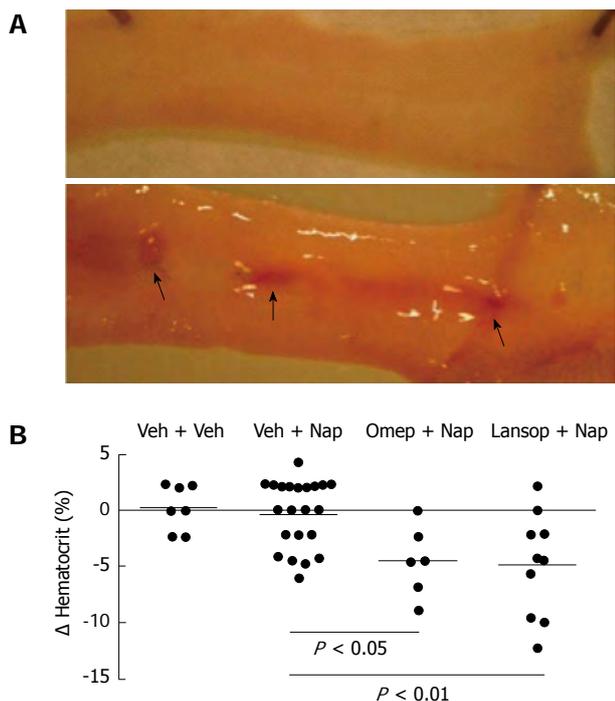

Figure 1 Proton pump inhibitors exacerbate naproxen-induced ulceration and bleeding. In panel A, the top image is of the jejunum of a rat treated with naproxen for 4.5 d (10 mg/kg twice-daily). There are no ulcers present. The bottom image is of a jejunum of a rat receiving the same naproxen treatment, but also treated with omeprazole at a dose that suppressed gastric acid secretion^[37]. The arrows indicate the numerous hemorrhagic ulcers that form with this combination of treatments; Panel B shows the change in hematocrit of rats treated with naproxen (Nap) plus vehicle (Veh), omeprazole (Omep) or lansoprazole (Lansop)^[37]. The two proton pump inhibitors significantly enhanced the decrease in hematocrit when co-administered with naproxen (no decrease in hematocrit was observed in rats treated with a proton pump inhibitors alone).

intestinal damage and bleeding were very low (Figures 1 and 2). However, when co-administered with a PPI or with low-dose aspirin, the levels of small intestinal damage and bleeding in rats treated with naproxen or celecoxib increased significantly (Figures 1 and 2). This effect has been confirmed in a recent study by Satoh *et al*^[39]. The combination of an NSAID with both a PPI and low-dose aspirin resulted in extensive damage and bleeding (the latter was evident post-mortem and also by marked decreases in hematocrit). ATB-346 did not produce small intestinal damage alone or in combination with a PPI and/or low-dose aspirin (Figure 2).

We then performed experiments to try to determine the mechanisms underlying the exacerbation of small intestinal damage by the PPIs. As discussed in more detail below, there is evidence that the bacteria residing in the small intestine play a significant role in the pathogenesis of NSAID-enteropathy. Given the evidence that marked suppression of gastric acid secretion by PPIs can alter the numbers of bacteria in the small intestine^[40-42], we focused our investigation on potential changes in intestinal microbiota. Treatment of rats with omeprazole resulted in a dramatic shift in the types of bacteria in the small intestine (dysbiosis). In particular, there was a marked reduction of the Actinobacteria, particularly of *Bifidobacteria*

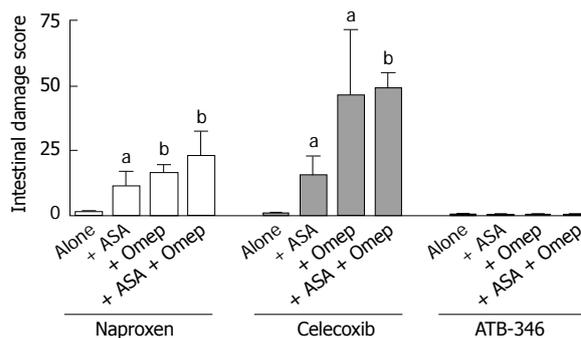

Figure 2 Proton pump inhibitors and low-dose aspirin significantly exacerbate nonsteroidal anti-inflammatory drug-induced small intestinal ulceration. Rats were treated orally, twice-daily for 4.5 d with equi-effective anti-inflammatory doses of naproxen (10 mg/kg), celecoxib (10 mg/kg) or ATB-346 (14.5 mg/kg). ATB-346 is a hydrogen sulfide-releasing derivative of naproxen^[38]. Starting 5 d before the nonsteroidal anti-inflammatory drugs (NSAIDs), the rats began receiving twice-daily treatments with omeprazole (Omep) (10 mg/kg) or vehicle. Starting 3 d before the NSAIDs, the rats began receiving daily doses of low-dose aspirin (10 mg/kg) or vehicle. The results are shown as the mean \pm SE of at least 6 rats per group. ^a $P < 0.05$, ^b $P < 0.01$ vs the corresponding group treated with the NSAID alone. No intestinal damage was observed in rats treated with aspirin (ASA) alone. The exacerbation of small intestinal ulceration with omeprazole was also observed with another proton pump inhibitor, lansoprazole^[37]. This figure was constructed using data from Blackler *et al*^[175].

spp. (> 80% reduction in the jejunum). This diminution of *Bifidobacteria* was an important factor in the PPI-induced increase in NSAID-induced intestinal damage: replenishment of intestinal *Bifidobacteria* in PPI-treated rats reduced levels of naproxen-induced intestinal damage those seen in rats not receiving a PPI. Further evidence that it was the dysbiosis induced by the PPI that resulted in elevated susceptibility to NSAID-enteropathy came from studies of germ-free mice^[37]. Groups of germ-free mice were colonized with intestinal contents from rats that had been treated with a PPI or vehicle. Beginning one week later, the mice were treated with naproxen for 4 d, and the severity of intestinal damage was then blindly evaluated. Mice that had been colonized with bacteria from PPI-treated rats developed significantly worse intestinal damage than those colonized with bacteria from vehicle-treated rats.

While no clinical studies have been published that directly tested the hypothesis that treatment with PPIs could cause dysbiosis and thereby exacerbate NSAID-induced intestinal damage, there are several reports with data that are consistent with our hypothesis, as summarized by Daniell^[43]. In addition to numerous studies documenting that PPIs altering the gut microbiota, resulting in diarrhea^[40-42,44], there is evidence from two studies for the presence of intestinal inflammation (detected by elevated fecal calprotectin levels) in patients taking PPIs^[45,46], and evidence for microscopic colitis in patients taking NSAIDs or PPIs^[47-49], and particularly in patients taking both types of drugs concurrently^[49]. In addition, two studies reported greater small intestinal damage in healthy volunteers taking an NSAID plus a PPI as compared to a group taking only a selective COX-2 inhibitor^[50,51], and it

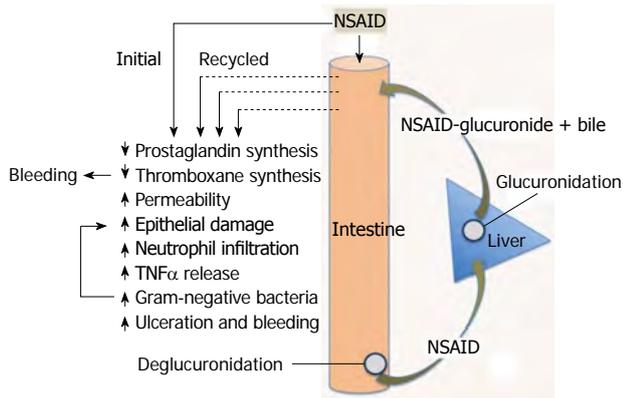

Figure 3 Pathogenesis of nonsteroidal anti-inflammatory drugs-induced enteropathy. Nonsteroidal anti-inflammatory drugs (NSAIDs) produce effects during their initial exposure to the small intestine, and when secreted back into the proximal small intestine, along with bile, following their absorption in the distal intestine, and glucuronidation in the liver. Suppression of thromboxane synthesis likely plays an important role in promoting bleeding (especially with aspirin, an irreversible inhibitor of platelet thromboxane synthesis). Repeated exposure of the intestinal epithelium to the combination of NSAIDs and bile will promote damage, and the damage is likely exacerbated by the shift in intestinal bacteria stimulated by the NSAID (elevated gram-negative bacteria). These effects appear to be mediated by endotoxin, acting at least in part through toll-like receptor-4. The interplay among bile, bacteria and recirculation of the NSAID is complex. For example, bacterial enzymes convert primary bile acids to secondary bile acids (which may be more damaging) and bacterial enzymes are necessary for deglucuronidation, which permits reabsorption and enterohepatic recirculation of NSAIDs. TNF α : Tumor necrosis factor- α .

is now clear that the ability of selective COX-2 inhibitors to damage the small intestine is comparable to that of non-selective NSAIDs^[17].

PATHOGENESIS

The key to development of treatments and prevention strategies for NSAID-enteropathy lies in better understanding of the pathogenesis of this injury. Fortunately, the animal models of NSAID enteropathy are very good, reproducible and simple, and can serve as useful tools for gaining a better understanding of the pathogenesis of this disorder and for testing potential therapeutic/preventative agents. Administration of NSAIDs to rats, for example, results in ulceration predominantly in the distal jejunum and ileum^[52], the same regions where ulcers are concentrated humans^[53,54]. While there will undoubtedly be some differences between rodent models and humans, the existing data suggest that the animal models will be predictive in terms of treatment and prevention strategies. Figure 3 shows some of the key mechanisms suggested to be involved in NSAID-enteropathy, which are discussed in more detail below.

Inhibition of cyclooxygenase activity

Flower *et al*^[55] first suggested the existence of more than one isoform of COX in 1972. It was almost 20 years later that the two isoforms, now known as COX-1 and COX-2, were sequenced^[56,57]. In the decade that followed, a tremendous amount of research was focused on un-

derstanding the physiology and pharmacology of these enzymes, largely fueled by the interest of several large pharmaceutical companies in the notion that selective inhibitors of COX-2 would provide all of the anti-inflammatory activities of NSAIDs without the major adverse effects. However, as the science of COX-2 caught up with the marketing of COX-2, it became evident that the delineation of functions of the two COX isoforms was not so clear-cut as had been proposed and heavily promoted. COX-1 contributes significantly to inflammation while COX-2 contributes significantly to many physiological functions, including mucosal defence^[58]. This was shown clearly both by studies of mice lacking the gene for one of the COX isoforms and pharmacological studies^[59-63]. A striking finding from our laboratory was that injection of carrageenan into the hind-paw of COX-2-deficient mice resulted in inflammation that did not resolve, as it would in a normal mouse^[60], suggesting an important role for COX-2-derived prostanoids in resolution of inflammation and healing. Gilroy *et al*^[61] provided compelling evidence from animal models of pleurisy showing the same, and identifying specific COX-2-derived prostanoids that contributed significantly to down-regulating inflammation. Serhan *et al*^[64] described a family of previously unrecognized lipid mediators (lipoxins, resolvins, protectins), some of which were derived from COX-2, that act at several levels of the inflammatory cascade to “turn off” inflammation and allow for a coordinated restoration of tissue homeostasis^[65].

The same was true in the GI tract, as COX-2-derived prostanoids were found to contribute significantly to maintenance of the integrity of the tissue, to repair of mucosal injury and to resolution of inflammation^[58]. Thus, COX-2 is the isoform that produces PGs at the margins of gastric ulcers, which contribute significantly to the healing of those ulcers^[66,67]. In the colon, prostaglandins derived from COX-2 play a very important role in down-regulating inflammation and promoting repair of mucosal injury^[52,68,69]. Suppression of COX-2 activity has been shown to exacerbate experimental colitis^[52,69]. Indeed, COX-2 is up-regulated throughout the GI tract when the tissue is injured or when there is insufficient PG production *via* COX-1^[52,63,70]. For example, COX-2 is rapidly induced in the stomach in response to suppression of COX-1 by aspirin^[70], and it helps to enhance mucosal defence in such circumstances. One of the mechanisms through which this is achieved is *via* the production, *via* COX-2, of a potent gastroprotective and anti-inflammatory substance, 15-epi-lipoxin A₄^[71,72]. Induction of damage in the stomach, in the absence of any other toxic challenge, requires suppression of both COX-1 and COX-2^[62], and this also appears to be the case in the small intestine^[63].

Clinical studies generally show that selective COX-2 inhibitors produce less gastroduodenal injury and bleeding than conventional NSAIDs, but the small intestinal damage may not differ substantially between the two sub-classes of NSAIDs. For example, Maiden *et al*^[73] performed a VCE study comparing the enteropathy

produced in patients on long-term NSAID or selective COX-2 inhibitor therapy, and the key finding was that NSAIDs and selective COX-2 inhibitors produced comparable levels of small bowel damage (small intestinal injury was observed in 50% of the patients treated with a selective COX-2 inhibitor *vs* 62% of patients treated with a conventional NSAID; not significantly different).

While suppression of COX activity undoubtedly contributes to the pathogenesis of NSAID-enteropathy, it is clear that other factors probably play a more significant role. Suppression of COX activity likely contributes to this disorder mainly through the impairment of repair processes, such as angiogenesis^[74], and through inhibition of platelet aggregation, leading to bleeding. The latter effect, however, is most apparent with aspirin, which irreversibly inhibits platelet COX-1, and with NSAIDs that have a long half-life.

Mitochondrial injury

One of the earliest changes that can be detected after NSAID administration, in addition to inhibition of COX activity, is mitochondrial injury^[75]. Morphological evidence of mitochondrial damage can be detected within 1 h of administration of an NSAID to rats, and *in vitro* studies of liver showed that the NSAID could rapidly cause uncoupling of oxidative phosphorylation^[75]. This provides a mechanistic explanation for the ability of NSAIDs to damage intestinal epithelial cells and to increase epithelial permeability, as have been demonstrated by several groups^[22,52,76]. On the other hand, this mechanism does not explain the localization of ulcers in the jejunum and ileum in animal models and in humans. In their endoscopic study of diclofenac-induced small intestinal injury, Fujimori *et al*^[54] observed denuded regions throughout the small intestine (perhaps indicative of a topical erosive effect), but ulcers were concentrated in the distal jejunum and ileum.

Role of bile and enterohepatic circulation

Several observations suggest important roles for bile and for enterohepatic circulation of NSAIDs in the pathogenesis of NSAID-enteropathy (Figure 3). Ligation of the bile duct in rats prevents NSAID-induced intestinal damage^[75-78]. There have also been reports that NSAIDs that do not re-circulate enterohepatically do not cause small intestinal damage^[52,75], although aspirin is a notable exception, at least when administered intraduodenally or in an enteric-coated formulation^[11,78]. Also, in rats lacking the hepatocanalicular conjugate export pump, which is required for excretion of conjugated NSAIDs into bile, but not for the flow of bile itself, intestinal damage induced by an NSAID (diclofenac) was prevented^[79]. On the other hand, induction of higher expression of the export pump aggravated NSAID-induced intestinal damage^[79]. A number of studies have demonstrated that a combination of an NSAID and bile is damaging to intestinal epithelial cells^[80,81] and non-GI cells^[82]. It is noteworthy that in all of these studies, it was secondary bile acids

that were found, in combination with NSAIDs, to be effective in damaging cells. Moreover, it has been shown that administration of an NSAID to rats results in increased concentrations of secondary bile acids in bile^[83]. Thus, when an NSAID recirculates enterohepatically, the intestinal epithelium is repeatedly exposed to a damaging combination of the NSAID and bile. If this were the primary mechanism of injury in NSAID-enteropathy, however, one would expect to see ulcers produced where the highest concentrations of NSAID and bile would be found (*i.e.*, near the Sphincter of Oddi), whereas the most severe tissue injury is concentrated in the more distal parts of the small intestine^[54]. It has been suggested that the sites of ulceration correspond to the sites of NSAID re-absorption, and related to the deconjugation of the NSAIDs at those sites by bacterial β -glucuronidases^[79,84-86].

Role of bacteria

There is an abundance of evidence that intestinal bacteria contribute to the pathogenesis of NSAID-enteropathy, but it remains unclear if there is a primary role, initiating the tissue damage, or just a secondary role, exacerbating tissue injury and impeding repair. One of the key observations leading some to propose a primary role of bacteria in NSAID-enteropathy is that germ-free rats and mice develop little or no intestinal damage when given an NSAID, but when colonized by gram-negative bacteria, these animals become susceptible to NSAID-enteropathy^[87,88]. Several studies have documented dramatic shifts in the types of bacteria in the small intestine following NSAID administration, with increases in gram-negative bacteria generally being observed, and a concomitant reduction in gram-positive bacteria^[89-93]. In some studies, there appeared to be an enrichment of specific bacteria, such as *Enterococcus faecalis*, *Clostridium*, *Bacteroides* and *Escherichia coli* (*E. coli*)^[89-91]. A number of studies reported protective effects of antibiotics against NSAID-enteropathy, particularly when the antibiotics were effective in reducing number of gram-negative bacteria^[88,89,93,94]. Similarly, some probiotics have been reported to reduce the severity of NSAID-enteropathy, especially when they prevent increases in the number of gram-negative bacteria in the intestine^[93,95,96]. Despite a considerable number of studies examining the potential contribution of bacteria to NSAID-enteropathy, there remains a lack of clear evidence for a primary role of bacteria in initiation of tissue injury. Bacteria rapidly colonize sites of ulceration and can interfere with ulcer healing^[97,98]. In one of the earliest papers on the pathogenesis of NSAID-enteropathy, Kent *et al*^[89] remarked "since the antibiotics do not prevent completely the ulceration, we think that these agents reduce the severity of the lesion by allowing healing to start sooner". A similar conclusion was drawn by Yamada *et al*^[99].

The apparent importance of gram-negative bacteria in the pathogenesis of NSAID-enteropathy is consistent with reports of a role for lipopolysaccharide (LPS) in driving tissue inflammation and impairment of ulcer healing. Hagiwara *et al*^[91] showed that heat-killed *E. coli*

and their purified LPS caused “deterioration” of NSAID-induced ileal ulcers, but could not cause ulcers themselves in the absence of the NSAID). Koga *et al*^[94] reported that systemic administration of LPS reversed the beneficial effects of an antibiotic in reducing the severity of NSAID-enteropathy in rats, and further demonstrated that T cell function was not required for NSAIDs to induce intestinal ulceration. Watanabe *et al*^[93] demonstrated that mice lacking the endotoxin receptor, toll-like receptor-4, developed much less (about 80%) intestinal damage when given an NSAID than the normal counterparts. These data are once again consistent with the notion that bacteria play a secondary role in NSAID-enteropathy, exacerbating tissue injury and interfering with ulcer healing. These effects may be in part attributable to activation of neutrophils in the mucosal microcirculation, which has been shown to contribute significantly to ulceration^[100-104], and local generation of tumor necrosis factor-alpha may be one of the main triggers leading to neutrophil recruitment and/or activation^[93,105-107].

As mentioned above, one of the key observations supporting an important role of bacteria in the pathogenesis of NSAID-enteropathy was that germ-free animals do not develop significant small intestinal damage following NSAID administration^[75-78]. However, one must bear in mind that ligation of the bile duct blocks the secretion of bile and the enterohepatic circulation of NSAIDs, both of which have been implicated in intestinal injury by these drugs (Figure 3). The conversion of primary bile acids to secondary bile acids is dependent on intestinal bacterial enzymes. Thus, germ-free animals lack secondary bile acids. As mentioned above, most studies that have shown that bile acids (alone or in combination with an NSAID) can cause damage to intestinal epithelial cells have used secondary, rather than primary bile acids^[80,81]. Moreover, the re-absorption of NSAIDs in the distal small intestine is largely dependent on bacterial β -glucuronidase activity, which de-conjugates NSAID-glucuronides, allowing the NSAID to be transported across the epithelium^[84]. Enterohepatic circulation of NSAIDs is negligible in animals that lack intestinal bacteria, resulting in decreased exposure of the intestine to the NSAID, and therefore decreased tissue injury. Recently, LoGuidice *et al*^[85] demonstrated that an inhibitor of bacterial β -glucuronidase could significantly reduce the severity of diclofenac-induced small intestinal injury in mice. β -glucuronidase has been shown to be expressed in *Clostridium*, *Peptostreptococcus*, *Staphylococcus* and *E. coli*^[85,108].

TREATING AND PREVENTING NSAID-ENTEROPATHY

In sharp contrast to NSAID-induced gastroduodenal damage, where several options are available to provide protection to a patient, no treatments or prevention strategies for NSAID-enteropathy have been convincingly shown to be effective. As outlined above, PPIs provide upper GI protection against NSAIDs but worsen NSAID-enteropathy

in animals, and there is emerging evidence that the same is the case in humans. There are novel NSAIDs in development that do not cause enteropathy in animals (discussed below).

Misoprostol, metronidazole and sulfasalazine have all been suggested to be beneficial in treatment or prevention of NSAID-enteropathy in humans, but the studies suggesting this had significant limitations (open-label, not controlled, and/or small sample sizes)^[22,24,109-111]. Misoprostol, H₂RA and sucralfate were found to be ineffective in reducing NSAID-induced intestinal permeability in humans^[112,113], though in one, open-label study misoprostol reduced the elevated intestinal permeability induced by indomethacin^[114]. Based on the animal data showing beneficial effects of metronidazole in reducing NSAID-enteropathy^[99], Bjarnason *et al*^[24] performed an open-label human study of chronic NSAID users. The patients took metronidazole for 2-12 wk while continuing their NSAID treatment. The endpoints were fecal excretion of ⁵¹Cr-labeled erythrocytes and ¹¹¹In-labelled neutrophils. Both markers declined significantly during metronidazole treatment, leading the authors to conclude that “these results suggest that the neutrophil is the main damaging effector cell in NSAID induced enteropathy” and that the main chemoattractant “may be a metronidazole sensitive microbe”.

The observations from animal studies that NSAID-enteropathy was accompanied by dramatic shifts in numbers and types of intestinal bacteria led to a number of studies of the potential value of probiotics for treatment or prevention of NSAID-enteropathy. In studies in rats, Kinouchi *et al*^[95] demonstrated that *Lactobacillus acidophilus* and *Bifidobacteria adolescentis* administration markedly reduced the severity of NSAID-induced ileal ulceration. Syer *et al*^[96] also showed a marked protective effect of *Bifidobacteria adolescentis* in a rat model of NSAID-enteropathy. Only two clinical trials of a probiotic for NSAID-enteropathy have been reported to date. Montalto *et al*^[115] performed a randomized, double-blind, placebo-controlled trial of VSL#3, a probiotic formulation consisting of 8 different live bacteria. Volunteers received indomethacin daily for 4 d, and fecal calprotectin levels were the endpoint. The placebo-treated volunteers exhibited markedly elevated fecal calprotectin levels during the period of indomethacin treatment, while during treatment with VSL#3 the fecal calprotectin levels remained within the normal range. In a study by Endo *et al*^[116], 25 patients with unexplained iron deficiency anemia who had been taking low-dose enteric-coated aspirin plus omeprazole for more than 3 mo were given either *Lactobacillus casei* (*L. casei*) or placebo for 3 mo while continuing the aspirin and omeprazole therapy. VCE at the end of the treatment period showed a significant reduction of mucosal breaks and “capsule endoscopy score” in the group receiving *L. casei*. The results of this small clinical study are consistent with a study of *L. casei* (strain Shirota) in a rat model of indomethacin-induced enteropathy^[117].

Lactoferrin has been shown to prevent NSAID-

induced bleeding in rodents^[118] and this effect may be related to its ability to promote the growth of *Bifidobacteria* in the small intestine^[119]. Oral treatment of healthy volunteers with recombinant lactoferrin was shown to reduce indomethacin-induced changes in small intestinal permeability^[120]. However, in this short-term study, only a very modest increase in intestinal permeability was seen, with only a single administration of lactoferrin that would have been unlikely to have significantly affected the intestinal microbiome.

Rebamipide is a quinolinone derivative that is used to promote the healing of GI ulcers and for mucosal protection. Its mechanism of action is not fully understood, though it appears to stimulate mucus secretion and PG synthesis^[121] and to scavenge oxygen-derived free radicals^[6]. It has been shown to significantly reduce the severity of NSAID-induced enteropathy in rats^[122]. Niwa *et al*^[123] performed a pilot study in healthy humans to examine the effectiveness of rebamipride in preventing NSAID-enteropathy. The volunteers received placebo or rebamipride together with diclofenac for 7 d. The small intestine was examined at the end of the study by VCE. Damage was observed in 8 of the 10 of placebo-treated group (2 ulcers, 1 bleed), but in only 2 of the 10 of rebamipride-treated group (no ulcers or bleeding). However, a larger study of healthy volunteers treated for 14 d with an NSAID (diclofenac), a PPI (omeprazole) and either rebamipride or placebo, failed to detect a significant benefit of rebamipride in terms of reducing the incidence of intestinal mucosal injury^[124]. Larger studies of rebamipride, ideally in patients receiving NSAID therapy for an inflammatory disorder, are needed to clarify if this drug will have benefit in reducing the incidence and/or severity of NSAID-enteropathy.

Studies in animal models have suggested other possible approaches to prevention of NSAID-enteropathy, but have not yet been assessed in humans. For example, in a mouse model of acute indomethacin-induced intestinal damage, Yasuda *et al*^[125] found that dopamine D2 receptor antagonists reduced the severity of damage, and these effects were mediated through the activation of endogenous anti-inflammatory pathways mediated by *via* α 7-nicotinic acetylcholine receptors, as had been observed previously^[126]. Using the same model, Kato *et al*^[127] demonstrated that certain 5-HT receptors could modulate susceptibility to NSAID-enteropathy. They reported that antagonists of the 5-HT₃ receptor (ondansetron and ramosetron) dose-dependently reduced intestinal damage, while a 5-HT₄ antagonist (GR113808) aggravated damage. A 5-HT₄ agonist (mosapride) significantly reduced damage. As in the case of protection with dopamine D2 receptor antagonists, the authors suggested that the beneficial effects the 5HT₄ agonist may be mediated through activation of α 7-nicotinic acetylcholine receptors. There have also been studies demonstrating a significant increase in intestinal motor activity after administration of NSAIDs, and have suggested that this contributes to the generation of injury, but pharmacological approaches targeting this 5-HT/ α 7-

nicotinic acetylcholine receptor axis have not yet been evaluated in human NSAID-enteropathy.

NSAID pro-drugs: The enteropathy remains

Pro-drugs have been defined as “bioreversible derivatives of drug molecules that undergo an enzymatic and/or chemical transformation *in vivo* to release the active parent drug, which can then exert the desired pharmacological effect”^[128,129]. A number of NSAID pro-drugs have been developed, based on the premise that if the drug can pass through the stomach in an inactive form, it will not inhibit PG synthesis in the stomach, and therefore will not be ulcerogenic. In essence, an NSAID pro-drug of this design does not differ significantly from an enteric coated NSAID, and the problems associated with the latter are well documented^[8,36]. Moreover, there are several problems with the premise upon which NSAID pro-drugs are based. First, once the drug is absorbed and transformed to release the parent drug, that drug will produce “the desired pharmacological effect”. That effect, reduction of pain and inflammation, is attributable to systemic inhibition of COX activity. In the absence of any “protective” intervention, systemic inhibition of COX activity will result in damage and bleeding in the upper GI tract. Thus, NSAIDs administered systemically induce significant gastrointestinal ulceration and bleeding^[130-132]. If a pro-drug is formulated such that it produces a marked delay in the release of the parent drug, there will be a similar delay in the onset of the desired activity. Second, the pro-drug approach is focused entirely on sparing the upper GI tract of injury, ignoring the potential of the drug to cause small intestinal injury, particularly if it undergoes enterohepatic recirculation. Once the pro-drug is metabolized to release the parent drug, the parent drug will behave, pharmacokinetically and pharmacodynamically, in the same way as if the parent drug itself had been administered. These are points that have been acknowledged on the website of a company that is developing a naproxen pro-drug: “the pro-drug approach will not address the GI damage associated with the systemic inhibition of COX after release of the parent drug, nor will it address the toxic effects of metabolites delivered into the gut lumen with bile”^[133].

Clinical trials of pro-drugs have often produced data that are very favourable to the pro-drug. However, this is largely because such studies have typically focused on acute gastric or gastroduodenal damage (erosions and “endoscopic ulcers”)^[134] that are of questionable clinical significance, since they do not necessarily predict the incidence of true ulcers^[135]. Indeed, the same is true for most of the trials of selective COX-2 inhibitors and of PPIs, which gave a false signal of the GI safety of those classes of drugs because of reliance on inappropriate endpoints for upper GI damage and lack of consideration of the potential damaging effects of these drugs on the small intestine. When examined in “real world” scenarios, using clinically meaningful endpoints^[135], there is little, if any, evidence of significant benefit of NSAID pro-drugs over

the parent drugs or over other NSAIDs. This topic has been very well reviewed by Graham^[135]. Thus, while the pro-drug sulindac rarely caused erosions or “endoscopic ulcers” in short-term studies of human volunteers^[136,137], longer term studies in at-risk patients showed this drug to offer no upper GI safety benefit as compared to other NSAIDs^[138]. Likewise, nabumetone was purported to be a GI-safe pro-drug, and acute upper GI studies suggested that this was the case^[139], but in at-risk patients the drug did not offer any benefit over other NSAIDs^[140]. Neither sulindac nor nabumetone have been specifically examined with respect to their propensity to cause small intestinal ulceration and bleeding. Moreover, there are suggestions in the literature^[132,141], supported by animal studies^[130,131], that systemic administration of NSAIDs, which completely avoids contact of the drug with the lining of the stomach and duodenum, does not offer significant benefit in terms of reducing the incidence of significant GI ulceration and bleeding.

Novel intestinal-sparing NSAIDs

The advances that have been made in understanding the pathogenesis of NSAID-enteropathy provide important clues for designing novel NSAIDs that will not damage in the small intestine (or the stomach). Several approaches have been taken that show promise, mainly using the “co-drug” model of drug design^[142]. Co-drugs are somewhat like pro-drugs, with the key difference being that the promoiety is not inert; rather, it exerts important pharmacological effects^[129]. Two such classes of co-drugs are the nitric oxide (NO)-releasing NSAIDs and the hydrogen sulfide (H₂S)-releasing NSAIDs^[143-145]. In each case, the NSAID portion of the co-drug behaves the same as expected (inhibition of COX-1 and COX-2, leading to anti-inflammatory and analgesic effects), while the gaseous mediator portion of the co-drug exerts mucosal protective effects, very similar to the effects of endogenous prostaglandins^[146,147]. Both of these gaseous mediators are vasodilators and can inhibit leukocyte adherence to the vascular endothelium^[148,149]. Suppression of mucosal synthesis of NO or H₂S reduces the resistance of the stomach to the damaging effects of NSAIDs and other irritants, and impairs the healing of pre-existing damage^[148,150-156]. NO and H₂S donors can increase the resistance of the gastric mucosa to injury induced by NSAIDs and other noxious substances^[148,151,156,157] and can accelerate healing of ulcers in rodent models^[37,150,153,154,158]. Some of the other actions of NO-NSAIDs and H₂S-NSAIDs and their underlying mechanisms have been reviewed previously^[143,145,152].

NO-NSAIDs were shown to cause significantly less intestinal damage than the parent drugs^[159,160], and to be well tolerated in rats with pre-existing colitis^[159]. In a small, short-term clinical trial, an NO-NSAID produced significantly less of an increase in small intestinal permeability than was produced by an equivalent dose of the parent drug (naproxen)^[161]. Despite very promising results from clinical trials that demonstrated efficacy and safety

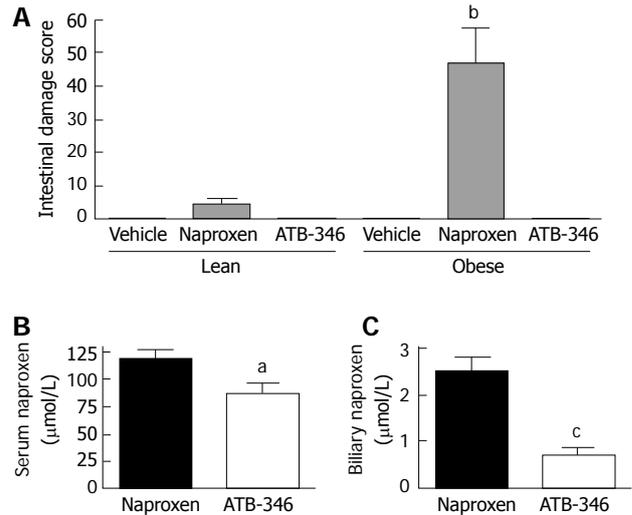

Figure 4 Intestinal safety and altered biliary excretion of ATB-346. A: ATB-346 is a hydrogen sulfide-releasing derivative of naproxen^[38]. When administered to obese Zucker rats, twice-daily for 4.5 d at 10 mg/kg, naproxen induced small intestinal damage that was significantly more severe in the obese rats ($P < 0.01$). However, at an equimolar dose, ATB-346 did not induce intestinal damage in lean or obese rats^[175]; B: The serum levels of naproxen in normal rats after 4.5 d of twice-daily administration of ATB-346 were marginally, but significantly ($P < 0.05$) lower than those in rats treated with an equimolar dose of naproxen; C: Biliary levels of naproxen in rats treated with ATB-346 (as above) were markedly reduced compared to those in rats treated with an equimolar dose of naproxen ($P < 0.001$). The data shown in this graph are from Blackler *et al*^[175].

in osteoarthritis^[162-166], NO-NSAIDs have not obtained regulatory approval because the safety advantages over the parent drug (naproxen) have not been sufficiently demonstrated. One key GI safety clinical trial fell just short of showing a significant benefit as compared to naproxen ($P = 0.066$)^[167].

H₂S-releasing NSAIDs exhibit enhanced anti-inflammatory activity relative to the parent drugs^[37,151,155,168,169], presumably attributable to the anti-inflammatory and pro-resolution effects of the H₂S released from these drugs^[149,158,170-174]. In addition to sparing the gastric mucosa of damage in several circumstances of impaired mucosal defence^[38,175], H₂S-releasing NSAIDs have been shown not to cause damage in the small intestine of rats^[38,155,175]. Moreover, when tested in co-morbidity and polypharmacy models, with repeated administration over several days, an H₂S-releasing derivative of naproxen (ATB-346) did not cause small intestinal damage^[175] (Figures 2 and 4). For example, obese rats that exhibited markedly greater naproxen-induced enteropathy than was observed in lean rats, but ATB-346 did not elicit damage in lean or obese rats^[175]. Interestingly, Zucker obese rats have a microbiota distinct from that of their lean littermates, with a marked reduction in intestinal levels of *Bifidobacteria*^[176]. Recall that we observed that PPIs increased the severity of NSAID-enteropathy in rats, and found that this was largely attributable to a decrease in intestinal *Bifidobacteria* levels^[37]. ATB-346 retained its favourable profile in the intestine even when co-administered with a PPI and/or low-dose aspirin^[175] (Figure 2).

A particularly important feature of ATB-346 that may be very important in terms of its lack of damaging effects in the small intestine is that, though metabolized to release naproxen, there are relatively low levels of naproxen in bile after administration of this compound^[175] (Figure 4). Moreover, the biliary levels of naproxen-glucuronide were reduced by 72% in the ATB-346 group as compared to the naproxen group^[175]. These altered pharmacokinetics of ATB-346 *vs* naproxen did not alter the anti-inflammatory activity of the drug^[37], but could contribute significantly to the intestinal-sparing properties of ATB-346.

Recently, a class of drugs was described that consists of an NSAID attached to moieties releasing both NO and H₂S^[177]. These compounds show comparable actions as the parent drugs in terms of inhibiting COX activity, but there are no available data on their GI toxicity.

NSAIDs pre-associated with phospholipids are a unique type of “co-drug”.

Surface-active phospholipids have been proposed to constitute an important component of the epithelial “barrier” to acid back-diffusion, and NSAIDs can to disrupt this barrier^[178,179]. Lichtenberger *et al*^[180] demonstrated that pre-associating an NSAID with a zwitterionic phospholipid prevents the NSAID from disrupting the barrier function of the epithelium. Thus, covalently linking phosphatidylcholine to aspirin, ibuprofen and other NSAIDs results in compounds with equivalent anti-inflammatory properties to the parent drug, but with markedly reduced gastric toxicity^[181]. This has been demonstrated in endoscopic clinical trials for an aspirin derivative^[181], and also with an ibuprofen derivative^[182], though in the latter trial, statistical significance was only seen in an older subset of the patients studied. Recently, Lichtenberger *et al*^[78] demonstrated that pre-associating aspirin with phosphatidylcholine greatly reduced the small intestinal damage produced by intraduodenal administration of this compound, as compared to aspirin alone.

CONCLUSION

NSAID-enteropathy has largely been ignored for decades as a result of the focus on NSAID-gastropathy, driven largely by the development of several commercially successful drugs targeting that disorder (H₂RA, PPIs, selective COX-2 inhibitors). Moreover, the difficulty in detecting NSAID-enteropathy and the lack of any proven-effective preventative or treatment options has contributed to an under-appreciation of the magnitude of this significant adverse reaction to a very widely used class of drugs. With the development of video capsule endoscopy, the frequency and severity of NSAID-enteropathy has become more evident. Techniques such as VCE also permit more conclusive studies of the safety of novel NSAIDs and of potential prevention or treatment strategies.

The animal models for NSAID-enteropathy are very good, and they have provided a great deal of information on the pathogenesis of this disorder. Moreover, the ani-

mal studies have given some direction as to viable strategies for preventing NSAID-enteropathy, and the models are useful for testing novel therapeutics agents.

As is the case with NSAID-induced injury in the upper GI tract, it is important that studies of NSAID-enteropathy focus on animal models that are most similar to the patients that use these drugs and most often develop serious adverse effects. Thus, future studies should focus on the use of animal models with relevant co-morbidities that display increased susceptibility to NSAID-enteropathy, and on patients most at risk of developing intestinal damage and bleeding.

ACKNOWLEDGMENTS

Dr. Wallace is a founder and shareholder of Antibe Therapeutics Inc., a company developing novel NSAIDs.

Abstract

Virus-specific T cells play an important role in the resolution of hepatic infection. However, during chronic hepatitis infection these cells lack their effector functions and fail to control the virus. Hepatitis B virus and hepatitis C virus have developed several mechanisms to generate immune tolerance. One of these strategies is the depletion of virus-specific T cells by apoptosis. The immunotolerogenic liver has unique property to retain and activate naïve T cell to avoid the over reactivation of immune response against antigens which is exploited by hepatotropic viruses to persist. The deletion of the virus-specific T cells occurs by intrinsic (passive) apoptotic mechanism. The pro-apoptotic molecule Bcl-2 interacting mediator (Bim) has at-

tracted increasing attention as a pivotal involvement in apoptosis, as a regulator of tissue homeostasis and an enhancer for the viral persistence. Here, we reviewed our current knowledge on the evidence showing critical role of Bim in viral-specific T cell death by apoptotic pathways and helps in the immune tolerance.

INTRODUCTION

Hepatotropic, non-cytopathic viruses such as hepatitis B virus (HBV) and hepatitis C virus (HCV) behave as intracellular parasites. The activation of cellular immune response by priming of naïve specific CD4⁺ and CD8⁺ T cells in the lymph nodes is very important to control viral infection. However, the unique ability of the liver to retain and activate naïve CD8⁺ T cells leads to liver tolerance, by-passing normal activation in the lymph nodes. The continuous triggering of antigen presenting cells (APCs) in the sinusoids by the antigen-rich blood leads to peripheral tolerance to protect the liver tissue. This physiological feature can be used by hepatotropic viruses as a persistence mechanism. The depletion of liver activated CD8⁺ T cells is the critical part of the peripheral tolerance in HBV/HCV infection. The anticipated mecha-

nisms for immune tolerance in liver specific pathogens are linked to virus-specific T cells death. The vital role of pro-apoptotic molecule, Bcl-2 interacting mediator (Bim) in the death of the virus-specific T cells has been shown after intrahepatic T cell activation by hepatocytes^[1], in chronic HBV and HCV infection^[2,3]. Therefore, this review provides glimpse of the recent advances to understand the cellular and molecular mechanism involved on “T cell death” during viral hepatitis as a viral escape mechanism through the induction of a specific-immunotolerant status on the host.

VIRAL HEPATITIS

HBV and HCV viruses are two hepatotropic non-cytopathic, human blood-borne viruses. HBV is a small, enveloped DNA virus that undergoes a pro-viral state to persist in the host. HCV is an enveloped virus with a plus-strand RNA genome. It has been estimated that more than 350 million for HBV and 170 million people for HCV are infected. Approximately 80% of infections in HCV and > 90% of infected neonates, 5%-10% of infected adults in HBV succeed in establishing a chronic infection, with the potential for developing severe liver diseases such as cirrhosis and hepatocellular carcinoma^[4,5].

Highly productive and replicative viruses such as HBV and HCV are associated with ineffective antiviral immunity during persistent viral infections. The complex ineffective immunity involves the functional deterioration of antiviral T cell responses and contraction of the size of this response. In persistent HBV/HCV infections, T cells are continuously challenged by high levels of viral antigens that eventually result in limiting the antiviral T cell response and ultimately leading to T cell exhaustion. This is a progressive process, starting with the deficiency in cytokine production, proliferation and survival^[6], to end with physical deletion of specific antiviral T-cell populations^[7].

Meticulously, cytotoxic T lymphocytes (CTLs) play a vital role in viral eradication^[8] and in the pathogenesis of hepatitis^[9-11]. A strong, multi-specific and long-lasting T-cell immune response emerges to be important for control of viral infection^[12-14]. Appropriate, polyclonal, vigorous and multi-specific CTL responses can facilitate complete viral clearance, in which long-lasting protective T cell response is observed. However, specific CTL responses are usually not strong enough to eradicate the virus, hence contributing to persistent infection^[15,16].

HBV and HCV are hepatotropic viruses that replicate in the liver. This organ features a unique immune tissue, where the deletion of antiviral T cell populations has been shown, being involved in local and systemic immune tolerance.

LIVER AS A FOUNDATION OF IMMUNE TOLERANCE

Liver situates at a hemodynamic convergence, receiving

the splanchnic stream, which means an intense contact with exogenous antigens. This fact leads to the development of tolerance mechanisms to avoid inappropriate immune system activation, but it also allows antigen presentation by resident cells. Therefore, the liver is progressively more being recognized as an immune organ^[17]. Liver sinusoids, hepatic arteries and portal venous carry blood containing digested nutrients and micro antigens from intestine, and as a primary metabolic organ, the liver produces multiple neo-antigens. All these molecules pass through sinusoids and finally are taken up and metabolized by different hepatic resident cells. The liver has acquired specialized mechanisms of immune tolerance to avoid the over reactivation of immune response against antigens that are metabolized in the liver. In fact, this process may be beneficial for inducing tolerance to liver grafts but also to the liver specific pathogens. Therefore, hepatotropic viruses exploit these immunotolerogenic liver features to persist. It is important to remind that the liver has the ability to retain and activate naïve CD8+ T cells ineffectively, in contrast to other lymphoid tissues. This fact may allow pathogens to escape from T cell mediated immunity and establish a persistent hepatic infection due to immune tolerance induction. This immunotolerant state can be reached by the development of T cell anergy but also by specific T cell deletion.

Uniqueness of the liver

The unique character of the hepatic tissue to tolerate liver allograft across major histocompatibility complex (MHC) mismatch in the pig without immunosuppression was described by first time in 1969^[17]. Later studies confirmed that this occurred because of the induction of immunological tolerance in the liver^[18]. Initially, “graveyard theory” suggested that the exclusive ability of the liver to get rid of activated T cells, programmed to undergo apoptosis, was the root of the hepatic tolerance effect^[19]. This theory proposed two functions of the liver as a T cell graveyard: (1) passive killer of the liver cells after their life cycle; and (2) efficient killer of the activated antigen specific T cells. According to this theory, T cell receptor (TCR) triggering by cognate antigen on TCR transgenic T cells leads to activation and accumulation of those cells in the liver and undergoes depletion of mature T cells^[20].

The theory was again proved by Mehal *et al.*^[21] by indicating that the normal liver is a “sink” for activated T cells. The liver was perfused by T cells showing retention of activated, but neither resting nor apoptotic T cells^[21]. Liver as a graveyard for activated T cells theory forced to believe that all the immune response in the liver would be silent; in spite of this, the presence of an effective virus specific T cells in patients controlling hepatic viral infections^[22,23] could challenge this theory. Nonetheless, the removal of activated T cells by the liver cannot be excluded, as evidenced by the ability of liver allograft to rescue rejecting skin grafts^[21], in which lately tolerising capacity of the liver for activated allo-specific T cells occurs. In some cases, the limited capacity of the liver to induce tolerance

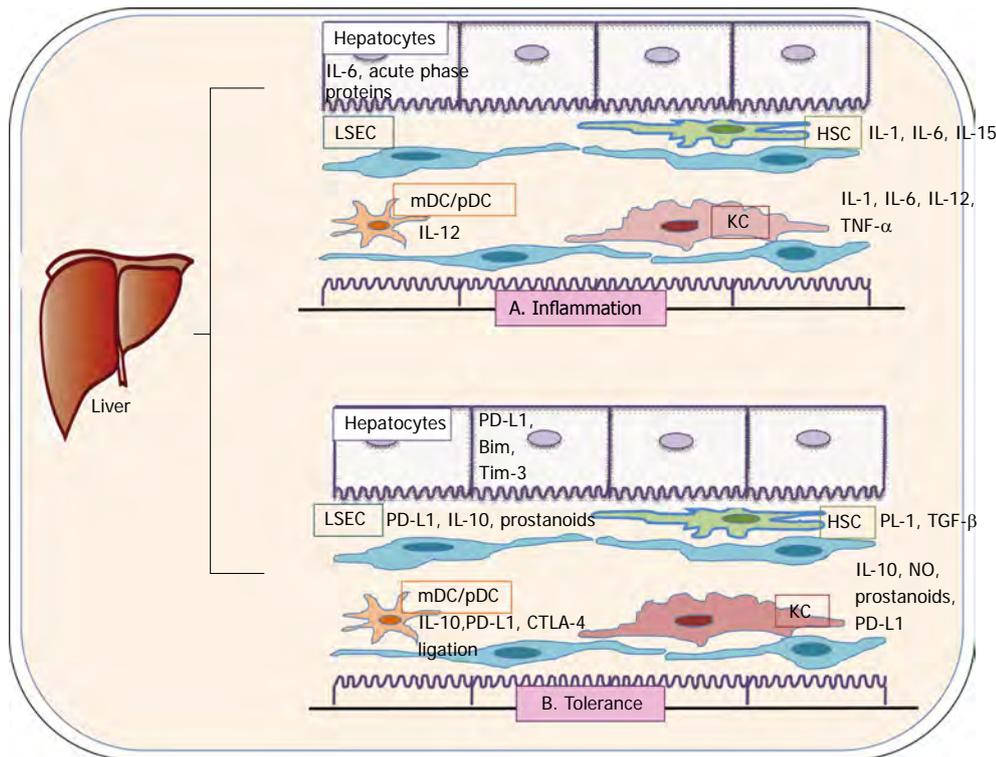

Figure 1 Collective illustration of the hepatic cells with inflammatory and tolerance activities by stimulation of different molecules or receptors. could be due to large number of activated T cells^[24].

Naïve T cells activation in the liver

The site of T cell activation is a determinant of the outcome of an immune response in the liver^[22]. Tolerance will occur when T cells are activated in the liver. On the other hand, an effective immune response will be generated, when T cells are activated in the lymph nodes. This model put forward the theory that tolerance during viral hepatitis could be the result of early deletion of antigen-specific T cells from the T cell repertoire in the liver^[22]. Usually, naïve T cells are activated in secondary lymphoid organs with consequent up regulation of adhesion molecules and integrins expression, which can bind to endothelial layer of the target organ and ultimately direct T cells to the parenchyma^[25]. Moreover, T cells are not able to interact with parenchymal cells easily and thus they are not usually activated in the solid organs. In spite of this, the situation in the liver is slightly different. Fenestrated endothelial layer in the liver makes available interactions between naïve T cells and liver cells^[26]. It has been showed by MHC class I -restricted, hepatitis B surface Ag-specific CD8+ polyclonal CTL adoptively transferred into wide-spread antigen expressing transgenic mouse model, leading to retention of those cells within the liver^[26]. Moreover, it has been shown that primary antigen-specific T cell can be activated in the liver independently of lymphoid tissues^[27].

Liver APCs in tolerance

Retention, activation and tolerance of naïve T cells in the liver is the result of the action of resident liver cells, including liver sinusoidal endothelial cells (LSEC), Kuffer

cells (KC), liver dendritic cells (DC), hepatic stellate cells (HSC) and hepatocytes. Their collective function in induction of inflammatory response and tolerance has been illustrated in the Figure 1.

Endocytosis specialist-LSEC can express MHC class I and II, accessory CD80, CD86 and CD40 molecules. These features enable those cells to behave as potent APCs with the ability to activate both naïve CD4 and CD8 T cells as well as to cross-present exogenous antigen towards CD8 T cells^[28]. However, LSEC primed naïve CD4+ T cells produce cytokines typical from Th0 rather than Th1 cells^[29]. In addition, LSECs constitutively expressed ICAM-1, which helped in trapping of specific CD8+ T cells in the liver, resulting this process in activated T cell apoptosis^[21]. Furthermore, the cross presentation of antigen by LSEC mainly leads to CD8+ T cells tolerance rather than immunity, demonstrating that LSEC-induced tolerance is an active and dynamic process^[30].

Bone marrow derived and largest group of liver resident macrophages-KC mediate host resistance to infection. Interleukin (IL)-1, IL-6, IL-12 and tumor necrosis factor- α (TNF- α) pro-inflammatory cytokines released by KC^[31] are involved in the inflammatory activities, whereas the nitric oxide, prostaglandin and IL-10 released by KC^[29,32] down-regulate the production of pro-inflammatory cytokines and thereby may contribute to induction of hepatic tolerance. Furthermore, DC-induced antigen-specific T cell activation can be inhibited by KCs^[29], which could also favor tolerance development. In addition, as in LSECs, KCs expressed ICAM-1 mediated trapping of specific CD8+ T cells in the liver resulting in activated T cell death^[21].

Liver DCs are primarily located within periportal areas

and around central veins, which exert tolerogenic properties due to “immature” phenotype. The production of PD-1 and cytotoxic T lymphocyte antigen-4 (CTLA-4) by resting DCs, which are crucial negative co-stimulatory molecules, helps in inducing peripheral CD8+ T cell tolerance by inhibiting proliferation and cytokine production of liver infiltrating effector T cells^[33]. In addition, liver generated DCs are more tolerogenic than DC in lymphatic tissue^[34].

The role of HSCs in hepatic fibrosis includes stimulation of CD4, CD8+ T cells and NKT cells^[35,36]. However, function of HSCs involves not only the inflammatory response^[36], but also a tolerogenic role^[37,38], which is the result of induction of T cell death^[38] by intrinsic mechanism of immune inhibition. The HSCs regulate immune modulation by inducible B7-H1 expression, an inhibitor molecule of B7 family, resulting in T cell apoptosis induction.

Hepatocytes are also capable of activating naïve CD8+ T cells^[39,40] and their interactions with CD8+ T cells may occur through LSEC fenestrations^[38]. However, hepatocytes fail to promote activated CD8+ T cells survival, leading to an impaired T cell activation^[39]. In addition, hepatocyte-activated T cells *in vitro* acquired activity and secrete cytokines but both levels are not constant and T cells consequently appeared to die by passive mechanisms^[41]. Furthermore, infiltrating CD4+ T cells differentiate into a less inflammatory phenotype due to the interaction with MHC II-expressing hepatocytes, which also helps to abrogate antiviral CD8+ T-cell response and viral clearance^[42], which conclude in the tolerance during infection. It has been already proved that T cells activated by hepatocytes undergo premature death^[43], whereas naïve CD8+ T cells priming by DC in the lymph nodes acquired effector functions in the liver.

The site of primary T cell activation could also induce emperipolesis of CD8+ T cells in the liver^[43], which leads to non-apoptotic, destruction of these CD8+ T cells after degradation by lysosomal proteolytic enzymes. This distinct form of emperipolesis has been termed as “suicidal emperipolesis” (SE)^[44]. Benseler *et al*^[44] suggested that SE is a significant mechanism by which death of activated naïve CD8+ T cells occur in the liver within the first few hours before T cells are able to divide and expand. It is also involved in maintenance of tolerance, which is reinforced by break of tolerance in immune-mediated liver damage by treatment of wortmannin^[44], inhibitor of phosphoinositide 3-kinases that blocks emperipolesis. Therefore, SE is an extremely efficient mechanism, able to rapidly delete T cells.

T cell stimulation in the liver encourages tolerance by using mechanisms such as, immune divergence^[45], generation of regulatory T cells^[46], T cell anergy^[47] and T cell death^[1]. Undeniably, hepatic tolerance can explain the elevated frequency of viral persistence during hepatotropic virus infections^[1]. Although there are evidences showing that most infectious microorganisms are promptly removed from the liver, a favorable situation for evading immune responses occurs in some viruses, leading to the

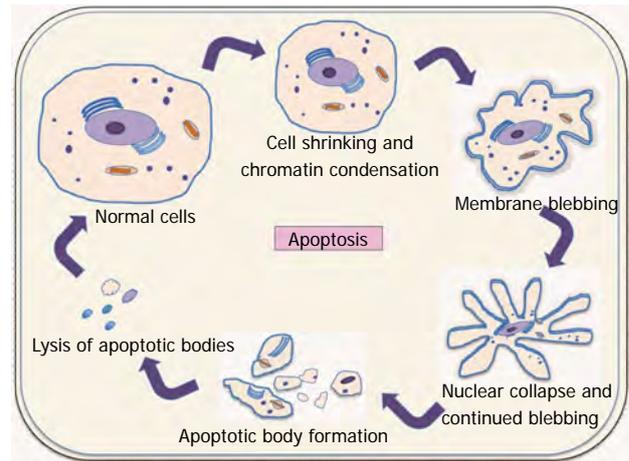

Figure 2 Apoptosis-programmed cell death.

triumph of certain pathogens such as HBV and HCV. Till date, there are two main mechanisms by which HBV and HCV could successfully escape from CTL action: escape mutant generation, and immunosuppressive effects exertion (effector T cell exhaustion and T cell death by apoptosis)^[2,48-50]. Among these mechanisms involved in viral hepatitis persistence, new advances on the role of T cell death induction have been obtained recently and our review in the apoptosis role, paying special attention to the last new insights in this issue will be discussed in the following pages.

APOPTOSIS

A normal cellular process involving physiologically relevant cell death and deletion of unwanted cells is called apoptosis. Apoptosis is essential for cell selection, tissue homeostasis, morphogenesis, and host defense in multicellular organisms. A cell that undergoes apoptosis dies neatly, without damaging its neighbors. The apoptotic signals give rise to activate various proteins and follow a specific classical caspase chain reaction set activation^[51]. Quickly and neatly dismantlement process includes membrane blebbing with shrinking of the cytoplasm and condensation of the nucleus. Phagocytic cells begin to pick up the apoptotic bodies, preventing the release of cellular content and ultimately avoiding inflammation^[52] (Figure 2). Apoptosis occurs by two mechanisms: active and passive mechanism. No presence of antigen gives a signal for termination of immune response by passive apoptotic mechanism (intrinsic pathway). On the other hand, the ligation of Fas (CD95) and TNF receptors-“death receptors” triggered apoptosis lead to active mechanism of apoptosis (extrinsic pathway). Briefly, apoptosis mechanisms involve a family of cysteine proteases, called caspases. These molecules are synthesized in the cell as inactive precursors, or pro-caspases for self-protection against accidental death, which are usually activated after receiving proper trigger by cleavage (Figure 3). Structurally, pro-caspases contain three domains: N terminal prodomain, a large subunit

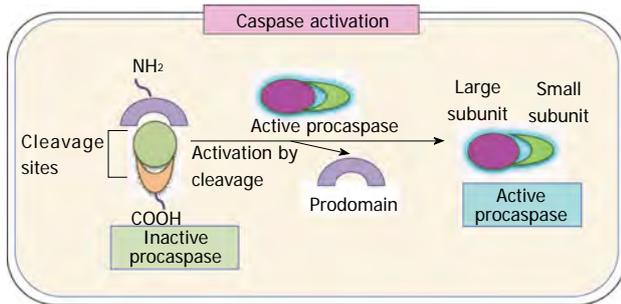

Figure 3 Caspase activation: Inactive proenzyme (procaspase) activated by proteolytic cleavage by another member of caspase family and cleaved two fragments associate to form the active site of the caspase.

and a small subunit. After activation, the active caspase enzyme is formed by heterodimerization of small and large subunits^[43]. Moreover, active caspase molecules are ready to cleave target proteins such as structural or signaling proteins and other effector caspases, preventing other proteins cleavage randomly^[52].

Extrinsic pathway

The extrinsic pathway initiates from outside the cell through triggering the activation of transmembrane “death receptors” that are members of the TNF receptor gene superfamily. Members of this receptor family bind to extrinsic ligands known as pro-apoptotic ligands^[53] and transduce intracellular signals that ultimately result in the destruction of the cell^[54,55]. To date the most well characterized ligands of these receptors are FasL, TNF- α , Apo3L and Apo2L and corresponding receptors are FasR, TNFR1, DR3 and DR4/DR5, respectively^[55-57]. The signal transduction of active cell death process involves several caspases. Activated caspases have an effect on several cellular functions as part of the process that results in the death of the cells^[53].

The signal transduction of mitochondrial-independent active cell death process involves binding of a pro-apoptotic ligand (such as FasL) with its receptors (Fas) on the surface of a target cell. The cytosolic tail of receptors contains a death domain, which when activated, binds to an adaptor protein, which in turn recruits the specific procaspase-8 and -10 and activates them by proteolytic cleavage^[58] that finally initiates the proteolytic caspase cascade leading to apoptosis. Activated caspase 8 triggers the caspase cascade *via* two different pathways, leading to cell death. In type 1 apoptosis, such as in lymphocytes, caspase 8 activates caspase 3 whereas in type 2 apoptosis, like in hepatocytes and pancreatic cells, caspase 8 activate the pro-apoptotic molecule Bid and go ahead for apoptosis *via* the disruption of mitochondrial membrane and cytochrome C release^[59] (Figure 4). The T cell death by type 1 and type 2 Fas induced apoptosis fate is decided by the ratio between proteolytically activated effector caspases, X-chromosome linked inhibitor of apoptosis protein and proto-typical effector caspase substrate inhibitor of caspase-activated DNase. Interestingly, HCV specific in-

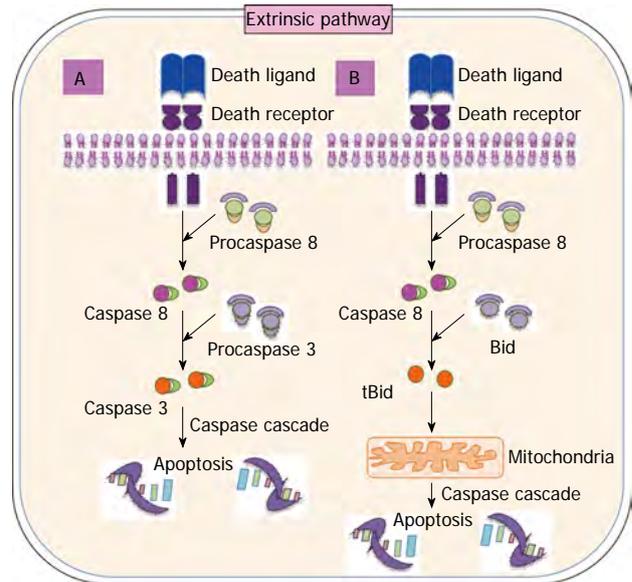

Figure 4 Extrinsic pathway. A: Mitochondria-independent extrinsic pathway: Fas-FasL ligation strikes to recruit pro-caspase 8 activation and induction of caspase cascade by caspase 3 leading to apoptosis; B: Mitochondria-dependent extrinsic pathway: Fas-FasL ligation trigger to activate the pro-caspase 8, which cleave Bid (pro-apoptotic Bcl-2 family molecule) to form truncated Bid (tBid). Then, mitochondrial dependent cell death begins with tBid.

trahepatic lymphocytes contribute to bystander killing *via* Fas-FasL interaction^[60], which support the fact that the liver facilitates liver-trapped activated T cell apoptosis^[61].

Intrinsic pathway

The intrinsic or mitochondrial pathway is initiated within the cell, involving non-receptor-mediated intracellular signals and inducing activities in the mitochondria that initiate apoptosis. DNA damage, loss of cell-survival factors or other types of severe cell stress causes the induction signal for the intrinsic pathway. This passive death process pivots on the balance of activity between pro- and anti-apoptotic signals of the B cell lymphoma 2 (Bcl-2) family proteins^[62]. This balance is maintained by regulation of the permeability of the mitochondrial membrane and by the pro- or anti-apoptotic signal that will be released inside the cell^[63]. Following mitochondrial permeabilization, the intrinsic pathway divides into two pathways: Apoptosis protease-activating factor-1 (Apaf-1) dependent and Apaf-1 independent pathway. In Apaf-1 dependent pathway, release of cytochrome c from mitochondria, by triggering the pro-apoptotic Bcl-2 family member^[64], and ATP activate monomer inactive Apaf-1 proteins by a conformational change, leading to form a heptamer of Apaf-1 molecules called apoptosome^[65]. Apoptosome allows activation of pro-caspase 9, which consequently triggers the caspase cascade^[66]. On the other hand, in Apaf-1 independent pathway, permeabilization of mitochondrial membrane release DIABLO like proteins, which activates effector caspases by provoking inhibitors of apoptosis proteins^[67] and triggers caspase cascade^[68] (Figure 5).

The balance of pro- and anti-apoptotic proteins main-

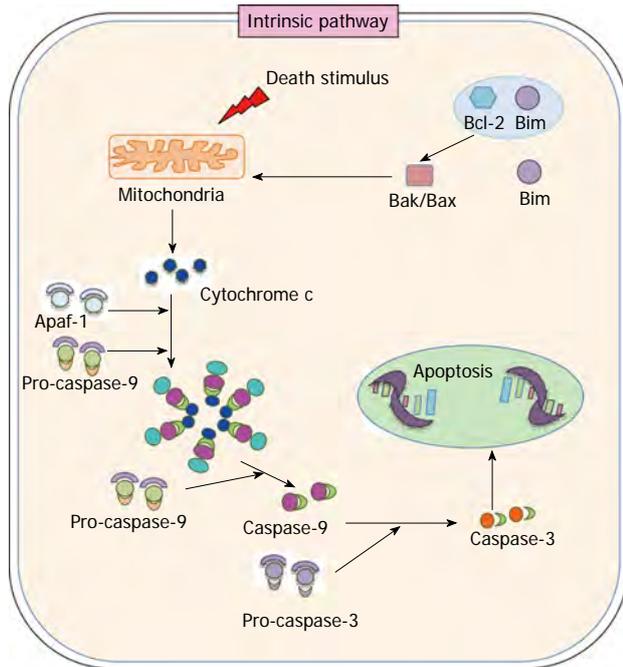

Figure 5 Intrinsic pathway. Death stimulation up regulates Bcl-2 interacting mediator leading to the separation from Bcl-2, favoring the activation of Bax, Bak, which form pores in the mitochondrial membrane leading to release of cytochrome c. Cytochrome c with Apaf-1 and procaspase 9 participate in the formation of apoptosome, which activate caspase 9. Caspase-9 activates caspase 3 after cleavage of pro-caspase-3. That caspase-3 triggers to induction of caspase cascade and cell death. Apaf-1: Apoptosis protease-activating factor-1. Bim: Bcl-2 interacting mediator.

tains the apoptotic activity^[69]. The Bcl-2 family members regulate mostly neglect or intrinsic pathway. This family is subdivided into three groups of proteins on the basis of their functions and the number of Bcl-2 homology (BH) motifs included in their primary structure; first group: “anti-apoptotic multidomain” members, such as Bcl-xL, have four BH domains (BH1 to BH4) which inhibits apoptotic process. Other two groups of “pro-apoptotic multidomain” members, which are Bax-like proteins and “BH3-only” proteins^[70]. Bax-like proteins possess three BH domain (BH1 to BH3), including Bax, Bak, and Bok, which are referred as death effector members. BH3-only members contain BH3 domain, including Bim, Bad, Bik, Puma, Noxa and Bid and are known as messengers of death. In addition, C-terminal transmembrane (TM) fragment is thought to confer anchorage to mitochondrial membranes, which is also possessed by most multi-BH members and several BH3-only proteins.

Three models (Figure 6) have been postulated by which the BH3 family promotes passive cell death in which Bax and Bak bind directly or indirectly with cell death sensitizer (*e.g.*, Bad, Bik) and activators of cell death (*e.g.*, Bim, tBid). The direct activation model proposes that sensitizer BH3-only proteins displace the activator BH3-only proteins from the anti-apoptotic proteins to promote apoptosis. Anti-apoptotic proteins inhibit the activator BH3-only proteins but not Bax and Bak to suppress apoptosis. In the displacement model, Bax and Bak

are sequestered by anti-apoptotic proteins for cell survival and constitutively active in cells. BH3-only proteins play the sensitizer role and inhibit their respective anti-apoptotic proteins to promote apoptosis. The third model, called embedded together model, highlights the interactions occurring in and on membranes, which were not explained by direct activation and displacement model. In embedded together model, Bcl-2 family proteins insert into and change their conformations according to their functions in membrane^[71]. The predominantly studied messenger death molecule, Bcl-2 interacting protein (Bim) will be focused further.

BIM

Bim/Bod is a pro-apoptotic protein belonging to the BH3-only group of Bcl-2 family members and is being called the “ghost” molecule or “suicide” molecule, which enables cells to expire gracefully. Two independent studies discovered Bim as a Bcl-2 binding protein and Mcl1-binding protein in 1998^[72,73]. Bim induces apoptosis by binding to and antagonizing anti-apoptotic members of the Bcl-2 family. The Bim interactions have been observed with Bcl-2 family members, such as Bcl-2, Bcl-xL, Mcl-1, Bcl-w, *etc*^[72,73].

Bim is a well-known pivotal initiator of apoptosis in thymocyte-negative selection^[74]. Bim has 19 Bim isoforms including three major isoforms, which have distinct sizes and pro-apoptotic activities in the mammals, caused by alternative splicing: BimEL (extra long), BimL (long) and BimS (small)^[73]. The shortest form, BimS, is the most potent and is generally only transiently expressed during apoptosis^[75]. The other two isoforms are sequestered to the dynein motor complex, and apoptotic activity of these longer isoforms is regulated by phosphorylation^[75,76], which is triggered by environmental stress, resulting in its dissociation from the dynein complex and increasing apoptotic activity.

Expression of Bim is up regulated in human T cells in response to TCR-triggering by protein kinase C and calcineurin pathways^[77]. Nevertheless, there are other mechanisms involved in Bim up-regulation during chronic infection, such as the effect of certain cytokines. In fact, in a persistent viral infection animal model, Bim-mediated apoptosis correlates with low IL-7 receptor expression on specific T cells^[78].

The regulation of Bim expression at transcriptional level in growth factor deprivation and in endoplasmic reticulum stress has observed by the class O fork-head box transcription factor (FOXO3A) and transcriptional factor CEPB- α respectively^[79,80]. Post-transcriptional phosphorylation of Bim can also regulate its function. Phosphorylated Bim is targeted for proteasomal degradation and avoid its interaction with Bax, thus maintaining cell existence^[81,82]. The signaling adaptor TNFR-associated factor 1 (TRAF1) negatively correlates with Bim and it contributes to CD8 T cell-mediated control of chronic viral infections. In addition, linking between survival

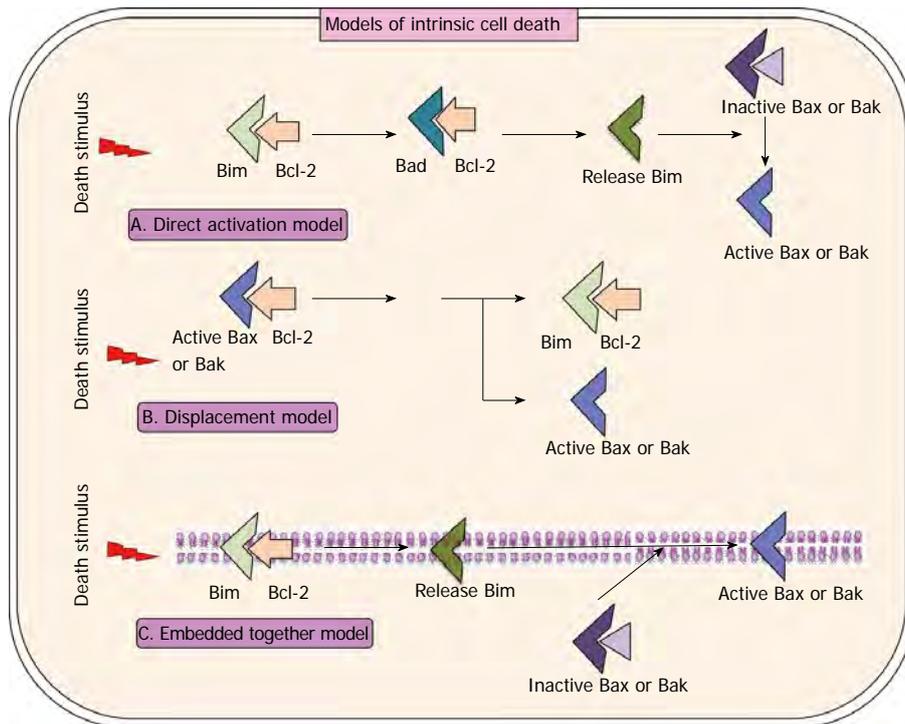

Figure 6 Models for intrinsic cell death. A: Direct activation model postulates Bcl-2 interacting mediator (Bim) is required for activating Bax and Bak. Anti-apoptotic proteins inhibit BH3-only proteins to suppress apoptosis, but not Bax or Bak. Replacement of Bim to sensitizer BH3-proteins from the anti-apoptotic proteins occurs to promote apoptosis; B: The displacement model proposes that anti-apoptotic proteins for cell survival must sequester constitutively active Bax and Bak in cells. Bim inhibits their respective anti-apoptotic proteins by playing sensitizer role to promote apoptosis; C: Embedded together model highlights the active role of the membrane, which is not defined in direct activation model and displacement model. Bcl-2 family proteins insert into and change their conformations that dictate their functions at the membrane. Sensitizer BH3-only proteins relocate the activator BH3-only proteins and Bax/Bak from the anti-apoptotic proteins to endorse apoptosis. Activator BH3-only proteins recruit Bax to the membrane to induce mitochondrial outer membrane permeabilization and apoptosis. These reversible interactions are directed by equilibrium constants that are depended on the concentrations and interactions of the proteins with each other and with membranes.

effects of TRAF1 and TRAF1-dependent Bim down-modulation has been shown in CD8 T cells^[83-85]. TRAF1 is particularly vanished from virus-specific CD8 T cells during the chronic human immunodeficiency virus and lymphocytic chorio-meningitis virus (LCMV) infection^[86].

Bim plays a vital role in the immune system, in bone biology and in tumor-genesis by inducing apoptosis^[87]. Bim in T cells, B cells, neurons and many other cell types can trigger apoptosis^[87]. Gene targeting in mice for the important region for apoptosis, BH3 region, uncovered the important physiological role in Bim^[88]. In fact, in the absence of Bim leukocytes in blood as well as in LNs, thymus, spleen were high in number^[88]. The role of Bim in apoptosis has been revealed in Bim^{-/-} thymocytes, which were more resistant to apoptosis after different apoptotic treatment such as ionomycin, taxol, γ irradiation^[88].

DEATH OF ACTIVATED T CELLS BY BIM

The liver is having a property that might explain its role in inducing tolerance due to its recognition as an alternative primary activation of CD8 T cells site. The phenotype of activated CD8 cells in the liver was the same as in lymph nodes. However, liver-activated CD8 T cells displayed poor effector functions and a unique CD25^{low} CD54^{low} phenotype, which was associated with increased expression of the Bim and caspase-3, demonstrating that these cells are programmed to apoptosis following intrahepatic activation. Strikingly, Bim deficient T cells survived following intrahepatic activation^[1]. Therefore, the phenotype and fate of naïve CD8 T cells activated by hepatocytes *in vivo* could explain the death penalty role of Bim in chronic hepatotropic viral infection^[1]. The dis-

tinct phenotype can be due to the lack of co-stimulatory molecule expression on hepatocytes^[43]; however the treatment with IL-2 or anti-CD28 antibodies could rescue hepatocyte-activated cells from death^[44].

Lymphocyte fate deciding pathways synergize to kill activated T cells in chronic herpes simplex viral immune responses, whereas death of activated T cells in acute immune responses relies only on the mitochondrial pathway involved only Bim with no contribution by Fas, which showed critical overlapping roles for Fas and Bim in T cell death during immune response shutdown, leading to immune tolerance^[23].

BIM IN HEPATITIS

Bim has been shown to be important for CD8 T cell viability during chronic LCMV infection in mice^[89]. In this study, in Bim mutated mice, Bim mutation almost completely blocked the deletion of cognate antigen specific CD8 T cells in liver during chronic viral infection. Bim has a critical role in maintaining naïve and memory T cells in LCMV infection^[90]. In another study, it has been shown that a defect in apoptosis dramatically not only enhances the antigen-specific memory T cells but also increased the number of virus-specific CD4⁺ T cells in the lymph nodes following acute LCMV infection, compared to the parental genotypes or wild type mice^[91]. Therefore, the loss of both Bim and Fas caused the increase in memory T cells in acute LCMV infection^[91]. The Bim role has been demonstrated in the development of LCMV-induced, T cell-mediated hepatitis by controlling the apoptosis of both T cells and hepatocytes^[92].

Bim attrition of virus specific CTLs during HBV

infection has also been confirmed^[3,93]. The gene expression profile in HBV infection showed different patterns of gene expression on HBV-specific CD8+ T cells according to viral control. Bim was one of the up-regulated genes in HBV-specific CD8+ T cells from patients with chronic HBV infection. Blocking Bim-mediated apoptosis improved recovery of HBV-specific CD8+ T cell function^[3]. Furthermore, the elevated apoptosis has been observed not only with Bim tolerogenic phenotype, but also with co-inhibitory signals through CTLA-4^[93] or T cell-intrinsic transforming growth factor- β ^[94].

As discussed earlier, robust CD8 responses are essential to control HCV infection. However, in HCV chronic infection, HCV specific CD8 are depleted by Bim mediated attrition, and remaining cells are functionally exhausted. The cell survival factor CD127 counteracts the induction of apoptosis after antigen encounter through myeloid cell leukemia sequence-1 (Mcl-1) expression and

Bim down-regulation^[95] after the cognate antigen recognition by TCR. Similarly, our group has shown in previous work, HCV-specific CTLs displayed a high Bim expression in persistent infection respect to resolved infection patients^[2], suggesting a similar apoptotic mechanism to the one described in chronic HBV infection.

The procedure of T cell death during chronic viral infection is determined by a carefully balanced and complex group of pro- and anti-apoptotic proteins of the Bcl-2 family, such as Bim and Mcl-1^[96] (Figure 7). Interestingly, persistent hepatotropic viral infection is characterized by continuous TCR triggering and CD127 down-regulation on viral-specific CTLs^[97], which could favor Bim up-regulation. In addition, it is well known that Bim is clearly involved in intrahepatic specific-CTL apoptosis in animal models^[1]. Furthermore, Bim pro-apoptotic effect is blocked by the action of Bcl-2 family anti-apoptotic proteins such as Mcl-1 and Bcl-2^[78,98], clearly pointing out that T cell death also depends on the anti-apoptotic protein expression. Bearing in mind all these facts, recently our group has suggested a model to explain specific CTL deletion during persistent hepatotropic viral infection (Figure 8). This model shows that CD127 phenotype modulates Bim and Mcl-1 expression on virus-specific CTLs, leading to Mcl-1/Bim imbalance during persistent infection, which impairs T cell reactivity and suggesting that restoration of T cell function could occur by correcting the levels of Mcl-1 and Bim expression.

In our work, Bim up-regulation has been observed on CD127^{low}-expressing HCV-specific CTLs but not on CD127^{high} cells after antigen encounter, suggesting that TCR triggering can only lead to Bim up-regulation in absence of IL-7 stimulation on HCV-specific CTLs. Nevertheless, Bim level is not enough to lead to T cell apoptosis. Our data also showed the Mcl-1/Bim ratio could decide the fate of the activated T cells by sequestration of experienced CD127^{low}/Mcl-1^{low}-expressing T cells to the liver and subsequent Bim up-regulation after antigen encounter due to the absence of IL-7 stimulus^[99]. Finally, Bim

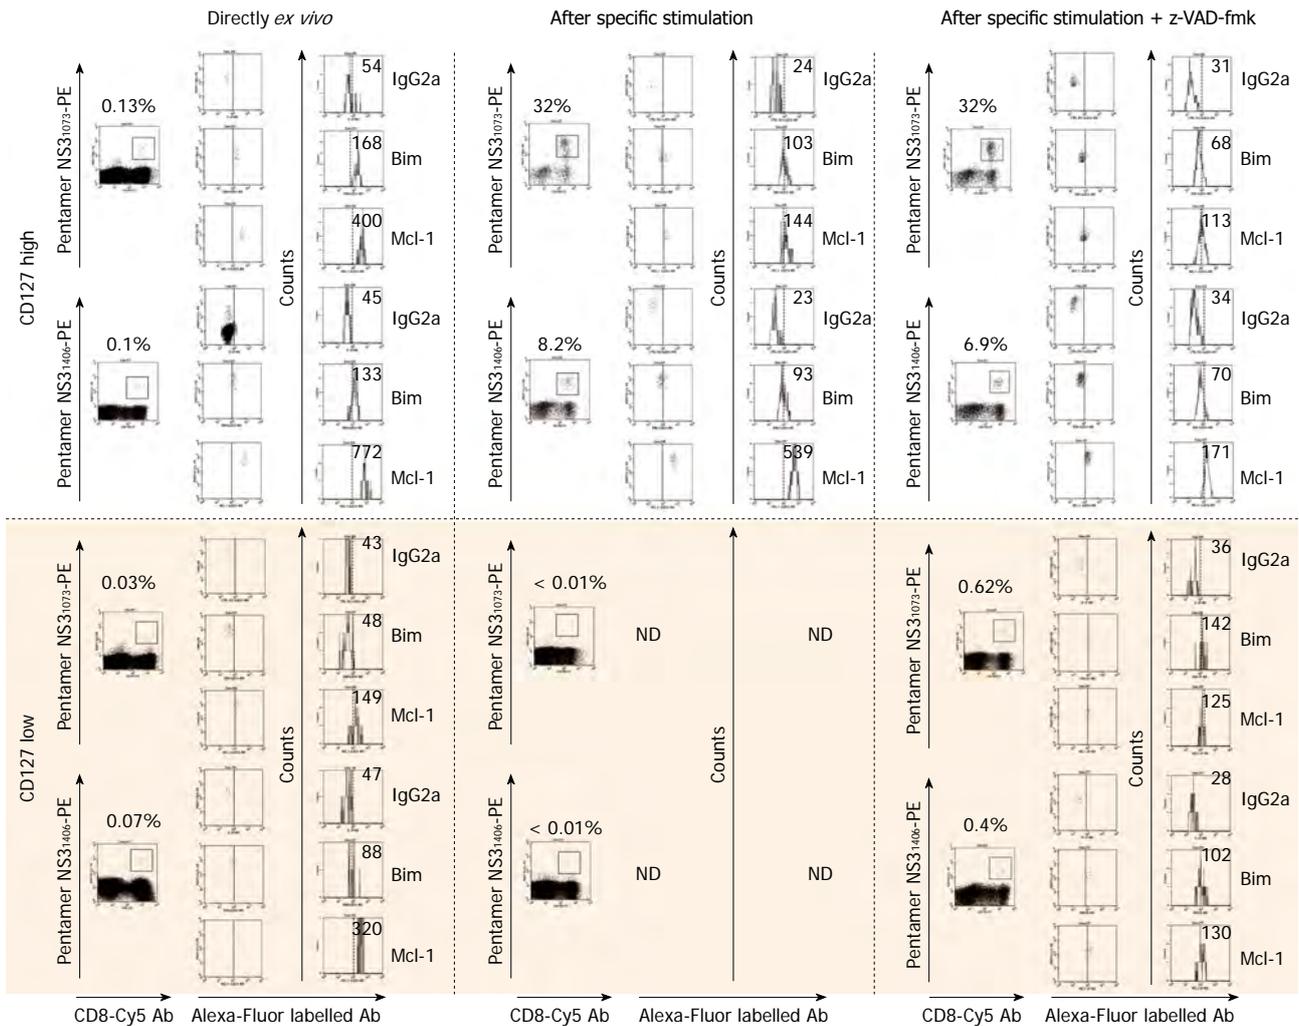

Figure 9 Figure illustrated the FACS[®] dot plots and histograms from peripheral blood lymphocytes from two hepatitis C virus patients with different CD127 expression on hepatitis C virus-specific cytotoxic T lymphocytes (CD8⁺/Pentamer⁺ cells). The different plots show the Bcl-2 interacting mediator (Bim) and myeloid cell leukemia sequence-1 (Mcl-1) expression directly *ex vivo* and after specific stimulation on peripheral CD8⁺/pentamer⁺ cells according to CD127 level. The figure on the top of the dot-plots represents the frequency of pentamer⁺ cells out of total CD8⁺ cells. The figure in the upper right corner in the histogram plot represents the MFI for Bim and Mcl-1 staining. The continuous and dashed line in the dot-plots and histograms represents the cut-off point to consider a staining positive according to the negative control. ND: Not done due to lack of pentamer⁺/CD8⁺ proliferation after specific stimulation.

would be released freely to activate Bax, due to the low level of the anti-apoptotic protein Mcl-1 during chronic HCV infection. Consequently, CD127 level play a central role in hepatotropic virus-specific CD8⁺ T cell apoptosis by regulation of Mcl-1 expression *in vivo* and by Bim modulation after antigen encounter, which is checked by T cell reactivity restoration and Mcl-1/Bim phenotype on CD127^{low} specific CTLs after apoptosis blockade (Figure 9), that suggested a link between apoptosis after TCR triggering and low CD127 expression on experienced specific CTLs during persistent infection that could be related to Mcl-1/Bim imbalance.

Therefore, CD127 phenotype modulates Bim and Mcl-1 expression on specific CTLs and this affect to T cell reactivity through apoptosis regulation. Specifically, during chronic infection, Mcl-1/Bim imbalance could be involved on CD127^{low} specific CTL hyporeactivity, but it could be overcome by blocking apoptosis.

For control of hepatotropic viral infection is essential

to develop a robust viral-specific cellular response. However, during chronic infection this response is altered, showing a pro-apoptotic phenotype due to the deprivation of IL-7 secondary to the low expression of CD127. Recently, it has been investigated that TRAF1 is a signal adapter for positive co-stimulatory receptors whose level depends on the action of IL-7 and inhibits the expression of the pro-apoptotic molecule Bim^[86]. Therefore, in situations of deprivation of IL-7, action of TRAF1 could be impaired, favoring an imbalance between anti- and pro-apoptotic molecules. On the other hand, in an experimental model, IL-7 deprivation during stressing conditions leads to Mcl-1 down-regulation on T cells, conducting to T cell death that could be avoided by IL-7 treatment^[100]. Consequently, strategies directed to block the pro-apoptotic effect of IL-7 deprivation should be designed to increase the effectiveness of CTL response restoration, by enhancing the TRAF1 and Mcl-1 expression level that could restore Bim/Mcl-1 balance. On of those strategies

could be short-term use of cyclosporine-A or FK506 could block the induction of the pro-apoptotic molecule Bim on CD127⁺ cells^[77]. This strategy could favor specific-CTL restoration during anti-viral treatments in combination with the standard of care. Another possible strategy to restore hepatotropic virus-specific CTL reactivity during chronic infection could be the administration of IL-7, in order to increase the stimulation of the reduced number of IL-7R molecules on specific CTLs, to modulate the balance between Bim and Mcl-1. In fact, in an animal model of cytotoxic T cell exhaustion, IL-7 treatment resulted in amplified cytokine production, increased T cell effector function, and viral clearance^[101].

CONCLUSION

The deletion of hepatitis virus-specific CD8⁺ T cells is likely to represent the deregulation of the Bim pro-apoptotic pathway. The balance between pro- and anti-apoptotic molecules is critical for cell survival. The unavailability of appropriate survival marker modulates Bim and Mcl-1 expression on virus hepatitis-specific CTLs and this affect to T cell reactivity through apoptosis regulation. The level of those molecules is regulated by CD127 (IL-7R) expression, which is down-modulated during persistent infection. Consequently, Mcl-1/Bim imbalance could be the reason for the deletion of virus hepatitis-specific T cells, but it could be overcome by interruption of apoptosis. The interruption of this tolerizing mechanism may provide a new strategy to restore the balance between apoptotic molecules in order to achieve viral specific T cell immunity, as a future treatment strategy of chronic viral hepatitis.

Abstract

Accurate determination of the presence and degree of fibrosis in liver is of great importance, because the prognosis and management strategies for chronic liver disease depend mainly on these factors. To date, liver biopsy (LB) remains the "gold standard" for assessing the severity of liver fibrosis; however, LB is often limited by its invasiveness, sampling error, and intra/inter-observer variability in histological interpretation. Furthermore, repeated LB examinations within a short time interval are indeed ineligible in a real clinical practice. Thus, due to the pressing need for non-invasive surrogates for liver fibrosis, transient elastography (TE),

as a novel ultrasound based technology, has allowed a noninvasive measurement of liver stiffness and has gained in popularity over recent years. In the past few years, additional roles for transient TE beyond the initial purpose of a non-invasive surrogate for LB have included the prediction of the most two critical consequences of fibrosis progression: the development of portal hypertension-related complications and hepatocellular carcinoma. This indicates that the role of transient TE is not merely limited to reducing the need for LB, but transient TE can enable the establishment of tailored management strategies by providing more detailed prognostic information. In particular, under the concept in which the clinical course of liver fibrosis is dynamic and bidirectional, especially when appropriate intervention is commenced, transient TE can be used to track the dynamic changes in fibrotic burden during antiviral or antifibrotic treatment. This review discussed extended applications of transient TE in prediction of the development of real clinical endpoints from a longitudinal perspective.

Clinical application of liver stiffness measurement using transient elastography in chronic liver disease from longitudinal perspectives. *World J Gastroenterol* 2013; 19(12): 1890-1900 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1890.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1890>

INTRODUCTION

The prognosis and management of chronic liver disease (CLD) depend mainly on the amount and progression

of liver fibrosis, which is defined as the excessive accumulation of extracellular matrix proteins, resulting from chronic liver insults^[1,2]. The initiation of its deposition is an important phase of CLD. As liver fibrosis eventually progresses without appropriate intervention, this process will lead to architectural change of the liver, followed by deterioration of liver function and hemodynamics, complications due to portal hypertension, and an increased tendency for hepatocarcinogenesis^[3].

Thus, accurate determination of the presence and degree of liver fibrosis is of paramount importance in choosing treatment strategies, evaluating responses to treatment and the risks of developing liver-related complications, and predicting prognosis in patients with CLD. To assess the severity of liver fibrosis, liver biopsy (LB) remains the “gold standard”. However, LB is often limited by its invasiveness and rare, but serious, complications, including bleeding, pneumothorax, and procedure-related death^[4,5]. Moreover, repeated LB examinations within a short time interval are impractical. Additionally, concerning the reliability of pathological examinations, not only sampling error inherent in the percutaneous approach, but also intra- and inter-observer variability in histological interpretation may still occur^[6]. Even if the LB is performed by an experienced physician and interpreted by an expert pathologist, it has an up to 20% error rate in disease staging^[7,8].

Ideally, a method of evaluating liver fibrosis should accurately determine the presence of significant fibrosis, and be readily available, highly reproducible, and widely applicable to liver diseases of various etiologies. Although LB does not fulfil all these criteria, it has remained the gold standard, likely due to the absence of a better alternative. Recently, liver stiffness measurement using transient elastography (TE) was introduced as a promising non-invasive method for assessment of liver fibrosis^[9-15]. In many studies, TE proved to be a reliable and accurate surrogate for LB in terms of prediction of significant fibrosis or cirrhosis^[8,16-19]. In a large-scale meta-analysis including 50 studies, the mean areas under the receiver operating characteristic curves (AUROCs) for the diagnosis of significant fibrosis and cirrhosis were 0.84 and 0.94, respectively, with optimal cutoff values of 7.6 and 13.1 kPa, respectively^[20].

Most studies to date have focused on assessing the performance of TE, reflected by AUROC, from a cross-sectional perspective, with reference to histological fibrosis. However, because LB as a reference standard is imperfect, it may have only limited clinical implications in terms of increasing the AUROC of TE to 1 (*i.e.*, perfect concordance with LB). Thus, additional roles for TE, namely prediction of long-term prognosis of the disease and monitoring clinical courses, have recently begun to attract attention. This indicates that the role of TE is not merely limited to lessening the frequency of unnecessary LB, but TE can also enable establishment of tailored management strategies by providing more detailed prognostic information^[21]. In this regard, the “classical” end-points of “static” liver fibrosis in recent cross-sectional

studies on TE are shifting to the “real and solid” end-points of the development of clinical events related to liver fibrosis progression, including hepatic decompensation, hepatocellular carcinoma (HCC), or liver-related death in a longitudinal study from a prospective cohort with long-term follow-up. Additionally, the performance of non-invasive methods is being judged and compared from this viewpoint.

In this article, we reviewed recent studies that focused on the prognostic value of TE for prediction of clinical end-points related to liver fibrosis progression, such as decompensation events, HCC development, or liver-related death, from a longitudinal perspective.

PREDICTION OF THE DEVELOPMENT OF LIVER-RELATED COMPLICATIONS

Portal hypertension-related complications

The development of portal hypertension is a common consequence of fibrosis progression, leading to the formation of esophageal and gastric varices responsible for variceal bleeding, and other severe complications, such as portosystemic encephalopathy, spontaneous bacterial peritonitis and sepsis^[22-24]. Measurement of the hepatic venous pressure gradient (HVPG) is the gold standard for portal hypertension assessment in patients with cirrhosis; however, it is invasive and is routinely available only in experienced centers^[25-29]. Although TE was initially proposed for assessment of liver fibrosis, a good correlation between TE values and HVPG has been reported, as well as the presence of esophageal varices, suggesting that it may be a valuable tool for the non-invasive evaluation of portal hypertension^[30-32]. Subsequent studies have investigated correlations between TE values and the hepatic decompensation due to increased portal hypertension. A significant correlation between TE values and portal hypertension, expressed as the HVPG, was reported by Vizzutti *et al*^[33] suggesting that TE may reflect a progressive rise in portal pressure due primarily to increased hepatic vascular resistance, caused by fibrillar extracellular matrix accumulation. Based on this concept, Foucher *et al*^[34] first reported that cutoff values of 27.5, 37.5, 49.1, 53.7 and 62.7 kPa had > 90% negative predictive values for the presence of large esophageal varices (stage 2/3), Child-Pugh score B or C, past history of ascites, HCC and esophageal bleeding, respectively.

As variceal bleeding is a life-threatening complication of portal hypertension, the relationship between TE values and the presence of esophageal varices has been investigated in several studies^[35-40]. All demonstrated a significant correlation between TE values and the presence of esophageal varices and that TE values could predict the presence of large varices (more than grade 2)^[38,40]. Table 1 summarizes reports of the relationship between TE values and esophageal varices^[33,38,40-44].

Although TE can predict the presence of esophageal varices and consequently assist in selection of candidates for endoscopic screening or prophylactic treatment, sever-

AUROC: Area under the receiver operating characteristic curve; PPV: Positive predictive value; NPV: Negative predictive value; CLD: Chronic liver disease; EV: Esophageal varix; HCV: Hepatitis C virus; HBV: Hepatitis B virus; NA: Not available.

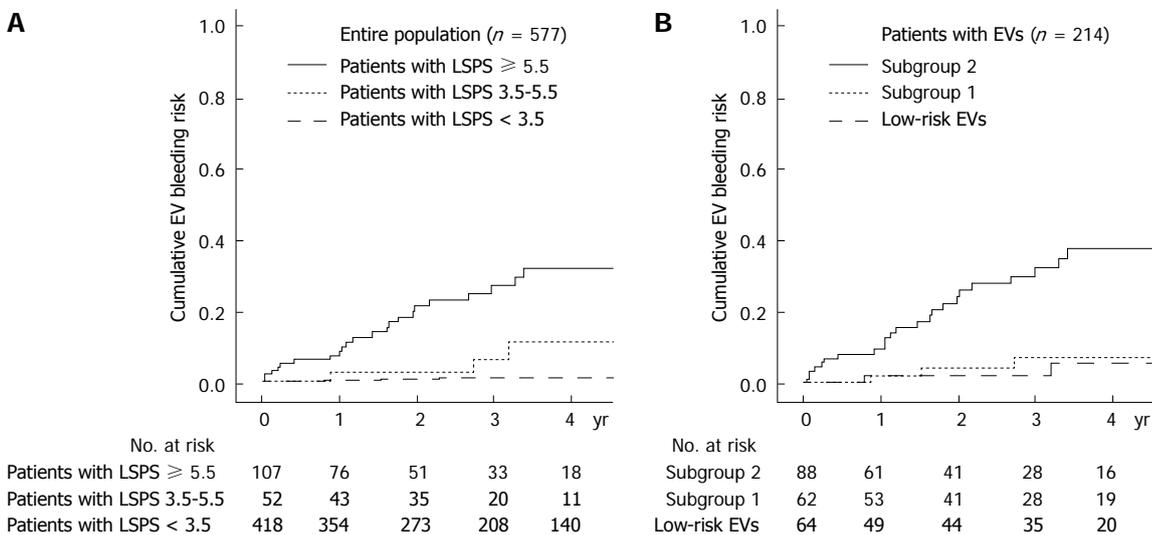

Figure 1 Cumulative incidences of variceal bleeding based on liver stiffness-spleen diameter to platelet ratio score values. A: The incidence of variceal bleeding increased significantly in association with higher liver stiffness-spleen diameter to platelet ratio score (LSPS) values (long-rank test, $P < 0.001$); B: In particular, among patients with high risk esophageal varices (EV), the incidence of variceal bleeding was significantly higher in patient with LSPS ≥ 6.5 (subgroup 2) than those with LSPS < 6.5 (subgroup 1).

al issues remain unresolved. First, the cutoff values (range, 13.9-21.5 kPa) and performance of TE varied (AUROC range, 0.76-0.85) among studies^[38-40]. Second, from data currently available, diagnostic performances of TE are acceptable for the prediction of esophageal varices, but far from satisfactory for screening cirrhotic patients without endoscopy confidently. Thus, Kim *et al*^[45] recently proposed a novel prediction model [liver stiffness-spleen diameter to platelet ratio score (LSPS)] to address this issue, achieving higher accuracy using TE values and other parameters simultaneously that reflect portal hypertension as constituent variables. Overall, this model had excellent diagnostic accuracy for the prediction of high-risk esophageal varices (HEV, AUROC = 0.953; negative predictive value 94.7%, positive predictive value 93.3%).

Beyond this cross-sectional analysis, a subsequent study by the same group recently showed that LSPS can be a reliable predictor of the development of variceal

bleeding^[20]. In this prospective, longitudinal study analyzing 577 patients with hepatitis B virus-related cirrhosis, those with LSPS ≥ 5.5 had higher cumulative incidences of esophageal variceal bleeding during the follow-up period and LSPS score ≥ 6.5 was an independent risk factor of variceal bleeding among those with HEV, indicating that further prophylactic treatment such as endoscopic ligation in addition to a non-selective beta-blocker should be considered in these high-risk patients (Figure 1). In a similar context, Kim *et al*^[46] stratified the risk of hepatic decompensation, such as ascites, hepatic encephalopathy, variceal hemorrhage, and deterioration of liver function to Child-Pugh class B or C, based upon three classes of TE values (TE value < 13 , 13-18 and ≥ 18 kPa) in histologically proven hepatitis B virus-related cirrhosis with well-preserved liver function and no history of decompensation. In a multivariate analysis, patients with a TE value of 13-18 kPa [hazard ratio (HR), 4.547; $P = 0.044$] and ≥ 18

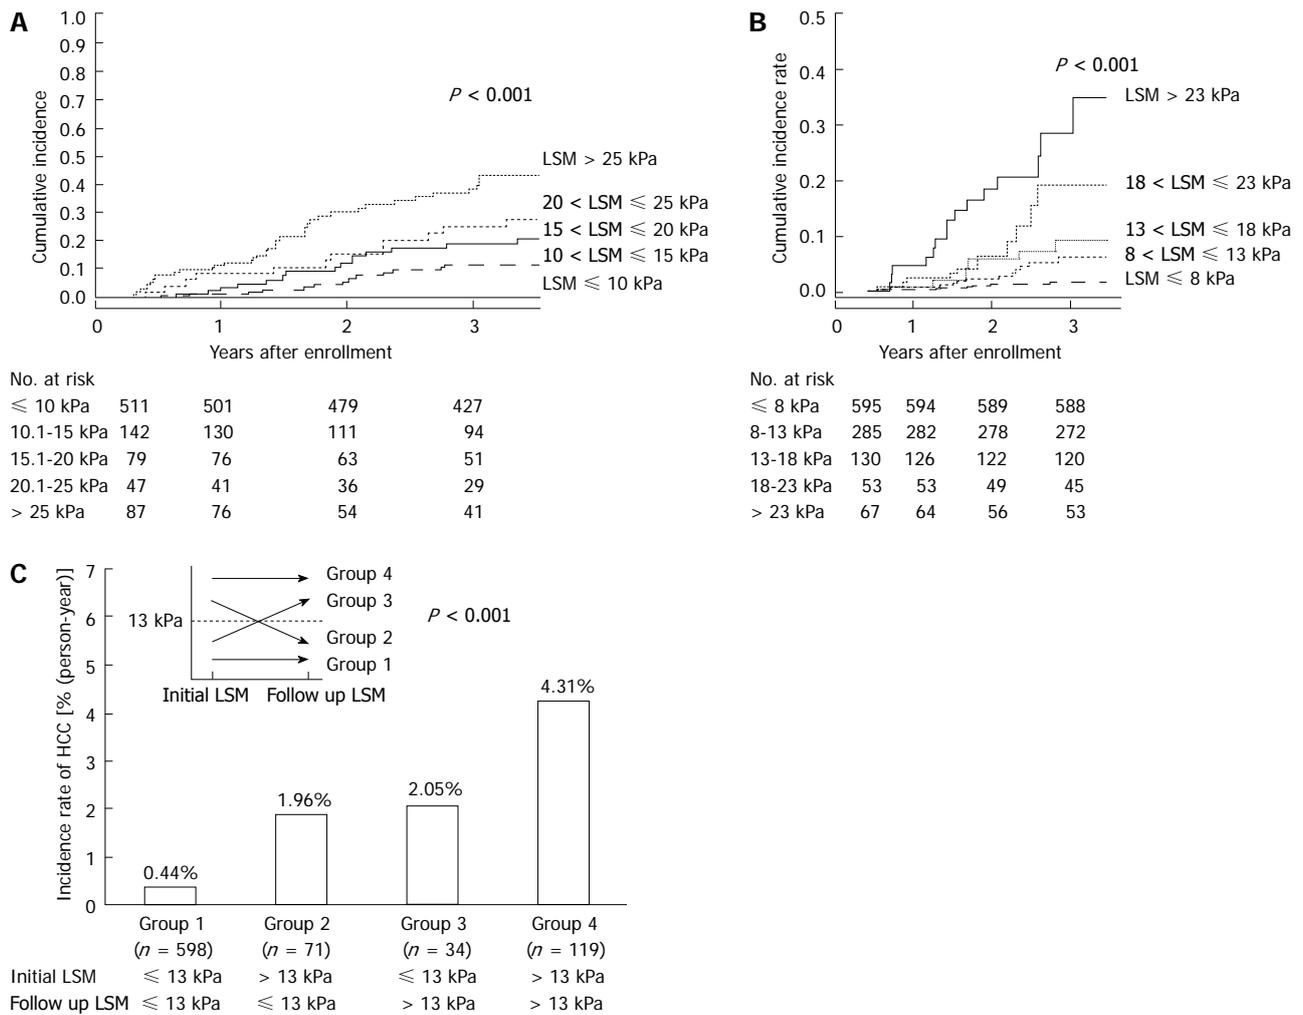

Figure 2 Cumulative incidence of hepatocellular carcinoma development based on stratified transient elastography values in patients with chronic hepatitis C (A, $n = 866$) and those with chronic hepatitis B (B, $n = 1130$). The cumulative incidences increased significantly in association with higher TE values (log-rank test, all $P < 0.001$). In particular, the overall incidence of HCC differed significantly among the four groups (C) (both initial and follow-up TE values ≤ 13 kPa (group 1), initial TE value > 13 kPa and follow-up TE value ≤ 13 kPa (group 2), initial TE value ≤ 13 kPa and follow-up TE value > 13 kPa (group 3), and both initial and follow-up TE values > 13 kPa (group 4) according to changing patterns of TE value during follow-up ($P < 0.001$; Figure 2C). A: Cited from Masuzaki *et al*^[52]; B and C: Cited from Jung *et al*^[53]. HCC: Hepatocellular carcinoma; TE: Transient elastography; LSM: Liver stiffness measurement.

kPa (HR, 12.446; $P < 0.001$) showed independently higher risks than patients with TE value < 13 kPa.

HCC

Another promising area for the application of TE, other than portal hypertension-related decompensation events, is the prediction of HCC development. Unless HCC is diagnosed at an early stage, a poor prognosis is expected due to the limited treatment options^[47-51]. Thus, early prediction of HCC development is of great importance, especially in high-risk patients. Among traditional risk factors, advanced liver fibrosis and cirrhosis is known to have a close association with risk of HCC development^[47]. Thus, assessment of the severity of liver fibrosis at a given time point with subsequent monitoring of liver fibrosis progression by serial check-up is essential for effective and optimized surveillance strategies for the early detection of HCC^[3].

Recently, several Asian studies have investigated the

clinical role of TE in the noninvasive prediction of HCC development^[52-56]. The first large prospective cohort study of 866 Japanese patients with chronic hepatitis C (CHC) tested whether TE can predict the future development of HCC^[52]. During a mean follow-up of 3 years, 77 patients developed HCC. By multivariate analysis, together with age, male gender, and clinical cirrhosis, stratified TE value was identified as an independent risk factor for HCC development, with relative risks of 16.7, 20.0, 25.6 and 45.5 for TE values of 10-15, 15-20, 20-25 and > 25 kPa, respectively, *vs* an TE value of < 10 kPa as the reference and the cumulative incidence of HCC showed a step-wise increase according to stratified TE value (Figure 2A). Despite there being no histological analysis in relation to TE values and inclusion of patients with high alanine aminotransferase (ALT) levels [$> 5 \times$ upper limit of normal (ULN)] both of which can attenuate the accuracy of TE, this study confirmed that severity of liver fibrosis, reflected by higher TE values, was closely associated with higher

risk of HCC development and suggested a clinical role for TE in a longitudinal setting using HCC development as a solid clinical endpoint. Interestingly, in this study, even patients with not so high level of TE (10-15 kPa) were still more subject to HCC development with an adjusted HR of 16.7, compared to those with a TE value < 10 kPa.

Another large Korean cohort study with 1130 patients with chronic hepatitis B (CHB) also confirmed the longitudinal role of TE on HCC development^[53]. Together with age, male gender, heavy alcohol consumption, lower serum albumin, and HBeAg positivity, stratified TE value was identified as an independent risk factor for HCC development, with relative risks of 3.07, 4.68, 5.55 and 6.60 for liver stiffness measurement (LSM) values of 8-13, 13-18, 18-23 and > 23 kPa, respectively, when compared with a LSM value of < 8 kPa as a reference (Figure 2B). In contrast to the Japanese study^[52], several additional issues were further analyzed in this Korean study. First, when the diagnosis of cirrhosis showed discordant results between TE-based and clinical-based criteria, patients with cirrhosis based on TE were at a higher risk of HCC development than those with cirrhosis based on clinical criteria, indicating the superiority of TE for diagnosis of compensated liver cirrhosis. Second, patients with TE values below the cutoff level for cirrhosis, 8-13 kPa, had a higher relative risk of HCC development than those with LSM values < 8 kPa. Although this finding should be validated in large prospective studies, the issue of expansion of the high-risk group for HCC surveillance to include those with significant fibrosis was raised by this study. Furthermore, when patients with available follow-up TE values were analyzed, the risk of HCC development changed according to the pattern of the changes in TE values, suggesting a potential role for serial measurements of TE as a dynamic monitoring tool for risk estimation of HCC development (Figure 2C). However, other confounding factors including lack of histological information, insensitive HBV DNA tests, and heterogeneity in antiviral treatment should be noted when interpreting these results. Recently, Chon *et al.*^[56] compared the performance of various noninvasive fibrosis prediction methods [aspartate aminotransferase-to-platelet ratio index (ARRI), age-spleen-to-platelet ratio index (ASPRI), TE, LSPS, P2/MS and FIB-4] for prediction of HCC development in patients with CHB and concluded that TE and LSPS showed the best performance (AUROC = 0.789 and 0.788, respectively). Using multivariate analyses, TE and LSPS were identified as independent predictors of HCC development.

In another study^[54] from Hong Kong, which followed up 528 patients with HBeAg negative CHB for a median length of 35 mo and identified seven patients with HCC development, the cumulative incidence of HCC was higher in patients with TE values \geq 10 kPa than those with TE values < 10 kPa (9% *vs* 0%, respectively; $P < 0.001$), and the cumulative liver-related mortality was also higher in patients with TE values < 10 kPa compared with those with TE values \geq 10 kPa (4% *vs* 0%, respec-

tively; $P < 0.001$). By multivariate analysis, only TE value was significantly associated with HCC development and liver-related mortality.

Similarly, Kim *et al.*^[55] investigated the prognostic role of TE in predicting the development of overall liver-related events (LREs), defined as development of HCC, hepatic decompensation, or liver-related mortality, among 128 patients with CHB showing histologically advanced liver fibrosis (\geq F3) and high viral loads (HBV DNA \geq 2000 IU/mL) before starting nucleos(t)ide analogs. When the study population was stratified into two groups using the optimal cutoff value (19 kPa), patients with TE values > 19 kPa were at significantly greater risk for LRE development than those with TE values \leq 19 kPa (HR, 7.176; $P = 0.001$). Moreover, the incidence of LREs was similar in patients with F3 and F4 (22.2% *vs* 13.6%; $P = 0.472$); however, it differed significantly between patients with TE values \leq 19 kPa and those with TE values > 19 kPa (6.9% *vs* 44.4%; $P < 0.001$), indicating the superior performance of TE to that of histology in prediction of LRE development.

Apart from predicting HCC development, the application of TE was validated in a study by Vergniol *et al.*^[57], in which 1457 patients with CHC were followed up; 5-year survival outcomes worsened as TE values increased. The prognostic values of TE were demonstrated to be statistically significant ($P < 0.0001$) after adjustment for other important factors, including treatment response, patient age, and estimates of necroinflammatory grade. For example, the 5-year overall survival was 96% in patients with TE value < 9.5 kPa, and 47% in patients with TE value > 40 kPa.

Overall, TE has shown the potential for a clinical role in predicting the development of portal hypertension-related hepatic decompensation and/or HCC and, in part, demonstrated superior performance to histology and other noninvasive tools^[41,58-63]. This is most likely due to the wider dynamic range of TE values in the evaluation of liver cirrhosis. In fact, as the stage of "cirrhosis" has to date been defined by histopathological evidence of one or two qualitative categories (METAVIR stage F4 or ISHAK S5-S6), or more generally by the presence of so-called "regenerative" or "cirrhotic nodules", an interval scale cannot be used in this setting^[64-66]. However, the degree of liver fibrosis may vary widely among patients in this category, and the risk of hepatic decompensation and HCC may not be uniform. Thus, in this regard, because TE value, expressed in kPa as a continuous variable, has a wide dynamic range within the cirrhotic stage from the cutoff level from non-cirrhosis (15-17 kPa) to the upper measurement limit of present devices (75 kPa), it would seem to be a more reasonable tool for detailed prognostication.

UTILITY OF TE IN THE SURGICAL SETTING

Because TE values show significant correlations with portal hypertension and HCC development, prediction

of postoperative short-term outcomes, such as hepatic insufficiency, and long-term outcomes, such as recurrence or liver-related death using TE has been tested in several pilot studies^[67-69]. Although further studies are required to validate these results, TE may facilitate stratification of patients undergoing curative resection according to different prognoses.

In the first place, Kim *et al.*^[67] investigated whether preoperative TE values could predict the development of postoperative hepatic insufficiency after curative resection of HCC. In this study, multivariate analyses revealed that a TE value > 25.6 kPa was the only predictor of postoperative insufficiency. The AUROC of 25.6 kPa was higher than that of indocyanine green R15, which is a popular method for assessment of preoperative functional reserve liver function (0.824 *vs* 0.620, respectively). Similar results were obtained in a subsequent investigation by the same group^[68]. In this study, the performance of TE was superior to that of diffusion-weighted magnetic resonance imaging, which has also been shown to be a noninvasive fibrosis prediction tool for the assessment of liver fibrosis and the prediction of postoperative hepatic insufficiency.

Another issue is prediction of HCC recurrence after curative resection, that is, *de novo* recurrence in the background liver with fibrotic burden, using preoperative TE. In an analysis of 133 patients who underwent preoperative TE and curative resection (HCC recurred in 62 patients), TE was selected as an independent predictor of recurrence, whereas histological fibrosis status was not^[69]. In the study, patients with preoperative TE values > 13.4 kPa were at a greater risk of recurrence, with an HR of 1.925 ($P = 0.010$). More specifically, when recurrence was stratified into early (< 2 years) and late (≥ 2 years), TE values were significantly related to late recurrence, thus supporting the hypothesis. These results suggest that preoperative TE could reveal the potential influence of liver fibrosis on recurrence and explain multicentric carcinogenesis in a fibrotic liver. However, more data are needed to clarify this issue.

ROLE OF TE IN MONITORING FIBROTIC BURDEN DURING ANTIVIRAL THERAPY

Recently, the concept of “cirrhosis” has changed from static and uncompromisingly progressive to rather dynamic and bidirectional, especially when treatment against the causative agent of tissue damage (*i.e.*, antiviral agents against CHB or CHC and antifibrotic agents) can be introduced successfully at this stage of the disease. The ideal approach to evaluate histological outcomes during antiviral therapy, such as fibrosis regression and necroinflammation stabilization, is serial LB examinations. However, this is impractical, primarily due to the inherent invasiveness of LB. Instead, because of the ease, safety, and rapidity of TE, it may be useful for monitoring the dynamic changes in liver fibrosis during antiviral or antifibrotic treatment. Indeed, several studies have reported

the clinical usefulness of TE for monitoring potential fibrosis regression during antiviral treatment in patients with CHC and CHB^[57,70-77].

Kim *et al.*^[71] analyzed 41 patients with CHB who received antiviral treatment using nucleos(t)ide analogs. To prevent the confounding effect of high ALT, patients with high ALT levels more than 2× ULN, were excluded. Although ALT levels did not show a statistically significant change during the first 12 or 24 mo of antiviral treatment, TE values decreased significantly, indicating potential fibrosis regression due to prolonged antiviral treatment. Indeed, fibrosis regression and stabilization of necroinflammation was noted in two patients with available paired LBs. Enomoto *et al.*^[70] reported the changes in LSM values during the first 12 mo of entecavir treatment in 20 patients. Median TE values decreased significantly from 11.2 to 7.8 kPa after 12 mo of treatment, and serum fibrosis markers, such as PIIINP and type IV collagen 7S domain, also decreased significantly. In one patient with available paired LBs, histological fibrosis regression and stabilization of necroinflammation were noted. Although these studies suggest a role for TE for monitoring fibrosis regression due to prolonged antiviral treatment, the short duration of observation and small sample sizes with paired biopsies are major limitations of these studies.

Recently, data regarding a longer antiviral treatment duration (more than 3 years) have become available^[72-74,78]. Fung *et al.*^[72] reported a significant decline in TE values from baseline after subsequent ALT normalization with 3-year treatment ($n = 110$, 7.8 to 6.1 kPa; $P = 0.002$). In this study, independent factors associated with a significant decline in TE value of ≥ 1 kPa included antiviral therapy and ALT levels at the follow-up time point. Another study by Andersen *et al.*^[78] also noted significant declines in TE values after a median antiviral treatment duration of 50.5 mo ($n = 66$), and concluded that prolonged antiviral treatment in patients with CHB resulted in significant declines in TE values, suggesting regression of fibrosis in a majority of patients with advanced fibrosis or cirrhosis.

Likewise, for patients with CHC, changes in TE values during antiviral treatment have been investigated in several studies. Two prospective studies by Vergniol *et al.*^[57] and Ogawa *et al.*^[75] demonstrated that patients with CHC showing sustained virological responses to pegylated interferon-ribavirin combination therapy had significantly reduced TE values at the end of follow-up. Moreover, Ogawa *et al.*^[75] reported that patients with non-sustained virological responses, but with a biochemical response, showed a greater reduction in TE values than did those with a non-biochemical response. Subsequent studies reported similar results, suggesting that changes in TE values during antiviral treatment in patients with CHC may represent alterations in the severity of liver fibrosis^[76,77]. However, it should be further confirmed whether the favorable changes in LSM values during or after antiviral treatment does have a significant influence

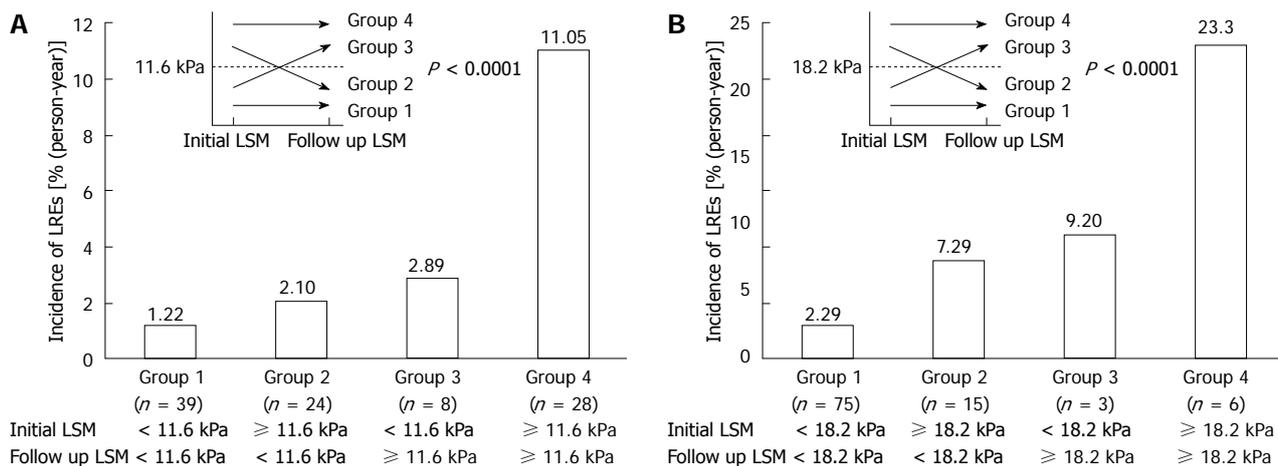

Figure 3 Incidence of liver-related events according to changes in transient elastography values after 6 mo of antiviral therapy. The overall incidence of liver-related events differed significantly among the four groups using TE value cutoffs of 11.6 kPa (A) and 18.2 kPa (B) (both $P < 0.0001$). Adapted from Kim *et al.*^[79]. TE: Transient elastography; LSM: Liver stiffness measurement; LREs: Liver-related events.

on the long-term prognosis such as disease-specific survival in patients with CHC.

Taken together, TE value seems to decrease during and after antiviral therapy. However, without paired histological results through repeated LB, whether the reduction in TE values is closely correlated with regression of liver fibrosis or improvement in necroinflammatory scores remains unclear. To clarify this, Lim *et al.*^[73] investigated patterns of TE values among patients who were treated with entecavir. In all subjects, the median TE value at baseline was 15.1 (range, 5.6-75.0) kPa and decreased significantly, to 8.8 (range, 3.0-33.8) kPa after 12 mo of therapy, and a decrease in TE values correlated significantly with increase in albumin, decrease in bilirubin, decrease in ALT level, and decrease in aspartate aminotransferase levels (all $P < 0.05$). However, among 15 patients with available paired LBs, decreases in TE values were correlated significantly with improved necroinflammatory scores, but not with fibrosis regression. Similarly, Wong *et al.*^[74] insisted that the decline in absolute TE values during antiviral treatment did not reflect the change in histologically assessed liver fibrosis, probably due to the confounding influence of ALT reduction caused by antiviral treatment.

However, regardless of whether TE values during antiviral treatment are due to fibrosis regression, activity stabilization, or both, changes in TE value during antiviral treatment can be translated into the overall response of chronically diseased liver to antiviral treatment from the viewpoint of its long-term clinical implications. Thus, it is more logical to investigate whether the decline in TE value can be used as a favorable predictor of long-term prognosis. Encouraging results were recently published by Jung *et al.*^[53] suggesting that the change in TE values in patients with CHB showed a significant correlation with differential future risk of HCC development. Additionally, Kim *et al.*^[79] insisted that changes in TE values were significantly associated with the difference risk of liver-related event occurrence, such as hepatic decompensation, HCC

development, and LREs (Figure 3). This would suggest that the assessment of overall background liver status using TE may be an important end-point in the management of CHB and prediction of long-term outcomes. Further research is needed to evaluate the reproducibility of such findings in independent populations.

LIMITATIONS OF TE

Although TE has demonstrated reliable diagnostic accuracy with excellent inter-observer and intra-observer agreement, additional space-occupying tissue abnormalities, such as edema and inflammation, cholestasis, and congestion may interfere with TE, regardless of the degree of liver fibrosis, because the liver is wrapped in a distensible, but non-elastic, envelope (Glisson's capsule)^[80].

First, the extent of histological necroinflammatory activity has been shown to influence TE results in patients with viral hepatitis, resulting in an overestimation of TE values that increases in parallel with the degree of necroinflammatory score^[81-85]. Consistent with these results, a risk of overestimation of TE values has been reported in cases of ALT flares in patients with acute viral hepatitis or CHB^[86-92]. Thus, in such subjects, TE examinations should be delayed until ALT levels have stabilized. In this regard, several studies have investigated the optimal period (3 to 6 mo) for restoration of the reliability of TE values in patients with acute flares^[88,91,93,94]. Furthermore, even mild to moderate elevation in ALT can be associated with higher liver stiffness values, and may cause discrepancies between TE results and the actual underlying fibrosis. Apart from necroinflammation, extrahepatic cholestasis^[95] and congestive heart failure^[96-98] may also contribute to the overestimation of TE.

Additionally, the performance of TE may be limited in patients with a high body mass index (BMI), narrow intercostal space, or ascites^[9]. Although TE reproducibility has been shown to be excellent in terms of inter-observer and intra-observer agreement, a high BMI (> 28

Table 2 Proposal of application of transient elastography in each clinical setting

| Clinical setting | Role of TE |
|--|--|
| Prediction of portal hypertension | TE with platelet counts and spleen size complementary to HVPG |
| Prediction of esophageal varices | TE with platelet counts and spleen size complementary to endoscopy |
| Prediction of developing esophageal variceal bleeding | TE with platelet counts and spleen size |
| Prediction of developing portal hypertension-related complications | TE with platelet counts and spleen size |
| Prediction of developing hepatocellular carcinoma | TE |
| Prediction of developing postoperative hepatic insufficiency after surgical resection | TE |
| Prediction of developing recurrence of hepatocellular carcinoma after curative resection | TE |
| Monitoring of fibrotic burden during antiviral treatment | TE |

TE: Transient elastography; HVPG: Hepatic venous pressure gradient.

kg/m²) and waist circumference were significantly associated with TE failure^[99]. These results emphasize the need for adequate operator training and for technological improvements in specific patient populations, such as those with non-alcoholic fatty liver disease. For this, a new TE probe (the XL probe) was recently introduced to lessen the TE failure rate in obese patients; however, its efficacy should be further validated^[100].

CONCLUSION

Over the past decade, significant progress has been made in the non-invasive assessment of liver fibrosis in patients with CLD. Of the methods now available, TE appears to be an excellent tool for assessing liver fibrosis, particularly for diagnosis of cirrhosis, and also has prognostic value from a longitudinal perspective. Although TE cannot completely obviate the need for invasive tests, such as LB, endoscopic examination for identification of varices, or HVPG, it represents an important non-invasive tool, enabling more efficient and tailored management strategies for patients with CLD (Table 2). We hope that other researchers will evaluate the usefulness of other similar techniques such as the measurement of spleen stiffness in comparison or in combination with TE in the future.

Abstract

AIM: To investigate the efficacy of Magliasa, a traditional Iranian formula, on experimental colitis.

METHODS: After botanical authentication of herbal

ingredients, formulation of Magliasa, quantitative determination of total glucosinolates and total phenolic content, and analysis of the thin layer chromatography profile were performed. Colitis was then induced in male rats by instillation of 2,4,6-trinitrobenzenesulfonic acid (TNBS) in all groups, aside from the Sham group. The experimental groups consisted of: the Sham group that received only normal saline; the Mag-50, Mag-100 and Mag-200 groups, which received 50, 100 and 200 mg/kg per day of Magliasa, respectively; the control group, which received vehicle water orally; the infliximab group, which received infliximab (5 mg/kg per day, subcutaneously); and the Dexa group, which received dexamethasone (1 mg/kg per day, orally). After completing the treatment period (2 wk), the rats were sacrificed, the colon was removed, its macroscopic and microscopic changes were recorded, and tumor necrosis factor-alpha (TNF- α), interleukin-1 beta (IL-1 β), total antioxidant capacity, myeloperoxidase (MPO), and lipid peroxidation (LPO) were assessed in colon homogenate.

RESULTS: The mean value of total glucosinolates in one gram of Magliasa was $19 \pm 1 \mu\text{mol}$. The mean value of the total phenolic content was $293.8 \pm 17.6 \text{ mg gallic acid equivalents per } 100 \text{ gram of Magliasa}$. Macroscopic scores were significantly decreased in Mag-100 (1.80 ± 0.58 , $P = 0.019$) and Mag-200 (1.20 ± 0.20 , $P = 0.001$) compared to the control group (3.40 ± 0.24), although some inflammation and hyperemia were evident. Treatment of rats by dexamethasone (0.33 ± 0.21 , $P < 0.001$) and infliximab (0.83 ± 0.31 , $P < 0.001$) remarkably attenuated scores where mild hyperemia was observed macroscopically. In comparison to the control group (4.00 ± 0.32), only Mag-200 (1.60 ± 0.40) showed a significant decrease in colonic histopathological scores ($P = 0.005$). Minimal mucosal inflammation was observed in the Dexa group (0.67

± 0.21 , $P < 0.001$). The levels of TNF- α , IL-1 β and MPO were significantly lower in all groups compared to the controls ($P < 0.05$). A significant decrease in LPO was seen in the Mag-200 (3.27 ± 0.77 , $P = 0.01$) and Dexa (3.44 ± 0.22 , $P = 0.011$) groups in comparison to the control group (6.43 ± 0.61). Only dexamethasone caused a significant increase in antioxidant power in comparison to the control group (346.73 ± 9.9 vs 228.33 ± 2.75 , $P < 0.001$). Infliximab and different doses of Magliasa did not show any remarkable increase in antioxidant capacity ($P > 0.05$). The effect of Magliasa in all of mentioned parameters, except antioxidant capacity, was dose dependent.

CONCLUSION: The effects of Magliasa in TNBS-induced colitis are encouraging and warrant clinical trials for further confirmation.

Promising effect of Magliasa, a traditional Iranian formula, on experimental colitis on the basis of biochemical and cellular findings. *World J Gastroenterol* 2013; 19(12): 1901-1911 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1901.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1901>

INTRODUCTION

Inflammatory bowel disease (IBD) includes two main types (Crohn's disease and ulcerative colitis), and is categorized as one of the chronic disorders of the gastrointestinal tract with an unclear etiology. Related to the involvement of possible pathological factors such as immunological abnormalities^[1], oxidative stress^[2], gut microflora^[3], abnormal epithelial barrier^[4], and inflammatory factors^[5-9], various drugs are used for the management of IBD, including anti-tumor necrosis factor-alpha (TNF- α) drugs^[10-12], immunosuppressants^[13,14], antibiotics^[15,16], probiotics^[17,18], corticosteroids^[19], aminosalicylates^[20,21], selective cyclooxygenase-2 inhibitors^[9], nicotine preparations^[22], potassium channel openers^[23], adenosine triphosphate donors^[24], and phosphodiesterase inhibitors^[25-27]. It cannot be ignored that most of the conventional treatments for the management of IBD have serious adverse effects that reduce compliance in patients^[28-30], and therefore has led researchers to work on complementary and alternative medicines that can induce remission in disease activity with better safety and tolerability^[31-33]. As recently reviewed by Rahimi *et al.*^[32], there are many plants in traditional Iranian medicine (TIM) that were historically used for the management of IBD. Magliasa is a TIM herbal prescription that has been used to treat tenesmus and di-

arrhea mixed with blood and mucus for a long time^[34]. It consists of 6 components: the seeds of *Lepidium sativum*, *Linum usitatissimum*, and *Allium ampeloprasum* cv. Porrum, the fruit of *Bunium persicum* and *Terminalia chebula*, and the gum resin of *Pistacia lentiscus* (Table 1). Different mechanisms have been described in TIM for the usefulness of these plants in the treatment of colitis, including anti-inflammatory, antiulcer, wound healing, and anti-diarrheal effects^[35,36]. Regarding the aforementioned knowledge, the present study was planned to investigate the effect of Magliasa in an experimental model of colitis to determine the involved mechanisms.

MATERIALS AND METHODS

Materials

Plant materials (seeds of *Lepidium sativum*, *Linum usitatissimum*, and *Allium ampeloprasum* cv. Porrum, fruit of *Bunium persicum* and *Terminalia chebula*, and gum resin of *Pistacia lentiscus*), were obtained from the local market at the Tehran bazaar in 2010. After confirmation by a botanist, voucher samples were deposited at the herbarium of the Faculty of Pharmacy, Tehran University of Medical Sciences (Tehran, Iran). 2,4,6-trinitrobenzenesulfonic acid (TNBS, Sigma-Aldrich), ethanol, methanol, ethyl acetate, n-hexane, thiobarbituric acid, trichloroacetic acid, n-butanol, hexadecyl-trimethyl-ammonium bromide, 2,4,6-tri(2-pyridyl)-S-triazine (TPTZ), hydrochloric acid, anisaldehyde, malondialdehyde, ethylenediaminetetraacetic acid, Folin-Ciocalteu reagent, toluene, dichloromethane, o-dianisidine hydrochloride, hydrogen peroxide, acetic acid, sodium acetate, Coomassie reagent, bovine serum albumin (BSA), FeCl₃-6H₂O, Na₂SO₄, H₂SO₄, H₃PO₄, KH₂PO₄, K₂HPO₄, H₂O₂, Na₂CO₃, NaHCO₃, Na-K-tartrate, CuSO₄-5H₂O, Silica gel 60F254 (Merck, Germany), glucose kit (ZistChem, Iran), and rat-specific TNF- α and interleukin-1 β (IL-1 β) enzyme-linked immunosorbent assay (ELISA) kits (Bender Med Systems, Austria) were used in this study.

Botanical authentication

All 6 herbal ingredients were authenticated macroscopically and microscopically. Macroscopic examinations included measurements of appearance, size, shape, color, texture, odor, taste, fracture, and other characteristics according to pharmacopoeias^[36,37]. Microscopic examinations determined the characteristic elements of each ingredient in powder form. For this purpose, each herbal material was mounted on a microscope slide after tissue disintegration with potassium hydroxide and cleared with sodium hypochlorite. The examination protocols followed the World Health Organization's quality control methods for medicinal plant materials^[38]. Characteristic elements were photographed *via* a Leitz optical microscope.

Preparation of Magliasa

Bunium persicum fruit (22%), *Linum usitatissimum* seeds (8%), *Allium ampeloprasum* cv. Porrum seeds (8%), *Terminalia che-*

Table 1 Magliasa powder ingredient characteristics

| Scientific name | Iranian name | Part | Major constituents | Pharmacological activities | Herbarium No. |
|---------------------------------------|--------------|-----------|--|--|---------------|
| <i>Lepidium sativum</i> | Taretizak | Seed | Glucosinolates, imidazole alkaloids, fatty acids, and sterols ^[60-63] | ↓IL-2, TNF- α , leukotriene B4 and nitric oxide in immune cells; anti-inflammatory and analgesic in rats; prokinetic, and laxatives in mice; anti-diarrheal and spasmolytic in rats; anticholinergic and phosphodiesterase inhibitor ^[64-68] | PMP-716 |
| <i>Bunium persicum</i> | Zire kermani | Fruit | Flavonoids, essential oils, and tannins ^[69,70] | Antioxidant and radical scavenger; antinociceptive and anti-inflammatory in rats ^[70-73] | PMP-627 |
| <i>Linum usitatissimum</i> | Katan | Seed | Mucilage, cyanogenic glycoside, lignans, fatty acids, and phenylpropan derivatives ^[74] | Antiulcer, antioxidant, and protective against intestinal tumors in mice ^[75-77] | PMP-717 |
| <i>Allium ampeloprasum</i> cv. Porrum | Tare | Seed | Saponins, flavonoids, carotenoids, and sulfur-containing compounds ^[78-80] | Antioxidant ^[78] | PMP-718 |
| <i>Terminalia chebula</i> | Halile siah | Fruit | Tannins, anthraquinones, triterpene glycosides, and beta-Sitosterol ^[81,82] | Antioxidant, anti NF- κ B, antiulcer, ↓TNF- α , IL-1 β and IL-6, and antibacterial against intestinal bacteria ^[83-87] | PMP-606 |

bula fruit (8%), and *Pistacia lentiscus* gum resin (4%) were individually powdered by milling, and then mixed. Intact non-milled seed of *Lepidium sativum* (50%, w/w) was added to the powdered material and again mixed.

Quantitative determination of total glucosinolates and total phenols Magliasa

The amount of total glucosinolates as major constituents of *Lepidium sativum* and the amount of total phenolic compounds as major constituents of *Bunium persicum*, *Allium ampeloprasum* cv. Porrum, and *Terminalia chebula* were measured in Magliasa.

Total glucosinolates were determined by the measurement of enzymatically-released glucose^[59]. For this purpose, four accurately weighed 1 g samples of Magliasa were transferred into separate loaded ball-mill cups. To three cups 1 mL of water was added (samples), while the last cup had 1 mL of acidified 40% v/v methanol/water added instead (sample blank). All cups were milled side by side for 2 min, allowed to stand for 5 min, and then had 19 mL of acidified 40% v/v methanol added to each cup. After recapping and shaking vigorously, the cup contents were filtered through charcoal-coated papers. Immediately prior to colorimetric assay, each of the filtrates was diluted ten-fold with water, and then 0.2 mL was poured into separate 10 mL tubes. About 0.2 mL of water was added into a fifth tube (water blank), with 0.2 mL of standard glucose solution (1 mg/mL) (ZistChem, Iran) added into a sixth tube. Five mL of buffer/enzyme/chromogen reagent (ZistChem, Iran) was added to all tubes, mixed, and then placed in a water bath at 37 °C and read within 10-15 min. The absorbance of each solution against the water blank was measured at 610 nm.

The total phenolic contents in the medicinal plants

were determined spectrophotometrically according to the Folin-Ciocalteu method^[40]. Gallic acid was used to set up the standard curve. The phenolic compound content of the samples was expressed as gallic acid equivalents (GAE) in mg per 100 g of Magliasa. All the samples were analyzed in triplicate.

Thin layer chromatography profile of Magliasa

Thin layer chromatography (TLC) was performed to obtain preliminary data from essential oils and lipophilic substances. For this purpose, 1 g of Magliasa was extracted by shaking for 15 min in 10 mL of dichloromethane at room temperature. The suspension was filtered, and the clear filtrate evaporated to dryness. The residue was dissolved in 1 mL of toluene. Samples were then applied to the plates, which were developed at room temperature in glass chambers previously saturated for 1 h. The development distance was 5 cm. The mobile phase was n-hexane-ethyl acetate 5:4 (v/v). The spray reagent was anisaldehyde- sulfuric acid^[41].

Animals

Male Wistar-albino rats, weighing between 220 and 230 g, were maintained under standard conditions of temperature (23 °C \pm 1 °C), relative humidity (55% \pm 10%), a 12-h dark and light period, and fed with a standard pellet diet and water *ad libitum*. All ethical themes of the animal studies were considered carefully, and the experimental protocol was approved by the ethical committee of Tehran University of Medical Sciences (code number of 88-04-33-10094).

Interventions

Rats were randomly divided into seven groups containing six individuals in each group. Colitis was induced

by the instillation of TNBS in all groups except group 1. The groups were: (1) Sham which received normal saline; (2) Mag-50 which received 50 mg/kg per day of Magliasa; (3) Mag-100 which received 10 mg/kg per day of Magliasa; (4) Mag-200 which received 200 mg/kg per day of Magliasa; (5) control which received vehicle water orally; (6) Infliximab which received infliximab (5 mg/kg per day, subcutaneously); and (7) Dexa which received dexamethasone (1 mg/kg per day, orally). Magliasa was dissolved in water and administered by gavage. The doses for Magliasa were selected after a pilot study. The effective doses of infliximab and dexamethasone were selected from our previous studies^[42].

Induction of colitis

For induction of colitis, 36 h fasted rats were anesthetized with an intraperitoneal administration of 50 mg/kg of pentobarbital sodium, positioned on their right side, and then had 0.3 mL of a mixture containing six volumes of TNBS 5% w/v in H₂O (equal to 15 mg TNBS) plus four volumes of ethanol (99%) instilled *via* the rectum using a rubber cannula (8 cm long)^[43]. Following instillation of TNBS, rats were maintained in a supine Trendelenburg position in order to prevent anal leakage of TNBS. Medications were then administered to the animals for 14 d as described above. On the 15th day, the animals were sacrificed by an overdose of ether inhalation. The abdomen was rapidly dissected open and the colon was removed. The colon was cut open in an ice bath, cleansed gently using normal saline, observed normally for macroscopic changes, and scored in a manner described later. Samples were then cut into two pieces; one piece for histopathology assessment (fixed in 5 mL formalin 10%) and one piece for measuring biomarkers weighed and maintained in -20 °C for 24 h. The colonic samples were then homogenized in 10 volume ice-cold potassium phosphate buffer (50 mmol/L, pH 7.4), sonicated, and centrifuged for 30 min at 3500 × *g*. The supernatants were transformed into several microtubes for separate biochemical assays, and all were kept at -80 °C until analyses^[44].

Macroscopic and microscopic assessment of colonic damage

The macroscopic damage was assessed and scored according to criteria as described in our previous work^[45,46]. For microscopic analysis, the fixed segments in formalin 10% were embedded in paraffin and stained with hematoxylin and eosin. The scoring was performed by one who was blind to the treated groups.

Determination of TNF- α and IL-1 β

Quantitative detection of TNF- α and IL-1 β levels in colon tissues were performed using an ELISA kit. The absorbance of the final colored product was measured in 450 nm as the primary wavelength and 620 nm as the reference wavelength. TNF- α and IL-1 β levels were expressed as pg/mg protein of tissue, as described in our previous work^[44].

Total ferric reducing antioxidant power assay

Total antioxidant power of the colon was evaluated by measuring the ability to reduce Fe³⁺ to Fe²⁺. Interaction of TPTZ with Fe²⁺ results in the formation of a blue color, with a maximum absorbance at 593 nm. Data were expressed as mmol/L ferric ions reduced to ferrous per mg of protein, as described in our previous work^[47].

Myeloperoxidase activity measurement

In this test, supernatant was combined with o-dianisidine and 0.0005% H₂O₂ that resulted in an absorbance at 460 nm that was measured for 3 min. One unit of myeloperoxidase (MPO) activity is described as the change in absorbance per min at room temperature in the final reaction. Details of the procedure have been described in our previous work^[48].

Thiobarbituric acid-reactive substances assay

Levels of lipid peroxidation were assessed in colon tissue using thiobarbituric acid reactive substances (TBARS) assay as described in our previous work^[49]. Data were reported as μ g/mg of protein.

Total protein of colon homogenate

Total protein of the tissue was measured according to the Bradford method, using BSA as the standard^[50]. Results were reported as mg of protein per mL of homogenized tissue.

Determination of LD50

In order to determine the acute toxicity (LD50) of Magliasa, doses of 5, 50, 300 and 2000 mg/kg per day were gavaged to rats. The animals were observed for 1 wk and any mortality was recorded at the end of this period^[51].

Statistical analysis

Data were analyzed by StatsDirect ver. 2.7.8. One-way analysis of variance followed by a Newman-Keuls *post hoc* test for multiple comparisons were used. *P* values less than 0.05 were considered significant. Results are expressed as mean \pm SE.

RESULTS

Botanical authentication

Microscopic characteristics of different herbal components of Magliasa are shown in Figure 1.

Quantitative determination of total glucosinolates and total phenols in Magliasa

The mean value of total glucosinolates in one gram of Magliasa was 19 \pm 1 μ mol. The mean value of total phenolic content was 293.8 \pm 17.6 mg GAE per 100 g of Magliasa.

TLC analysis

Table 2 summarizes the retention value of spots visible in the TLC profile of Magliasa.

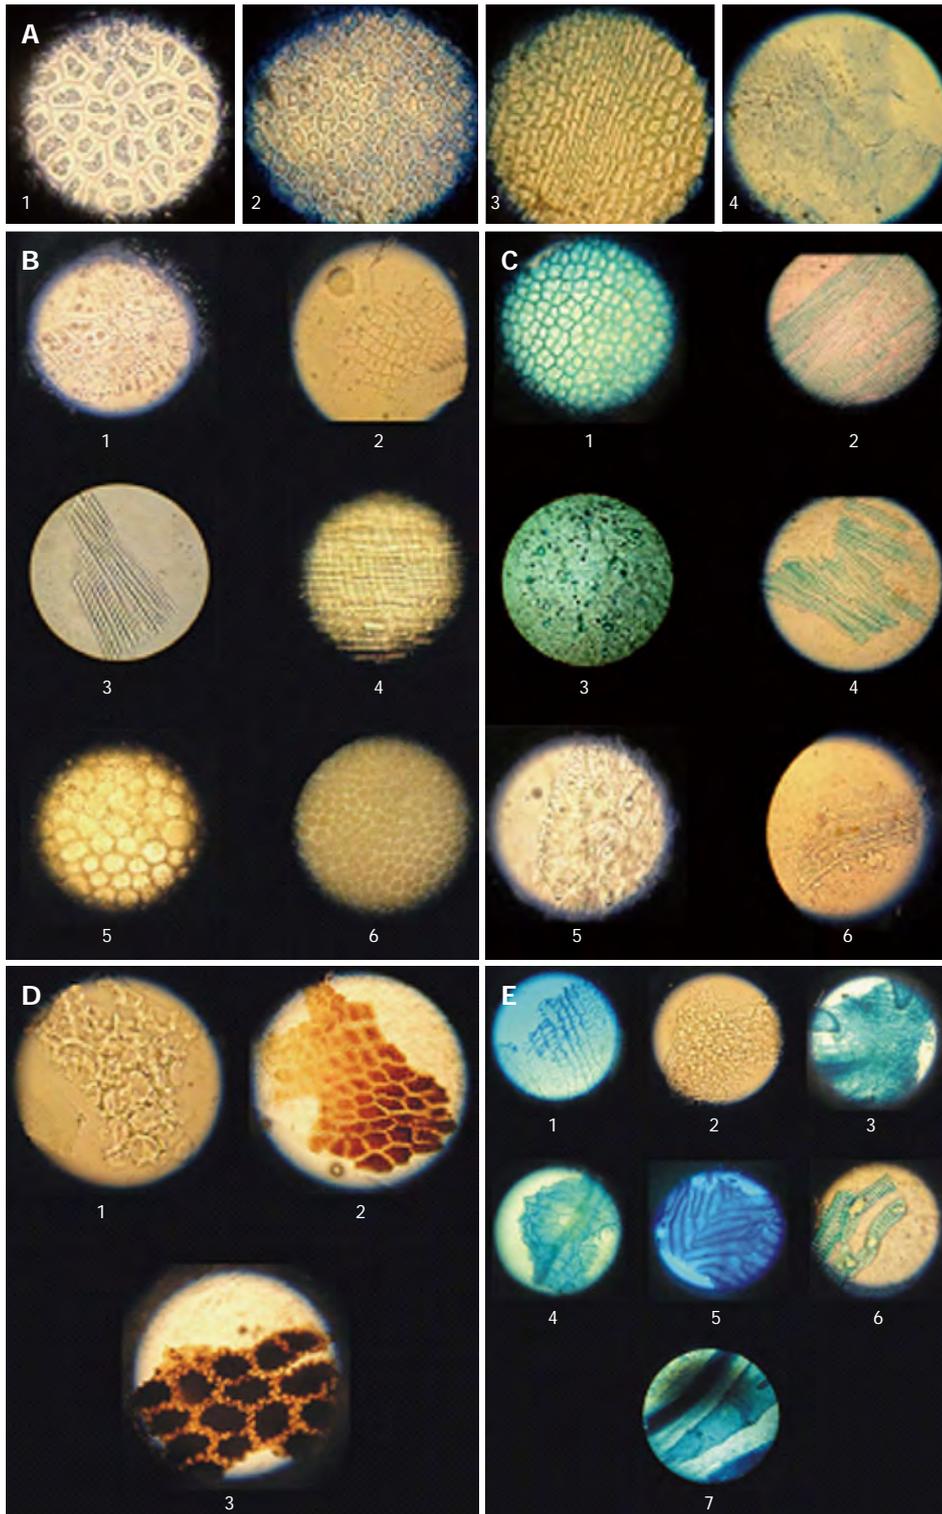

Figure 1 Microscopic characteristics of the herbal ingredients of Maglisa. A: *Lepidium sativum* seed. A1: Pericarp; A2 and A3: Sclereids of the mesocarp; A4: Parenchyma of the endosperm; B: *Linum usitatissimum* seed. D1: Endosperm; D2: Mesoderm; D3: Epidermis of the testa; E: *Bunium persicum* fruit. E1: Endocarp; E2 and E3: Endosperm; E4 and E5: Sclereids of the mesocarp; E6: Vessels; E7: Vittae. Magnification of all images was 40.

Macroscopic and microscopic assessment of colonic damage

Data are shown in Table 3. The colons of the Sham group appeared normal. In contrast, intracolonic administration of TNBS led to mucosal ulceration, inflammation, adhesion, and wall thickening in the control group. Treatment with Mag-50 did not significantly reduce macroscopic scores where linear ulceration and mesenteric inflammation were observed in some samples. Administration of Maglisa re-

duced the macroscopic score in a dose-dependent manner, and a significant effect was observed in the Mag-100 and Mag-200 groups, although some inflammation and hyperemia were evident. The median effective dose (ED50) value was 104.78 mg/kg. Treatment of rats by dexamethasone and infliximab remarkably attenuated scores where mild hyperemia was observed macroscopically.

Histopathological examination of the control group showed extensive severe transmural inflammation, dif-

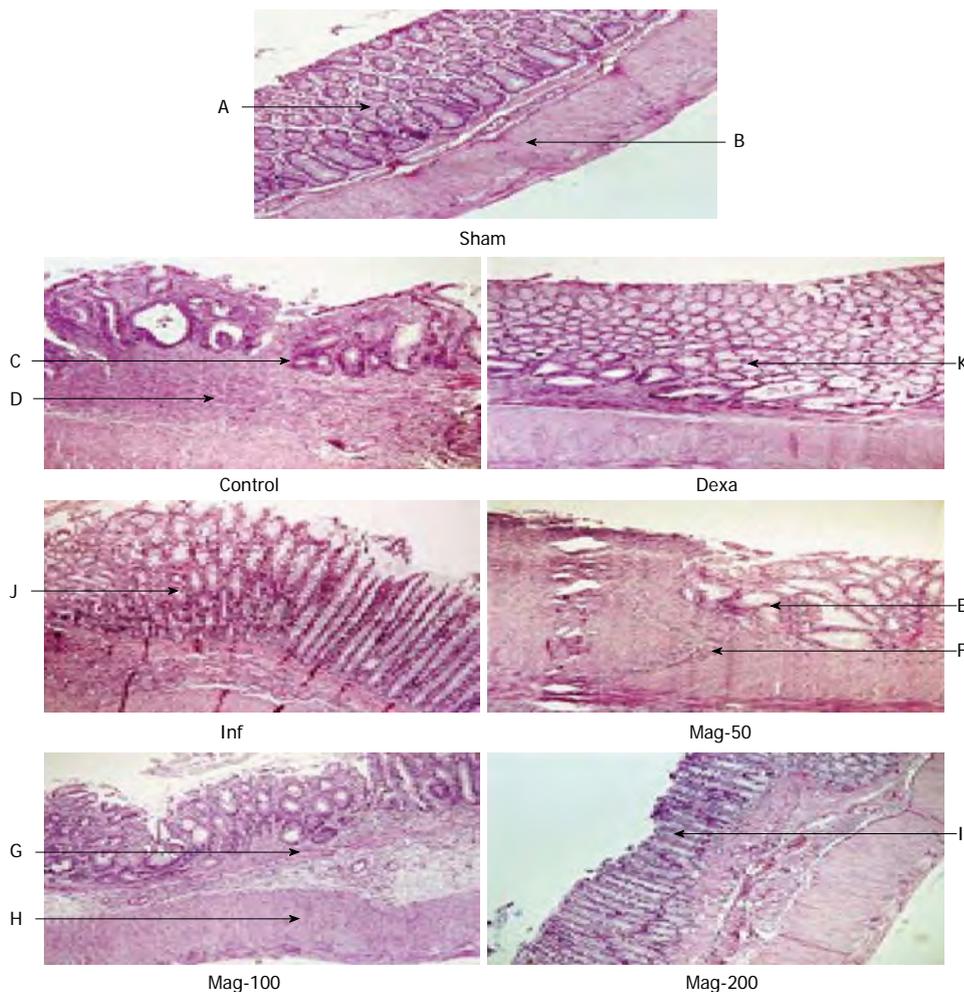

Figure 2 Histological images of colon samples. In the Sham group, colons were within normal limits including crypts (A) and submucosal tissue (B), but intense transmural inflammation (C), and severe crypt destruction (D) were observed in the control group. Moderate crypt distortion (E and G) and inflammatory cell infiltration (F and H) was seen in the Mag-5 and Mag-100 groups. Mild focal inflammation and crypt abscess were observed in the Mag-20 and infliximab groups (I and J). Mild focal inflammation was observed in the Dexa group (K). Magnification of all images was 100. Dexa: Dexamethasone; Inf: Infliximab; Mag-50: Magliasia at a dose of 50 mg/kg; Mag-100: Magliasia at a dose of 100 mg/kg; Mag-200: Magliasia at a dose of 200 mg/kg.

Values are mean \pm SE. ^a $P < 0.05$ vs the Sham group; ^c $P < 0.05$ vs the control group; ^e $P < 0.05$ vs the dexamethasone group. Dexa: Dexamethasone; Inf: Infliximab; Mag-50: Magliasa at a dose of 50 mg/kg; Mag-100: Magliasa at a dose of 100 mg/kg; Mag-200: Magliasa at a dose of 200 mg/kg.

in the Mag-200 group, with an ED50 of 132.29 mg/kg.

Colonic TNF- α

A significant difference was seen in TNF- α between the control and Sham groups ($P = 0.000$). TNF- α was significantly lower in all groups compared to the control, with an ED50 of 55.36 mg/kg. The level of TNF- α in the Mag-100 group (21.99 ± 3.54) was near to that of the infliximab group (20.18 ± 4.29), and both were lower than that of the Mag-50 (42.85 ± 10.87) and Dexa (39.72 ± 3.97) groups. TNF- α in the Mag-200 group (11.60 ± 1.83) was lower than that of the infliximab group, but the difference was not significant ($P = 0.98$, Figure 3A).

Colonic IL-1 β levels

IL-1 β was higher in the control group compared to the Sham ($P = 0.000$). IL-1 β in all groups was lower than that of the control, with an ED50 of 48.78 mg/kg. IL-1 β in the Mag-100 group (1.21 ± 0.10) was near to that of the Dexa group (1.64 ± 0.42), and both were higher than that of the infliximab (0.83 ± 0.14) and Mag-200 (0.48 ± 0.09)

groups. IL-1 β in the Mag-200 group was near to that of the Sham (0.44 ± 0.07), and was lower than infliximab, but the difference was not significant ($P = 0.998$, Figure 3B).

Colonic total antioxidant power as ferric reducing/antioxidant power

The ferric reducing/antioxidant power (FRAP) value was significantly lower in the control compared to the Sham ($P = 0.008$). Among interventions, only dexamethasone caused a significant increase in FRAP when compared to the control ($P = 0.000$). None of the Mag-50, Mag-100, Mag-200 or infliximab groups showed a significant difference to the control in FRAP (Figure 3C). The effect of Magliasa in FRAP was not dose dependent.

Colonic lipid peroxidation level as TBARS

The TBARS value was significantly higher in the control compared to the Sham ($P = 0.005$), while TBARS in the Mag-200 (3.27 ± 0.77 , $P = 0.010$) and Dexa (3.44 ± 0.22 , $P = 0.011$) groups was significantly lower than that of the control (6.43 ± 0.61). Other groups did not show a signif-

icant difference from the control in TBARS (Figure 3D). Administration of Magliasia reduced TBARS in a dose-dependent manner, with an ED50 value of 216.4 mg/kg.

Colonic MPO activity

MPO in the control was significantly higher than that of the Sham ($P < 0.002$). Treatment with Magliasia in all groups significantly decreased MPO activity compared to the control. MPO in the Mag-200 group (10.65 ± 2.53) was lowest amongst the Mag groups, and close to the Dexa group (10.42 ± 3.18). MPO in the Mag-200 group was lower than that of the infliximab group (16.41 ± 2.89) (Figure 3E). The ED50 value was 34.38 mg/kg.

LD50

The acute toxicity test (LD50) demonstrated that Magliasia is not lethal up to a dose of 2000 mg/kg after oral administration. In the treated groups, no sign of toxicity was observed. It can therefore be considered as practically non-toxic.

DISCUSSION

There is a strong potential in the traditional and folkloric medicines of various countries, including Iran, for developing new and efficacious drugs for diseases that have a challenging treatment. One such disease is IBD. In this paper, Magliasia, one of the remedies recommended for colitis in TIM, was prepared, and its efficacy and possible mechanisms of action in different doses were evaluated in TNBS-induced colitis and compared with standard drugs. Macroscopic and microscopic scores, as criteria for colonic damage, improved by doses of 100 and 200 mg/kg per day with Magliasia. The microscopic score reduced only in the Mag-200 group, while the Mag-50 group showed no significant benefit against colonic damage. Colonic TNF- α , IL-1 β and MPO activities were significantly decreased by all doses of Magliasia. TNF- α and IL-1 β have been described as important mediators that contribute to intestinal inflammation in IBD patients^[52-54]. Increased TNF- α has been found in the serum and mucosa of patients with IBD^[55,56]. Moreover, inhibition of TNF- α by anti-TNF- α drugs, such as infliximab, has been an efficacious strategy in the management of IBD^[10,57]. MPO is located in the granules of neutrophils and released upon stimulation by free radicals. The activity of MPO has been known as a marker of neutrophil penetration to the site of inflammation^[58,59]. Magliasia did not affect oxidative stress as a factor involved in the pathophysiology of IBD^[2]. Lipid peroxidation in the colon decreased only with a high dose of Magliasia (Mag-200). The effects of Magliasia in all investigated parameters were dose-dependent, except in total antioxidant power.

The total phenolic content of Magliasia was determined because phenolic compounds have pharmacological activities (antioxidant, anti-inflammatory, anti-diarrheal, and antimicrobial) that are all useful for the management of IBD, considering its pathogenesis. There is concern

about the content uniformity of Magliasia, as intact non-milled seed of *Lepidium sativum* comprises 50% of the product. In addition to a reference marker for the standardization of Magliasia, total glucosinolates can be used for evaluating the content uniformity of the product.

There are some reports on the herbal ingredients of Magliasia that confirm their efficacy in IBD^[32]. These reports are summarized in Table 1. Anti-inflammatory, antioxidant, analgesic, spasmolytic, antiulcer, ulcer healing, immunomodulatory, antibacterial, and anti-diarrheal activity are among the pharmacological properties of these ingredients that make them useful for IBD. It seems that the efficacy of Magliasia in IBD is due to the combination of the mentioned activities.

Overall, the results obtained from the efficacy of Magliasia on TNBS-induced colitis of rats are encouraging, although clinical trials are required for confirmation of these results.

COMMENTS

Background

Conventional treatments for the management of inflammatory bowel disease (IBD) have serious adverse effects that reduce patient compliance, and therefore investigators are trying to find useful compounds from complementary and alternative medicines with better safety and tolerability. There are many herbal preparations in traditional Iranian medicine (TIM) that were used for the management of IBD. Magliasia is one of them, and contains 6 components: seeds of *Lepidium sativum*, *Linum usitatissimum*, and *Allium ampeloprasum* cv. Porrum, fruit of *Bunium persicum* and *Terminalia chebula*, and gum resin of *Pistacia lentiscus*. Although, the efficacy of some herbal components of Magliasia in IBD have been confirmed by previous studies, no other study to date has investigated the beneficial effects of this preparation.

Research frontiers

In the present study, after formulation and explanation of the quality control methods of Magliasia, its effects were investigated in trinitrobenzenesulfonic acid-induced colitis of rats to determine the involved mechanisms.

Innovations and breakthroughs

Magliasia demonstrated a significant reduction in macroscopic colonic damage, tumor necrosis factor-alpha, interleukin-1 beta, and neutrophil infiltration. Determination of total glucosinolates and total phenolic contents, as well as performing thin layer chromatography, can be used successfully for quality control of this herbal preparation.

Applications

Since the effects of Magliasia in the experimental model of colitis were encouraging, it could potentially be used as an effective medicine for IBD after confirmation of obtained results by clinical trials. Moreover, this study is a step toward strengthening TIM evidence.

Peer review

Hopefully reviewers are positive to this article and believe that this TIM formula has enough support to go forward future clinical trials.

Abstract

AIM: To investigate the expression of CD73 and hypoxia-inducible factor-1 α (HIF-1 α) in human gastric carcinoma, and explore their clinical significance and prognostic value.

METHODS: CD73 and HIF-1 α expressions were detected by immunohistochemistry in consecutive sections of tissue samples from 68 gastric carcinoma patients. The peritumor tissues 2 cm away from the tumor were obtained and served as controls. The presence of CD73 and HIF-1 α was analyzed by immunohistochemistry using the Envision technique.

RESULTS: CD73 and HIF-1 α expressions in gastric carcinoma were significantly higher than those in gas-

tric mucosal tissues as control ($P < 0.001$) and showed a close correlation (Spearman $r = 0.390$, $P = 0.001$). Overexpression of CD73 was positively correlated with differentiation of tumor ($P = 0.000$), histopathology ($P = 0.041$), depth of invasion ($P < 0.001$), nodal status ($P = 0.003$), metastasis ($P = 0.013$), and the American Joint Committee on Cancer (AJCC) stage ($P < 0.001$). High expression of HIF-1 α was positively correlated with tumor diameter ($P = 0.031$), depth of invasion ($P = 0.022$), and AJCC stage ($P = 0.035$). The overall survival rate was low in the patients with high expression of CD73 ($P < 0.001$). Moreover, CD73+/HIF-1 α + patients had the worst prognosis ($P < 0.001$). CD73 expression was proven to be an independent predictor for patients with gastric carcinoma by both multivariate Cox regression analysis ($P = 0.021$) and receiver operating characteristic curves ($P = 0.001$).

CONCLUSION: CD73 expression correlates closely with HIF-1 α expression in gastric carcinoma. CD73 could be an independent prognostic indicator for gastric carcinoma.

Lu XX, Chen YT, Feng B, Mao XB, Yu B, Chu XY. Expression and clinical significance of CD73 and hypoxia-inducible factor-1 α in gastric carcinoma. *World J Gastroenterol* 2013; 19(12): 1912-1918 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1912.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1912>

INTRODUCTION

Gastric carcinoma has been the fourth most common cancer in the world since the latter half of the 20th century^[1,2]. In spite of the recent advances in diagnostic techniques

for early detection and the improvement in surgical treatment, gastric carcinoma remains the second leading cause of cancer-related deaths^[3]. In China, Japan and Korea, the incidence of gastric carcinoma now has reached up to 80 new cases per 100 000 population annually^[4]. Changes observed in expression of tumor specific biomarkers in gastric carcinomas may be helpful to understand the transformation of histological heterogeneity and the underlying molecular mechanisms. Searching for specific biomarkers which determine the biological nature and behavior of gastric carcinoma would be of utmost importance to optimize individualized therapy.

Ecto-5'-nucleotidase/CD73 is a homodimer linked to the plasma membrane through a glycosylphosphatidylinositol lipid anchor, which was found in most tissues^[5]. It is a part of extracellular ATP metabolism, which dephosphorylates AMP into adenosine rapidly after CD39 catalyzes ATP, ADP and AMP^[6]. Recent studies have demonstrated that CD73 could participate in a variety of physiological responses including ischemic preconditioning, platelet function, hypoxia, vascular leak and tissue injury^[7,8]. CD73 was up-regulated in various human cancers, including those of lung, colon, breast, pancreas and ovary^[9,10]. Importantly, the high expression of CD73 was correlated with tumor neovascularization, invasiveness, metastasis, as well as shorter patient survival^[9-13]. These results suggested that CD73 might play a significant role in controlling tumor progression.

Oxygen is only able to diffuse 100-180 μ m from a capillary to cells, which makes hypoxia a common feature of rapidly growing solid tumors^[14]. Hypoxia-inducible factor-1 (HIF-1) is a heterodimeric basic helix-loop-helix transcription factor composed of HIF-1 α and HIF-1 β subunits; and HIF-1 α determines HIF-1 activity^[15]. It is found that HIF-1 α is widely expressed in various types of carcinomas, such as those of brain, breast, lung and colon^[16-18]. These results revealed that HIF-1 α was correlated with tumor progression, aggressive behavior, and patient prognosis. As is known, pathophysiologic conditions of hypoxia can cause adenine nucleotide metabolic changes. A recent study found that CD73 is transcriptionally regulated by ambient hypoxia and is one of the mechanisms involved HIF-1^[19].

The purpose of this study was to ascertain the correlation between CD73 and HIF-1 α expressions and their clinicopathological significance in gastric carcinoma, including patient survival. We hypothesized that CD73 expression would be correlated with clinicopathological factors and HIF-1 α expression, and the combination of the two molecules would predict recurrence and overall survival.

MATERIALS AND METHODS

Patients

Samples of gastric carcinoma were collected from the resected stomach of 68 patients who were diagnosed histologically as gastric carcinoma and underwent gastrec-

tomy at the Nanjing General Hospital of Nanjing Military Command. None of the patients had previously received radiotherapy, chemotherapy or other medical interventions before surgery. Among them, 43 (63%) patients were male and 25 (37%) were female, with a mean age of 49.86 years. All patients were followed up from the date of surgery until either the date of death or December 2011. For analysis of patient survival, the patients who were lost to follow-up or those who died from causes other than gastric carcinoma were regarded as censored data.

This study was approved by the Institutional Review Board, and informed consent was obtained from each patient.

Immunohistochemistry

The peritumor tissues 2 cm away from the tumor were collected and served as healthy controls. Tumor specimens and healthy control gastric mucosal tissues, which were fixed in 10% buffered formalin and embedded in paraffin, were cut into 4- μ m sections and placed on polylysine-coated slides. The staining was conducted by the avidin-biotin-peroxidase complex method. Each paraffin section was deparaffinized and rehydrated through graded alcohols, followed by antigen retrieval with epitope retrieval solution (10 mmol citrate buffer, pH 6.0) in a pre-heated water bath at 98 $^{\circ}$ C for 10 min. Endogenous peroxidase was blocked using 3% hydrogen peroxide. Subsequently, sections were incubated with the primary mouse monoclonal CD73 antibody (1:100, ab71322 Abcam) and mouse monoclonal HIF-1 α antibody (1:100, MAB1935 R and D) overnight at 4 $^{\circ}$ C, and then were stained with secondary antibody for 30 min. The sections were finally counterstained with haematoxylin (Zymed Laboratories Inc, San Francisco, CA, United States). Negative control was performed by replacing the primary antibody with a normal murine immunoglobulin G. Known immunostaining-positive sections were used as positive controls.

Evaluation of immunohistochemical analysis

We used semi-quantitative method. Five different perspectives were randomly selected under ordinary optical microscope at a magnification of 400. The percentage of positive cells was scored 0 for staining of < 1%, 1 for staining of 2%-25%, 2 for staining of 26%-50%, 3 for staining of 51%-75%, and 4 for staining > 75% of the cells examined. Staining intensity was calculated, no coloring, slightly yellow, brown yellow and tan stains were marked as 0, 1, 2 and 3. Finally, we calculated the product of staining intensity and positive cell percentage: ≤ 5 was defined as negative and ≥ 6 as positive. Two pathologists blinded to the clinical details reviewed the pathological films and staining points.

Statistical analysis

Categorical data were analyzed using the χ^2 or nonparametric test, while measurement data were evaluated with Student's *t* or one-way analysis of variance test. Correlation coefficient between expression of CD73 and HIF-1 α was estimated by the Spearman correlation method.

HIF-1 α : Hypoxia-inducible factor-1 α ; AJCC: American Joint Committee on Cancer.

The Kaplan-Meier method was used to estimate the overall survival and the log-rank test was used to analyze the differences between the curves. Multivariate Cox proportional hazard regression model and receiver operating characteristic (ROC) curve analysis were established to assess the prognostic values of protein expression. All statistical analysis were performed using the SPSS software version 16.0 (SPSS, Chicago, IL, United States) and $P < 0.05$ was considered statistically significant.

RESULTS

Patient characteristics

The demographic and clinicopathological variables of

the 68 patients are shown in Table 1. The ages of the patients ranged from 24 to 59 years with the mean age 49.82 years. Based on the American Joint Committee on Cancer (AJCC) classification, there were 26 stage I / II patients and 42 stage III / IV patients. The patients were followed up for a period of 1-84 mo. Two were lost to follow-up and 37 patients died during the follow-up.

Immunohistochemical analysis of CD73 and HIF-1 α expression

CD73 and HIF-1 α were detected on consecutive sections and were found to be mainly expressed in the cytoplasm of gastric carcinoma (Figure 1). We repeated the experiment twice to exclude false positive results. Immunohistochemical analysis showed that in gastric carcinoma, 31 (45.6%) of 68 samples were CD73-positive and 36 (52.9%) of 68 were HIF-1 α -positive, while in healthy control gastric mucosa, 8 (11.8%) of 68 were CD73-positive and 12 (17.6%) of 68 were HIF-1 α -positive. CD73 ($P < 0.001$) and HIF-1 α ($P < 0.001$) expression was significantly higher than in healthy controls. CD73 expression was concordant with HIF-1 α expression in 69.1% (47 of 68) of gastric carcinoma cases (Spearman $r = 0.390$, $P = 0.001$). CD73 and HIF-1 α were found double-positive in 23 cases, double-negative in 24 cases, and either CD73-positive or HIF-1 α -positive only in 21 cases. The Spearman's rank correlation method was used to estimate the expression correlation coefficient ($r = 0.390$, $P = 0.001$), indicating a close correlation between CD73 and HIF-1 α expression in gastric carcinomas.

Correlation of CD73 and HIF-1 α expression with clinicopathological variables

Chi-squared test was used to investigate the correlation of CD73 and HIF-1 α expression with clinicopathological variables. Statistically, CD73 overexpression was significantly correlated with tumor differentiation ($P = 0.000$), histopathology ($P = 0.041$), depth of invasion ($P = 0.000$), nodal status ($P = 0.003$), metastasis ($P = 0.013$), and AJCC stage ($P = 0.000$) (Table 1). In contrast, there was no correlation between the expression of CD73 and age, gender, tumor size, or Borrmann type ($P > 0.05$, Table 1). In addition, HIF-1 α expression was significantly correlated with tumor size ($P = 0.031$), depth of invasion ($P = 0.036$) and AJCC stage ($P = 0.035$) (Table 1), but not with age, gender, tumor differentiation, histopathology, depth of invasion, nodal status, metastasis, or Borrmann type ($P > 0.05$, Table 1).

Survival analysis

Further Kaplan-Meier analysis demonstrated that high expression of CD73 (log-rank, $P < 0.001$) had a statistically significant correlation with a poor overall survival (Figure 2). But there was no significant correlation between overexpression of HIF-1 α and survival time (log-rank, $P = 0.103$). Moreover, we classified the patients into four groups stratified according to CD73/HIF-1 α expression, and a significant difference was observed

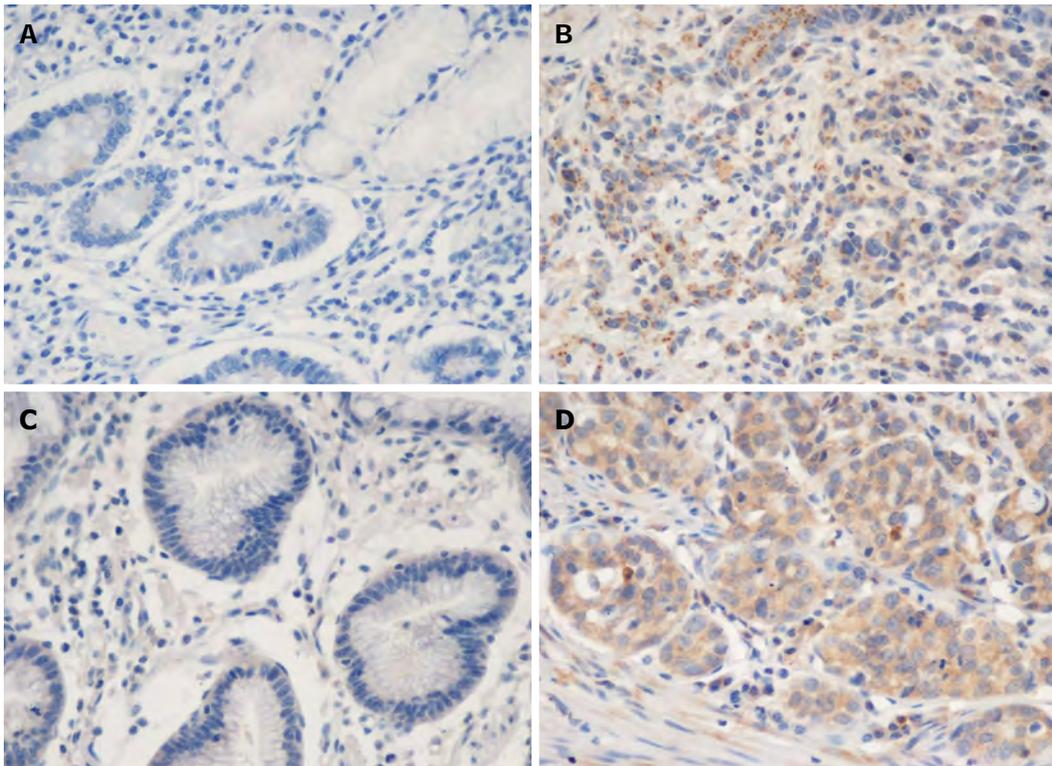

Figure 1 Expression of CD73 and hypoxia-inducible factor-1 α in gastric carcinoma (immunohistochemical stain, $\times 400$). A, C: Negative staining for CD73 (A) and hypoxia-inducible factor-1 α (HIF-1 α) (C) in healthy control gastric mucosa; B, D: Positive staining for CD73 (B) and HIF-1 α (D) in gastric carcinoma.

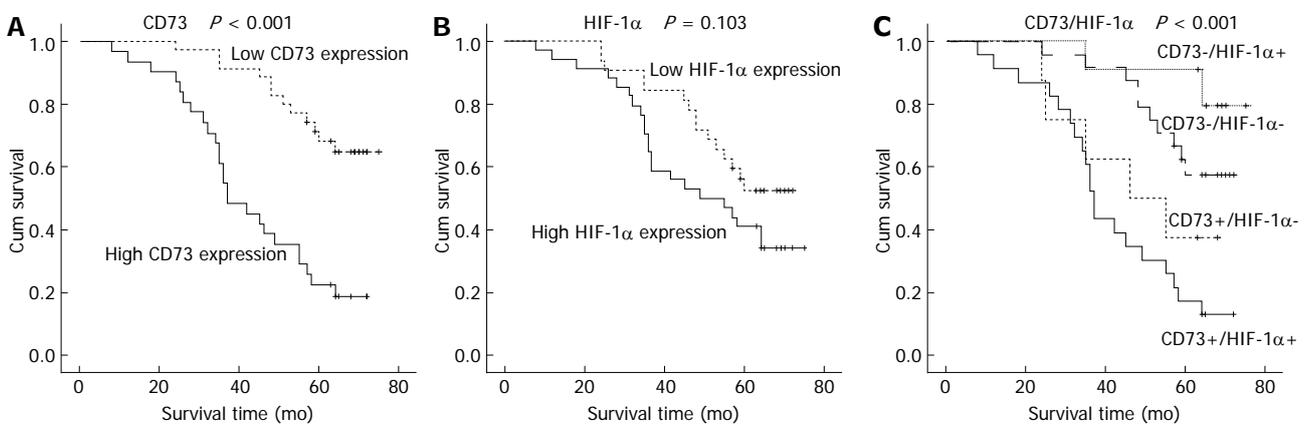

Figure 2 Kaplan-Meier curves for postoperative survival. A: The median survival time of patients with positive CD73 was shorter than that of patients with negative CD73 (log-rank test: $P < 0.001$); B: Hypoxia-inducible factor-1 α (HIF-1 α) expression had no correlation with the survival time of patients (log-rank test: $P = 0.103$); C: There was a significant difference among groups stratified according to CD73/HIF-1 α expression ($P < 0.001$). Patients with CD73+/HIF-1 α + had the worst prognosis.

among the groups (log-rank, $P < 0.001$). The patients with CD73+/HIF-1 α + carcinomas had the worst prognosis. The independent effects of all the significant factors were tested using the Cox proportional hazards model. The exploratory multivariate analyses demonstrated that CD73 [$P = 0.021$, hazard ratio (HR) = 0.385, 95%CI: 0.171-0.865] and AJCC stage ($P = 0.035$, HR = 1.585, 95%CI: 1.032-2.433) were independent prognostic factors, while HIF-1 α and others were not independent predictors. ROC curve analysis was also performed to further evaluate the prognostic value of CD73 and HIF-1 α expression, which revealed that CD73 expression was

encouragingly useful in predicting the overall survival of gastric carcinoma patients (area under the curve = 0.850, $P < 0.001$, Figure 3).

DISCUSSION

Gastric carcinoma is diagnosed with a high frequency throughout the world. In spite of improved diagnostic techniques and therapeutic methods, gastric carcinoma remains a major public health problem. Recently, some investigations showed that biomarkers might be promising predicting factors, and some of them were found

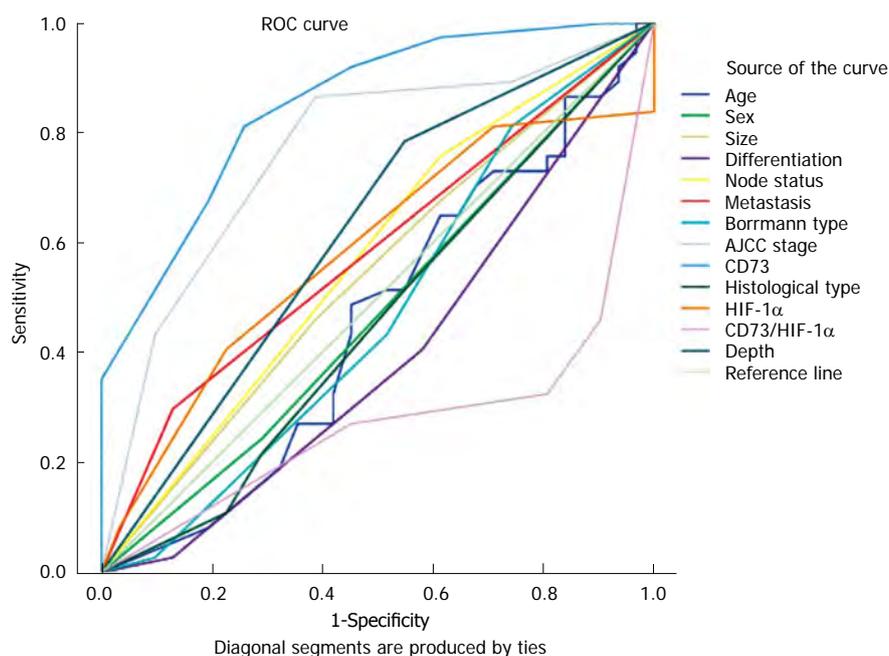

Figure 3 Receiver operating characteristic curves of clinicopathological variables, CD73 expression and hypoxia-inducible factor-1 α expression based on outcomes of gastric carcinoma patients. CD73 expression (AUC = 0.850; $P < 0.001$), hypoxia-inducible factor-1 α (HIF-1 α) (AUC = 0.582; $P = 0.247$), AJCC stage (AUC = 0.765; $P < 0.001$), CD73/HIF-1 α (AUC = 0.275; $P = 0.001$), Borrmann type (AUC = 0.472; $P = 0.689$), metastasis (AUC = 0.584; $P = 0.235$), nodal status (AUC = 0.572; $P = 0.310$), differentiation (AUC = 0.394; $P = 0.135$), histopathology (AUC = 0.459; $P = 0.559$), tumor diameter (AUC = 0.541; $P = 0.559$), gender (AUC = 0.476; $P = 0.740$), and age (AUC = 0.456; $P = 0.534$). ROC: Receiver operating characteristic; AJCC: American Joint Committee on Cancer; AUC: Area under the curve.

even superior to the AJCC staging system^[20,21]. Increasingly more researches have been conducted to discover the specific biomarkers although some of the results remained conflicting and inconsistent.

CD73, known as a purine salvage enzyme, might play a regulatory role in the immune system response^[22,23]. Jin *et al*^[22] found that the adenosine generated by tumor-derived CD73 could inhibit both the activation phase and effector phase of the antitumor T cell response and promote T cell apoptosis. Besides, some studies have indicated that CD73 could promote invasion, migration and adhesion of cancer cells^[24]. Moreover, the tumor-inhibiting effects of CD73 using siRNA or anti-CD73 antibody could restore efficacy of adoptive T cell therapy, leading to a long-term tumor-free survival^[22,25,26]. Host-derived CD73 was also observed in recent years, which provided evidence that CD73 knockdown could significantly delay tumor growth by regulating host immune system^[27-29].

The prognostic significance of CD73 has been studied in several cancers such as papillary thyroid carcinoma and breast cancer^[9-13]. It was suggested that high expression of CD73 in papillary thyroid carcinomas could be a useful indicator in the differential diagnosis of thyroid tumors. Moreover, strong expression of CD73 was found to be associated with invasiveness, metastasis, and shorter clinical survival in breast cancer. However, few studies have investigated the correlation between CD73 and gastric carcinoma.

CD73 expression of tumor cells may be induced by the selective pressure of the host immune system. Among other influencing factors in tumor microenvironment, hypoxia is the one which has been clearly defined^[19]. Hypoxia could induce upregulation of CD73 expression in brain microvessel endothelial cells, which will be reversed by reoxygenation of a short duration^[30]. Synnestvedt *et al*^[19] reported that hypoxia induced CD73 mRNA, increased protein expression levels and enhanced the CD73 activity

in intestinal epithelial cells (T84 cells) and this involved direct binding of HIF-1 to the *Nf5e* gene.

In tumor cells, adaptations to hypoxia are regulated by the activation of specific genes through HIF. And the transcription factor HIF-1 α which determines HIF activity is regarded as a hypoxia marker^[31]. Overexpression of HIF-1 α has been observed in various cancers, such as brain, bladder, lung, breast, esophagus, pancreas, colon, ovary, kidney, and prostate^[16-18,32-35]. Furthermore, it was reported that HIF-1 α overexpression was significantly correlated with highly aggressive disease, resistance to radiotherapy and chemotherapy, and poor prognosis in various carcinomas^[36,37]. Dellas *et al*^[38] found that high expression of HIF-1 α was associated with tumor progression and metastasis in advanced cervical cancer. Lu *et al*^[37] reported that elevated HIF-1 α expression was significantly correlated with poor prognosis of rectal adenocarcinoma patients.

In this study, we investigated the relationship between CD73, HIF-1 α , clinicopathological significance, and clinical prognosis in gastric carcinoma. We found that the expression of CD73 was significantly higher in gastric carcinoma than that in normal gastric mucosa, indicating the important role of CD73 in carcinogenesis. Furthermore, CD73 expression was closely correlated with differentiation, histopathology, depth of invasion, nodal status, metastasis, and AJCC stage, but not associated with age, gender, tumor diameter, or Borrmann type. Overexpression of HIF-1 α was found to be associated with tumor size, depth of invasion, and AJCC stage. The Spearman's rank correlation analyses indicated a close correlation between CD73 and HIF-1 α expressions in gastric carcinoma.

Our data also demonstrated that the overall survival curves in the CD73-negative group were significantly higher than in the CD73-positive group. However, there was no significant correlation between HIF-1 α overexpression and the poor overall survival. We classified the

patients into four groups stratified according to CD73/HIF-1 α expression, and a significant difference was observed among the groups. The patients with CD73+/HIF-1 α + carcinomas had the worst prognosis. Multivariate analyses showed that only CD73 expression was a prognostic factor independent of certain well-established clinicopathological parameters.

In conclusion, CD73 was correlated with the clinicopathological features in gastric carcinoma. High expression of CD73 was an indicator of poor clinical prognosis in patients with gastric carcinoma. Moreover, immunoreactivity of the combined CD73 and HIF-1 α could be a useful prognostic marker of gastric carcinoma.

COMMENTS

Background

Gastric carcinoma has been the fourth most common cancer in the world since the latter half of the 20th century. Changes observed in expression of tumor specific biomarkers in gastric carcinomas may be helpful to understand the transformation of histological heterogeneity and the underlying molecular mechanisms. Searching for specific biomarkers which determine the biological nature and behavior of gastric carcinoma would be of utmost importance to optimize individualized therapy.

Research frontiers

Overexpression of CD73 has been observed in various cancers. However, few studies have investigated the correlation between CD73 and gastric carcinoma. Previous studies indicated that hypoxia could induce up-regulation of CD73 expression in different cells, but the correlation between CD73 expression and hypoxia-inducible factor-1 α (HIF-1 α) expression has not been observed. In this study, the authors demonstrate that CD73 expression is up-regulated in gastric carcinoma and shows close correlation with HIF-1 α expression.

Innovations and breakthroughs

In this paper, data firstly shows that there are close correlation between the two biomarkers in gastric carcinoma and the combination of CD73 and HIF-1 α could be a useful marker of the prognosis of gastric carcinoma. Moreover, high expression of CD73 was found to be an indicator of poor clinical prognosis in patients with gastric carcinoma.

Applications

Examination of CD73 and HIF-1 α expression by immunohistochemistry (IHC) analysis could be used as an additional effective way to identify patients at high risk of tumor progression, thus to optimize individual treatment of patients with gastric carcinoma.

Terminology

Ecto-5'-nucleotidase/CD73 is a homodimer linked to the plasma membrane through a glycosylphosphatidylinositol lipid anchor, which was found in most tissues. It is a part of extracellular ATP metabolism, which dephosphorylates AMP into adenosine rapidly after CD39 catalyzes ATP, ADP and AMP; HIF-1 is a heterodimeric basic helix-loop-helix transcription factor composed of HIF-1 α and HIF-1 β subunits; and HIF-1 α determines HIF-1 activity

Peer review

This manuscript investigate the expression of CD73 and HIF-1 α in human gastric carcinoma by IHC. The results showed that CD73 and HIF-1 α were higher expressions in gastric carcinoma than that of control and showed close correlation. They concluded that the combination of the two molecules and CD73 expression in gastric cancer tissue is associated with prognosis. The results are interesting and may represent an additional effective way to identify patients at high risk of tumor progression.

Abstract

AIM: To describe the histology of the digestive tract and to investigate the occurrence of endocrine cells in *Oligosarcus hepsetus* (*O. hepsetus*).

METHODS: The digestive tract (DT) of *O. hepsetus* was divided into esophagus, two stomach regions (glandular and non-glandular) and two intestinal regions (anterior and posterior). These specimens were processed by routine histological techniques and stained with hematoxylin-eosin, Gomori's trichrome, periodic acid Schiff (PAS) and Alcian blue (AB). An immunohistochemical method using avidin-biotin-peroxidase was employed.

RESULTS: The esophagus is lined with a non-keratin-

ized stratified squamous epithelium that is reactive to PAS and AB. The stomach has a mucosa lined with a simple columnar epithelium with mucus-secreting cells that are reactive only to PAS. The intestine has a simple columnar epithelium with a brush border and goblet cells that are reactive to PAS and AB. Somatostatin, serotonin and cholecystokinin immunoreactive cells were identified throughout the DT.

CONCLUSION: This study revealed adaptations for the species' diet and showed that the distribution and relative frequency of immunoreactive cells are similar to those of other fish.

INTRODUCTION

The literature stresses the importance of knowledge of the anatomy of the digestive tract (DT) of fishes, because this structure is highly variable, related to the diversity of feeding habits, type of food and lifestyles^[1-3].

The histological architecture of the DT includes a layer of mucus-secreting cells, observed by histochemical techniques in various studies of teleosts. The secretions vary among different fish species and also according to the location in the DT within the same species^[4]. These secretions play an important role in lubricating the or-

gan and protecting against proteolytic degeneration and pathogenic microorganisms^[5].

Besides this, to control the functions of the different DT segments, endocrine cells compose a complex system disseminated among the epithelial components, with the ability to secrete physiologically active polypeptide hormones and amines^[6]. According to Deveney *et al.*^[7], hormones have important functions in the overall regulation of the digestive process, such as nutrient absorption, the secretion of intestinal and associated glands, gut motility and intestinal blood flow

Oligosarcus hepsetus (*O. hepsetus*), known commonly as the thin dogfish, belongs to the Characidae family. It is carnivorous, with a diet basically composed of small fish. It mainly lives in rivers and reservoirs, generally at the middle to the bottom of the water column. It has a slightly rounded body with small fins and is considered a good swimmer^[8]. Many articles have been published about this species' distribution, ecology, feeding habits and diet, but no study has been published reporting the microscopic analysis of the organs of the DT of *O. hepsetus*. Although it does not have economic importance, it is one of the most abundant species in the reservoirs of Rio de Janeiro^[9] and the Paraíba do Sul River^[10], with distribution in the coastal region of south to south-eastern Brazil between Santa Catarina and Rio de Janeiro^[11].

Studies involving microscopic anatomy and histochemistry provide information to characterize the organs of the digestive system, facilitating understanding of the physiology of the DT and the feeding habits of the species under investigation^[12]. These studies are essential for efforts to restock native species to improve the condition of ecosystems^[13].

The purpose of the present work was to describe histological and histochemical aspects of the DT of *O. hepsetus* and to investigate immunohistochemically the occurrence of the endocrine cells secreting somatostatin (SOM), serotonin (5-hydroxytryptamine, 5-HT), cholecystokinin (CCK), gastrin (GAS), glucagon (GLUC) and insulin (INS) in the DT of this fish, seeking to relate them to its feeding habits, in order to provide data for future studies.

MATERIALS AND METHODS

Collection area

The specimens were collected from two reservoirs: Funil (22°30'S, 44°45'W), and Ribeirão das Lajes (22°43'S, 44°46'W), as well as two points of the Paraíba do Sul River: Ilha dos Pombos (21°84'S, 42°58'W) and Santa Cecília (22°48'S; 43°84'W), all located in Rio de Janeiro state, Brazil.

Tissue processing

Fourteen specimens were used in this study without sexual distinction, four collected in Funil Reservoir, four in Ribeirão das Lajes Reservoir, and three each from the Ilha dos Pombos and Santa Cecília sites of the Paraíba do

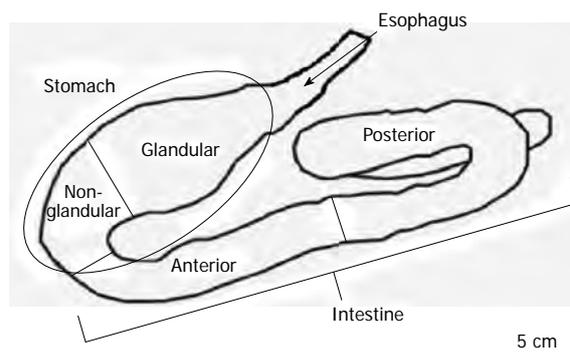

Figure 1 Anatomical diagram of the digestive tract of *Oligosarcus hepsetus*.

Sul River. The fish were dissected in the field, after being anesthetized with benzocaine hydrochloride (50 mg/L) and killed rapidly by hypothermia for immediate removal of the DT. Fragments of the DT were fixed for 8 h in Bouin's fluid and then placed in 70% alcohol. The esophagus, two stomach regions (glandular and non-glandular) and two intestinal regions (anterior and posterior) were obtained from each specimen (Figure 1). These materials were taken to the Histology and Embryology Laboratory of Rio de Janeiro Federal Rural University where they were processed by routine histological techniques, consisting of: dehydration (in a rising ethanol series - 70° GL to 100° GL), diaphanization in xylol and embedding in Histosec-Paraffin, to obtain 5 µm histological sections.

Histological and histochemical analysis

The sections obtained from the DT of *O. hepsetus* were stained with hematoxylin-eosin for analysis of the tissue architecture and with Gomori's trichrome for differential visualization of the connective tissue and collagen fibers.

The histochemical analysis involved periodic acid Schiff (PAS) and Alcian blue (AB) pH 2.5 staining to reveal the neutral and acid glycoconjugates (GCs), respectively. Five slides from each specimen were prepared for each protocol, one from each of the five sectioned regions.

Immunohistochemistry

For the immunohistochemical procedure, 5 µm-thick sections were cut by microtome and mounted on glass slides precoated with 0.1% poly-L-lysine, after being dewaxed and dehydrated by the routine protocol. They were incubated in citrate buffer (pH 6.0-0.01 M) and placed in a microwave oven for 15 min to recover the antigen, then they were incubated with a solution of 3% H₂O₂ in methanol for 15 min to block any endogenous peroxidase. Subsequently, the sections were incubated at room temperature in a humid chamber with a 1:100 µL dilution of bovine serum albumin in phosphate buffered saline (PBS) solution for 30 min. The sections were first incubated overnight at 4 °C with the primary antisera against the individual gastrointestinal hormones (Table 1). The sections were then incubated with biotinylated "Universal" secondary antibody diluted to 1:200 µL for 30 min at room temperature, then with avidin-biotin-peroxidase complex,

Table 1 Details of primary antisera used in this study

| Primary antisera | Donor | Code No. | Working dilution | Source |
|------------------|--------|----------|------------------|------------------------------------|
| Somatostatin | Rabbit | A566 | 1:300 | Dako Corp., CA, United States |
| Serotonin | Rabbit | S5545 | 1:8.000 | Sigma-Aldrich, Inc., United States |
| Cholecystokinin | Rabbit | C2581 | 1:8.000 | Sigma-Aldrich, Inc., United States |
| Gastrin | Rabbit | G0785 | 1:1.000 | Sigma-Aldrich, Inc., United States |
| Glucagon | Mouse | G2654 | 1:2.000 | Sigma-Aldrich, Inc., United States |
| Insulin | Mouse | I2018 | 1:1.000 | Sigma-Aldrich, Inc., United States |

Table 2 Regional distribution and intensity of immunoreaction in endocrine cells in the digestive tract of *Oligosarcus hepsetus*

| Antisera | Segment of the esophagus | Segments of the stomach | | Segments of the gut | |
|-----------------|--------------------------|-------------------------|-----|---------------------|------|
| | | GI | NGI | ANT | POST |
| Somatostatin | +++ | ++ | + | - | - |
| Serotonin | - | +++ | ++ | - | - |
| Cholecystokinin | - | - | - | - | ++ |
| Glucagon | - | - | - | - | - |
| Gastrin | - | - | - | - | - |
| Insulin | - | - | - | - | - |

Intensity of immunoreactions: (-), absent; (+), low; (++) , medium; (+++) , strong. GI: Glandular; NGI: Non-glandular; ANT: Anterior; POST: Posterior.

diluted at 1:200 µL for 30 min at room temperature. Subsequently, the peroxidase label was revealed by reaction with Stable DAB/Plus, prepared according to the kit's instructions. All dilutions and thorough washes between stages were performed using PBS (pH 7.4). The sections were counterstained with Harris hematoxylin, rinsed with deionized water, dehydrated through a series of ethanol and methylcyclohexane solutions and mounted using Entellan. To investigate the specificity of the reactions, negative and positive controls were used. The negative control was prepared by replacement of the primary antibody with non-immune serum and PBS (pH 7.4). Positive controls were produced using tissue sections for each respective antiserum, as indicated in the product data sheet.

Observation and photomicrography

Photomicrographs of all samples from each of the fourteen specimens were obtained with a digital camera Nikon Coolpix 4300 attached to a microscope Olympus BX41. The number of immunoreactive endocrine cells to each antiserum per analyzed segment was recorded and the intensity of immunoreaction was classified: absent (-) or low (+), medium (++) and strong (+++) immunoreactivity (Table 2).

RESULTS

Histological and histochemical study of digestive tract

The following layers were observed in the DT of *O.*

hepsetus: mucosa, submucosa, muscular and adventitia or serosa. The muscularis mucosae is absent in this species.

Esophagus

Histological examination revealed that the mucosa of the esophagus of *O. hepsetus* has many longitudinal folds and is lined with a stratified epithelium with non-keratinized squamous surface cells. The majority of the mucus-secreting cells are interspersed with a smaller number of non-secretory cells (Figure 2A).

The secretory cells reacted positively to PAS and AB staining, indicating the presence of neutral and acid GCs, respectively. The lamina propria is composed of connective tissue and does not have glands. The muscular layer is formed by two sub-layers of striated skeletal muscle, with an internal longitudinal and an external circular layer. Externally, the esophagus is enveloped by an adventitia, composed of connective tissue with some nerve fibers and blood vessels (Figure 2).

Stomach

In the stomach of *O. hepsetus*, the mucosa is lined with a simple epithelium layer composed of columnar mucus-secreting cells with basal nuclei. These were reactive to PAS but not to AB, revealing the presence of only neutral GCs. The stomach epithelium forms crypts along the gastric mucosa. The mucosa layer projects toward the organ's lumen, forming various gastric folds, arranged longitudinally. In the non-glandular region, the submucosa and muscular layers accompany the mucosa in forming these folds, making the lumen very small (Figure 3).

The division of the stomach observed in the present work is in accordance with the structural characteristics of the two regions. The glandular region is characterized by having well-developed tubular gastric glands, composed of oxynticopeptic cells, occupying the entire lamina propria (Figure 3B). These are smaller and less numerous in the initial portion and increase in number and size in the direction of the non-glandular region. The non-glandular region has a well-developed muscular layer (Figure 3D and E). The submucosa layer is composed of connective tissue and blood vessels.

In the stomach, the muscular layer is composed of smooth muscle fibers arranged in two directions: internal circular and external longitudinal (Figure 3E). The glandular region contains myenteric plexuses arranged in sparse groups, composing the enteric nervous system and located between the muscular sub-layers, and there is a serosa layer which surrounds these structures.

Intestine

Just as for the stomach, the adopted division of the intestine follows specific structural patterns in relation to the mucosa layer. The histological analysis of the intestine of *O. hepsetus* revealed that the pattern of folds varies, characterizing two distinct regions: anterior and posterior. The anterior region has numerous thin and elongated folds with villi (Figure 4A). In contrast, in the posterior

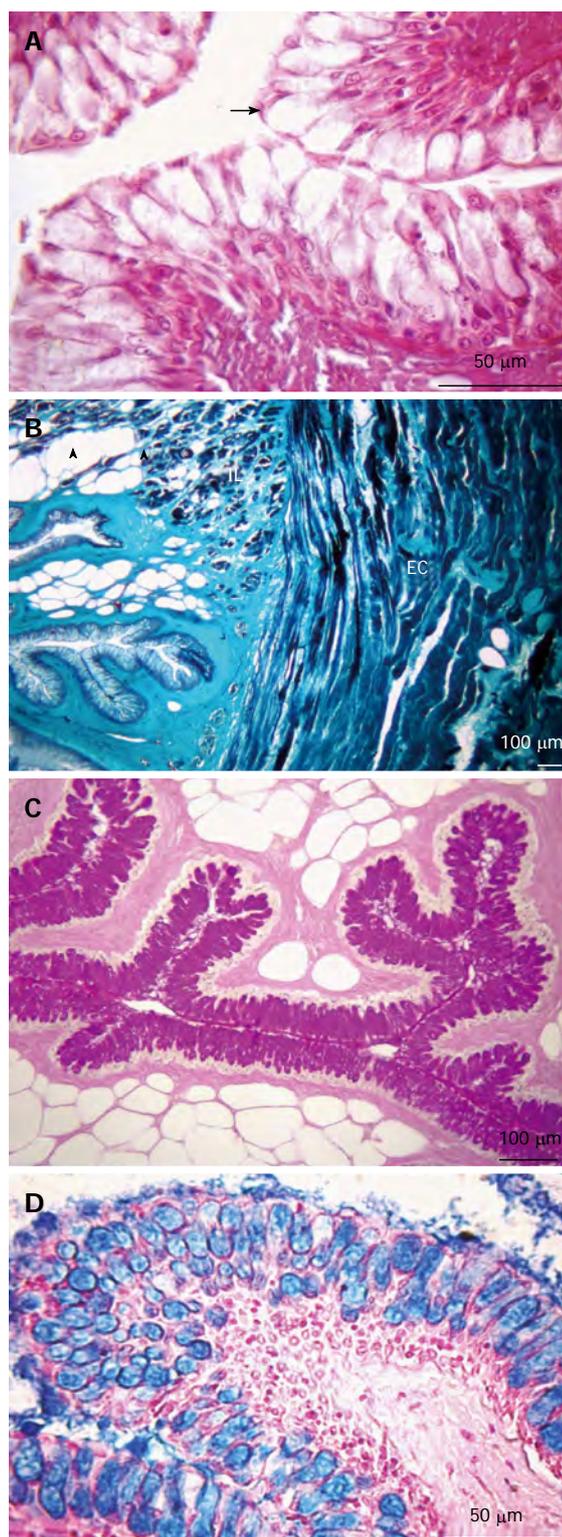

Figure 2 Transversal sections of the esophagus. A: Non-keratinized stratified squamous epithelium (arrow). Hematoxylin and eosin stain; B: Presence of adipose tissue (arrowheads) in the submucosa layer. Muscular layer formed by two sub-layers, internal longitudinal (IL) and external circular (EC). Gomori's trichrome stain; C: Presence of neutral glycoconjugates (GCs). Periodic acid-Schiff stain; D: Acid GCs. Alcian blue stain.

part the folds are less sinuous due to the absence of villi and are thicker, with some being leaf-shaped, and also have a greater number of goblet cells (Figure 4B).

The intestinal mucosa is lined by a simple columnar epithelium with a striated border and goblet cells, which were positive to PAS and AB stainings, with pink (PAS) and blue (AB) coloration (Figure 4), indicating the presence of neutral and acid GCs, respectively.

The limits between the lamina propria and the submucosa layer are not evident, with connective tissue and blood vessels present in both these regions. In both parts of the intestine, the muscular layer has the same organization as in the stomach, with an internal circular layer and an external longitudinal one, observed in the cross-sections, both composed of smooth muscle cells (Figure 4A). The posterior part of the intestine contains a continuous layer of nervous tissue and a myenteric plexus between the muscular sub-layers (Figure 4E). Externally there is a serosa layer.

Immunohistochemical study of digestive tract

SOM-, 5-HT- and CCK-immunoreactive (IR) cells were identified in the DT of *O. hepsetus*, but GAS-, GLUC- and INS-IR cells were not present (Table 2).

Esophagus

Somatostatin immunoreactivity: In the esophagus, SOM-IR cells were detected in the basal layer of the stratified squamous epithelium (Figure 5). Morphologically, these cells were totally colored by chromogen, making it impossible to visualize a nuclear halo. The nucleus of these cells is very small, occupying a tiny area inside them.

Stomach

Serotonin and somatostatin immunoreactivity: Serotonin (5-HT)-IR cells (Figure 6) and SOM-IR cells (Figure 7) were observed in the lining epithelium and glandular epithelium of the stomach. Regarding the morphology of immunoreactive cells, two types were found in this portion, namely closed-type cells and open-type cells.

Intestine

Cholecystokinin immunoreactivity: CCK-IR cells were only observed in the lining epithelium of the posterior part of the intestine of *O. hepsetus* (Figure 8). Closed-type and open-type immunoreactive cells were found.

DISCUSSION

The stratification of the wall of the DT of *O. hepsetus* has the same organization observed in the majority of other teleosts, with some modifications associated with the species' feeding habits. We observed four layers: mucosa, submucosa, muscular and serosa. The muscularis mucosae is not present in the examined areas of the DT, unlike that observed in *Pimelodus maculatus* (*P. maculatus*)^[14] and *Semaprochilodus insignis*^[15]. These authors assumed that the existence of muscular tissue between the lamina propria and submucosa aids in the elimination of the substances produced by the glands.

The very large longitudinal folds of the mucosa layer

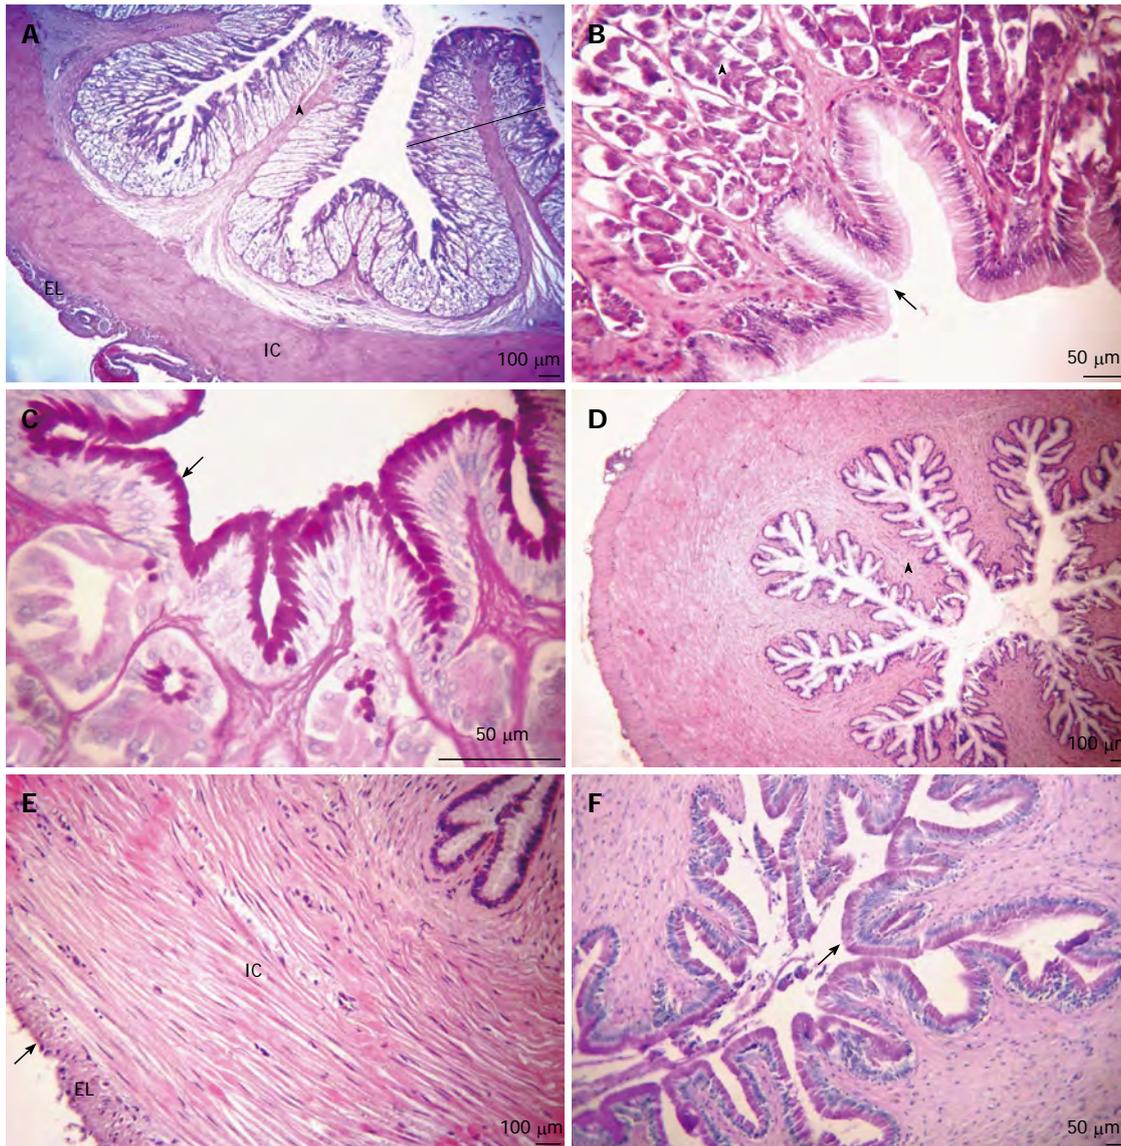

Figure 3 Transversal sections of the stomach. **A:** Mucosa layer with many high gastric folds (arrowhead), thickening of the lamina propria caused by a large number of tubular gastric glands (outline). Organization of the internal circular (IC) and external longitudinal (EL) muscular layers. Hematoxylin and eosin (HE) stain; **B:** The simple columnar epithelium with mucus-secreting cells forming faveola gastrica (arrow) and fundic glands composed of oxynticopeptic cells (arrowhead). HE stain; **C:** Presence of neutral glycoconjugates (GCs) (arrow). Periodic acid Schiff (PAS) stain; **D:** Mucosa layer, together with the sub-mucosa and internal muscular layers, forming large longitudinal folds (arrowhead). HE stain; **E:** The muscular layer of smooth muscle fibers, composed of IC and EL sub-layers and serosa (arrow). HE stain; **F:** Neutral GCs (arrow). PAS stain. (A-C: Glandular region; D-F: Non-glandular region).

of the esophagus of *O. hepsetus* substantially increases the organ's capacity for distension, an effect described by other researchers^[16,17]. The digestive capacity is related to the volume of the folds in the mucosa, with a greater number of folds implying more efficient digestion.

The lining of the mucosa by a stratified squamous epithelium, according to Hunbert *et al.*^[18], acts to protect the fish against mechanical aggression and invasive bacteria. The same pattern was found in *Prionotus carolinus* by Blake^[19], but was not observed in *Salmo trutta* by Burnstock^[20] or in *P. maculatus* by Santos *et al.*^[14]. The submucosa contains bundles of adipose tissue and blood vessels; the same was found in *Dentex dentex* (*D. dentex*)^[21].

The positive reaction of the epithelium to PAS and AB staining revealed the production of neutral and acid

GCs, respectively, in the esophagus. The first type of mucus has low viscosity and is important to assure laminar flow during the lubrication and treatment of particles, to enable digestion to be conducted by the esophagus until the upper region of the stomach. In turn, acid GCs have high viscosity and are fundamental to trap particles^[22]. The presence of these GCs was also reported in *Anguilla anguilla*^[23], *D. dentex*^[21], *P. maculatus*^[14], *Cynoscion guatucupa* (*C. guatucupa*)^[24], *Pelteobagrus fulvidraco* (*P. fulvidraco*)^[25] and *Hyphessobrycon anisitsi* (*H. anisitsi*)^[26].

The transition from the esophagus to the stomach is characterized by an abrupt change in the lining epithelium, which starts to present a single layer of columnar cells secreting mucus. This type of stomach lining epithelium has been observed in the majority of other teleosts as

well^[4,14,21,23,24], but in *Plecostomus plecostomus*^[27] and *Epinephelus marginatus*^[28], the epithelium described at the beginning of the stomach was of the squamous and cubic type, respectively, becoming simple columnar in the posterior regions.

The mucus-secreting cells were only reactive to PAS in the two stomach regions; the same was found in *C. guatuncupa*^[24], *P. fulvidraco*^[25] and *H. anisitsi*^[26], but was not like that observed in *Anguilla anguilla* (*A. anguilla*)^[23] and *Chanos cha-*

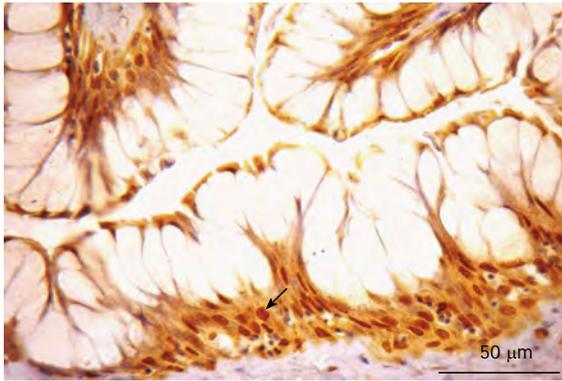

Figure 5 Somatostatin-immunoreactive cells in the esophagus. Somatostatin-immunoreactive cell were detected in the basal layer of the stratified squamous epithelium (arrow).

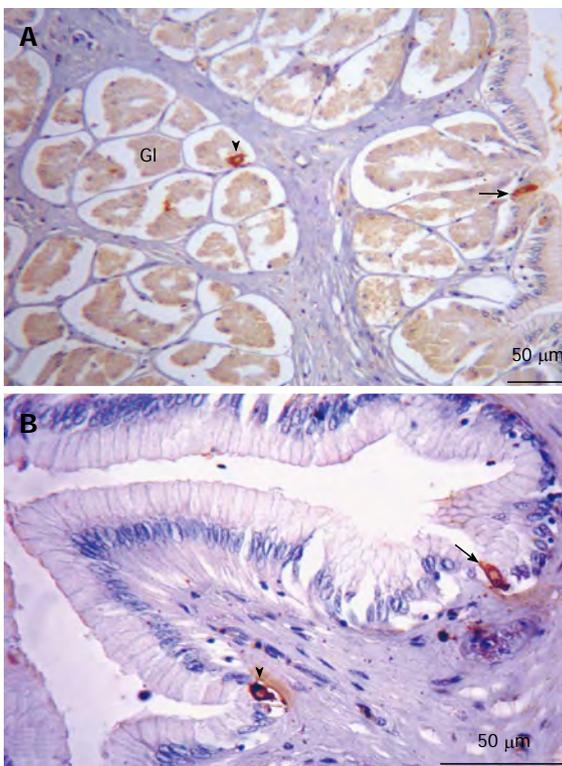

Figure 7 Somatostatin-immunoreactive cells in the stomach. A: Glandular region. Immunoreactive (IR) cells along the entire region, of the open (arrow) and closed (arrowhead) types, present both in the lining epithelium and the glandular epithelium; B: Non-glandular region. Indications of IR cells of the open (arrow) and closed (arrowhead) types. Gl: Glandular.

nos^[29]. As mentioned, the probable function of this mucus is to promote a flow able to carry the food bolus to the intestine. Besides this, since cells producing hydrochloric acid (HCL), essential for digestion, were identified in the stomach region, this mucus also functions as a layer to protect the epithelial cells.

The invaginations formed by the lining epithelium are called gastric crypts, which in the glandular region communicate with well-developed and branched tubular glands, as also observed by Díaz *et al*^[24] in *C. guatucupa* and by Domeneghini *et al*^[23] in *A. anguilla*. These are common

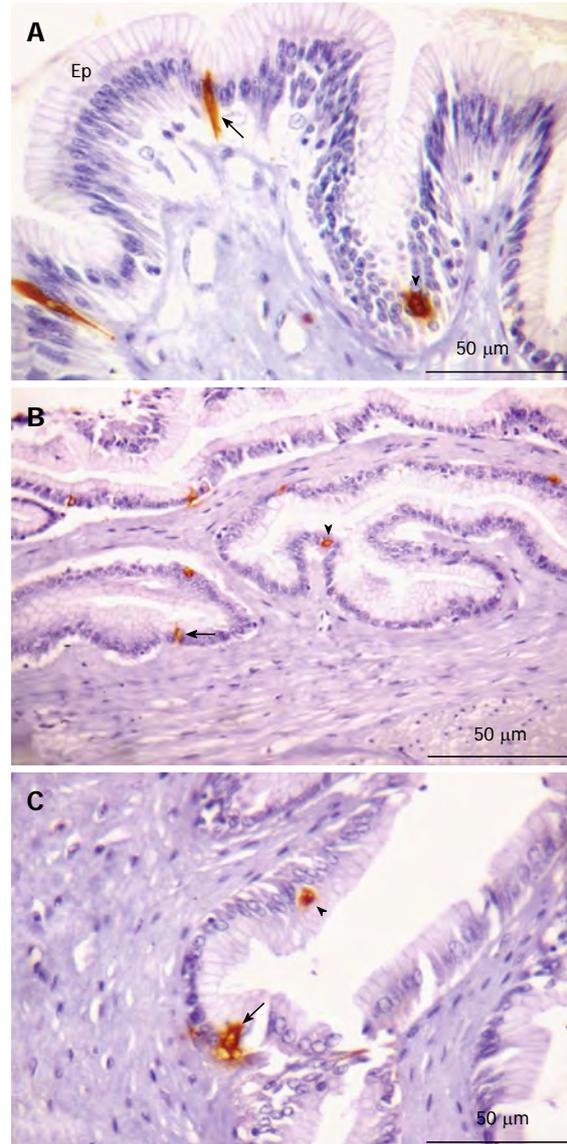

Figure 6 Serotonin-immunoreactive cells in the stomach. A-B: Glandular region; C: Non-glandular region. characteristics of carnivorous fish species^[30]. The gastric glands are composed of oxynticopeptic cells, which play a role similar to that of the principal and parietal cells in mammals, by synthesizing HCL and pepsinogen. In this case, we believe the glandular region has digestive functions while the non-glandular region only acts to carry the food to the gut with the epithelial secretions, with the help of the muscular layer, which in this region is thicker^[14]. As seen in the esophagus, the stomach regions also contain well-developed longitudinal folds, whose function is to allow expansion of the organ's diameter to store a large volume of food^[16,17], another common characteristic of carnivorous fish species^[30].

The intestine of *O. hepsetus* has two distinct parts, the same as in *Tilapia spp.*^[31]. The anterior part is characterized by a larger number of thin and elongated longitudinal folds,

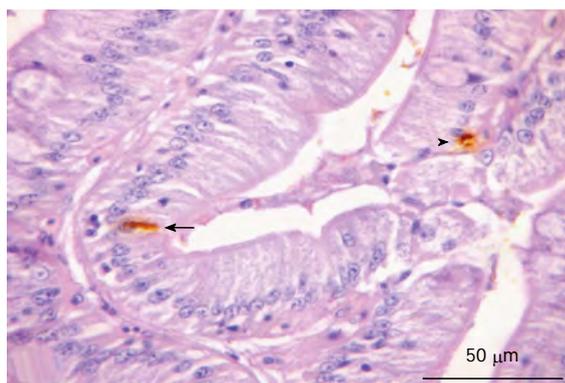

Figure 8 Cholecystikinin-immunoreactive cells in the posterior region of the intestine. Epithelial marking of open (arrow) and closed (arrowhead) immunoreactive cells.

which branch out to form villi, making the organ's lumen very small. The posterior region, endowed with thicker and less sinuous longitudinal folds, contains a larger number of goblet cells, similar to the pattern observed in the large intestine of mammals. This pattern of ample folds of the mucosa is common in carnivores, acting to expand the surface absorption area, since carnivores have a relatively short intestine compared to animals with other feeding habits^[30]. Sections of the lining epithelium of both regions, when submitted to the PAS and AB histochemical protocols, reacted positively, showing cells with pink (PAS) and blue (AB) coloring, indicating the presence of neutral and acid GCs, respectively, as also observed by Cinar *et al.*^[32] in *Pseudophoxinus antalyae*, by Carrasón *et al.*^[21] in *D. dentex* and by Leknes^[26] in *H. anisitsi*, but unlike that observed in *P. fulvidraco*^[25] and *Chanos chanos*^[29].

This allows the hindgut to lubricate the tube and to trap particles to be eliminated, permitting the food bolus to reach this region in dehydrated form^[33].

The organization of the muscular layer along the entire DT of *O. hepsetus* is the same as observed in *P. maculatus*^[14] and *P. fulvidraco*^[25], except in the esophagus, where the pattern resembled that found in mammals. The function of this layer is to promote motility in the DT, carrying and mixing food with the digestive secretions. This motility and also the release of these secretions are favored by the existence of a myenteric plexus between the muscular tissue sub-layers, observed in the glandular region of the stomach as well as in the posterior intestine. Unlike in mammals, the myenteric plexus does not have the form of ganglia, but rather appears in sparse form or in continuous layers, as seen in *Pimelodus maculatus*^[34], but unlike that observed in *Salmo trutta*^[20] and *P. fulvidraco*^[25].

The results obtained in this study demonstrate that the DT of *O. hepsetus* has three types (5-HT-, SOM- and CCK) of endocrine cells, but three other types (GAS-, GLUC- and INS-IR cells) were not present. However, these cells have been observed in other fish, such as: GLU-IR cells in the gastric mucosa of cartilaginous fishes^[35]; GAS-IR cells in the stomach pyloric region of *Oncorhynchus mykiss*; and INS-IR cells in the stomach py-

loric region of *Monopterus albus* (*M. albus*) and the stomach cardiac and pyloric regions of *Pelteobagrus fulvidraco*^[36]. The reason for the absence of these endocrine cells in the DT of *O. hepsetus* may be related to its digestive histophysiology, but further studies should be conducted to confirm this relationship.

The peptide SOM is a component responsible for inhibiting many substances, such as GAS, CCK, GLUC, INS, secretin, motilin and gastric acid^[37]. In mammals, it also controls the absorption of amino acids and glucose^[38]. It is thus essential in the DT, since it participates in basic mechanisms for efficient food processing. Ku *et al.*^[39] identified the production of this hormone along the DT of the reptile *Trachemys scripta elegans*, including in the esophagus, where we found SOM-IR cells in *O. hepsetus*. Other studies investigating the presence of this hormone in the DT have been performed by Lee *et al.*^[40] and Pan *et al.*^[36], the latter analyzing the presence of endocrine cells in eight fish species: *P. fulvidraco*, *M. albus*, *Siniperca chuatsi* (*S. chuatsi*), *Colossoma brachypomum* and *Tilapia nilotica*, all of which presented SOM-IR cells in the gastric mucosa, as observed in *O. hepsetus*. Although we did not visualize this hormone in the intestinal parts of the thin dogfish, it was reported in the gut of the spiny dogfish *Squalus acanthias*^[41], *Oncorhynchus mykiss*^[42], *P. fulvidraco*, *M. albus*, *S. chuatsi*^[36], *Zacco platypus*^[43] and *Coreoperca herzi* (*C. herzi*)^[44].

5-HT-IR cells have been detected in the DT of various vertebrates: fish^[44], amphibians^[45], reptiles^[46], birds^[47] and mammals^[48,49]. Researchers state that all vertebrates have this type of endocrine cell in the DT, assuming that these cells' location is based on the evolution of these higher life forms^[50]. It is known that in fish, serotonin promotes gastrointestinal motility^[51] and blood flow, in the latter case by triggering vasoconstriction^[52,53]. In *O. hepsetus*, 5-HT-IR cells were observed only in the regions of the stomach, both in the lining epithelium and the glandular epithelium, as also observed in *C. herzi* by Lee *et al.*^[44].

As was described for the fish species *Oncorhynchus mykiss*^[54], *Salmo trutta*^[55], *Odontesthes bonariensis*^[56] and *Rhamdia quelen*^[57], in *O. hepsetus* we observed CCK-IR cells in the intestine; in this case only in the posterior part, while in *O. bonariensis*^[56] these cells were observed throughout the gut, but with greater concentration in the hindgut. There were no CCK-IR cells in the other regions of the DT of *O. hepsetus*. This hormone controls intestinal motility, by stimulating the release of pancreatic juice and inhibiting gastric emptying^[58,59]. The existence of these cells has been verified in fish^[35,42], reptiles^[39], birds^[60] and mammals^[61].

In conclusion, our histological and histochemical study of the DT of *O. hepsetus* revealed adaptation for the species' feeding habits, to protect the tract and increase the absorptive processes. The immunohistochemical study showed that the DT of this fish species contains different types of endocrine cells similar to those found in other vertebrate species. This study will help comprehension of the digestive physiology of this species and provide a basis for diagnosing diseases that affect the digestive tract of carnivorous teleosts.

COMMENTS

Background

Studies indicate the importance of knowledge of the morphology of the digestive tract (DT) because of the different physiological conditions in which animals live and their varied eating habits, which are manifested by adaptations and modifications in the digestive system. Information about the morphological aspects of the DT provides support for research on physiology and nutrition, aiming to improve the diet and management of livestock and support activities for restocking and restoration of natural ecosystems, besides being important for various research areas, including biological systems and conservation.

Research frontiers

The integration of the motor, secretory and absorptive phenomena of the DT is fundamental for the reduction of food into simpler particles that can be absorbed. This association is achieved by actions and interactions of the nervous and endocrine systems, which in the digestive system are represented by the endocrine cells. The diffuse neuroendocrine system (DNS) acts to control the motility and transit speed of the ingesta, the various secretions of the DT, the absorption of nutrients and the blood flow, to assure the activation and action of enzymes at the proper moment. Therefore, the products of the digestive system can be absorbed by the organism and reach the blood and lymphatic circulation systems.

Innovations and breakthroughs

The avidin-biotin-peroxidase complex method was applied to study the endocrine cells in the DT of *Oligosarcus hepsetus* (*O. hepsetus*). This method involves the use of three reagents: the primary antibody, which binds to the receptor of the specific hormone of interest; the secondary antibody, which is produced linked to a molecule of the vitamin biotin (C) and binds to receptors of the primary antibody; and the glycoprotein-avidin complex, produced from biotin and peroxidase, with joins with the previous reagent, the secondary antibody.

Applications

The immunohistochemical study showed that the DT of *O. hepsetus* contains different types of endocrine cells similar to those found in other vertebrate species. This study will help comprehension of the digestive physiology of this species and provide a basis for diagnosing diseases that affect the digestive tube of carnivorous teleosts.

Terminology

The gastrointestinal epithelium is permeated by a set of cells, originating from the DNS, called endocrine cells. The secretions of these cells control the digestion of food to ensure it is efficient, by regulating the digestive processes. Besides controlling the absorption of nutrients, they play an important role in determining secretions from the gut and associated glands and in regulating the intestinal blood flow.

Peer review

In this study, the authors describe the microscopic anatomy of the DT of a carnivorous fish species and analyze the functional components that aid the digestion of food. The results are relevant by enabling comparison with other fish species, contributing to phylogenetic studies.

compare it with the previously known prevalence in a pediatric group living in the same geographical area.

METHODS: The research protocol was approved by the Ethics Committee of the University of Brasilia School of Medicine, Brasilia, Brazil. Blood samples from 946 individuals (295 male and 651 female) aged 60 years or older were collected between May 2010 and July 2011. The study subjects' mean and median ages were 68.1 and 67 years, respectively, ranging from 60 to 92 years. That age distribution closely corresponded to the age distribution of the Brazilian population according to the Brazilian 2010 census. The participants were consecutive and unselected outpatients undergoing blood tests at the University of Brasilia Hospital's Clinical Pathology Laboratory. All sera were tested for immunoglobulin A anti-transglutaminase antibodies (IgA-tTG) by enzyme-linked immunosorbent assay, and those that were positive were further tested for immunoglobulin A anti-endomysium antibodies (IgA-EMA). Human leukocyte antigen (HLA) genotyping was performed for all individuals who exhibited positive serologic results for IgA-tTG and/or IgA-EMA.

RESULTS: Out of the 946 studied patients, only one previously diagnosed case of biopsy-proven celiac disease was detected. For the remaining subjects, nine serum samples tested positive for IgA-tTG antibodies; however, none of them tested positive for IgA-EMA antibodies. The HLA genotyping of those nine subjects revealed that one was carrying DQA1*0501 and two were carrying DQB1*0201 alleles. These data showed that, among those 946 elderly individuals, the prevalence of celiac disease (CD) was 0.1% (95%CI: 0.00-0.59). The prevalence of CD for the elderly group was compared with that observed for the group of 2034 children younger than 15 years (age range, 1-14 years; mean age, 8 years) who took part in our previous CD prevalence screening study. All the children came from the same geographical region and shared a similar ethnic and low-income background. As in the elderly group in

Abstract

AIM: To evaluate the prevalence of celiac disease in a group of Brazilian individuals over 60 years of age and

the current study, the younger group was made up of consecutive outpatients who underwent blood evaluation at the University of Brasilia Hospital's Clinical Laboratory. The prevalence of biopsy-proven CD among those children was 0.54% (95%CI: 0.27-0.57). The comparative analysis between the two groups resulted in the following values: odds ratio = 0.19 (95%CI: 0.01-1.45) Fisher test $P = 0.06$.

CONCLUSION: The prevalence of CD among the children of our previous study was 5.4 times higher than that found in the present elderly group.

Decreased prevalence of celiac disease among Brazilian elderly. *World J Gastroenterol* 2013; 19(12): 1930-1935 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1930.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1930>

INTRODUCTION

Celiac disease (CD) is a chronic autoimmune-mediated disease with both intestinal and systemic manifestations that are induced by the ingestion of gluten in genetically predisposed individuals. CD-related intestinal abnormalities are mainly characterized by villous atrophy, crypt hyperplasia, and lymphocyte infiltration of the small mucosa caused by T-cell responses to the enzyme transglutaminase 2^[1] and gluten-derived gliadin peptides^[2]. CD is a lifelong disease that can start at any age. As it involves multiple organs or systems, it may manifest in a wide range of clinical pictures. The only effective therapy for CD is strict dietary abstinence from gluten-containing foods.

During the last few decades, the advent of reliable serologic tests has greatly facilitated in the diagnosis of CD, allowing large-scale screening studies to be performed. Worldwide prevalence rates, determined by a similar sequential testing paradigm [*i.e.*, immunoglobulin A anti-transglutaminase (IgA-tTG) antibodies and/or anti-endomysium antibodies (IgA-EMA) tests] averaged 1:160 in the Western world^[3]. Recent epidemiological data showed that CD is also a common disease in developing countries (Middle East, South Asia, Africa, and South America), with a prevalence similar to that in Western countries^[4]. The prevalence of CD in Brazil has shown significant variation, probably due to the different degrees of miscegenation of the ethnic groups that make up the Brazilian population, especially Amerindians, Afro-descendants, and Europeans. Screening studies performed during the last decade in distinct Brazilian regions showed prevalence rates varying from 1:214 to 1:681 in presumably healthy blood donors^[5-8], and from 1:119 to 1:417 in the

general population^[9,10]. The geographical variation in the prevalence rates may also be due to differences in genetic background, age-related differences of exposure to gluten, and/or to changes in environmental risk factors. Due to the widely variable pattern of its clinical spectrum, the confirmatory diagnosis of CD can be delayed, after being left unrecognized for many years^[11,12].

Traditionally, CD has been regarded as a disease of childhood and early adulthood that rarely develops in older people. Nevertheless, during the last few decades, diagnosis of CD among adults and the elderly has increased, including patients 70 years of age and older. CD is considered a lifelong disease and consequently a progressive increase in its prevalence would be expected in older age groups.

Nevertheless, studies focusing on this topic are rather controversial. While some of the studies pointed to a high prevalence of CD in older age groups^[13,14], others showed a higher prevalence in children and adolescents^[10,15,16].

In a previous study, we found an increased prevalence of CD in children compared with adults and elderly individuals^[10]. Following the same line of research, in this study we aimed to determine the prevalence of CD in elderly Brazilians over 60 years of age, all of them living in the same geographic region and belonging to similar socioeconomic and cultural backgrounds as the children evaluated in our previous study.

MATERIALS AND METHODS

The research protocol was approved by the Ethics Committee of the University of Brasilia School of Medicine. All individuals included in the protocol were informed about the objectives, related risks, and benefits of this study, and agreed with the use of the collected specimens for research. Between May 2010 and July 2011, a total of 946 outpatients (295 male and 651 female) aged 60 years or older had a blood sample collected and stored at -20 °C until their use. The subjects' mean and median ages were 68.1 and 67 years, respectively, ranging from 60 to 92 years. That age distribution closely corresponded to the age distribution of the Brazilian population according to the 2010 census^[17].

The participants were consecutive and unselected outpatients undergoing blood tests at the Clinical Pathology Laboratory of the University of Brasilia Hospital. The most frequent reasons for blood testing were routine health check-up, suspected or recurrent infections, chronic ailments, metabolic disorders, and pre-operative check-up. Patients from the gastroenterology outpatient clinic were excluded to avoid a selection bias. No other exclusion criteria were applied, regardless of the possible existence of symptoms or conditions commonly associated with CD.

The University of Brasilia Hospital is a public reference hospital that predominately serves a low-income population from the city of Brasilia and the surrounding area in the midwest region of Brazil. Such individuals usually depend on the Governmental National Health

System. They exhibit mixed ancestry, with a considerable contribution of European intermixed with variable parcels of other races, mainly Afro-descendants and Amerindians.

The serum samples from the patients were tested for IgA-human anti-tissue-transglutaminase-IgA (htTG) antibodies using an IgA-htTG enzyme-linked immunosorbent assay Kit (QUANTA Lite® h-tTG IgA Inova Diagnostic, Inc. San Diego, CA, United States). The limit of positivity was set at 20 arbitrary units, in accordance with the manufacturer's instructions. As a second step, all IgA-htTG positive samples were further tested for the presence of IgA-EMA antibodies using indirect immunofluorescence on primate distal esophagus cryostatic sections (Inova Diagnostic, Inc. San Diego, CA, United States).

All individuals who exhibited positive serologic results for IgA-tTG and/or IgA-EMA antibodies underwent HLA genotyping. Genomic DNA was extracted from peripheral venous blood samples using the Illustra™ blood genomicPrep. Mini Spin Kit (GE Healthcare, Buckinghamshire, United Kingdom). HLA-DQA1*0501 (DQ2 α chain), HLA-DQB1*02 (DQ2 β chain), HLA-DQA1*0301 (DQ8 α chain), and DQB1*0302 (DQ8 β chain) genotyping was performed by polymerase chain reaction amplification using sequence-specific primers (PCR-SSP). For internal positive amplification control, each PCR reaction included a primer pair for a conserved region of the *DRB1* gene. The amplified products were separated using 2% agarose gel, stained with ethidium bromide and then visualized under an ultraviolet transilluminator.

RESULTS

Out of the 946 subjects, only a single previously diagnosed case of biopsy-proven CD in a 66-year-old woman was detected. Among the remaining subjects, nine serum samples tested positive for IgA-tTG antibodies. None of the patients tested positive for IgA-EMA antibodies. HLA genotyping disclosed the presence of one CD predisposing allele in three of the IgA-tTG positive elderly. The clinical and laboratory data of the nine patients who tested positive for IgA-tTG antibodies are depicted in Table 1. These data showed that among those 946 elderly individuals, the prevalence of CD ($n = 1$) was 0.1% (95%CI: 0.00-0.59).

The prevalence of CD for the elderly group was compared with that observed for the group of 2034 children younger than 15 years (age range, 1-14 years; mean age, 8 years) who took part in our previous CD prevalence screening study^[10]. All the children came from the same geographical region and presented a similar ethnic and low-income background. As in the elderly group in the current study, the younger group was made up of consecutive outpatients who underwent blood evaluation at the University of Brasilia Hospital's Clinical Laboratory. The prevalence of biopsy-proven CD ($n = 11$) among

those 2034 children was 0.54% (95%CI: 0.27-0.57).

DISCUSSION

Out of the 946 elderly individuals tested in this study, only a single case of previously-detected CD was found. Although nine individuals showed moderately increased levels of anti-tTG antibodies ranging from 30.6 to 52.3, no subjects tested positive for IgA-EMA antibodies. Although IgA-tTG is an effective screening test for CD, occasional anti-tTG false positive results cannot be excluded, especially in the presence of other autoimmune diseases^[18,19]. The clinical effectiveness of the IgA-tTG test is improved if its positive results are confirmed with the IgA-EMA test^[20] and by the presence of predisposing alleles on HLA PCR-SSP typing. Typing for HLA-DQ2 and HLA-DQ8 is a useful tool for either excluding CD or making its diagnosis unlikely in the case of a negative test result for both markers^[21,22]. Predisposing HLA alleles were present in only three of the subjects who tested positive for IgA-tTG antibodies. A jejunal biopsy was suggested and refused by both patients carrying the higher degree of risk allele DQB1*0201, although they agreed in being followed with periodical clinical evaluations and serological testing.

The results of this current screening are in agreement with the result obtained in our previous study, in which an unanticipated variation in the prevalence of CD was found^[10]. In this study performed in the same geographical area with a similar population group, most cases of CD were clustered in the younger age group, with the prevalence of CD in children aged 1 to 14 years being 2.6 times higher than the one found for adults and elderly individuals (5.44 *vs* 2.11 per 1000, respectively). This variation in the prevalence of CD between different age groups was actually unexpected, considering that intestinal sensitivity to gluten is a permanent condition. Aside from gluten ingestion, CD might be triggered at any stage of life by additional environmental factors that remain largely unknown. Thus, a progressive increase in prevalence rates towards advanced ages or, at least, a similar rate throughout life would be expected. Recent studies in Finland by Vilppula *et al*^[13,14] showed an increase in the prevalence of CD among individuals over 52 years of age compared with the general prevalence in Finnish children (2.13% *vs* 1%). Furthermore, the authors also demonstrated an increasing prevalence throughout a three-year period for the same group, going from 2.13% to 2.34%, and resulting in an annual CD incidence of 0.08% in that population. However, several other studies report contradictory results by showing a higher prevalence of CD in younger populations^[15,16,23,24].

Several hypotheses have been suggested to explain this discordance in the prevalence rates among different age groups, although none have been definitely proven. One hypothesis offered to justify a higher prevalence in the younger age group is that the incidence of CD, similarly to other autoimmune diseases, is progressively

Table 1 Clinical and laboratory data of patients who tested positive for immunoglobulin A anti-transglutaminase antibodies by enzyme-linked immunosorbent assay

| Patient | Sex | Age (yr) | tTG | EMA | HLA | Symptomatology and associated disorders |

increasing worldwide. CD was considered a rare disease until the late 1970s, and its prevalence was estimated to be as low as 0.03%^[25]. With the advent of highly sensitive and specific serological tests, a dramatic rise in its prevalence was observed during the following decades. However, this increase would not be solely due to better diagnostic methods that enabled extensive screening studies and diagnosis of atypical forms of the disease; consistent with other autoimmune disorders that have shown rising incidence rates over the last few decades^[26], CD would also have shown a significant increase in its prevalence, consequently justifying the increased number of cases found among younger age groups^[27,28]. Although the causes underlying this increased age-related prevalence remain unknown, likely explanations include environmental influences (such as changes in quantity and quality of cereal processing), changed patterns of early childhood exposure to infectious agents that impair the natural development of the immune system (hygiene hypothesis)^[29], and changes in infant dietetic habits^[30].

Another possible cause for an increased CD prevalence in the younger population was suggested by Mariné *et al*^[15], who proposed that a significant number of CD cases that appear during childhood progress to a latent form or into total gluten tolerance. Those patients would therefore exhibit negative serologic results as they got older. Several other studies support this hypothesis^[31-33], although the number of described spontaneous recoveries of normal villous architecture in CD patients on a gluten-containing diet is generally small^[34] and it is uncertain as to whether these clinically silent periods accompanied by negative serologic tests can be considered only temporary remissions or actual definitive recoveries. Extended follow-up is therefore required for these patients^[32,35].

A third explanation is the postulated existence of an increased mortality rate among CD patients. Publications addressing this issue are numerous, but conflicting^[28,36,37]. The reported overall mortality rates among CD patients vary from 1.26%^[29] to 3.9%^[19] in studies focusing on undiagnosed CD in adults. Despite the differing results, at least two publications point to undiagnosed CD as a major cause of increased morbidity and mortality among individuals with the disease^[28,38].

These three hypotheses are not mutually exclusive, and it is both possible and probable that each of these factors contribute, to a greater or lesser degree, to the observed variation in the prevalence of CD in elderly individuals, depending on the different environmental conditions found in distinct regions or countries.

In Brasilia, many of the low-income adult population came from poor regions of the country, where they have had little or no access to medical care during childhood, and awareness of CD was somehow deficient among healthcare professionals. In these regions, CD knowledge several decades ago was not much different from that before effective treatment for CD was established. Even with the current facilities for the proper diagnosis and compliance of CD patients, diet behaviors among individuals of economically disadvantaged backgrounds in Brazil is still far from ideal.

In Finland, the higher prevalence of CD in patients aged over 52 years and the lower CD mortality rate^[13,14] are noteworthy. Comparisons between Finland and Brazil are contentious at best, since they occupy different positions in the World Health Organization's health system ranking of countries^[39] (31st and 125th, respectively). If this same survey was again performed in Brasilia, but instead focused on a higher socioeconomic group with a higher quality of life, the outcomes would probably have been different.

Our study has potential limitations that should be noted. The screening of the elderly group was conducted in a single geographic setting and the participants were unselected outpatients undergoing routine blood tests, although both groups, children and elderly, were similar with regard to their ethnicity and socioeconomic level. In addition, the number of elderly screened was insufficient to reach statistical significance ($P = 0.06$). In spite of these drawbacks, this study supports our previous findings of an age-related variation in the prevalence rate of CD. Only a single biopsy-proven previously diagnosed case of CD was identified among the elderly group, showing that the prevalence of CD among the children of our previous study was 5.4 times higher than that found in the present elderly group. These findings reinforce that, for the low socioeconomic populations

of our region, prevalence of CD is unexpectedly higher in children compared to older individuals, and that this discrepancy increases towards older ages. We hypothesize that among the plausible explanations for the discrepancy between the CD prevalence rates among children and elderly, the most likely culprit would be an increased mortality rate among undiagnosed celiac disease patients.

COMMENTS

Background

Epidemiological studies during the last few decades have shown an increasing prevalence of celiac disease over time, not only in Europe and in people of European ancestry, but also in developing countries. Socioeconomically disadvantaged population groups in developing countries additionally suffer from a low level of awareness, clinical suspicion of this disorder among physicians, and difficult access by the patient to diagnostic methods, which result in unrecognized or delayed diagnosis of celiac disease (CD). Additionally, patients in whom an appropriate diagnosis is reached have their treatment hampered by an impossibility to use commercial gluten-free products, which are too expensive for these populations, as well as the lack of patients' awareness and information regarding their diet gluten content.

Research frontiers

Overcoming the difficulties of treating CD in the context of developing countries implies the introduction of CD diagnostic laboratory tests as routine in the State Health System, funding research of cheap sources of gluten free foods, and an increased recognition of CD and of its symptoms.

Applications

The results obtained in this study may provide support for future epidemiological studies to map the onset of CD in different age groups in at-risk populations in developing countries. It can additionally contribute to the adoption of public health policies that will allow the socioeconomically disadvantaged access to health services for medical consultations, laboratory tests and, after diagnosis, financial support for a lifelong gluten-free diet.

Peer review

In this interesting survey, the authors report their results on the prevalence of celiac disease in a typical Brazilian population. The manuscript is very well written. The abstract is appropriate in length and content. The results are reported clearly. The discussion is exhaustive and provides an interesting view of this controversial topic.

Abstract

AIM: To compare the new Olympus V-scope (VS) to conventional endoscopic retrograde cholangiopancreatography (ERCP).

METHODS: Forty-nine patients with previous endoscopic papillotomy who were admitted for interventional ERCP for one of several reasons were included in this single-centre, prospective randomized study. Consecutive patients were randomized to either the VS group or to the conventional ERCP group. ERCP-naïve patients who had not undergone papillotomy were excluded. The main study parameters were interventional examination time, X-ray time and dose, and premedication dose (all given below as the median, range) and were investigated in addition to each patient's clinical outcome and complications. Subjective scores to assess each procedure were also provided by the physicians and endoscopy assistants who carried out the procedures. A statistical analysis was carried out using the Wilcoxon rank-sum test.

RESULTS: Twenty-five patients with 50 interventions were examined with the VS ERCP technique, and 24 patients with 47 interventions were examined using the conventional ERCP technique. There were no significant differences between the two groups regarding the age, sex, indications, degree of ERCP difficulty, or interventions performed. The main study parameters in the VS group showed a nonsignificant trend towards a shorter interventional examination time (29 min, 5-50 min vs 31 min, 7-90 min, $P = 0.28$), shorter X-ray time (5.8 min, 0.6-14.1 min vs 6.1 min, 1.6-18.8 min, $P = 0.48$), and lower X-ray dose (1351 cGy/m², 159-5039 cGy/m² vs 1296 cGy/m², 202.2-6421 cGy/m², $P = 0.34$). A nonsignificant trend towards fewer adverse events occurred in the VS group as compared with the conventional ERCP group (cholangitis: 12% vs 16%, $P = 0.12$; pain: 4% vs 12.5%, $P = 0.33$; post-ERCP pancreatitis: 4% vs 12.5%, $P = 0.14$). In addition, there were no statistically significant differences in assessment by the physicians and endoscopy assistants using subjective questionnaires.

CONCLUSION: ERCP using the short-guidewire V-system did not significantly improve ERCP performance or patient outcomes, but it may reduce and simplify the ERCP procedure in difficult settings.

Conventional endoscopic retrograde cholangiopancreatography vs the Olympus V-scope system. *World J Gastroenterol* 2013; 19(12): 1936-1942 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1936.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1936>

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is a complex diagnostic and therapeutic approach that is used to identify and treat various hepatobiliary and pancreatic diseases. ERCP is a time-consuming, expensive, and laborious method that requires the patient to be exposed to substantial doses of premedication, contrast medium, and X-rays, especially when difficult cannulation of the papilla, biliary, or pancreatic ducts or strictures occurs and/or difficult interventions are performed^[1-5]. Thus, future advances to simplify the technical process of ERCP, reduce known ERCP risks for the patient, and reduce the time and effort of the physician for this procedure, as well as attempts to reduce costs, are important issues given the restricted financial resources of hospitals regarding radiation protection, hygiene, and the need for greater patient safety^[5-10].

With the release of a specialised side-viewing endoscope from Olympus [V-scope (VS)], which contains a specialised elevator lever with a V-groove in combination with the use of a specialised short guidewire system and a V-holder, further optimization of the entire ERCP process appears possible. The VS, including the V-groove of the elevator lever and the V-holder and its dedicated guidewires, was constructed to help the endoscopist secure the guidewire at a particular visible length during accessory exchange. This allows the physician to perform a guidewire or accessory exchange by him/herself and may thus lead to quicker instrumentation when working with or without assistance^[11-14]. In addition, the availability of a specialised short guidewire (2.6 m in length) and corresponding accessories promises to improve guidewire handling during ERCP and to increase hygienic aspects of ERCP, and it may also reduce the efforts of physicians and assistants^[12-14].

To analyse this procedure systematically, we performed a randomized prospective pilot trial to explore and document whether clinical, practical, and subjective improvements occur in daily ERCP practice when using the VS and its dedicated guidewire system as compared with conventional ERCP (without a VS, usually using long guidewires of 4.0-4.5 m in length). The main objectives were to evaluate the parameters of interventional examination time, X-ray time and dose, premedication dose, and interventions. In addition, subjective scores from physicians and endoscopy assistants were obtained to provide information about practical handling, hygienic aspects, and the convenience of this new ERCP method at a tertiary care university medical centre.

MATERIALS AND METHODS

Patient population

From June to October, 2007, 49 consecutive patients who were admitted to the Department of Medicine 1 of the University Erlangen-Nuremberg for interventional ERCP were included in this ERCP pilot trial if they

ERCP: Endoscopic retrograde cholangiopancreatography.

had a previous endoscopic papillotomy and had one or more of the following conditions choledocholithiasis or hepaticolithiasis, malignant or benign bile duct stenosis, and chronic pancreatitis or pancreatic tumour. In addition, patients agreed to participate in this pilot trial with randomization to one ERCP technique, the collection of prospective scientific documentation, and the evaluation of their clinical and ERCP findings. Patient characteristics and indications for interventional ERCP are given in Table 1. All patients gave informed consent to participate and agreed to the collection of scientific documentation of the examination results. This clinical study was carried out in accordance with the Helsinki declaration.

Because cannulation of native papilla, papillotomy, and potential treatment of its associated risks may require a substantial amount of time, ERCP-naïve patients without papillotomy were excluded from this study, as were patients with coagulation disorders, septic cholangitis, or severe cardiovascular or pulmonary disease or who were pregnant^[5,9,15,16].

Informed consent to participate in this practice study was obtained the evening before the scheduled ERCP. Thirty minutes before the scheduled ERCP procedure, patients were randomized either to ERCP using the VS and its dedicated (short) guidewire system (VS group) or to conventional ERCP.

ERCP and interventions

ERCP in the VS group was performed with the commercially available Olympus side-viewing VS (TJF160 VR; Olympus, Hamburg, Germany), which contains a modified elevator lever with a V-groove and a specialised fixable guidewire system. The V-groove of the elevator lever induces an increased angle of articulation in the VS and allows complete locking of a specialised guidewire for use with the VS^[13,14,17]. This guidewire consists of a linear guide and a flexible hydrophilic tip (5 cm in length) combined with a long, stiff nitinol wire (0.35 mm in diameter, 2.6 or 4.2 m in length); both the linear guide and the nitinol wire have endoscopically visible markings at 5 cm (Olympus). In addition, a V-holder, which attaches to the working channel of the VS, allows the physician, in conjunction with securing the guidewire with the newly constructed V-elevator, to perform changes of instru-

ments and accessories (*e.g.*, appropriate baskets, balloons, papillotomes, *etc.*; Olympus) with or without assistance. This procedure accelerates instrumentation and may reduce X-ray time because of endoscopically visible control of the fixed guidewire^[13,14,17].

ERCP in the conventional ERCP group was performed with a side-viewing duodenoscope (Olympus TJF160) and typical 4.0- to 4.8-m-long guidewires (Terumo radifocus guidewire, flexible hydrophilic; Terumo Corporation, Leuven, Belgium; straight green guidewire, Teflon coated; Dispomedica, Hamburg, Germany; tracer metro wire guide; Aqua Coat Tip, Cook Ireland Ltd., Limerick, Ireland) and corresponding accessories (catheters, bougies, baskets, balloons, *etc.*)^[1,2,18-20]. Exchange of instruments was performed conventionally, and only if necessary, using fluoroscopy with the endoscopist pressing down the elevator lever and carefully withdrawing the instrument, while the assistant tried to retain the position of the guidewire in the cannulated area.

In brief, interventional ERCP in both groups was performed using the following steps: first prosthesis extraction (if necessary for exchange), cannulation of the papilla, visualization of the biliary system or pancreatic ducts with contrast medium (Peritrac 300/60%; Dr. Köhler Chemie GmbH, Alsbach Hähnlein, Germany), radiological documentation of pathological findings in two radiological axes, selective cannulation of pathologically changed biliary or pancreatic ducts using appropriate guidewires, performance of one or more interventions (*e.g.*, bougienage, concrement extraction, prosthesis insertion, *etc.*), and radiological and endoscopic documentation of results.

Of note, the interventional examination time for ERCP did not include insertion of the side-viewing duodenoscope down to the papilla or extraction of the endoprosthesis. To appropriately determine the effects of VS-guided ERCP, the interventional examination time was defined as the start of the ERCP once the side-viewing endoscope had been appropriately positioned in front of the papilla. Timing was started with a stopwatch once the cannulation catheter had been introduced to the working channel of the endoscope for the first time. The interventional examination time ended when the last intervention (endoprosthesis insertion, stone extraction, *etc.*) was completed and the final endoscopic photograph for documentation had been taken. Withdrawal of the endoscope from the patient was not included in the interventional examination time.

X-ray time and dose of each ERCP procedure from the first cannulation until the entire procedure and the final intervention had been finished were automatically registered and documented with the multifunctional digital Axiom artis fluoroscope (AXIOM Artis MP, Siemens, Munich, Germany) for each patient.

ERCPs were performed by two experienced investigators with > 10 years experience in gastrointestinal endoscopy, each of whom had performed more than 1500 ERCPs. Before the start of the trial, both investigators and the endoscopy assistants underwent 2 mo of

learning and training to become familiar with the VS and its fixable guidewire system. During this learning phase, each investigator performed more than 20 VS ERCPs. From this training phase, it became clear that handling, time requirements, radiological or endoscopic control of intrahepatically or intrapancreatically placed guidewires, and the method of performing instrument exchange had to be learned and require repeated training to improve skills and perhaps to reduce intervention times. From the team of endoscopy assistants, four individuals, each with experience of > 1000 ERCPs, were involved in this prospective randomised study.

Physicians and assistants completed the study documents immediately after the end of the ERCP and independently gave subjective scores (0-10, best to worst) in terms of “overall performance of ERCP”, “difficulty of ERCP” and “hygienic performance”. “Overall performance of ERCP” concerned global assessment of the course of the entire ERCP process. “Difficulty of ERCP” was described as the degree of interventional technical difficulty of the ERCP. “Hygienic performance” concerned whether the guidewire or accessories exchange was perfectly hygienic and whether guidewires contacted the patient’s face or head, were ever outside the covered sterile working area, *etc.*

Premedication was achieved in most patients with midazolam/pethidine and in younger patients with high levels of anxiety or in patients with high consumption of alcohol with propofol/pethidine. Conscious sedation was administered and monitored by a second physician who was responsible for analgo-sedation and documentation of all findings relevant to the study. All patients received continuous measurement of cutaneous oxygen saturation, pulse, blood pressure, and adequate oxygen supply during ERCP, which was performed in the prone position.

Cost analysis was also performed for each ERCP case for all consumables used during the study. The institutional costs for the side-viewing endoscopes and personnel costs for training purposes were not included in this analysis.

Statistical analysis

Statistical analysis was done using SPSS (SPSS for Windows Version 16.0.2, Ehningen, Germany) with descriptive statistics (median and range) for all parameters and performance of the Wilcoxon rank-sum test (*U* test). The statistical hypothesis was that use of the Olympus VS and its fixable guidewire system in the VS group would make ERCP faster (interventional examination time), reduce the X-ray time and dose, and reduce the premedication dose. Additional statistical descriptions are provided for subjective scores describing the convenience and performance of each ERCP procedure given by the endoscopists and the assistants.

RESULTS

Table 2 list all objective and subjective parameters used to

Table 2 Objective and subjective score results from comparison of endoscopic retrograde cholangiopancreatography by using the V-scope with conventional endoscopic retrograde cholangiopancreatography

| | ERCP with V-scope/V-system | Conventional ERCP | P value |

| Overall performance of ERCP | 3 (1–8) | 2 (1–7) | 0.51 |
| Hygienic aspects of ERCP | 3 (1–6) | 3 (1–7) | 0.33 |
| Endoscopists (n = 2), median (range) | | | |
| Overall performance of ERCP | 3 (1–8) | 3 (1–7) | 0.47 |
| Position to papilla | 3 (1–7) | 4 (1–7) | 0.29 |
| Difficulty of ERCP, median (range) | 2 (1–2) | 2 (1–3) | 0.49 |

¹Cholangitis was diagnosed by post-procedural elevation of inflammatory markers in conjunction with an intermittent increase in cholestatic enzymes and/or bilirubin, or subfebrile/febrile temperatures after endoscopic retrograde cholangiopancreatography (ERCP). Cholangitis was mild, and cases resolved within a median of 8 d (range, 2–10 d); ²Post-ERCP pancreatitis was diagnosed by elevation of lipase (more than twofold of the upper normal value) and the presence of abdominal pain after ERCP. These patients had mild pancreatitis, and cases resolved after a median of 4 d (range, 2–7 d).

compare ERCP in the VS group and in the conventional group.

Age, indications, and the number and difficulty of interventions were not different between the VS group and the control group. Although the median interventional examination time was 2 min shorter in the VS group (29 min *vs* 31 min), the difference was not statistically signifi-

cant. Similarly, the median X-ray time and dose, as well as the premedication dose, were nearly the same in both groups. Interestingly, fewer adverse events were seen in the VS group, but this difference was also not statistically significant, perhaps because of the low number of cases (Table 2).

Subjective assessment scores by physicians and endoscopy assistants concerning “overall performance of ERCP” also did not reveal any significant differences between the VS group and the conventional ERCP group. Scores were also the same for “hygienic aspects of the ERCP” as assessed by the assistants.

Individual cost analysis of the ERCP materials and accessories used during the ERCP study revealed no significant difference in consumables used. Accessories used in the VS group amounted to 349 EUR (range, 44–673 EUR), and costs in the conventional ERCP group were 335 EUR (range, 135–604 EUR).

DISCUSSION

ERCP is a resource-intensive, complex, interventional, multi-step endoscopic-radiologic procedure for the treatment of various biliary and pancreatic diseases^[1–5,19,22]. However, performance of ERCP, whether it results in therapeutic success or technical failure, harbours a known risk of side effects for the patient (*e.g.*, cholangitis, post-ERCP pancreatitis, analgo-sedation-induced complications, *etc.*), including a radiation risk, which the endoscopy team also experiences. ERCP requires the substantial use of fluoroscopy and expensive materials (balloons, guidewires, *etc.*), and technical success is often accompanied by substantial time and physical efforts on the part of the endoscopist and his/her team of assistants. Thus, further innovations are currently being studied to make ERCP safer for patients, to reduce X-ray dose and premedication, and to simplify the technical ERCP process^[2,6,9,17,21].

One possible future approach for a more convenient and perhaps safer, faster, and easier ERCP procedure may be the use of specialized fixable (short) guidewire systems as compared with the use of conventional long guidewires (4.0–4.5 m), which require longer exchange times. Several studies have been published using prototype VSs and prototype linear guidewires that demonstrated shorter accessory exchange times and a reduced need for guidewire adjustments^[13,14,17,23]. However, the benefit of the use of this Olympus V-system with respect to the overall ERCP outcome, interventional examination time, and fluoroscopy requirements has not been completely evaluated in daily ERCP practice. Thus, in an effort to optimize ERCP quality and hospital costs in a high-volume ERCP centre, an investigator-driven, prospective, randomized pilot trial was performed to explore whether the use of the Olympus VS and its dedicated guidewire system significantly improves the outcome of patients undergoing ERCP or reduces intervention time, fluoroscopy, or the endoscopists’ and assistants’ work, handling, and efforts.

This prospective, single-centre study did not, how-

ever, reveal any statistically significant differences between ERCP using the V-system and conventionally performed ERCP in terms of interventional examination time, fluoroscopy, analgo-sedation requirements, or subjective assessments obtained from the endoscopists and the endoscopy assistants. Interestingly, interventional examination time was somewhat shorter in the VS group (29 min) than in the control group (31 min), despite the need to perform additional endoprosthesis insertions in the VS group (Table 2), raising the question of whether the study population was too small to observe significant differences. Alternatively, this result may merely reflect the high quality and training status of the individuals who carry out conventional ERCP at a high-volume tertiary ERCP centre (> 1000 ERCPs per year).

Joyce *et al*^[17], in a previous multicentre comparative trial, also did not demonstrate any significant effect of the V-system on ERCP examination time or on fluoroscopy time, although they did demonstrate significant benefits of the V-system when particular individual ERCP working steps were analysed, such as the median exchange time of accessories or the need for guidewire repositioning. Combined with our findings, these data show that a possible improvement in one single working step in ERCP (*e.g.*, exchange of accessories) is not necessarily coupled with an improvement or reduction in the entire examination or fluoroscopy time, especially when varying degrees of case difficulties are being treated by various experienced endoscopists^[5,7,11-14,17,24]. However, the real benefit of V-system-guided ERCP may become relevant when the high interindividual variation in ERCP complexity and the different experiences of endoscopists are compensated for in an appropriate follow-up study protocol in which one patient is examined by the same investigator during follow-up interventions, such as endoprosthesis replacement, stone extraction, *etc.*, using both ERCP techniques. Such a stratified study protocol that would compare both ERCP techniques performed by one endoscopist on the same patient with the same therapeutic indication promises to better demonstrate whether a real benefit exists concerning interventional examination time and possibly other ERCP parameters including quality or outcome findings when using the V-system.

This small, prospective, randomized, single-centre pilot ERCP study in routine patients showed that several other uncontrolled factors during ERCP intervention influenced the examination time and radiation requirements more than the proposed time saving that is attributed to the V-system^[11-14,17-19,21,25,26]. Thus, from the experience gained during the use of the VS and its short guidewire system, it became apparent that the V-system may be helpful in individual cases with repetitive interventions and several instrument changes (*e.g.*, multiple stenting, numerous stone extractions), but these impressions have not yet been objectively proven with a corresponding interventional ERCP study.

Although previous studies dealing with the use of the V-system have focused primarily on technical aspects and

time requirements of single ERCP working steps^[14,15,17], this prospective pilot trial also documented all adverse events and analgo-sedation requirements in each group. Interestingly, in the VS group, the frequency of adverse events in terms of abdominal pain lasting longer than 24 h, cholangitis, and post-ERCP pancreatitis was not significantly different as compared with that of the conventional ERCP group. However, the tendency of fewer instances of post-ERCP pancreatitis in the VS group raises the question of whether the completely fixed guidewire within the pancreatic duct reduces mechanical irritation of the pancreatic tissue, which may be a cause of an inflammatory response during conventional ERCP. This unexpected observation warrants further prospective studies, because post-ERCP pancreatitis is still a major adverse event following ERCP procedures^[4,16,18,19].

Cost evaluation of the consumables used in each case revealed that both ERCP techniques have nearly the same cost to the hospital according to Germany University prices. This analysis does not favour the exclusive use of only one ERCP technique.

In addition, evaluation of the subjective assessment scores from endoscopists and the endoscopy assistants also demonstrated no advantage of the V-system as compared with the conventional ERCP technique. The overall performance of ERCP and the hygienic aspects of ERCP were similar in the VS group and in the conventional group, although working with shorter guidewires may be more convenient for the personnel than longer guidewires^[12-15,17]. However, as discussed above, these results may be related to the high training status of the personnel at our high-volume ERCP centre and to the fact that performing a safe and effective bougienage within the biliary system or pancreas requires the use of the long linear guidewire (4.2 m), which may have influenced the judgement of the personnel. Subjective assessment may vary according to the training status of the endoscopy team, which would preclude the translation of these results to low-volume endoscopy hospitals.

In conclusion, this prospective ERCP trial using the VS and V-system did not show a significant advantage of this dedicated short guidewire system at a high-volume ERCP centre as compared with the conventional ERCP technique. The real value of this V-system in ERCP practice requires further investigation in follow-up interventional studies that compensate for interindividual variation in both patients and endoscopists. Studies should be performed in low-volume endoscopy centres as well.

ERCP materials were provided by Olympus, Hamburg, Germany.

COMMENTS

Background

Endoscopic retrograde cholangiopancreatography (ERCP) is a complex and cost-intensive diagnostic and therapeutic approach for the identification and

treatment of hepatobiliary and pancreatic disorders. To simplify this method, many new endoscopic techniques and instruments are currently being developed. In this pilot study, authors compared the new Olympus V-Scope (VS) system with the normal Olympus duodenoscope in patients admitted for interventional ERCP.

Research frontiers

The new VS system with its specialized fixable guidewire system (Olympus TJF160 VR) was evaluated and compared to the conventional ERCP technique (Olympus TJF160) with respect to the interventional examination time, X-ray time and dose, premedication dose, frequency of adverse events, handling in daily routine, and cost effectiveness.

Innovations and breakthroughs

Although detailed parameters of the ERCP technique and the outcomes were carefully assessed, no statistically significant differences were found between ERCPs performed with the VS and V-system and those performed using the conventional ERCP technique. Objective parameters such as interventional examination time and X-ray dose, outcome parameters such as adverse events, and subjective assessment scores by the endoscopy personnel were all similar in both ERCP technique groups. However, the study group was small, various levels of ERCP difficulty were included, and the results may have been influenced by the high-level training status of the personnel at our high-volume ERCP centre.

Applications

Regarding the fairly small number of patients, this study was designed as a pilot study to provide preliminary results concerning future study parameters for sample size estimations, outcome parameters and cost assessments. In further studies with a larger number of patients, the potential benefits of the Olympus V-system may be better evaluated when including only one or two defined ERCP indications and by including endoscopists who examine the same patient during follow-up and use both ERCP techniques.

Terminology

ERCP: A diagnostic and therapeutic tool for selective radiographic illustration of the biliary tract and pancreatic ducts that enables important interventions such as endoprosthesis insertion for drainage, stone extraction, or tumour palliation *via* short or long guidewire techniques. The Olympus side-viewing VS contains a modified elevator lever with a V-groove, which allows the use of short guidewires that can be fixed. However, these potential advantages have not yet been shown to improve the technical aspects of ERCP instrumentation, patient outcomes, or adverse events.

Peer review

This pilot study carefully assessed several outcomes and technical and subjective parameters of both ERCP techniques. Perhaps because of the small number of patients, no significant differences were demonstrated between ERCP using the V-system technique and conventional ERCP. The results obtained may be used for sample size calculation for a larger, more definitive study with more homogeneous ERCP indications.

Abstract

AIM: To evaluate the impact of sociodemographic/clinical factors on early virological response (EVR) to peginterferon/ribavirin for chronic hepatitis C (CHC) in clinical practice.

METHODS: We conducted a multicenter, cross-sectional, observational study in Hepatology Units of 91 Spanish hospitals. CHC patients treated with peginterferon α -2a plus ribavirin were included. EVR was defined as undetectable hepatitis C virus (HCV)-ribonucleic acid (RNA) or ≥ 2 log HCV-RNA decrease after 12 wk of treatment. A bivariate analysis of sociodemographic and clinical variables associated with EVR was carried out. Independent factors associated with an EVR were analyzed using a multiple regression analysis that included the following baseline demographic and clinical variables: age (≤ 40 years *vs* > 40 years), gender, race, educational level, marital status and family status, weight, alcohol and tobacco consumption, source of HCV infection, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels, and gamma glutamyl transpeptidase (GGT) (≤ 85 IU/mL *vs* > 85 IU/mL), serum ferritin, serum HCV-RNA concentration ($< 400\,000$ *vs* $\geq 400\,000$), genotype (1/4 *vs* 3/4), cirrhotic status and ribavirin dose (800/1000/1200 mg/d).

RESULTS: A total of 1014 patients were included in the study. Mean age of the patients was 44.3 ± 9.8 years, 70% were male, and 97% were Caucasian. The main sources of HCV infection were intravenous drug abuse (25%) and blood transfusion (23%). Seventy-eight percent were infected with HCV genotype 1/4 (68% had genotype 1) and 22% with genotypes 2/3. The HCV-RNA level was $> 400\,000$ IU/mL in 74% of patients. The mean ALT and AST levels were 88.4 ± 69.7 IU/mL and 73.9 ± 64.4 IU/mL, respectively, and mean GGT level was 82 ± 91.6 IU/mL. The mean ferritin level was 266 ± 284.8 μ g/L. Only 6.2% of patients presented with cirrhosis. All patients received 180 mg of peginterferon α -2a. The most frequently used ribavirin doses were 1000 mg/d (41%) and 1200 mg/d (41%). The planned treatment duration was 48 wk for 92% of patients with genotype 2/3 and 24 wk for 97% of those with genotype 1/4 ($P < 0.001$). Seven percent of patients experienced at least one reduction in ribavi-

rin or peginterferon α -2a dose, respectively. Only 2% of patients required a dose reduction of both drugs. Treatment was continued until week 12 in 99% of patients. Treatment compliance was $\geq 80\%$ in 98% of patients. EVR was achieved in 87% of cases (96% *vs* 83% of patients with genotype 2/3 and 1/4, respectively; $P < 0.001$). The bivariate analysis showed that patients who failed to achieve EVR were older ($P < 0.005$), had higher ALT ($P < 0.05$), AST ($P < 0.05$), GGT ($P < 0.001$) and ferritin levels ($P < 0.001$), a diagnosis of cirrhosis ($P < 0.001$), and a higher baseline viral load ($P < 0.05$) than patients reaching an EVR. Age < 40 years [odds ratios (OR): 0.543, 95%CI: 0.373-0.790, $P < 0.01$], GGT < 85 IU/mL (OR: 3.301, 95%CI: 0.192-0.471, $P < 0.001$), low ferritin levels (OR: 0.999, 95%CI: 0.998-0.999, $P < 0.01$) and genotype other than 1/4 (OR: 4.716, 95%CI: 2.010-11.063, $P < 0.001$) were identified as independent predictors for EVR in the multivariate analysis.

CONCLUSION: CHC patients treated with peginterferon- α -2a/ribavirin in clinical practice show high EVR. Older age, genotype 1/4, and high GGT were associated with lack of EVR.

INTRODUCTION

Until recent approval of the first direct acting antivirals (DAAs) against hepatitis C virus (HCV)^[1-4], the combination of pegylated interferon and ribavirin was the standard of care (SOC) for chronic hepatitis C (CHC)^[5-8] with the goal of achieving a sustained viral response (SVR) [undetectable hepatitis C virus ribonucleic acid (HCV-RNA) at week 24]. However, the overall SVR rate with standard peginterferon and ribavirin combination does not exceed 56%-63%^[5,9,10], and is even lower in some patient subgroups^[10]. Indeed, pivotal studies showed that HCV genotype 1 patients achieve a SVR rate of 41%-56%, whereas in those infected with HCV genotype 2/3, a SVR is obtained in 74%-80%^[5,9,11]. Variability in virological response depends on diverse patient factors as well as virological and histological factors. Genotype other than 1, low baseline viral load, age less than 40 years, body weight ≤ 75 kg and absence of advanced fibrosis and/or cirrhosis have been identified as predictive factors of SVR in the studies evaluating peginterferon α -2a plus

ribavirin combination^[9,12].

Pivotal studies have shown that early virological response (EVR) is highly predictive of SVR^[9,13]. Accordingly, patients who do not achieve an EVR have an almost null probability of achieving a SVR^[9,13-15]. The study conducted by Fried *et al*^[9] showed that only 3% of patients who did not obtain an EVR with peginterferon α -2a plus ribavirin achieved a SVR. The high negative predictive value (PPV) of EVR has great clinical value as it allows us to decide whether to continue or discontinue treatment at week 12, therefore preventing or minimizing the adverse effects related to treatment continuation. Current treatment guidelines for hepatitis C include this decision criteria at week 12^[5,7,8,16] and recommend discontinuation of treatment in patients who fail to achieve an EVR. In addition, the clinical utility of EVR has been demonstrated in the routine clinical practice setting, particularly in genotype 1-infected patients^[17].

Limited data have been reported regarding the EVR predictive factors in patients receiving peginterferon α -2a plus ribavirin combination therapy. Correct identification of these factors could be a useful strategy to optimize treatment in CHC and improve SVR rates, particularly in patients with genotype 1. On the other hand, treatment adherence is key to achieve successful treatment. The occurrence of adverse effects associated with peginterferon and/or ribavirin is the main reason for dose reduction or treatment discontinuation. As a result, 15%-20% of patients participating in clinical trials and approximately 25% of those in routine clinical practice discontinue treatment^[18]. Lack of adherence during the first 12 wk of treatment has been shown to have a particularly negative impact on EVR^[13,19]. Thus, the PPV of EVR associated with good treatment compliance is very high, achieving a SVR in 75% of cases with EVR and good treatment adherence^[9].

Given that sociodemographic and clinical factors associated with EVR are not well known and considering that treatment adherence is a variable closely related to EVR, characterization of viral and patient factors associated with treatment compliance, and hence EVR, has important clinical implications. The present study was designed to analyze baseline sociodemographic and clinical characteristics associated with EVR and antiviral treatment compliance in CHC patients treated with peginterferon α -2a in the routine clinical practice setting in Spain.

MATERIALS AND METHODS

Study design

This was a national, multicenter, cross-sectional, observational study. The study was carried out in the Hepatology Units of 91 Spanish hospitals. All participating patients gave their written informed consent, and the study was approved by the Clinical Research Ethics Committee of the Hospital Carlos III of Madrid. The study was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice Guidelines and their amendments.

The study included adult patients (over 18 years of age) diagnosed with CHC and treated with peginterferon α -2a plus ribavirin under routine clinical practice conditions. Patients with any contraindication to hepatitis C treatment according to the prescribing information and those with HBV and/or human immunodeficiency virus coinfection were excluded.

The main purpose of the study was to analyze EVR in relation to sociodemographic and clinical characteristics. For this purpose, the following variables were recorded at the start of treatment: age, sex, race, nationality, educational level, marital status, occupation and family status, weight, cigarette smoking, alcohol consumption, source of HCV infection, methadone replacement therapy, alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma glutamyl transpeptidase (GGT) and ferritin levels, cirrhotic status, viremia and HCV genotype. In addition, ribavirin dose and scheduled duration of treatment, dose reductions of peginterferon α -2a and/or ribavirin up to week 12, data on premature treatment discontinuation (week and reason for discontinuation) were also collected. Furthermore, data on HCV-RNA concentrations at week 12 were recorded and EVR was analyzed (complete/partial). HCV-RNA levels were measured using quantitative polymerase chain reaction assays, mostly the Amplicor HCV Monitor (Roche, Kenilworth NJ, United States), although other commercial tests were used in some centers. A lower limit of detection of 50 IU/mL was considered in all participating hospitals. The secondary objective of the study was to evaluate treatment adherence at week 12.

Virological response criteria

EVR was defined as undetectable levels of HCV-RNA at week 12 (complete EVR) or ≥ 2 log reduction in HCV viral load from baseline (partial EVR).

Treatment adherence criteria

To evaluate treatment adherence, compliance was recorded according to the 80/80/80 rule^[20] and modified according to the study design. Treatment compliant or adherent patients were those receiving 80% or more of the total dose of peginterferon α -2a plus ribavirin during 80% of the time until week 12. Likewise, noncompliant patients included those who received $< 80\%$ of the prescribed dose of one or both drugs during $< 80\%$ of the expected duration (12 wk).

Statistical analysis

A descriptive statistical analysis was performed on the sociodemographic and clinical variables collected from the medical records at the start of treatment with peginterferon α -2a plus ribavirin. Quantitative variables were described using measures of central tendency and dispersion (mean, median, SD, minimum, maximum, first quartile and third quartile) and the results are expressed as mean \pm SD or median (range). Qualitative variables are presented as absolute and relative frequencies. To characterize the population based on patient sex and the

influence of sociodemographic and clinical characteristic on EVR, a bivariate analysis was carried out using Student's *t* test for quantitative variables and the chi-square test for the remaining sociodemographic and clinical qualitative independent variables. Similarly, a bivariate analysis of sociodemographic and clinical variables associated with EVR was carried out based on patient race. Variables with statistical significance or with $P < 0.10$ in the bivariate model were analyzed in a multivariate logistic regression model. Some factors that were not statistically significant were retained in the model based on previous clinical evidence. Odds ratios (OR) and 95%CI were calculated for the independent predictive factors of EVR. In the multivariate logistic regression analysis, only patients with available data for all the variables taken into account for the analysis were included. Significance level was set at $P < 0.05$. The statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS) version 17.0 (SPSS Inc, Chicago, IL, United States).

RESULTS

Baseline patient characteristics

Baseline patient characteristics are shown in Table 1. A total of 1202 patients were included in the study. Thirty-six were excluded as they met at least one of the following criteria: peginterferon dose other than 180 mg (30 patients), negative HCV-RNA at baseline visit (1 patient), HCV-RNA level not available at week 12 when withdrawal had not occurred (8 patients). The number of evaluable patients was 1166, of which 1014 were analyzed and 152 were excluded for having a detectable viral load at week 12 without specifying the value and/or detection level.

Sociodemographic characteristics

Seven hundred and twelve (70%) patients were male. The vast majority of patients were Spanish (91%) and Caucasian (97%). Fifty percent of patients had completed compulsory education. Of the total number of patients, 580 (57%) were married and 898 (89%) patients lived with another person (Table 1).

The mean age was 43.3 ± 9.0 years in men and 46.6 ± 11.4 years in women ($P < 0.001$). No differences were found in race, educational level or family status based on gender. No significant differences were found in baseline sociodemographic characteristics based on race. The only differences noted were a greater proportion of women over 40 who were Caucasian ($P < 0.005$) and a higher educational level among Caucasian patients ($P < 0.01$).

Clinical characteristics

Alcohol consumption was reported in 154 (15%) patients and 514 (51%) were smokers. The most common source of HCV infection was intravenous drug use (25%) followed by transfusion (23%). Mean ALT and AST levels

¹The percentage of patients with dose reduction of peginterferon α -2a and the frequency of patients with dose reduction of ribavirin coincide, but are not exactly the same patients. The frequencies presented correspond to valid percentages. Percentages may not add up to 100 due to rounding error.

with tobacco and alcohol consumption habit was greater in men ($P < 0.001$). The diagnosis of cirrhosis was also more common in men ($P < 0.05$). Intravenous drug abuse as the source of HCV infection was more frequent in men and transfusion was more frequent in women ($P < 0.001$). Among the clinical variables analyzed, there were no differences in baseline viral load level or HCV genotype according to gender, but men had higher ALT, AST and GGT values ($P < 0.001$) and higher levels of ferritin ($P < 0.001$). With regard to ribavirin dose, 800 mg/d and 1000 mg/d were the most common doses given to women, whereas men received the 1200 mg/d dose more frequently ($P < 0.001$).

Peginterferon α -2a plus ribavirin treatment

All patients received 180 μ g of peginterferon α -2a. The most frequently used ribavirin doses were 1000 mg/d (41%) and 1200 mg/d (41%) (Table 2). In accordance with current treatment recommendations, the 1000 mg/d and 1200 mg/d doses of ribavirin were used more often for patients with genotype 1/4 (49% and 45% of patients received doses of 1200 and 1000 mg/d, respectively), whereas more than half of those with genotype 2/3 (58%) received 800 mg/d of ribavirin ($P < 0.001$).

In more than three-quarters of patients, the scheduled duration of treatment was 48 wk (Table 2). For 97% of patients with genotype 1/4, the planned treatment duration was 48 wk and in 92% of those with genotype 2/3 the scheduled duration was 24 wk ($P < 0.001$).

Treatment discontinuation and dose reduction

Sixty-six (7%) patients had their peginterferon α -2a dose reduced on at least one occasion. Of these, 46 (81%) patients had only one dose reduction. Similarly, 66 (7%) patients experienced at least one dose reduction of ribavirin. Of these, 56 (89%) patients had at least one dose

EVR: early virological response; HCV-RNA: Hepatitis C virus ribonucleic acid; IV route: Intravenous route; NS: Not significant.

reduction before week 12. Only 15 (2%) patients required a dose reduction of both drugs (Table 2).

Early virological response

Of 1014 patients included in the analysis, 866 (87%) achieved an EVR. Of these patients, 699 (70%) had a complete EVR and 176 (18%) achieved a partial EVR. The results showed significant differences in EVR depending on genotype, and the percentage of patients with EVR at week 12 was higher in the group of patients with genotype 2/3 (96% *vs* 83% of patients with genotype 2/3 and genotype 1/4, respectively; *P* < 0.001).

Predictive factors of early virological response

Table 3 shows the sociodemographic and clinical characteristics of the early responders (EVR) and non-responders (non-EVR). According to the results obtained from the bivariate analysis, the only sociodemographic variable associated with EVR was age (*P* < 0.005). The clinical variables associated with EVR were ALT (*P* < 0.005), AST (*P* < 0.05) and GGT values (*P* < 0.001), ferritin levels (*P* < 0.001), presence of cirrhosis (*P* < 0.001), viral genotype (*P* < 0.001), and baseline viral load (*P* < 0.05).

In the multivariate analysis, the only sociodemographic factor identified as a predictor of EVR was age (OR: 0.543, 95%CI: 0.373-0.790, *P* < 0.01) and the clinical factors predictive of EVR were GGT level (OR: 3.301, 95%CI: 0.192-0.471, *P* < 0.001), ferritin level (OR: 0.999, 95%CI: 0.998-0.999, *P* < 0.01) and genotype (OR: 4.716, 95%CI: 2.010-11.063, *P* < 0.001). Age ≤ 40 years, GGT level ≤ 85 IU/mL, low ferritin levels and HCV genotype other than 1/4 were independent predictors of EVR (Figure 1).

Adherence to treatment and predictive factors associated with compliance

Treatment compliance was greater than 80% in 971 (97.8%) patients. No significant differences were found between patients with treatment adherence greater than 80% and those whose compliance was less than 80% with regard to their sociodemographic and clinical characteristics (data not shown).

DISCUSSION

The response to treatment with peginterferon plus ribavirin is heterogeneous and non-optimal in several HCV patients, as occurs in those infected with genotype 1, high viral load, advanced fibrosis, metabolic syndrome or non-CC polymorphisms of the interleukin 28b gene (*IL28b*)^[12,13,15,21,22].

EVR is highly predictive of SVR^[9,23] and provides hepatologists with a valuable tool to decide on continuation and duration of treatment, as well as providing patients with an additional motivation to adhere to treatment. The predictive value of EVR in patients infected with genotype 1 in the clinical practice setting in Spain^[17] was previously shown to be comparable to that obtained in pivotal trials^[9,23]. However, although identification of both viral and host factors associated with EVR may be very useful to predict SVR and therefore guide thera-

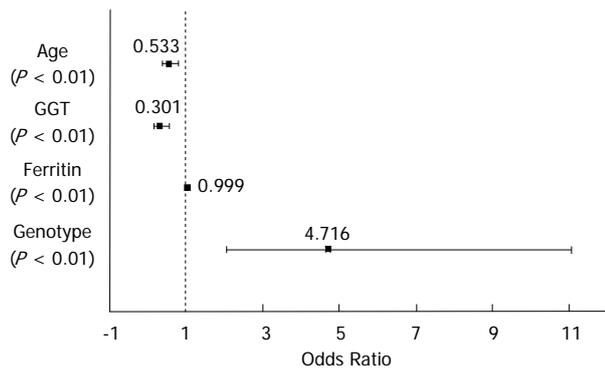

Figure 1 Independent factors associated with an early virologic response according to multiple logistic regression analysis. Baseline demographic factors used in the multiple regression analysis included age (≤ 40 years vs > 40 years), gender, race, educational level, marital status and family status. Clinical baseline factors included in the multiple regression analysis were weight, alcohol and tobacco consumption, source of hepatitis C virus (HCV) infection, alanine aminotransferase, aspartate aminotransferase and gamma glutamyl transpeptidase (GGT) levels (≤ 85 vs > 85), serum ferritin, serum HCV-RNA concentration ($< 400\,000$ vs $\geq 400\,000$), genotype (1/4 vs 3/4), cirrhotic status and ribavirin dose (800/1000/1200 mg/d). An odds ratio equal to 1 (dashed lines) indicates no difference between the subgroups defined according to the given factors. Bars indicate 95%CI. The results demonstrated that age ≤ 40 years ($P < 0.01$), low levels of GGT (≤ 85 IU/L) ($P < 0.001$), low ferritin ($P < 0.01$) and genotype 1/4 ($P < 0.001$) were independent predictors of early virological response.

py^[13], to date, there are limited data available addressing this issue.

To our knowledge, the present study is the largest series from a clinical setting to analyze factors associated with EVR in CHC patients treated with peginterferon plus ribavirin under routine clinical practice conditions. The data analysis showed that 87% of patients achieved EVR. This response rate is comparable or even higher than that reported in international pivotal trials with peginterferon α -2a plus ribavirin^[9,23] and confirm the results reported in previous studies conducted in Spain, also under routine clinical practice conditions, but with a considerably lower number of patients^[17,24]. A complete EVR was observed in 70% of our patients and again this rate was higher than that reported in other previous studies, which ranged from 34% to 64%^[9,10,12,25,26].

As expected, the percentage of patients with EVR was higher in the group of patients with genotype 2/3 than in those with genotype 1/4 according to previous studies^[9,10,27-29]. However, despite including a high percentage of patients with genotype 1 (the most difficult to cure), our study achieved response rates as high as those in the pivotal trials.

Patients who failed to achieve EVR were older, had higher ALT, AST, GGT and ferritin levels, a more frequent diagnosis of cirrhosis and a higher baseline viral load than patients achieving EVR. Most of the limited available studies on factors associated with EVR have shown that low baseline viral load, younger age, absence of overweight/obesity and lack of cirrhosis are independent factors associated with EVR^[30-33]. In our study, age < 40 years, GGT levels < 85 IU/mL, low ferritin levels and

genotype non-1/4 were identified as independent predictive factors of EVR in the multivariate analysis.

Interestingly, a recent study has identified high GGT as a predictor of nonresponse to treatment with peginterferon in patients infected with genotype 1^[34]. The precise mechanism whereby increased GGT levels may affect treatment response in CHC remains a matter of debate, although it may be related either to a more intense degree of necroinflammatory activity, more advanced fibrosis, or to hepatic steatosis^[35,36]. In this regard, a positive correlation between serum GGT levels and the hepatic expression of proinflammatory tumor necrosis factor- α (TNF- α) mRNA in CHC has been suggested^[37]. Indeed, hepatic levels of TNF- α mRNA have been found to be significantly higher in nonresponders to IFN- α -based therapy than in those with a SVR. On the other hand, although the multivariate analysis identified high levels of ferritin as an independent predictor of EVR, this association was clearly irrelevant (OR = 0.999). Therefore, ferritin level may lack clinical validity as a predictive factor of EVR in this setting.

Age was found to be an independent factor for EVR in our study, in agreement with previous series where it was shown that age greater than 40 years is an independent predictor of nonresponse to treatment^[12,29,34]. Furthermore, older patients have been suggested to be more resistant to peginterferon-based therapies since they are more frequently infected by HCV genotype 1b, have a longer disease duration and exhibit greater liver damage than younger patients.

Consistent with most published studies^[10,12,17,38], our findings show that the proportion of women with CHC treated with peginterferon plus ribavirin in routine practice in Spain is much lower in comparison to the proportion of men, in the absence of demographic variables justifying this difference, or known barriers of access to treatment for women. In addition, women are treated at an older age than men. We can speculate that the lower fibrosis severity as well as the higher rate of normal ALT levels in women with CHC can explain the relatively low proportion of female patients treated in our series. Although in some studies women have shown higher response rates than men^[31,38], our data did not show differences in EVR based on gender despite the high proportion of male patients. In light of these results, new epidemiological studies on the prevalence of HCV infection, as well as clinical studies including a larger number of women are needed to determine if there is gender inequality in the prescription of antiviral therapy.

Baseline HCV viral load is a well-known independent predictive factor of treatment response^[12,29-31,33]. In agreement with previous evidence, the patients in our study who achieved EVR were those who had lower baseline viral loads ($< 400\,000$ IU/mL), although viral load did not constitute a predictive factor for EVR in the multiple logistic regression analysis.

Race has been identified as a predictive factor of EVR in previous studies^[12]. The data from our study, despite its large sample size, does not allow us to conclude

that race plays a role in EVR because the vast majority of patients included in the study were Caucasian (97.3%). Furthermore, when the study was designed, genetic analysis of *IL28b* gene polymorphisms, which are related to race^[21], was not available. Indeed, one limitation of our study is the lack of information on IL-28B genotype as it has been described as a relevant predictor of treatment response^[39,40]. However, the impact of the imbalance of this genetic polymorphism between groups on treatment response was described just after the data from this study were collected.

Our study also revealed that Spanish CHC patients treated in routine clinical practice receive the correct doses of each drug according to current treatment guidelines, and this is critical since both dose optimization and treatment duration are essential to maximize response^[17]. The treatment regimen is individualized, according to current guideline recommendations, based on the viral genotype, so that patients with genotype 1/4 are treated with ribavirin in weight-adjusted doses of 1000-1200 mg/d for 48 wk, whereas patients carrying genotypes 2/3 are treated in most cases with ribavirin at a dose of 800 mg/d for 24 wk.

Combination therapy frequently causes adverse effects. Most are mild and controlled by reducing the dose of each drug or with additional treatments including growth factors, but in some cases they require discontinuation of treatment. Various studies have shown that dose reductions and particularly treatment discontinuation are associated with a marked reduction in the EVR rate^[20]. Other reports have noted that dose reductions of peginterferon and/or ribavirin are quite frequent during the first 12 wk of treatment^[13]. However, in the current analysis, only 7% of patients required dose reduction of peginterferon or ribavirin. Moreover, it should be noted that only 7 patients of the total population analyzed discontinued treatment due to serious adverse effects in the first 12 wk. This percentage (less than 1%) is markedly lower than that reported in other studies^[11,41].

Treatment compliance is a variable closely related to EVR^[13,19,20]. It has been shown that lack of adherence during the first 12 wk of treatment has a negative impact on EVR. Previous studies have demonstrated that patients who met the 80/80/80 rule have a greater response than those receiving lower doses or for less time^[20]. In our series, 98% of patients met the 80/80/80 rule up to week 12. Good treatment compliance is one of the factors explaining the high rate of EVR seen in our study. Treatment modifications and the motivation of patients may have had a significant impact on adherence to treatment. The low dose reductions required for both drugs could have encouraged patients to complete the prescribed course of treatment. Additionally, determination of EVR provides patients and physicians with an early goal and motivates them to adhere to treatment recommendations. Moreover, it is noteworthy that patients were treated by hepatologists belonging to units with wide experience in the care of CHC patients.

The main limitations of this study arise from the oc-

currence of the major advance in CHC in the last years, the development of DAAs and the recent approval of the triple therapy as the new SOC for CHC. Nevertheless, despite the obvious change in treatment paradigm, therapy based on peginterferon plus ribavirin will continue to play an important role as SOC, especially for non-1 HCV patients, considering that protease inhibitors must be combined with peginterferon plus ribavirin in genotype 1 patients. In addition, while remarkably effective, the recently approved protease inhibitors are also accompanied by frequent serious toxicities and considerable costs. Therefore, some patients who cannot tolerate protease inhibitors will need to be treated with dual combination given that triple combination regimens have a higher side effect burden^[3,42,43]. Additionally, the high cost of the DAAs will probably preclude the use of triple-combination therapies in health care systems constrained by rising costs and economically disadvantaged regions. It is well known that patients with rapid virological response to dual combination achieve SVR in higher rates, close to 90%, and therefore, despite the above limitations, our findings may be relevant and applicable at the onset of the DAAs era. Furthermore, our findings provide a meaningful assessment of factors associated with EVR regarding applicability to guide therapy of real-world patients given that our study population comprises a larger, more representative cohort of patients than those included in clinical trials evaluating predictive factors of EVR. However, further studies will be needed to validate whether the predictive factors of EVR to dual therapy remain a predictive tool in the context of new DAA agents in the routine clinical practice setting.

In summary, CHC patients treated with peginterferon α -2a plus ribavirin in routine clinical practice in Spain have high EVR rates, similar to those obtained in pivotal studies, and a high level of treatment compliance. Age > 40 years, genotype 1/4 and GGT \geq 85 IU/mL were independent predictive factors of lack of EVR. In the new era of hepatitis C treatment where standard treatment is incorporated with DAAs, identification of predictive factors such as the new definitions of extended rapid viral response will be an essential tool to achieve maximum response rates.

COMMENTS

Background

Peginterferon plus ribavirin is the standard therapy for chronic hepatitis C (CHC) world-wide. Early virological response (EVR) predicts sustained virological response (SVR) in CHC. Although identification of both viral and host factors associated with EVR may be very useful to predict SVR and therefore guide therapy, to date, there are limited data available addressing this issue in clinical practice.

Research frontiers

The high negative predictive value of EVR has remarkable value in clinical practice since it allows to decide whether to continue or discontinue treatment at week 12, therefore preventing or minimizing the adverse effects related to treatment continuation. Indeed, current treatment guidelines for hepatitis CHC include this decision criterion and recommend discontinuing treatment in patients who fail to achieve an EVR.

Innovations and breakthroughs

The present study is the largest series from a clinical setting to analyze predictive factors of EVR in CHC patients treated with peginterferon α -2a plus ribavirin in routine clinical practice. The remarkably high EVR rates obtained in our study were similar to those reported with this dual therapy in pivotal studies, and confirm the data from previous studies in clinical practice in Spain which included a significantly lower number of patients. Age > 40 years, genotype 1/4 and gamma glutamyl transpeptidase (GGT) \geq 85 IU/mL were identified as independent predictive factors of lack of EVR.

Applications

The results from this study may be useful in guiding treatment decision making. In particular, early prediction of virological response to dual therapy can help to

identify candidates who are unlikely to have a SVR before treatment initiation or in the early treatment phase.

Terminology

EVR indicates EVR which is defined as undetectable hepatitis C virus ribonucleic acid (HCV-RNA) or \geq 2 log decrease in HCV-RNA after 12 wk of treatment.

Peer review

This study is well constructed and it is based in a big CHC patient cohort coming from 91 hospitals through all Spanish territory. This is an interesting and relevant study which confirms the results of previous studies with a notably lower number of Spanish cases. Moreover, this study consolidates some basal factors such a GGT levels, age or viral genotype as predictive factors of EVR. This study also highlights the higher rate of ERV in Spain compared with other regions.

Abstract

AIM: To investigate the indications, resection rate, and safety of endoscopic submucosal dissection (ESD) for neoplastic lesions in the gastrointestinal tract at a European referral center.

METHODS: We carried out a retrospective analysis of the ESD procedures performed in our center for mucosal neoplastic and submucosal lesions of the gastrointestinal tract. The duration of the procedure, *en bloc* and complete (R0) resection rates, and complication rates were evaluated. Variables were reported as mean \pm SD or simple proportions. Univariate analysis and

comparisons of procedure times and resection rates were performed using Mann-Whitney *U* tests, or χ^2 tests for dichotomous variables.

RESULTS: Between 2007 and 2011, ESD was performed in a total of 103 patients (46.7% male, mean age 64.0 ± 12.7 years). The indications for the procedure were epithelial tumor ($n = 54$), submucosal tumor ($n = 42$), or other ($n = 7$). The total *en bloc* resection rate was 90.3% (93/103) and R0 resection rate 80.6% (83/103). The median speed of the procedure was 15.0 min/cm². The complete resection rate was lower for submucosal tumors arising from the muscle layer (68%, 15/22, $P < 0.05$). Resection speed was quicker for submucosal tumors localized in the submucosal layer than for lesions arising from the muscularis propria layer (8.1 min/cm² vs 17.9 min/cm², $P < 0.05$). The R0 resection rate and speed were better in the last 24 mo (90.1%, 49/54 and 15.3 min/cm²) compared to the first 3 years of treatment (73.5%, 36/49, $P < 0.05$ and 22.0 min/cm², $P < 0.05$). Complications occurred in 14.6% ($n = 15$) of patients, including perforation in 5.8% ($n = 6$), pneumoperitoneum in 3.9% ($n = 4$), delayed bleeding in 1.9% ($n = 2$), and other in 2.9% ($n = 3$). Only one patient with delayed perforation required surgical treatment. During the mean follow-up of 26 ± 15.3 mo, among patients with R0 resection, recurrence occurred in one patient (1.2%).

CONCLUSION: ESD is an effective and safe method for resection of neoplastic lesions with low recurrence. Speed and the R0 resection rate increased after 50 procedures.

Endoscopic submucosal dissection for the treatment of neoplastic lesions in the gastrointestinal tract. *World J Gastroenterol* 2013; 19(12): 1953-1961 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1953.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1953>

INTRODUCTION

In Japan and South Korea, endoscopic submucosal dissection (ESD) is a commonly accepted method for the resection of early neoplastic lesions in the upper and lower gastrointestinal tract. Good results from and the safety of procedures performed in the last few years have resulted in an increase in the number of procedures. Publications of the results of treatment with this method include more than 1000 patients. Although the dynamic development of this method is visible in Far East countries, this method is still in development in Europe and has not gained in popularity. A few publications describe the results of treatment in more than 50 patients, and some small series of patients or case reports have been published, but there is an overall lack of new European data.

ESD involves the removal of both benign neoplastic (pre-malignant) and malignant non-invasive lesions, aiming for the highest R0 resection rate (83%-98%) and lowest rate of local recurrence (0%-3%) of all endoscopic techniques^[1]. The removal of submucosal lesions is also possible, including those growing out of the proper muscle layer^[2].

The papers from Japan and Asia focus on confirming that ESD is a safe method with few complications and a mortality rate of 0%. The time needed to perform the procedure significantly decreases with the number of procedures performed, but it is still longer than the time needed for mucosectomy.

The present paper is one of the few European reports showing the results of treating gastrointestinal malignancies with ESD in a referral center. We present the indications, results, and complications with regard to different parts of the gastrointestinal tract.

MATERIALS AND METHODS

Patients

The procedures were performed between April 2007 and December 2011. Before qualifying for the procedure, patients received both oral and written explanations of the endoscopic examination and possible treatment options, and they signed an informed written consent form.

For each patient with pathology of the upper gastrointestinal tract, endoscopic ultrasound (EUS) was performed before admission for ESD. The sector-scanning echoendoscope (Olympus GF-UM130 or GF-UE160 Olympus Medical Systems Co., Tokyo, Japan) or linear echoendoscope (Olympus GF-UCT140) were used to

examine lesion size, EUS layer from which it derives (submucosal tumors, SMTs) or infiltrated layers (other lesions), SMT growth type (inside or outside the walls of the gastrointestinal tract), and lymph node diameter.

Neoplastic lesions of the upper gastrointestinal tract

Neoplastic mucosal tumors were included in the study if > 10 mm with a low risk of lymph node metastases. Lesions in the stomach were included based on the expanded criteria from the Japanese Gastric Cancer Association (JGCA)^[3]: well-differentiated carcinoma without ulceration, irrespective of size; well-differentiated carcinoma with ulceration (type III) ≤ 30 mm; or well-differentiated carcinoma with submucosal invasion and no more than 500 μm in size.

Exclusion criteria were lack of consent from the patient for the endoscopic procedure, massive infiltration of the submucosal layer or infiltration of muscle layers assessed in EUS, or enlarged local lymph nodes or metastases found in imaging studies (*i.e.*, EUS, ultrasound, and computed tomography).

Neoplastic lesions of the lower gastrointestinal tract

Patients were qualified for ESD if any of the following were in the previous endoscopic examination: large sessile polyp (LST) (type I s) that could not be removed in one piece, granular type (LST-G) flat polyps with a dominant nodule greater than 2 cm, non-granular type (LST-NG) flat polyps of any size, or scars from previous non-therapeutic tumor resections. Exclusion criteria were a lack of consent from the patient for the endoscopic procedure or deep ulceration apparent in the lesion, suggesting massive submucosal invasion.

Submucosal tumors

Resection of SMT by ESD was performed if the tumor was 1 to 8 cm in size with no growth outside the gastrointestinal tract on EUS. Patients who did not meet these criteria were referred to follow-up (submucosal lesions < 1 cm), mucosectomy (smaller or pedunculated lesions), or surgical treatment (submucosal lesions > 8 cm, epithelial tumors). All cases but one lipoma (bleeding gastric tumor) were excluded from endoscopic treatment.

Procedural technique

Before the treatment of epithelial malignancies by ESD, indigo carmine chromoendoscopy, magnifying endoscopy, NBI, or a combination of these techniques was performed to qualify the patients for the procedure based on the classification of Paris^[4] and properly assess the lateral margins of the lesion. ESD in the upper gastrointestinal tract was performed under general anesthesia, whereas analgesedation with midazolam (2.5-5 mg *iv*) and fentanyl (50-100 μg *iv*) was used for procedures in the lower gastrointestinal tract. An Olympus endoscope GIF-T140 with a transparent cap (Olympus D-201-12 704) was used, allowing a better view of the submucosal layer during the procedure. For submucosal injection, 0.9% NaCl solution

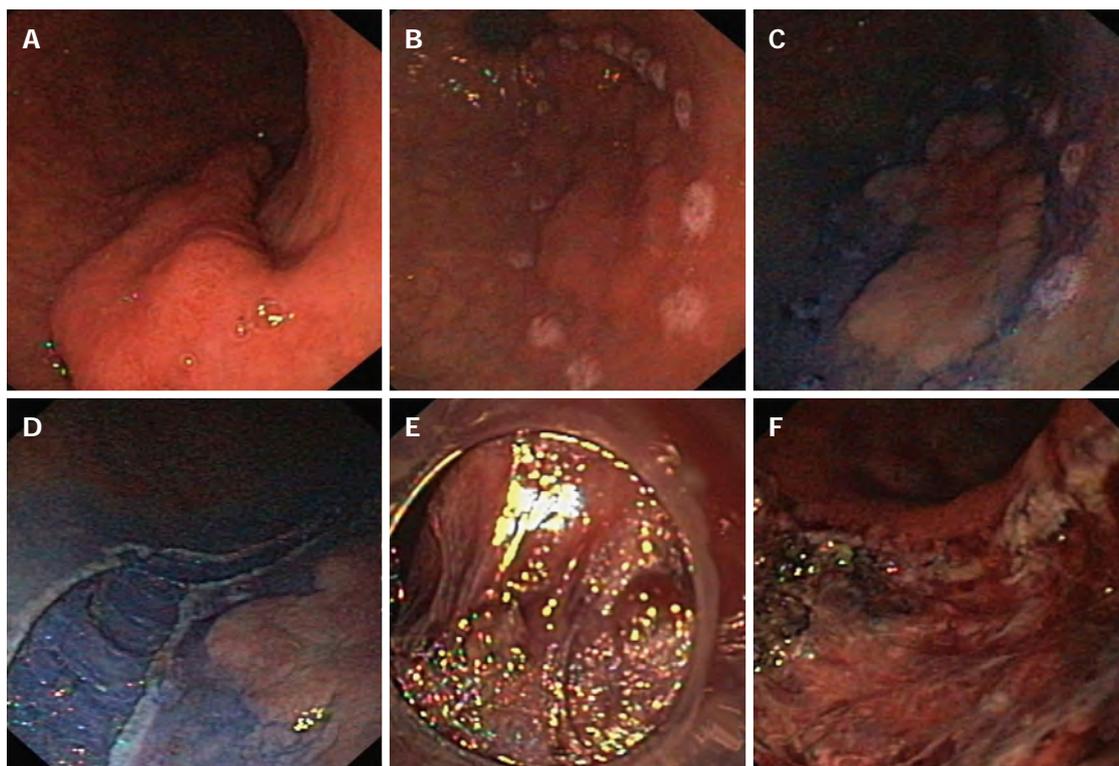

Figure 1 Endoscopic submucosal dissection of gastric neoplastic lesion. A: Lesion type II a+c localized in the antrum; B: Margins of the lesion border were marked with the needle knife; C: Solution of indigo carmine in saline was injected into the submucosal space; D: An incision was made in the mucosa and submucosa around the lesion with normal mucosal margin; E: Submucosal dissection performed directly under vision control; F: Mucosal defect after the completed procedure.

with epinephrine (1 mg/250 mL NaCl) and indigo carmine dye was used. In some cases in which the elevation of the mucosa after the injection of the solution was too short, a solution of hyaluronic acid was used (Sigmavisc, Hyaltech Ltd, Livingston, United Kingdom).

The resection was started by marking the lesion borders with the needle knife (Olympus KD-441Q) or dual knife (Olympus KD-650L) using forced coagulation of 35 W (Erbe ICC 200, Erbe Elektromedizin GmbH, Tübingen, Germany). The solution was injected submucosally next to the markers. The initial incision, approximately 3-5 mm in length, was made with a needle knife, and then a circular incision was made around the lesion using the isolated-tip knife IT or IT-2 (Olympus KD-611L, EndoCut mode, effect 3, 100 W) or a dual knife (EndoCut mode, effect 3, 35-50 W). The next step was the injection of the same solution directly into the submucosal layer under the lesion. The blue color of the indigo carmine allowed this layer to be distinguished from the proper muscle and the lesion itself. Dissection of the submucosal layer and the tumor was performed using the IT knife, hook-knife (Olympus KD-620LR, EndoCut mode, effect 2-3, 50-90 W), flex-knife (Olympus KD-630L), or dual knife (Figures 1 and 2). Muscular SMTs attached to the muscle layer by muscle fibers or muscle pedicle were cut away from the muscle layer of the wall (Figure 3). Tumors that were fused tightly with muscle and over a larger area were cut away to obtain enough material for pathological examination. Scar tissue was cut using a

needle knife along the muscle layer. Lesions located in the cardia and just behind the anal canal were removed mostly in retroflexion. During the procedure and immediately after the removal of a tumor, all visible blood vessels in the submucosal and muscle layer were coagulated using a coagrasper (Olympus FD-410LR, soft coagulation 35 W) or argon coagulation (Erbe APC 300, 35 W, flow 1.6 L/min), or hemoclips (Olympus HX-610-135) applied. The removed lesion was affixed to a polystyrene substrate, fixed in formalin, and examined morphologically.

Bleeding during the procedure that did not cause hemodynamic disorders or anemia was not considered a complication. All bleeding was treated endoscopically with coagrasper hemostatic forceps, argon beamer coagulation, or hemoclip application. Perforations noticed during the procedure were treated endoscopically by closing the wall defect using hemoclips. After the procedure, antibiotics were administered intravenously (amoxicillin 2 × 1000 mg) for 5 d, as well as proton pump inhibitors if the lesion was resected in the upper gastrointestinal tract (omeprazol 8 mg/h *iv* for 2 d, then 2 × 20 mg orally for 8 wk). After ESD in the lower gastrointestinal tract, patients received ciprofloxacin (2 × 200 mg *in*) and metronidazol (3 × 500 mg *in*). On the day of the procedure (day zero) the patients fasted. The first day after the procedure the patients received neutral fluids orally, and normal diet the next day. Colon patients received normal diet from the first day after the procedure. The patients were discharged from the hospital on day 3-5 after the procedure.

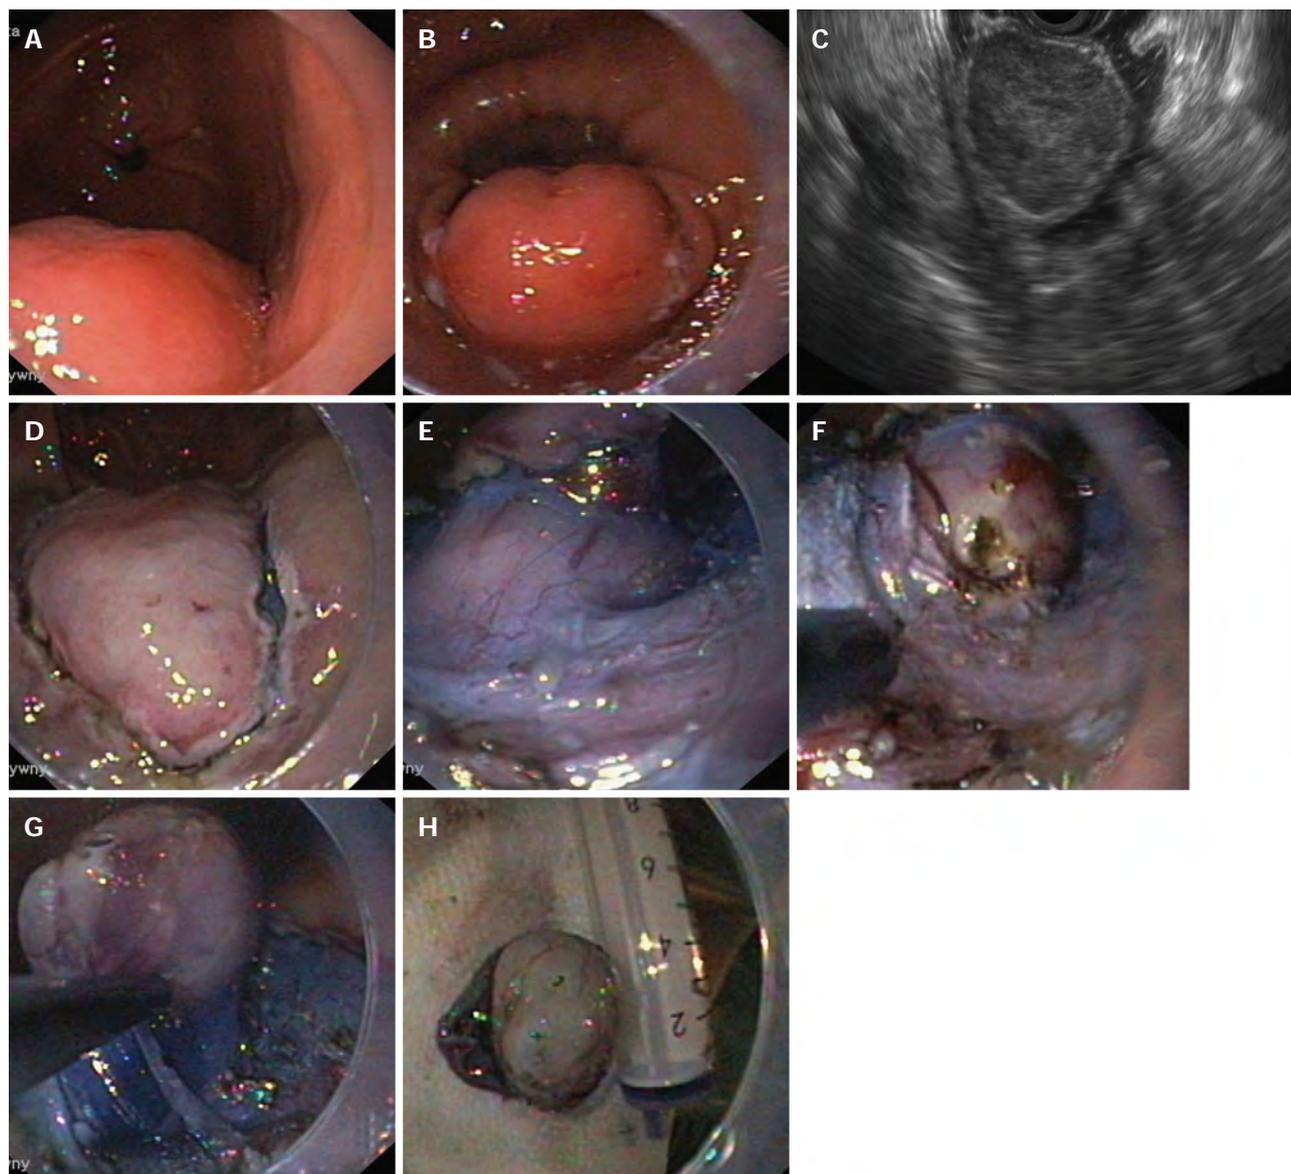

Figure 2 Endoscopic submucosal dissection of gastric submucosal tumor. A, B: Submucosal tumor in the stomach; C: Endosonographic view of the tumor, which is not connected to the muscle layer of the gastric wall; D: An incision was made in the mucosa and submucosa after indigo carmine solution injection into the submucosal layer around the lesion; E-G: Submucosal dissection of the tumor, exposing the tumor in the submucosa and carefully cutting after injecting the solution; H: Resected tumor (GIST, 25 mm, MI 2/50 HPF). GIST: Gastrointestinal stromal tumor; MI: Mitotic index; HPF: High power field.

Pathological examination

The resected specimens were pinned to a mounting board with clearly marked oral and anal orientations and routine formalin fixation performed. The borders of each specimen were colored with ink and sections taken every 2 mm. The pathological reports of the resected specimens included the macroscopic appearance, size, histological type (the most important Lauren classification of gastric cancer), and extent of the tumor depth. The presence of ulceration and lymphovascular involvement, as well as the status of the vertical and lateral resection margins, were reported in detail.

In addition, the SMT preparations were labeled with DAKO antibodies (Dako Polska Sp.z o.o.). Gastrointestinal stromal tumors (GISTs) were characterized by a positive reaction to c-KIT (CD 117) or DOG-1 and CD34

antibodies. Leiomyomas were diagnosed when the mesenchymal tumors had a positive reaction for smooth muscle actin and desmin. A positive reaction for S-100 protein and negative reaction for muscle markers and CD117 indicated nerve tumors. The neoplastic potential of the stromal tumors was determined on the basis of their size and mitotic index (MI, number of mitoses counted in 50 large fields) according to the classification of Miettinen *et al*^[5].

The criteria for curative resection of cancer lesions were: the depth of neoplasm infiltration limited to the mucosal or superficial submucosal layer (up to 500 μm in the cardia and stomach and up to 1000 μm in the large intestine as measured from the lower border of the muscle layer of the mucosa), no infiltration or congestion of carcinoma cells in blood vessels and lymph vessels (angioinvasion), lateral and bottom margins free of neoplasm, and

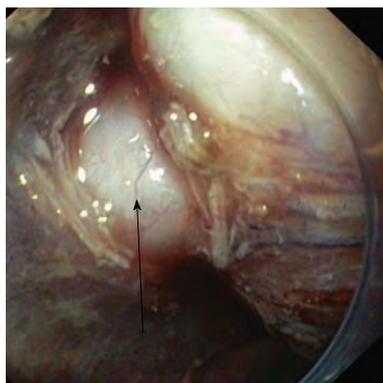

Figure 3 Submucosal tumor (leiomyoma) resected by endoscopic submucosal dissection and connected to the gastric wall with the muscle peduncle (arrow).

well or medium-differentiated cancer. For GIST, the only criterion was confirmed tissue-free margins.

Follow-up

All side effects of the dissection were recorded according to standard procedures^[6,7]. The first follow-up visit was 2-3 wk after ESD. The first follow-up endoscopy was performed 3 or 12 mo after surgery using a standard endoscope or EUS. Patients with incompletely resected neoplastic changes were referred for surgery. A control endoscopy after 3 mo was performed in the case of piecemeal resection of the tumor or uncertain histopathological confirmation of the complete tumor resection (Rx). The following cases were qualified for endoscopy after 12 mo: removal of a tumor that fulfilled the criteria for R0, resection of non-neoplastic lesions, and incomplete SMT resection of non-stromal tumors.

Statistical analysis

Variables were reported as mean \pm SD or simple proportions. Univariate analysis and comparisons of procedure times and resection rates were performed using Mann-Whitney *U* tests, or χ^2 tests for dichotomous variables. Statistica 9.1 software was used for all data analyses (StatSoft, Inc. 2010; Statistica).

RESULTS

Over a period of 57 mo, ESD was performed in 103 patients (46 males, 44.66%). The mean patient age was 64.0 ± 12.7 years. A total of 69 procedures were performed in the upper gastrointestinal tract, 34 in the colon. The indications for resection were epithelial tumors ($n = 54$), SMT ($n = 42$), scars from previous non-therapeutic tumor resection ($n = 2$), and others ($n = 5$). All procedures were performed by two physicians (Bialek A, Pertkiewicz J).

The total *en bloc* and R0 resection rates were 90.3% (93/103) and 80.6% (83/103), respectively. The rate of *en bloc* and R0 resection for epithelial lesions reached 85.3% (52/61), for overall SMT the rates were 97.6% (41/42) and 73.8% (31/42), respectively, but did not differ significantly. The complete resection rate for SMTs arising from the muscle layer was 68% (15/22), which is significantly

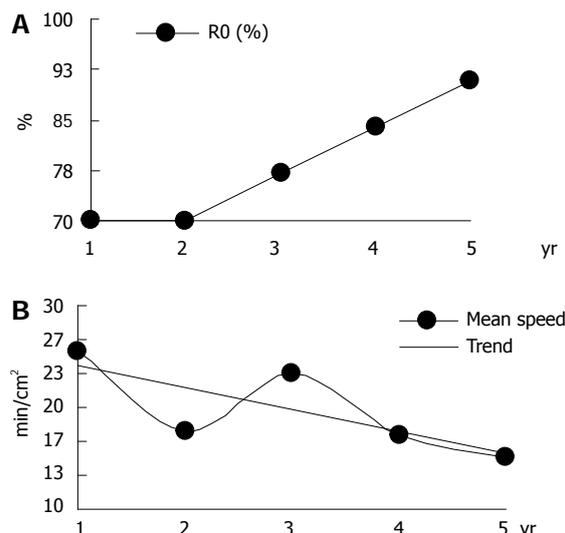

Figure 4 R0 resection rate and mean speed of the procedure in the years following endoscopic submucosal dissection. A: R0 resection rate; B: Mean speed of the procedure.

lower than that of epithelial lesions ($P < 0.05$).

The mean speed of performing the procedure was 19.0 ± 14.6 min/cm². The overall resection speed for SMTs was 15.85 ± 10.99 and 21.17 ± 16.41 min/cm² for mucosal lesions, but this difference was not significant. The resection speed was faster for SMTs localized in the submucosal layer compared to lesions arising from the muscularis propria layer (8.1 min/cm² *vs* 17.9 min/cm², $P < 0.05$).

During the first 3 years following ESD, 49 procedures were performed. Thirty-six of the procedures (73.5%) were R0 resections, and the procedure speed was 22.02 ± 15.33 min/cm². In the last 24 mo, the R0 resection rate increased to 90.1% (49/54, $P < 0.05$, Table 1; Figure 4) with a mean speed of 15.3 ± 13.25 min/cm² ($P < 0.05$, Table 1; Figure 4). The complication rates did not differ significantly. During a mean follow-up of 26 ± 15.3 mo, recurrence was detected in only one patient who underwent R0 resection (1.2%, 1/83), a 54-year-old female with intestinal type gastric cancer (G1, M2), and recurrence occurred within 6 mo of the procedure. The patient was sent for surgery and middle grade dysplasia diagnosed in the resected specimen.

Esophagus and cardia

ESD procedures were performed in the lower esophagus and cardia in 14 patients. The indications for the procedure were SMTs suspected to be GISTs in 5 patients and mucosal tumors in 9 patients.

Morphologically, tumors were type I -1, II a-2, II a+c-3, II b+c-2 and II b-1 according to the Paris classification. The mean tumor size was 2.37 ± 0.95 cm for all lesions, 2.36 ± 1.0 cm for mucosal lesions, and 2.4 ± 0.96 cm for SMTs. The *en bloc* and R0 resection rates as well as the histological diagnoses of resected tumors are shown in Table 2.

The mean procedure duration was 99 ± 77.2 min and significantly shorter for the resection of SMTs (38

Table 1 Mean speed of endoscopic submucosal dissection and R0 resection rate related to time

| Performing ESD (yr) | Procedures (n) | Speed (min/cm ²) (mean ± SD) | R0 |
|---------------------|----------------|--|-------|
| 1 | 10 | 25.5 ± 25.54 | 70.0% |
| 2 | 17 | 17.6 ± 25.54 | 70.0% |
| 3 | 22 | 23.4 ± 11.87 | 77.0% |

ESD: Endoscopic submucosal dissection.

± 13.03 min) than for mucosal lesions (128 ± 80.06 min, *P* < 0.05). Overall, the speed of resection was 24.96 ± 22.71 min/cm² and significantly slower for the resection of mucosal lesions (33.29 ± 24.4 min/cm²) than for SMTs (9.96 ± 6.9 min/cm², *P* < 0.05). The overall rate of *en bloc* and R0 resection was 100% (14/14) and 64.3% (9/14), respectively, and it did not differ significantly between mucosal lesions and SMTs.

Both of the incompletely removed SMTs were leiomyomas. The three neoplastic lesions were adenocarcinomas; cancerous infiltration was present in the lower margin (SM3) in two cases and in the lateral margin in one case. One of the patients was treated surgically; the adenocarcinoma was found in neither the cardia nor the lymph nodes of the surgical specimen. The other two patients were not qualified for surgery because of a lack of consent and high risk of surgery due to serious comorbidities.

Stomach

ESD was performed in the stomach in 54 patients, among which 35 were suspected to have GIST (mean size 2.9 ± 1.2 cm) and 19 mucosal neoplastic lesions (mean size 2.6 ± 1.1 cm). According to the Paris classification, the mucosal lesions were type I s-2, II a+c-11, II a-4, II b-1 and II b+c-1. Histological diagnoses and the rates of *en bloc* and R0 resection are shown in Table 2. Four lesions in the stomach qualified according to JGCA classic criteria^[7] were removed completely (R0 resection rate 100%). Out of 12 lesions, only 9 (75.0%) reached R0 resection according to expanded criteria.

In two cases of incomplete resection of SMT, GIST was diagnosed. In one of these patients, the tumor was 4 cm, MI = 6 (risk of progression: moderate), and the patient referred for surgery; in the other, the tumor was 1.9 cm, MI = 3 (risk of progression: low), and the patient referred for follow-up examination. In two cases of incomplete resection of adenocarcinoma, one had a lower margin positive for cancer (sm3) and the other a lateral margin positive for cancer (piecemeal resection). The first patient qualified for surgical resection, but the other did not give consent for surgical treatment; in 33 mo of follow-up no tumor recurrence was found.

The mean duration of the endoscopic procedure was 103.8 ± 77.3 min for all lesions, 108.1 ± 88.0 min for epithelial lesions, and 101.4 ± 72.1 min for SMTs. The

^a*P* < 0.05 vs non-submucosal tumor (SMT). GIST: Gastrointestinal stromal tumor; HGD: High grade dysplasia.

mean speed of dissection was 18.05 ± 12.1 min/cm² for all lesions, 20.1 ± 13.4 min/cm² for epithelial lesions, and 16.9 ± 11.4 min/cm² for SMTs. The speed of the resection of SMTs connected to the muscle layer (*n* = 19) was 19.7 ± 8.5 min/cm² and 14.2 ± 15.2 min/cm² for tumors without such a connection (*n* = 12).

Colon

In the large intestine, ESD was performed in 34 patients. The main indications were laterally spreading tumor (LST) type II a-11 or II a+c-9 and polyps type I s-10. In two cases, ESD was performed for the radicalization of previously incomplete polypectomy procedures and in two cases due to symptomatic SMTs of the rectum. Low or middle grade dysplasia was diagnosed in 11 cases, and high-grade dysplasia or adenocarcinoma in 21 cases (Table 2). Two SMTs were diagnosed as fibroepithelioma and leiomyoma. The majority of lesions were located in the rectum (*n* = 28), followed by the sigmoid colon (*n* = 5) and ascending colon (*n* = 1). The rate of *en bloc* and R0 resection was 87.5% (28/32) and 90.6% (29/32), respectively. Among the lesions with incomplete resection, two adenocarcinomas with infiltration of the lower cut border (sm3) and tubular adenoma with low-grade dysplasia were diagnosed. In both cases of adenocarcinoma, the patients underwent surgical treatment, but cancerous tissue was not found in the surgical specimen. The patient with non-radically resected adenoma was administered follow-up examinations (20 mo) with no recurrence.

The average overall time and speed of treatment was 82.0 ± 56.6 min and 17.9 ± 14.2 min/cm², respectively,

Table 3 Complications after endoscopic submucosal dissection according to location

| | Patients | Delayed bleeding | Perforation | Other (n) | |
|-------------|----------|------------------|-------------|---|---|
| Cardia | 14 | 0 | 1 | Pneumoperitoneum | 2 |
| Stomach | 54 | 2 | 5 | | |
| Upper part | 21 | 1 | 4 | Mucosal tear of lower pharyngeal sphincter region, pneumoperitoneum | 3 |

| Lower part | 26 | 1 | 0 | Stenosis of the pylorus | 2 |
| Colon | 34 | 0 | 0 | | 0 |
| Duodenum | 1 | 0 | 0 | | 0 |
| All | 103 | 2 | 6 | | 7 |

85.1 ± 56.9 min and 18.2 ± 14.5 min/cm², respectively, for epithelial neoplastic lesions, and 32.5 ± 3.5 min/cm² and 11.9 ± 9.3 min/cm², respectively, for SMTs.

Complications after ESD

Severe complications occurred in two patients in the form of perforations, resulting in prolonged hospitalization for more than 10 d, including surgical treatment in one case. Mild or moderate complications occurred in 13 patients: 2 patients with delayed bleeding treated by transfusion, 1 patient with a mucosal pharyngeal sphincter tear who required prolonged hospitalization for less than 3 d, 4 with pneumoperitoneum who required prolonged hospitalization for less than 3 d, 4 patients with perforation treated conservatively and requiring prolonged hospitalization for 4-10 d, and 2 patients with pyloric stenosis requiring additional endoscopy. The complication rate according to localization is presented in Table 3.

In six patients with perforation, endoscopic closure of the defect was performed using hemoclips, decompression of the peritoneum by puncture, and conservative treatment with fasting, antibiotic therapy, and active suction with a nasogastric tube. In one of the patients, delayed perforation occurred on the fourth day when trying to implement oral feeding.

Bleeding in two patients was controlled by hemoclip application, and patients required the transfusion of two units of blood. In two patients, stenosis occurred within 4 wk after dissection of neoplastic lesions in the pylorus. Both patients were successfully treated with 20-mm balloon dilatation in one and two sessions. In one patient a mucosal tear in the throat sphincter occurred when removing a large, > 3 cm resected SMT. The patient had no symptoms and did not require additional treatment.

DISCUSSION

ESD is a technique aimed at resecting early neoplastic lesions in the gastrointestinal tract without compromising the integrity of the wall. The technique allows R0 resection to be achieved, even for large mucosal and submucosal lesions, by removing them in one piece (*en bloc*), which

allows proper pathological evaluation of specimens. The method is the most effective of the endoscopic resection techniques and used by many centers in Japan and the Far East. Many papers, including the multicenter studies and those presenting the results of treatment in over 1000 patients, confirm the technique's efficacy in both the upper and lower parts of the gastrointestinal tract^[8-12]. The percentage of *en bloc* resection is estimated to range from 92%-100% in the upper gastrointestinal tract and 81.6%-92.7% in the lower gastrointestinal tract, and the rate of R0 resection is estimated to be 73.6%-94.7% in the upper gastrointestinal tract and 69.7%-89% in the lower gastrointestinal tract, which is significantly higher than that of mucosectomy techniques, in which R0 resection is estimated to be 33%-56%^[1,9,13], especially for the resection of large tumors (> 2 cm in size). ESD also allows resection of SMTs, even those growing from the muscularis propria^[2,10-18], and allows surgeons to save the organ via a minimally invasive resection of the lesion itself.

Despite such good results of treatment, the method is still rarely used in Europe^[2,19-22]. To the best of our knowledge, only two European papers from Augsburg, Germany, present the results of treating more than 100 patients in one center^[19,20]. One of the reasons for this low usage could be the time it takes to perform the procedure, especially at the beginning of the learning curve. In the Japanese centers, which have published the results of treating more than 1000 patients, the average time for ESD in the stomach is approximately 37 min^[19]. In the present study, both time and speed were worse than in the Japanese studies due to the relatively low volume at the center. The number of ESD procedures necessary to master the method is thought to be approximately 50. In the present study, the speed of performing the procedure increased approximately 30% after the first 49 procedures over 3 years. Similarly, Probst *et al.*^[20] and Japanese authors noted a significant increase in the speed of the resection after 40-50 procedures^[13,19].

The location of the lesions in the upper part of the stomach, their size, and the presence of submucosal fibrosis are associated with longer procedure duration, a lower resection rate, and a higher rate of complications^[23-25]. In the present study, the percentage of resection related to lesion localization and timing in the stomach did not differ significantly, probably due to a heterogeneous patient group and a small number of procedures in different locations.

The other factor responsible for the small number of ESD procedures in Europe may be the greater number of complications compared to mucosectomy. The most serious complication of ESD is perforation, which occurs in 1.2%-9.7% of cases, and bleeding, which occurs in 0.1%-15.6% of procedures^[1,8,13,20]. In the present study, the percentage of complications was similar, 4.9% for perforation and 1.9% for delayed bleeding, and surgical treatment was required in only one case. Importantly, the mortality rate after endoscopic treatment is 0% in both the present study and most published papers. Factors associated with a higher incidence of complications have

been identified, including location in the upper and middle part of the stomach, lesion size, and the number of procedures performed when less than 50^[11-12,25,26]. Also, in the present study, lesions located in the upper and middle third of the stomach were associated with a higher incidence of perforation, as five of six perforations occurred in these locations.

In the present study, the rate of *en bloc* resection and R0 resection was 90.3% and 80.6%, respectively, which is comparable with other European studies but lower than that of studies from Japan and South Korea. This difference is due to the lesser experience of authors in the first years of implementing the procedure. In the last two years, the rate of R0 resection increased from 73.5% to 90.1%, which approached the level of Japanese authors (Table 1; Figure 2). This finding confirms a long learning curve for this technique, which was nearly three years in our study, with 49 treatments completed. A similar tendency has been noticed by other authors, with the rate of total *en bloc* resection beginning at 50%-65.7% and increasing to 72.2%-100%^[11,19]. An important factor in achieving R0 resection was a larger proportion of eligible patients fulfilling extended ($n = 12$), compared to classical ($n = 4$), indications for endoscopic resection of gastric cancer. The rate of R0 resection for classical indications in the present study was 100% (4/4), which was higher than the rate with the extended criteria (9/12, 75%). A similar tendency was observed by Probst *et al.*^[20], who reported 90% (9/10) and 68.6% (35/51), respectively, and Japanese authors, who reported 97.1% and 91.1%, respectively^[19,27,28].

In the present study, the significant effect on the lower total resection rate comprised a relatively large proportion of patients with SMTs, including tumors arising from the muscularis propria layer, for which the R0 resection rate was significantly lower. Among the patients with confirmed complete R0 resection, only one recurrence occurred within 6 mo of the procedure (1.2%). In the publications from the last few years, the rate of recurrence after R0 resection was 0%-5.1%^[29-31].

A limitation of this study is the relatively small number of procedures performed in the reference center and retrospective type of analysis.

In summary, ESD allows endoscopic resection of tumors with high efficacy and low complication rates, even in a low-volume center. Most complications, including perforation, are mild or moderate in severity and can be treated endoscopically or conservatively. Both speed and complete resection rate improved after approximately 50 procedures.

COMMENTS

Background

In Japan and South Korea, endoscopic submucosal dissection (ESD) is a commonly accepted method for the resection of early neoplastic lesions in the upper and lower gastrointestinal tract. Although the dynamic development of this method is visible in Far East countries, ESD is still in development in Europe and has not gained in popularity. A few publications have described the results of treatment in more than 50 patients, and some small series of patients or case reports have been published, but new European data is lacking overall. The

present paper is one of the few European reports showing the results of treating gastrointestinal malignancies with ESD in a referral center. Authors present the indications, results, and complications with regard to different parts of the gastrointestinal tract.

Research frontiers

ESD is a technique aimed at resecting early neoplastic lesions in the gastrointestinal tract without compromising the integrity of the wall. The technique allows R0 resection to be achieved, even for large mucosal and submucosal lesions, by removing them in one piece (*en bloc*), which allows for proper pathological evaluation of specimens. The method is the most effective endoscopic resection technique to date and is used by many centers in Japan and the Far East.

Innovations and breakthroughs

One of the reasons for the lack of usage of ESD could be the time required to perform the procedure, especially at the beginning of the learning curve. In the present study, the speed of performing the procedure and R0 resection rate increased approximately 30% after the first 49 procedures over 3 years. Other authors have also noted a significant increase in the speed and R0 resection rate after 40 to 50 procedures. Another factor potentially responsible for the small number of ESD procedures in Europe may be the greater number of complications associated with ESD compared to mucosectomy. The most serious complications of ESD are perforation, which occurs in 1.2%-9.7% of cases, and bleeding, which occurs in 0.1%-15.6% of cases. In this study, the percentage of complications was similar: 4.9% for perforation and 1.9% for delayed bleeding, irrespective of the center experience. Surgical treatment was required in only one case. The significant effect on the total resection rate included a relatively large proportion of patients with submucosal tumors, including tumors arising from the muscularis propria layer, for which the R0 resection rate was significantly lower. Among the patients with confirmed complete R0 resection, only one recurrence occurred within 6 mo of the procedure (1.2%). In publications from the last few years, the rate of recurrence after R0 resection has been 0%-5.1%.

Applications

ESD allows endoscopic resection of tumors with high efficacy and low complication rates, even in a low-volume center. Most complications, including perforations, are mild or moderate in severity and can be treated endoscopically or conservatively. Both speed and the complete resection rate improved after approximately 50 procedures.

Terminology

R0 resection: Complete resection of the lesion confirmed by a pathologist by microscopic examination of the tumor-free borders of resected species.

Peer review

The authors report European experience for ESD. Though the number of cases is small and some points need to be clear, this is valuable study as they mentioned that is European own experience.

(serum glutamic oxaloacetic transaminase and serum glutamic pyruvic transaminase) and inflammatory cytokines [interleukin (IL)-12 and IL-18] levels by enzyme linked immunosorbent assay.

RESULTS: Serum transaminase, hepatic MDA, and inflammatory cytokines increased significantly in the APAP compared with the control group. Curcumin supplementation in APAP + CUR 200 and APAP + CUR 600 groups significantly decreased these parameters compared with the APAP group. The level of GSH decreased significantly in the APAP compared with the control group. Curcumin supplementation in APAP + CUR 200 and APAP + CUR 600 groups significantly increased these parameters compared with the APAP group. The histological appearance of the liver in the control group showed normal. In the APAP-treated group, the liver showed extensive hemorrhagic hepatic necrosis at all zones. Curcumin supplementation in APAP + CUR 200 and APAP + CUR 600 groups, caused the liver histopathology to improve. In the APAP + CUR 200 group, the liver showed focal necrosis and but the normal architecture was well preserved in APAP + CUR 600 group.

CONCLUSION: APAP overdose can cause liver injury. Results indicate that curcumin prevents APAP-induced hepatitis through the improvement of liver histopathology by decreased oxidative stress, reduced liver inflammation, and restoration of GSH.

Abstract

AIM: To investigate whether curcumin could attenuate hepatitis in mice with paracetamol overdose.

METHODS: Male mice were divided into four groups. Group 1 (control, $n = 8$); was fed with distilled water; Group 2 [N-acetyl-P-aminophenol (APAP), $n = 8$]; was fed with a single dose of 400 mg/kg APAP dissolved in distilled water; Group 3 [APAP + curcumin (CUR) 200, $n = 8$], was fed with a single dose of 400 mg/kg APAP and 200 mg/kg CUR; Group 4 (APAP + CUR 600, $n = 8$), was fed with a single dose of 400 mg/kg APAP and 600 mg/kg CUR. Twenty-four hours later, the liver was removed to examine hepatic glutathione (GSH), hepatic malondialdehyde (MDA), and histopathologically. Then whole blood was withdrawn from heart to determine transaminase

Somanawat K, Thong-Ngam D, Klaikeaw N. Curcumin attenuated paracetamol overdose induced hepatitis. *World J Gastroenterol* 2013; 19(12): 1962-1967 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1962.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1962>

INTRODUCTION

In therapeutic doses, N-acetyl-P-aminophenol (APAP) or paracetamol is mainly metabolized *via* glucuronidation and sulfation pathway and in conjugated forms is excreted from the cells. Besides, APAP is partly metabolized by cytochrome P450 (CYP 2E1), to produce toxic metabolites such as N-acetyl-p-benzoquinone imine. These metabolites are produced in the liver and detoxified by reduced glutathione (GSH) and then removed from cells. In APAP overdose, it is mainly metabolized by CYP 2E1 and causes increase of toxic metabolites and GSH depletion. These metabolites interact with biomolecules such as protein, lipid, and nucleic acid *via* covalent binding, which disrupts hepatocytes function causing hepatic necrosis and liver injury^[1-6].

A previous study demonstrated that APAP overdose treatment showed significantly increase in serum transaminase, hepatic malondialdehyde (MDA), and decreased hepatic GSH. Histological examination showed a severe centrilobular hepatic necrosis with fatty changes^[7-9].

Curcumin (diferuloylmethane), a polyphenol, is an active ingredient of turmeric (*Curcuma longa*) and is pharmacologically safe for humans and animals. Curcumin has many biological activities, including anti-inflammatory, antioxidant, anti-carcinogenic, anti-mutagenic, and anti-diabetic activities^[10-13]. The hepatoprotection of curcumin has been widely acknowledged and used in traditional medicines for treatment of inflammatory conditions such as hepatitis^[14].

A previous study demonstrated that curcumin treatment showed significantly decrease in serum transaminase, hepatic MDA, increase hepatic GSH, and caused improvement of liver histopathology^[7-9].

However, it is still unclear whether curcumin has any effect in APAP-induced hepatotoxicity. Therefore, the present study aims to examine the protective effect of curcumin on hepatitis in mice with APAP overdose.

MATERIALS AND METHODS

Animal preparation

Male mice (4-5 wk), weighing 25-30 g, were purchased from the National Laboratory Animal Center, Mahidol University (Bangkok, Thailand). They were acclimatized at least 1 wk in a climate-controlled room on a 12-h light-dark cycle and were fed *ad libitum*. The experimental protocol was approved by the Ethical Committee of Faculty of Medicine, Chulalongkorn University, Thailand.

Paracetamol and curcumin preparation

A single dose of 400 mg/kg of APAP (Tylenol®) was dissolved in distilled water that was freshly prepared for the experiment. A single dose of 200 and 600 mg/kg of curcumin (95% purified curcumin, Cayman Chemical Company, Ann Arbor, MI, United States) were dissolved in corn oil that was freshly prepared for the experiment.

Experimental protocol

All mice were fasted, with free access to water *ad libitum*,

for 18 h before the experiment. They were randomly divided into four experimental groups.

Group 1 (control, $n = 8$); mice were fed distilled water orally *via* an intragastric tube; Group 2 (APAP, $n = 8$); mice were fed a single dose of 400 mg/kg of APAP orally *via* an intragastric tube; Group 3 [APAP + curcumin (CUR) 200, $n = 8$]; mice were fed a single dose of 400 mg/kg of APAP with a single dose of 200 mg/kg of curcumin orally *via* an intragastric tube; Group 4 (APAP + CUR 600, $n = 8$); mice were fed a single dose of 400 mg/kg of APAP with a single dose of 600 mg/kg of curcumin orally *via* an intragastric tube.

Twenty-four hours later, the mice were anesthetized with intraperitoneal injection of thiopental (50 mg/kg body weight). The abdominal wall was incised and liver was removed and washed with cold normal saline (4 °C -8 °C). The liver was chopped into small pieces, frozen in liquid nitrogen, and stored at -80 °C to examine hepatic MDA and hepatic GSH. The hepatic MDA was quantified by thiobarbituric acid reaction as described by Ohkawa *et al.*^[15]. The hepatic GSH was quantified by GSH Assay Kit (Cayman Chemical Company, United States). The remaining liver was fixed in 10% formalin solution to examine histologically. Then whole blood was withdrawn from heart. The blood was allowed to coagulate at room temperature (2 h) and centrifuged for 20 min at 3000 × *g* to obtain serum. The serum was collected to examine transaminase (serum glutamic oxaloacetic transaminase, serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase, SGPT) and inflammatory cytokines interleukin (IL)-12 (R and D Systems, Inc., United States) and IL-18 (Medical and Biological Laboratory Co., Ltd, Japan) by enzyme-linked immunosorbent assay method.

Histopathology

Samples of the liver were excised and transferred to formalin and later processed by routine techniques prior to embedding in paraffin. Sections were cut at the thickness of 5 μm and stained with hematoxylin and eosin (HE). An experienced pathologist blinded to the experiment evaluated all samples. All histopathological changes were observed under light microscope. Hepatic necroinflammation score in each section was graded according to the criteria described by Brunt *et al.*^[16] from 0 to 3 as follow; Score 0 = No hepatocyte injury/inflammation; Score 1 = Sparse or mild focal zone 3 hepatocyte injury/inflammation; Score 2 = Noticeable zone 3 hepatocyte injury/inflammation; Score 3 = Severe zone 3 hepatocyte injury/inflammation.

Statistical analysis

The data were expressed as mean ± SD. For comparison among all groups of animals, one-way analysis of variance (one-way ANOVA) and Tukey PostHoc comparisons were employed. *P*-value at less than 0.05 was considered statistically significant. The data were analyzed using the SPSS software version 17.0 for windows.

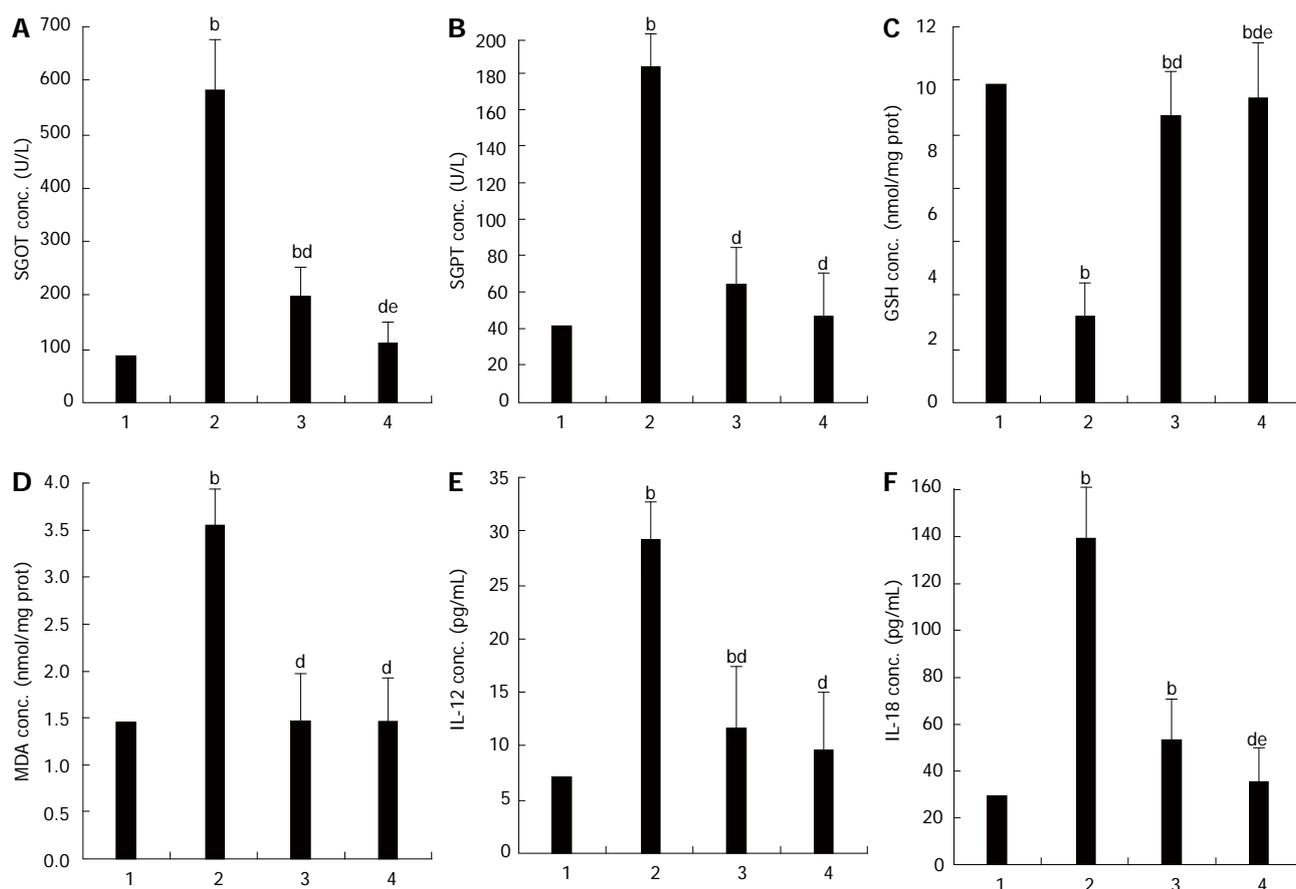

Figure 1 Effects of curcumin on serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, hepatic glutathione, hepatic malondialdehyde, interleukin-12, interleukin-18 in mice with paracetamol overdose. A: Serum glutamic oxaloacetic transaminase (SGOT); B: Serum glutamic pyruvic transaminase (SGPT); C: Hepatic glutathione (GSH); D: Hepatic malondialdehyde (MDA); E: Interleukin (IL)-12; F: IL-18. ^b $P < 0.01$ vs control group; ^d $P < 0.01$ vs N-acetyl-P-aminophenol (APAP) group; ^e $P < 0.05$ vs APAP + curcumin (CUR) 200 group. 1: Control; 2: APAP; 3: APAP + CUR 200; 4: APAP + CUR 600.

RESULTS

Effects of curcumin on serum transaminase in mice with paracetamol overdose

Serum SGOT increased significantly in the APAP when compared to the control group (SGOT, 583.25 ± 118.30 U/L *vs* 86.13 ± 6.90 U/L, $P < 0.001$). These were significantly lower in the APAP + CUR 200 and APAP + CUR 600 groups than that in the APAP group (197.38 ± 14.39 U/L *vs* 583.25 ± 118.30 U/L and 111.38 ± 8.33 U/L *vs* 583.25 ± 118.30 U/L, $P < 0.001$, respectively). There was statistically significant difference in serum SGOT in APAP + CUR 200 and APAP + CUR 600 groups (197.38 ± 14.39 U/L *vs* 111.38 ± 8.33 U/L, $P < 0.05$) (Figure 1A).

Serum SGPT increased significantly in the APAP group when compared to the control group (186.00 ± 43.73 U/L *vs* 42.63 ± 6.95 U/L, $P < 0.001$). They were significantly lower in the APAP + CUR 200 and APAP + CUR 600 groups than in the APAP group (65.25 ± 3.11 U/L *vs* 186.00 ± 43.73 U/L and 47.50 ± 4.72 U/L *vs* 186.00 ± 43.73 U/L, $P < 0.001$, respectively). There was no statistically significant difference in serum SGPT in APAP + CUR 200 and APAP + CUR 600 groups (65.25 ± 3.11 U/L *vs* 47.50 ± 4.72 U/L, $P > 0.05$) (Figure 1B).

Effects of curcumin on hepatic GSH in mice with paracetamol overdose

Hepatic GSH were significantly lower in the APAP group compared to the control group (2.75 ± 0.16 nmol/mg protein *vs* 10.17 ± 0.11 nmol/mg protein, $P < 0.001$). Hepatic GSH in APAP + CUR 200 and APAP + CUR 600 groups were significantly higher than in the APAP group (9.16 ± 0.49 nmol/mg protein *vs* 2.75 ± 0.16 nmol/mg protein and 9.72 ± 0.22 nmol/mg protein *vs* 2.75 ± 0.16 nmol/mg protein, $P < 0.001$, respectively). There was statistically significant difference in hepatic GSH in APAP + CUR 200 and APAP + CUR 600 groups (9.16 ± 0.49 nmol/mg protein *vs* 9.72 ± 0.22 nmol/mg protein, $P < 0.05$) (Figure 1C).

Effects of curcumin on hepatic MDA in mice with paracetamol overdose

Hepatic MDA was elevated significantly in the APAP group when compared to the control group (3.55 ± 0.05 nmol/mg protein *vs* 1.45 ± 0.01 nmol/mg protein, $P < 0.001$). Hepatic MDA in APAP + CUR 200 and APAP + CUR 600 groups were significantly lower than in the APAP group (1.47 ± 0.01 nmol/mg protein *vs* 3.55 ± 0.05 nmol/mg protein and 1.46 ± 0.01 nmol/mg protein *vs* 3.55 ± 0.05 nmol/mg protein, $P < 0.001$, respectively). There

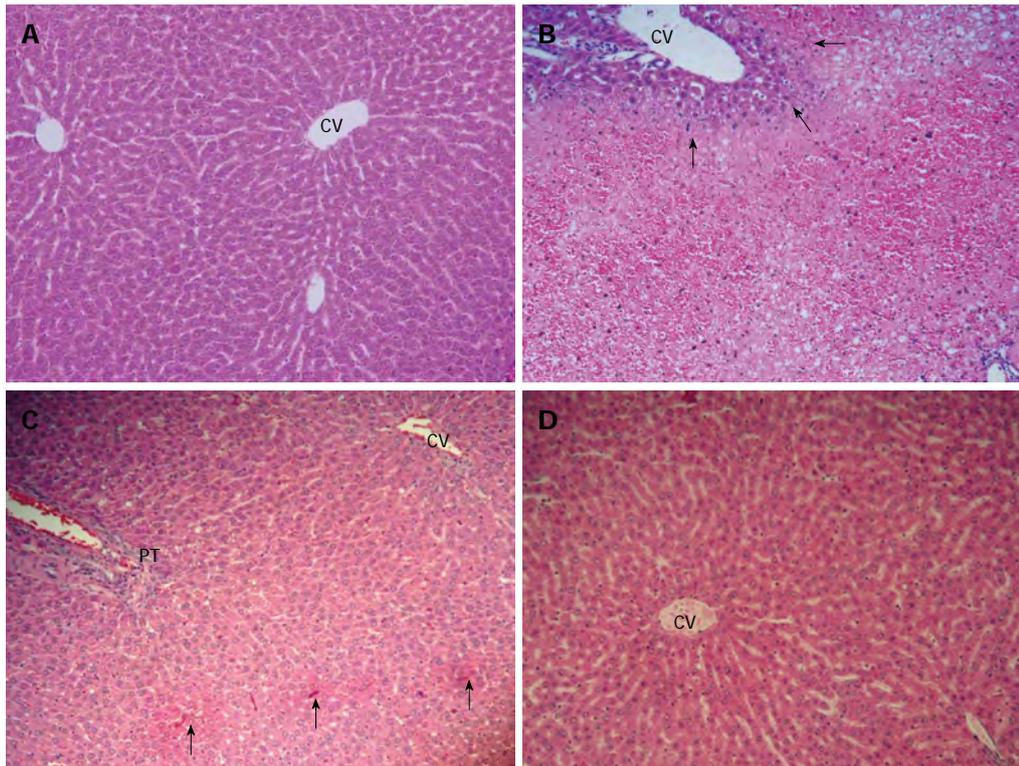

Figure 2 Effects of curcumin improved liver histopathology (hematoxylin and eosin stain, $\times 10$). A: Control group showed normal; B: N-acetyl-P-aminophenol (APAP) group showed extensive hemorrhagic hepatic necrosis at all zones; C: APAP + curcumin (CUR) 200 group showed mild focal necrosis and hepatic lobule was preserved; D: APAP + CUR 600 group showed the hepatic lobule was preserved with limited hepatic change. Arrows indicate hepatic necrosis, CV indicate central vein, and PT indicate portal system.

was no statistically significant difference in hepatic MDA in APAP + CUR 200 and APAP + CUR 600 groups (1.47 ± 0.01 nmol/mg protein *vs* 1.46 ± 0.01 nmol/mg protein, $P > 0.05$) (Figure 1D).

Effects of curcumin on serum IL-12 and IL-18 in mice with paracetamol overdose

The level of serum IL-12 increased significantly in the APAP group compared with the control group (29.16 ± 3.34 pg/mL *vs* 7.08 ± 1.40 pg/mL, $P < 0.001$). Serum IL-12 significantly decreased in the APAP + CUR 200 and APAP + CUR 600 groups compared with the APAP group (11.60 ± 1.68 pg/mL *vs* 29.16 ± 3.34 pg/mL and 9.63 ± 1.38 pg/mL *vs* 29.16 ± 3.34 pg/mL, $P < 0.001$, respectively). There was no statistically significant difference in serum IL-12 in APAP + CUR 200 and APAP + CUR 600 groups (11.60 ± 1.68 pg/mL *vs* 9.63 ± 1.38 pg/mL, $P > 0.05$) (Figure 1E).

The level of serum IL-18 increased significantly in the APAP group compared with the control group (139.52 ± 15.59 pg/mL *vs* 29.17 ± 3.72 pg/mL, $P < 0.001$). Serum IL-18 significantly decreased in the APAP + CUR 200 and APAP + CUR 600 groups compared with the APAP group (53.48 ± 18.19 pg/mL *vs* 139.52 ± 15.59 pg/mL and 35.21 ± 2.18 pg/mL *vs* 139.52 ± 15.59 pg/mL, $P < 0.001$, respectively). There was statistically significant difference in serum IL-18 in APAP + CUR 200 and APAP + CUR 600 groups (53.48 ± 18.19 pg/mL *vs* 35.21 ± 2.18 pg/mL, $P < 0.05$) (Figure 1F).

Effects of curcumin on histopathology in mice with paracetamol overdose

The histological appearance of the liver in the control

group showed normal (Figure 2A). In the APAP group, the liver showed extensive hemorrhagic hepatic necrosis of all zones (Figure 2B). In APAP + CUR 200 and APAP + CUR 600 groups, the liver histopathology improved. The APAP + CUR 200 group showed focal necrosis (Figure 2C), whereas the majority of hepatic lobules were preserved as normal architecture with limited hepatic change in the APAP + CUR 600 groups (Figure 2D). The summary of hepatic necroinflammation score in the control and experimental groups are shown in Table 1.

DISCUSSION

This study demonstrated that treatment of APAP overdose induced hepatitis in mice and could be attenuated by treatment with curcumin. This result corresponds to previous observations studied in mice and rat models^[7-9].

Chemoprevention is promising as a preventive approach for hepatitis. Curcumin (diferuloylmethane), a polyphenol compound, is an active ingredient of turmeric (*Curcuma longa*)^[10]. The phenolic and methoxy groups on the benzene rings of curcumin are important structural features that contribute to its anti-oxidant properties and its ability to reduce the amount of free radicals^[17-20]. Curcumin shows beneficial effects in inflammatory conditions including hepatitis^[14].

To assess lipid peroxidation we used MDA as a marker^[21] and reduced GSH as indicator of hepatoprotectivity for cells. In this study the oxidative damage caused by APAP overdose was significantly attenuated by administering curcumin. It was conceivable that curcumin could protect against free radical mediated oxidative stress by scavenging for free radicals that limits lipid peroxidation

Table 1 Summary of the hepatic necroinflammation score in all groups

| Group | n | Hepatic necroinflammation scores | | | |
|----------------|---|----------------------------------|---|---|---|
| | | 0 | 1 | 2 | 3 |
| Control | 8 | 8 | - | - | - |
| APAP | 8 | - | 1 | 1 | 6 |
| APAP + CUR 200 | 8 | 5 | 2 | 1 | - |
| APAP + CUR 600 | 8 | 5 | 3 | - | - |

Data are expressed as the number of mice exhibiting each score of hepatic necroinflammation ($n = 8$). Hepatic necroinflammation score in each section was graded according to the criteria described by Brunt *et al*^[16] from 0 to 3 as follow; Score 0: No hepatocyte injury/inflammation; Score 1: Sparse or mild focal zone 3 hepatocyte injury/inflammation; Score 2: Noticeable zone 3 hepatocyte injury/inflammation; Score 3: Severe zone 3 hepatocyte injury/inflammation. 0 = None; 1 = Mild; 2 = Moderate; 3 = Severe; APAP: N-acetyl-P-aminophenol; CUR: Curcumin.

involved in membrane damage. In this study the GSH depletion caused by APAP overdose was significantly attenuated by administering curcumin. The protective action of curcumin can be explained by GSH inducer through induction of glutathione reductase enzyme system.

Serum transaminase, SGOT and SGPT, are often used as markers as their increase indicates liver damage^[22,23]. There is a significant increase of both SGOT and SGPT in APAP overdose. We demonstrated that this increase was reduced by the administration of curcumin.

It has been reported that IL-12 is produced by dendritic cells, monocytes, Langerhans cells, neutrophils, and keratinocytes^[24]. IL-18 is produced by activated macrophages, keratinocytes, intestinal epithelial cells, oestoblasts, adrenal cortex cells, and the murine diencephalon. IL-18 is synthesized as a precursor 24 kilodalton molecule without a signal peptide and must be cleaved to produce an active molecule. IL-1 converting enzyme (or caspase-1) cleaves pro-IL-18, producing the mature, bioactive peptide that is readily released from cells^[25-29]. Importantly, both of these cytokines are produced from Kupffer cells or hepatic macrophages in the liver. It may be possible that inflammation is due to hepatocytes releasing cytokines into the blood stream. Furthermore, IL-12, in combination with IL-18, causes inflammation *via* the activity of interferon-gamma, which is produced from T-lymphocyte and NK cells.

Curcumin is modulates the inflammatory response by down-regulating the activity of COX-2, inducible NO synthase, tumor necrosis factor- α , IL-1, IL-2, IL-6 and IL-8^[30]. This shows that curcumin is an anti-inflammatory substance. These cytokines are required for the expression of many cells linked with the inflammatory response. However, there are no experiments which study the effect of curcumin in preventing hepatitis resulting from APAP overdose and influence the levels of cytokines IL-12 and IL-18. Therefore, we studied the effect of curcumin on decreasing hepatitis resulting from APAP overdose. We showed that curcumin could prevent hepatitis resulting from APAP overdose and cause decrease in IL-12 and

IL-18 levels. It may be possible that curcumin can inhibit caspase-1 enzyme, which is cleaved pro-IL-18 into bioactive peptide or active-IL-18^[26]. This could explain that another pathway may also reduce liver inflammation that is indirectly mediated by oxidative stress inhibition.

In the present study, APAP overdose caused extensively hepatic necrosis. In curcumin supplementation, liver histopathology improved and showed only a focal hepatic necrosis of lobules.

In conclusion, APAP overdose can cause liver injury. Our results show curcumin could attenuate APAP-induced liver injury by decrease oxidative stress, reduce liver inflammation, restore hepatic GSH, and improve liver histopathology. In addition, curcumin at the dose of 600 mg/kg tends to be more potent than 200 mg/kg in preventing the effects of APAP hepatotoxicity. Hence, curcumin might be a novel therapeutic strategy against hepatitis caused by APAP overdose.

COMMENTS

Background

N-acetyl-P-aminophenol (APAP) overdose induced liver damage is one of the most widespread drug-induced side-effects. Although the exact mechanism of APAP remains largely unknown, it appears to involve two pathways: direct hepatotoxicity and adverse immune reactions. This impairment of liver functions can culminate in cell death, leading to a variety of pathological conditions, including acute hepatitis. Curcumin has been shown to possess a wide spectrum of biological actions. These include anti-inflammatory and anti-oxidant activities. Authors postulated that curcumin, acting through the oxidative stress inhibition, could reduce the production of inflammatory cytokines; thus resulting in the attenuation of liver injury in APAP-induced hepatitis in mice.

Research frontiers

Curcumin (diferuloylmethane) is the main yellow bioactive component of turmeric (*Curcuma longa*). It has been shown to possess a wide spectrum of biological actions by the inhibition of oxidative stress and reduction of inflammatory cytokines. APAP can cause liver injury through the increase in oxidative stress and release of inflammatory cytokines leading to liver injury. The hallmark of this study was that we showed an attenuation of liver damage and decrease in oxidative stress, reduced liver inflammation, restoration of hepatic glutathione (GSH), and improved liver histopathology after curcumin administration in APAP-treated animals.

Innovations and breakthroughs

The previous study showed that curcumin is an anti-inflammatory and anti-oxidant agent in an *in vivo* study. However, it is unclear whether curcumin has any effect in APAP-induced hepatitis *in vivo*. Therefore, in this study, authors examined the protective effects of curcumin in APAP-induced liver damage in mice and authors found that curcumin could attenuate APAP-induced liver injury through the decrease in oxidative stress, reduce liver inflammation, restoration of hepatic GSH, and improve liver histopathology.

Applications

Curcumin might be a novel therapeutic strategy against hepatitis caused by APAP overdose.

Peer review

This is an interesting study of the effects of curcumin on APAP-induced hepatitis in mice. This study showed the effects of curcumin in attenuation of APAP-induced hepatitis reflected in attenuated levels of hepatic malondialdehyde, transaminase, inflammatory cytokines, hepatic GSH, and improved liver histopathology.

Abstract

AIM: To investigate the expression deficiency of key molecular markers in the homologous recombination pathway.

METHODS: Expression loss of breast cancer type 1 susceptibility protein (BRCA1), ataxia telangiectasia mutated (ATM), ATM-Rad3-related (ATR), mediator of DNA damage checkpoint protein 1 (MDC1) and meiotic recombination 11 (Mre11) were correlated with their clinicopathological parameters in gastric cancer (GC). One hundred and twenty treatment-naïve GC samples were formalin-fixed and paraffin-embedded into tissue blocks. Two representative cores from each block were extracted and constructed into tissue microarrays. Expression levels of BRCA1, ATM, ATR, MDC1 and Mre11 were determined using immunohistochemical analysis, and correlated with clinical parameters, including age, gender, Lauren subtype, tumor grades, clinical stage and overall survival.

RESULTS: Expression loss of BRCA1, ATM, ATR, MDC1, and Mre11 was found in 21.4%, 20.2%, 21.0%, 11.1% and 4.6%, respectively, of interpretable cases. BRCA1 loss was significantly associated with patients of diffused subtype (intestinal *vs* diffused, 8.2% *vs* 31.7%, $P = 0.001$), higher tumor grade (I/II *vs* III, 10.7% *vs* 20.5%; I/II *vs* IV, 10.7% *vs* 54.5%, $P = 0.047$) and advanced clinical stage (I/II *vs* III, 12.9% *vs* 16.9%; I/II *vs* IV, 12.9% *vs* 45.5%, $P = 0.006$). MDC1 loss was significantly associated with patients of diffused subtype (intestinal *vs* diffused, 0% *vs* 19.7%, $P = 0.001$) and higher tumor grade (I/II *vs* III, 0% *vs* 12%; I/II *vs* IV, 0% *vs* 30.8%, $P = 0.012$). In addition, the survival time of the patients with expression loss of BRCA1 was significantly shorter than those with positive expression of BRCA1 (2-year survival rate, 32.4% *vs* 62.8%, $P = 0.015$). No correlations were found between clinicopathological parameters and expression loss of ATM, ATR and Mre11.

CONCLUSION: Our results support the hypothesis that homologous recombination deficiency plays an important role in the progression of gastric carcinoma. Loss of expression of BRCA1 and MDC1 may serve as predictive factors in tumor development or progression in GC patients.

INTRODUCTION

DNA lesions constantly threaten the integrity of our genome. Of the major DNA lesions, double-strand DNA breaks (DSBs) pose the most dangerous threat^[1]. DSBs occur when both complementary strands of DNA break simultaneously, and failure to repair these DSBs can result in chromosomal aberrations including mutations, deletions, amplifications, translocations, all of which can lead to cancer predispositions. Cells employ two major pathways to repair DSBs: homologous recombination (HR) and non-homologous end joining (NHEJ). HR and NHEJ differ mainly in two aspects. First, they differ in the frequency of errors that occur during DSB repairs. NHEJ employs a direct ligation mechanism that is highly error-prone, while HR utilizes the genomic information stored in homologous strands to proof-read the repair process and thus is essentially error-free. Second, the two pathways differ in the cell cycles in which they are primarily involved. NHEJ is most commonly found in G0 and G1 phases; meanwhile HR predominates in S and G2 phases, which are two critical stages that require high-fidelity transmission of genetic information. Attributed to its error-free mechanism and deployment in key cell-cycle phases, HR plays a central role in the protection against DSBs and hence is crucial in maintaining the genomic stability of the cells^[2].

A complex and hierarchical network of proteins is implicated in the HR pathway to detect, signal and repair DSBs. In this network, breast cancer type 1 susceptibility protein (BRCA1), ataxia telangiectasia mutated (ATM), ATM-Rad3-related (ATR), mediator of DNA damage checkpoint protein 1 (MDC1) and meiotic recombination 11 (Mre11) are most important functionally. In brief, ATM/ATR located at the top of the signaling cascades act as the core sensors of DSBs^[3] by collaborating with other sensor molecules, including MDC1^[4] and the complex of MRE11-Rad50-NBS1^[5]. Downstream substrates that are involved in checkpoint activation, among them BRCA1/2^[6], are then phosphorylated by ATM and ATR, causing cell cycle arrest until DSBs are repaired^[7].

Defects in the HR pathway or homologous recombination deficiency (HRD) directly compromise the genomic stability and predispose to cancer formation^[8]. The relationship between HRD and development of many cancer types has been well established^[9]. Genetic aberrations of BRCA1/2, the most widely studied markers in the HR pathway, have been found to promote both tumor initiation and progression^[10,11]. These genetic abnormalities, together with BRCA1/2 protein loss, were reported in many carcinomas^[12], especially in breast cancer (BC) and ovarian cancer (OC). In BC, *BRC1/BRC2* mutations are responsible for 3%-8% of all cases and 30%-40% of familial cases. Ten percent of patients with OC have a genetic predisposition. About 80% of families with a history of OC have *BRC1* mutations, while 15% have *BRC2* mutations^[13]. Aberrations in ATM function are linked with head and neck squamous cell carcinoma^[14], chronic lymphocytic leukemia^[15], colorectal can-

cer^[16], BC and OC^[17]. Genetic alterations of ATR were frequently reported in BC and OC^[18-20]. Dysfunctional MDC1 was implicated in BC development^[21,22] among other cancer types^[23,24]. Abnormal Mre11 signaling is strongly linked with BC, with mutations and protein loss found to be associated with BC pathogenesis^[25-28].

These HRD tumors also demonstrated enhanced sensitivity toward DNA-damaging agents, through the so-called "synthetic lethality"^[29]. These specific populations of tumor cells, under DNA-damaging agents, such as poly (ADP-ribose) polymerase (PARP) inhibitors^[30], are unable to recruit the necessary cellular machinery for the repair of DSBs and will undergo apoptosis. Pre-clinical studies of PARP inhibitors had raised the expectations for this highly selective therapeutic approach in HRD patients although these hypotheses need to be further validated in the clinical studies^[31,32]. Therefore, it is useful to understand the status of HRD-specific markers in different tumor types, such as GC.

GC is the second leading cause of cancer-related death worldwide and is particularly prevalent in Asia. Previous reports suggested that HRD could play a role in the carcinogenesis of the stomach^[33-37]. Yet, HRD's prognostic perspective in GC has not been fully explored and this study aims to address these questions. In order to assess the involvement of HRD in gastric tumorigenesis, we have analyzed the immunohistochemical expression of BRCA1, ATM, ATR, MDC1 and Mre11 in 120 GC samples and correlated them with clinicopathological parameters.

MATERIALS AND METHODS

Clinical samples and patient information

One hundred and twenty formalin-fixed and paraffin-embedded (FFPE) tissue samples were collected from Shanghai Renji Hospital for the study. All patients underwent radical resection between 2007 and 2010. The median age of the patients (82 males and 38 females) was 61.3 years (range: 22-87 years). All tumor tissues were diagnosed with gastric adenocarcinomas by two qualified pathologists.

Immunohistochemistry

GC tumor tissue and adjacent non-tumor tissue samples were collected after surgery following standard FFPE procedure. Tissue microarray (TMA) was then made with 2 representative cores withdrawn from FFPE block for each case. Four μm -thick tissue sections were cut from TMA for immunohistochemical (IHC) study. The slides were baked at 56 °C for 1 h, then de-paraffinized in xylene for 20 min and rehydrated through a graded series of ethanol concentrations (5 min in 100% ethanol first, followed by 5 min in 70% ethanol). Antigen retrieval was done in pressure cooker for 5 min using Target Retrieval Solution (Dako, Copenhagen, Denmark). Endogenous peroxidase activity was blocked by Peroxidase Blocking Reagent (Dako, Copenhagen, Denmark) for 5 min. Primary antibodies (ATM, 1:50, Epitomics, cat. No. 1549-1; ATR,

BRCA1: Breast cancer type 1 susceptibility protein; ATM: Ataxia telangiectasia mutated; ATR: ATM-Rad3-related; MDC1: Mediator of DNA damage checkpoint protein 1; Mre11: Meiotic recombination 11.

1:100, Santa-Cruz Technology, cat. No. sc-1887; BRCA1, 1:100, Merck, cat. No. OP92; MDC1, 1:500, Sigma, cat. No. M2444; Mre11, 1:200, Abcam, cat. No. ab214) were then applied to cover the specimen for 1 h at room temperature, followed by incubation with labeled polymer-HRP anti-rabbit or anti-mouse secondary antibody (Dako, Copenhagen, Denmark) for 30 min at room temperature. Thorough rinsing with TBST was done after incubation with each reagent. The slides were visualized using DAB substrate-chromagen (Dako, Copenhagen, Denmark) and washed with deionized water before counterstaining with haematoxylin. The slides were then dehydrated through a graded series of ethanol concentrations, cleared in xylene and coverslipped in DPX mounting medium.

Immunohistochemical scoring

The intensity of the staining in the nuclear of tumor cells was recorded. Scoring was established as follows: 0, if absence of staining was observed; 1+, if the tumor cells had weak staining; 2+, if tumor cells had moderate staining; and 3+, if tumor cells had strong staining. Tumors with 1+, 2+ and 3+ expression were interpreted as positive and tumors with no expression (0 score) were interpreted as expression loss. Given the heterogeneity of protein expression in tumor cells, the highest scoring from either one of TMA cores was counted as the final result.

Statistical analysis

The analysis was conducted with SPSS 16.0 software. Characteristics of the two groups were compared using the χ^2 likelihood ratio test. Logistic regression model was applied to interrogate association of IHC data and individual clinical parameter. The Kaplan-Meier method was used to estimate the survival distributions. The log-rank test was

used to compare the survival distributions. Two-sided *P* values < 0.05 were considered statistically significant.

RESULTS

Among the 120 cases, 69.2% of tumors (83/120) involved the ventricular sinuses, 14.1% (17/120) involved the ventricle corpora and 16.7% (20/120) involved the cardia in the stomach. All tumor samples were diagnosed with adenocarcinoma with different tumor grade and Lauren subtypes.

The overall follow-up rate is 87% with a median follow-up time of 32 mo. At the time of analysis, 49.2% (49/120) patients were alive and 50.8% (61/120) patients died. The overall 2-year survival rate was 54.2%. Loss of BRCA1 expression was observed in 21.4% (24/112), ATM in 20.2% (23/114), ATR in 20.9% (18/86), MDC1 in 11.1% (13/117), and Mre11 in 4.7% (4/86) of the GC patients (Figure 1). Clinicopathological parameters and expression of HRD biomarkers in the samples are displayed in Table 1.

Expression loss of each marker and its correlation with clinicopathological parameters

The clinicopathological parameters of patients in the study included age, gender, Lauren type, tumor grade and clinical stage according to 2010 World Health Organization tumor-node-metastasis classification. Statistical analysis of IHC data and clinicopathological parameters are shown in Table 1. Loss of ATM, ATR and Mre11 expression was not associated with gender or clinical stage. BRCA1 loss was significantly associated with patients of diffused subtype (*P* = 0.001), higher tumor grade (*P* = 0.047) and advanced clinical stage (*P* = 0.006). MDC1

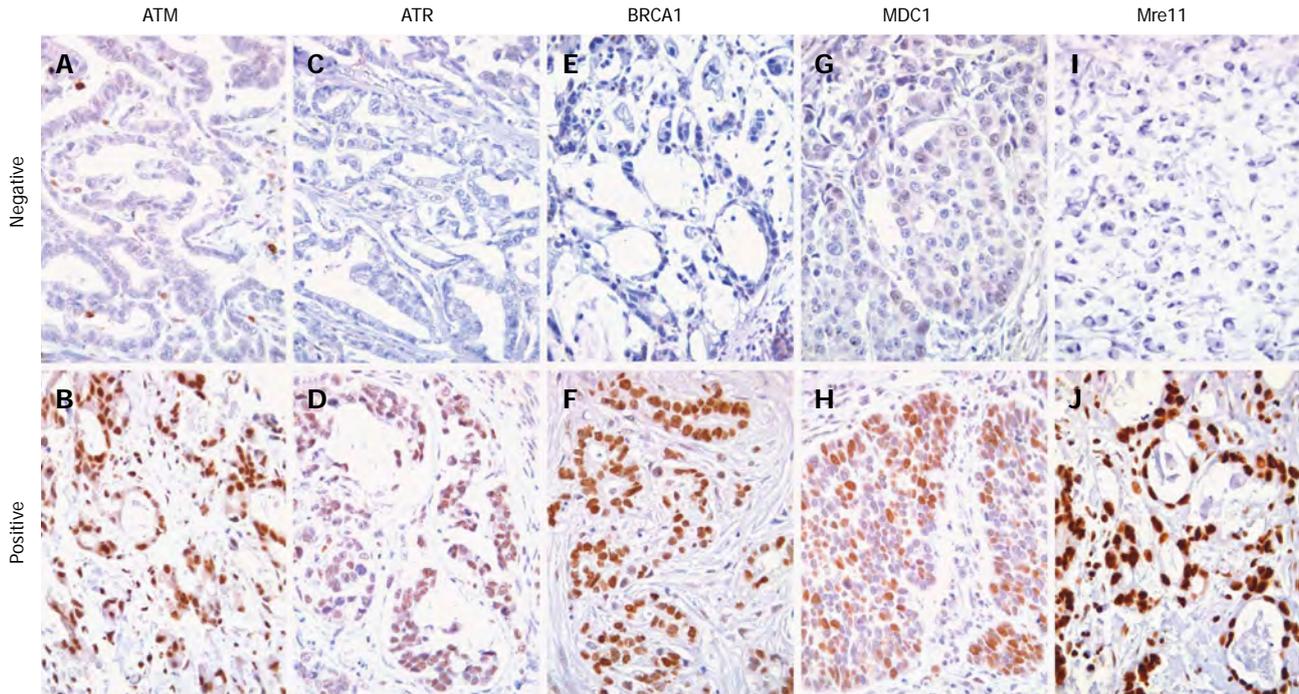

Figure 1 Immunohistochemical expression of ataxia telangiectasia mutated, ataxia telangiectasia mutated-Rad3-related, breast cancer type 1 susceptibility protein, mediator of DNA damage checkpoint protein 1 and meiotic recombination 11 in gastric cancer tissues. ATM: Ataxia telangiectasia mutated; ATR: Ataxia telangiectasia mutated-Rad3-related; BRCA1: Breast cancer type 1 susceptibility protein 1; MDC1: Mediator of DNA damage checkpoint protein 1; Mre11: Meiotic recombination 11. 3,3'-Diaminobenzidine staining, $\times 200$.

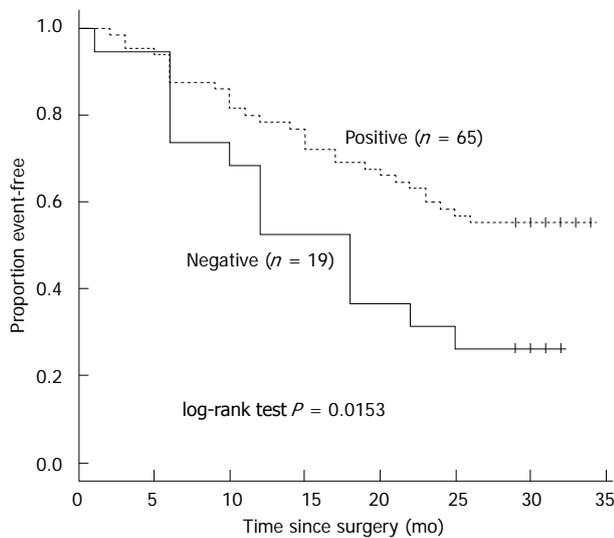

Figure 2 Negative effect of breast cancer type 1 susceptibility protein loss on patient overall survival. The survival time of the patients with positive expression of breast cancer type 1 susceptibility protein (BRCA1) was significantly longer than those with negative expression of BRCA1.

loss was significantly associated with patients of diffused subtype ($P = 0.001$) and higher tumor grade ($P = 0.012$).

Correlation between BRCA1 expression and survival

Expression loss of BRCA1 was significantly associated with the progression of the GC patients. The survival time of the patients with BRCA1 expression loss was

significantly shorter than BRCA1-positive patients (2-year survival rate, 32.4% *vs* 62.8%, $P = 0.015$; Figure 2). Expression of the other four markers was not significantly associated with survival ($P > 0.05$).

Combined biomarker analysis

Twenty-seven (51.9%, 27/52) cases had positive expression of all 5 protein kinases (HR+ group) and 25 (48.1%, 25/52) cases had expression loss of at least one protein kinase (HRD group). Significant difference of tumor grade was observed between the two groups, with the HRD group showing significant association with higher tumor grades ($P = 0.013$). But there was no significant difference in gender, Lauren type or clinical stage. Survival analysis also showed no significant difference between the two groups.

DISCUSSION

Gastric cancer is one of the leading causes of cancer-related death worldwide, and although the incidence has decreased in Western countries, Asia remains the specific high-risk area. Various reports have suggested that HRD could play a role in gastric tumorigenesis. However, a systematic analysis of the key markers in the HR pathway is largely missing. In the present study, the expression losses of the five key markers, namely BRCA1, ATM, ATR, MDC1 and Mre11 were correlated with the clinicopathological parameters in a cohort of Chinese GC patients.

Recent studies of the relationship between BRCA1

and tumors mainly focused on BC and OC. The frequency of BRCA1 mutations among breast cancer patients is less than 5%^[38], while the loss of BRCA1 protein expression is higher at around 20%^[39]. However, BRCA1 expression in gastric cancer has rarely been studied. Our data showed that BRCA1 expression deficiency occurred in 24/112 (21.4%) GC patients. BRCA1 deficiency was significantly associated with patients of diffused Lauren type, higher tumor grades and advanced clinical stage. Patients with BRCA1 deficiency lived significantly shorter ($P = 0.015$) than those patients with positive expression of BRCA1, indicating that loss of BRCA1 can serve as a prognostic marker. Mutations of *BRCA1* in gastric cancer were not found commonly^[40]. Rather, microsatellite instability and loss-of-heterozygosity of *BRCA1* gene at locus D17S855 were shown to be the predominant genetic abnormalities found in GC^[41]. Both of these genetic instabilities may lead to the reduction or loss of the functional BRCA1 protein. Recently, a high frequency of hypermethylation on the BRCA1 promoter was found in tumor tissues and these epigenetic changes correlated with the loss or reduction of protein expression^[42]. These reports together with our data, suggest that BRCA1 protein loss may be a suitable indicator of cancer development in GC.

Lack of reports on *MDC1* mutations suggests that down-regulation of the marker at the protein level may serve as a better prognostic marker. MDC1 protein loss/reduction was previously described^[22], although its correlation with survival was not assessed. Patel *et al.*^[21] addressed this question by profiling MDC1 in subsets of early-stage BC patients who underwent breast-conserving surgery and radiation therapy and found that decreased MDC1 was not related to overall survival. However, they found that MDC1 reduction correlated with nodal failure and concluded the role of MDC1 in early cancer development. To our knowledge, our study is the first to assess MDC1 expression in GCs. The strong association between MDC1 deficiency and diffused subtype indicates that MDC1 plays a major role in this subtype's development. In addition, the association between MDC1 and higher tumor grade also suggests that MDC1 deficiency is implicated in GC pathogenesis. Although MDC1 loss failed to establish a significant correlation with survival, the strong linkage of MDC1 loss with diffused type and higher tumor grades warrants further research into this marker.

Our data suggested ATM, ATR and Mre11 deficiencies were commonly found in GC patients. But there was no significant difference in clinicopathological features between the patients with negative and positive expression for each marker. Mutations of *ATM* have been suggested to play a possible role in the carcinogenesis of other cancer types. The rate of *ATM* mutations in advanced GC has been previously studied and although several variants were found, there were no hot spots. In the same study, decreased level of phosphorylated ATM at Ser1981 significantly correlated with poor differentiation, lymph node metastasis and poor 5-year survival^[43]. Mutation of *ATR* was previously reported in BC^[19], OC^[18] and colon

cancers^[44], but has never been found in GC. In addition, protein loss of ATR has never been studied in GC and we report here for the first time that protein loss of ATR is a common feature in GC. We investigated whether Mre11 mutation could play a role in GC. In a previous study^[45] that correlated MRE11 poly(I)11 mutations with clinicopathological features, a significant association was found only in patients with a family history of GC. In addition, the authors demonstrated that this *MRE11* mutation was associated with absent or strongly reduced Mre11 immunostaining, indicating that protein loss of Mre11 may be a suitable surrogate for the detection of Mre11-related HRD in GC. In our study, the same antibody (Clone 12D7) for the detection of Mre11 was used and the results agreed with those from the previous studies.

In the combined biomarker analysis, we found significant difference in tumor grade between the HR+ and HRD groups, under the assumption that loss of one protein kinase is sufficient to cause a non-functional HR pathway. Our data suggested that HR deficiency played an important role in the GC pathogenesis but is not necessarily crucial in gastric tumor maintenance. Further work will be done to address whether significant association would appear when a larger patient population and a longer follow-up time are available.

These results have made possible the clinical use of DNA-damaging agents in HRD GCs, although finding markers that could predict response is still a daunting challenge^[46]. While most of the PARP inhibitors in BC and OC employed *BRCA1/2*-mutation as the patient selection criteria^[47,48], this may not be the best strategy in GC, as protein loss is evidently the driver. For the other HRD biomarkers, their prognostic and predictive values need to be further investigated. In our opinion, unless they are validated in both pre-clinical and clinical settings, BRCA1 remains the strongest predictor of response to compounds that are exploiting the HRD pathway.

COMMENTS

Background

DNA lesions constantly threaten the integrity of our genome. Of the major DNA lesions, double-strand DNA breaks (DSBs) pose the most dangerous threat. DSBs occur when both complementary strands of DNA break simultaneously, and failure to repair these DSBs can result in chromosomal aberrations, including mutations, deletions, amplifications and translocations, all of which can lead to cancer predispositions.

Research frontiers

Various reports have suggested that homologous recombination deficiency (HRD) could play a role in gastric tumorigenesis. However, a systematic analysis of the key markers in the homologous recombination pathway is largely missing. In the present study, the expression losses of the five key markers, namely breast cancer type 1 susceptibility protein (BRCA1), ataxia telangiectasia mutated, ataxia telangiectasia mutated-Rad3-related, mediator of DNA damage checkpoint protein 1 and meiotic recombination 11, were correlated with the clinicopathological parameters in a cohort of Chinese gastric carcinoma (GC) patients.

Innovations and breakthroughs

The results have made possible the clinical use of DNA-damaging agents in HRD GCs, although finding markers that could predict response is still a daunting challenge.

Applications

For the other HRD biomarkers, their prognostic and predictive values need to be further investigated. In author's opinion, unless they are validated in both pre-clinical and clinical settings, BRCA1 remains the strongest predictor of response to compounds that are exploiting the HRD pathway.

Peer review

This is an interesting study in which authors investigated the expression deficiency of key molecular markers in the HR pathway. The results are interesting and suggest that homologous recombination deficiency plays an important role in the progression of GC.

Abstract

AIM: To compare the prognostic assessment of lymph node ratio and absolute number based staging system for gastric cancer after D2 resection.

METHODS: The clinical, pathologic, and long-term follow-up data of 427 patients with gastric cancer that underwent D2 curative gastrectomy were retrospectively analyzed. The relationships between the metastatic lymph node ratio (MLR), log odds of positive lymph nodes (LODDS), and positive lymph nodes (pN) staging methods and the long-term prognoses of the patients were compared. In addition, the survival curves, accuracy, and homogeneity were compared with stratification to evaluate the prognostic assessment of the 3 methods when the number of tested lymph nodes was insufficient (< 10 and 10-15).

RESULTS: MLR [hazard ratio (HR) = 1.401, $P = 0.012$], LODDS (HR = 1.012, $P = 0.034$), and pN (HR = 1.376, $P = 0.005$) were independent risk factors for gastric cancer patients. The receiver operating characteristic (ROC) curves showed that the prognostic accuracy of the 3 methods was comparable ($P > 0.05$). Spearman

correlation analysis confirmed that MLR, LODDS, and pN were all positively correlated with the total number of tested lymph nodes. When the number of tested lymph node was < 10, the value of survival curves staged by MLR and LODDS was superior to those of pN staging. However, the difference in survival curves between adjacent stages was not significant. In addition, the survival rate of stage 4 patients using the MLR and LODDS staging methods was 26.7% and 27.3% with < 10 lymph node, respectively which were significantly higher than the survival rate of patients with > 15 tested lymph nodes (< 4%). The ROC curve showed that the accuracy of the prognostic assessment of MLR, LODDS, and pN staging methods was comparable ($P > 0.05$), and the area under the ROC curve of all 3 methods were increased progressively with the enhanced levels of examined lymph nodes. In addition, the homogeneity of the 3 methods in patients with ≤ 15 tested lymph nodes also showed no significant difference.

CONCLUSION: Neither MLR or LODDS could reduce the staging bias. A sufficient number of tested lymph nodes is key to ensure an accurate prognosis for patients underwent D2 radical gastrectomy.

Xu J, Bian YH, Jin X, Cao H. Prognostic assessment of different metastatic lymph node staging methods for gastric cancer after D2 resection. *World J Gastroenterol* 2013; 19(12): 1975-1983 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1975.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1975>

INTRODUCTION

Gastric carcinoma is one of the most common cancers in

many Asian countries including South Korea and Japan, and the second most common cause of cancer-related death worldwide^[1]. There are nearly 470 000 newly diagnosed cases every year in China. Of these cases, approximately 75% of the patients will die, making gastric cancer the third leading cause of cancer deaths^[2]. Because of its long-term efficacy, D2 radical gastrectomy has been accepted in most countries, including those in the Europe and the United States, as the standard surgery for gastric cancer^[3-5]. The pathological staging of gastric cancer after D2 radical gastrectomy is not only closely related to the long-term survival of patients but is also the main basis to guide subsequent adjuvant therapy. In the currently accepted criteria of postoperative tumor-node-metastasis (TNM) staging of gastric cancer, the staging of regional lymph node metastasis (N) is of great significance. This staging is currently controversial and changes frequently. In both the latest 7th edition of the American Joint Cancer Committee (AJCC)^[6] and the 14th edition of the Statute of Gastric Cancer Treatment in Japan^[7] in 2010, the absolute number of positive lymph nodes (pN) in the perigastric region was used as the staging basis, and the staging criteria for each stage were unified. Meanwhile, many studies have supported the N staging by computing the metastatic lymph node ratio. Currently, there are 2 main methods in the staging of relative number of positive lymph nodes, the metastatic lymph node ratio (MLR)^[8] and the log odds of positive lymph nodes (LODDS)^[9]. The former calculates the ratio of the number of pN over the total number of the tested lymph nodes, while the latter calculates the log value, $\log[(\text{pnod} + 0.5)/(\text{tnod} - \text{pnod} + 0.5)]$, of the ratio between positive and negative lymph nodes. Previous studies have shown that, especially when the number of the tested lymph nodes was insufficient, the staging of MLR and LODDS could more accurately assess the prognosis of patients with gastric cancer than staging using the absolute value (pN)^[9-13]. However, a unified standard of specific staging for relative number of positive lymph nodes is not currently available, and whether this ratio is superior to the pN staging is also unknown^[14,15]. Therefore, the clinical data and long-term follow-up results of the gastric cancer patients that received D2 radical gastrectomy were retrospectively analyzed in this study, and the values of the above staging methods for regional lymph node metastasis in assessing patient prognosis were compared.

MATERIALS AND METHODS

Clinical data

The clinical data of 427 gastric cancer patients who were admitted and underwent standard D2 radical gastrectomy at Affiliated Renji Hospital, Shanghai Jiaotong University School of Medicine from June 2005 to December 2008 and had complete follow-up data were collected. All patients underwent either distal partial gastrectomy, proximal partial gastrectomy or total gastrectomy with regional lymph nodes dissection to D2 with curative intent

by the same gastrointestinal professional operation team. However, due to the defects of pathological examination, the number of examined lymph nodes of most patients (65.1%) failed to reach the 7th edition of AJCC requirement, which recommended at least 16 lymph nodes should be retrieved for adequate staging. The clinical and pathological data are shown in Table 1. All surviving cases were followed for 39-81 mo with a median follow-up time of 55 mo. The last follow-up was on March 11, 2012. The overall survival rate was 52.5% for all patients. The survival rate was 38.9% for the patients with lymph node metastasis and 80.6% for the patients without lymph node metastasis. The overall median survival time was 44 mo.

Lymph node staging

Of the 427 patients, those without lymph node metastasis were staged as MLR 0. For the remaining patients, the ratio of the number of pN over the number of tested lymph nodes was calculated, and 20 layers were established from 0 to 1 in 5% intervals. The log-rank test was used to compare differences in the survival curves of 2 adjacent layers. The layers with no differences were merged. Finally, based on prognosis, all patients with lymph node metastases were staged MLR 1-4. Similarly, the patients were staged LODDS 0-4 by the log-rank survival test. The pN staging criteria was defined in accordance to the 2010 AJCC/UICC 7th edition TNM staging criteria. The staging criteria and the number of cases for each group are shown in Table 2.

Statistical analysis

The cumulative survival rate was obtained using a Kaplan-Meier curve, and the differences in cumulative survival rates were compared by the log-rank test. The multivariate prognostic analysis was conducted with the Cox proportional risk regression model. The correlation between MLR, LODDS, and pN, as well as the total number of the tested lymph nodes, was analyzed with the Spearman correlation analysis. The accuracy of the prognosis assessment of each staging method was compared using the receiver operating characteristic curve (ROC) and the area under the curve (AUC). The group in each pN stage was re-grouped in accordance with MLR and LODDS, and the overall survival differences within groups and between groups were analyzed using the log-rank survival test to compare the homogeneity of the 3 staging methods. All statistical analyses were completed with SPSS 17.0 software; $P < 0.05$ was considered significant.

RESULTS

Correlation between MLR, LODDS, and pN and the prognosis of patients with gastric cancer

The results of univariate analysis of the correlation between various prognostic factors related to lymph node status and the prognosis of gastric cancer patients after D2 radical gastrectomy showed that the total number of

Table 1 Clinical and histopathological characteristics of the patients

| Factors | n |
|--|--------------|
| Gender (male/female) | 281/146 |
| Age (≤ 60 yr/> 60 yr) | 200/227 |
| Site (antrum/body/fundus/others) | 234/163/22/8 |
| Size (< 3 cm/3-6 cm/≥ 6 cm) | 36/216/175 |
| Histological grade (well/moderately/poorly) | 11/313/103 |
| Depth of invasion (T1/T2/≥ T3) | 4/79/344 |
| Lymphatic/venous invasion (absence/presence) | 359/68 |
| Perineural invasion (absence/presence) | 396/31 |
| Examined lymph nodes (< 10/10-15/> 15) | 126/152/149 |

the tested lymph nodes, MLR, LODDS, and pN staging all had an impact on the patient prognosis (Table 3). When the above factors were individually fitted into the Cox proportional risk model, the results showed that MLR [hazard ratio (HR) = 1.401, *P* = 0.012], LODDS (HR = 1.012, *P* = 0.034), and pN (HR = 1.376, *P* = 0.005) were independent risk factors for the prognosis of patients with gastric cancer.

Comparison between MLR, LODDS, and pN staging methods in the prognostic assessment of gastric cancer patients

The 5-year survival of the 427 patients after surgery was used as the gold standard to draw the ROC curve to compare the accuracy of the 3 staging methods in the prognostic assessment of gastric cancer patients. In the groups with no staging, the corresponding area under the curve for MLR, LODDS, and pN was 0.784 ± 0.022 , 0.790 ± 0.022 , and 0.765 ± 0.023 respectively (Figure 1A), with no significant differences (*P* > 0.05). In the groups with staging, the corresponding areas under the curve for MLR, LODDS, and pN were 0.775 ± 0.023 , 0.767 ± 0.023 , and 0.765 ± 0.023 , respectively (Figure 1B), with no significant differences.

Correlation between the MLR, LODDS, and pN staging methods and the total number of the tested lymph nodes

The results of Spearman correlation analysis showed that MLR, LODDS, and pN staging were all positively correlated with the total number of the tested lymph nodes, with a correlation coefficient of 0.177, 0.053, and 0.410, respectively, and all *P* values were < 0.01, which suggested that all of the 3 staging methods were more or less affected by the total number of tested lymph nodes. pN was positively correlated with MLR and LODDS with a correlation coefficient of 0.919 and 0.871, respectively, and the *P* values were both < 0.001.

Assessment value of the MLR, LODDS, and pN staging methods in patients with an insufficient number of tested lymph nodes

Some previous studies have suggested that, for the patients with an insufficient number of tested lymph nodes,

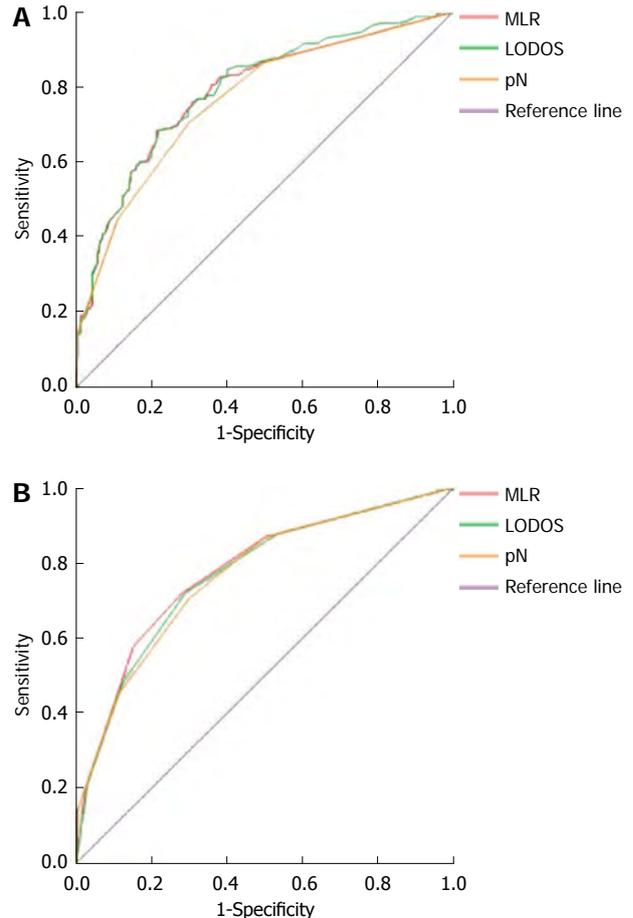

Figure 1 Comparison of receiver operating characteristic curves with metastatic lymph node ratio, log odds of positive lymph nodes, and positive lymph nodes staging methods. A: Receiver operating characteristic (ROC) curves with no staging; B: ROC curves with staging. MLR: Metastatic lymph node ratio; LODDS: Log odds of positive lymph nodes; pN: Positive lymph nodes.

the prognosis-assessment value of MLR staging was superior to that of the staging based on absolute number of positive lymph nodes^[9-12]. Therefore, all patients were divided into 3 subgroups according to the total number of tested lymph nodes: the number of the tested lymph nodes was < 10 (*n* = 126), 10-15 (*n* = 152) or > 15 (*n* = 149). A comparison was performed to compare the differences in the postoperative survival curve, the prognostic accuracy, and the homogeneity of the 3 staging methods in the patients with < 15 tested lymph nodes.

Comparison of survival curves

For the patient group with < 10 tested lymph nodes, the 5-year survival rate of patients exhibited a downward trend with the enhanced levels of MLR and LODDS staging. A log-rank test was conducted to compare the difference between adjacent stages, and the results showed that only the difference in survival curves between stage MLR 0 and MLR 1, and stage LODDS 2 and LODDS 3 was significant, with the *P* values of 0.026 and 0.028 respectively; The difference of remaining survival curves between adjacent stages was not significant. The value of

MLR: Metastatic lymph node ratio; LODDS: Log odds of positive lymph nodes; pN: Positive lymph nodes.

prognostic assessment based on pN staging system was not satisfactory, and the 5-year survival rate for each pN stage was 76.3% for pN 0, 44.4% for pN 1, 34.5% for pN 2, and 45.5% for pN 3a.

For the patient group with 10-15 tested lymph nodes, no significant difference in survival curves between any adjacent stages was found in the subgroup of MLR. Similar with MLR staging, the difference in survival curves also was not significant between any adjacent stages of LODDS.

For the group of patients with > 15 tested lymph nodes, the 5-year survival rates for each stage between MLR, LODDS and were comparable. However, the survival curves of pN staging appeared to better assess prognosis than the ratio-based staging methods, with significant difference in survival curves between any various stages (*P* < 0.05; Figure 2).

Comparison of the accuracy of prognostic assessment

The ROC curves showed that, regardless of staging, the corresponding areas under the curves of the MLR, LODDS, and pN staging methods were all increased progressively with the enhanced levels of examined lymph nodes. the AUC using the MLR, LODDS and pN staging methods increased from 0.716 ± 0.047, 0.718 ± 0.046 and 0.688 ± 0.048 with < 10 lymph node to 0.843 ± 0.031, 0.818 ± 0.034 and 0.836 ± 0.032 with > 15 tested lymph nodes, which were significantly larger than former groups. However, the AUC was not significantly different between the 3 methods within groups.

Comparison of the homogeneity of prognostic assessment

The various pN groups in which patients had < 10 or 10-15 tested lymph nodes were re-grouped according to MLR staging, and the results were shown in Table 4. When the numbers of retrieved lymph nodes were less than 10, only for patients in stage pN 1, the difference in the 5-year survival rate among different MLR stages was significant (*P* < 0.05). Furthermore, there was no significant difference in the 5-year survival rate among the different pN groups within the one MLR group. In 10-15 retrieved-node group, there was no significant difference of 5-year survival rates between the different MLR groups in one pN group. In addition, the difference of

MLR: Metastatic lymph node ratio; LODDS: Log odds of positive lymph nodes; pN: Positive lymph nodes.

5-year survival rates between different pN groups in one MLR group was also not significant.

Because the staging of the patients in MLR 0 (no pN detected) was the same as in pN 0, some studies have stated that the prognostic assessment of LODDS staging was more accurate for these patients^[9,16]. Therefore, when comparing the homogeneity of pN staging and LODDS staging, according to different numbers of the tested lymph nodes, the stage pN 0 was divided into two layers. The results showed that the pN0 patients with < 10 tested lymph nodes could be further staged LODDS 0-2, and the 5-year survival rate for the 3 stages was 81.8%, 70.0%, and 66.7%, respectively (Figure 3). However, the log-rank survival test showed that the differences between the 3 stages were not significant (*P* = 0.476). Furthermore, the pN 0 patients with 10-15 tested lymph nodes had the same LODDS stage. Generally, the difference in the 5-year survival rates between the different LODDS groups in one pN group was not significant. In addition, the difference in the 5-year survival rates between the different pN groups in one LODDS group was also not significant (Table 5).

DISCUSSION

Due to the decent long-term survival rate, surgical resection, represented by standard D2 radical gastrectomy, is currently the preferred treatment for gastric cancer. However, in recent years, with the rise of the concept of individualized treatment and the application of new adjunct treatment in clinical practice, an accurate prognostic assessment of patients with gastric cancer after surgery

LODDS: Log odds of positive lymph nodes; 5-YSR: 5-year survival rate; LN: Examined lymph nodes; pN: Positive lymph nodes.

is essential to the development of relevant follow-up treatment strategies^[17,18]. Currently, the postoperative pathological TNM staging is accepted and widely applied as the prognostic evaluation indicator in clinical practice. With regard to the N portion of the TNM staging, there has been considerable controversy ranging from earlier staging based on anatomical sites of metastatic lymph nodes^[19] to the specific staging criteria based on the number of regional metastatic lymph nodes^[20,21]. The N staging criteria were not unified until the 7th edition of the AJCC^[4] and the 14th edition of the Statute of Gastric Cancer Treatment in Japan^[5] unified the criteria for the first time in 2010. However, many researchers still believe that when the staging is based on the absolute number of metastatic lymph nodes, the number of pN is easily influenced by the numbers of removed and tested lymph nodes. When the number of tested lymph nodes is insufficient, staging bias may occur, affecting the accuracy of the prognostic assessment^[22,23]. The N staging based on MLR can overcome the above shortcomings^[24,25]. Therefore, when comparing the prognostic assessment of dif-

ferent lymph node metastasis staging methods in gastric cancer patients after D2 radical gastrectomy, this study focused on the impact of the 3 staging methods on long-term survival rate when the number of pathologically tested lymph nodes after surgery was insufficient.

To date, neither MLR nor LODDS staging has accurate and widely accepted criteria; therefore, the log-rank survival test was first conducted to verify the staging criteria of MLR and LODDS (Table 2). The 5-year survival rates of various stages according to the above criteria were similar to those of the corresponding pN stages (TNM staging criteria in the 7th edition of AJCC/UICC). The correlation analysis of the 3 staging methods also showed that MLR and LODDS were significantly positively correlated with pN. The ROC curves also showed that the accuracy of prognosis assessment of the 3 staging methods in gastric cancer patients was not significantly different. The subsequent univariate and multivariate analyses both showed that the MLR, LODDS, and pN staging methods were all closely related to patient prognosis-they were all independent risk factors for the

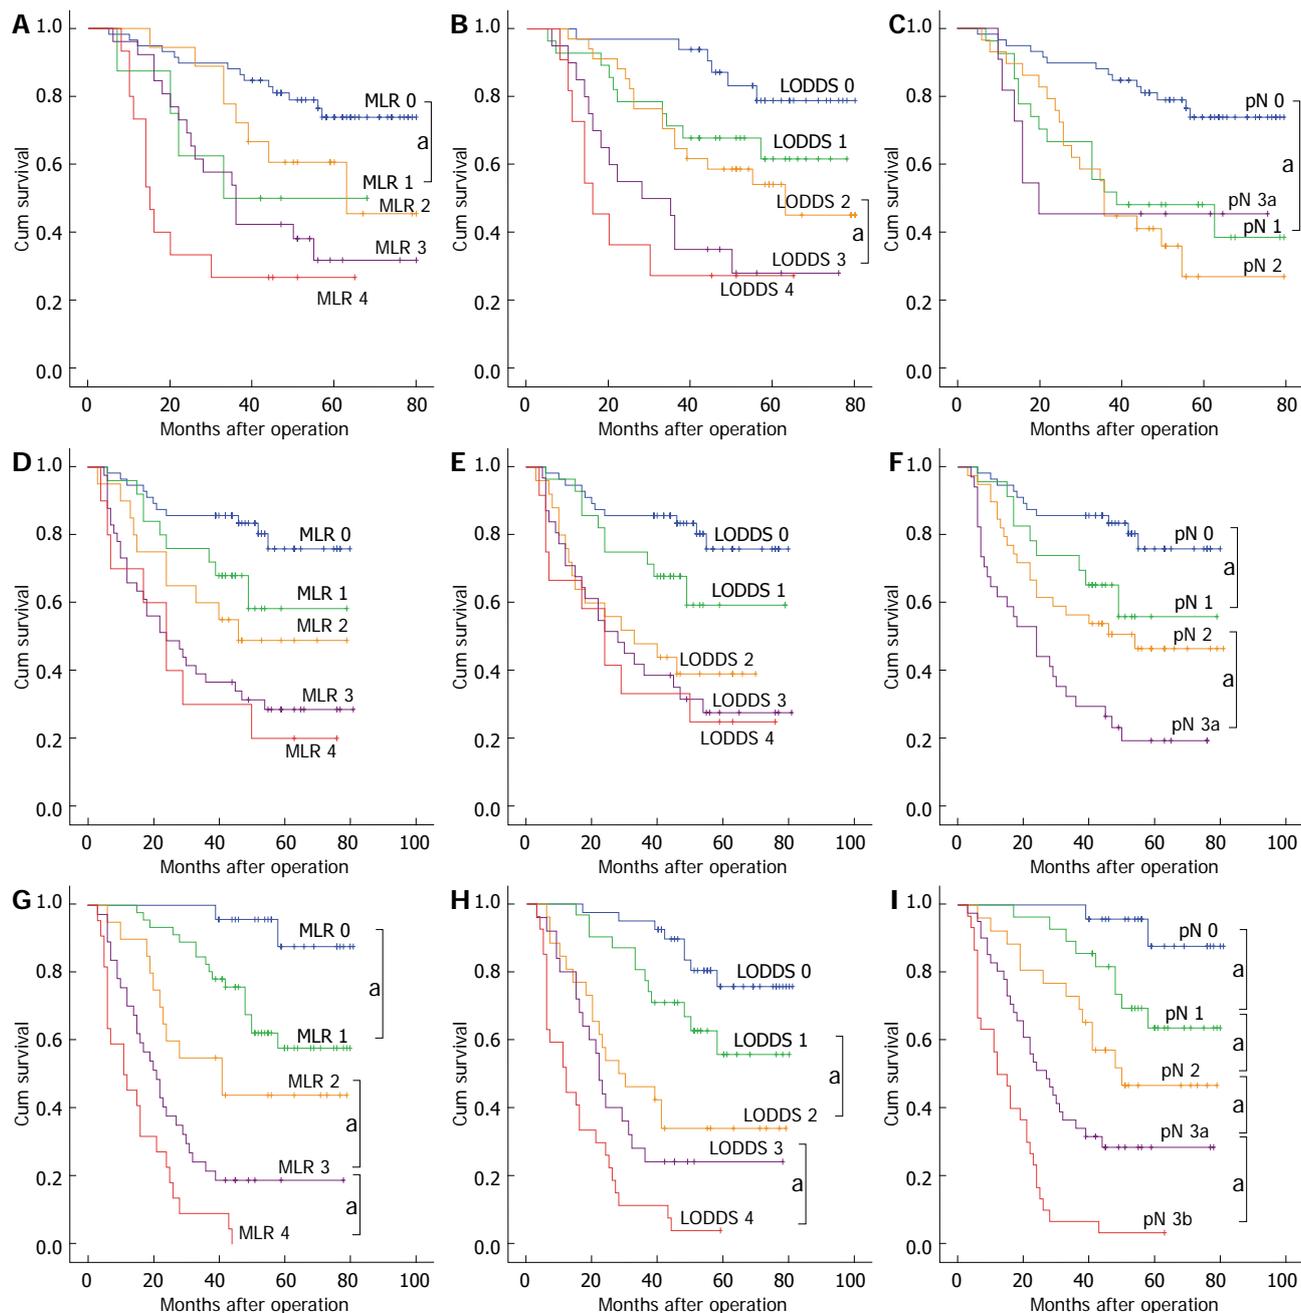

Figure 2 Comparison of survival curves in 3 staging system according to the number of lymph nodes retrieved. ^a $P < 0.05$ between adjacent stages. A: MLR, LN < 10; B: LODDS, LN < 10; C: pN, LN < 10; D: MLR, $10 \leq \text{LN} \leq 15$; E: LODDS, $10 \leq \text{LN} \leq 15$; F: pN, $10 \leq \text{LN} \leq 15$; G: MLR, LN > 15; H: LODDS, LN > 15; I: pN, LN > 15. MLR: Metastatic lymph node ratio; LODDS: Log odds of positive lymph nodes; pN: Positive lymph nodes; LN: Examined lymph nodes.

prognoses of gastric cancer patients. The above results suggest that MLR, LODDS, and pN staging methods can all be used for the prognostic assessment of gastric cancer, and the assessment efficacies of the 3 methods were similar.

Although the total number of tested lymph nodes in the Cox proportional risk regression model was not a significant independent risk factor for patient prognosis, univariate analysis showed that as the number of tested lymph nodes increased, the 5-year survival rate of patients exhibited a downward trend ($P = 0.039$); moreover, a correlation analysis showed that MLR,

LODDS, and pN were all positively correlated with the number of tested lymph nodes. When only the correlation coefficient of the number of tested lymph nodes was considered ($pN > \text{MLR} > \text{LODDS}$), the impact of the number of tested lymph nodes on the MLR and LODDS was smaller than that of the absolute number of pN, which suggests that compared with pN staging system, the MLR and LODDS were less affected by the total number of tested lymph nodes. The subsequent results of the survival curve of patients with insufficient tested lymph nodes also showed that, when the number of tested lymph node was < 10 , the MLR and LODDS

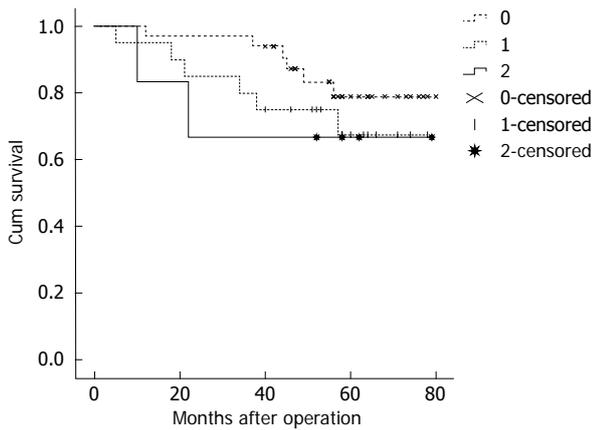

Figure 3 Survival curve of no positive lymph nodes patients with < 10 tested lymph nodes re-staged with the log odds of positive lymph nodes staging method.

staging methods appeared to better assess prognosis than pN staging. However, as shown in Figure 2, although the MLR and LODDS staging methods could more accurately assess the 5-year postoperative survival rate of gastric cancer patients at the early-middle stages (stage 0-2), the difference in the prognostic assessment of the patients at middle-late stages (stage 3 and 4) was not significant. The main reason was that, although the ratio could reduce the impact of sampling error compared with the absolute number, as the number of pN increased, the impact of the sampling error due to the insufficient number of tested lymph nodes also increased. Therefore, the difference in the prognoses of patients in the middle-late stages was not significant. In addition, for the patients in the middle-late stages of MLR and LODDS, especially those in stage 4, the 5-year survival rates were all $\geq 20\%$, which was significantly higher than that of the patients with > 15 ($< 4\%$) tested lymph nodes. The reason for this result may be that when the total number of tested lymph nodes was insufficient, the sampling sites were too concentrated near the lesion; therefore, the ratio of pN was higher, resulting in an overestimation of the actual pathological staging of patients. Moreover, the comparison of the 5-year survival rate of the 3 methods in patients with ≤ 15 tested lymph nodes also confirmed that the accuracy and homogeneity of the staging methods based on the MLR, LODDS or the absolute number of pN were similar, with no significant difference. At the same time, the comparison of the survival curve and ROC curve of the 3 staging methods in the < 10 , $10-15$ and > 15 group showed that the difference in the 5-year survival rate between stages and the assessment accuracy of survival rate were all increased progressively with the enhanced levels of examined lymph nodes, and the 3 staging methods exhibited no significant difference. The above results all confirmed that, regardless of the staging method, a sufficient number of tested lymph nodes was the key factor. When the number of tested lymph nodes was ≤ 15 , the staging based on MLR or LODDS could not compensate for the inadequacy of pN staging, and thus could not ac-

curately assess patient prognosis.

Although the number of cases did not affect the results of the statistical analysis significantly, it could be observed from the survival curve that the LODDS staging method appeared to better assess prognosis for patients at MLR and pN stage 0 with an insufficient number of tested lymph nodes. However, the advantage of the LODDS staging method was only apparent when the number of tested lymph nodes was < 10 . Additionally, because the 5-year survival rate for patients in stage pN0 was relatively high, the survival rates of patients in various LODDS stages were not significantly different after re-staging. Finally, the calculation method of LODDS was complicated. All of the above factors limited the practical application of LODDS staging method, and the practical value was low.

Some studies have found that the staging methods based on the MLR and LODDS could more accurately predict the prognosis of gastric cancer patients than the staging method based on the absolute number (pN), especially when the number of tested lymph nodes was insufficient^[9-13]. The above conclusions in this study appeared to be inconsistent with those previous findings. Different surgical methods may be the main cause of the contradictory findings^[26]. In a study recently published in *Annals of Surgery* in 2012^[13], the postoperative clinical, pathologic and follow-up data of 18 043 gastric cancer patients retrieved from the Surveillance, Epidemiology, and End Results database of United States were retrospectively analyzed, and the results showed that when the number of tested lymph nodes was insufficient, the MLR staging method could more accurately assess the patient prognosis than the pN staging method. However, only 10% of the patients in this study underwent D2 radical gastrectomy, and the scope of lymph node removal in the remaining patients was D1 or below. The insufficient number of tested lymph nodes was mainly limited by the scope of lymph node removal. Some studies have confirmed that the average number of removed lymph nodes during D2 radical gastrectomy could reach 32^[27]. The smaller the number of tested lymph nodes, the greater the sampling error. A sufficient number of tested lymph nodes is key to reducing sampling error. Therefore, to accurately assess the prognosis of patients after D2 radical gastrectomy, no staging method can replace a sufficient number of tested lymph nodes.

In summary, the MLR, LODDS and pN are all independent risk factors for the long-term postoperative survival of gastric cancer patients. The accuracy of the prognostic assessment of the MLR and LODDS staging methods is comparable to that of the pN staging method in gastric cancer patients. However, for the patients that undergo a D2 radical gastrectomy, when the number of tested lymph nodes is insufficient (≤ 15), neither the staging method based on metastatic lymph node ratio nor the pN staging method can avoid staging bias. Therefore, as D2 radical gastrectomy is increasingly accepted, a sufficient number of tested lymph nodes is the only key to

ensure an accurate prediction of gastric cancer patient prognosis.

COMMENTS

Background

Gastric cancer is one of the leading fatal malignancies worldwide. D2 radical gastrectomy has been accepted in most countries as the standard surgery for gastric cancer. In the currently widely applied criteria of postoperative tumor-node-metastasis staging system, the staging of regional lymph node metastasis (N) is of great significance for accurate prognosis-assessment.

Research frontiers

Currently, the metastatic lymph node ratio has been considered as an alternative to the absolute number of positive lymph nodes. Although the 7th edition of the American Joint Cancer Committee and the 14th edition of the Statute of Gastric Cancer Treatment in Japan unified the pN staging criteria for the first time in 2010, many researchers still believe that the prognostic assessment of ratio staging was superior to that of the staging based on absolute number of positive lymph nodes, which demands the examination of at least 15 lymph nodes.

Innovations and breakthroughs

The clinical, pathologic, and long-term follow-up data of 427 patients underwent D2 radical gastrectomy were stratified and compared to evaluate the prognostic assessment of the 3 metastatic lymph node staging methods. The findings from this study suggested that neither metastatic lymph node ratio nor log odds of positive lymph nodes could avoid the staging bias due to the insufficient number of tested lymph nodes for patients underwent D2 radical gastrectomy.

Applications

This study compared three lymph node based N staging systems for gastric cancer patients with radical resection and D2 lymphadenectomy, and then demonstrated that a sufficient number of tested lymph nodes was key to ensure an accurate prognosis-assessment. The results are clinical significance in the prognostic assessment of patients with gastric cancer after surgery.

Peer review

This is a retrospective research of 427 gastric cancer patients undergoing radical resection plus D2 lymphadenectomy, with a median follow-up of 55 mo. The authors have analyzed patient outcomes in considerable depth, their data is well characterized. They provide an in depth analysis of factors contributing to survival and have utilized multivariate analysis in doing this. The information in the manuscript is highly relevant and useful.

Abstract

AIM: To study the efficacy of marrow mesenchymal stem cells (MSCs) transplantation combined with interleukin-1 receptor antagonist (IL-1Ra) for acute liver failure (ALF).

METHODS: Chinese experimental miniature swine were randomly divided into four groups ($n = 7$), and all animals were given D-galactosamine (D-gal) to induce ALF. Group A animals were then injected with 40 mL saline *via* the portal vein 24 h after D-gal induction;

Group B animals were injected with 2 mg/kg IL-1Ra *via* the ear vein 18 h, 2 d and 4 d after D-gal induction; Group C received approximately 1×10^8 green fluorescence protein (GFP)-labeled MSCs (GFP-MSCs) suspended in 40 mL normal saline *via* the portal vein 24 h after D-gal induction; Group D animals were injected with 2 mg/kg IL-1Ra *via* the ear vein 18 h after D-gal induction, MSCs transplantation was then carried out at 24 h after D-gal induction, and finally 2 mg/kg IL-1Ra was injected *via* the ear vein 1 d and 3 d after surgery as before. Liver function, serum inflammatory parameters and pathological changes were measured and the fate of MSCs was determined.

RESULTS: The optimal efficiency of transfection (97%) was achieved at a multiplicity of infection of 80, as observed by fluorescence microscopy and flow cytometry (FCM). Over 90% of GFP-MSCs were identified as CD44+ CD90+ CD45- MSCs by FCM, which indicated that most GFP-MSCs retained MSCs characteristics. Biochemical assays, the levels of serum inflammatory parameters and histological results in Group D all showed a significant improvement in liver injury compared with the other groups ($P < 0.05$). The number of GFP-MSCs in Group D was also greater than that in Group B, and the long-term cell proliferation rate was also better in Group D than in the other groups.

CONCLUSION: MSCs transplantation is useful in ALF, IL-1Ra plays an important role in alleviating the inflammatory condition, and combination therapy with MSCs transplantation and IL-1Ra is a promising treatment for ALF.

INTRODUCTION

Acute liver failure (ALF) is defined by the development of coagulopathy and encephalopathy within a short period of time in patients with no previous history of liver disease^[1]. The essence of ALF is severe inflammation leading to cell necrosis in a large number of liver cells caused by paracetamol, idiosyncratic drug reactions, hepatitis B, or seronegative hepatitis^[2,3]. The key to the treatment of ALF is the reduction of liver cell necrosis and the stimulation of liver cell regeneration.

Liver transplantation is the only efficient treatment for ALF; however, difficulties including severe donor shortage, numerous complications, immunological rejection and high medical costs limit its use^[1,4]. Mesenchymal stem cells (MSCs) due to their sufficient source, low immunogenicity and the potential ability for differentiation into hepatocyte-like cells make MSCs transplantation a promising treatment for ALF^[5-7]. In order to achieve better results, we transplanted MSCs into a pig model of acute liver failure in addition to interleukin-1 receptor antagonist (IL-1Ra) injection which is used to improve liver inflammation^[8,9]. IL-1 is primarily a proinflammatory cytokine due to its ability to stimulate the expression of a number of inflammation-associated genes through the IL-1 signaling cascade^[10-12]. IL-1Ra can bind to the IL-1 receptor and blocks IL-1 action through competitive inhibition, but will not initiate the IL-1 signaling cascade due to its IL-1-like structure which will not induce a signal at all^[8]. In this study, we evaluated the efficiency of combination therapy with IL-1Ra and MSCs transplantation for the treatment of ALF in swine.

MATERIALS AND METHODS

Animals

Chinese experimental miniature swine (10 ± 3 kg, aged approximately 5 to 8 mo) were obtained from the Laboratory Animal Centre of the Affiliated Drum Tower Hospital of Nanjing University Medical School. All experiments were approved by the Institutional Animal Care and Use Committee.

In vitro experiment

MSCs were isolated by density gradient centrifugation from pig bone marrow and cultured in L-Dulbecco's modified Eagle's medium supplemented with 10% foetal bovine serum, 100 U/mL penicillin, and 100 µg/mL streptomycin (all from Gibco BRL, Grand Island, NY, United States). The cells were then transfected with a lentiviral vector carrying the gene encoding green fluorescence protein (GFP), and the multiplicity of infection

(MOI) of transfection was determined by fluorescent inverted phase contrast microscopy and flow cytometry (FCM). The surface markers (CD44, CD45, and CD90) of GFP-labeled MSCs (GFP-MSCs) were identified by FCM for their MSCs characteristics.

ALF model

The animals received a single intravenous injection of D-galactosamine (D-gal) 0.3 g/kg to induce experimental hepatic injury.

Experimental groups and treatments

Twenty-eight pigs were randomly divided into four groups, Group A (control, $n = 7$), Group B (IL-1Ra, $n = 7$), Group C (MSCs transplantation, $n = 7$), Group D (combined therapy, $n = 7$). Group A received 40 mL normal saline *via* the portal vein 24 h after D-gal induction; Group B received 2 mg/kg IL-1Ra (Institute of Process Engineering, Chinese Academy of Sciences, China) *via* the ear vein 18 h, 2 d and 4 d after D-gal induction; Group C received approximately 1×10^8 GFP-MSCs suspended in 40 mL normal saline *via* the portal vein 24 h after D-gal induction; Group D received 2 mg/kg IL-1Ra *via* the ear vein 18 h after D-gal induction, MSCs transplantation was carried out 24 h after D-gal induction, and finally 2 mg/kg IL-1Ra was injected *via* the ear vein 1 d and 3 d after surgery as before. Liver function, and inflammatory cytokines IL-1β, IL-2 and tumor necrosis factor α (TNF-α) were measured using enzyme-linked immuno sorbent assay Kits (Corbett Life Science, Australia) pre-operatively, intra-operatively, 1-6 d and 1-4 wk after surgery.

Histological analysis

Swine were humanely killed for histological examination at 3 d and every week after surgery. Liver tissues were immersion fixed, embedded in paraffin and sectioned at 5 µm, and the slices were submitted for hematoxylin and eosin (HE) and anti-Ki67 (Abcam Ltd., United Kingdom) staining. To determine liver cell proliferation, six high-powered fields of vision were obtained for each slice, and the average number of Ki67⁺ cells was used for statistical analysis. To trace transplanted MSCs, cells expressing GFP were analyzed by fluorescent microscopy and conventional immunohistochemistry using anti-GFP (Abcam Ltd., United Kingdom).

Statistical analysis

All statistical analysis were performed using SPSS 16.0. The data are reported as mean ± SD. The statistical significance was analyzed by two-way analysis of variance. $P < 0.05$ was considered to denote statistical significance.

RESULTS

In vitro experiment

The optimal efficiency of transfection (97%) was achieved at an MOI of 80, as observed by fluorescence microscopy (Figure 1A and B) and FCM (Figure 1C). Over 90% of

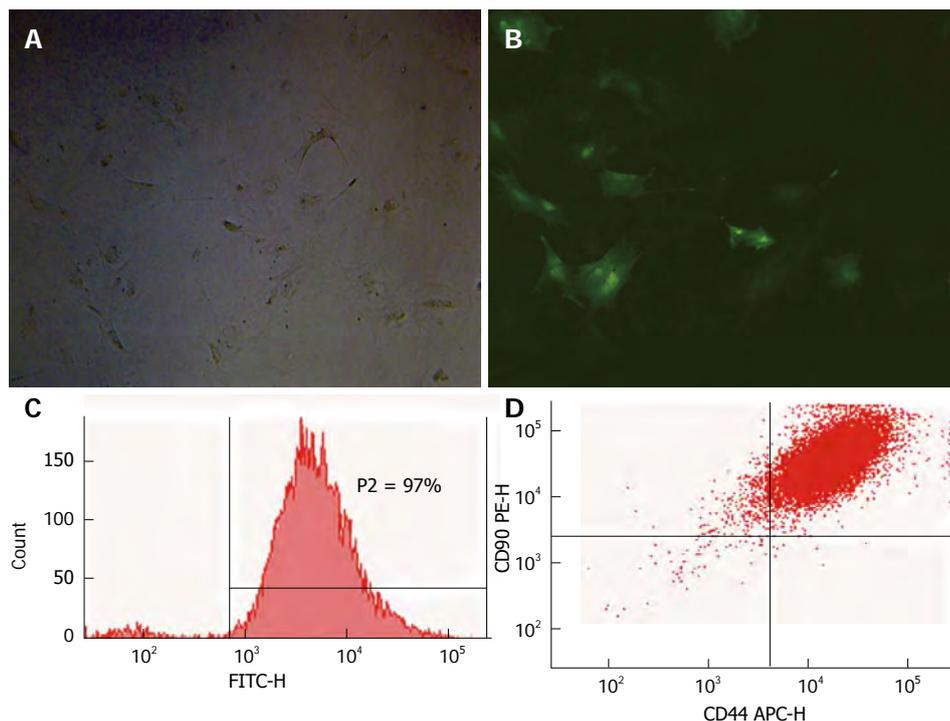

Figure 1 Mesenchymal stem cells transfected with a lentiviral vector carrying the gene encoding green fluorescence protein *in vitro*. A: GFP-MSCs cultivated for 3 d and observed by light microscopy ($\times 400$); B: GFP-MSCs with green fluorescence ($\times 400$); C: Over 97% of GFP-MSCs successfully expressed GFP after propagation; D: Most GFP-MSCs were identified as CD44⁺ CD90⁺. GFP: Green fluorescence protein; MSCs: Mesenchymal stem cells; GFP-MSCs: GFP-labeled MSCs.

GFP-MSCs were identified as CD44⁺ CD90⁺ CD45⁻ MSCs (Figure 1D) by FCM, which indicated that most GFP-MSCs retained MSCs characteristics.

Liver function

Dramatic changes in alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TB), ammonia and prothrombin time (PT) demonstrated that acute liver injury was successfully achieved by D-gal induction in all four groups. Highly significant increases in ALT, AST, TB, ammonia and PT were found in all groups within 48 h after D-gal injection, and then gradually declined. The most significant improvements were found in Group D following combination therapy compared with the other groups; ALT and ammonia in Group D were significantly lower than those in Group A ($P < 0.05$) within 1 to 4 d after combination therapy, and the low level of TB in Group D lasted longer than that in Group A ($P < 0.05$) and Group B ($P < 0.05$) from the first day to 1 wk, the improvement in ALB in Group D appeared the second day after treatment; Group B showed a significant reduction in ALT level within 1 to 3 d after IL-1Ra injection compared with Group A ($P < 0.05$); MSCs transplantation showed a slight effect on reducing TB and ammonia level in Group C (Table 1).

Serum inflammatory cytokines

Following D-gal induction, the levels of inflammatory cytokines, IL-1, IL-2 and TNF- α , in all groups increased significantly and reached a peak within 3 d, which lasted for several days before gradually declining. Group B and Group D had a faster improvement in IL-1 and TNF- α than the other groups, Group D had the lowest inflammatory level of all, with IL-1 and TNF- α levels signifi-

cantly lower than Group A ($P < 0.05$) from the first injection of 2 mg/kg IL-1Ra; serum inflammatory cytokine levels were better in Group C than in Group A, however, no statistically significant difference between the groups was observed (Figure 2).

Histological analysis

D-gal-induced liver damage was observed by HE staining in all groups, however, less inflammatory cell infiltration and relatively complete lobular architecture were found in Group D, and liver damage was worst in Group A (Figure 3). The number of Ki-67⁺ cells increased quickly after D-gal induction and reached a peak within 1 wk in all groups, and then a sharp decline was observed in Group A to a normal proliferation level at the end of 3 wk after operation, however, the Ki-67 positive cell index in Group D was maintained at a high level ($P < 0.05$); the performance of Group B and Group C were better than Group A, but there were no significant differences between the groups (Figure 4). Fluorescent microscopy revealed that there were more GFP-MSCs in Group D than in Group B at 1 wk after treatment, and most of these were distributed in the hepatic lobule along the central vein. Similar results were obtained by immunohistochemistry using anti-GFP (Figure 5).

DISCUSSION

ALF is a severe liver disease with large quantities of liver cell necrosis; liver transplantation is the only effective treatment, but has a number of difficulties. MSCs can be easily obtained from bone marrow and have multilineage potential. Petersen *et al*^[13] and Schwartz *et al*^[5] showed that MSCs possess the potential ability for hepatocyte differ-

A: Extensive neutrophil infiltration and lobular architecture collapse was seen in Group A (control group); B: Lobular architecture can be seen in Group B (interleukin-1 receptor antagonist injection group), however, hepatic lobules were filled with cell necrosis and inflammatory cells; C: The lobular architecture in Group C (mesenchymal stem cells transplantation group) was destroyed but can still be recognized; D: Group D had clear hepatic lobular architecture and slight inflammatory cell infiltration. Magnification, $\times 200$.

entiation *in vitro* and *in vivo*. Sakaida *et al*^[14] confirmed that MSCs were involved in both liver repair and reconstruc-

tion. In their research, MSCs transplantation was used to reduce CCl₄-induced liver fibrosis in mice, and their

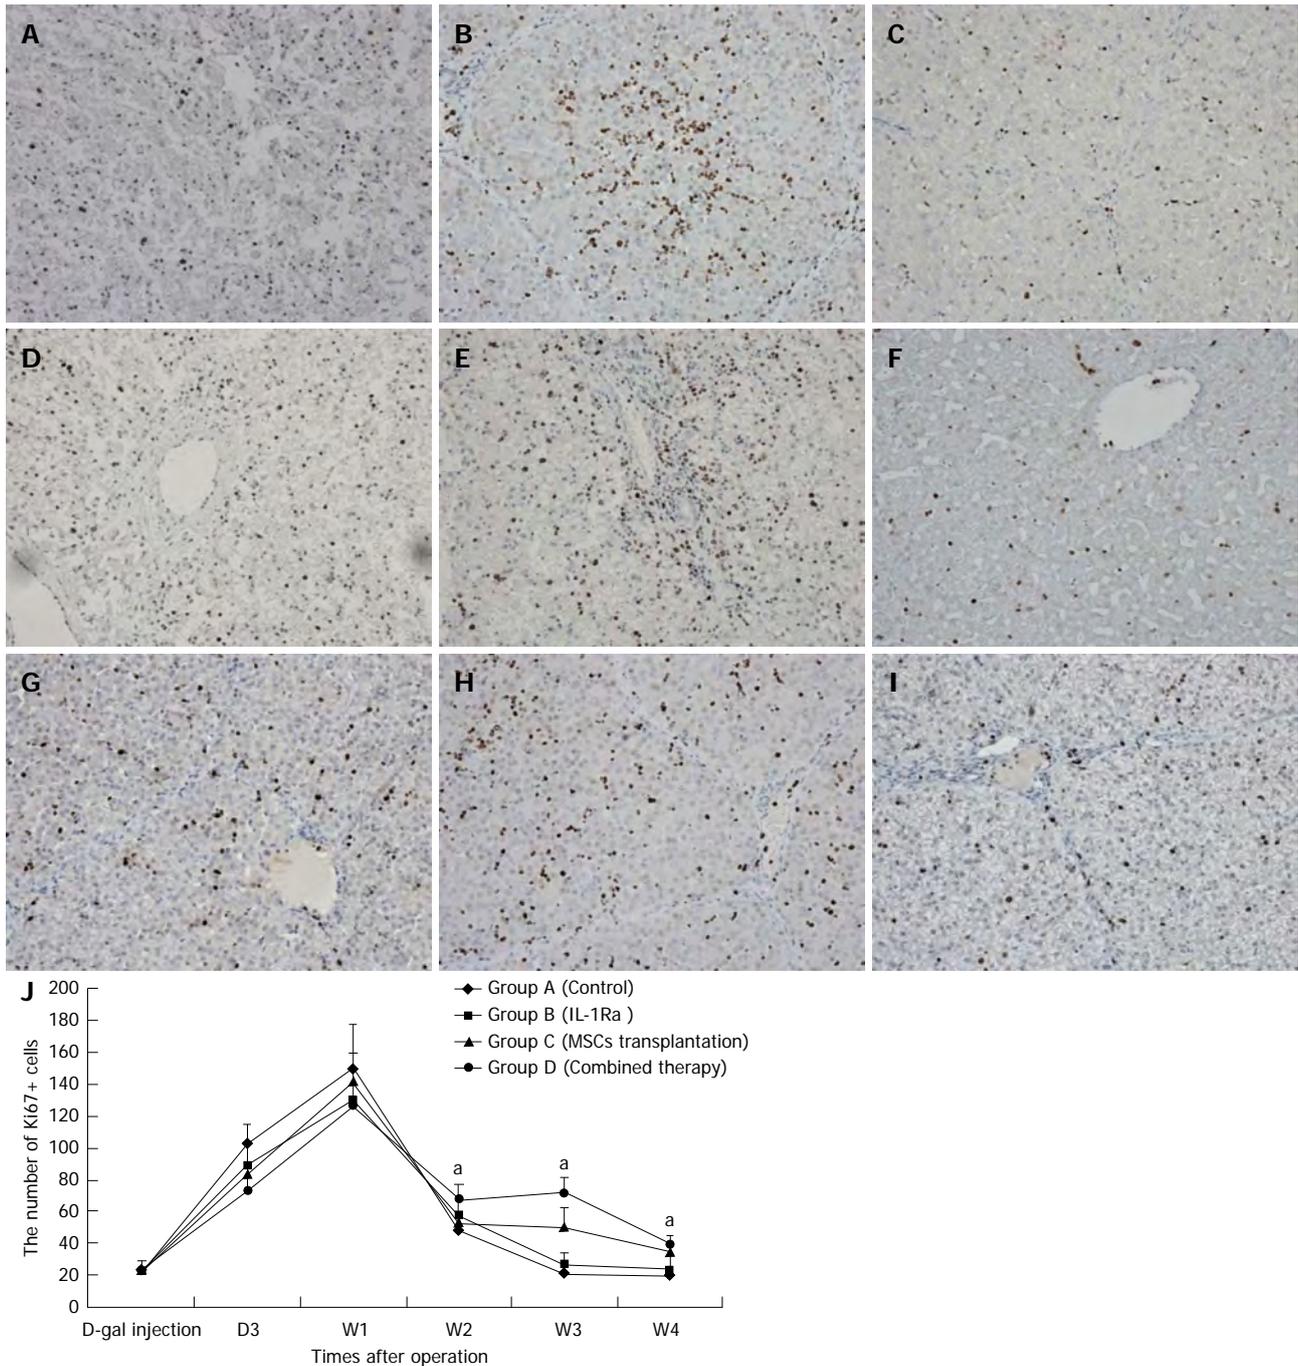

Figure 4 Changes in liver cell proliferation in all four groups. A, B and C showed the anti-Ki67 stain of Group A at the time point of D3, W1 and W4, respectively ($\times 200$); D, E, F and G, H, I showed anti-Ki67 stain of Group B and Group C, respectively, just as Group A did ($\times 200$); J: Changes in the number of Ki67+ cells demonstrated that Group D had better long-term proliferation. ^a $P < 0.05$ vs control group. IL-1Ra: Interleukin-1 receptor antagonist; MSCs: Mesenchymal stem cells; D-gal: D-galactosamine.

findings showed that MSCs transplantation was an ideal candidate treatment for liver disease. What will happen if MSCs transplantation is used for the treatment of ALF? di Bonzo *et al*^[15] xenografted human MSCs into acute liver injured NOD/SCID mice and CCl₄-induced liver injury in mice and demonstrated that the number of original human MSCs in acute liver injured mice was less than in chronically injured livers, and the number of hepatocytes undergoing differentiation was even less. In our study, there was no obvious improvement in liver function in the MSCs transplantation group (Group C), few GFP-

MSCs were observed on fluorescent microscopy, and little differentiation was seen. Therefore, we concluded that MSCs transplantation for the treatment of ALF is largely limited by its low implantation and differentiation rate in acute liver injured patients.

In recent years, experimental studies have demonstrated that microcirculatory dysfunction and an inflammatory environment are determinants of ALF, and pro-inflammatory mediators such as IL-1, IL-2 and TNF- α are the key players^[9,12,16-18]. Vodovotz also proved that the levels of these cytokines in ALF patients were significant-

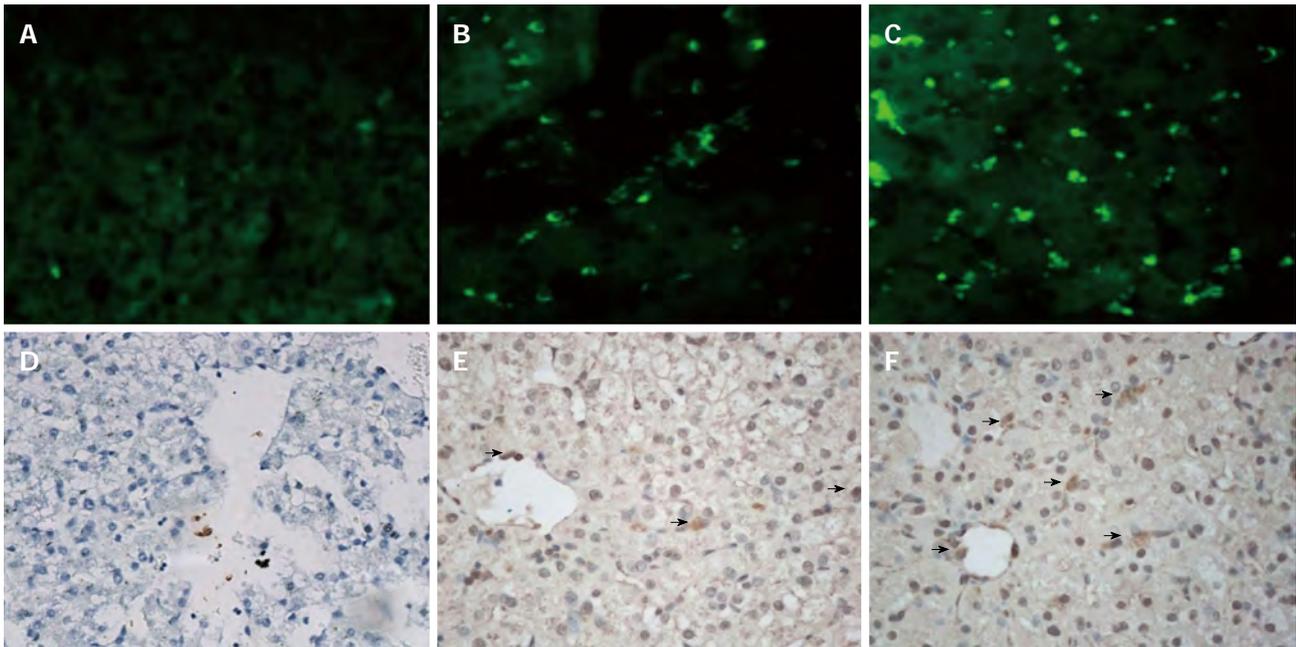

Figure 5 Fluorescence and anti-green fluorescence protein stained images of liver tissue 2 wk after surgery. A, B and C are fluorescence images of Group B, Group C and Group D, respectively; D, E and F are anti-green fluorescence protein immunohistochemical images of Group B, Group C and Group D, respectively. More cells expressing green fluorescence protein were seen in Group D (arrow). Magnification, $\times 400$.

ly higher than in normal and chronic hepatitis patients; IL-1 may be a main driver of late inflammation which leads to further injury^[3,9,19]. Given this, we presume that the inflammatory environment in ALF patients may be largely related to the low efficiency of MSCs transplantation, that is the inflammatory environment caused by proinflammatory mediators leads to the low survival and differentiation rate of transplanted MSCs. Our pre-experiment results proved this assumption: animals with lower levels of inflammatory cytokines had a higher MSCs implantation rate and differentiation rate. Therefore, we realized that reducing the inflammation level in the acutely injured liver may be a way of improving the efficacy of MSCs transplantation in ALF patients. IL-1Ra is a natural IL-1 antagonist, and can block the inflammatory process by competitively binding to the IL-1 receptor with an avidity equal to that of IL-1, but fails to stimulate downstream signals, thereby reducing the inflammation level^[8,20]. An imbalance between IL-1 and IL-1Ra can be observed in a variety of inflammatory diseases including ALF^[3,8,12,20]. IL-1Ra is significantly associated with the level of liver inflammation and is an independent marker unaffected by obesity, alcohol consumption, and insulin resistance^[21], and can inhibit the process of hepatocellular apoptosis in mice with acetaminophen-induced ALF significantly improving their survival rate^[22]. Therefore, will MSCs transplantation become an efficient treatment for ALF when it is combined with IL-1Ra used to relieve liver inflammation?

In this research, the combined therapy of IL-1Ra with MSCs transplantation was administered for acute liver injury, and the results obtained were very promising. Increased levels of proinflammatory cytokines such as

IL-1, IL-2 and TNF- α were seen in all animals injected with D-gal, a slight improvement was observed when MSCs were transplanted in Group B animals, and better results were achieved in Group C and Group D animals following IL-1Ra injection. Thus, exogenous IL-1Ra had an enormous effect in reducing some proinflammatory mediators, and improving the inflammatory environment. This effect may last for at least a month as the animals in Group C and Group D showed a continuous reduction in these proinflammatory mediators compared with the other two groups in later experiments, which was thought to be mainly related to the damaged inflammatory cycle caused by IL-1Ra in the very early phase. Improved liver inflammation was then observed following MSCs transplantation. As shown in the results section, Group D treated with combination therapy had the highest GFP-MSCs implantation rate and the best liver function. In addition, the trend in proliferation level in the four groups was different, although the level in all groups peaked at a similar time point after surgery, Group D had a higher proliferation level than the other groups at the end of 2 wk of combination therapy and this difference was maintained for at least 2 wk; which was thought to be caused by both IL-1Ra and MSCs transplantation. IL-1Ra improved the liver inflammatory environment then increased liver cell proliferation rate and MSCs transplantation efficiency, and high MSCs transplantation efficiency may directly lead to a higher hepatocyte differentiation rate, proliferation level and better liver function.

Thus, IL-1Ra can improve liver inflammation and then enhance the effect of MSCs transplantation. Combination therapy with IL-1Ra and MSCs transplantation can promote the restoration and reconstruction of acute

liver injury in swine, and is a promising future treatment for patients with ALF.

COMMENTS

Background

Cell transplantation is an effective therapy for acute liver failure; however, the activity and function of transplanted cells are largely limited by the inflammatory environment of acute liver failure (ALF) liver. Interleukin-1 (IL-1) is primarily a proinflammatory cytokine and IL-1 receptor antagonist (IL-1Ra) is the most effective antagonist. The combination therapy with IL-1Ra and mesenchymal stem cell (MSC) transplantation for the treatment of ALF is an interesting way and responded well.

Research frontiers

The essence of ALF is severe inflammation leading to cell necrosis in a large number of liver cells. Microcirculatory dysfunction and an inflammatory environment are determinants of ALF, and proinflammatory mediators such as IL-1, IL-2 and tumor necrosis factor α are the primary players. The key to the treatment of ALF is the reduction of liver cell necrosis and the stimulation of liver cell regeneration.

Innovations and breakthroughs

Recent reports have highlighted the effect of IL-1Ra injection on ALF models. In this study, the authors investigated the effect of bone marrow MSCs transplantation combined with IL-1Ra injection on ALF swine. Based on the results of the study, the authors concluded that MSCs transplantation is somewhat useful for ALF swine and that the combined therapy of IL-1Ra with MSCs transplantation is a promising treatment for ALF.

Applications

According to this article, it may represent a future strategy for therapeutic intervention in the treatment of patients with ALF.

Terminology

IL-1Ra is the interleukin-1 receptor antagonist, which can bind to the IL-1 receptor and blocks IL-1 action through competitive inhibition, but will not initiate the IL-1 signaling cascade due to its IL-1-like structure which will not induce a signal at all.

Peer review

The authors evaluated the effect of bone marrow mesenchymal stem cell transplantation combined with IL-1Ra injection on ALF swine. Group D (combine therapy of MSC transplantation + IL-1Ra) showed significantly improvement of biochemical assay, serum inflammation level and histological results compared with other groups ($P < 0.05$), labeled MSCs of Group D were more than Group B, and the long-term cell proliferation rate was the best in all groups too. They concluded that MSC transplantation is somewhat useful for ALF swine, IL-1Ra plays an important role in alleviating inflammatory condition, and the combined therapy is a promising treatment for ALF. These results are interesting and important in the therapy for ALF.

deoxyglucose positron emission tomography combined with computed tomography (PET-CT). The endoscopic findings of these 4 cases included lesions with wall thickening, which comprised macroscopically clusters of nodules, dense clusters of whitish granules or small nodules, fold thickening and ulcers with irregular margins that occupied the whole lumen with edematous mucosa. All patients fulfilled the World Health Organization grade 1 criteria. ¹⁸F-fluorodeoxyglucose PET-CT can help predict the risks that may result from certain endoscopic examinations, such as DBE and video capsule endoscopy.

Usefulness of positron emission tomography in primary intestinal follicular lymphoma. *World J Gastroenterol* 2013; 19(12): 1992-1996 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1992.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1992>

Abstract

Double-balloon enteroscopy (DBE) and video capsule endoscopy are useful for the diagnosis of lymphoma in the small intestine. However, DBE cannot be safely performed in cases with passage disturbance due to wall thickening and stenosis. Additionally, video capsule endoscopy cannot be performed in such cases because of the risk of retention. Here, we report 4 cases of primary follicular lymphoma of the gastrointestinal tract that could be detected using ¹⁸F-fluoro-

INTRODUCTION

Primary follicular lymphoma of the gastrointestinal tract (FL-GI) is often diagnosed by initially detecting duodenal lesions using esophago-gastro-duodenoscopy (EGD)^[1,2]. FL-GI lesions can exist in broad areas, ranging from the descending portion of the duodenum to the ileum, and may include lymph node involvement^[1,2]. The correct diagnosis of the locations of lesions is vital to decisions regarding therapeutic plans^[3]. Double-balloon enteroscopy (DBE) and video capsule endoscopy (VCE) are useful for the diagnosis of lesions in the small intestine^[4].

However, DBE cannot be safely performed in cases with passage disturbance due to wall thickening and stenosis, and VCE cannot be performed in these cases because of the risk of retention^[4]. Conversely, ¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography combined with computed tomography (PET-CT) has been reported to be useful for detecting lymph node involvement in the diagnosis of the clinical stages of follicular lymphomas^[5]. This study reports the cases of 4 patients for whom PET-CT was useful in the detection of FL-GI in the digestive tract, the location of which ranged from the duodenum to the ileocecal valve.

CASE REPORT

Twenty FL-GI patients (male/female 9/11, age 46-82 years, mean 58 years) consulted the Division of Gastroenterology, Department of Internal Medicine, Hiroshima Red Cross Hospital and Atomic-Bomb Survivors Hospital from December 2004 to May 2010. In 2 of the 18 patients with duodenal lesions, FL-GI lesions were detected using PET-CT. One of the 14 patients with jejunal lesions and 2 of the 12 patients with ileal lesions had abnormal accumulations according to the PET-CT results.

Table 1 shows the 4 FL-GI patients with abnormal accumulations by PET-CT who had gastrointestinal lesions detected from the duodenum to the ileocecal valve. Case 1 had duodenal lesion, case 2 had jejunal lesions, case 3 had lesions from the terminal ileum to the ileocecal valve and case 4 had lesions in broad areas from the duodenum to the ileum. All lesions were diagnosed by endoscopic examination with biopsy.

The mandatory examinations included palpation of the superficial lymph nodes, blood tests, urinalysis, chest radiography, abdominal ultrasonography, contrast-enhanced computed tomography (CT) scan (General Electric, Fairfield, CT, United States) (CT/CE+) of the neck, chest, abdomen and pelvis, PET-CT (General Electric, Fairfield, Connecticut, United States), bone marrow aspiration, endoscopy with biopsies [EGD (Olympus, Tokyo, Japan), colonoscopy (Fujinon, Tokyo, Japan), DBE (Fujinon, Tokyo, Japan)] and VCE (Given Imaging, Yoqneam, Israel). Each patient was classified by the location of the lesions, clinical stage (Lugano International classification^[6]), FL histological grade (World Health Organization grade)^[7] and follicular lymphoma international prognosis index^[8]. The macroscopic findings of FL-GI were classified by endoscopy into the following 6 types: whitish granules, multiple small nodules, fold swelling and thickening, mass forming, ulcers with irregular margins and rough mucosa^[1].

Case 1 is a 52-year-old man who had no symptoms but was diagnosed to have abnormalities in the descending portion of the duodenum by EGD for gastric cancer screening (Table 1). This patient had wall thickening with abnormal accumulation at the descending portion of the duodenum and at the duodenojejunal flexure [maximum

standardized uptake value (SUVmax) 6.6 and 5.5, respectively] (Figure 1A) by PET-CT. However, there were no abnormal findings in the small intestine by PET-CT. EGD showed lesions with dense clusters of whitish granules, making it difficult to see the folds in the descending and horizontal portions of duodenum (Figure 1B). The jejunum showed only rough clusters of whitish granules. The terminal ileum of this patient showed mucosa with normal lymphoid tissues.

Case 2 is a 62-year-old woman who presented with swelling of the mesenteric lymph nodes (max, 1.5 cm in diameter) by abdominal ultrasonography and a mild accumulation of FDG (SUVmax, 3.0) by PET-CT. A laparotomic lymph node biopsy led to the diagnosis of FL. Regarding the intestinal lesions, localized accumulation was demonstrated by PET-CT (SUVmax, 3.9) performed in the jejunum 25 mo later. The EGD showed swelling and thickening of the folds that occupied half of the lumen (Table 1).

Case 3 is a 66-year-old woman who underwent EGD because of a 1-wk history of postprandial epigastric discomfort and dyspepsia. There were abnormal findings in the papillae of Vater (Table 1). This case showed intestinal wall thickening with abnormal accumulation from the terminal ileum to the cecum by PET-CT (SUVmax, 6.73) (Figure 2A and C). The endoscopic findings in the duodenum included eruptions with mild swelling and erosion at the papillae of Vater. The jejunum and the ileum had sparse clusters of small nodules. Portions from the terminal ileum (Figure 2B) to the ileocecal valve (Figure 2D) had dense clusters of granules and nodules.

Case 4 is a 61-year-old woman undergoing examinations for leukocytosis (white blood cells, 29 740) (Table 1). The PET-CT of this patient showed abnormal accumulations (SUVmax, 5.6) in broad areas from the descending portion of the duodenum through the jejunum to the ileum (Figure 3A). The color of the duodenal bulb was normal, and the macroscopic finding was rough mucosa. The mucosa of the descending and horizontal portions of the duodenum showed clusters of numerous whitish granules. The jejunum and the ileum had multiple ulcers with irregular margins that occupied the whole lumen, with edematous change in broad areas of the mucosa (Figure 3B).

DISCUSSION

FL-GI patients frequently have duodenal and small intestinal lesions, as has been already reported^[2]. The macroscopic findings of patient endoscopies that were also detected using PET-CT were clusters of numerous whitish granules spreading over the mucosa, concealing the folds, obvious swelling and thickening of folds and dense clusters of granules and nodules (Cases 1-3). PET-CT could detect lesions of ulcers with irregular margins that occupied the whole lumen with edematous mucosa as well as lesions with clusters of numerous whitish granules

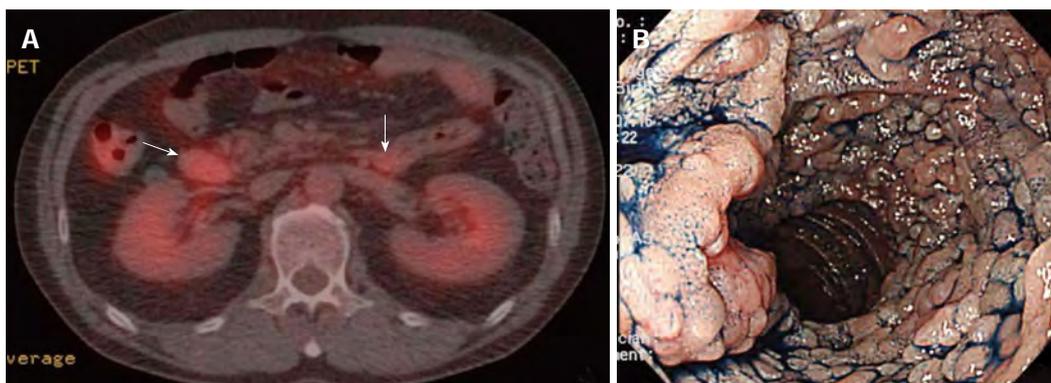

Figure 1 A 52-year-old man with follicular lymphoma of the gastrointestinal tract. A: ^{18}F -fluorodeoxyglucose positron emission tomography combined with computed tomography in transaxial images showed focal hypermetabolic activities (maximum standardized uptake value, 6.6 and 5.5, respectively) in the lesions of the descending portion of the duodenum and the duodenojejunal flexure (arrows), respectively; B: The esophago-gastro-duodenoscopic view with indigo carmine dye-spray of the descending portion of the duodenum. Numerous whitish granules densely clustered together.

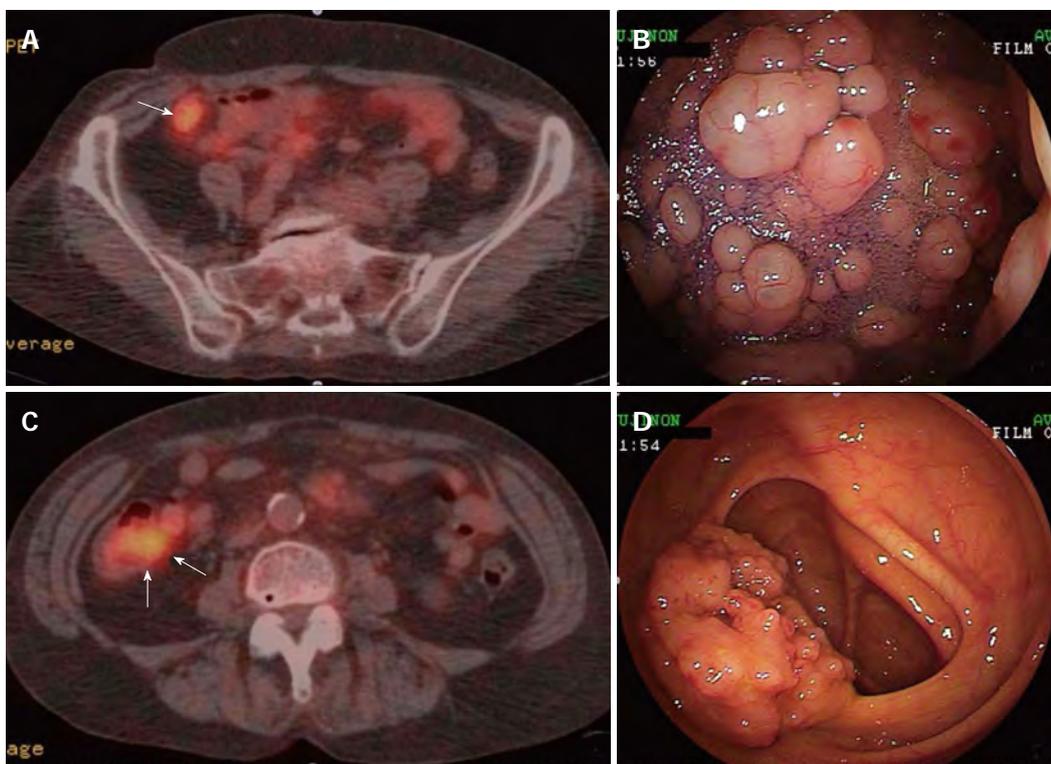

Figure 2 A 66-year-old woman with follicular lymphoma of the gastrointestinal tract. A, C: ^{18}F -fluorodeoxyglucose positron emission tomography combined with computed tomography in transaxial images showed focal hypermetabolic activities (maximum standardized uptake value, 6.73) in the lesion of the terminal ileum (A) (arrow) and the cecum (C) (arrows); B: The colonoscopic view with indigo carmine dye-spray of the terminal ileum. Numerous polypoid lesions of varying sizes (granules to small nodules) were densely clustered; D: The colonoscopic view of the ileocecal valve. Numerous polypoid lesions of varying sizes (granules to small nodules) were densely clustered.

(Case 4). Lesions with a scattered distribution of whitish granules and small nodules were not shown as abnormal accumulations by PET-CT (Cases 1 and 3). It is assumed that a greater wall thickness of a GI lesion results in a greater possibility of abnormal accumulation according to the PET-CT results.

There were 2 FL-GI patients with small intestinal tumors whose initial symptom was ileus (4.3% of FL-GI at our division in April 2012). PET-CT is a valuable tool for the detection of the lesions in these patients (PET-

CT findings not shown). The detection rate of the GI lesions of FL by PET-CT is generally reported to be rather low^[9,10]. However, among the gastrointestinal lesions that were detected by PET-CT were cases with wall thickening and macroscopic clusters of nodules, dense clusters of whitish granules or small nodules, fold thickening or ulcers that showed irregular margins and occupied the whole lumen with edematous mucosa. Therefore, PET-CT is useful in cases with lesions that are difficult to approach using DBE and in cases that have a risk of

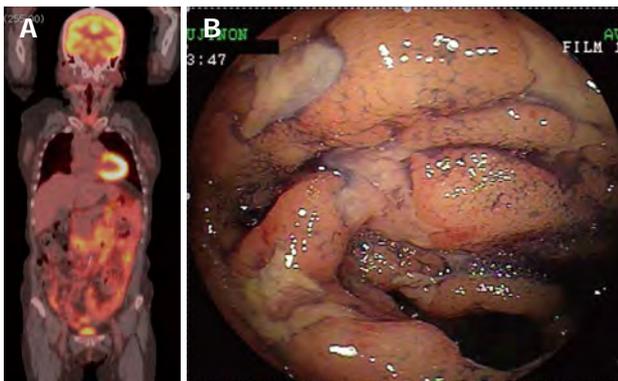

Figure 3 A 61-year-old woman with follicular lymphoma of the gastrointestinal tract. A: ¹⁸F-fluorodeoxyglucose positron emission tomography combined with computed tomography in a projected image showed hypermetabolic foci in broad areas of the gastrointestinal tract from the 2nd portion of the duodenum to the terminal ileum (maximum standardized uptake value, 5.6); B: The colonoscopic view with indigo carmine dye-spray of the terminal ileum. Multiple ulcers with irregular margins were observed.

retention with VCE because of stenosis due to tumors or wall thickening of the deep portion of small intestine. PET-CT is a useful tool for detecting the involvement of lymph nodes and other organs in follicular lymphoma^[3]. It is not only useful for deciding whether VCE should be performed, but also for deciding the method by which lesions in the small intestine are approached using DBE, which is necessary for the pathological diagnosis of the biopsy.

Abstract

Transmesenteric hernias have bimodal distribution and occur in both pediatric and adult patients. In the adult population, the cause is iatrogenic, traumatic, or inflammatory. We report a case of transmesocolic hernia in an elderly person without any preoperative history. An 84-year-old Korean female was admitted with mid-abdominal pain and distension for 1 d. On abdominal computed tomography, we diagnosed transmesocolic hernia with strangulated small bowel obstruction, and performed emergency surgery. The postoperative period was uneventful and she was discharged 11 d after surgery. Hence, it is important to consider the possibility of transmesocolic hernia in elderly patients with signs and symptoms of intestinal obstruction, even in cases with no previous surgery.

Jung P, Kim MD, Ryu TH, Choi SH, Kim HS, Lee KH, Park JH. Transmesocolic hernia with strangulation in a patient without surgical history: Case report. *World J Gastroenterol* 2013; 19(12): 1997-1999 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/1997.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.1997>

INTRODUCTION

The incidence of internal hernia is less than 1%^[1], and transmesocolic hernia is a particularly rare type of internal hernia. The overall mortality is more than 50% in cases with strangulated small bowel obstruction^[2]. In adults, transmesocolic hernias are most often caused by previous surgical procedures, abdominal trauma or intraperitoneal inflammation, and transmesocolic hernia in a person without a surgical history is extremely rare. We report such a case of transmesocolic hernia with strangulated intestinal obstruction.

CASE REPORT

An 84-year-old Korean female, with no past history of surgery, was admitted with mid-abdominal pain and distension for 1 d. Upon admission, her blood pressure was 120/80 mmHg, heart rate 72 beats/min, and body temperature 36.6 °C. On physical examination of the area of concern, mid-abdominal tenderness was observed. On admission, laboratory assessments were as follows: white blood cell count 14 500/mm³ (segmented neutrophil 91.4%), hemoglobin concentration 12.8 g/dL, platelet count 272 000/mm³, sodium 135 mmol/L, potassium 4.5 mmol/L, blood urea nitrogen 21.5 mg/dL, creatinine 0.9 mg/dL, aspartate aminotransferase 18 IU/L, alanine aminotransferase 10 IU/L, alkaline phosphatase 256 IU/L,

Figure 1 Abdominal computed tomography findings. Crowded small bowel loop (from distal jejunum to proximal ileum) with circumferential wall thickening and decreased enhancement in the middle and lower abdomen, stretched mesenteric vessels with mesenteric edema. A: Sagittal view; B: Transverse view.

Figure 2 Intraoperative findings. Herniated small intestine with strangulation by perforated omentum (arrow) below the transverse colon.

lactate dehydrogenase 415 IU/L, γ -glutamyltransferase 17 IU/L, and C-reactive protein 1.04 mg/dL. A simple abdominal X-ray showed distended small bowel loops. Abdominal computed tomography (CT) revealed crowded small bowel loops (from distal jejunum to proximal ileum), with circumferential wall thickening and decreased enhancement in the middle and lower abdomen, and stretched mesenteric vessels with mesenteric edema (Figure 1). We diagnosed transmesocolic hernia with intestinal obstruction and performed emergency surgery. During the operation, a herniated small intestine with strangulation by perforated omentum was noted below the transverse colon (Figure 2). Strangulated herniation was seen 190 cm from the ligament of Treitz, for a length of 160 cm. The strangulated small intestine herniation was resected and the omentum defect was closed. The postoperative course was uneventful and the patient was discharged on postoperative day 11, with a favorable follow-up as an outpatient for 1 mo.

DISCUSSION

An internal hernia is the protrusion of an abdominal organ through a normal or abnormal mesenteric or peritoneal aperture^[3]. An internal hernia can be acquired as a result of trauma or a surgical procedure, or may be

constitutional and related to congenital peritoneal defects. In the broad category of internal hernias, there are several main types based on their location, as traditionally described by Meyers. These consist of paraduodenal (53%), pericecal (13%), foramen of Winslow-related (8%), transmesenteric and transmesocolic (8%), intersigmoid (6%), and retroanastomotic (5%), with the overall incidence of internal hernia being 0.2%-0.9%^[2]. The transmesenteric hernia has three main types: transmesocolic, through a small-bowel mesenteric defect, and Peterson's hernia^[1]. Most transmesocolic hernias in children result from a congenital defect in the small bowel mesentery close to the ileocecal region. Congenital defects occur following the embryonic formation of an intestinal loop in thin avascular areas of the mesentery (*e.g.*, the mesenteries of the lower ileum, the sigmoid mesocolon, and the transverse mesocolon). As a consequence, there are multiple theories of congenital causes of such mesenteric defects^[4]. It is likely that the congenital condition is associated with prenatal intestinal ischemic accidents due to the observed frequently in infants with atretic bowel segments. In adults, transmesocolic hernias are most often caused by previous surgical procedures, abdominal trauma or intraperitoneal inflammation. When the small bowel is herniated through a defect in the mesentery or omentum, the herniated bowel is compressed against the abdominal wall. In this case, the herniated bowel is clustered and lies outside the colon which is displaced centrally^[5].

Transmesocolic hernias are more likely than other subtypes to develop volvulus and strangulation, or ischemia, the reported incidence of which are as high as 30% and 40%, respectively, with mortality rates of 50% for treated groups and 100% for non-treated subgroups^[2,6]. Clinically, internal hernias can be asymptomatic, or can cause discomfort ranging from constant vague epigastric pain to intermittent colicky periumbilical pain, while additional symptoms include nausea and vomiting^[1].

An internal hernia is difficult to diagnosis by physical examination, and the most important diagnostic method is abdominal CT. It has been suggested that the two findings of a peripherally located small bowel, and lack

of omental fat between the loops and the anterior abdominal wall, might be the most helpful CT signs, with an overall sensitivity of 85% and 92% for each respective finding^[6,7]. Observation of the clustering of small bowel loops and an abnormality in the mesenteric vessels are helpful findings on abdominal CT.

In adults, a previous surgical procedure, as well as trauma or inflammation are the most common causes of transmesocolic hernia. Our case was a rare presentation in an elderly person without a history of trauma, and without previous surgery^[8-12]. The patient had non-specific symptoms and signs on plain abdominal X-ray, but also non-specific abdominal distension upon physical examination. In the case of internal hernia, these defects may be idiopathic, but we can speculate that a small congenital defect existed without any hernia, and enlarged due to the aging. A transmesocolic hernia is difficult to diagnosis preoperatively despite the array of diagnostic techniques currently available. In patients suspected of having an internal hernia, early surgical intervention may be advisable due to the high morbidity and mortality rates. Therefore, it is important to consider the possibility of a transmesocolic hernia when patients have signs and symptoms of intestinal obstruction, even in cases of elderly patients with no previous surgical history.

Abstract

Helicobacter pylori (*H. pylori*) is a pathogen and the most frequent cause of gastric ulcers. There is also a close correlation between the prevalence of *H. pylori* infection and the incidence of gastric cancer. We present the case of a 38-year-old woman referred by her primary care physician for screening positron emission tomography-computed tomography (PET-CT), which showed a nodular strong accumulation point with standardized uptake value 5.6 in the gastric fundus. Gastroscopy was then performed, and a single arched ulcer, 12 mm in size, was found in the gastric fundus. Histopathological examination of the lesion revealed chronic mucosal inflammation with acute inflammation and *H. pylori* infection. There was an obvious mitotic phase with widespread lymphoma. Formal anti-*H. pylori* treatment was carried out. One month later, a gastroscopy showed a single arched ulcer, measuring 10 mm in size in the gastric fundus. Histopathological ex-

amination revealed chronic mucosal inflammation with acute inflammation and a very small amount of *H. pylori* infection. The mitotic phase was 4/10 high power field, with some heterotypes and an obvious nucleolus. Follow-up gastroscopy 2 mo later showed the gastric ulcer in stage S2. The mucosal swelling had markedly improved. The patient remained asymptomatic, and a follow-up PET-CT was performed 6 mo later. The nodular strong accumulation point had disappeared. Follow-up gastroscopy showed no evidence of malignant cancer. *H. pylori*-associated severe inflammation can lead to neoplastic changes in histiocytes. This underscores the importance of eradicating *H. pylori*, especially in those with mucosal lesions, and ensuring proper follow-up to prevent or even reverse early gastric cancer.

Rare case of *Helicobacter pylori*-related gastric ulcer: Malignancy or pseudomorphism? *World J Gastroenterol* 2013; 19(12): 2000-2004 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i12/2000.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i12.2000>

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a Gram-negative microaerophilic bacterium that colonizes the stomach of approximately two-thirds of the human population and is involved in the pathogenesis of various gastroenterological diseases including gastric ulcer and gastric cancer. *H. pylori*'s interaction with the host has an impact on the severity of these diseases and their clinical outcome^[1,2].

The mechanisms of *H. pylori*-related colonization are not fully understood. However, different types of *H. py-*

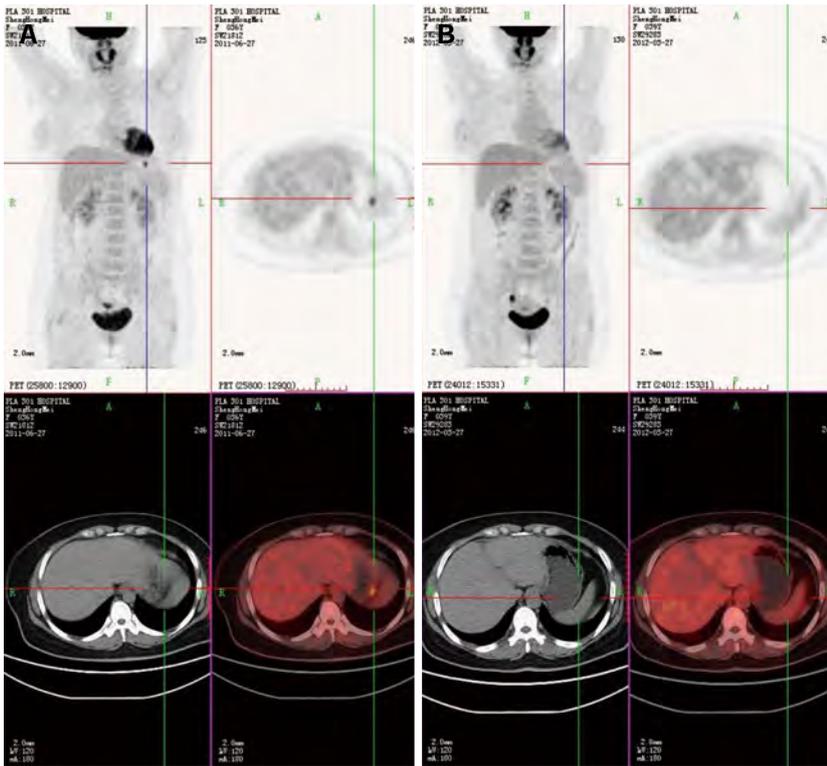

Figure 1 Positron emission tomography-computed tomography. A: Positron emission tomography-computed tomography showed a nodular strong accumulation point with standardized uptake value 5.6 in the gastric fundus; B: After treatment, the nodular strong accumulation point in the gastric fundus had disappeared.

lori virulence factors, especially cytotoxin-associated gene A (*CagA*), vacuolating cytotoxin A (*VacA*), outer inflammation protein A and so on are reported to be correlated with *H. pylori*-related diseases. One of the major bacterial virulence factors, the *VacA*, seems to be involved in the physiologic mechanism. The *VacA* protein encoded by the polymorphic *H. pylori VacA* gene, is produced and secreted by all bacterium strains and induces the formation of intracellular vacuoles in epithelial cell lines *in vitro*. Environmental and demographic data also interfere with the pathophysiology of *H. pylori*-associated gastric diseases^[3].

CASE REPORT

We present a case of a 38-year-old woman with a history of thyroid cancer who was referred by her primary care physician for a screening positron emission tomography-computed tomography (PET-CT). She was essentially asymptomatic and did not report any abdominal pain, dysphagia, nausea, or vomiting. Findings of a physical examination were unremarkable.

PET-CT showed a nodular strong accumulation point with standardized uptake value (SUV) 5.6 in the gastric fundus (Figure 1A). Gastroscopy was then performed, and demonstrated a single arched ulcer, measuring 12 mm in size, in the gastric fundus (Figure 2A and B). Histopathological examination revealed that the lesion had chronic mucosal inflammation with acute inflammation and *H. pylori* infection. There was an obvious mitotic phase with widespread lymphoma immunohistochemical staining was positive for CD4 (T cell), CD3 (T cell), CD20, Ki-67 (+25%), CD79a (+++), PAX-5, CD45RO and negative for CD56, TIA-1, TIF-1, Bcl-6, CD10,

CD30, CD34, CD117, CK, MUM-1, MPO (Figure 3A).

The patient was given *H. pylori* eradication therapy, based on proton pump inhibitor-clarithromycin-amoxicillin-mucosal protective agent treatment, the so-called quadruple 14 d therapy. One month later, gastroscopy was performed and showed a single arched ulcer, measuring 10 mm in size in the gastric fundus (Figure 2C). Histopathological examination revealed that the lesion had chronic mucosal inflammation with acute inflammation and a small amount of *H. pylori* infection (Figure 3B). The mitotic phase was 4/10 high power field with some heterotypes and an obvious nucleolus. Immunohistochemical staining showed tissue cell-like cells positive for S-100, vimentin, CD68, Ki-67 (30%) and negative for CD1a, CD21, Bcl-2, CD3, CD20, CD30, CD45RO, CD117 and PAX-5 (Figure 3C). For further examination, immunohistochemical staining was repeated by the Beijing Cancer Hospital and showed that staining for CD1a was positive for focal lesions (Figure 3D). The shape and immunophenotype indicated Langerhans histiocytosis. Because of the active growth of cancer cells, the patient was referred for medical oncology evaluation for this unusual pathologic finding with malignant potential.

Follow-up gastroscopy 2 mo later showed that the gastric ulcer was in stage S2 (Figure 2D). The mucosal swelling was markedly reduced. Endoscopic ultrasonography showed that the local echo was normal and each layer was clearly divided (Figure 2E). Histopathological examination showed chronic mucosal inflammation with lymphoid tissue hyperplasia in the lamina propria (Figure 3E).

The patient remained asymptomatic, and a follow-up PET-CT was performed 6 mo later. The nodular strong accumulation point with SUV 5.6 in the gastric fundus

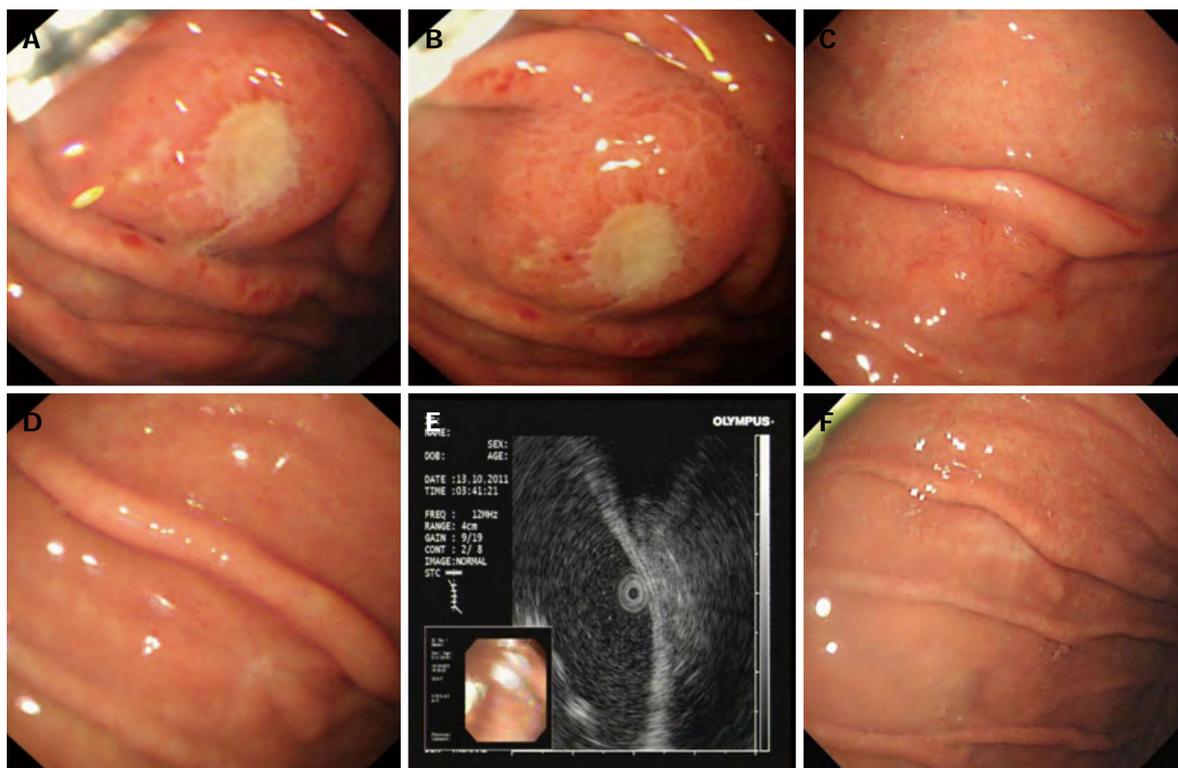

Figure 2 Gastroscopy showed a single arched ulcer and changes after treatment. A, B: A single arched ulcer, measuring 12 mm in size, was found in the gastric fundus (July 1, 2011); C: A single arched ulcer, measuring 10 mm in size, was found in the gastric fundus (August 16, 2011); D: The gastric ulcer was in stage S2 (October 13, 2011); E: Endoscopic ultrasonography showed that the local echo was normal and each layer was clearly divided (October 13, 2011); F: The gastric ulcer was in stage S2 (April 25, 2012).

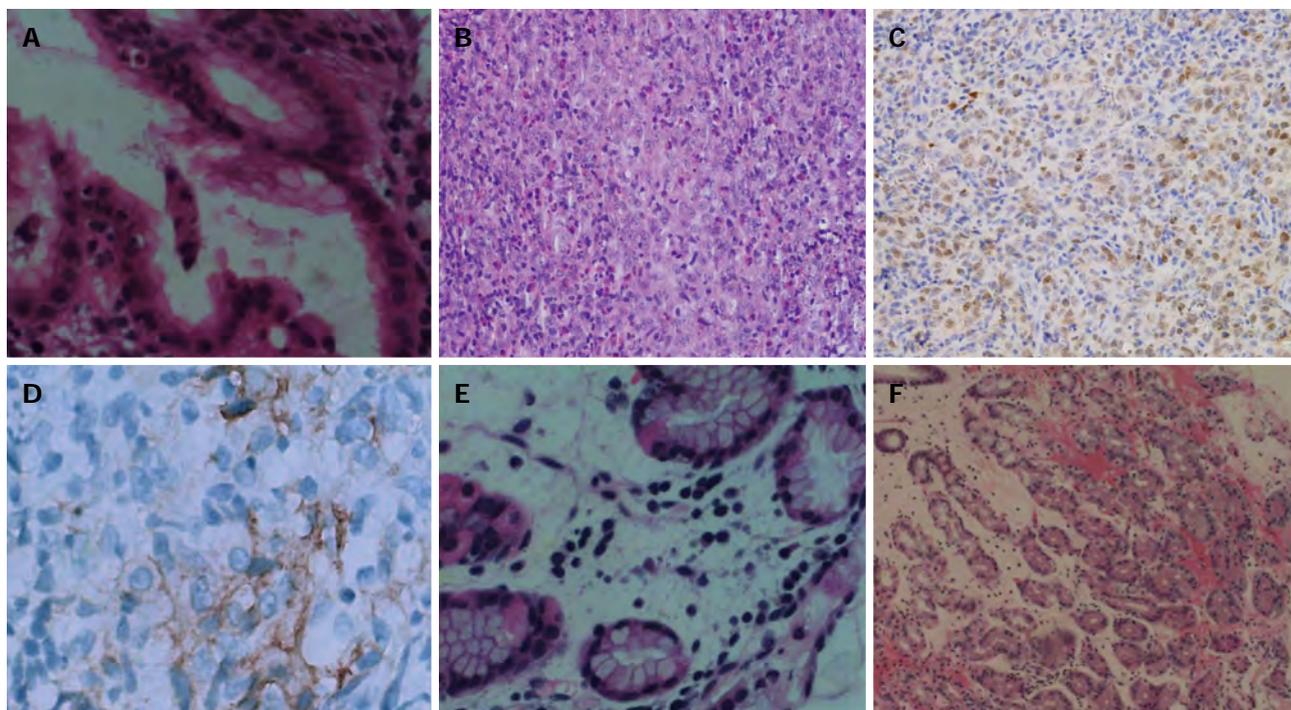

Figure 3 Histopathology changes after treatment. A: Histopathological examination revealed that the lesion had chronic mucosal inflammation with acute inflammation and a small amount of *Helicobacter pylori* (*H. pylori*) infection. The mitotic phase was obvious and lymphoma was widespread [hematoxylin and eosin (HE), $\times 400$, July 2, 2011]; B: Histopathological examination revealed chronic mucosal inflammation with acute inflammation and a only a small amount of *H. pylori* infection. The mitotic phase was 4/10 high power field (HE, $\times 400$, August 17, 2011); C: Immunohistochemical staining showed tissue cell-like cells with S-100 ($\times 400$, August 17, 2011); D: Immunohistochemical staining was repeated by the Beijing Cancer Hospital and showed that staining for CD1a was positive for focal lesions ($\times 400$, August 25, 2011); E: Histopathological examination showed chronic mucosal inflammation with lymphoid tissue hyperplasia in the lamina propria (HE, $\times 400$, October 14, 2011); F: Histopathological examination revealed that chronic mucosal inflammation with acute inflammation (HE, $\times 10$, May 8, 2012).

had disappeared (Figure 1B). Follow-up gastroscopy at the same time showed that the gastric ulcer was in stage S2 (Figure 2F). Histopathological examination revealed that the lesion had chronic mucosal inflammation with acute inflammation (Figure 3F). Therefore, we found no evidence of malignant cancer.

DISCUSSION

H. pylori infection is a worldwide disease, with about half of the world's population harboring this bacterium in their stomach. The infection is asymptomatic in most individuals. However, it is the leading cause of non-ulcer dyspepsia, peptic ulcers and gastric tumors^[4].

H. pylori is able to survive in the gastric acidic environment because of its ability to synthesize urease, an enzyme which can neutralize the stomach acidic pH. It seems to play a role in the mechanisms which lead to gastric cancer by inducing methylation in different genes, interfering with apoptotic pathways and by causing inflammatory events leading to gastritis, then to atrophic gastritis and possibly to gastric cancer^[5]. It may affect the acid secretion of the parietal cells by causing mucosal inflammation. Gastric acid secretion depends on the localization and the degree of the inflammation. Acute infection with *H. pylori* results in hypochlorhydria, whereas chronic infection can cause either hypo- or hyper-chlorhydria, depending on the distribution of the infection and the degree of corpus gastritis^[6]. *H. pylori* is a powerful carcinogen, since it is able to induce genetic changes, such as hypermethylation events, contributing to cell transformation^[5].

H. pylori is well recognized as a class I carcinogen because long-term colonization by this organism can provoke chronic inflammation and atrophy, which can further lead to malignant transformation^[7]. Chronic inflammation plays important roles in the development of various cancers, particularly in digestive organs, including *H. pylori*-associated gastric cancer^[8]. During chronic inflammation, *H. pylori* can induce genetic and epigenetic changes, including point mutations, deletions, duplications, recombinations, and methylation of various tumor-related genes through various mechanisms, which act in concert to alter important pathways involved in normal cellular function, and hence accelerate inflammation-associated cancer development^[9]. Alfizah *et al*^[10] reported that variant of *H. pylori* CagA proteins induce different magnitudes of morphological changes in gastric epithelial cells. In his study, the CagA protein was injected into gastric epithelial cells and supposedly induced morphological changes termed the "hummingbird phenotype", which is associated with scattering and increased cell motility. The molecular mechanisms leading to the CagA-dependent morphological changes are only partially known^[11,12]. The activity of different CagA variants in the induction of the hummingbird phenotype in gastric epithelial cells depends at least in part on EPIYA motif variability. The difference in CagA genotypes might influence the potential of individual CagAs to cause morphological changes

in host cells. Depending on the relative exposure of cells to CagA genotypes, this may contribute to the various disease outcomes caused by *H. pylori* infection in different individuals^[10].

Epidemiologic studies have demonstrated that *H. pylori* infection is associated with increased risk of the development of gastric cancer^[13-15]. Animal studies have also shown that *H. pylori* infection leads to gastric carcinogenesis, especially intestinal phenotypes. Yu *et al*^[16] carried out an *in vitro* study of cell transformation induced by *H. pylori* and showed that *H. pylori* induced morphologic changes in GES-1 cells and significantly increased the proliferation of GES-1 cells. Because the transition from inflamed mucosa to atrophic change is a common route to carcinogenesis, the effect of *H. pylori* eradication on the incidence of this early precursor lesion is of interest^[17]. Since *H. pylori* infection is associated with gastric carcinoma, therapy is warranted for its eradication^[5,18,19].

This was a rare case of a *H. pylori*-related gastric ulcer that resembled gastric cancer. PET-CT SUV was high, and gastroscopy showed a large ulcer with malignant-like histopathological features. However, after *H. pylori* eradication treatment, the lesion recovered quickly and follow-up examination showed no evidence of malignant cancer.

Abstract

Gastric gastrointestinal stromal tumor (GIST), esophageal squamous cell carcinoma and gastric cardia adenocarcinoma are distinct neoplasms originating from different cell layers; therefore, simultaneous development of such carcinomas is relatively rare. Auxiliary examinations revealed coexistence of esophageal and gastric cardia carcinoma with lymph node metastasis in a 77-year-old man. Intraoperatively, an extraluminal tumor (about 6.0 cm × 5.0 cm × 6.0 cm) at the posterior wall of the gastric body, a tumor (about 2.5 cm × 2.0 cm) in the lower esophagus, and an infiltrative and stenosing tumor (about 1.0 cm × 2.0 cm) in the gastric cardia were detected. Wedge resection for extraluminal gastric tumor, radical esophagectomy for lower esophageal tumor, and cardiac resection with gastroesophageal (supra-aortic arch anastomoses) were performed. Postoperative histological examination showed synchronous occurrence of gastric GIST, esophageal squamous cell carcinoma, and gastric car-

dia adenocarcinoma. Furthermore, immunohistochemistry indicated strong staining for c-Kit/CD117, Dog-1, Ki-67 and smooth muscle, while expression of S-100 and CD34 was negative.

INTRODUCTION

Recently, cases of synchronous development of a gastrointestinal stromal tumor (GIST) and another neoplasm with different incidence, etiology, evolution and prognosis have been reported more frequently^[1-3]. Although squamous cell carcinoma and adenocarcinoma constitute the most common type of esophageal and gastric cardia tumor, respectively, simultaneous development of a GIST is relatively rare. Here, we report a case of synchronous occurrence of gastric GIST, esophageal squamous cell carcinoma, and gastric cardia adenocarcinoma.

CASE REPORT

A 77-year-old man presented with dysphagia for 2 mo. Upper gastrointestinal endoscopy was performed, which showed a tumor arising from the lower esophagus and extending into the lumen, and an ulcerated tumor located in the cardia, just below the gastroesophageal junction.

Figure 1 Esophagography showed a filling defect in the anterior wall of the lower esophagus.

He had no relevant past history or family history. Clinical examination did not find any palpable abdominal mass. Laboratory examination was normal. Esophagography showed a filling defect in the anterior wall of the lower esophagus (Figure 1). Computed tomography (CT) showed circumferential thickening of the lower esophageal wall with loss of the lumen. Scanning at a lower level displayed focal thickening of the gastric cardia wall with marked enhancement. Furthermore, scans obtained at lower levels displayed a large, heterogeneous, round mass close to the greater curvature of the stomach. The patient was diagnosed presumptively with synchronous esophageal and gastric cardia carcinoma with lymph node metastasis (Figure 2).

Intraoperatively, an extraluminal tumor (about 6.0 cm × 5.0 cm × 6.0 cm) at the posterior wall of the gastric body, a tumor (about 2.5 cm × 2.0 cm) in the lower esophagus, and an infiltrative and stenosing tumor (about 1.0 cm × 2.0 cm) in the gastric cardia was detected. Wedge resection for extraluminal gastric tumor, radical esophagectomy for lower esophageal tumor, and cardiac resection with gastroesophageal (supra-aortic arch anastomoses) were performed.

On histopathological examination, the gastric cardia tumor was a mid-differentiated gastric adenocarcinoma (pT_{1b}N₀M₀), and the lower esophageal tumor was a low-mid-differentiated squamous cell carcinoma (pT₃N₀M₀) (Figure 3). There was no vascular invasion and no lymph node metastasis.

Further histopathological examination of the extraluminal gastric tumor revealed GIST of the high-risk category, which showed a high mitotic index (> 10 mitoses/50 high-power fields). Immunohistochemistry indicated strong staining for c-Kit/CD117, Dog-1, Ki-67 and smooth muscle, while expression of S-100 and CD34 was negative (Figure 3). The patient was diagnosed with high-grade gastric GIST due to large tumor size (> 5 cm) and unfavorable histopathological features (high mitotic index and strong positivity for Ki-67).

DISCUSSION

GISTs are rare, accounting for only 0.1%-3% of all

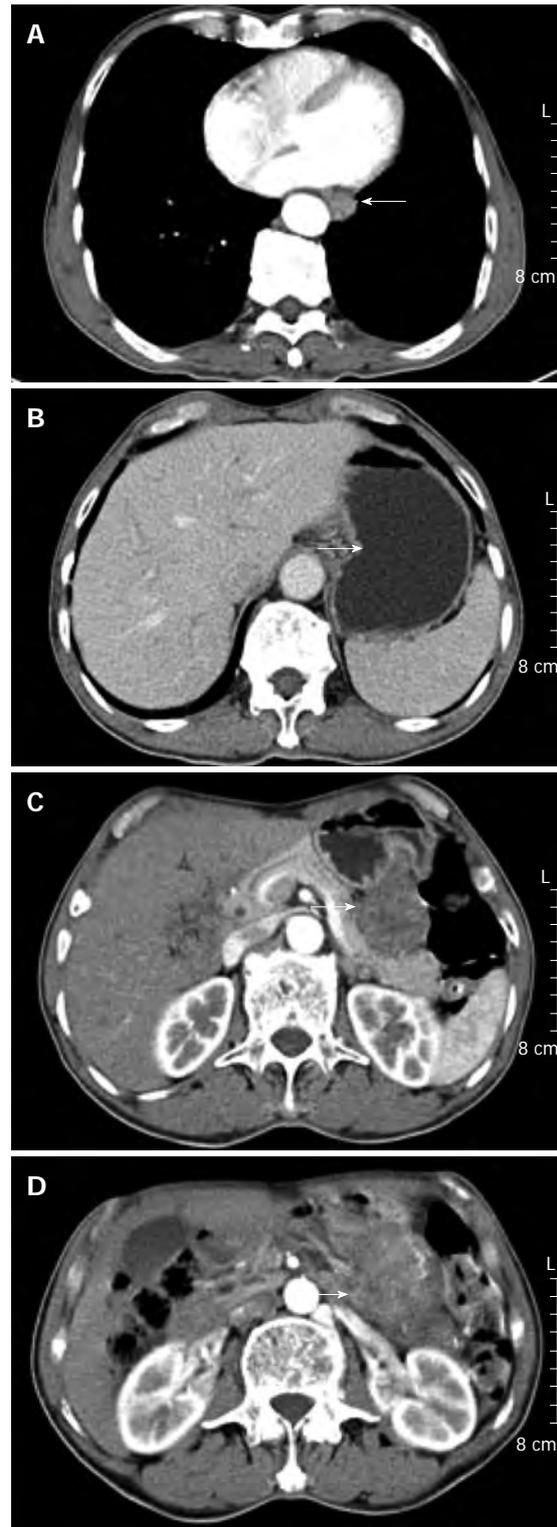

Figure 2 Computed tomography scan. A: Circumferential thickening (arrow) of the lower esophageal wall with loss of lumen; B: Lower level displayed focal thickening (arrow) of the gastric wall with marked enhancement; C and D: Lower levels displayed a large, heterogeneous, round mass close to the greater curvature of the stomach (arrows).

gastrointestinal malignancies. Primary GISTs arise most commonly in the stomach (50%-70%), followed by the small intestine (25%-35%), colon and rectum (5%-10%) and esophagus (< 5%)^[4]. These tumors are considered

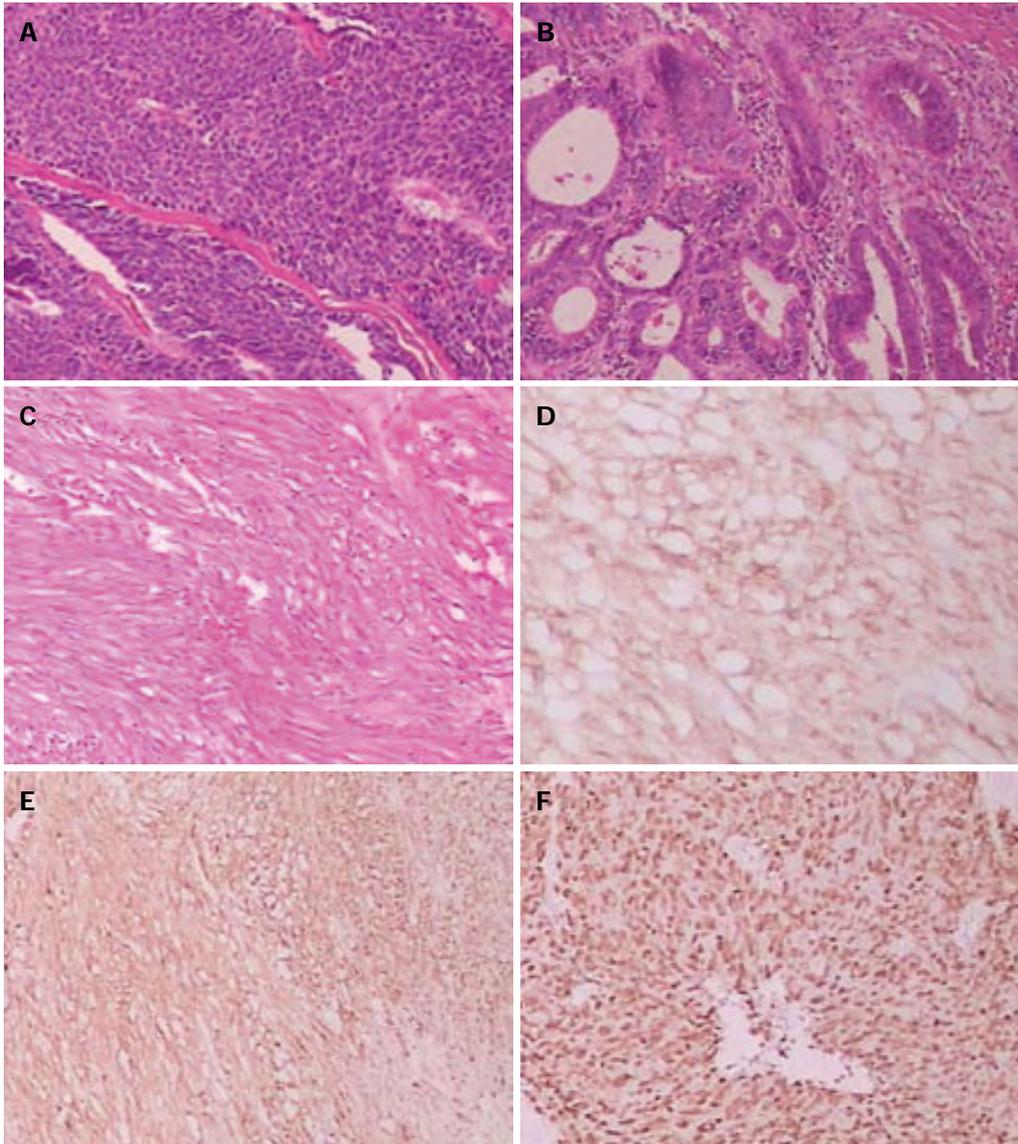

Figure 3 Microscopic images. A: Esophageal squamous cell carcinoma ($\times 10$); B: Gastric cardia adenocarcinoma ($\times 10$); C: Gastric gastrointestinal stromal tumor ($\times 10$); D-F: Immunohistochemistry indicated strong staining for Dog-1 (D, $\times 40$), c-Kit/CD117 (E, $\times 10$), Ki-67 (F, $\times 10$).

to originate from interstitial cells of Cajal or their precursors, because both strongly express the c-Kit protein (CD117; a type III tyrosine kinase receptor encoded by the c-Kit proto-oncogene)^[5].

Radical surgery is the main treatment in primary resectable GISTs. Recurrence, metastatic disease or unresectable tumors could be treated with imatinib (a small-molecule tyrosine-kinase inhibitor)^[6].

Adenocarcinoma of the stomach ranks as the second most common cancer worldwide, which comprises 80% of all stomach cancers. Squamous cell carcinoma mainly occurs in the mid to lower esophagus, and is not commonly accompanied by other cancerous lesions. Suzuki *et al*^[7] have reported that most lesions are in the stomach (59.6%), followed by the colon and rectum (12.3%). Various hypotheses, such as gene mutation, expression of metallothioneins, neighboring tissues being influenced by the same carcinogens, have been proposed regarding the simultaneous development of GIST and other

cancers^[8,9]. However, at present, no data are available to support such hypotheses. Furthermore, simultaneous occurrence of gastric GIST, esophageal squamous cell carcinoma, and gastric adenocarcinoma has not often been reported in the literature. Simple coincidence could be the most reasonable explanation.

For patients with primary GIST, surgical resection is the only chance for cure. Resection can usually be accomplished with only wedge resection of the stomach or segmental resection of the small bowel for small GISTs, whereas extensive surgery is occasionally required for larger or poorly positioned GISTs^[6].

The only curative treatment for esophageal or gastric cardia cancer is surgical resection. After esophagectomy, digestive tract reconstruction can be accomplished using the remaining stomach, depending on the location of the gastric tumor. The colon or jejunum is the frequent choice for esophageal substitution. In our opinion, digestive tract reconstruction with the remaining stomach

should be a reasonable choice for old people (age > 75 years). Although the GIST is large, only wedge resection of the stomach was performed to keep enough stomach for digestive tract reconstruction.

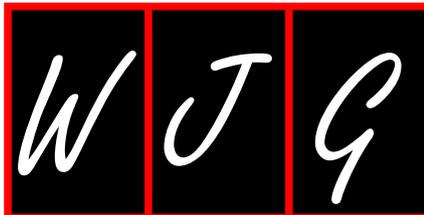

In our case, we considered gastric adenocarcinomas to be an early stage gastric cancer and esophageal squamous cell carcinoma to be a middle stage esophageal cancer. Meantime, the patient was diagnosed with high-grade gastric GIST due to large tumor size (> 5 cm) and unfavorable histopathological features (high mitotic index and strong positivity for Ki-67). Therefore, we suggested that the patient should undergo chemoradiation therapy and adjuvant imatinib treatment. However, the patient refused. A postoperative CT scan performed 3 mo later showed no evidence of tumor recurrence. The patient needs a long follow-up period.

Abstract

In a recently published letter to the editor, we debated the proposal by Coccolini *et al* to treat gastrointestinal stromal tumors (GISTs) of the esophagogastric junction with enucleation and, if indicated, adjuvant therapy. We highlighted that, because the prognostic impact of a T1 high-mitotic rate esophageal GIST is worse than that of a T1 high-mitotic rate gastric GIST, enucleation may not be adequate surgery for esophagogastric GISTs with a high mitotic rate. In rebuttal, Coccolini *et al* pointed out the possible bias in assessment of the mitotic rates due to the lack of standardized methods and underlined that the site and features of the tumor need to be carefully considered in evaluation of the risk-benefit balance. Here we confirm that, apart from the problematic issue of mitotic counting, enucleation should not be indicated for GISTs at any site to reduce the risk of tumor rupture, which has been recently considered to be an unfavorable prognostic factor, and to avoid microscopic residual tumor.

TO THE EDITOR

In a recent issue of *World Journal of Gastroenterology*, we debated^[1] the proposal by Coccolini *et al*^[2] to treat gastrointestinal stromal tumors (GISTs) of the esophagogastric junction with enucleation and, if indicated, adjuvant therapy. We highlighted that, because the prognostic impact of a T1 high-mitotic rate esophageal GIST is worse than that of a T1 high-mitotic rate gastric GIST, enucleation may not be adequate surgery for esophagogastric GISTs with a high mitotic rate. In rebuttal, Coccolini *et al*^[3] pointed out the possible bias in the assessment of the mitotic rate due to the lack of standardized methods and underlined that the site and features of the tumor need to be carefully considered in the evaluation of the risk-benefit balance.

Apart from the prognostic differences related to the anatomic localization of the gastric GISTs (gastroesophageal junction-body-distal antrum), problematic mitotic counting is a significant issue in the staging and therapy of GISTs. Controversies exist regarding how large the 50 high-power field areas should be^[4], varying from 5 mm² to 10 mm². The area recommended by the European Guideline represents half of the area recommended by TNM Classification of Malignant Tumors^[5,6].

However, tumor rupture is a highly unfavourable prognostic factor, which should be considered rather than the mitotic rate, tumor site and tumor size in planning an effective treatment for GISTs. According to the modified risk stratification proposed by Joensuu *et al*^[7] and Rutkowski *et al*^[8], patients with tumor rupture are in-

cluded in high-risk category GISTs.

On the other hand, according to updated National Comprehensive Cancer Network Guidelines^[9], Coccolini *et al.*^[2] pointed out the value of complete resection, leaving a negative margin and an intact pseudocapsule. GISTs may be soft and fragile because of intratumoral hemorrhage and/or necrosis; anyway they are surrounded by a pseudocapsule that should not be torn during surgery to avoid intra-abdominal seeding. From technical point of view, enucleation of GIST implies that the plane of dissection is conducted along the pseudocapsule with no distance margin on the entire surface of the tumor - *i.e.*, at best microscopic residual tumor (R1) surgery - or rather, enucleation maximizes the risks of R1 and tumor rupture.

We think that complete resection should remain the standard surgical treatment for localized GISTs at any site through wedge resection for small size favorably positioned GISTs and variably extended segmental organ resection depending on the size and site for large and/or unfavourably positioned GISTs. To reduce the risk of tumor rupture with consequent risk of tumor relapse and avoid microscopic residual tumor enucleation should not be indicated for any GISTs. For the risk of tumor rupture, laparoscopic surgery should be avoided with large GISTs^[5].

Abstract

The arrival of both high-throughput and bench-top next-generation sequencing technologies and sequence enrichment methods has revolutionized our approach to dissecting the genetic basis of cancer. These technologies have been almost invariably employed in whole-genome sequencing (WGS) and whole-exome sequencing (WES) studies. Both WGS and WES approaches have been widely applied to interrogate the somatic mutational landscape of sporadic cancers and identify novel germline mutations underlying familial cancer syndromes. The clinical implications of cancer genome sequencing have become increasingly clear, for example in diagnostics. In this editorial, we present these advances in the context of research discovery and discuss both the clinical relevance of cancer genome sequencing and the challenges associated with the adoption of these genomic technologies in a clinical setting.

INTRODUCTION

Sporadic cancers are complex diseases that are caused by the accumulation of somatic mutations that are acquired by the genomes of the cells of the tissue in which the cancer originated^[1]. The importance of identifying the “driver” (causal) somatic mutations amongst the much more numerous “passenger” mutations has long been recognized. However, previous cancer genome sequencing studies have also been constrained by technological limitations. Although several early attempts were made to sequence the coding regions of the majority of the consensus coding sequence and/or RefSeq genes in several cancers (*e.g.*, breast and colorectal), these studies were conducted in “brute-force” mode employing traditional low-throughput polymerase chain reaction-Sanger sequencing methods^[2,3]. The advent of next-generation sequencing (NGS) technologies has revolutionized the sequencing of cancer genomes, the first example of which employed whole-genome sequencing (WGS) to characterize an acute myeloid leukemia (AML) genome thereby identifying numerous tumor-specific mutations^[4]. This study clearly demonstrated the technical feasibility of applying NGS to interrogate the genome-wide somatic mutational spectra of entire cancer genomes in tandem with paired constitutional DNA samples.

In parallel, the development of a variety of exome enrichment methods to selectively capture the entire collection of exons in the human genome has made whole-exome sequencing (WES) technically feasible^[5]. Coupling this development to the high-throughput NGS techniques has allowed the exome to be sequenced very

rapidly and in unprecedented detail. In comparison to WGS, WES is more affordable for larger sample sizes and is analytically less challenging since only 1%-2% of the entire genome needs to be sequenced^[6-8]. As a result, a larger number of cancer DNA samples have been sequenced by WES than WGS in attempts to identify recurrent mutations (*i.e.*, identical mutations that recur in different samples) and highly mutated genes (genes harboring multiple mutations in a significant proportion of the cancer samples)^[9-12]. The other reason for the more widespread adoption of WES has been that the mutations identified within protein coding regions are inherently easier to interpret than those in the non-coding regions, which still remain largely uncharacterized in functional terms. In addition to the advances being made in characterizing the somatic mutational landscape in various cancers, the applications of cancer genome sequencing in a clinical setting have also become increasingly numerous.

SOMATIC MUTATIONS IN SPORADIC CANCERS

WGS and WES have been commonly applied to study the patterns of somatic mutation in a range of different cancers^[13,14]. Collectively, these endeavors have generated new insights into the mutational landscape of various cancers, and have resulted in the identification of a large number of recurring mutations as well as many highly mutated genes. For example, in the context of gastrointestinal cancers, WES of 15 gastric adenocarcinomas and their matched normal DNAs succeeded in identifying several frequently mutated genes such as *TP53*, *PIK3CA* and *ARID1A*^[15]. In addition, it was found that cell adhesion was the most enriched biological pathway among the frequently mutated genes. More importantly, mutations in three chromatin remodeling genes (*ARID1A*, *MLL3* and *MLL*) were detected in almost half of the gastric cancers examined^[15]. In fact, an earlier study which performed WES in 22 gastric cancer samples also identified frequent inactivating mutations in *ARID1A*, which encodes a member of the switch/sucrose non-fermenting chromatin remodeling family. Further, the mutational spectrum for *ARID1A* was found to differ between molecular subtypes of gastric cancer^[7]. In similar vein, mutations in multiple chromatin regulator genes such as *ARID1A*, *ARID1B*, *ARID2*, *MLL* and *MLL3* were also found in about half of hepatocellular carcinomas through WGS^[16]. The consistent finding of mutations in chromatin remodeling genes in different cancers, which also included renal carcinoma and glioblastoma multiforme, further highlights a close inter-relationship (or possibly a “synergy” interaction effect) between somatic mutations and aberrant epigenetic regulation in the pathogenesis of cancers^[8,17-19].

In addition to individual studies, technological advances have made possible large-scale international projects such as the International Cancer Genome Consor-

tium which aims to interrogate the somatic mutational landscape of at least 50 different cancer types and subtypes in thousands of samples, with the eventual aim of integrating these genomic data with both transcriptomic and epigenomic data. NGS technologies are instrumental in generating these “omics datasets”^[20]. The concept of an integrative approach for a range of different omics data is not new, but in recent years it has resurfaced and become reinvigorated by technological advancement. The integrative analysis of different omics datasets (providing information in different dimensions, from DNA sequence to the transcriptional and translational levels) is expected to be more informative, and hence ought to provide new and more detailed biological insights, than would be possible using individual datasets^[21].

Although most of the cancer genome sequencing studies were not conducted with a view to investigating their applications in a direct clinical context *per se* (but rather to characterize the somatic mutational spectrum in order to understand better the genetic basis and biology of the cancer in question), the data generated are nevertheless important as a means to identify the drug targets as well as potential biomarkers (*e.g.*, single mutations or mutational patterns that could be used for diagnostic and prognostic applications). The potential of driver mutations to shape the future science of cancer taxonomy was recently outlined by Stratton (2011) *i.e.*, the drawing up of a system based on causal mutations rather than the conventional organ-based (*e.g.*, breast, lung or colorectum tissue) classification and TNM-staging system that are widely applied in the clinic^[22].

So far, what are the potential implications of cancer genome sequencing for the clinical setting? The application of cancer genome sequencing in diagnostics has been increasingly evident, as demonstrated by two recent studies using WGS^[23,24]. WGS has demonstrated both its discovery and confirmatory role in a specific patient characterized by an ambiguous diagnosis or clinical presentation. More specifically, it has been used to determine the genetic aberration in a patient with a diagnosis of AML of unclear subtype^[23]. The ambiguity came from the observation that the patient’s clinical presentation was consistent with acute promyelocytic leukemia (which is a subtype of AML with a favorable prognosis), but it was contradicted by cytogenetic analysis. The cytogenetic analysis revealed a different subtype associated with a poor prognosis for which bone marrow transplantation in first remission is recommended. The diagnostic and treatment uncertainty was resolved by WGS performed on the original leukemic bone marrow and from a skin biopsy. The WGS analysis detected a novel insertional translocation on chromosome 17 which generated a pathogenic *PML-RARA* gene fusion thereby confirming a diagnosis of acute promyelocytic leukemia. This type of complex rearrangement could not have been made by targeted sequencing (as the genetic etiology was unsuspected), further demonstrating that WGS represents both a discovery and a comprehensive

analytical tool for the entire genome. More importantly, the molecular confirmatory diagnosis carries important clinical implications for the treatment and management of the patient^[23]. Similarly, WGS was also employed to resolve the genetic basis of a suspected cancer susceptibility syndrome based upon the early onset of several primary tumors^[24]. Further, therapeutic prediction has also benefited from NGS as a powerful discovery tool. For example, a recent study employed a targeted NGS approach to sequence 138 cancer genes in melanomas derived from a patient (before and after relapse) and succeeded in identifying the underlying genetic mutation in the *MEK1* gene responsible for acquired resistance to PLX4032 (vemurafinib) after an initial dramatic response, revealing a novel mechanism of acquired drug resistance^[25].

The potential applications of cancer genome sequencing in the clinical arena are promising, but what are the challenges associated with their adoption? As WGS and WES are high-throughput methods which generate huge amounts of data, our ability to perform both the analysis and the interpretation of the data in a clinically relevant time-frame is critical. This challenge is being addressed in the context of a “comprehensive genomic approach” where WGS, WES and transcriptome sequencing are applied to cancer samples to evaluate their clinical utility and feasibility (in terms of technical, time and cost)^[26]. In particular, the time required, from biopsy sampling and wet-lab experiments to computational analysis and initial results, was streamlined to just 24 d with the cost of all the sequencing and analysis estimated to be only USD5400. An obvious advantage of this “integrative genomic approach” is that the findings can be cross-validated more efficiently. For example, both WGS and WES detected an amplification event on chromosome 13q spanning the *CDK8* gene in a metastatic colorectal carcinoma; the over-expression of *CDK8* was confirmed by transcriptome sequencing. Although this “comprehensive genomic approach” was shown to be both time- and cost-effective, the handling and interpretation of the huge amount of genomic data remains a key issue. To address this challenge, it was proposed that a multi-disciplinary “sequencing tumor board” (which included professionals from multiple disciplines such as clinicians, geneticists, pathologists, biologists, bioinformatic specialists and bioethicists) should take responsibility for the clinical interpretation of the sequencing data obtained from each patient^[26].

FAMILIAL CANCER SYNDROMES

In addition to the investigation of somatic mutations in sporadic cancers, cancer genome sequencing has also made significant advances in relation to the study of the germline mutations underlying familial cancer syndromes. The early successes in the identification of causal mutations and genes for familial cancer syndromes (e.g., *RB1* and *APC*) were achieved by painstaking family

linkage analysis and positional cloning. However, the genetic causes of many familial cancer syndromes have remained elusive. For example, *CDH1* was the first and only causal gene identified for hereditary diffuse gastric cancer through linkage analysis^[27], but germline mutations in this gene account for only a proportion of hereditary diffuse gastric cancer cases. Thus germline mutations in *CDH1* were found in 30%-40% of clinically defined families with hereditary diffuse gastric cancer from different ethnic backgrounds^[28,29]. This suggests that an as-yet-to-be identified gene(s) is likely to be responsible for the remaining cases unexplained by *CDH1*. On the other hand, whereas most Lynch syndrome cases can be accounted for by mutations in DNA mismatch repair genes, the genetic basis of familial colorectal cancer type X still remains elusive^[30,31]. Similarly, the genetic causes of other familial cancer syndromes, such as familial pancreatic cancer, still remain largely unknown^[32,33]. In a fashion similar to that noted with the identification of somatic mutations, cancer genome sequencing provides new opportunities to identify germline mutations for familial cancer syndromes. This is well exemplified by the case of hereditary pheochromocytoma, a rare neural crest cell tumor; by harnessing the latest technological advances, germline mutations in *MAX* were identified in three unrelated individuals with hereditary pheochromocytoma by WES^[34]. The segregation of two *MAX* gene variants with hereditary pheochromocytoma was observed in families from whom DNA from affected relatives was available. Further, additional data to support the causative role of the *MAX* variants came from their absence (or non-detection) in more than 750 population-matched control chromosomes. Additional screening for *MAX* mutations in 59 cases lacking germline mutations in known genes for hereditary pheochromocytoma then identified two additional truncating mutations and three missense variants in the gene^[34]. Following this discovery, a recent study found that germline mutations in *MAX* are responsible for 1.12% pheochromocytomas or paragangliomas (both are genetically heterogeneous neural crest-derived neoplasms) by sequencing *MAX* in 1694 patients^[35].

In addition to its role in research discovery, cancer genome sequencing has also been used as a diagnostic tool to detect known germline mutations for familial cancer syndromes. Indeed, by leveraging technological advances in genomic sequence enrichment methods and NGS technologies, studies have developed NGS-based diagnostic tests for breast and ovarian cancers and Lynch syndrome. For example, Walsh *et al.*^[36] designed custom oligonucleotides in solution to capture 21 genes responsible for hereditary breast and ovarian cancers, and the enriched genomic DNA was then subjected to sequencing using an NGS platform. This NGS-based test was evaluated in 20 women diagnosed with breast or ovarian cancer and with a known mutation in one of the genes responsible for inherited predisposition to these cancers. The results were very promising in that all the known

point mutations and small indel mutations (ranging from 1 bp to 19 bp), as well as large genomic duplications and deletions (ranging from 160 bp to 101 013bp), were detected in all the samples. The potential to detect different mutations of various sizes has further demonstrated the technical advantages of NGS-based tests over conventional PCR-Sanger sequencing methods. For example, two different tests were offered separately to detect point mutations and large deletions/amplifications for genetic testing of *BRCAl/2* genes, respectively^[36]. Similarly, attempts have also been made to incorporate custom genomic enrichment and NGS methods into the genetic diagnostic testing of Lynch syndrome by capturing every exon in a panel of 22 genes (most of which are known to be associated with hereditary colorectal cancer) followed by NGS^[37].

Technological advances have facilitated the accessibility of cancer genome sequencing in the clinical arena. In addition to the custom sequence enrichment methods (*i.e.*, either based on polymerase chain reaction amplification such as Fluidigm and RainDance technologies, or based on target-probe hybridization such as the Agilent and Nimblegen technologies) that allow one to selectively capture the genomic regions of interest, the arrival of several bench-top NGS instruments has not only made the sequencing of a panel of genes highly feasible technically but also cost-effective^[5,38,39]. This is an important step towards the development and adoption of NGS-based diagnostic tests in the clinic. The bench-top NGS instruments (Roche 454 Genome Sequencer Junior, Ion Torrent Personal Genome Machine Sequencer and IlluminaMiSeq) have a much lower throughput (ranging from > 10 Mb to > 1 Gb per run) than the conventional high-throughput NGS machines^[38,39]. The bench-top NGS instruments are therefore more suitable in terms of their throughput for sequencing panels of genes (as discussed earlier for the panels of genes for breast/ovarian cancers and Lynch syndrome) than WES or WGS. Further, sample indexing (or barcoding) is also available for the bench-top NGS instruments which can further optimize sample throughput and cost-effectiveness by multiplexing up to several tens of samples for sequencing. However, the level of multiplexing is dependent on the sizes of the regions to be sequenced and the throughputs of the instruments being used. Although it remains to be demonstrated in the context of cancer, WES has been widely assessed and shown as a promising diagnostic tool for various Mendelian disorders^[40-43]. In addition to diagnosis, WGS has also been applied to optimize patient treatment regimens, although not in the context of cancer. In the context of inherited disease, WGS has been applied to sequence a fraternal twin pair diagnosed with dopa (3,4-dihydroxyphenylalanine)-responsive dystonia (OMIM 128230); germline compound heterozygous mutations were identified in the *SPR* gene encoding sepiapterin reductase. As a result, supplementation of L-dopa therapy with 5-hydroxytryptophan has led to clinical improvements in both twins^[44].

PERSPECTIVES AND CONCLUSIONS

NGS technologies have already made a major contribution to characterizing somatic mutations in cancer genomes. This endeavor will be further accelerated by international initiatives such as the International Cancer Genome Consortium. Although the number of studies is currently still very limited, NGS should also be applied to identify germline mutations in those familial cancer syndromes whose genetic causes have not yet been fully characterized. On the other hand, the successful demonstration of the applications of NGS/WGS/WES in a clinical setting such as cancer diagnostics are likely to be just the first examples of how the new technologies will prove their worth; the numbers are expected to increase in the coming year.

So far, the applications of NGS in a clinical setting have been very promising. However, challenges ranging from technical, analytical and interpretational, to the need for a considerable number of well-trained professionals from a range of disciplines in these genomic technologies must be further addressed before the adoption of NGS-based tests in the clinic. The technical challenges include, for example, incomplete capture of the exons in WES and uneven sequencing across the genome which might result in poor sequence coverage in some of the regions and affect both the sensitivity and specificity of variant detection^[39]. Having specialists trained in genomic technologies is critical to (1) obtaining fully informed consent from patients in relation to the genomic tests; (2) ensuring accurate and reliable interpretation of the data for clinical decision-making; and (3) counselling the patients on the basis of the results obtained. It is also evident from the Global Cancer Genomics Consortium (GCGC) that the translation of emerging cancer genomics knowledge into clinical applications can only be achieved through the integration of multi-disciplinary expertise^[45]. The GCGC is an international collaborative platform that brings cancer biologists and cutting edge high-throughput genomics expertise together with medical oncologists and surgical oncologists to address the most important translational questions that are central to cancer research, diagnosis and treatment.

As to test affordability, although the total cost of sequencing for several genomic experiments was only a few thousands of USD per patient, it should be appreciated that this is unlikely to be the final chargeable cost to the patients. The cost of sequencing is currently plummeting and will become ever cheaper in the future with new developments. However, it should be appreciated that hidden costs are likely to be incurred for data storage, interpretation of results and subsequent clinical consultation.

Further, handling of the complex ethical issues such as revealing findings that might be considered incidental to the initial testing (WGS and WES) procedure must also be given serious consideration^[46]. Determining what to disclose and what not to disclose to the patients is

likely to be quite challenging *e.g.*, those results which are deemed clinically important *i.e.*, those which could have a direct impact on the patient's care or management, but which are irrelevant to the initial purpose of the diagnostic test (*i.e.*, incidental findings). Have the patients the right to be informed about those results which are/might be clinically important but not actionable *e.g.*, mutations that are considered likely to predispose to certain inherited diseases, although preventive treatments are not yet available? Adequate consultation must also be given to the reporting of results that are of unknown clinical importance. This raises concerns as to whether periodic re-analysis of the WGS/WES data might be needed, which in turn would lead to some practicality issues potentially incurring additional costs. Finally, any results from WGS- and WES-based tests that would affect clinical decision-making must be properly validated or the tests must be performed in a heavily regulated clinical setting according to the College of American Pathologists/Clinical Laboratory Improvement Amendments.

It is widely anticipated that cancer genome sequencing or the NGS-based tests will gradually become more accessible in clinical practice once the associated challenges and ethical issues have been adequately addressed. Irrespective of the challenges that still remain to be overcome, the application of NGS in the clinic appears inevitable.

Abstract

Recent research has shown that microRNA (miRNA), which is involved in almost every step of gastric carcinogenesis, has broad prospective application in diagnosis and therapy of gastric carcinoma. Eastern Asia (South Korea, Japan and China) has the highest incidence of gastric cancer in the world. There were 988 000 new cases of gastric cancer worldwide and 736 000 deaths in 2008. Approximately 60% of the cases of gastric cancer are found in East Asia (mainly China). We herein provide a brief review of the clinical applications of miRNA, which include the following aspects: (1) miRNA may serve as a potential new generation of tumor markers; (2) a complete miRNA expression profile is highly specific, can reflect the evolutionary lineage and differentiation of tumors, and be used to carry out diversity analysis; (3) detecting specific miRNA expression in peripheral blood will become a new method for diagnosis of gastric cancer; (4) miRNA can predict prognosis of gastric cancer; (5) miRNA has predictive value in determining chemotherapy and radiotherapy resistance; and (6) miRNA could be a type

of innovative drug. Finally, we focus on assessing the value of miRNA from laboratory to clinical application and the challenges it faces in East Asia.

INTRODUCTION

Gastric cancer is a leading disease in Eastern Asia (South Korea, Japan and China) (Figure 1). The incidence and mortality of gastric cancer in East Asian areas rank respectively the second and the third among the most common cancers worldwide^[1,2]. According to World Health Organization^[3] statistics, there were 988 000 new cases of gastric cancer worldwide and 736 000 deaths in 2008. Approximately 60% of the cases are found in East Asia (mainly China). In China, approximately two-thirds of patients develop advanced or metastatic disease, and more than half have recurrent disease after curative surgery. The median survival time for these patients is only 6-9 mo^[4-6]. Several reasons restrict the diagnosis and treatment of gastric cancer: (1) limited diagnostic measures for early detection; (2) weak prognostic value of outcome; (3) poor effect of surgery or cytotoxic cell treatment for advanced disease; and (4) lack of biomarkers for targeted therapy. The discovery of microRNA (miRNA) may change the above-mentioned difficulties, and improve the level of diagnosis and treatment of gastric cancer.

miRNAs include 20-24 nucleotides and are a class of noncoding small molecular single chain RNAs, and

have highly conservative, temporal and tissue-specific characteristics^[7-9]. Through complete or incomplete base pairing with target gene mRNA, RNA-induced silencing complex degrades mRNA or blocks its translation, and regulates target gene expression at the post-transcriptional level^[10]. They exist widely in eukaryotic organisms and regulate cell proliferation, differentiation and apoptosis. Although the tissues of the body appear malignant, specific miRNAs are overexpressed or underexpressed in different tumors and at different stages, which implies a correlation with occurrence and development of tumor and prognosis^[11-13]. Further study of the relation of miRNA and gastric cancer could provide new applications in early tumor detection, monitoring, prognosis, gene therapy, and resolving chemotherapy resistance.

miRNA AND CANCER DIAGNOSIS

Specific tumor markers are often ideal screening tools. Existing clinical tumor markers [such as carcinoembryonic antigen (CEA), cancer antigen (CA)19-9, and CA72-4] for gastric cancer lack specificity and sensitivity^[14]. miRNA may serve as a potential new generation of tumor markers for the following reasons^[15-17]: (1) good tissue specificity - Rosenfeld *et al*^[18] have detected unknown sources of miRNA in order to make clear its sources, and its specificity is 90%; (2) expression of miRNA in tumors differs significantly from that in normal tissues; (3) miRNA participates in tumor occurrence and development; (4) expression of miRNA has stage specificity - the same tumors at different stages have different expression profiles^[19,20]; and (5) miRNA in fresh tissues, paraffin-embedded tissues, and cells and peripheral blood shows good stability^[21].

Detection methods of miRNA and miRNA expression in gastric cancer: miRNA is a good tumor marker in clinical application^[22,23]. At present, the detection method for miRNA has become mature. By deep sequencing, we can discover unknown miRNAs, and miRNA chips can be used for identification of the differences in miRNAs between the study and control groups. Finally, they can be verified by real-time quantitative polymerase chain reaction (qPCR)^[24].

In diagnosis of gastric cancer, a single miRNA is often characterized by poor specificity or sensitivity, but a complete miRNA expression profile is highly specific, can reflect the evolutionary lineage and differentiation of tumors, and be used to carry out diversity analysis^[25,26]. Through horizontal comparison of gastric carcinoma with adjacent normal tissues, we have found specific expression of miRNAs in cancer tissues. Further longitudinal comparison at different tumor stages has enabled us to identify the different miRNAs at each stage and to complete final tumor diagnosis and staging^[27,28].

We acquired gastric cancer miRNA expression profiles from numerous Chinese and international study groups from 2008 to 2012^[29-36] (Table 1). These results differed considerably and lacked stability and consistency

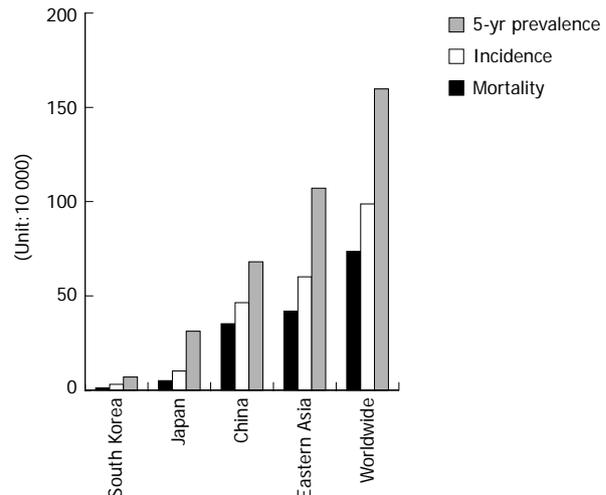

Figure 1 Gastric cancer incidence, mortality and prevalence in South Korea, Japan, China, Eastern Asia, and worldwide in 2008.

for the following reasons: (1) differences in miRNA chips and software; (2) individual differences between races and patients; (3) differences in collected specimen standards; (4) differences in sample size; and (5) miRNA expression profile differences for different cancer types and stages. According to the above expression profiling, we confirmed several reliable miRNAs in the multiple experiments which had 1.5 fold differential expressions between gastric cancer and normal gastric tissues. We are looking forward to having a large sample multi-center study or even international cooperation to compare complete miRNA expression profiling based on different pathological types and stages of gastric cancer. In particular, countries like China, Japan and South Korea should cooperate using the same platform in complete standard miRNA expression profiling of gastric cancer in East Asian populations.

Change in miRNA expression is an early event during the development of gastric tumor^[37,38]. Tracking the changes in miRNA expression profiling in the relevant gastric tissues might enable early tumor diagnosis. Traditional methods for the detection of gastric cancer are endoscopy and biopsy. A minimally invasive examination method would be helpful for screening and early detection of cancer in high-risk populations^[39]. Detection of tumor in the peripheral blood of patients with specific miRNA expression level has been a research hotspot in recent years, which will perhaps become a new method for diagnosis of gastric cancer^[40-42].

Researchers have shown that 90% of plasma miRNA is based on protein-miRNA complex formation. As tumor markers in peripheral blood, miRNAs have the following advantages: (1) miRNAs exist in great volume in peripheral blood^[43,44]; (2) miRNAs can resist enzymatic digestion^[45-47]; (3) miRNAs have strong resistance to the external environment; and (4) miRNAs show abnormal expression in tumor patients' serum^[48].

In the past two years, Japanese and Chinese research-

qRT-PCR: Quantitative reverse transcriptase polymerase chain reaction.

ers have investigated miRNA in the peripheral blood of patients with gastric cancer^[49-55] (Table 2) and have obtained some positive results. For example, by comparing serum of 61 gastric cancer patients with that of 61 healthy persons, Liu *et al*^[49] found that the expression of miR-378 in the gastric cancer group was significantly higher than that in the healthy group. The area under the receiver-operating characteristic curve was 0.861 (95%CI: 0.766-0.928), and sensitivity/specificity was 87.5%/70.7%, respectively. Similarly, after investigating the peripheral serum in 69 gastric cancer patients and 30 healthy volunteers by qRT-PCR, Tsujiura *et al*^[55] found that the plasma concentrations of miRNAs (miR-106a and miR-106b) were significantly higher in the patients than in the controls, whereas let-7a concentration was lower in the patients, in which the area under the curve (AUC) for miR-106a and let-7a was 0.879, and sensitivity/specificity was 85.5%/80.0%, respectively. These miRNAs could become ideal tumor markers for gastric cancer. In addition, Liu *et*

al^[49] observed that the plasma miRNAs (miR-1, miR-20a, miR-27a, miR-34, and miR-423-5P) in the gastric cancer patients had significantly higher expression than in the control group (164 gastric cancer patients *vs* 127 healthy individuals). The AUC was 0.879 (95%CI: 0.822-0.936). It is interesting that, in the same sample, they also compared the AUC values of CEA and CA19-9 which were only 0.503 and 0.600, respectively. The results show that miRNA has some advantages as a tumor marker. We have found that miRNAs have good sensitivity and specificity for gastric cancer and are promising tumor markers. However, at present, some factors still limit their clinical diagnostic applications^[56]: (1) relative difficulty of detection (in quality and quantity); (2) lack of a unified testing platform and standardization; (3) plasma miRNA source and release mechanism are not clear; and (4) differences in expression of tissue and peripheral blood miRNA still exist^[57]. Thus, searching and identifying specific miRNAs for the diagnosis of gastric cancer is the first task that

Table 2 Expression of miRNA and area under curve, sensitivity and specificity in serum samples of patients with gastric cancer

| Group | Sample | MicroRNA | AUC | Method | Sensitivity/specificity (%) |
|--|--------------|--|-------|----------------------|-----------------------------|
| Liu <i>et al.</i> ^[49] | 61 GC/61 C | miR-378↑ | 0.861 | qRT-PCR | 87.5/70.7 |
| Liu <i>et al.</i> ^[50] | 164 GC/127 C | (miR-1, miR-20a, miR-27a, miR-34, miR-423-5P)↑ | 0.879 | Microarray + qRT-PCR | 79.3/86.5 |

| Tsujiura <i>et al.</i> ^[55] | 69 GC/30 C | miR-106b↑ | 0.72 | Microarray + qRT-PCR | NA |
| | | miR-106a↑, let-7a↓ | 0.879 | | 85.5/80.0 |

qRT-PCR: Quantitative reverse transcriptase polymerase chain reaction; GC: Gastric cancer, C: Control; AUC: Area under curve; NA: Not available; ↑: Upregulated; ↓: Downregulated.

Table 3 Gastric cancer with potential predictive role of miRNAs

| | Potential predictive role of miRNA | |
|-------------------------|--|--|
| | MiRNAs of high expression | MiRNAs of low expression |
| Short survival time | miRNA-20b, miRNA-150 ^[29] , miRNA-142-5p ^[61] , miRNA-375, miRNA-214 ^[62] | miRNA-451, let7g ¹ , miRNA-433 ^[33] , miRNA-125-5p ^[63] |
| Lymph node metastasis | miRNA-27a ^[29] , miRNA-650 ^[64] | miRNA-126 ^[65] , miRNA-146a ^[66] , miRNA-148 ^[67] , miRNA-218 ^[68] , miRNA-335 ^[69] , miRNA-429 ^[70] |
| Relapse | miRNA-375 ^[61] , miRNA-451 ² , miRNA-199-3p ² , miRNA-195 ^[71] | miRNA-142-5p ^[61] |
| Advanced gastric cancer | miRNA-221 ^[72] | miRNA-126 ^[65] , miRNA-148a ^[67] , miRNA-218 ^[68] |
| Invasion, metastasis | miRNA-223 ^[35] , miRNA-148a ^[73] , miRNA-107 ^[74] | miRNA-610 ^[75] , miRNA-200b ^[576] , miRNA-7 ^[77] |

¹The two miRNAs also indicate short survival and lymph node metastasis, and deeper invasion; ²The three miRNAs also indicate short survival and recurrence, especially miRNA-451; ³The miRNA also indicates short survival and hepatic metastases, deeper invasion, and tumor enlargement; ⁴The miRNA also indicates lymph node metastasis and deeper invasion, and advanced gastric cancer; ⁵The miRNA also indicates lymph node metastasis and deeper invasion, and the tumor is enlarged.

must be undertaken. Establishment of a suitable standard testing system for clinical application, including quality control, and diagnostic threshold determination are still issues that require some work. There is a high incidence of gastric cancer in East Asian countries. High-risk populations could be screened by miRNAs, which should be able to increase the detection rate of early gastric cancer and improve the effects of treatment.

miRNA AND PROGNOSIS PREDICTION

Predicting patient survival time, disease progression, prognostic outcome or response to treatment is challenging. Because of the stability and specificity of expression in tissues and circulation, miRNA may be regarded as a forecasting tool for disease outcomes. A lot of the literature suggests that miRNAs have a close relationship with survival time of gastric cancer patients, disease stage, tumor recurrence, and lymph node metastasis. Li *et al.*^[58] have shown that a seven-miRNA signature (miR-10b, miR-21, miR-223, miR-338, let-7a, miR-30a-5p, and miR-126) is an independent predictor of overall survival [hazard ratio (HR) = 3.046; $P = 0.015$] and relapse-free survival (HR = 3.337; $P = 0.012$). It can predict the prognosis of the patient in relation to tumor stage, cytological

subtypes, and Lauren classification^[59,60]. In gastric cancer, many Chinese and other research teams have discovered a number of miRNAs that play a role as a predictor. For example, high expression of miRNA-20b, miRNA-150, miRNA-142-5p^[61], miRNA-375 and miRNA-214^[62] and low expression of miRNA-451, let7g, miRNA-433 and miRNA-125-5p^[63] are associated with short survival time. High levels of miRNA-27a and miRNA-650^[64] and low levels of miRNA-126^[65], miRNA-146a^[66], miRNA-148^[67], miRNA-218^[68], miRNA-335^[69] and miRNA-429^[70] indicate lymph node metastasis. Patients with overexpression of miRNA-375, miRNA-451, miRNA-199-3p and miRNA-195^[71] and decreased expression of miRNA-142-5p are more likely to relapse. High levels of miRNA-221^[72] and decreased levels of miRNA-126, miRNA-148a and miRNA-218 indicate advanced gastric cancer. High expression of miRNA-223, miRNA-148a^[73] and miRNA-107^[74] and reduced expression of miRNA-610^[75], miRNA-200b^[76] and miRNA-7^[77] were associated with invasion and metastasis (Table 3). Therefore, many potential predictors have proved useful for judging the prognosis of gastric cancer patients and are the basis for targeted therapy. However, researching miRNAs as prognostic factors involves small sample sets, high volume of work in validation, and research of independent cohorts,

Table 4 Expression of miRNA and prediction of the effect of chemotherapy and radiotherapy

| | Upregulated | Downregulated |
|------------------|--|--|
| Chemosensitivity | (let-7g, miR-342, miR-16, miR-181, miR-1, miR-34) ^[81] | |
| Chemoresistance | (miR-518f, miR-520a, miR-520d, miR-519e, miR-363, miR-517) ^[81] | (miR-196a, miR-200family, miR-338, miR-126, miR-31, miR-98, let-7g, miR-7) ^[82] miR-15b, miR-16 ^[83] |
| Radiosensitivity | miR-451 ^[85] | |
| Radioresistance | miR-221/222 ^[97] | |

¹Drugs were cisplatin and 5-fluorouracil; ²Drug was hydroxy camptothecin.

all of which are required before assays for miRNAs can be used clinically.

miRNAs AND CHEMOTHERAPY AND RADIOTHERAPY

Resistance to chemotherapy and radiotherapy is a major obstacle to improving the survival of the patients with gastric cancer^[78-80]. We can predict the occurrence of resistance to chemotherapy and radiotherapy^[81-83] (Table 4) through detecting the miRNA expression profile of the patients. Through investigating drug resistance to cisplatin and 5-fluorouracil in 90 patients with gastric cancer and comparing patients' miRNA expression before and after chemotherapy, Kim *et al.*^[81] found that high expression of let-7g, miR-342, miR-16, miR-181, miR-1 and miR-34 indicated sensitivity to chemotherapy, and high expression of miR-518f, miR-520a, miR-520d, miR-519e, miR-363 and miR-517 indicated resistance to chemotherapy. By predicting miRNAs, we used a new method for choosing chemotherapy regimen and monitoring its effects, and even reversing the chemotherapy resistance through transfecting specific pre-miRNA. miRNA-15b and miRNA-16 are downregulated severely in the multi-drug resistant gastric carcinoma cell line SGC7901/VCR. By improving miRNA-15b and miRNA-16 expression levels, sensitivity to vincristine was enhanced. Chen *et al.*^[84] transfected miRNA-200c into SGC7901/DDP gastric cancer cells, which increased sensitivity to DDP, 5-fluorouracil, paclitaxel and doxorubicin. The same situation occurred in radiotherapy on gastric cancer by transfection into AS-miRNA-221/222, which down-regulated the miRNA-221/222 expression in gastric cancer cell line SGC7901. Zhang *et al.* found that the survival rate of cancer cell was significantly lower than that in the control group. Radiosensitivity was promoted through 0-6 Gy irradiation. In addition, Bandres *et al.*^[85] transfected cancer cells with pre-miRNA-451, which improved expression of miRNA-451 in AGS gastric cancer cells. Under 0-4 Gy irradiation, the effect of treatment was significantly better than that in the control group.

miRNAs AND TREATMENT

miRNAs are regulatory factors for gene expression and act as a control center in the process of tumor development^[86,87]. miRNAs can modulate protein expression

and affect multiple information pathways^[88]. miRNAs will be more effective than coding genes as a biological treatment of tumor target molecules. The basic strategy of current treatment based on miRNAs is to adopt gene knockout to inhibit or downregulate the expression level of oncogene miRNAs. On the contrary, for anti-oncogenes, we used the method of gene knock-in to introduce foreign miRNAs, increase the expression level, and achieve the purpose of tumor treatment. The following strategies were used: administration of small molecule drugs for inhibiting miRNA, *e.g.*, anti-miRNA oligonucleotides (AMOs) following base pairing rules, competitively blocked the miRNA with target gene interaction^[89], such as locked nucleic acid^[90-91]; miRNA sponges, *e.g.*, the adsorption with miRNA could not combine with the natural target^[92]; and miR-Mask^[93], miRNA inhibitors and so on. miRNA expression is often increased by using viruses as a carrier to introduce a specific miRNA or miRNA mimics and finally upregulate miRNA and inhibit the tumor^[94].

A number of Eastern Asian researchers followed the above principle of miRNA-mediated treatment and achieved good results *in vitro* and in animal experiments. For example, miRNA-221/222 is upregulated in gastric cancer cell line SGC7901. By transfecting AS-miRNA-221/222 2000 into cancer cells with liposomes, miRNA-221/222 is knocked out. This inhibits gastric cancer cell growth and invasion. Their target molecule is PTEN^[95]. MiR-516-3p has been transfected into the gastric scirrhous carcinoma cell line 44AS3 with liposomes, was significantly overexpressed, and finally inhibited cancer cell growth, invasion and metastasis^[96]. Similar results were obtained in a nude mouse transplantation model of human gastric cancer. Zhang *et al.*^[97] through AMOs, knocked down the originally high expression of miRNA-21 and caused the proliferation of gastric cancer cells to slow and apoptosis to increase visibly. In addition, Ji *et al.*^[98] have added a miRNA-34 analog to *p53* mutated gastric cancer cell lines to restore its function and upregulate its expression, which inhibited cell growth and maintained them at phase G1.

Many studies based on treatment of gastric cancer by miRNA have shown good results. In particular, Chinese, Japanese and South Korean researchers have attempted this. However, we still have several major obstacles to overcome. First, the multi-targeting nature of miRNAs brings the risk of unconscious off-target effects. Second, the expression of target genes may often be regulated by

multiple miRNAs, which could greatly reduce the effect of treatment based on a specific miRNA. Finally, we still lack good specificity and an efficient miRNA delivery system for treatment^[99,100].

CONCLUSION

miRNAs are involved in almost all stages of gastric carcinogenesis, and may have broad applications in early diagnosis of gastric carcinoma, prognosis, detection of radiotherapy and chemotherapy efficacy, and be a new target for treatment. However, studies based on the clinical application of miRNAs for gastric cancer still lack reliable and exact data from large multi-center studies. In recent years, miRNAs have been a focus of biomedical research. New miRNAs have been discovered and research techniques constantly updated. It will be a great challenge to integrate new data and establish standard procedures. For diagnosis, we need unified standards and testing platforms. For treatment, we need better-designed small-molecule drugs based on a well detailed and more accurate medication carrier without toxic side effects. We look forward to further studies of miRNAs improving their clinical applications for the diagnosis and treatment of gastric cancer. East Asia, as an area with a high incidence of gastric cancer, should undertake more studies for the application of miRNAs in gastric cancer.

Measurement of calprotectin in ascitic fluid to identify elevated polymorphonuclear cell count

Emanuel Burri, Felix Schulte, Jürgen Muser, Rémy Meier, Christoph Beglinger

Emanuel Burri, Felix Schulte, Christoph Beglinger, Gastroenterology and Hepatology, University Hospital Basel, 4031 Basel, Switzerland

Emanuel Burri, Rémy Meier, Gastroenterology, Hepatology and Clinical Nutrition, Cantonal Hospital, 4410 Liestal, Switzerland

Jürgen Muser, Central Laboratories, Cantonal Hospital, 4410 Liestal, Switzerland

Author contributions: Burri E and Beglinger C participated in study concept and design; all authors participated in data acquisition, analysis, interpretation, drafting and critical revision of the manuscript, all of them read and approved the final manuscript.

Supported by Unrestricted Research Grants (to Burri E) by the Freiwillige Akademische Gesellschaft (Basel, Switzerland) and the Gottfried und Julia Bangerter-Rhyner-Stiftung (Bern, Switzerland); Bühlmann Laboratories AG (Schönenbuch, Switzerland) provided the assays to measure ascitic calprotectin. Researchers were independent of funding

Abstract

AIM: To evaluate the diagnostic capability of calprotectin in ascitic fluid for detecting a polymorphonuclear (PMN) cell count > 250/μL ascites.

METHODS: In this prospective observational study, a total of 130 ascites samples were analysed from 71 consecutive patients referred for paracentesis. Total and differential leukocyte cell counts were determined manually with a Neubauer chamber and gentian-violet stain. Calprotectin was measured in 1 mL ascetic fluid by enzyme-linked immunosorbent assay (ELISA) and a point-of-care (POC) lateral flow assay with the Quantum Blue® Reader (Bühlmann Laboratories). All

measurements were carried out in a central laboratory by senior personnel blinded to patient history. A PMN count > 250/μL was the primary endpoint of the study. The diagnostic value of ascitic calprotectin measurement was assessed by comparing to the final diagnosis of each patient that had been adjudicated by investigators blinded to calprotectin values.

RESULTS: The PMN count was > 250/μL in 19 samples (14.6%) from 15 patients (21.1%) and varied widely among the study population (range 10-19 800/mL and 1-17 820/mL, respectively). Spontaneous bacterial peritonitis (SBP) was the final diagnosis in four patients (5.6%). All patients with PMN ≤ 250/μL had negative bacterial culture. PMN count was elevated in five patients with peritoneal carcinomatosis, three with lymphoma, one with neuroendocrine carcinoma, and two with secondary peritonitis due to abdominal perforation. PMN cell counts correlated with ascitic calprotectin values (Spearman's rho; $r = 0.457$ for ELISA, $r = 0.473$ for POC). A considerable range of ascitic calprotectin concentrations was detected by ELISA [median 0.43 μg/mL, interquartile range (IQR) 0.23-1.23 (range 0.10-14.93)] and POC [median 0.38 μg/mL, IQR 0.38-0.56 (range 0.38-13.31)]. Ascitic calprotectin levels were higher in samples with PMN > 250/μL, by both ELISA [median (IQR) 2.48 μg/mL (1.61-3.65) vs 0.10 μg/mL (0.10-0.36), $P < 0.001$] and POC [2.78 μg/mL (2.05-5.37) vs 0.38 μg/mL (0.38-0.41), $P < 0.001$]. The area under the receiver operating characteristics curve for identifying an elevated PMN count was 0.977 (95%CI: 0.933 to 0.995) for ELISA and 0.982 (95%CI: 0.942 to 0.997) for POC ($P = 0.246$ vs ELISA). Using the optimal cut-off value for ELISA (0.63 μg/mL), ascitic calprotectin had 94.8% sensitivity, 89.2% specificity, positive and negative likelihood ratios of 8.76 and 0.06 respectively, positive and negative predictive values of 60.0% and 99.0% respectively, and 90.0% overall accuracy. Using the optimal cut-off value for POC (0.51 μg/mL), the respective values were 100.0%, 84.7%, 6.53, 0.00, 52.8%, 100% and 87.7%. Correlation be-

tween ELISA and POC was excellent ($r = 0.873$, $P < 0.001$). The mean \pm SD of the difference was -0.11 ± 0.48 $\mu\text{g/mL}$ with limits of agreement of $+ 0.8$ $\mu\text{g/mL}$ (95%CI: 0.69 to 0.98) and -1.1 $\mu\text{g/mL}$ (95%CI: -1.19 to -0.91).

CONCLUSION: Ascitic calprotectin reliably predicts PMN count $> 250/\mu\text{L}$, which may prove useful in the diagnosis of SBP, especially with a readily available bedside testing device.

Burri E, Schulte F, Muser J, Meier R, Beglinger C. Measurement of calprotectin in ascitic fluid to identify elevated polymorphonuclear cell count. *World J Gastroenterol* 2013; 19(13): 2028-2036 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2028.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2028>

INTRODUCTION

Liver cirrhosis is the clinical end-stage of different entities of chronic liver disease when patients suffer from substantial mortality and morbidity, both of which are positively correlated with disease severity^[1,2]. Ascites is the most common complication, and around 60% of patients with compensated cirrhosis develop ascites within 10 years of disease onset^[3]. Spontaneous bacterial peritonitis (SBP) is an important cause of morbidity and mortality in cirrhotic patients with ascites. SBP is estimated to affect 10%-30% of cirrhotic patients hospitalised with ascites, and mortality in this group approaches 30%^[4,5]. Many of these patients are asymptomatic, and it is therefore recommended that all patients with ascites undergo paracentesis at the time of admission to confirm the SBP status^[5]. Although SBP is less prevalent in an outpatient setting, it is reasonable to also evaluate the ascitic fluid of outpatients because of the high mortality associated with SBP.

The diagnosis of SBP is based upon the polymorphonuclear (PMN) leukocyte cell count exceeding $250/\mu\text{L}$ in ascitic fluid^[6,7]. Currently, differential cell count is usually performed by a manual method using light microscopy and counting chambers. However, the diagnosis is often delayed when laboratory personnel are not readily available or in the private practice setting where specimens are sent to an offsite laboratory. This is a major drawback, as rapid diagnosis of SBP and immediate initiation of antibiotic treatment is of paramount importance. Alternative methods using automated PMN counting^[8,9], reagent strips (urine dipsticks)^[10-26], or ascitic lactoferrin^[27] have been developed; unfortunately, their diagnostic accuracies are limited and their use is dependent upon availability of laboratory personnel and reagents/components from

the commercial source. Therefore, an accurate and convenient method of rapid diagnosis of SBP remains an unmet clinical need.

Calprotectin, a calcium and zinc-binding protein, is detected almost exclusively in neutrophils^[28], and its presence in body fluids is proportional to the influx of neutrophils^[29-33]. However, only one study to date has investigated calprotectin levels in ascites and found higher concentrations in patients with malignant disease than in those with non-malignant disease^[34]. In contrast, faecal calprotectin is a well-established marker of inflammation and is used to monitor inflammatory bowel disease^[35]. A rapid bedside test has been developed to measure calprotectin in faeces; systematic comparison with the established enzyme-linked immunosorbent assay (ELISA) technique showed good correlation between the two tests' results^[36] and the rapid bedside test has been suggested as an equally valuable tool for diagnosing inflammatory bowel disease^[37]. It is possible that such a rapid bedside test may be useful for measuring calprotectin in ascitic fluid to indicate PNM levels and SBP status, however the diagnostic accuracy of such a measurement in ascitic fluid is unknown.

This study was designed to test our hypothesis that calprotectin in ascitic fluid could be useful as a surrogate PMN marker for identifying SBP patients ($> 250/\mu\text{L}$ PNM). To this end, we measured calprotectin in ascites of consecutive patients referred for paracentesis using a rapid bedside test and compared the results to those from the traditional ELISA.

MATERIALS AND METHODS

Setting and participants

In this prospective observational study, we recruited patients with ascites referred for paracentesis to the Department of Gastroenterology and Hepatology at the University Hospital Basel, and to the Department of Gastroenterology, Hepatology and Clinical Nutrition at the Cantonal Hospital Liestal in Switzerland. All patients with ascites were eligible for study enrolment, irrespective of the aetiology of ascites. The decision to perform paracentesis was based on clinical findings evaluated by the referring physician who was otherwise not involved in the study. Exclusion criteria were age < 18 years and recent abdominal surgery (< 3 mo). Standardised patient history, clinical symptoms, and demographic data were obtained from all participants. The study was carried out in accordance with the principles of the Declaration of Helsinki and with pre-approval from the local Ethic Committees of both study sites. All patients provided written informed consent prior to participation in any protocol-specific procedures.

Endpoint

The diagnostic value of ascitic calprotectin measurement was assessed in comparison to the adjudicated final diagnosis. A PMN count $> 250/\mu\text{L}$ was the primary endpoint of the study.

Adjudication of the final diagnosis

One month after study participation, the final diagnosis (SBP) and the aetiology of ascites were independently adjudicated in a blinded fashion by two board-certified gastroenterologists not involved in the patients' care. Their final assessment was based upon available medical records, including PMN count and the results of all diagnostic investigations, as well as the patient's response to treatment. Current recommendations were followed^{16,71}. The two physicians designated the aetiology of ascites by choosing one or more of the following diagnoses from a standardized list: liver cirrhosis (alcoholic, chronic hepatitis, non-alcoholic steatohepatitis, hemochromatosis, primary biliary cirrhosis, others to be specified), hepatocellular carcinoma, cholangiocellular carcinoma, liver metastasis, peritoneal carcinomatosis, right heart failure, nephrotic syndrome, and others to be specified. If more than one cause of ascites was identified, the leading disorder responsible for the current episode was established and recorded. Any disagreements in the final diagnosis of a given study participant were resolved by consensus with a third clinician who was considered an expert in the field and recruited to independently review and adjudicate the cases.

Paracentesis

Paracentesis was performed under aseptic conditions with the patient in the supine position and the puncture site in the left or right lower quadrant. Prior to needle insertion, ultrasound was performed to visualise the intra-abdominal structures. No study participant suffered complications related to the abdominal puncture procedure. All samples for diagnostic testing were immediately collected at the bedside and processed by laboratory personnel without further delay. Specifically, aliquots of approximately 1 mL ascites were centrifuged for 15 min at $500 \times g$. The supernatant phase was transferred to a fresh tube and stored at -20°C until analysis by ELISA or POC, which occurred within 72 h.

Blood samples were also obtained at this time. The ascites samples were used to measure total cell count, PMN count, calprotectin, albumin, total protein, glucose, and lactate dehydrogenase. In addition, two 10 mL aliquots of ascites were subjected to bacterial culture (bottle method) respectively. The serum-ascites albumin gradient (SAAG) was calculated as the difference of albumin in serum and albumin in ascites.

Differential cell count and cytopathology

All laboratory analyses were performed in the Central Laboratories BL (Schönenbuch, Switzerland) by senior laboratory personnel blinded to patient history and calprotectin levels. Total and differential leukocyte cell counts were determined by the manual method using a Neubauer chamber and gentian-violet staining (Leukotic®; bioanalytic GmbH, Freiburg, Germany). The Central Laboratories BL is accredited according to ISO/IEC 17 025 and ISO 15 189 standards. For all study participants who underwent repeated paracentesis, the cytopathological analysis was performed at least once.

Laboratory-based quantitative calprotectin measurement

Ascitic calprotectin in ascites was assayed using a commercially-available ELISA (Bühlmann Laboratories AG, Schönenbuch, Switzerland) and following the manufacturer's instructions. Briefly, 10 μL aliquots of the supernatant samples were diluted 1:50 in incubation buffer and 100 μL was applied to a microtiter plate coated with a monoclonal capture antibody highly specific for the calprotectin heterodimeric and polymeric complexes. After incubation, washing and further incubation with a detection antibody conjugated to horseradish peroxidase, the tetramethylbenzidine chromogenic substrate was added. The reaction was terminated by a stop solution and the absorbance (optical density at 450 nm) was measured by spectrophotometry. The measuring range of the test was 0.2–12 μg calprotectin/mL ascites with an intra- and inter-assay coefficient of 4.7% and 11.3%, respectively.

Point-of-care quantitative calprotectin measurement

The Quantum Blue® quantitative calprotectin lateral flow assay (Bühlmann Laboratories AG) was used for the point-of-care (POC) measurement of ascitic calprotectin. The Quantum Blue® reader is currently marketed for 2500 USD (\$), and the test cartridges cost 20 USD per sample and analysis. Aliquots of 60 μL 1:10 diluted ascites samples (20 μL ascites in 180 μL extraction buffer) were pipetted respectively onto the sample loading port of the test cartridge. After a 12 min incubation, the test cartridge was quantitatively read by the Quantum Blue® Reader. The measurement range of the lateral flow test was 0.38–3.8 μg calprotectin/mL ascites, with an inter-assay coefficient of 15.6%. Specimens with concentrations above this measurement range were further diluted with extraction buffer.

In addition, a random subgroup of samples ($n = 17$) was immediately measured by POC, without first performing the centrifugation step of processing. These results were compared to the results from the POC measurements obtained in the laboratory setting after processing and storage.

Statistical analysis

All statistical analyses were performed using the SPSS software package, version 19.0 (SPSS Inc., Chicago, IL, United States). A P -value of less than 0.05 indicated statistical significance. Intergroup comparisons were made using the Mann-Whitney U test and the χ^2 test where appropriate. Correlations between numerical data were determined with the Spearman's rank correlation coefficient. All hypothesis testing was two-tailed. The Bland-Altman plot was used to assess agreement between ELISA test results and POC test results, in which the differences between the results of the two tests for each individual patient were plotted against the corresponding mean of the two readings. The mean and SD of the differences and the limits of agreement, defined as the mean \pm 2 SD of the difference (95%CI), were calculated. Analysis of the receiver operator characteristics (ROC) and calculation of the area under the curve (AUC) were used to evaluate the capability of calprotectin to identify a PMN count >

Table 1 Baseline characteristics of patients with liver cirrhosis ($n = 54$)

| | |
|-------------------------------|------------------|
| Aetiology of liver cirrhosis | |
| Alcoholic | 36 (66.6) |
| Viral hepatitis | 7 (13.0) |
| Alcoholic + viral hepatitis | 5 (9.3) |
| Non alcoholic steatohepatitis | 1 (1.9) |
| Others | 5 (9.3) |
| Child-turcotte-pugh class | |
| Child A | 0 |
| Child B | 29 (53.7) |
| Child C | 25 (46.3) |
| MELD score | 12.2 (10.0-16.0) |

Others included 2 patients with autoimmune hepatitis, 2 patients with primary biliary cirrhosis and 1 patient with primary sclerosing cholangitis. The child-turcotte-pugh classification contains five variables, including serum levels of bilirubin and albumin, prothrombin time, ascites, and encephalopathy. Child A: 5-6 points; Child B: 7-9 points; Child C: 10-12 points. The model for end-stage liver disease (MELD) score: $9.57 \ln$ [serum level of creatinine (mg/dL)] + $3.78 \ln$ [serum bilirubin (mg/dL)] + $11.2 \ln$ (international normalised ratio for prothrombin time) + 6.43. Data are presented as number of patients (%) or medians (25th to 75th percentiles).

250/ μ L. The ROC analysis identified the cut-off points for maximal diagnostic capability. The test characteristics of sensitivity, specificity, positive and negative likelihood ratios (LR+ and LR-), and positive and negative predictive values (NPV) were determined. Overall accuracy of the test was calculated according to the following formula: [(true positive test results + true negative test results)/total population]. As this study was exploratory in design, no formal power calculations were carried out.

RESULTS

Patient characteristics

A total of 136 samples from 75 patients were prospectively collected from October 2010 to January 2012. Among these, 130 samples were included in the final analysis, representing 71 patients (94.7% of the total; 40 males and 31 females) with a median age of 64 years (IQR 55-71 years). Sixty-three of the patients (88.7%) had been referred for diagnostic paracentesis. Twenty-four of the patients (33.8%) underwent the procedure more than once (median 3, range 2-12).

The majority of patients (54, 76.1%) suffered from liver cirrhosis (Table 1). A total of 11 patients (15.5%) had malignant ascites, which included three ovarian, two lymphomas, two breast, one stomach, one colorectal, one pancreatic cancer, and one neuroendocrine carcinoma. Of those 11 patients, two also had liver cirrhosis. Additionally, three patients with ascites also had heart failure and five patients with ascites also had portal hypertension from metastatic liver disease (but no malignant cells were present in the ascites). No intervention-related complications occurred after paracentesis.

Ascitic fluid cell count

Total cell count and PMN cell count at presentation varied widely among the study population (range 10-19 800/

Table 2 Ascitic fluid analysis

| Variable | PMN count > 250/ μ L ($n = 19$) | PMN count \leq 250/ μ L ($n = 111$) |
|------------------|---------------------------------------|---|
| Total cell count | 1300.0 (350.0-19 800.0) | 250.0 (10.0-1970.0) |
| PMN count | 553.0 (277.0-17 820.0) | 21.0 (1.0-212.0) |
| Albumin, g/L | 13.0 (4.8-16.8) | 7.0 (3.0-10.0) |
| Protein, g/L | 22.0 (9.3-37.5) | 12.0 (8.0-20.0) |
| LDH, U/L | 117.0 (100.8-138.5) | 55.0 (42.0-81.0) |
| Glucose, mmol/L | 7.6 (6.2-9.7) | 7.0 (6.2-8.2) |

Values are given as medians (range) for total cell count and polymorphonuclear cell count (PMN) count and median (25th to 75th percentiles) for all other values. LDH: Lactate dehydrogenase.

mL and 1-17 820/mL, respectively). PMN count > 250/mL was detected in 19 samples (14.6%) from 15 patients (21.1%). Among the study population, SBP was the final diagnosis for four patients (5.6%) and only one of these four had positive ascitic bacterial cultures (*Streptococcus pneumoniae*). All bacterial cultures from patients with PMN \leq 250/mL were negative. Additionally, PMN count was elevated in five patients with peritoneal carcinomatosis (two with ovarian cancer, and one each with gastric, colorectal and pancreatic cancer), in three patients with lymphoma, in one patient with neuroendocrine carcinoma, and in two patients with secondary peritonitis due to an abdominal perforation. All patients with SBP received antibiotic treatment and recovered well. None of the patients died. Table 2 details the findings from ascitic fluid analysis.

Calprotectin measurement in ascitic fluid

The ascitic calprotectin concentrations ranged considerably in the ELISA [median 0.43 μ g/mL, IQR 0.23-1.23 (range 0.10-14.93)] and POC test [median 0.38 μ g/mL, IQR 0.38-0.562 (range 0.38-13.31)]. However, the calprotectin values measured by the laboratory-based ELISA and the POC test correlated well with the PMN count ($r = 0.476$, $P < 0.001$ and $r = 0.473$, $P < 0.001$, respectively), and the correlation between the two tests was excellent ($r = 0.873$, $P < 0.001$). The degree of agreement between the measurements of ascitic calprotectin from the ELISA and the POC test is illustrated in Figure 1. The mean \pm SD of the difference was -0.11 ± 0.48 μ g/mL, with limits of agreement of $+0.8$ μ g/mL (95%CI: 0.69 to 0.98) and -1.1 μ g/mL (95%CI: -1.19 to -0.91).

Comparative analysis of the POC detection of ascitic calprotectin levels in samples measured at the bedside (unprocessed and processed after centrifugation) and in the lab (after centrifugation) showed that the calprotectin measurements correlated well. For unprocessed samples, $r = 0.831$ ($P < 0.001$), and for processed samples, $r = 0.656$ ($P = 0.004$).

Diagnostic value of ascitic calprotectin

Ascitic calprotectin levels were higher in samples ($n = 19$) with PMN > 250/ μ L, both when measured by ELISA [median (IQR) 2.48 μ g/mL (1.61-3.65)] *vs* 0.10 μ g/mL (0.10-0.36), $P < 0.001$] and the POC test [median 2.78

Table 3 Test characteristics of ascitic calprotectin to identify > 250 polymorphonuclear leukocytes per mL ascites

| | AUC (95%CI) | Best cut-off ($\mu\text{g/mL}$) | Sens (%) | Spec (%) | LR+ | LR- | PPV (%) | NPV (%) | Accuracy (%) |
|-------|---------------------|-----------------------------------|----------|----------|------|------|---------|---------|--------------|
| ELISA | 0.977 (0.933-0.995) | 0.63 | 94.8 | 89.2 | 8.76 | 0.06 | 60.0 | 99.0 | 90.0 |
| POC | 0.982 (0.942-0.997) | 0.51 | 100 | 84.7 | 6.53 | 0.00 | 52.8 | 100 | 87.7 |

Area under the receiver operating characteristics curve (AUC) with corresponding sensitivity (Sens), specificity (Spec), positive and negative likelihood ratio (LR+, LR-), and negative and positive predictive values (NPV, PPV) for ascitic calprotectin to identify polymorphonuclear > 250/ μL . Overall accuracy was calculated using the following formula: (true positive test results + true negative test results)/total population. ELISA: Enzyme-linked immunosorbent; POC: Point-of-care.

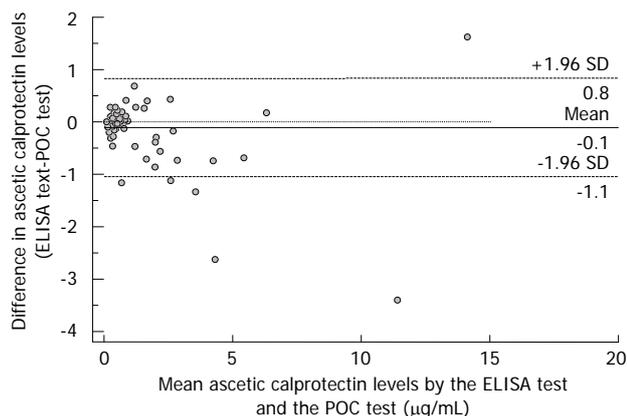

Figure 1 Measurement of ascitic calprotectin with the enzyme-linked immunosorbent test and the point-of-care test (Bland Altman plot). The differences between the results of the enzyme-linked immunosorbent (ELISA) and point-of-care (POC) tests in each patient are plotted against the mean of the two measurements, showing the limits of agreement, defined as the mean \pm 2 SD of the difference.

$\mu\text{g/mL}$ (2.05-5.37) *vs* 0.38 $\mu\text{g/mL}$ (0.38-0.41), $P < 0.001$) (Figure 2). Evaluation of the ascitic calprotectin measurement as a diagnostic test to identify patients with PMN count > 250/ μL yielded an AUC of 0.977 (95%CI: 0.933-0.995) for the ELISA and an AUC of 0.982 (95%CI: 0.942-0.997) for the POC test. Furthermore, the two tests did not show significantly different diagnostic capacity ($P = 0.246$ *vs* ELISA) (Figure 3).

Using the optimal cut-off value from the ROC of ELISA (0.63 $\mu\text{g/mL}$), ascitic calprotectin yielded a sensitivity of 95%, a specificity of 89.2%, and an accuracy of 90.0% (Table 3). To identify all patients with PMN count > 250/ μL and to obtain 100% test sensitivity, a slightly lower cut-off value (0.44 $\mu\text{g/mL}$) is necessary. However, use of this lower value is accompanied by lower specificity (82.9%) and lower LR+ (5.84).

Analysis of the POC test characteristics revealed a nearly identical profile to the ELISA characteristics (Table 3). The optimal cut-off value for POC (0.51 $\mu\text{g/mL}$) yielded a sensitivity of 100% and a specificity of 84.7%, with 6.53 LR+ and 0.0 LR-. The overall accuracy of the POC test was 87.7% (Figure 4).

Patients with false positive test results had PMN counts between 3 and 212 (median 70.0, IQR 35.0-127.5) for the ELISA, and between 3 and 197 (median 45.0, IQR 16.0-100.0) for the POC test.

The ELISA and POC test had similar diagnostic capability for identifying PMN > 250/ μL in the subgroup of

patients with liver cirrhosis (95 samples from 54 patients; ELISA AUC 0.987, and POC test AUC 0.982). In addition, when the ascites samples were analysed according to the SAAG > 11g/L (115 samples from 62 patients), the AUCs of ascitic calprotectin were 0.983 for the ELISA and 0.988 for the POC test (data not shown).

DISCUSSION

This prospective study evaluated the diagnostic utility of measuring calprotectin in ascites to identify ascitic PMN counts > 250/ μL in patients referred for paracentesis, and provides the following new information: Patients with an elevated PMN count (> 250/ μL) had higher ascitic calprotectin levels than those with normal cell counts; this finding indicates that ascitic calprotectin levels correlate well and reliably with PMN count. It is clinically significant that calprotectin levels in ascitic patients can identify elevated PMN counts using both laboratory-based ELISA and bedside POC testing. Indeed, ascitic calprotectin may serve as a surrogate marker for PMN count and would be amenable to routine SBP screening, especially when measured by a bedside test.

Ascites is commonly found in patients with liver cirrhosis and may promote bacterial translocation, enhancing the risk of SBP^[3]. SBP in outpatients is rare, but when it occurs it often requires hospitalisation to manage to disease course^[4,5]. In our study, four of 71 patients were diagnosed with SBP (5.6%). In general, SBP symptoms are nonspecific and current guidelines recommend paracentesis be performed in all patients with ascites to rule out abdominal infection^[6,7]. The diagnosis of SBP in patients with liver cirrhosis is based on a PMN count of > 250/ μL in ascitic fluid, with or without positive bacterial cultures^[5-7]. This cut-off is recognized as more sensitive than other criteria (PMN > 500/ μL ; white blood cell count > 500/ μL)^[38,39] for identifying SBP^[40]. SBP diagnosis based solely on bacterial culture is considered unreliable, since up to 60% of patients with increased PMN count are reported as culture-negative^[41,42]. In our study, all patients with culture-positive abdominal infection, including both SBP and secondary peritonitis patients, had elevated PMN counts. In the four SBP patients, the bacterial cultures were positive for only one (25.0%).

Our study measured calprotectin in ascitic fluid in 130 unselected samples from 71 consecutive patients. Ascitic calprotectin levels correlated well and reliably with PMN counts, and the samples with PMN > 250/ μL also had higher ascitic calprotectin levels than the samples with

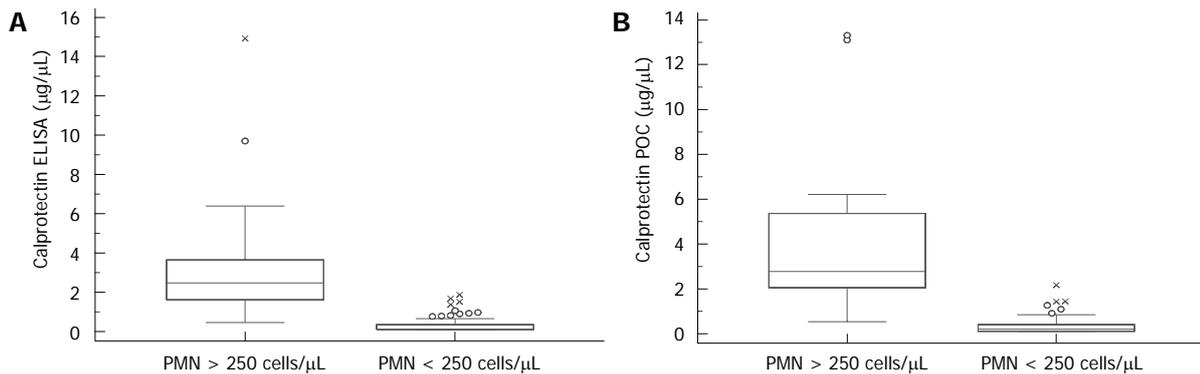

Figure 2 Ascitic calprotectin values in patients with normal and elevated ascitic polymorphonuclear cell count. Box-and-whisker plot representing the median, 25th to 75th percentiles, minimum/maximum values, and outliers outside 1.5 times (circle) and 3 times (cross) the interquartile range of ascitic calprotectin values, measured with the enzyme-linked immunosorbent (ELISA) test (A) and the point-of-care (POC) test (B). PMN: Polymorphonuclear.

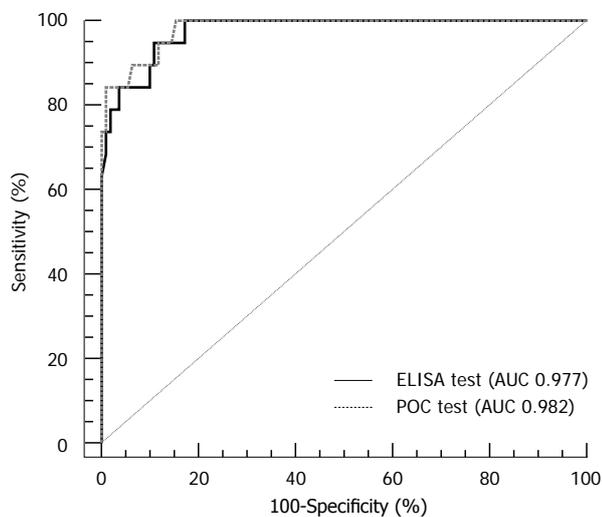

Figure 3 Receiver operating characteristics analysis of the enzyme-linked immunosorbent test and the point-of-care test to identify elevated ascitic polymorphonuclear cell count. The area under the receiver operating characteristics curve (AUC) for ascitic calprotectin for identifying a polymorphonuclear count > 250/ μ L. No differences between the two tests ($P = 0.155$) were detected. The diagonal line represents no discrimination. POC: Point-of-care; ELISA: Enzyme-linked immunosorbent.

PMN $\leq 250/\mu\text{L}$. Both the ELISA and the POC test accurately measured ascitic calprotectin, and the correlation between the two tests was excellent with high sensitivity (95% and 100%, respectively) and high specificity (89% and 85%, respectively) at the optimal cut-off points (from ROC analysis). In a diagnostic test that is used to screen for a specific disease, it is preferred to test all patients at risk, especially when potentially life-threatening complications may occur. In screening tests, high sensitivity is therefore favoured over high specificity. In our study, the NPVs of calprotectin testing in ascites were excellent (99% for the ELISA and 100% for the POC test). Notably, these results suggest that no patient with elevated PMN count would have been missed by the bedside test.

In daily clinical practice, PMN count is often not readily available and clinicians frequently rely on total cell count when initiating empiric antibiotic treatment^[43]. It has been suggested that a total cell count < 1000/ μL

(obtained from automated cell counting procedures) is unlikely to signify SBP, having a NPV of 96%^[44]. In our study, using such a criteria would have misclassified five patients (26.3%) with elevated PMN counts. Moreover, the use of total cell count in combination with ascitic calprotectin measurement did not increase the diagnostic accuracy of calprotectin testing, as calculated by ROC analysis (data not shown).

To avoid diagnostic delay, it has been proposed that automated PMN counting should replace the laborious and time-consuming manual cell counting technique^[8,9]. Studies have demonstrated that automated blood cell counts correlate well with manual ascitic leukocyte differential counts^[45]. However, despite the potential benefit of automated cell counters in clinical practice, widespread use of this technology is limited by the cost of the sophisticated laboratory equipment and requirement for trained operators; this is a particular challenge for practitioners' office settings and small clinics without in-house laboratories.

The use of reagent strips (urine dipsticks) for PNM counting (by colorimetric detection of leukocyte esterase activity) has also been evaluated as a rapid SBP diagnostic tool^[45,46]. A number of these studies have reported sensitivities between 85% and 100% and specificities between 90% and 100%^[10-25]. However, these results came from mostly single-centre studies with small numbers of SBP cases. The only large, multicentre study reported in the literature produced very different results; in particular, using 2123 paracenteses, the sensitivity was only 45% for identifying PMN > 250/ μL in cirrhotic patients^[26]. Although specificity was still high, it was concluded that urinary dipstick testing lacks sufficient accuracy for diagnosing SBP. The risk of false negative results seemed to be especially problematic in patients with lower PMN counts^[46]. These results dampened the initial enthusiasm for reagent strips, and currently this method is not recommended for rapid diagnosis of SBP^[45].

Only one study in the literature, to date, has provided data on calprotectin measurement in ascites^[35]. In that study, Homann *et al*^[34] compared ascites from patients with malignant disease to ascites from patients with non-

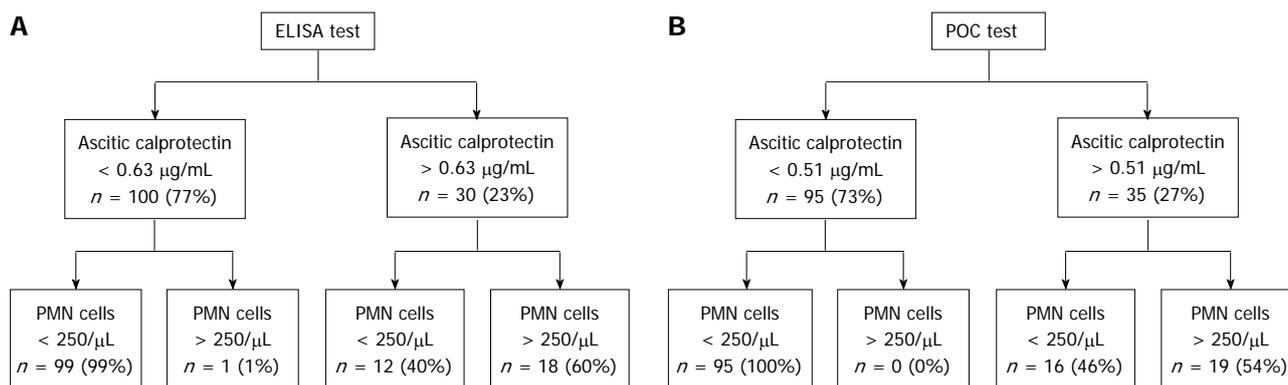

Figure 4 Diagnostic accuracy. For the enzyme-linked immunosorbent (ELISA) test, the overall test accuracy of ascitic calprotectin was 87% when 0.63 µg/mL was used as the best cut-off value (A) and was 84% for the point-of-care (POC) test when 0.51 µg/mL was used as best cut-off (B). PMN: Polymorphonuclear.

malignant disease. Higher ascitic calprotectin levels were found in the malignant patients and shown to correlate with increased mortality in patients with decompensated liver cirrhosis. However, the authors did not investigate the diagnostic potential of ascitic calprotectin. More recently, Parsi *et al*²⁷¹ measured ascitic lactoferrin (an iron-binding protein also found in PMNs) in cirrhotic patients with ascites and investigated its potential for identifying SBP. The lactoferrin measurements correctly identified PMN counts > 250/µL in 22 of 218 samples (10.1%), yielding a sensitivity of 95.5% and specificity of 97.0%. However, the quantitative assay (ELISA) used in that study is not commercially available, and to date no bedside test, qualitative or quantitative, exists for lactoferrin.

The results from our current study confirm the findings reported by Parsi *et al*²⁷¹. Specifically, we show that measurement of calprotectin, a leukocyte-specific protein, may serve as a surrogate marker for the PMN count in ascitic fluid. A particular strength of our study is the quantitative measurement of calprotectin by two methods, a laboratory-based ELISA and a commercially available bedside test. Rapid bedside measurement is advantageous for hospitalised patients, as it supports early antibiotic intervention and limits unnecessary treatments. It will also benefit the outpatient setting by providing on-site testing, since samples are otherwise required to be transported to an offsite laboratory. The POC test that we used can accomplish quantitative measurement of ascitic calprotectin within minutes, and this feature is expected to minimize the problems associated with diagnostic delay that clinicians currently face. Additionally, the cost of POC testing may be less than the other methods, such as contracting with the offsite laboratories.

There are several limitations to the current study that merit consideration. First, the prevalence of SBP in our study cohort was lower than expected from the literature. Second, we included all patients with ascites, irrespective of the aetiology, and it may be that our results cannot be generalised to all patients with liver cirrhosis. Third, this was an exploratory study that aimed to establish the concept of measuring a PNM-related inflammatory protein, rather than PNM cells themselves, as an indicator of elevated cell count in ascites; therefore, no formal sample

size calculation was performed. Finally, our sample size was small and larger studies are needed to evaluate this test in different clinical settings and to establish a reliable cut-off for ascitic calprotectin for optimal identification of PMN counts > 250/µL.

In conclusion, we have demonstrated that measurement of calprotectin in ascitic fluid correlates well with the PMN count and reliably predicts levels > 250/µL. Additionally, we showed that an elevated PMN count could easily be measured by a POC test device which may enable a treating physician to obtain useful bedside measurements, especially those practicing in settings with limited equipment and/or technical personnel. Further studies are warranted to define a clinically useful cut-off for the diagnosis of SBP in cirrhotic patients with ascites.

ACKNOWLEDGMENTS

We would like to express our sincere gratitude to the patients and staff of the Gastroenterology Department, especially to Eric Pflimlin and Margot Brenneisen, and to the laboratory technicians, especially Chantal Brühlhardt, for their valuable efforts. In addition, we would like to thank Kathleen A Bucher for English language editing of the manuscript.

COMMENTS

Background

Ascites is the most common complication of patients with cirrhosis, and around 60% of patients will develop ascites within 10 years of disease commencement. Spontaneous bacterial peritonitis (SBP) is an important cause of morbidity and mortality in these patients. SBP is estimated to affect 10%-30% of hospitalised patients with ascites, and it is recommended that all patients with ascites undergo paracentesis at the time of admission to assess SBP status and initiate timely therapy.

Research frontiers

The diagnosis of SBP is based on a polymorphonuclear leukocyte (PMN) cell count > 250/µL in the ascitic fluid. Currently, differential cell count is usually performed manually using light microscopy and counting chambers. This procedure is time consuming, and diagnosis may be further delayed when laboratory personnel are not readily available. Several other methods to diagnose SBP (automated cell counting and urine dipstick-based screening for leukocytes) have proven unreliable in clinical practice and are inferior to the manual method. In this study, authors investigated the potential of calprotectin, a neutrophilic

protein and established marker of intestinal inflammation, to screen for SBP when measured in ascites.

Innovations and breakthroughs

To date, only one study in the public literature has measured calprotectin in ascites, and the conclusion was that higher concentrations of calprotectin exist in malignant disease conditions as compared to non-malignant conditions. However, diagnostic accuracy was not assessed and calprotectin was measured using a laboratory-dependent enzyme-linked immunosorbent assay (ELISA). In this study, authors have demonstrated that measurement of calprotectin in ascitic fluid correlates well with PMN count and reliably indicates PNM levels > 250/ μ L. Additionally, we showed that an elevated PMN count could be easily measured within minutes using a point-of-care (POC) bedside test, suggesting its potential as a rapid diagnostic approach for SBP.

Applications

The rapid diagnosis of SBP and immediate start of antibiotic treatment is of paramount importance as mortality estimates approach 30%. A particular strength of this study is the quantitative measurement of ascitic calprotectin by two methods: a laboratory-based ELISA and a commercially available POC test device. Rapid bedside measurement is advantageous for hospitalised patients, since it facilitates timely antibiotic therapy and minimizes unnecessary treatments. However, it may be especially beneficial to an outpatient setting, where samples are otherwise required to be transported to an offsite laboratory for testing. The POC test device that we used allows quantitative measurement of ascitic calprotectin within minutes and is likely to minimize the diagnostic delay that clinicians currently face.

Terminology

Calprotectin, a calcium and zinc-binding protein, is found almost exclusively in neutrophils. The presence of calprotectin in body fluids is proportional to the influx of neutrophils during inflammation.

Peer review

This article discusses a new method for the diagnosis of SBP. This is a well-designed and methodologically correct exploratory study.

Abstract

AIM: To determine the efficacy of a cap-assisted endoscopy (CAE) to completely visualize the ampulla of Vater (AV) in patients failed by conventional endoscopy.

METHODS: A prospective study was conducted on 120 patients > 20 years of ages who visited the Health Promotion Center of Chungbuk National University Hospital for conscious sedation esophagogastroduodenoscopy (EGD) as a screening test from July to October, 2011. First, forward-viewing endoscopy was performed with reasonable effort using a push and pull method. We considered complete visualization of the AV when we could observe the entire AV including the orifice clearly, and reported the observation as complete or incomplete (partial or not found at all). Second, in cases of complete failure of the observation, an additional AV examination was conducted by attaching a short cap

(D-201-10704, Olympus Medical Systems, Tokyo, Japan) to the tip of a forward-viewing endoscope. Third, if the second method failed, we replaced the short cap with a long cap (MH-593, Olympus Medical Systems) and performed a re-examination of the AV.

RESULTS: Conventional endoscopy achieved complete visualization of the AV in 97 of the 120 patients (80.8%) but was not achieved in 23 patients (19.2%). Age (mean \pm SD) and gender [male (%)] were not significantly different between the complete observation and the incomplete observation groups. Additional short CAE was performed in patients in whom we could not completely visualize the AV. This group included 13 patients (10.9%) with partial observation of the AV and 10 (8.3%) in which the AV was not found. Short CAE permitted a complete observation of the AV in 21 of the 23 patients (91.3%). Patients in whom visualization of the AV failed with short CAE had satisfactory outcomes by replacing the short cap with a long cap. The additional time for CAE took an average of 141 ± 88 s. There were no complications and no significant mucosal trauma.

CONCLUSION: CAE is safe to use as a salvage method to achieve complete visualization of the AV when a regular EGD examination fails.

Efficacy of cap-assisted endoscopy for routine examining the ampulla of Vater. *World J Gastroenterol* 2013; 19(13): 2037-2043 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2037.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2037>

INTRODUCTION

It is recommended to visualize the second portion of the duodenum including the ampulla of Vater (AV) during a standard esophagogastroduodenoscopy (EGD) procedure^[1,2]. Adequate visualization of the AV is important for early detection of periampullary or pancreaticobiliary diseases^[3,4].

EGD textbooks and guidelines have emphasized complete visualization of the AV^[1,2], but at the same time indicated that complete visualization of the AV is difficult due to the anatomical characteristics of the second portion of the duodenum, including the tangential angle, the periampullary diverticulum, and loop formation in the scope^[5]. Thus, a side-viewing endoscope has been recommended for complete visualization of the AV in patients with a suspected AV lesion or in whom the AV cannot be observed completely. However, a side-viewing endoscope is not always available in an ordinary endoscopy suite^[6]. So clinicians should refer the patient for side-viewing endoscopy. In the case of South Korea, 4.2 million EGDs being performed as a screening test per year. Among them, 84% were performed in clinics that not equipped with side-viewing endoscope^[6]. And, although tertiary referral center were equipped with side-viewing endoscope, the Health Promotion Center for screening test were separated from Hospital Endoscopy Center for inpatient. So many endoscopists for screening test are not familiar with side-viewing endoscope for endoscopic retrograde cholangiopancreatography (ERCP). Therefore an additional examination using a side-viewing endoscope is expensive, time-consuming and difficult.

Cap-assisted endoscopy (CAE) has been used widely to facilitate detection of polyps^[7-10], improve the success rate of cecal intubation^[11,12], and to facilitate inspection of lesions situated in blind areas of the colon^[13-15]. We have found that the complete visualization rate of the AV in patients who are referred for incomplete visualization of the AV can be improved by attaching a transparent cap. Therefore, we conducted a prospective observational study to investigate the complete visualization rate of the AV during routine EGD and to evaluate the efficacy and safety of endoscopic examination using a transparent cap to completely visualize the AV in patients in whom this procedure failed with a conventional endoscope.

MATERIALS AND METHODS

Patients

A prospective study was conducted on 120 patients > 20 years of ages who visited the Health Promotion Center of Chungbuk National University Hospital for conscious sedation EGD as a screening test from July to October, 2011. The following patients were excluded from the study: (1) those with poor general condition who had an American Society of Anesthesiology classification ≥ 3 ; (2)

those who received previous upper gastrointestinal tract surgery or ERCP; and (3) patients with severe comorbidities. All patients provided written informed consent to participate in the study. This study was reviewed and approved by the Institutional Review Board of Chungbuk National University Hospital (D-2011-06-006).

Procedure

All examinations were conducted with the patient lying on their left side, and midazolam was administered as a sedative and pain medication. Approximately 30-40 mg of propofol was also administered depending on patient weight^[16]. Additional administration of propofol was used when deemed necessary, according to procedure time. Heart rate and oxygen saturation were checked in real time. Demographic data, procedure time, visualization of the AV, and complications were recorded. All examinations were carried out with a forward-viewing endoscope (GIF 230; Olympus Optical Co, Ltd, Tokyo, Japan) by a well-qualified endoscopist (Han JH), who has conducted more than 1500 EGDs including 400 ERCPs annually. Two types of transparent caps were used: disposable distal attachments; "soft and short" cap (D-201-10704, outer diameter: 11.35 mm, length from distal end of endoscope: 4 mm, Olympus Medical Systems) and a "hard and long" cap (MH-593, outer diameter: 12.9 mm, length from distal end of endoscope: 11 mm; Olympus Medical Systems) (Figure 1).

First, forward-viewing endoscopy was performed with reasonable effort using a push and pull method. We considered complete visualization of the AV when we could observe the entire AV including the orifice clearly, and reported the observation as complete or incomplete (partial or not found at all). Second, in cases of complete failure of the observation, an additional AV examination was conducted by attaching a short cap to the tip of a forward-viewing endoscope. Third, if the second method failed, we replaced the short cap with a long cap and performed a re-examination of the AV.

Statistical analysis

Descriptive statistical analyses were performed using the SPSS software, version 12.0 (SPSS Inc, Chicago, IL, United States), and frequency, percentage, mean, and range were used for descriptive analyses. A *P* value < 0.05 was considered statistically significant.

RESULTS

Patients' characteristics and outcomes of conventional endoscopy

A total of 181 patients were examined, 61 were excluded. 120 patients were enrolled and agreed to participate in the study by signing an informed consent (Figure 2). Conventional endoscopy achieved complete visualization of the AV in 97 of the 120 patients (80.8%) but was not achieved in 23 patients (19.2%) (Figure 3). The reasons

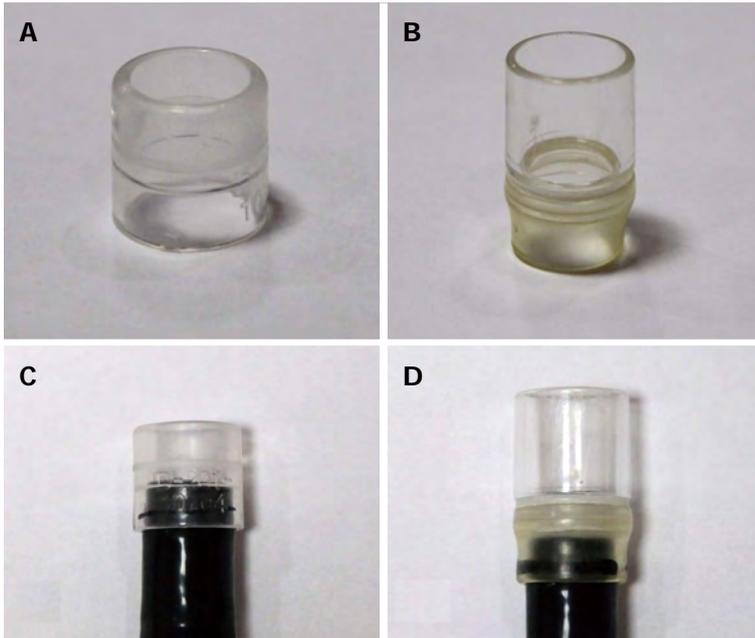

Figure 1 Endoscopic transparent cap. A: Short transparent cap (Olympus distal attachment D-201-10704, outer diameter: 11.35 mm, length from distal end of endoscope: 4 mm; Olympus Tokyo, Japan); B: Long transparent cap (Olympus distal attachment MH-593, outer diameter: 12.9 mm, length from distal end of endoscope: 11 mm; Olympus); C: Short cap attached to the tip of a forward-viewing endoscope; D: Long cap attached to the tip of a forward-viewing endoscope.

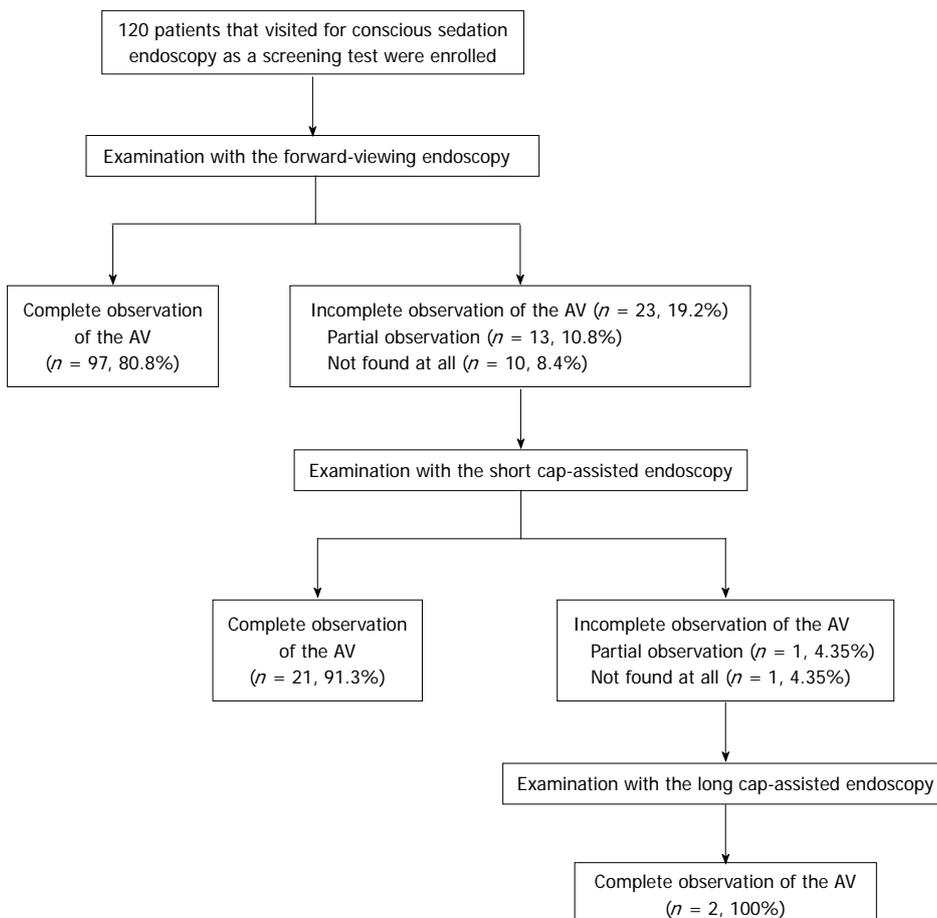

Figure 2 Flow diagram of patient enrollment and examinations. In total, 120 patients were examined by forward-viewing endoscopy. In cases when complete observations of the ampulla of Vater (AV) were unsuccessful, an additional examination for the AV was conducted by short cap-assisted endoscopy. If that examination was unsuccessful, the short cap was replaced with a long cap, and a re-examination was performed.

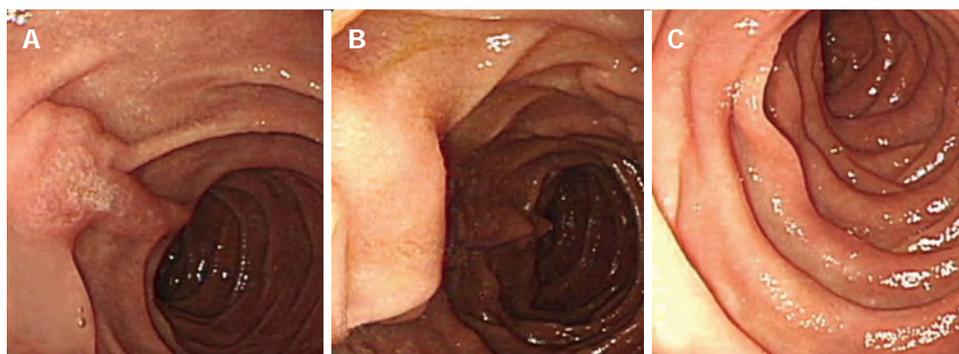

Figure 3 Outcomes of conventional endoscopy. A: Complete observation of the ampulla of Vater (AV), including the orifice, by forward-viewing endoscopy; B: Partial observation of the AV with a folded mucous membrane by forward-viewing endoscopy; C: The AV was not found during forward-viewing endoscopy.

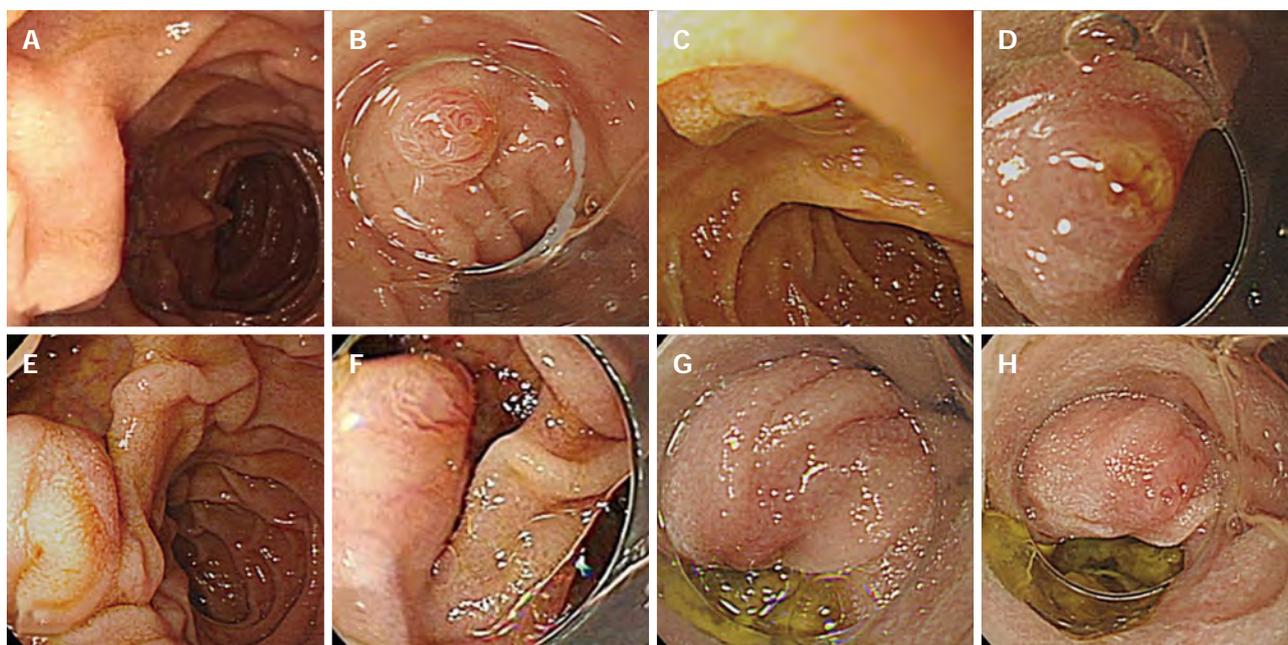

Figure 4 Incomplete observation of the ampulla of Vater by conventional endoscopy and outcomes of cap-assisted endoscopy. A: Incomplete observation of the ampulla of Vater (AV) by forward-viewing endoscopy due to a folded mucous membrane; C: Incomplete observation of the AV due to the close proximity of the endoscope tip to a superior ampulla lesion; E: Incomplete observations of the AV on the edge of diverticulum; B, D, F: Complete observation of the AV, including the orifice, by short cap-assisted endoscopy (A→B, C→D, E→F); G: Incomplete observation of the AV by short cap-assisted endoscopy due to a loop in the scope; H: Complete observation of the AV by long cap-assisted endoscopy (G→H).

for failure to visualize the ampulla were large fold in 16 patients, and diverticulum in 7 patients. Age (mean \pm SD) and gender [male (%)] were not significantly different between the complete observation and the incomplete observation groups [55.3 ± 12.6 years, 59 (60.8%); 55.2 ± 16.2 years, 12 (52.2%)], respectively.

Outcomes of CAE

Additional short CAE was performed in patients in whom we could not completely visualize the AV. This group included 13 patients (10.8%) with partial observation of the AV and 10 (8.4%) in which the AV was not found. Short CAE permitted a complete observation of the AV in 21 of the 23 patients (91.3%).

In cases of an incomplete visualization due to folded mucous membranes, complete observation of the orifice

areas was achieved by uncovering the fold with a short cap (Figure 4A and B). Due to a too close proximity of the endoscope tip to the superior ampulla lesion, the short cap provided a proper distance and the ability to straighten the mucosal fold by pressing the area surrounding the lesion (Figure 4C and D). The cap made it easier to access the AV at the edge of the diverticulum by directing the force vector along the tip of the endoscope (Figure 4E and F). Patients in whom visualization of the AV failed with short CAE had satisfactory outcomes by replacing the short cap with a long cap; one AV was observed only partially due to the deep location of the AV in the large diverticulum, whereas the other was not found due to a loop in the scope (Figure 4G and H). The time for CAE was 141 ± 88 s. No complications or significant mucosal trauma occurred. In one case of

suspected abnormal lesions, an additional side-viewing endoscopy with biopsy revealed a tubular adenoma, so an endoscopic ampullectomy was performed.

DISCUSSION

The transparent cap was first proposed in 1990 by Inoue *et al.*^[17] to improve the accessibility of the forward-viewing endoscope. Since then, transparent CAE has been used widely as a method to increase the success rate of the procedure^[18,19]. For example, CAE improves cecal intubation times and polyp detection rates during colonoscopy^[9,11], it achieves higher success rates of afferent loop intubation and bile-duct cannulation in patients with a Billroth II gastrectomy^[20-22], and it possible to clip a lesion too tangential to be clipped by routine endoscopy^[23-27].

Although there is a growing need to identify CAE as an effective approach to visualize the AV, no studies have investigated the AV observation rate during routine EGD or the efficacy of CAE for AV observation. Although small studies (preliminary data of Leal-Salazar *et al.*^[28] described the feasibility of visualizing the AV by attaching a long cap from a variceal band ligation set to a conventional endoscope) have been conducted, almost all cases (19 of 20) required emergency endoscopic hemostasis treatment, were not for screening test. That study reported conventional endoscopy permitted an inadequate observation of the AV in all cases (20 of 20), which is questionable, although they reported that observations of the AV using CAE were effective.

Although our cases had a wide variation in procedure duration, complete visualization of the AV was possible in up to 100% by attaching a cap to the tip of a conventional endoscope. The additional time for this procedure was short (average, 141 s). Moreover, the AV could be visualized completely in almost all patients using short CAE. Although a long cap has been used widely, the long cap is hard and difficult to pass over the larynx and pylorus, so it is easy to damage the mucosa, whereas the short cap is soft, safer, and relatively simple and easy to handle.

The transparent cap made the following multiple mechanisms possible: (1) The transparent cap provided a proper distance between the AV and the tip of the endoscope, which may prevent sticking of the endoscope to the duodenal lumen; (2) The cap allowed efficient manipulation of a tangentially placed AV to a more square approach; (3) The cap made it easier to access hidden areas by straightening the mucosal folds by pressing the surrounding lesion areas; and (4) the cap reduced loop formation by "hooking" the tip of the endoscope in the second portion of the duodenum and directing the force vector of the endoscope tip^[29-33]. Moreover, the long cap improved all of these functions; thus, it allowed an approach to a deeply AV located deep in the diverticulum^[34-36].

This study had some limitations. First, data collection was limited to screening tests in a healthy population that visited the Health Promotion Center; these patients can

have lower disease prevalence or anatomical variations in the AV than those in the general population. Thus, the success rate of CAE may be different in the general population. Second, because EGD was performed by one ERCP expert, the results cannot be generalized to a conventional endoscopist with less experience visualizing the AV.

In conclusion, CAE was an effective salvage technique when regular EGD was ineffective for visualizing the AV properly. CAE can increase the diagnostic accuracy of a forward-viewing endoscope and decrease the need for side-viewing endoscopy.

ACKNOWLEDGMENTS

This study was presented as an Abstract at Digestive Disease Week, 7-10 May 2011, Chicago, IL, United States.

COMMENTS

Background

Adequate visualization of the ampulla of Vater (AV) is important for early detection of periampullary or pancreaticobiliary diseases. But visualization of the AV with a forward-viewing endoscope is difficult due to the anatomical characteristics of the second portion of the duodenum. Thus, a side-viewing endoscope has been recommended for complete visualization of the AV. However, a side-viewing endoscope is not always available in an ordinary endoscopy suite.

Research frontiers

Cap-assisted endoscopy (CAE) has been used widely to facilitate detection of polyps, improve the success rate of cecal intubation, and to facilitate inspection of lesions situated in blind areas of the colon. The authors have found that the complete visualization rate of the AV in patients who are referred for incomplete visualization of the AV can be improved by attaching a transparent cap.

Innovations and breakthroughs

Although there is a growing need to identify CAE as an effective approach to visualize the AV, no studies have investigated the AV observation rate during routine esophagogastroduodenoscopy or the efficacy of CAE for AV observation. This is the first study to determine the efficacy and safety of an endoscopic examination using a transparent cap to completely visualize the AV in patients failed by conventional endoscopy.

Applications

CAE can increase the diagnostic accuracy of a forward-viewing endoscope and decrease the need for side-view endoscopy. This study may represent a future strategy for effective endoscopic examination as a screening test.

Terminology

Endoscopic caps are commonly used for both diagnosis and therapy during endoscopy. Transparent caps are attached to the distal end of the endoscope. Currently, many different sized caps are available. Cap-assisted endoscopic mucosal resection is the most common application of endoscopic caps. The appropriate selection of an endoscopic cap based on indication and location of the lesion is important for procedural success.

Peer review

The authors examined the efficacy of a CAE to completely visualize the AV in patients failed by conventional endoscopy. It revealed that CAE can increase the diagnostic accuracy of a forward-viewing endoscope and decrease the need for side-view endoscopy. The result are interesting and promising for endoscopic examination as a screening test.

Abstract

AIM: To compare effects of different resuscitation fluid on microcirculation, inflammation, intestinal barrier and clinical results in severe acute pancreatitis (SAP).

METHODS: One hundred and twenty patients with SAP were enrolled at the Pancreatic Disease Institute between January 2007 and March 2010. The patients were randomly treated with normal saline (NS group), combination of normal saline and hydroxyethyl starch (HES) (SH group), combination of normal saline, hydroxyethyl starch and glutamine (SHG group) in resuscitation. The ratio of normal saline to HES in the SH and SHG groups was 3:1. The glutamine (20% glutamine dipeptide, 100

mL/d) was supplemented into the resuscitation liquid in the SHG group. Complications and outcomes including respiratory and abdominal infection, sepsis, abdominal hemorrhage, intra-abdominal hypertension, abdominal compartment syndrome (ACS), renal failure, acute respiratory distress syndrome (ARDS), multiple organ dysfunction syndrome (MODS), operation intervention, length of intensive care unit stay, length of hospital stay, and mortality at 60 d were compared. Moreover, blood oxygen saturation (SpO₂), gastric intramucosal pH value (pHi), intra-abdominal pressure (IAP), inflammation cytokines, urine lactulose/mannitol (L/M) ratio, and serum endotoxin were investigated to evaluate the inflammatory reaction and gut barrier.

RESULTS: Compared to the NS group, patients in the SH and SHG groups accessed the endpoint more quickly (3.9 ± 0.23 d and 4.1 ± 0.21 d *vs* 5.8 ± 0.25 d, $P < 0.05$) with less fluid volume (67.26 ± 28.53 mL/kg/d, 61.79 ± 27.61 mL/kg per day *vs* 85.23 ± 21.27 mL/kg per day, $P < 0.05$). Compared to the NS group, incidence of renal dysfunction, ARDS, MODS and ACS in the SH and SHG groups was obviously lower. Furthermore, incidence of respiratory and abdominal infection was significantly decreased in the SH and SHG groups, while no significant difference in sepsis was seen. Moreover, less operation time was needed in the SH and SHG group than the NS group, but the difference was not significant. The mortality did not differ significantly among these groups. Blood SpO₂ and gastric mucosal pHi in the SH and SHG groups increased more quickly than in the NS group, while IAP was significantly decreased in the SH and SHG group. Moreover, the serum tumor necrosis factor- α , interleukin-8 and C-reactive protein levels in the SH and SHG groups were obviously lower than in the NS group at each time point. Furthermore, urine L/M ratio and serum endotoxin were significantly lower in the SH group and further decreased in the SHG group.

CONCLUSION: Results indicated that combination of normal saline, HES and glutamine are more efficient in resuscitation of SAP by relieving inflammation and sustaining the intestinal barrier.

INTRODUCTION

Severe acute pancreatitis (SAP) has a mortality rate about 30% and is characterized by pancreatic necrosis, cytokine activation, systemic inflammatory response syndrome (SIRS), and multiple organ dysfunction syndrome (MODS)^[1,2]. Accumulative results have demonstrated that microcirculation perfusion and hypoxia have a significant impact on the early stages of disease and play an important role in the pathogenesis of necrosis^[3]. Different from normal hypovolemia caused by trauma or bleeding, microcirculatory disorder of SAP is caused by special SIRS. Overexpressed inflammatory media such as tumor necrosis factor (TNF)- α , interleukin (IL)-6 and IL-8 in SIRS will injury the microcirculation endothelium and then increase capillary permeability and fluid sequestration, leading to capillary leakage syndrome and MODS^[4].

Moreover, the microcirculatory disorder of the intestinal will lead to intestinal ischemia reperfusion injury and damage the intestinal barrier, which could facilitate translocation of intestinal bacteria and enhance leukocyte activation and inflammatory cytokine release^[5]. If the microcirculatory disorder cannot be blocked at the initial stage, it will be exaggerated and form positive feedback. Thus, the excess cytokine will further injury the distal organs and lead to irreversible multiorgan failure^[6,7]. Moreover, bacterial translocation from the gut will cause severe infection^[8]. Therefore, adequate prompt fluid resuscitation is crucial for prevention of systemic complications^[9-11]. Thus, the purpose of effective fluid resuscitation of SAP is not only to supply the deficiency of blood volume, but also especially to stabilize the capillary permeability, modulate the inflammation reaction, and sustain the intestinal barrier function.

Two types of fluids frequently used today for active resuscitation are colloid fluids with large molecules (hetastarch, dextran 40, and albumin) that keep fluid intravascular, and crystalloid fluids with added electrolytes (normal saline, Ringer's, and lactated Ringer's). Both crystalloid and colloid solutions are considered effective

for the resuscitation of a hypovolemic patient, because neither fluid provides a survival benefit that is superior to the other^[12]. When trying to augment cardiac output and blood pressure, colloids have an advantage over crystalloid solutions, because a larger percentage enters the intravascular space and remains there for a longer period of time. This is because colloids provide the greatest effect on intravascular volume expansion and improve flow secondary to their low viscosity, which is equal to that of water^[13].

In the septic shock model with concomitant capillary leakage in the presence of a marked albumin loss, the hydroxyethyl starch (HES) could preserve systemic oxygenation and hemodynamics^[14]. Increased capillary permeability leading to fluid loss from the intravascular space and fluid sequestration into the third space are hallmarks of SAP^[15]. Clinically, capillary leakage is reflected by intravascular fluid loss leading to hypovolemia [low central venous pressure (CVP)], hemoconcentration (high packed cell volume), and extravascular fluid sequestration in the retroperitoneal, lungs, pleural and abdominal cavities^[16]. Although colloids such as HES are supposed more suitable than crystalloids for volume resuscitation of hypovolemia, prospective clinic studies have seldom involved comparing effects of crystalloids and HES in volume resuscitation in SAP^[10,11,17].

Some research has shown that HES reduces intestinal permeability by modulating inflammatory response and has a promising effect on survival, together with antibiotics under septic conditions^[18]. Although glutamine has been proved to protect the intestinal barrier as a nutrient supplement in nutritional support of SAP, the effects of glutamine delivered as a supplement in resuscitation fluid in the early stage of SAP have not been defined^[19-21].

In the present study, we compared the clinical results of different resuscitation fluids including normal saline, combination of normal saline and HES, and combination of normal saline, HES and glutamine in resuscitation of SAP. Moreover, the effects on microcirculation, inflammation reaction and intestinal barrier were investigated.

MATERIALS AND METHODS

Patients

One hundred and twenty patients with SAP were enrolled at the Pancreatic Disease Institute, Union Hospital (Wuhan, China) between January 2007 and March 2010. All of the patients were diagnosed with SAP according to the Atlanta Classification System^[22], and were aged 18-60 years. Exclusion criteria were heart disease, severe renal and hepatic dysfunction, coagulation disturbances, and allergy to HES or glutamine. Those patients with manifestation more than 48 h or who received resuscitation from the other hospital were also excluded. Informed consent was obtained from the patients and approval was obtained from the Ethics Committee of Union Hospital, Huazhong University of Science and Technology. The demographic information of the patients is shown in

Table 1 Demographic information of patients with severe acute pancreatitis treated by different resuscitation fluid (mean \pm SD)

| | NS group (n = 40) | SH group (n = 40) | SHG group (n = 40) |
|-----------------|----------------------|----------------------|-----------------------|
| Age (yr) | 41.86 \pm 13.85 | 44.50 \pm 9.77 | 45.11 \pm 11.57 |
| Sex n (%) | | | |
| Male | 20 (50) | 22 (55) | 21 (52.5) |
| Female | 20 (50) | 18 (45) | 19 (47.5) |
| Height (cm) | 165.86 \pm 6.04 | 165.00 \pm 9.03 | 169.25 \pm 6.67 |
| Weight (kg) | 66.5 \pm 8.63 | 69.00 \pm 9.68 | 72.38 \pm 8.43 |
| APACHE II score | 11.2 \pm 0.7 | 10.9 \pm 0.6 | 11.3 \pm 0.4 |
| MAP (mmHg) | 62.3 \pm 9.3 | 64.8 \pm 9.2 | 63.6 \pm 8.9 |
| BUN/Cr ratio | 23.9 \pm 3.6 | 24.2 \pm 3.2 | 23.7 \pm 3.7 |

No significant differences were observed among the study groups regarding demographic data. APACHE: Acute physiology and chronic health evaluation; MAP: Mean arterial pressure; BUN/Cr: Blood urea nitrogen/creatinine; NS group: Normal saline; SH group: Combination of normal saline and hydroxyethyl starch; SHG group: Combination of normal saline, hydroxyethyl starch and glutamine.

Table 1. If the patient could not successfully achieve a balance of output and input within 7 d, we considered them to have failed resuscitation. However, these cases were not removed from the study and all the results were still included.

Management of resuscitation

The patients were randomly divided into three groups that were resuscitated with normal saline (NS group), combination of normal saline and hydroxyethyl starch (SH group; 130 kD, Sino-Swed Pharmaceutical Corp. Ltd.), or combination of normal saline, hydroxyethyl starch and glutamine (SHG group; glutamine dipeptide, Sino-Swed Pharmaceutical Corp. Ltd.). The ratio of normal saline to HES in the SH and SHG groups was 3:1. Glutamine (20% glutamine dipeptide, 100 mL/d) was supplemented into the resuscitation liquid in the SHG group.

All of the patients with suspected SAP were initially transferred to the pancreatic intensive care unit (PICU). The vital signs, oxygen saturation (SpO₂), gastric intramucosal PH value (pHi), arterial blood-gas analysis, mean arterial pressure (MAP) and intra-abdominal pressure (IAP) were monitored to guide the treatment. All the patients received a central venous catheter capable of measuring central venous oxygen saturation (ScvO₂) and CVP.

Meanwhile, the fluid resuscitation was promptly conducted as early as possible. Generally, we infused 1 L normal saline in the NS group or combination of 500 mL normal saline and 500 mL HES in the SH and SHG groups in the first 2 h (500 mL/h) to achieve a CVP of 8-12 mmHg. If the MAP was < 65 mmHg, vasopressors were given to maintain a MAP of at least 65 mmHg. If the MAP was > 90 mmHg, vasodilators were given until it was \leq 90 mmHg^[23]. If the urine output was < 0.5 mL/kg/h after the CVP and MAP were stabilized, 20 mg dihydrochlorothiazide bolus was infused and followed with 1-2 mL/h continuous infusion *via* syringe pump to maintain the urine output at > 0.5 mL/kg per hour. After that,

resuscitation fluid was continually infused at a speed of 150-300 mL/h (approximately 2-3 mL/kg per hour, ratio of normal saline to HES is 3:1) and modulated depending on the reaction of early resuscitation and parameters in the later course, which maintained the urine at 0.5-1 mL/kg per hour and prevented excess resuscitation.

Moreover, if the oliguria continued for > 2 d and the ratio of blood urea nitrogen/creatinine (BUN/Cr) significantly increased, continuous venovenous hemofiltration (CVVH) with ultrafiltration modulation was performed to extra the liquid sequestration in the "3rd space" and overexcited inflammatory mediators. Most of the patients were accompanied with respiratory dysfunction, and for those patients with ScvO₂ < 70% after stabilization of CVP and MAP, we did not perform blood transfusion but intensified oxygen supplementation through pressure oxygen mask or tracheal intubation with artificial respirator. Except for the CVP, MAP, urine and ScvO₂ adopted as early resuscitation parameters, IAP was also used to assess the microcirculation dysfunction. Even without significant abnormality in the other parameters, the infusion was carefully controlled and the CVVH applied to balance the output and input in those patients with significantly increased IAP. The input of resuscitating liquid depended on the output including ultrafiltration volume of CVVH, urine and non-dominant water loss. The ultimate endpoint of resuscitation was defined as the balance of input and output. Those patients who approached the endpoint in 7 d were considered to have successful resuscitation, otherwise it had failed.

Complications and clinical outcomes

Complications and outcomes were recorded throughout the whole course, including respiratory infection, abdominal infection, sepsis, abdominal hemorrhage, intra-abdominal hypertension (IAH), abdominal compartment syndrome (ACS), renal failure, acute respiratory distress syndrome (ARDS), MODS, operation intervention, length of intensive care unit stay, length of hospital stay and mortality at 60 d.

All the clinical parameters were recorded from day 1 to day 7 after administration. Resuscitation fluid input, abdominal drainage fluid and urine output were recorded every day. Oxygen supply and microcirculation perfusion was evaluated by pulse SpO₂ and pHi, which were detected by bedside monitor (Life Scope A, Nihon Kohden, Irvine, CA, United States) and gastric mucosal pH monitor (Tonocap, Datex-Ohmeda, Finland) respectively^[24]. Harvested heparinized blood was centrifuged and the plasma was removed and stored at -80 °C for later examination.

Measurements of IAP

IAP was measured according to the method of Oda *et al.*^[25]. In brief, an 18-gauge catheter was inserted into the culture aspiration port of the urine catheter, and a line filled with saline was connected to the pressure transducer. After urine had been completely drained from the bladder, the urine catheter line was clamped, and then 100 mL of saline was instilled in the bladder and the pres-

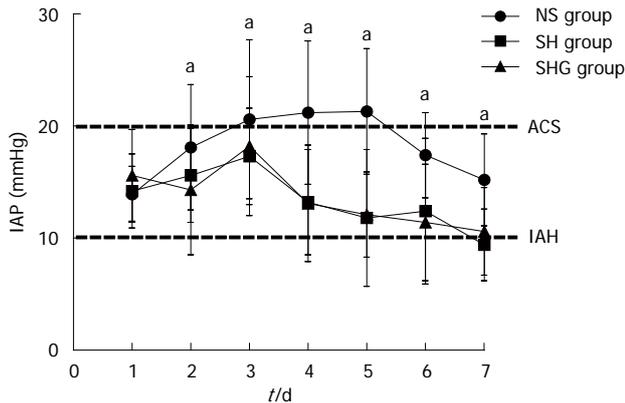

Figure 1 Effect of different resuscitation fluids on changes in intra-abdominal pressure in severe acute pancreatitis. Intra-abdominal pressure (IAP) was indirectly measured via a bladder catheter during 7 d and performed twice daily. All of the patients had intra-abdominal hypertension on d 1 (IAP > 10 mmHg). ^a $P < 0.05$ vs normal saline (NS group). SH group: Combination of normal saline and hydroxyethyl starch; SHG group: Combination of normal saline, hydroxyethyl starch and glutamine; ACS: Abdominal compartment syndrome; IAH: Intra-abdominal hypertension.

sure was measured at the end of expiration. IAP was measured first on admission to the PICU, and twice daily thereafter in the morning and evening, in principle. According to the consensus guidelines, IAH was defined as IAP ≥ 12 mmHg and ACS as IAP > 20 mmHg with evidence of organ dysfunction.

Plasma cytokines assay

Serum TNF- α , IL-8 and C-reactive protein (CRP) from day 1 to day 7 were evaluated by enzyme-linked immunosorbent assay (R-D Systems, Minneapolis, MN, United States) according to the manufacturer's instructions.

Urine lactulose/mannitol ratio assay

Urine lactulose/mannitol (L/M) ratio during 7 d was analyzed to evaluate intestinal permeability as described before^[21]. All the patients fasted for at least 6 h and their bladders were emptied before the test. The test solution consisted of 10 g lactulose and 5 g mannitol in a total volume of 50 mL through nasojunal tube. The urine volume was collected for the subsequent 6 h. The urine volume was recorded, and 10 mL was frozen and stored at -80°C . L/M ratio in urine was analyzed by Hi-Crush Partners LP.

Endotoxin assay

Serum concentration of endotoxin at 7 d was detected by quantitative chromogenic limulus amoebocyte lysate assay (QCL-1000; Whittaker MA Bioproducts, Walkersville, MD, United States) according to the manufacturer's instructions. Blood was drawn aseptically into lipopolysaccharide-free tubes. All samples were processed in a laminar flow hood. To minimize nonspecific plasma inhibitors, samples were diluted with pyrogen-free water and heat inactivated at 100°C for 10 min. *Escherichia coli* 055:B5 reference endotoxin (1 endotoxin unit = 0.6 ng/mL) was used for the standard curve (Whittaker MA

Bioproducts).

Statistical analysis

Statistical analyses were performed with SPSS version 12.0.2. Data are presented as mean \pm SD. χ^2 analysis and one-way repeated-measures analysis of variance were used for the analysis of differences. $P < 0.05$ was considered significant.

RESULTS

Demographic information

As shown in Table 1, no significant differences were observed between the study groups regarding demographic data including age, agenda, height, weight, Acute physiology and chronic health evaluation II score, MAP and BUN/Cr ratio at the initial time.

Fluid resuscitation and fluid balance

All patients in the three groups received resuscitation at an early stage after manifestation of SAP (12.8 ± 6.7 h, 13.1 ± 5.4 h, and 12.2 ± 6.3 h). The balance of input and output was considered as the ultimate endpoint of resuscitation. Compared to the NS group, it took a significantly shorter time to approach the resuscitation endpoint in the SH and SHG groups (5.8 ± 0.25 d vs 3.9 ± 0.23 d and 4.1 ± 0.21 d, $P < 0.05$). Nevertheless, the volumes of fluid administered in the SH and SHG groups was obviously lower than that in the NS group (67.26 ± 28.53 and 61.79 ± 27.61 vs 85.23 ± 21.27 mL/kg per day, $P < 0.05$), while the abdominal drainage fluid in the SH and SHG groups was significantly lower than that in the NS group (Table 2).

Complications and outcomes

When infection was suspected, ultrasound-guided percutaneous aspiration of pancreatic tissue, sputum and blood was performed with Gram's stain and culture. If ultrasound-guided percutaneous aspiration confirmed the infection, antibiotics were administered following the results of culture and antibiotic sensitivity. If the episode is not effectively relieved, the patient should undergo debridement. Compared to the NS group, the incidence of renal dysfunction, ARDS, MODS and ACS in the SH and SHG groups was obviously lower. Furthermore, the incidence of respiratory and abdominal infection was significantly decreased in the SH and SHG groups, while no significant difference in sepsis was seen. Moreover, less operation time was needed in the SH and SHG groups than in the NS group, but the difference was not significant (Table 3). IAP in the NS group was significantly higher than in the SH and SHG groups at each time point (Figure 1). Patients in the SH and SHG groups had a notably shorter length of stay in the intensive care unit (ICU) and hospital than the NS group had. Although mortality in the NS group was higher than in the SH and SHG groups, no significant difference was observed. No significant difference in any of the parameters was noted between the SH and SHG groups.

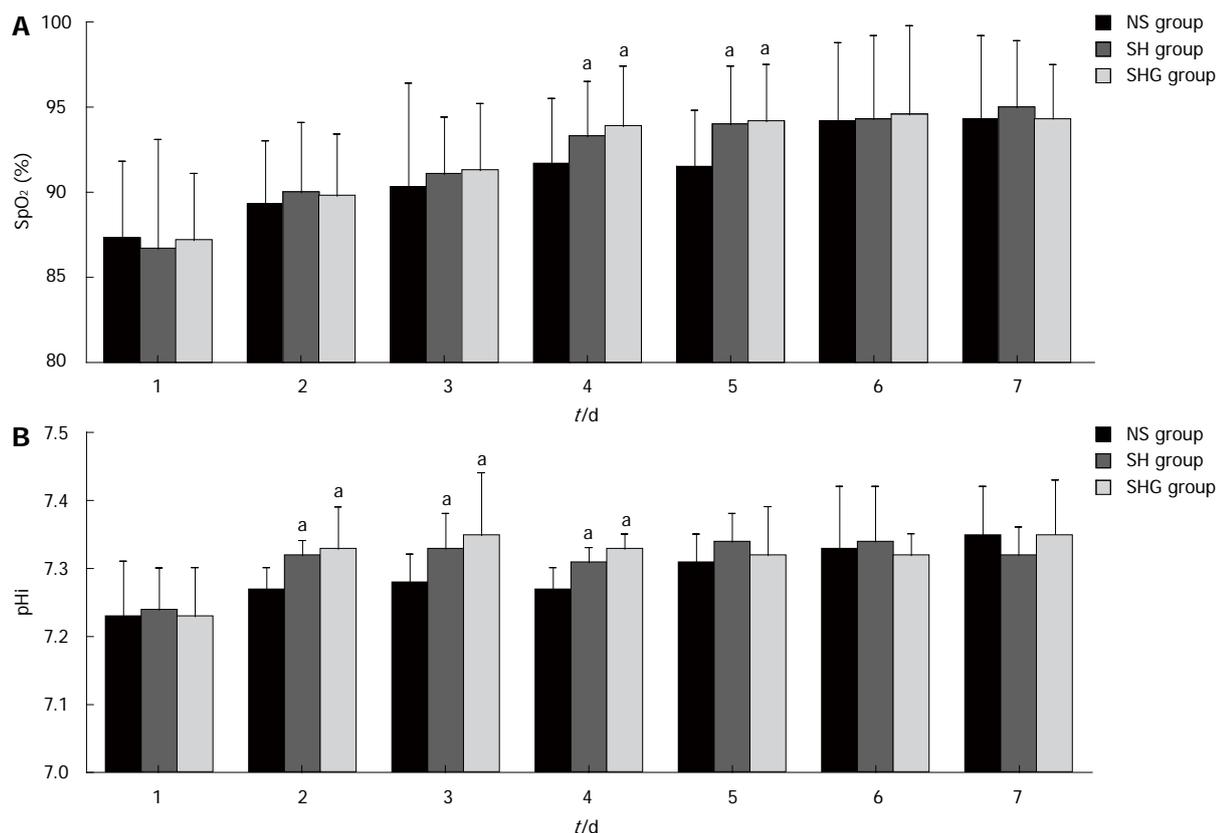

Figure 2 Effect of different resuscitation fluids on circulation oxygen supply and microcirculation perfusion. A: Effect of different fluids on circulation oxygen supply was evaluated with pulse oxygen saturation (SpO₂) by automatic monitoring; B: Microcirculation perfusion was assessed with gastric intramucosal pH value (pHi) by Tonocap monitor. ^aP < 0.05 vs normal saline (NS group). SH group: Combination of normal saline and hydroxyethyl starch; SHG group: Combination of normal saline, hydroxyethyl starch and glutamine.

SpO₂ and microcirculation perfusion

The SpO₂ of the SH and SHG groups increased more quickly than in the NS group and was significantly higher at day 4 and day 5. Similarly, pHi in the SH and SHG groups also increased faster than in the NS group from day 2 to day 4 (Figure 2).

Serum cytokine and CRP concentration

Serum TNF-α, IL-8 and CRP were detected daily from

Table 3 Complications and outcomes of patients treated by different resuscitation fluid

day 1 to day 7. Although the TNF-α concentration in all three groups increased to a peak at d 3 and then gradually decreased, it was significantly higher in the NS group at days 3-5 (Figure 3A). Unlike the highest IL-8 concentration in the NS group at day 4, the SH and SHG groups had the highest IL-8 concentration at day 3 and then it

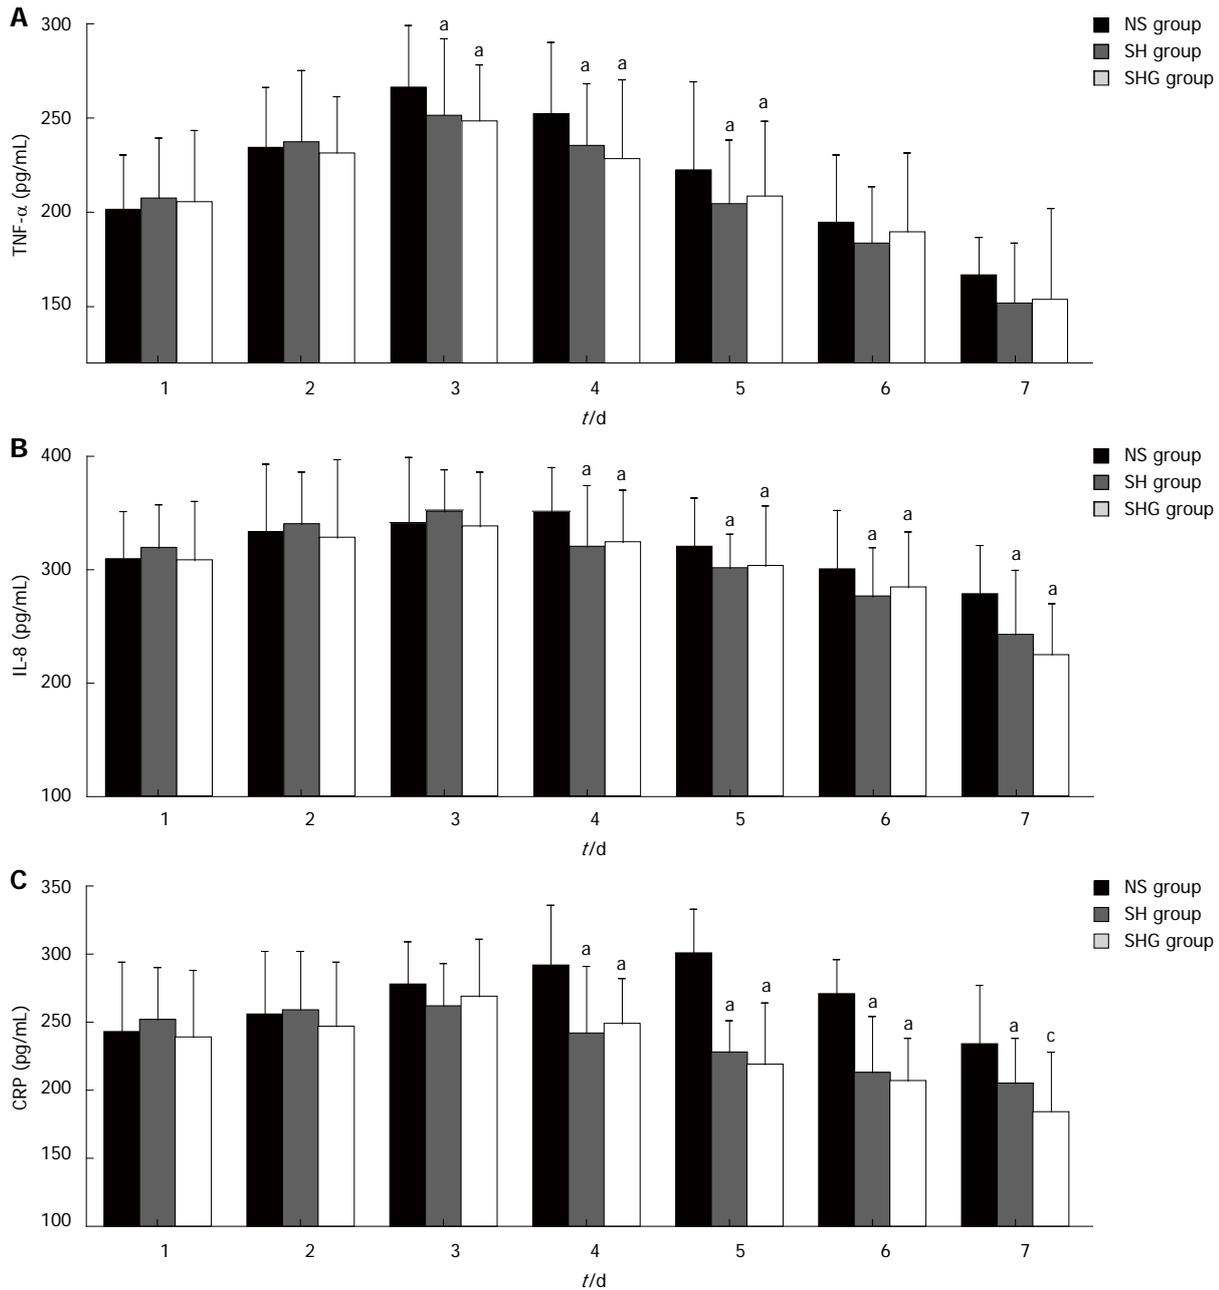

Figure 3 Effects of different resuscitation fluids on serum cytokine and C-reactive protein. Serum tumor necrosis factor (TNF)-α (A), interleukin (IL)-8 (B) and C-reactive protein (CRP) (C) concentration was evaluated by enzyme-linked immuno sorbent assay. ^a*P* < 0.05 vs normal saline (NS) group; ^c*P* < 0.05 vs combination of normal saline and hydroxyethyl starch (SH group). SHG group: Combination of normal saline, hydroxyethyl starch and glutamine.

significantly decreased. Furthermore, the IL-8 concentration in the SHG group was obviously lower than in the SH group at days 4-7 (Figure 3B). The CRP concentration in the NS group continually increased until day 5, while it was significantly decreased in the SH and SHG groups after day 3. Moreover, the CRP concentration in the SHG group was significantly lower than that in the SH group after day 7 (Figure 3C).

Intestinal permeability

Intestinal permeability was assessed by urine L/M ratio and serum endotoxin. Urine L/M ratio in all three groups increased after administration of SAP. Compared to the

NS group, urine L/M ratio in the SH and SHG groups was significantly lower after day 4. Moreover, compared to the SH group, it further decreased in the SHG group after day 5. Parallel to urine L/M ratio, serum endotoxin in the NS group was also significantly higher than that in the SH and SHG groups. Nevertheless, serum endotoxin in the SHG group was markedly lower than that in the SH group after day 6 (Figure 4).

DISCUSSION

Many studies have indicated that colloids such as HES are more suitable than crystalline solutions for volume

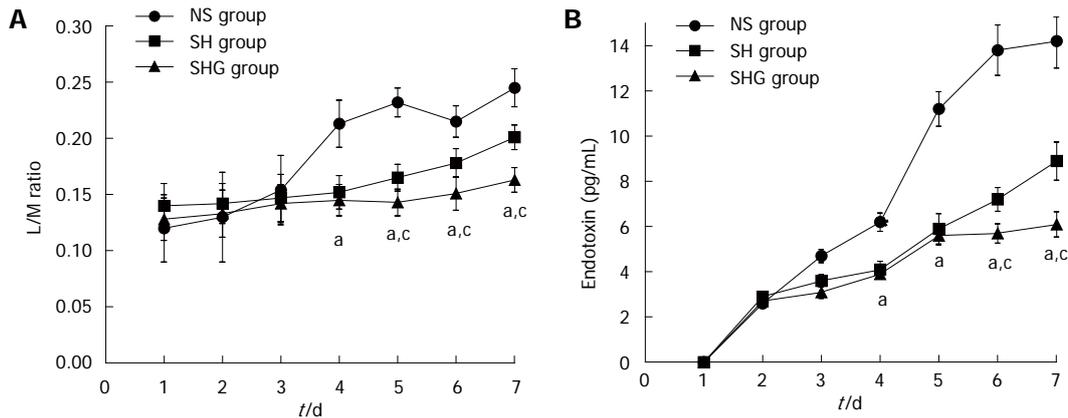

Figure 4 Effect of different fluids on intestinal mucosa barrier function. A: Lactulose/mannitol (L/M) ratio of urine in normal saline (NS group), combination of normal saline and hydroxyethyl starch (SH group) and combination of normal saline, hydroxyethyl starch and glutamine (SHG group) was measured by Hi-Crush Partners LP; B: Serum endotoxin in different groups was detected by quantitative chromogenic limulus amoebocyte lysate assay reagent. ^a*P* < 0.05 vs NS group; ^c*P* < 0.05 vs SH group.

resuscitation in hypovolemia of sepsis, of which microcirculation arrangement are same as SAP^[26-28]. Our present study demonstrated that less time and volume were needed to achieve the resuscitation endpoint in the SH and SHG groups. Moreover, higher urine output and lower abdominal drainage were seen in the SH and SHG groups. Furthermore, the incidence of MODS and ACS were significantly decreased in the SH and SHG groups.

This indicated that combination of HES and crystalloids might effectively attenuate the capillary leakage by maintaining colloid osmotic pressure and then decreasing extravascular fluid sequestration, such as pleural effusion and abdominal ascites. As an important clinical clue for extensive sequestration, the IAP and IAH in the SH and SHG groups were decreased significantly more than those in the NS group.

Although the mortality was not significantly decreased, the incidence of respiratory infection and abdominal infection was significantly reduced in the SH and SHG groups. This indicated that the decreased liquid sequestration in the abdomen and lungs significantly reduced the infection risk. Furthermore, less operation time was needed and a lower level of organ dysfunction occurred in the SH and SHG groups. Thus, shorter length of ICU and hospital stay was seen in the SH and SHG groups. These results further suggest that combination of HES and normal saline might be effective in resuscitation and effectively decrease infective complications and organ failure in SAP. Although the NS group had a higher incidence of respiratory and abdominal infection, incidence of sepsis and mortality in the NS did not differ significantly from that in the SH and SHG groups. This might be because the treatment of SAP is multimodal including resuscitation, organ support, nutrition support, operative intervention, and antibiotics and these different single resuscitation managements were not sufficient to affect mortality.

The target of effective resuscitation is not only maintaining the blood volume, but more importantly, to improve tissue oxygenation and microcirculation perfusion.

In our research, arterial SpO₂ and pHi were detected to evaluate the oxygenation and microcirculation perfusion. We showed that SpO₂ and pHi in the SH and SHG groups recovered more quickly than in the NS group. We showed that combination of HES and normal saline was effective in expanding the blood volume and improving the microcirculation and tissue oxygenation.

Our research demonstrated that inflammatory factors including TNF- α , IL-8 and CRP, in the SH and SHG groups were significantly lower and decreased earlier than those in the NS group, which indicates that HES might modulate the inflammatory reaction. Other research has also discovered that HES attenuates capillary leakage through modulation of the inflammation reaction in sepsis and abdominal surgery. It is speculated that HES may inhibit nuclear factor- κ B activation and neutrophil adhesion and migration^[29-31], but the exact mechanism has not been defined. Other research implies that HES prevents the inflammatory reaction through relieving ischemia-reperfusion injury in the intestine^[18,32]. The present study demonstrated that intestinal permeability significantly decreased in the SH and SHG groups, which also implied that the inflammation reaction was modulated by improvement of intestinal ischemia-reperfusion injury.

Flint *et al.*^[33] have shown that the severity of SAP can be exacerbated by intestinal ischemia-reperfusion injury. When the intestinal barrier is disrupted, the luminal content invades the portal venous and lymphatic systems. This translocation activates immune cells downstream from the intestinal mucosa to release inflammatory mediators that drive the onset of SIRS and MODS in SAP^[34-36]. Our present study demonstrated that urine L/M ratio and endotoxin were significantly decreased after treatment with HES and normal saline. It indicated that sustaining the intestinal barrier by HES is one of the important reasons for decreased mortality from infection and MODS.

Many studies have shown that nutrition support supplemented with specific immunonutrients such as glutamine may protect the intestinal barrier and modulate the acute phase responses, thereby potentially improving

outcome in SAP^[19-21]. We speculated that supplementation of glutamine in resuscitation could further sustain intestinal function and improve the clinical outcomes of SAP. Our results showed that the IL-8, CRP, urine L/M ratio and serum endotoxin were further decreased after supplementation with glutamine, while the clinical outcomes and complications had no significant change. This implies that ischemia-reperfusion injury is a major reason for intestinal dysfunction in the early stage of SAP.

In summary, the present study showed that combination of HES and normal saline was more efficient in fluid resuscitation of SAP by modulating inflammation and the intestinal barrier, which resulted in a lower level of infection and organ failure. Nevertheless, although supplementation with glutamine could further modulate inflammatory reaction and intestinal, while no significant changes were seen in clinical results.

COMMENTS

Background

Accumulative results demonstrated that microcirculation perfusion and hypoxia leading to capillary leakage syndrome (CLS) and multiple organ dysfunction syndrome (MODS) in severe acute pancreatitis (SAP). Although the colloid such as hydroxyethyl starch (HES) are supposed more suitable than crystalloid in volume resuscitation in hypovolemia, seldom prospective clinic researches have involved in SAP. Given to protect intestinal barrier as nutrient supplement in SAP, the effects of glutamine delivered as supplement of resuscitation fluid in early stage of SAP were not defined. Thus, the present in present set to compare clinical results of different resuscitation fluid including normal saline, combination of normal saline and HES as well as combination of normal saline, HES and glutamine in resuscitation of SAP, respectively.

Research frontiers

Overexpressed inflammatory cytokine of SAP such as tumor necrosis factor- α (TNF- α), interleukin (IL)-6, IL-8 will injury the capillary permeability and lead to CLS, which further damage the intestinal barrier and induce translocation of intestinal bacterial. Thus, the effective fluid resuscitation of SAP should be not only to sustain body volume but also improve capillary permeability and intestinal barrier function. Although the colloid such as HES are supposed more suitable than crystalloid in volume resuscitation in hypovolemia, seldom prospective clinic researches have involved in comparing effects of crystalloid and HES in volume resuscitation in SAP.

Innovations and breakthroughs

Many researches indicated that colloid such as HES are supposed more suitable than crystalline in volume resuscitation in hypovolemia of sepsis, but it is unknown whether the HES is also more efficient in SAP which microcirculation arrangement is similar to septic. The present results firstly demonstrated that less time and volume were needed to get resuscitation endpoint in combination of normal saline and hydroxyethyl starch (HS) group and HES and glutamine (SHG group). Moreover, higher urine output and lower abdominal drainage were showed in SH and SHG groups. Furthermore, the incidence of MODS and abdominal compartment syndrome (ACS), were significantly decreased in SH and SHG groups. The results displayed that oxygen saturation and intramuscular pH value of combination of normal saline and hydroxyethyl starch (SH group) and SHG group recovered more quickly than normal saline (NS) group which implied that combination of HES and normal saline is not only effective expanding blood volume but also improving the microcirculation and tissue oxygenation. This research demonstrated that the inflammatory factor including TNF- α , IL-8 and C-reactive protein of SH and SHG group were significantly lower and decreased earlier than those of NS group. Moreover, our present study demonstrated that urine lactulose/mannitol ration and endotoxin were significantly decreased after treated with HES and normal saline.

Applications

The present study showed that combination of HES and normal saline was more efficient in fluid resuscitation of SAP by modulate inflammation and intestinal barrier, which resulted in lower modality of infection and organ failure.

Moreover, the supplementary with glutamine could further modulate inflammatory reaction and intestinal. It implied that combination of normal saline, HES and glutamine might be an efficient resuscitation fluid in SAP which deserves to be investigated in further clinical study.

Terminology

CLS is a rare medical condition characterized by self-reversing episodes during which the endothelial cells which line the capillaries are thought to separate for a few days, allowing for a leakage of fluid from the circulatory system to the interstitial space, resulting in a dangerous hypotension (low blood pressure), hemoconcentration, and hypoalbuminemia. It is a life-threatening illness because each episode has the potential to cause damage to, or the failure of, vital organs due to limited perfusion. ACS occurs when the abdomen becomes subject to increased pressure. Specific cause of ACS is not known, although some causes can be sepsis and severe abdominal trauma. Increasing pressure reduces blood flow to abdominal organs and impairs pulmonary, cardiovascular, renal, and gastro-intestinal function, causing MODS and death.

Abstract

AIM: To evaluate clinical and laboratory parameters for prediction of bleeding from esophageal varices (EV) in children with portal hypertension.

METHODS: Retrospective study of 103 children (mean age: 10.1 ± 7.7 years), 95.1% with intrahepatic portal hypertension. All patients had no history of bleeding and underwent esophagogastroduodenoscopy for EV screening. We recorded variceal size (F1, F2 and F3), red-color signs and portal gastropathy, according to the Japanese Research Society for Portal Hypertension classification. Patients were classified into two groups: with and without EV. Seven noninvasive markers were evaluated as potential predictors of EV: (1) platelet count; (2) spleen size z score, expressed as a standard deviation score relative to normal values for age; (3)

platelet count to spleen size z score ratio; (4) platelets count to spleen size (cm) ratio; (5) the clinical prediction rule (CPR); (6) the aspartate aminotransferase to platelet ratio index (APRI); and (7) the risk score.

RESULTS: Seventy-one children had EV on first endoscopy. On univariate analysis, spleen size, platelets, CPR, risk score, APRI, and platelet count to spleen size z score ratio showed significant associations. The best noninvasive predictors of EV were platelet count [area under the receiver operating characteristic curve (AUROC) 0.82; 95%CI: 0.73-0.91], platelet: spleen size z score (AUROC 0.78; 95%CI: 0.67-0.88), CPR (AUROC 0.77; 95%CI: 0.64-0.89), and risk score (AUROC 0.77; 95%CI: 0.66-0.88). A logistic regression model was applied with EV as the dependent variable and corrected by albumin, bilirubin and spleen size z score. Children with a CPR < 114 were 20.7-fold more likely to have EV compared to children with CPR > 114. A risk score > -1.2 increased the likelihood of EV (odds ratio 7.47; 95%CI: 2.06-26.99).

CONCLUSION: Children with portal hypertension with a CPR below 114 and a risk score greater than -1.2 are more likely to have present EV. Therefore, these two tests can be helpful in selecting children for endoscopy.

Key words: Portal hypertension; Clinical predictors; Pediatric patients; Esophageal varices

Core tip: Children with portal hypertension (PH) are at risk for variceal bleeding. The standard test for screening varices is endoscopy, an invasive method. We evaluated non-invasive markers for diagnosing esophageal varices (EV) in 103 children (95% intrahepatic PH). All patients had no bleeding history and underwent endoscopy for EV screening. Platelet count (< 115 000), clinical prediction rule (< 114) and risk score (cutoff > -1.2) were the best predictors of EV. Limitations are the retrospective

design and the small number of pre-hepatic PH patients. The strength is the paucity of pediatric studies related to this issue and the assessment of risk score in children.

Adami MR, Ferreira CT, Kieling CO, Hirakata V, Vieira SMG. Noninvasive methods for prediction of esophageal varices in pediatric patients with portal hypertension. *World J Gastroenterol* 2013; 19(13): 2053-2059 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i13/2053.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2053>

INTRODUCTION

Portal hypertension is the underlying pathophysiological process that leads to the formation of portosystemic collaterals and heralds the onset of a severe complication: variceal hemorrhage. It is estimated that approximately 50% of pediatric patients with chronic liver disease and 90% of those with extrahepatic portal vein obstruction (EHPVO) will experience gastrointestinal bleeding^[1,2]. Esophagogastroduodenoscopy (EGD) is considered the primary modality for detection and surveillance of esophageal varices (EV) and to determine the risk of bleeding.

Guidelines for adult cirrhotic patients recommend universal EV screening by EGD at the time of the diagnosis of cirrhosis^[3-7].

Many studies have sought to determine clinical, laboratory, or other noninvasive methods that could predict the presence of EV. Preliminary data suggests that laboratory tests such as platelet count, albumin and ultrasonographic parameters such as presence of splenomegaly, spleen size z score and platelet count to spleen size ratio and the clinical prediction rule (CPR; calculated from platelet count, spleen size z-score, and albumin concentration) developed by Gana may be useful as first-line tools for identification of adults and pediatric patients at risk of variceal development and thus reduce the number of unnecessary EGDs^[8-22].

The aim of this study was to analyze the following non-invasive methods for predicting EV in pediatric patients with portal hypertension submitted to EGD: platelet count, spleen size z score, platelet count to spleen size (cm) ratio, platelet count to spleen size z score ratio, CPR, risk score and the aspartate aminotransferase to platelet ratio index (APRI).

MATERIALS AND METHODS

We conducted a retrospective evaluation of patients aged < 18 years with a diagnosis of chronic liver disease or EHPVO who underwent EGD between the 2000 and 2011 at Hospital de Clinicas de Porto Alegre, a tertiary referral center in Southern Brazil. Portal hypertension was defined after the diagnosis of some conditions which natural progression occurs along with portal hypertension such as chronic liver disease and extra hepatic portal vein thrombosis. The following exclusion criteria were

applied: active or previous variceal bleeding, prior variceal treatment (any type) or variceal bleeding prophylaxis (including nonselective β -blocker use, endoscopic variceal ligation or sclerotherapy, surgical portosystemic shunt or transjugular intrahepatic portosystemic shunt insertion), liver transplantation, and malignancy.

The presence of EV on endoscopy was the primary endpoint. Clinical and demographic data, diagnoses, medication use, physical examination findings, and severity of liver disease, as assessed by pediatric end-stage liver disease and model for end-stage liver disease (for children > 12 years old) and the Child-Pugh classification, were reviewed. The results of laboratory tests and ultrasound scans were considered for analysis if performed within 3 mo of EGD.

Endoscopy was carried out as part of routine clinical care. Four different endoscopists, recorded variceal size (F1, F2 and F3), red-color signs, and portal gastropathy, according to Japanese Research Society for Portal Hypertension classification^[23], and gastric varices according to the Sarin classification^[24].

Three thousand EGDs were reviewed and 127 patients with chronic liver disease or EHPVO were identified. Twenty-four patients were excluded: eleven due to previous variceal bleeding, four due to non-selective β -blocker therapy, four due to liver transplantation, two with laboratory test performed over than 3 mo of EGD, one due to surgical shunting, one due to no etiologic confirmation and one due to band ligation.

Seven non-invasive markers, previously described in adults and pediatric patients with portal hypertension, were evaluated as potential predictors of EV: (1) platelet count; (2) spleen size z score, expressed as a standard deviation score relative to normal values for age^[25]; (3) platelet count to spleen size z score ratio; (4) platelet count to spleen size (cm) ratio; (5) the CPR, proposed by Gana *et al*^[22] which is calculated according to the following formula: $[(0.75 \times \text{platelets}) / (\text{spleen z score} + 5)] + (2.5 \times \text{albumin})$; (6) the APRI test; and (7) a risk score, calculated as follows: $[14.2 - 7.1 \times \log_{10} \text{platelets} (10^9/\text{L})] + [4.2 \times \log_{10} \text{bilirubin} (\text{mg/dL})]$ ^[21].

For statistical analyses, patients were classified into two groups: patients with EV and patients without EV.

Statistical analysis

Data are expressed as mean and standard deviation, median and interquartile range, and proportions and 95%CI as appropriate. A *P* value of < 0.05 was considered statistically significant in all analyses. Continuous variables (such as laboratory data, spleen size z score, CPR, risk score) were compared using the Student *t*-test or the Mann-Whitney *U* test. Categorical variables (such as ascites, encephalopathy, and splenomegaly) were compared by the chi-square test or Fisher's exact test.

To determinate test performance for prediction of EV, a receiver operator characteristic (ROC) curve was constructed and the area under the ROC curve (AUROC) was calculated. The cutoff value of the variables was determined at the point of highest sensitivity and specific-

¹Determined clinically or by electroencephalogram: 1 = none; 2 = grade 1 or 2; 3 = grade 3 or 4; ²Determined clinically or by ultrasound: 1 = no ascites; 2 = controlled or mild; 3 = moderate or tense. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; INR: International normalized ratio; APRI: Aspartate aminotransferase to platelet ratio index.

ity. Sensitivity, specificity, predictive values and likelihood ratios were calculated for these cutoff values. A logistic regression model was used to evaluate the variables that reached statistical significance on univariate analysis, with EV as the dependent variable. All statistical analyses were performed in the SPSS 18.0. This study was approved by the local Research Ethics Committee.

RESULTS

A hundred and three patients were included, with a mean age of 8.9 (± 4.7) years. Fifty-six (56/103; 54.3%) patients were female. Ninety-eight (98/103; 95%) patients had a diagnosis of chronic liver disease and five (5/103; 4.8%) had EHPVO. Seventy-one of the (71/103; 68.9%) patients had EV. Varices were classified as F2 and F3 in 35 patients, with red spots in 12 patients. Sixteen (16/71; 22.5%) patients presented both esophageal and gastric varices, and one had isolated gastric varices. Twenty (20/103; 19.4%) patients had portal hypertensive gastropathy.

Spleen size, platelet count, CPR, APRI, platelet count to spleen size ratio, platelet count to spleen size z score ratio, and the risk score were able to discriminate patients with and without varices (Table 1).

On ROC curve analysis, the best predictors of EV

Table 2 Odds ratios for esophageal varices

| Variables | OR ¹ | 95%CI | P value |
|------------------------------------|-----------------|-------------|---------|
| CPR < 115 | 7.99 | 1.45-43.82 | 0.017 |
| CPR < 114 | 20.74 | 2.66-161.50 | 0.004 |
| Platelets/spleen size z score < 25 | 4.27 | 0.90-20.26 | 0.067 |
| Platelets/spleen size < 1 | 2.20 | 0.65-7.43 | 0.203 |
| Platelets | 0.98 | 0.97-0.99 | 0.016 |
| Platelets < 115 | 3.10 | 0.97-9.88 | 0.056 |
| Risk score > -1.2 | 7.47 | 2.06-26.99 | 0.002 |
| APRI > 1.4 | 1.85 | 0.56-6.10 | 0.309 |

¹Odds ratio computed by multivariate logistic regression model. CPR: Clinical prediction rule; APRI: Aspartate aminotransferase to platelet ratio index.

were: platelet count; platelet count to spleen size z score ratio; CPR; risk score; platelet count to spleen size (cm) ratio; spleen size z score; and the APRI test (Figure 1). The cutoff points were established with the best relationship between sensitivity and specificity for each variable as follows: platelet count, 115 000; platelet count to spleen size z score ratio, 25; CPR, 114; risk score, -1.2; platelet count to spleen size ratio, 1.0; APRI test, 1.4.

A logistic regression model was applied with EV as the dependent variable, corrected by albumin, bilirubin and spleen size z score. Patients with a CPR < 114 were 20.74-fold more likely to have EV compared to children with CPR > 114. Risk score > -1.2 increased the likelihood of varices (odds ratio 7.47; 95%CI: 2.06-26.99) (Table 2). Sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratio and negative likelihood ratio values for CPR, platelet count, platelet count to spleen size z score ratio, platelet count to spleen size (cm) ratio, risk score and APRI as EV predictors are presented on Table 3.

DISCUSSION

We evaluated seven non-invasive markers, two of which had never been tested in children, the platelet count to spleen size (cm) ratio and the risk score. We found that platelets, the platelet count to spleen size z score ratio, CPR, and the risk score were able to predict EV. The prevalence of EV observed in our sample was similar to those reported elsewhere^[22,26,27].

Thrombocytopenia is a common complication of chronic liver disease, affecting 76% of cirrhotic patients^[28]. Unlike in adults^[13], isolated platelet count has been described as a predictor of EV in four out of four studies of pediatric patients^[22,26,27,29]. Nevertheless, there is still no consensus as to the best cutoff points, ranging from 100 000 to 130 000^[22,26]. Gana *et al*^[27] demonstrated that platelet count (cutoff point = 115 000) was the best predictor of EV, with an area under the AUROC curve of 0.79 (95%CI: 0.69-0.90). In the present study, the cutoff of point was similar to that observed by Gana *et al*^[22] with an area under the ROC curve = 0.82 (95%CI: 0.73-0.91).

Splenomegaly is an important clinical sign of portal hypertension, especially in patients with chronic liver dis-

Table 3 Diagnostic performance of variables as esophageal varices predictors

| Variables | Sensitivity (95%CI) | Specificity (95%CI) | Positive predictive value (95%CI) | Negative predictive value (95%CI) | Positive likelihood ratio (95%CI) | Negative likelihood ratio (95%CI) |

ease^[30]. It has been used as such in several studies, both as an isolated parameter and as a component of scores or mathematical algorithms^[22,26,27,29]. In cirrhotic children

studied by Fagundes *et al*^[26] patients with splenomegaly were almost 15-fold more likely to have EV compared with those without splenomegaly. In our study, 83.5%

of patients had splenomegaly on physical examination, and, as observed by others, this variable discriminated patients with and without EV ($P = 0.001$).

Based on the premise that both thrombocytopenia and splenomegaly may depend on several factors related to chronic liver disease *per se*, Giannini *et al*^[8] proposed studying the platelet count to spleen diameter ratio as a noninvasive rule predicting EV. According to the authors, a ratio less than 909 was independently associated with the presence of EV, the negative predictive value found was reproducible even in patients with compensated disease, and it was cost effective^[8].

In our study, a platelet count to spleen size (cm) ratio < 1.0 was able to discriminate patients with and without EV ($P < 0.000$), but did not reach statistical significance on logistic regression (OR = 2.2; 95%CI: 0.65-7.43; $P = 0.203$). This could be explained by age and gender differences in spleen size. We tried to minimize the impact of this factor by using the spleen size z score, but this parameter was also not able to reach statistical significance on logistic regression (OR = 4.7; 95%CI: 0.90-20.26; $P = 0.067$). A disadvantage of considering platelet count and spleen size is that this evaluation needs to be synchronously due the great variability of both.

More recently, a systematic review and meta-analysis sought to determine the evidence on the diagnostic accuracy of platelet count to spleen diameter ratio < 909 as a noninvasive predictor of EV and concluded that the quality of evidence of these studies was low, raising questions about the reliability of the platelet count to spleen diameter ratio as a good predictor of EV. We agree with Chawla *et al*^[20] that the heterogeneity of patients studied may limit the value of this ratio as a noninvasive predictor of EV. The etiological diversity of patients in our sample may have played a role in our findings.

An interesting CPR was developed and validated by Gana *et al*^[22] in a retrospective study, using platelet count, spleen size z score and albumin as variables^[22]. In a prospective, multicenter clinical trial, a CPR ≤ 116 had a sensitivity of 81%, a specificity of 73% and an AUROC of 0.84. The authors suggested that CPR under 115 could screen patients for endoscopy^[27].

Apart from Gana *et al*^[22], we are the first group to test the CPR in children. To do so, we used two different cutoff points: 115 and 114. The best specificity was observed with a cutoff of 114 (79%). Others predictors identified by Gana *et al*^[22] were platelet count under 115 000 and serum albumin level. On multivariate analysis, CPR (OR 0.62; 95%CI: 0.45-0.84; $P = 0.002$) and albumin (OR 3.1; 95%CI: 1.5-6.7; $P = 0.004$) were independent predictors^[27]. In our study, logistic regression, adjusted for albumin, bilirubin and spleen size z score, had an OR of 7.79 (95%CI: 1.45-43.82) with a CPR cutoff of 115 and an OR of 20.74 (95%CI: 2.66-161.5; $P = 0.004$) with a CPR cutoff of 114. This mathematical algorithm is simple, composed by available and noninvasive variables, and our results suggest that it is reproducible.

The degree of fibrosis can determine significant changes in the hepatic venous pressure gradient, and seems related to complications such as the development of EV^[7]. Non-invasive markers for fibrosis have been tested in children with biliary atresia^[29,31]. There was good correlation between APRI and Metavir scores in patients studied by Kim *et al*^[31], suggesting that the APRI test could predict the appearance of fibrosis in those patients (a cutoff of 1.42 was correlated with grade 4 fibrosis).

The APRI was studied by Colecchia *et al*^[29] as a non-invasive marker of EV in pediatric patients with chronic liver disease. A cutoff > 0.96 had a total accuracy of 83%. These results were not confirmed on multivariate analysis^[29]. APRI, with a cutoff of > 1.4 , was also used as a variable in this study, and we did not find this parameter to be statistically significant for prediction of EV on logistic regression. We did not test other cutoffs. In fact, the exact thresholds of APRI for prediction of fibrosis constitute the main issue related to its diagnostic accuracy^[32].

The risk score was another clinical model tested for predicting EV in adults with advanced fibrosis and portal hypertension. The AUROC of the risk score for prediction of EV was 0.82. The -1.0 cutoff had a sensitivity of 82% and a specificity of 76%. The authors suggested that this score should be validated as a noninvasive test to detect the presence of EV^[29]. This was the first pediatric study to use the risk score. The cutoff of -1.2 had a sensitivity of 80.3%, a specificity of 70.9%, an AUROC of 0.77 (95%CI: 0.66-0.88), and an OR of 7.47 (95%CI: 2.06-26.99; $P = 0.002$). This method is also composed by simple and available variables that proved to be good noninvasive parameters for EV detection in our patients. Furthermore, this method avoids the frequent use of ultrasound. It is worth noting that this method has not been tested in patients with pre-hepatic portal hypertension, and may not be an effective method in such patients, whose bilirubin levels are usually normal.

We tried to apply all known non-invasive clinical methods for prediction of EV to the study population. According to other pediatric studies, we also found platelet count to be a good predictor of EV, with a cutoff of 115 000. Children with a CPR under 114, in a logistic regression model, were 20.7-fold more likely to have EV compared to children with CPR > 114 . More studies of this rule are required to find the optimal cutoff value.

The risk score, previously studied in adults, was a good and inexpensive predictor of EV in our patients. We believe it should be tested as a tool that can potentially limit the number of endoscopies in pediatric patients.

This study has some limitations. The retrospective design precludes blinding of the endoscopists or controlling for interobserver variability in ultrasound tests. The small number of patients with pre-hepatic portal hypertension could not be compared with those with intrahepatic portal hypertension.

In conclusion, the results of this study suggest that

platelet count, the CPR and risk score could be used to screen children with portal hypertension for endoscopy. Further studies with a prospective design are necessary to confirm these suggestions.

ACKNOWLEDGMENTS

The authors would like to acknowledge Professor Renato Borges Fagundes and Dr. Alexandre Araújo for suggestions.

COMMENTS

Background

Esophageal varices (EV) bleeding is a severe complication of portal hypertension. The standard diagnostic screening tool for EV is endoscopy, which is considered an invasive procedure in pediatric patients. Evaluate clinical and laboratory parameters for prediction of EV is very important to avoid unnecessary endoscopy, especially in children. Some studies have reported that platelet count and spleen size could be used to predict EV, but there is no agreement in the cut-off point.

Research frontiers

The development of mathematical models, such as clinical prediction rule (CPR) and risk score, that involves variables associated with intrahepatic portal hypertension seems to be promising. The research hotspot is to evaluate the parameters that could predict EV in children and reduce the indication of endoscopy.

Innovations and breakthroughs

Few previous studies in pediatric patients evaluated platelet count, CPR splenomegaly isolated in different population. The risk score was studied only in adults and aspartate aminotransferase to platelet ratio index was not used to predict EV in children. The risk score, that use platelet count and bilirubin as variables, should be used as a tool that can limit endoscopies indications in pediatric patients with the advantage of not using spleen size. The predictive value was similar to CPR and better than platelet count isolated.

Applications

The study suggests that both CPR and risk score could be used to screen children with portal hypertension for endoscopy.

Terminology

CPR is a clinical prediction rule, proposed by Gana *et al* that use as independent variables platelet count, spleen size z score (based on age and gender) and albumin. Risk score is a score proposed by Park *et al* to be used in patients with advanced fibrosis to determine clinically significant portal hypertension and was used to predict EV, using platelet count and bilirubin.

Peer review

This is a very interesting manuscript that further delineates clinical variables that are readily available and which can be used to increase the yield of endoscopy for identifying EV in children with portal hypertension. Though the variables studied have all been reported previously, the validation of these variables in children is an important extension of this work.

Abstract

AIM: To study the association between atrophic gastritis (AG) and esophageal squamous cell carcinoma (ESCC) in a Latin-America population.

METHODS: A case-control study was performed at two reference Brazilian hospitals including patients diagnosed with advanced ESCC and dyspeptic patients who had been subjected to upper gastrointestinal endoscopy, with biopsies of the gastric antrum and body.

All cases with ESCC were reviewed by a single pathologist, who applied standard criteria for the diagnosis of mucosal atrophy, intestinal metaplasia, and dysplasia, all classified as AG. The data on the patients' age, sex, smoking status, and alcohol consumption were collected from clinical records, and any missing information was completed by telephone interview. The association between AG and ESCC was assessed by means of univariate and multiple conditional logistic regressions.

RESULTS: Most patients were male, and the median age was 59 years (range: 37-79 years) in both the ESCC and control groups. Univariate analysis showed that an intake of ethanol greater than 32 g/d was an independent risk factor that increased the odds of ESCC 7.57 times ($P = 0.014$); upon multiple analysis, alcohol intake of ethanol greater than 32 g/d exhibited a risk of 4.54 ($P = 0.081$), as adjusted for AG and smoking. Smoking was shown to be an independent risk factor that increased the odds of ESCC 14.55 times ($P = 0.011$) for individuals who smoked 0 to 51 packs/year and 21.40 times ($P = 0.006$) for those who smoked more than 51 packs/year. Upon multiple analyses, those who smoked up to 51 packs/year exhibited a risk of 7.85 ($P = 0.058$), and those who smoked more than 51 packs/year had a risk 11.57 times higher ($P = 0.04$), as adjusted for AG and alcohol consumption. AG proved to be a risk factor that increased the odds of ESCC 5.33 times (95%CI: 1.55-18.30, $P = 0.008$) according to the results of univariate conditional logistic regression.

CONCLUSION: There was an association by univariate conditional logistic regression between AG and ECSS in this sample of Latin-American population.

Atrophic gastritis: Risk factor for esophageal squamous cell carcinoma in a Latin-American population. *World J Gastroenterol* 2013; 19(13): 2060-2064 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2060.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2060>

INTRODUCTION

Esophageal cancer (EC) is the eighth most common cancer worldwide with 481 000 new cases (3.8% of all cancers) estimated in 2008, and is the sixth most common cause of death from cancer with 406 000 deaths (5.4%)^[1]. The two main histological types of EC are adenocarcinoma and esophageal squamous cell carcinoma (ESCC), which differ regarding their risk factors and demographic distributions. Although adenocarcinoma has been the most frequent subtype among white males in the United States since the beginning of the 90s^[2], ESCC remains as the most frequent subtype worldwide, corresponding to more than 80% of all cases^[3]. The highest mortality rates of ESCC are found in East Asia, Southern and Eastern Africa^[1]. In Brazil, which is the largest Latin-American country, ESCC represents 96% of all cases^[4]. The main risk factors for ESCC in the West are alcohol consumption and smoking^[5,6]. An increased risk of ESCC was initially reported among patients with pernicious anemia^[7], and more recently, patients with atrophic gastritis (AG) were also found to be more susceptible^[8]. This hypothesis was strengthened by a Swedish study that assessed the association among *Helicobacter pylori* (*H. pylori*) infection, gastric mucosal atrophy, and ESCC. These researchers discovered that an infection by cytotoxin-associated gene A (CagA)-positive *H. pylori* was associated with a higher risk of ESCC, particularly among patients with gastric atrophy. When the correlation between gastric atrophy and ESCC was assessed independently from the *H. pylori* serotype, gastric atrophy exhibited a strong association with increased risk for ESCC. The authors suggest that gastric mucosal atrophy represents an intermediate step in the pathway from a CagA-positive *H. pylori* infection to ESCC^[9]. More recently, a meta-analysis^[10] selected and analyzed seven studies that investigated this association and concluded that AG increases the risk of ESCC^[3,9,11-15]. However, this meta-analysis did not address any studies that considered populations outside Northern Europe or Asia; therefore, the association has not been studied in Latin-American populations. Considering that the South American and Caribbean populations include 572 million people and represent 8.6% of the world population^[16], the present study aimed to investigate the correlation between gastric mucosal atrophy and ESCC in a sample from that unexamined population.

MATERIALS AND METHODS

All of the patients with ESCC who were treated at the

Cancer Hospital of Barretos between April 2011 and April 2012 were retrospectively analyzed. Exclusion criteria included the following: a diagnosis of obstructive ESCC, *i.e.*, where endoscopic access to the stomach was hindered; previous gastrointestinal (GI) tract surgery and age greater than 80 years. For each case, a gender- and age-matched control was randomly selected among patients who had been subjected to upper GI endoscopy due to dyspeptic complaints at the General Hospital of the Botucatu Medical School. The controls were chosen from patients with dyspeptic complaints, because in Brazil there is no protocol to screen asymptomatic individuals by means of upper GI endoscopy. Because the two centers that participated in the present study are referral centers for patients nationwide, demographic characteristics were not taken into account for matching.

Following routine protocols at both hospitals, all of the patients were subjected to endoscopic biopsies of the gastric antrum and body. The *H. pylori* infection was diagnosed by urease test (pink color after 30 min) and Warthin-Starry stain (Artisan-Dako, Denmark), was used for the visualization of *H. pylori* (with this method *H. pylori* is stained black while the background is stained golden yellow). The criteria for the diagnosis of ESCC were based on the endoscopy aspects and the final pathology report. The histopathologic features included true invasion of lamina propria, at least, by tumoral isolated cells or tumor clusters from the squamous esophagic epithelium. The cells were generally polygonal with pink cytoplasm and distinct cell borders and the nuclei were enlarged, hyperchromatic and pleomorphic. At high power intercellular bridges and keratinization within the cells were commonly seen, although they were absent in poorly differentiated tumors. The adjacent surface epithelium sometimes exhibited the same neoplastic cells, containing therefore, an intraepithelial (“*in situ*”) component. All cases with ESCC were reviewed by a single pathologist, who applied standard criteria for the diagnosis of mucosal atrophy, intestinal metaplasia, and dysplasia. All three conditions were classified as AG in the present study.

The data on the patients’ age, sex, smoking status, and alcohol consumption were collected from clinical records, and any missing information was completed by telephone interview. Alcohol consumption was calculated as grams of ethanol per day, and tobacco consumption was calculated as number of packs per year.

Statistical analysis

For statistical analysis, categorical values are given in frequencies and percentages. Means, medians, and standard deviations were calculated for numerical variables. To assess the risk factors of ESCC, univariate and multiple conditional logistic regressions were used. In addition, to assess the correlation between the use of alcohol or smoking and AG, non-conditional logistic regression was performed. The level of significance was established as 5%. Analyses were performed using software SPSS version 19 and Stata/SE. The research ethics committees of both participating centers approved the present study.

Table 1 Clinical, lifestyle, and diagnostic characteristics between cases and controls *n* (%)

| Characteristic | Category | Case | Control |
|----------------------------|-----------------|-----------|-----------|
| Gender | Female | 7 (14.3) | 7 (14.3) |
| | Male | 42 (85.7) | 42 (85.7) |
| Age group (yr) | 36-45 | 3 (6.1) | 3 (6.1) |
| | 46-55 | 14 (28.6) | 14 (28.6) |
| | 56-65 | 21 (42.9) | 21 (42.9) |
| | 66-75 | 8 (16.3) | 8 (16.3) |
| | 76-85 | 3 (6.1) | 3 (6.1) |
| Alcohol | Never drinker | 10 (20.4) | 16 (32.7) |
| | Current drinker | 39 (79.6) | 16 (32.7) |
| | Former drinker | 0 (0.0) | 17 (34.7) |
| Tobacco | No | 8 (16.3) | 24 (49.0) |
| | Yes | 41 (83.7) | 25 (51.0) |

SCC: Squamous cell carcinoma.

RESULTS

The comparison between both investigated groups is described in Table 1. Most patients were male, and the median age was 59 years (range: 37-79 years) in both the ESCC and control groups.

Only one individual in the ESCC group exhibited achalasia, and none of the patients exhibited any of the following classic risk factors: consumption of warm beverages, caustic esophagitis, squamous cell carcinoma of the head and neck, Plummer-Vinson syndrome or tylosis.

Table 2 describes the association between risk factors and ESCC. Univariate analysis showed AG to be an independent risk factor, which increased the odds of ESCC 5.332 times ($P = 0.008$). On multiple analysis, AG exhibited risk of 3.76 ($P = 0.063$), as adjusted for alcohol and smoking.

Univariate analysis showed that an intake of ethanol greater than 32 g/d was an independent risk factor that increased the odds of ESCC 7.57 times ($P = 0.014$); upon multiple analyses, alcohol intake of ethanol greater than 32 g/d exhibited a risk of 4.54 ($P = 0.081$), as adjusted for AG and smoking.

Smoking was shown to be an independent risk factor that increased the odds of ESCC 14.55 times ($P = 0.011$)

Table 2 Univariate and multiple logistic regression for case-control study according to gastric atrophy, alcohol intake, and tobacco consumption

| Variables | Univariate | | Multiple | |
|-----------------|------------------|----------------|-------------|----------------|
| | OR unadjusted | <i>P</i> value | OR adjusted | <i>P</i> value |
| Gastric atrophy | 5.332 | 0.008 | 3.76 | 0.063 |
| Alcohol | Non-drinker | 1 | 1 | |
| | 0-32 g ethanol/d | 1.29 | 0.736 | 0.98 |
| | > 32 g ethanol/d | 7.57 | 0.014 | 4.54 |
| Tobacco | No smoker | 1 | 1 | |
| | 51 pack/yr | 14.55 | 0.011 | 7.85 |
| | > 51 pack/yr | 21.40 | 0.006 | 11.57 |

OR: Odds ratio.

for individuals who smoked 0 to 51 packs/year and 21.40 times ($P = 0.006$) for those who smoked more than 51 packs/year. Upon multiple analyses, those who smoked up to 51 packs/year exhibited a risk of 7.85 ($P = 0.058$), and those who smoked more than 51 packs/year had a risk 11.57 times higher ($P = 0.04$), as adjusted for AG and alcohol consumption.

Non-conditional logistic regression assuming alcohol consumption and smoking as risk factors for AG did not find evidence for an association.

In the present study, *H. pylori* infection did not exhibit association with ESCC [odds ratio (OR) = 0.81, $P = 0.578$] and behaved as a protective factor against AG (OR = 0.3, $P = 0.009$).

DISCUSSION

Recent interest in the correlation between AG and ESCC led to a meta-analysis of seven studies from Asia and northern Europe that demonstrated an association between the conditions^[10].

The present case-control study also discovered significant statistical associations from a non-adjusted analysis between the following: AG and ESCC; heavy use of alcohol (more than 32 g of ethanol/d) and ESCC; and smoking and ESCC. Nevertheless, the use of adjusted models to investigate AG, alcohol, and smoking found a statistically significant association between ESCC and heavy smoking (more than 51 packs/d) alone. From the seven studies included in the aforementioned meta-analysis, three did not adjust their analysis for other risk factors besides AG^[12,13,15]. The fact that the associations discovered by the present study often lost statistical significance after adjustment could be explained by the small sample sizes ($n = 49$ cases, $n = 49$ controls). The loss of significance attributable to heavy alcohol consumption, in particular, corroborates this interpretation; alcohol consumption is a classic risk factor for ESCC in Western countries. de Vries *et al.*^[15] suggest that the association between AG and ESCC might be explained by confounding factors, such as smoking, after demonstrating an association between AG and small cell lung car-

cinoma. However, in the present study, univariate non-conditional logistic regression did not indicate an association between alcohol consumption or smoking with AG. It is worth noting that four other studies performed logistic regression adjusted for risk factors, and each study found a statistically significant association between AG and ESCC^[3,9,11,14].

The present study did not find an association between ESCC and *H. pylori*, which, in fact, proved to be protective against AG. Although seemingly paradoxical, this finding may be explained by the fact that *H. pylori* does not colonize atrophic mucosa nor areas with intestinal metaplasia.

This study, as well as other similar studies, encountered limitations regarding the selection of healthy controls. Although some Japanese studies, such as the one by Akiyama *et al.*^[3], have been able to use healthy controls undergoing screening upper GI endoscopy, these studies also report difficulty in selecting appropriate controls. As such screening programs do not exist in Brazil, the controls used in the present study were individuals subjected to endoscopy due to dyspeptic complaints; consequently, higher odds of exhibiting pathological findings in the GI tract may exist.

Although related literature shows an association between AG and ESCC, whether that relationship is causal is still unknown. A possible mechanism of this relationship is that achlorhydria in patients with gastric atrophy may generate an intragastric environment that favors bacterial overgrowth and n-nitrosation, thus resulting in increased exposure of the esophageal mucosa to carcinogenic endogenous nitrosamines^[17].

Other explanations for the positive association between gastric atrophy and ESCC are worth exploring. It is possible that both conditions share genetically determined pathogenetic mechanisms that facilitate a similar destructive process (*i.e.*, inflammatory response or defective DNA repair), damaging both gastric and esophageal epithelia^[15,18-20].

It is also possible that the observed association between ESCC and AG is due to the fact that patients with advanced ESCC can only ingest small amounts of food, owing to esophageal stenosis and lack of appetite, and this reduced ingestion may lead to disuse atrophy. That hypothesis, however, is contested in the study by Kamanagar *et al.*^[13], which found that a lower serum PGI/II ratio was linearly associated with higher risk of esophageal squamous dysplasia, a preneoplastic condition of ESCC. It is worth noting that patients with esophageal dysplasia do not exhibit dysphagia.

Despite the abovementioned limitations, the present study, as far as we know, is the first to identify a statistically significant association by univariate conditional logistic regression between AG and ESCC in the Latin-American population. In conclusion, in the present study the AG was an independent risk factor in this sample from Latin-America population, as has been demonstrated in studies of population samples from Asia and northern Europe. This fact highlights the importance of conducting pro-

spective, multicenter studies enrolling larger populations that represent different ethnic groups, to investigate the causal relationship between AG and ESCC.

COMMENTS

Background

Esophageal cancer (EC) is the eighth most common cancer worldwide with 481 000 new cases (3.8% of all cancers) estimated in 2008, and is the sixth most common cause of death from cancer with 406 000 deaths (5.4%). The highest mortality rates of esophageal squamous cell carcinoma (ESCC) are found in East Asia, Southern and Eastern Africa. In Brazil, which is the largest Latin-American country, ESCC represents 96% of all EC. The main risk factors for ESCC in the Western countries are alcohol consumption and smoking. More recently, a meta-analysis concluded that AG increases the risk of ESCC. However, this meta-analysis did not address any studies that considered populations outside of Northern Europe or Asia; therefore, the association has not been studied in Latin-American populations. Considering that the South American and Caribbean populations include 572 million people and represent 8.6% of the world population, the present study aimed to investigate the correlation between gastric mucosal atrophy and ESCC in a sample from that unexamined population.

Research frontiers

The better knowledge of risk factors and pathophysiological mechanisms of EC can lead to better preventive and therapeutic options in a cancer type that presents with low survival rates.

Innovations and breakthroughs

An increased risk of ESCC was initially reported among patients with pernicious anemia and more recently, patients with atrophic gastritis (AG) were also found to be more susceptible. This hypothesis was strengthened by a Swedish study that assessed the association among *Helicobacter pylori* (*H. pylori*) infection, gastric mucosal atrophy and ESCC. These researchers discovered that an infection by cytotoxin-associated gene A (CagA)-positive *H. pylori* was associated with a higher risk of ESCC, particularly among patients with gastric atrophy. When the correlation between gastric atrophy and ESCC was assessed independently from the *H. pylori* serotype, gastric atrophy exhibited a strong association with increased risk for ESCC. The authors suggest that gastric mucosal atrophy represents an intermediate step in the pathway from a CagA-positive *H. pylori* infection to ESCC.

Applications

The study results suggest an association between AG and ESCC.

Terminology

All three conditions (mucosal atrophy, intestinal metaplasia, and dysplasia) were classified as AG in the present study.

Peer review

This is a small but well conducted study that shows that also in South America AG seems to predispose to ESCC thus showing that the association can be found despite the obvious environmental differences between Asia, Europe and North America. The study thus further generalizes the hypothesis and should encourage research into the mechanism behind this.

Abstract

AIM: To elucidate the mechanisms of mesenteric vasodilation in portal hypertension (PHT), with a focus on endothelin signaling.

METHODS: PHT was induced in rats by common bile duct ligation (CBDL). Portal pressure (PP) was measured directly via catheters placed in the portal vein tract. The level of endothelin-1 (ET-1) in the mesenteric circulation was determined by radioimmunoassay, and the expression of the endothelin A receptor (ETAR) and endothelin B receptor (ETBR) was assessed by immunofluorescence and Western blot. Additionally, expression of G protein coupled kinase-2 (GRK2) and β -arrestin 2, which influence endothelin receptor sensitivity, were also studied by Western blot.

RESULTS: PP of CBDL rats increased significantly (11.89 ± 1.38 mmHg vs 16.34 ± 1.63 mmHg). ET-1 expression decreased in the mesenteric circulation 2 and

4 wk after CBDL. ET-1 levels in the systemic circulation of CBDL rats were increased at 2 wk and decreased at 4 wk. There was no change in ETAR expression in response to CBDL; however, increased expression of ETBR in the endothelial cells of mesenteric arterioles and capillaries was observed. In sham-operated rats, ETBR was mainly expressed in the CD31⁺ endothelial cells of the arterioles. With development of PHT, in addition to the endothelial cells, ETBR expression was noticeably detectable in the SMA⁺ smooth muscle cells of arterioles and in the CD31⁺ capillaries. Following CBDL, increased expression of GRK2 was also found in mesenteric tissue, though there was no change in the level of β -arrestin 2.

CONCLUSION: Decreased levels of ET-1 and increased ETBR expression in the mesenteric circulation following CBDL in rats may underlie mesenteric vasodilation in individuals with PHT. Mechanistically, increased GRK2 expression may lead to desensitization of ETAR, as well as other vasoconstrictors, promoting this vasodilatory effect.

Key words: Portal hypertension; Mesentery; Endothelin; Endothelin B receptor; G protein coupled kinase-2

Core tip: Portal hypertension (PHT) is a life-threatening condition which frequently develops in patients with liver cirrhosis, and has limited treatment options. For many years, endothelin-1 (ET-1) has received considerable interest in the area of liver cirrhosis for its potential contribution to PHT. The aim of the present study was to directly examine the expression of ET-1 and its receptors in the mesentery of rats with PHT, and to clarify how the ET-1 signaling system changed with the development of PHT.

Du QH, Han L, Jiang JJ, Li PT, Wang XY, Jia X. Increased en-

dothelin receptor B and G protein coupled kinase-2 in the mesentery of portal hypertensive rats. *World J Gastroenterol* 2013; 19(13): 2065-2072 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2065.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2065>

INTRODUCTION

Portal hypertension (PHT) is one of the most significant complications associated with liver cirrhosis, which can give rise to many other severe and often lethal conditions, such as bleeding esophageal varices. Increased resistance to portal blood flow is the primary factor leading to PHT and is aggravated by a hyperdynamic, vasodilated, splanchnic circulation^[1]. Though the pathophysiology of PHT is becoming better understood, excepting β -receptor blockers, there is no effective treatment approach for PHT. One reason to explain this shortfall is that the mechanism of splanchnic vasodilation is unclear. The organs involved in splanchnic hyperdynamic circulation are those whose blood flows into the portal vein, including the intestine, mesentery, colon, spleen and stomach. Previous studies have indicated that vasodilation of the mesenteric vascular bed plays the greatest role in PHT, by increasing portal inflow^[2]. In previous work from our laboratory, we also observed vasodilation of the mesenteric vascular bed; thus in the present study we focused on this tissue to try to explain splanchnic vascular dilation and possibly to identify new therapeutic targets for treating PHT.

Splanchnic vasodilation is associated with the imbalance of vasoactive mediators^[3,4] and hyporeactivity to vasoconstrictors^[5]. Endothelin-1 (ET-1) is a potent endothelium derived vasoactive peptide. For many years, ET-1 has received considerable interest in the area of liver cirrhosis for its potential contribution to PHT^[6-9]. This has led to many studies being focused upon the effect of ET-1 and its receptors in the liver; however, there are only a few studies examining the possible mechanism of the endothelin signaling system in hyperdynamic circulation. It has been established that the divergent effect of ET-1 on blood vessels depends on the different expression of endothelin receptors on smooth muscle and endothelial cells^[10]. There are two known types of ET-1 receptor: the endothelin A receptor (ETAR) and the endothelin B receptor (ETBR)^[11]. ETBR has two recognized subtypes: ETB1 and ETB2^[10-13]. ETAR and ETB2 are predominantly expressed in vascular smooth muscle cells, whereas ETB1 is characteristic of endothelial cells. ET-1 binds to ETAR and ETB2 to induce vasoconstriction, while ET-1 binds to ETB1 to cause vascular relaxation^[14]. Both mixed ETAR-ETBR antagonists and selective ETBR antagonists have been proven to decrease portal pressure (PP) and increase mean arterial pressure (MAP), while ETAR antagonists have been shown to have no effect on MAP^[14,15]. Moreover, selective ETBR inhibition *in vivo* significantly ameliorated hepatopul-

monary syndrome (HPS)^[16-18], which is also known to be caused by dilation of the microcirculation, similar to PHT^[18]. Based on this literature, we speculate that ETBR may play a primary role in the hyperdynamic circulation associated with PHT.

In addition to the localization and expression level of ET-1, its signaling is known to be affected by other regulators. For example, it has been observed that in some instances of high splanchnic ET-1 expression, the vascular bed of this tissue was still dilated, leading the authors to speculate that the sensitivity of the ET-1 receptor(s) was decreased^[19]. Endothelin receptors may be desensitized by phosphorylation through G-protein-coupled receptor kinases (GRKs) and binding of β -arrestin 2^[20]. So far, seven kinds of GRKs have been cloned^[21]. GRK2 is the most likely of the GRKs to initiate human human endothelin A and B receptor desensitization^[22]. Endothelin signalling in arterial smooth muscle is tightly regulated by GRK2^[23]. As such, in this study we also focused on two known regulators, GRK2 and β -arrestin 2. The current literature has indicated a possible role for ET-1 signaling in splanchnic vasodilation, though there is a lack of experimental data to support this hypothesis. The aim of the present study was to directly examine the expression of ET-1 and its receptors in the mesentery of rats with PHT, and to clarify how the ET-1 signaling system changed with the development of PHT.

MATERIALS AND METHODS

Animal models

Male Sprague-Dawley rats (approximately 250 g; Vital River Laboratory Animal Technology Co. Ltd., Beijing, China) underwent sham surgery or common bile duct ligation (CBDL). In brief, the common bile ducts of rats were exposed after median laparotomy and ligated twice. In each animal, the segment between the 2 ligations was resected, and the animal's abdomen was sutured closed. Sham-operated rats served as controls. In these rats, the common bile duct was exposed, but no ligation or resection was performed. Seven animals were used in each group. The study was approved by the local committee for animal studies.

Measurement of portal blood pressure and ET-1

In brief, after 2 wk or 4 wk following CBDL, a PE-50 catheter was inserted into the portal vein to measure portal blood pressure. After stable recordings of portal venous pressure were obtained, blood was drawn from the superior mesenteric artery (SMA) for further analysis. The level of ET-1 was measured in the mesenteric circulation using a commercial RIA kit (PLA Institute of RIA, Beijing, China) according to the manufacturer's protocol.

Immunofluorescence

For immunofluorescence double staining of ETAR and ETBR, mesentery tissues were harvested at 2 and 4 wk

and fixed in 4% neutral paraffin. After antigen retrieval, all sections were incubated with PBS containing 1% bovine serum albumin (block buffer) for 60 min in a wet chamber at room temperature. Then, for ETAR, sections were incubated with primary anti-ETAR (polyclonal antibody; Santa Cruz Biotechnology, Santa Cruz, CA; 1:100 dilution) and anti-smooth muscle actin SMA (Santa Cruz Biotechnology, Santa Cruz, CA, United States; 1:200 dilution); for ETBR, slides were incubated with primary anti-ETBR (polyclonal antibody; Santa Cruz Biotechnology, Santa Cruz, CA, United States; 1:300 dilution) and anti-CD31 (polyclonal antibody; Santa Cruz Biotechnology, Santa Cruz, CA, United States; 1:100 dilution) antibodies at 4 °C overnight. Then all sections were washed with PBS. For the ETAR, the slides were incubated with goat anti-rabbit/mouse secondary antibodies at the same time. For the ETBR, the sections were incubated with rabbit anti-sheep and goat anti-rabbit antibodies at the same time (Invitrogen, San Diego, CA, United States) for 1 h at room temperature. Subsequently, sections were washed with phosphate-buffered saline (PBS). Control sections were incubated with secondary antibody in the absence of primary antibody. The results were analyzed using confocal laser scanning microscope.

Western blot analysis

For Western blot analysis, samples of rat mesentery were homogenized in radio immunoprecipitation assay (RIPA) lysis buffer containing 50 mmol/L Tris (pH 7.4), 150 mmol/L NaCl, 1% Triton X-100, 1% sodium deoxycholate, 0.1% sodium dodecyl sulfate (SDS), 5 mmol/L ethylenediamine tetraacetic acid, 1 mmol/L sodium orthovanadate, 20 mmol/L pepstatin A, 20 mmol/L leupeptin and 1 mmol/L phenylmethanesulfonyl fluoride. The protein content of the cleared homogenates was assessed with bicinchoninic acid assay kit (Applygen, Beijing, China). After boiling with SDS sample buffer (Applygen, Beijing, China), 50 µg of protein per lane of each sample was subjected to SDS-polyacrylamide gel electrophoresis (10% gels for GRK2, 12.5% gels for ETAR, ETBR and β-arrestin 2). After blotting on polyvinylidene difluoride membrane (Millipore, Bedford, MA, United States), the membranes were probed with primary antibodies diluted in TBS containing blocking protein and 0.1% Tween, and left to incubate overnight at 4 °C. The following primary antibodies in the indicated dilutions were used: mouse anti-GRK2, 1:500 (Abcam); rabbit anti-ETAR/ETBR and mouse β-arrestin 2, 1:200 (Santa Cruz Biotechnology, Santa Cruz, CA, United States). Thereafter, the membranes were washed and incubated with appropriate peroxidase-coupled secondary antibodies diluted 1:5000 in TBS containing blocking protein and 0.1% Tween for 45 min (goat anti-rabbit or goat anti-mouse; Jackson, West Grove, PA, United States). Detection was performed with enhanced chemiluminescence (Applygen, Beijing, China), and films were developed using Kodak film. Densitometric quantification was performed using Phoretix 1D gel image analysis software for free.

Statistical analysis

All data are presented as the mean ± SD; statistical comparisons were performed using one way analysis of variance. Physiological and biochemical findings represent averages of seven rats. Results of molecular assays represent averages of samples from at least five rats in each group. *P* values < 0.05 were considered statistically significant.

RESULTS

Increased PP following CBDL

PP was measured in sham and experimental rats 2 and 4 wk after CBDL; PP of CBDL rats increased significantly (16.34 ± 1.63 mmHg *vs* 11.89 ± 1.38 mmHg for sham-operated animals). The increase in PP in CBDL rats was statistically significant compared with sham-operated rats at the 2 and 4 wk timepoint (*P* < 0.005).

Concentration of ET-1 in the mesenteric and systemic circulation

The concentration of ET-1 was measured in the mesenteric and systemic circulation 2 and 4 wk after CBDL. At 2 and 4 wk, ET-1 levels in the mesenteric circulation of CBDL rats were 92.09 ± 13.26 pg/mL and 100.35 ± 16.36 pg/mL, which were significantly lower than that in sham-operated rats. Furthermore, in the systemic circulation, compared with sham-operated rats, ET-1 levels of CBDL rats were also significantly increased at 2 wk (142.77 ± 27.67 pg/mL); however, systemic ET-1 levels were decreased at 4 wk (88.62 ± 15.40 pg/mL).

ETAR and ETBR immunofluorescence

The expression pattern of ETAR and ETBR in mesenteric tissues was determined by immunofluorescence (Figures 1 and 2). From these pictures, the expression of ETAR was observed on SMA⁺ smooth muscle cells (Figure 1). In sham-operated rats, ETBR was mainly expressed in CD31⁺ endothelial cells of the vasculature, though the microcirculation also had weak immunostaining (Figure 2A). Our data indicates that with PHT development, in addition to endothelial cells, ETBR expression was noticeably detectable in the CD31⁺ capillaries (Figure 2B and C). We also noted increased vasodilation in the mesentery and formation of hyperdynamic circulation in CBDL rats, which was associated with increased angiogenesis (Figure 2B and C).

Quantification of ETAR, ETBR, GRK2 and β-arrestin 2 expression by Western blot

To confirm our immunofluorescence results, we investigated ETAR and ETBR expression by Western blot; we also used this method to assess GRK2 and β-arrestin 2 expression, as it relates to the sensitivity of the ET-1 receptors during the development of a hyperdynamic circulation (Figure 3). In agreement with our immunostaining, we found no statistically significant difference in ETAR expression between sham-operated and CBDL

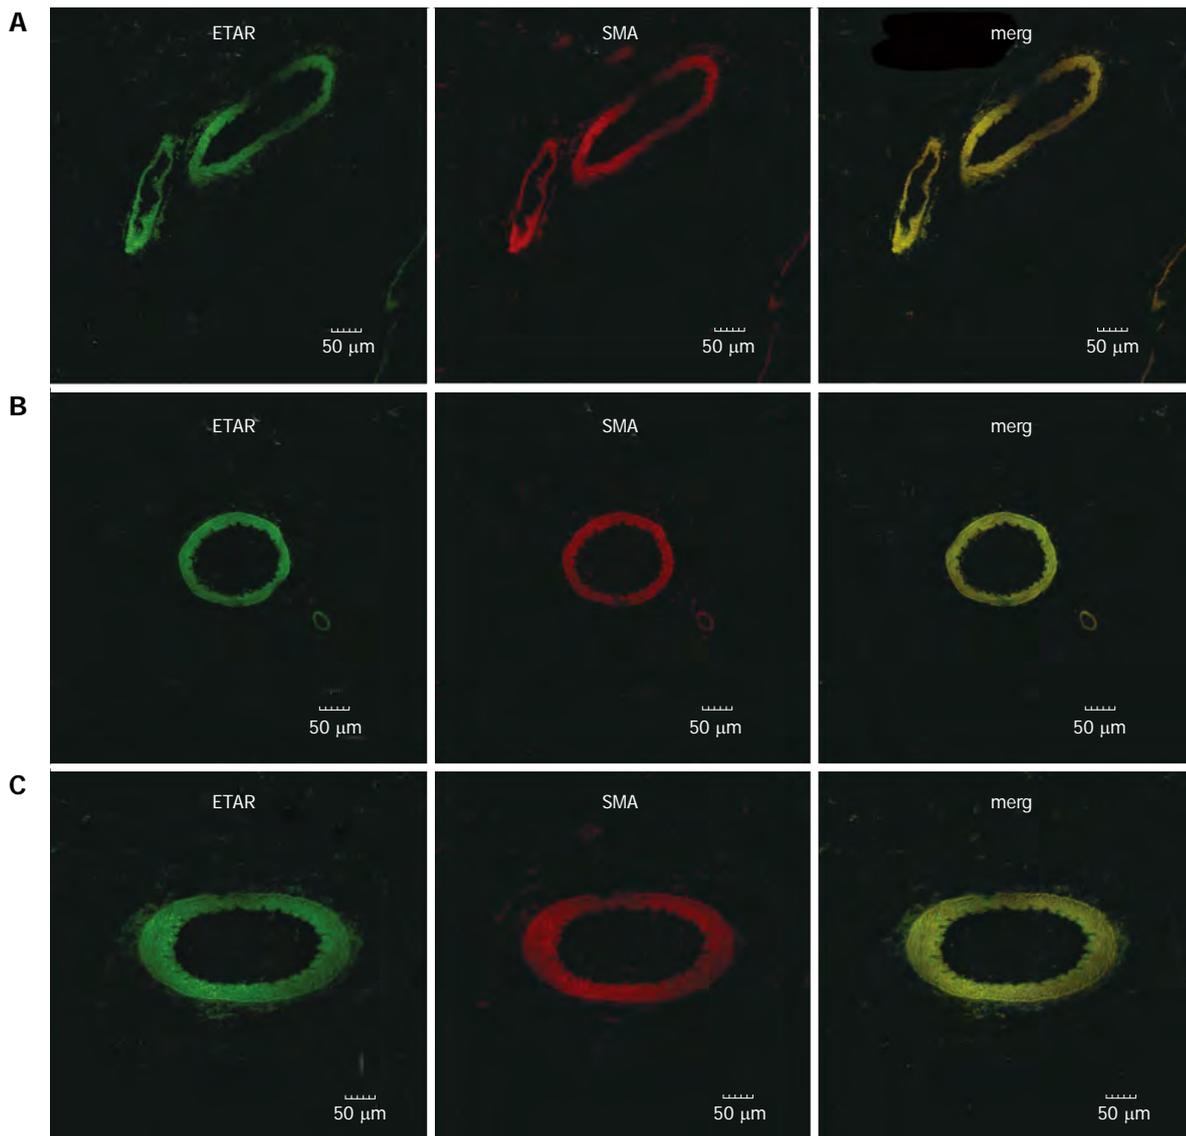

Figure 1 Expression of endothelin A receptor in rat mesentery. Expression of endothelin A receptor (ETAR, green) on smooth muscle cells (red) in mesentery of sham-operated rats (A), and common bile duct ligation rats at 2 wk (B) and 4 wk (C). ETAR was expressed extensively in smooth muscle cells of the vascular.

rats at the 2 and 4 wk timepoints (Figure 3A). ETBR was significantly upregulated in CBDL rats after 2 wk ($P < 0.01$) and 4 wk ($P < 0.01$), as compared to sham-operated rats (Figure 3B). Similar to previous research, which has shown that GRK2 levels are increased in the aortas of CBDL rats^[24], we also observed an upregulation of GRK2 protein levels in the mesentery of CBDL rats at both timepoints, which was statistically significant ($P < 0.005$; Figure 3C). We also observed no significant change in the protein expression level of β -arrestin 2 between sham-operated and CBDL rats after 2 or 4 wk ($P > 0.05$; Figure 3D).

DISCUSSION

In accordance with Ohm's law, PP depends on intrahepatic resistance and portal inflow. In cases of cirrhosis, both intrahepatic resistance and splanchnic blood flow are increased. The initiating factor is an increase in in-

trahepatic vascular resistance, whereas the increase in splanchnic blood flow is a secondary phenomenon that maintains or worsens the increased PP and gives rise to the hyperdynamic systemic state^[25]. In terms of the relevant literature^[16,17], it has been speculated that the ET-1 signaling system may play an important role in the hyperdynamic circulation, even though there is no direct experimental evidence. Moreover, there are also articles about endothelin receptor antagonism treatment in humans with PHT^[26,27]. In this regard, this is the first *in vivo* study examining the expression of the ET-1 signaling system in the mesentery of PHT rats.

We have found that the concentration of ET-1 in the mesenteric circulation decreases as the liver becomes fibrotic. We also found that ETBR expression, but not ETAR expression, increased in vascular smooth muscle cells and in the microcirculation of mesentery tissue, which may mean decreased vasoconstriction and increased vasodilatation induced by local ET-1 in the mesen-

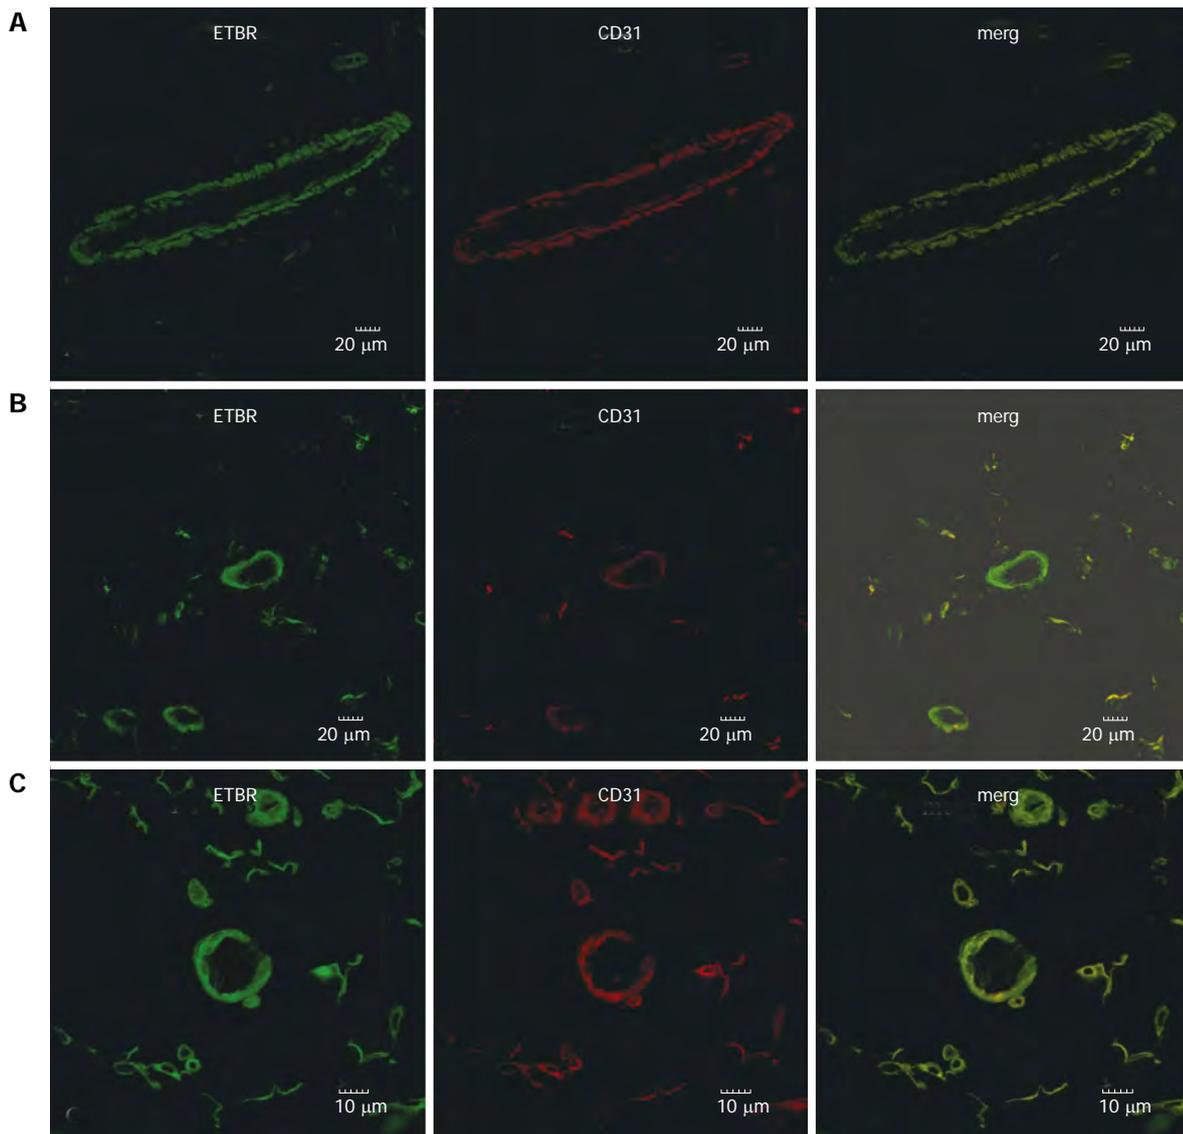

Figure 2 Expression of endothelin B receptor in rat mesentery. Expression of endothelin B receptor (ETBR) in the mesentery of sham-operated rats (A), and common/L on bile duct ligation rats at 2 wk (B) and 4 wk (C). In the mesentery of sham-operated rats, ETBR (green) was mainly expressed in CD31⁺ endothelial cells (red) of the vascular, with weak staining in the microcirculation. With portal pressure rising, ETBR expression was detected in the smooth muscle cells of arterioles and the microcirculation.

tery of PHT rats. Furthermore, the expression of GRK2 increased significantly in CBDL rats, which may imply that desensitization of ETAR and other vasoconstrictor receptors also promotes splanchnic vasodilatation.

The ET-1 signaling system is associated with vascular dysfunction at three levels, changes in: ET-1 concentration, ET-1 receptor expression and sensitivity, and the ET-1 signaling transduction pathway. Thus, the ability to modulate ET-1 signaling at either of these levels may provide ways to improve splanchnic vascular dysfunction. Previous studies have shown that ET-1 was upregulated in the liver tissue and systemic circulation of patients^[9], but the expression level of ET-1 in the splanchnic circulation is not consistent. The observed decrease in ET-1 in the splanchnic circulation 2 and 4 wk after CBDL leads us to speculate that one reason for mesenteric vascular bed dilation in this model is a local

decrease in ET-1.

ET-1 must bind to its receptor to modulate vascular tone, so variations in receptor subtype expression and quantity affect the action of ET-1 on blood vessels. Using an animal model of HPS, which is also applicable to PHT, it was found that the extensive dilation of the pulmonary microcirculation was related to a selective increase in ETBR expression^[16,17]. PHT and HPS can both be induced by CBDL in rats, and dilation of the microcirculation exists in both syndromes, raising the question whether ET-1 signaling through ETBR plays the same role in the hyperdynamic circulation as it does in HPS? Further research will be required to address this important question and establish if this hypothesis is correct. In the present study, we observed that ETAR expression in the mesentery was not different between sham-operated and CBDL rats. Interestingly however, ETBR expression

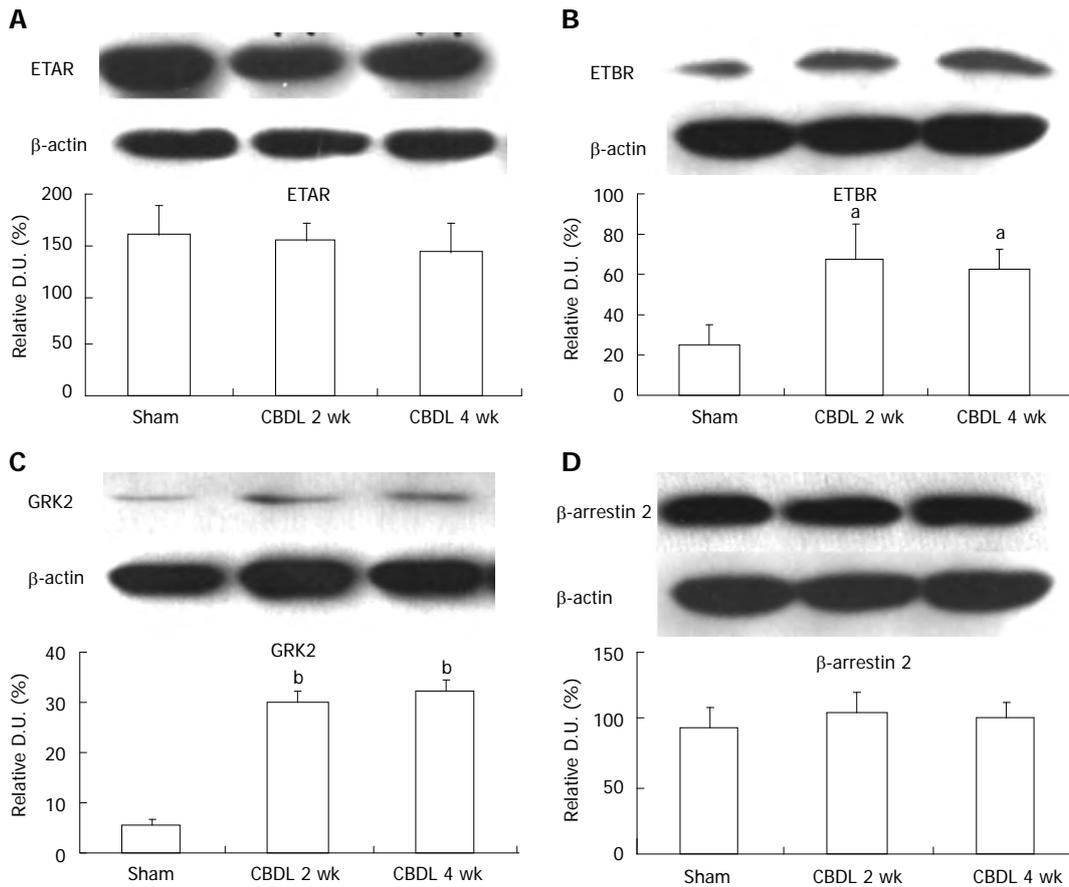

Figure 3 Western blots of endothelin A receptor (A), endothelin B receptor (B), G protein coupled kinase-2 (C) and β -arrestin 2 (D) in rat mesentery. Expression of the investigated proteins in mesentery from sham-operated rats and mesentery from common bile duct ligation (CBDL) rats was compared by Western blot. Representative Western blots are shown for each protein and densitometric quantification of all experiments are provided (data are mean \pm SE; $n = 3-6$ /group). ^a $P < 0.05$, ^b $P < 0.01$ for CBDL rats vs sham-operated rats. ETAR: Endothelin A receptor; ETBR: Endothelin B receptor; GRK2: G protein coupled kinase-2; D.U.: Densitometric units.

was obviously increased by CBDL. Our immunofluorescence data indicates that, under normal physiological conditions, ETBR is primarily expressed in the endothelial cells of the vasculature, whereas the microcirculation also has weak positive staining. With the development of liver fibrosis and liver cirrhosis, ETBR was not only expressed in endothelial cells but was also strongly observed in the microcirculation. Given that the primary function of the microcirculation is to accumulate blood, we interpreted from our data that in the mesentery of CBDL rats, signaling through ETBR mediates vasodilation *via* release of nitrogen oxide from endothelial cells, leading to an increased blood volume. It is possible that ETBR expression in the smooth muscle cells is a compensatory mechanism to facilitate contraction of blood vessels and oppose the overdilation. Analysis of ETBR by Western blot confirmed the increase in expression following CBDL. Though we observed immune-positive staining for both ETAR and ETBR in fat tissue, this would not affect our Western blot data because the fat tissue in mesentery cannot be dissolved by the RIPA lysis buffer and was discarded during homogenization.

ET-1 binds to its Gq protein-coupled receptor to send an extracellular signal into the cell, an event which is limited by the sensitivity of the receptor. Under nor-

mal conditions, the receptor is desensitized to prevent excessive stimulation by vasoactive substances. Available experimental evidence demonstrates that augmentation of receptor sensitivity, by factors like norepinephrine, vasopressin, ET-1 or angiotensin, impairs the transduction of vasoconstrictor signals and promotes dilation of the splanchnic vascular bed^[24]. It is known that GRKs and arrestins are key participants in the canonical pathways leading to phosphorylation-dependent or independent G protein-coupled receptor desensitization and endocytosis^[28]. GRK2 is one member of the GRK family and has been shown to be able to specifically phosphorylate human ETAR and ETBR^[20]. Our findings demonstrate that the increased PP following CBDL resulted in an upregulation of mesenteric GRK2 expression, but not β -arrestin 2. GRK2 and β -arrestin 2 may modulate ETAR and ETBR desensitization through the following mechanisms: (1) phosphorylation of ETAR by GRK2 promotes the receptor binding to β -arrestin 2, which blocks the activation of the G proteins and leads to rapid homologous desensitization; and (2) independent of phosphorylation, GRK2 interacts with G alpha(q) directly, which results in uncoupling of ET-1 receptor and its associated G proteins, thus impairing the ET-1 signal transduction pathway^[29]. Increased GRK2 expression in the mesentery of

PHT rats not only results in desensitization of ETAR, but also the receptors of norepinephrine and angiotensin, which indicates that such vasoactive substances are unable to mediate vasoconstriction, regardless of ligand concentration or the level of receptor expression.

In summary, PHT induced by CBDL in rats was associated with decreased levels of ET-1 in the mesenteric circulation, and increased mesenteric expression of ETBR and GRK2. We conclude that these changes underlie mesenteric vasodilation in an animal model of PHT, and are also applicable to patients with this condition. We interpret our data to indicate that the ET-1 signaling pathway is an important factor in the development of splanchnic vasodilation associated with PHT. These findings have major therapeutic implications not only for individuals with liver disease, but also for other diseases with vascular dysfunction.

COMMENTS

Background

Portal hypertension (PHT) is a life-threatening condition which frequently develops in patients with liver cirrhosis, and has limited treated options. During PHT, vasodilation results in increased blood flow into the mesenteric circulation, thereby increasing flow into the portal circulation, which can worsen PHT. For many years, endothelin-1 (ET-1) has received considerable interest in the area of liver cirrhosis for its potential contribution to PHT. The aim of the present study was to directly examine the expression of ET-1 and its receptors in the mesentery of rats with PHT, and to clarify how the ET-1 signaling system changed with the development of PHT.

Research frontiers

PHT can give rise to many other severe and often lethal conditions, such as bleeding esophageal varices. Increased resistance to portal blood flow is the primary factor leading to PHT and is aggravated by a hyperdynamic, vasodilated, splanchnic circulation. Though the pathophysiology of PHT is becoming better understood, excepting β -receptor blockers, there is no effective treatment approach for PHT. One reason to explain this phenomenon is that the mechanism of splanchnic vasodilation is unclear. So in this study, the authors choose mesentery tissue of hypertensive rats to research the mechanisms of vasodilation based on ET-1 and its receptors.

Innovations and breakthroughs

The current literature has indicated a possible role for ET-1 signaling in splanchnic vasodilation, though there is a lack of experimental data to support this hypothesis. This is the first *in vivo* study examining the expression of the ET-1 signaling system in the mesentery of PHT rats.

Applications

These findings have major therapeutic implications not only for individuals with liver disease, but also for other diseases with vascular dysfunction.

Terminology

PHT is the main complication of cirrhosis and is defined as a hepatic venous pressure gradient (HVPG) of more than 5 mmHg. Clinically significant PHT is defined as HVPG of 10 mmHg or more; Hyperdynamic circulation: The hyperdynamic circulatory state of PHT is characterized by splanchnic and peripheral vasodilation, increased plasma volume and increased cardiac output.

Peer review

In this paper, the authors show that expression of G protein coupled kinase-2 is downregulated while expression of the endothelin B receptor is increased in the mesentery after common bile duct ligation, a model for PHT. These findings are interesting and might represent some mechanisms underlying vasodilatation in the mesentery.

Abstract

AIM: To evaluate the expression of galectin-1 and vascular endothelial growth factor (VEGF) in gastric cancer and investigate their relationships with clinicopathologic factors and prognostic significance.

METHODS: Galectin-1 and VEGF were immunohistochemically investigated in tumor samples obtained from 214 gastric cancer patients with all tumor stages. Immunohistochemical analyses for galectin-1 and VEGF expression were performed on formalin-fixed, paraffin-embedded sections of surgical specimens. The relationship between the expression and staining intensity of galectin-1 and VEGF, clinicopathologic variables, and patient survival were analyzed. All patients underwent follow-up until cancer-related death or more than five years after tumor resection. *P* values < 0.05 were considered statistically significant.

RESULTS: Immunohistochemical staining demonstrated that 138 of 214 gastric cancer samples (64.5%) were positive for galectin-1, and 116 out of 214 gastric cancer samples (54.2%) were positive for VEGF. There was a significant association between galectin-1 and VEGF expression; VEGF was detected in 60.1% of galectin-1-positive samples and 43.4% of galectin-1-negative samples (*P* < 0.05). Galectin-1 expression was associated with tumor size, tumor location, stage, lymph node metastases, and VEGF expression (all *P* < 0.05). VEGF expression was related to tumor size, stage, and lymph node metastases (all *P* < 0.05). The 5-year survival rate was 56.6% for galectin-1-positive patients and 69.2% for galectin-1-negative patients, and the prognosis for galectin-1-positive patients was significantly poorer compared with galectin-1-negative patients ($\chi^2 = 13.880$, *P* = 0.000). The 5-year survival rates for VEGF-positive and VEGF-negative patients were 53.4% and 70.5%, respectively ($\chi^2 = 4.619$, *P* = 0.032). The overall survival rate of patients with both galectin-1 and VEGF overexpression in gastric cancer tissue samples was significantly poorer than other groups (both *P* < 0.05).

CONCLUSION: Galectin-1 expression was positively associated with VEGF expression. Both galectin-1 and VEGF can serve as independent prognostic indicators of poor survival for gastric cancer after gastrectomy.

Key words: Galectin-1; Vascular endothelial growth factor; Gastric cancer; Prognosis

Core tip: Galectin-1 and vascular endothelial growth factor (VEGF) played important roles in angiogenesis and progression of malignant tumor, while their expression in Chinese gastric cancer and relationship between the two parameters and clinicopathological features, as well as prognostic value remained largely unknown. In this present study, we examined 214 gastric cancer samples

for the presence of galectin-1 oncoprotein and VEGF by immunohistochemistry and found that overexpressions of galectin-1 and VEGF were related with tumor progression and poor survival, and our findings supported an association between galectin-1 and VEGF expression. These two molecules may serve as independent predictive markers for patient prognosis in gastric cancer.

Chen J, Zhou SJ, Zhang Y, Zhang GQ, Zha TZ, Feng YZ, Zhang K. Clinicopathological and prognostic significance of galectin-1 and vascular endothelial growth factor expression in gastric cancer. *World J Gastroenterol* 2013; 19(13): 2073-2079 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2073.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2073>

INTRODUCTION

Gastric cancer is one of the most common cancers in the world. It is the second leading cause of cancer death after lung cancer^[1,2]. The incidence of gastric cancer is highest in Eastern Asia, including China, Japan and South Korea^[3]. Despite advances in diagnostic techniques, neoadjuvant chemoradiotherapy, and surgery, the 5-year survival rate for gastric cancer remains poor, particularly in more advanced stages^[4]. Recently, therapeutic strategies have been improved by the availability of monoclonal antibodies. Additionally, studies have evaluated new biologic and molecular targets for their potential roles as prognostic markers and targets for therapy in patients with gastric cancer.

Galectin-1, a β -galactoside-binding protein, is a 14 kDa homodimer and the first protein discovered in the galectin family^[5-7]. Accumulating evidence clearly shows that galectin-1 is involved in numerous essential cancer-related processes, including immunosuppression, angiogenesis, and metastasis^[8-15]. Galectin-1 overexpression in tumor stromal cells has been detected in several malignant tumors, such as colon cancer^[16], breast cancer^[17], hepatocellular cancer^[18], prostate cancer^[19], and pancreatic ductal adenocarcinoma^[20]. Furthermore, high galectin-1 expression was shown to correlate with poor survival in several types of cancer^[21-25].

Vascular endothelial growth factor (VEGF) is an angiogenic factor produced by tumor cells that stimulates intratumoral microvessel proliferation. Angiogenesis is a fundamental process in tumor growth and metastasis, and it contributes to the metastatic process by providing large numbers of leaking blood vessels for vascular invasion^[26,27]. VEGF is the most potent and specific promoter of tumor angiogenesis^[28]. It is able to stimulate the growth of epithelial cells of various origins, promote vasculature construction, and enhance blood vessel permeability, especially microvessels^[29]. A few published studies have shown that VEGF overexpression in gastric cancer is associated with poor prognosis^[30-32]. However, no previous studies have clarified the correlation between

galectin-1 and VEGF overexpression in gastric cancer. In this study, we performed immunohistochemical staining and extensively examined galectin-1 and VEGF expression in gastric cancer tissues. The aims of this study were to determine whether the expression levels of galectin-1 and VEGF were correlated with each other and with clinicopathological features and prognosis, including patient survival.

MATERIALS AND METHODS

Patient information

From January 2004 to October 2006, a total of 214 patients with gastric cancer who underwent gastrectomy at the Department of General Surgery of the Affiliated Hospital of Jiangsu University were enrolled in this retrospective study. There were 129 men and 85 women between the ages of 31 and 84 years (mean, 64.5 years). None had received chemotherapy or radiotherapy before surgery. Follow-up was completed on 30 October 2012. Patient clinicopathologic parameters were collected, including age, gender, differentiation, and pathological tumor-node-metastasis classification (according to the International Union Against Cancer).

Immunohistochemistry

Immunohistochemical analyses of galectin-1 and VEGF expression were performed on formalin-fixed, paraffin-embedded sections of surgical specimens. Tissue microarray blocks were serially cut into 4 μ m-thick sections and stained. Paraffin sections were deparaffinized in xylene and rehydrated in a gradient of ethanol solutions. Endogenous peroxidases were blocked with 3% hydrogen peroxide in methanol for 10 min. The slides were immersed in 10 mmol/L citrate buffer (pH 6.0) and heated for 30 min for antigen retrieval. The slides were then cooled at room temperature for 20 min and washed with phosphate-buffered saline (PBS). Non-specific binding was blocked by pre-incubation with 10% fetal calf serum in PBS with 0.01% sodium azide. The slides were then incubated in a humidified chamber for 1 h with antibodies against galectin-1 (titer 1:100, New Castle, United Kingdom) and VEGF (titer 1:50, DakoCytomation, Denmark). After washing three times in PBS, the slides were incubated with the envision-HrP complex (undiluted; Dako) for 60 min and visualized with diaminobenzidine and counterstained with hematoxylin. For substitute negative controls, the primary antibodies were replaced with PBS. Positive controls were provided by the kit supplier. The results were assessed by two independent pathologists who had no knowledge of the patient clinical status.

Evaluation of immunohistochemical staining

A scoring system was used to evaluate the immunoreactivity of gastric cancer. Galectin-1 staining was scored semiquantitatively using the following criteria: 0, no staining and less than 10% of tumor cells or stromal cells with membrane staining; 1+, more than 10% of tumor cells or stromal cells with faint partial membrane staining; 2+,

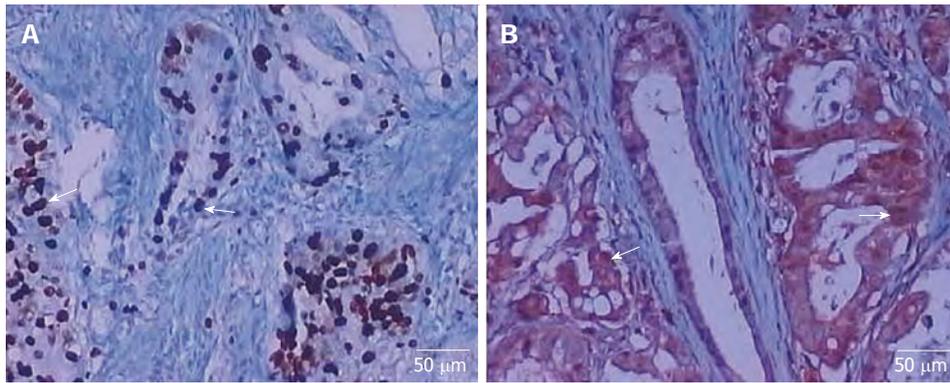

Figure 1 Immunohistochemical staining for galectin-1 and vascular endothelial growth factor (original magnification, $\times 200$). A: Positive galectin-1 expression in gastric cancer tissue; B: Positive vascular endothelial growth factor expression in gastric cancer tissue. The over-expressed markers are shown with arrows.

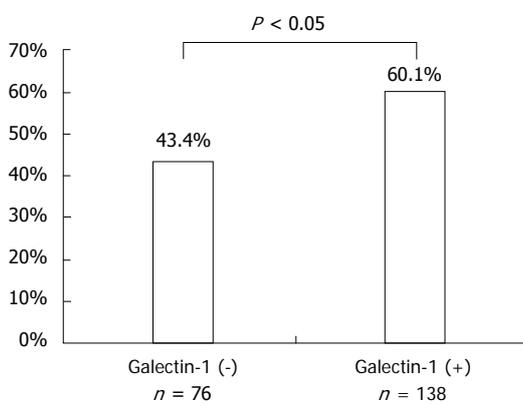

Figure 2 Vascular endothelial growth factor was expressed more frequently in galectin-1-positive gastric cancers than galectin-1-negative.

more than 10% of tumor cells or stromal cells with weak to moderate partial membrane staining; 3+, more than 10% of tumor cells or stromal cells with strong partial membrane staining. Specimens with scores of 0 or 1+ were considered negative, and scores of 2+ or 3+ were considered positive for galectin-1 expression. VEGF staining was considered positive when at least 10% of the tumor cells were stained, as previously described^[33,34].

Follow-up

Patients underwent continuous follow-up up to September 2012. No patients were lost to follow-up. The median follow-up duration was 48.5 mo (range, 0-60 mo) after surgery.

Ethics

This work was performed in accordance with the Declaration of Helsinki of the World Medical Association. This study was ethically approved by the Affiliated Hospital of Jiangsu University (JSUH-EC-189923). All patients provided written informed consent.

Statistical analysis

Statistical analyses were performed with SPSS 16.0 for Windows (SPSS, Chicago, IL, United States). The correlations between galectin-1 and VEGF expression and

clinicopathological features were analyzed using the χ^2 test. The Kaplan-Meier test was employed to evaluate the survival rate, and the survival rate curves were compared using the log-rank test. P values < 0.05 were considered statistically significant.

RESULTS

Galectin-1 and VEGF expression in gastric cancer tissues

Galectin-1 expression in tumor stromal cells was detected in 197 (92.1%) of 214 tumor tissues. Galectin-1 expression was positive in 138 out of 214 gastric cancer samples (64.5%) and negative in the remaining 76 samples (35.5%); 86 samples were 2+ (40.2%), and 52 were 3+ (24.3%). VEGF expression was positive in 116 of 214 gastric cancer samples (54.2%) and negative in the remaining 98 samples (45.8%); 30 samples were 1+ (14.0%), 53 were 2+ (24.8%), and 33 were 3+ (15.4%). Figure 1 shows galectin-1 and VEGF staining in gastric cancer tissues.

Correlation between galectin-1 and VEGF expression and clinicopathological features

There was a significant association between galectin-1 and VEGF expression; VEGF was detected in 60.1% of galectin-1-positive tumors and 43.4% of galectin-1-negative tumors ($P < 0.05$, Table 1, Figure 2). The correlations between galectin-1 and VEGF expression and clinicopathological features are shown in Table 2. Galectin-1 expression was positively associated with tumor size, tumor location, stage, and lymph node metastases (all $P < 0.05$), but it was not correlated with gender, age, or differentiation grade (all $P > 0.05$). VEGF expression was positively correlated with tumor size, stage, and lymph node metastases (all $P < 0.05$), but it was not correlated with the other clinicopathological features assessed (all $P > 0.05$).

Correlation between galectin-1 and VEGF expression and patient survival

All patients underwent follow-up until cancer-related death or more than five years after tumor resection. The median follow-up interval was 48.5 mo. The 5-year sur-

Table 1 Relationship of galectin-1 and vascular endothelial growth factor expression in gastric cancer tissues

| VEGF | Galectin-1 | | P value |

| | Positive (n = 138) | Negative (n = 76) | |
| Positive (n = 116) | 83 | 33 | 0.022 |
| Negative (n = 98) | 55 | 43 | |

VEGF: Vascular endothelial growth factor.

vival rate was 56.6% for galectin-1-positive patients and 69.2% for galectin-1-negative patients, and the prognosis for galectin-1-positive patients was significantly poorer than that of galectin-1-negative patients ($\chi^2 = 13.880$, $P = 0.000$). The 5-year survival rates for VEGF-positive and VEGF-negative patients were 53.4% and 70.5%, respectively ($\chi^2 = 4.619$, $P = 0.032$). Additionally, VEGF-positive patients had a shorter survival time than VEGF-negative patients. The cumulative overall survival rates for these two populations were determined (Figure 3A and B).

To evaluate the combined effect of galectin-1 and VEGF expression on the prognosis of gastric cancer, we classified patients into four subgroups according to galectin-1 and VEGF expression: group I, low expression of both markers; group II, high galectin-1 expression and low VEGF expression; group III, low galectin-1 expression and high VEGF expression; and group IV, high expression of both markers. We found that the 5-year survival rate in group IV was 40.9%, which was significantly lower compared with groups I (53.5%), II (49.1%), and III (48.5%) (Figure 3C, $P < 0.05$).

DISCUSSION

Despite the development of surgical techniques and new cytotoxic agents, which have improved the prognosis of gastric cancer, once patients develop resistance to chemotherapeutic regimens, no other treatment options are available. Given the frequent failure of conventional treatment strategies, many cancer-related molecules have been characterized with the goal of developing novel anticancer therapies^[35]. To guide clinical decision making in therapy and prognosis prediction, efforts have been made to identify prognostic biomarkers for patients with gastric cancer.

Galectin-1 is a β -galactoside-binding protein that is abundantly secreted by almost all types of malignant tumor cells. Galectin-1 expression is regulated by hypoxia-inducible factor-1, and it plays vital protumorigenic roles within the tumor microenvironment. Furthermore, galectin-1 suppresses T cell-mediated cytotoxic immune responses and promotes tumor angiogenesis. Recent evidence has demonstrated that galectin-1 plays an important role in tumor progression and metastasis^[36]. The amplification and overexpression of galectin-1 have been demonstrated in several tumors, including colon cancer, breast cancer, and hepatocellular cancer. The frequency

TNM: Tumor-node-metastasis; VEGF: Vascular endothelial growth factor.

of positivity appears to increase with the clinical stage of the disease and is associated with a worse prognosis^[16-18]. However, the prevalence of galectin-1 overexpression in gastric cancer and its relationship with prognosis is not clear. There are only two studies in the literature evaluating the correlation between galectin-1 expression and survival. In these studies, galectin-1 expression in tumor cells was significantly correlated with short survival in astrocytic neoplasms and colon cancer^[16,37]. In the present study, we examined 214 gastric cancer samples for the presence of the galectin-1 oncoprotein by immunohistochemistry. In all, 138 samples (64.5%) showed positive galectin-1 expression, and galectin-1 expression was related to tumor size, differentiation grade, stage, and lymph node metastases, suggesting that this protein may participate in tumor growth and distant metastasis. We also confirmed a significant prognostic value of galectin-1 in gastric cancer using a Kaplan-Meier survival analysis. The outcome of galectin-1-positive patients was significantly poorer than galectin-1-negative patients. Thus, detecting galectin-1 expression in gastric cancer tissues might be helpful for predicting patient prognosis.

Angiogenesis is essential for tumor growth and metastasis^[38]. VEGF is the most potent angiogenic factor identified to date. Tumor angiogenesis and neovascularization require VEGF expression^[39]. VEGF is primarily secreted by tumor cells, and its functions are largely restricted to endothelial cells^[40]. VEGF strongly stimulates the growth of endothelial cells, leading to the formation of new blood vessels and providing essential nutrients

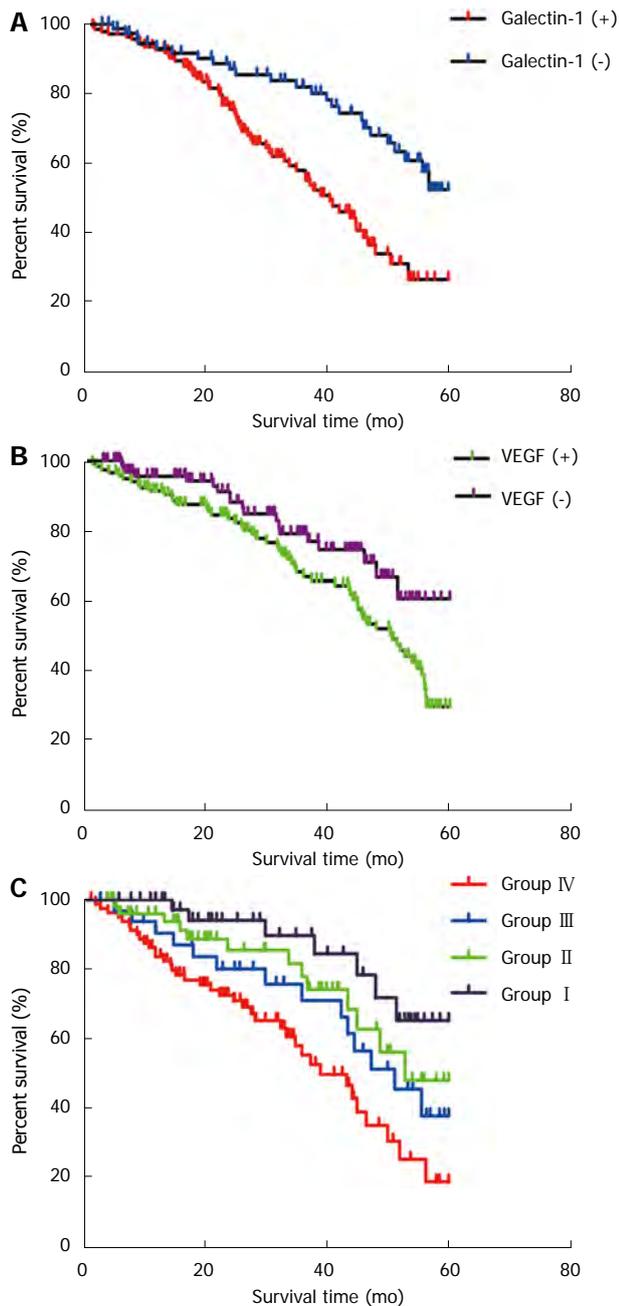

Figure 3 Overall survival rate of patients. A: The overall survival rate of patients relative to galectin-1-positive expression and galectin-1-negative expression in gastric cancer tissue samples. Galectin-1 overexpression was significantly associated with poor patient survival ($P < 0.05$); B: The overall survival rate of patients relative to vascular endothelial growth factor-positive expression and vascular endothelial growth factor-negative expression in gastric cancer tissue samples. Vascular endothelial growth factor overexpression was significantly associated with poor patient survival ($P < 0.05$); C: The overall survival rates of patients relative to groups I, II, III and IV. Both galectin-1 and vascular endothelial growth factor overexpression was significantly associated with poor patient survival ($P < 0.05$).

for tumor growth. Therefore, VEGF-based antiangiogenesis therapy may be of therapeutic benefit against solid tumors and has been tested in several tumor types, including gastric cancers. In our study, VEGF expression was detected in more than half of gastric cancers (54.2%). Both the incidence and proportion of VEGF expres-

sion increased with the progression of gastric cancer, and it was correlated with tumor size, stage, and lymph node metastases. VEGF expression has been identified as a significant marker for tumor recurrence and reduced survival independent of conventional clinicopathological variables in gastric cancer^[41,42]. In this study, using Kaplan-Meier analysis, we also demonstrated a significant association between VEGF expression and poor survival.

VEGF is one of the most potent inducers of angiogenesis, whereas galectin-1 has been implicated in the regulation of VEGF. Koopmans *et al.*^[43] demonstrated that galectin-1 activation led to the translational up-regulation of VEGF and increased angiogenesis through the JAK/STAT pathway in myeloproliferative neoplasia. Fischer *et al.*^[44] demonstrated that galectin-1 inhibited rearranged during transfection and Janus kinase 2 signals and up-regulated vascular endothelial growth factor receptor 3 signaling in trophoblast tumor cells. Hsieh *et al.*^[45] found that galectin-1 was overexpressed in the connective tissue surrounding cancer cells in tumor-associated vascular endothelial cells. Galectin-1 can increase angiogenesis by interacting with neuropilin-1 on the endothelial cell surface. Galectin-1 binding to neuropilin-1, which acts as a co-receptor of VEGF in endothelial cells, enhances VEGF receptor phosphorylation and the subsequent activation of mitogen-activated protein kinases^[16]. However, few studies have evaluated the correlation between VEGF and galectin-1 in gastric cancer.

The present study showed that VEGF expression was increased in galectin-1-positive tumors compared to galectin-1-negative tumors. Meanwhile, galectin-1 expression was also increased in VEGF-positive tumors compared to VEGF-negative tumors. Galectin-1 expression was positively associated with VEGF expression. Galectin-1 and VEGF played concordant roles in tumor angiogenesis, progression, metastasis, and prognosis, which suggests a connection between them. Our results also indicated that galectin-1 and VEGF overexpression was significantly correlated with poor survival in Chinese gastric cancer patients, especially patients with both galectin-1 and VEGF expression. Therefore, detecting galectin-1 and VEGF expression might help to identify gastric cancer patients with a poor prognosis and could therefore be a novel prognostic marker. To date, the galectin-1 regulatory mechanism of VEGF in gastric cancer has not been well explored and requires further study.

COMMENTS

Background

Galectin-1 and vascular endothelial growth factor (VEGF) played important roles in angiogenesis and progression of malignant tumor. The high expression of galectin-1 and VEGF are correlated with disease behavior in some cancers, while their expression in Chinese gastric cancer and relationship between the two parameters and clinicopathological features, as well as prognostic value remained largely unknown.

Research frontiers

Even with the advancement of diagnosis, neoadjuvant chemoradiotherapy and surgery, the 5-year survival for gastric cancer remains poor, especially in more

advanced stages. Recently therapeutic strategies have been improved by the availability of monoclonal antibodies. Researches have been evaluating new biologic and molecular targets for their potential role as prognostic markers and as targets for therapy in patients with gastric cancer.

Innovations and breakthroughs

Given the frequent failure of conventional treatment strategies, many cancer-related molecules have been characterized with the goal of developing novel anticancer therapies. In order to guide clinical decision-making in therapy and prognosis prediction, efforts have been invested in identifying prognostic biomarkers for patients with gastric cancer. Galectin-1 is a β -galactoside binding protein that is abundantly secreted by almost all types of malignant tumor cells. The expression of galectin-1 is regulated by hypoxia-inducible factor-1 (HIF-1) and it plays vital protumorigenic roles within the tumor microenvironment. However, the prevalence of galectin-1 overexpression in gastric cancer as well as its relationship with prognosis is not clear. There are only two studies in the literature evaluating the correlation between galectin-1 expression and survival. In these studies, galectin-1 expression in tumor cells significantly correlated with short survival in astrocytic neoplasms and in colon cancer. In this present study, the authors examined 214 gastric cancer samples for the presence of galectin-1 oncoprotein by immunohistochemistry.

Applications

The study aimed at evaluating the expression of galectin-1 and VEGF in gastric cancer by immunohistochemical methods. The authors found that overexpressions of galectin-1 in tumor stroma cells and VEGF in tumor cells were related with tumor progression and poor survival in gastric cancer, and our findings supported an association between galectin-1 and VEGF expression. These two molecules may serve as independent predicative markers for patient prognosis in gastric cancer.

Terminology

Galectin-1 is a β -galactoside binding protein that is abundantly secreted by almost all types of malignant tumor cells. The expression of galectin-1 is regulated by HIF-1 and it plays vital protumorigenic roles within the tumor microenvironment. Galectin-1 suppresses T cell-mediated cytotoxic immune responses and promotes tumor angiogenesis. VEGF is the most potent angiogenic factor identified so far. Tumor angiogenesis and neovascularization require VEGF expression. VEGF is mainly secreted by tumor cells with its functions largely restricted to endothelial cells, and it strongly stimulate the growth of endothelial cells leading to the formation of new blood vessels, thus providing essential nutrients for tumor growth.

Peer review

This manuscript describes convincingly the expression of galectin-1 and VEGF in gastric cancer patients. The paper is well prepared and its publication in the journal is recommended with minor corrections.

RESULTS: There were no significant differences between the groups in terms of the numbers of patients, sex distribution, age, American Society of Anesthesiologists score, serum bilirubin, γ -glutamyl transpeptidase, mean diameter of common bile duct stones, and previous medical and surgical history ($P = 0.54$, $P = 0.18$, $P = 0.52$, $P = 0.22$, $P = 0.32$, $P = 0.42$, $P = 0.68$, $P = 0.70$, $P = 0.47$ and $P = 0.57$). There was no significant difference in the surgical operation time between the two groups (112.1 ± 30.8 min vs 104.9 ± 18.2 min). Compared with the sequential operation group, the incidence of pancreatitis was lower (1.4% vs 6.3%), the incidence of hyperamylasemia (1.4% vs 10.0% , $P < 0.05$) was significantly reduced, and the length of the hospital stay was significantly shortened in the synchronous operation group (3 d vs 4.5 d, $P < 0.001$).

CONCLUSION: For treatment of cholecystocholedocholithiasis, synchronous LC combined with EST reduces incidence of complications, decreases length of hospital stay, simplifies the surgical procedure, and reduces operation time.

Synchronous vs sequential laparoscopic cholecystectomy for cholecystocholedocholithiasis. *World J Gastroenterol* 2013; 19(13): 2080-2086 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2080.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2080>

Abstract

AIM: To compare synchronous laparoscopic cholecystectomy (LC) combined with endoscopic sphincterotomy (EST) and sequential LC combined with EST for treating cholecystocholedocholithiasis.

METHODS: A total of 150 patients were included and retrospectively studied. Among these, 70 were selected for the synchronous operation, in which the scheme was endoscopic retrograde cholangiopancreatography combined with EST during LC. The other 80 patients were selected for the sequential operation, in which the scheme involved first cutting the papillary muscle under endoscopy and then performing LC. The indexes in the two groups, including the operation time, the success rate, the incidence of complications, and the length of the hospital stay, were observed.

INTRODUCTION

Cholelithiasis, including cholecystolithiasis and common

bile duct stones (CBDSs), is common in clinical practice. The incidence of concurrent cholecystolithiasis and CBDSs is 10%-33%, and varies according to age^[1]. Cholelithiasis can be associated with serious complications, including biliary pancreatitis and suppurative cholangitis. Therefore, it is important to regularize and improve the process of clinical diagnosis and treatment of this disease.

Laparotomy for gallbladder excision, with common bile duct (CBD) exploration or endoscopic sphincterotomy (EST) through duodenal papilla, was once the standard treatment plan for concurrent cholecystolithiasis and CBDSs. In the past 10 years, with the rapid development of laparoscopic techniques, laparoscopic cholecystectomy (LC) has become the main treatment for cholecystolithiasis. However, many studies have shown that LC combined with laparoscopic common bile duct exploration (LCBDE) has a high success rate (up to 83%-89%) for concurrent cholecystolithiasis and CBDSs. It also has many merits, such as a significantly shortened hospital time and synchronous minimally invasive surgery^[2-6]. Moreover, there is no significant difference in the incidence of complications with this technique when compared with EST^[7]. Unfortunately, it is not widely applied because of the complex surgical technique^[3,8].

With the rapid development of endoscopic retrograde cholangiopancreatography (ERCP), a variety of operations can be chosen on the basis of the LC scheme for concurrent cholecystolithiasis and CBDS. Besides LC with LCBDE, the so-called double endoscopy joint operation is also an option, which comprises LC combined with ERCP and EST before, during, or after the operation to remove CBDSs^[9-11]. The most widely used operation scheme is LC combined with preoperative ERCP and EST. This scheme often requires two hospitalizations, longer hospital stays, and correspondingly higher medical costs. Even after strict preoperative screening, a proportion of CBDS cases with preoperative diagnoses is still found to be biliary stone negative during the ERCP process. Therefore, some patients must pay unnecessary ERCP-related medical expenses and undergo potential risks of surgery^[12]. In recent years, there have been reports on the laparoendoscopic rendezvous (LRV) operation to treat concurrent cholecystolithiasis and CBDSs. The LRV operation has the advantages of high stone clearance, a low incidence of complications, and reduced hospital time, but it also has disadvantages that include a complex surgical procedure and a longer single operation time^[13,14].

In our study, we used synchronous LC combined with EST to treat concurrent cholecystolithiasis and CBDSs. This approach combined LRV with conventional surgical procedures to perform endoscopic retrograde bile duct intubation. We compared the efficacy and safety of synchronous LC with LRV *vs* sequential LC with the conventional operation.

MATERIALS AND METHODS

Patients

A total of 167 patients with cholecystolithiasis and CBDSs

were enrolled in this study from June 2009 to October 2012 at the Second Clinical Medical School, Yangzhou University. The preliminary diagnosis was established by the clinical symptoms (abdominal pain and vomiting), signs (right upper-quadrant abdominal pain and jaundice), serum biochemical index (high bilirubin or transaminase level), and abdominal ultrasound (gallstones and suspicious CBDSs, or CBD diameter > 8 mm). All of these cases were further examined by magnetic resonance cholangiopancreatography (MRCP) to diagnose cholecystolithiasis and choledocholithiasis.

The exclusion criteria were: (1) age > 80 years or < 18 years; (2) American Society of Anesthesiologists (ASA) score^[15] ≥ 4; (3) suppurative cholangitis (body temperature > 38.5 °C, with right upper-quadrant abdominal pain and pressure pain, or hyperbilirubinemia); (4) acute pancreatitis (serum amylase 3 times higher than normal); (5) pregnancy; (6) abdominal surgical history; and (7) decompensated cirrhosis that is not suitable for endoscopic and laparoscopic surgery.

A total of 150 patients were retrospectively studied and the treatment procedure is shown in Figure 1. Among these, 70 were selected for the synchronous operation, in which ERCP was combined with EST during LC. The other 80 patients were selected for the sequential operation, in which the papillary muscle was cut under endoscopy, and then LC was performed after 24-72 h. All ERCPs were performed by one of two endoscopic technologists, while LC was performed by one of three expert surgeons. Our study was approved by the Ethics Committee of the Second Clinical Medical School, Yangzhou University, and signed informed consent was obtained from each patient for the operative procedures.

Surgical procedures

The entire procedure was performed with the patient under general anesthesia. Patients in the synchronous group were placed on a C-arm-compatible table. Pneumoperitoneum was routinely established and laparoscopic instruments were put into the peritoneal cavity. The triangle of Calot was first dissected, then the gallbladder artery was ligated close to the gallbladder side, the gallbladder duct was exposed and cut open near the CBD side to make an oblique incision, and the angiographic catheter was inserted (Figure 2A). The contrast agent was injected to confirm the presence of bile duct stones (Figure 2B). The duodenoscope was inserted into the descending part of the duodenum, and a selective CBD intubation was made. Stones were removed by balloon or basket after successful intubation, and lithotripsy or balloon expansion was carried out if it was difficult to remove the stones (Figure 2C). If selective bile duct intubation failed, a yellow zebra guide wire was intubated using an angiographic catheter under laparoscopy (Figure 2D). The yellow zebra was across the duodenal papilla to the descending part of duodenum (Figure 2E), drawn out, and plugged into the duodenum again with the end of guide wire. The duodenoscope was inserted in the descending part of duodenum through the mouth, and the guide wire was pulled

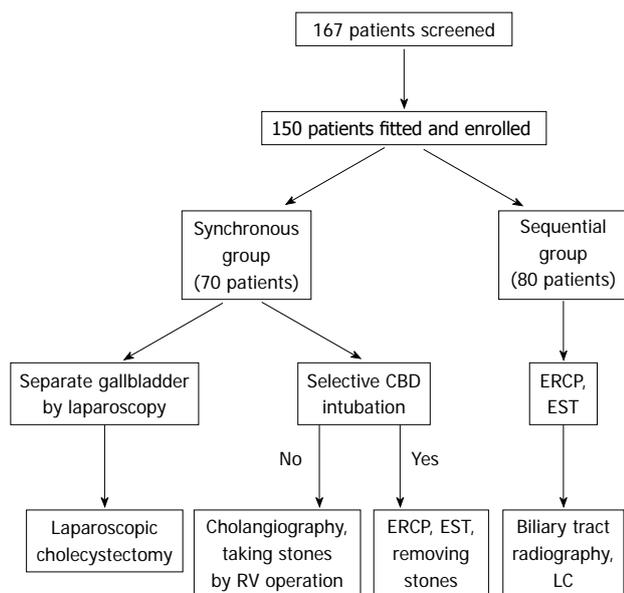

Figure 1 Treatment procedure for this study. CBD: Common bile duct; ERCP: Endoscopic retrograde cholangiopancreatography; EST: Endoscopic sphincterotomy; RV: Rendezvous; LC: Laparoscopic cholecystectomy.

out with the duodenal trap of the duodenoscope. The duodenal papillary muscle was cut with an incision knife, which followed the guide wire retrograde to the duodenal papilla (Figure 2F). Gas inside the gastrointestinal tract was exhausted at the end of the endoscopic operation, the gallbladder duct was ligated by routine laparoscopic procedure, and the gallbladder was removed.

Patients in the sequential operation group were placed in the left supine or prone position. The duodenoscope was inserted, and radiography was performed to confirm the situation of the biliary tract. The duodenal papillary muscle was cut, and stones were removed by balloon or basket. Endoscopic nasobiliary drainage was performed and biliary tract radiography was completed during 24-48 h. Residual stones were removed, and LC was carried out if no residual stone was observed.

Operation time was defined as the time from anesthesia to when the patient awoke after the operation in the synchronous group. In the sequential group, the operation time was the sum of the time for the ERCP operation before LC and the LC operation time. Major complications were defined as any intraoperative or postoperative (42 d) events that altered the clinical course, such as ERCP complications (including pancreatitis, hyperamylasemia, perforation, and bleeding) and LC complications (bile duct leakage, bleeding, pneumonia, and organ failure).

The success rate included the ERCP and LC success rates. ERCP success was defined as smoothly cannulating the CBD and achieving complete CBD stone clearance at the time of final cholangiography. LC success was defined as performing LC smoothly without converting to open surgery. Postoperative hospitalization time was the hospital time for LC combined with ERCP in the synchronous group, while it was the length of the hospital stay after ERCP in the sequential group.

Table 1 Basic characteristics and intraoperative and postoperative parameters of patients who underwent synchronous and sequential operations

| | Synchronous group | Sequential group | P value |
|--------------------------------|-------------------|------------------|---------|
| Total patients | 70 | 80 | |
| M/F ratio | 46/24 | 53/27 | 0.54 |
| Mean age, yr | 59.0 (38-75) | 56.6 (36-74) | 0.18 |
| ASA score (I - II / III) | 62/8 | 70/10 | 0.52 |
| Symptoms | | | |
| Abdominal pain | 59 (84.3) | 72 (90.0) | 0.22 |
| Jaundice | 51 (71.4) | 62 (77.5) | 0.32 |
| Nausea or vomiting | 39 (55.7) | 47 (58.8) | 0.42 |
| Mean serum bilirubin, mg/dL | 5.4 (0.5-24) | 5.9 (0.6-27) | 0.68 |
| Mean γ -GGT, μ /dL | 116.2 (27-342) | 122.8 (35-396) | 0.70 |
| MRCP diagnosis | | | |
| Mean diameter of CBDS, mm | 9.7 (7-21) | 9.2 (6-20) | 0.47 |
| Stone number (single/multi) | 49/21 | 56/24 | 0.57 |
| Mean operative time, min | 112.1 \pm 30.8 | 104.9 \pm 18.2 | 0.08 |
| Success rate | | | |
| Endoscopic sphincterotomy | 70 (100) | 77 (96.3) | 0.15 |
| Laparoscopic cholecystectomy | 69 (98.6) | 80 (100) | 0.74 |
| Major complications rate | | | |
| Acute pancreatitis | 1 (1.4) | 5 (6.3) | 0.14 |
| Hyperamylasemia | 1 (1.4) | 8 (10) | 0.03 |
| Bleeding/perforation/infection | 0 (0) | 0 (0) | |
| Hospital stay, d | 3 (2-6) | 4.5 (3-12) | < 0.001 |

Data are expressed as absolute *n* (%) or median (range). M: Male; F: Female; γ -GGT: γ -glutamyl transpeptidase; ASA: American Society of Anaesthesiologists; MRCP: Magnetic resonance cholangiopancreatography; CBDS: Common bile duct stone.

Follow-up procedure

Patients were scheduled for follow-up 2 and 6 wk after surgery. During that time, no patients were lost to follow-up. The patients were reviewed by color ultrasound and for liver function. MRCP was performed if there was a question of residual bile duct stones, and stones were removed by remedial ERCP if they were confirmed.

Statistical analysis

The SPSS software package (versions 17.0, SPSS, Chicago, IL, United States) was used for all statistical analyses. Categorical variables were compared with the χ^2 test. Continuous variables were compared with the Student's *t* test or the Mann-Whitney *U* test, depending on the distribution. *P* < 0.05 was considered statistically significant.

RESULTS

The baseline characteristics of the patients are shown in Table 1. There were no significant differences between the groups in terms of the numbers of patients, sex distribution, age, ASA score, serum bilirubin, γ -glutamyl transpeptidase, mean diameter of CBDSs, and previous medical and surgical history (*P* > 0.05 each).

The intraoperative and postoperative parameters are shown in Table 1. The mean operation time in the synchronous group was 112.1 \pm 30.8 min. The LRV operation was performed in 15 cases, because it was difficult to complete selective bile duct intubation during the endo-

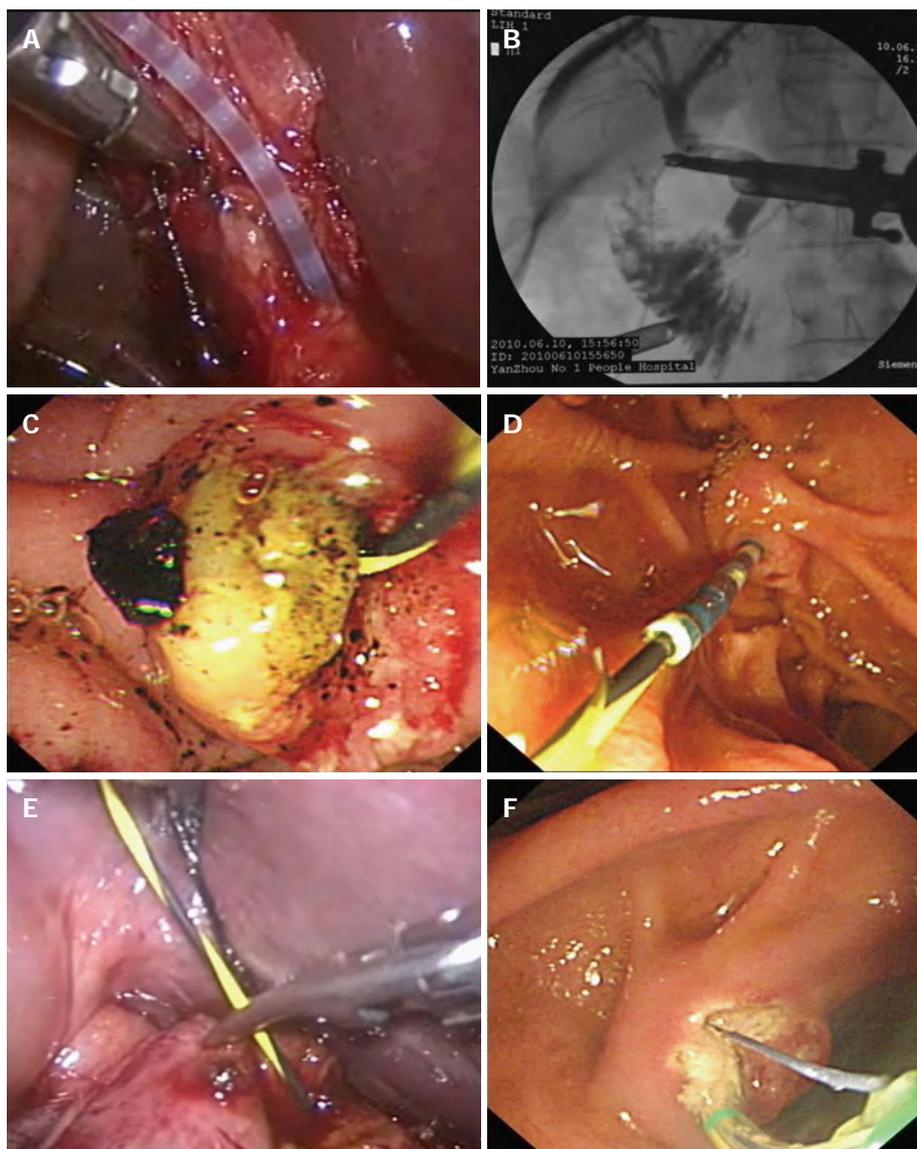

Figure 2 Surgical procedures. A: Angiographic catheter was inserted; B: Cholangiography was performed; C: Stones were removed by balloon or basket; D: Yellow zebra guide wire was inserted into cystic duct; E: Angiographic catheter was inserted following the guide wire; F: Duodenal papillary muscle was cut.

scopic process, and the average operation time of the 15 cases was 132.3 ± 29.0 min. The mean ERCP operation time in the sequential operation group was 38.4 ± 12.1 min, the LC operation time was 66.6 ± 14.4 min, and the overall operation time was 104.9 ± 18.2 min. There was no significant difference in the average operation time between the two groups ($P > 0.05$).

The hyperamylasemia incidence in the synchronous group was 1.4% (1/70), and 10.0% (8/80), in the sequential group, and there was a significant difference in incidence between the two groups ($P < 0.05$). The incidence of acute pancreatitis in the synchronous group was 1.4% (1/70) and 6.3% (5/80) in the sequential group, and there was a trend toward significance between the two groups ($P > 0.05$). Bleeding, perforation, death, and serious complications were not observed in either of the groups. The acute pancreatitis that occurred after the operation was mild, and it did not develop into severe pancreatitis after timely treatment.

The length of the hospital stay in the sequential group was 4.5 d (range, 3-12 d), and five patients with acute pancreatitis had lengthened hospital stays. The length of hospital stay in the synchronous group was 3 d (range, 2-6 d), which was significantly lower than that in the sequential group ($P < 0.001$).

All 150 patients were followed up for a mean 65 wk (range, 8-135 wk). At the 6-wk follow up, color Doppler ultrasound, liver function tests, and MRCP did not identify recurrence of stones and complications related to the operation, except for one patient in the synchronous group. This patient was readmitted 8 wk after the LRV procedure with residual choledocholithiasis and treated successfully with repeat ERCP and CBD clearance.

DISCUSSION

LC combined with EST is the most commonly used minimally invasive treatment for concurrent cholecystolithi-

asis and CBDS^[16,17]. LC combined with postoperative EST is an important remedial treatment measure for stones, which appear in LC but are not removed by instant LCBDE. Its weakness is that EST has a greater need for operative success because, if EST fails to remove stones, patients could require additional surgical procedures. The success rate of ERCP is 85%-90%^[18]. Even if the postoperative ERCP is successful, the hospitalization time is longer than for synchronization^[19,20]. The scheme in most medical units is conventional LC combined with preoperative ERCP, which also has some disadvantages. Even if the preoperative ERCP is successful in removing the stones, the few cases for which LC fails still require laparotomy. If preoperative ERCP is complicated by acute pancreatitis, it is not possible to perform LC. In this study, there were five patients with acute pancreatitis in the sequential group for whom LC had to be delayed, and these patients had extended hospital stays. In addition, intraoperative exploration confirms only 27%-54% of stones, in spite of the clinical history characteristics, medical examination, serum biochemical index, abdominal ultrasound diagnosis, and CBDS preoperative examination, which means that a considerable proportion of patients incur unnecessary ERCP-related medical expenses and potential risks of surgery^[12]. The ERCP serious complication rate was 2.5%-11%, and the mortality rate was 0.5%-3.7%^[18].

In recent years, there have been reports that synchronous ERCP and EST are carried out in LC to treat concurrent cholecystolithiasis with CBDSs^[21]. One meta-analysis of 27 published intraoperative ERCP studies including a total of 795 patients by La Greca *et al.*^[22] showed that the operation success rate was 69.2%-100%, with an average of 92.3%; the average intraoperative endoscopic operation time was 35 min; and the average surgical operation time was 104 min. In these 27 studies, 4.7% of cases required laparotomy, the complication incidence was 5.1%, and the mortality rate was 0.37%. Intraoperative synchronous EST in LC has no obvious differences in terms of complications, such as acute pancreatitis and hyperamylasemia, compared with sequential LC and EST operations, but it significantly improves the operation success rate, shortens the average hospitalization time, and decreases the medical treatment charges^[23]. A randomized study with 120 cases of concurrent cholecystolithiasis with CBDSs observed the risk factors of postoperative ERCP-related pancreatitis, and found that no case was complicated by acute pancreatitis in synchronous surgery, and six patients suffered from iatrogenic acute pancreatitis in sequential surgery^[24]. These data suggest that the synchronous operation has the advantages of high stone clearance, high success rate, and a low complication rate for treating CBDSs when compared to sequential double endoscopy.

Although synchronous surgery has obvious advantages, its implementation faces a few difficulties. First, the synchronous double endoscopy combined operation mostly uses the LRV operation during laparoscopic transcystic intubation into the filar guide and can extend the

operation time. A clinical study with 45 patients showed that the average time for double endoscopy synchronous surgery was 119.09 ± 14.4 min^[13]. Another study showed that the operation time for LC combined with intraoperative ERCP was 192.0 ± 8.9 min, which was 85 min longer than for separate laparoscopic gallbladder resection and CBD exploration^[14]. In the beginning, we used the LRV operation, which is similar to the approach used by ElGeidie's team^[25]. We found that there were certain difficulties in the operation that extended the time required. Now, we prefer LC combined with conventional endoscopic retrograde bile duct intubation, and turn to the LRV operation when there is difficulty in selective intubation. This method can avoid associated risks, including acute pancreatitis and bleeding caused by repeated intubation, contrast agent injection, and pre-cut sphincterotomy. It can also simplify the operation process and reduce the time. In our study, there were difficulties during the selective intubation of 15 patients in the synchronous operation group, so we turned to the LRV operation. There was no difference in the operation time between the synchronous and sequential treatment groups. The incidence of hyperamylasemia and iatrogenic pancreatitis was lower in the synchronous than in the sequential operation group. Besides the operation time, time was required for the positional adjustment of the X-ray machine and endoscopic equipment by the operators. This timing can be addressed after improving the surgical process. Second, the synchronous operation required cooperation between the surgeons and endoscopic physicians. The latter must perform intraoperative ERCP immediately and synchronously with surgery once biliary angiography has confirmed CBDSs. Thus, we can try to reduce the operation time. However, clinical practice often faces certain difficulties. All of the cases in our study were diagnosed with CBDSs by MRCP preoperatively, because the surgeons, endoscopic physicians, and equipment were in the right place from the beginning. This design guaranteed the effective organization of the synchronous double endoscopy operation. The sensitivity and specificity of MRCP diagnosis in CBDS are 95% and 97%, respectively^[26], and all cases diagnosed with CBDSs by MRCP were confirmed in the perioperative period in this study. Third, some researchers think that general anesthesia by endotracheal intubation is an unfavorable factor in duodenoscopy operations^[15], so we used general anesthesia by nasal intubation to reduce this negative influence.

Our study also had several limitations. First, it was a retrospective study that was not performed in a double-blind and randomized fashion. Second, our work was in the preliminary stage, and it did not assess the learning curves for the two types of surgery. Third, the length of follow up was short, and the number of patients was small. Therefore, further studies with larger patient populations are needed to draw more valid conclusions.

In conclusion, we found that both synchronous and sequential laparoscopic operations combined with endoscopic operations were minimally invasive surgical proce-

dures for effective treatment of concurrent cholecystolithiasis and CBDs. Moreover, the synchronous double endoscopy combined operation may selectively apply the LRV scheme. Synchronous surgery has advantages, such as reducing complications and shortening hospital stay, and it can also simplify the operation process and reduce the time required.

COMMENTS

Background

Cholecystolithiasis, combined with common bile duct stones (CBDs), is common in clinical practice. In the management of cholelithiasis, laparoscopic cholecystectomy (LC) is the treatment of choice, but the ideal management of choledocholithiasis with LC is controversial. Today a number of options exist, including endoscopic sphincterotomy (EST) before LC, laparoscopic common bile duct exploration, and postoperative endoscopic retrograde cholangiopancreatography.

Research frontiers

Several studies have shown the efficacy of the combined laparoendoscopic rendezvous (LRV) technique for treatment of cholecystolithiasis and CBDs. Studies have demonstrated that this method has advantages of easier cannulation, prevention of pancreatic trauma, and reduced hospital time, but it also has disadvantages, including a complex surgical procedure and a longer single operation time.

Innovations and breakthroughs

In this study, the authors used synchronous LC combined with EST to treat concurrent cholecystolithiasis and CBDs, with selective application of the LRV procedure. Study data showed that synchronous surgery had advantages, such as reducing complications and shortening hospital stay, and it also simplified the surgical procedure and reduced the operation time in most cases.

Applications

Elective application of the LRV procedure in a synchronous double endoscopy combined operation is a minimally invasive surgical procedure for the effective treatment of concurrent cholecystolithiasis and CBDs.

Terminology

LRV is a technique in which the sphincterotome is driven across the papilla into the choledochus by a Dormia basket passed into the duodenum through the cystic duct during LC.

Peer review

This was a well-designed retrospective study in which the authors compared the efficacy and safety of synchronous LC with LRV vs sequential LC with the conventional operation. The results are interesting and suggest that synchronous surgery has advantages, such as reducing complications, and shortening operation time and hospital stay.

Abstract

AIM: To investigate the features of hepatic paragonimiasis on contrast-enhanced ultrasound (CEUS) imaging.

METHODS: Fifteen patients with hepatic paragonimiasis who were admitted to our hospital between March 2008 and August 2012 were enrolled to this study. The conventional ultrasound and CEUS examinations were performed with a Philips IU22 scanner with a 1-5-MHz convex transducer. After conventional ultrasound scanning was completed, the CEUS study was performed. Pulse inversion harmonic imaging was used for CEUS. A bolus injection of 2.4 mL of a sulfur hexafluoride-filled

microbubble contrast agent (SonoVue) was administered. CEUS features were retrospectively reviewed and correlated with pathological findings.

RESULTS: In total, 16 lesions were detected on CEUS. The mean size of the lesions was 4.4 ± 1.6 cm (range, 1.7-6.6 cm). Subcapsular location was found in 12 lesions (75%). All the lesions were hypoechoic. Six lesions (37.5%) were of mixed content, seven (43.8%) were solid with small cystic areas, and the other three (18.8%) were completely solid. Ten lesions (62.5%) were rim enhanced with irregular tract-like nonenhanced internal areas. Transient wedge-shaped hyperenhancement of the surrounding liver parenchyma was seen in seven lesions (43.8%). Areas with hyper- or iso-enhancement in the arterial phase showed contrast wash-out and appeared hypoenhanced in the late phase. The main pathological findings included: (1) coagulative or liquefactive necrosis within the lesion, infiltration of a large number of eosinophils with the formation of chronic eosinophilic abscesses and sporadic distribution of Charcot-Leyden crystals; and (2) hyperplasia of granulomatous and fibrous tissue around the lesion.

CONCLUSION: Subcapsular location, hypoechogenicity, rim enhancement and tract-like nonenhanced areas could be seen as the main CEUS features of hepatic paragonimiasis.

Key words: Paragonimiasis; Liver; Infection; Contrast-enhanced ultrasonography

Core tip: We retrospectively investigated the contrast-enhanced sonographic features of hepatic paragonimiasis. Hepatic paragonimiasis has its own features on contrast-enhanced ultrasound. Knowledge of these findings is helpful in differentiating hypoechoic lesions in the liver. When a subcapsular hypoechoic lesion with irregular tract-like non-enhancing necrosis is presented in non-

cirrhotic liver, the diagnosis of hepatic paragonimiasis should be suspected.

INTRODUCTION

Paragonimiasis is a parasitic infestation caused by the lung fluke. Although the primary site of paragonimiasis is the lungs, ectopic infestation can occur in locations such as the brain, muscles, retroperitoneum, and liver^[1-6]. The liver is known to be an organ in which ectopic paragonimiasis may occur. Hepatic paragonimiasis often appears as a mass that should be differentiated from other cancerous lesions. Contrast-enhanced ultrasound (CEUS) has been widely used in characterization of focal liver lesions (FLLs)^[7-14]. The enhancement patterns of several FLLs have been described and are well known^[7,15-17]. However, to the best of our knowledge, the CEUS features of hepatic paragonimiasis have not been investigated or reported in the English-language literature. In this study, we retrospectively investigated the CEUS features of hepatic paragonimiasis.

MATERIALS AND METHODS

Patients

We retrospectively reviewed the results of conventional and CEUS examination of 15 patients with hepatic paragonimiasis who were admitted to our hospital between March 2008 and August 2012. There were eight men and seven women with a mean age of 42.5 ± 12.3 years (range, 29-65 years). All patients in this study were residents of China's Sichuan Province, which is an endemic area of paragonimiasis, especially the paragonimiasis skrjabini variety, and a majority of them (10/15) had a history of eating crayfish. The study was approved by the Ethical Committee of the hospital. All the patients underwent surgery and the diagnoses were confirmed histologically.

Ultrasound examination

The conventional ultrasound and CEUS examinations were performed with a Philips IU22 scanner (Philips Medical Solutions; Mountain View, CA, United States) with a 1-5-MHz convex transducer. The CEUS imaging technique used in this study was pulse inversion harmonic imaging. The mechanical index for CEUS was 0.06. After conventional ultrasound scanning was completed, the CEUS study was performed. A bolus injection of 2.4 mL sulfur hexafluoride-filled microbubble contrast agent (SonoVue; Bracco SpA, Milan, Italy) was administered through a 20-gauge needle placed in the antecubital vein.

A flush of 5 mL 0.9% sodium chloride solution was followed after the injection of SonoVue. On completion of the SonoVue injection, the timer was started simultaneously. The target lesion and surrounding liver parenchyma were observed continuously for 6 min. As previously described by Albrecht *et al*^[18], the arterial phase was defined as 7-30 s after contrast agent injection; the portal phase was 31-120 s after injection; and the late phase was 121-360 s after injection. The entire CEUS examination was stored as a dynamic digital video file on the hard disk of the ultrasound system and recorded on a digital video recorder. All of the procedures were performed by Lu Q or Luo Y who had > 5 years of experience of CEUS study of the liver.

Image analysis

The diameters and echogenicity of the tumors on conventional ultrasound were recorded. The enhancing pattern and enhancement level in different phases of CEUS imaging of the lesion were reviewed. The degree of enhancement was divided into nonenhancement, hypoenhancement, isoenhancement, and hyperenhancement according to the enhancement level of the lesion compared with that of the surrounding normal liver parenchyma. Contrast enhancement patterns were classified as homogeneous, heterogeneous, and rim enhancement.

RESULTS

CEUS findings

In total, 16 lesions were detected on CEUS. The mean size of the lesions was 4.4 ± 1.6 cm (range: 1.7-6.6 cm). Subcapsular location was found in 12 lesions (75%). All the lesions were hypoechoic. Six lesions (37.5%) were of mixed content, seven (43.8%) were solid with small cystic areas, and the other three (18.8%) were completely solid. Ten lesions (62.5%) were rim enhanced with irregular tract-like nonenhanced internal areas (Figure 1). Transient wedge-shaped hyperenhancement of the surrounding liver parenchyma was seen in seven lesions (43.8%). Areas with hyperenhancement or isoenhancement in the arterial phase showed contrast wash-out and appeared hypoenhanced in the late phase.

Pathological findings

Microscopy revealed that there was an egg present in one case, but no larvae were present in any of the lesions. There were areas of track-like or sinus structures. The main pathological findings included: (1) coagulative or liquefactive necrosis within the lesion, infiltration of a large number of eosinophils with the formation of chronic eosinophilic abscesses and sporadic distribution of Charcot-Leyden crystals; and (2) hyperplasia of granulomatous and fibrous tissue around the lesion.

DISCUSSION

Hepatic paragonimiasis is an infestation caused by inges-

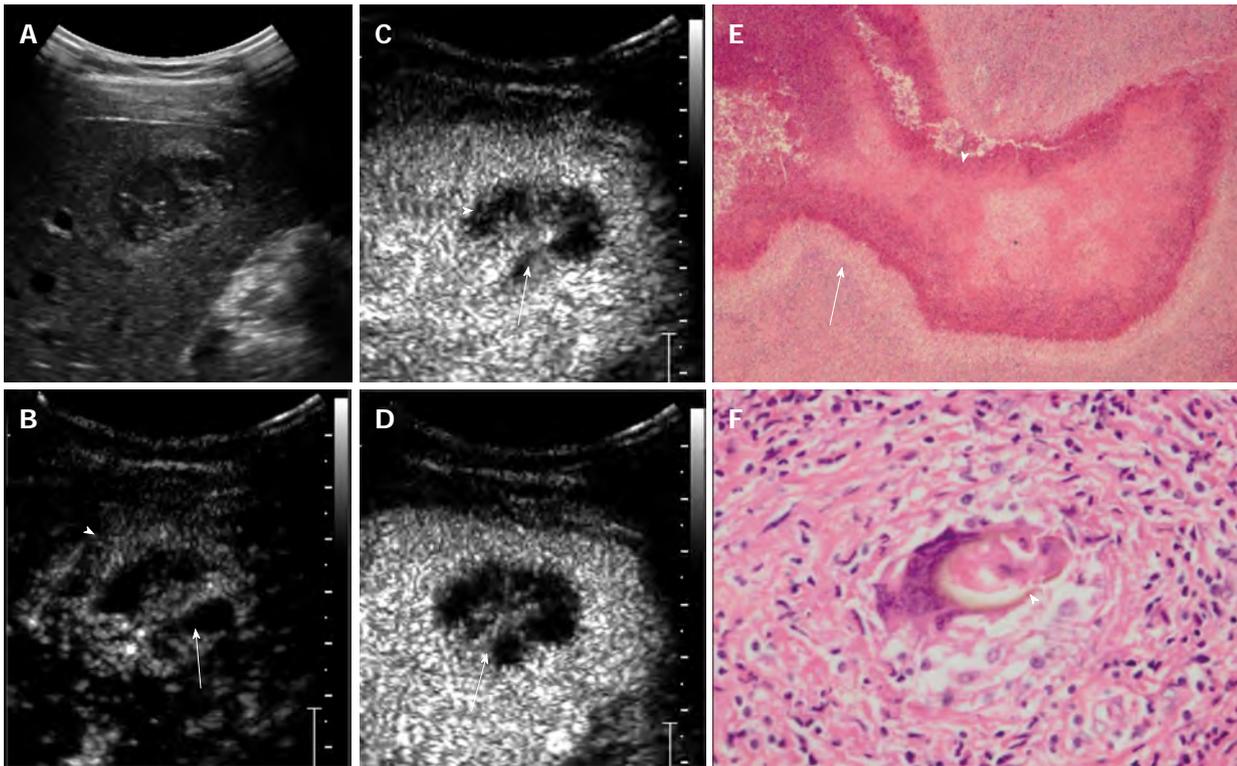

Figure 1 A 29-year-old woman with hepatic paragonimiasis. A: Hypoechoic lesion measuring 3.2 cm × 2.2 cm was seen in the right posterior inferior segment of the liver; B: Contrast-enhanced ultrasound showed rim enhancement (arrow head) and hyperenhanced internal septa (arrow) with irregular unenhanced areas in arterial phase; C and D: In portal phase (C) and late phase (D), contrast agent wash-out was seen at the enhanced septa (arrow), and the unenhanced area remained unenhanced (arrow head); E: Pathological findings showed coagulative necrosis (arrow head) within the lesion, surrounded by infiltration of a large number of barrier-like arrayed epithelioid cells (arrow); F: An egg (arrow head) was engulfed by a macrophage.

tion of raw or incompletely cooked freshwater crabs or crayfish infected with metacercariae. Only two species pathogenic to humans exist in Sichuan Province, namely, *Paragonimus skrjabini* and *Paragonimus westermani*^[19]. During the journey from the intestine to the lung where juvenile worms mature, the juvenile worms often cause damage to the liver capsule and parenchyma^[20,21]. Definitive diagnosis of paragonimiasis is based on the presence of eggs in patients' sputum or feces, or flukes in histological specimens. Polypide and eggs usually cannot be found in most of the lesions. However, with the epidemiological information, diagnosis can be made histopathologically^[22].

The lesion is often incidentally detected by ultrasonography in routine examination. Accurate diagnosis of suspected FLLs is important to determine the most effective therapy. If hepatic infection is correctly diagnosed, the need for surgery can be reduced or even avoided, compared with other abnormalities such as malignant tumors^[12,23].

Like other inflammatory lesions, hepatic paragonimiasis typically shows heterogeneous hyperenhancement in the arterial phase and hypoenhancement in the late phase on CEUS. Pathologically, the imaging feature of these lesions was eosinophilic abscesses, in which the enhanced septa in mixed-content lesions and enhanced area in solid lesions represented hyperplasia of granulomatous and fibrous tissue, whereas the unenhanced area represented necrotic debris, and Charcot-Leyden crystals.

The preponderance of subcapsular involvement and tract-like necrosis is characteristic and it may be attributed to the penetrating behavior of juvenile worms and eosinophilic abscess. The wedge-shaped enhancement in adjacent parenchyma in the arterial phase was similar to that reported by Kim *et al*^[5], and can be explained as inflammatory congestion adjacent to eosinophilic abscess^[19].

When a hypoechoic lesion in the liver is encountered by sonographic imaging, the differential diagnoses should include hepatocellular carcinoma, pyogenic abscesses, and hemangioma. In hepatocellular carcinoma, the hepatic parenchyma is more likely to be cirrhotic^[24]. Necrosis is readily visible by CEUS and is less common in small hepatocellular carcinoma. In pyogenic abscess, fever and pain in the right upper abdomen are more frequent^[12]. On CEUS, nonenhancing abscess and enhancing septa are often seen in pyogenic abscess, and lobulated abscess coalesces into a larger abscess cavity, whereas the eosinophilic abscess of hepatic paragonimiasis is irregular and arranged in tract-like fashion. Hepatic hemangioma may present as a hypoechoic lesion, whereas the CEUS manifestations typically show peripheral nodular enhancement in the arterial phase and gradual filling in the portal phase and hyperenhancement in late phase.

In our review of the literature, besides the imaging findings, blood eosinophilia was often seen in hepatic paragonimiasis patients, which was suggestive of parasitic

infection^[21]. For patients with symptoms of acute infection, praziquantel is the drug of choice to treat paragonimiasis, whereas partial liver resection is more suitable for those who have localized lesions without acute infection symptoms^[25,26].

The main limitation of this study was the small number of patients presented. Although hepatic paragonimiasis is rare, further investigation is mandatory.

In conclusion, hepatic paragonimiasis has its own features at CEUS. Thus, knowledge of these findings is helpful in differentiating hypoechoic lesions found in the liver. When a subcapsular hypoechoic lesion with irregular tract-like nonenhancing necrosis is present in noncirrhotic liver, diagnosis of hepatic paragonimiasis should be suspected.

COMMENTS

Background

Hepatic paragonimiasis is rare, but it often appears as a mass that should be differentiated from other cancerous lesions. Accurate diagnosis of suspected focal liver lesions (FLLs) is important to determine the most effective therapy. For hepatic infection, the need for surgery can be reduced or even avoided if it is correctly diagnosed, as compared with other abnormalities such as malignant tumors. Therefore, it is necessary to investigate the contrast-enhanced ultrasonography (CEUS) features of hepatic paragonimiasis.

Research frontiers

CEUS has been widely used in characterization of FLLs. The enhancement patterns of several FLLs have been described and are well known. However, the CEUS features of hepatic paragonimiasis have not been investigated or reported in the English-language literature.

Innovations and breakthroughs

The CEUS feature of hepatic paragonimiasis has been reported in this study. When a subcapsular hypoechoic lesion with irregular tract-like nonenhancing necrosis is present in noncirrhotic liver, a diagnosis of hepatic paragonimiasis should be suspected.

Applications

CEUS is a convenient and useful method for the detection and discrimination of hepatic paragonimiasis. Hepatic paragonimiasis could be better managed if ultrasound technicians and physicians are familiar with its features on CEUS.

Terminology

CEUS is the application of ultrasound contrast medium to traditional medical sonography. Microbubble contrast agents produce a unique sonogram with increased contrast due to the high echogenicity difference. CEUS can be used to image blood perfusion in organs.

Peer review

The authors described the CEUS findings of hepatic paragonimiasis. They analyzed 16 lesions of hepatic paragonimiasis, and demonstrated several specific findings. The article is well organized and well written.

Abstract

AIM: To investigate the causes of missed diagnosis of early gastric cancer (EGC) or high-grade intraepithelial neoplasia (HGIN) in Chongqing, China.

METHODS: The present study summarizes 103 cases of EGC/HGIN detected by esophagogastroduodenoscopy (EGD) and pathological analysis from January 2010 to December 2011. Dimethyl silicone oil was administered orally 15 min before the EGD procedures. The stomach was cleaned by repeated washing with saline when the gastroscope entered the stomach cavity. Suspected EGC lesions were subject to conventional biopsy sampling and pathological examinations. The correlation between lesion locations, endoscopic morphology of cancerous sites, training level of the examiners, pathological biopsies, and missed diagnosis was analyzed.

RESULTS: Twenty-three cases were missed among the 103 cases (22.23%) of EGC/HGIN. The rate of missed EGC in the gastroesophageal junction (8/19, 42.1%) was significantly higher than at other sites (15/84, 17.86%) ($\chi^2 = 5.253$, $P = 0.022$). In contrast, the rate of missed EGC in the lower stomach body (2/14, 14.29%) was lower than at other sites (21/89,

23.6%), but there were no significant differences ($\chi^2 = 0.289$, $P = 0.591$). The rate of missed EGC in the gastric antrum (5/33, 15.15%) was lower than at other sites (18/70, 25.71%), but there were no significant differences ($\chi^2 = 1.443$, $P = 0.230$). Endoscopists from less prestigious hospitals were more prone to not diagnosing EGC than those from more prestigious hospitals ($\chi^2 = 4.261$, $P = 0.039$). When the number of biopsies was < 4 , the rate of missed diagnosis was higher (20/23, 89.96%) than for when there were > 4 biopsies (3/23, 13.04%) ($P < 0.001$). In addition, there was no significant difference in the rate of missed diagnosis in patients with 1-3 biopsy specimens ($\chi^2 = 0.141$, $P = 0.932$).

CONCLUSION: Endoscopists should have a clear understanding of the anatomical characteristics of the esophagus/stomach, and endoscopic identification of early lesions increases with the number of biopsies.

Key words: Missed diagnosis; Early gastric cancer; High-grade intraepithelial neoplasia; Endoscopic diagnosis; Biopsies

Core tip: Early gastric cancer (EGC) detection rate in China is much lower than that in Japan, where $> 80\%$ of EGC is detected. How to avoid missed diagnosis of EGC is most important for digestive endoscopy practice. We found that there were many influencing factors for missed diagnosis of EGC. The most critical issue for endoscopists to avoid missed diagnosis is being cautious about each individual patient.

INTRODUCTION

Gastric cancer (GC) is one of the most common malignant carcinomas, which is highly prevalent worldwide. There were 989 600 estimated new cases and 738 000 deaths in 2008, and > 70% of new cases and deaths occurred in developing countries^[1-5]. Although the incidence of GC has been declining in recent years, China still has the most GC patients in the world. Recent statistics show that > 400 000 new cases of GC are confirmed in China annually^[6-8]. The prognosis of advanced GC is poor and its 5-year survival rate is only 20%-40%, but there could be a 5-year survival rate of 90% for early gastric cancer (EGC) after surgical treatment^[9]. Therefore, timely and accurate diagnosis is important for the treatment and prognosis of patients with GC. However, detection rate of EGC in China is generally about 2%-5%. Although at some hospitals in Shanghai, the detection rate of EGC has increased to 20%-28% in recent years, the detection rate is still significantly lower than that in Japan or South Korea^[10,11]. Therefore, it is imperative for endoscopists to make efforts to improve the detection rate of EGC and reduce missed diagnosis in China^[12]. Our study summarizes the missed cases among 103 patients with EGC or high-grade intraepithelial neoplasia (HGIN) admitted to our hospital from 2010 to 2011, and explored the causes of missed diagnosis.

MATERIALS AND METHODS

General information

From January 2010 to December 2010, gastroscopic examinations were performed on 21 500 patients in Xin Qiao Hospital, Chongqing, China and 245 of these were diagnosed with GC. EGC/ HGIN accounted for 17.56% (43/245) of all the cases of GC. From January to December 2011, gastroscopic examinations were performed on 23 000 patients and 230 were found to have GC, and 26.08% (60/230) of them had EGC/HGIN. There were 69 men and 34 women, aged 44-79 years, with an average age of 60.2 years.

Examination methods

In this study, all cases were examined by gastroscopy (Olympus H260 and PENTAX EPK-i-san, Japan). The date of examination and the results, along with the attending doctor and hospital, were recorded. Dimethyl silicone oil was administered orally, 15 min before the esophagogastroduodenoscopy procedures. The stomach was cleaned by repeated washing with saline, when the gastroscope entered the stomach cavity. Suspected EGC lesions were subject to conventional biopsy sampling and pathological examination. The shape and location of the lesions, as well as the extent and site of the biopsies were recorded. Endoscopic diagnosis was performed in accordance with the Paris endoscopic classification of superficial neoplastic lesions^[13]. Pathological diagnosis of EGC/HGIN followed the 2010 version of the World Health Organization classification of tumors of the digestive system^[14].

Missed diagnosis was defined as follows. Patients who were previously diagnosed with other diseases (*e.g.*, gastric polyps or chronic gastritis) at two examinations at < 3 mo apart, and were later confirmed to have EGC/HGIN.

Statistical analysis

Data analysis was conducted using SPSS 20.0 software (Chicago, IL, United States). Comparison between the groups was performed by using χ^2 test or Fisher's exact probability test and $P < 0.05$ was considered statistically significant.

RESULTS

Different lesion locations correlated with different rates of missed diagnosis of EGC/HGIN

There were 23 cases of EGC/HGIN that were not found by endoscopy but were diagnosed later by pathological examination, so the overall rate of missed EGC/HGIN was 22.23% (23/103) (Table 1). In detail, 42.1% (8/19) of cases of EGC/HGIN that occurred in the gastroesophageal junction were missed, and the rate was higher than for other parts of the stomach (15/84, 17.86%; $\chi^2 = 5.253$, $P = 0.022$). The rate of missed EGC in the lower stomach body (2/14, 14.29%) was lower than at other sites (21/89, 23.60%), but there were no significant differences ($\chi^2 = 0.289$, $P = 0.591$). The rate of missed EGC in the gastric antrum (5/33, 15.15%) was also lower than at other sites (18/70, 25.71%), but there were no significant differences ($\chi^2 = 1.443$, $P = 0.230$).

Endoscopists from hospitals of different standing had different rates of missed diagnosis

Among the 23 missed cases of EGC/HGIN, 15 were found to have no abnormalities or were diagnosed with other diseases (*e.g.*, gastric polyps or chronic gastritis) by endoscopy in the less prestigious hospitals (15/23, 65.21%), but were later diagnosed with EGC/HGIN in our hospital (a more prestigious hospital). The other eight cases (8/23, 34.78%) were initially diagnosed with other diseases by endoscopy physicians in our hospital and then with EGC/HGIN after further examinations. The rate of missed diagnosis of EGC/HGIN by endoscopists from less prestigious hospitals was higher than that from more prestigious hospitals ($\chi^2 = 4.261$, $P = 0.039$) (Table 2).

Endoscopic appearance of cancerous lesions affected missed diagnosis of EGC/HGIN

The rate of missed diagnosis of 0-IIc type lesions was 91.3% (21/23), which was higher than that for 0-I (1/23, 4.35%) or 0-IIb (1/23, 4.35%) lesions. However, one 0-IIb lesion in the lesser curvature was missed. At the first gastroscopy examination, no cancerous lesions were found and the patient was treated for gastritis for 1 mo but the symptoms did not improve. The second gastroscopic examination was performed at the request of the

Table 1 Missed diagnosis of early gastric cancer or high-grade intraepithelial neoplasia in different parts of the stomach *n* (%)

| Locations | Total EGC/HGIN | Missed cases |
|---------------------------|----------------|------------------------|
| Gastroesophageal junction | 19 | 8 (42.10) ^a |
| Upper stomach body | 12 | 2 (16.67) |
| Middle stomach body | 11 | 3 (27.27) |
| Lower stomach body | 14 | 2 (14.29) ^b |
| Antrum of stomach | 33 | 5 (15.15) ^b |
| Gastric angle | 14 | 3 (21.42) |
| Total | 103 | 23 (22.33) |

^a*P* < 0.05 *vs* non-missed diagnosis cases; ^bNo statistical differences. EGC: Early gastric cancer; HGIN: High-grade intraepithelial neoplasia.

Table 2 Early gastric cancer or high-grade intraepithelial neoplasia missed by endoscopists at our and other hospitals

| Lesion locations | Other hospitals | Our hospital |
|---------------------------|-----------------|--------------|
| Gastroesophageal junction | 7 | 1 |
| Upper stomach body | 1 | 1 |
| Middle stomach body | 2 | 1 |
| Lower stomach body | 1 | 1 |
| Antrum of stomach | 2 | 3 |
| Gastric angle | 2 | 1 |
| Total | 15 | 8 |

Table 3 Number of biopsies and missed diagnosis *n* (%)

| Biopsies | Missed cases |
|----------|--------------|
| 1 | 7 (30.43) |
| 2 | 7 (30.43) |
| 3 | 6 (26.09) |
| ≥ 4 | 3 (13.64) |
| Total | 23 (100.00) |

patient's family, and flaky red regions were observed in the middle of the gastric body near the lesser curvature. It was further confirmed as intramucosal differentiated-type GC by pathological diagnosis after endoscopic submucosal dissection.

More biopsies resulted in less missed diagnosis

There were 20 patients in whom diagnosis was missed from 1-3 biopsy specimens. The rate of missed diagnosis was 86.96% (20/23). There were three patients in whom diagnosis was missed with four biopsy specimens. The rate of missed diagnosis was 13.04% (3/23). When the number of biopsies was < 4, the rate of missed diagnosis (20/23, 86.96%) was higher than for > 4 biopsies (3/23, 13.04%) (*P* < 0.001). In addition, there was no significant difference in the rate of missed diagnosis in patients with 1, 2 or 3 biopsy specimens ($\chi^2 = 0.141$, *P* = 0.932) (Table 3).

DISCUSSION

The incidence of GC is about 30/100 000 in East Asian countries including China and Japan^[1]. In some regions

of China, the incidence even exceeds 100/100 000^[15,16]. Every year, mass screening in Japan shows the presence of GC in a low proportion of patients receiving gastroscopic examination. It has been reported that in some Japanese hospitals that the diagnosed cases of GC account for only approximately 0.4% of the gastroscopy examinations each year^[17], but the incidence of GC was 1%-1.2% in our endoscopy center, which was significantly higher than that in Japan. In addition, although there are no accurate statistics for EGC detection rate, it is believed that the rate in China is much lower than that in Japan, where > 80% of EGC is detected^[17]. Many factors contribute to the low detection rate of EGC in China, but how to avoid missed diagnosis of EGC is important for digestive endoscopy practice.

We found that lesion location, training level of doctors (doctors from less prestigious hospitals and fewer years of endoscopy experience are considered to have a low level of training), lesion morphology, and the number of biopsies can affect the diagnosis when EGC is not identified. Previous studies have shown that lesion location has a significant effect on EGC missed diagnosis. Hosokawa *et al.*^[18-20] have conducted a survey in Fukui Hospital, where 562 cases of GC were diagnosed from 51 411 (1.05%) gastroscopic examinations, and 188 cases were confirmed as GC within the next 3 years, with an overall missed diagnosis rate of 25.8%. They have also found that doctors with < 10 years experience as an upper gastrointestinal endoscopist missed 32.4% of GC cases, but the missed diagnosis rate was only 19.5% when doctors with > 10 years of experience conducted the examination (*P* < 0.01).

Importantly, EGC in the gastric cardia or body, especially at the lesser curvature or posterior wall, is usually overlooked^[18,19]. Consistent with this, we found that the rate of missed EGC in the gastroesophageal junction near the stomach side was significantly higher than at other sites. Due to the anatomical structure of the cardia, cancerous lesions in these parts are often difficult to observe when the endoscope is withdrawn or reversed. This requires that the endoscopists should carefully investigate the morphological changes in the gastric fundus near the cardia. On one hand, we should not withdraw the gastro-scope too quickly. On the other hand, to avoid the shield of scope itself, it is necessary to observe from both sides of the scope when it is reversed.

Additionally, we found that the proportion of EGC occurring in the gastroesophageal junction was higher than that previously reported. This may have been due to the increased incidence of GC at this site, which needs further large epidemiological investigations. Compared to other sites, the gastric antrum is easy to expose and the rate of missed diagnosis was lower at this site. The rate of missed diagnosis in the gastric antrum was still approximately 15%, therefore, every part of the stomach should be fully and carefully investigated. We also noticed that there was a significant difference in missed diagnosis of EGC between doctors with different training levels in endoscopy, suggesting that the standardization

of endoscopy records and long-term cognitive training for EGC are crucial. The main cause of missed diagnosis of EGC in many primary hospitals is the inadequate knowledge and cognitive ability^[20]. For example, in our study there were several cases of EGC that were misdiagnosed as gastric erosion. Thus, it is urgent for physicians to strengthen their endoscopic training for diagnosis of EGC. Endoscopic appearance also has a significant effect on EGC diagnosis. Compared to the protruding lesions, the depressed lesions were more prone to be missed. This may have been due to the high proportion of depressed lesions in EGC, because we found that superficially depressed lesions accounted for the vast majority of all cases of EGC. However, the rate of missed diagnosis of EGC 0-IIc lesions (IIc, IIc + IIa, IIa + IIc) was still significantly higher than that of 0-II or 0-III lesions. Although the rate of missed diagnosis of 0-IIb EGC was 100% (1/1) in this study, it still calls for more observation on a larger scale. However, we can conclude that 0-II lesions are more easily missed than 0-I and 0-III lesions. Number of biopsies also affected the rate of missed diagnosis. For cases with ≥ 4 biopsies, the rate of missed diagnosis was significantly lower than for those with < 4 biopsies^[21]. In our study, no patients were subjected to other techniques, such as chromoendoscopy, narrow-band imaging (NBI), magnified endoscopy, and NBI + magnified endoscopy, because these new techniques have not been widely adopted in most hospitals in China. If we use these techniques, the results will be better^[22-25]. In addition, whether targeted biopsy sampling can increase the positive rate of EGC/HGIN requires further research.

In summary, there are many influencing factors for the missed diagnosis of EGC. We agreed with Axon that the most critical issue for endoscopists to avoid missed diagnosis is being cautious about each individual patient^[26].

COMMENTS

Background

Gastric cancer (GC) is one of the most common malignant carcinomas. China has the most GC patients in the world. The prognosis of advanced GC is poor but there could be a 90% 5-year survival rate for early gastric cancer (EGC) after surgical treatment. However, detection rate of EGC in China is very low.

Research frontiers

Research of EGC is a hotspot in digestive diseases at present and how to improve the diagnosis rate of EGC is a key problem. This study aimed to analyze the reasons for missed diagnosis of EGC and provide methods to avoid missed diagnosis. With rapid EGC research and development, more new technology will apply.

Innovations and breakthroughs

Few studies have been carried out focusing on the rate of diagnosis of EGC, due to lack of recognition. The present study was a detailed and systematic study in this field. Furthermore, the study also provides a brighter future in the diagnosis and treatment of EGC, with the development of understanding and new technology.

Applications

This study provides reference data for the diagnosis of EGC. It can be applied to gastroenterologists in hospitals of different rank. There are many influencing factors for missed diagnosis of EGC, but the most critical issue for endoscopists

to avoid missed diagnosis is to be cautious about each individual patient.

Peer review

This is an important analysis of the factors involved in the missed diagnosis of EGC. The authors should use other important techniques, for example: chromoendoscopy, narrow-band imaging (NBI), magnified endoscopy, and NBI + magnified endoscopy. These techniques could change the results.

Abstract

AIM: To investigate the effect of surgery and chemotherapy for gastric cancer with multiple synchronous liver metastases (GCLM).

METHODS: A total of 114 patients were entered in this study, and 20 patients with multiple synchronous liver metastases were eligible. After screening with preoperative chemotherapy, 20 patients underwent curative gastrectomy and hepatectomy for GCLM; 14 underwent major hepatectomy, and the remaining six underwent

minor hepatectomy. There were 94 patients without aggressive treatment, and they were in the non-operative group. Two regimens of perioperative chemotherapy were used: S-1 and cisplatin (SP) in 12 patients, and docetaxel, cisplatin and 5-fluorouracil (DCF) in eight patients. These GCLM patients were given preoperative chemotherapy consisting of two courses chemotherapy of SP or DCF regimens. After chemotherapy, gastrectomy and hepatectomy were performed. Evaluation of patient survival was by follow-up contact using telephone and outpatient records. All patients were assessed every 3 mo during the first year and every 6 mo thereafter.

RESULTS: Twenty patients underwent gastrectomy and hepatectomy and completed their perioperative chemotherapy and hepatic arterial infusion before and after surgery. Ninety-four patients had no aggressive treatment of liver metastases because of technical difficulties with resection and severe cardiopulmonary dysfunction. In the surgery group, there was no toxicity greater than grade 3 during the course of chemotherapy. The response rate was 100% according to the Response Evaluation Criteria in Solid Tumors Criteria. For all 114 patients, the overall survival rate was 8.0%, 4.0%, 4.0% and 4.0% at 1, 2, 3 and 4 years, respectively, with a median survival time (MST) of 8.5 mo (range: 0.5-48 mo). For the 20 patients in the surgery group, MST was 22.3 mo (range: 4-48 mo). In the 94 patients without aggressive treatment, MST was 5.5 mo (range: 0.5-21 mo). There was a significant difference between the surgery and unresectable patients ($P = 0.000$). Three patients in surgery group were still alive at the end of the cut-off date.

CONCLUSION: Perioperative weekly DCF and SP achieved a good response, and combined with surgery, they could improve prognosis of GCLM.

Chemotherapy and resection for gastric cancer with synchronous liver metastases. *World J Gastroenterol* 2013; 19(13): 2097-2103 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2097.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2097>

INTRODUCTION

Surgery for gastric cancer with multiple synchronous liver metastases (GCLM) is a major challenge to every surgeon; not only because of coexisting factors, but each GCLM patient has his/her own clinicopathological features. It is difficult to determine the suitable candidates for treatment. At present, the justification for surgical resection is still controversial^[1], and the prognosis is dismal. In contrast, for patients with colorectal carcinoma with liver metastases, a second liver resection is safe and feasible. Hepatic resection has been widely accepted as a potentially curative approach in patients with liver metastases of colorectal carcinoma^[2].

One study demonstrated that patients with GCLM limited to one lobe, who underwent radical gastrectomy with D2 lymphadenectomy, had the most favorable outcomes following hepatic surgical treatment^[3]. A further study found that the number of metastases was no longer considered to be an important predictor of long-term survival^[4]. Some positive effect of liver resection in these patients seemed to imply that hepatic surgical treatment should be recommended for appropriate GCLM candidates^[5-7]. The United Kingdom myoblast autologous grafting in ischemic cardiomyopathy (MAGIC) trial of perioperative chemotherapy in gastric cancer found that perioperative systemic chemotherapy improved 5-year survival from 23% to 36%^[8], compared with surgery alone. What is the optimal dosing appropriate for Chinese patients, and how do we schedule perioperative chemotherapy that could improve tolerability while maintaining efficacy? In our previous pilot study, we found that liver resection combined with a weekly docetaxel-based regimen (docetaxel, cisplatin and 5-fluorouracil, DCF) were well tolerated, with a good response. In the present study, we assessed more GCLM patients who underwent aggressive treatment, in comparison with non-surgical treatment.

MATERIALS AND METHODS

From July 2007 to October 2012, 1821 patients with

gastric cancer were treated in Beijing Cancer Hospital of Beijing University and Qingdao Municipal Hospital. Only patients with adenocarcinoma were enrolled in this study. Among these patients, 114 developed multiple liver metastases. The inclusion and exclusion criteria are described in our previous study^[9]. Patients had adequate physical condition and received two course of preoperative chemotherapy. After effective screening with preoperative chemotherapy, 20 patients underwent curative gastrectomy and hepatectomy for GCLM. Two regimens of perioperative chemotherapy were used. Twelve patients received the S-1 and cisplatin (SP) regimen: 40 mg S-1 orally, twice daily for 3 consecutive weeks, and 60 mg/m² cisplatin intravenously on day 8, followed by a 2-wk rest period, within a 5-wk cycle^[10]. Eight patients received the DCF regimen: 20 mg/m² cisplatin over 1 h; 20 mg/m² docetaxel, over 30 min; and 350 mg/m² 5-fluorouracil over 15 min on day 1. This was administered weekly for 6 wk, followed by a 2-wk break^[9].

According to the Japanese Research Society for Gastric Cancer guidelines, our surgical procedure was total or subtotal gastrectomy, at a minimum of 5 cm clearance. Hepatic resection with D2 lymphadenectomy was performed^[11].

After surgery, two courses of chemotherapy (SP or DCF regimen) were administered. After completion of chemotherapy, patients without other distant disease, except for hepatic metastasis, underwent hepatic arterial infusion (HAI). If liver lesions progressed in the course of postoperative chemotherapy, HAI was commenced immediately. Safety evaluation was standardized by the National Cancer Institute Common Terminology Criteria for Adverse Events version 4.0 (May 28, 2009). Evaluations were classified by the Response Evaluation Criteria in Solid Tumors (RECIST) guidelines^[12]. The study was approved by the medical ethics committees of Qingdao Municipal Hospital and Beijing Cancer Hospital. Written informed consent was obtained according to the principles of the institution.

Evaluation of patient survival was by follow-up contact using telephone and outpatient records. All patients were assessed every 3 mo during the first year and every 6 mo thereafter. Patient follow-up lasted until death or the cut-off date of October 1, 2012. Three patients (2.6%) were lost to follow-up, and survival information was censored at their last visit. Four (3.5%) patients were still alive and were censored at the cut-off date. The median follow-up period for the 114 patients was 10 mo (range: 2-53 mo).

Statistical analysis

Statistical analysis was performed with SPSS version 13.0 (SPSS, Chicago, Illinois, United States). For univariate analysis, binomial and categorical data were evaluated by cross-linked tables and the Fisher's exact test. Results were regarded as being statistically significant when $P < 0.05$. For survival analysis, the Kaplan-Meier method was used.

Table 1 Clinicopathological characteristics of patients with and without hepatectomy

| Clinicopathological characteristics | With hepatectomy | Without hepatectomy |
|--|------------------|---------------------|
| Sex | | |
| Male | 12 | 59 |
| Female | 8 | 35 |
| Primary gastric tumors | | |
| Median diameter of primary gastric tumors (cm) | 4.3 (2.4-8.8) | 4.5 (2.1-9.3) |
| Tumor location | | |
| Upper | 7 | 27 |
| Lower | 13 | 67 |
| Pathological T-stage of the primary ¹ | | |
| pT1 | 2 | 9 |
| pT2 | 4 | 21 |
| pT3 | 12 | 51 |
| pT4 | 2 | 13 |
| N stage of the primary tumor | | |
| N0 | 3 | 18 |
| N1 | 9 | 48 |
| N2 | 5 | 21 |
| N3 | 3 | 7 |
| Differentiation of the primary tumor | | |
| Well | 2 | 9 |

| Present | 5 | 28 |
| Absent | 15 | 66 |

¹According to tumor-nodes-metastasis-classification.

RESULTS

Patient characteristics

The mean age of the 114 patients was 56.7 years (range: 33-75 years), and the male to female ratio was 3.1:1. Twenty patients underwent gastrectomy and hepatectomy. These 20 patients completed their perioperative chemotherapy and HAI before and after surgery. The other 94 patients were not considered for aggressive treatment of liver metastases. In most cases ($n = 91$), the reason for deciding against aggressive treatment was patient refusal; the remaining three were not eligible for surgery due to severe cardiopulmonary dysfunction. There was no perioperative mortality. There were no obviously different clinicopathological characteristics between patients with and without hepatectomy.

Surgery

There were 12 male and 8 female patients in the surgery

Table 2 Response evaluation after first two courses of preoperative chemotherapy

| No. of cases | Diameter of metastases (mm ³) | | Evaluation of response (according to RECIST) | Adverse events grade |
|--------------|---|-----------|--|----------------------|
| | Pre-chem | Post-chem | | |
| 1 | 128 | 0-10 | CR | 2 |
| 2 | 135 | 56 | PR | 3 |

| 20 | 78 | 43 | PR | 3 |

When the number of liver lesions was > 5, the diameters of the five largest lesions were summed. RECIST: Response Evaluation Criteria in Solid Tumors; CR: Complete response; PR: Partial response; Pre-chem: Pre-chemotherapy; Post-chem: Post-chemotherapy.

group. The median age of this group was 54 years (range: 31-74 years). Seventeen patients had a lymph-node-positive stage of the primary tumor, and only three had no lymph node involvement. There were 13 patients with distal gastric cancer, seven had proximal gastric cancer, and nine had bilobar metastases. The clinicopathological characteristics of the patients who underwent hepatectomy are listed in Table 1.

The patients in the surgery group finished two courses of SP or DCF chemotherapy before the operation. In the two courses of chemotherapy with different regimens, no patients had toxicity greater than grade 3. The most common adverse effects in the two regimens were diarrhea, nausea, leukopenia, neutropenia and thrombocytopenia, at grade 1 or 2 intensity. Most adverse effects could be modified by premedication, such as dexamethasone and antiemetics. Granulocyte colony-stimulating factor support was given to 12 patients. Response to treatment was assessed by monthly magnetic resonance imaging or computed tomography. All patients achieved a partial response according to the RECIST^[12] criteria (Table 2). The response rate was 100% according to the RECIST (Figures 1 and 2). There was no treatment-related mortality.

We performed gastric and liver resection only in cases that were potentially curative. The common complications in the perioperative course were impaired wound healing (surgical therapy in two patients), and pleural effusion in four. Fourteen patients underwent major hepatectomy (hepatic resection of more than three segments:

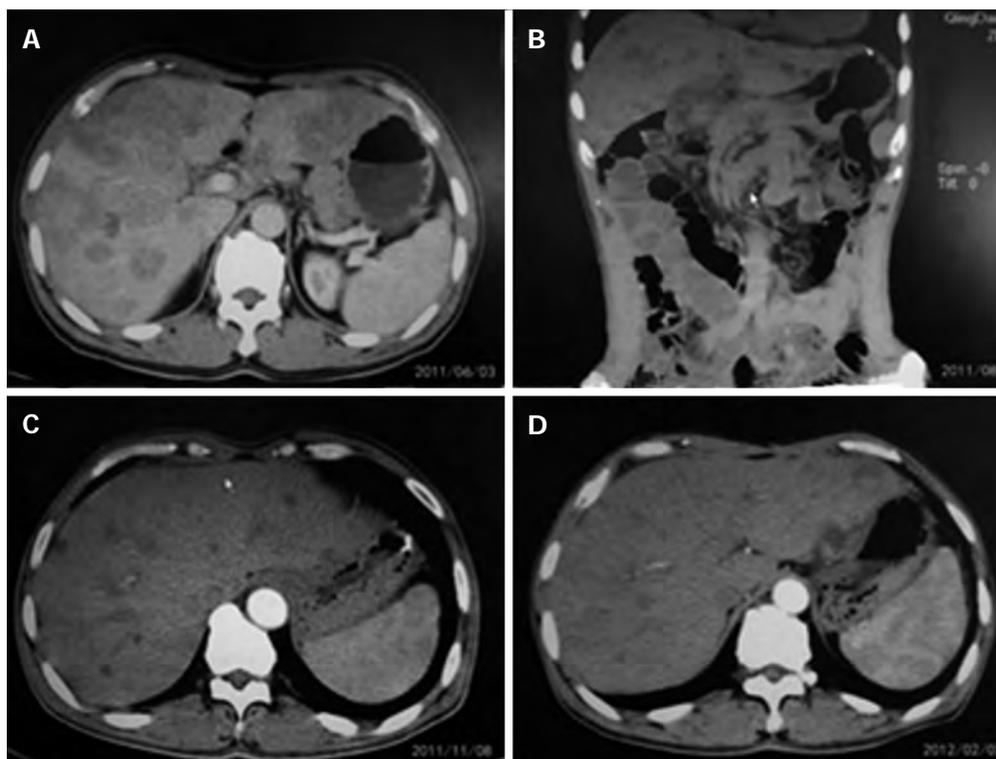

Figure 1 Patients with complete response. A: Abdominal computed tomography (CT) in gastric cancer with multiple synchronous liver metastases (GCLM) patient treated with preoperative chemotherapy (June 3, 2011); B: Abdominal CT in patient with GCLM after neoadjuvant chemotherapy (August 29, 2011); C: Abdominal CT in patient with GCLM after neoadjuvant chemotherapy (November 8, 2011); D: Abdominal CT in patient with GCLM after neoadjuvant chemotherapy (February 2, 2012).

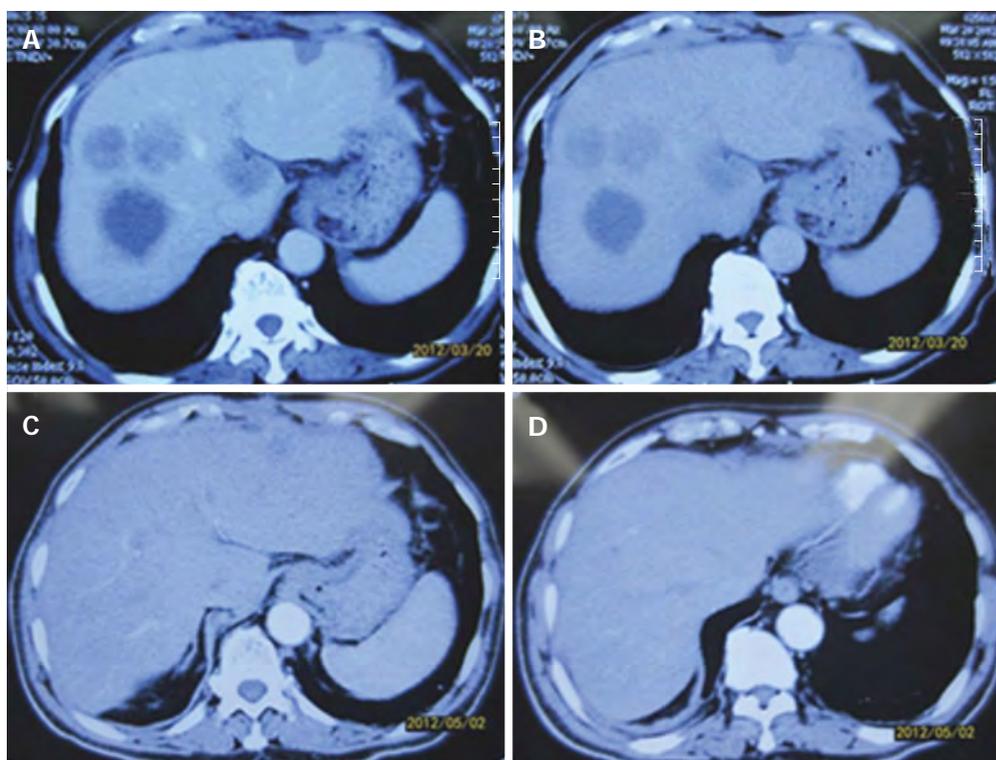

Figure 2 Patients with partial response. A, B: Abdominal computed tomography (CT) in patients with gastric cancer with multiple synchronous liver metastases (GCLM) after preoperative chemotherapy; C, D: Abdominal CT in patients with GCLM after neoadjuvant chemotherapy.

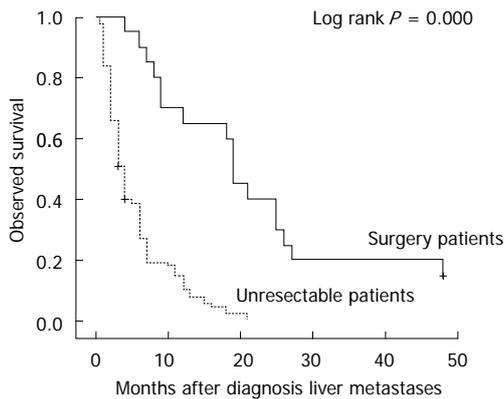

Figure 3 Overall survival of patients with hepatic metastases from gastric cancer.

hemihepatectomy in 12 and trisectionectomy in 2); and the remaining six patients underwent minor hepatectomy (sectionectomy in 2 and limited resection in 4). The types of hepatectomy were classified according to the Brisbane 2000 terminology^[13].

Survival rate in surgery and nonoperative groups

For all 114 patients, the overall survival rate was 8.0%, 4.0%, 4.0% and 4.0% at 1, 2, 3 and 4 years, respectively, with an median survival time (MST) of 8.5 mo (range: 0.5-48 mo). For the 20 patients in the surgery group, MST was 22.3 mo (range: 4-48 mo). In the 94 patients without aggressive treatment, MST was 5.5 mo (range: 0.5-21 mo). A significant difference was observed between the surgery and nonoperative patients ($P = 0.000$, Figure 3). Three patients in the surgery group were still alive at the end of the cut-off date.

DISCUSSION

We reviewed retrospectively 20 macroscopically complete liver resections for patients with GCLM at two institutions. After hepatectomy, their MST was 22.3 mo. These results compare favorably with patients without surgery, whose MST was only 5.5 mo. The survival time in patients with hepatectomy was longer than in those without hepatectomy. However, our MSTs were shorter than the 34 mo reported by Takemura *et al.*^[14]. The discrepancy may have been caused by the different operating procedures. In the Takemura *et al.*^[14] study, 14/64 (21.9%) patients underwent major hepatectomy and the remaining 50 (78.1%) minor hepatectomy. In our study, 70% patients had major hepatectomy and 30% had minor hepatectomy. Both studies indicate that hepatectomy is beneficial for some patients with GCLM despite the remaining controversy surrounding surgical resection.

Liver metastases is reported to develop in 5%-9% of patients with gastric cancer^[15]. One study has shown that only a limited number of GCLM patients are eligible for surgical treatment^[4]. After the promising results of the MAGIC trial, in Europe, current practice for treatment

of GCLM patients has become surgery with perioperative chemotherapy^[10,16]. However, the optimal surgical strategy for GCLM remains a matter of debate. Only some patients with GCLM are ideal candidates for hepatectomy, therefore, many patients are unsuitable for surgical resection, either due to other distant metastases, extensive lymph node metastases, multiple bilateral metastases, or comorbidity.

In recent decades, multimodality approaches using chemotherapy, radiotherapy, or both have been evaluated in an attempt to improve outcomes following gastric cancer surgery. Some benefit has been seen in adjuvant chemotherapy after gastric cancer resection. One recent trial conducted in East Asia, ACTS-GC30, evaluated S-1 chemotherapy and found significant 10% improvement in 3-year overall survival with adjuvant chemotherapy after surgery^[17]. A more compelling study of perioperative chemotherapy was the phase 3 United Kingdom MAGIC trial. This trial demonstrated that perioperative chemotherapy could significantly improve overall survival and progression-free survival in 503 patients with resectable adenocarcinoma. However, this trial also highlighted the challenges involved in delivering postoperative treatment; only 50% of patients were able to receive postoperative chemotherapy, compared with nearly 91% who received preoperative chemotherapy.

In the late stage of gastric cancer, with high rates of toxicity in perioperative chemotherapy, adoption of the perioperative approach could be useful for a large proportion of GCLM patients. Our results also showed that weekly SP and low-dose DCF in perioperative chemotherapy had a positive effect in GCLM. In our study, two patients with initially unresectable multiple liver metastases were converted to resectable after preoperative chemotherapy. Our results also showed that D2 resection provides better locoregional control and significantly better survival compared with unresectable patients. We recommend more personally tailored multimodality treatment approaches (surgery + chemotherapy \pm radiation) in patients with GCLM.

Some researchers have reported that even a generous surgical margin may not be essential for curative hepatic resection of liver metastases, because recurrence is strongly associated with systemic spread rather than local invasion^[6]. This conclusion highlights the essentiality of perioperative chemotherapy. GCLM recurrence after surgery is most likely due to occult metastatic disease in the tumor bed and at distant sites, so locoregional resection alone is not a complete 100% successful procedure. Therefore, multimodality approaches using systemic chemotherapy or radiation, or a combination of both have been used in an attempt to improve outcomes following surgery, especially in patients with multiple metastases.

However, adequate chemotherapy can lead to intolerance and morbidity and mortality. In the present study, we wanted to explore some safe and effective regimens available to Chinese patients with GCLM. We investigated the safety and efficacy of liver resection combined

with perioperative S1 regimen in patients with GCLM. We performed a retrospective analysis based on recent prospectively collected data. S-1 is an orally active combination of tegafur (5-fluorouracil prodrug), gimeracil (an inhibitor of dihydropyrimidine dehydrogenase, which degrades fluorouracil), and oteracil (which inhibits phosphorylation of 5-fluorouracil in the gastrointestinal tract) in a molar ratio of 1:0.4:1. S-1 has been the standard regimen for adjuvant chemotherapy for advanced primary gastric cancer^[18], and its mild side effect profile and ease of administration make it a preferred choice. The DCF regimen has major myelotoxicity^[19-25]. However, weekly DCF in our study was well tolerated, and both the regimens were well tolerated and achieved a good response. All GCLM patients with adequate physical condition obtained a benefit from preoperative chemotherapy, which assisted with their subsequent surgical procedure. Appropriately modified chemotherapy is necessary for the improvement of the GCLM resection rate and complete elimination of micrometastases^[26-31]. In our initial results, weekly DCF yielded an unexpected high response as preoperative chemotherapy for GCLM^[9]. We found that S-1 combined with cisplatin also yielded a high response and had better applicability. These modifications of altering the dose and frequency of the cytotoxic agents are an individualized approach for treatment of GCLM. Our aim is to improve the generally poor prognosis of this aggressive disease and further phase II and III trials are warranted to confirm the feasibility and efficacy of preoperative chemotherapy for GCLM.

COMMENTS

Background

Liver metastasis is a fatal event in gastric cancer patients, and remains a major cause of cancer-related death. Surgery for multiple liver metastases from gastric cancer (GCLM) has favorable outcomes. However, the efficacy and safety of perioperative chemotherapy is still a matter of debate.

Research frontiers

The glycosylated and myristoylated smaller surface antigen trial was conducted to compare gastrectomy with metastasectomy plus systemic therapy versus systemic therapy alone. The results of this trial showed that aggressive surgical resection in combination with systemic chemotherapy may improve the outcomes of the patients with metastatic gastric cancer.

Innovations and breakthroughs

In a previous pilot study, the authors found that liver resection combined with weekly docetaxel-based chemotherapy were well tolerated and had a good response. In the present study, the authors found that perioperative weekly docetaxel, cisplatin and 5-fluorouracil (DCF), and S-1 and cisplatin (SP) in patients with GCLM who underwent aggressive surgical treatment could improve prognosis and overall survival.

Applications

The study results suggest that perioperative weekly DCF and SP could be used to treat GCLM patients who underwent aggressive surgical treatment.

Terminology

Synchronous liver metastases are detected before or during surgery, or occur within 1 year after gastrectomy. Metachronous liver metastases are usually detected within a 2-year period following initial gastrectomy.

Peer review

This is a good study in which the authors evaluated the effect of perioperative weekly DCF and SP in GCLM patients who underwent aggressive surgical treatment. The results are interesting and suggest that perioperative weekly DCF and SP combined with resection could be applied in patients with GCLM.

Abstract

AIM: To investigate the efficacy of extended antimicrobial prophylaxis (EAP) after gastrectomy by systematic review of literature and meta-analysis.

METHODS: Electronic databases of PubMed, Embase, CINAHL, the Cochrane Database of Systematic Reviews, the Cochrane Controlled Trials Register and the China National Knowledge Infrastructure were searched systematically from January 1980 to October 2012. Strict literature retrieval and data extraction were carried out independently by two reviewers and meta-analyses were conducted using RevMan 5.0.2 with statistics tools risk ratios (RRs) and intention-to-treat analyses to evaluate the items of total complications, surgical site infection, incision infection, organ (or space) infection, remote site infection, anastomotic leakage (or dehiscence) and mortality. Fixed model or random model was selected accordingly and forest plot was conducted to display RR. Likewise, Cochrane Risk of Bias Tool was applied to evaluate the quality of ran-

domized controlled trials (RCTs) included in this meta-analysis.

RESULTS: A total of 1095 patients with gastric cancer were enrolled in four RCTs. No statistically significant differences were detected between EAP and intraoperative antimicrobial prophylaxis (IAP) in total complications (RR of 0.86, 95%CI: 0.63-1.16, $P = 0.32$), surgical site infection (RR of 1.97, 95%CI: 0.86-4.48, $P = 0.11$), incision infection (RR of 4.92, 95%CI: 0.58-41.66, $P = 0.14$), organ or space infection (RR of 1.55, 95%CI: 0.61-3.89, $P = 0.36$), anastomotic leakage or dehiscence (RR of 3.85, 95%CI: 0.64-23.17, $P = 0.14$) and mortality (RR of 1.14, 95%CI: 0.10-13.12; $P = 0.92$). Likewise, multiple-dose antimicrobial prophylaxis showed no difference compared with single-dose antimicrobial prophylaxis in surgical site infection (RR of 1.10, 95%CI: 0.62-1.93, $P = 0.75$). Nevertheless, EAP showed a decreased remote site infection rate compared with IAP alone (RR of 0.54, 95%CI: 0.34-0.86, $P = 0.01$), which is the only significant finding. Unfortunately, EAP did not decrease the incidence of surgical site infections after gastrectomy; likewise, multiple-dose antimicrobial prophylaxis failed to decrease the incidence of surgical site infection compared with single-dose antimicrobial prophylaxis.

CONCLUSION: We recommend that EAP should not be used routinely after gastrectomy until more high-quality RCTs are available.

Extended antimicrobial prophylaxis after gastric cancer surgery: A systematic review and meta-analysis. *World J Gastroenterol* 2013; 19(13): 2104-2109 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i13/2104.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i13.2104>

INTRODUCTION

Although the incidence of gastric cancer is sharply declining, it still remains the second cause of cancer-related death worldwide^[1,2]. Administration of a first-generation cephalosporin as intraoperative antimicrobial prophylaxis (IAP) to prevent surgery-associated infection has been recommended^[3]. Nevertheless, most patients after gastrectomy still receive further extended antimicrobial prophylaxis (EAP) routinely to reduce surgical site infection even until 3-4 postoperative days^[4-6]. Few randomized controlled trials (RCTs) have investigated the efficacy of EAP^[7-10]. Moreover, EAP administration is controversial and there is no worldwide accepted validation as a result of its scarce efficacy.

However, the administration of antimicrobial prophylaxis may result in antibiotics-associated diarrhea (AAD), which can occur as early as few hours after the first dose of antibiotics^[11]. The incidence of AAD varies from 10% to 30%, and AAD has been identified as the leading cause of diarrhea in hospitalized patients, especially in patients with surgery of gastrointestinal tract^[12]. Abuse of antibiotics also aggravates the burden of patient hospital costs.

A total of 21 320 new gastric cancer cases and 10 540 deaths from gastric cancer were projected to occur in the United States in 2012^[2]. Generally, complete surgical resection of gastric cancer with negative margin (R0 resection) and D2 lymphadenectomy is considered as the most effective treatment strategy for gastric cancer in East Asia^[13-15]. Surgical site infections have suggested the essential administration of IAP. However, only few RCTs have investigated the efficacy of EAP^[7-10], and almost no meta-analysis has been conducted to assess the efficacy of EAP. Meta-analysis is considered a more powerful evidence for clinical decision making compared with RCTs. In light of these considerations, we performed this meta-analysis to assess the efficacy of EAP in patients after gastrectomy.

MATERIALS AND METHODS

Literature search

To identify additional studies and published abstracts, electronic databases of PubMed, Embase, CINAHL, the Cochrane Database of Systematic Reviews, the Cochrane Controlled Trials Register and the China National Knowledge Infrastructure were searched systematically

from January 1980 to October 2012. MeSH terms of “stomach neoplasm”, “gastrectomy”, “antibiotic prophylaxis” and “randomized controlled trial” were used. The reference lists of all retrieved articles were reviewed for further identification of potentially relevant trials.

Data collection process

Two reviewers (Zhang CD and Zeng YJ) in our group independently extracted relevant data, including: study and population features, outcomes, titles, abstracts, and even full articles when it was necessary. They compared the results and synthesized the same opinions, and disagreements were solved by discussion with a third reviewer in our group.

Inclusion and exclusion criteria

The inclusion criteria and exclusion criteria were established based on the Cochrane Handbook for Systematic Review of Interventions (Version 5.0.2). The inclusion criteria were: (1) all originally published and unpublished high-quality RCTs; (2) trials concerning antimicrobial prophylaxis after gastrectomy; (3) if studies were from the same author or institution, the most informative and latest ones were selected; and (4) no restriction on publishing language. Exclusion criteria were as follows: (1) studies with little information about the items to be investigated; (2) loss to follow-up exceeding 10%; and (3) non-RCTs.

The following data were acquired: study and year, country, sample size, sex ratio, median age, body-mass index, operation time, blood loss, median follow-up time, participants, interventions, total complications, surgical site infection, incision infection, organ/space infection, anastomotic leakage/dehiscence, and mortality (Tables 1-3).

Quality evaluation

Methodological quality of RCTs was evaluated according to the Cochrane Risk of Bias Tool with regard to randomization, allocation concealment, blind, withdrawal and dropout, and selective reporting bias (Table 4).

Statistical analysis

Data analysis was conducted using Review Manager 5.0.2 (RevMan 5.0.2) with statistics tools risk ratios (RRs). Intention-to-treat analyses were performed. Dichotomous variables were analyzed with RRs. $P < 0.05$ was defined as statistically significant and 95%CI was applied. Fixed model was used if $I^2 < 50\%$ and $P > 0.1$, while random model was selected if $I^2 \geq 50\%$ or $P \leq 0.1$. Likewise, forest plot was conducted to display RR.

RESULTS

Among a total of 52 studies retrieved, 48 studies were found unrelated to our selection criteria after further assessment. Thus, only four RCTs^[7-10] were eligible for the meta-analysis: three RCTs^[7-9] comparing EAP with IAP and one RCT^[10] comparing multiple-dose with single-

NM: Not mentioned.

dose antimicrobial prophylaxis after gastrectomy, including 1095 patients (Tables 1-5).

Primary outcomes: Intraoperative *vs* EAP

Total complications: Three RCTs^[7-9] were included (303 EAP and 306 IAP) and fixed model was applied ($I^2 = 42\%$, $P = 0.18$). No statistically significant difference was detected (RR of 0.86, 95%CI: 0.63-1.16, $P = 0.32$).

Surgical site infection, incision infection and organ/space infection: Only one RCT^[9] comparing EAP and IAP reported surgical site infection, which showed no statistical difference (RR of 1.97, 95%CI: 0.86-4.48, $P = 0.11$). There were also no significant differences in the analysis of incision infection (RR of 4.92, 95%CI: 0.58-41.66, $P = 0.14$) and organ or space infection (RR of 1.55, 95%CI: 0.61-3.89, $P = 0.36$).

Table 4 Quality assessment of the randomized controlled trails included based on the Cochrane Risk of Bias Tool

Table 5 Summary of comparisons between extended antimicrobial prophylaxis and intraoperative antimicrobial prophylaxis

| Items | Heterogeneity | | Analysis model | Overall effect | | RR (95%CI) | Ref. |
|--------------------------------|---------------|------|----------------|----------------|------|-------------------|-------|
| | I^2 | P | | Z | P | | |
| Total complications | 42% | 0.18 | Fixed | 0.99 | 0.32 | 0.86 (0.63-1.16) | [7-9] |
| Surgical site infections | NP | NP | Fixed | 1.61 | 0.11 | 1.97 (0.86-4.48) | [9] |
| Incision infections | NP | NP | Fixed | 1.46 | 0.14 | 4.92 (0.58-41.66) | [9] |
| Organ/space infections | NP | NP | Fixed | 0.92 | 0.36 | 1.55 (0.61-3.89) | [9] |
| Remote site infections | 0% | 0.90 | Fixed | 2.58 | 0.01 | 0.54 (0.34-0.86) | [7-9] |
| Anastomotic leakage/dehiscence | 0% | 0.97 | Fixed | 1.47 | 0.14 | 3.85 (0.64-23.17) | [8,9] |
| Mortality | 62% | 0.10 | Random | 0.10 | 0.92 | 1.14 (0.1-13.12) | [8,9] |

NP: Not applicable; RR: Risk ratio.

Remote site infection: Three RCTs (303 EAP and 306 IAP)^[7,9] evaluated remote site infection and fixed model was conducted ($I^2 = 0\%$, $P = 0.90$), however, there was a significantly decreased remote site infection rate in EAP compared with IAP (RR of 0.54, 95%CI: 0.34-0.86, $P = 0.01$).

Anastomotic leakage or dehiscence: Two RCTs (201 EAP and 203 IAP)^[8,9] were evaluated, showing no statistical difference in anastomotic leakage or dehiscence (RR of 3.85, 95%CI: 0.64-23.17, $P = 0.14$).

Mortality: Two RCTs (124 EAP and 130 IAP)^[7,8] were included, which suggested no survival benefit of EAP compared with IAP (RR of 1.14, 95%CI: 0.10-13.12, $P = 0.92$).

Secondary outcomes: Multiple-dose antimicrobial prophylaxis vs single-dose antimicrobial prophylaxis

Only one RCT^[10] compared the efficacy of multiple-dose antimicrobial prophylaxis with single-dose antimicrobial prophylaxis, however, no significant differences were detected in surgical site infection (RR of 1.10, 95%CI: 0.62-1.93, $P = 0.75$), incision infection (RR of 1.27, 95%CI: 0.59-2.75, $P = 0.54$) and organ/space infection (RR of 1.20, 95%CI: 0.53-2.73, $P = 0.66$). The incidence of surgical site infection after gastrectomy was similar by the two antimicrobial prophylaxis regimens.

DISCUSSION

Meta-analysis is considered an ideal statistical tool increasing the statistical power, in other words, meta-analysis is a more powerful evidence for clinical decision making compared with RCTs. In light of these considerations, this meta-analysis was conducted to assess the efficacy of EAP after gastrectomy.

Although it has been widely accepted that patients with gastrectomy will benefit from preoperative antimicrobial prophylaxis and IAP^[16,17], there is still no worldwide accepted validation for EAP. In this meta-analysis, we found that postoperative EAP did not decrease the incidence of total complications in patients with gastrectomy. Additionally, EAP failed to improve surgical site infection rate, including incision infection and organ/space infection; likewise, no significant difference was detected in anastomotic leakage/dehiscence and mortality between EAP and IAP. The same striking finding was that patients did not benefit from multiple-dose antimicrobial prophylaxis compared with single-dose antimicrobial prophylaxis; yet, only one RCT^[10] was included in this meta-analysis. Based on the present evidence, we do not recommend the administration of EAP after gastrectomy; however, our results need to be validated and re-evaluated by more high-level RCTs.

Surgical site infections remain a substantial cause of postoperative mortality^[18]. We therefore conjecture that if EAP can decrease the surgical site infection rate, it may subsequently decrease the postoperative mortality. Unfortunately, EAP failed to decrease the surgical site infection rate. We assessed the mortality of EAP and IAP groups, and found no significant differences between the two groups. In light of these considerations, our findings suggested that EAP fails to decrease mortality in patients after gastrectomy; in other words, no survival benefit can be observed from EAP after gastrectomy based on the present evidence.

Many factors, such as male ratio, median age, obesity, operation time and intraoperative blood loss, may affect the postoperative infection risk^[18-23]. For example, the effect of antibiotics will be diminished as a result of intraoperative blood loss; likewise, longer operation time will increase blood loss; meanwhile, obesity may increase

the difficulty of operation and the operation time. Taking all these factors into consideration, we evaluated the statistical difference systematically; fortunately, we did not detect any significant difference among these items. Therefore, these factors have not affected the outcomes in these RCTs (Table 1).

The only significant difference between EAP and IAP is the remote site infection rate. However, we recommend that EAP should not be applied routinely unless the individuals experience a remote site infection. Therefore, we suggest delivering an “individualized treatment” rather than a routine treatment. The drugs used for EAP in these trials varied from cefazolin 1-1.5 g^[9,10], erythromycin 0.5 g + gentamicine 0.08 g + nystatin sulfate 0.1 g^[8], polymyxin B 0.1 g, tobramycin 0.08 g, vancomycin 0.125 g to amphotericin B 0.5g^[7]. The incidence of surgical site infection in these RCTs ranged from 4.5% to 9.5%, which is in keeping with published rates of 5%-14%^[24,25]. Despite these differences, the infection rates were similar, and no difference was detected (Table 2). However, our results still need to be validated for patients who require surgery on other sites of the body because the micro-flora in these operation sites differs from that in gastrointestinal tract^[26].

There was no country or language restriction in the data search process for this meta-analysis. It is the first meta-analysis concerning the efficacy of EAP after gastrectomy. There are some limitations of these studies, such as various antimicrobial prophylaxis regimens used and disappointing statistical power, thus, more high-level RCTs are needed to validate our results.

Based on the present evidence, EAP fails to decrease the incidence of surgical site infections after gastrectomy; multiple-dose antimicrobial prophylaxis fails to decrease the incidence of surgical site infection compared with single-dose antimicrobial prophylaxis. Therefore, we believe that our findings are significant to all patients with gastrectomy, and suggest that EAP should not be used routinely after gastrectomy until more high-level RCTs are available.

COMMENTS

Background

Administration of intraoperative antimicrobial prophylaxis (IAP) to prevent surgery-associated infection has been recommended. Although extended antimicrobial prophylaxis (EAP) has been recommended to be discontinued within 24 h of surgery, most patients after gastrectomy still receive further EAP routinely, as a result of insufficient evidence. This meta-analysis was conducted to investigate the effectiveness of EAP aimed at guiding clinical practice.

Research frontiers

Meta-analysis was conducted to evaluate the effectiveness of EAP vs IAP for patients undergoing gastric cancer surgery.

Innovations and breakthroughs

The evidence obtained from this meta-analysis proved that EAP failed to dem-

onstrate the advantages over IAP for patients with gastric cancer surgery with regard to total complications, surgical site infection, incision infection, organ or space infection, anastomotic leakage or dehiscence and mortality. These findings suggested that EAP should not be used routinely after gastrectomy.

Applications

The results of this meta-analysis suggest that EAP should not be administrated routinely after gastric cancer surgery and IAP is a standard treatment strategy for gastric cancer surgery.

Terminology

Surgical site infection: Infection occurs within one month after operation and involves superficial incision, deep incision, organ or space, which may generate some symptoms of infection, such as pain or tenderness, local swelling, redness, heat and so on.

Peer review

The period of the investigation extended over 32 years, during which different types and combinations of antibiotics have been used, but does not permit any evaluation of any particular antibiotics which might have been valuable. It is a valuable finding that intra-operative antibiotic prophylaxis is as efficient as an extended post-operative course in preventing post-operative infections.
