Data are presented as mean ± SD unless otherwise noted. Patients with non-alcoholic activity score (NAS) of five or higher were considered to have non-alcoholic steatohepatitis. Those with NAS equal to two or lower were defined as simple fatty liver[14]. NAFLD: Non-alcoholic fatty liver disease.

hepatitis (*n* = 1) (phase 2). Finally, fifty-four patients with biopsy proven NAFLD were included in the study (phase 3). The clinico-demographic and laboratory data of the participants are presented in Table 1.

Participants showed NAS of 4.87 ± 1.71. The frequency of histological findings in the study population is depicted in Figure 1.

Binary logistic regression showed a positive association between serum visfatin, IL-8 and TNF-α level and the grades of steatosis. Similarly, serum IL-6 and IL-8 levels were independently associated with the degrees of lobular inflammation. Serum TNF-α, resistin and hepcidin levels were independently associated with perisinusoidal fibrosis stage. Serum IL-8 and TNF-α values were positively associated with NAS (Table 2).

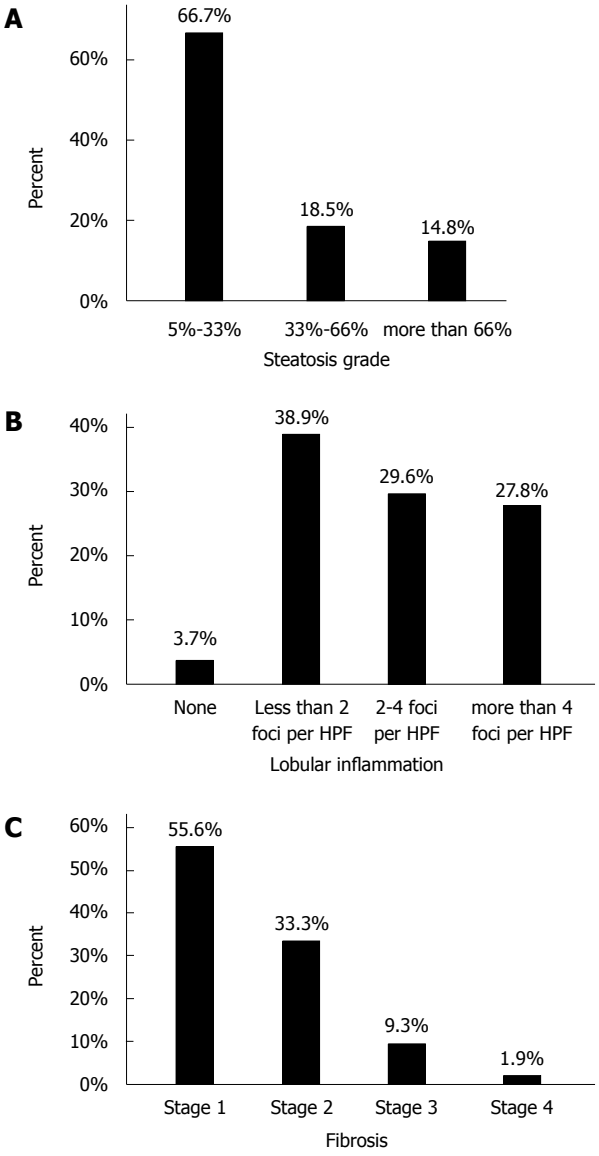

Figure 1 Frequency of histological findings in the participants. Frequency of patients with different degrees of steatosis (A), lobular inflammation grade based on foci of lobular inflammation in high power field of microscopic view (B), and fibrosis stage (C) are presented.

The ROC curves with calculated AUC (± 95%CI) to determine the best cut-off values of serum adipokines to differentiate histological groups are shown in Figure 2. The sensitivities and specificities of the cut-off values of biomarkers to identify histological groups appear in Table 3.

DISCUSSION

This study concluded that serum visfatin, IL-8 and TNF-α levels were independently associated with liver steatosis degree; serum IL-6 and IL-8 concentrations were independently associated with lobular inflammation grade; and TNF-α, resistin and hepcidin levels were independently associated with fibrosis stage in a cohort of biopsy-proven NAFLD patients. Moreover, the best cut-off values for the above-mentioned

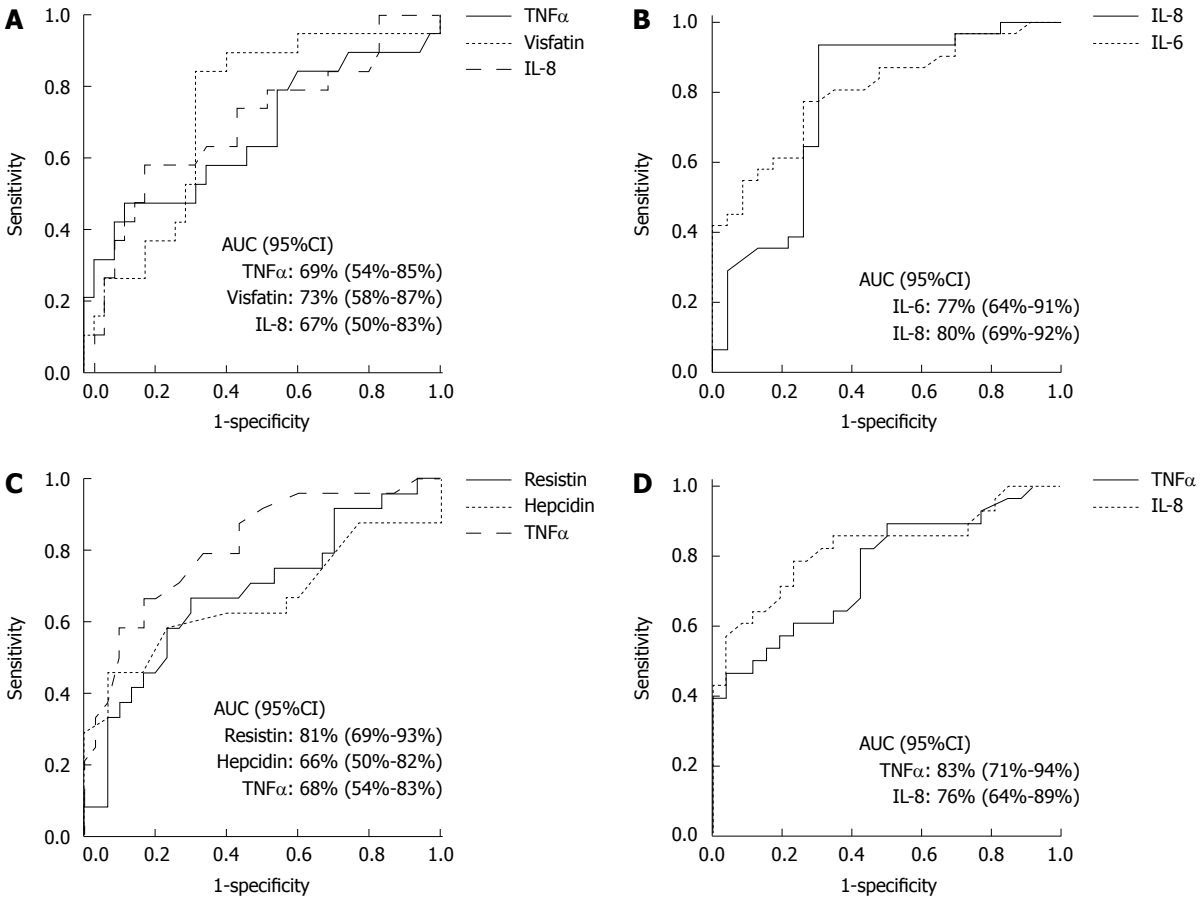

Figure 2 Receiver operating characteristic analysis to determine cut-off values of serum adipokines for differentiating histological severity. A: ROC curve of serum TNF-α, Visfatin, and IL-8 levels to differentiate steatosis degree of less than 33% from more advanced degrees of steatosis; B: ROC curve of serum IL-6 and IL-8 levels to differentiate lobular inflammation grade of less than two foci per high power field from more advanced grades of inflammation; C: ROC curve of serum Resistin, Hepcidin, and TNF-α levels to differentiate fibrosis stage of perisinusoidal or periportal from more advanced stages of fibrosis; D: ROC curve of serum TNF-α and IL-8 levels to differentiate steatohepatitis from simple fatty liver based on non-alcoholic fatty liver disease activity score. AUC: Area under curve; IL: Interleukin.

Table 2 Association between histological findings and serum adipokine levels

Adipokine	OR	95%CI	*P* value
Steatosis degree			
Visfatin	1.08	1.030-1.14	0.001
TNF-α	1.04	1.004-1.08	0.030
Interleukin 8	1.04	1.006-1.07	0.020
Lobular inflammation grade			
Interleukin 6	1.4	1.090-1.80	0.008
Interleukin 8	1.07	1.003-1.15	0.040
Fibrosis stage			
Resistin	19.86	2.790-141.19	0.003
Hepcidin	560.72	5.980-5255.33	0.006
TNF-α	1.06	1.002-1.12	0.040
NAS			
Interleukin 8	1.05	1.01-1.10	0.040
TNF-α	1.13	1.04-1.22	0.004

TNF-α: Tumor necrosis factor-alpha; NAS: Non-alcoholic fatty liver activity score.

serum adipokines were calculated to identify the liver histological findings.

The associations between certain adipokines with NAFLD were evaluated in previous reports[3-9]. We investigated several key adipokines, together with metabolic profiles and LFT, which provided an advantage over the previous studies. To improve the accuracy of the study, the cases were recruited from a cohort of biopsy-proven NAFLD patients. We used NAS for to determine the severity of the liver histology. Notably, NAS is a valid scoring system for NAFLD that differentiates the spectrum of disease with an acceptable reliability and validity[14].

Visfatin is a new adipokine with proinflammatory and metabolic properties. It is increased in IR syndrome. The expression of visfatin in VAT facilitates the maturation of preadipocyte cells to differentiated adipocytes (Paracrine effect)[3]. This fact might explain the correlation between serum visfatin levels and hepatic steatosis degree in our study. Visfatin is also associated with body fat mass in alcoholic fatty liver disease[15]. Previous studies have reported a correlation between visfatin and fibrosis stage, but not with steatosis or lobular inflammation grade in NAFLD[16]. Meanwhile, an increase in serum visfatin was shown to be associated with portal inflammation[17].

TNF-α is a pro-inflammatory cytokine and is asso-

Table 3 Best cut-off values of serum adipokine levels to differentiate histological groups according to receiver operating characteristic analysis

Adipokine	Serum concentration	Sensitivity (%)	Specificity (%)
TNF-α (pg/mL)	2.13	74	58
Visfatin (ng/mL)	13.00	84	69
Interleukin 8 (pg/mL)	24.25	58	66
Cut-off values of serum adipokine levels to differentiate lobular inflammation grade of less than 2 foci per high power field from more advanced grades of inflammation.			
Interleukin 6 (pg/mL)	3.70	94	70
Interleukin 8 (pg/mL)	13.00	77	74
Cut-off values of serum adipokine levels to differentiate perisinusoidal or periportal fibrosis from more advanced stages of fibrosis.			
Resistin (mg/mL)	1.65	79	66
Hepcidin (ng/mL)	45.00	63	60
TNF-α (pg/mL)	2.44	67	70
Cut-off values of serum adipokine levels to differentiate steatohepatitis from simple fatty liver group based on non-alcoholic fatty liver disease activity score (NAS).			
Interleukin 8 (pg/mL)	9.80	82	54
TNF-α (pg/mL)	2.44	71	81
Cut-off values of serum adipokine levels to differentiate steatosis degree of less than 33% from more advanced degrees of steatosis.			

TNF-α: Tumor necrosis factor-alpha.

ciated with hepatic IR in NAFLD[4]. It mediates the early stage of NAFLD by fat accumulation in hepatocytes. In addition, it facilitates disease progression to a more advanced stage[18]. The relationship between serum TNF-α and liver steatosis and fibrosis in our research is in line with previous observations.

IL-8 is also a pro-inflammatory cytokine that activate monocytes and attracts polymorphonuclear leukocytes to the site of inflammation[19]. It is increased in obese individuals with IR. In accordance with the literature, our results showed that serum IL-8 was associated with steatosis degree and lobular inflammation[5].

IL-6 is a liver and adipose tissue-derived proinflammatory cytokine that is implicated in hepatic and skeletal muscle IR. IL-6 is thought to act as a second hit in the pathophysiology of NAFLD, causing the progression of simple fatty liver to NASH[19]. The correlation of IL-6 with lobular inflammation grade in our study is comparable to the findings by other groups[6,20,21].

With regard to hepcidin, the circulatory level was strongly associated with fibrosis stage in our study. Nevertheless, a previous found no correlation between hepcidin and histological findings[7]. Body iron stores in NAFLD regulate hepcidin levels[22]. Therefore, it seems reasonable to adjust for patients iron storage when evaluating hepcidin levels in NAFLD patients.

Resistin is an adipokine that is considered an indicator of IR in obesity[23]. However, the pathophysiological role of resistin in NAFLD is not clear. In this study, we observed that serum resistin levels were related with fibrosis stage. On the other hand, advanced liver fibrosis was associated with reduced resistin concentration in chronic hepatitis C patients with normal body weight, glucose and lipid profiles[24]. Previous studies demonstrated a correlation between high serum resistin levels and the presence of steatosis and necroinflammation in NAFLD[8,25]. Meanwhile, another study demonstrated an association of low serum resistin levels with excessive fat accumulation in the liver[26].

Adiponectin is a well-known adipokine that regulates hepatic IR[27]. It was suggested that adiponectin might be related to steatosis grade and the severity of NAFLD; however, its definitive role remains to be addressed[28]. A decrease in serum adiponectin is the primary event in children with NAFLD before the rise of inflammatory cytokines and the development of overt diabetes[9,29]. One previous study showed that adiponectin could predict patients with higher necroinflammatory grade and fibrosis stage from those with milder histological findings[30]. Another study showed that adiponectin is related to hepatic fat content and not to necroinflammatory activity and fibrosis stage[31]. Meanwhile, our study showed no correlation between adiponectin and liver histology. This study, despite its advantages, suffers from several drawbacks: first, the study was performed in a single institution; therefore, the findings need to be generalized with caution. Second, our study was cross-sectional, which limited the interpretation of causal associations.

There is currently no defined "normal range" for serum adipokines. Moreover, adipokine levels might fluctuate over time according to the metabolic environment. These concerns might explain the differences in the results of the above-mentioned studies with our results. Further well-controlled prospective studies to determine the association of VAT-derived proteins (including proinflammatory cytokines and polypeptide hormones) and liver histological findings are recommended.

The associations of some important adipokines, together with the currently used serum biomarkers, with the liver histological findings were evaluated. Certain adipokines were independently associated with the liver histological findings. Finally, the best cut-off values of these serum adipokines were determined to detect the severity of liver steatosis, lobular inflammation and fibrosis.

In conclusion, this study suggested that certain adipokines might determine accurately the severity of NAFLD based on histological findings.

ACKNOWLEDGMENTS

We are grateful to Dr. Hassan Ehteram at the Kashan University of Medical Sciences for reviewing the liver histology samples, and to Dr. Ayat Ahmadi at the Tehran University of Medical Sciences (TUMS) for reviewing the statistical analysis. The authors would like to expand their gratitude to Drs. Vafa Rahimi

Movaghar and Arsia Jamali at TUMS for their critical review of the manuscript.

COMMENTS

Background

Non-alcoholic liver disease (NAFLD) is a health concern worldwide. The burden of disease is increasing because of an epidemic of obesity. Considering the limitations of current modalities, finding an appropriate serum biomarker to diagnose and assess the severity of liver damage in NAFLD is crucial.

Research frontiers

The roles of adipokines in the pathogenesis of NAFLD have received research interest recently. Nevertheless, there is a paucity of studies that used serum levels of adipokines in the diagnosis and follow up of NAFLD patients.

Innovations and breakthroughs

The associations between certain adipokines with NAFLD were evaluated in previous reports. The authors investigated several key adipokines together with metabolic profiles and LFT, providing an advantage over the previous studies. To improve the accuracy of the study, the cases were selected from a cohort of biopsy-proven NAFLD patients. To assess the severity of NAFLD based on histology, we applied NAS, a valid scoring system for NAFLD that categorizes the spectrum of disease with acceptable reliability and validity.

Applications

This study suggested that certain adipokines might determine accurately the presence and severity of NAFLD.

Peer-review

This manuscript evaluated the association between histological grade of NAFLD and serum biomarkers, and suggested cut-off values of the biomarkers for NASH. The authors used a direct method to define NASH, and measured various biomarkers related to adiposity and inflammation. Finally, the authors showed successfully that the indices were related to each component of NASH.

Abstract

AIM: To elucidate influencing factors of treatment response, then tolvaptan has been approved in Japan for liquid retention.

METHODS: We herein conducted this study to clarify the influencing factors in 40 patients with decompensated liver cirrhosis complicated by liquid retention. Tolvaptan was administered at a dosage of 7.5 mg once a day for patients with conventional diuretic-resistant hepatic edema for 7 d. At the initiation of tolvaptan, the estimated hepatic venous pressure gradient (HVPG) value which was estimated portal vein pressure was measured using hepatic venous catheterization. We analyzed the effects of tolvaptan and influencing factors associated with treatment response.

RESULTS: Subjects comprised patients with a median age of 65 (range, 40-82) years. According to the Child-Pugh classification, class A was 3 patients, class B was 19, and class C was 18. Changes from the baseline in body weight were -1.0 kg (P = 2.04 × 10^{-6}) and -1.3 kg (P = 1.83 × 10^{-5}), respectively. The median HVPG value was 240 (range, 105-580) mmH_2O. HVPG was only significant influencing factor of the weight loss effect. When patients with body weight loss of 2 kg or greater from the baseline was defined as responders, receiver operating characteristic curve analysis showed that the optimal HVPG cutoff value was 190 mmH_2O in predicting treatment response. The response rate was 87.5% (7/8) in patients with HVPG of 190 mmH_2O or less, whereas it was only 12.5% (2/16) in those with HVPG of greater than 190 mmH_2O (P = 7.46 × 10^{-4}). We compared each characteristics factors between responders and non-responders. As a result, HVPG (P = 0.045) and serum hyaluronic acid (P = 0.017) were detected as useful factors.

CONCLUSION: The present study suggests that tolvaptan in the treatment of liquid retention could be more effective for patients with lower portal vein pressure.

Key words: Tolvaptan; V_2 receptor antagonist; Portal vein pressure; Hepatic venous pressure gradient; Decompensated chirrosis

Core tip: To clarify the factors influencing the effect of tolvaptan, a V_2 receptor antagonist, in patients with decompensated liver cirrhosis complicated by liquid retention, we conducted this study. As a result, hepatic venous pressure gradient (HVPG) was the only significant factor that influenced the weight loss effect of tolvaptan. The response rate was 87.5% (7/8) in patients with HVPG of 190 mmH_2O or less, whereas it was only 12.5% (2/16) in those with HVPG of greater than 190 mmH_2O. The present study suggests that tolvaptan in the treatment of liquid retention related to decompensated liver cirrhosis could be more effective for patients with lower portal vein pressure.

Nakagawa A, Atsukawa M, Tsubota A, Kondo C, Okubo T, Arai T, Itokawa N, Narahara Y, Iwakiri K. Usefulness of portal vein pressure for predicting the effects of tolvaptan in cirrhotic patients. *World J Gastroenterol* 2016; 22(21): 5104-5113 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i21/5104.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i21.5104

INTRODUCTION

Liquid retention is a primary complication associated with decompensated liver cirrhosis. Ascites develops at an incidence of approximately 50% within 10 years of the onset of liver cirrhosis[1]. Existence of ascites reduces dietary intakes and deteriorates nutritional statuses, which, in turn, have a negative impact on the quality of life of liver cirrhosis patients[2,3]. Furthermore, the 5-year survival rate after the development of ascites is reportedly 45%[1].

Resting, salt restriction, and therapy with diuretics, such as loop diuretics and anti-aldosterone drugs, have been performed as conventional treatments for ascites related to liver cirrhosis[4,5]. Loop diuretics reduce the reabsorption of sodium and potassium by inhibiting sodium/potassium/chloride cotransporters in the ascending limb of Henle's loop. Anti-aldosterone drugs promote sodium excretion and consequently decrease the excretion of potassium by inhibiting aldosterone receptors. However, the effects of these diuretics are compromised by the progression of liver cirrhosis, leading to electrolyte abnormalities, including hyposodiumemia, a reduction in plasma osmotic pressure, and kidney hypofunction due to a decrease in renal blood flow. The effects of the loop diuretic, furosemide, were previously suggested to be attenuated in patients with liver cirrhosis characterized by a decrease in serum albumin level and reduction in renal blood flow/the glomerular filtration rate[6,7]. If ascites is not improved by these treatments, it is defined as refractory ascites, which is treated with abdominal paracentesis, albumin reinfusion, peritoneal venous shunt (Denver shunt), cell-free and concentrated ascites reinfusion therapy (CART), and transjugular intrahepatic portosystemic shunt (TIPS), but not liver transplantation[4,6,7]. However, there are quite a few patients who are not able to receive these treatments due to complications or conditions that do not meet the indication criteria.

On the other hand, previous studies reported that the V_2 receptor antagonist, tolvaptan, exhibited diuretic effects on heart failure and hyposodiumemia[8-11]. The antidiuretic hormone, vasopressin, enhances water permeability and promotes water reabsorption through V_2 receptors, which exist in the renal collecting ducts. Tolvaptan has been shown to inhibit the vasopressin-related reabsorption of water, thereby increasing water excretion without enhancing the excretion of electrolytes (water-diuretic actions). Since tolvaptan acts on the vascular side around the renal collecting ducts, it differs from the loop diuretic, furosemide. Therefore, its actions are not influenced by a kidney hypofunction-related decrease in the glomerular filtration rate or hypoalbuminemia[12]. Previous studies indicated that tolvaptan prevented conventional diuretic-induced hyposodiumemia in patients with liquid retention[10,13]. Sakaida *et al*[14] conducted a clinical study of tolvaptan for cirrhotic patients with liquid retention and reported increases in the initial 24-h urine volume, even in those with low serum albumin levels. Zhang *et al*[15] indicated that adverse reactions to tolvaptan administration with a daily

dosage of 15 mg included thirst and dry mouth, which were tolerable and safe. Accordingly, tolvaptan for liquid retention in cirrhotic patients who do not respond to conventional diuretics, such as loop diuretics, has been approved in Japan in 2013.

However, not all patients with liquid retention respond to tolvaptan. Furthermore, little is known about the characteristics of patients who respond well to tolvaptan and factors predictive of the therapeutic effect. The present study was conducted to clarify the baseline factors that influence the effect of tolvaptan in cirrhotic patients with conventional diuretic-resistant liquid retention.

MATERIALS AND METHODS

Study design

Forty-seven patients with decompensated liver cirrhosis and liquid retention (pleural effusion, ascites, or lower-limb edema) were recruited for this prospective study in Nippon Medical School Chiba Hokusoh Hospital between September 2013 and August 2015. Patients were eligible for enrollment if they fulfilled the following criteria: (1) patients aged 20 to 85 years; (2) patients diagnosed as liver cirrhosis based on the results of imaging modality (abdominal CT or ultrasonography) or proven by liver biopsy; (3) conventional diuretic-resistant patients in whom liquid retention was not improved with furosemide at a dosage of 20 mg/d or more and/or spironolactone at a dosage of 25 mg/d or more for at least 7 d with salt-restricted diet (5-7 g salinity/day) in-hospital or on an outpatient basis; and (4) patients in whom body weight before breakfast was stable (within the range of ± 1 kg) during the pretreatment observation period. Criteria for exclusion included: (1) uncontrollable hepatocellular carcinoma, such as the Barcelona clinic liver cancer (BCLC) stage D. BCLC stage D is end-stage hepatocellular carcinoma in a patient with disturbed liver function (Child-Pugh C) and/or performance status 3-4, and with an average predicted survival of 3 months; (2) esophageal varices with requiring treatment; (3) existence of portal vein thrombosis based on imaging modality (abdominal CT or ultrasonography); (4) hepatic encephalopathy stage 2 or higher according to The West Haven classification of hepatic encephalopathy including Asterixis[16,17]; (5) type 1 hepatorenal syndrome; and (6) a serum sodium level of 147 mEq/L or higher. All patients and their families received a sufficient explanation of the aim and contents of this study before the entry. Patients who provided written informed consent participated in this study. All procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation and with Helsinki Declaration of 1975, as revised in 2008. The protocol was approved by the Ethics Review Board of Nippon Medical School Chiba Hokusoh Hospital (approval No. 526012). All patients and their families received a sufficient explanation of the aim and contents of this study before the entry.

Treatment protocol

Patients were initially instructed to receive salt-restricted diet therapy (5 to 7 g/d) and conventional diuretics for at least 7 d. Tolvaptan (SAMUSKA, Otsuka Pharmaceutical Co., Ltd., Tokyo, Japan) was orally administered at a dosage of 7.5 mg once a day. Water intake was not restricted during the administration of tolvaptan. No albumin preparation was infused, and ascites and pleural effusion were not removed by paracentesis during the first 7 d of tolvaptan treatment. Based on previous clinical studies using tolvaptan, patients with a decrease of 2 kg or greater from the baseline in body weight were regarded as responders[18,19].

Laboratory tests

Body weight and 24-h urine volume were daily measured before the administration of tolvaptan and during at least 7 d of treatment. Body weight was measured at the time of awaking. Clinical symptoms and vital signs (blood pressure, pulse rate, body temperature, and arterial blood oxygen saturation) were closely monitored every day. Biochemical tests (serum sodium, creatinine, urea nitrogen, albumin, and blood ammonia levels) and urinalysis (urinary osmotic pressure) were performed at 1, 3, 5 and 7 d of treatment.

Measurement of portal vein pressure

At the initiation of tolvaptan, the estimated portal vein pressure [*i.e.*, the hepatic venous pressure gradient (HVPG)][20,21] was measured using hepatic venous catheterization to investigate whether or not HVPG influenced the response of tolvaptan, when patients agreed with the optional HVPG measurement study. The right internal jugular vein (or the left internal jugular vein when the right-sided puncture was difficult or failed) was punctured with an 18-gauge needle, and subsequently a 5F sheath (Super Sheath: MEDKIT, Tokyo) was inserted along a guide wire. A 2.9F balloon catheter (Selecon MP catheter 2: TERUMO CLINICAL SUPPLY, Gifu, Japan) was then inserted into the inferior vena cava (IVC) to measure IVC pressure, which was used as a zero adjustment in portal vein pressure measurement. The balloon catheter was further inserted into the right hepatic vein to occlude it with the balloon. Hepatic venography was performed using Iopamidol (Bayer Medicine, Osaka, Japan) to confirm retrograde contrast enhancement involving the portal trunk and the presence of a hepatic vein-hepatic vein shunt and portal thrombosis. Wedged hepatic venous pressure (WHVP) was subsequently measured, and the balloon was removed to determine the free hepatic venous pressure (FHVP). The difference between WHVP and FHVP, which is equal to HVPG, was

Table 1 Demographic and clinical characteristics at baseline

Characteristics	*n* = 40
Age (yr)	65 (40-82)
Gender (M/F)	26/14
Body weight (kg)	61.9 (44.8-88.5)
Liver disease etiology

[1]Hepatic venous pressure gradient was measured in 24 patients. Categorical variables are given as number. Almost continuous variables are given as median (range). Dose of furosemide and spironolactone are given as mean ± SD). BUN: Blood urea nitrogen; PBC: Pimary biliary cirrhosis; PSC: Primary sclerosing cholangitis; NASH: Nonalcoholic steatohepatitis; eGFR: Estimated glomerular filtration rat.

regarded as the estimated portal vein pressure. Seven days after the start of tolvaptan, HVPG was repeatedly measured using the same procedures to evaluate the influence of tolvaptan on portal vein pressure, when patients agreed with the optional HVPG measurement study.

Statistical analysis

Changes in 24-h urine volumes and body weights after the administration of tolvaptan were evaluated using Wilcoxon's signed rank test. Subjects were divided into two groups based on the medians of baseline values in quantitative variables, and the two groups were compared using the Mann-Whitney *U*-test. Categorical data were analyzed using the Fisher's exact test. The cut-off value of HVPG for the efficacy assessment was calculated using a receiver operating characteristic (ROC) curve. A *P* value of 0.05 was regarded as significant. Excel Statistics 2015 software (SSRI Institute, Tokyo) was used for statistical analyses.

RESULTS

Patients

Among the 47 recruited patients, 7 were excluded from this prospective study: 4 met the exclusion criteria and 3 did not provide informed consent. Therefore, 40 patients were subjected to the clinical study and subsequent analysis. Patient characteristics are shown in Table 1. Patients consisted of 26 males (65.0%) and 14 females (35.0%), with the median age of 65 years (range, 40-82 years). The etiology of liver diseases was hepatitis C for 15 patients, hepatitis B for 3, alcoholic hepatitis for 15, primary biliary cirrhosis for 3, primary sclerosing cholangitis for 1, and non-alcoholic steatohepatitis for 3. According to the Child-Pugh classification, 3 patients were classified into class A, 19 into class B, and 18 into class C. Twelve patients had hepatocellular carcinoma. Twenty-five patients had esophageal varices, but did not require the treatment at the entry. Median serum albumin, sodium and creatinine levels were 2.6 (range, 1.6-3.7) g/dL, 139 (range, 124-146) mEq/L, 0.95 (range, 0.45-6.45) mg/dL, respectively. The median HVPG value and hyaluronic acid value were 240 (range, 105-580) mmH_2O and 420.7 (range, 122-6984), respectively. The median urinary osmotic pressure was 414.5 (range, 254-954) mOsm/L. The daily dosages of furosemide and spironolactone before the administration of tolvaptan were 37.0 ± 29.5 mg and 43.4 ± 26.8 mg, respectively.

Effects of tolvaptan, biochemical tests, and urinalysis

Changes in body weight and 24-h urine volume after the administration of tolvaptan are shown in Figure 1. Median 24-h urine volumes on days 1 and 7 were 1600 mL and 1582 mL, respectively. The median volume increases from the baseline were +492 mL ($P = 6.97 \times 10^{-5}$) and +474 mL ($P = 4.87 \times 10^{-4}$), respectively. The median body weight decreases from the baseline on days 1 and 7 were 1.0 kg ($P = 2.04 \times 10^{-6}$) and 1.3 kg ($P = 1.83 \times 10^{-5}$), respectively.

Patients were divided into two groups based on the median value of each baseline quantitative variable. Changes in body weight loss during 7 d were compared between the two groups (Figure 2A-G). Hyaluronic acid level was a marginally significant factor influencing the weight loss effect. Patients with lower hyaluronic acid level had favorable response to tolvaptan compared with those with higher hyaluronic acid level, though not significant ($P = 0.088$) (Figure 2G).

Association between HVPG and the effect of tolvaptan

Twelve patients rejected measurement of the HVPG. Therefore, the HVPG measurement procedures were performed in 28 patients before the administration of tolvaptan. Of these, 4 were excluded from subsequent analysis due to a hepatic vein-hepatic vein shunt on hepatic venography.

Patients were divided into two groups: those with HVPG of higher than 200 mmH_2O, which is the cutoff value for the diagnosis of portal hypertension and those with HVPG of 200 mmH_2O or lower. The median changes in body weight loss on day 7 were -0.2 kg in the former and -3.05 kg in the latter ($P = 0.012$) (Figure 2H). Using the ROC curve, the cutoff value of 190 mmH_2O (sensitivity: 75.0%, specificity: 93.3%, area under the curve: 0.825) was the most useful in discriminating responders from non-responders (Figure 3). Among patients with HVPG of 190 mmH_2O or lower,

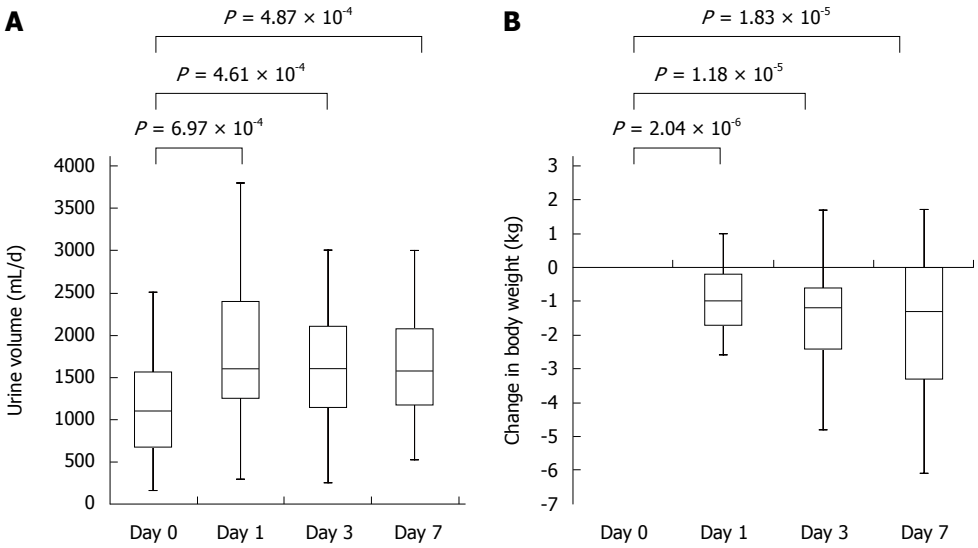

Figure 1 Effects of tolvaptan on liquid retention in all of the patients included in this study. A: Box and whisker plots of daily urine volumes during the first week of tolvaptan administration in all of the patients. Median values were 1108 mL, 1600 mL, 1500 mL and 1582 mL on day 0, 1, 3 and 7, respectively; B: Box and whisker plots of changes in body weight from baseline during the first week of tolvaptan administration in all of the patients. Median changes in body weight were -1 kg, -1.2 kg, and -1.3 kg on day 1, 3 and 7, respectively. Difference between day 0 (= baseline) and day1, 3 and 7 were compared by using Wilcoxon signed rank test.

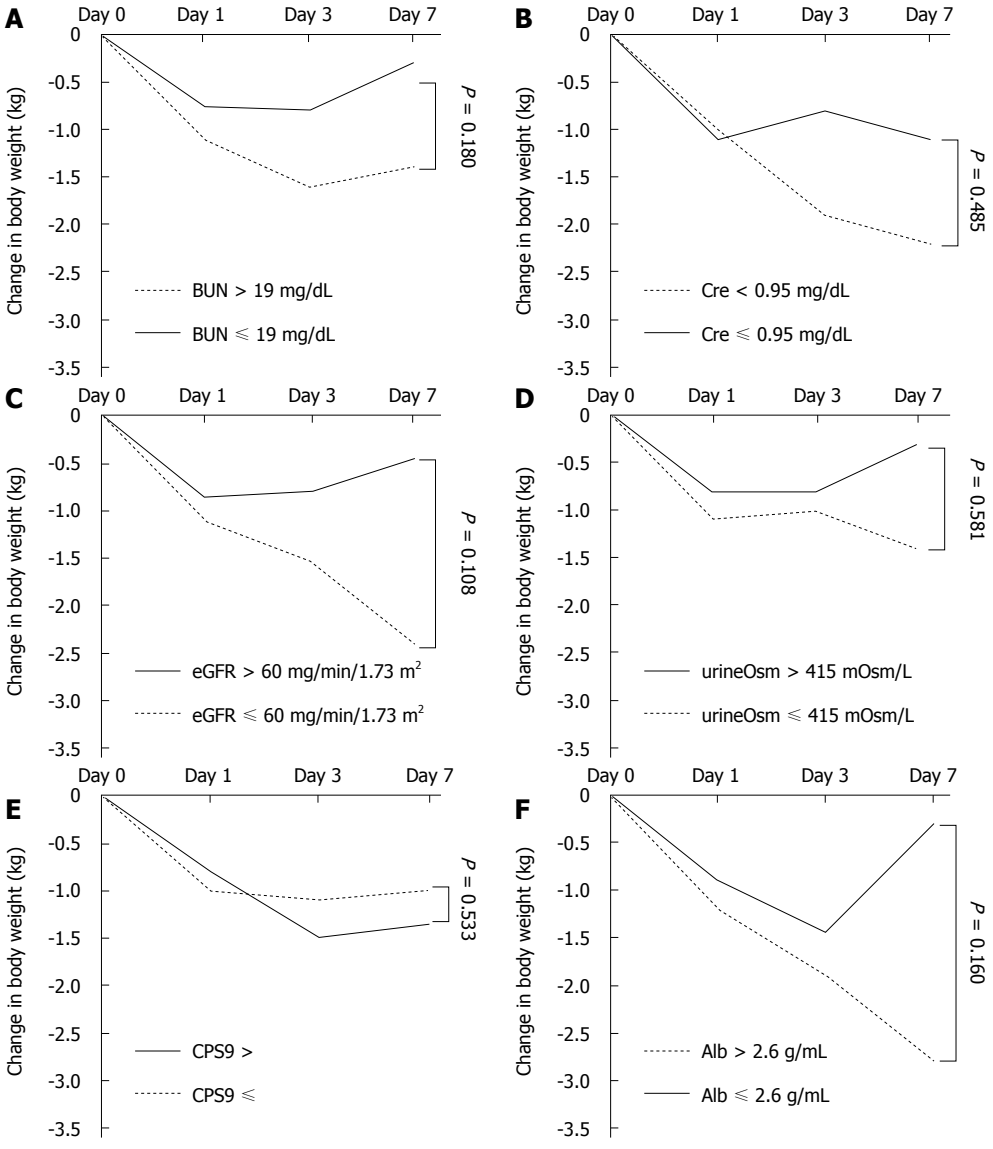

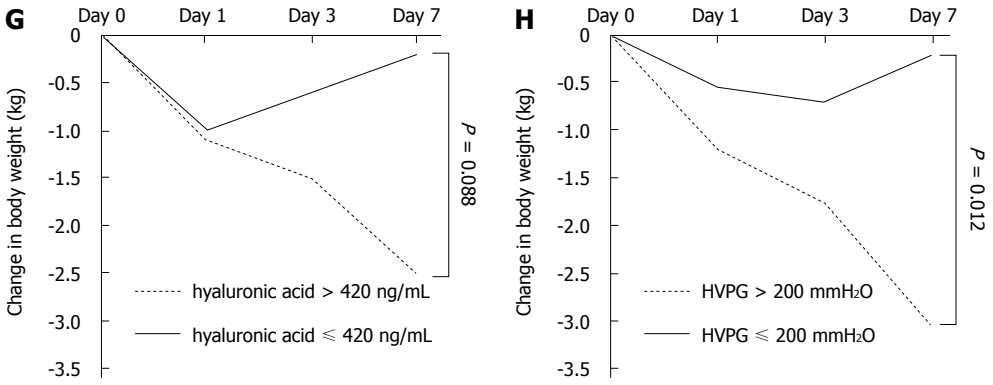

Figure 2 Change in body weight from baseline on each baseline factor during the first week of tolvaptan administration. Data are expressed as median. Patients were divided into two groups using the median value of each baseline variable: (A) serum BUN; (B) serum creatinine; (C) serum eGFR; (D) urine osmolality; (E) Child-Pugh Score (CPS); (F) serum albumin (Alb); (G) serum hyaluronic acid; and (H) Hepatic venous pressure gradient (HVPG).

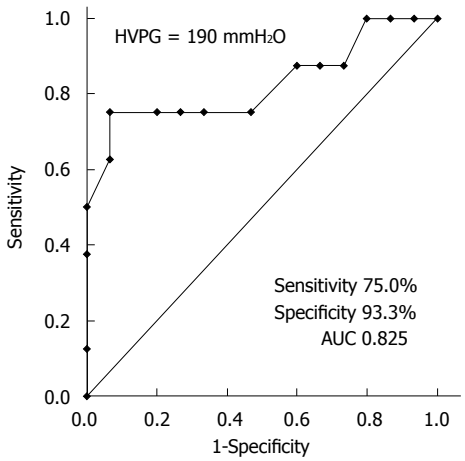

Figure 3 Optimal cutoff value of hepatic venous pressure gradient of the efficacy assessment was determined using ROC curve. The value of 190 mmH2O [sensitivity, 75.0%; specificity, 93.3%; and area under the curve (AUC), 0.825] was the most useful in predicting treatment response, defined as body weight loss of 2 kg or greater from the baseline. HVPG: Hepatic venous pressure gradient.

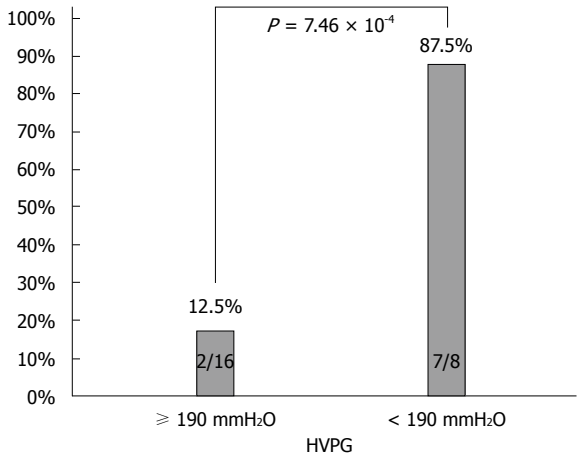

Figure 4 Difference in treatment response rates between patients with low and high hepatic venous pressure gradient. The response rate of 87.5% in the latter with 190 mmH2O or greater was significantly higher than that of 12.5% in the former with less than 190 mmH2O (P = 7.46 × 10^{-4}). HVPG: Hepatic venous pressure gradient.

7 of 8 patients (87.5%) were responders. By contrast, among those with HVPG of higher than 190 mmH2O, only 2 of 16 patients (12.5%) were responders (P = 7.46 × 10^{-4}) (Figure 4).

To examine the influence of tolvaptan on portal vein pressure, changes in HVPG after the administration of tolvaptan were evaluated in 19 patients, in whom the post-treatment HVPG was measured. HVPG values prior to and after the treatment were 213 (range, 105-305) and 210 (range, 150-340) mmH2O, respectively (not significant, P = 0.938, Figure 5A). Even when patients were sub-divided into two groups: those with HVPG of 190 mmH2O and lower (n = 7) and higher than 190 mmH2O (n = 12), no significant changes in HVPG prior to and after the treatment were observed in both subgroups (P = 0.108 and 0.684, respectively; Figure 5B and C).

Differences in background factor according to responses for tolvaptan

Next, based on previous clinical studies using tolvaptan, patients with a body weight decrease of 2 kg or greater from the baseline were regarded as responders. On the other hand, patients with decreases of less than 2 kg or increases from the baseline were regarded as non-responders. We analyzed differences in background factor according to responses for tolvaptan. HVPG (P = 0.045) and serum hyaluronic acid (P = 0.017) were detected as useful factors. All other characteristics factors did not have the significant difference between both groups (Table 2).

Safety

Adverse events were observed in 13 of 40 subjects (32.5%). The most frequent adverse event was pollakiuria, which occurred in six patients (15.0%).

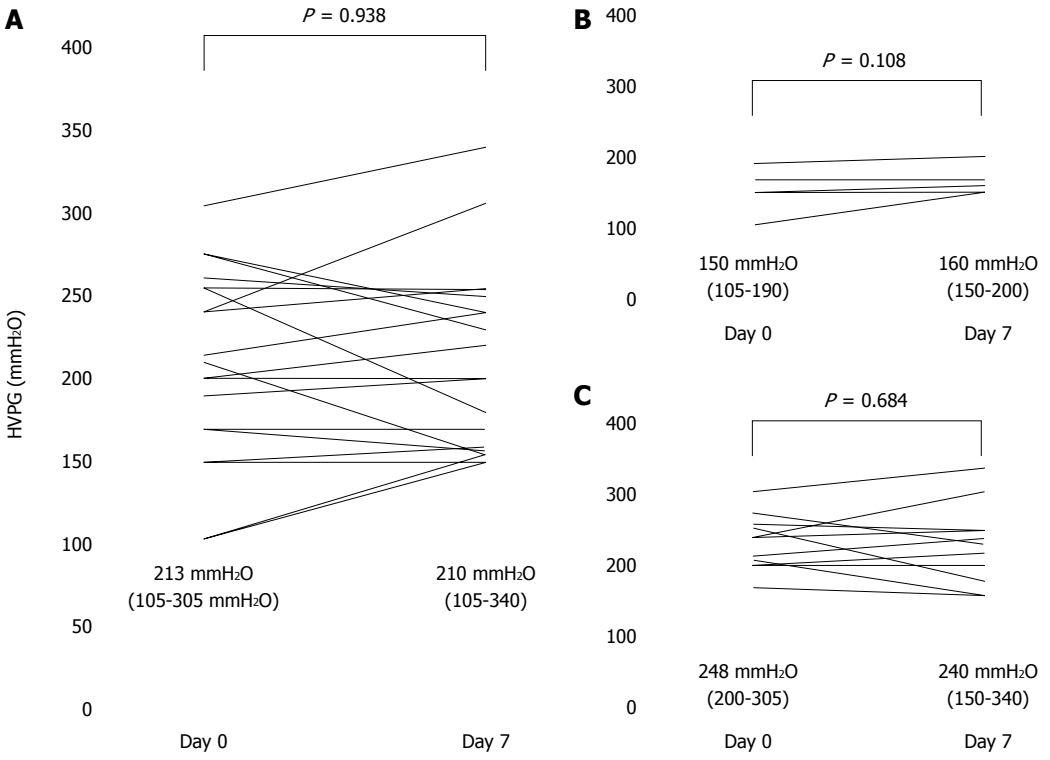

Figure 5 Changes in hepatic venous pressure gradient levels at day 0 and 7. Data are expressed as median (range in parenthesis). A: Overall patients (*n* = 19); B: Patients (*n* = 7) with low HVPG (≤ 190 mmH2O); C: Patients (*n* = 12) with high HVPG (> 190 mmH2O). There was not significant difference in any groups, indicating that tolvaptan had little impact on HVPG. HVPG: Hepatic venous pressure gradient.

Table 2 Comparison of demographic and clinical characteristics at baseline between responders and non-responders

Characteristics	Responder (*n* = 17)	Non-responder (*n* = 23)	*P* value
Age (yr)	66 (45-80)	61 (40-82)	0.8137
Body weight (kg)	62.3 (44.8-88.5)	61.7 (50.3-79.2)	0.7857
Liver disease etiology (Hepatitis B/Hepatitis C/Alcohol/PBC/PSC/NASH)	3/5/5/2/1/1	0/10/10/1/0/2	-
Child-Pugh classification (A-B/C)	9/8	13/10	1.000
Total bilirubin (mg/dL)	0.8 (0.4-11.4)	1.3 (0.5-26.2)	0.332
Serum albumin (g/dL)	2.5 (1.9-3.5)	2.6 (1.6-3.7)	0.733
Serum creatinine (mg/dL)	0.91 (0.62-1.83)	1.1 (0.45-6.45)	0.480
Serum eGFR (mL/min/1.73 m^2)	62 (24-85)	51 (8-112)	0.290
Serum sodium (mEq/L)	137.5 (125-146)	140 (124-144)	0.855
Serum hyaluronic acid (ng/mL)	335 (181-2843)	567.9 (122-6984)	0.017
BUN (mg/dL)	18.1 (8.1-81)	20.9 (10.1-81.8)	0.211
Urine osmolality (mOsm/L)	418 (257-700)	361.5 (254-954)	0.293
Hepatic venous pressure gradient (mmH2O)[1]	170 (105-580)	255 (150-350)	0.045
Hepatocellular carcinoma (with/without)	6/11	6/17	0.729
Esophageal varix (with/without)	10/7	15/8	0.518

[1]Hepatic venous pressure gradient was measured in 24 patients. Categorical variables are given as number. Continuous variables are given as median (range). BUN: Blood urea nitrogen; PBC: Pimary biliary cirrhosis; PSC: Primary sclerosing cholangitis; NASH: Nonalcoholic steatohepatitis.

Thirst was noted in five patients. Malaise was observed in two patients. Serum creatinine levels increased in three patients: one of them discontinued tolvaptan after 5 d of treatment [serum creatinine = 2.34 mg/dL (+1.59 mg/dL from baseline)] and recovered rapidly after the cessation. No other severe adverse events were noted.

DISCUSSION

Tolvaptan was approved as a drug for heart failure in Japan in 2010. Thereafter, its favorable therapeutic effects have been reported[22]. Furthermore, a phase Ⅲ study of tolvaptan for liquid retention was conducted in Japan. Sakaida *et al*[23] reported that body weight decreased by 1.95 kg and 24-h urine volume increased by 633 mL during a 7-d administration period, suggesting the efficacy and safety of tolvaptan in the treatment of liquid retention. In response to the encouraging data, tolvaptan is clinically available in Japan since 2013. In some patients, however, tolvaptan does not improve liquid retention. Little is known about the characteristics of patients who respond well to tolvaptan and the factors influencing the therapeutic effect. Furthermore, the role of tolvaptan in the therapeutic strategy for liquid retention currently remains unclear: whether tolvaptan is used separately from or in combination with conventional diuretics should be determined, and the commencing time of

tolvaptan needs to be clarified.

The present study is the first to show that response to tolvaptan correlated closely with HVPG, which reflects portal vein pressure in cirrhotic patients. Measurement of HVPG makes it possible to estimate the stage of liver fibrosis regardless of disease etiology[24,25], and to assess the severity and prognosis of liver cirrhosis[26,27] and the risk of complications, such as the rupture of esophageal varices, ascites, hepatic encephalopathy, and hepatorenal syndrome[28,29]. Ripoll *et al*[30] reported that decompensated liver cirrhosis was more likely to deteriorate in patients with HVPG of 10.0 mmHg (approximately 136 mmH_2O) or higher. Kumar *et al*[31] found that HVPG of 13.0 mmHg (approximately 177 mmH_2O) or higher was predictive of advanced fibrosis. In the present study, the cut-off value of 190 mmH_2O was the most useful in predicting treatment response, suggesting that tolvaptan exerts its effects on conventional diuretic-resistant patients with lower HVPG. For those with higher HVPG, combination with other treatments, such as TIPS, may be needed to improve tolvaptan-resistant liquid retention. However, HVPG was not decreased even in responders, indicating that tolvaptan has little impact on portal vein pressure. This phenomenon may be attributed to the antagonistic action site of tolvaptan, a vasopressin V_2 receptor, which is in the uriniferous tubules of the kidney alone, and thus does not cause vasoconstriction[12]. In other words, tolvaptan has no anti-vasoconstrictive effect on splanchnic vessels. By contrast, terlipressin, which acts on the vasopressin V_1 receptor, has vasoconstrictive effects on the visceral vessels and consequently reduces portal blood flow[32].

The direct relationship between high portal vein pressure and low responsiveness to tolvaptan is unclear. We examined the correlations between HVPG and various biochemical data in the present study. Although no significant factor could be found, low serum albumin and low eGFR levels might be associated with relatively high HVPG (data not shown). These variables reflect the reserved function of the liver and kidneys. Such patients with impaired liver and kidney functions are likely to have high HVPG, which attenuates the effect of tolvaptan.

The limitations of this study included the small number of patients examined and variations in the etiology of liver diseases. Only the short-term effect of tolvaptan was evaluated, water restriction and water intake were not measured, and drinking-related changes in body fluid volumes were not accurately assessed. However, a response criterion used in the present study (body weight loss of 2 kg or greater) may be appropriate, because the change in body weight after the administration of tolvaptan was reported to correlate with that in ascites volume[33]. Akiyama *et al*[34] administered tolvaptan for 42 d to patients: the initial significant effects lasted during the treatment period, though the mid- to long-term effects of tolvaptan remain controversial. A large-scale clinical trial has not yet been conducted, and it remains unknown whether tolvaptan improves the prognosis of patients with liquid retention.

Since hepatic venous catheterization to measure HVPG is relatively invasive, simple non-invasive tests and biomarkers are required. Previous studies reported that hepatic/splenic stiffness on transient elastography correlated with HVPG[35,36], whereas others indicated that the portal blood flow velocity and intrahepatic passage time measured using contrast-enhanced ultrasonography reflected severe portal hypertension[37]. However, these examinations are not useful in decompensated liver cirrhosis patients with ascites[38]. A recent study reported that the ICG value at 15 min[39] and inflammatory biomarkers, such as IL-1β and VCAM-1, correlated with portal blood pressure[40], though these studies involved only patients with compensated liver cirrhosis. A previous study showed that von Willebrand Factor antigen correlated with HVPG in decompensated liver cirrhosis patients with HVPG of 12 mmHg (approximately 163 mmH_2O) or more[41], though this test is not clinically available. Further studies are needed to develop an easy-to-implement, non-invasive method that sufficiently reflects HVPG even in patients with decompensated liver cirrhosis and predicts the therapeutic effects of tolvaptan.

The present study showed that responders to tolvaptan were likely to have lower HVPG and that tolvaptan had little impact on portal vein pressure. If high portal vein pressure in non-responders is decreased by beta-blocker, splenic artery embolization or TIPS, which could reduce portal vein pressure[42-46], the effect of tolvaptan may be improved. Additive or synergistic effects on liquid retention may be produced by lowering portal vein pressure in combination with these treatments.

In conclusion, the present study suggests that tolvaptan is effective for liquid retention in decompensated liver cirrhosis patients with lower portal vein pressure. By contrast, patients with higher HVPG have the likelihood of treatment failure. In the future, therapeutic strategy needs to be established to treat liquid retention in refractory patients.

ACKNOWLEDGMENTS

We thank Yoshiko Seki (Division of Gastroenterology, Nippon Medical School Chiba Hokusoh Hospital) for their excellent technical support.

COMMENTS

Background

A V_2 receptor antagonist became clinically available in Japan in 2013 for the treatment of liquid retention. On the other hand, factors influencing treatment response have not yet been elucidated. The authors conducted this prospective study to clarify such factors in 40 patients with decompensated liver cirrhosis complicated by liquid retention.

Research frontiers

Changes from the baseline in body weight were -1.0 kg and -1.3 kg on days 1 and 3, respectively. Hepatic venous pressure gradient (HVPG) was only significant factor influencing the weight loss effect of tolvaptan. When patients with body weight loss of 2 kg or greater from the baseline were defined as responders, the response rate was 87.5% (7/8) in patients with HVPG of 190 mmH_2O or less, whereas it was only 12.5% (2/16) in those with HVPG of greater than 190 mmH_2O.

Innovations and breakthroughs

At the initiation of tolvaptan treatment, the HVPG value, which was estimated from portal vein pressure, was measured using hepatic venous catheterization. The authors analyzed factors influencing the effects of tolvaptan including HVPG.

Applications

Since hepatic venous catheterization to measure HVPG is relatively invasive, simple non-invasive tests and biomarkers are required.

Terminology

The present study suggests that tolvaptan in the treatment of liquid retention is more effective for patients with lower portal vein pressure. On the other hand, patients with high portal vein pressure need to be treated by beta-blocker, splenic artery embolization or TIPS, which may reduce portal vein pressure.

Peer-review

The paper is devoted to the analysis of the efficacy of a V_2 antagonist used in heart failure and hyponatemia in cirrhotic patients with severe liquid retention.

Abstract

AIM: To determine the efficacy of rectally administered naproxen for the prevention of post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis (PEP).

METHODS: This double-blind randomized control trial conducted from January 2013 to April 2014 at the Gastrointestinal and Liver Diseases Research Center in Rasht, Iran. A total of 324 patients were selected from candidates for diagnostic or therapeutic ERCP by using the simple sampling method. Patients received a single dose of Naproxen (500 mg; n = 162) or a placebo (n = 162) per rectum immediately before ERCP. The overall incidence of PEP, incidence of mild to severe PEP, serum amylase levels and adverse effects were measured. The primary outcome measure was the development of pancreatitis onset of pain in the upper abdomen and elevation of the serum amylase level to > 3 × the upper normal limit (60-100 IU/L) within 24 h after ERCP. The severity of PEP was classified according to the duration of therapeutic intervention for PEP: mild, 2-3 d; moderate 4-10 d; and severe, > 10 d

and/or necessitated surgical or intensive treatment, or contributed to death.

RESULTS: PEP occurred in 12% (40/324) of participants, and was significantly more frequent in the placebo group compared to the naproxen group ($P < 0.01$). Of the participants, 25.9% (84/324) developed hyperamylasemia within 2 h of procedure completion, among whom only 35 cases belonged to the naproxen group ($P < 0.01$). The incidence of PEP was significantly higher in female sex, in patients receiving pancreatic duct injection, more than 3 times pancreatic duct cannulations, and ERCP duration more than 40 min (Ps < 0.01). There were no statistically significant differences between the groups regarding the procedures or factors that might increase the risk of PEP, sphincterotomy, precut requirement, biliary duct injection and number of pancreatic duct cannulations. In the subgroup of patients with pancreatic duct injection, the rate of pancreatitis in the naproxen group was significantly lower than that in the placebo (6 patients *vs* 23 patients, $P < 0.01$, RRR = 12%, AR = 0.3, 95%CI: 0.2-0.6). Naproxen reduced the PEP in patients with $\geqslant$ 3 pancreatic cannulations ($P < 0.01$, RRR = 25%, AR = 0.1, 95%CI: 0.1-0.4) and an ERCP duration > 40 min ($P < 0.01$, RRR = 20%, AR = 0.9, 95%CI: 0.4-1.2).

CONCLUSION: Single dose of suppository naproxen administered immediately before ERCP reduces the incidence of PEP.

Key words: Naproxen; Nonsteroidal anti-inflammatory drugs; Pancreatic duct injection; Post-endoscopic retrograde cholangiopancreatography; Pancreatitis; Serum amylase

Core tip: Acute pancreatitis is the most common serious complication of endoscopic retrograde cholangiopancreatography (ERCP); prevention of post-ERCP pancreatitis (PEP) has become more challenging. The use of nonsteroidal anti-inflammatory drugs is effective in this condition. This study evaluated the efficacy of rectally administered naproxen for the prevention of PEP in composition with placebo immediately before ERCP.

Mansour-Ghanaei F, Joukar F, Taherzadeh Z, Sokhanvar H, Hasandokht T. Suppository naproxen reduces incidence and severity of post-endoscopic retrograde cholangiopancreatography pancreatitis: Randomized controlled trial. *World J Gastroenterol* 2016; 22(21): 5114-5121 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i21/5114.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i21.5114

INTRODUCTION

Acute pancreatitis is the most common complication of endoscopic retrograde cholangiopancreatography (ERCP), with an incidence rate of 1%-10% that can reach 40% or more, depending on the presence of risk factors[1-5]. Factors predicting post-ERCP pancreatitis (PEP) include young age, female sex, pancreas divisum, sphincter of Oddi dysfunction, previous ERCP-induced pancreatitis, multiple attempts for pancreatic duct cannulation, and pancreatic duct injection[6,7]. Although most cases of PEP are clinically mild or moderate in severity, 10% present severe manifestations[8,9].

ERCP complications may be minimized by reducing pancreatic secretion, interrupting inflammatory cascades, relaxing the sphincter of Oddi, and preventing intra-acinar trypsinogen activation infection[10,11]. Several pharmacologic agents, including octreotide[12], diclofenac[13,14], and recombinant interleukin-10[15,16], have been investigated to reduce the incidence and severity of PEP. Additionally, the protease inhibitors gabexate mesylate[17], and somatostatin[18,19] had been shown are effective in preventing PEP, particularly when administered as an intra-venous infusion[20,21].

Evidence suggests that the patient's inflammatory response to pancreatic duct imaging and instrumentation contribute to the development of PEP[7,22-27]. As phospholipase A_2 may play a vital role in the initial inflammatory cascade of acute pancreatitis[24], identifying pharmacologic agents that inhibit or disturb this cascade may prevent or limit the pancreatitis and its consequences. In some randomized controlled trials, various Oral and suppository of nonsteroidal anti-inflammatory drugs (NSAIDs) have shown promising prophylactic activity with regard to PEP[13,14,28-30]. However, different result were seen about the effectiveness of the intraduodenal indomethacin[30,31]. NSAIDs are easily administered, inexpensive, and relatively safe when given as a single dose, making them an attractive treatment option. Despite these benefits of NSAIDs and findings of the recent meta-analysis[32,33] indicated that rectal diclofenac or indomethacin reduce the incidence and severity of PEP, results of the several studies appear to contradict these conclusions[10,34-36]. Tilak Shah *et al*[35] mentioned several questions in this area; comparison between various NSAID, higher dose of drug and different rout of administration. Additionally, there are some study[37,38] reported NSAIDs can cause acute pancreatitis with the highest risk for diclofenac (OR = 5.0, 95%CI: 4.2-5.9) and the lowest for naproxen (OR = 1.1, 95%CI: 0.7-1.7)[39]. Therefore, we conducted a double-blind, randomized, and controlled clinical trial to evaluate the prophylactic effect of a naproxen suppository for the prevention of PEP.

MATERIALS AND METHODS

Study population

Participants were serially enrolled as they were seen for diagnostic or therapeutic ERCP at the gastroenterology ward of Razi Hospital, a referral center in Rasht, Iran between January 2013 and April 2014. Patients over 18 years of age who were scheduled to undergo ERCP and willing to provide written informed consent for study participation were included. Patients who had acute or active pancreatitis, a history of chronic pancreatitis and/or previous endoscopic sphincterotomy, active peptic ulcer disease, rectal disease, aspirin-induced asthma, use of NSAIDs during the preceding two weeks, hypersensitivity to NSAIDs, renal dysfunction, or were pregnant or breastfeeding, were ineligible for the study.

Study design

The protocol for this randomized, controlled clinical trial (IRCT201105301155N14) was approved by the ethics committee of the Gastrointestinal and Liver Diseases Research Center of Guilan University of Medical Science, and written informed consent (per the Helsinki declaration) was obtained from each participant. Eligible participants (n = 324) were selected from candidates for diagnostic or therapeutic ERCP by using the simple sampling method. The sample size was based on the frequency of pancreatitis in the placebo group (P_1 = 0.1)[28] compared to the study drug group (P_2 = 0.04) with α = 0.05 and β = 20%. Selected patients were randomly assigned using permuted-block randomization to receive either a naproxen (500 mg; Behvazan Pharmacy Co., Tehran, Iran) (n = 162) or placebo (n = 162) suppository immediately before ERCP. Concealed envelopes with naproxen or placebo, which appeared identical, were dispensed in sequence. Study participants, ERCP physicians, and nurses who administered treatment were unaware of the nature of the drugs. The group assignment was only known by the programmer of the database used during the study.

ERCP was performed by using a standard therapeutic duodenoscope (Olympus CO.) with the patient under local anesthesia with 2% lidocaine and after premedication by intravenous administration of 0.05 mg/kg of Midazolam or in cases with contraindication, intravenous administration 1 mg/kg pethidine. Blood pressure, heart rate, and oxygen saturation were monitored with automated devices. Contrast medium (Meglumine Compound 76%) was injected manually, under fluoroscopic guidance. ERCPs were carried out by 3 experienced endoscopists, with a mean number of sphincterotomy procedures performed of about 5 to 7 per week.

Outcome and data measurements

The primary outcome measure was the development of pancreatitis, defined according to the guideline of Cotton *et al*[7] as onset of pain in the upper abdomen and elevation of the serum amylase level to > 3 × the upper normal limit (60-100 IU/L) within 24 h after ERCP. The severity of PEP was classified according to the duration of therapeutic intervention for PEP: mild, 2-3 d; moderate 4-10 d; and severe, > 10 d and/or necessitated surgical or intensive treatment, or contributed to death[7].

Serum amylase was measured before, 2 h after, and any time the patients complained of pain within 24 h after ERCP; otherwise, it was routinely measured 24 h after ERCP. After 2 h, patients with normal serum amylase or no history of abdominal pain, nausea and vomiting were permitted to resume oral intake. All patients with prolonged pancreatitis symptoms (> 48 h) were assessed for complications of pancreatitis (abscess, pseudocyst, or fluid collection) by CT.

Demographic characteristics, risk factors, ERCP procedural elements, and follow-up data were collected at the time of the procedure and 24 h after ERCP by a trained physician who was unaware of study-group assignments. ERCP duration, the number of biliary and pancreatic cannulations, findings of the biliary and/or pancreatic duct, and interventions such as sphincterotomy, papillary balloon dilation, and stenting were recorded.

Table 1 Patient characteristics *n* (%)

Characteristic	Naproxen (n = 162)	Placebo (n = 162)
Age, yr	46.3 ± 8.3	44.7 ± 9.7
Female	78 (48.1)	73 (45.1)
Pancreatitis severity		
Mild	8 (20.0)[b]	18 (45.0)
Moderate	4 (10.0)[b]	10 (25.0)
Severe	0 (0)[b]	0 (0)

[b]P < 0.01 *vs* Placebo. Data are presented as mean ± SD or n (%).

Statistical analysis

A two-tailed χ^2 test was used to analyze the difference in the proportion of patients with PEP in the naproxen and placebo groups. Data are expressed as odds ratio (OR) with 95% confidence interval (CI). Additional exploratory subgroup analyses were performed according to age, sex, and procedure, and are reported as relative risk (RR), absolute risk (AR) and relative risk reduction (RRR). All comparisons were carried out on a two-tailed basis. Statistical analysis was carried out with the SPSS (version 16) and P < 0.05 was considered statistically significant. Ninety-five percent significant intervals (CI) for the proportions were calculated.

RESULTS

There were 78 (48.1%) women in the naproxen group and 73 (45.1) women in the control group. The mean age ± SD of the patients in the intervention group was

[1]Pancreatitis/naproxen (12/162, 7.4%); [2]Pancreatitis/placebo (28/162, 17%). [b]$P < 0.01$ *vs* Placebo.

46.3 ± 8.3, and in the control group it was 44.7 ± 9.7. The characteristics of trial participants are presented in Table 1. PEP occurred in 12% (40/324) of participants, and was significantly more frequent in the placebo group (28/162, 17%) compared to the naproxen group (12/162, 7.4%) ($P < 0.01$). Of the participants, 25.9% (84/324) developed hyperamylasemia within 2 h of procedure completion, among whom only 35 cases belonged to the naproxen group ($P < 0.01$).

Analyses in different group indicated that the incidence of PEP was significantly higher in patients receiving pancreatic duct injection, cases with 3 times or more pancreatic duct cannulations, ERCP duration > 40 min and female sex (*P*s < 0.01) (Table 2). Logistic regression analysis of possible risk factors for PEP indicated that pancreatic duct injection, duration of ERCP, female sex and age were significant risk factors (*P*s < 0.05) (Table 3). There were no statistically significant differences between the groups regarding the procedures or factors that might increase the risk of PEP, including, sphincterotomy, precut requirement and biliary duct injection.

In the subgroup of patients with pancreatic duct injection, the rate of pancreatitis in the naproxen group was significantly lower than that in the placebo group (6 patients *vs* 23 patients; $P < 0.01$, RRR = 12%, AR = 0.3, 95%CI: 0.2-0.6). Naproxen reduced the PEP in patients with ⩾ 3 pancreatic cannulations ($P < 0.01$, RRR = 25%, AR = 0.1, 95%CI: 0.1-0.4) and an ERCP duration > 40 min ($P < 0.01$, RRR = 20%, AR = 0.9, 95%CI: 0.4-1.2).

The most common final diagnosis after ERCP was choledocholithiasis, followed by several cases of sphincter of Oddi dysfunction, common bile duct tumors, and choledochal cysts (Figure 1). We did use pancreatic duct stenting in the nobody of study subjects. All patients were discharged in good health and there were no reported side effects.

DISCUSSION

A systematic review of five clinical trials[39], as well as two subsequent meta-analyses[40,41], indicate that administration of NSAIDs significantly decreases the incidence of PEP. Our findings show that a single dose of suppository naproxen given immediately before ERCP significantly reduces the overall incidence and severity of PEP. Elmunzer *et al*[42] in a multicenter, randomized, placebo-controlled, double-blind clinical trial showed post-ERCP pancreatitis developed in 16.9% of placebo group *vs* 9.2% in the indomethacin group, as well as, indomethacin decrease the incidence of moderate to severe PEP. Andrade-Dávila *et al*[43] conducted a controlled clinical trial where patients at least one major and/or two minor risk factors for developing post-ERCP pancreatitis. They suggested rectal indomethacin reduced the incidence of post-ERCP pancreatitis among patients at high risk of developing this complication. In our randomized controlled trial, the number of patients who would need to be treated to prevent one episode of pancreatitis was 10. Sethi *et al*[44] in a meta analysis concluded rectal NSAIDs can decrease PEP with 11 patients needed to treatment. However, another meta-analysis showed the number needed to treat was 17[30]. On the other hand, recent controlled clinical trial a number needed to treat of 6.5 patients were calculated to prevent an episode of post-ERCP pancreatitis[43].

The occurrence of PEP varies according to patient characteristics and the type of intervention performed. We found that pancreatic duct injection, duration of ERCP (> 40 min), female sex and age (< 40 year) were significant risk factors for developing PEP, consistent with other studies[9,14,25,42]. European Society of Gastrointestinal Endoscopy Guideline presented cannulation attempts duration > 10 min and younger age increase the incidence of PEP[29]. Similarly, Sotoudehmanesh *et al*[14] demonstrated the protective effect of indomethacin for PEP in the patients with pancreatic duct injection. Furthermore, Elmunzer *et al*[42] showed that indomethacin significantly reduced the risk of moderate to severe PEP from 16.1% to 9.7% in patients with pancreatic injections. In our study, the risk of PEP was not associated with undergoing sphincterotomy, having sphincter of Oddi dysfunction. These findings are in contrast to those of Murray *et al*[13] who found that diclofenac was protective in patients who had sphincterotomy and those without sphincter of Oddi hypertension. Furthermore, recent guideline updated in 2014[29], female gender presented

as a risk factor for PEP. In parallel our study, in recent controlled clinical trial, Suspected sphincter dysfunction oddi were not risk factor for PEP[43]. Till now, several meta-analyses[3,30,39-41,45] conclude that NSAIDs used in the different routes of administration decrease the incidence of pancreatitis and severity of pancreatitis. Although, the results of our study are relevant because the drug was rectally administrated immediately before procedure, the main difference between our study and those previously reported was the use of naproxen instead of indomethacin or diclofenac. Hence, to support the conclusion, a high-quality multicenter randomized clinical trial is required to better describe the effectiveness of naproxen as a NSAID.

In conclusion, a single-dose prophylactic naproxen suppository significantly decreases the occurrence and severity of PEP, particularly in those with pancreatic duct injections, multiple pancreatic duct cannulation attempts, those younger than 40 years of age, and requiring a procedure lasting more than 40 min. Moreover, this treatment produced no adverse events, consistent with previous works[10,28,40], and should therefore be administered immediately before ERCP procedures.

ACKNOWLEDGMENTS

We would like to thank all the Gastrointestinal and Liver Diseases Research Center personnel.

COMMENTS

Background

Acute pancreatitis is the most feared complication of endoscopic retrograde cholangiopancreatography (ERCP) because it has the greatest potential for causing prolonged hospitalization, major morbidity, and occasionally death.

Research frontiers

Acute pancreatitis is the most common complication of ERCP; prevention of post-ERCP pancreatitis (PEP) has become more challenging.

Innovations and breakthroughs

Prevention of PEP has become more challenging. The use of nonsteroidal anti-inflammatory drugs (NSAIDS) is effective in this condition but selection the best effective drug is required more examination of it. This study is based on this real.

Applications

This study evaluated the efficacy of rectally administered Naproxen for the prevention of PEP in patients received a single dose of naproxen or a placebo immediately before ERCP.

Peer-review

This study provides useful information for prevention of PEP. The authors show that a single dose of suppository naproxen administered immediately before ERCP reduces the incidence and severity of PEP.

Abstract

AIM: To determine the efficacy of probiotic supplementation on intestinal transit time (ITT) in adults and to identify factors that influence these outcomes.

METHODS: We conducted a systematic review of randomized controlled trials of probiotic supplementation that measured ITT in adults. Study quality was assessed using the Jadad scale. A random effects meta-analysis was performed with standardized mean difference (SMD) of ITT between probiotic and control groups as the primary outcome. Meta-regression and subgroup analyses examined the impact of moderator variables on SMD of ITT.

RESULTS: A total of 15 clinical trials with 17 treatment effects representing 675 subjects were included in this analysis. Probiotic supplementation was moderately efficacious in decreasing ITT compared to control, with an SMD of 0.38 (95%CI: 0.23-0.53, $P < 0.001$). Subgroup analyses demonstrated statistically greater reductions in ITT with probiotics in subjects with *vs* without constipation (SMD: 0.57 *vs* 0.22, $P < 0.01$) and in studies with high *vs* low study quality (SMD: 0.45 *vs* 0.00, $P = 0.01$). Constipation ($R^2 = 38\%$, $P < 0.01$), higher study quality ($R^2 = 31\%$, $P = 0.01$), older age ($R^2 = 27\%$, $P = 0.02$), higher percentage of female subjects ($R^2 = 26\%$, $P = 0.02$), and fewer probiotic strains ($R^2 = 20\%$, $P < 0.05$) were predictive of decreased ITT with probiotics in meta-regression. Medium to large treatment effects were identified with *B. lactis* HN019 (SMD: 0.67, $P < 0.001$) and *B. lactis* DN-173 010 (SMD: 0.54, $P < 0.01$) while other probiotic strains yielded negligible reductions in ITT relative to control.

CONCLUSION: Probiotic supplementation is moderately efficacious for reducing ITT in adults. Probiotics were most efficacious in constipated subjects, when evaluated in high-quality studies, and with certain probiotic strains.

Key words: Constipation; Gastrointestinal; Intestinal transit time; Meta-analysis; Probiotics

Core tip: We performed a contemporary systematic review and meta-analysis of randomized controlled trials to determine the effects of short-term probiotic supplementation on transit time in adults. Probiotic supplementation is moderately efficacious for reducing intestinal transit time in adults. Probiotics were most efficacious in constipated subjects, when evaluated in high-quality studies, and with certain probiotic strains.

INTRODUCTION

The human colonic microbiota is a complex ecosystem involved in maintenance of health and physiological functions of the host. Disturbances within the microbiota may result in gastrointestinal disorders such as constipation, irritable bowel syndrome, or periodic bouts of irregularity. Functional gastrointestinal disorders are a highly prevalent group of persistent and recurring conditions with a prevalence of 69% in the general population[1]. Slow intestinal transit is a common manifestation of functional gastrointestinal disorders affecting the bowel[2] and may also occasionally affect otherwise healthy individuals. Although the benefits of reducing intestinal transit time (ITT) in patients with constipation are obvious, reductions in ITT are also considered a beneficial physiological effect in the non-diseased general population[3]. Over-the-counter and prescription medications intended to normalize intestinal transit are widely utilized although no known treatment is considered efficacious, safe, and cost effective[4]. Probiotics are live micro-organisms that confer a health benefit on the host when administered in adequate dosages[5] and have been extensively studied for enhancement of gastrointestinal health[6,7]. Previously, we performed the first systematic review and meta-analysis on the efficacy of probiotic supplementation on ITT in adults[8]. The purpose of this study was to update these findings with data from randomized controlled trials (RCTs) published over the 3-year period since our last review.

MATERIALS AND METHODS

Literature search

This study was performed according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA)[9]. We searched MEDLINE and EMBASE for RCTs of probiotic supplementation that reported ITT in adults by using a combination of relevant keywords. The details of the MEDLINE search strategy are listed in Table 1. The syntax for EMBASE was similar, but adapted as necessary. Additionally, manual searches were conducted using the Directory of Open Access Journals, Google Scholar, and the reference lists of included papers and other relevant meta-analyses. No date restrictions were applied to the searches. The final search was conducted in October 2015.

Study selection

Two researchers independently selected studies for inclusion in the review. Disagreements were resolved by consensus. Titles and abstracts were initially screened to exclude manuscripts published in non-English journals. Next, review articles, commentaries, letters, and case reports were excluded. Lastly, we excluded studies of subjects where ITT reduction was undesirable or uninterpretable (*e.g.*, diarrhea or mixed IBS subtypes). Full-text of the remaining manuscripts was then retrieved and reviewed. Publications that failed to report ITT or that described non-randomized, non-controlled, or otherwise irrelevant studies were also excluded.

Data extraction

Data were extracted from eligible peer-reviewed articles by one author and then verified by a second author. Data extraction discrepancies between the two researchers were resolved by consensus. The following variables were recorded in a pre-designed database: general manuscript information (author, institution name and location, journal, year, volume, page numbers), study design characteristics (study quality, study design, sample size, method of ITT assessment,

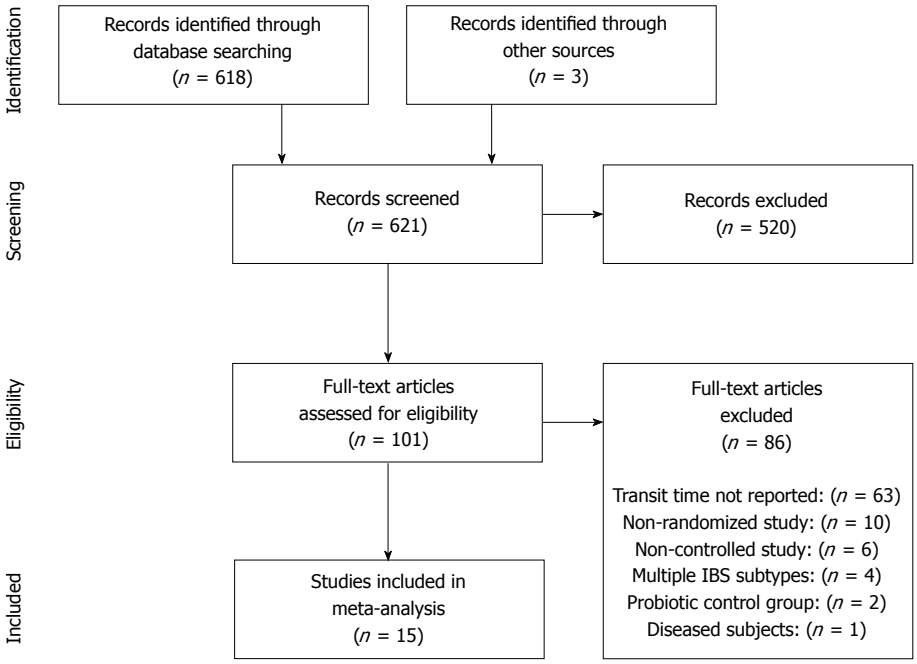

Figure 1 PRISMA flow diagram.

probiotic strain, daily dosage, product delivery method, and treatment duration), subject characteristics (age, gender, body mass index, and condition), and ITT summary statistics necessary for meta-analysis.

Quality assessment

The Jadad scale was used to assess RCT study quality[10]. Studies were scored according to the presence of three key methodological features: randomization, blinding and subject accountability. Randomization was scored from 0 to 2, blinding was scored from 0 to 2, and subject accountability was scored 0 or 1. RCTs with a score of 3 to 5 were classified as high quality; studies with a score of 0 to 2 were classified as low quality.

Statistical analysis

A random effects meta-analysis model was selected *a priori* based on the assumption that treatment effects were heterogeneous given the differences in probiotic strain, study design characteristics, and subject characteristics among studies. The standardized mean difference (SMD) and 95% confidence interval (CI) were the statistics of interest to describe treatment effects since different measures of ITT (*e.g.*, whole gut, colonic, oro-cecal, *etc*.) were utilized in the included studies. The SMD is calculated as the mean difference in ITT between probiotic and control groups divided by the pooled standard deviation in ITT. SMD values of 0.2, 0.5, and 0.8 are defined as small, medium, and large, respectively[11]. Positive SMDs imply that probiotics were more effective in reducing ITT *vs* control while negative SMDs imply a greater treatment effect with control *vs* probiotics. A forest plot was used to illustrate the individual study findings and the random effects meta-analysis results. Heterogeneity of effects across studies was estimated with the I^2 statistic where values of $\leqslant$ 25%, 50%, and $\geqslant$ 75% represent low, moderate, and high inconsistency, respectively[12]. In addition, a one study removed meta-analysis was performed to assess the influence of individual studies on the meta-analysis findings. Publication bias was visually assessed with a funnel plot and quantitatively assessed using Egger's test[13]. Meta-regression and subgroup analyses were performed to explore sources of heterogeneity. All analyses were performed using Comprehensive Meta-analysis (version 2.2, Biostat, Englewood NJ). The statistical methods of this study were reviewed by Clinton Hagen, MS (Mayo Clinic, Rochester, MN).

RESULTS

Study selection

Our initial database search retrieved 618 titles and abstracts; hand searching relevant bibliographies identified 3 additional records. After screening records for inclusion criteria, 101 full text articles were reviewed for eligibility. Ultimately, 15 RCTs with 17 treatment effects representing 675 unique subjects were included in the final analysis[14-28]. A flow chart of study identification and selection is shown in Figure 1.

Study characteristics

Sample sizes ranged from 10 to 36 per treatment arm for parallel groups designs (9 studies) and from 12 to 83 for cross-over designs (6 studies). Thirteen RCTs contributed one treatment effect each and two RCTs contributed two effects each; the study of Rosenfeldt

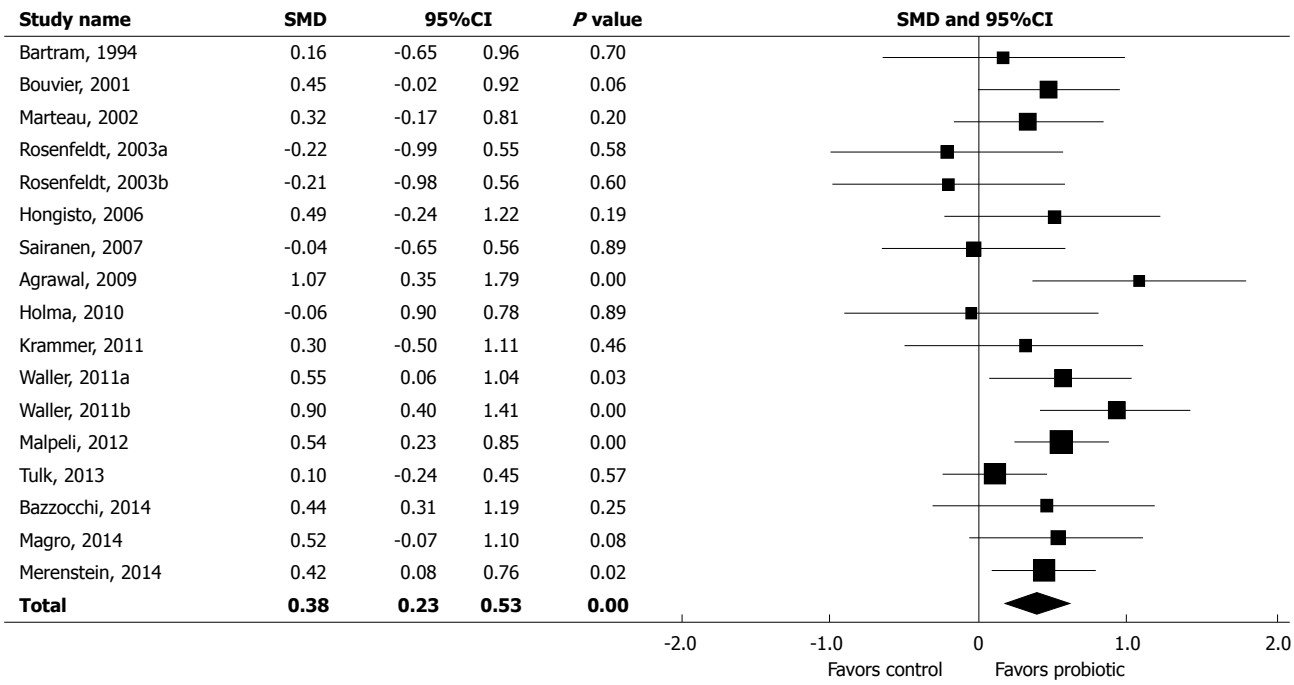

Figure 2 Forest plot of standardized mean difference in intestinal transit time across studies. Random effects model. I^2 = 20%, P = 0.22. SMD: Standardized mean difference.

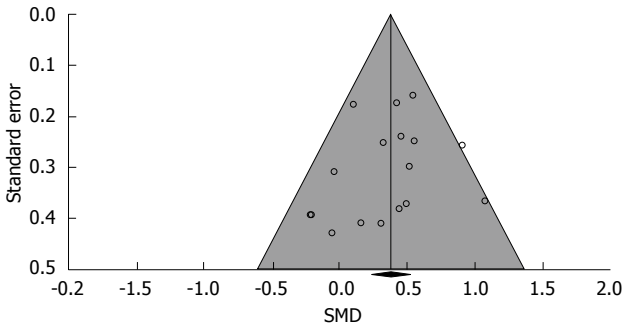

Figure 3 Funnel plot of standardized mean difference in intestinal transit time across studies. Egger's P value = 0.44 for publication bias. SMD: Standardized mean difference.

and colleagues[21] assessed two different probiotic formulations and the study of Waller and colleagues[23] assessed two different dosages of the same probiotic strain. Daily probiotic dosages varied considerably among studies, ranging from 5×10^8 to 9.8×10^{10} colony forming units (CFU) per day (median 1.6×10^{10} CFU per day). Probiotic treatment periods ranged from 10 to 28 d (median 18 d). Intestinal transit time was measured using radiopaque markers in 13 studies and with carmine red dye in 2 studies. The most commonly tested product format was yogurt or other forms of fermented milk. Six (40%) studies included other components in the active product known to influence ITT such as lactulose, psyllium, inulin, polydextrose, maltodextrose, and oligofructose (Table 2).

Subject characteristics

Nine treatment effects were calculated for subjects with constipation or IBS-C while 8 effects were based on healthy subjects. Subjects were predominantly female, mean age ranged from 23 to 50 years, and mean body mass index ranged from 19 to 32 kg/m^2 (Table 3).

Study quality assessment

Overall, the quality of RCT reporting was medium with a median Jadad score of 3 (range: 1-5). Twelve of 17 treatment effects were based on high quality (Jadad score 3-5) trials. The method of randomization was inadequately described in most studies. Descriptions of blinding were adequate overall. Subject accountability in RCTs was sufficiently detailed in 11 of 17 cases (Table 4).

Main results

In relation to controls, probiotic supplementation statistically decreased ITT, with an SMD of 0.38 (95%CI: 0.23-0.53, $P < 0.001$) (Figure 2). Only 5 of 17 treatment effects statistically favored probiotic supplementation. There was low heterogeneity among studies (I^2 = 20%, P = 0.22) with no evidence of publication bias (Egger's regression test: P = 0.44) (Figure 3). A one study removed sensitivity analysis was performed to determine the influence of individual studies on main outcomes. Overall, no single study significantly influenced the observed SMD of ITT with probiotics *vs* control. SMDs ranged from 0.35 to 0.42 (all $P < 0.001$) following removal of each study one at a time from the meta-analysis (Figure 4).

< 1.6^{10} CFU (n = 7)	0.34	0.16-0.52	< 0.001	

[1]Categorized by median value; [2]Body mass index not reported for 5 treatment effects; [3]Includes studies where treatment included probiotics plus fiber or non-digestible sugar. Variables sorted from lowest to highest between-groups *P* value; n represents the number of treatment effects. IBS-C: Irritable bowel syndrome, constipation predominant; SMD: Standardized mean difference.

(MR) (Table 6) were performed to determine the influence of study- and subject-related characteristics on ITT. Probiotic supplementation reduced ITT in comparison to controls in several of the analyzed subgroups. Greater reductions in ITT were observed with probiotics in subjects with *vs* without constipation (SA and MR, $P < 0.01$) and in high-quality (Jadad score ⩾ 3) *vs* low-quality (Jadad score < 3) studies (SA and MR, $P = 0.01$). There were trends for greater probiotic efficacy with older age (SA, $P = 0.08$, MR, $P = 0.02$), in recently published studies (SA, $P = 0.08$), with parallel groups study designs (SA, $P = 0.08$), higher percentage of female subjects (SA, $P = 0.08$,

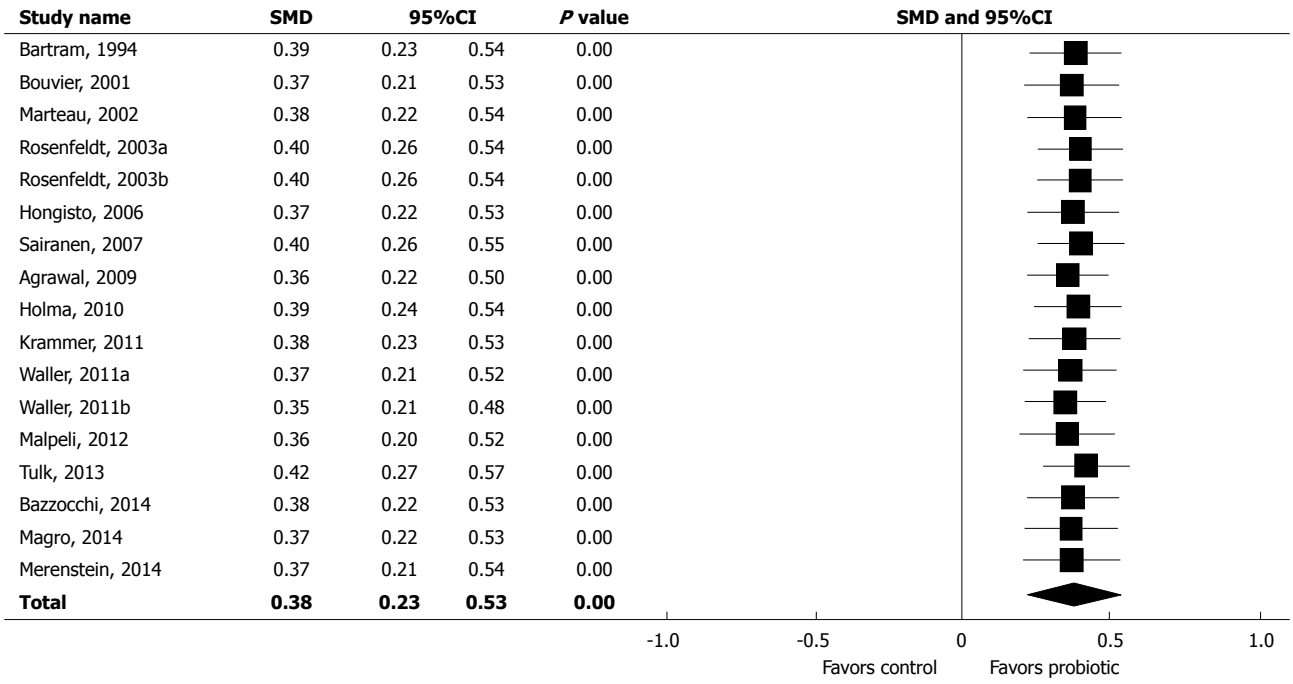

Figure 4 One study removed forest plot of standardized mean difference in intestinal transit time across studies. SMD: Standardized mean difference.

Table 6 Meta-regression of study- and subject-related factors on intestinal transit time

Variable	Unit of measure	Intercept	Point estimate	Explained variance (%)	*P* value
Constipation/ IBS-C	1 = Yes; 0 = No	0.218	0.352	38	< 0.01
Jadad score	Per 1 unit	-0.117	0.141	31	0.01
Age	Per 1 yr	-0.352	0.021	27	0.02
Female gender proportion	Per 10%	-0.045	0.055	26	0.02
Number of probiotic strains	Per 1 strain	0.618	-0.133	20	< 0.05
Body mass index[1]	Per 1 kg/m^2	-0.526	0.037	22	0.08
Treatment duration	Per 1 d	0.392	-0.004	0	0.96
Daily probiotic dosage	Per 10 × 10^9 CFU	0.385	-0.001	0	0.98

[1]Body mass index not reported for 5 treatment effects. Variables sorted from greatest to least explained variance.

Table 7 Subgroup analysis of probiotic strains on intestinal transit time

Probiotic strain	No. of treatment effects	SMD	95%CI	*P* value
B. lactis HN019	3	0.67	0.37-0.97	< 0.001
B. lactis DN-173 010	3	0.54	0.16-0.92	< 0.01
L. casei CRL 431	2	0.33	-0.10-0.75	0.14
B. lactis BB12	2	0.33	-0.10-0.75	0.14
L. rhamnosus GG	3	0.10	-0.35-0.55	0.67

Probiotic strains sorted from highest to lowest standard mean difference. SMD: Standardized mean difference.

MR, $P = 0.02$), single-strain probiotics (SA, $P = 0.09$, MR, $P < 0.05$) and higher body mass index (SA, $P = 0.16$, MR, $P = 0.08$). Treatment duration, geographic location of study, inclusion of potentially confounding treatments, and daily probiotic dosage were not found to have a significant influence on probiotic efficacy in subgroup analysis and meta-regression. Analysis of outcomes by probiotic strain identified medium to large treatment effects with *B. lactis* HN019 (SMD: 0.67, $P < 0.001$) and *B. lactis* DN-173 010 (SMD: 0.54, $P < 0.01$) while treatment effects with other strains were small (SMD: 0.10-0.33) and not statistically significant (Table 7).

DISCUSSION

An ever-increasing body of evidence implicates the gastrointestinal microbiome in defining states of health and disease[29]. Probiotics may restore the composition of the gut microbiome and support beneficial functions to gut microbial communities, resulting in amelioration of gut inflammation and other disease phenotypes[30]. Consequently, probiotic supplementation is increasingly touted as an effective and accessible means of improving gut health, even in the general population of healthy adults. The current systematic review and meta-analysis demonstrates that short-term probiotic supplementation yielded moderate ITT reductions in adults. Additionally, the treatment effect of probiotics was greater in subjects with constipation, in high-quality studies, and with certain probiotic strains. In contrast to the moderate treatment effect observed in constipated subjects, probiotics only minimally influenced ITT in non-constipated adults. Given this finding, it appears that probiotic consumption will

not lead to undesired short ITT or diarrhea. However, probiotic consumption for the sole purpose of reducing ITT is unjustified in healthy adults. Nevertheless, this finding does not diminish other beneficial effects that have been observed with probiotics in healthy adults[31,32].

In this meta-analysis, there was a trend for greater treatment effects with probiotics in parallel groups study designs compared to crossover studies (SMD: 0.48 *vs* 0.26, $P = 0.09$). Although there is no clear explanation for this finding, data from one included study deserves further discussion. The study of Merenstein *et al*[27] enrolled 68 healthy women using a crossover design, with a 6-wk washout between treatment periods. However, a significant carry-over effect was observed at the start of the second treatment period. For purposes of this meta-analysis, we treated this study as a parallel groups design using data from the first treatment period only[33]. Although the presence of a carry-over effect was not mentioned in the other crossover studies included in this analysis, the fact that washout periods ranged from 2 to 6 wk with significant carryover identified even after 6 wk in the Merenstein study raises the question of whether carry-over effects may have influenced outcomes of other crossover studies. Although crossover studies may initially appear attractive to researchers given the smaller sample size requirements compared to parallel groups designs, we propose that crossover designs are inappropriate in probiotic clinical trials unless the washout period for the probiotic has been previously established for the specific condition under study.

In comparison to our previous meta-analysis on this topic, the treatment effect of probiotics on ITT was largely unchanged (SMD: 0.40 *vs* 0.38). Importantly, with the addition of more studies, we were able to explore potential sources of heterogeneity among studies with greater precision. Novel subgroup findings included the observation of moderate probiotic treatment effects (SMD: 0.45) in high-quality studies, but no treatment effect (SMD: 0.0) in low-quality studies. Although the treatment effect sizes in parallel groups and crossover studies remained largely unchanged, study design is now a considerably stronger predictor of heterogeneity in ITT outcomes given the inclusion of additional studies. We also identified that single-strain probiotics were more efficacious than multiple strain probiotics. Although *B. lactis* HN019 and *B. lactis* DN-173 010 remained the most efficacious probiotic strains, we were able to analyze additional probiotic strains that yielded modest improvements in ITT relative to placebo.

The strengths of this systematic review and meta-analysis are inclusion of only RCTs and a comprehensive assessment of the influence of moderator variables on ITT with probiotic supplementation. Our study also revealed several limitations in the design of ITT studies with probiotics. First, the treatment duration of included studies ranged from 10 to 56 d. Although the long-term safety of probiotics is well established[34], probiotic efficacy on ITT beyond 8 wk cannot be interpreted with the current analysis. Second, although the therapeutic benefit of probiotics appears to be strain-specific, the small number of studies performed with each strain prevented robust strain-specific comparisons. Finally, subject characteristics were relatively homogenous among studies with regard to age and gender. Therefore, the generalizability of these findings to the general population, particularly males and the elderly, is unknown. These findings give specific suggestions for future research in this field.

In conclusion, probiotic supplementation is moderately efficacious for reducing ITT in adults. Probiotics were most efficacious in constipated subjects, when evaluated in high-quality studies, and with certain probiotic strains.

COMMENTS

Background

Functional gastrointestinal disorders are common in the general population, with slow intestinal transit a common symptom. No therapy is highly efficacious, safe, and cost effective for treatment of slow-transit bowel disorders. Probiotics have been extensively studied for treatment of gastrointestinal disorders and may confer improvements in bowel regularity.

Research frontiers

Clinical trials of probiotic supplementation on intestinal transit time (ITT) yield discrepant results. The authors performed a contemporary systematic review and meta-analysis on the efficacy of probiotic supplementation on ITT in adults, with a secondary focus on exploring sources of heterogeneity through meta-regression and subgroup analyses.

Innovations and breakthroughs

Probiotics are most efficacious in constipated subjects, when evaluated in high-quality studies, and with certain probiotic strains.

Applications

Probiotic supplementation appears to confer clinically meaningful improvements in intestinal transit in subjects with constipation. Probiotic efficacy also significantly differs according to strain.

Terminology

Probiotics are live micro-organisms that confer a health benefit on the host when administered in adequate dosages. Intestinal transit time is an indicator of the time taken for a food bolus to travel through the gastrointestinal system. The standardized mean difference is a statistical measure of effect size for continuous outcomes, defined as the mean difference between groups divided by the pooled standard deviation.

Peer-review

Very nice manuscript.

Abstract

We report a successful endoscopic ultrasonography-guided drainage of a huge infected multilocular walled-off necrosis (WON) that was treated by a modified single transluminal gateway transcystic multiple drainage (SGTMD) technique. After placing a wide-caliber fully covered metal stent, follow-up computed tomography revealed an undrained subcavity of WON. A large fistula that was created by the wide-caliber metal stent enabled the insertion of a forward-viewing upper endoscope directly into the main cavity, and the narrow connection route within the main cavity to the subcavity was identified with a direct view, leading to the successful drainage of the subcavity. This modified SGTMD technique appears to be useful for seeking connection routes between subcavities of WON in some cases.

Key words: Endoscopic ultrasonography; Infected pancreatic necrosis; Walled-off necrosis; Endoscopic ultrasonography-guided drainage; Acute pancreatitis

Core tip: Walled-off necrosis (WON) remains difficult to endoscopically manage because of insufficient drainage of solid necrotic tissues. Here, we present a case of successful drainage of a huge WON *via* a modified single transluminal gateway transcystic multiple drainage technique. After placing a wide-caliber covered metal stent, follow-up computed tomography revealed an undrained subcavity of WON. A large fistula created by the metal stent enabled the insertion of an upper endoscope directly into the main cavity, and the narrow connection route within the main cavity to the subcavity was identified with a direct view, leading to the successful drainage of the subcavity.

INTRODUCTION

Endoscopic ultrasonography (EUS)-guided drainage for pancreatic fluid collection (PFC) is increasingly used as a minimally invasive alternative to surgical and percutaneous drainage[1-3]. However, walled-off necrosis (WON) remains difficult to endoscopically manage because of insufficient drainage of solid necrotic tissues. Various techniques, such as the use of wide-caliber metal stents[4,5], direct endoscopic necrosectomy[6,7] and multiple transluminal gateway technique[8] are reportedly useful for managing WON. However, responses to these advanced techniques remain unsatisfactory in some cases. Recently, a single transluminal gateway transcystic multiple drainage (SGTMD) was developed for treating complicated multilocular WON[9]. Here, we present a case of successful endoscopic drainage of a huge infected multilocular WON *via* a modified SGTMD technique.

CASE REPORT

A 49-year-old male presented with upper abdominal pain and high fever of 7 d duration. He was diagnosed with alcohol-induced severe acute pancreatitis 1 mo before and was discharged 6 d after admission from a neighbouring general hospital. His computed tomography (CT) severity index[10] was 6. He was re-admitted to our hospital with the above-mentioned chief complaints. Laboratory tests revealed elevated C-reactive protein (CRP) and procalcitonin levels (27.8 mg/dL and 6.17 ng/mL, respectively). Elevated levels of kidney function parameters were also noted (blood urea nitrogen level, 77 mg/dL; serum creatinine level, 3.14 mg/dL). An abdominal CT revealed a huge multilocular WON measuring 31 cm × 16 cm, which spread from the pancreas to pelvis (Figure 1). Clinically, infection of the necrosis was assumed. Doripenem was intravenously introduced; however, his clinical symptoms and elevated inflammatory reaction persisted. As the main cavity of WON was close to the gastric lumen, we decided to puncture WON under EUS guidance. EUS-guided transluminal drainage was performed; a wide-caliber fully covered TTS Niti-S esophageal stent (internal diameter, 16 mm; maximum flange diameter, 24 mm; length, 40 mm; Taewoong Medical, Seoul, South Korea) was placed (Figure 2). Through the metal stent, a 7-Fr double-pigtail plastic stent (length, 80 mm) and a 7-Fr nasocystic catheter were inserted (Figure 3). During the procedure, approximately 2.4 L of purulent fluid were suctioned. A follow-up abdominal CT obtained 1 wk after the procedure demonstrated a significant reduction in the size of the main cavity; however, the undrained subcavity remained, which was mainly located in the left anterior pararenal space and extended to the left pelvis (Figure 4). Additional drainage targeting the subcavity was required because high fever continued after the procedure. Because the subcavity was not adjacent to the stomach or duodenum, additional EUS-guided puncture was difficult. CT suggested communication between the subcavity and main cavity; therefore, a SGTMD procedure was considered. Repeated attempts to determine the connection route within the main cavity to the subcavity using an ERCP catheter and 0.025-inch guidewire were unsuccessful. The metal stent was removed, and a large fistula that was created by the metal stent enabled the insertion

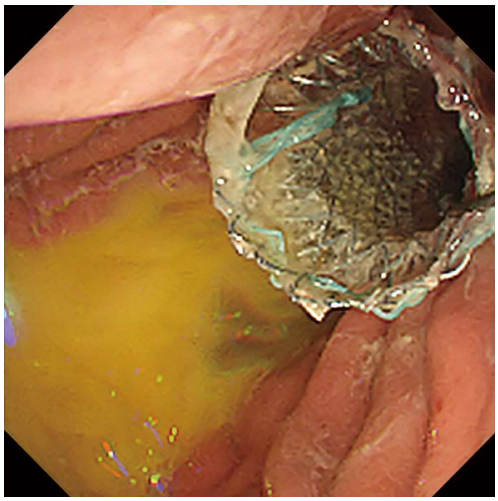

Figure 2 Successful deployment of a wide-caliber fully covered TTS Niti-S esophageal stent. Purulent fluid was observed in the gastric lumen.

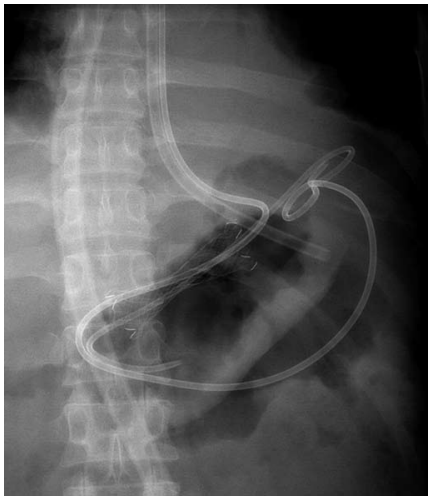

Figure 3 A 7-Fr double-pigtail plastic stent and a 7-Fr nasocystic catheter were deployed through the fully covered metal stent.

of a forward-viewing upper endoscope directly into the main cavity. After the endoscope was advanced into the cavity, a narrow connection route was identified (Figure 5). Contrast medium was injected into the connection. Having confirmed the detection of the subcavity, the guidewire was inserted into the cavity and two 7-Fr double-pigtail plastic stents (lengths, 120 and 80 mm, respectively) were deployed (Figure 6). No procedure-related complications were observed. After additional endoscopic management, high fever resolved over the course of a few days and CRP levels significantly decreased. CT revealed that the subcavity of WON was well drained. The patient completely recovered and was discharged after 3 wk of hospitalization. Follow-up CT obtained 1 month after discharge revealed that WON had mostly collapsed (Figure 7) and the patient remained symptom free.

Figure 4 Computed tomography one week after initial drainage showed an undrained subcavity, located mainly at the left anterior pararenal space that extended to the left pelvis.

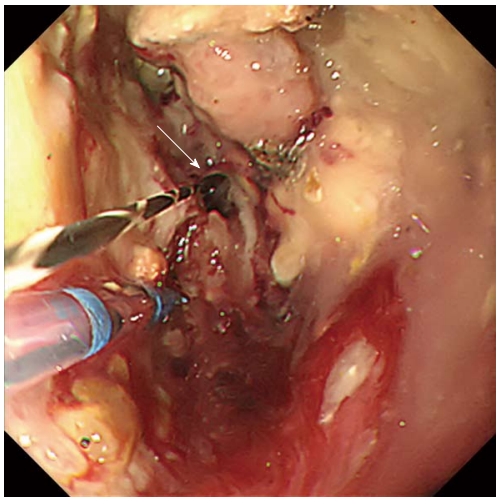

Figure 5 Endoscopic view of the cavity of walled-off necrosis by a modified single transluminal gateway transcystic multiple drainage technique. An upper endoscope was inserted into the walled-off necrosis (WON) through the fistula and a narrow connection route within the main cavity to the subcavity could be identified directly (white arrow).

DISCUSSION

Over the last decade, techniques for pancreatic fluid collection have shifted toward minimally invasive approaches. Since first reported in 1992 by Grimm *et al*[1] EUS-guided transluminal drainage for pancreatic fluid collection has played a pivotal role and spread worldwide as a minimally invasive alternative to surgical and percutaneous drainage[1-3]. However, the clinical response rate of the conventional single transluminal gateway technique deploying single or multiple stenting for treating WON is not satisfactory (described as 45%-63%)[8,11]. Recently, various techniques, such as the use of wide-caliber metal

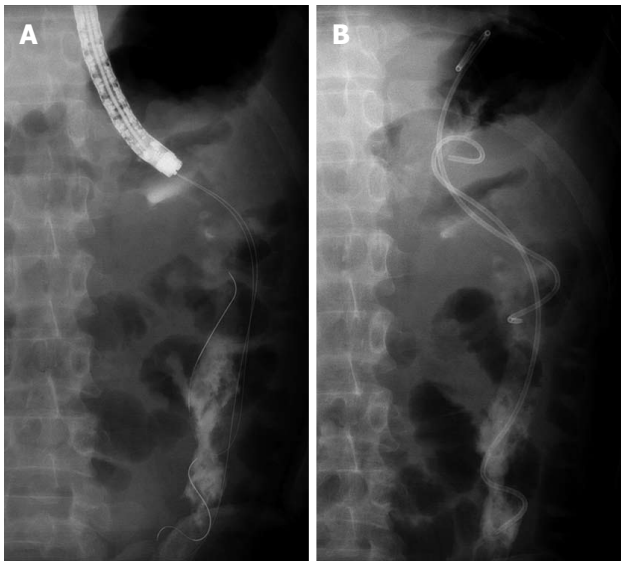

Figure 6 Fluoroscopic view of modified single transluminal gateway transcystic multiple drainage technique. With a direct view of the connection route, a 0.025-inch guidewire was inserted into the subcavity (A) and two 7-Fr double-pigtail plastic stents were deployed (B).

Figure 7 Follow-up computed tomography obtained one month after discharge revealed the WON had mostly collapsed.

stents[4,5], direct endoscopic necrosectomy[6,7] and multiple transluminal gateway technique[8] have improved the clinical success rate of endoscopic management of WON. However, response to these advanced techniques remains unsatisfactory in some cases. Mukai *et al*[9] recently described a novel SGTMD procedure for complicated multilocular WON and reported successful drainage in five cases using this technique. When subcavities are located far from the gastrointestinal lumen, percutaneous approach would have been used conventionally. Mukai *et al*[9] hypothesized that the multilocular cavity may have originally been unilocular and separated into subcavities with tiny, narrow connections during the process of treatment and collapse. They used an ERCP catheter and soft guidewire to locate tiny, narrow connections. In this case, we repeatedly attempted to identify the connection using an ERCP catheter and soft guidewire through the metal stent under fluoroscopic guidance, but the guidewire curled up in the main cavity and failed to locate a connection route. Instead, we inserted the upper endoscope into the cavity through the large fistula, which enabled the narrow connection route to be directly observed. The guidewire was easily and safely advanced into the subcavity, and successful drainage of the subcavity was achieved. This is a modified technique of the previously described SGTMD. In addition to SGTMD, having a direct view to identify the connection route may lead to a higher success rate in some cases.

In this case, the pig-tail stents have been left in place during 6 mo follow-up. This is because the previous studies revealed that stent retrieval was associated with higher PFC recurrence rates[12,13].

In conclusion, we presented a case of successful endoscopic drainage of a huge infected multilocular WON by a modified SGTMD technique with direct endoscope insertion into the cavity. This modified SGTMD technique appears to be useful in seeking connection routes between the subcavities of WON and might avoid the requirement for a more invasive drainage procedure, such as endoscopic or surgical necrosectomy.

COMMENTS

Case characteristics

One month after being diagnosed with alcohol-induced severe acute pancreatitis, a 49-year-old male presented with upper abdominal pain and high fever of 7 d duration.

Clinical diagnosis

The patient had upper abdominal pain and high fever.

Differential diagnosis

Pancreatic pseudocyst.

Laboratory diagnosis

The laboratory findings showed elevated C-reactive protein, procalcitonin levels and renal dysfunction.

Imaging diagnosis

Abdominal computed tomography demonstrated a huge multilocular WON measuring 31 cm × 16 cm, which spread from the pancreas to pelvis.

Pathological diagnosis

Pathological examination was not performed in this case.

Treatment

Endoscopic drainage with a modified single transluminal gateway transcystic multiple drainage (SGTMD) technique was performed.

Related reports

WON remains difficult to endoscopically manage because of insufficient drainage of solid necrotic tissues. Various techniques, such as the use of wide-caliber metal stents, direct endoscopic necrosectomy, multiple transluminal gateway technique and SGTMD technique were developed for treating WON.

Term explanation

Modified SGTMD is a novel alternative technique for drainage of WON which means a single transluminal gateway transcystic multiple drainage with direct endoscope insertion into the cavity.

Experiences and lessons

Modified SGTMD technique appears to be useful in seeking connection routes between the subcavities of WON and might avoid the requirement for a more invasive drainage procedure, such as endoscopic or surgical necrosectomy.

Peer-review

This case report is interesting and well documented.

Abstract

Over the last few years, we have expanded our knowledge on numerous facets of the hepatitis C virus (HCV). Beginning with its discovery and viral life cycle, its impact on health, the development of liver disease and currently, effective antiviral treatments. The latter point has become of great interest throughout the developed world, where the possible eradication of HCV through specific strategies to reach all HCV-infected people has been announced. However, this scenario is very different in the countries of Latin America (LA), in which < 2% of infected patients requiring treatment have access to HCV medications. It has been estimated that at least ten million Latin Americans may be infected with HCV. Despite the numbers, viral hepatitis does not seem to be considered a health problem in this region of the world. This reality poses a challenge for politicians and governments of these countries, as well as to the pharmaceutical industry, the medical practitioners, and academics in LA. In this editorial, we state the need for alterations in the attitudes of the integral players involved in this situation. A recognition shift could help to create preventive strategies of viral hepatitis and to advocate for accessibility to new HCV treatments.

Key words: Low-income; Antiviral agents; Public health; Medical societies; Drug industry

Core tip: Global eradication of hepatitis C virus (HCV) infection is causing considerable interest, especially in the developed world. However, the accessibility to the new direct-acting antiviral regimens in low- and middle- income countries is an unmet need. At least ten million HCV-infected persons in Latin America (LA) are confronted by multiple barriers to HCV treatment. Moreover, for the LA countries, paradoxically at it seems, money may not be the only issue. The health authorities, the medical community, and the pharmaceutical industry are the key players that need to alter their attitude towards the delivery of HCV treatments to all patients irrespective of their socio-

economic status.

INTRODUCTION

Early years of hepatitis C virus infection

The history of the hepatitis C virus (HCV) is a strong example of a bench-to-bedside approach illustrating how basic scientific knowledge is applied to patient care.

Following the discovery of hepatitis B virus (HBV) in 1965[1], and hepatitis A virus (HAV) in 1973[2], a clinical entity known as post-transfusion non-A non-B (NANB) hepatitis became more evident[3]. This was regardless of the banning of commercial blood donations systems, and the implementation of HAV and HBV blood testing in 1975[3,4]. Furthermore in 1989, after years of intensive research[5], a scientific breakthrough discovered another virus consisting of a single positive strand of RNA, the HCV, classified in the *Flaviridae* family[6]. HCV was determined to be the causing agent of the post-transfusion NANB hepatitis[4,5].

In 1992, following the cloning of HCV, an evolving series of sensitive and specific anti-HCV antibody immunoassays were developed which allowed for the mandatory testing of blood collections in the United States[3]. Subsequently, third-generation immunoassays and RNA-HCV nucleic acid amplification tests improved the diagnostics of HCV for blood transfusion safety[7]. During the 90's, the HCV genotypes and subtypes, as well as their heterogeneous geographic distribution became apparent through basic research and molecular epidemiology[8]. Additionally in the United States, blood transfusions, injection drug use (IDU) and several medical procedures were identified as high-risk factors[3].

During the 90's but before 2011, the first antivirals to be marketed were standard interferon, followed by pegylated-interferon which was later combined with ribavirin[9]. Unfortunately, these antivirals achieved a low-level of sustained viral response (SVR) among patients with HCV genotype 1 compared to other genotypes[10]. However after 2011, the first and second generation direct-acting antivirals based on targeting the specific molecules of the HCV life cycle have proven more efficient regardless of genotype reaching an SVR in more than 90% or 95% of the patients who receive treatment[10].

In recent years, DNA sequencing and bioinformatics of HCV strains worldwide have allowed the evolutionary analysis and molecular tracing of the HCV epidemic across countries, mainly focusing on genotype 1a and 1b[11]. These studies have documented the prevalence of HCV in Japan since 1920, in Europe since 1940 and the United States since 1960[11,12]. Further studies have confirmed that the introduction of HCV in the United States may have occurred even earlier (in the 1950's) and is related to the use of contaminated blood obtained from commercial blood donors and the return of World War Ⅱ soldiers[13]. These reasons, along with the fact that hepatitis C is a stealthy virus causing injury to the liver in a silent manner, people who were born from 1945-1965 are currently in the target population of the "baby boomers" screening campaign for HCV in the United States[14].

Transmission of HCV infection in Latin America

Mexico's geographic location serves as a common pathway of intracontinental migration between the United States and other countries of LA. Thus, HCV could have spread from the United States to this region. However in LA, awareness of an NANB hepatitis did not intensify until the late 1970s and early 1980s[15]. During this period, the United States veterans returning from Vietnam, as well as the migration of Latin Americans to their homeland as retirees or by multiple processes of deportation and migration between countries became a major social-demographic phenomenon.

The first HCV epidemic outbreak was associated with the emergence of HIV in the mid-1980s, at a time where the presence of paid blood donors was a common situation[16]. This parenteral route of transmission may have been the primary source of dispersion in Central and South America since IDU, during those decades, was very rare in LA[17]. Furthermore, even though in the United States mandatory screening of blood-borne viruses had been implemented in 1992, it was not fully established in Mexico and LA until 1996[18,19]. This information indicates that even before 2000, blood donations contaminated with HCV were still a relevant risk factor[20]. Moreover, an additional route of HCV infection in the LA may have been the indiscriminate use of caesarean births and other medical procedures that took place during the same period[21]. Brazil and Mexico[22] are the two countries with the highest rates of cesarean sections within the Americas[23]. This could explain why Mexico has a female-to-male ratio of 2:1 of HCV infection[21].

Although partial reports were stating the frequency of HCV in countries of LA during the 1990s, it was not until after 2000 that HCV-related liver cirrhosis began to rise. In Mexico, this disease entity represents over 12 deaths per 100000 inhabitants and the estimated number of people infected with HCV may range from 1.5 to 2 million[24-26], and at least ten million in LA[26-28]. In this region the route of transmission of HCV may have been similar as it was in Mexico, taking into account that as of 2000 the use of IDU, as well as tattooing and piercing, had increased from that year

forward[17].

HCV TREATMENT IN LATIN AMERICA

HCV infection can only be prevented by evading or eradicating the virus. To achieve eradication, treatment with highly effective drugs to all who are infected is required. Currently with the introduction of the new, but very costly, direct-acting antivirals (DAAs) an enormous feeling of success is felt. This elation may be comprehensible for the developed countries, but it may not be true for many developing countries worldwide[29-32], including those in LA[33-37].

However, there are two sides to this story. On one hand, the feasibility of eradicating HCV is closer than ever due to new treatments[38]; yet, on the other hand, neither the authorities nor the physicians, recognize that many infected patients are the result of an iatrogenic spread of HCV. More than 95% of patients infected with viral hepatitis belong to a lower social class in their respective countries, and they can not afford to pay the current market prices of these new antiviral drugs[39].

Additionally, a significant challenge for the eradication of HCV is that there is more than one genotype of the human virus. There are seven genotypes and multiple subtypes[40], which have infected populations with heterogeneous genetic makeups worldwide. This point indicates that research data on HCV needs to be population-based, especially in LA. Further studies are required to identify the genotypes that circulate[41,42], the main risk factors[17,20,21] and the immunogenetic background of the population[43-45].

To date, less than 2% of the people infected with HCV have been treated with the standard pegylated-interferon/ribavirin therapy. The new DAAs, such as boceprevir, telaprevir, simeprevir, and sofosbuvir have been slowly licensed in a limited number of countries in LA. Moreover, HCV treatments are based on the United States and European guidelines which provide evidence of the SVR obtained in clinical trials carried out in populations other than LA.

Thus, under these circumstances who will have access to treatment in Latin America? A substantial body of literature has documented the multiple barriers to health care in HCV-infected patients[46-49]. Although crucial, they are not within the scope of this editorial. Alternatively, we address several issues regarding the health authorities, the medical community, and the pharmaceutical industry. These are key players involved in the prevention, diagnosis, and treatment of this disease.

KEY PLAYERS

Health authorities

The health officials have not considered viral hepatitis to be a severe health problem, which in turn has manifested ignorance or reluctance towards a state program of detection or treatment of this disease. Consequently, there are a limited number of up-to-date population-based epidemiological studies of viral hepatitis in most LA countries[35,36] sponsored by the government. The few that do exist are accomplished by the attention and personal interest of researchers, rather than the concern of the health authorities. This lack of concern from the health authorities translates into key factors and information being overlooked. Some of these factors include; lack of precision of who and how many people are infected, primary risk factors involved[50], transition in genotypes[17] and co-morbidities (obesity, diabetes, alcoholism, co-infection with HVB and HIV)[51]. Furthermore, these epidemiological studies need to be documented in the population of LA because most clinicians assume that the same SVR achieved in Caucasians will replicate in people from this region.

Medical community

In LA, including Mexico, most medical societies involved in the study of the liver have a limited number of members with a solid scientific career, based on their poor scientific productivity in indexed and high impact factor journals in their dedicated fields[52,53]. These society members are hosted by the pharmaceutical companies to attend international forums. In turn, they are the only speakers that echo their experience at the liver meetings to their fellows but do not contribute with scientific data or share their clinical experience. This circumstance has led to the situation that some members only intend to be their society's President (or Chairperson) without the actual contribution of new knowledge in their field of expertise. Moreover, it is precisely these "leaders of the field" who take part, on multiple occasions, as representatives of the health authority, sometimes playing a dual role as clinician and politician.

Therefore, when the support of the medical community is required to establish health policies that have an impact on vulnerable social groups, the members are left without a voice, and vote, on these issues. Consequently, the decisions are made in an unipersonal manner. Furthermore, if the clinician-politician now has a position within the health institutions or the government, he/she may now have a conflict of interest with his/her private practice.

Unfortunately, the lack of an official standpoint in many educational or health institutions to promote a high standard of scientific and academic quality is a serious weakness. This challenge, paired together with a high level of corruption and preferential treatment that prevails among some government authorities, makes it tough to provide treatment for this virus. This situation has created elitist groups of treating physicians being sponsored by the pharmaceutical industry. These doctors may be knowledgeable, however, in some cases, this information does not

necessarily apply to their respective countries or communities.

Furthermore, many of these physicians focus on his/her private practice and have negligible interest in understanding the reality of the disease in their community or country of origin. A reminder of the Hippocratic Oath is "We as doctors should seek the best benefit for the patients, including those who do not have access to treatment".

Likewise, in the majority of LA countries, there are no specialists in hepatology. Patients living with liver diseases are treated mainly by a gastroenterologist or internist[54]. However, with the introduction of the new effective antivirals, and the possibility of the pharmaceutical industry involvement, medical specialists from different fields now claim the liver-diseased patient. Thus, a specialty or subspecialty in hepatology supported by academic institutions should be established as soon as possible.

Pharmaceutical industry

The pharmaceutical industry has declared a responsibility to eradicate HCV by creating agreements based on the economy of each country for the marketing of the antiviral drugs. In general, the standard procedure for the pricing of these drugs is to achieve a full refund of the R and D investment in the developed countries, intermediate reimbursement in the middle-income countries, and the possibility to offer a generic product at a lower and accessible cost for the low-income countries (defined as a win-win situation).

Unfortunately, there are still some well-known challenges to overcome in many developing countries, such as corruption and slow bureaucracy to introduce these drugs[55]. Additionally, the lack of precise epidemiological information about HCV infection is an ongoing difficulty.

Another obstacle is performing the diagnostic tests. Each patient should be evaluated before treatment because not all patients that are positive for anti-HCV antibodies have detectable viral loads or have a similar grade of liver damage. Thus, a pretreatment algorithm including initial and follow-up viral loads, genotyping and identification of possible resistance mutations, and staging of liver damage (fibrosis/cirrhosis) should be considered. A conservative estimate of the costs of these tests may exceed up to $2000 to $4000 United States dollars before paying at least $10000 to $80000 United States dollars for a three-month period of treatment[56]. If the patient is a potential non-responder or present with advanced liver damage, this cost may rise even higher.

Considering these conditions several options have been proposed, such as the establishment of non-profit societies that aid in the funding of these high costs for the poor. This creates a risky situation, given the lack of transparency and poor attitudes of some key players previously mentioned, there is a chance that these "non-profit" organizations may end up as personal or family businesses, or in the hand of small groups who are in power.

Nevertheless, with the justification of "supporting updated scientific medical education", the pharmaceutical companies focus mainly on the treating physicians (clinicians) by selecting medical "leaders", doctors who have influence among the medical groups or societies, or are representatives of health institutions. Whereas, the few scholars or scientists who are knowledgeable in the field of viral hepatitis are not considered under the argument that they are not clinicians or do not treat patients.

This situation leads to the lost opportunity to be supported by the pharmaceutical industry. Thus, in the absence of proposals and sanitary laws, the pharmaceutical industry is interested in selling their drug; but the academic or research sector in the developing countries do not fall within their scope.

RECOMMENDATIONS

HCV infection imposes a large challenge in the world, and it certainly will be eradicated faster in some regions than others. In low- and medium-income countries of LA the health problem of HCV may not depend entirely on money, other nations with fewer resources are proactively establishing public-private partnerships to lower the cost of the DDAs (*e.g.*, Egypt). Hopefully, these strategies will close the gap between the number of patients who are infected (diagnosed) versus those who are treated.

The advancement of scientific knowledge and its impact on health are correlated with the progressive changes in the attitude and behavior of key players and others responsible. The increase in knowledge should benefit all people irrespective of their socio-economic status. To achieve such impact, and to reach all those who need an efficient antiviral therapy, this change in attitude needs to become a reality.

Where and how to start to face this critical situation in Latin America? One recommendation is that both politicians and authorities must consider viral hepatitis as a health problem in their respective region, and establish support strategies to investigate the burden of HCV infection. It is no longer safe to assume that any health issue can be resolved without recognizing the magnitude of the situation.

In the medical communities, a good start would be to establish a partnership between the academic sector, researchers, and physicians, instead of independently acting on their own. This collaborative shift could strengthen the figure of the MD/PhD in each medical society. This may be achieved if alongside, the academic institutions in LA make every effort towards higher standards of education and professionalism. This would greatly strengthen the quality of the medical associations with academic leaders that contribute with knowledge publishable in indexed

international journals. In countries such as Spain and Brasil, the use of the h-index (Hirsch-index) has been considered to grant membership to their respective National Academy of Medicine.

Another important change would be to educate the younger generations that the purpose of belonging to a medical society is not only to be their president or chairperson. As mentioned above, the ultimate goals are to provide prestige and effectiveness by contributing to new knowledge about their country or city in matters of health. The higher income groups require treatments, however, so does the general population. If we reconsider and always remember the Hippocratic Oath, this will help to reflect and advance the field quickly to achieve these goals.

To conclude, the disclosure of the clinicians (speakers), in regards to their sponsorship by the pharmaceutical industry, should be regulated by law and enforced by an ethical practice. Likewise, academics, scientists, medical practitioners and the pharmaceutical companies should equally engage and commit to solving the problem of HCV infection in this region of the world. Moreover, grants given by the pharmaceutical industry in LA to support research in liver disease would be extremely beneficial. These are recommendations that need to be heavily considered by all key players.

Abstract

Iran is known as an endemic country for hepatitis E virus (HEV) infection, while there are variations in the epidemiology of HEV infection throughout the country. The available epidemiological studies in different regions of Iran show HEV seroprevalence of 1.1%-14.2% among general population, 4.5% -14.3% among blood donors, 6.1%-22.8% among injecting drug users, 6.3%-28.3% among hemodialysis patients, 1.6%-11.3% among patients infected with other hepatitis viruses, 27.5% among patients with chronic liver disease, 30.8% among kidney transplant recipient patients, and 10%-16.4% among human immunodeficiency virus-infected patients. These variations reflect differences in the status of public health and hygiene, risk factors, and routes of transmission in different regions and groups. Therefore, it is necessary to review the epidemiology of HEV infection to determine the most prevalent risk factors and routes of transmission, and to evaluate the effectiveness of preventive strategies employed in the public health services of the country. Moreover, the other epidemiological aspects of HEV, including the genotypic pattern, extra hepatic manifestations, and incidence of chronic infection need to be investigated among Iranian population to expand the current knowledge on the epidemiology of HEV and to clarify the real burden of HEV infection. Therefore, this review was performed to provide a general overview regarding the epidemiology of HEV in Iran.

Key words: Hepatitis E virus; General population; Blood donors; Injecting drug users; Hemodialysis; Immunocompromised patients; Chronic liver disease; Prevalence; Epidemiology; Iran

Core tip: Iran is considered as an endemic country for hepatitis E virus (HEV) infection, while there are variations in the epidemiology and prevalence of hepatitis E throughout the country. These variations reflect differences in the life styles, status of public health, risk factors, and routes of transmission in different groups and geographical regions of Iran.

Therefore, this study was conducted to review the epidemiological aspects of HEV infection in Iran.

INTRODUCTION

Hepatitis E virus (HEV) is the causative agent of hepatitis E infection[1]. This infection is usually asymptomatic or acute self-limiting[1] but might lead to fulminant hepatitis or even long-term chronic infection and cirrhosis with a high rate of mortality due to severe liver failure in high-risk groups, such as pregnant women, organ transplant recipient patients, immunocompromised patients, and those with pre-existing liver problems[1-6]. HEV is predominantly transmitted *via* the fecal-oral route; however, transmission of HEV through blood transfusion, organ transplantation, hemodialysis, placenta and sexual intercourse is also possible[1,7,8]. Among these, sexual transmission of HEV is less common and has mostly been reported in homosexual males[7,9].

HEV is a small spherical virus with a positive-sense RNA genome and an icosahedral non-enveloped capsid[5,10-12]. The viral genome contains three partially overlapping open reading frames[5,13,14]. HEV has been classified into the family *Hepeviridae*, the genus *Orthohepevirus*, and the species *Orthohepevirus A*[1,15]. There are four genotypes of HEV capable of causing human infection with different epidemiological features[3,16]. These genotypes have further been subdivided into 24 subgenotypes[5,17,18]. Genotypes 1 and 2 are only recognized in human beings, while genotypes 3 and 4 are found in domestic and wild animals as well[7,19-21]. Despite this genetic heterogeneity, only one serotype has been recognized so far[1,5,22].

HEV genotypes differ in their severity, pathogenecity, mortality rates, mode of transmission, age distribution, and geographical distribution[1,7-9,23]. HEV genotype 1 is frequently found in North Africa and Asia[9]. HEV genotype 2 is more common in West Africa and Mexico[7,9]. HEV genotype 3 is considered to have a worldwide distribution and is more prevalent in several European and American countries, as well as Japan, China, Australia, and New Zealand[7,9,10]. HEV genotype 4 has been reported in Asian countries and more recently in Central Europe[5,9,23]. Genotypes 3 and 4 appear to be less virulent than genotypes 1 and 2[1,24]. HEV genotype 1 is associated with the most cases of fulminant hepatitis and high mortality during pregnancy[8,10]. While HEV genotype 3 is the cause of almost all cases of chronic HEV infections worldwide[5,7,8]. Infection with HEV genotype 4 seems to be asymptomatic and mostly remains undiagnosed[6,9].

Hepatitis E is usually an asymptomatic or acute self-limited infection and only requires supportive care. However, when fulminant or chronic hepatitis arises, therapeutic intervention is an obligation[9,10]. Reduction of immunosuppressive therapy is considered as the first-line therapy in immunocompromised patients with chronic HEV infection. Nevertheless, at the same time, it can increase the risk of graft rejection[3,5,9,25-27]. In such conditions, organ transplant recipient patients benefit most from antiviral therapy, including pegylated interferon (peg-IFN) monotherapy or combination therapy with ribavirin and peg-IFN[3,10,25].

These antiviral agents are associated with severe side effects. IFN-therapy may result in acute graft rejection[3,5,8,25]. Ribavirin administration induces severe hemolytic anemia; and when the dose of ribavirin is reduced, the viral clearance is not achieved[8]. Therefore, the combination of ribavirin with a reduction in the doses of immunosuppressive drugs has been found to be the most promising treatment option[5,10,25]. In addition, these antiviral drugs should be administered with caution during pregnancy due to their teratogenicity[10,27,28]. Early delivery of fetus or termination of pregnancy should be considered as another option to save mothers' lives[28,29]. Administration of the antiretroviral drugs in human immunodeficiency virus (HIV)-positive patients can result in an increase in the proportion of T helper cells and subsequently clearance of HEV infection[25].

Considering the side effects and limitations of the currently available treatment regimens as well as the absence of a specific antiviral treatment for HEV infection, preventive measures and vaccination against HEV infection are the most desirable approaches for controlling HEV infection[25,30]. HEV vaccines using the truncated forms of capsid protein have been evaluated in human clinical trials, and one of them, HEV 239 vaccine, has been approved in china in 2011. Although this vaccine has shown promising results, it is not commercially available worldwide[5,20,27,31]. Therefore, preventive measures are still known to be the best option. Providing clean drinking water supplies, improving the hygienic infrastructure and sanitary status, washing hands and vegetables properly, boiling drinking water, and avoiding consumption of undercooked foods and unpeeled fruits are some of these preventive measures[1,5,11,23,31,32]. In addition, proper chlorination of water supplies, sanitary preparation of food, and public awareness regarding the possible routes of HEV transmission are essential to reduce the risk of exposure to HEV in the community[1,11,23].

HEV has infected one-third of the world's population[13,17]. In addition, 20 million new cases and 3.3

million acute cases of HEV infection occur globally each year[3,33], and HEV-related hepatic failure is responsible for approximately 56600 deaths per year[33,34]. The mortality rate of HEV infection is 1%-2% in the general population[17], but it may rise to 10%-25% in pregnant women[7,20] and over 75% in individuals with pre-existing liver problems[20].

HEV is a considerable global health concern. Although HEV infection was traditionally believed to be limited to developing countries, currently it is known that this infection has a worldwide distribution with different epidemiological patterns[9]. In developing countries where the infection is endemic, acute outbreaks or large epidemics of hepatitis E occur due to contamination of water supplies mainly at the time of heavy rainfall or following floods. These outbreaks are largely due to genotypes 1 and 2 and more frequently affect young adult males[1,3,5,8,9,18]. Whereas in developed countries, HEV infection is non-endemic and mostly occurs as sporadic locally-acquired disease due to consumption of contaminated food supplies. The infection is due to genotypes 3 and 4 and predominantly found among middle-aged elderly males throughout the year[1,3,5,9,18].

Apart from variations in the global epidemiological patterns of HEV, there is a wide range of variation in the prevalence and epidemiology of HEV infection within a country[5,16,35,36]. These variations reflect differences in the lifestyle, status of public health, risk factors, and routes of transmission in different regions and groups[35-37]. It is therefore necessary to review the epidemiology of HEV infection to determine the most prevalent risk factors and routes of transmission and to evaluate the effectiveness of prevention strategies employed in the public health services of a country. These epidemiological studies are not only essential for improving the current strategies to minimize the risk of acquiring HEV infection in the society but also clarify the real burden of HEV infection.

This study has the objective to review the epidemiology of hepatitis E in Iran, a vast country located in the Middle East, with an extension of about 1700000 km^2 and an estimated population of 70 million inhabitants in different provinces with various ethnicities[38].

HEV IN GENERAL POPULATION

With an overall prevalence rate of more than 5% in the general population, Iran is considered as an endemic country for HEV infection[36,39]. However, the seroprevalence of hepatitis E in the general population varies considerably in different parts of the country, ranging from 0.0% to 0.9% for anti-HEV IgM and 1.1% to 14.2% for anti-HEV IgG and the total HEV antibodies in different studies[35,39-46] (Table 1[35,39-46]). Differences in the lifestyles, risk factors, levels of exposure, the geographic regions, study population, study periods, sample sizes, time of sampling, and the diagnostic accuracy of kits used to determine anti-HEV antibodies in various studies can explain these variations[35-37]. However, the role of public health services, hygienic conditions, socioeconomic status, and environmental factors should not be dismissed[36,37,42].

The predominant mode of transmission in Iran is fecal-oral route, especially feces-contaminated drinking water; however, the other routes of transmission might also have a minor role in the spread of HEV but with undetermined importance[35,43,47]. Food-borne transmission of zoonotic origin is unlikely, since wild animal hunting and swine farming are prohibited in Iran[35]. Person-to-person transmission is most likely rare in Iran, since no association between the household size and seroprevalence rate of HEV has been reported[42]. Overall, the importance of the other probable routes of transmission in spread of HEV infection in the society still requires to be determined.

Despite the epidemiological pattern in developing countries, where HEV most often affects young adults[1,5,9], the seroprevalence rate in Iran increases with age due to cumulative exposure to HEV over time with the highest prevalence rate among middle-aged and elderly individuals aged over 50 years[35,36,40,41,45]. Another possible reason is improvement in public hygiene, sanitation, sewage disposal and drinking water supply systems, which has resulted in decreased prevalence of HEV infection in young population of the country over time[36,47].

Except two reports[44,45], in the majority of studies, the seroprevalence of HEV was higher in females compared to males. However, none of these differences were significant[35,36,39-42]. In rural areas, inhabitants were more likely to be positive for HEV serological markers compared to individuals living in urban areas[39,43]. Appropriate access to the public health services, sewage disposal systems, and safe water supplies in cities can explain these differences in the seroprevalence rates regarding the place of residence[35,37,43]. Taken together, in studies from Iran, socioeconomic status, level of sanitation, population density, age, level of education, and place of residency were found to be risk factors for acquiring HEV infection in the society[35,42,43,48].

In one study from Iran, the prevalence of anti-HEV IgG antibody in the general population was as high as 46.1% in South-West of the country[36]. The reason of this high endemicity is most likely Karun River as the drinking water source of the inhabitants, where the city sewage is also discharged in. It is also worthy to note that the participants in the mentioned study were all adults, mostly middle-aged and elderly adults[36]. Iran is located in the Middle East between HEV high endemic countries on the eastern and western borders. This considerable geographic location has affected epidemiological pattern of HEV infection in Iran[35,47].

A few occasional waterborne outbreaks of hepatitis E have also occurred in Iran[47]. The first documented outbreak was reported in Kermanshah city, West of

Table 1 Seroprevalence of hepatitis E virus in different population groups in Iran

ND: Not defined; HEV: Hepatitis E virus.

Iran, in 1991. At the same time, a suspected outbreak was reported in Isfahan province, during which over 100 inhabitants were infected in Fereidon-Shahr. Another outbreak occurred in Lordegan, Southwest of Iran, in 1999 and affected 154 people[45,47]. The history of these outbreaks clearly implies that HEV infection is not new to Iran, and probability of future outbreaks in the country should be considered and preventive strategies for controlling transmission of HEV infection should be provided.

The prevalence rate of HEV infection in the general population is likely underestimated due to the lack of adequate population-based studies, asymptomatic nature of HEV infection, and the fact that hepatitis E is not a reportable infection in the public health system of Iran. In addition, the incidence and case fatality rate of hepatitis E in the general population of Iran are unclear and need further investigation.

HEV IN BLOOD DONORS

Even though HEV infection is an old enterically transmitted disease, it is also considered an emerging transfusion-transmitted infection[4,7]. Since only recently, HEV has been recognized as a threat to blood safety[4,6]. The possibility of HEV transmission through blood transfusion dates back to 2002 and 2004, when two molecular studies in Japan introduced HEV as a transfusion transmissible virus[6,7,18]. Since then, several studies from Japan, the United Kingdom, France, and Saudi Arabia have confirmed HEV transmission through blood transfusion[6,7,18,23].

These studies have reported high prevalence of anti-HEV antibodies, and viral RNA among blood donors[6,23]. Donor-recipient linked studies have also confirmed transmission of HEV to blood transfusion recipients[6,7]. In addition, higher incidence of hepatitis E in multi-transfused individuals compared to controls suggests this transmission[7,18,23]. Moreover, the high rate of asymptomatic or undiagnosed infection among blood donors increases the risk of HEV transmission[7,18,23]. Fortunately, these unnoticeable infections are preventable through screening of blood donations for HEV infection. Screening methods are based on the detection of anti-HEV antibodies and HEV RNA in serum or plasma samples of blood donors[1,4,7,8,16,18].

The presence of elevated liver enzymes and HEV RNA in blood is short lived, and becomes normalized or undetectable approximately 6 weeks and 3 weeks after the onset of clinical illness, respectively[5,7,16]. In some instances, viremia may persist for a longer period, especially in children after acute hepatitis E[4,7]. In addition, HEV RNA has been detected up to 3 years in immunocompromized patients, especially those with renal transplantation[4]. IgM increases during the acute phase of infection and becomes undetectable after 3-8 mo[16]. While IgG appears after the increase of IgM level and persists for years with unknown duration[5,8,16]. Therefore, anti-HEV IgG positive samples in the absence of IgM and HEV RNA are defined as past HEV infection. While a positive anti-HEV IgM test can be indicative of current

infection if HEV RNA is detected[1,16]. Some patients in viremic phase of infection do not show anti-HEV IgM responses[49]. Majority of risks are due to the presence of HEV RNA in blood of apparently healthy donors with normal levels of liver enzymes and negative anti-HEV IgM, which is indicative of asymptomatic viremia[7,18]. In these instances, blood transfusion is capable of trasmitting HEV infection despite negative serological markers. Therefore, HEV is a potential threat to blood safety[7,18].

Since 2005, Japan has implemented HEV RNA testing of all donors along with screening for elevated liver enzymes levels[7]. While some other countries perform selective HEV screening for high-risk recipients[8]. The necessity to screen all blood donations or at least a part of them for HEV infection needs to be considered in Iran.

Studies on the seroprevalence of HEV in blood donors are limited in Iran and mainly have been conducted in main cities, while the seroprevalence varies from 4.5% to 14.3% in these studies[49-55] (Table 1[49-55]). Despite this high prevalence, screening of blood donors for HEV is not performed in the blood banks of Iran until more evidence becomes available regarding the potential threat of HEV to blood safety[49,53]. In addition, the risk of incidence and transmission of hepatitis E by blood transfusion in Iran is unknown. Since the studies in Iran have only reported the rate of seropositivity, which is incapable of estimating the rate of viremic blood donors[49,53]. Therefore, additional studies to investigate the possibility of HEV transmission through blood transfusion seem to be necessary. Even if the risk of transmission through blood transfusion is low, we should not neglect the importance of this infection. Since HEV causes serious consequences in high-risk recipients, who often require blood transfusion. Therefore, access to HEV-free blood and blood products is the highest priority for this group of patients[4,7,18,50].

The seroprevalence of HEV among hemophilia and thalassemia patients in Iran is lower than expected and is in the range of that found in the general population of Iran[56]. The reason of this low prevalence may be that the blood donor population in Iran has mostly been consisted of young individuals, while HEV mostly affects middle-aged or old population in Iran[49,50,54]. This suggests that blood transfusion may not be a risk factor for transmission of HEV infection among hemophilia and thalassemia patients in Iran[56]. Still, more studies are required to confirm this issue.

HEV IN INJECTING DRUG USERS

With having approximately 180000 injecting drug users (IDUs) among Iranian adults aged 15-64 years, Iran is considered one of the countries with the highest numbers of injection drug users in the world[38]. While only two studies have assessed the possible effect of injecting drug use on the seroprevalence of HEV among IDUs in Iran[57,58]. Alavi *et al*[57] reported high seroprevalence of HEV in IDUs (22.8%) compared to inhalant drug users (9.1%) and oral opiate drug users (6.2%) and suggested an association between injection drug abuse and HEV seropositivity in Ahvaz in 2005-2006. While some other studies from France, the United States (US), and Denmark have rejected this association[59-62]. Keramat *et al*[58] reported high prevalence of HEV in IDUs (6.1%) compared to non-IDUs control group (1.5%) and found no relationship between duration of injection and HEV seroprevalence in Hamadan in 2011-2012.

These studies indicated high seroprevalence of HEV infection among IDUs in Iran[57,58], while this seroprevalence was not influenced by the type of substance abused but was associated with the route of administration[57]. According to the results of these studies, IDUs in Iran are at risk of acquiring HEV infection most likely due to exposure to infected blood through sharing syringe[58]. As a result, injection drug use was proposed as a possible route of HEV transmission. However, still more investigations are required to confirm this issue.

HEV IN HEMODIALYSIS PATIENTS

The seroprevalence of hepatitis E among patients on maintenance hemodialysis (HD) varies considerably from 4% to 28.3% in different cities of Iran[63-69] (Table 1[63-69]). The reason of this vast geographic variation in different HD centers is unknown, but it may be due to the different levels of safety strategies in HD units, as well as the public health and prevalence of HEV infection in the community[30,64,69]. In some studies, HEV seroprevalence in HD patients is lower than or in the range of HEV seroprevalence in the general population of Iran[64,65,67], indicating a low risk of exposure to HEV in these areas or maybe a negligible HEV transmission in HD centers. While in some other studies, it is noticeably higher than HEV seroprevalence in the general population, which may be indicative of parenteral transmission of HEV infection[30,63,66,69]. Similar high prevalence of anti-HEV antibodies in HD patients has been reported in Egypt (22.9%)[70], Japan (30%)[71], and Turkey (20.6%)[72]. In contrast, reports from Italy (6.0%)[73], Brazil (6.2%)[74], and Spain (6.3%)[75] have indicated a low seroprevalence of HEV among HD patients.

The seroprevalence of HEV infection among Iranian HD patients was associated with almost no risk factor in most of these studies[63,64,67,68]. While duration of HD was significantly associated with HEV seropositivity in two studies[65,69]. In addition, in one study, 41.7% of HEV seropositive HD patients had a history of blood transfusion[69]. These studies support the nosocomial transmission of HEV infection[30,47,65]. While the others indicate a rare acquisition of HEV infection through hemodialysis[64,67]. Overall, the epidemiology of HEV infection among HD patients in Iran seems to be

a controversial issue due to these variations in the results of so far conducted studies. Therefore, more extensive or comprehensive studies in different geographical regions of Iran are required to resolve these conflicts between the results and to determine the exact epidemiological pattern of HEV infection among HD patients.

Considering the clearance of a significant level of anti-HEV antibodies during the process of dialysis as well as weak antibody responses due to chronic renal disease, a considerable proportion of HEV seropositive HD patients may be reported as seronegative[30,67,69,76-81]. Except one study[65], the serum levels of liver enzymes were normal or low in HEV seropositive patients on maintenance hemodialysis due to the fast reduction of these enzymes to the normal levels[30,67]. Therefore, some HEV-infected HD patients may remain undiagnosed. These HD patients with inapparent HEV infection might be the main source of HEV transmission as a nosocomial infection in HD units[30]. Overall, neither anti-HEV antibodies nor level of liver enzymes can be valid diagnostic markers in case of HEV infection among HD patients[30]. Therefore, serious safety measures and proper screening of HD patients for hepatitis E in HD centers should be considered to prevent transmission of HEV during the process of hemodialysis.

HEV IN PATIENTS INFECTED WITH OTHER HEPATITIS VIRUSES

Viral hepatitis infections are believed to be associated with an increased risk of hepatitis E occurrence, and co-infection or superinfection with HEV will enhance the risk of liver failure[11,17,82,83]. In recent years, several studies have reported high prevalence of hepatitis E among patients with chronic viral hepatitis and supported the possibility of parenteral transmission of HEV[30,82,84], while other studies have demonstrated a low occurrence of these co-infections or superinfections and found no association between HEV and other viral hepatitis[85,86]. This variation in the prevalence of HEV among patients with other viral hepatitis reflects differences in the routes of transmission and distribution of these hepatotropic viruses in different parts of the world. Although HEV is predominantly transmitted *via* the fecal-oral route, the possibility of parenteral transmission has also been reported in endemic countries[82,87].

Currently, only a few reports are available regarding the prevalence of HEV infection among patients with viral hepatitis in Iran. Keyvani *et al*[51] reported high prevalence of anti-HEV antibody in HBV (11.3%) and HCV (7%)-infected patients compared to healthy blood donors (4.5%) in Tehran. In another study by Karimi Elizee *et al*[56], the seroprevalence of HEV among thalassemia and hemophilia patients with chronic hepatitis C was reported to be 1.6% and 3.2%, respectively, which is similar to HEV seroprevalence in Iranian general population. Kelishadi *et al*[77] reported the absence of anti-HEV IgG antibody in GB virus C positive hemodialysis patients in Gorgan. These studies were unable to determine the effect of hepatitis E on the clinical outcomes of the other viral hepatitis. Overall, data concerning dual infection with hepatitis E and the other viral hepatitis in Iran are scarce, and the routes of HEV transmission in this group of patients are unclear. Therefore, further studies are required to determine the association between HEV and other viral hepatitis in Iran.

HEV IN IMMUNOCOMPROMISED AND IMMUNOSUPPRESSED PATIENTS

HEV infection in immunocompromised and immunosuppressed patients may lead to chronic hepatitis E, with an increased risk of developing liver fibrosis and cirrhosis, and subsequently lower survival of the infected patients[9,10,27]. Chronic HEV infection is characterized by the persistent presence of detectable HEV-RNA in serum and stool for more than 6 mo (more than 3 mo in organ transplant recipient patients) along with persistently elevated liver enzymes[3,5,8,9,33]. So far, chronic hepatitis E has been observed in HIV-infected patients, organ transplant recipient patients, and those with hematological malignancies, who receive anticancer chemotherapy[5,10,25-27,88]. However, the possibility of HEV chronicization in other patients with immunosuppressive conditions is currently under investigation, and this chronic infection may identify in more categories of patients in near future[3].

More recently, some cases of chronic HEV infection have also been observed in elderly immunocompetent individuals[8]. While no report of chronic infection has been documented in pregnant women and infants[16,28]. Almost all cases of chronic hepatitis E have been observed following infection with HEV genotype 3[3,5,7,25]. The first case of chronic hepatitis E caused by HEV genotype 4 has recently been identified in a Chinese patient[3,9].

The seroprevalence of hepatitis E among organ transplant recipient patients varies from 2.3% to 43.9% in different studies[5]. While the prevalence of HEV infection based on the detection of viral RNA ranges from 0.9% to 3.5%[5]. This prevalence among transplant recipient patients with elevated liver enzymes is 4.3%-6.5%[5]. The chronicity rate of hepatitis E is approximately 60% in organ transplant recipient patients without therapeutic interventions[25,26,30].

Indeed, progression to chronicity in immunocompromised patients could be mediated by inability to clear the virus after acute infection, which is related to the degree of immunosupression and immunological status of transplant recipient patients at the time of HEV infection as well as the time period between the transplantation and incidence of HEV infection[3,5,10,29].

Therefore, suboptimal HEV-specific cellular immune responses, low lymphocyte and platelet counts, the occurrence of HEV infection immediately after transplantation, and the use of more effective immunosuppressive drugs such as tacrolimus are risk factors for the incidence of chronic hepatitis E in immunocompromised patients following exposure to HEV[1,3,5,26,88]. Even the presence of anti-HEV IgG antibodies prior to re-exposure to HEV cannot exclude the chance of reinfection in transplant recipient patients, and such reinfections may lead to chronic infection[3]. The main route of HEV transmission in immunocompromised patients seems to be fecal-oral, especially *via* consumption of contaminated food[3,5,16]. However, acquisition of HEV infection following blood transfusion and liver transplantation is also possible but seems to be uncommon[3,5,26]. Most patients with chronic hepatitis E are asymptomatic, and the rest show nonspecific symptoms, including fatigue, fever, abdominal pain, asthenia, and very rarely jaundice[5,25]. Chronic hepatitis E can rapidly progress to liver fibrosis, cirrhosis, and subsequently fatal liver failure in immunocompromised patients[3,5,25]. In addition, numerous hepatitis E-associated extrahepatic manifestations, including neurological, hematological, musculoskeletal, renal manifestations, as well as acute pancreatitis, autoimmune thyroiditis, myocarditis, mixed cryoglobulinemia, thrombocytopenia, arthralgia, Henoch-Schonlein purpura, myasthenia gravis, haemolysis, membranous glomerulonephritis associated with immunological disorders and many others have been reported in patients with acute or chronic HEV infection[7,9,25,33,89,90].

Such extrahepatic complications sometimes outshine clinical manifestations of hepatic injury, and the causative agents, hepatitis E, might not be suspected. Therefore, the probability of hepatitis E in extrahepatic manifestations should be considered[33].

Chronic hepatitis E results in graft loss and subsequently retransplantation in organ transplant recipient patients. However, recurrent hepatitis E and subsequently progressive chronic infection after retransplantation may also occur if the viral clearance is not achieved before retransplantation[5].

In this situation, early diagnosis of hepatitis E in this group of patients is the highest priority. The diagnosis should be based on the detection of HEV RNA in serum, cerebrospinal fluid (CSF) in case of neurological complications or stool samples, not levels of liver enzymes and results of serological tests[3,26,33,91]. Since various factors can elevate liver enzymes, including drugs, toxin, graft rejection, infections, and biliary tract dysfunction[30]. Furthermore, the presence of chronic HEV infection in organ transplant recipient patients is sometimes accompanied by normal liver enzymes[30]. In addition, the delay or absence of seroconversion and loss of anti-HEV antibodies are frequently observed in this group of patients due to immunosuppressive conditions, which result in suppression of antibody development over time[5,91]. Therefore, immunocompromised or immunosuppressed patients with chronic HEV infection may have normal liver enzymes and negative serological tests[26,30,81].

In these conditions of uncertainty, the awareness of physicians regarding chronic HEV infection is crucial. Since most cases of chronic HEV infection may be missed due to the lack of HEV consideration among physicians or inappropriate choose of diagnostic assays[3,25].

Reports on HEV prevalence in immunocompromised patients in Iran are scarce. Rostamzadeh Khameneh *et al*[81] assessed the seroprevalence of HEV among 91 Iranian kidney transplant recipient patients. Overall, the seroprevalence of HEV was 30.8%. Joulaei *et al*[80] reported a HEV seroprevalence of 16.4% among 158 HIV-infected individuals in Shiraz in 2013. In another study by Ramezani *et al*[79], the seroprevalence of HEV infection was found to be 10% among 100 HIV-positive individuals in Tehran in 2012. These limited studies were unable to determine the incidence and prevalence of chronic HEV infection among immunocompromised patients in Iran. Since only the seroprevalence of anti-HEV IgG antibodies has been assessed, while HEV-RNA has not been measured in these studies[81,88]. Therefore, more studies are required to gain insight into the burden of chronic HEV infection in Iran.

CONCLUSION

However, Iran is classified as an endemic region for HEV infection, but we do not know much about this infection in Iran. The available epidemiological data have demonstrated the seroprevalence of HEV infection in different groups and regions of Iran, while the presence of HEV-RNA has not been evaluated in the studies published so far. In addition, the distribution pattern of HEV genotypes is unknown in Iran.

From historical aspect, hepatitis E is not new in Iran but is underestimated due to the lack of awareness amongst physicians and inappropriate diagnosis of the infection. The importance of HEV infection as a main public health problem cannot be neglected any longer. The identification of HEV-associated extrahepatic manifestations and chronic hepatitis E in immunocompromised patients has attracted attention to the study of HEV in recent years. While these new aspects of so thought acute self-limited hepatitis remain unknown in Iran. Overall, still a long way is ahead to determine the epidemiological patterns of HEV in Iran. To approach this goal, further epidemiological investigations at the national level are needed to more clearly delineate the incidence and prevalence of HEV infection in Iran. In addition, nationwide efforts should be pursued to control and prevent HEV infection in Iran.

ACKNOWLEDGMENTS

We would like to express our sincere thanks to Professor Saeed Tajbakhsh, PhD, Bushehr University of Medical Sciences, for editing the manuscript.

Abstract

AIM: To develop a new rat model we wanted to gain a better understanding of stricture formation in Crohn's disease (CD).

METHODS: Chronic colitis was induced locally by the administration of 2,4,6-trinitrobenzenesulfonic acid (TNBS). The relapsing inflammation characteristic to CD was mimicked by repeated TNBS treatments. Animals were randomly divided into control, once, twice and three times TNBS-treated groups. Control animals received an enema of saline. Tissue samples were taken from the strictured colonic segments and also adjacent proximally and distally to its 60, 90 or 120 d after the last TNBS or saline administrations. The frequency and macroscopic extent of the strictures were measured on digital photographs. The structural

features of strictured gut wall were studied by light- and electron microscopy. Inflammation related alterations in TGF-beta 2 and 3, matrix metalloproteinases 9 (MMP9) and TIMP1 mRNA and protein expression were determined by quantitative real-time PCR and western blot analysis. The quantitative distribution of caspase 9 was determined by post-embedding immunohistochemistry.

RESULTS: Intestinal strictures first appeared 60 d after TNBS treatments and the frequency of them increased up to day 120. From day 90 an intact lamina epithelialis, reversible thickening of lamina muscularis mucosae and irreversible thickening of the muscularis externa were demonstrated in the strictured colonic segments. Nevertheless the morphological signs of apoptosis were frequently seen and excess extracellular matrix deposition was recorded between smooth muscle cells (SMCs). Enhanced caspase 9 expression on day 90 in the SMCs and on day 120 also in myenteric neurons indicated the induction of apoptosis. The mRNA expression profile of TGF-betas after repeated TNBS doses was characteristic to CD, TGF-beta 2, but not TGF-beta 3 was up-regulated. Overexpression of MMP9 and down-regulation of TIMP1 were demonstrated. The progressive increase in the amount of MMP9 protein in the strictures was also obvious between days 90 and 120 but TIMP1 protein was practically undetectable at this time.

CONCLUSION: These findings indicate that aligned structural and molecular changes in the gut wall rather than neuronal cell death play the primary role in stricture formation.

Key words: Crohn's disease; Rat model; TGF-beta; Intestinal strictures; MMP9; TIMP1

Core tip: Intestinal strictures in Crohn's disease (CD) cause hardly treatable complications in patients. The aim of this study was to find the correlation between the intestinal stricture formation, the damaged innervation of smooth muscle cells (SMCs) and the changed expression of TGF-beta 2, 3 and MMP9/TIMP1 in rats with CD by using different light- and electron microscopic and molecular biological methods. Our findings indicate that disintegration of SMCs due to the up-regulation of TGF-beta 2 and off-balance in MMP9/TIMP1 expression rather than neuronal cell death play the primary role in the formation of intestinal strictures in CD.

Structural and molecular features of intestinal strictures in rats with Crohn's-like disease. *World J Gastroenterol* 2016; 22(22): 5154-5164 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5154.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5154

INTRODUCTION

Despite the fact that the formation of obstructive strictures is the leading cause of surgical intervention in patients with Crohn's disease (CD), little is known about their etiopathogenesis, and no direct therapies are available for the effective prevention or reversal of this condition[1]. Lasting deep remission has emerged as a major therapeutic goal in CD[2,3]. This implies not only alleviation of the symptoms, but also the achievement of complete mucosal healing, with the accompanying decrease in the risk of irreversible pathological alterations of the gut wall[4]. However, total mucosal regeneration to prevent stricture formation is unattainable[5,6].

The spread of fibrosis deep into the gut wall leads to disorganization of the lamina muscularis mucosae (LMM) and thickening of all layers of the gut wall due to the accumulation of extracellular matrix (ECM) elements[5,6]. Previous studies have demonstrated that the cytokines transforming growth factor-beta (TGF-β) isoforms and the tissue-degrading matrix metalloproteinases (MMPs) are the key contributors to these processes[7,8]. Both TGF-beta and its receptors are overexpressed in the intestine of CD patients. However, the expression of the TGF-beta isoforms varies with the nature of the tissue. Fibrotic tissue exhibits a reduced expression of TGF-beta 3 and an enhanced expression of TGF-beta 2[9-11]. MMPs are secreted as inactive zymogens which must undergo proteolytic cleavage to become active, and their activity is regulated by specific tissue inhibitors of metalloproteinases (TIMPs)[12-14]. The MMPs do not simply degrade ECM as their name might suggest, but are also responsible for the homeostatic regulation of the ECM. Previous studies have shown that the gene transcription of MMP9 is inducible and that the promoter region is highly responsive to most growth factors and cytokines. They directly cleave and activate growth factors into active ligands, and therefore regulate their bioavailability and/or activity[15-17]. In consequence of these complex interactions of the regulatory processes, the development of the intestinal strictures characteristic of CD cannot be explained simply by the lower or higher expression of one or other of these factors. The key driver of stricture formation rather appears to be an off-balance between the TGF-betas, MMPs and TIMPs which develops in the chronic phase of inflammation. MMP9 is the most abundant MMP expressed in colonic tissue from CD patients, and may therefore be regarded as a biomarker in the evaluation of the clinical activity of inflammatory bowel diseases (IBDs)[18].

The intestinal symptoms common among CD patients are often related to enteric neuropathy. The evidence suggests that both the quantitative properties and function of the myenteric neurons are altered substantially by intestinal inflammation[19-22] and in fact complete loss of the myenteric neurons has been

observed in the strictured regions[23]. However, the extent to which the deficient innervation of the smooth muscle cells (SMCs) and/or the imbalance in the regulation in the molecular events behind the tissue remodelling are responsible for the stricture formation remains unclear.

We recently reported on a rat model of chronic colitis where the mortality was negligible despite the severity of the intestinal symptoms. We demonstrated that experimentally provoked recurring periods of acute inflammation exerted a preconditioning effect against the mucosal damage and reduced the rapid, significant and widespread loss of myenteric neurons observed after the induction of the colitis[24]. In the present work, we used this model to investigate the long-term consequences of acute inflammation on the structural and molecular alterations in the strictured gut wall. The aim of the study was to investigate the possible coincidence between the expressions of TGF-betas, MMP9 and TIMP1 behind the structural remodelling of the strictured gut wall. The structural findings at the light- and electron microscopic levels and the molecular findings at the mRNA and protein levels will be discussed.

MATERIALS AND METHODS

Animal model

All procedures involving experimental animals were approved from the Local Ethics Committee for Animal Research Studies at the University of Szeged. Adult male Sprague-Dawley rats weighing 200-220 g were used throughout the experiments. The animal protocol was designed to minimize pain or discomfort to the animals. The rats were acclimatized to laboratory conditions (23 ℃, 12 h/12 h light/dark, 50% humidity, *ad libitum* access to food and water) for two weeks prior to experimentation. Colitis was induced locally under pentobarbital anaesthesia (45 mg/kg *ip*) by the administration of 2,4,6-trinitrobenzenesulfonic acid (TNBS; Sigma-Aldrich, St. Louis, MO, United States; 10 mg) dissolved in 0.25 mL of 25% ethanol, as described earlier[24]. Repetitive relapsing inflammation (RRI) was mimicked through repeated administration of the same TNBS doses. The rats were treated once (n = 8), twice (n = 7) or three times (n = 8) with TNBS, 2 weeks passed between the treatments. Control rats (n = 18) received an enema of 0.25 mL of 9 g/L saline at the same time as the TNBS was administered. The rats were weighed and monitored daily for activity, bloody diarrhoea and mortality and were sacrificed 60, 90 or 120 d after the last TNBS or saline administrations.

Tissue handling

The animals were killed by cervical dislocation under pentobarbital anaesthesia. After this the last 8 cm region of the descending colon from the anus was dissected. Digital photographs were taken to evaluate the frequency and macroscopic extent of the strictures. Three colonic tissue samples were taken from each animal: the stricture itself and samples adjacent proximally and distally to it. Colonic samples of age-matched controls were also collected. Small pieces (2-3 mm) of the colonic segments for light- and electron microscopic morphometry and post-embedding immunohistochemistry were fixed in 20 g/L formaldehyde and 20 g/L glutaraldehyde solution and embedded in Epon (Electron Microscopy Sciences, Hatfield, PA, United States). Gut segments for molecular studies were cut along the mesentery and pinched flat. After longitudinal cutting, the mucosa and submucosa were removed. Half of the colon samples were immediately frozen in liquid N_2 and later processed for western blot analysis. The other half were incubated overnight at 4 ℃ in RNA Later (Qiagen, Venlo, The Netherlands) and stored at -80 ℃ until processing for quantitative real-time PCR (qRT PCR).

Light- and transmission electronmicroscopic morphometry

The Epon blocks were used to prepare semithin (0.7 μm) sections, which were stained with 10 g/L toluidine blue solution for the light-microscopic study. In the selected area of interest in the semithin cross-sections, all the layers of the gut wall were well oriented. The thicknesses of the LMM and the external circular (CM) and longitudinal (LM) smooth muscle layers were measured at random points with Image J 1.44 (National Institute of Health, Bethesda, MD, United States). The same Epon blocks were used to prepare ultrathin (70 nm) sections and the samples were mounted on nickel grids. Three grids per block were stained with uranyl acetate (Merck, Darmstadt, Germany) and lead citrate (Merck) and were examined and photographed with a Philips CM 10 electronmicroscope equipped with a MEGAVIEW II camera. The width of 15 tight junctions (TJs), *i.e.,* the distance between adjacent enterocytes, was measured at a magnification of × 46000 in the control samples and in the strictures by using the AnalySIS 3.2 program (Soft Imaging System GmbH, Münster, Germany). The distance between SMCs was determined to evaluate the expansion of the ECM within the muscularis externa (ME). Ten montage photographs per intestinal segment were made at a magnification of × 10500 and the distance of SMCs was evaluated in limited-size (2000 nm × 2000 nm) grids for all images, at the intersection of the grid lines, perpendicularly to the cells and calculated by using the AnalySIS 3.2 program. The mean distance was calculated by using the AnalySIS 3.2 program.

Post-embedding immunohistochemistry

The Epon-embedded tissue blocks used previously for the morphometry also served for the post-embedding immunohistochemistry of caspase 9, as described

earlier[25]. Briefly, ultrathin sections from each block were sequentially incubated with anti-caspase 9 (Sigma-Aldrich, St. Louis, MO, United States; final dilution 1:50) primary antibodies overnight, followed by protein A-gold-conjugated anti-rabbit (18 nm gold particles, Jackson ImmunoResearch, West Grove, PA, United States; final dilution 1:20) secondary antibodies for 3 h, with extensive washing between. Sections were counterstained with uranyl acetate and lead citrate, and then examined and photographed with a Philips CM10 electronmicroscope equipped with a MEGAVIEW II camera. The numbers of gold particles were counted on digital photographs at a magnification of × 25000 in 10 SMCs and at a magnification of × 34000 in 5 myenteric ganglia (MGs) per colonic segment in each experimental groups with the AnalySIS 3.2 program.

Statistical analysis

Statistical analysis of the histological results was performed by using one-way ANOVA and the Newman-Keuls test with GraphPad Prism 4.0 (GraphPad Software, La Jolla, CA, United States), and a probability $P < 0.05$ was set as the level of significance. The results were expressed as mean ± SE. The statistical methods of the study were reviewed by Mária Bagyánszki from University of Szeged.

Quantitative real-time polymerase chain reaction

Tissue samples were homogenized in AccuZol (Bioneer, Daejeon, South Korea) directly before qRT PCR. Total RNA was prepared from tissue homogenates as suggested by the manufacturer (Bioneer, Daejeon, Korea). The reverse transcription was achieved by using a High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA, United States) as described earlier[24]. qRT PCR was performed in an Exicycler 96 (Bioneer, Daejeon, Korea) in a total volume of 20 μL containing 10 μL of FastStart SYBR Green PCR Master Mix, 1 μL of specific primer (0.5 pmol/μL) and 50 ng of cDNA template. The PCR program began with a 15-min initial step at 95 ℃, followed by 45 cycles of 15 s at 95 ℃ for denaturation, 45 s at 60 ℃ for annealing and 25 s at 72 ℃ for extension. The sequences of primers were derived from NCBI RefSeq Database entry NM_031131.1 for TGF-beta 2 (forward: 5′ agtgggcagcttttgctc 3′ and reverse: 5′ gtagaaagtgggcgggatg 3′), NM_013174.2 for TGF-beta 3 (forward: 5′ gaagagggccctggacac 3′ and reverse: 5′ gcgcacacagcagttctc 3′), NM_031055.1 for MMP9 (forward: 5′cctctgcatgaagacgacataa 3′ and reverse: 5′ ggtcaggtttagagccacga 3′) and NM_053819.1 for TIMP1 (forward: 5′ cagcaaaaggccttcgtaa 3′ and reverse: 5′ tggctgaacagggaaacact 3′). Hypoxanthine guanine phosphoribosyltransferase (HPRT) (NBCI RefSeq Database entry: NM_012583.2; forward: 5′ gaccggttctgtcatgtcg 3′ and reverse 5′ acctggttcatcatcactaatcac 3′) was used as a housekeeping gene to normalize the expression data. The results were expressed as mean ± SD.

Western blotting analysis and gelatine zymography

Tissue samples were homogenized in TRIS-mannitol buffer and the total cellular protein was then denaturated (mixing and boiling with v/v 20 mmol/L Tris 7-9, 3 mmol/L EDTA, 20 g/L sodium dodecyl sulphate (SDS), 100 g/L mercaptoethanol and 200 g/L glycerol) from each sample as described earlier[26]. Aliquots of 10 μg of total cellular protein were electrophoresed by 100 g/L SDS-polyacrilamide gel, and transferred to nitrocellulose membrane (Amersham, Buckinghamshire, United Kingdom). Two hours after blocking (with PBS pH 7.4, 2.5 g/L Tween 20 (v/v) and 50 g/L non-fat dried milk), the membranes were probed with anti-MMP9 mouse monoclonal antibody (Abcam PLC, Cambridge, United Kingdom; final dilution 1:1000) or TIMP1 (H150) rabbit polyclonal antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA, United States; final dilution 1:1000) for 2 h, and then incubated with horseradish peroxidase-conjugated anti-mouse or anti-rabbit antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA, United States; final dilution 1:2000) for 1 h at room temperature with extensive PBS-Tween 20 washing between. Immunoreaction was visualized with an Immobilon Western HRP Substrate enhanced chemiluminescence system (Millipore Corporation, Billerica, MA, United States) and scanned with a LI-COR C-DiGit™ Blot Scanner (Li-Cor Corporate, Lincoln, NE, United States).

The activity of MMP9 was determined by gelatine zymography, performed by diluting colonic homogenates in zymogram sample buffer (Bio-Rad, Hercules, CA, United States) and electrophoresing the samples in precast 100 g/L SDS-PAGE containing gelatine (20 mg/mL; Sigma-Aldrich, St. Louis, MO, United States) at 120 V until resolution was achieved. The gels were removed from their casings, gently rinsed in ddH_2O, placed onto a shaker in 1X renaturation buffer (Bio-Rad, Hercules, CA, United States) for 40 min, and then placed in 1X development buffer (Bio-Rad Hercules, CA, United States). With change of the buffer once at 20 min, the gels were next incubated at 37 ℃ for 20 h and stained with Coomassie Blue (Bio-Rad, Hercules, CA, United States) for 40 min before being destained in water for 1 h and scanned with a LI-COR C-DiGit™ Blot Scanner.

RESULTS

General observations

Despite the severity of the acute intestinal inflammation of the TNBS-treated rats, the mortality was negligible: only 2 rats died throughout the 120-d experimental period. By 1 d following the TNBS treatment, all the animals had developed symptoms such as weakness, weight loss and bloody diarrhoea. However, by 7 or 8

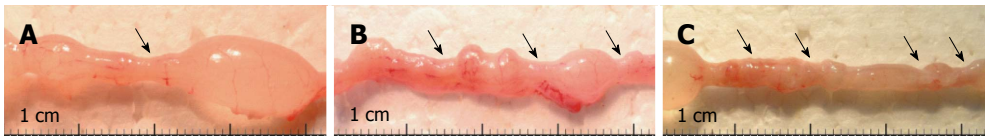

Figure 1 Representative micrographs from the distal colon of rats with chronic colitis 90 d after the first (A), second (B) or third (C) treatment with 2,4,6-trinitrobenzenesulfonic acid. The frequency and size of the strictures (arrows) increased in the time and with the number of 2,4,6-trinitrobenzenesulfonic acid (TNBS) administrations.

d after TNBS administrations, all the visible symptoms accompanied by acute inflammation had resolved. By day 60 following TNBS treatments, all the rats that had previously been exposed to acute colitis had regained their initial body weight and strictures had appeared in each TNBS-treated group. We, therefore, investigated the structural and molecular characteristics of the strictured gut wall from this timepoint on. Whereas the numbers and sizes of the strictures increased in time and with the number of TNBS treatments, they always developed within the previously inflamed colonic areas (Figure 1) and, once they had appeared, their structure and molecular characteristics did not differ. To avoid repetitions therefore, representative results will be presented here, obtained after the processing of tissue samples collected exclusively after the third TNBS administration.

Light microscopy

Representative images of toluidine blue-stained semithin sections of colon where the thickness of the ME was measured are shown in Figure 2. Such colonic sections were collected for measurements on days 90 and 120 following TNBS administrations and also from age-matched controls. The strictured colonic regions displayed normal mucosal architecture and clearly defined, yet thickened muscle layers (not shown). Morphometric analyses revealed the approximately 2-fold thickening of the LMM and layers of the ME in the strictured region relative to the control samples on 90 d. While further significant thickening of the ME was measured beyond day 90 after TNBS administrations, the thickness of the LMM at later than 90 d was similar to that in the controls (Figure 2).

Transmission electronmicroscopy

Transmission electronmicroscopic examination of the colonic epithelium in the strictured region on days 90 and 120 after TNBS administrations showed that the apical surface of the enterocytes with intact brush-border and closed TJs was similar to that in the controls (Figure 3). The width of the TJs between adjacent enterocytes was evaluated morphometrically and was always found to be less than 3 nm (data not shown). However, autophagosome-like double-membrane vesicles of different sizes were frequently seen within the enterocytes (Figure 3).

Because of the excess accumulation of ECM elements in the strictured colonic regions, the SMCs had moved away from each other significantly by day 90 after TNBS administrations, and by 120 d there was more than 2-fold increase in the distance between adjacent SMCs as compared with the controls (Figure 4). Because of the ECM deposition, the SMCs also moved away from the MGs (Figure 4). By day 120 post-TNBS treatments, swollen and empty confluent vacuoles and autophagosomes were frequently seen in the SMCs and also in their close environment, together with different cell organelles in the strictured colonic areas (Figure 4). The vast majority of the axons appeared normal, but necrotic axons were seen rarely in the MGs (Figure 4). Quantitative post-embedding immunohistochemistry in the strictured areas revealed a progressive increase in the number of gold particles indicating caspase 9 antigen in the SMCs and MGs relative to the control samples (Figure 5). The caspase 9-labelling gold particles in the MGs were mainly associated with the mitochondria (Figure 5), the ultrastructure of which was well preserved even 120 d after TNBS treatments.

Quantitative changes in TGF-beta, MMP9 and TIMP1 mRNA and protein expression

On day 90, the TGF-beta 2 mRNA was up-regulated, while the TGF-beta 3 mRNA was down-regulated in the strictured gut wall and also in the colonic segments adjacent proximally and distally to the strictures as compared with the controls. The TGF-beta 2 mRNA expression progressively increased, while the TGF-beta 3 mRNA expression further decreased by day 120 in all three segments (Figure 6A).

A marked overexpression of MMP9 mRNA was detected in all the colonic segments examined on days 90 and 120 after TNBS treatments (Figure 6B). At the same timepoints, the TIMP1 mRNA expression was up-regulated in the colonic segments adjacent proximally and distally to the strictures, but was down-regulated in the strictures themselves (Figure 6B). MMP9 and TIMP1 expression was also evaluated at the protein levels. Although a high amount of MMP9 protein was demonstrated in the tissue samples from the control rats, the progressive increase in the amount of MMP9 protein in the strictures was obvious between days 90 and 120 (Figure 6C). Gelatine zymography demonstrated that an active form of MMP9 protein rather than pro-MMP was expressed (Figure 6C). While the amount of TIMP1 protein also decreased acutely between days 90 and 120 in the control samples, it was

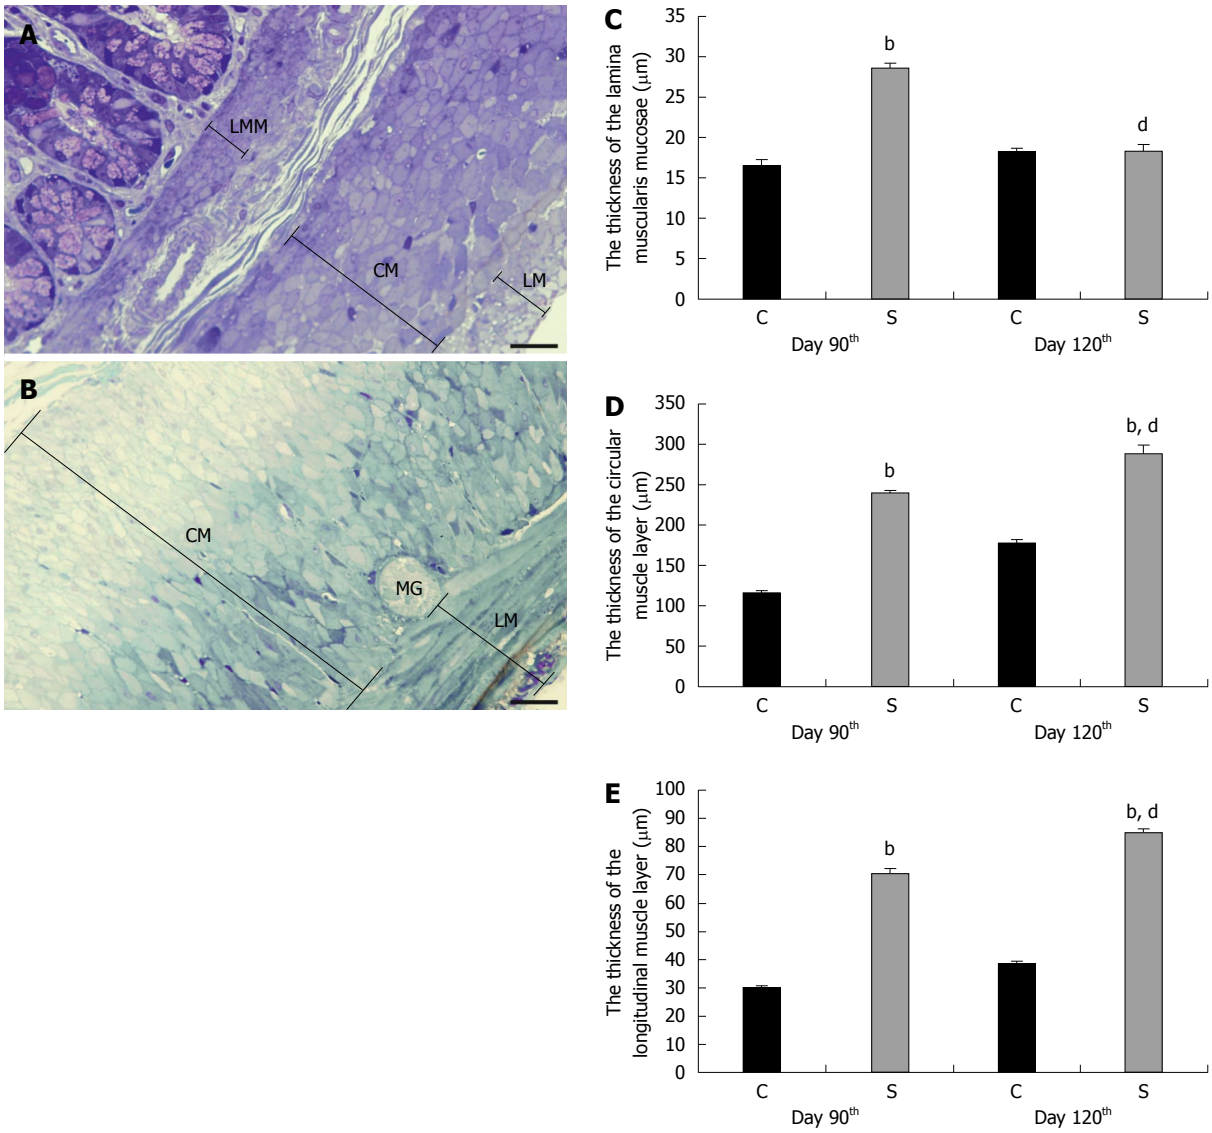

Figure 2 Thickness of the smooth muscle layers in the colon of control animals and in rats treated three times with 2,4,6-trinitrobenzenesulfonic acid. A: Representative light micrographs of a toluidine blue-stained semithin section from the colon of a control rat; B: TNBS-treated rat on day 120 of the experimental period. Bar: 25 μm. Significant thickening of the LMM (C), CM (D) and LM (E) was demonstrated in the strictured gut wall of the TNBS-treated rats (S) relative to the controls (C) on day 90. Whereas a further significant thickening was measured in the CM and LM on day 120, the thickness of the LMM was similar to that in the controls at this timepoint. Data are expressed as mean ± SE. $^{b}P < 0.001$ TNBS-treated groups *vs* age-matched controls; $^{d}P < 0.001$ 2,4,6-trinitrobenzenesulfonic acid (TNBS)-treated group on day 90 *vs* TNBS-treated group on day 120. practically undetectable in the strictures (Figure 6C).

DISCUSSION

We recently reported on a rat model in which alleviated inflammatory damage in association with the persistent up-regulation of HO-1 were salient features in the acute phase of intestinal inflammation induced by repeated TNBS administrations[24]. The same model was used in the present work to investigate the structural and molecular events leading to the formation of a strictured gut wall. Concerning the long-term consequences of the acute inflammation in this model, all the visible symptoms had resolved by day 60 after TNBS administration, the body weight of the treated rats was similar to that of the age-matched controls, and intestinal strictures developed in all of the rats that had previously displayed intestinal inflammation. These findings accord well with the clinical observations that mucosal healing and clinical remission alone cannot be treatment endpoints in CD, because this does not prevent later stricturing[27,28]. The increases in size and frequency of the strictures observed here after 60 d provide experimental evidence in favour of the view that strictures, once present, gradually progress and, once fibrosis develops, it cannot be reversed[29].

Aligned thickening of all the muscle layers in the strictured gut wall until up to day 90 after TNBS administrations was characteristic. Whereas the thic-

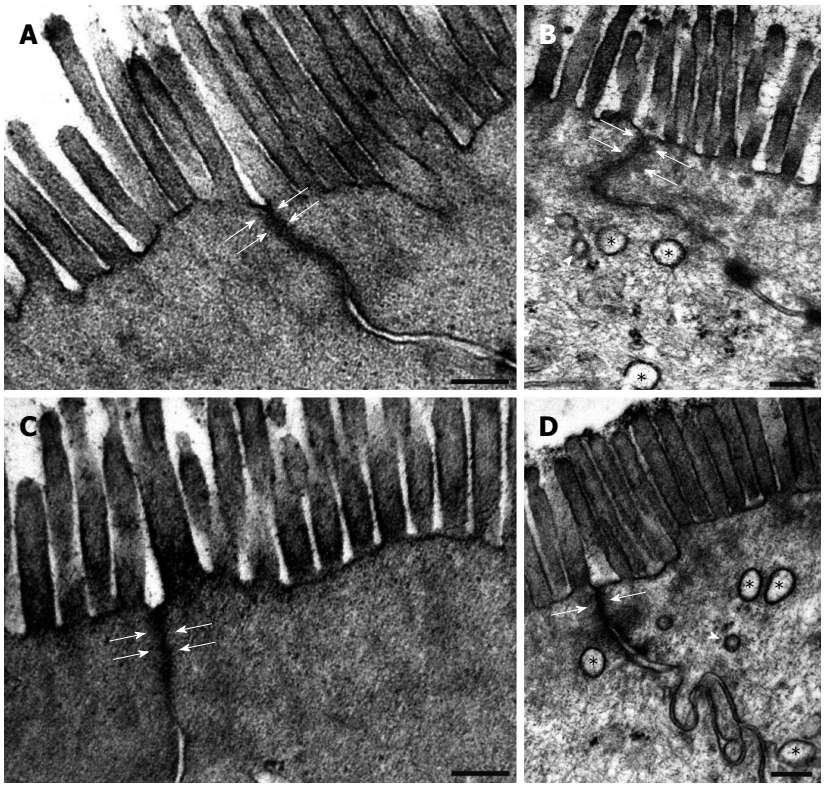

Figure 3 Representative electron micrographs of two neighbouring enterocytes from the colon of control animals (A, C) and in rats treated three times with 2,4,6-trinitrobenzenesulfonic acid. On days 90 (B) and 120 (D) following the third 2,4,6-trinitrobenzenesulfonic acid (TNBS) administration, both the microvillar surface and the width of the apical intercellular tight junctions (arrows) of the enterocytes in the strictured regions were similar to those in the age-matched controls (A on day 90 and C on day 120). However, autophagosomes (asterisks) and lysosomes (arrowheads) were commonly observed within the epithelial cells of the strictured gut wall. Bars: 200 nm.

kening of the ME progressed further and became a decisive element of the strictured gut wall, the thickness of the LMM did not change after day 90, and did not differ from that in the controls by the end of the experimental period. Since the LMM is most involved in maintaining the mucosal integrity[30], we suppose that the earlier cessation of excess ECM deposition in the LMM is a consequence of the differential regulation of inflammation-related events here through cytokines derived from the epithelium[31,32].

At 90 and 120 d following TNBS administrations, transmission electronmicroscopy showed that the structures of the epithelium necessary to maintain the barrier functions were intact. However, the frequent presence of double-membrane autophagosomes indicated high levels of intracellular stressors in the previously affected epithelium. It has been well documented that induction of autophagy is a determining factor for the maintenance of cellular homeostasis in chronic colitis[33,34]. The importance of autophagy in the pathogenesis of chronic intestinal inflammation has also been demonstrated by genome-wide association studies which indentified a link between the genes involved in autophagy regulation and IBDs[35,36].

While the rapid and widespread loss of myenteric neurons was a characteristic feature of the onset of acute inflammation[24], the precise timing of the cellular events in the chronic phase leading to the intestinal stricturing here showed that the SMCs in the ME were affected first in these processes. Since the excess deposition of ECM in the ME was sustained throughout the experimental period, the SMCs progressively moved away from each other and also from the MGs, leading eventually to deficient innervation and severe cellular damage. After day 60 following TNBS treatments, the appearance of autophagosomes, the leakage of cellular contents and the increasing number of gold particles labelling caspase 9 expression indicated that all three types of cell death mechanisms had already progressed in the SMCs by day 90 when necrotic axons were only rarely seen in the MGs. As the pathological environment became more extensive with time, by day 120 after TNBS administration locally severe neuronal injury also occurred in the strictured tissue as a significant sign of chronic inflammation, similarly as described in other models[23,37]. As regards the timing of the events, we presume suppose that the neuronal injury is a consequence and not the cause of the stricturing processes.

Evidence from both animal models[38,39] and human studies[18,40,41] has suggested that the up-regulation of TGF-beta 2 and of MMP9 may be considered to be biomarkers in the post-inflammatory tissue

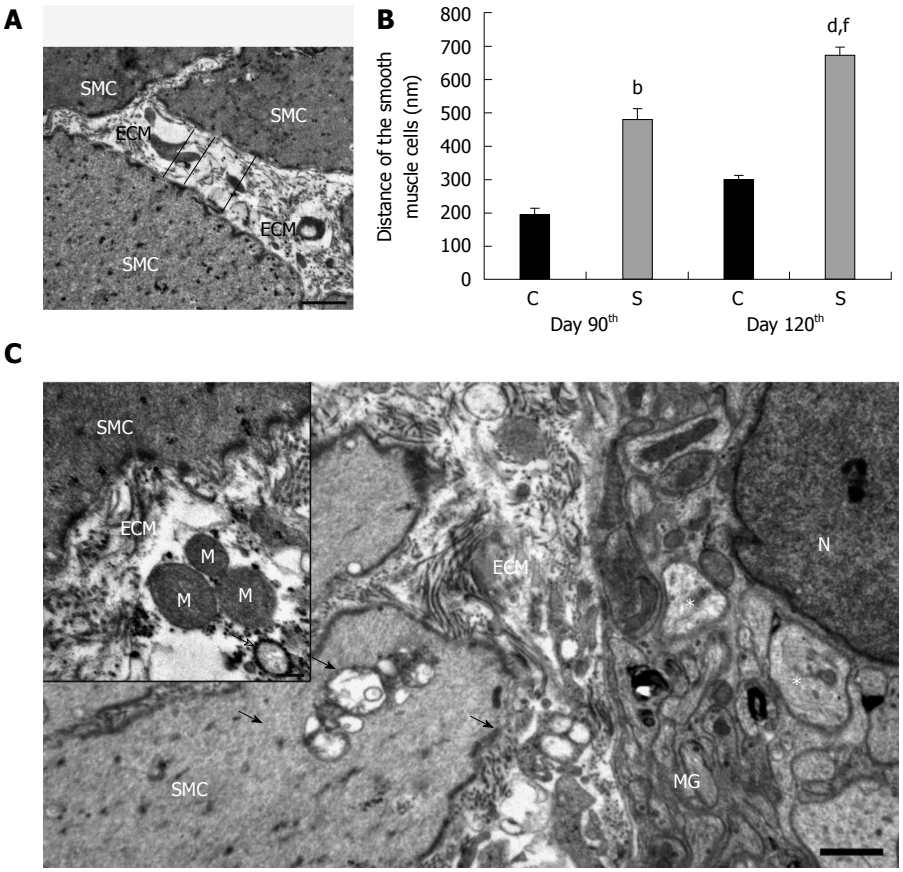

Figure 4 Ultrastructural alterations within the colon of control animals and in rats treated three times with 2,4,6-trinitrobenzenesulfonic acid. Excess deposition of extracellular matrix (ECM) was observed within the smooth muscle layers in the ultrathin sections derived from the strictured region (A); Electronmicroscopic morphometry revealed that the distance between adjacent smooth muscle cells (SMCs) was significant larger in the strictured gut wall of the 2,4,6-trinitrobenzenesulfonic acid (TNBS)-treated rats (S) as compared with the gut wall of the control rats (C) on day 90 (B); A further significant increase in the mean separation distance of the SMCs was recorded on day 120 post-TNBS treatment (B). Data are expressed as mean ± SE. $^{b}P < 0.01$, $^{d}P < 0.001$ TNBS-treated groups *vs* age-matched controls; $^{f}P < 0.001$ TNBS-treated group on the day 90 *vs* TNBS-treated group on day 120. Representative electron micrograph of the strictured colonic area 120 d after the third TNBS administration (C). Because of ECM accumulation, the SMCs also moved away from the myenteric ganglia (MGs). Swollen and empty confluent vacuoles of different sizes (arrows) were frequently seen in the SMCs and also in their close environment. Rupture of the plasma membrane and subsequent leakage of the cell organelles into the microenvironment, *e.g.*, the mitochondria (M) and autophagosomes (hollow arrow), were frequently seen in the intercellular spaces (insert). However, the vast majority of the axons appeared normal; necrotic axons were rarely seen in the MGs (asterisks). N: Nucleus. Bars: 1 μm and 200 nm (insert).

remodelling leading to stricturing in CD. The mRNA expression profile of the TGF-beta isoforms, the up-regulation of TGF-beta 2 and the down-regulation of TGF beta 3 in the colonic segments examined in our model accorded well with the distinctive expressional profile of the secreted TGF-beta isoforms in human CD primary intestinal myofibroblasts[41]. The spreading of this characteristic expression pattern both proximally and distally to the strictures indicated the bidirectional diffusion of the disease along the colon in our model. We also detected progressive up-regulation of MMP9 mRNA in all three colonic segments, suggesting again the proximally and distally directed diffusion of the pathological environment. However, the MMP9 up-regulation in the strictured gut wall was coupled with the down-regulation of TIMP1, and an increased amount of active MMP9, but no TIMP1 protein was detected here, indicating a stricture-specific off-balance in the production of proteases and their inhibitors. This expression pattern is very reminiscent of that which develops in the fistulae in approximately one-third of patients with CD[42]. The apparent differences in expression profiles between our study and the literature data in tissue samples prepared from the control guts could be explained by the different methodological approaches. The novelty of our studies was that we prepared tissue homogenates for molecular studies not from the mucosa overlying the strictures, but exclusively from the ME, where the background events of the chronic inflammation leading to stricture formation actually occurred.

In conclusion, The structural and molecular events leading to stricturing as a long-term consequence of acute intestinal inflammation that were demonstrated earlier in animal models and in human studies also characterized the stricture formation induced in our rat model by repeated TNBS administrations. Since the exact timing of the stricturing processes was possible in this model, we reached the conclusion that, in contrast with the general view, the ME, and not the

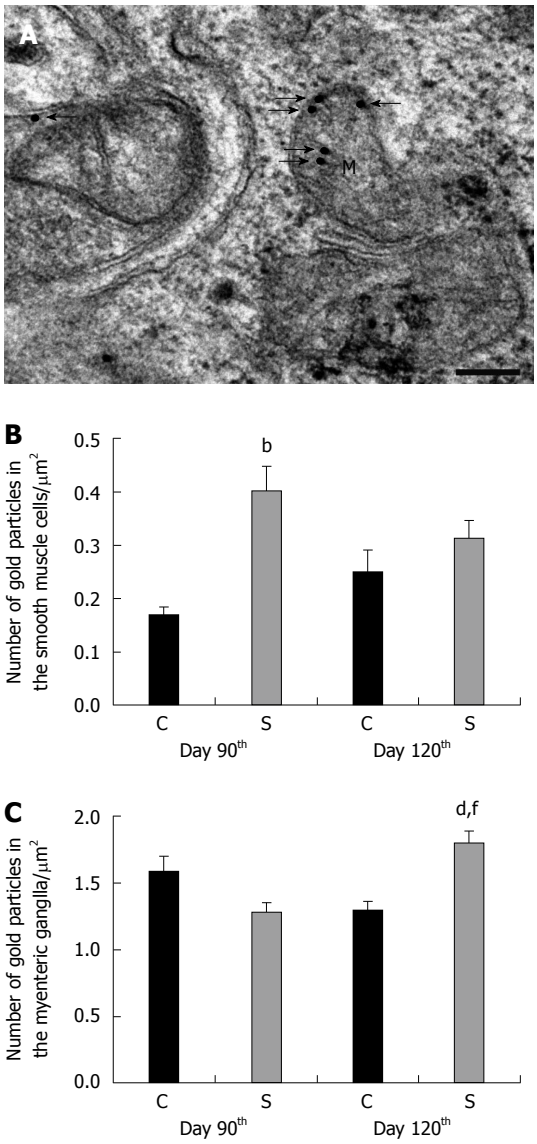

Figure 5 Post-embedding immunogold labelling for caspase 9 in the smooth muscle cells and myenteric ganglia in the colon of control animals and in rats treated three times with 2,4,6-trinitrobenzenesulfonic acid. Representative electron micrograph of a myenteric ganglion (MG) from the strictured gut wall (S) 120 d after the third 2,4,6-trinitrobenzenesulfonic acid (TNBS) administration (A). The 18 nm gold particles labelling caspase 9 immunoreactivity (arrows) were mainly associated with mitochondria (M). Bar: 200 nm. The number of gold particles in the S was increased significantly in the smooth muscle cells on day 90 (B) and also in the MGs on day 120 (C) as compared with the gut wall in the control rats (C). Data are expressed as mean ± SE. $^{b}P < 0.01$, $^{d}P < 0.001$ TNBS-treated groups *vs* age-matched controls; $^{f}P < 0.01$ TNBS-treated group on the day 90 *vs* TNBS-treated group on day 120.

epithelial barrier or the MGs, was the primary target of the events leading to stricture formation. Moreover, this TNBS-induced rat model has provided the first experimental demonstration of the molecular diffusion of the disease both proximally and distally along the gut wall. The off-balance in MMP9/TIMP1 expression profile found strictly within the border of the strictures may well allow use of this model to investigate the molecular mechanisms leading to fistulated CD.

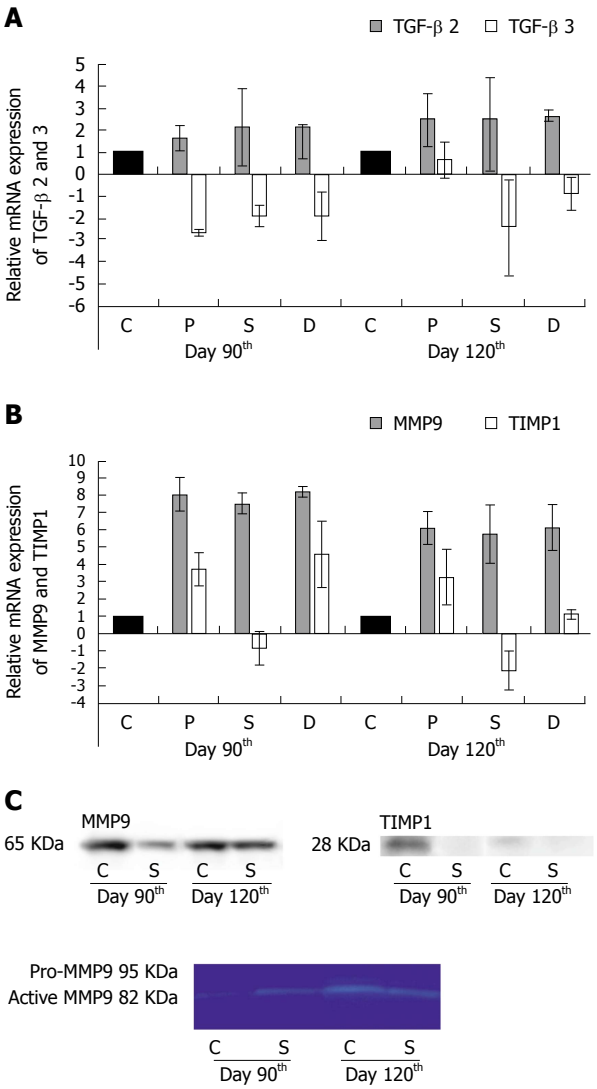

Figure 6 Relative mRNA and protein expression of transforming growth factor-beta 2 and 3, matrix metalloproteinase 9 and tissue inhibitor of metalloproteinases 1 in the colon of control animals and in rats treated three times with 2,4,6-trinitrobenzenesulfonic acid. TGF-beta 2 was up-regulated in the strictured region (S) and also in the adjacent proximal (P) and distal (D) segments of the colon as compared with the controls (C) on day 90 and day 120 (A). TGF-beta 3 gene repression was detected both 90 and 120 d after the third TNBS treatment in each colonic segment (A). The marked overexpression of MMP9 mRNA was confirmed in each colonic segment in the chronic phase of the inflammation (B). TIMP1 mRNA expression was detected in the P and D colon segments at both timepoints examined, but in the S the gene was down-regulated (B). Data are expressed as mean ± SD. 90 d after the third TNBS treatment, a decreased MMP9 protein level was detected in the S relative to the C (C, upper). Nevertheless, on day 120 the MMP9 protein expression was similar to that in the C. The activity of MMP9 was determined by gelatine zymography (C, lower). An active form of the MMP9 protein rather than pro-MMP9 was expressed in the C and S segments at both timepoints examined. Well-detectable amounts of TIMP1 protein were revealed only in the control samples from day 90 (C, right side).

COMMENTS

Background

Intestinal strictures are characteristic complications of Crohn's disease (CD) affecting more than one third of all patients. Its can lead to partial or total

intestinal obstruction with potentially life-threatening consequences. Although the treatment of the chronic complications of CD is a serious medical problem, the pathogenesis, factors, and cell types involved in stricture formation are largely unknown.

Research frontiers

Despite of the huge amount of animal models and human studies, the structural and molecular events leading to stricturing as a long-term consequence of acute intestinal inflammation are still not clear until today. Besides, the ultrastructure of the intestinal strictures is still unknown.

Innovations and breakthroughs

This TNBS-induced rat model has provided the first experimental demonstration of that, in contrast with the general view, the muscularis externa, and not the epithelial barrier or the myenteric ganglia, was the primary target of the events leading to stricture formation.

Applications

The authors hypothesize form the results derived our rat model with chronic colitis and very low mortality that the experimentally provoked recurrent relapsing inflammations characteristic to CD can provoke the recrudescence of the strictures post-surgically despite of the complete mucosal healing and restoring myenteric neuronal injury.

Terminology

The authors described earlier that experimentally provoked repetitive relapsing inflammations develop preconditioning effect by speeding up mucosal healing and restoring myenteric neuronal injury.

Peer-review

This is a well-written manuscript with carefully designed and described experiments. The observations are interesting and certainly add to our knowledge in the inflammation-induced fibrosis in the large intestine.

Abstract

AIM: To determine whether high-protein, high-fat, and low-carbohydrate diets can cause lesions in rat livers.

METHODS: We randomly divided 20 female Wistar rats into a control diet group and an experimental diet group. Animals in the control group received an AIN-93M diet, and animals in the experimental group received an Atkins-based diet (59.46% protein, 31.77% fat, and 8.77% carbohydrate). After 8 wk, the rats were anesthetized and exsanguinated for transaminases analysis, and their livers were removed for flow cytometry, immunohistochemistry, and light microscopy studies. We expressed the data as mean ± standard deviation (SD) assuming unpaired and parametric data; we analyzed differences using the Student's *t*-test. Statistical significance was set at $P < 0.05$.

RESULTS: We found that plasma alanine aminotransferase and aspartate aminotransferase levels were significantly higher in the experimental group than in the control group. According to flow cytometry, the percentages of nonviable cells were 11.67% ± 1.12% for early apoptosis, 12.07% ± 1.11% for late apoptosis, and 7.11% ± 0.44% for non-apoptotic death in the experimental diet group and 3.73% ± 0.50% for early apoptosis, 5.67% ± 0.72% for late apoptosis, and 3.82% ± 0.28% for non-apoptotic death in the control diet group. The mean percentage of early apoptosis was higher in the experimental diet group than in the control diet group. Immunohistochemistry for autophagy was negative in both groups. Sinusoidal dilation around the central vein and small hepatocytes was only observed in the experimental diet group, and fibrosis was not identified by hematoxylin-eosin or Trichrome Masson staining in either group.

CONCLUSION: Eight weeks of an experimental diet resulted in cellular and histopathological lesions in rat livers. Apoptosis was our principal finding; elevated plasma transaminases demonstrate hepatic lesions.

Key words: Apoptosis; Liver injury; High-protein diet; High-fat diet; Low-carbohydrate diet

Core tip: Obesity is a serious and growing health problem. A high-protein, high-fat, and low-carbohydrate diet known as the Atkins diet has been adopted since the 1970s. Many people adhere to this diet in an attempt to lose weight, and it has recently been introduced for children with difficult-to-control seizures and elderly suffering from Alzheimer's and Parkinson's diseases. The benefits and effects of the Atkins diet remain unclear, especially in hepatic metabolism. Since the primary metabolic reactions involving macronutrients occur in the liver, it is essential to understand the potential hepatic lesions that can result from dietary modifications.

Apoptosis induced by a low-carbohydrate and high-protein diet in rat livers. *World J Gastroenterol* 2016; 22(22): 5165-5172 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5165.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5165

INTRODUCTION

The prevalence of obesity is increasing worldwide among adults, youth, and children; this serious health problem requires widespread public mobilization in the search for solutions. Extremely high numbers of people adhere to special diets in an attempt to lose weight[1]. A high-protein, high-fat, and low-carbohydrate diet was announced by the American cardiologist Robert C. Atkins in the mid-1970s as the best and healthiest way to become slim[2]. This so-called "Atkins diet" or "protein diet" has continued to be viewed as "a matter of love or hate"[3]. This diet was recently introduced for children with difficult-to-control seizures and elderly with Alzheimer's and Parkinson's diseases[4]. Despite numerous medical publications related to the Atkins diet, the results from a majority of such studies are inconclusive and have failed to demonstrate benefits and effects, especially in hepatic metabolism[5].

Several studies have reported associations between a high-protein diet and alterations in the liver[6], intestinal mucosa[7], kidneys[8,9], pancreas[10], adipose tissue[11], and bones[9,12]. Since the primary metabolic reactions involving macronutrients occur in the liver, it is essential to understand the potential hepatic lesions that may result from dietary modifications. It has been shown that high-fat or low-carbohydrate diets can cause hepatic steatosis related to excessive demand for fatty acids from diet and from adipose tissues as a consequence of gluconeogenesis[5]. In a recently published study, a high-protein diet (independent of the amount and type of fat or carbohydrate) was found not to lead to steatosis and may actually reverse it[13].

Hepatic cells are important targets for lesions in the presence of excessive dietary components since they are absorbed through the intestinal mucosa and quickly reach the liver through the portal vein[6]. Among macronutrients, carbohydrates and fat are largely responsible for the observed alterations since they promote changes in gene transcription and glycolytic and lipogenic enzymes [sterol responsive binding protein 1/2 (SREBP) and the mammalian target of rapamycin - mTOR), insulin, and adipokines][14].

Hepatocytes respond to injuries *via* various mechanisms, of which the most important are autophagy, apoptosis, and non-apoptotic death[15]. Autophagy may be considered to be an adaptive process associated with different types of liver injury, such as nutrient deprivation, insufficient growth factor, hypoxia, and the accumulation of fat in hepatocytes. Autophagy can be reversed if conditions improve. The cell digests its own components for use as an energy substrate; and when these components are insufficient to maintain cell homeostasis, either apoptosis or non-apoptotic death occurs[16,17]. Apoptosis, a cellular suicide program, is a natural process that is necessary to remove damaged, senescent, or mutagenic cells that have completed their mission. However, this process may lead to the development of various liver diseases. It is responsible for the development of nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) when the capacity of hepatocytes to store free fatty acids from the diet is exceeded[18]. Apoptosis is an active process that requires energy; when energy is insufficient, the process decelerates and non-apoptotic death begins. Non-apoptotic death differs from apoptosis in many ways since it sparks an

inflammatory response that can aggravate the initial lesion[15,18].

Additional histopathological studies of livers of animals fed a low-carbohydrate and high-protein diet are required since the results to date have been conflicting[19,20].

Here, we hypothesized that a high-protein (59.46%), high-fat (31.77%), and very low-carbohydrate (8.77%) diet can cause hepatocyte lesions, as identified by flow cytometry and immunohistochemistry (IHC). We aimed to correlate the cytometry findings with light microscopy alterations and plasma transaminase levels.

MATERIALS AND METHODS

Animals

The experimental study was performed from March-May 2015 in the Experimental Nutrition Laboratory of the Nutrition College, Fluminense Federal University, Niterói, RJ, Brazil. The animal protocol minimized pain and discomfort to the rats. The experiment used 20 female Wistar rats (*Rattus norvegicus*) ranging in age from 11-13 wk. The animals weighed 211-249 g and were reared at the Laboratory Animal Facility of the Oswaldo Cruz Foundation, Ministry of Health, Rio de Janeiro, Brazil. The animals were kept in group cages with four animals each, for adaptation, over the course of 5 d, receiving water and laboratory diet *ad libitum*. After this period, the rats were separated randomly into two groups of 10 animals each [the control diet group (CDG) and the experimental diet group (EDG)] and individually housed in polypropylene cages with controlled temperature (24 ± 2 ℃) and humidity (60% ± 10%) and an alternating light-dark cycle consisting of 12 h of lightness and darkness.

Diets

The CDG diet consisting of the AIN 93M diet[21] was formulated for the maintenance of adult rats by the American Institute of Nutrition in 1993; we based the elaborated EDG diet on the Atkins diet. Both groups received water and an *ad libitum* diet for 8 wk. The diets were prepared by Pragsoluções Biociências Comércio e Serviços, LTD, Jaú, São Paulo, Brazil. The control diet had the following composition: carbohydrate (76.98%), protein (13.56%), and fat (9.46%). The experimental diet was composed of carbohydrate (8.77%), protein (59.46%), and fat (31.77%). The amount of vitamins, minerals, L-cysteine, choline, and fiber were the same in the two groups, and tert-butylhydroquinone was calculated as 0.002 mg per gram of fat, all based on AIN 93M determinations (Tables 1 and 2).

Experimental procedures and sample collection

On the morning of the day of sacrifice, all of the animals underwent vaginal smears to determine their estrous cycle phase. Animals in estrus were separated and given no more access to food. After 8 h of fasting, the animals were anesthetized *via* an intraperitoneal injection of a solution containing 11.50 mg/100 g body mass of ketamine and 0.10 mg/100 g body mass of xylazine and were exsanguinated by cardiac puncture[22]. They were then sacrificed one at a time, alternating between the experimental and control group. The blood was placed in a heparinized tube and centrifuged for 20 min at 314 rad/s, and the plasma was separated and stored at -80 ℃ until analysis. The liver was removed after withdrawing the blood, and six liver fragments measuring 1 cm^3 each were washed gently with NaCl 0.9%, submerged in a recipient with the same solution and stored in the freezer at -4 ℃ for 2 h prior to performing flow cytometry.

Table 1 Composition of control diet (AIN-93M)

Ingredients	g/100 g	CH (g)	PTN (g)	LIP (g)	FI (g)
Cornstarch	46.5	39.52			
L-cysteine	0.18		0.18		
Choline bitartrate	0.25		0.25		
Mineral mix	3.50	0.77			
Vitamin mix	1	0.97			
Tert-butylhydroquinone	0.008				
Fiber	5				5
Soybean oil	4			4	
Casein (> 85% Protein)	14		11.06		
Sucrose	10	10.00			
Dextrinized cornstarch	15.5	13.95			
Kcal (%)	338.8	260.84	45.96	32	
Macronutrients (%)	100	76.98	13.56	9.46	

The control diet group was fed this diet for 8 wk, elaborated by the American Institute of Nutrition in 1993 for laboratory rodents, with adequate percentages of macronutrient carbohydrate (CH), protein (PTN) and Lipids (LIP), vitamins, minerals and fiber (FI).

Table 2 Composition of experimental diet (based on the Atkins diet)

Ingredient	(g/100 g)	CH (g)	PTN (g)	LIP (g)	FI(g)
Agar	2				2
L-cysteine	0.18		0.18

The experimental diet group was fed this diet for 8 wk, elaborated by the authors based on the Atkins diet. The percentage of macronutrients was 2:1 carbohydrate (CH) + protein (PTN)/lipids (LIP) with fiber (FI). The others ingredients had the same amount as recommended for the AIN-93M.

Analytical methods

We measured plasma aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels using

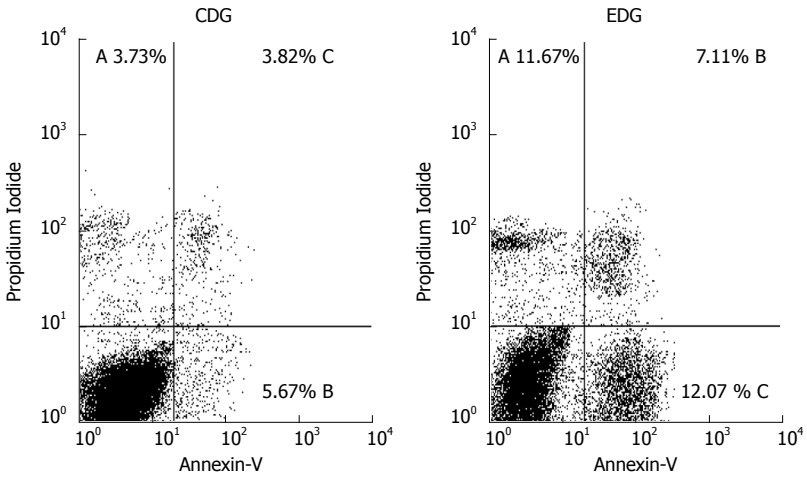

Figure 1 Flow cytometry in hepatocytes from the experimental diet group and control diet group at 8 wk. Annexin-V was used to identify late apoptosis and non-apoptotic death and propidium iodide for early apoptosis. A-% early apoptosis; B-% non-apoptotic death; C-% late apoptosis; D-% viable cells. EDG: Experimental diet group; CDG: Control diet group.

automatic analysis (Vitalab Selectra E, Vital Scientific, Spankaren, Netherlands) with commercial kits from BioSystems Reagents and Instruments (Barcelona, Spain) located in the Multidisciplinary Research Support Laboratory (LAMAP), School of Medicine, UFF, Niterói, RJ, Brazil. The flow cytometry used the following fluorescein isothiocyanate (FITC) Annexin V Apoptosis Detection Kit I components: 10X Annexin V Binding Buffer; FITC Annexin V; propidium iodide solution from BD Pharmingen (San Diego, CA, United States). The flow cytometer was the FACF-Calibur BD model. The liver fragments were fixed in Bouin's solution, processed in graded alcohols and xylene, embedded in paraffin blocks, stained for optical microscopy [hematoxylin-eosin (HE) and Trichrome Masson (TM) stains], and prepared for IHC. Alexa fluor 647 rat anti-mouse blimp-1 from BD Pharmingen was used for identifying autophagy by IHC. We performed flow cytometry and IHC in the Biomedical Science Institute of the Federal University of Rio de Janeiro, Rio de Janeiro, RJ, Brazil. We relied on a Zeiss (Oberkochen, Germany) Axioscop 20 microscope and Canon (Tokyo, Japan) G10 camera JPG with 14.7 megapixels at the Pathology Department of the School of Medicine, UFF, Niterói, RJ, Brazil for the optical microscopy.

Statistical analysis

The results of this study are presented using descriptive statistics, such as arithmetic mean and standard deviation. The two-tailed unpaired Student' *t* test was used to compare means between the two groups. It was considered that 95% confidence interval contains the true difference between the means ($P < 0.05$). An *F* test was performed to prove that the data came from two groups that have identical standard deviations (and thus identical variances). The computer program used was Graphpad-Prism version 6.0e (La Jolla, CA, United States) for Mac OS X, 2015, and WinMDI 2.9 was used for flow cytometry. The statistical analyses were reviewed by a biomedical statistician. The IHC and optical microscopy were based on observational evaluation by an expert.

RESULTS

Plasma transaminases

Plasma ALT and AST levels were significantly higher in the EDG than in the CDG. The mean ALT in the EDG was 61.70 ± 4.16 U/L compared with 28.10 ± 4.06 U/L in the CDG ($P < 0.0001$). AST in the EDG was 238.30 ± 15.85 U/L and 179.20 ± 13.86 U/L in the CDG ($P = 0.0117$).

Flow cytometry

Flow cytometry revealed a significantly higher percentage of nonviable cells in the EDG compared with the CDG (30.85% ± 2.20% and 13.22% ± 1.43%, respectively; $P < 0.0001$).

In the EDG, the percentages of nonviable cells were 11.67% ± 1.12% for early apoptosis, 12.07% ± 1.11% for late apoptosis, and 7.11% ± 0.44% for non-apoptotic death. In the CDG, the comparable values were 3.73% ± 0.50% for early apoptosis, 5.67% ± 0.72% for late apoptosis, and 3.82% ± 0.28% for non-apoptotic death (Figure 1).

When comparing the nonviable cells in the two groups, only the mean percentage of early apoptosis was statistically significant (Table 3).

Considering only non-apoptotic death and total apoptosis (early + late), the EDG demonstrated 23.99% ± 2.12% non-apoptotic death and 76.01% ± 2.12% total apoptosis ($P < 0.0001$); the CDG exhibited 29.20% ± 1.29% non-apoptotic death and 70.80% ± 1.29% total apoptosis ($P < 0.0001$).

Immunohistochemistry

IHC was negative for autophagy in both groups.

Table 3 Nonviable cells in experimental diet group and control diet group

	Early apoptosis	Late apoptosis	Non-apoptoic death
EDG[1]	37.34% ± 1.30%	38.67% ± 1.73%	24.00% ± 2.12%
CDG[1]	28.43% ± 1.19%	42.37% ± 1.10%	29.20% ± 1.29%
P-value	< 0.0001	0.0882	0.0512

[1]Each value expressed as mean ± SD (n = 10) significance $P < 0.05$. EDG: Experimental diet group; CDG: Control diet group.

Optical microscopy

Upon examining the livers of the rats in the EDG, the pathologist identified marked sinusoidal dilation around the central vein, with smaller perisinusoidal hepatocytes compared with rats in the CDG, which showed no alteration. The central vein was normal in both groups. Five animals in the CDG had isolated periportal cytoplasmic microvesicles compared with three animals in the EDG. Small and heterogeneously distributed structures were found in the liver of all animals in both groups; these structures likely corresponded to deposition of glycogen. In the EDG, these structures decreased and even absent in some zones. The pathologist observed acute and chronic inflammatory periportal cells in both groups, which are considered to be normal in rats. Fibrosis was not identified by HE or TM in either group (Figure 2).

DISCUSSION

As expected, we found that a high-protein, high-fat, and low-carbohydrate diet caused cellular and histopathological lesions in the livers of experimental rodents. ALT and AST were increased in the EDG compared with the CDG. Since these tests are considered to be precise liver function tests, our results confirmed the presence of liver damage involving hepatocyte destruction with plasmatic membrane disruption and late-phase apoptosis and non-apoptotic death in the EDG[23,24].

In a study by Jean *et al*[25], a group of animals that received a diet consisting of 50% protein exhibited high ALT and normal AST compared with controls that received a modified AIN-93M diet. The results were interpreted as hepatic lesions since ATL is a specific liver enzyme located in the hepatocyte cytoplasm; AST can also be expressed by muscles and kidneys[23,25]. Oarada *et al*[6] demonstrated that when rats were fed increasing amounts of protein (35%, 40%, 45%, and 50%), ALT and AST increased to the same degree. These authors accordingly concluded that protein-independent of other macronutrients and energy consumption-was a risk factor for liver injury. In a recent study, Kostogrys *et al*[26] found no changes in plasma transaminase levels with a diet of 50.0% protein, 37.7% fat, and 12.3% carbohydrate, although the liver was enlarged compared to animals receiving the AIN93-M diet. Comparing our results with those noted in the literature may be difficult since the percentages of macronutrients fed to the rats vary from one study to another.

Flow cytometry confirmed the hepatic damage, as demonstrated by increased plasma transaminase levels; 30.85% of the hepatocytes were nonviable in the EDG compared with 13.22% in control animals. Nonviable cells in the CDG included 3.73% early apoptosis, 5.67% late apoptosis, and 3.82% non-apoptotic death. These findings in the control group can be considered to be physiological since apoptosis and non-apoptotic death represent a continuous process that is responsible for maintaining the balance between proliferation and cellular death. Non-apoptotic death is part of the same process since it is the ultimate fate of cells that undergo apoptosis[24].

Apoptosis was markedly increased in the EDG, with 11.67% early apoptosis, 12.07% late apoptosis, and 7.11% non-apoptotic cells exhibiting a non-physiological state. Any dysregulation of apoptosis is deleterious and results in tissue damage[15]. Similar results were found by Chiang *et al*[27] who demonstrated that mice receiving an 8-wk diet with 60% protein exhibited changes in bodyweight, liver histology, and expression of apoptosis and fibrosis.

Another important finding of the present study was that the percentage of early apoptosis, degeneration of mRNA, was significantly higher in the EDG (37.34%) compared with that in the CDG (28.43%) ($P < 0.0001$), indicating that apoptosis was progressing in the liver[18]. This finding might be evidence that the rats did not adapt to the experimental diet over the 8 wk of the study.

IHC was negative for autophagy in both groups. Autophagy was likely not found in this study because the percentage of nonviable cells increased (*i.e.*, the cytoprotective mechanism was probably suppressed), and apoptosis continued to be active since early apoptosis was higher in the experimental group than in the control group. The two pathways are controlled by common mechanisms: when autophagy is inhibited, apoptosis is induced[16-18]. For comparison, we note that Garbow *et al*[5] fed animals a similar diet and found autophagy among others alterations.

A histological examination of the rats' livers in the EDG revealed sinusoidal dilation around the central vein with smaller perisinusoidal cells compared to the livers of control animals. Similarly Bollo *et al*[28] found small hepatocytes around the central vein in alpine chamois during winter and considered this change an adaptation to under-nutrition. Bollo *et al*[28] asserted that the central vein region was a metabolic zone from which nutrients were distributed to the rest of the organ. The hepatocytes atrophied, and the size of the core was reduced. This probable adaptation to inadequate nutrition could be considered a strategy to minimize energy expenditures.

Cytoplasmic microvesicles were observed in five rats fed the control diet and three rats fed the

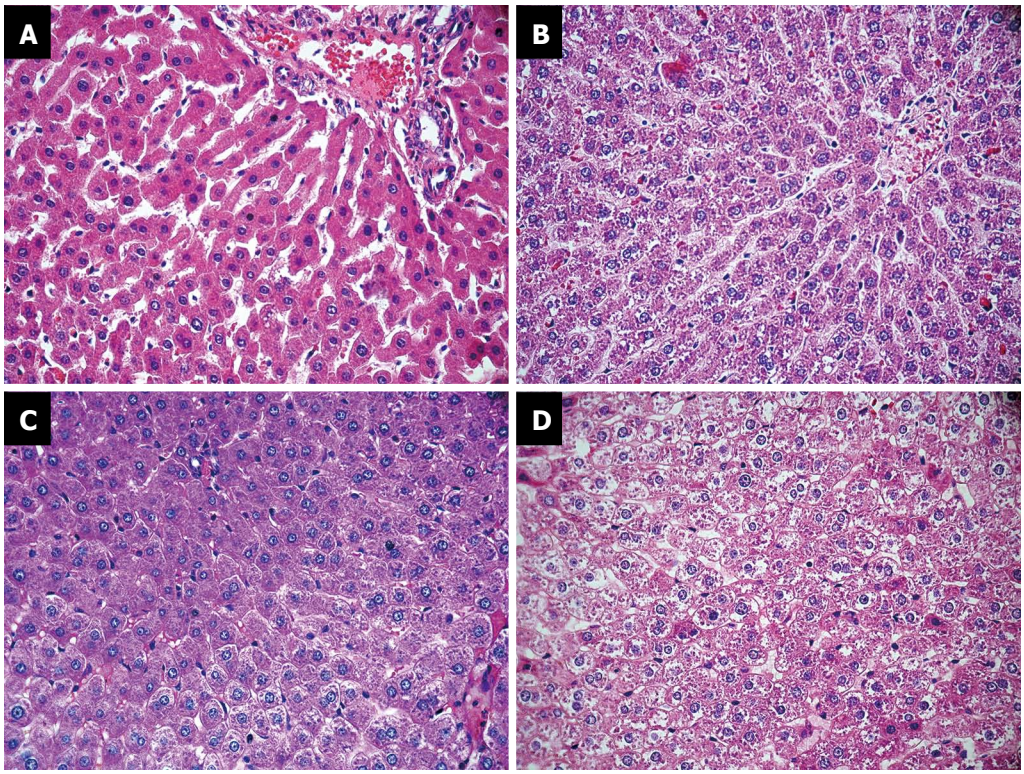

Figure 2 Staining of liver fragments at 8 wk: experimental diet group and control diet group. A: Normal central vein, functional sinusoidal dilation, and small hepatocytes in the EDG (HE, original magnification 400 ×); B: Normal central vein, sinusoidal cells, and hepatocytes in the CDG (HE, original magnification 400 ×); C: Zones without glycogen in the EDG (HE, original magnification 400 ×); D: Homogeneous distribution of glycogen in the CDG (HE, original magnification 400 ×). EDG: Experimental diet group; CDG: Control diet group; HE: Hematoxylin and eosin.

experimental diet. The stain method that we used was unable to differentiate fat from water. Other authors have recovered similar results. Lacroix *et al*[19], in an experimental study with rats fed a high-protein diet (50%) versus a normal-protein diet (14%) over the course of 6 mo, found no serious histological lesions in either group. Rats in the normal-protein diet group exhibited more microvesicular hepatic steatosis than rats in the high-protein group. Caraballo *et al*[13] showed that rats fed a high-protein and high-fat diet did not develop steatosis compared with rats fed a high-fat and low-protein diet; they concluded that the high-protein diet had an anti-steatotic effect on rat livers regardless of the amounts of others macronutrients that the rats ingested. On the other hand, Garbow *et al*[5] found hepatocellular damage, inflammatory response, severe hepatic steatosis, apoptosis, and autophagy in mice that were fed a ketogenic diet (low-carbohydrate, low-protein, high-fat) for 12 wk. Only Caraballo *et al*[13] used a stain specific to fat. For energy, high-protein diet associated gluconeogenesis improves glucose disposal from amino acids and glycogen and reduces fat deposition; neo-lipogenesis does not occur[20]. York *et al*[29] showed that a low-carbohydrate diet might be an option to treat patients with NAFLD and NASH since such a diet improves liver histology and reduces fat deposits, insulin resistance, and metabolic syndrome. Although the prevalence of NAFLD in rich countries is between 20% and 30% and this condition is considered to be part of the Metabolic Syndrome, which is responsible for high morbidity and mortality, many aspects of its pathology and treatment remain only partially understood. Apoptosis is considered an important point of NAFLD lesion and a common mechanism of hepatic injury[15,30].

We found that the amount of glycogen was likely lower in the experimental group and that both groups exhibited a heterogeneous glycogen distribution. Since the animals of each group were sacrificed in an alternating fashion, changed in glycogen content cannot be due to the duration of fasting. It was not possible to be certain that it was glycogen since no specific stain (periodic acid-Schiff reagent PAS) was conducted. Caraballo *et al*[13] reported similar results in animals fed a high-protein and high-fat diet. However, with a low-fat and low-protein diet, glycogen was not decreased and was instead concentrated in the periportal area. With a high-fat and low-protein diet, the glycogen was concentrated in the pericentral area[28]. In contrast, when Azzout-Marnich *et al*[20] compared two diets with 14% and 50% protein, respectively, glycogen levels were not different between the groups, but hey considered glyconeogenesis to be the primary pathway of the high-protein diet metabolism. Caraballo *et al* and Azzout-Marniche *et al*[20] also did not use a specific stain for glycogen.

We found no evidence for inflammation in the liver, as expected, since apoptosis (76.01%) was the primary mechanism of hepatocyte damage in the experimental group, not non-apoptotic death (23.99%). Furthermore, literature results have shown that apoptosis does not lead to a local inflammatory response[18].

Although neither group exhibited evidence of fibrosis, apoptosis may be considered not only an important mechanism of liver injury but also a contributor to liver fibrosis[27,31,32]. It is probable that if the rats had received the experimental diet for a longer period of time, fibrosis may have eventually appeared.

Additional studies are necessary to determine the exact mechanism by which changes in the percentage of macronutrients induce apoptosis. The lack of suitable nutrients may be considered to be a possible hypothesis. Gluconeogenesis, the primary metabolic pathway associated with a low-carbohydrate diet, leads to an increased production of keto acids and fatty acids, but they may not be the better energy substrate for hepatic cells[33]. When gluconeogenesis occurs, mitochondria exert important functions in energy metabolism (*i.e.*, the oxidation of fatty acids and oxidative phosphorylation for the production of adenosine triphosphate). Dysregulation of this pathway results in energy deficiencies and/or the production of reactive oxygen species that may be responsible for cell damage[34-36].

In conclusion, this study furthers our understanding of the hepatic cellular and histological changes caused by a high-protein, high-fat, and low-carbohydrate diet. The findings revealed that rats fed this diet had elevated levels of plasma transaminases and a higher percentage of nonviable cells in flow cytometry, which is evidence of hepatic lesions. Apoptosis was the principal pathway of hepatic injury. The primary findings from the optical microscopy-small hepatocytes and a decreased amount of glycogen-correlated well with changes in flow cytometry and can be attributed to modification of essential macronutrients to the liver. No inflammation or fibrosis was found in the livers of either the experimental or control animals. A better understanding of the mechanism of hepatic lesions associated with a high-protein, high-fat, and low-carbohydrate diet requires investigating the metabolic effects of diet in the liver.

The authors wish to acknowledge the collaboration of the Experimental Nutrition Laboratory, School of Nutrition, UFF, Niterói, RJ, Brazil; the Laboratory Animal Facility of the Oswaldo Cruz Foundation, Rio de Janeiro, Ministry of Health, Brazil; the Biomedical Science Institute, UFRJ, Rio de Janeiro, RJ, Brazil, the Multidisciplinary Support Laboratory for Research, School of Medicine, UFF, Niterói, RJ, Brazil, and the School of Pharmacy of UFF, Niterói, RJ, Brazil. They also thank Dr. Prof. Antônio Orestes de Salvo Castro for his valuable collaboration with the statistical analysis.

COMMENTS

Background

The authors did an experimental study comparing two groups of rats, one fed an experimental diet based on Atkins' (59.46% protein, 31.77% fat, and 8.77% carbohydrate) and the other an AIN-93M diet, so that they could study the effect of the experimental diet on hepatic metabolism. The modification of dietary components might result in hepatic cell damage since they are important targets for lesions when excessive macronutrients are absorbed and go through the intestinal mucosa to reach quickly the liver through the portal vein.

Research frontiers

The prevalence of obesity is increasing and may be considered a serious health problem. Worldwide, many people adopt various diets to lose weight without a particular orientation. The Atkins diet is a low-carbohydrate and high protein diet formulated by Dr. Robert Atkins in 1972. More recently, it was introduced for children with difficult-to-control seizures and elderly with Alzheimer's and Parkinson's diseases. Despite these indications, the effect of the diet on hepatic metabolism remains unclear.

Innovations and breakthroughs

This study demonstrated a strong association between low-carbohydrate, high-protein, and high fat diet and hepatic apoptosis, as identified by flow cytometry. These changes were correlated with alterations found by optical microscopy and may be due to metabolic changes.

Applications

A better understanding of the mechanism underlying hepatic lesions associated with this diet in rats and its effects on human metabolism is essential. The article emphasizes that the use of this diet should be used with caution for children, adults, and elders.

Terminology

Alanine aminotransferase) and aspartate aminotransferase are two enzymes found mainly in the liver that are considered hepatic markers of liver damage. Flow cytometry is a biophysical laser technology that was employed in this cell study; it detects cells in early apoptosis, late apoptosis, and nonapoptotic death.

Peer-review

Rats fed a low-carbohydrate, high-protein, and high-fat diet for 8 wk have hepatic cellular damage, as demonstrated by flow cytometry.

Abstract

AIM: To elucidate the molecular mechanisms leading to development of functionally impaired dendritic cells (DCs) in chronic hepatitis C (CHC) patients infected with genotype 3 virus.

METHODS: This prospective study was conducted on the cohorts of CHC individuals identified as responders or non-responders to antiviral therapy. Myeloid DCs were isolated from the peripheral blood of each subject using CD1c (BDCA1)$^+$ DC isolation Kit. Monocytes from healthy donor were cultured with DC growth factors such as IL-4 and GM-CSF either in the presence or absence of hepatitis C virus (HCV) viral proteins followed by LPS stimulation. Phenotyping was done by flowcytometry and gene expression profiling was evaluated by real-time PCR.

RESULTS: Non-responders [sustained virological response (SVR)-ve] to conventional antiviral therapy had significantly higher expression of genes associated with interferon responsive element such as *IDO1* and *PD-L1* (6-fold) and negative regulators of JAK-

STAT pathway such as *SOCS* (6-fold) as compared to responders (SVR+ve) to antiviral therapy. The down-regulated genes in non-responders included factors involved in antigen processing and presentation mainly belonging to major histocompatibility complex (MHC) Class-Ⅱ family as *HLA-DP*, *HLA-DQ* (2-fold) and superoxide dismutase (2-fold). Cells grown in the presence of HCV viral proteins had genes down-regulated for factors involved in innate response, interferon signaling, DC maturation and co-stimulatory signaling to T-cells, while the genes for cytokine signaling and Toll-like receptors (4-fold) were up-regulated as compared to cells grown in absence of viral proteins.

CONCLUSION: Underexpressed MHC class-Ⅱ genes and upregulated negative regulators in non-responders indicate diminished capacity to present antigen and may constitute mechanism of functionally defective state of DCs.

Key words: Dendritic cells; Hepatitis C; Non-responders; Negative regulators; Major histocompatibility complex Class-Ⅱ genes

Core tip: The study was aimed to understand the mechanisms of dendritic cells dysfunction during chronic hepatitis C (CHC) infection. The findings highlight the association between different immune response genes and viral persistence in non-responders to antiviral therapy. Up regulation of negative regulators and down-regulation of molecules involved with antigen presentation seems to associate with non-responsiveness to antiviral therapy. Some novel pathways can be targeted to achieve better management of CHC patients.

INTRODUCTION

Hepatitis C virus (HCV), a positive sense single stranded RNA virus, infecting around 180 million people worldwide, is becoming a significant global health problem[1,2]. Transmitted through infected blood and body fluids, it is responsible for chronic hepatitis, which ultimately leads to life threatening liver diseases like fibrosis, cirrhosis, steatosis and finally causing hepatocellular carcinoma (HCC), thus a need for liver transplant[3]. Genotype 3 of HCV being more prevalent in South Asia, accounts for more than 50% of all the genotypes[4]. Although more patients infected with genotype 3 respond successfully to therapy as compared to genotype 1, yet approximately 25%-30% patients fail to achieve sustained virological response (SVR) and are considered as non-responders (NR) to antiviral therapy containing IFN-α and ribavirin, offered till recently[5,6].

Dendritic cells (DC) are professional Antigen-presenting cells (APC) having the unique property to induce a primary immune response[7]. Antigen uptake, processing and presentation to naïve T-cells for activation of the immune system are the main functions carried out by DC. There have been studies reported from our laboratory which showed that DC are numerically, functionally and phenotypically dysfunctional in patients infected with CHC[8,9]. The study also showed that functionally defective monocyte-derived dendritic cells (moDC) from CHC patients who did not achieve SVR, failed to reconstitute the capacity to mature, indicating that the dysfunctional status of DC in CHC patients was directly associated with the persistence of the virus.

The expression of many genes is responsible for regulation of DC maturation. They involve genes associated with antigen processing and presentation[10], interferon α, β response[11,12], cytokine signaling[13], adhesion and migration[14], phagocytosis[15], interferon responsive elements[16], anti-inflammatory process[17], negative regulators of JAK-STAT pathway[18] and genes involved in TLR mediated signaling[19].

Effective cellular immune response directed against HCV is mediated through T-cell and DC crosstalks[20]. A subdued adaptive immune response in chronic HCV patients might be due to the suboptimal antigen presentation and signaling via impaired DCs in these individuals. So, in the proposed study, we wanted to find out whether this non-responsiveness to standard anti-viral therapy in a proportion of CHC patients is associated with the virus-modulated expression of certain genes, which may culminate into dysfunctional status of DC (maturation as well as functional defects). So, we planned to investigate the expression levels of a set of selected genes in the myeloid dendritic cells (MDC) of CHC patients with the hypothesis that, an analysis of the association of immune response genes and non-responsiveness to therapy may reveal molecular mechanisms of DC dysfunction in the non-responders.

MATERIALS AND METHODS

Ethical statement

The study was approved by the Institute Ethics Committee of the PGIMER, Chandigarh (Reg. No. NKG/947). An informed written consent was obtained from all the subjects before taking blood samples.

Subjects and sampling

A total of 20 CHC patients were recruited for the study. Patients were divided into two groups on the basis of response to therapy in terms of SVR *i.e.,* HCV RNA negative at 24 wk after cessation of antiviral therapy. Patients achieving SVR (SVR+ve) were considered as "Responders" whereas those who failed to achieve SVR (SVR-ve) were termed as "non-responders". Responders (n = 10, MDC-R) and Non-responders (n = 10, MDC-NR) were recruited on the basis of inclusion and exclusion criteria. Inclusion criteria included patients positive for anti-HCV antibodies and serum HCV RNA, HCV RNA genotype 3 only, no prior history of any treatment for HCV, negative for auto-antibodies (ANA, SMA, LKM, AMA and PCA) and non-viral factors (alcoholism, inherited metabolic disorders). Exclusion criteria included patients with HBV, HCV genotype 1, 2 or 4, HIV and other co-infections, patients with regular use of hepato-toxic drugs and alcohol intake and any evidence of auto-immune or metabolic disease. Venous blood was taken in heparin vacutainer vials (BD) from each recruited patient in the hepatology clinic of PGIMER, Chandigarh. Age and sex matched healthy volunteers were recruited as control subjects (HC; n = 10). Inclusion criteria for HC included those subjects who had normal liver function tests with no history of jaundice or viral hepatitis infection in the past.

PBMC isolation and enrichment of myeloid dendritic cells using magnetic beads

Plasma was stored at -80 ℃ before isolation. From heparinised blood, peripheral blood mononuclear cells (*PBMCs*) were isolated by ficoll-hypaque density gradient centrifugation using Hisep (Himedia, Mumbai, India). MDC enrichment was performed by using CD1c (BDCA-1)$^+$ Dendritic Cell Isolation Kit (MiltineyiBiotec, Germany) following manufacturer's instructions. Briefly, the procedure included two steps: In the 1st step, CD1c (BDCA-1) expressing B cells labeled with CD19 magnetic microbeads got depleted by separation over a MACS column placed in a magnetic field of a MACS Separator. In the second step, CD1c (BDCA-1)$^+$ MDC labeled with CD1c-Biotin and Anti-biotin microbeads in B cell depleted flow-through fraction were retained within the column and eluted after removing the column from magnetic field. These cells (MDC) were used for further experiments.

Flow cytometric analysis for purity check

PBMCs and MDCs (10 μL each) were stained with fluorochrome-labeled antibodies (2 μL): Allophy-cocyanin (APC)-conjugated anti-HLA-DR, Fluorescein isothiocyanate (FITC)-conjugated Lineage Cocktail 1 (Lin1: CD3, CD14, CD16, CD19, CD20, CD56) and Phycoerythrin-Cy5 (PE-Cy5) - conjugated anti-CD11c from BD Biosciences (San Jose, CA, United States) for 15 min in the dark. Cells washed with staining buffer for 5 min at 1400 rpm were re-suspended in buffer for acquisition on Flowcytometer (FACS Calibur, BD, United States). Percent purity was calculated.

Generation of monocyte-derived DCs from HCs PBMCs

Monocyte-derived dendritic cells (moDCs) were derived according to the method described by Romani *et al*[21] and modified in our laboratory[8]. Cells were cultured in the presence (moDC-Ag) or absence (moDC-N) of HCV viral proteins. Briefly the PBMCs were isolated from venous blood as described above. Cells were suspended in RPMI 1640 medium (Sigma-Aldrich) and monocytes were made to adhere for 2 h at 37 ℃ (Plate adherence method). After incubation, non-adherent cells were removed. Adherent cells were cultured in the DC culture medium (DCCM) consisting of RPMI 1640 supplemented with: 2 mmol/L L-glutamine, 5 mmol/L HEPES buffer, 100 IU/mL penicillin and 100 μg/mL streptomycin, 10% fetal bovine serum (GIBCO), 20 ng/mL recombinant human GM-CSF (Peprotech Asia) and 20 ng/mL recombinant human IL-4 (Peprotech Asia) at 37 ℃ in a humidified incubator with CO_2 volume fraction, 50 mL/L CO_2 for six days. The cells were cultured in different sets as: either in presence or absence of viral proteins: core, NS3, NS4 and NS5 (Peprotech Asia). At the end of six days, these moDCs were stimulated with bacterial lipopolysaccharide (LPS) and further cultured for 48 h in maturation cocktail which comprised of DCCM with LPS (500 ng/mL). On the 8th day, moDCs were harvested and gene expression studies were carried out.

Gene expression analysis (RNA extraction, cDNA preparation and real time PCR)

MDCs and moDCs were centrifuged and dissolved in 1 mL TRIzol (Sigma, United States). RNA was extracted and reverse transcribed to cDNA using the RT^2 First Strand Kit (Qiagen, Germany) according the manufacturer's protocol, and cDNA was stored at -20 ℃ till further use. A custom PCR array (RT^2 Custom Profile PCR Array Human, Qiagen) was designed which included a panel of immune-stimulatory genes (ISGs) and genes involved in DC functioning (Table 1). Real-time PCR was undertaken using RT SYBR Green Master Mix (Qiagen, Germany) in a 96-well PCR plate pre-dispensed with primers in a Light Cycler 480 (Roche, Germany). Values were normalized against housekeeping genes (*GAPDH, β-actin*) in the same sample. Each experiment included positive PCR control (PPC), reverse transcription control (RTC) and human genomic DNA contamination (HGDC) control. Ct values were obtained for calculation of delta-CtCt and further analysis.

Statistical analysis

Statistical analysis for viral load (baseline and 4 wk) and other clinical features were done using GraphPad Prism software v 5.03 statistical package. Parametric

and non-parametric *t*-tests were carried out and $P < 0.05$ was considered significant. For flow cytometry results, Cellquest software (BD Biosciences, United States) was used. Analysis of up-regulated and down-regulated genes was done using web based online software RT^2 Profiler PCR array data analysis version 3.5 software. To check interactions and associations between different genes, string software available online was used.

RESULTS

Clinical and demographic details of patients

A total of 20 patients were recruited for the study. Their clinical and demographic parameters like gender, age, genotype, liver enzyme (AST-ALT) levels, total bilirubin/conjugated bilirubin, Alkaline Phosphatase (ALP) levels were recorded (Table 2). At the baseline, there was no significant difference in the viral loads of responders vs non-responders, but when compared between baseline *vs* 4 wk (at RVR - rapid virological response) the viral load became undetectable in responders, while remained detectable in non-responders although was significantly decreased (Figure 1). Also, the degree of liver fibrosis (LSM - liver stiffness measurements) which provides useful information in prognostication, therapeutic planning, and assessment of the impact of treatment in chronic liver diseases, was significantly increased in non-responders ($P < 0.05$), which suggests that the persistence of virus in the liver leads to cirrhosis of the liver.

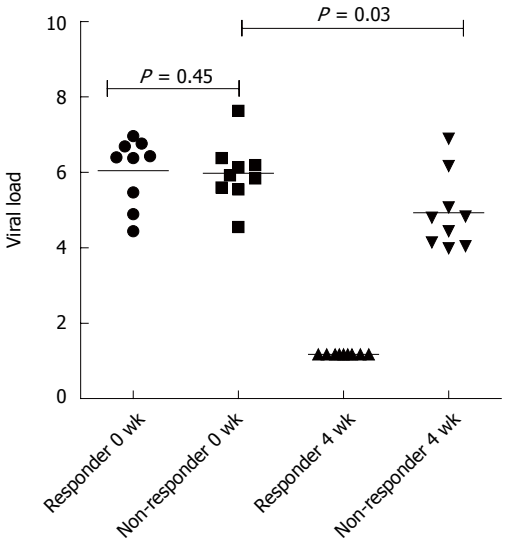

Figure 1 Difference between viral load in responders to antiviral therapy (at 0 and 4 wk) *vs* non-responders (0 and 4 wk). No significant difference in the viral loads of responders vs non-responders at baseline, but when compared between baseline *vs* 4 wk (at RVR - rapid virological response) the viral load became undetectable in responders, while remained detectable in non-responders.

Flow cytometric analysis of MDC

For phenotyping and purity of the isolated MDC, the cells negative for Lineage (CD3, CD14, CD16, CD19, CD20, CD56) and dual positive for CD11c and HLA-DR were gated. Percent enrichment of MDC was 65% after magnetic sorting as compared to 10% in PBMCs before sorting.

Gene expression profiles by PCR array

The gene expression profiles of the selected genes (as in Table 1) using custom-designed PCR array are shown in the heat map of genes indicating the differentially expressed genes (Figure 2). The genes upregulated or down-regulated are shown in Figure 3.

Upregulated genes

Non-responders (MDC-NR) *vs* Responders (MDC-R) group: Genes involved in negative signaling of JAK-STAT pathway, such as suppressor of cytokine signaling (*SOCS1*; six-fold, *SOCS2, SOCS4* and *SOCS5* all two-fold) and genes involved with down-modulation of immune response such as Indoleamine 2,3-Dioxygenase (*IDO1*) and Programmed death-

Figure 2 Heat map showing the expression of all the genes in different groups recruited. Graphical representation showed up-regulated and down-regulated genes in all the recruited groups. NR: Non-responder; HC: Healthy controls; HT: Healthy treated; RESP: Responder.

ligand 1 (*PD-L1*) were found to be significantly upregulated (two-fold or more) in non-responders as compared to responders to therapy (Figure 4).

Further, the genes for antiviral innate response such as TLR, ISGs and JAK/STAT pathway were also found to be up-regulated in non-responders as compared to responders to antiviral therapy.*TLR3* which is activated by viral RNA (HCV RNA) was four-fold up-regulated whereas *TLR4* and *TLR7* showed two-fold up-regulation in non-responders. The genes for Interferon regulatory factors (*IRF 7* and *IRF 9*) and the Interferon stimulatory genes (*ISG15* and *ISG20*) were also found to be significantly (six-fold) upregulated in non-responders. Further, the genes involved in JAK-STAT signaling, the *STAT1* and *STAT2,* showed two-fold upregulation along with the increased expression of IFN-induced proteins with tetratricopeptide repeats (*IFIT1*; six-fold, *IFIT3*; two-fold), IFN-Inducible transmembrane family (*IFITM1*; two-fold), Interferon-induced GTP-binding protein encoding gene (*MX1*, *MX2*; both two-fold), 2′,5′-oligoadenylate synthetase (*OAS1*; six-fold, *OAS2*; two-fold), IFN-inducible genes (*IFI6*; two-fold, *IFI27*; two-fold, *IFI35*; four-fold), Adenosine deaminase acting on RNA (*ADAR*; two-fold) and eukaryotic translation initiation factor 2-alpha kinase 2 (*EIF2AK2*; two-fold). Also gene associated with apoptosis such as Fas cell surface death receptor (*FAS*) showed increased expression (two-fold) in non-responders to antiviral therapy.

moDC from healthy donor differentiated in presence (moDC-Ag) or absence (moDC-N) of viral proteins: Sixteen genes were upregulated in the moDC differentiated from monocytes grown in presence of HCV viral proteins as compared to the cells grown in absence of proteins. Amongst these, included the chemokine and their receptor genes (*CXCR3*, *CXCR6*, *CXCL12*, *CCL8*; all two-fold) and Toll-like receptor genes (*TLR2*, *TLR4*, *TLR9*; all two-fold).

Downregulated genes

Non-responders (MDC-NR) *vs* Responders (MDC-R) group: The genes downregulated in non-responders as compared to responders included the genes belonging to MHC-Class Ⅱ family (*HLA-DPB1*, *HLA-DQA1*, *HLA-DQB1*) and Superoxide dismutase (*SOD*), the enzyme involved in transforming toxic superoxide anion radicals into hydrogen peroxide and oxygen for protecting DNA from oxidative stress showed two-fold reduced expression in non-responders as compared to responders (Figure 4).

DCs from healthy donor grown with (moDC-Ag) or without (moDC-N) viral proteins: A decreased expression of 21 genes in the cells grown in presence of viral proteins was observed as compared to the cells grown in absence of proteins. The genes found down-regulated (two-fold) include the ones involved in innate response and Interferon signaling (*EIF2AK2, IFI27, OAS1, OAS2, MX1, IFIT1, IFIT3, GBP1, GBP2, ISG20*); the genes involved with DC maturation (*CD83, LY75, LAMP3*) and genes involved in delivering co-stimulatory signals to T-cells (*CD40, CD80, CD86*) (Figure 4).

DISCUSSION

Non-responsiveness to antiviral therapy has been linked to defective phenotype of MDC by previous reports including our laboratory[8,9]. This indicates a direct association of immune defects with response to treatment in CHC, which could be attributed to many reasons such as (1) defect in IFN-α interactions with its receptors on MDCs; (2) defect in signal transduction machinery after this interaction; and (3) abnormal expression of certain transcription factors and immune response genes which are involved with the activation and maturation of DCs.

Although it has already been reported that there are functional and maturation defects in MDCs during CHC infection, yet the molecular mechanisms involved have not been fully elucidated[8]. The present study was designed with a view to understand these mechanisms and the role of different immune response genes that are involved in regulation of DC functions and may be associated with non-responsiveness to therapy and viral persistence during CHC. In order to achieve the objectives, gene expression profiles were studied in MDC isolated from the peripheral blood of CHC patients put on standard anti-viral treatment consisting of

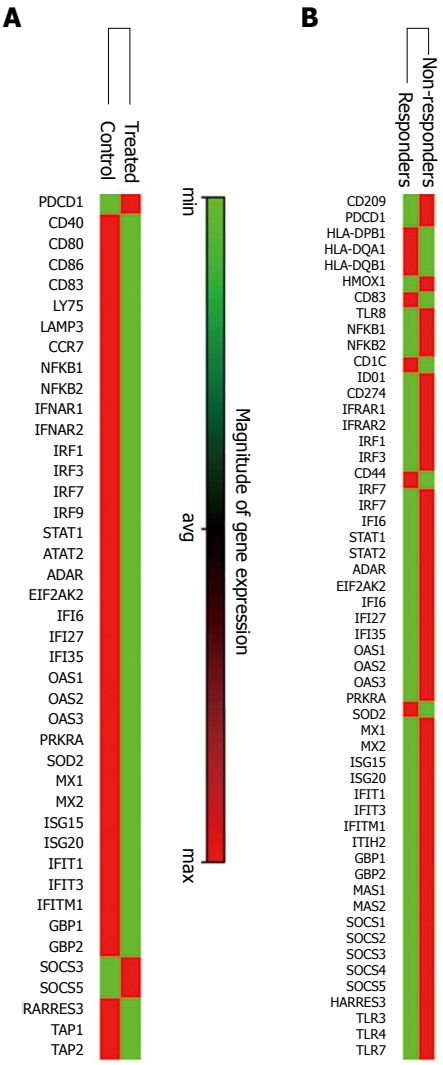

Figure 3 Clustergram showing up-regulated and down-regulated gene expression in dendritic cells of A: moDCs from healthy volunteer differentiated in presence of HCV viral proteins (Test group) and moDCs differentiated in absence of viral antigens (control group); B: Responders and non-responders. Graph showing the differentially expressed genes in different groups. Green represents the lower expression of a particular gene and red represents the higher expression of a particular gene in that particular group as compared to control.

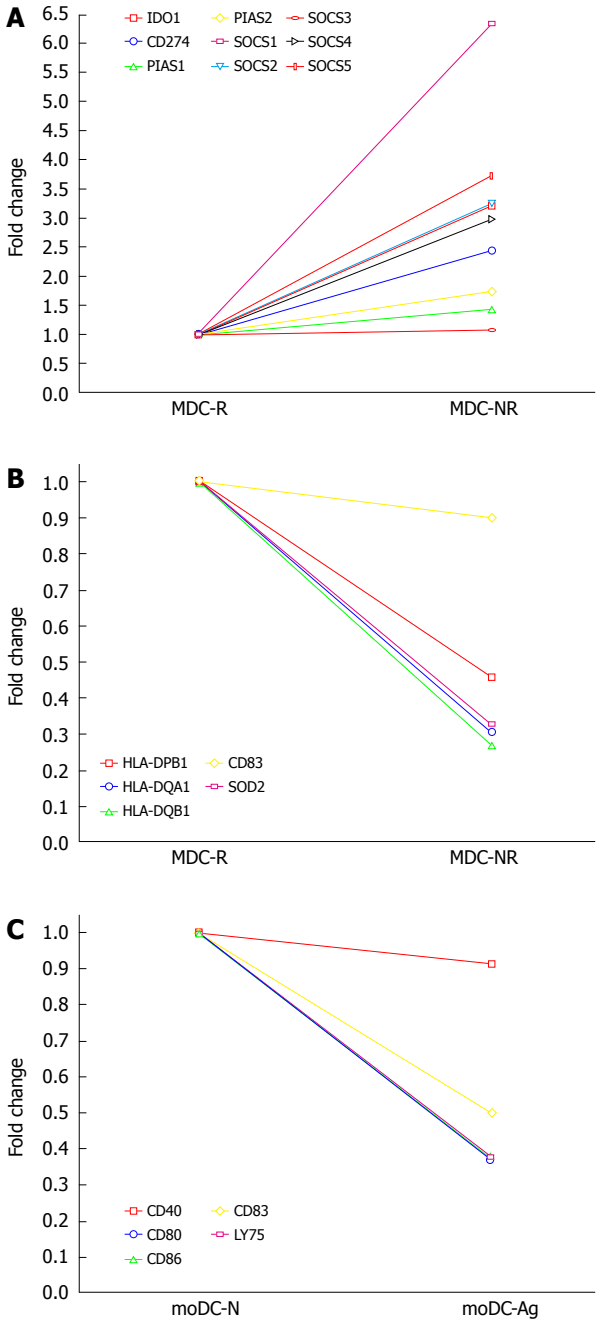

Figure 4 Multigroup plot showing A: up-regulation of down modulatory genes (negative regulators) in MDC-NR (non-responders) as compared to MDC-R (responders); B: Down-regulated genes in MDC-NR (Non-responders) as compared to the MDC-R (Responders); C: Down-regulation of genes involved with DC maturation and co-stimulatory molecules in the cells differentiated in the presence of viral antigens (moDC-Ag) as compared to cells without antigens (moDC-N). The genes which are negative regulators of JAK-STAT such as suppressors of cytokine signaling (SOCS), protein inhibitors of activated STATs are up-regulated in non-responders as compared to responders whereas the genes which belong to MHC class Ⅱ family such as HLA-DPB1, HLA-DQA1 and HLA-DQB1 and dendritic cell maturation marker such as CD83 is down-regulated in non-responders as compared to responders.

Type 1 IFN and ribavirin, some of those who achieved SVR were termed "responders" and those who did not achieve SVR were termed "non-responders". The differentially expressed genes were identified after analysis of the expression profile results. Further, these findings were confirmed in an *ex vivo* moDC model where gene expression profiles were analyzed in monocytes from a healthy donor, differentiated to DC, either in presence or absence of some HCV proteins, using same custom-designed PCR array. Interestingly results from both these experiments although not exactly overlapping, yet revealed the set of genes down-regulated in "non-responders" or in cells grown in presence of viral proteins were those, which are involved with DC maturation and function. Similarly the genes that were found to be up-regulated in these cells were mainly of the negative regulators of DC functions suggesting that the continuous presence of virus or viral proteins in individuals infected with HCV, would facilitate the development of functionally

defective phenotype of DCs in these individuals.

The monocytes cultured and differentiated in the presence of HCV viral proteins to dendritic cells in a culture system *ex vivo,* in the present study, induced the development of a defective phenotype of DCs with hampered maturation capabilities in a similar manner and also confirmed the findings from CHC patient experiments as described above. The analysis of gene expression profiles of these cells revealed downregulated expression of some important genes associated with DC maturation (*LAMP3* and *LY75*), co-stimulatory signaling (*CD80* and CD86) and many immune-stimulatory genes, the ISGs (*EIF2AK2*, *IFI27*, *OAS1*, *OAS2*, *MX1*, *ISG20*, *IFIT3*, *IFIT1*, *GBP1* and *GBP2*), which are the first line of defense in innate antiviral immunity, suggesting that persistence of HCV down-modulates the host defense mechanisms and make conditions favorable for its own survival. These results are consistent with the earlier reports, which also indicated that different HCV viral proteins disrupt the host IFN signaling and ISGs to establish chronic infection[22].

Entry of the virus in the host results in up-regulation of many TLRs like *TLR2*, *TLR3*, *TLR4*, *TLR7*, *TLR8* and *TLR9* on PBMCs and monocytes[23]. The expression of *TLR3*, *TLR4* and *TLR7* was also found to be increased on the MDC of non-responders in our study, suggesting the immune activation due to the constant presence of viral RNA. Besides, *RARRES* (Retionic acid receptor responder protein 1), which is also activated by viral RNA, was also upregulated in non-responders. The *TLR7* and *RARRES* cause *IRF7* activation and induction of Type1 IFN gene, leading to activation of JAK-STAT signaling and upregulated expression of *STAT1*, *STAT2* and *IRF9*, which further lead to enhanced expression of ISGs namely *IFIT1*, *IFIT3*, *ISG15*, *ISG20*, *ADAR*, *GBP1*, *PRKRA*, *EIF2AK2* (PKR), *IFITM1*, *MX1*, *MX2*, *OAS1*, *OAS2*, *IFI16*, *IFI27* and *IFI35*. The administration of exogenous IFN and upregulation of ISGs may be effective to a certain limit because virus replication and copy number gets significantly reduced from baseline to week 4 (RVR) in these patients, but complete removal was not achieved as viral load was still detectable, which suggests that there are other factors that are associated with the persistence of the virus.

The possible reasons may be attributed to dampening of the immune response (functionally impaired immature CD4+ cells) by Type 1 IFN, which leads to impaired T-cell immunity as evident in these patients. Moreover the genes important for optimal antigen presentation like MHC-Ⅱ (*HLA-DP*, *HLA-DQ*) and co-stimulatory molecules (*CD80*, *CD86*) as well as the homing receptors like *CCR7* were all found to be down-regulated in MDC from non-responder patients as compared to responders in our study, which again supports the hypothesis that such maturation defective DCs with hampered antigen-presenting and migration capabilities would be responsible for the generation of functionally impaired set of immature T-cells, which are incapable of clearing the virus in CHC. Also, it has been reported earlier that excessive or prolonged IFN-αβ signaling is associated with severe disease in HIV infection and favors the replication of virus in the host[23]. Although HCV has different mechanisms to down-regulate Type 1 IFN production, still ISGs are induced in infected hepatocytes in most of the chronically infected CHC patients. Earlier reports suggest that HCV patients having high pre-existing levels of ISGs are less likely to respond to IFN-α therapy in comparison to those with lower levels[24].

Besides, the genes for factors such as *SOCS1*, *SOCS2*, *SOCS4* and *SOCS5* which negatively regulate the inflammatory pathways such as JAK-STAT signaling[25]; *PDL1* responsible for exhaustion of T-cell function and its blocking on DCs shown to enhance T-cell activation[26,27]; *IDO1* which alters DC by decreasing its APC function and capable of suppressing local T-cell immune responses and promoting systemic tolerance[28], were all up-regulated in non-responders. Our findings corroborate the study reported earlier that up-regulation of PD-1 and SOCS-1 inhibitory molecules mediates functional impairment of the early immune response during HCV infection[29].

The expression of CD209 (DC-SIGN), a molecule expressed more on immature DCs and involved in innate immune responses also plays a critical role in viral pathogenesis, was also upregulated in non-responders[30,31]. Immature DCs bind more strongly to E1 and E2 (HCV Envelope proteins) through DC-SIGN with a difference in internalization pathway. These HCV viral like particles are targeted to non-lysosomal compartment in immature DCs and are protected from lysosomal degradation[32]. Thus, HCV may use DC-SIGN as an entry portal and facilitate viral infection of nearby hepatocytes and also use these DCs as reservoirs resulting in establishment of viral infection. HIV gp120 also binds to DC-SIGN and results in horizontal and vertical transfer and also helps in spreading the virus in the host[33].

HCV induces chronic increase in hepatic oxidative stress which plays an important role in pathogenesis of HCV[34]. Expression of genes of the factors involved with stress conditions such as Heme Oxygenase (*HMOX1*) was up-regulated in non-responders, suggesting higher oxidative stress in these patients. Since the *HMOX1* catabolizes heme to bilirubin, this might be responsible for significantly higher bilirubin levels observed in non-responders as compared to responders. The *HMOX1* being mainly expressed in immature DCs and its overexpression induces down-regulation of co-stimulatory molecules on DCs, might be responsible for inhibition of T-cell proliferation in CHC[35]. On the other hand, *SOD* responsible for transforming toxic superoxide anion radicals, showed down-regulated expression in non-responders resulting in increased levels of reactive oxygen species (ROS) and oxidative stress in these patients, might

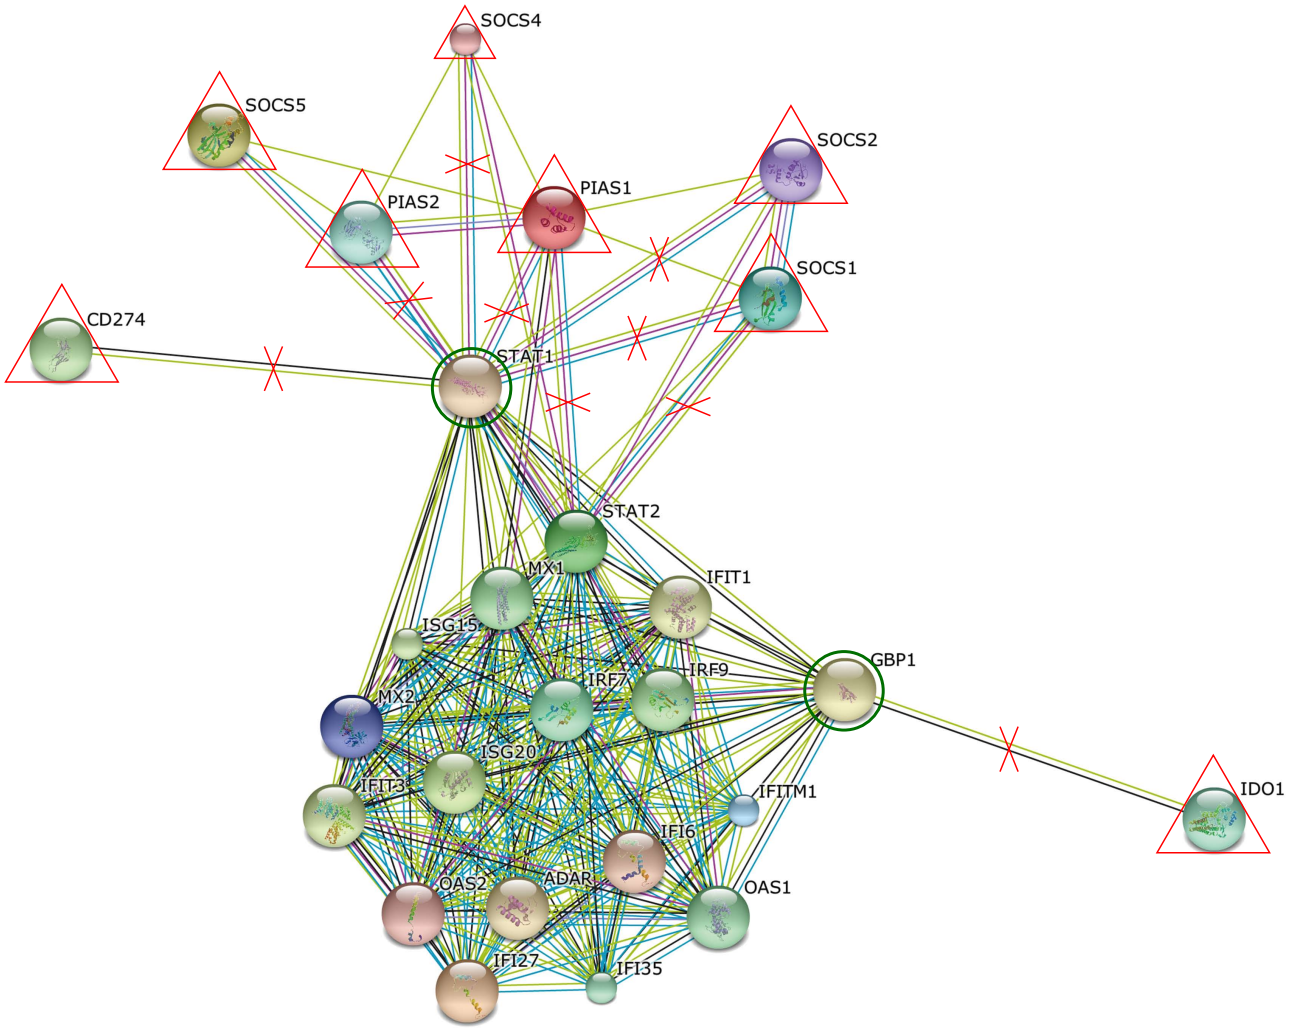

Figure 5 Interactions between different interferon stimulatory genes and negative regulatory genes of immune system. Using string software, possible interaction pathways between different Interferon Stimulatory genes and Negative regulatory genes were drawn. Negative regulators such as SOCS, PIAS when upregulated results in the inhibition of *STAT* and *GBP* genes which in turn result in the induction of transcription of many genes involved in innate immunity and interferon signaling such as *IRF7*, *IRF9* and *ISG20*. ISG: Interferon stimulatory genes.

be responsible for increased apoptosis of cells, which is also supported by up-regulated expression of *FAS* gene observed in these patients in our study. Thus, these patients are unable to destroy superoxide anion radicals, which are normally produced within the cells and are toxic to biological systems. Earlier report has also shown increased levels of *HMOX1* and decreased levels of *SOD2* in PBMC of patients with CHC[36].

In summary, our study indicates that there is up-regulation of negative regulators and down-regulation of molecules involved with maturation and antigen-presentation on DCs of non-responders. This imbalanced state, possibly modulated by the continuous replication of HCV, results in the generation of maturation-defective phenotype of DCs which are not capable of presenting the viral antigens to the naïve T-cells and lead to the generation of functionally defective immature T-cells incapable of clearing the virus (Figure 5). Whether this defective state of DCs in these patients is the cause or effect of viral persistence, is not really clear, but possibly this vicious cycle might be the cause of non-responsiveness to anti-viral therapy. Never the less, the study points to some novel pathways that may be targeted to achieve better management of this chronic disease.

COMMENTS

Background

In patients infected with hepatitis C, it had already been reported that dendritic cells are numerically, functionally and phenotypically dysfunctional. Also functionally defective monocyte-derived dendritic cells (DCs) from chronic hepatitis C (CHC) patients who did not achieve sustained virological response (SVR) failed to reconstitute the capacity to mature, indicating the dysfunctional status of DC in CHC patients, however the molecular mechanisms regulating this defect have not been elucidated.

Research frontiers

Previous experiments have indicated that CHC patients having dysfunctional dendritic cells led to therapy non-responsiveness in these patients.

Innovations and breakthroughs

The expression profile of selected genes related to hepatitis C virus (HCV) infection have been studied in various hepatocytes cell lines but, the role

of dendritic cells in non-responsiveness to antiviral therapy has not been elucidated as yet.

Applications

The molecular profile of dendritic cells on their role to standard therapy may be used in better prognosis and will help in designing newer therapeutic modalities that might help in better management of non-responders who do not respond to extended regimens to antiviral therapy.

Terminology

SVR - HCV RNA negative 24 wk after cessation of treatment. It is the best predictor of a long-term response to treatment.

Peer-review

The paper of Tomer S *et al* discusses the effects of HCV on DCs isolated from PBMC of IFNα-treated HCV patients. The comparisons in gene expression have been done between the responders and non-responders to treatment *vs* DC from healthy donors exposed or not to HCV proteins. This is an interesting attempt to elucidate the role of HCV-infection in impairment of DC function and to link this situation to non-responsiveness to IFNα treatment, which provides a promising connection to translational research.

Abstract

AIM: To investigate the effect of miR-106b on tumor progression in hepatitis B virus (HBV)-associated hepatocellular carcinoma (HCC).

METHODS: A total of 120 patients who underwent liver resection for HCC at National Cheng Kung University Hospital were enrolled in the present study. MicroRNA (miRNA) array was first used to screen the miRNA expression profiles in HCC patients. The clinical records were retrospectively analyzed, and correlations with the miRNA expression profiles were evaluated. The mRNA expression levels of the miR-106b-25 cluster (miR-106b, miR-93 and miR-25), and MCM7 in tumor and non-tumor samples were quantitated using quantitative real-time reverse transcription-polymerase chain reaction (q-RT-PCR) analysis, and correlations in the levels of miR-106b, miR-93 and miR-25 expression were calculated. Kaplan-Meier overall and disease-free survival rates of HBV-associated HCC patients were analyzed using the log-rank test based on miR-106b expression. The comparison of the miR-106b expression levels in patients with different clinical outcomes was analyzed using Mann-Whitney *U* tests. Furthermore, a hepatitis B virus X protein (HBx) expression plasmid was transfected into Huh7 and Hep

3B cells. The expression levels of the miR-106b-25 cluster and MCM7 in HBx-expressing Huh7 and Hep 3B cells were detected using q-RT-PCR.

RESULTS: miRNA array screening showed that miR-106b and its cluster, miR-93 and miR-25 were up-regulated in HCC patients ($P < 0.01$). The value of miR-106b expression in HBV-associated HCC patients was significantly higher than that in HCV- ($P < 0.05$) or non-B/non-C- ($P < 0.001$) associated HCC patients. The expression of the miR-106b-25 cluster was significantly higher in tumor tissue ($P < 0.001$) and associated with the host gene, MCM7, in clinical specimens from HBV-associated HCC patients. Furthermore, the expression levels of miR-106b, miR-93 and miR-25 were positively correlated in HBV-associated HCC tissues (miR-106 *vs* miR-93, $r = 0.75$; miR-93 *vs* miR-25, $r = 0.69$; miR-106b *vs* miR-25, $r = 0.33$). The overall and disease-free survival curves showed that high-miR-106b expression was correlated with the poor prognosis of HBV-associated HCC. HCC differentiation was significantly correlated with miR-106b expression ($P < 0.05$). Lower miR-106b expression levels resulted in the well differentiation of HCC. Moreover, the expression of the miR106b-25 cluster and MCM7 was up-regulated in Huh7 and Hep 3B cells after transfection with the HBx expression plasmid.

CONCLUSION: The data obtained in the present study suggests that HBx enhances miR-106b transcription to promote tumor progression in HBV-associated HCC.

Key words: miR-106b; Hepatitis B virus; Hepatocellular carcinoma; Tumor progression; Hepatitis B virus X protein

Core tip: The role of miR-106b in tumor progression of hepatitis B virus (HBV)-associated hepatocellular carcinoma (HCC) and how it be regulated are still unclear. In this study, we analyzed the expression levels of miR-106b in HBV-associated HCC tissues and correlated the data with clinical records of patients. Our results indicated that miR-106b expression was up-regulated and related with tumor progression in HBV-associated HCC. In addition, hepatitis B virus X protein may contribute to enhance the transcription of miR-106b. These findings provide potential diagnostic and therapeutic targets for HBV-associated HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) ranks among the 10 most common cancers in the world and is a major cause of cancer death in Southeast Asian countries[1,2]. The carcinogenesis of HCC is a multi-factor, multi-step and complex process, associated with chronic and persistent hepatitis B virus (HBV) infection[3,4]. Chronic hepatitis infection causes liver inflammation damage, subsequent fibrosis, liver cell regeneration and liver cell proliferation leading to the malignant transformation of the liver[5]. Most HCC patients die as a result of the rapid tumor progression and hepatic resection or transplantation is the only potential curative treatment for HCC patients when the HCC is diagnosed early[6]. However, the effective diagnostic and therapeutic targets remain unclear.

Several mechanisms of HBV-related tumorigenesis have been proposed[5]. HBV X (HBx) protein has recently been implicated as an oncoprotein in HBV-related tumorigenesis and HCC progression[7,8]. Previous studies have shown that HBx modulates cytoplasmic signal transduction pathways, such as Ras/Raf-1, through the transactivation of cellular signaling molecules to promote HCC proliferation[9].

MicroRNAs (miRNAs) are small non-protein coding gene (19-22 or 19-25 nucleotides) with important role in the regulation of gene expression at the post-transcriptional level[10]. Studies have demonstrated that miRNA plays a role in the regulation of fundamental cellular processes, including development and proliferation, cell fate determination and apoptosis[10,11]. Nearly 60% of human genes are controlled through miRNAs[11]. Several studies have shown that miRNA might affect on numerous types of cancer, and the dysregulation of miRNA has been associated with certain cancer types[11-14]. The dysregulated miRNA promotes or suppresses tumorigenesis through the down-regulation tumor suppressor gene or oncogene expression[15,16]. The miR-106b-25 polycistron is located within intron 13 of the minichromosome maintenance protein 7 (MCM7) genes on chromosome 7q22.1[17]. The results of previous sequence study indicated that miR-106b-25 is homologous with the known oncogene miR-17-92[18]. Previous studies have shown that the miR-106-25 cluster is overexpressed as a group of oncogenic miRNAs in many cancer types including prostate cancer, breast cancer, and gastric cancer[14,19-21]. MCM7, the host gene of the miR-106b-25 cluster, belongs to a family of the minichromosome maintenance (MCM) complex, comprising six replication proteins including MCM2, MCM3, MCM4, MCM5, MCM6 and MCM7 (termed MCM2-7). Previous studies have implicated MCM7 in the replication licensing and synthesis of DNA[22,23]. The expression of MCM7 can be a prognostic indicator in diverse cancers, such as prostate cancer, ovarian cancer, endometrial cancer,

Table 1 Characteristics of hepatocellular carcinoma patients in the present study[1]

Characteristics	Patient numbers *n* (%)

[1]A total of 120 hepatocellular carcinoma (HCC) patients were divided into two cohorts. A total of 12 HCC patients with distinct types of HCC were included in the 1st cohort, and the remaining 108 hepatitis B virus (HBV)-associated HCC patients were enrolled in the 2nd cohort.

etc[24-26]. Moreover, the dysregulation of MCM7 might be involved in tumor development and associated with the miR-106b-25 cluster.

In the present study, we analyzed the expression levels of miR-106b in HBV-associated HCC tissues and correlated the data with the clinical records of patients to clarify the role of miR-106b in tumor progression and regulation in HBV-associated HCC. These results indicated that miR-106b expression is up-regulated and associated with tumor progression in HBV-associated HCC. In addition, HBx might enhance miR-106b transcription. Thus, these findings highlight a potential diagnostic marker and a therapeutic target for HBV-associated HCC.

MATERIALS AND METHODS

Patients and HCC tissue

A total of 120 patients who underwent liver resection for HCC at the National Cheng Kung University Hospital from September 2012 to July 2015 were enrolled in the present study. Informed consent regarding use of specimens for this research was obtained from all patients and all protocols were reviewed and approved through the National Cheng Kung University Hospital Institutional Review Board. The patients were regularly followed up at clinical visits every 1 to 3 mo after curative surgery. The patients included 94 (78%) males and 26 (22%) females ranging in the age from 34 to 90 years (mean age 61.6 years). The median follow-up time was 35 mo (range, 1 to 118.8 mo). At the end of the follow-up, 25 patients had died of disease. HCC patients were divided into two study cohorts: 12 patients with distinct types of HCC were included in the 1st cohort to screen the miRNA expression profile using miRNA array, and the other 108 HBV-associated HCC patients were enrolled in the 2nd cohort for further analysis of the role of miR-106b in HBV-associated HCC. The characteristics of the HCC patients are listed in Table 1. The HCC tissue specimens were collected during surgery. The clinical records of the patients were retrospectively analyzed and correlated with the miRNA expression profiles. In the survival analysis, the mean of miR-106b level in adjacent non-tumor tissues was defined as the threshold (0.4 arbitrary unit from q-RT-PCR analysis). Samples with miR-106b expression levels higher than the threshold were classified into the "high-expression of miR-106b" group. Patients with levels lower than the threshold were classified into "low-expression of miR-106b" group. The overall and disease-free survival rates of patients were calculated using the Kaplan-Meier analysis.

Cells

Human hepatocellular carcinoma, Hep-3B 2.1-7 and Huh7 cells (American Type Culture Collection) were maintained in Dulbecco's modified Eagle's medium (DMEM, Hyclone) and minimum essential medium (MEM, Hyclone) containing 10% fetal bovine serum (FBS, GIBCO) and 100 IU of penicillin, 100 μg of streptomycin, and 0.25 μg of amphotericin B per milliliter, respectively. The cells were cultured in a humidified incubator with 5% CO_2 at 37 ℃.

RNA extraction and real-time RT-PCR

Total RNA was extracted using the RNeasy Plus Mini Kit (QIAGEN) according to the manufacturer's instructions. A total of 500 ng RNA was used to synthesize cDNA using a quantitative reverse transcription (RT) kit (Qiagen). The expression levels of miRNAs were analyzed using the TaqMan MicroRNA Assay Kit (Applied Biosystems) according to the manufacturer's instructions. The mRNA levels of human GAPDH and MCM7 were detected using the validated specific primers/probes of TaqMan Gene Expression Assays (Thermo Fisher Scientific) and the TaqMan Universal PCR Master Mix (Thermo Fisher Scientific). Real-time PCR assays were performed using the StepOne Real-Time PCR System (Applied Biosystems). The signals for miRNAs and inducible cellular MCM7 mRNAs were normalized to a small nuclear RNA, RUN48 and the mRNA signal of the housekeeping gene, human GAPDH.

Plasmid and transfection

The HBx protein expression plasmid was isolated and purified using the Plasmid Midi Kit (Qiagen). The Plasmid was transiently transfected into Hep-3B 2.1-7 and Huh7 cells using HyfectTM DNA transfection

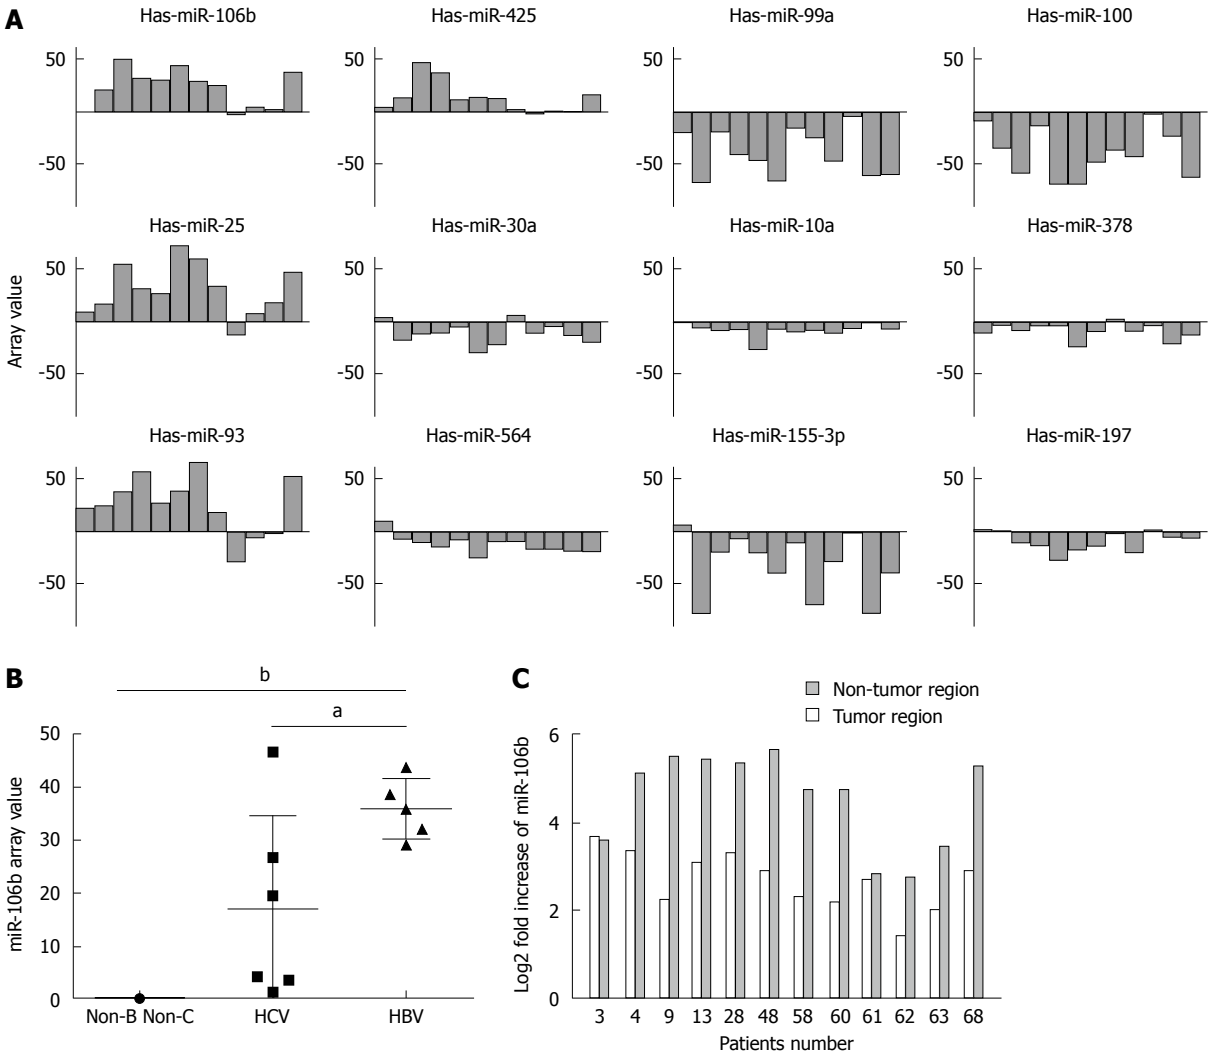

Figure 1 miRNA array analysis of the miRNA expression patterns in patients with distinct types of hepatocellular carcinoma (*n* = 12). A: The top 12 miRNAs significantly dysregulated in the tumor regions of hepatocellular carcinoma (HCC) patients based on statistical results ($P < 0.01$); B: miR-106b expression levels in tumor regions of patients with hepatitis B virus (HBV) -associated HCC, HCV-associated HCC, and non-B/non-C HCC; C: q-RT-PCR analysis of miR-106b expression values in the tumor and adjacent non-tumor regions of patients. Fold-increases were calculated after comparing the results with the miR-106b expression levels in normal liver samples. Data represent the mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.001$ *vs* HCV.

reagent (LEADGENE) according to the manufacturer's instructions. The expressions of HBx protein in the cell lines was confirmed using q-RT-PCR with HBx-specific primers/probe.

Statistical analysis

Statistical evaluation was completed using GraphPad Prism software version 5.01 (GraphPad, Inc., San Diego, CA, United States). The normal distribution of variables was assessed prior to selecting the tests to use for statistical analyses. The *W* value for the Shapiro-Wilk's method and the *D* value for the Kolomogorove method were used in the tests for normality. The values of miRNAs and MCM7 mRNA were analyzed using either the nonparametric one-way analysis of variance or unpaired *t* test, and the survival rates were analyzed using log rank analysis. The correlation between the patient outcomes and the miR-106b expression profiles were analyzed using Mann-Whitney *U* tests. The results are expressed as the mean ± SEM. A *P* value of less than 0.05 ($P < 0.05$, $P < 0.01$, $P < 0.001$) was considered significant.

RESULTS

miR-106b expression was up-regulated in HCC patients

Dysregulated miRNAs is a common characteristic of human tumors that could play an important role in oncogenesis or tumor suppression. To investigate the different miRNA expression profiles in HCC patients, we used miRNA array to analyze the miRNA expression patterns in 12 patients with distinct types of HCC including HBV-associated HCC, HCV-associated HCC, and non-B/non-C HCC in the 1st study cohort. The top 12 dysregulated miRNAs in HCC patients are listed in Figure 1A. miR-106b and the members of its associated cluster, miR-93 and miR-25 were up-regulated in HCC patients (Figure 1A). The value of

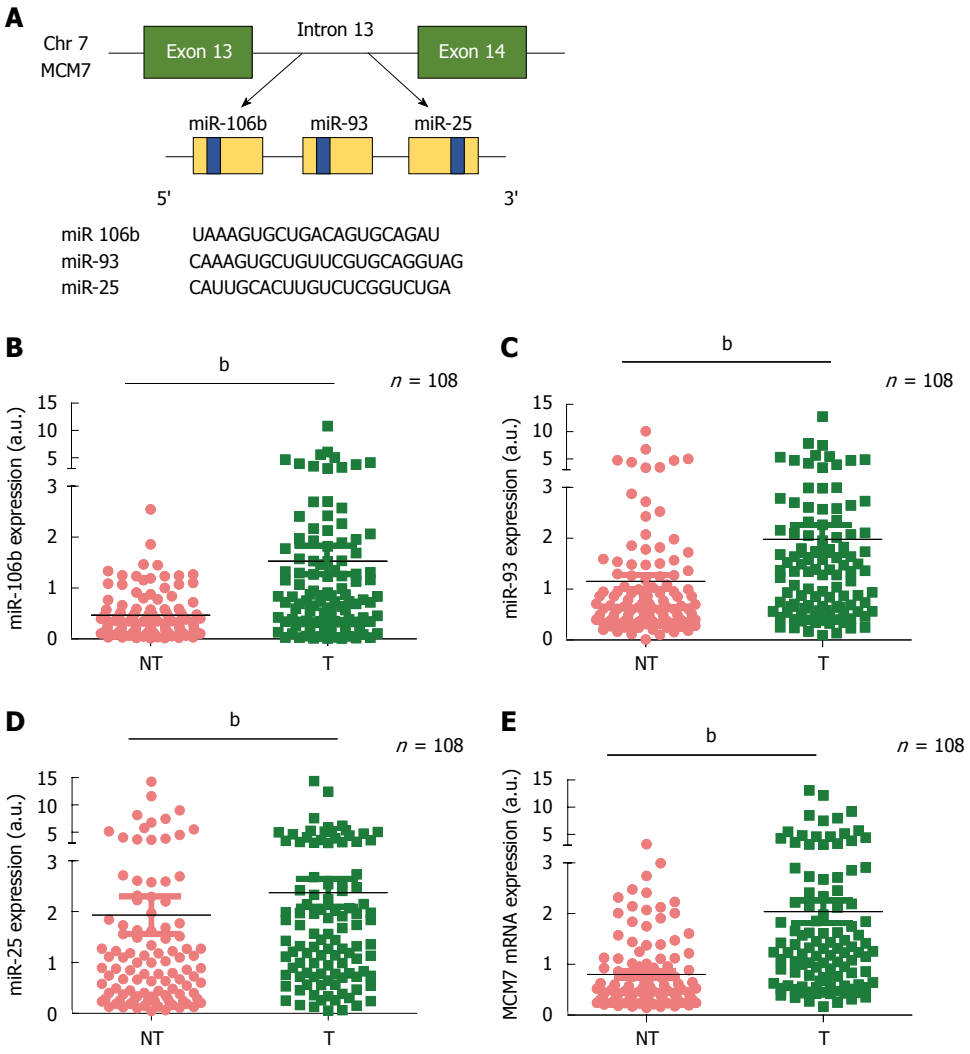

Figure 2 The mRNA expression levels of the miR-106b-25 cluster and MCM7 in tumor and non-tumor regions of hepatitis B virus-associated hepatocellular carcinoma patients (*n* = 108). A: Schematic representation of the miR-106b-25 cluster of miRNA (miR-106b, miR-93 and miR-25) within the 13th intron of the MCM7 gene. The yellow boxes represent pre-miRNAs. The blue boxes represent mature miRNAs; B-E: miR-106b (B), miR-93 (C), miR-25 (D), and MCM7 (E) expression levels in the tumor and non-tumor regions of hepatitis B virus (HBV)-associated hepatocellular carcinoma (HCC) patients, determined using q-RT-PCR. $^{b}P < 0.001$ NT *vs* T. a.u.: Arbitrary unit.

miR-106b expression in HBV-associated HCC patients was significantly higher than that in HCV- ($P < 0.05$) or non-B/non-C- ($P < 0.001$) associated HCC patients (Figure 1B). Furthermore, the levels of miR-106b expression in the 12 patients were confirmed using q-RT-PCR. In most cases, the values of miR-106b in the tumor regions were higher than in non-tumor regions (Figure 1C). These results indicated that miR-106b was significantly up-regulated in the tumor regions of HCC patients, particularly HBV-associated HCC patients.

miR-106b-25 cluster was co-transcribed with its host gene, MCM7 in HBV-associated HCC

miR-106b is located in an intergenic region embedded within intron 13 of the MCM7 gene in chromosome 7q22.1. This miRNA belongs to a cluster comprising miR-93 and miR-25 (Figure 2A). To determine whether the miR-106b promoter transcribes the associated gene or this gene is co-transcribed with the host gene, MCM7, Mass array EpiTyper was performed to detect the methylation landscape of MCM7 in the 12 patients. The results demonstrated that only the promoter and 3'-UTR of MCM7 could be detected within the methylation landscape suggesting that miR-106b is also co-transcribed with its host gene, MCM7 in HCC (data not shown). To further confirm whether the expression of miR-106b is higher in the tumor tissues of HBV-associated HCC patients, we expanded the sample size to 108 patients and validated the miRNA levels through q-RT-PCR in the 2nd study cohort. The results showed that the miR-106b levels were significantly higher in tumor tissues compared with normal tissues ($P < 0.001$) and this phenomenon was observed in more than 70% of HBV-associated HCC patients (Figure 2B). In addition, the expression of miR-93 and miR-25 was significantly up-regulated in the tumor tissues of HBV-associated HCC patients ($P <$

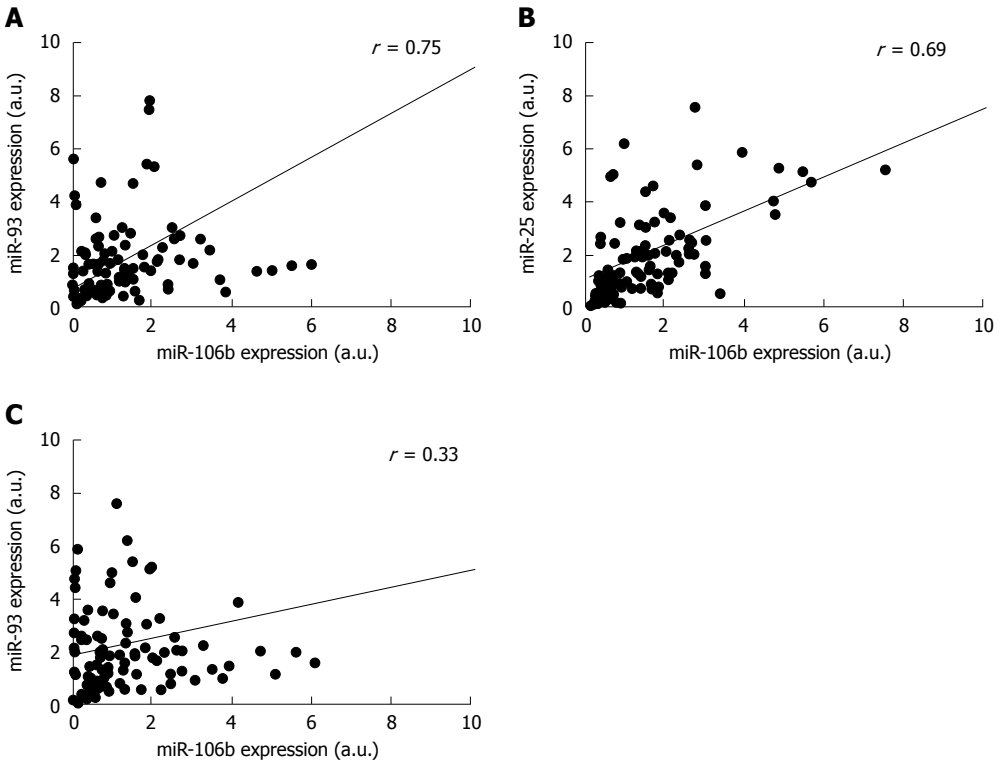

Figure 3 The correlation analysis miR-106b *vs* miR-93, miR-106b *vs* miR-25, and miR-93 *vs* miR-25 expression in tumor regions of patients with hepatitis B virus-associated hepatocellular carcinoma (*n* = 108). A: The correlation between miR-106b and miR-93 expression; B: The correlation between miR-106b and miR-25 expression; C: The correlation between miR-93 and miR-25 expression. Data represent the correlation coefficient (r). a.u.: Arbitrary unit. HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus.

0.001) (Figure 2C and D). The mRNA expression level of the MCM7 gene was also significantly increased in tumor regions compared with the adjacent non-tumor regions ($P < 0.001$) (Figure 2E). Furthermore, the expression of miR-106b, miR-93 and miR-25 showed a positive correlation in HBV-associated HCC tissues (miR-106 *vs* miR-93, $r = 0.75$; miR-93 *vs* miR-25, $r = 0.69$; miR-106b *vs* miR-25, $r = 0.33$) (Figure 3A-C). These results indicated that the miR106b-25 cluster is up-regulated in the tumor regions and co-transcribed with its host gene, MCM7 in HBV-associated HCC.

Up-regulation of miR-106b expression corresponds with decreased survival time in HBV-associated HCC patients

We further evaluated the relationship between the miR-106b expression and clinical outcomes in HBV-associated HCC patients; the patients were divided into two groups, high miR-106b expression and low miR-106b expression and the overall and disease-free survival rates in these two groups were analyzed. The data showed a negative correlation between the miR-106b expression level and survival time of HBV-associated HCC patients (Figure 4A and B). Relatively poor overall and disease-free survival rates were observed for the individuals in the high miR-106b expression group (overall survival in the 5th year: 65%; disease-free survival in the 5th year: 40%) compared with the low miR-106b expression group (overall survival in the 5th year: 93%; disease-free survival in the 5th year: 57%) ($P < 0.05$). These results demonstrated that poor prognosis is correlated with HBV-associated HCC patients with higher miR-106b expression.

miR-106b expression levels are correlated with HCC differentiation

The demographic and clinical features of patients were retrospectively analyzed and correlated with the miR-106b expression profiles to determine the specific features associated with miR-106b expression. HCC differentiation but not underlying liver disease, microvascular invasion, tumor number, tumor size, recurrence after surgery, and pathological staining were significantly correlated with miR-106b expression (Table 2). The miR-106b expression level in patients with well HCC differentiation (2.24 ± 0.44 a.u.) was significantly lower than that in patients with moderate (5.32 ± 1.00 a.u.) and poor HCC differentiation (4.85 ± 1.02 a.u.) (well *vs* moderate, P=0.0359; well *vs* poor, P=0.0145). These results indicated that low levels of miR-106b expression result in well HCC differentiation.

HBx promotes miR-106b expression in HCC cells

Next, we investigated the mechanism of how miR-106b expression is regulated in HBV-associated HCC. HBx protein is necessary for HBV replication and acts as a trans-activator for the modulation of the signaling

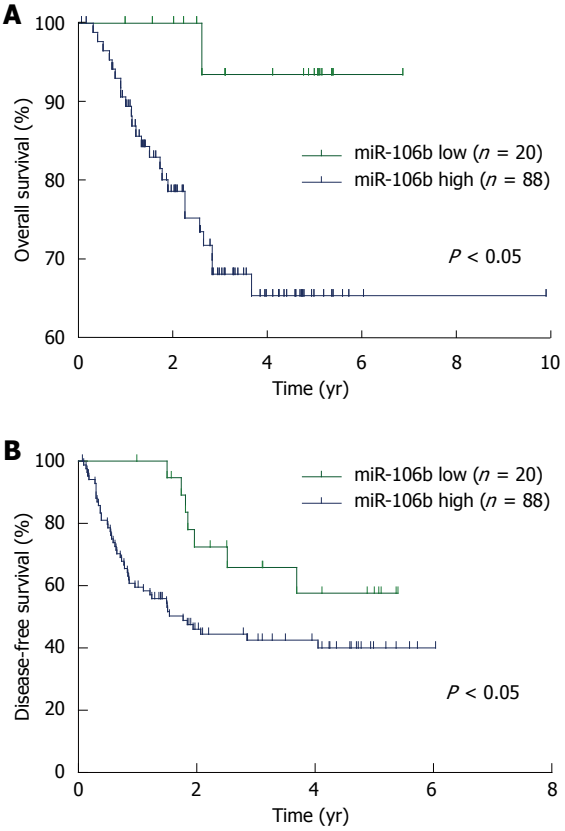

Figure 4 Kaplan-Meier overall and disease-free survival curve of patients with hepatitis B virus-associated hepatocellular carcinoma based on miR-106b expression (*n* = 108). Hepatitis B virus (HBV)-associated hepatocellular carcinoma (HCC) patients were divided into two groups including miR-106b low (*n* = 20) and miR-106b high (*n* = 88) groups based on the expression levels of miR-106b. A: Overall survival curve; B: Disease-free survival curve. Log-rank test was used for statistical analysis. $P < 0.05$ was considered significant.

pathways involved in the HBV replication and HCC development. To determine whether HBx protein contributes to the regulation of miR-106b expression in HBV-associated HCC, we used an HBx protein over-expression system. Huh7 and Hep 3B cells were transiently transfected with an HBx-expression plasmid, and subsequently the expression levels of the miR-106b-25 cluster and MCM7 were analyzed. The levels of miR-106b, miR-93, and miR-25 were significantly increased (all $P < 0.05$), peaking at 6 h post transfection in both Huh7 and Hep 3B cells (Figure 5A and B). The MCM7 mRNA levels were also gradually increased after 6 h post transfection compared with the un-transfected control group in both Huh7 ($P < 0.01$) and Hep 3B ($P < 0.05$) cells (Figure 5C and D). These results suggested that the HBx protein might contribute to the up-regulation of the miR-106b-25 cluster and MCM7 in HBV-associated HCC.

DISCUSSION

HCC ranks as the third leading cause of cancer-related deaths worldwide with increasing cases in many countries[1,27]. Increasing evidence has shown that many miRNAs are dysregulated in HCC and play a crucial role in the development of HCC by affecting cell proliferation, apoptosis, migration, *etc*[28]. Therefore, the identification of a key miRNA associated with tumor progression in HCC could provide an accurate marker for diagnosis and a new direction for a novel therapeutic approach. In the present study, we found that miR-106b plays an important role in tumor progression in HBV-associated HCC.

Recent studies have demonstrated that several miRNAs are involved in the life cycle and infectious processes of HBV and HBV-associated liver diseases, including fibrosis, cirrhosis and HCC[29,30]. Herein, we observed the up-regulation of the miR-106b-25 cluster in HCC, particularly in HBV-associated HCC. The expression of miR-106b, miR-93 and miR-25 was positively correlated in HBV-associated HCC tissues, consistent with the results of previous study showing a similar correction pattern in gastric cancer, suggesting the co-transcription of miR-106b-25 in biosynthesis[31]. Interestingly, the correlation coefficients between each other were not consistent, indicating that additional mechanisms might be involved in the regulation of miRNA expression. Notably, the up-regulation of

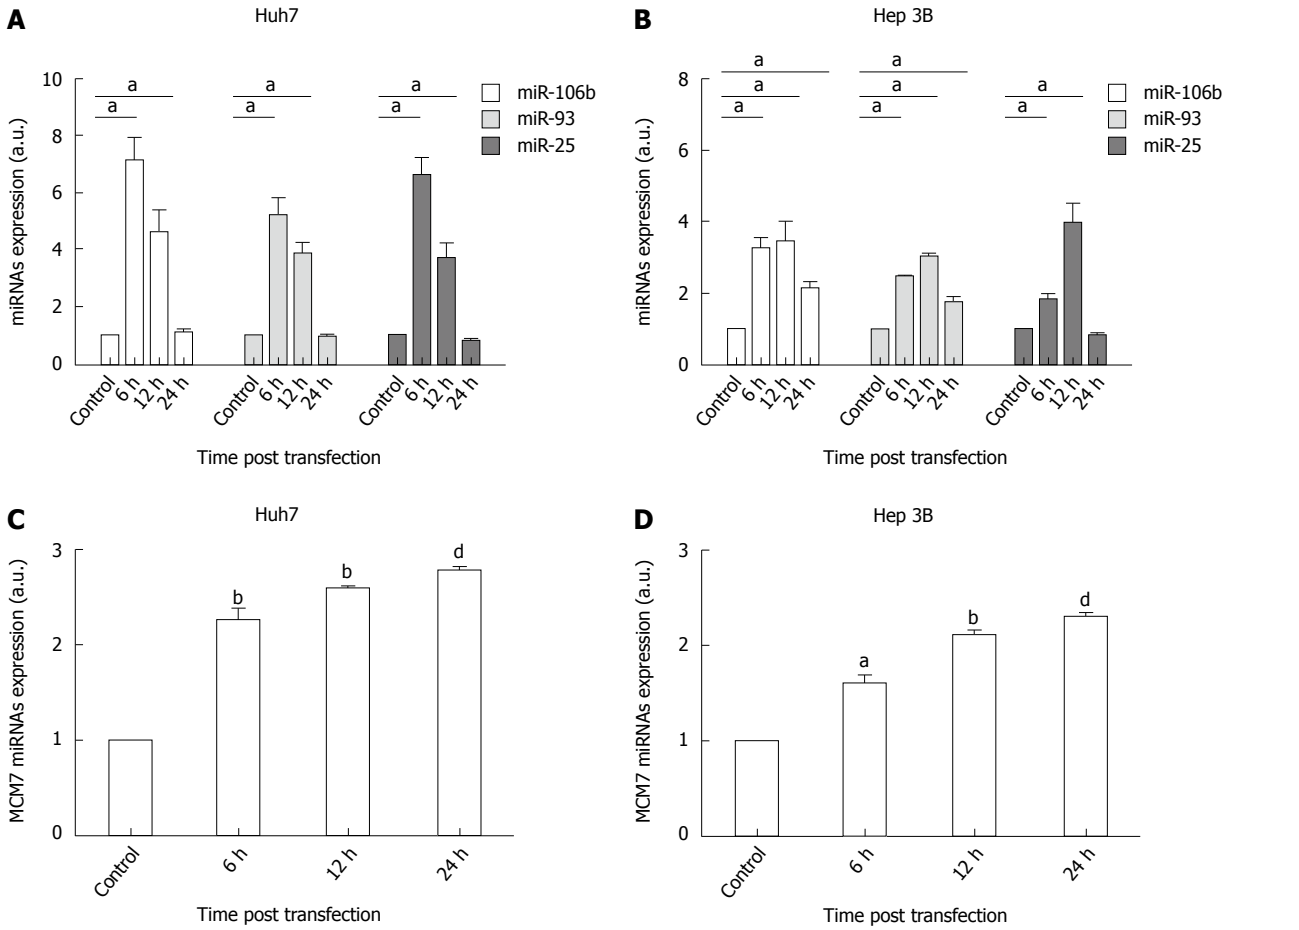

Figure 5 The mRNA expression levels of miR-106b-25 cluster and MCM7 in hepatitis B virus X protein-transfected hepatocellular carcinoma cell lines (*n* = 3). The hepatitis B virus X protein (HBx) protein expression plasmid was transiently transfected into Huh7 and Hep-3B cells. miR-106b, miR-93, miR-25, and MCM7 expression levels at 0 (control), 6, 12, and 24 h post transfection were detected using q-RT-PCR. A: miRNAs expression levels in HBx-transfected Huh7 cells; B: miRNAs expression levels in HBx-transfected Hep-3B cells; C: MCM7 expression levels in HBx-transfected Huh7 cells; D: MCM7 expression levels in HBx-transfected Hep-3B cells. Data represent the mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{d}P < 0.001$ *vs* control. a.u.: Arbitrary unit. HCC: Hepatocellular carcinoma.

miR-106b but not miR-93 and miR-25 expression corresponds to decreased survival times, increased recurrence rates and HCC differentiation in HBV-associated HCC patients (data not shown). This effect might reflect the different biological functions of individual miRNAs. Previous studies have indicated that miR-106b and miR-93 directly target the cell-cycle inhibitor, CDKN1A (p21), and miR-25 inhibits cell apoptosis through the down-regulation of a the pro-apoptotic gene, *BCL2L11* (Bim), in gastric cancer[31]. Other studies have shown that miR-106b is not only involved in cell cycle inhibition but might also play an anti-apoptosis role in cancer cells[32]. The data obtained in the present study, support the idea that miR-106b has a greater effect on promoting tumor progression compared with the other members in the same cluster.

However, HBV-associated protein regulates the expression of several miRNAs to assist with viral replication and survival and HCC development[33,34]. In a previous study, we showed that HBx protein up-regulates mTOR signaling through IKKβ to increase cell proliferation and VEGF production in HCC[35]. Furthermore, HBx protein is highly expressed in the cytoplasm of hepatocytes after HBV infection, thereby promoting tumorigenesis through the induction of mitochondrial dysfunction, involving several signaling pathways associated with tumorigenesis through the regulation of non-coding RNAs (ncRNAs) and epigenetic changes[8,34,36]. The results of present study showed that HBx over-expression promoted the transcription of miR-106 in HCC cell lines. This finding might explain why miR-106b was remarkably up-regulated in HBV-associated HCC but not in other types of HCC. However, the precise regulatory mechanism of HBx in miR-106b expression should be further investigated.

Based on these results, the miR-106b-25 cluster was co-transcribed with its host gene, MCM7 in HBV-associated HCC. Previous studies have indicated that MCM proteins are involved in critical steps of DNA synthesis[37]. MCM proteins bind to DNA replication origins during the initiation step, and subsequently the MCM proteins provide the helicase activity to unwind the template DNA ahead of the fork for DNA elongation. In primary gastric tumors and normal mucosa, the mRNA expression of MCM7 is precisely

correlated with the expression of the miR-106b-25 cluster[18]. The detailed regulatory mechanism between miR-106b-25 and MCM7 and whether MCM7 is involved in the miR-106b-mediated influence on HBV-associated HCC need to be further examined.

In conclusion, the results of present study indicate that miR-106b is up-regulated and co-transcribed with its host gene MCM7 in HBV-associated HCC. The up-regulation of miR-106b expression corresponds with a decrease in survival time, and an increase in the recurrence rate and HCC differentiation in HBV-associated HCC patients. Furthermore, HBx over-expression increased the RNA levels of the miR-106b-25 cluster and MCM7 in human hepatocellular carcinoma cell lines. These results suggest that HBx enhances the transcription of miR-106b to promote tumor progression in HBV-associated HCC. These findings provide a potential diagnostic marker and therapeutic target for HBV-associated HCC.

COMMENTS

Background

MicroRNAs (miRNAs) are involved in the progression of numerous types of cancers. Chronic hepatitis B virus (HBV) infection is one of the major risks for hepatocellular carcinoma (HCC), and through the regulation of miRNA expression, the virus promotes carcinogenesis in HCC.

Research frontiers

HBV infection not only induces liver inflammation but also produces viral oncoproteins to influence HCC progression. Previous studies have reported that many miRNAs are dysregulated in the HBV-associated HCC. However, the role of miRNA in tumor progression and regulation remains unclear. In the present study, the authors report that the hepatitis B virus X protein (HBx) protein enhances miR-106b expression to promote HCC progression.

Innovations and breakthroughs

Previous studies regarding the role of miRNA in tumors are limited in the use of correlation analyses and use small-scale cohort studies to address this issue. In addition, the function of the HBx protein in HCC progression is controversial. This work represents the first large-scale cohort study demonstrating that the miR-106b-25 cluster and its host gene, MCM7, are overexpressed in HBV-associated HCC. The results also suggest that the HBx protein enhances miR-106b transcription to promote tumor progression.

Applications

Because miR-106b is up-regulated in patients with HBV-associated HCC and correlates with poor disease outcome, these finding could provide a novel diagnostic marker and a therapeutic target for HBV-associated HCC.

Peer-review

In this manuscript the authors investigated the effect of miR-106b on tumor progression in HBV-associated HCC in a clinical model. This study provides evidence that enhanced transcription of miR-106b with its host gene MCM7 in HBV-associated HCC is associated with tumor progression and poor outcome. This study is well designed and the results are acceptable to draw the conclusions stated herein.

Abstract

AIM: To investigate the anti-proliferation and radiosensitization effect of chitooligosaccharides (COS) on human colon cancer cell line SW480.

METHODS: SW480 cells were treated with 0, 1.0, 2.0, 3.0, 4.0 and 5.0 mg/mL of COS for 48 h. CCK-8 assay was employed to obtain the cell survival ratio of SW480 cells, and the anti-proliferation curve was observed with the inhibition ratio of COS on SW480 cells. The RAY + COS group was treated with 1.0 mg/mL of COS for 48 h, while both the RAY and RAY+COS groups were exposed to X-ray at 0, 1, 2, 4, 6 and 8 Gy, respectively. Clonogenic assay was used to analyze cell viability in the two groups at 10 d after treatment, and a cell survival curve was used to analyze the sensitization ratio of COS. The RAY group was exposed to X-ray at 6 Gy, while the RAY+COS group was treated with 1.0 mg/mL of COS for 48 h in advance and exposed to X-ray at 6 Gy. Flow cytometry was employed to detect cell cycle and apoptosis rate in the non-treatment group, as well as in the RAY and RAY + COS groups after 24 h of treatment.

RESULTS: COS inhibited the proliferation of SW480 cells, and the inhibition rate positively correlated with the concentration of COS ($P < 0.01$). Cell viability decreased as radiation dose increased in the RAY and RAY+COS groups ($P < 0.01$). Cell viabilities in the RAY+COS group were lower than in the RAY group at all doses of X-ray exposure ($P < 0.01$), and the sensitization ratio of COS on SW480 cells was 1.39. Compared with the non-treatment group, there was a significant increase in apoptosis rate in both the RAY

and RAY + COS groups; while the apoptosis rate in the RAY+COS group was significantly higher than in the RAY group ($P < 0.01$). In comparing these three groups, the percentage of G_2/M phase in both the RAY and RAY + COS groups significantly increased, and the percentage of the S phase and G_0/G_1 phase was downregulated. Furthermore, the percentage in the G_2/M phase was higher, and the percentage in the S phase and G_0/G_1 phase was lower in the RAY + COS group *vs* RAY group ($P < 0.01$).

CONCLUSION: COS can inhibit the proliferation of SW480 cells and enhance the radiosensitization of SW480 cells, inducing apoptosis and G_2/M phase arrest.

Key words: Chitooligosaccharides; Cancer of colon; Radiotherapy; Radiosensitization; Apoptosis; Cell cycle

Core tip: In this study, the colorectal cancer cell line SW480 that is homologous with colon-rectum was used as the research tool. It was confirmed that chitooligosaccharides (COS) not only directly blocked SW480 cell proliferation, but also enhanced radiotherapy effects. Furthermore, COS induced a large amount of SW480 cell apoptosis, and induced a large number of cells to remain in the G2/M phase with radiation-sensitive killing effect. Thus, the sensitivity of SW480 cells to radiation was effectively enhanced 1.39 times. This is beneficial for the therapeutic effect.

INTRODUCTION

According to the latest Chinese cancer epidemic profile survey, the 2010 cancer morbidity and mortality rates in China were 235.23/100000 and 148.81/100000, respectively. Among these cancers, colorectal cancer incidence and mortality have shown an obvious predominantly evident upward trend again, causing this to be the focus of medical experts[1-4]. In China, colorectal cancer has a prevalence of 16.14%, allowing a leap up to fifth place among cancers; and the incidence in males is as high as 18.75%. In 2012, over 250000 colorectal cancer cases were added nationwide; this total accounts for 18.6% in the world[5,6]. China has become a big focus at the forefront of colorectal cancer research, since efficient and low toxicity treatments are needed. Since the discovery of radiation, radiotherapy has lasted for centuries as the main indispensable weapon against cancer that is active in clinic. Statistics have shown that more than 70% and 50% of cancer patients are in need of this kind of therapy in China and the United States, respectively[7,8]. Although radiotherapy has great significance for cancer treatment, killing cancer cells could injure healthy tissues, causing malignant complications. This has been a researcher's hurdle that is difficult to bypass. However, radiosensitizers then emerged as a necessity of the times. Chitooligosaccharides (COS) are products of chitin, having good solubility and a high absorption rate, making the ratio of the carbohydrate polymer more advantageous for biological applications; and they have become the new favorite of medical researchers[9,10]. Although there have been many reports about COS anticancer effects[11-14], there are few studies on the applications of radiation sensitization. In this study, human colon cancer SW480 cells were selected and treated with COS application in parallel with radiation, to verify that COS can enhance radio sensitivity for colorectal cancer cell line; this is reported below. We expect to further explore this superior and low-damage anticancer therapies.

MATERIALS AND METHODS

Seven COS concentration levels were established and 3-hole samples were simultaneously cultured in parallel with each level SW480 cells were subcultured to the logarithmic phase (human colon cancer cells SW480; Shanghai Cell Institute of Chinese Academy of Sciences). After digestion, the cells were diluted to a concentration of 5×10^4 cells/mL according to the 0.1 mL/hole access in a 96-well plate. A suitable environment was set (CO_2 incubator, Shanghai Gemtop Scientific Instrument CO.,Ltd.) for adherent growth, and diluted COS (Chitooligosaccharides, Shanghai Huich Biotech Inc.) was replaced after 24 h with fresh medium at 0.11 mL/hole, and added into each well at COS concentrations of 0, 0.5, 1.0, 2.0, 3.0, 4.0 and 5.0 mg/mL After 48 h of COS application, CCK-8 reagent (CCK-8 Kit, Shanghai Liruibio Technology Co., Ltd.) was added along the pore walls at 0.01 mL/hole. Then, the culture plate was tapped to mix reagent and culture medium. After four hours of sufficient reaction, OD absorbance at $\lambda = 450$ nm was detected at all levels. The experiment was repeated three times to investigate the inhibitory effect of COS on SW480 cell proliferation. Accordingly, 1.0 mg/mL of COS concentration was selected for follow-up studies.

Six X-ray dose levels were established and levels were divided into the RAY group and RAY+COS group; each group was simultaneously cultured in parallel with the 3-hole sample. According to 0-, 1- and 2-Gy dose levels at 200/well, 4- and 6-Gy dose levels at 400/well, and 8-Gy dose level at 800/well inoculation amounts, respectively, different concentrations of single-cell suspensions in 6-well culture plate were set in an incubator with a suitable environment for growth

Table 1 Inhibition of chitooligosaccharides for the proliferation of SW480 cells

COS concentration (mg/mL)	OD (mean ± SD)	Inhibition rate
0	1.019 ± 0.007	-
0.5	0.969 ± 0.005[1]	4.91%
1.0	0.908 ± 0.008[2]	10.89%
2.0	0.804 ± 0.006[3]	21.10%
3.0	0.692 ± 0.007[4]	32.09%
4.0	0.580 ± 0.006[5]	43.08%
5.0	0.433 ± 0.008[6]	57.51%
P	0	-
F	137.6	-

Compared with COS concentrations in the 0 mg/mL Group: [1]P = 0.000, q = 17.437; [2]P = 0.000, q = 31.326; [3]P = 0.000, q = 80.047; [4]P = 0.000, q = 99.096; [5]P = 0.000, q = 142.849; [6]P = 0.000, q = 165.379. COS: Chitooligosaccharides.

adherence. After six hours, appropriate amounts of COS were added into each well to reach a 1.0 mg/mL concentration in the RAY + COS group, while equal amounts of infiltrating medium were added into each hole and cultured for 48 h in the RAY group. Both groups were stamped with 1-cm thick tissue analogs in the culture plates and X-ray irradiated (Electron linear accelerator, Nanjing Chuang Rui Ying Biotechnology Co., Ltd.) at a distance of 100 cm with a dose rate of 2 Gy/min. Incubation continued for 10 d, the cells were washed, fixed and stained again; then, the number of cells were counted as 50 or more units of cell clusters. The experiment was repeated three times for statistical data, and the cell survival curve was draw up from the final slope of the D_0 value obtained by sensitizing ratio SER = $D_{0\,(RAY)}/D_{0\,(RAY+COS)}$.

The three groups were established simultaneously in parallel with the 3-hole samples. The concentration of 1 × 10^5/mL cell suspension was inoculated into 6-well culture plate with a suitable growth-adherent environment for 24 h. In the RAY + COS group, the correct amount of COS was added to reach a 1.0 mg/mL concentration. In the non-treatment group and RAY group, equal amounts of medium were added. In the RAY group and RAY + COS group, infiltration was carried out for 48 h and samples were exposed to 6-Gy X-ray irradiation. After replacing with fresh medium, cells were cultured for 48 h. After digestion, rinsing, dilution and other treatments were performed to determine the cell cycle stage and extent of apoptosis in each group.

Statistical analysis

Using SPSS19.0 statistical software for statistical analysis, OD value, survival rate, apoptosis rate and cell cycle distribution ratios were presented as mean ± SD. OD values for each COS concentration level and cell survival rates at X-ray dose levels were compared among multiple groups using ANOVA analysis and compared between the two groups using SNK-q test. For the RAY group and RAY + COS group, cell survival rates under different X-ray doses, cell cycle control experiments among the three groups, and apoptosis rates between the three groups were compared by *t*-test. $P < 0.05$ was considered statistically significant.

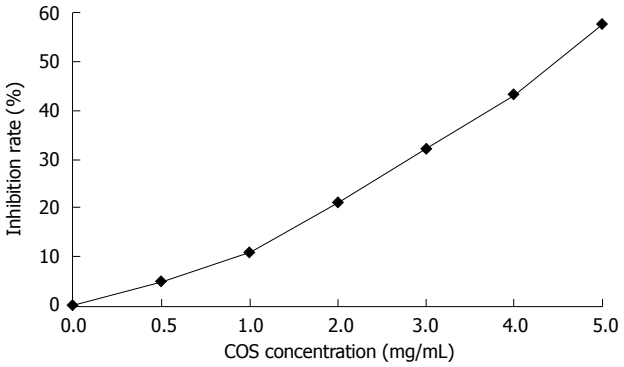

Figure 1 Inhibition curve of chitooligosaccharides for proliferation of SW480 cells.

RESULTS

Inhibitory effect of COS on SW480 cell proliferation

In comparing the COS concentration of the OD value in the 0 mg/mL group, OD values progressively reduced at all levels as COS concentration increased, and the difference was statistically significant ($P < 0.01$). After 48 h of treatment with 0.5, 1.0, 2.0, 3.0, 4.0 and 5.0 μmg/mL of COS concentration, SW480 cell survival rates were significantly lower than in the negative control group; and the differences were statistically significant ($P < 0.01$). The inhibition rate and the concentration of COS showed a positive correlation (Table 1, Figure 1).

Comparison of effects of different radiation dose on cell survival rate between groups

With an irradiation dose of 0 Gy as a reference standard, survival rate in the RAY and RAY + COS groups progressively reduced with increased radiation dose, and the difference was statistically significant ($P < 0.01$). The reduction in cell survival rate was greatest in the RAY + COS group. At dose levels 1, 2, 4, 6 and 8 Gy, survival rate in the RAY+COS group was significantly lower than in the RAY group, and the difference was statistically significant ($P < 0.01$). SER was 1.39 for COS in SW480 cells (Table 2, Figure 2).

Cell apoptosis rate between groups

Compared with proliferation in the non-treatment group, apoptosis rate in the RAY and RAY + COS groups increased sharply, the differences were statistically significant ($P < 0.01$). Apoptosis rate in the RAY+COS group also revealed a significant increase compared with the RAY group, and the difference was statistically significant ($P < 0.01$; Table 3, Figure 3).

Comparison of cell cycle distribution between groups

Compared with the non-treatment group, the proportion in G2/M phase in the RAY and RAY + COS

Table 2 Comparison of cells survival rates for different radiation doses between the RAY and RAY + COS group

Irradiation dose (Gy)	Cell survival rate (%)	
	RAY	RAY + COS
0	99.22 ± 3.51	99.17 ± 4.06[1]
1	90.67 ± 3.82	85.30 ± 3.38[2]

4	45.95 ± 3.41	28.64 ± 2.76[4]
6	23.84 ± 2.20	12.53 ± 2.03[5]
8	8.68 ± 1.75	3.81 ± 1.16[6]
P	0	0
F	182.7	243.2

Compared with RAY group: [1]P = 0.978, t = 0.028; [2]P = 0.006, t = 3.158, [3]P = 0.000, t = 11.619; [4]P = 0.000, t = 11.837; [5]P = 0.000, t = 11.335; [6]P = 0.000, t = 6.959. COS: Chitooligosaccharides.

Table 3 Comparison of cell apoptosis rates among the three groups

Groups	Cell apoptosis rate
Non-treatment group	1.79 ± 0.37
RAY group	9.33 ± 1.05[1]
RAY + COS group	22.64 ± 1.27[2,3]

Compared with the control group: [1]P = 0.000, t = -20.318; [2]P = 0.000, t = -47.286; compared with the RAY Group: [3]P = 0.000, t = -24.232. COS: Chitooligosaccharides.

Table 4 Comparison of cell cycle distribution among the three groups

Groups	S (%)	G0/G1 (%)	G2/M (%)
Non-treatment group	30.15 ± 0.82	39.41 ± 1.05	30.44 ± 0.68
RAY group	22.48 ± 0.74[1]	30.51 ± 0.86[2]	47.01 ± 0.52[3]
RAY + COS group	18.89 ± 0.65[4,7]	24.34 ± 0.46[5,8]	56.77 ± 0.28[6,9]

Compared with the control group: [1]P = 0.000, t = 20.832; [2]P = 0.000, t = 19.672; [3]P = 0.000, t = -58.070; [4]P = 0.000, t = 32.283; [5]P = 0.000, t = 39.438; [6]P = 0.000, t = -107.412; compared with the RAY group: [7]P = 0.000, t = 10.935; [8]P = 0.000, t = 18.979; [9]P = 0.000, t = -49.577. COS: Chitooligosaccharides.

groups significantly increased, while the proportions in S and G0/G1 phase all reduced; the differences were statistically significant (P < 0.01). Compared with the RAY group, the proportions in S phase and G0/G1 phase in the RAY + COS group were smaller, while the G2/M phase was significantly longer; the differences were statistically significant (P < 0.01). See Table 4, Figure 4.

DISCUSSION

Rapid economic growth gives rise to the rapid development of science and technology. However, improvements in medical technology have failed in stopping cancer from affecting human health. Modern unhealthy diets and living habits stimulate and mainly cause the continuous rise in colorectal cancer

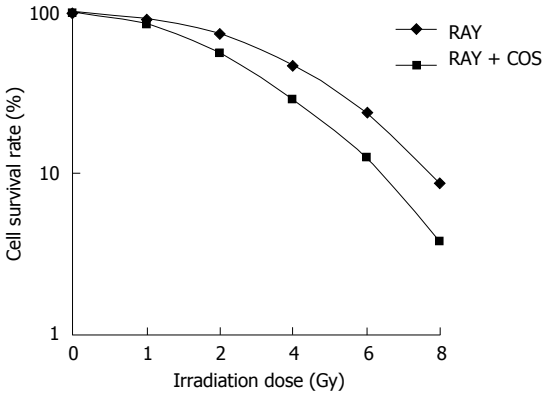

Figure 2 Cells survival rates at different radiation doses between the RAY and RAY + COS groups. COS: Chitooligosaccharides.

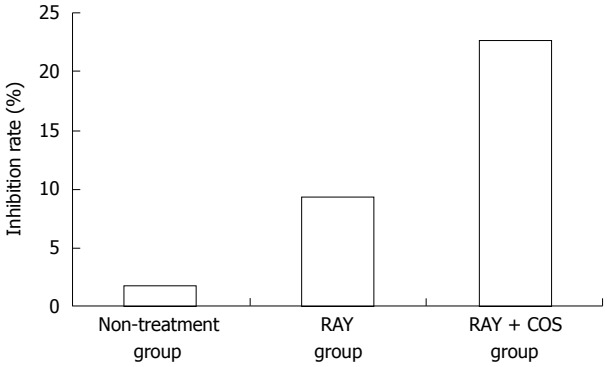

Figure 3 Cell apoptosis comparison between the three groups.

morbidity[15-17]. Statistical data from international cancer research institutions have indicated that China's 2012 annual new-onset cases of colorectal cancer reached 1.47 times that of cases in 2006, and the total incidence grew by nearly 50% in six years[18]. Regarding the incidence of colorectal cancer in China, the annual growth rate rose sharply to more than two times the international average[19]. This situation is not optimistic, and the exploration of more effective drugs and treatment without delay is of great significance.

Inhibitory effect of COS on proliferation of colon cancer SW480 cells

Derived from the depolymerization of chitosan, COS has been considered as the human healthy "almighty" guardian by the biomedical field. It can improve body acid-base balance, activate immune function, remove blood lipids, lower blood sugar, and regulate a variety of physiological activity[20-22]. Particularly, it has anti-tumor effects, which have been a research focus for domestic and foreign scholars in recent years. Based on historical reports, COS has a widespread growth-blocking effect on HL-60, RBL-2H3, SGC-7901 and tumor cell lines of other organs, and there are a variety of ways to achieve this effect[23-25]. In this study, the colorectal homologous colorectal SW480 cell line was the target. This study confirms that COS directly

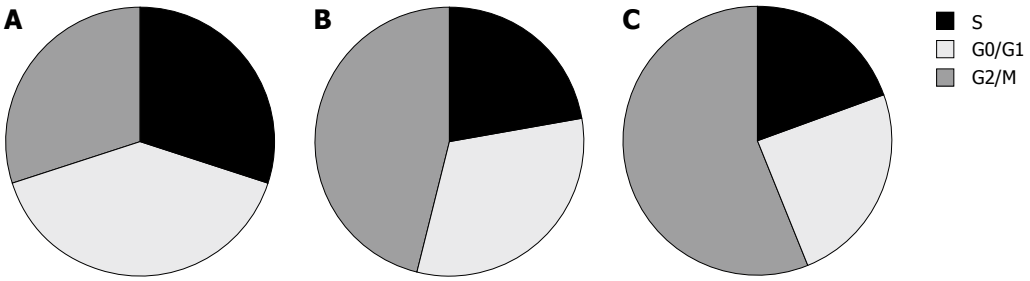

Figure 4 Comparison of cell cycle distribution among the three groups. A: Non-treatment group; B: RAY group; C: RAY + COS group. COS: Chitooligosaccharides.

blocks SW480 cell proliferation, and its inhibitory effect increases with the concentration of COS application showing increase in increments; 5 mg/mL of COS treatment for 48 h induced SW480 cell viability to decrease by 57.51%.

COS enhances SW480 cell sensitivity to radiation

Radiotherapy has an irreplaceable position in the treatment of cancer. It is widely used in various stages of the disease course; preoperatively it shrinks tumors to create conditions for radical enterectomy, it removes residues postoperatively to prevent recurrence, and it cooperates with chemotherapy to prevent metastasis. Early radiotherapy for nasopharyngeal carcinoma, skin cancer and cervical cancer has a possibility of more than 9% cure[26-28]. Early exposure to radiotherapy also can improve the 5-year survival rate from 70% to 80% for esophagus and prostate cancer[29,30]. Although radiotherapy has significantly prevents pain in patients with organ disease, there are also shortcomings. Radiation attack precision is limited, and often implicates normal tissue surrounding lesions, leading to tissue damage, which adds to the double burden of cancer patients both physically and mentally. This study found that X-rays have a mass destruction effect on SW480 cells, and cell death increased with radiation dose; while before radiotherapy, COS application obviously makes the cell survival rate decrease, COS can effectively increase SW480 cell sensitivity to radiation by 1.39 times. Furthermore, this controlled experiment has shown that the RAY + COS group had significantly improved treatment efficacy with the increase in apoptosis rate, and the cell cycle distribution changed significantly.

COS achieves radiosensitization by promoting SW480 cell apoptosis

Apoptosis maintains homeostasis in the body. However, it has an independent regulatory program that takes the initiative to open the "die" mode to conserve limited resources when cells are faced with adverse living conditions. Tumor cells lose this order of regulation and fall into a disordered and uncontrolled proliferation cycle. Radiation-induced apoptosis has been demonstrated for a long time[31-34]. COS combined with radiotherapy reverses the deactivation of the mechanism of apoptosis in a cancer cell to a greater degree, and pulls it back to its normal life trajectory. The complexity of the entire process of cell apoptosis involves cooperation of multiple genes and proteins. Krysko's research has indicated that COS can activate apoptosis promoter Caspase-3[35,36]. Tan believes that COS can damage mitochondrial membrane stability and release Cyt C into the cytosol[37]. Mates has also reported that COS can down-regulate environmental GSH activity and stimulate oxidative damage[38,39]. A number of conclusions have confirmed that COS has a positive effect on the apoptosis of tumor cells.

COS achieves radiosensitization by changing the SW480 cell cycle distribution

The mechanism of action of radiotherapy is to destroy DNA strand integrity including breaking the connection of ester bond sequences and destroying base modifications. From the initial point of its life cycle, radiotherapy blocks various physiological functions of the tumor cell and genetic information delivery[40,41]. Cell cycle distribution has a deep influence on radiotherapy[40,42-45]. Flow cytometry analysis revealed that COS treatment leaves a large number of SW480 cells stranded in the G2/M phase that is very sensitive to radiation, while reducing the G1 phase and S phase that are responsible for DNA damage repair, reducing the resistance of cancer cells to radiotherapy and enhancing its therapeutic effect. Radiation biological research pointed out that in order to ensure a smooth and orderly replication, the whole proliferation process speed is controlled at G1, S and G2 levels, respectively, by three regulatory processes[46-49], speculating that COS control in cell cycle distribution is most likely related to the start-up and expression of these three processes.

In summary, COS not only directly arrests SW480 cell growth, but also helps radiotherapy. COS induces SW480 cells apoptosis accompanied by a large number of proliferation process changes. Thus, this greatly enhances radiation lethality and has a beneficial therapeutic effect. In-depth exploration of COS as radiosensitizer is expected to bring a new dawn for the life of colorectal cancer patients.

COMMENTS

Background

Modern unhealthy diets and living habits are major causes that stimulate the prevalence of colorectal cancer to continue to soar. In China, colorectal cancer has a prevalence of 16.14%, which has clinically already leapt up to fifth place among cancers; and the incidence in males is as high as 18.75%. In 2012, over 250000 cases of patients were added nationwide; this total accounts for 18.6% in the world. China has become a big focus in the forefront of colorectal cancer research, and efficient and low toxicity treatments are needed. Although radiotherapy has great significance for cancer treatment, killing cancer cells could injure healthy tissues, causing malignant complications. This has been a researcher's hurdle that is difficult to bypass. Radiosensitizers have now emerged as a timely aid.

Research frontiers

In order to reduce the toxicity of radiotherapy, current research has focused on primarily two aspects: increase in the accuracy of positioning, and enhancement of radiation radiosensitivity of tumor tissues. Using radiation sensitizers has become popular because it is simple to apply. Previous studies have shown that radiosensitization mechanisms include improved cell hypoxia, increased DNA damage and influence of the cycle phase distribution. In addition to 5-fluorouracil, cisplatin and gemcitabine, the conventional radiotherapy sensitizers, C225, L-778-123 and COX-2 inhibitors and other new sensitizers have gained attention in recent years. Further interdisciplinary approaches have also started to introduce new drugs and new mechanisms of action in the field of radiation sensitizer agents.

Innovations and breakthroughs

Derived from the depolymerization of chitosan, COS has been considered as the human healthy "almighty" guardian by the biomedical field. It can improve body acid-base balance, activate immune function, remove blood lipids, lower blood sugar, and regulate a variety of physiological activity. Particularly, it has anti-tumor effects, which has been a research focus by domestic and foreign scholars in recent years. Based on historical reports, COS has a widespread growth blocking effect on HL-60, RBL-2H3, SGC-7901 and tumor cell lines of other organs, and there are a variety of ways to achieve this effect. Although there are many reports about COS anticancer effects, there are few studies on the applications of radiation sensitization. In this study, human colon cancer SW480 cells were selected and treated with COS application in parallel with radiation, to verify that COS can enhance radiosensitivity in colorectal cancer cell lines.

Applications

This study showed that chitooligosaccharides can effectively enhance the sensitivity of SW480 cancer cells to radiation; chitosan oligosaccharide combined with radiotherapy treatment would be helpful and promising for colorectal cancer. Regarding the effect of chitooligosaccharides on radiosensitization, an in-depth study would be expected to explore this efficient and low-damage anticancer therapeutic breakthrough.

Peer-review

This is a very interesting study about the chitooligosaccharide promotion of radiosensitivity in a colon cancer line. The study is well designed and the manuscript is well written.

Abstract

AIM: To explore the preventive and therapeutic effects of *Faecalibacterium prausnitzii* (*F. prausnitzii*) supernatant on dextran sulfate sodium (DSS) induced colitis in mice.

METHODS: Forty C57BL/6J male mice were randomly

divided into four groups: control group, model group, treatment group, and prevention group. Mice were weighed daily. On day 10, the colon length was measured, the colorectal histopathologic damage score (HDS) was assessed, and plasma interleukin (IL)-17A, IL-6, and IL-4 levels were detected by enzyme-linked immunosorbent assay. The expression of transcription factor retinoic acid-related orphan receptor-γt (RORγt) and IL-17A in colon inflammatory mucosa tissue were determined by immunohistochemical assay, and the expression levels of RORγt mRNA, IL-17A mRNA, and IL-6 mRNA were detected by real-time quantitative polymerase chain reaction (PCR). The proportion of Th17 in mononuclear cells in spleen was assayed by fluorescence activated cell sorter.

RESULTS: When compared with the model group, the colon length ($P < 0.05$) and body weight ($P < 0.01$) in the treatment and prevention groups were significantly increased, and the colon HDS was decreased ($P < 0.05$ and $P < 0.01$). There was no statistical difference between the treatment group and prevention group. After treatment with *F. prausnitzii* supernatant, the plasma levels of IL-17A and IL-6 ($P < 0.05$), the protein and mRNA expression of IL-17A and RORγt, and the Th17 cell ratio of spleen cells ($P < 0.01$) were significantly decreased compared to the model group. Plasma IL-4 level in the prevention group was significantly higher than that in the model group ($P < 0.05$), but there was no significant difference between these two groups in the expression of IL-6 in both the plasma and colon mucosa tissues.

CONCLUSION: *F. prausnitzii* supernatant exerts protective and therapeutic effects on DSS-induced colitis in mice, probably *via* inhibition of Th17 differentiation and IL-17A secretion in the plasma and colon mucosa tissues. It can also improve colitis in mice by downregulating IL-6 and prevent colitis by upregulating IL-4.

Key words: *Faecalibacterium prausnitzii*; Ulcerative colitis; Animal model; Th17 cell; Treatment; Prevention

Core tip: *Faecalibacterium prausnitzii* (*F. prausnitzii*) supernatant has anti-inflammatory and immune regulatory activity. This study showed that the preventive and therapeutic use of *F. prausnitzii* supernatant could ameliorate dextran sulfate sodium (DSS)-induced colitis in mice by inhibiting Th17 cell differentiation and inflammatory cytokines release.

INTRODUCTION

Inflammatory bowel diseases (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), are multifactorial ailments characterized by intestinal inflammation. Although the precise etiology and pathogenesis of IBD are not fully elucidated, multiple factors contribute to IBD, including genetic background, environment, intestinal flora imbalance, and immune disorder[1-4]. It has been hypothesized that an undesired intestinal mucosal immune response to intestinal flora imbalance contributes to the onset of IBD in genetically susceptible individuals.

A T helper (Th)17 cell is defined as a cell producing the cytokine interleukin (IL)-17A, but it also can secrete many other cytokines, such as IL-17F, IL-6, and IL-23, during an inflammatory response[5]. Th17 cells are characterized by the expression of the transcription factor retinoic acid-related orphan receptor (RORγt), and there is growing evidence that Th17 cells are paramount in the development of human autoimmune diseases, including IBD[6-8]. In the intestine of IBD patients, elevated numbers of Th17 cells and increased RORγt and IL-17 levels are found[9]. The differentiation of Th17 cells from naïve CD4+ T cells is known to be affected by multiple cytokines, such as transforming growth factor (TGF)-β, IL-6, IL-4, and IL-23[10,11]. IL-6 plays a key role in cooperating with TGF-β to initiate Th17 differentiation, while IL-4 inhibits Th17 differentiation.

Faecalibacterium prausnitzii (*F. prausnitzii*) is the major bacterium of the Clostridium leptum group, and is one of the most abundant anaerobic bacteria in the human gut[12]. *F. prausnitzii* plays an important role in maintaining the intestinal health and providing energy to the colonocytes[13]. A recent study indicated that *F. prausnitzii* levels were decreased in IBD patients compared with healthy controls[14]. Previously, we confirmed in animals that both the bacteria and its supernatant relieved trinitro-benzene-sulfonic acid induced colitis in rats[15]. Nevertheless, the specific mechanism is largely unclear.

Dextran sulfate sodium (DSS) induced colitis is a well-established animal model for IBD pathogenesis, and it has been used in preclinical studies for over two decades[16,17]. Furthermore, it has been shown that the clinical features and pathological changes of DSS-induced colitis in mice were similar to human UC[18]. Here, we determined whether the *F. prausnitzii* supernatant could relieve DSS-induced colitis in mice by reducing Th17 cells and inflammatory cytokines.

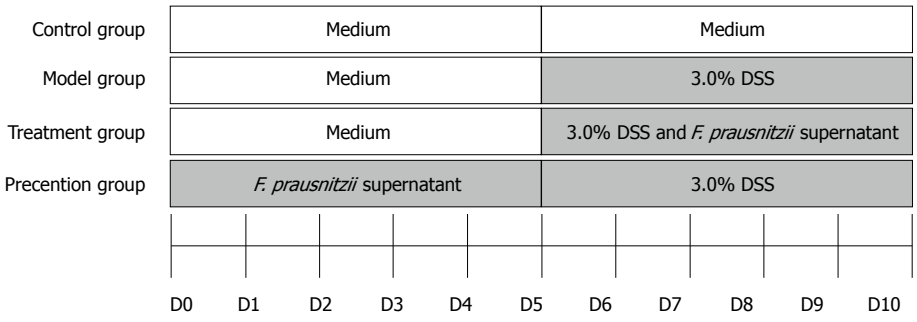

Figure 1 Flow diagram of the study design. DSS: dextran sulfate sodium; *F. prausnitzii*: *Faecalibacterium prausnitzii*.

MATERIALS AND METHODS

Animals

All experiments were approved by the Experimental Animal Ethical Committee of Nanjing Drum Tower Hospital, the Affiliated Hospital of Nanjing University Medical School. Forty male C57BL/6J mice aged 8-10 wk and weighing 18-22 g were obtained from the Animal Center, Nanjing Drum Tower Hospital (Nanjing, China). The mice were allocated equally and randomly to four groups: control group, model group, treatment group, and prevention group. The group divisible design is shown in Figure 1. The period of observation was 10 d. In the first 5 d, the mice in the prevention group were given supernatant of *F. prausnitzii* (five times concentrated, 0.1 mL/10 g) through gavage once a day, while the other groups received the same dosage of medium. For the next 5 d, all groups, except for the control group, were treated with 3.0% DSS in their drinking water *ad libitum*, the treatment group was fed *F. prausnitzii* supernatant by gavage once a day.

Mice were weighed daily and sacrificed by cervical dislocation at day 10. Colons were dissected, and the distance from cecum to anus was measured. The colon tissues were fixed in 4% formalin for later pathological examination and immunohistochemical study. The peripheral blood and spleen were isolated for testing Th17 cells and cytokines.

F. prausnitzii culture

F. prausnitzii (ATCC 27766, Manassas, VA, United States) was cultured anaerobically at 37 ℃ in LYHBHI medium [main component of brain-heart infusion medium (37 g/L, BD, Franklin Lakes, NJ, United States), yeast extract (5 g/L, Oxoid, Basingstoke, United Kingdom), cellobiose (1 g/L, Sigma, St. Louis, MO, United States), maltose (1 g/L, Amresco, Solon, OH, United States), hemin (5 mg/L, Sigma), and cysteine (0.5 g/L, Sigma)]. The number of live bacteria (colony-forming units, CFU) was calculated according to optical density (OD) at 600 nm. The supernatant was collected from cultures with 109-1010 CFU/mL (OD = 1.9). Sterile culture medium acted as placebo. Bacterial supernatant and sterile culture medium were lyophilized and stored at -80 ℃. They were thawed and diluted to five times concentrated solution with phosphate buffered saline (PBS) before administration.

Colon histopathologic grading

The histopathologic grading of colon damage was scored by two blinded pathologists under microscope based on Neurath Scoring criteria as previously described[19]. In short, 4: transmural leukocyte infiltrations, high vascular density, loss of goblet cells, and thickening of the colon wall; 3: high level of leukocyte infiltration, thickening of the colon wall, high vascular density; 2: low level of leukocyte infiltration; 1: very low level of leukocyte infiltration; and 0: no inflammation.

Isolation of splenic mononuclear cells

Splenic mononuclear cells were isolated from spleens through Ficoll–Isopaue density gradient centrifugation[20]. Fresh spleens were placed in Roswell Park Memorial Institute (RPMI)-1640 (Gibco, Carlsbad, NY, United States) and mechanically disrupted by a 2 mL syringe plunger into cell suspensions. Cell suspensions were repeatedly aspirated with a sterile Pasteur pipette and gently filtered through a 200 μm strainer. Splenic single-cell suspensions were layered over an equal volume of Ficoll-Hypaque Solution (Haoyang BioScience Corporation, Tianjin, China) per spleen and centrifuged at 1500 rpm for 20 min. The band of leukocyte enriched fraction at the interface was collected after centrifugation at 1800 rpm for 10 min without brake. The resulting splenic mononuclear cell density was counted in a hemocytometer, and viability was assessed by Trypan blue staining.

Fluorescence activated cell sorter analysis of Th17 in mononuclear cells

Flow cytometry followed routine procedures by using 2 × 10^6 cells per sample. The splenic mononuclear cells were stimulated by phorbol-12-myristate-13-acetate (PMA), ionomycin, and brefeldin A for 5 h at 37 ℃ in a 5% CO2 incubator, then labeled with fluorescein isothiocyanate (FITC) anti-mouse CD4 (eBioscience, San Diego, CA, United States) and APC anti-mouse CD3 (eBioscience). After permeabilization and fixed

treatment, cells were labeled with PE anti-mouse IL-17 (eBioscience). The stained cells were tested by flow cytometry (BD, San Jose, CA, United States) and analyzed by the Cell Quest software.

Enzyme-linked immunosorbent assay cytokines in murine plasma

Cytokines (IL-17A, IL-6, IL-4) were measured using a commercially available enzyme-linked immunosorbent assay kit (Yunhan Biological Technology Corporation, Shanghai, China) according to the manufacturers' instructions.

Real-time quantitative polymerase chain reaction

Total RNAs were extracted from mid-colon samples taken from mice in each group using the Trizol reagent (Invitrogen, Carlsbad, CA, United States) with the following procedure. The concentration was determined by NanoDrop TM 1100 (NanoDrop Technologies, Wilmington, DE, United States). Total RNA was reversely transcribed into cDNA using reverse transcription kit. The polymerase chain reaction (PCR) reactions were performed in a 96-well Optical Reaction Plate (Applied Biosystems, Foster City, CA, United States) with the following procedure: degeneration 95 ℃ for 30 s, annealing 95 ℃ for 5 s, 40 cycles of 60 ℃ for 34 s. All primers and probes used in this study are listed in Table 1.

Immunohistochemistry

Paraffin slides of colon were re-hydrated in different concentrations of ethanol and washed in PBS. Sections were microwaved in sodium citrate buffer. After blocking with 10% goat serum for 30 min, sections were incubated with rabbit anti-rat IL-17 antibodies (Abcam, Cambridge, United Kingdom) overnight at 4 ℃. Slides were then incubated with the corresponding secondary antibody (Zsbio, Beijing, China), labelled with horseradish peroxidase, developed using a diaminobenzidine (DAB) reaction, and counterstained with hematoxylin. Cells stained with the antibodies were calculated by random selection of five fields under a microscope at 200 × magnification.

Statistical analysis

The GraphPad Prism version 5.0 (La Jolla, CA, United States) was used for data analysis. Data are presented as mean ± SD and were analyzed using one-way analysis of variance. $P < 0.05$ was considered to be statistically significant.

RESULTS

Symptoms and body weight of mice

Mice became symptomatic (*e.g.*, bloody diarrhea, weight loss, shakes andsloth) by day 3 of drinking 3.0% DSS *ad libitum*. The symptoms worsened with prolonged 3.0% DSS drinking time.

The mice in the model group had obvious weight loss compared to the control group ($P < 0.001$), and the mice from the model group weighed significantly less than those from the treatment and prevention groups. There was no significant difference in weight loss between the treatment group and prevention group (Figure 2).

Colon length and pathological changes

Compared with the control group, the mice in the model group had markedly shorter colon length (7.89 ± 1.536 *vs* 4.92 ± 0.925, $P < 0.001$), more serious colon damage, and higher histopathologic damage scores (0.8 ± 0.632 *vs* 3.7 ± 0.483, $P < 0.01$). Histological examination of model group mice showed that the normal colon mucous membrane structure disappeared, extensive ulceration developed, and a large number of inflammation cells infiltrated. However, culturing supernatant of *F. prausnitzii* in treatment and prevention group mice significantly ameliorated the colon damage by increasing colon length ($P < 0.01$ and $P < 0.05$) and reducing high histopathologic damage scores ($P < 0.05$) as compared with model group (Figure 2).

Th17 cell percentage change in splenic mononuclear cells

The ratio of Th17 cells in splenic mononuclear cells of the model group was significantly higher than that of the control group (4.02 ± 1.111 *vs* 1.34 ± 0.417, $P < 0.001$). It was obviously decreased after preventive and therapeutic application of *F. prausnitzii* supernatant (4.02 ± 1.111 *vs* 2.60 ± 0.839, $P < 0.01$ and 4.02 ± 1.111 *vs* 2.21 ± 1.030, $P < 0.05$), and there was no significant difference between the treatment and prevention groups (Figure 3).

IL-17A, IL–6, and IL-4 levels in peripheral plasma

Plasma IL-17A, IL-6, and IL-4 levels of the control group were significantly different from the model group [15.73 ± 4.382 (pg/mL) *vs* 28.44 ± 4.116 (pg/mL) $P < 0.01$, 81.19 ± 13.609 (pg/mL) *vs* 111.82 ±

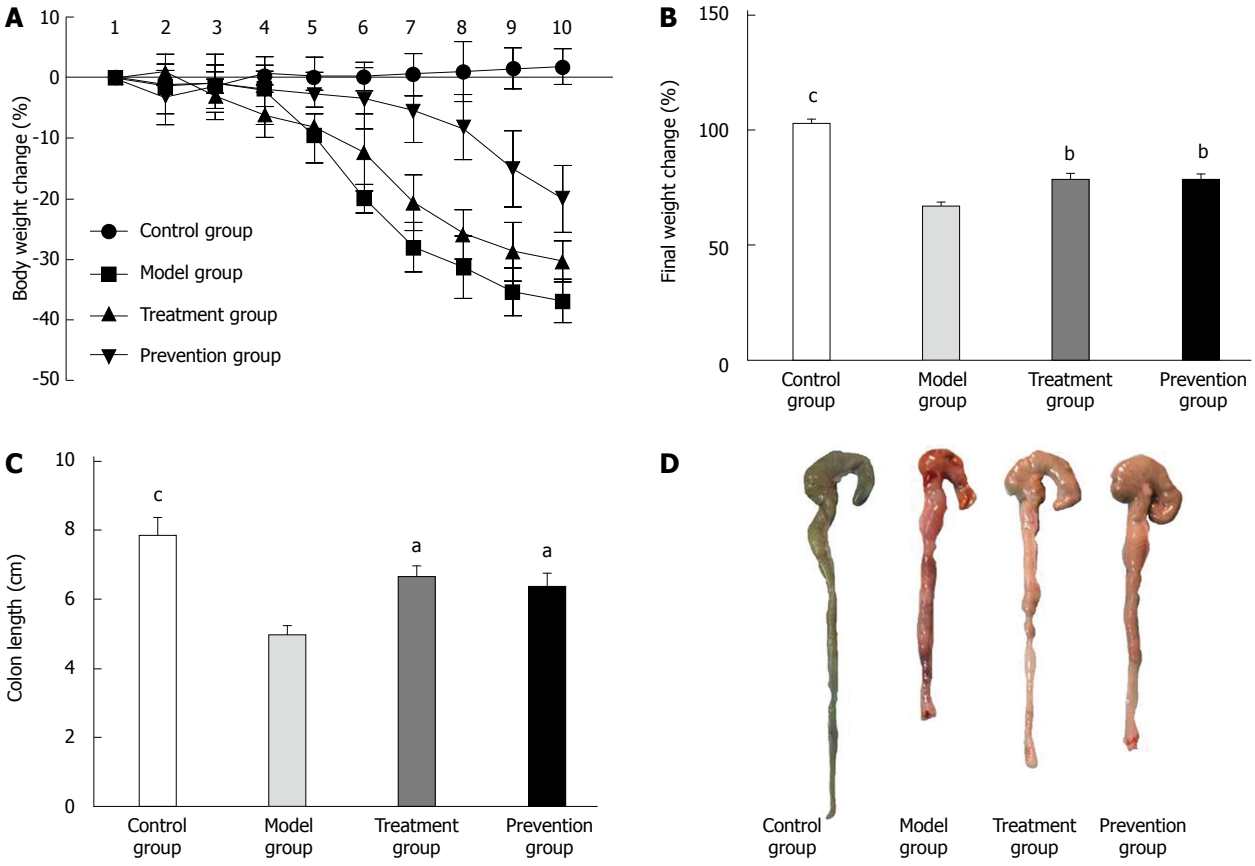

Figure 2 Body weight and colonic length in mice. A, B: Body weight change; C, D: Colon length. Data are the mean ± SD. n = 8-10. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* model group.

14.369 (pg/mL) $P < 0.05$, 79.91 ± 12.245 (pg/mL) *vs* 38.16 ± 9.507 (pg/mL) $P < 0.001$]. The plasma levels of IL-17A in the treatment and prevention groups were significantly lower than that in the model group ($P < 0.05$). Plasma IL-6 level in the treatment group was also significantly less than that in the model group ($P < 0.05$), but the difference was not statistically significant between the prevention group and model group. On the contrary, level of plasma IL-4 in the prevention group was obviously higher than that in the model group ($P < 0.05$), while no difference was found between the treatment group and the model group (Figure 3).

Expression of cytokines and RORγt mRNA in colon mucosal tissue

The expression of IL-17A, IL-6, and RORγt mRNA in colon tissue of mice in the model group was significantly higher than that in the control ($P < 0.001$) and treatment groups ($P < 0.05$). When compared with the model group, the expression of IL-17A and RORγt mRNA in colon inflammatory tissue of the treatment and prevention groups was significantly decreased ($P < 0.01$ or $P < 0.05$). There was no difference, however, in IL-6 between the model group and prevention group. As shown in Figure 4, the expression of cytokines and RORγt mRNA in colon mucosal tissue did not significantly differ between the treatment and prevention groups.

Immunohistochemistry

To investigate the effects of IL-17A and RORγt on colon tissue, we conducted immunohistochemical staining of proinflammatory cytokines in tissue sections. Consistent with the results of quantitative real time PCR, the expression of IL-17A and RORγt in the colon tissue of model group mice was significantly increased compared to that in the control group ($P < 0.001$) and treatment group ($P < 0.05$). Although the expression of RORγt in colon tissue was declined after protective use of *F. prausnitzii*, there was no difference between the model and prevention groups (Figure 5).

DISCUSSION

In this study, we found that *F. prausnitzii* supernatant ameliorated colitis in mice by regulating Th17 cell differentiation and inhibiting the excretion of relevant inflammatory cytokines. We also found that *F. prausnitzii* supernatant was effective in the treatment and prevention of DSS-induced mice colitis by inhibiting differentiation of Th17 cell.

Both living *F. prausnitzii* and *F. prausnitzii* supernatant, which contains a mixture of secreted products,

have been shown to have an anti-inflammatory effect[21]. Compared to *F. prausnitzii*, its supernatant could be more effective therapeutically, as it may have a longer shelf-life, which would facilitate delivery, handling, and administration[22]. However, the exact composition and the anti-inflammatory mechanism of *F. prausnitzii* supernatant are currently largely unknown. Therefore, we explored the effects and immune mechanisms of *F. prausnitzii* supernatant on DSS-deduced colitis. Our study showed that the plasma levels of IL-17A and IL-6, the protein and mRNA expression of IL-17A and RORγt in intestinal mucosa, and the Th17 cell ratio of spleen cells ($P < 0.01$) in supernatant treatment group were significantly decreased compared to those in the model group. This finding indicated that the therapeutic use of *F. prausnitzii* supernatant could ameliorate DSS-induced colitis through inhibiting Th17 cells. Carlsson *et al*[23] previously demonstrated that the supernatant of *F. prausnitzii* affected the function of the intestinal barrier.

Th17-related gene polymorphisms are associated with IBD susceptibility[24]. Th17-derived cytokines, such as IL-17A, IL-6, and IL-22, have been shown to be upregulated in the inflamed intestine of IBD patients[25,26]. IL-17A is a strong inflammatory cytokine, which can enhance cell permeability and promote the generation of other pro-inflammatory cytokines and chemokines[27]. Animal experiments, however, have found that neither IL-17A knockout nor neutralization of IL-17 could protect DSS-administrated mice from colitis, suggesting that the role of IL-17 in intestinal inflammation may not be entirely pathogenic[14,28]. Adequate expression of IL-17A plays an important role in maintaining intestinal immune function. Consistent with previous studies, we found that IL-17A levels in the plasma, spleen, and colon tissue were significantly increased in mice with colitis and that these levels were remarkably downregulated in mice treated with *F. prausnitzii* culture supernatant. Therefore, *F. prausnitzii* supernatant could attenuate DSS-induced mice colitis, possibly by inhibiting the expression of IL-17A[15,29].

We also found that levels of IL-6 in plasma and colon tissues of colitis mice were significantly reduced after *F. prausnitzii* supernatant treatment. *F. prausnitzii* supernatant could alleviate mice colitis by downregulating IL-6 levels and inhibiting Th17 cell differentiation, thus leading to reduced secretion of inflammatory cytokines (such as IL-17A and IL-6) and attenuation of the local inflammatory response. However, the regulation of IL-6 expression in the treatment and prevention groups was inconsistent, suggesting that there might be other ways of inhibiting Th17 differentiation. Fu *et al*[29] demonstrated that boosting of Th2 associated cytokines (IL-4, IL-13, and IL-10) can reverse Th17-mediated intestinal inflammation. We also found that plasma IL-4 levels in mice of the prevention group were significantly greater than those in the model group.

In conclusion, *F. prausnitzii* supernatant can prevent DSS-deduced colitis in mice by inhibiting the generation of Th17 cells in the spleen and intestinal mucosa, leading to a reduction of IL-17A and IL-6 levels and attenuation of intestinal inflammation. This study provides the theoretical basis for the application of *F. prausnitzii* supernatant in UC treatment and prevention. However, what specific substances in the supernatant of *F. prausnitzii* possess biological activity needs to be elucidated in future studies. The safety

and efficacy of *F. prausnitzii* supernatant also warrant further investigation by more large scale clinical trials.

ACKNOWLEDGMENTS

The study has an internal teamwork from Institute of Digestive Disease, Nanjing Drum Tower Hospital. We thank the people who generously gave their precious time to take part in this study. We are also grateful to professor Jun Yang (pathology, Nanjing Tower Hospital) for his help on pathological diagnosis.

COMMENTS

Background

Inflammatory bowel disease (IBD) is a multifactorial ailment characterized by intestinal inflammation, and its etiology is complicated and ambiguous. Factors that contribute to IBD include genetic background, environment, intestinal flora imbalance, and immune disorder as well as the interactions between them.

Research frontiers

Faecalibacterium prausnitzii (*F. prausnitzii*) is a common anaerobic bacteria that colonizes the human gut, and it plays a critical role in IBD. *F. prausnitzii* supernatant has anti-inflammatory and immune regulatory activity. Previously, the authors showed in animals that both the bacteria and its supernatant relieved trinitro-benzene-sulfonic acid-induced colitis in rats. However, the specific mechanism is largely unclear.

Innovations and breakthroughs

This study is the first to show that the preventive and therapeutic use of *F. prausnitzii* supernatant could ameliorate dextran sulfate sodium (DSS) induced mice colitis through inhibiting Th17 cells. The molecular mechanism of proliferation and differentiation of Th17 cells was different. *F. prausnitzii* supernatant may treat colitis in mice by downregulating IL-6 and preventing the upregulation of IL-4.

Applications

This study investigated the molecular mechanism of the preventive and therapeutic use of *F. prausnitzii* supernatant for IBD and provided evidence for the prevention and treatment of the disease.

Terminology

F. prausnitzii is the major bacterium of the Clostridium leptum group and is one of the most abundant anaerobic bacteria in human gut.

Peer-review

The study investigates the preventive and therapeutic role of *F. prausnitzii* supernatant in a mouse model of DSS-induced ulcerative colitis. The topic is interesting, and the design and methods have clear scientific values. The data are clear and well presented.

Abstract

AIM: To evaluate gut microbial dysbiosis in two visceral hypersensitive models in comparison with irritable bowel syndrome (IBS) patients and to explore the extent to which these models capture the dysbiosis of IBS patients.

METHODS: Visceral hypersensitivity was developed using the maternal separation (MS) rat model and post-inflammatory rat model. The visceral sensitivity of the model groups and control group was evaluated using the abdominal withdraw reflex score and electromyography in response to graded colorectal distention. The 16S ribosomal RNA gene from fecal samples was pyrosequenced and analyzed. The correlation between dysbiosis in the microbiota and visceral hypersensitivity was calculated. Positive findings were compared to sequencing data from a published human IBS cohort.

RESULTS: Dysbiosis triggered by neonatal maternal separation was lasting but not static. Both MS and post-inflammatory rat fecal microbiota deviated from that of

the control rats to an extent that was larger than the co-housing effect. Two short chain fatty acid producing genera, *Fusobacterium* and *Clostridium XI*, were shared by the human IBS cohort and by the maternal separation rats and post-inflammatory rats, respectively, to different extents. *Fusobacterium* was significantly increased in the MS group, and its abundance positively correlated with the degree of visceral hypersensitivity. *Porphyromonadaceae* was a protective biomarker for both the rat control group and healthy human controls.

CONCLUSION: The dysbiosis MS rat model and the post-inflammatory rat model captured some of the dysbiosis features of IBS patients. *Fusobacterium*, *Clostridium XI* and *Porphyromonadaceae* were identified as targets for future mechanistic research.

Key words: Animal model; Irritable bowel syndrome; Microbiota; Pyrosequencing; 16S rRNA gene

Core tip: Dysbiosis of the gastrointestinal microbiota and hypersensitivity to colonic distension are critical features of irritable bowel syndrome (IBS). For animal models, the correlation between dysbiosis in the microbiota and visceral hypersensitivity remains unknown. This study identified common biomarkers between the animal models and IBS patients, which may be targets for future mechanistic research.

INTRODUCTION

The human intestinal tract is home to trillions of bacteria that have co-evolved with their host over millennia[1]. Their combined genomes, called a metagenome, contain 150-fold more genes than do the human hosts, and they provide functions that humans otherwise do not have[2]. Complex interactions exist between the gut microbiota and the host[3]. Irritable bowel syndrome (IBS) is a common gastrointestinal disorder that is characterized by abdominal pain and alterations in bowel habits; statistically, IBS affects 7%-10% of people worldwide[4]. Accumulating evidence has indicated that the gut microbiota may participate in the pathogenesis of IBS[5]. Because collecting fecal samples both before and after a gastrointestinal infection from the same IBS patients is unfeasible for clinics, only gut dysbiosis in standing IBS patients has been evaluated to date[6,7]. However, how gut microbiota abnormalities arise and are maintained over time is unclear. These questions are critical for interventions targeting the microbiota, such as probiotic usage. In this work, we used visceral hypersensitive rat models to investigate the longitudinal changes of gut microbiota.

Currently, both post-infectious/inflammatory models and stress-related models have been frequently used to study the pathophysiology of IBS[8,9]. There are more than 12 major post-infectious/post-inflammatory models to mimic post-infectious IBS, which occurs after an initial episode of acute gastrointestinal infection. Chemicals such as trinitrobenzene sulfonic acid (TNBS)[10], mustard oil[11] and dextran sulfate sodium[12] were used to cause mucosal injury in the post-inflammatory models, and pathogens such as *Trichinella spiralis*[13] and *Campylobacter*[14] were used to infect the gut; both led to visceral hypersensitivity. Stress-related models[15] could also induce the modulation of visceral pain, and this may involve changes in the brain-gut axis[9]. However, one of the unsolved problems is the extent to which these models recapture the characteristics of gut dysbiosis in IBS patients. In this work, we used two visceral hypersensitive models, the TNBS post-inflammatory (pTNBS) model and the maternal separation (MS) model, to investigate: (1) whether and the extent to which these models reproduce the disturbance of gut microbiota in a similar way to that of the IBS patients; and (2) whether microbial dysbiosis, if it exists, is static or shifting in these visceral hypersensitive models. We also hoped to identify targets in the models' gut microbial communities that are suitable for use in developing probiotics to specifically modulate the microbiota.

MATERIALS AND METHODS

Animal maintenance and modeling

Sprague-Dawley rats were purchased from the animal center of Shandong University of Traditional Chinese Medicine. The rats were allowed to habituate for 7 d to the breeding facility prior to mating. They were kept under standardized specific pathogen-free conditions (21-22 ℃, 12:12-h light-dark cycle) with access to pellet food and water *ad libitum*. All experiments were approved by the Ethical Committee and Institutional Animal Care and Use Committee of Qilu Hospital (KYLL-2013-005), and the methods were performed in strict accordance with the Animal Management Rules of the Chinese Ministry of Health. The overall design and co-housing relationship of involved rats are indicated in Figure 1A.

The MS visceral hypersensitive models were developed as previously described[15]. Briefly, rat pups that were randomly assigned to the MS group were stressed by separating them from their mothers for 3 h daily between postnatal days 2-14. The control group (Ctl) received normal breeding during this session. All pups were weaned on postnatal day 22, and only the

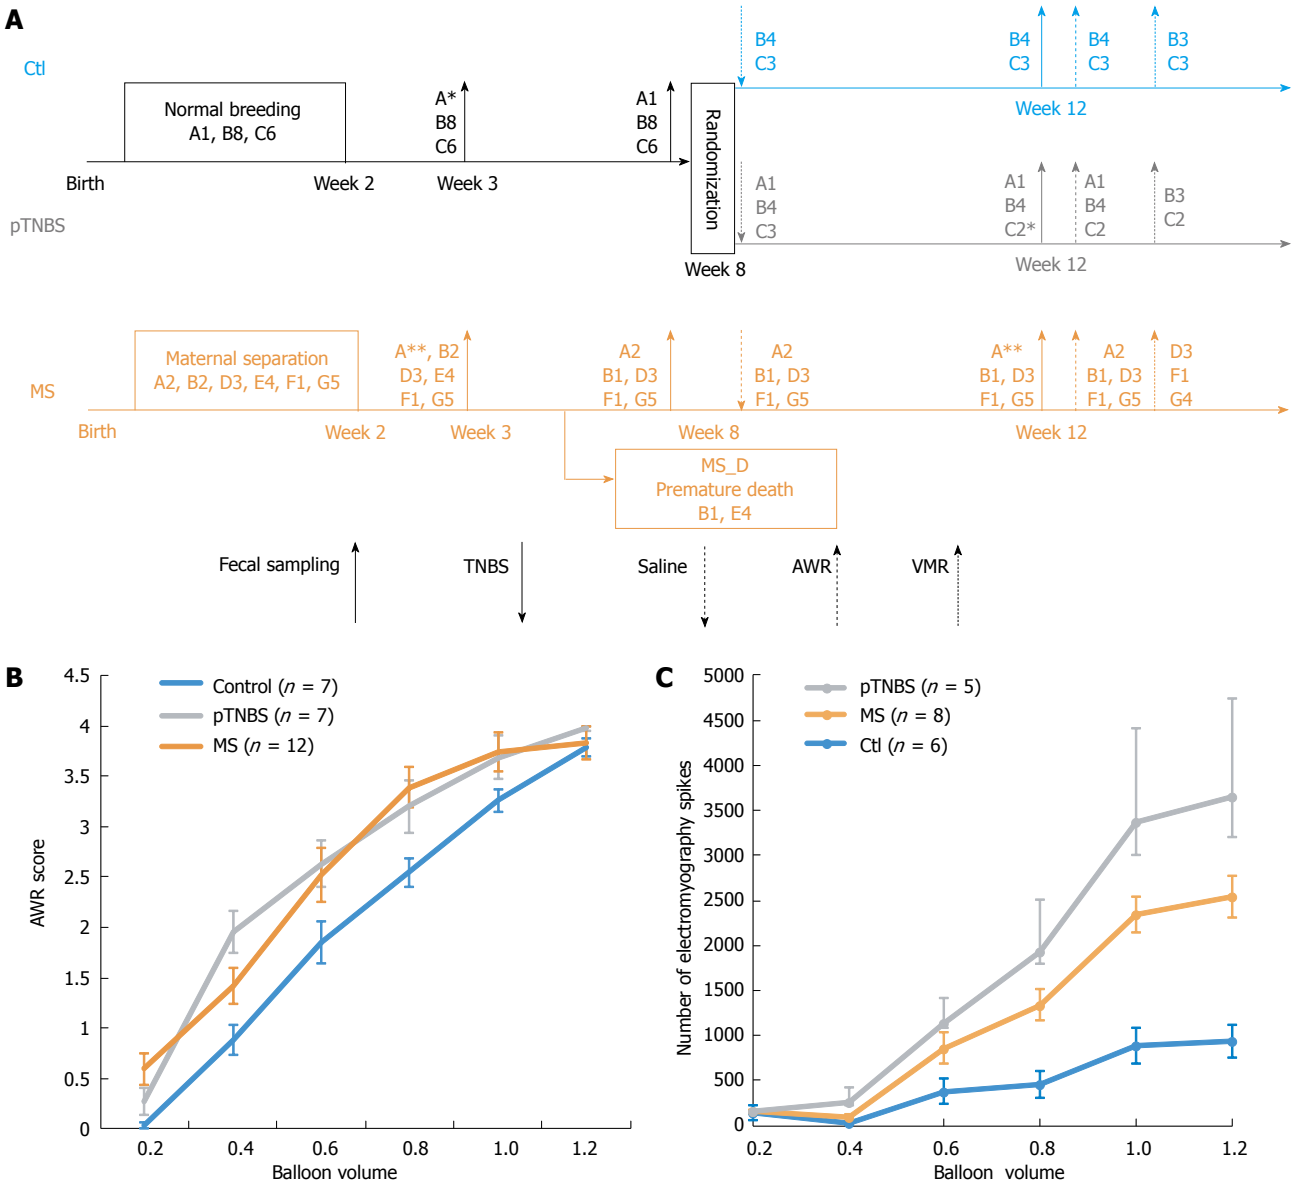

Figure 1 Study design and visceral sensitivity evaluation. A: Schematic flow chart showing the treatment and co-housing relationship of involved rats. For each code, such as "B8", the character "B" indicates the nest and number 8 indicates the number of rats. They were cohoused until "B4", which indicates that four of them were randomly chosen and cohoused together. The asterisk indicates fecal samples that failed to return the sequencing data; B: Abdominal withdrawal reaction (AWR) score in response to the graded colorectal distention (CRD); C: Visceromotor response (VMR) score in response to graded CRD. MS: Maternal separation; MS_D: MS early death; pTNBS: TNBS post-inflammatory.

male pups were used for the following study. Because some MS pups naturally died before they aged, 5 male rats were randomly chosen from those that were sampled at week 3 but did not survive to week 8. We indicated this group as the MS early death (MS_D) group. By including the MS_D group, we could test whether the dysbiosis caused by MS stress was more severe in the early dying pups.

After the second fecal collection at week 8, half of the control group was randomly assigned to the post-TNBS inflammation group (pTNBS). The pTNBS group was fasted for 24 h with free access to tap water, and then 0.4 mL of 5% (v/v) TNBS (P2297, Sigma, Shanghai, diluted to 0.8 mL using 50% ethanol) was administered into the colorectum.

Visceral hypersensitivity evaluation

After the last fecal collection at week 12, visceral hypersensitivity was evaluated using both the abdominal withdraw reflex (AWR) score and electromyography in response to graded colorectal distention (CRD). Graded CRD was induced by rapidly injecting (0.2, 0.4, 0.6, 0.8, 1.0, and 1.2 mL) saline into a urinary catheter balloon placed in the colon over 1 s and maintaining the distention for 20 s. AWR score was recorded according to a previously described method[16]. To represent the overall visceral sensitivity, a visceral hypersensitive index (VHI) for each rat was calculated by summing the rank of the AWR score at 0.4, 0.6, 0.8 and 1.0 of the total balloon volume.

The visceromotor responses (VMRs) to CRD were

quantified through electromyography of the rat obliqus external abdominis. Briefly, 5 d after embedding an electrode in the rat obliqus externus abdominis, the raw electromyography was recorded, rectified and quantified by counting the increased spike bursts during a 20 s window after graded CRD stimulation. The VMR index for each rat was calculated by summing the rank of electromyography spikes at 0.4, 0.6, 0.8 and 1.0 of the total balloon volume.

Fecal sample collection, DNA extraction, and pyrosequencing

Fecal samples were collected 3, 8 and 12 wk after birth. The samples from the pTNBS group at weeks 3 and 8 were indicated as Ctl-pTNBS and were analyzed as the controls because their treatment was the same as that for the Ctl group. A chart illustrating the overall treatment, fecal collection and model evaluation time points is shown in Figure 1A.

The samples were snap-frozen in liquid nitrogen and stored at -80℃. Genomic DNA was extracted with a TIANamp Stool DNA Kit according to the manufacturer's instructions (Cat# DP328, Tiangen, Beijing). DNA purity and concentration were measured using a Nanodrop2000 (Thermo Fisher). The DNA samples were shipped to Majorbio (Shanghai), where the DNA integrity check, PCR amplification, DNA quantification, emPCR (using Roche GS FLX Titanium emPCR Kits) and pyrosequencing of the 16S rRNA gene V3 to V1 region (using Roche Genome Sequencer FLX+) were performed according to their optimized protocols. The sequencing results were archived in the Short Reads Achieve (number pending).

Taxonomy quantification using 16S rRNA gene sequences

Raw sequencing data were prepared using Mothur v 1.33.0 according to their proposed 454 SOP (http://www.mothur.org/wiki/454_SOP)[17]. The raw sff files were decoded, denoised, trimmed and then aligned to Silva references (Release 102) using the default parameters. Chimeras were detected using the chimera.uchime command and were then removed. Distances between sequences were calculated with a cutoff value of 0.15. The sequences were clustered to the same operational taxonomic units (OTUs) if their distances were less than 0.03. The Shannon index and the inverse Simpson index (1/D) were calculated to indicate the diversity in each sample. Both indexes were calculated using Mothur, and the detailed formula can be accessed online (http://www.mothur.org/wiki/Shannon and http://www.mothur.org/wiki/Simpson). The OTU table was converted to biom files and the taxa abundance from domain to genus levels was generated using the summarize_taxa.py command in QIIME v1.8.0.

Statistical analysis

The richness of each taxonomy and the Shannon index between groups were compared using the Kruskal-Wallis test (KW) or a student's *t*-test in SAS V.9.3 statistical software. The heatmap plot with dendrograms was drawn using the heatplot function in the made4 packages in R (version 3.1.1). For primary component analysis (PCA), the axis value of all 80 samples was calculated together using the prcomp function in the stats package in R, and then the samples were plotted by each time point (week 3, 8, and 12). Within each time point, samples were clustered based on the Euclidian distance using the vegdist and hclust in the vegan package. According to the cluster results, the PCA plot points were grouped and connected using the ordispider and ordiellipse functions, where the ellipse was estimated to cover 75% of the dots in this group. The distribution of each group in each cluster was checked using Fisher's exact test in SAS. The community dissimilarity was tested by the weighted and unweighted UniFrac test using Mothur. The specific taxa that were differentially present in each group were identified using the LEfSe [linear discriminant analysis (LDA) coupled with effect size measurements] method with an LDA cut-off value of 2.0[18]. The Spearman correlation between the VHI and the taxonomy richness was calculated using the cor.test function in the stats package in R.

Comparing rat models and human IBS cohort

We downloaded the published 16S rRNA V4 region Miseq sequencing data by Jeffery *et al*[6]. This data set was analyzed by the same pipeline described above. We used LEfSe analysis on this dataset. Each positive finding from the rat experiment was checked against the human cohort. The relationship between human and rat biomarkers was indicated using a Venn plot.

RESULTS

Modeling and visceral hypersensitivity evaluation

The design and co-housing relationship of the rats involved in this study is shown in Figure 1A. Twenty-six of the 27 rats in this study (7 Ctl, 7 pTNBS, and 12 MS, see Figure 1B) were evaluated using AWR. The VHI score was calculated by summing the rank of the AWR score at 0.4, 0.6, 0.8 and 1.0 of the total balloon volume. A significant difference existed in the VHI among the three groups (χ^2 = 9.98, *df* = 2, *P* = 0.0068, KW). The VHI difference in the pTNBS to Ctl comparison was 38.4 (95%CI: 15.7 to 61.0, *P* < 0.05), and the VHI difference in the MS to Ctl comparison was 32.9 (95%CI: 12.7 to 53.0, *P* < 0.05). There was no significant difference in the MS to pTNBS comparison, with a VHI difference of 5.48 (95%CI: -14.7 to 25.7, *P* > 0.05). Nineteen of the 27 rats were evaluated by VMRs (Figure 1C). The VMR index for each rat was calculated by summing the rank of electromyography spikes at 0.4, 0.6, 0.8 and 1.0 of the total balloon volume. The VMR index among groups was insignificant although the control group tended to

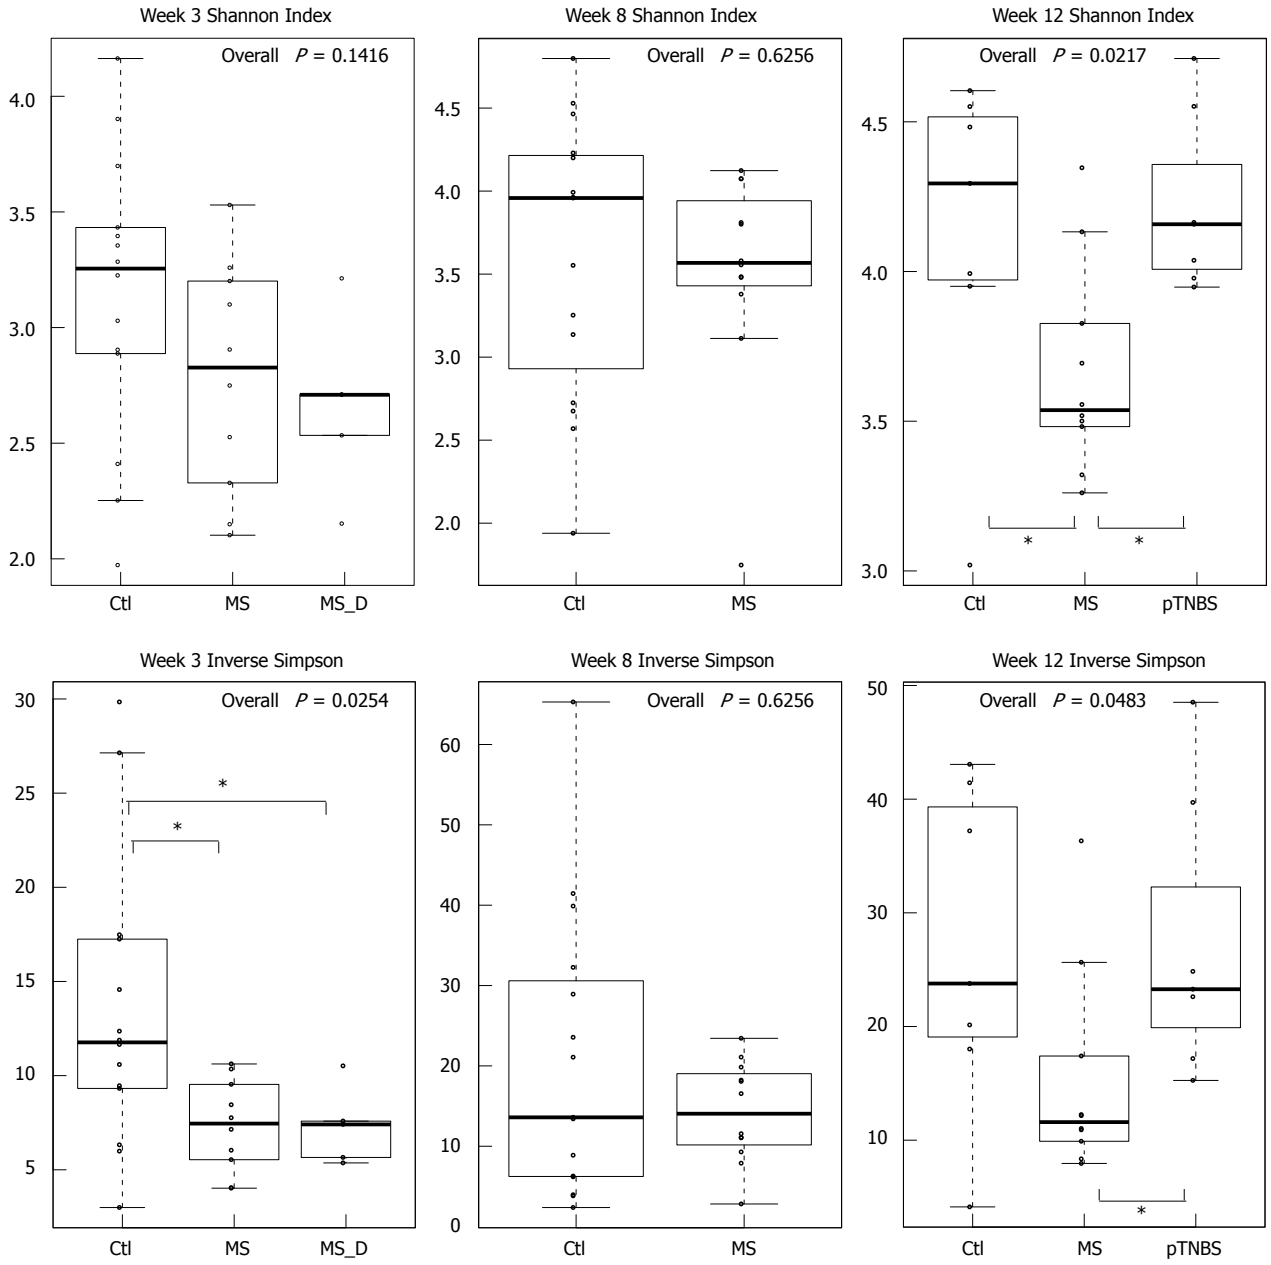

Figure 2 Microbial diversity. Shannon index (upper panel) and inverse Simpson (lower panel) of fecal microbiota at weeks 3, 8 and 12. Asterisk indicates $P < 0.05$ in pairwise comparison. MS: Maternal separation; MS_D: MS early death; pTNBS: TNBS post-inflammatory.

be lower than the MS and pTNBS groups (43.5 *vs* 86.5 and 60, respectively, $\chi^2 = 2.235$, $df = 2$, $P = 0.3271$, KW). Overall, these data indicate that both the MS and pTNBS groups developed visceral hypersensitivity at a comparable level.

DNA sequence data and microbial diversity comparison

A total of 489556 valid reads were assigned to 80 sequenced samples after barcode trimming. Sequence length varied between 230 and 327 bp per read. After removing chimeras and non-bacterial reads, 434594 reads remained. Each fecal sample included 3313 to 8161 reads. Based on a 97% species similarity, 2413 OTUs were identified from all of the fecal samples. Good's coverage for each sample varied from 95.57% to 99.72%. The rarefaction curve reached a plateau for most samples, suggesting that the present study captured the dominant phylotypes.

We first compared the microbial diversity among groups using the Shannon index and the inverse Simpson index (Figure 2). By week 3, the inverse Simpson index was significantly higher in the Ctl group ($\chi^2 = 7.34$, $df = 2$, $P = 0.0254$, KW). By week 8, the Shannon index and the inverse Simpson index were similar between the control group and the MS group. By week 12, the MS group has the lowest Shannon index ($\chi^2 = 7.67$, $df = 2$, $P = 0.217$, KW) and inverse Simpson index ($\chi^2 = 6.06$, $df = 2$, $P = 0.0483$, KW) compared with other groups. The pTNBS group had roughly same diversity indexes compared to the Ctl

group. These data indicate that the MS model, but not the pTNBS model, developed fecal microbiota with reduced diversity in a non-static manner.

Dysbiosis of major phyla

We then investigated whether differences in the phylum abundance exist at different time points (Figure 3). *Bacteroidetes* was the dominant phylum across all samples, and *Firmicutes* and *Proteobacteria* were the second and third most abundant phyla. No significance was reached for these three phyla at any of the 3 time points. The *Firmicutes* to *Bacteroidetes* (F/B) ratio was not significantly different ($P > 0.05$, KW).

Fusobacteria was abundant by week 3 (up to 0.25) and dropped to zero in most control rats. No difference in *Fusobacteria* existed by week 3 and week 8; however, by week 12, the MS group had significantly more *Fusobacteria* ($\chi^2 = 6.83$, $df = 2$, $P = 0.0328$, KW, $P < 0.05$ in MS-Ctl comparison). The control group had significantly more *Actinobacteria* than the MS group at week 8 ($P = 0.0034$, $\chi^2 = 8.58$, $df = 1$, KW). However, by week 12, the pTNBS group had significantly more *Actinobacteria* than the Ctl and MS groups ($\chi^2 = 8.07$, $df = 2$, $P = 0.0176$, KW, $P < 0.05$ in the pTNBS-Ctl and pTNBS-MS comparison). These data suggest that the dysbiosis of the major phyla may be phase dependent and different among the visceral hypersensitive rat models.

PCA and cluster analysis

We based the cluster analysis and PCA on the OTU data from the 16S rRNA gene pyrosequencing. The primary components for all 80 samples were calculated from the relative abundance of the 2413 OTUs. The relative importance of the first 20 primary components is plotted in Figure 4A. Primary component 1 and primary component 2 explained 27.7% and 14.6% of the total variance, respectively (Figure 4A). The differences in the primary components between the time points and experimental groups are listed in Table 1. Primary component 1 mainly reflected the effect of time points ($\chi^2 = 37.7$, $df = 2$, $P = 0.0000$, KW). Primary components 2 and 4 reflected the effect of experimental groups on fecal microbiota composition. The other 3rd, 6th, and 9th components were different both among time points and among groups.

We then used cluster analysis to test whether the groups would fall into the same or different clusters. At each time point, the samples were fitted into the 3 top clusters based on the Euclidean distance. We designated the names of each cluster according to the samples it included. By week 3, the normal cluster included 8 Ctl, and the MS cluster included 4 MS and 4 MS_D samples. The mixed cluster included 6 Ctl, 6 MS and 1 MS_D samples (Figure 4B). The 3 groups' distribution in the clusters was significantly different ($P = 1.702 \times 10^{-4}$, Fisher's test). This result suggests that MS caused dysbiosis in rat models at early ages.

By week 8, the 27 fecal microbiota samples clustered into 3 mixed clusters (Figure 4C). The control group dominated mixed cluster 3 (12/16) while the MS group dominated mixed cluster 2 (7/8). The cluster distribution of the MS and control groups was significantly different ($P = 0.0114$, Fisher's test). By week 12, the 24 fecal microbiota samples formed 3 clusters (Figure 4D). The MS cluster included 5 MS samples, and the mixed cluster included roughly the same number of samples from the Ctl ($n = 6$), MS ($n = 5$), and pTNBS ($n = 7$) groups. Another "orphan" cluster included only one control sample. The difference among groups was significant ($P = 0.0150$, Fisher's test). These data suggest that the dysbiosis triggered by MS during childhood is still substantial in a fraction of adult rats. Four weeks after TNBS administration, the fecal microbiota of the post-inflammatory rat model was more similar to that of the control group as revealed by PCA and cluster analysis.

We tracked the longitudinal dysbiosis of 23 rats whose fecal samples were collected at all 3 time points. We analyzed whether the 10 MS rats clustered to the different or same clusters at week 3 and week 12. Seven out of 10 rats shifted to different clusters (mixed-to-MS or MS-to-mixed) from week 3 to week 12. The agreement Kappa value for cluster classification at week 3 and week 12 was -0.4000 (95%CI: -0.9566 to 0.1566). This result indicates that although MS stress generated an isolated dysbiosis cluster in a fraction of rats, each rat's gut microbiota might shift between the less disturbed (mixed) cluster and the severely disturbed (MS) cluster.

UniFrac test on animal models and co-housing effect

We further tested the effect of modeling and co-housing on fecal microbiota using the weighted and unweighted UniFrac test (Table 2). A phylogenetic tree was built for all samples at each time point, and weighted and unweighted UniFrac scores were calculated to evaluate the community similarity. According to the unweighted UniFrac test, we found that by week 3, the fecal community in Ctl and MS groups was significantly different ($P < 0.001$). The co-housing effect caused community dissimilarity in the 2 houses of control rats (B8 *vs* C6, $P < 0.001$) but not in the 2 houses of MS rats (D3 *vs* G5, $P = 0.507$). By week 8, the co-housing effect was non-significant within the MS and Ctl groups, but the difference was still significant between these two groups. By week 12, a significant community difference existed among the Ctl, MS, and pTNBS groups; the co-housing effect was not obvious within any of the groups. The weighted UniFrac test was significant in all of the above comparisons. Overall, these data suggest that both the MS model and the pTNBS model developed dysbiosis of the fecal microbiota, and the differences were not caused by the co-housing relationship.

Biomarkers and correlation to visceral hypersensitivity

We performed linear discriminant analysis coupled with effect size measurement (LEfSe) analysis at different time points to screen biomarkers for each group (Figure 5, Figure S1-3). By week 3, 29 samples were analyzed using LEfSe. The control group was strongly associated with higher abundances of unclassified *Bacteroidales*, *Veillonella*, *Treponema*, and unclassified *Clostridiales*. The MS group was associated with higher abundances of unclassified *Burkholderiales*, *Coprobacillus*, and *Clostridium_XIVa*. By week 8, 27 samples were analyzed. The MS group was associated with higher abundances of *Helicobacter*, unclassified *Burkholderiales*, and unclassified *Desulfovibrionaceae*,

[1]The *P*-value is less than 0.05. MS: Maternal separation; pTNBS: TNBS post-inflammatory.

which all belong to *Proteobacteria*. The control group was associated with higher abundances of *Barnesiella*, *Actinobacteria*, *Clostridium_XI*, *Allobaculum*, and *Odoribacter*.

To investigate whether the differentially abundant taxa correlated with the visceral hypersensitivity level, we listed the biomarkers in each group by week 12, and calculated their Spearman correlation to the VHI both within the respective group and across groups (Table 3). By week 12, *Fusobacterium* was associated with the MS group (LDA Score = 2.766). The *Fusobacterium* abundance was also significantly and positively correlated with the VHI across the all 24 samples by week 12 (r = 0.4564, P = 0.0250). Unclassified *Erysipelotrichaceae* was associated with the control group (LDA Score = 3.097) and significantly and negatively correlated with the VHI across groups (r = -0.4944, P = 0.0140). These data suggest that *Fusobacterium* may participate in the pathogenesis of visceral hypersensitivity and that *Erysipelotrichaceae* might protect against the hypersensitivity.

Comparing visceral hypersensitive rat models to IBS patients

Next, we asked to what extent visceral hypersensitive rats' dysbiosis resembles that of IBS patients. We downloaded the pyrosequencing data published by Jeffery *et al*[6], which included 37 IBS patients and 20 controls. We used the LEfSe method to analyze disease and healthy biomarkers in human fecal samples (Figure 6A); this data was further compared to the data from our animal models (Figure 6B). We identified 36 biomarkers of IBS patients and 15 biomarkers of human controls[6] (Figure 6A). The biomarkers of disease were largely different in human IBS and visceral hypersensitive rats, and only a few disease or control biomarkers were shared between the human study[6] and our rat model study. *Fusobacteria* marginally increased in IBS patients compared with human controls[6] (P = 0.063, KW, Figure 6C). The MS rat model did not share increased common biomarkers with human patients. Both control rats and human health controls have fecal microbial markers of *Porphyromonadaceae* and unclassified *Porphyromonadaceae* (Figure 6B). In the IBS cohort published by Jeffery *et al*[6], *Porphyromonadaceae* was significantly lower in the IBS groups (P = 0.0006, KW, Figure 6D), and the MS rats also had lower *Porphyromonadaceae* concentrations (P = 0.0097, KW, Figure 6D). The genus *Clostridium_XI* (belonging to family *Peptostreptococcaceae*, order *Clostridiales*) was a biomarker of both IBS patients and pTNBS rats (Figure 6E). *Clostridium_XI* accounted for up to 6% of the fecal microbiota in the IBS group and was significantly higher than the level in the healthy control group (P = 0.0484, KW). Additionally, *Clostridium XI* also colonized at a higher level in the pTNBS rats (P = 0.0422, KW).

DISCUSSION

In this study, we found that (1) both the MS and the pTNBS rat models developed dysbiosis of fecal microbiota; (2) the fecal microbiota of the MS model was characterized by a lower diversity and a higher level of *Fusobacteria* at week 3 and week 12. A fraction of the MS rats formed an isolated MS cluster that indicated clear-cut dysbiosis in comparison to the controls but the rats in this cluster tended to alternate; (3) the pTNBS model was characterized by higher *Actinobacteria* but did not develop any isolated clusters; (4) among the biomarkers observed by week 12, the *Fusobacterium* positively and unclassified *Erysipelotrichaceae* negatively correlated to visceral hypersensitivity; and (5) in comparison to a previously published fecal microbial profile in human IBS patients[6], *Porphyromonadaceae* was a protective biomarker for both healthy humans and rat controls;

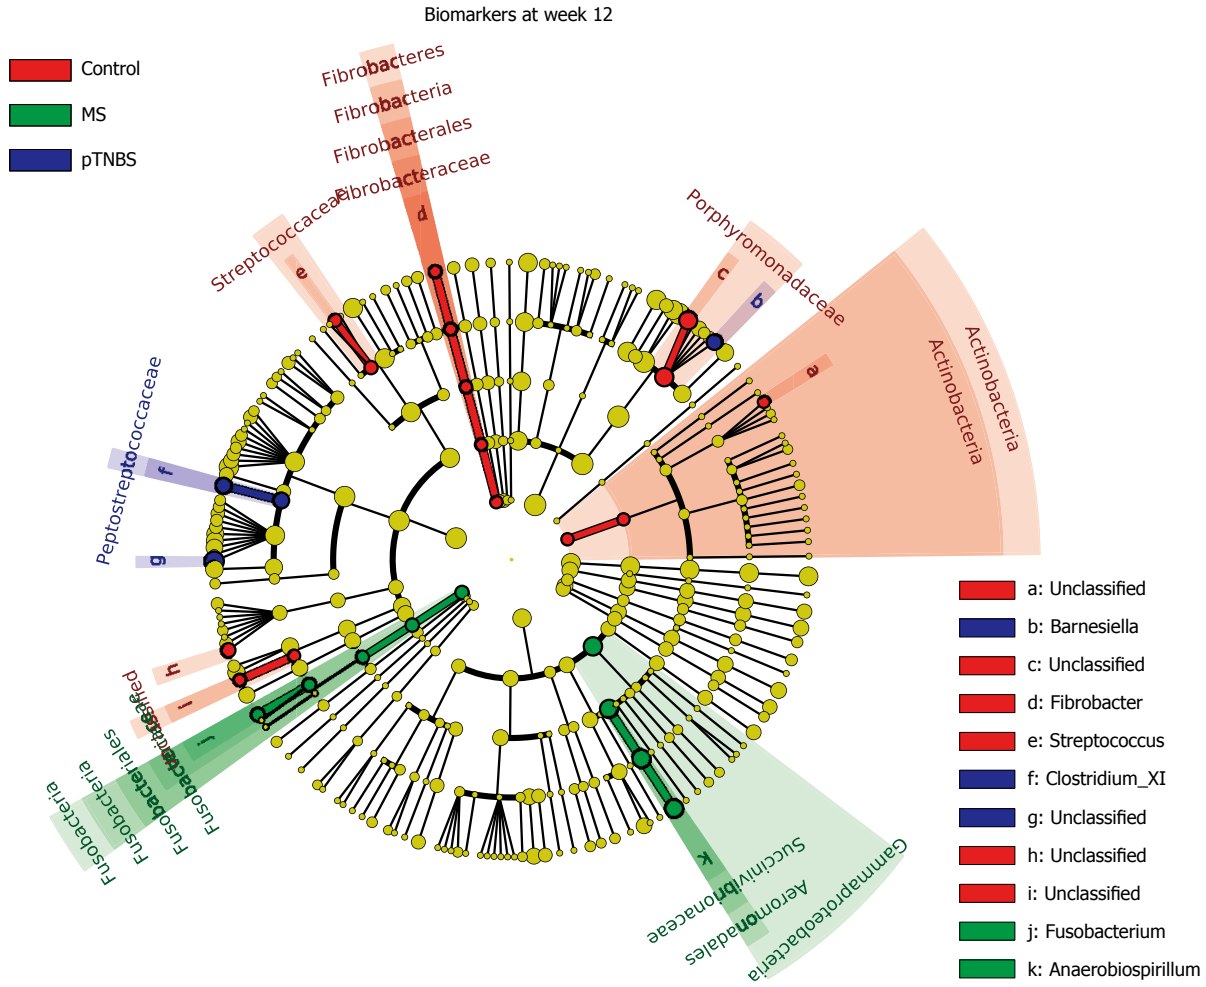

Figure 5 Microbial markers for different groups at weeks 3, 8 and 12. Biomarkers for each time point were calculated using the LEfSe Method. The abundances of taxa at the phylum, class, order, family, and genus levels were compared between the groups. Taxa with different abundances between groups and with an LDA score larger than 2.0 were considered to be a biomarker; biomarkers were indicated with corresponding colors on the cladogram. See also Figure S1, S2, and S3. MS: Maternal separation; MS_D: MS early death; pTNBS: TNBS post-inflammatory.

Clostridium_XI was a shared biomarker for human IBS patients and pTNBS rats.

Rodent models have been frequently used to study the pathogenesis and treatment of IBS, where the intestinal microbiota plays an important role. Before this study, dysbiosis in IBS rat models had not been specifically profiled, and whether any members in microbial community were correlated to visceral hypersensitivity was not known. We evaluated the fecal microbiota of MS and control rats at three time points and found that dysbiosis happened shortly after weaning (third week) and at the adult phase (12 wk). The pTNBS rat model did not develop an isolated microbial cluster but had biomarkers of *Barnesiella*, *Clostridium_XI*, and unclassified *Ruminococcaceae*. Through the unweighted UniFrac test, we found that the co-housing effect was no more significant at week 8 or week 12. Thus, both models developed significant dysbiosis of the fecal microbiota.

Approximately 10% of IBS patients believe that their symptoms began with an infectious illness, and prospective studies have shown that 3% to 36% of enteric infections lead to IBS symptoms[19]. Understanding underlying gut microbial dysbiosis associated with PI-IBS is critical for the prevention and management of this disease. *Campylobacter jejuni*, *Campylobacter rodentium*, and *Salmonella enterica* are available bacterial infectious murine models that mimic aspects of the pathogenesis of post-infectious IBS[8]. In this study, two rat models, MS and pTNBS, were not given any specific infector but were colonized more frequently by *Fusobacterium* and *Clostridium XI,* respectively. The latter includes the *Clostridium difficile*, *Clostridium litorale*, and *Clostridium lituseburense*. These two genera were also found to increase or tend to increase in the downloaded Miseq 16S rRNA gene sequencing data from Jeffery's IBS cohort[6]. Thus, these two bacteria may be common dysbiosis features across human and rat models. In a chip-based study by Jalanka-Tuovinen *et al*[7], *C. cellulosi* and its relatives (members from *Clostridium* cluster IV) significantly decreased in IBS-D patients. Thus, whether *Clostridium* plays a mechanistic role in the pathogenesis of IBS warrants further study.

[1]The P-value is less than 0.05. LDA: Linear discriminant analysis; MS: Maternal separation; pTNBS: TNBS post-inflammatory.

By week 12, *Fusobacterium* colonized in significantly greater abundance in MS rats, and its abundance was positively correlated with higher VHI scores. The *Fusobacteria* phylum also tends to be higher in published IBS cohorts[6]. *Fusobacterium* was invasive to the gut epithelial cells and has already been documented as being involved in the pathogenesis of colorectal adenoma[20-22] and inflammatory bowel disease[23,24]. This represents the first study documenting that *Fusobacterium* was involved in visceral hypersensitivity. Whether the increased colonization of *Fusobacterium* caused low grade inflammation and thus contributed to visceral hypersensitivity is not currently known. Moreover, both *Fusobacterium* and members in *Clostridium* are known short chain fatty acid (SCFA) producers[24-26]. The low fermentable oligo-, di-, and monosaccharides and polyol (FODMAP) diet has been shown to be an efficacious therapy for the reduction of IBS symptoms in randomized controlled trials[27-29]. Supplementing food containing FODMAP to IBS patients and healthy people would trigger gastrointestinal symptoms to a larger extent in the patient group[30]. However, the mechanism of treatment with a low FODMAP diet and why IBS patients are more sensitive to FODMAP remains unknown[31]. In this study, we identified two butyric producing taxa, *Fusobacterium* and *Clostridium*, which significantly correlate to visceral hypersensitivity or are disease biomarkers. Their colonization may render patients more ready to produce SCFA and gas in the presence of FODMAP. It was reported that the butyrate-producing *Clostridium* cluster XIVa significantly increased in IBS patients consuming a typical high FODMAP diet compared with those on a low FODMAP diet[32]. Farmer *et al*[33] showed that caecal intraluminal pH was significantly lower in IBS patients compared to controls. Thus, the detailed mechanistic role of *Fusobacterium* and *Clostridium* in IBS warrants further study.

Porphyromonadaceae is a family belonging to the order of *Bacteroidales* and the class *Bacteroidetes*. Among others, *Barnesiella* and *Butyricimonas* are genera under *Porphyromonadaceae*. Unfortunately, the biological function of *Porphyromonadaceae* has not been characterized in detail, and little attention has been paid to their role in gastrointestinal diseases. A previous study documented that *Barnesiella* was enriched in dextran sulfate sodium-induced colitis[34]. In our study, *Barnesiella* was also enriched 4 weeks after TNBS instillation. Whether *Barnesiella* promoted the inflammation or was passively enriched under inflammatory conditions was not determined in the current study. A recent review paper[35] summarized 29 relevant original research articles concerning microbiota analysis and IBS. Durbán's pyrosequencing

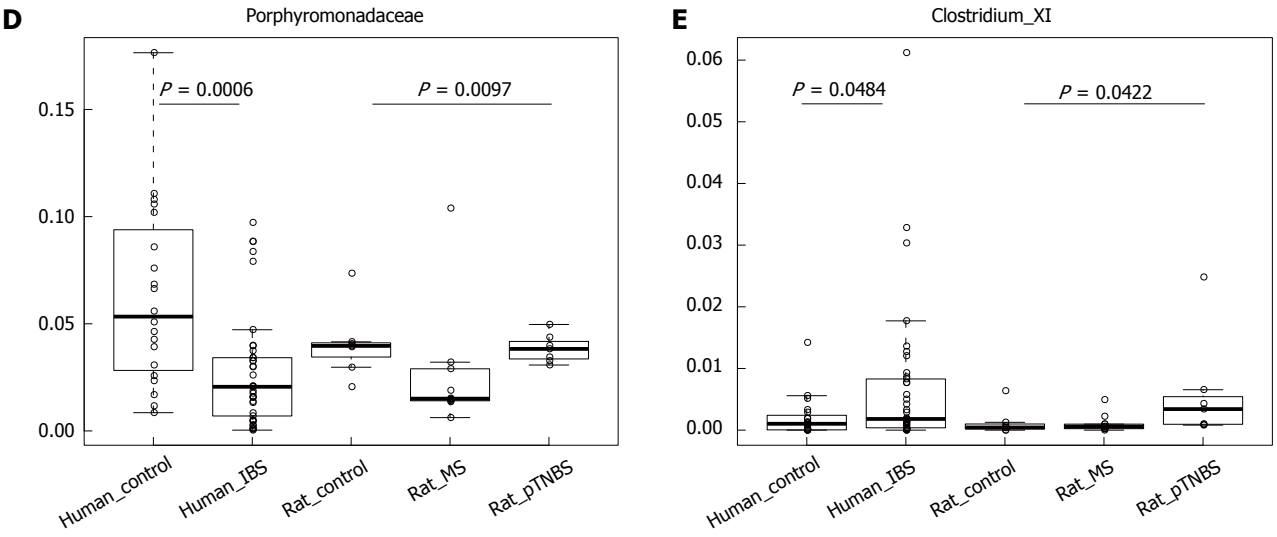

Figure 6 Comparing rat model dysbiosis to that of Jeffery's human irritable bowel syndrome cohort. A: Cladogram indicates the biomarkers of different abundances between groups; B: Venn plot of the positive (increased) biomarkers shared by rat models and Jeffery's human IBS cohort. The overlapped area indicates that the two groups have common biomarkers. The MS rat does not share biomarkers from the human cohort; C: Abundance of the *Fusobacteria* phylum marginally increased in the human IBS cohort; D: Abundance of *Porphyromonadaceae* in fecal samples of healthy human controls, human IBS patients, control rats, MS rats, and pTNBS rats. *Porphyromonadaceae* was depleted in both the human IBS group and the MS rats; E: Abundance of *Clostridium XI* in fecal samples of healthy human controls, healthy IBS patients, control rats, MS rats, and pTNBS rats. *Clostridium XI* increased in both human IBS patients and pTNBS rats. IBS: Irritable bowel syndrome; MS: Maternal separation; pTNBS: TNBS post-inflammatory.

study[36] found that the family *Porphyromonadaceae* was increased in the fecal samples of IBS subjects. In our study, the *Porphyromonadaceae* was highest in the control group by week 12. The discrepancy may be explained by the different nature between human patients and rat models.

IBS is a human disease with multifactorial pathophysiology[37], and the prevalence of IBS is associated with social-economic factors[38]. To date no available model could ideally model the IBS pathogenesis. IBS is heterogeneous and thus unlikely to be modeled in any single model. Although common biomarkers were found between human IBS patients and rat models, the limitations of rat models should also be taken into consideration. The pTNBS model was triggered by a pro-inflammatory molecule (TNBS). Therefore, this model resembles the human inflammatory bowel disease to some extent and can only mimic the post-infectious IBS, which is associated only to a percentage of patients. Furthermore, the causal relationship between visceral hypersensitivity, dysbiosis, and the symptoms of IBS is not clear and remains to be untangled in the future.

In summary, both the MS and the post-inflammation rat models developed dysbiosis in the fecal microbiota, and the models captured parts of the dysbiosis features of human IBS patients. The potential pathogenic role of *Fusobacterium* and *Clostridium XI*, as well as the protective role of *Porphyromonadaceae* warrants further mechanistic study.

ACKNOWLEDGMENTS

We acknowledge Dr. Ian Jeffery and Dr. Paul W. O'Toole for sharing their sequencing data from human IBS patients and healthy controls.

COMMENTS

Background

Previous studies have indicated that the gut microbiota participated in the pathogenesis of irritable bowel syndrome (IBS).

Research frontiers

Dysbiosis of the gastrointestinal microbiota and hypersensitivity to colonic distension are critical features of IBS. For animal models, the correlation between dysbiosis in the microbiota and visceral hypersensitivity remains unknown.

Innovations and breakthroughs

Dysbiosis triggered by neonatal maternal separation (MS) was lasting but not static. Both MS and post-inflammatory rat fecal microbiota deviated from that of the control rats to an extent that was larger than the co-housing effect. *Fusobacterium*, *Clostridium XI* and *Porphyromonadaceae* were identified as targets for future mechanistic research.

Applications

This study indicated that the two animal models could capture part of the dysbiosis features of IBS. Further mechanistic study on the biomarkers' role in the pathogenesis is warranted.

Peer-review

The manuscript is excellent and addresses adequately the relationship between dysbiosis and visceral hypersensitivity in experimental animals. The quality of the study design and experimental investigations are very high.

Abstract

AIM: To investigate the factors influencing the occurrence of gastric varioliform lesions (GVLs) and their possible link with gastric cancer.

METHODS: A 1:1 matched case-control study was performed to retrospectively analyze data from 1638 chronic gastritis patients who had undergone gastroscopy at one of two Chinese hospitals between 2009 and 2014. Patients with GVLs (cases) were compared to those without such lesions (controls). Endoscopic and pathological findings were recorded, along with interview information on *Helicobacter pylori* (*H. pylori*) infection, medical, drug and family histories, lifestyle and eating habits. The association between each factor and the occurrence of GVLs was estimated, and then multivariate conditional logistic regression was used to evaluate the independent factors.

RESULTS: The frequency and severity of glandular

atrophy, intestinal metaplasia (IM) and low-grade intraepithelial neoplasia were significantly increased in the GVL group ($P < 0.01$). Overall analysis showed that *H. pylori* infection [3.051 (2.157, 4.317), $P < 0.001$], allergic respiratory diseases [3.636 (2.183, 6.055), $P < 0.001$], work-related stress [2.019 (1.568, 2.600), $P < 0.001$], irregular meals [2.300 (1.462, 3.619), $P < 0.001$], high intake of spicy food [1.754 (1.227, 2.507), $P = 0.002$] and high intake of fresh fruit [0.231 (0.101, 0.529), $P = 0.001$] were significantly correlated with the occurrence of GVLs (positively, except for the latter). Stratified analyses indicated that pickled food consumption in patients over 50 years old [7.224 (2.360, 22.115), $P = 0.001$] and excessive smoking in men [2.013 (1.282, 3.163), $P = 0.002$] were also positively correlated, and that, for antral GVLs, vegetable consumption [0.491 (0.311, 0.776), $P = 0.002$] was negatively correlated.

CONCLUSION: Seven risk factors and two protective factors are determined for GVLs, which were found to be associated with premalignant abnormalities.

Key words: Gastric cancer; Gastric varioliform lesions; Precancerous lesion; Risk factor; Varioliform gastritis

Core tip: To our knowledge, this is the first case-control study investigating the factors influencing the formation of gastric varioliform lesions, which were supposed to be associated with gastric neoplasia in previous reports. Our results indicate a potentially increased cancer risk for the affected patients, and that *Helicobacter pylori* infection, allergic respiratory diseases, high work-related stress, irregular meals, high intake of spicy food, pickled food consumption in elder people, excessive smoking in men, consumption of vegetables and high intake of fresh fruit are found to be correlated with the occurrence of gastric varioliform lesions.

INTRODUCTION

Varioliform gastritis (VG), or "octopus sucker" gastritis in the foreign literature and verrucous gastritis in the national literature, is a disease with a characteristic endoscopic manifestation but no specific clinical symptoms. The major endoscopic feature is the presence of gastric varioliform lesions (GVLs), namely, widespread small lesions, manifesting as round, oval or irregularly shaped elevations, often possessing a central umbilical-like depression covered in gray-colored secretion or tiny bleeds. In 1947, Moutier and Martin[1] first described two cases of this distinctive gastric mucosal disease, and then in 1978, Lambert *et al*[2] classified the disease, according to its site of occurrence, into "diffuse" VG when spread throughout the stomach, and "antral" VG when restricted to the antrum. These two forms of VG are thought to have different etiopathogenesis and histological manifestations[3]. VG has been recognized as a protruded type of chronic erosive gastritis in the Consensus on Chronic Gastritis in China (2012)[4], but endoscopists more often present the diagnosis as chronic gastritis with varioliform lesions.

Until recently, very little was known about the etiopathogenesis of GVLs. Malfertheiner *et al*[5] reported that the *Helicobacter pylori* (*H. pylori*) infection rate was 89% among 37 patients with GVLs, and their clinical symptoms and mucosal inflammation were substantially improved after effective eradication of the infection. In the national literature, most authors support this point of view and regard *H. pylori* as the main cause of GVLs. On the other hand, several studies have provided compelling evidence that type Ⅰ hypersensitivity may play a role[6]. Andre *et al*[7] found a large number of IgE-containing cells in the affected gastric mucosa and a significantly increased incidence of allergic diseases in patients with GVLs, as compared with the normal population. Furthermore, they performed a randomized double-blind placebo-controlled trial to compare clinical and endoscopic outcomes in patients treated with sodium cromoglycate, cimetidine or placebo[8]. The result stated that treatment with sodium cromoglycate greatly improved both sets of outcomes, whereas treatment with cimetidine or placebo showed no appreciable effect. Other previously reported pathogenic factors include hyperacid[9] and viral infection[10].

Some reports suggest a possible association between GVLs and gastric neoplasia. In 1960, Munoz Monteavaro *et al*[11] observed "*in situ*" carcinomatous transformation in a patient with VG, and other groups have reported similar findings more recently[12,13]. The elevated lesions can persist and transform into sessile polyps and appear as a gastric carcinoma several years later; as a result, the disease was classified as a precursor to gastric cancer at the World Congress of Gastroenterology (WCOG) in 1994. Diverse risk factors are involved in gastric carcinogenesis, including bacterial, environmental, dietary and genetic variables[14]. Numerous epidemiological studies have attempted to shed light on the factors impacting gastric neoplasia and precancerous lesions; these include a history of diabetes[15], aspirin consumption[16], excessive smoking[17] and drinking[18], pickled food consumption[19], tea consumption[20], amongst others. However, the results are somewhat inconsistent due

to the ethnic diversity and limited sample size. A recent systematic review concluded that smoking, drinking, red meat and pickled food were risk factors, and that fresh vegetables and fruit may be protective; there was insufficient evidence to draw conclusions regarding coffee, tea or seafood[21]. GVLs may share some of these risk factors, and clarifying the matter should provide a better understanding of this potentially premalignant condition, allowing physicians to better identify at-risk patients and to devise more effective treatment strategies. Therefore, we carried out a retrospective 1:1 matched bi-center case-control study, analyzing endoscopic and pathological data from 1638 patients with chronic gastritis. The association between potentially relevant variables and the occurrence of GVLs was systematically evaluated, with an aim to find independent risk factors and protective factors.

MATERIALS AND METHODS

Study sample and selection criteria

A 1:1 matched case-control study was conducted, analyzing data from outpatients who had undergone gastroscopy at Renji Hospital, Shanghai Jiao-Tong University School of Medicine or the Nanjing Drum Tower Hospital, Nanjing University School of Medicine between 2009 and 2014. A total of 1638 chronic gastritis patients were enrolled, all of which fell into one of two categories: those with GVLs (cases; n = 819) or those without such lesions (controls; n = 819).

To populate the case group, we searched the electronic databases of the aforementioned hospital endoscopic centers, using the following keywords: "varioliform gastritis" or "with gastric varioliform lesions" or "with erosive elevations"; then we closely examined the corresponding patient images and selected those patients having at least three typical lesions. Any disagreement was discussed by T.H. Zou and R.H. Zheng before reaching a consensus. Control patients, who were diagnosed with chronic gastritis at the same time, but without varioliform lesions, were matched one by one with the case group members, based on gender, age ± 2 years, month of examination and endoscopist. The exclusion criteria were strictly adhered to and were as follows: those who had no biopsy, those who were diagnosed with gastric cancer and those who had undergone partial or total gastrectomy. For those who had repeated examinations, we only recorded data from the first diagnostic gastroscopy.

Data extraction

The endoscopic and pathological findings were recorded. All the patients were required to undergo a gastroscopy with biopsies for the diagnosis. All parts of the upper gastrointestinal tract were carefully examined for any lesions by experienced endoscopists, and at least two biopsies were taken from the antrum. If suspected lesions were found, 2 to 5 more biopsies were taken. Pathological examinations for chronic gastritis were made by experienced pathologists according to the visual analogue scale (VAS) in the updated Sydney System[22,23] that is associated with the Consensus on Chronic Gastritis in China. Histological diagnosis of intraepithelial neoplasia was made based on the World Health Organization (WHO) classification[24]. To concretely differentiate the severity of inflammation, glandular atrophy or IM in the present study, a scheme was introduced using the following calculation: grading index = $(S_1 \times B_1 + S_2 \times B_2 + \ldots + S_n \times B_n)/B_n$, where S is the severity of a particular biopsy specimen, B is the number of the relevant specimen and n is the quantity of specimens[25].

H. pylori infection was detected using a *H. pylori* rapid urease test during endoscopic examination, HE and Giemsa staining of biopsy specimens, and a ^{13}C urea breath test. We defined a positive result as meeting one of the following two criteria: (1) the rapid urease test or HE staining was positive; or (2) if both urease and HE results were negative, yet the specimen was highly inflamed, Giemsa staining was added or a ^{13}C urea breath test was performed, and a positive outcome was considered indication of *H. pylori* infection. A ^{13}C urea breath test was subsequently used when evaluating the effect of eradication on *H. pylori* infection.

A questionnaire was designed by the authors and it was used to conduct telephone interviews with all patients in the study. The investigators were trained to be polite and methodical during interviews and they avoided calling patients at working, or otherwise busy hours. The questionnaire requested information on the patient's gender, age, *H. pylori* infection history, medical history, allergic diseases, drug history, family history, long-term lifestyle and eating habits. *H. pylori* infection history was categorized according to four different conditions: currently infected, but with no previous history of infection; chronic (repeated or persistent) infection; past infection that has been completely eradicated; no current or past infection. Allergic diseases consisted of bronchial asthma, allergic rhinitis, allergic skin disease, drug allergy, *etc*. The presence of allergic diseases was mainly based on the interview data, and the authors made the judgment with reference to the guideline of diagnosis for each disease. Lifestyle variables included sleep quality, work-related stress, tobacco smoking and alcohol consumption. Eating habits comprised irregular meals, intake of spicy food, pickled food, fried food, fresh fruit and vegetables; consumption of a particular food type over four time per week was considered high.

Statistical analysis

Statistical analyses were performed using SPSS Version 20.0 (SPSS Inc., Chicago, IL, United States).

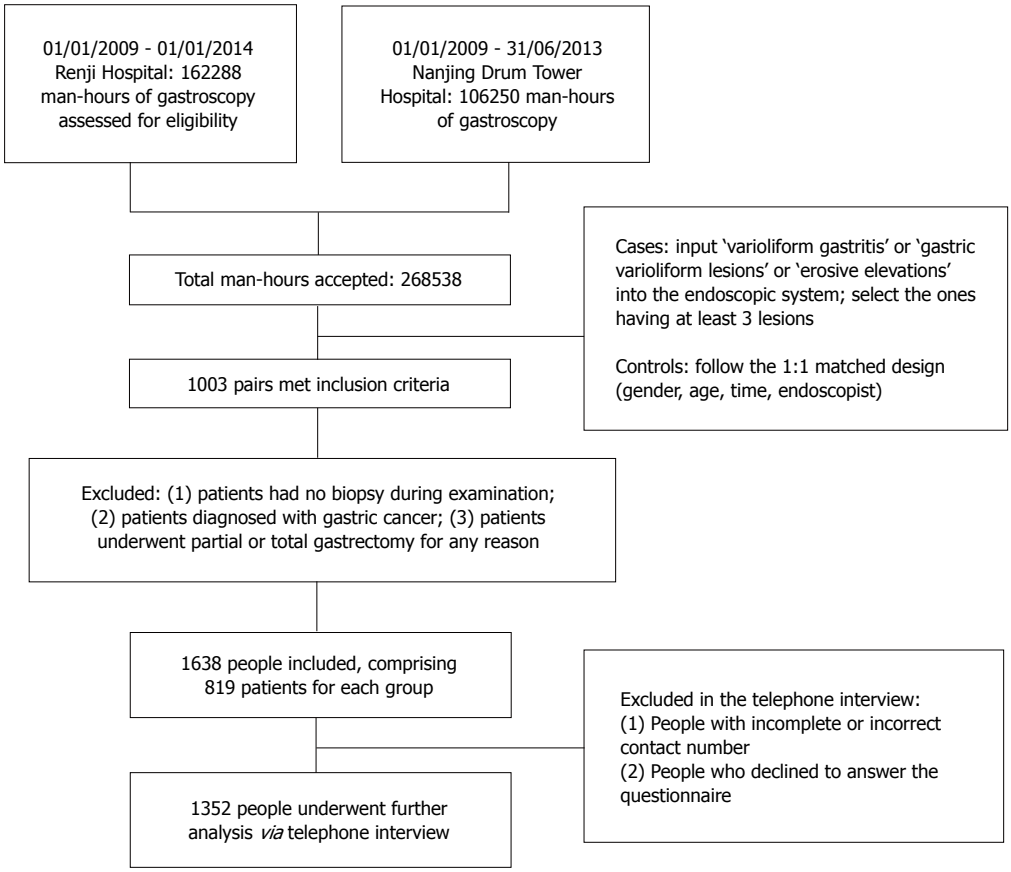

Figure 1 Flow chart of participant selection in the case-control study.

Table 1 Characteristics of the case group *n* (%)

Characteristic

Glandular atrophy	363 (44.3)
IM	265 (32.4)
Intraepithelial neoplasia	92 (11.2)

H. pylori: *Helicobacter pylori*.

Measurement data were compared between the two groups using a paired *t*-test; where appropriate, numerical data were subjected to a chi-square test, while categorical data using a Mann-Whitney test. Single-factor analysis was used to estimate the association between each potential factor and GVLs, and then multivariate conditional Logistic regression analysis was applied to determine the independent risk and protective factors. Odds ratios (ORs) with 95% confidence intervals (95%CIs) were used to assess the magnitude of the associations. A two-sided *P*-value < 0.05 was considered statistically significant.

RESULTS

The systematic database search yielded 268538 man-hours of gastroscopy over the five-year period of interest. Following the inclusion/exclusion criteria and the 1:1 matched design, 1638 subjects were selected to populate the case and control groups. A flow chart of the selection process is presented in Figure 1. There were 448 men and 371 women in the case group, with a mean age of 53.40 ± 11.41 years (ranging from 18 to 87 years old). The basic, endoscopic and pathological characteristics of the case group are shown in Table 1.

Analysis of histological data

We compared the frequencies of *H. pylori* infection, glandular atrophy, IM and intraepithelial neoplasia between the cases and controls using a χ^2 test. The difference was significant for *H. pylori* infection (OR

Table 2 Overall and stratified analyses of histological data in the case-control study

	Case	Control	OR [95%CI]	*P*-value
Overall analysis				
H. pylori (+)	263	141	2.275 [1.801, 2.872]	< 0.001[b]

= 2.275, 95%CI: 1.801-2.872, $P < 0.01$), especially in the patients with diffuse GVLs. We also noted statistically significant findings in the pooled analysis for the association between glandular atrophy, with or without IM, and the formation of such lesions. Furthermore, a significantly increased risk of low-grade intraepithelial neoplasia was observed in the case group (OR = 1.468, 95%CI: 1.052-2.049, P = 0.023); this is known to be a premalignant condition. When the patients were further stratified according to VG form, the differences between patients with antral lesions and their matched controls were significant for glandular atrophy and IM, but not for intraepithelial neoplasia. On the other hand, diffuse lesions were strongly associated with all these histological parameters, including intraepithelial neoplasia. The results of the overall and stratified analyses are presented in Table 2.

Indices for grading inflammation, glandular atrophy and IM were calculated separately for the GVL patients and their matched controls. Paired *t*-tests showed that all these indices were significantly increased in the case group ($P < 0.01$).

Analysis of telephone interview data

For 49 patients, the contact number was incomplete or incorrect, and 94 declined to answer the questionnaire. Thus, there was a total of 1352 participants, comprising 676 people from each group; the answering ratio was 82.5%. Single-factor analyses of potential factors demonstrated that current infection with *H. pylori* (OR = 2.203), chronic infection with *H. pylori* (OR = 2.493), bronchial asthma (OR = 6.837), allergic rhinitis (OR = 2.963), family history of gastric cancer (OR = 1.926), high work-related stress (OR = 1.871), irregular meals (OR = 1.703), and high intake of spicy food (OR = 1.540) were positively associated with the occurrence of GVLs, while high intake of fresh fruit was negatively associated (OR = 0.721).

We found a negative correlation between current and chronic infection with *H. pylori* (Pearson coefficient, -0.113), and a positive correlation between bronchial asthma and allergic rhinitis (Pearson coefficient, 0.151). No correlation was found for any other factors. For subsequent analyses, we combined current and chronic infection into a single "*H. pylori* infection" category, and asthma and rhinitis were combined into "allergic respiratory diseases". Based on the results of single-factor analyses, we included the factors with a *P*-value less than 0.05 into the multivariate conditional Logistic regression equation. The adjusted analysis suggested that *H. pylori* infection, allergic respiratory diseases, high work-related stress, irregular meals and high intake of spicy food were independent risk factors for the formation of GVLs; and that high intake of fresh fruit was an independent protective factor. Table 3 shows the overall results of the single-factor and multivariate analyses.

Stratified analysis of telephone interview data

The participants were stratified by age, gender and VG form, and the results of the subsequent analysis are shown in Table 4. For those under 50 years old, high intake of fried food was significantly more common in the GVL group (P = 0.038) under univariate analysis; however, the correlation was not significant in the final multivariate analysis, suggesting that fried food intake may be a confounding factor. In those $\geqslant$ 50 years old, univariate and multivariate analyses indicated that pickled food consumption was a new independent risk factor for GVLs. In males, excessive smoking was also found to be a new independent risk factor, while in females, allergic skin diseases seemed to be a confounding factor. For antral form, single-factor analyses showed significant differences between cases and controls for fried food consumption and intake of vegetable side dishes, but only the latter factor was confirmed as an independent factor by the adjusted multivariate analysis. For diffuse form, current or chronic *H. pylori* infection was found in more than half

Table 3 Overall single-factor and multivariate analyses of impact factors in the case-control study

Impact factor	Univariate analysis			Multivariate analysis		
	OR	95%CI	*P*-value	OR	95%CI	*P*-value

of the affected patients, whereas only two matched controls had ever been infected. The diffuse form seemed to be more highly correlated with *H. pylori* infection, but with only thirteen pairs of participants making up the sample, no more than a general tendency could be assessed. Allergic respiratory diseases and a family history of gastric cancer were more frequent in patients with diffuse varioliform lesions *vs* matched controls.

DISCUSSION

As is widely accepted, intestinal-type gastric carcinogenesis is a multi-stage process, developing from chronic gastritis through a series of precancerous abnormalities to gastric carcinoma[26,27]. In addition, *H. pylori* infection is thought to be the key promoter[28,29]. These precursor conditions include chronic atrophic gastritis with or without IM, with a reported malignancy rate of 0.5%-1%[30,31], and intraepithelial neoplasia[32], which is classified from low to high grade according to WHO specifications. It is reported that 0%-15% of low-grade intraepithelial neoplasia could progress to high-grade, which has an extremely high malignancy rate of 25%-85%[33]. In the present study, the frequency and severity of glandular atrophy, IM and low-grade intraepithelial neoplasia were significantly elevated in the case group, indicating that the presence of GVLs is a potential risk factor for cancer. Nevertheless, no high-grade intraepithelial neoplasia was observed, and the results were inconsistent when analysis was restricted to antral varioliform lesions. Thus, this malignancy risk should be further investigated *via* a large-scale prospective study.

In view of the association between GVLs and *H. pylori* infection status, the literature is somewhat inconclusive[34]. Our analysis showed a statistically significant difference in infection rates between GVL patients (32.1%) and controls (17.2%). The adjusted analysis of the interview data indicated that *H. pylori* infection, especially chronic persistent infection, was a pathogenic factor. In contrast, no correlation existed where infections had been successfully treated. Thus, *H. pylori* eradication and regular endoscopic follow-ups should be key components of the treatment for GVLs.

European researchers have suggested that there may be an allergic component in the pathogenesis of the disease, specifically that excessive histamine release could play a central role[7,35]; however, no evidence for this has been reported for Chinese patients. Interestingly, we found that the frequency of allergic diseases was increased in patients with varioliform lesions, in particular bronchial asthma and allergic rhinitis. There were 112 GVL patients (16.6%) with at least one allergic disease, and the multivariate analysis confirmed that allergic respiratory disease was an independent risk factor. Family history of gastric carcinoma has been reported as a risk factor for gastric carcinogenesis[36,37], but it was not associated with GVLs in our study. Diffuse form appeared to have a more positive association with allergic diseases and family history of gastric cancer, yet the results were not conclusive owing to the limited sample size, and will thus need to be verified by larger studies in the future.

In the pooled multivariate analysis, the independent risk factors were high work-related stress, irregular meals, and high intake of spicy food, and the one potentially protective factor was high intake of fresh fruit. The stratified analyses indicated that pickled food consumption in people over 50 years old and excessive smoking in men were also risk factors. Intake of vegetable side dishes was found to be negatively correlated with the antral form of GVLs. Indeed, certain habits of daily life could serve as important risk factors for gastric cancer. Previous studies revealed a close association between negative psychological factors like nervousness or anxiety and susceptibility to neoplasia[38,39]. Our participants with high work-related stress could have an increased risk of gastric malignancy, which may be related to constant anxiety-induced stimulation of the sympathetic system. Smoking is also considered a pathogenic factor for multiple cancers. A 50-year observational study of 34439 British doctors indicated that cigarette smoking was a risk factor in the progression of 14 different cancers including gastric carcinoma[40]. In the present study, excessive smoking in men contributed significantly to the risk of GVLs, but not in women, indicating possible male predominance in the morbidity

of the disease. Concerning food consumption, pickled foods have been associated with the development of esophageal and gastric cancers, which can damage gastric mucosa and exacerbate the inflammation caused by *H. pylori*[41]. In recent times, Chinese dietary habits have changed dramatically. Pickled food may now be less popular in younger sections of the population, whereas spicy foods have greatly increased in popularity. Although capsaicin in spicy food has been shown to help counter the growth of *H. pylori*[42], we found that high intake of spicy food was a risk factor for varioliform lesions. The reason could be related to oncogene exposure or a chemical process during production. Meanwhile, the present study also provided factors that potentially offer some protection against GVLs. Intake of fresh vegetables and fruit has been reported to beneficial for avoidance of gastric neoplasia[43], which is consistent with the corresponding reduction in the frequency of GVLs seen in our study.

Several limitations of the present study must be taken into account. First, it is a retrospective analysis, for which recall bias and selection bias cannot be completely removed; a prospective study would be required to establish a convincing causal relationship between the factors and the disease. Second, the conclusions of the stratified analyses may be of limited value because of the small sample size, especially in the diffuse form group. Thus, some of the results in our study should be interpreted cautiously. Third, other relevant variables such as body mass index (BMI), hyperlipidemia, ABO blood group, consumption of coffee, carbonated drinks and bean products were not included; in addition, several factors such as the type of cigarette or alcohol consumed, medication dose and professional mental scale were not precisely classified. If the above factors were included in the multivariate regression equation, our results could have been very different. Future studies should therefore use a more complete set of variables.

To the best of our knowledge, this is the first case-control study investigating the factors influencing the formation of GVLs. The results suggest a potentially increased cancer risk for the affected patients, and that *H. pylori* infection, allergic respiratory diseases, high work-related stress, irregular meals, high intake of spicy food, pickled food consumption in older people, and excessive smoking in men were all positively correlated with the occurrence of GVLs. In contrast, consumption of vegetables and high intake of fresh fruit were found to be negatively correlated and therefore potentially protective. In summary, our results suggest that formation of GVLs can be reduced by maintaining a healthy lifestyle and positive attitude, while ensuring that allergic diseases and *H. pylori* infection are treated effectively. We suggest that a prospective study should be carried out in the future to examine the morphological and pathological evolution of GVLs, and thereby clarify their relationship with gastric malignancy. A large-scale, well-designed clinical trial is also warranted to provide more precise and robust conclusions on this matter.

COMMENTS

Background

Researchers discovered the presence of gastric varioliform lesions (GVLs) over 60 years ago, but until now, very little was known about the etiopathogenesis and progression. So the authors try to provide a better understanding of this potentially premalignant disease in the present case-control study.

Research frontiers

Previous reports suggested a possible association between GVLs and gastric cancer. And the disease was classified as a precursor to gastric cancer at the World Congress of Gastroenterology in 1994. More recently, Zhang *et al* performed a proteomic analysis to provide more molecular biological details of GVLs. The important differential proteins could serve as potential biomarkers for the early diagnosis of gastric cancer.

Innovations and breakthroughs

This is the first case-control study investigating the factors influencing the formation of GVLs, and the manuscript provide a better understanding of this potentially premalignant condition, allowing physicians to better identify at-risk patients and to devise more effective treatment strategies.

Applications

A large-scale, well-designed prospective study should be carried out in the future to examine the morphological and pathological evolution of GVLs, and thereby clarify their relationship with gastric malignancy.

Terminology

The term GVLs in the present study is a synonym of varioliform gastritis. The major endoscopic feature of such lesions is widespread small lesions, possessing a central umbilical-like depression covered in gray-colored secretion or tiny bleeds. Patients in China are affected more often by the antral type of the disease, thus endoscopists present the diagnosis as GVLs.

Peer-review

Patients diagnosed in an early stage of gastric cancer present an excellent prognosis, with a five-year survival rate greater than 90%. This well conducted and written retrospective case-control study considers the different risk and protective factors influencing the occurrence of GVLs and their possible link with development of gastric cancer.

Abstract

AIM: To investigate the long-term oncologic outcomes and prognostic factors in patients with obstructive colorectal cancer (CRC) at multiple Japanese institutions.

METHODS: We identified 362 patients diagnosed with obstructive colorectal cancer from January 1, 2002 to December 31, 2012 in Yokohama Clinical Oncology Group's department of gastroenterological surgery. Among them, 234 patients with stage Ⅱ/Ⅲ disease who had undergone surgical resection of their primary lesions were analyzed, retrospectively. We report the long-term outcomes, the risk factors for recurrence, and the prognostic factors.

RESULTS: The five-year disease free survival and cancer-specific survival were 50.6% and 80.3%, respectively. A multivariate analysis showed the ASA-PS (HR = 2.23, P = 0.026), serum Albumin ⩽ 4.0 g/dL (HR = 2.96, P = 0.007), T4 tumor (HR = 2.73, P = 0.002) and R1 resection (HR = 6.56, P = 0.02) to be independent risk factors for recurrence. Furthermore, poorly differentiated cancers (HR = 6.28, P = 0.009), a T4 tumor (HR = 3.46, P = 0.011) and R1 resection (HR = 6.16, P = 0.006) were independent prognostic factors in patients with obstructive CRC.

CONCLUSION: The outcomes of patients with obstructive CRC was poor. T4 tumor and R1 resection were found to be independent prognostic factors for both recurrence and survival in patients with obstructive CRC.

Key words: Obstructive colorectal cancer; Prognostic factor; Survival

Core tip: Obstructive colorectal cancer (CRC) still have poor prognosis. However, the prognostic factor of obstructive CRC is unclear. The aim of this article is to clarify the long-term outcome and the risk factors for obstructive CRC at multiple institutions. The five-year disease free survival and cancer-specific survival were 50.6% and 80.3%, respectively. T4 tumor and R1 resection were independent prognostic factors for both recurrence and survival.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer in Japan, and the incidence of CRC has been increasing rapidly. CRC is difficult to diagnose due to it early atypical symptoms and signs. Around 7%-16% of patients with colorectal malignancy present with acute colorectal obstruction[1-3]. It is generally accepted that right sided obstructive CRC can best be treated by right hemicolectomy with ileocolic anastomosis. On the other hand, the optimal treatment for left-sided obstructive CRC remains controversial[4-7]. The treatment options range from an emergency radical operation, such as Hartmann's procedure, to bowel decompression using metallic stents or transanal tube or proximal diversion with a subsequent staged resection. The choices of surgical intervention for obstructive CRC vary greatly, according to the tumor location, general condition of the patients, and the experience level of the surgeons[8]. Therefore, It has been reported that CRC patients with obstruction have an advanced stage and worse long-term survival compared to non-obstructive CRC[3,9-11]. Although the negative impact of obstruction on the postoperative outcomes has been well documented, few studies have examined the outcomes of obstructive CRC patients in Japan[11-13]. Furthermore, the risk factors for recurrence and the prognostic factors are unclear owing to the small number of patients in previous study.

The aim of this study is to investigate the long-term oncologic outcomes and prognostic factors in patients with obstructive CRC at multiple Japanese institutions.

MATERIALS AND METHODS

Three hundred and sixty-two patients who were diagnosed to have obstructive colorectal cancer from January 2002 to December 2012 at the Yokohama Clinical Oncology Group's Department of Gastroenterological Surgery (10 institutions) were enrolled. Obstructive CRC was diagnosed based on medical history, physical examination, abdominal computed tomography (CT), and colonoscopy, and the surgical findings. We first performed emergency decompression of bowel obstruction by ileostomy/colostomy or the insertion of a decompression tube, or emergency resection of the primary lesion. The type of decompression method was chosen according to the surgeon's judgment and preference. Patients with distant metastatic lesions (n = 103), who only underwent stoma creation and best supportive care (n = 23), stage Ⅰ (n = 2) were excluded from this study. As a result, 234 patients who underwent surgical resection were analyzed retrospectively (Figure 1). The prognostic factors

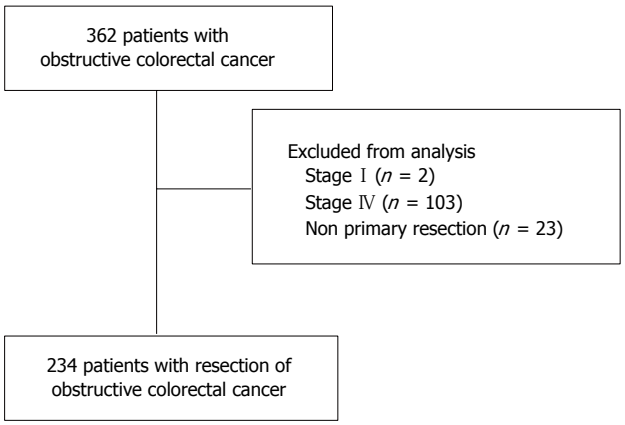

Figure 1 Study flowchart.

influencing survival and risk factors for recurrence were analyzed.

Clinicopathological information was obtained from the medical records of the patients including gender, age, The American Society of Anesthesiologists (ASA)-physical status (PS), serum albumin, CEA, preoperative decompression, location of the tumor, tumor size, differentiation of the tumor, depth of the tumor, intramural lymphatic invasion, intramural vascular invasion, lymph node dissection, number of lymph nodes harvested, lymph node involvement, postoperative complication, anastomotic leakage, curability, and adjuvant chemotherapy. There were missing values for BMI in 13 patients, for serum albumin in 14 patients, for CEA in 19 patients, for tumor size in 4 patients, for lymphatic invasion in one patient and for harvested lymph nodes in 10 patients because this was a retrospective study.

Japanese D3 lymphadenectomy is equivalent to complete mesocolic excision (CME) with central vascular ligation (CVL)[14]. D2 lymphadectomy includes pericolic and intermediate nodes region, and D0-1 includes only pericolic nodes region.

Statistical analysis

The disease-free survival (DFS) and cancer-specific survival (CSS) were estimated using the Kaplan-Meier method, and statistical significance was determined by the log-rank test. A multivariate analysis was performed using the Cox proportional hazard model to examine the independent prognostic factors and risk factors of recurrence. A *P* value of < 0.05 indicated statistical significance. All analyses were performed using the IBM SPSS, version 21 (SPSS Inc., Chicago, IL, United States).

This study received approval from the institutional review board of Yokohama City University.

RESULTS

Characteristic of the patients

The clinicopathological characteristics of the patients are summarized in Table 1. There were 234 patients who underwent surgical resection for obstructive CRC. The median age of the patients was 71 years (range 35-96) and there were 141 (60.3%) men and 93 (39.7%) women. Of these patients, 183 patients (72.2%) received preoperative decompression by colostomy/ileostomy (*n* = 56) or transanal tube insertion (*n* = 127)[15]. The most common tumor site was the sigmoid colon (*n* = 95). Other primary tumors were located in the descending colon (*n* = 36), ascending colon (*n* = 33), transverse colon (*n* = 33), rectum (*n* = 27), and cecum (*n* = 10). Among the 234 patients in this study, 165 patients (70.5%) had obstructing cancers at a site distal to the splenic flexure. T4 tumors were found in 125 patients (53.4%). There were 113 stage Ⅱ patients and 121 stage Ⅲ patients. In the stage Ⅲ cases, 90 patients had N1 disease and 31 patients had N2.

Table 1 Clinicopathological characteristic of patients with obstructive colorectal cancer *n* (%)

Variable	Category	*n* = 234
Gender	Male	141(60.3)
	Female	93 (39.7)
Age (yr)[1]		71 (35-96)
ASA	Ⅰ	70 (30)
	Ⅱ	128 (54.7)
	Ⅲ	36 (15.3)
Location of tumor	Cecum	10 (4.3)
	Ascending colon	33 (14.1)
	Transverse colon	33 (14.1)
	Descending colon	36 (15.4)
	Sigmoid colon	95 (40.6)
	Rectum	15 (10.5)
Decompression	+	183 (78.2)
	-	51 (21.8)
CEA (mg/dL)[1]		4.9 (0.3-2470)
Serum albumin[1]		3.4 (1.4-4.9)
Tumor size(mm)		48 (10-140)
Depth of tumor	pT3	109 (46.6)
	pT4a	93 (39.7)
	pT4b	32 (13.7)
Lymph node involvement	N0	113 (48.3)
	N1	90 (38.5)
	N2	31 (13.2)
R0 resection	+	219 (93.6)
	-	15 (6.4)
Adjuvant chemotherapy	+	91 (38.9)
	-	143 (61.1)

[1]Median (range).

A total of 219 patients (93.6%) underwent R0 resection of the primary lesion. The reasons of R1 resection (*n* = 15) were positive surgical margins in 11 patients, other organ involvement in 3 patients and residual lymph node metastasis in 1 patient.

Ninety-one of the 234 patients underwent adjuvant chemotherapy. The chemotherapeutic regimen was oral 5-fluorouracil (5-FU) in 47 patients, oral 5-FU plus leucovorin in 36, oxaliplatin-based chemotherapy in 5, and a Roswell Park Memorial Institute (RPMI) regimen in 3[16].

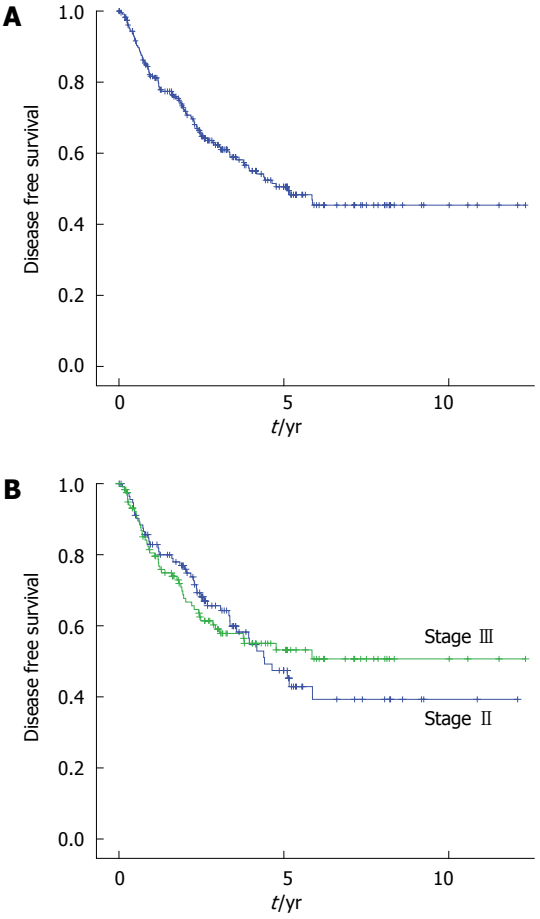

Figure 2 Kaplan-Meier curves showing the disease free survival after primary tumor resection in patients with obstructive colorectal cancer. A: All stage (n = 234); B: Stage Ⅱ (n = 114, blue line), Stage Ⅲ (n = 120, green line).

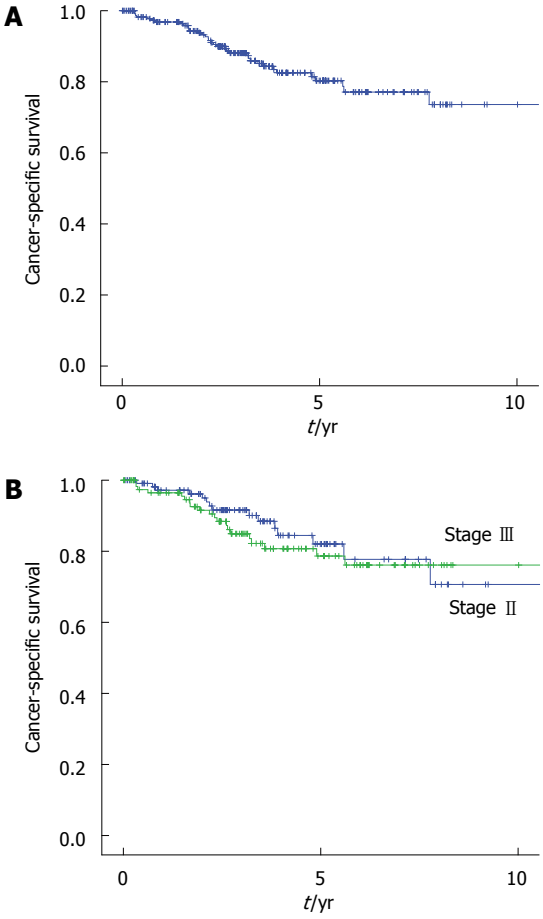

Figure 3 Kaplan-Meier curves showing the cancer-specific survival rates after primary tumor resection in patients with obstructive colorectal cancer. A: All stage (n = 234); B: Stage Ⅱ (n = 114, blue line), Stage Ⅲ (n = 120, green line).

Long-term outcomes

The median follow-up interval was 39 mo. The five-year DFS and CSS for all patients were 50.6% and 80.3%, respectively. The 5-year DFS of the patients with stage Ⅱ and stage Ⅲ disease were 47.4% and 55.1%, respectively. The 5-year CSS were 78.7% and 82.0%, respectively. There were no significantly differences in both the DFS and CSS between stage Ⅱ and stage Ⅲ disease (P = 0.856, P = 0.560) (Figures 2 and 3).

Recurrence site

A total 71 patients (30.3%) experienced recurrence during the study follow-up (Table 2). The most common site of recurrence was the liver (n = 27, 11.5%), followed by the lung (n = 22, 9.4%), peritoneum (n = 21, 9.0%), and local recurrence (n = 9, 3.8%). Other sites of recurrence included the non-regional lymph nodes (n = 6), anastomosis (n = 3), abdominal wall (n = 2), and pleural dissemination (n = 2). The rate of the recurrence sites did not differ substantially between stage Ⅱ and stage Ⅲ disease (data not shown).

Table 2 Patterns of recurrence following colorectal resection of obstructive colorectal cancer (n = 71)

Site of recurrence	n (%)
Liver	27 (11.5)
Lung	22 (9.4)
Peritoneal dissemination	21 (9.0)
Local recurrence	9 (3.8)
Lymph node	6 (2.6)
Anastomosis	3 (1.3)
Abdominal wall	2 (0.9)
Pleural dissemination	2 (0.9)

Risk factors for recurrence

The risk factors for recurrence according to our analysis are shown in Table 3. According to a univariate analysis, the factors associated with recurrence were age ⩾ 75 years (P = 0.011), ASA-PS (P = 0.017), serum albumin ⩽ 4.0 g/dL (P = 0.001), T4 tumor (P = 0.001), and R1 resection (P < 0.001). A multivariate analysis of these factors confirmed significant differences for ASA-PS (HR = 2.234, P = 0.026) serum albumin (HR = 2.967, P = 0.007), depth of tumor

Table 3 Result of the univariate and multivariate analysis of risk factors for recurrence

Factor		*n*	Univariate analysis			Multivariate analysis	
			3-yr RFS	5-yr RFS	*P* value	HR (95%CI)	*P* value
Gender	M	141	59.2%	47.6%	0.409		
	F	93	66.8%	54.7%			
Age (yr)	⩾ 75	96	55.0%	42.4%	0.011	1.228 (0.659-2.290)	0.518
	< 75	138	67.3%	55.9%

	-	114	59.1%	53.2%			
Lymph node dissection	D0,D1	31	44.3%	44.3%	0.067		
	D2,D3	199	64.7%	50.8%			
No. of lymph nodes harvested	< 12	73	54.8%	44.5%	0.085		
	⩾ 12	151	66.4%	52.5%			
Postoperative complication	+	78	57.3%	44.7%	0.071		
(≥ Grade 2)	-	156	64.7%	53.5%			
Anastomotic leakage	+	18	71.1%	56.9%	0.562		
	-	191	61.7%	50.0%			
Curability	R0	219	66.4%	54.8%	< 0.001	6.555 (1.344-31.970)	0.020
	R1	15	7.6%	0.0%			
Adjuvant chemotherapy	+	91	66.2%	55.6%	0.069		
	-	143	59.8%	47.2%			

(HR = 2.728, *P* = 0.002) and curability (HR = 6.555, *P* = 0.02). There were no differences in the relapse rate according to whether the patients underwent preoperative decompression or not. Furthermore, lymph node involvement was also not associated with recurrence.

Prognostic factors for CSS

The prognostic factors for CSS are shown in Table 4. A univariate analysis identified age ⩾ 75 (*P* = 0.027), poorly or mucinous differentiation(*P* = 0.001), T4 tumor (*P* = 0.001), D0 or D1 lymph node dissection(*P* = 0.0014), R1 resection (*P* < 0.001) as poor prognostic factors. According to a multivariate analysis, poorly differentiated cancers or mucinous differentiation (HR = 6.282, *P* = 0.009), T4 tumor (HR = 3.458, *P* = 0.011) and R1 resection (HR = 6.162, *P* = 0.006) were independent prognostic factors in patients with obstructive CRC (Figure 4).

DISCUSSION

In the present study, we evaluated the long-term oncologic outcomes and prognostic factors in patients with obstructive CRC in multiple Japanese institutions. Most previous studies have reported that patients with obstructive CRC have significantly poorer oncologic outcomes than patients with nonobstructive CRC[9,11,12,17]. Obstructive tumors have been reported to have a more advanced stage than nonobstructive tumors[11,18]. The reported 5-year survival ranges between 36% to 64.6% in patients with obstructive CRC[11,17,19,20]. Our retrospective data showed 5-year CSS to be 80.3%, which was higher than the previously reported findings. One reason for the good outcomes might be that Japanese standard surgical procedures include complete tumor resection and extended D2/D3 lymph node dissection, including the pericolic, intermediate and most central lymph

Table 4 Result of the univariate and multivariate analysis of prognostic factors for cancer-specific survival

Factor		*n*	Univariate analysis			Multivariate analysis	
			3-yr CSS	5-yr CSS	*P* value	HR(95%CI)	*P* value

nodes. West *et al* reported that the Japanese surgical procedures as well as CME with CVL eradicates tumors more effectively than the conventional procedures[14]. In our study, D2/D3 lymph node dissection was performed in about 70% of all patients.

Several authors have suggested preoperative obstruction to be a prognostic factor in CRC[12,17]. However, there are few data concerning the prognostic factors associated with obstructive CRC patients[4,19]. Jiang *et al*[4] reported a delayed resection to provide a better oncologic outcome than a primary resection for obstructive left-sided colorectal cancer. Other authors have showed that decompression followed surgery is better than emergency surgery in terms of the primary anastomosis rate, the stoma rate, the morbidity rate, the successful treatment of the patient's comorbidities, and preparation for elective surgery[21,22]. According to our results, however, no difference in the prognosis was found in regard to whether patients underwent preoperative decompression or not, It therefore remains inconclusive as to which approach may be superior to the other.

Malignant obstruction can occur in any part of the colon and rectum, however, the risk varies at different locations. In present study, 70.5% of the obstructive CRC occurred in the left-sided colon and most of them occurred in the sigmoid colon. This tumor distribution is similar to what has been reported by other series[11,19]. Our results showed that the prognosis was not different between right-sided and left-sided obstructive CRC.

Obstructive tumors are reported to be associated with a more advanced stage than nonobstruction[11,18]. Our data showed 53.4% to have T4 tumors, and 51.7% had positive lymph nodes. This is one of the reasons why obstructive CRC has a worse prognosis. In present study, especially, a T4 tumor was found to be a risk factor for recurrence in patients with

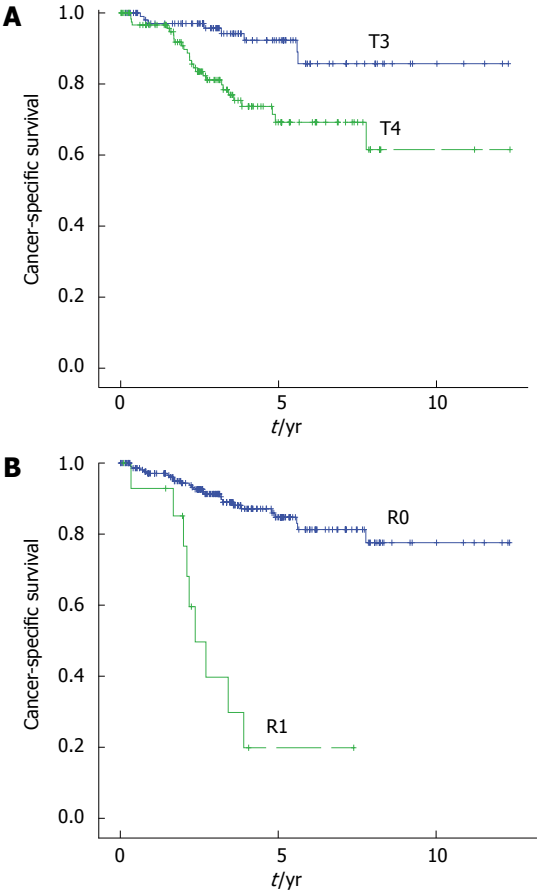

Figure 4 Kaplan-Meier curves showing the cancer-specific survival rates in patients with T4 tumor and R1 resection. A: T3 (*n* = 108, blue line); T4 (*n* = 126, green line); B: R0 (*n* = 219, blue line), R1 (*n* = 15, green line).

obstructive CRC.

Seventy-one patients had a recurrence of the disease as the first event in our study. The distant metastasis rate is significantly higher in obstructed patients when compared with nonobstructed patients[17]. The common sites of recurrence were the liver (11.5%) and lung (9.4%), which were similar to previous reports[23]. An interesting finding in the present study is that patients with obstructive CRC showed a higher rate of peritoneal dissemination (9.0%) than previously reported (1.9%-3.5%) in nonobstructive CRC[24,25]. These findings suggested that obstructive CRC was locally advanced cancer consisting of T4 tumors and which may be unexpectedly exposed during R1 resection. Therefore, reducing the rate of performing R1 resection might be a key to achieving improved surgical results.

In our study, patients with stage Ⅱ disease and those with stage Ⅲ disease had similar poor outcomes in terms of the 5-year DFS and CSS. This finding suggests that lymph node involvement, which is a well-known prognostic factor, does not have any significant impact on the outcomes in patients with obstructive CRC. One of the reasons for this finding is due to the fact that Japanese standard lymph node dissection procedures for advanced colorectal cancer include D2/D3 lymph node dissection, which is nearly the same method as that performed for CME and CVL[14]. In our clinical oncology group, lymphadenectomy for colorectal cancer was routinely performed during the study period. Therefore, a T4 tumor was identified as the most important prognostic factor, in which the 5-year DFS and OS were 38.7% and 60%, respectively.

In the present study, a lower level of albumin was also a predictive factor for survival. The serum albumin levels have recently been studied as the Glasgow Prognostic Score (GPS), based on a combination of albumin and C-reactive protein (CRP). Several authors have revealed the GPS to have prognostic value in patients with advanced colorectal cancer[26,27]. However, we failed to collect data of CRP because this was a retrospective analysis. It is estimated that low albumin levels are associated with a decreased survival time because a low albumin level likely reflects some type of systemic compromise[28].

Our results demonstrated that poorly differentiated tumors or mucinous differentiated tumors are also predictive factors for survival. Histologically, poorly differentiated CRC represents from 4.8% to 23.2% of all colorectal cancers[29]. The rate of poorly differentiated tumors was not higher than that described in previous reports. Poorly differentiated cancers have been linked to adverse prognoses in many studies[30].

Recently, several authors have suggested the feasibility of performing preoperative chemotherapy without the routine use of radiation therapy for locally advanced rectal cancer and a high R0 resection rate[31,32]. Furthermore, the FOxTROT Collaborative Group demonstrated the feasibility of performing preoperative chemotherapy for locally advanced colon cancer[33]. Our result suggested that obstructive colorectal cancer is also locally advanced cancer. Therefore, preoperative chemotherapy after the decompression of bowel obstruction may also be useful for the management of obstructive colorectal cancer.

Our retrospective study had several important limitations. First, there were several missing data and we could not obtain the clinical course related to the treatment of patients after recurrence. Second, the adjuvant therapy, which affects the outcome, was not uniform.

In conclusion, in addition to generally accepted knowledge, we found that T4 tumor and R1 resection were prognostic factors for both recurrence and survival. These results suggested that a curative resection of the tumor is very important and that systemic treatment for preventing distant metastasis, such as peritoneal dissemination associated with T4 tumors, is necessary in patients with obstructive colorectal cancer.

ACKNOWLEDGMENTS

We are grateful to the many members of the Yokohama Clinical Oncology Group and Dr. Mari S Oba (Department of Biostatistics, Yokohama City University) whose comments were extremely valuable throughout the course of our study.

COMMENTS

Background

Colorectal cancer (CRC) is one of most common cancer in the world. Around 7%-16% of patients with colorectal cancer present with acute colorectal obstruction. It has been reported that CRC patients with obstruction have an advanced stage and poor long-term survival compared to non-obstructive CRC. However, the risk factors for recurrence and the prognostic factors of patients with obstructive CRC are unclear.

Research frontiers

The authors often treat the obstructive CRC. However, there are few literatures concerning survival and prognostic factor of obstructive CRC. The research hotspot is to introduce long-term outcome of patients with obstructive colorectal cancer and prognostic factors in Japan.

Innovations and breakthroughs

The present study represents the characteristics and the long-term outcome of obstructive CRC patients in Japan and revealed that T4 tumor and R1 resection are risk factors of recurrence and prognostic factors. These results suggested that a curative resection of the tumor is very important and systemic treatment for preventing distant metastasis, such as peritoneal dissemination associated with T4 tumors, is necessary in patients with obstructive colorectal cancer.

Applications

This study showed the poor survival for obstructive colorectal cancer patients and prognostic factor. The present study provided readers the important information of treatment for patients with obstructive CRC.

Peer-review

The authors demonstrated that T4 tumor status and R1 resection are independent prognostic factors in patients with obstructive colorectal cancer.

Abstract

AIM: To identify rates of post-discharge complications (PDC), associated risk factors, and their influence on early hospital outcomes after esophagectomy.

METHODS: We used the 2005-2013 American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) database to identify patients ⩾ 18 years of age who underwent an esophagectomy. These procedures were categorized into four operative approaches: transhiatal, Ivor-Lewis, 3-holes, and non-gastric conduit. We selected patient data based on clinical relevance to patients undergoing esophagectomy and compared demographic and clinical characteristics. The primary outcome was PDC, and secondary outcomes were hospital readmission and reoperation. The patients were then divided in 3 groups: no complication (Group 1), only pre-discharge complication (Group 2), and PDC patients (Group 3). A modified Poisson regression analysis was used to identify risk factors associated with developing post-discharge complication, and risk ratios were estimated.

RESULTS: 4483 total patients were identified, with

8.9% developing PDC within 30-d after esophagectomy. Patients who experienced complications post-discharge had a median initial hospital length of stay (LOS) of 9 d; however, PDC occurred on average 14 d following surgery. Patients with PDC had greater rates of wound infection (41.0% *vs* 19.3%, $P < 0.001$), venous thromboembolism (16.3% *vs* 8.9%, $P < 0.001$), and organ space surgical site infection (17.1% *vs* 11.0%, $P = 0.001$) than patients with pre-discharge complication. The readmission rate in our entire population was 12.8%. PDC patients were overwhelmingly more likely to have a reoperation (39.5% *vs* 22.4%, $P < 0.001$) and readmission (66.9% *vs* 6.6%, $P < 0.001$). BMI 25-29.9 and BMI $\geqslant$ 30 were associated with increased risk of PDC compared to normal BMI (18.5-25).

CONCLUSION: PDC after esophagectomy account for significant number of reoperations and readmissions. Efforts should be directed towards optimizing patient's health pre-discharge, with possible prevention programs at discharge.

Key words: Reoperation; Hospital readmission; Post-discharge complications; Esophagectomy; Outcomes research

Core tip: In this study, we used the 2005-2013 ACS-NSQIP database to identify the rate of post-discharge complications, their associated risk factors, and their influence on early hospital readmission after esophagectomy. This report demonstrates that post-discharge complications after esophagectomy account for a significant number of reoperations and readmissions. We believe that implementing prevention strategies to decrease common post-discharge complications like venous thromboembolism and infection should be considered, and that directing our energies toward optimizing patient health prior to discharge may improve overall surgical outcomes.

Chen SY, Molena D, Stem M, Mungo B, Lidor AO. Post-discharge complications after esophagectomy account for high readmission rates. *World J Gastroenterol* 2016; 22(22): 5246-5253 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5246.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5246

INTRODUCTION

Esophagectomy is the mainstay treatment for localized esophageal carcinoma without medical contraindications[1]. It can also be indicated for certain benign conditions, including high-grade dysplasia in Barrett's esophagus, caustic ingestion, reflux esophagitis complications, esophageal stricture, and esophageal neuromotor dysfunction (achalasia, spasm, scleroderma)[2]. Over 5000 esophagectomies are performed in the United States and United Kingdom annually[3]. Despite improved surgical techniques and intensive care unit therapy[4], post-esophagectomy mortality and morbidity rates remain suboptimal, ranging from 7%-28%[5,6] and 10%-27%[7], respectively. Moreover, readmission rates after esophagectomy range from 5%-25%[8,9], and the overall 5-year survival rate following esophagectomy range from 15%-40%[10,11].

These dismal outcomes after esophagectomy, compounded with national health policy changes by the Centers for Medicare and Medicaid Services (CMS) and the Affordable Care Act that emphasize reducing hospital readmission rates to improve health care quality, have spurred growing interest in investigating quality measures related to esophagectomy. Although several studies have explored esophagectomy complications and readmission[12-16] none to date have delved into risk factors associated specifically with post-discharge complications (PDC) after esophagectomy. Given that approximately a third of post-operative surgical complications occur post-discharge, and that PDC may differ from pre-discharge complications[17], we hypothesize that several clinical factors may increase risk for developing PDC after esophagectomy.

Using 2005-2013 data from the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP), we sought to identify the rate of PDC, their associated risk factors, and their influence on early hospital outcomes including readmission and reoperation. We believe that understanding these risk factors will provide additional insights to improve esophagectomy quality outcomes.

MATERIALS AND METHODS

Data source

This study is a retrospective analysis using the 2005-2013 ACS-NSQIP database. ACS-NSQIP is a nationally-validated, risk-adjusted, and outcomes-based program created for the purpose of measuring and improving surgical quality care[18,19]. The program collects data on patients undergoing surgery from over 650 participating hospitals of varying size and academic affiliation[20]. Eligibility criteria for hospital participation include: hiring a surgical clinical reviewer who uses a standardized format to capture and review data from clinical records, identifying a Surgeon Champion to lead the program at the hospital, agreeing to program protocols, meeting minimum case standards, and paying an annual participation fee to ACS. Prospective, systematic data collection is performed on 150 preoperative and intraoperative variables, in addition to 30-d postoperative morbidity and mortality. This study was reviewed and approved by the Institutional Review Board of the Johns Hopkins University School of Medicine.

Study population

Patients ⩾ 18 years of age who underwent an esophagectomy (defined as current procedural terminology codes 43107, 43108, 43112, 43113, 43117, 43118, 43121, 43122, or 43123) were included. These procedures were then categorized into four operative approaches: transhiatal (if the chest was not entered and the stomach was used as a conduit), Ivor-Lewis (if the anastomosis was done in the chest and the stomach was used as a conduit), 3-holes (if the anastomosis was done in the neck, the chest was entered and the stomach was used as a conduit), and intestinal conduit (if any of the above approaches were used but intestine, either large or small, was used as a conduit). Patients who had missing data for days from operation to discharge, and days from operation to complication (for patients who had complication) were excluded. Patients who were not discharged within 30-d of operation were also excluded. Lastly, patients who died during initial hospitalization were excluded from the analysis that aimed to identify risk factors associated with PDC (univariate logistic regression), as these patients were not at risk for PDC.

Baseline characteristics of patients

We selected patient data based on clinical relevance to patients undergoing esophagectomy and compared demographic and clinical characteristics. Three groups of patients were defined: no complication (Group 1), only pre-discharge complication (Group 2), and PDC patients (Group 3). Patients with esophageal/gastric cancer were defined with a diagnosis (International Classification of Diseases, 9th Revision, codes of 150, 150.1, 150.2, 150.3, 150.4, 150.5, 150.8, 150.9, 151, 151.0).

Outcomes

The primary outcome was PDC, which we defined as an event for which the time interval (days) between the initial operation and a complication was greater than the interval from operation to discharge. The secondary outcomes included hospital readmission (2011-2013) and reoperation (2012-2013). Complication types included from ACS-NSQIP were investigated. Prolonged length of stay and prolonged operative time, defined as stay or time greater than the 75th percentile, respectively, were also investigated.

Statistical analysis

Categorical variables were compared using Pearson's χ^2 test or Fisher's exact test when appropriate. Student's *t*-test or ANOVA were used to compare continuous variables. Modified Poisson regression analysis was performed to identify factors associated with developing a PDC, and risk ratios (RR) were estimated. A *P*-value of $P < 0.05$ was determined statistically significant. We performed all data analyses and management using Stata/MP version 14 (StataCorp LP, College Station, TX, United States).

RESULTS

Study population

A total of 4872 patients underwent esophagectomy between 2005 and 2013. However, 389 (7.98%) patients were not discharged before the 30-day period and were excluded for this very reason. 4483 patients represented our study population, including 2497 (55.7%) patients who had no postoperative complications, 1588 (35.4%) who had at least one pre-discharge complication, and 398 (8.9%) who had at least one PDC. The mean age was 63.1 years, with 80.0% male and 85.9% whites. The mean BMI was 27.9 kg/m^2. PDC patients tended to be slightly older with greater ASA class, BMI, and more comorbidities including diabetes and, dyspnea compared to no complication group (Table 1).

Unadjusted outcomes

The overall PDC rate was 8.9%. Patients who experienced PDC had a median initial length of hospital stay of 9 d; however, PDC occurred on average 14 d after surgery. Among procedure types, PDC rates were 35.7% for transhiatal, 34.1% for Ivor Lewis, 36.9% for 3-holes, and 44.3% for intestinal conduit. Interestingly, PDC rates remained similar over the studied years (8.3% in 2005-2006 *vs* 8.9% in 2013) (Figure 1). Of the patients who experienced PDC, 127 of them (31.9%) also had pre-discharge complications. The overall readmission rate (2011-2013) after esophagectomy was 12.8%. Only from 2012 NSQIP identified if readmissions were likely related to the principle surgical procedure. There were 253 readmissions (253/1989, 12.72%) between 2012 and 2013 and 83.8% (212/253) of these readmissions were related to the initial surgical procedure. PDC patients were overwhelmingly more likely to have a reoperation (39.5% *vs* 22.4% for 2012-2013, $P < 0.001$) and to be readmitted (66.9% *vs* 6.6% for 2011-2013, $P < 0.001$). Moreover, pre-discharge and PDC differed by complication types (Figure 2). PDC patients had greater rates of wound infection (41.0% *vs* 19.3%), VTE (16.3% *vs* 8.9%), and organ space SSI (17.1% *vs* 11.0%) ($P \leqslant 0.001$ for each) than pre-discharge complication patients (Table 2). Although 30-day mortality rates were greater for patients who experienced PDC, this finding was not statistically significant.

Risk factors associated with post-discharge complications

Univariate modified Poisson regression analysis revealed that greater BMI, specifically BMI 25-29.9 (RR = 1.37, 95%CI: 1.08-1.74) and BMI ⩾ 30 (RR = 1.34, 95%CI: 1.04-1.72), were associated with increased risk of PDC, compared to normal BMI (18.5-25) (Table 3).

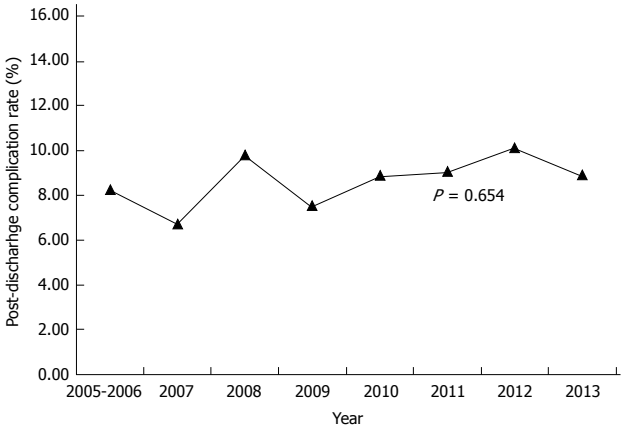

Figure 1 Post-discharge complications rates after esophagectomy by year.

DISCUSSION

Although several studies have investigated post-operative complications and readmissions following esophagectomy, none to our knowledge have explored the distinct role of PDC on early hospital outcomes. This is the first study to use ACS-NSQIP to examine the rate of PDC, their associated risk factors, and their influence on early hospital outcomes after esophagectomy. ACS-NSQIP offers a unique opportunity to assess at a national, multi-institutional level these specific health quality measures that may be unavailable in other large, population-level databases. Our retrospective analysis demonstrates that PDC occur at a low rate but account for a significant number of reoperations and readmissions.

[1]In-hospital and post-discharge mortality among patients with pre or post-discharge complications. The overall mortality rate was 3.12% (140/4483); [2]Serious morbidity: cardiac complication, shock/sepsis, unplanned intubation, on ventilator > 48 h, organ space SSI, and reoperation 2012-2013; [3]Defined as length of stay > 75th percentile; [4]Defined as operative time > 75th percentile. SSI: Surgical site infection.

Higher BMIs were associated with increased risk of PDC. PDC were different than pre-discharge complications and potentially preventable.

Of the patients with PDC, wound infection, pneumonia, and VTE were among common PDC that could serve as targeted areas for quality improvement. These PDC are consistent with prior studies examining perioperative complications after esophagectomy[21,22].

Table 3 Unadjusted risk and risk ratio for post-discharge complications after esophagectomy

Risk factor	PDC risk (*n*/total)	RR (95%CI)

[1]Defined as length of stay > 75th percentile; [2]Defined as operative time > 75th percentile. PDC: Post-discharge complication; RR: Risk ratio; ASA: American Society of Anesthesiology; COPD: Chronic obstructive pulmonary disease.

Interventions to reduce PDC, such as adopting best practices to prevent wound infection and VTE, may improve esophagectomy outcomes. In one study, selective anticoagulant thromboprophylaxis using a DVT risk factor index significantly decreased DVT rates after esophageal cancer surgery[23]. Another study showed that low molecular weight heparin prophylaxis resulted in a 72% reduction in DVT risk after general surgery[24]. These suggest that efforts aimed to reduce common complications after surgery may also be effective and applicable to esophagectomy and should be continued after discharge. Interestingly, PDC rates have remained similar over the studied years, revealing likely no significant changes in practice or indications.

Our modified Poisson regression analysis demonstrates several factors that may increase the risk of PDC and therefore enable us to stratify higher-risk patients for perioperative risk assessment. These include patients with BMI 25.0-29.9 and BMI ⩾ 30, compared to normal BMI 18.5-25.0. Although obesity is associated with higher incidence of medical comorbidities like hypertension, diabetes, and cardiovascular disease[25], the association of BMI and complications after esophagectomy is conflicting. Several studies have suggested that overweight and obese patients may have increased risk for complications after esophagectomy, such as longer operative times[26] and greater risks for anastomotic leaks[27], respiratory complications[27], and surgical site infections[28]. However, other studies have shown that obese patients do not have more postoperative complications and longer hospital stays compared to non-obese patients[14,29,30]. Several routine measures implemented in the hospital setting to decrease the most common post-operative complications (*i.e.,* early mobilization, incentive spirometry and pulmonary toilet, DVT prophylaxis, daily dressing changes) are not continued after discharge, and the lack of preventive actions may impact obese patients more than non-obese. As such, appropriate interventions for higher BMI patients may be beneficial and may include enhanced perioperative management of patient comorbidities, preoperative risk stratification, additional patient education, continuation of pulmonary toilet, exercise programs, and DVT prophylaxis after discharge and earlier follow-up. For example, one study has shown that performing preoperative risk analysis on pulmonary function and general status when selecting patients for transthoracic esophagectomy reduced postoperative morbidity rates[31]. Interventions targeting higher BMI patients undergoing esophagectomy may therefore reduce PDC rates.

We decided to separate the patients with pre-discharge complications to keep our groups as homogeneous as possible for fair comparison. Since these patients have a longer hospital stay (median LOS 14 d), a 30-d follow-up may not be long enough to record PDC. It was interesting, however, to see that the most common types of PDC are different than those occurring in the initial post-operative period. This information is helpful to the physician to identify patients at risk of PDC and to plan preventative measures.

The overall readmission rate in our study is 12.8%, consistent with another study's rate of 18.6%[12]. From our study, 39.5% of PDC patients underwent reoperation (2012-2013) compared to 22.4% of pre-discharge complication patients. This suggests that reoperation may have been indicated due to complications that developed after discharge and subsequent delays in management. Even more striking is our finding that 66.9% of PDC patients were readmitted, compared to 6.6% of pre-discharge complication patients. Recent changes in health policy and reimbursements have brought issues of health care costs to the forefront, resulting in some hospital

administrations advocating for earlier discharge of patients. Readmission has become a major focus from health care quality and cost-savings standpoints. However, the use of readmission as a quality metric is still debatable[32,33]. In the case of esophagectomy, efforts to reduce costs by promoting earlier discharge may increase readmission[16], reoperation, and PDC rates; hospital readmission after esophagectomy for esophageal cancer is also associated with poor survival[12]. One study has shown that postoperative complications lead to greater readmission rates after colon resection[34]. In bariatric surgery patients, PDC account for a substantial source of patient morbidity and readmissions[17]. Rather than emphasizing shorter hospital lengths of stay, putting more energy into preventing complications after esophagectomy, and optimizing patient health prior to discharge instead may lead to improved surgical quality outcomes and reduced hospital spending.

Despite the advantages of ACS-NSQIP, the database does pose some limitations to our study. ACS-NSQIP does not contain consistent information on tumor histology, margins, stage, surgical history, neoadjuvant chemotherapy (within 30 d preoperatively), and neoadjuvant radiation (within the last 90 d) that could otherwise provide greater context in interpreting our results. Several complications common to esophagectomy, such as anastomotic leaks, chyle leak, and delayed gastric emptying, are not captured in the database. ACS-NSQIP also identifies 30-d postoperative readmission rather than 30-d post-discharge readmissions, which may introduce immortal person-time bias and lead to shorter number of follow-up days for patients with longer hospital stays. Although PDC could lead to greater mortality, because ACS-NSQIP does not capture data beyond 30-d postoperatively, further studies examining long-term outcomes including mortality is warranted. Readmission data is available only from 2011-2013, but the large patient sample population within that cohort should prevent significant alterations in our conclusions. It is also uncertain whether our findings are applicable to all hospital settings, as hospital participation is voluntary and comprised primarily of academic, tertiary-care centers. Hospital size, setting, patient volume, teaching status, and individual surgeon experience also cannot be adjusted for.

In summary, PDC after esophagectomy account for a significant number of reoperations and readmissions. Adopting best practices to reduce common PDC like VTE and infection, and performing interventions for higher-risk individuals such as those with high BMI, should therefore be considered.

COMMENTS

Background

Esophagectomy is the mainstay treatment for esophageal carcinoma and can also be indicated for benign conditions with end-stage organ dysfunction or perforation. Despite improved surgical and medical care, post-esophagectomy mortality and morbidity rates remain suboptimal. Such disappointing outcomes after esophagectomy, compounded with national health policy changes that emphasize reducing hospital readmission rates and improving health care quality, have spurred growing interest in investigating quality measures related to esophagectomy. Using 2005-2013 data from the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP), we sought to identify the rate of post-discharge complications, their associated risk factors, and their influence on early hospital outcomes including readmission and reoperation.

Research frontiers

Although several studies have explored post-esophagectomy complications and readmission, none to date have delved into specifics of post-discharge complications and risk factors associated with them. The results from this study offer additional insights to improve esophagectomy quality outcomes.

Innovations and breakthroughs

No other studies have investigated the specific outcomes of post-discharge complications after esophagectomy. In this study, The authors demonstrated that post-discharge complications after esophagectomy occur a median of 14 d postoperatively and account for a significant number of reoperations and readmissions. Moreover, pre- and post-discharge complications differed by type, with venous thromboembolism and infection occurring more commonly after discharge.

Applications

These research findings can be applied to predict, identify, and prevent adverse outcomes in patients who have undergone esophagectomies. Implementing strategies to decrease common post-discharge complications like venous thromboembolism and infection should be considered, and directing our energies toward optimizing patient health prior to discharge may improve overall surgical outcomes.

Peer-review

This is a review of the ACS-NSQIP esophagectomy database, meant to identify post-discharge complications. It has a huge sample, a clear presentation and analysis, and an interesting discussion. It is without doubt an important topic deserving of evaluation.

Abstract

AIM: To detect the expression of the long noncoding RNA HOTAIR in colon cancer and analyze its relationship with clinicopathological parameters of colon cancer.

METHODS: Total RNA was extracted from 80 colon cancer tissues and matched tumor-adjacent normal colon tissues and reverse transcribed. Quantitative polymerase chain reaction was used to detect the expression of HOTAIR. The relationship between the expression of HOTAIR and clinicopathological parameters of colon cancer was analyzed.

RESULTS: The expression of HOTAIR was significantly higher in colon cancer tissues than in matched tumor-adjacent normal colon tissues ($P < 0.05$). HOTAIR expression was significantly higher in cases with lymph node metastasis than in those without metastasis; in lowly differentiated and undifferentiated cases than in highly and moderately differentiated cases; and in stages Ⅲ + Ⅳ cases than in stages Ⅰ + Ⅱ cases ($P < 0.05$).

CONCLUSION: HOTAIR expression is upregulated in colon cancer, suggesting that HOTAIR plays an important role in the tumorigenesis, development and metastasis of colon cancer. HOTAIR may act as an oncogene and represents a new molecular target for the treatment of colon cancer.

Key words: HOTAIR; Long non-coding RNA; Oncogene; Colon tumor

Core tip: This study aimed to detect the expression of HOTAIR in colon cancer and analyze its relationship with clinicopathological parameters of colon cancer. Total RNA was extracted from 80 colon cancer tissues and matched tumor-adjacent normal colon tissues and reverse transcribed. HOTAIR expression was upregulated in colon cancer, suggesting that it may play an important role in the tumorigenesis, development and metastasis of colon cancer. HOTAIR might acts as an oncogene and could be a new molecular target for the treatment of colon cancer.

INTRODUCTION

Colon cancer is a clinically common, highly malignant tumor of the digestive tract. Although drugs targeting epidermal growth factor receptor (EGFR) and KRAS mutations have significantly extended the survival of some colon cancer patients[1-3], only a small number of patients can benefit from these drugs because of the complex etiology of this malignancy. Overall, the effects of current therapies for colon cancer are not satisfactory[4,5].

Long noncoding RNAs (lncRNAs) are non-protein coding transcripts of around 200 nucleotides, which exist widely in the genome and can regulate gene expression[6]. HOTAIR is one of the extensively studied lncRNAs in recent years. Many studies have indicated that HOTAIR plays an important role in breast cancer, pancreatic cancer, liver cancer, gastric cancer, esophageal cancer and non-small cell lung cancer[7-10]. Studies in colon cancer suggest that HOTAIR is an important oncogene that affects the biological behavior of colon cancer[11] and can serve as an independent risk factor[12]. The latest research suggests that the expression of HOTAIR is associated with tumor metastasis[13].

In the present study, we detected the expression of HOTAIR in 80 colon cancer tissue samples by quantitative polymerase chain reaction (qPCR). Based on the clinical and pathological parameters of colon cancer patients, we analyzed the possible role of HOTAIR in colon cancer development, metastasis and sensitivity to treatment, with an emphasis on the role of HOTAIR in colon cancer treatment. The findings will provide a theoretical basis for developing a new, targeted therapy for colon cancer.

MATERIALS AND METHODS

Clinical materials and reagents

Eighty patients with pathologically proven colon cancer who underwent surgery at our hospital from September 2011 to September 2013, and had complete clinical records, were included. All patients provided written informed consent, and the study protocol was approved by the Medical Ethics Committee of Zhengzhou University. The mean age of the patients was 64 ± 16 years. There were 46 patients with stage Ⅰ or Ⅱ disease, and 34 patients with stage Ⅲ or Ⅳ disease. Forty-one patients had well or moderately differentiated tumors, and 34 patients had poorly differentiated or undifferentiated tumors. No patients had undergone radiotherapy or chemotherapy before surgery. Tumor tissues and normal colon tissues at least 7 cm away from the tumor were taken, frozen in liquid nitrogen within 30 min and preserved for further use.

Trizol was purchased from Invitrogen. The reverse transcription kit and DNA ladder were purchased from Takara. Primers for qPCR were designed and synthesized by Shanghai GenePharma. The qPCR kit was purchased from Thermo.

RNA preparation and reverse transcription

Tissue samples preserved in liquid nitrogen were put into an RNase-free mortar with liquid nitrogen and pulverized. For each 100 mg of tissue, 1 mL of Trizol was added. RNA preparation was then performed following the manufacturer's instructions. The obtained RNA was dissolved in DEPC-treated water, and the RNA concentration was measured using a micro UV-Vis fluorescence spectrophotometer (e-spect, Malcom, Japan). The obtained RNA was preserved at -80 ℃ for further use.

RNA reverse transcription was performed using a reverse transcription kit in a 20-μL system, containing 11 μL of DEPC-treated water, 1 μL of total RNA, 4 μL of 5 × buffer, 1 μL of RNase inhibitor, 2 μL of dNTPs, and 1 μL of reverse transcriptase. Reaction parameters were 42 ℃ for 60 min and 95 ℃ for 5 min. The obtained cDNA was preserved at -80 ℃ for further use.

qPCR: qPCR was performed in a 20-μL system containing 1 μL of cDNA, 10 μL of 2 × Master Mix with 0.03 × ROX added, 1 μL of forward primer (final concentration of 0.5 μmol/L), 1 μL of reverse primer, and 8 μL of DEPC-treated water on a Mx3005p cycler. PCR amplification was performed in triplicate. Cycling parameters were 95 ℃ for 7 min, followed by 40 cycles of 95 ℃ for 15 s and 60 ℃ for 30 s.

Statistical analysis

The expression levels of HOTAIR in tissues are expressed as mean ± SD and were compared using a

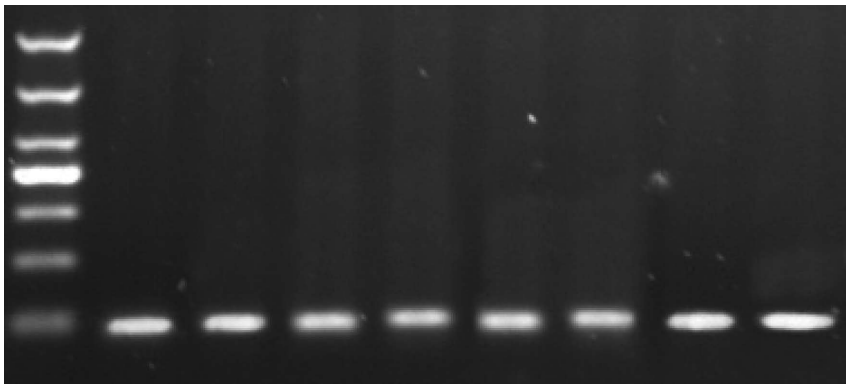

Figure 1 Quantitative polymerase chain reaction products of HOTAIR.

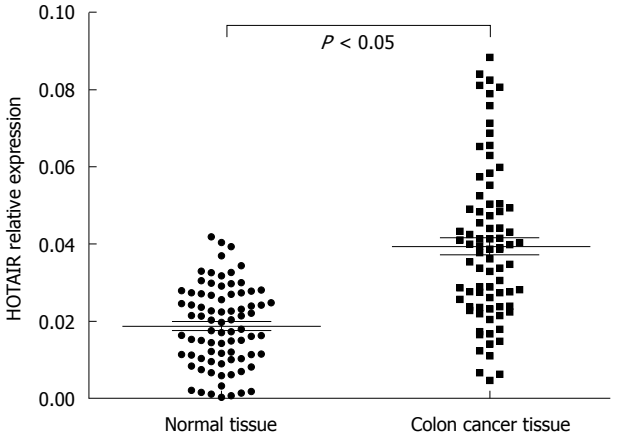

Figure 2 Expression of HOTAIR in colon cancer. The expression of HOTAIR in colon cancer is significantly higher in colon cancer tissues than in tumor-adjacent normal colonic tissues.

two-sample *t*-test. Statistical analyses were performed using SPSS13.0. *P*-values < 0.05 were considered statistically significant.

RESULTS

Agarose gel electrophoresis of qPCR products

The length of the expected PCR product for HOTAIR is 91 bp, and agarose gel electrophoresis showed that qPCR yielded PCR products of expected size (Figure 1).

Expression of HOTAIR is higher in colon cancer tissues than in tumor-adjacent normal colonic tissues

QPCR analysis showed that, although the expression of GAPDH showed no significant differences, the Ct value of HOTAIR was significantly lower in colon cancer tissues than in tumor-adjacent normal colonic tissues, suggesting that HOTAIR expression is upregulated in colon cancer. When the relative expression level is expressed as N ($N = 2^{-\Delta Ct}$, $\Delta Ct = Ct_{HOTAIR} - Ct_{GAPDH}$[14]), the relative expression level of HOTAIR was significantly higher in colon cancer tissues than in tumor-adjacent normal colonic tissues ($P < 0.05$, Figure 2).

Relationship between HOTAIR expression and clinicopathological parameters in colon cancer

HOTAIR expression was significantly correlated with lymph node metastasis, tumor differentiation and TNM stage ($P < 0.05$). HOTAIR expression was significantly higher in cases with lymph node metastasis than in those without metastasis, in lowly differentiated and undifferentiated cases than in highly and moderately differentiated cases, and in stages Ⅲ + Ⅳ cases than in stages Ⅰ + Ⅱ cases. By contrast, HOTAIR expression had no significant correlation with patient gender, age or tumor size ($P > 0.05$) (Tables 1-3).

Relationship between HOTAIR expression and survival in colon cancer

The Kaplan-Meier method was used to assess the impact of HOTAIR expression on survival of patients with colon cancer. The cumulative survival rate was significantly higher in patients with low HOTAIR expression than in those with high HOTAIR expression ($P < 0.05$) (Figure 3).

Risk factors for prognosis of colon cancer patients

Using prognosis of colon cancer patients as the dependent variable and factors possibly influencing the prognosis as independent variables, Cox multiple regression analysis was performed. The results showed that TNM stage, lymph node metastasis and HOTAIR expression were independent risk factors for prognosis of colon cancer patients.

Relationship between HOTAIR expression and prognosis in colon cancer

The relationship between prognosis of colon cancer patients after chemotherapy and HOTAIR expression was analyzed. The results showed that high HOTAIR expression was associated with poorer prognosis (Figure 4).

DISCUSSION

Colon cancer is a common malignancy[15,16]. With the

development of diagnostic technology, advances in endoscopy and imaging techniques, as well as the clinical application of the carcinoembryonic antigen assay, have greatly improved the early diagnosis and treatment effect of colon cancer[17,18]. Patients with early colon cancer have localized lesions, and surgery with adjuvant radiochemotherapy is the preferred treatment, which is often associated with a good prognosis. However, because of the unbalanced regional development in China, many patients with colon cancer, especially those in rural regions, are diagnosed at advanced stages, and some patients even present with metastases as the first manifestation. Although drugs targeting EGFR and

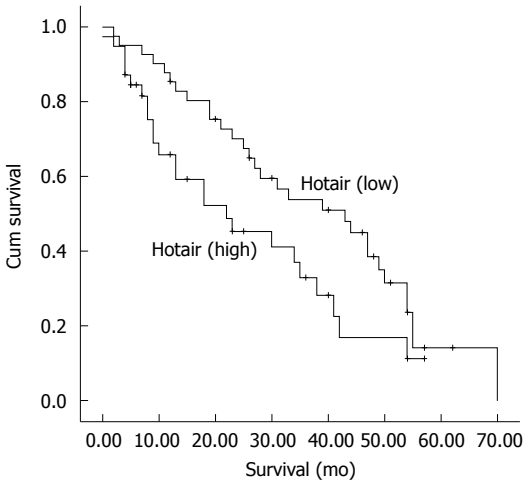

Figure 3 Relationship between HOTAIR expression and survival in colon cancer. The cumulative survival rate was significantly higher in patients with low HOTAIR expression than in those with high HOTAIR expression ($P < 0.05$).

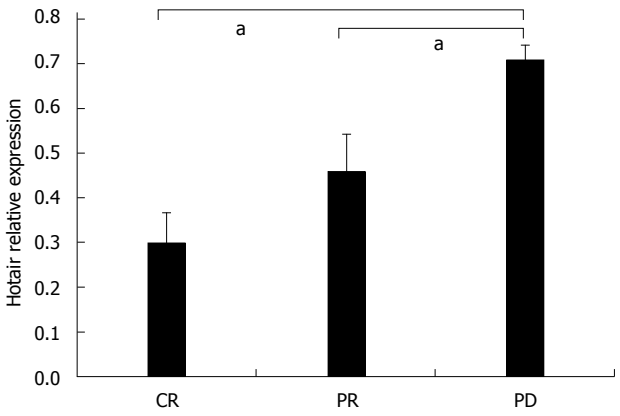

Figure 4 Relationship between HOTAIR expression and prognosis in colon cancer. [a]$P < 0.05$ *vs* PD group.

KRAS mutations have been effective in some patients with colon cancer[1-3], molecular targeted drugs, which often target only one or several molecules, are not suitable for all patients because of the complexity etiology of colon cancer. Therefore, there is an urgent need to find new therapeutic targets.

LncRNAs are non-protein coding transcripts of around 200 nucleotides that are widely distributed in the genome. Many lncRNAs can bind to DNA binding proteins and alter the chromosome state to participate in the regulation of many genes[6,19]. HOTAIR is an lncRNA located in the *HOXC* locus, and it can interact with polycomb repressive complex 2 and mediate the histone H3 lysine 27 methylation and lysine 4 demethylation in the *HOXD* locus, in which EZH2 also plays an important role[9,20,21]. HOTAIR can alter the state of chromosomes, thus affecting the expression of many genes. Researchers have found that HOTAIR expression is upregulated in cancer tissue samples from patients with breast cancer, pancreatic cancer, liver cancer, gastric cancer, or non-small cell lung cancer, and the expression is even higher in metastatic tissue.

Both *in vivo* and *in vitro* studies have confirmed that upregulated expression of HOTAIR enhances the ability of tumors to invade and metastasize[7-9]. The aim of this study was to detect the expression of HOTAIR in tissue samples from patients with colon cancer, analyze the relationship between HOTAIR expression and clinicopathological parameters and explore the role of HOTAIR in colon cancer development and metastasis.

The results showed that the expression of HOTAIR is upregulated in colon cancer, suggesting that HOTAIR may act as an oncogene in the development of colon cancer. We also discovered that HOTAIR expression was significantly higher in lowly differentiated and undifferentiated cases compared with highly and moderately differentiated cases; in stages Ⅲ + Ⅳ cases compared with stages Ⅰ + Ⅱ cases; and in cases with lymph node metastasis compared with those without. These results are similar to the findings of a previous study[22]; however, that study found that the expression of HOTAIR did not differ significantly between cases with and without lymph node metastasis, but was significantly higher in cases with liver metastasis compared with those without. The present study did not compare the HOTAIR expression between cases with and without liver metastasis. Low differentiation, late stage or lymph node metastasis in colon cancer are often associated with poor prognosis; therefore, our findings need to be validated by studies with a larger sample size.

Although HOTAIR might affect response to therapy in some tumors; for example, HOTAIR is associated with resistance to chemotherapy in ovarian cancer and sarcoma[23,24], there have been no reports in colon cancer. Our study, together with previous research, found that HOTAIR has an impact on the biological behavior of colon cancer[13], and detecting the level HOTAIR in blood could be used to predict prognosis of colon cancer. We speculated that this finding may be related to the role of HOTAIR in chemotherapy resistance, and this, therefore, was the focus of this study. We found that tumors with high expression of HOTAIR tended to develop resistance to chemotherapy, which may be the reason that high expression of HOTAIR is associated with a poor prognosis.

This finding also suggested that it is essential to explore the relationship between HOTAIR and resistance to chemotherapy *in vitro*, as well as the impact of HOTAIR on the biological behavior of tumor cells. Several studies have revealed that HOTAIR has an important role in tumor metastasis. On the basis of these findings, our subsequent follow-up study will expand the sample size to conduct prognostic and survival analyses to further define the relationship between HOTAIR and tumor metastasis in colon cancer, to explore the mechanism of pathogenesis of this malignancy and provide new targets for molecular therapy for colon cancer patients.

COMMENTS

Background

Long noncoding RNAs are non-protein coding transcripts of around 200 nucleotides that are widely distributed in the genome.

Research frontiers

The expression of HOTAIR, a long noncoding RNA, is upregulated in cancer tissue samples from patients with breast cancer, pancreatic cancer, liver cancer, gastric cancer, or non-small cell lung cancer, and the expression is even higher in metastatic tissue.

Innovations and breakthroughs

High expression of HOTAIR tended to develop resistance to chemotherapy, which may be the reason that high expression of HOTAIR is associated with a poor prognosis.

Applications

By exploration of the mechanism of HOTAIR expression in colon cancer, the authors might identify new targets for molecular therapy for colon cancer patients.

Terminology

HOTAIR might acts as an oncogene and represents a new molecular target for the treatment of colon cancer.

Peer-review

It is a very good and interesting study. The authors found that the expression of HOTAIR was significantly higher in colon cancer tissues than in matched tumor-adjacent normal colon tissues. HOTAIR expression was significantly higher in cases with lymph node metastasis than in those without metastasis, in lowly differentiated and undifferentiated cases than in highly and moderately differentiated cases. HOTAIR expression is upregulated in colon cancer, which may plays an important role in tumorigenesis, development and metastasis of colon cancer.

Abstract

AIM: To explore the effects and mechanism of action of antidepressant mirtazapine in functional dyspepsia (FD) patients with weight loss.

METHODS: Sixty depressive FD patients with weight loss were randomly divided into a mirtazapine group (MG), a paroxetine group (PG) or a conventional therapy group (CG) for an 8-wk clinical trial. Adverse effects and treatment response were recorded. The Nepean Dyspepsia Index-symptom (NDSI) checklist and the 17-item Hamilton Rating Scale of Depression (HAMD-17) were used to evaluate dyspepsia and depressive symptoms, respectively. The body composition analyzer was used to measure body weight and fat. Serum hormone levels were measured by ELISA.

RESULTS: (1) After 2 wk of treatment, NDSI scores were significantly lower for the MG than for the PG and CG; (2) After 4 or 8 wk of treatment, HAMD-17 scores were significantly lower for the MG and PG than for the CG; (3) After 8 wk of treatment, patients in the MG experienced a weight gain of 3.58 ± 1.57 kg, which was significantly higher than that observed for patients in the PG and CG. Body fat increased by 2.77 ± 0.14

kg, the body fat ratio rose by 4%, and the visceral fat area increased by 7.56 ± 2.25 cm^2; and (4) For the MG, serum hormone levels of ghrelin, neuropeptide Y (NPY), motilin (MTL) and gastrin (GAS) were significantly upregulated; in contrast, those of leptin, 5-hydroxytryptamine (5-HT) and cholecystokinin (CCK) were significantly downregulated.

CONCLUSION: Mirtazapine not only alleviates symptoms associated with dyspepsia and depression linked to FD in patients with weight loss but also significantly increases body weight (mainly the visceral fat in body fat). The likely mechanism of mirtazapine action is regulation of brain-gut or gastrointestinal hormone levels.

Key words: Mirtazapine; Functional dyspepsia; Weight loss; Depression

Core tip: A part of functional dyspepsia (FD) patients were found with weight loss in recent studies. As an antidepressant, mirtazapine was found not only to alleviate symptoms associated with dyspepsia and depression linked to FD with weight loss, but also to significantly increase body weight (mainly the visceral fat in body fat). Moreover, the likely mechanism of mirtazapine action is the regulation of brain-gut or gastrointestinal hormone levels.

Beneficial effects of antidepressant mirtazapine in functional dyspepsia patients with weight loss. *World J Gastroenterol* 2016; 22(22): 5260-5266 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5260.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5260

INTRODUCTION

Functional dyspepsia (FD) is a common clinical syndrome characterized by chronic and recurrent symptoms in the gastroduodenal region in the absence of any organic or metabolic disease that explains the symptoms[1]. It impairs the patient's quality of life and work efficiency, and increases the utilization of medical resources[2-4]. Psychosocial factors may play an important role in FD and lead to the use of antidepressant and anxiolytic agents in FD management[5].

Weight loss is a common symptom of digestive diseases, and may indicate an organic disease[6]. However, the indicators of weight loss for the diagnosis of an organic disease are limited[7-9]. Tack *et al*[10] found that of 40 FD patients, 55% had a weight loss that was > 5% of initial body weight. In a study investigating laboratory parameters and the nutritional status of 180 patients who were diagnosed with FD, 16.67% of patients had a weight loss from 5% to 10% of their initial body weight, and 4.44% had a weight loss of > 10% of their initial body weight[11]. Our previous multi-center research study of 1057 FD patients showed that with the onset of dyspepsia symptoms, 19.58% had lost ⩾ 5% of their initial body weight during the previous 12 mo or less. FD patients with weight loss had lower body mass index, more frequent physician visits, higher psychological disorders, poorer appetite and lower quality of life[12].

Antidepressant mirtazapine is clinically used in the treatment of depression or anxiety disorders. In recent years, many clinical trials associated with antidepressants for FD have indicated that antidepressants are effective in treating FD patients[13-15]. A case report about mirtazapine in the treatment of an FD patient with depression reported that the patient's indigestive symptoms, appetite, depression, and quality of life were improved after taking mirtazapine for 4 wk[16]. However, studies that have focused on the parts of the body that are involved in weight gain and the underlying mechanisms have been rare.

Clinical observations have shown that increases in appetite and food intake, and consequent weight gain occur in some patients undergoing mirtazapine treatment. Whereas such side effects may limit the general application of mirtazapine in antidepressant therapy, these very same effects proved to be beneficial in treating FD patients with weight loss.

Therefore, expanding upon previous work[12,17], in this study we comprehensively explored the effect of mirtazapine on depressive FD patients with weight loss by dynamic observation not only of the changes in dyspepsia and depressive symptoms but also the modifications of body weight and fat distribution and the levels of serum hormones.

MATERIALS AND METHODS

Ethics statement

This study was a prospective, randomized, controlled trial in depressive FD patients with weight loss and was approved by the hospital ethics committee (Clinical trial registration number: ChiCTR-TRC-13003161). Written informed consent was obtained from the patients according to the Declaration of Helsinki.

Patients

In this prospective study, 60 patients were recruited between September 2011 and June 2013 from the gastroenterology outpatient clinic of Guangzhou Nansha Central Hospital. All the patients fulfilled the following criteria[12]: (1) diagnosed with FD according to Rome Ⅲ criteria; (2) with a weight loss of ⩾ 5% of initial body weight since the onset of symptoms; (3) diagnosed with depression by psychiatrists according to the Chinese Classification of Mental Disorders (CCMD-3)

and scores of the Hamilton Rating Scale of Depression (HAMD) over 18; and (4) ranged in age from 18 to 65 years; and (5) signed informed consent statements.

The following exclusion criteria were adopted: (1) organic diseases such as peptic ulcers, atrophy or erosive gastroduodenal lesions, tumors, and esophagitis by gastroscopic examination; (2) liver, gallbladder, pancreas, spleen and bowel organic disease by laboratory, B ultrasonic or X-ray examination; (3) dyspepsia symptoms and weight loss that were explained by metabolic or infectious diseases such as diabetes, hyperthyroidism, or tuberculosis; (4) anorexia nervosa and patients with body weight management problems; (5) age < 18 or > 65 years; (6) pregnancy or breast feeding; (7) disabilities; (8) current use of other drugs in clinical research or use of similar drugs in the last half-month; (9) in a severe anxiety or depressive state, or with suicidal tendencies; (10) current use of non-steroidal anti-inflammatory drugs, steroids, or drugs affecting gastric acid secretion; and (11) contraindications for paroxetine or mirtazapine use including hypersensitivity, liver dysfunction or renal failure.

Grouping

Sixty depressive FD patients with weight loss were randomly divided into a mirtazapine group (MG), a paroxetine group (PG) or a conventional therapy group (CG) with 20 patients in each. The trial period spanned 8 wk. The CG was treated with histamine type 2 receptor antagonists or proton pump inhibitors or prokinetic agents; MG was treated with mirtazapine (Remeron®, N.V. Organon, Holland, 30 mg/d); and PG was treated with paroxetine (Seroxat®, SK&F, China, 20 mg/d). All protocols were based on conventional therapy.

Assessments

Adverse effects and treatment response were recorded and data collected at specific time points. These were before treatment (for baseline determination), 2 wk, 4 wk, 6 wk and 8 wk of treatment for the following assessments: dyspepsia symptoms were evaluated with NDSI; depressive symptoms, with HAMD-17; and the change in body weight and the distribution of body fat with the body composition analyzer (InBody720, Biospace, South Korea). Serum hormone levels were measured at baseline, 4 wk and 8 wk; expression levels of ghrelin, leptin, neuropeptide Y (NPY), 5-hydroxy tryptamine (5-HT), cholecystokinin (CCK), motilin (MTL) and gastrin (GAS) were assayed by ELISA.

NDSI: The NDSI evaluated the frequency, intensity, and practical impediments of 15 GI symptoms (including epigastric pain, epigastric burning, postprandial fullness, and early satiety) over a 2-wk period. We recorded each subscale score concerning daily activities/work (13 items), knowledge and control (7 items), eating/drinking (3 items), and sleep disturbance (2 items)[18]. We added each item score within each subscale to produce a subscale score. Low scores indicate mild symptoms.

HAMD-17: The rating standards of the HAMD[19] were as follows: no depression (0-6), mild depression (7-17), moderate depression (18-24), and severe depression (> 25). A higher score indicates worse depression.

Body composition analyzer (InBody720): Patient requirements included: empty stomach, empty bladder, light clothes and no shoes for measurement in the early morning on the body composition analyzer. Patients with a pacemaker or with metal in the body were excluded from measurement on this instrument.

Treatment response: Treatment response was defined as a > 50% reduction in the NDSI score. The response was calculated as: [(score at treatment - score at baseline)/score at baseline] × 100. The treatment responses of the three groups were calculated independently.

Statistical analysis

Data analyses were performed using SPSS 13.0 software (SPSS Inc., Chicago IL, United States), and measurement data are reported as the mean ± SD, and were compared across groups using one-way ANOVA and the Student-Newman-Keuls test for multiple comparisons. Count data were compared across groups using a χ^2 test. All tests were two-tailed and $P < 0.05$ was considered statistically significant.

RESULTS

Study participants

A total of 60 depressive FD patients with weight loss were enrolled in the study. All patients were randomized to receive mirtazapine, paroxetine or conventional treatment. No patient was lost to follow-up. The baseline characteristics of the patients are shown in Table 1. No differences were observed among the three groups in gender, age, height, weight, body mass index (BMI) or body loss when diagnosed.

Improvement of dyspepsia symptoms

As shown in Figure 1A, the patients' dyspepsia symptoms gradually improved over the course of treatment in the three groups. After 2 wk, the NDSI score was significantly lower in the MG than in the PG and CG ($P < 0.05$ for all), and this trend continued until the end of the study. Since 6 wk, NDSI score of the PG was significantly lower than that of the CG ($P < 0.05$).

Improvement of depressive symptoms

Patients' depressive symptoms were improved in the

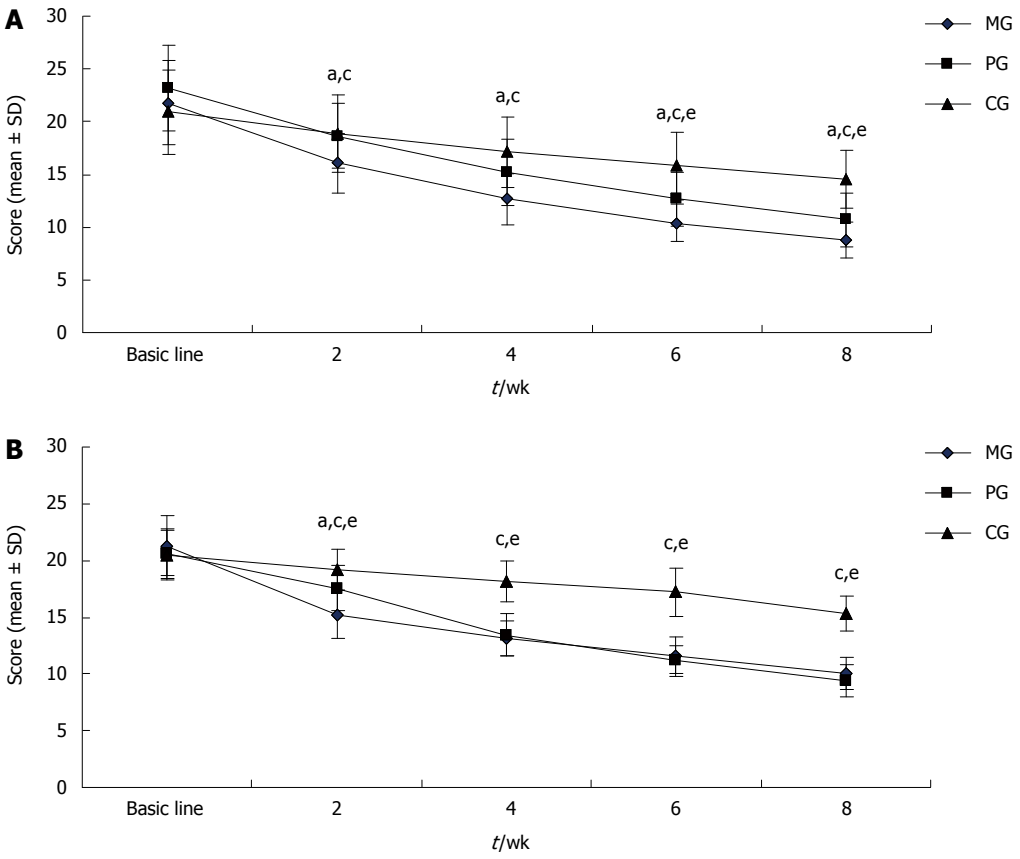

Figure 1 Comparison of Nepean Dyspepsia Index-symptom scores (A) or Hamilton Rating Scale of Depression-17 scores (B). [a]*P* < 0.05, MG *vs* PG; [c]*P* < 0.05, MG *vs* CG; [e]*P* < 0.05, PG *vs* CG. MG: Mirtazapine group; PG: Paroxetine group; CG: Conventional group.

Table 1 General characteristics of study patients

Variable	MG (*n* = 20)	PG (*n* = 20)	CG (*n* = 20)	*P* value
Gender (M/F)	8/12	11/9	7/13	0.725
Age (yr)	43.45 ± 11.50	37.75 ± 10.78	39.95 ± 6.84	0.914
Height (cm)	163.81 ± 12.36	162.36 ± 10.06	160.72 ± 10.63	0.834
Weight (kg)	49.77 ± 6.79	48.93 ± 5.89	48.22 ± 5.57	0.973
BMI (kg/m^2)	18.73 ± 5.62	18.65 ± 4.73	18.84 ± 6.38	1.005
Body loss when diagnosed	3.42 ± 0.54	3.72 ± 0.64	3.69 ± 0.71	0.872

MG: Mirtazapine group; PG: Paroxetine group; CG: Conventional group.

three treatment groups (Figure 1B). At all time points, the HAMD-17 score was significantly lower in the MG and PG than in the CG ($P < 0.05$). After 2 wk of treatment, the HAMD-17 score was sharply lower in the MG than in the PG ($P < 0.05$); however, at 4 wk, the score of PG became very close to that of the MG and remained so until the end of the study.

Change of body weight and its composition

As shown in Figure 2, the patients' body weights were not significantly different before treatment among the three groups. As treatment progressed, body weight of patients in the MG gradually increased. At 6 wk and 8 wk, patients' body weights were significantly heavier in the MG than those in the PG and CG ($P < 0.05$ for all); thus, there was no significant body weight change over the test period in either the PG or CG.

Further analysis of body weight and its composition is shown in Table 2. After 8 wk of treatment, 19 patients in the MG presented an increase in body weight and BMI. The patients in the MG gained 3.58 ± 1.57 kg, which was significantly higher than that gained in either the PG, at 0.53 ± 0.44 kg or the CG, at 0.56 ± 0.45 kg ($P < 0.05$). However, no obvious change of body weight was observed in the PG or CG throughout treatment. Body fat is one of the main components contributing to body weight. Over the course of treatment, body fat increased by 2.77 ± 0.14 kg; the body fat ratio rose by 4%; and visceral fat area was increased by 7.56 ± 2.25 cm^2 ($P < 0.05$). No significant change in muscle volume was detected over the treatment period.

Changes in expression levels of serum hormones

After 4 wk and 8 wk of treatment in MG, the levels of ghrelin, NPY, MTL, and GAS were significantly upregulated, while the levels of leptin, 5-HT and CCK were significantly downregulated ($P < 0.05$). After 8 wk of treatment, significant differences appeared between the levels in the MG and those in the PG and CG ($P < 0.05$). Moreover, at 4 wk in the PG, the levels of NPY, MTL and GAS sharply increased, whereas

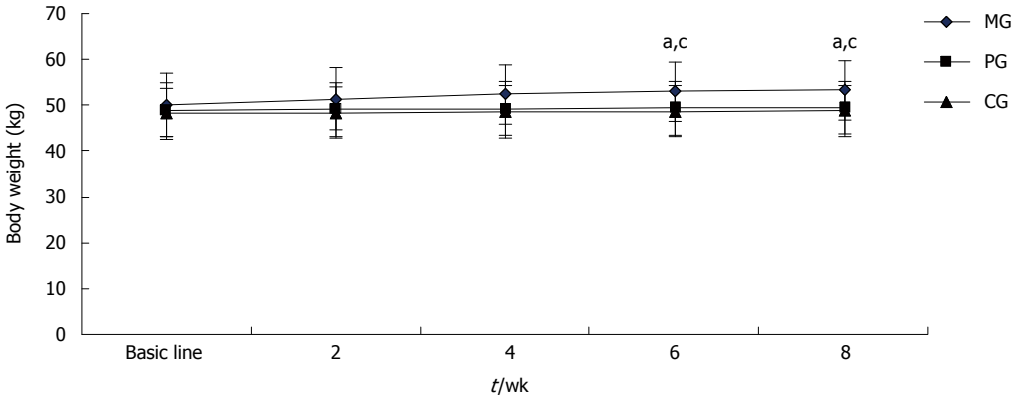

Figure 2 Change of body weight. [a]*P* < 0.05, MG *vs* PG; [c]*P* < 0.05, MG *vs* CG. MG: Mirtazapine group; PG: Paroxetine group; CG: Conventional group.

Table 2 Change of body weight and its composition in mirtazapine group

Variable	Baseline	2 wk	4 wk	6 wk	8 wk
Body weight (kg)	49.77 ± 6.79	51.35 ± 6.80	52.36 ± 6.60[a]	53.07 ± 6.46[a]	53.35 ± 6.52[a]
BMI (kg/m^2)	18.73 ± 5.62	18.97 ± 5.43	19.70 ± 4.52[a]	19.87 ± 4.62[a]	20.07 ± 5.23[a]
Body fat (kg)	8.36 ± 2.53	9.28 ± 2.33	11.05 ± 1.92[a]	11.09 ± 1.87[a]	11.13 ± 2.86[a]
Body fat ratio (%)	0.17 ± 0.02	0.18 ± 0.04	0.20 ± 0.07[a]	0.20 ± 0.09[a]	0.21 ± 0.08[a]
Visceral fat area (cm^2)	35.27 ± 8.12	36.12 ± 8.05	41.68 ± 9.23[a]	42.02 ± 9.14[a]	42.83 ± 10.64[a]
Muscle volume (kg)	38.25 ± 7.53	38.26 ± 7.49	38.46 ± 6.84	38.52 ± 6.64	38.62 ± 6.77

Table 3 Changes of expression level of serum hormones

Group		Ghrelin (ng/mL)	Leptin (ng/mL)	NPY (pg/mL)	5-HT (ng/mL)	CCK (pg/mL)	MTL (pg/mL)	GAS (pg/mL)
MG	Baseline	4.62 ± 1.53	9.87 ± 4.65	107.52 ± 26.21	237.83 ± 56.94	392.36 ± 27.21	32.53 ± 6.28	56.37 ± 21.15
	4 wk	6.02 ± 3.43[a,c,e]	7.25 ± 3.47[a,c,e]	114.56 ± 25.10[a]	208.47 ± 52.48[a]	221.69 ± 23.77[a]	49.46 ± 6.10[a,c,e]	48.37 ± 11.93[a,c,e]
	8 wk	8.97 ± 3.64[a,c,e]	4.03 ± 2.77[a,c,e]	149.27 ± 39.53[a,c,e]	176.92 ± 53.38[a,c,e]	183.85 ± 27.65[a,c,e]	66.28 ± 3.97[a,c,e]	41.61 ± 10.52[a,c,e]
PG	Baseline	4.68 ± 2.12	9.07 ± 4.65	105.12 ± 29.52	232.83 ± 50.94	390.82 ± 27.54	31.98 ± 9.34	54.98 ± 15.24
	4 wk	5.12 ± 2.23	8.75 ± 3.05	112.31 ± 15.10[a]	215.32 ± 24.91[a]	291.57 ± 31.76[a]	40.37 ± 8.23[a]	52.37 ± 12.97
	8 wk	6.01 ± 3.27[a]	8.25 ± 2.13	114.27 ± 28.53[a]	210.17 ± 49.17[a]	283.85 ± 47.15[a]	53.28 ± 6.84[a]	48.61 ± 11.17[a]
CG	Baseline	4.89 ± 2.47	8.87 ± 2.65	104.93 ± 17.95	235.81 ± 61.82	391.75 ± 24.96	36.26 ± 6.22	54.23 ± 26.83
	4 wk	5.48 ± 2.15	8.32 ± 3.57	108.92 ± 29.64	211.26 ± 46.28	224.67 ± 23.45	43.92 ± 7.24	49.21 ± 12.15
	8 wk	6.93 ± 2.35	8.02 ± 1.45	121.43 ± 13.92	208.95 ± 38.29	303.12 ± 26.76	55.53 ± 5.98	43.34 ± 13.72

[a]*P* < 0.05 *vs* baseline in the same group; [c]*P* < 0.05, MG *vs* PG; [e]*P* < 0.05, MG *vs* CG. MG: Mirtazapine group; PG: Paroxetine group; CG: Conventional group; NPY: Neuropeptide Y; 5-HT: 5-hydroxytryptamine; CCK: Cholecystokinin; MTL: Motilin; GAS: Gastrin.

the levels of 5-HT and CCK decreased. There was no obvious difference in CG hormone expression levels over the treatment period (Table 3).

Adverse effects and treatment response

The adverse effects associated with the different protocols were recorded for the 20 patients assigned to each treatment group**:** in the MG, these were dizziness (10%), lethargy (15%), and fatigue (15%); in the PG, they were dizziness (15%), lethargy (20%), nausea (5%) and fatigue (20%). As these adverse effects were mild, they dissipated without treatment within 1 wk. No obvious adverse effects were reported in the CG.

After 8 wk, 85% of patients in the MG, and 80% in the PG responded positively to treatment, which were significantly higher than that (55%) found in the CG; however, there was no significant difference in the results between the MG and PG.

DISCUSSION

FD is a common psychosomatic disease associated with a variety of mental disorders including anxiety, depression, panic attacks, and post-traumatic stress disorder, of which anxiety and depression are the most common. Negative spiritual, psychological and social factors can accelerate the onset of FD symptoms and exacerbate them and thereby ultimately affect treatment efficacy. However, at present, the impact of such factors on the incidence and progression of FD is not very clear; one intriguing possibility is that

they may work to change gastrointestinal motor or sensory function through the brain-gut axis. Weight loss is a common symptom of digestive diseases, and may indicate an organic disease[6], but recently, certain studies have found that patients with functional gastrointestinal diseases often showed weight loss[11,20].

Currently, there is no very effective treatment for depressive FD patients with weight loss, because of the chronic and recurrent characteristics of the disease. Antidepressants are often used to treat patients with depression. One of these, mirtazapine, a serotonin-norepinephrine reuptake inhibitor that is clinically used for the treatment of depression, acts rapidly with positive effects on sleep disorders, appetite loss, depressive symptoms, *etc*.

Herein, we analyzed the effects of mirtazapine on depressive FD patients with weight loss**.** Mirtazapine showed higher efficacy in relieving dyspeptic symptoms and lowering NDSI scores when compared to paroxetine and conventional treatment, and was equal to paroxetine in mitigating depressive symptoms. After 8 wk of treatment, 85% of MG patients were classified as treatment responsive, a proportion higher than 80% as observed in the PG, and significantly higher than 55% as seen in the CG. This may be related to specific aspects of mirtazapine action that not only may alleviate depression and improve the function of the nervous system, but also regulate gastrointestinal motor or sensory function.

In this study, we show that mirtazapine treatment of depressive FD patients with weight loss not only effectively treated symptoms of dyspepsia and depression, but also induced significant weight gain, an effect not observed with either paroxetine or conventional treatment. Specifically, 80% of the patients experienced weight gain after 4 wk of treatment with mirtazapine; furthermore, 95% of these patients continued to gain weight until the end of the treatment. The average weight gain was 3.58 ± 1.57 kg, resulting in significantly higher weight than the baseline weight recorded before treatment. In humans, weight is mainly composed of muscle volume, body fat, and inorganic salts, and muscle volume and body fat are the most affected. Through dynamic observation of the weight distribution of the various body components, we found that muscle volume stayed relatively constant throughout treatment, whereas body fat significantly changed. Body fat, which includes subcutaneous fat, visceral fat, muscle clearance fat, proved to be the main contributor to body weight gain. Further analysis of body fat distribution revealed that visceral fat showed a marked increase with mirtazapine treatment at 4 wk and 8 wk, which indicated that visceral fat was the key element responsible for the observed body weight gain.

Generally, significant imbalances of visceral fat are known to increase the incidence of cardiovascular disease, digestive disease, urinary disease, *etc*. In our study, although visceral fat did indeed increase after 8 wk of mirtazapine treatment, body fat ratios remained at normal levels. We speculate that most of the patients were at a low level of body weight and BMI before treatment, and even underweight according to BMI, whereas muscle volume remained at normal levels throughout; thus, the amount of body fat must have been seriously deficient before treatment. Moreover, through appetite growth and symptom relief, muscle volume may have gradually increased with treatment, whereas overall body fat may have grown at a slower rate.

In recent years, functional gastrointestinal disease has been closely associated with dysregulation of the brain-gut axis. The brain-gut axis, which is regulated by neuroendocrine and immune factors, is a bipolar system between the gastrointestinal tract and brain that is affected by psychosocial factors. The coordination between the central nervous system and gastrointestinal contractility is regulated through a variety of brain-gut peptides and gastrointestinal hormones. In this study, the levels of ghrelin, NPY, MTL, and GAS which may increase appetite, food intake or gastrointestinal dynamic promotion were significantly upregulated, whereas the levels of leptin, 5-HT and CCK which may decrease food intake, block gastrointestinal motility or increase gastrointestinal sensitivity were significantly downregulated.

In conclusion, antidepressant mirtazapine not only improved patients' conditions concerning indigestive and depressive symptoms, but also increased appetite and body weight (mainly the visceral fat in body fat), much more effectively than either paroxetine or conventional therapy. The clinical efficacy of mirtazapine may be mediated in part through the regulation of brain-gut or gastrointestinal hormones. To clarify these effects and the underlying mechanisms of mirtazapine action in FD patients with weight loss will require bigger sample sizes, and multi-center, randomized controlled trials in future studies.

COMMENTS

Background

Functional dyspepsia (FD) is a common psychosomatic disease associated with a variety of mental disorders, and weight loss was often found in FD patients. Such patients had lower body mass index, more frequent physician visits, higher psychological disorders, poorer appetite and lower quality of life. In recent years, many clinical trials indicated that antidepressant mirtazapine are effective in treating FD patients. Whereas some side effects may limit the general application of mirtazapine in antidepressant therapy, these may prove to be beneficial in treating FD patients with weight loss.

Research frontiers

This study comprehensively explored the effect of mirtazapine on depressive FD patients with weight loss by dynamic observation not only of the changes in dyspepsia and depressive symptoms but also the modifications of body weight and fat distribution and the level of serum hormones.

Innovations and breakthroughs

This study showed that antidepressant mirtazapine not only improved patients' conditions concerning indigestive and depressive symptoms, but also increased appetite and body weight, mainly the visceral fat in body fat, much more effectively than either paroxetine or conventional therapy. The clinical efficacy of mirtazapine may be mediated in part through the regulation of brain-gut or gastrointestinal hormones.

Applications

The findings can supply the evidence for the clinical application of mirtazapine in FD patients with weight loss.

Terminology

The Nepean Dyspepsia Index-symptom is a scale that evaluates the frequency, intensity, and practical impediments of 15 gastrointestinal symptoms.

Peer-review

This is a good and practical study in which the authors found that the beneficial effects and mechanism of action of antidepressant mirtazapine in FD patients with weight loss. It is believed that the findings can provide a new angle and evidence for the clinical application of mirtazapine in FD patients with weight loss.

Abstract

AIM: To demographically and clinically characterize inflammatory bowel disease (IBD) from the local registry and update data previously published by our group.

METHODS: A descriptive study of a cohort based on a registry of patients aged 15 years or older who were diagnosed with IBD and attended the IBD program at Clínica Las Condes in Santiago, Chile. The registry was created in April 2012 and includes patients registered up to October 2015. The information was anonymously downloaded in a monthly report, and the information on patients with more than one visit was updated. The registry includes demographic, clinical and disease characteristics, including the Montreal Classification, medical treatment, surgeries and hospitalizations for crisis. Data regarding infection with *Clostridium difficile*

(*C. difficile*) were incorporated in the registry in 2014. Data for patients who received consultations as second opinions and continued treatment at this institution were also analyzed.

RESULTS: The study included 716 patients with IBD: 508 patients (71%) were diagnosed with ulcerative colitis (UC), 196 patients (27%) were diagnosed with Crohn's disease (CD) and 12 patients (2%) were diagnosed with unclassifiable IBD. The UC/CD ratio was 2.6/1. The median age was 36 years (range 16-88), and 58% of the patients were female, with a median age at diagnosis of 29 years (range 5-76). In the past 15 years, a sustained increase in the number of patients diagnosed with IBD was observed, where 87% of the patients were diagnosed between the years 2001 and 2015. In the cohort examined in the present study, extensive colitis (50%) and colonic involvement (44%) predominated in the patients with UC and CD, respectively. In CD patients, non-stricturing/non-penetrating behavior was more frequent (80%), and perianal disease was observed in 28% of the patients. There were significant differences in treatment between UC and CD, with a higher use of corticosteroids, and immunosuppressive and biological therapies was observed in the patients with CD ($P < 0.05$ and $P < 0.01$). Significant surgical differences were also observed: 5% of the UC patients underwent surgery, whereas 38% of the CD patients required at least one surgery ($P < 0.01$). The patients with CD were hospitalized more often during their disease course than the patients with UC (55% and 35% of the patients, respectively; $P < 0.01$). *C. difficile* infection was acquired by 5% of the patients in each group at some point during the disease course. Nearly half of the patients consulted at the institution for a second opinion, and 32% of these individuals continued treatment at the institution.

CONCLUSION: IBD has continued to increase in the study cohort, slowly approaching the level reported in developed countries.

Key words: Inflammatory bowel disease; Crohn's disease; Ulcerative colitis; South America; Latin America; Chile; Epidemiology

Core tip: Several studies have found that the incidence of inflammatory bowel disease (IBD) has increased over the past several decades, even in countries where the frequency was extremely low. Industrialization, increased physician awareness, advancements in diagnostic methods and better access to medical services are factors that might explain this increase. Although few epidemiological studies have been conducted in Latin America, these analyses have described an increased incidence of IBD. In the present study, we analyzed single-center data of 716 patients with IBD. We collected data from a considerable number of patients diagnosed with IBD, enabling the demographic and clinical characterization of these individuals.

INTRODUCTION

Inflammatory bowel disease (IBD) includes a spectrum of typically progressive chronic diseases, including Crohn's disease (CD), ulcerative colitis (UC) and unclassified colitis. Unclassified colitis occurs in patients who have clinical and endoscopic evidence of chronic IBD affecting the colon without small bowel involvement and no definitive histological or other evidence suggesting either CD or UC[1]. Although IBD mortality is low, the onset of this disease during early adulthood and its chronicity as a lifelong disease result in a significant decline in the quality of life of the patients and a heavy burden on the healthcare system due to high treatment costs[2]. Natural history studies have helped identify subsets of patients whose disease prognosis can be stratified according to clinical features. These data might improve the management of patients with IBD by defining changes in disease phenotype and risks of relapse, hospitalization and surgery[3].

Several studies have reported that the incidence of IBD has markedly increased over the latter part of the 20th century, whereas other studies have suggested a plateau or even a decline in IBD incidence in certain geographical areas[4,5]. However, an increase in these diseases has been described in countries where their frequency was very low[6-9]. IBD has been associated with the industrialization of nations[10,11], and thus, the increasing incidence of these diseases in developing countries might reflect this phenomenon. However, other factors, such as increased physician awareness, advancements in diagnostic methods and better access to medical services, such as colonoscopies, should be considered[12]. Although few epidemiological studies have been conducted in developing Latin American countries, these analyses have also described an increased incidence of IBD[13-19]. As we previously published, the incidence and prevalence of IBD in Chile are unknown; however, consistently with two other studies, our data suggest increases in the numbers of local cases of CD and UC[16,18,20]. The objective of this study was to demographically and clinically characterize IBD from a local registry and thereby update previously published data.

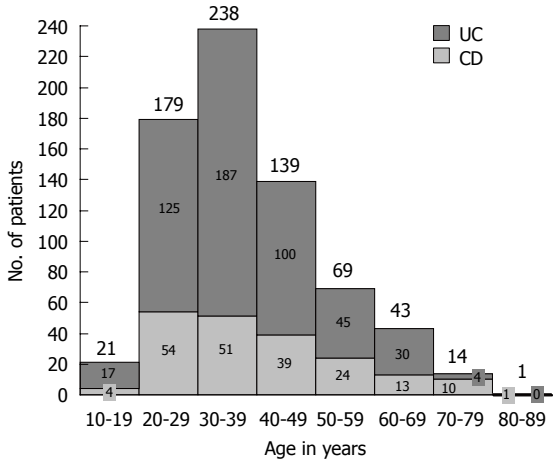

Figure 1 Frequency of patients with ulcerative colitis and Crohn´s disease at age of diagnosis. UC: Ulcerative colitis; CD: Crohn´s disease.

MATERIALS AND METHODS

This was a descriptive study of a cohort based on a registry of patients aged 15 years and older, diagnosed with IBD according to clinical, endoscopic, histological and radiologic findings and attending the IBD program at Clínica Las Condes in Santiago, Chile. The registry was created in April 2012 and includes patients who attended the program until October 2015. Retrospective data were obtained from those patients diagnosed prior to the indicated date. The registry is composed of online forms available in the electronic medical record of each patient that were completed by gastroenterologists and colorectal surgeons during clinic visits. On each subsequent visit, the information was prospectively updated as deemed necessary. The information was anonymously downloaded in a monthly report, and the information for patients with more than one total visit was updated. The registry includes demographic, clinical and disease characteristics, such as extension, location and behavior, changes in diagnosis from UC to CD, phenotype changes in CD, medical treatment, surgeries and hospitalizations for crisis. Data concerning *Clostridium difficile* (*C. difficile*) infection were incorporated into the registry in 2014. A polymerase-chain reaction assay for *C. difficile* detection was requested for patients presenting with moderate-to-severe activity. In CD, the Montreal Classification was used to define the phenotype as follows: B1, non-stricturing/non-penetrating; B2, stricturing; and B3, penetrating. A "p" was added to any of these classifications in case of perianal disease. The same classification was used to define the location of the disease: L1, ileum; L2, colon; L3, ileocolonic; and L4, concomitant upper gastrointestinal involvement. The extension of UC was defined according to the Montreal Classification: E1, ulcerative proctitis; E2, left-sided UC (distal UC); and E3, extensive UC (pancolitis)[1]. However, because Clínica Las Condes is a tertiary center that receives patients from locations throughout the country, the data for patients who received consultations as a second opinion and continued treatment at this institution were also analyzed. Patients with two or more visits over the next year were considered patients who were continuing treatment with the IBD program at this institution. This study was approved through the Institutional Ethics Committee.

Statistical analysis

The data were analyzed using the R Commander program. Continuous variables did not have a normal distribution and were described based on medians and ranges and compared using the Mann Whitney rank test for independent groups. Qualitative categorical variables were described with absolute frequency and percentage, and we used the χ^2 test for comparative statistical analysis. When the sample was less than 20, Fisher's exact test was used. Differences with a *P* value less than 0.05 were considered to be statistically significant. A biomedical statistician conducted a statistical review of the present study.

RESULTS

The study included 716 patients with IBD: 508 patients (71%) were diagnosed with UC, 196 patients (27%) were diagnosed with CD, and 12 patients (2%) were diagnosed with unclassifiable IBD. The UC/CD ratio was 2.6/1. The median age was 36 years (range 16-88), and 58% of the patients were female, with a median age at diagnosis of 29 years (range 5-76). Most patients with UC and CD were diagnosed between the ages of 20 and 29 years (Figure 1), without differences in gender. However, 22 patients (3%) were diagnosed when over 60 years of age. In the past 15 years, a sustained increase in the number of patients diagnosed with IBD has been observed, and significant increases were obtained from the comparison of the periods 1971-1985, 1986-2000 and 2001-2015, with 87% of patients diagnosed in the last period. The frequency of patients with IBD distributed according to the year of diagnosis is shown in Figure 2, illustrating an increase in the diagnosis of new cases of UC and CD over time. The demographic and disease characteristics of patients are shown in Table 1. In both UC and CD patients, articular symptoms were the most frequent extraintestinal manifestations. Primary sclerosing cholangitis (PSC) was diagnosed in eight patients (2%) with UC and two patients (1%) with CD.

Extent, location and behavior of IBD

Regarding the extent of UC, 50% of patients had extensive colitis. In CD, 44% of patients had colonic involvement, and only 3% of patients presented with concomitant upper disease. One patient in the registry presented with isolated perianal disease, and CD was confirmed through biopsies of the fistula,

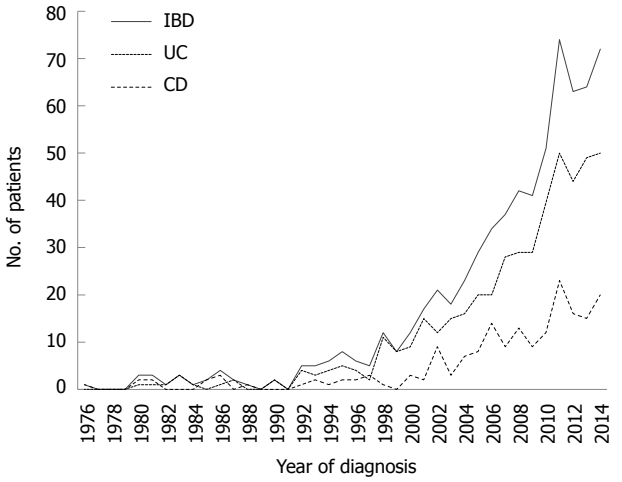

Figure 2 Frequency of patients with inflammatory bowel disease distributed by year of diagnosis. IBD: Inflammatory bowel disease; UC: Ulcerative colitis; CD: Crohn´s disease.

UC: Ulcerative colitis; CD: Crohn´s disease.

which demonstrated granulomas. Non-stricturing/non-penetrating behavior was predominant in CD (80%). Stricturing and penetrating behavior was observed in 10% and 9% of patients, respectively. Perianal disease was observed in 28% of the patients with CD (Table 2). During the course of IBD, the diagnosis of 19 patients changed: one patient with unclassifiable IBD was newly diagnosed with CD, and 18 UC patients were newly diagnosed with CD. In six patients, CD was posteriorly diagnosed because these individuals developed perianal fistulas. In addition, 16 patients with CD showed modified behavior, nine of these patients showed changes from non-stricturing/non-penetrating to stricturing disease and seven of them showed changes from non-stricturing/non-penetrating to penetrating disease. In addition, two patients who are included in the 16 patients mentioned above developed perianal disease. Changes in disease extension were observed in 36 UC patients. Specifically, 12 of these 36 patients presented disease extension from proctitis to left colitis, and the remaining 24 patients exhibited disease extension from proctitis or left colitis to extensive colitis.

Medical treatment for IBD

Significant differences in treatment were found between

[1]Fisher´s Test. UC: Ulcerative colitis; CD: Crohn´s disease.

UC patients and CD patients (Table 3). Mesalamine was used to treat 98% of UC patients and 68% of CD patients. Patients with CD received corticosteroids, mesalamine and immunosuppressive agents at equal frequency. A comparison of both groups revealed that the use of corticosteroids and immunosuppressive and biological therapies was significantly higher in patients with CD. A total of 102 patients (14%) were treated with biological therapy; specifically, 83 patients received infliximab, 13 patients received adalimumab, one patient received certolizumab pegol, one patient received golimumab and four patients received natalizumab. Biological therapy was initiated one year (median) after diagnosis for patients diagnosed since 2010 (39 patients) because biological therapy has become more accessible since then.

Surgery in IBD

A comparison revealed that more CD than UC patients required surgery. Specifically, only 27 UC patients (5%) underwent surgery, whereas 75 CD patients (38%) underwent surgery ($P < 0.01$) (Table 3). Fifty of the patients diagnosed with CD (25%) underwent intestinal resection, and six of these patients (3%)

required surgery for posteriorly based perianal disease. In addition, 24 CD patients (12%) underwent surgery due only to perianal disease, and one patient underwent a loop ileostomy.

Hospitalization and C. difficile infection

CD patients were hospitalized more often during the disease course than UC patients (55% and 35% of patients, respectively; $P < 0.01$). In addition, 21.3% of the CD patients had more than four hospitalizations compared with 10% of the UC patients ($P < 0.01$). The median number of hospitalizations for both was 2, with ranges from 1 to 24 for UC and 1 to 40 for CD (Table 3).

As previously described, data concerning *C. difficile* infection were incorporated into the registry in 2014, and a total of 490 patients (344 UC patients and 141 CD patients) were analyzed. No differences in the prevalence of infection was found between the groups, and 5% of the patients in each group acquired *C. difficile* infection at some point during the disease course.

Second opinion

The data obtained from the registry showed that 328 patients (46%) received consultations at the institution for a second opinion. Most of these patients (72%) were diagnosed with UC, and 107 of the 328 patients (32%) continued treatment at this center. However, 130 patients were not analyzed because these individuals received consultations late in 2015 and had therefore not completed more than one year of treatment since the first consultation at this institution. In addition, many patients live in other cities and receive consultations only for complex situations.

DISCUSSION

The number of patients in the registry more than doubled compared with the number detailed in our previous publication[20]. This increase not only allowed us to better characterize these patients but also facilitated a comparison with studies conducted worldwide. This population increase reflects not only the recognition of this institute as a referral center but also the increased rate of IBD diagnoses in recent years.

The cohort UC/CD ratio in 2014 was 2.9/1, and the current ratio has increased 2.6/1, showing a slow approaching to the ratio reported in developed countries (1/1)[6,13,21,22]. However, genetic, environmental and geographic factors may influence this difference. A gender-based analysis showed that the percentages of UC and CD were slightly higher in women, which is consistent with the results obtained by other series[13,14,17]. The median age at diagnosis was 29 years, and 64% of patients were diagnosed between 20 and 39 years of age. No second peak was observed at an older age, which is consistent with the results from recent studies[6,7,23-25].

An active smoking habit was almost twice as frequent in patients with CD (16%) compared with patients with UC (9%), regardless of whether the patients with CD received counseling and were told of the particular deleterious effect of smoking. This finding demonstrates that smoking education is important and that smoking cessation should be emphasized on every visit. Nonetheless, the frequencies of patients with active smoking habits observed in the present study were low compared with the frequency of active smokers in the general population. The last National Health Survey has demonstrated that 40.6% of the adult population smokes regularly, indicating that cigarette smoking is an important health problem in Chile and that other factors, such as environmental factors, may be influencing the increase in the diagnosis of CD[26].

A family history was obtained for 12% and 10% of the patients diagnosed with UC and CD, respectively, similarly to the results reported by Moller *et al*[27], who published a much larger study. The analysis of the clinical characteristics revealed that the most frequent extra-intestinal manifestation was articular symptoms, with frequencies of 31% and 44% in UC and CD patients, respectively. In previous studies, musculoskeletal manifestations were described as the most common extra-intestinal manifestation, and UC patients are more affected than CD patients. However, the percentage of affected patients was lower than that observed in the present study (20%-30%)[28]. It has been suggested that the risk of developing peripheral arthritis increases with an increase in the extent of IBD activity[29,30], and 70% of patients diagnosed with CD who showed musculoskeletal manifestations had either colonic or ileocolonic involvement, whereas 55% of the patients diagnosed with UC who showed musculoskeletal manifestations had pancolitis. This observation reflects the recognition of this institution as a tertiary referral center that receives complex patients. In addition, the etiology of peripheral arthritis in IBD might reflect a combination of genetic predisposition and exposition to the luminal bacterial bowel contents[30].

The analysis of the extent of UC showed that half of the patients had extensive colitis, different from the frequency described in previous studies, which reported that distal location predominates[9] and that extensive colitis varies between 20 and 40%[7,9,19,22,24,31]. Even a previous study published in Chile, which involved two different institutions, reported 38% and 15% extensive colitis; notably, the frequency of 15% was previously reported at our institution 10 years ago[18], before this institution was recognized as a referral center and before its association with an IBD program. The higher percentage of extensive colitis observed in the population examined in the present study might reflect the fact that it was conducted at a tertiary referral

center and included refractory cases that were difficult to treat.

Colonic involvement was more frequent in the CD patients examined in the present cohort, with a frequency of 44%. This finding is consistent with the results of a study conducted in Brazil, which found that colonic involvement predominates, although at a lower frequency (36%)[19]. Non-structuring/non-penetrating behavior was more frequently observed in the cohort examined in the present study, with a frequency of 80%. This value is consistent with the frequency described in previous studies, which showed that inflammatory phenotypes predominate during the first years of the disease[24]. During the disease course, approximately 10% of patients with non-stricturing/non-penetrating behavior exhibited a modification of this characteristic to a more aggressive behavior. However, other studies have reported that 31% to 60% of patients exhibit a disease progression to a more severe behavior[32-34]. Indeed, after 40 years, most patients experience complications and are classified as having a penetrating, or less often, a stricturing disease[16]. These differences might reflect the short follow-up period used in the present study. Additionally, it has been reported that colonic disease remains uncomplicated or inflammatory for many years[24], so predominant colonic involvement found in our study might play a role in this progression. Another factor potentially explaining this difference is that the patients at this institution were aggressively treated upon diagnosis with an "accelerated step-up approach", involving the initiation of biological therapy a median of one year after diagnosis for patients diagnosed since 2010; thus, patients might have a lower probability to exhibit a change in behavior[35,36].

During the IBD course, 12 patients (2.3%) with an initial diagnosis of UC developed perianal fistulas or showed ileal involvement, changing their diagnosis to CD, as confirmed through histological and image analyses. Previous studies have described a 5%-10% change in diagnosis after 25 years of the disease course[37]. This finding might reflect the short follow-up period in the present study.

The analysis of IBD treatment revealed that mesalamine was the most used drug in UC treatment (98%), whereas corticosteroids, mesalamine and immunosuppressive agents were used at equal frequencies (67%-68%) in CD treatment. In the present study, despite the frequent use of mesalamine for patients with CD, the use of this agent in CD is controversial. Indeed, the European Crohn's and Colitis Organization Consensus recently stated that oral aminosalicylates are not recommended for the treatment of mild to moderate CD[38]. However, both the American and British National Gastroenterology Associations recommend the use of high-dose 5-aminosalicylic acid as the first-line treatment of mild ileal, ileocolonic or colonic CD[38]. Because we had a high percentage of patients with colonic involvement, treatment with mesalamine could have had some implications because the action of mesalamine is predominantly topical at the site of inflammation, particularly within the colon[38]. However, many of these patients received mesalamine, regardless of the severity of the disease, prior to evaluation at this institution, possibly resulting from misinformation regarding the role of mesalamine in CD. On the other hand, according to the latest clinical guidelines, the use of immunosuppressive and biological therapies is significantly higher in CD patients compared with UC patients, as observed in the present study. In the series examined in the present study, the use of infliximab in UC treatment (7%) was similar to that reported in other countries[31,39,40]; however, the use of this drug in CD treatment (34%) was considerably higher than that detailed in Saudi Arabia, Israel and some European countries, which report frequencies between 2% and 10%[31,40]. Similarly, the use of immunomodulators was considerably higher in both groups compared with that observed in some European countries[31]. This discrepancy reflects the type of center where the present study was conducted, *i.e.*, a tertiary center that treats patients with more complex diseases. Unfortunately, the use of adalimumab and certolizumab pegol was extremely low in the cohort examined in the present study, reflecting the low coverage of these therapies by insurance companies. In addition, vedolizumab is still not available for use in Chile.

The investigation of the use of surgery for IBD treatment revealed that 38% of the CD patients required surgery for either intestinal resection or perianal disease. The frequency of intestinal resection was significantly higher in CD patients (25%) compared with that of colectomy in UC patients (5%), a result consistent with the findings reported by Niewiadomski *et al*[41], who showed that the risk of intestinal resection in CD was 13% after one year and 26% after five years. However, the colectomy rates in UC obtained in this study were 2% and 13% after one and five years, respectively. Notably, the early use of immunomodulators and biological therapies during the disease course could reduce the risk of surgery[24,42], particularly for those patients who achieve mucosal healing[43].

Relatively few data are available regarding the hospitalization rates in population-based cohorts[44,45]. The CD patients in the cohort examined in the present study had significantly more hospitalizations than the UC patients; however, higher percentages of patients belonging to both groups in this cohort were affected compared with the frequencies obtained in previous studies[41,46]. Nevertheless, it has previously been reported that more than one-third of UC patients require hospitalization within one year after diagnosis in the biological era[44]. Among the UC patients examined

in the present study, 35% required hospitalization at some point during the disease course. The disease extent at diagnosis and the need for steroids and anti-TNF therapy were associated with the risk of UC-related hospitalization[44]. For CD, a 52.7% cumulative risk of hospitalization within ten years of diagnosis has previously been described[45]. Among the CD patients in the present study, 55% required hospitalization at some point during the disease course.

The analysis of our data concerning IBD and *C. difficile* infection demonstrated that this bacterium was equally prevalent in patients with UC and patients with CD (5%). Notably, it is difficult to clinically distinguish between *C. difficile* infections and IBD flare-ups because both pathologies have similar presentations, *i.e.*, diarrhea and abdominal pain. Indeed, C. *difficile* might mimic or even trigger an IBD flare-up, and screening is therefore recommended at every flare-up experienced by these patients[47]. Because IBD patients with concomitant *C. difficile* infections have been associated with longer hospital stays, colectomy and even higher mortality, the diagnosis of this bacterial infection is important[48]. The data obtained in the present study differ from those detailed in previous publications, which reported that UC patients exhibit increased susceptibility to *C. difficile* compared with CD patients[48-50]; however, previous studies have reported that one of the major risk factors for *C. difficile* infection in patients with IBD is colonic IBD[51], and 44% of the patients with CD in the present study showed colonic involvement. Importantly, only patients with moderate-to-severe activity were examined for *C. difficile* infections, and hence, these data might be underestimated because patients with mild activity were not examined.

In conclusion, IBD has continued to increase in the present cohort, slowly approaching the levels reported in developed countries. The association of this institution with a multidisciplinary IBD program has improved the characterization of these patients and had therefore improved management options.

Limitations

The present study was conducted in a private single tertiary center, which may have resulted in bias because many of the patients received consultations for second opinions. Some of these individuals were inadequately treated, whereas others are refractory to therapy; therefore, these patients could represent more complex cases. In addition, more drugs are available for treatment in our center compared with those available at the public hospitals in Chile. In addition, the presented findings were obtained retrospectively, implying a selection bias. Nevertheless, we collected data from a considerable number of patients diagnosed with IBD, enabling a demographic and clinical characterization of these individuals. Unfortunately, in the present study, we were unable to determine incidence or prevalence rates because we did not receive patients from a determinate geographic area.

ACKNOWLEDGMENTS

We wanted to thank Magdalena Castro biomedical statistician and member of the Academic Research Unit from Clínica Las Condes who conducted the statistical review of this study.

COMMENTS

Background

Several studies have reported that the incidence of inflammatory bowel disease (IBD) has increased over the past several decades, even in countries where the frequency of this disease is low. Industrialization, increased physician awareness, advancements in diagnostic methods and greater access to medical services are factors that might explain this rise.

Research frontiers

Although few epidemiological studies have been conducted in Latin America, these studies have also described an increased incidence of IBD. The incidence and prevalence of IBD in Chile are unknown; however, increases in the numbers of Crohn's disease (CD) and ulcerative colitis (UC) cases have been suggested. The research goal of this study was to actualize previously published data to better demographically and clinically characterize IBD in patients from Chile.

Innovations and breakthroughs

The present study represents the largest series of IBD patients reported in Chile and even in South America. These data demonstrated an increase in the number of IBD cases.

Applications

The data used in this study not only enable the characterization of patients locally but also facilitate the comparison of these individuals with those included in other studies conducted worldwide. The characterization of these patients enabled treatment optimization, thereby improving patient quality of life.

Terminology

IBD includes a spectrum of typically progressive chronic diseases, including CD, UC and unclassified colitis. Although IBD mortality is low, the onset of this disease during early adulthood and its chronicity as a lifelong disease lead to a significant decline in the quality of life of IBD patients and an increase in the burden on the healthcare system due to high treatment costs.

Peer-review

The paper is good written, an intersting paper regarding IBD in developing country with different results about disease distrubution, severity and treatment.

Abstract

AIM: To evaluate the assessment of primary biliary cirrhosis degree by acoustic radiation force impulse imaging (ARFI) and hepatic fibrosis indicators.

METHODS: One hundred and twenty patients who developed liver cirrhosis secondary to primary biliary cirrhosis were selected as the observation group, with the degree of patient liver cirrhosis graded by Child-Pugh (CP) score. Sixty healthy individuals were selected as the control group. The four indicators of hepatic fibrosis were detected in all research objects, including hyaluronic acid (HA), laminin (LN), type Ⅲ collagen (PC Ⅲ), and type Ⅳ collagen (Ⅳ-C). The liver parenchyma hardness value (LS) was then measured by ARFI technique. LS and the four indicators of liver fibrosis (HA, LN, PC Ⅲ, and Ⅳ-C) were observed in different grade CP scores. The diagnostic value of LS and the four indicators of liver fibrosis in determining liver cirrhosis degree with PBC, whether used alone or in combination, were analyzed by receiver operating characteristic (ROC) curve.

RESULTS: LS and the four indicators of liver fibrosis within the three classes (A, B, and C) of CP scores in the observation group were higher than in the control

group, with C class > B class > A class; the differences were statistically significant (P < 0.01). Although AUC values of LS within the three classes of CP scores were higher than in the four indicators of liver fibrosis, sensitivity and specificity were unstable. The ROC curves of LS combined with the four indicators of liver fibrosis revealed that: AUC and sensitivity in all indicators combined in the A class of CP score were higher than in LS alone, albeit with slightly decreased specificity; AUC and specificity in all indicators combined in the B class of CP score were higher than in LS alone, with unchanged sensitivity; AUC values (0.967), sensitivity (97.4%), and specificity (90%) of all indicators combined in the C class of CP score were higher than in LS alone (0.936, 92.1%, 83.3%).

CONCLUSION: The diagnostic value of PBC cirrhosis degree in liver cirrhosis degree assessment by ARFI combined with the four indicators of serum liver fibrosis is of satisfactory effectiveness and has important clinical application value.

Key words: Acoustic radiation force imaging technology; Hepatic fibrosis index; Primary biliary cirrhosis; Diagnostic value

Core tip: One hundred and twenty patients who had developed liver cirrhosis from primary biliary cirrhosis were assessed by ARFI imaging and hepatic fibrosis index alongside sixty healthy individuals. The ROC curves of LS combined with four liver fibrosis indexes showed that the AUC values (0.967), sensitivity (97.4%), and specificity (90%) of all indexes combined in the C grade of CP score were higher than in those of LS alone (0.936, 92.1%, and 83.3%). The diagnostic value of PBC cirrhosis degree in liver cirrhosis degree assessment by ARFI combined with the four indicators of serum liver fibrosis is of satisfactory effectiveness and has important clinical application value.

Primary biliary cirrhosis degree assessment by acoustic radiation force impulse imaging and hepatic fibrosis indicators. *World J Gastroenterol* 2016; 22(22): 5276-5284 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5276.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5276

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic cholestatic disease[1] that can develop into liver fibrosis, cirrhosis[2-4], and even lead to liver failure[5]. When a patient is already in the liver cirrhosis stage, accurate diagnosis, and assessment of the extent of liver cirrhosis is vital to the diagnosis, treatment, and prognosis of the disease[6]. Therefore, exploring a high value examination method to diagnose liver cirrhosis is very significant[7-9]. It has been reported that liver cirrhosis can be divided into three classes according to the Child-Pugh (CP) scoring criteria, and the accuracy of their assessment methods have been demonstrated[10-13]. Although liver biopsy is still currently the preferred diagnostic method for cirrhosis, the resulting trauma to the patient's body leads to low acceptance[14-17]. Serum fibrosis indicators are a non-invasive examination method of cirrhosis diagnosis with a wide range of applications[18], however its accuracy in the assessment of cirrhosis degree remains to be studied[19]. Acoustic radiation force impulse imaging (ARFI) is a new ultrasound elastography technique[20] that can detect the hardness of the liver parenchyma for liver disease accurate assessment, and is non-invasive, simple, repeatable[21-23], and it can effectively compensate for the lack of liver biopsy and serum liver fibrosis markers. ARFI technology in China remains at the clinical development phase[24-26]. However, comparative studies of ARFI technology and other methods to assess the degree of liver cirrhosis and joint applications are few[27-30]. This study intends to use the CP score as a grading standard, as well as to observe the comparison of ARFI technology measured serum fibrosis markers alone and in combination with diagnostic accuracy to find a more satisfactory diagnostic method for PBC, with the aim of providing a theoretical basis for the clinical diagnosis and treatment of liver cirrhosis.

MATERIALS AND METHODS

General information

From January 2014 to September 2015, 120 patients with primary cholestatic cirrhosis that had developed to the stage of cirrhosis and were admitted to Huashan Hospital (Baoshan Branch Affiliated to Fudan University, Shanghai, China) were selected as the observation group. The patients consisted of 35 males and 85 females, with an average age of 56.33 ± 7.42 years. Patients were divided into different groups according to Child-Pugh score as follows: grade A, 39 cases; grade B, 43 cases; and grade C, 38 cases. Meanwhile, 60 healthy subjects were chosen as the control group, and consisted of 24 males and 36 females, with an average age of 54.27 ± 8.31 years. General information on the differences between these two groups was not statistically significant (P > 0.05). This study was approved by the ethics committee.

Diagnostic criteria

The degree of liver cirrhosis in patients was diagnosed based on symptoms, signs, CT, MRI, biochemical examination, and liver biopsy results.

Table 1 Child-Pugh scoring criteria

Indicator	Score		
	1 point	2 point	3 point
Hepatic encephalopathy (grade)	None	Slight	Occasional drowsiness
Ascites	None	Small amount of diuretics can be controlled	Numerous
Total bilirubin (μmol/L)	< 34	34-51	> 51
Albumin (g/L)	> 35	28-35	< 28
Prolonged prothrombin time(s)	< 4	4-6	> 6

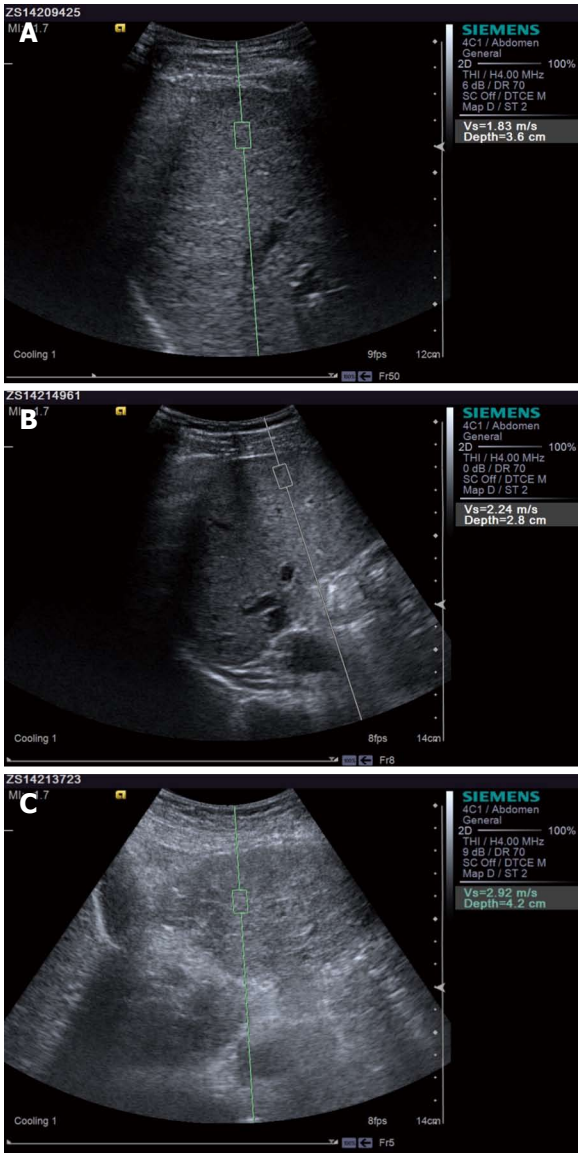

Figure 1 Observation group CP scores in the three classes. A: CP score patients with cirrhosis (Vs = 1.83 m/s); B: CP score patients with cirrhosis (Vs = 2.24 m/s); C: CP score patients with cirrhosis (Vs = 2.92 m/s).

Inclusion criteria

(1) Diagnosed with PBC that has developed to liver cirrhosis; (2) healthy subjects with no hepatobiliary diseases; (3) independent and able to cooperate with the test; and (4) provided written informed consent.

Exclusion criteria

(1) Patients with liver cancer or heart, lung, or other vital organs diseases; (2) disturbance of consciousness or mental illness; and (3) patients who provided written informed consent, but failed to cooperate with the test.

Child-Pugh scoring criteria

Patients were scored according to hepatic encephalopathy, peritoneal effusion, total bilirubin and albumin content, prolonged prothrombin time, and other conditions. Child-Pugh classification criteria (Table 1): class A, 5-6 points; class B, 7-9 points; and class C, ≥ 10 points.

Research methods

Liver fibrosis index detection: (1) After fasting, 5 ml of morning blood samples were collected from patients and kept at room temperature for approximately 30 min; (2) serum was separated and stored at -70 ℃; and (3) four indexes of liver fibrosis were determined using fluorescence immunoassay: hyaluronic acid (HA), laminin (LN), procollagen Ⅲ (PC Ⅲ), and collagen Ⅳ (Ⅳ-C).

ARFI detection: Siemens ACUSON S2000 color ultrasound diagnostic apparatus was used to conduct ARFI detection. (1) After fasting, the patient was placed on the left lateral position with the right hand on the head, and the right lobe of the liver tissue was detected; (2) elastic sampling frame was perpendicular to the surface of the liver, with a depth of approximately 2-5 cm while avoiding the surrounding blood vessels, and the patient was asked to hold their breath; and (3) the update button was pressed, a high-strength low-frequency pulse was launched, and the transverse shear wave velocity (Vs) was received. Units were in m/s and the value was recorded. Measurements were repeated 10 times and Vs were averaged to determine liver parenchyma hardness LS value.

Statistical analysis

SPSS 17.0 statistical software was used for all data results. LS value and the four indicators of liver fibrosis were measurement data presented as mean ± SD, with groups compared using two independent samples *t*-test. To evaluate the diagnostic value of LS value and the four serum indicators for liver fibrosis detected by ARFI (HA, LN, PCⅢ, and Ⅳ-C) for PBC, receiver operating characteristic (ROC) curve analysis with the area under the ROC curve (AUC), sensitivity and specificity representations were used. $P < 0.05$ was

considered statistically significant.

RESULTS

Test result indicators in the two groups

CP scores, LS values, and the four serum indicators for liver fibrosis in the three classes (A, B, and C) of patients in the observation group were significantly higher than controls; the difference was statistically significant (P < 0.01). In the observation group, CP scores in the three classes of patients, LS values (Figure 1), and the four serum indicators for liver fibrosis revealed that class C > class B > class A; differences were statistically significant (P < 0.01), as shown in Table 2.

ROC curve analysis of LS value and the four indicators of serum liver fibrosis in the observation group

ROC curve analysis of LS values and the four diagnostic indicators of liver fibrosis of CP rates in different cirrhosis grades and each index of the AUC showed: grade C > grade B > grade A, as well as that the sensitivity and specificity were different (Table 3). Comparison of results of CP levels of LS values and the four indicators of liver fibrosis in the ROC curve are as follows:

In CP score grade A, LS values in the AUC and the specificity were high compared with serum liver fibrosis, albeit with lower sensitivity (Figure 2A).

In grade B, the AUC value of LS and specificity were high compared with HA and Ⅳ-C, but with lower sensitivity; AUC and sensitivity were high compared with LN and PCⅢ, but with lower specificity (Figure 2B).

In grade C, AUC values of LS, sensitivity, and specificity were high compared with PCⅢ; AUC and sensitivity were high compared with HA, but with lower specificity; AUC and specificity were high compared with LN and Ⅳ-C, but with lower sensitivity (Figure 2C).

ROC curve analysis of LS value in the observation group combined with the four indicators of serum liver fibrosis

LS values detected by ARFI in the observation group combined with the four indicators of serum liver fibrosis in the ROC curve show the following (Table 4): in each indicator of CP score grade A, the AUC and sensitivity were higher than the LS value detected by ARFI alone, although its specificity decreased slightly (Figure 3A); in CP score grade B, the AUC and sensitivity were higher than LS detected by ARFI alone, with sensitivity being constant (Figure 3B); in CP score grade C, the AUC, sensitivity, and specificity were higher than the LS values detected by ARFI alone (Figure 3C).

DISCUSSION

Cholestatic liver cirrhosis is a chronic liver disease with a long and gradual progression to liver cirrhosis[31-34]. An accurate assessment of early liver cirrhosis can effectively prevent further liver damage that can result in liver failure[35-37]; this has great significance for the diagnosis, treatment, and prognosis of chronic liver disease[38-40]. In this study, by comparing the diagnostic values of AFRI detected LS values and the four indicators (HA, LN, PCⅢ, and Ⅳ-C) of serum liver fibrosis alone or in combination, we aimed to accurately and effectively explore this examination

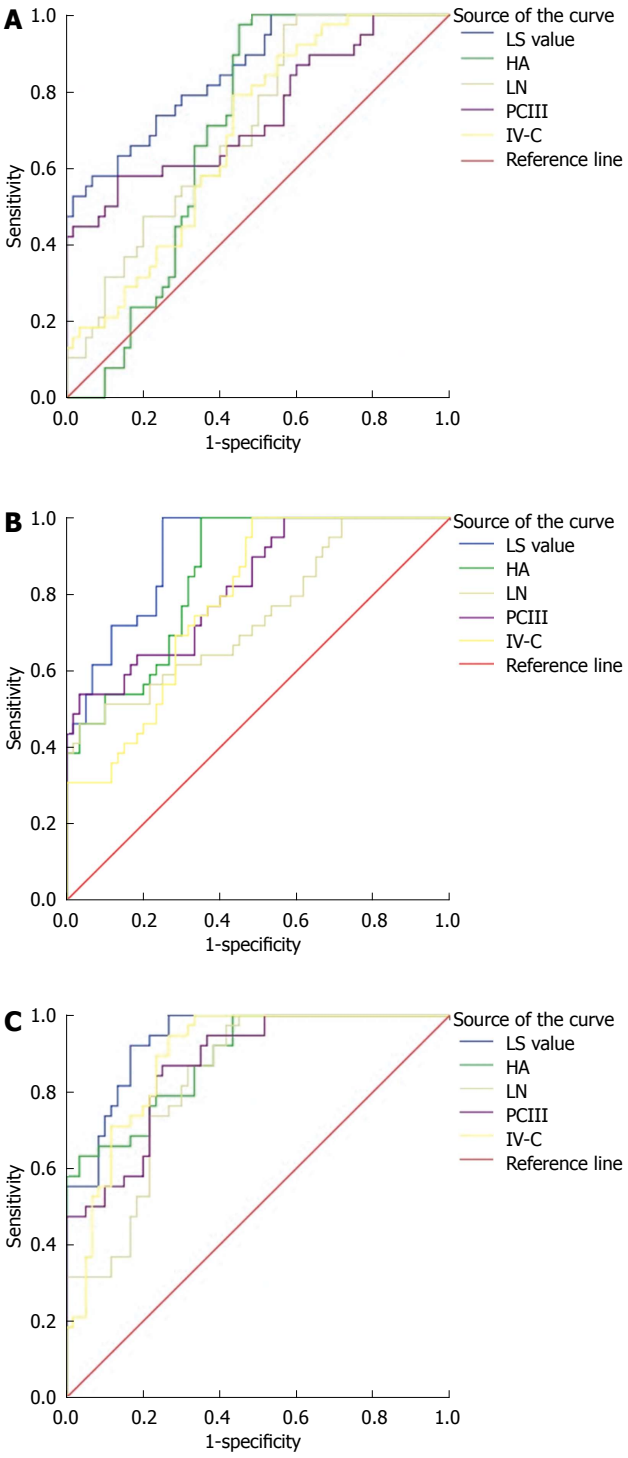

Figure 2 Comparison of the results of CP levels of LS values and the four indicators of liver fibrosis in the ROC curve. A: CP score for each indicator; B: CP score of the various indicators; C: CP score of the various indicators.

method for the assessment of cirrhosis degree.

LS values and the four indicators of serum liver fibrosis in observation and control groups

Liver stiffness increases as chronic liver disease develops to liver fibrosis and cirrhosis. In this study, the LS value results and four indicators of serum liver fibrosis in the observation group showed class C > class B > class A trends; the level of indicators were significantly higher. LS values and the four indicators of serum liver fibrosis of cirrhotic patients were higher than in the control group; this increased as liver cirrhosis degree increased. This also proves that ARFI-detected LS values and the four indicators of serum liver fibrosis can reflect changes in the degree of cirrhosis. Studies have reported[41] that AFRI-detected LS values increased as the degree of hepatic fibrosis increased; this can be widely used in patients with chronic liver disease. In recent years, this research has garnered more attention. The four serum fibrosis indicators for liver damage can be assessed via changes in each indicator, and thus can effectively diagnose cirrhosis. However, its detection accuracy for liver cirrhosis degree remains as yet unconfirmed[42].

Table 4 Receiver operating characteristic curve analysis for LS values combined with the four indicators of serum liver fibrosis

	LS value			Combination		
	AUC	Sensitivity	Specificity	AUC	Sensitivity	Specificity
A Class	0.852	57.9%	93.3%	0.881	68.4%	91.7%
B Class	0.911	97.4%	75.0%	0.973	97.4%	85.0%
C Class	0.936	92.1%	83.3%	0.967	97.4%	90.0%

ROC curve analysis of LS values and the four indicators of liver fibrosis

In the ROC curve analysis of LS value and the four indicators of liver fibrosis, we found the following: LS value and the four indicators of liver fibrosis in the AUC are present in class C > class B > class A trends, and that the diagnostic accuracy of each indicator can increase with increased liver cirrhosis degree (*i.e.*, each indicator can assess the degree of cirrhosis). While each indicator for the diagnostic value of different grades of liver cirrhosis are different, a comparison of results from the ROC curves show that the CP score of the three classes in the AUC were higher than in the four indicators of liver fibrosis, but that its sensitivity and specificity were unstable. CP score class A: LS values were higher than that of serum-specific liver fibrosis, but with lower sensitivity; CP score class B: LS values and specificity were higher than HA and Ⅳ-C, but with lower sensitivity (sensitivity was higher than LN and PCⅢ, but with lower specificity); CP score class C: LS values and sensitivity were higher than HA, but with lower specificity (specifically was higher than LN and Ⅳ-C, but with relatively lower sensitivity). The results show that the diagnostic value of LS values is high compared to the four indicators of liver fibrosis and that it has high diagnostic accuracy, although its diagnostic sensitivity and specificity is unstable. The sensitivity of the four indicators of liver fibrosis for the diagnosis of cirrhosis degree is strong, but its

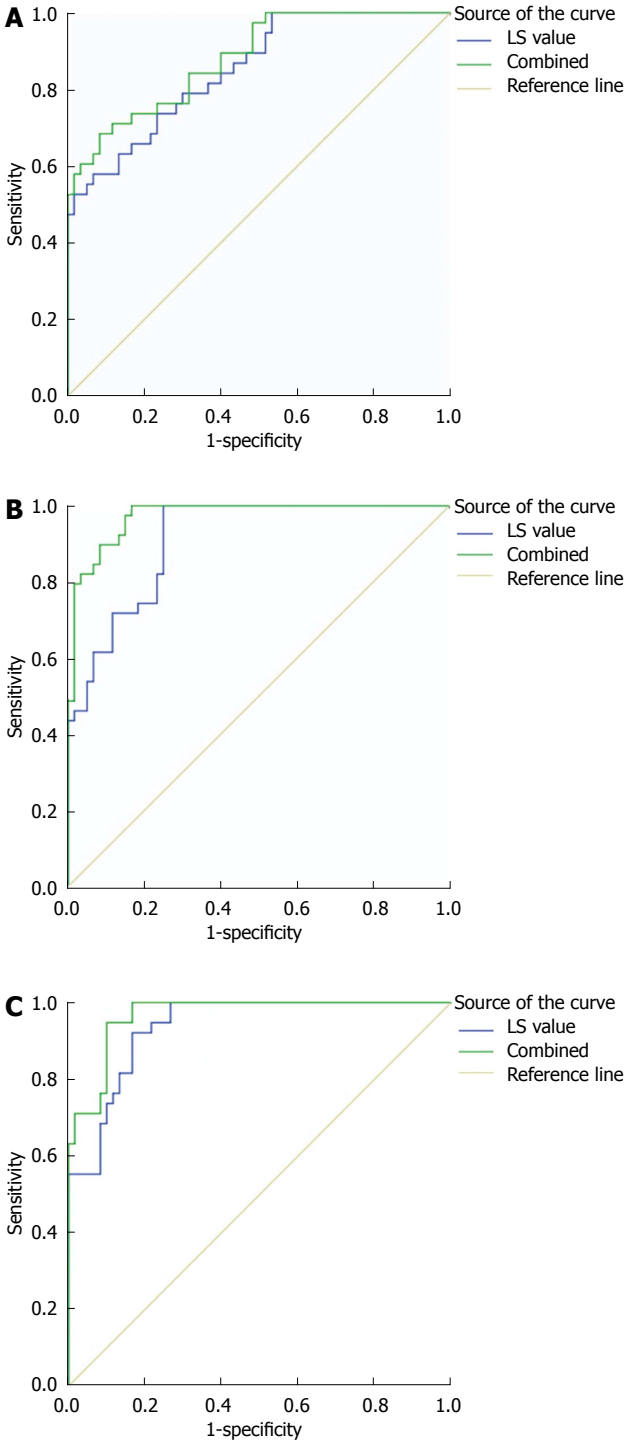

Figure 3 Receiver operating characteristic curve analysis for LS values combined with the four indicators of serum liver fibrosis. A: CP score of all indicators combined; B: CP score of all indicators combined; C: CP score of all indicators combined.

specificity and overall diagnostic value are insufficient. Detection of the four indicators of serum liver fibrosis can effectively diagnose cirrhosis, but lacks specificity in the accurate assessment of cirrhosis degree; thus, its technical support requires improvement[43]. The most commonly used method for the clinical diagnosis of cirrhosis is liver biopsy. However, due to its invasiveness, it has low acceptance limitations and causes more distress in clinical diagnosis and treatment to a certain extent[44-46]. On the other hand, ARFI ultrasound is a non-invasive detection technology. The degree of liver fibrosis can be determined by detecting LS value, which can compensate for the weakness of liver biopsy in detecting liver fibrosis[47].

ROC curve analysis of LS value combined with the four indicators of liver fibrosis

In the observation group, the results of the ROC curve analysis of LS value combined with the four indicators of serum liver fibrosis revealed that the CP score of the three classes combined with the diagnosis of AUC values were higher than ARFI-detected LS values alone, with sensitivity and specificity also improving. CP score class A: combined diagnosis sensitivity was higher than the LS value, albeit with slightly decreased specificity; CP score class B: the combined diagnostic specificity value was higher than the LS value, but sensitivity remained unchanged and there was no reduction; CP score class C: combined diagnostic sensitivity and specificity values were higher than the LS value. These results show that combined diagnosis improves the diagnostic accuracy of single-use LS values, and that diagnostic sensitivity and specificity can be guaranteed. The combined diagnostic value of LS values is high compared to the four indicators of liver fibrosis. It also proves that the LS value combined with the four indicators of serum liver fibrosis in the diagnosis of cirrhosis degree is higher than the diagnostic value of each indicator alone.

Limitation and prospects

Requirements for AFRI examination in patients were stringent. This may be due to insufficient coordination between doctors and patients, which affects the accuracy of the examination[48-50]. The detection operation for the four indicators of serum liver fibrosis is relatively simple, but also has its own shortcomings. Combined diagnosis can therefore play a complementary role and help improve diagnostic accuracy. Furthermore, LS values and indicators of liver fibrosis by way of motion detection can assist doctors in understanding the condition of a patient's liver disease, which is of great significance in the diagnosis and prognosis of liver cirrhosis.

In summary, the clinical diagnostic value of AFRI-detected LS value for determining liver cirrhosis degree is high compared to the four indicators of serum liver fibrosis. The diagnostic value of two combined diagnostics was more satisfactory compared to the indicators alone. Thus, detection by AFRI technology combined with the four indicators of serum liver fibrosis may serve as a powerful tool for determining liver cirrhosis degree, which has important clinical value and is worthy of wide promotion.

COMMENTS

Background

Primary biliary cirrhosis (PBC) is a chronic cholestatic disease that may develop into liver fibrosis, cirrhosis, and even lead to liver failure. When the patient is already in the liver cirrhosis stage, the accurate diagnosis and assessment of the extent of liver cirrhosis is vital in the diagnosis, treatment, and prognosis of the disease. Therefore, exploring a high value examination method to diagnose liver cirrhosis is very significant.

Research frontiers

It has been reported that liver cirrhosis can be divided into three classes according to the Child-Pugh (CP) scoring criteria, and the accuracy of their assessment methods have been demonstrated. Although liver biopsy is still currently the preferred diagnostic method for cirrhosis, the resulting trauma to the patient's body leads to low acceptance. Serum fibrosis indicators are a non-invasive examination method of cirrhosis diagnosis with a wide range of applications; however its accuracy in the assessment of cirrhosis degree remains to be studied. Acoustic radiation force impulse imaging (ARFI) is a new ultrasound elastography technique that can detect the hardness of the liver parenchyma for liver disease accurate assessment, and is non-invasive, simple, repeatable, and can effectively compensate for the lack of liver biopsy and serum liver fibrosis markers.

Innovations and breakthroughs

The clinical diagnostic value of AFRI-detected LS value for determining the degree of liver cirrhosis is high compared to the four indicators of serum liver fibrosis (HA, LN, PCIII, and IV-C). The diagnostic value of two combined diagnostics was more satisfactory compared to the indicators alone. Thus, detection by AFRI technology combined with the four indicators of serum liver fibrosis may serve as a powerful tool for determining liver cirrhosis degree, which has important clinical value and is worthy of wide promotion.

Applications

The diagnostic value of cirrhosis degree with PBC through liver cirrhosis degree assessment by ARFI combined with the four indicators of serum liver fibrosis is more satisfactory compared to the indicators alone and has important clinical application value. Results have shown that the higher the LS value, the higher the degree of liver fibrosis. This also confirmed that the diagnostic value of LS value was higher than that of the four indicators of liver fibrosis and, despite high diagnostic accuracy, that the diagnostic sensitivity and specificity were not stable. Further, the diagnosis value of liver cirrhosis degree for LS value combined with the four serum liver fibrosis was higher than each index alone.

Peer-review

The diagnostic value of cirrhosis degree with PBC through liver cirrhosis degree assessment by ARFI combined with the four indicators of serum liver fibrosis is more satisfactory compared to the indicators alone and has important clinical application value. The combination of AFRI and serum liver fibrosis four indicators can be used as a powerful tool to evaluate the degree of cirrhosis. It has important clinical application value and is worthy of clinical application.

Abstract

AIM: To address the therapeutic efficacy of various treatment regimens in genotype 3 selecting randomized clinical trials and prospective National Cohort Studies.

METHODS: (1) PEG-INF-based therapy including sofosbuvir (SOF) + RBV for 12 wk *vs* SOF + RBV 24 wk; (2) SOF + RBV therapy 12 wk/16 wk *vs* 24 wk; and (3) the role of RBV in SOF + daclatasvir (DCV) and SOF + ledipasvir (LDV) combinations. This meta-analysis provides robust information with the intention of addressing treatment strategy for hepatitis C virus genotype 3.

RESULTS: A combination treatment including SOF + RBV + PEG-IFN for 12 wk notes better SVR than with only SOF + RBV for 12 wk, although its association with more frequent adverse effects may be a limiting factor. Longer duration therapy with SOF + RBV (24 wk) has achieved higher SVR rates than shorter durations (12 or 16 wk). SOF + LDV are not an ideal treatment for genotype 3.

CONCLUSION: Lastly, SOF + DCV combination is probably the best oral therapy option and the addition of RBV does not appear to be needed to increase SVR rates substantially.

Key words: Hepatitis C; Genotype 3; Sofosbuvir; Daclatasvir; Ledipasvir

Core tip: The landscape of therapy for hepatitis C virus infection is changing rapidly. In genotype 3, the improvement in SVR rates has not been hugely spectacular, being considered the most difficult genotype to treat and representing a major challenge. The advent of direct acting antivirals has not solved all questions about the treatment, while challenges remain such as the use of RBV, the duration of PEG-IFN-free treatment and whether PEG-IFN still plays an important role. These questions are difficult to elucidate with the current data because of the small number of patients included in clinical trials (particularly, those with cirrhosis) and their different designs.

Ampuero J, Reddy KR, Romero-Gomez M. Hepatitis C virus genotype 3: Meta-analysis on sustained virologic response rates with currently available treatment options. *World J Gastroenterol* 2016; 22(22): 5285-5292 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5285.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5285

INTRODUCTION

The landscape of therapy for hepatitis C virus (HCV) infection is changing rapidly[1]. Ideally, new drugs should be all-oral regimen (once-daily, single pill) with pangenotypic activity, and have short treatment course (no more than 12 wk), and with high sustained virological response (at least 90%-95%). A multitude of direct acting antivirals (DAAs) have been developed with or without pegylated interferon (PEG-IFN) and ribavirin (RBV)[2], and others are being tested in promising clinical trials[3]. In genotype 3, the improvement in SVR rates has not relatively suboptimal and is being considered the most difficult genotype to treat and thus representing a major challenge[4]. Unique clinical features of genotype 3 and possible reasons for suboptimal response are: (1) a close relationship with insulin resistance and disturbances in lipid metabolism[5]; and (2) fibrosis progression[6] and higher incidence of hepatocellular carcinoma[7].

The advent of DAAs has not solved all questions regarding the treatment in genotype 3, and with emerging new challenges such as RBV use[8], duration of PEG-IFN-free treatment and whether PEG-IFN still plays an important role[9]. These questions are difficult to elucidate with the current data because of the small number of patients included in clinical trials (particularly, those with cirrhosis) and their different designs. In fact, more valuable data have been derived from prospective observational studies (clinical practice), and beyond randomized clinical trials. In this study, we aimed to address key questions on treatment outcomes through a meta-analysis.

MATERIALS AND METHODS

Data sources and search

The search strategy was in accordance with the recommendations of meta-analysis of clinical trials and observational studies. We searched in MEDLINE, EMBASE and Cochrane Library databases (to November 2015), as well as abstracts published and presented at EASL and AASLD (to November 2015) to identify potentially relevant publications in English language. We included FDA-approved DAA therapies that included SVR as a primary end point. Search terms were: "hepatitis C", "genotype 3", "HCV treatment", "sofosbuvir", "ledipasvir", "daclatasvir", "ribavirin", "interferon". The preceding terms were combined with appropriate Boolean logic. Manual search of cited bibliographies was also performed. Duplicated publications were deleted. Two researchers independently performed the literature search and data abstraction with regard to the inclusion and exclusion criteria by reading titles and abstracts. When reading titles and abstracts did not allow identification of eligible studies, articles were read in full. Relevant reviews and letters to the editor were excluded from the analysis, but read in full to identify potential relevant original studies. Disagreements between two observers were resolved by discussion.

Study selection criteria and data extraction

We selected randomized clinical trials (preferably) and prospective National Cohort Studies in which therapies were administrated in different arms. Therefore, studies including only a combination testing different doses or being administrated to different subset of patients were excluded. Inclusion and exclusion criteria (studies involving genotypes other than 3) were defined prior to initiation of the literature search. Twelve studies were included and classified according to the aims (Figure 1). The following data were extracted: (1) Study: year of publication, number of patients, location, design; (2) Patients: stage of liver disease (cirrhosis or chronic hepatitis), previous HCV treatment (naïve or treatment-experienced); (3) HCV treatment regimen and duration; and (4) SVR rates.

Objectives

We aimed to address the therapeutic efficacy of various treatment regimens in genotype 3. Firstly, we compared a PEG-INF-based therapy including sofosbuvir (SOF) + RBV during 12 wk with SOF + RBV 24 wk. Secondly, we assessed the importance of extending the course of SOF + RBV therapy (12 wk/16 wk *vs* 24 wk). Thirdly, we analyzed the role of RBV in SOF + daclatasvir (DCV) and SOF + ledipasvir (LDV) combinations.

Statistical analysis

Statistical analysis was performed using the Meta-Disc

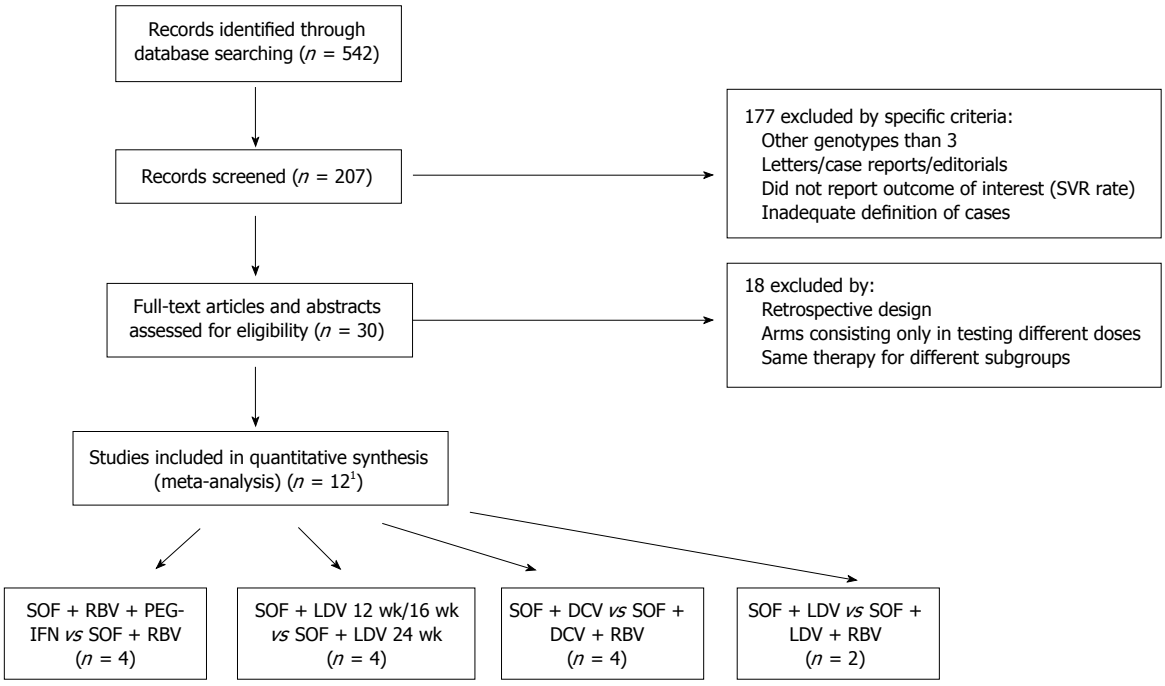

Figure 1 Flow chart of studies screened and included in meta-analysis. [1]Two studies included in two different sub-meta-analysis. SOF: Sofosbuvir; DCV: Daclatasvir; LDV: Ledipasvir; PEG-IFN: Polyethylene glycol interferon.

software 1.4[10], considering: (1) a summary of data from individual studies; (2) an investigation of the studies homogeneity, graphically and statistically; (3) calculation of clustered indexes; and (4) exploration of heterogeneity. Our assumption of heterogeneity was tested for each planned analysis using the Cochran-*Q* heterogeneity and I^2 statistics (low, moderate, and high heterogeneity according to I^2 values of 25%, 50%, and 75%, respectively)[11]. Random effects model using Der Simonian and Laird method and fixed effects model were used according to the presence of heterogeneity. To check for publication bias, we used the Begg and Egger tests. Only two-sided tests with a significance level of 0.05 were used. Confidence intervals (CIs) of individual studies were determined or approximated from the available data. Further, we assessed the quality of the studies using the "Quality Assessment of Diagnostic Accuracy Studies" (QUADAS) tool for observational studies ($\geqslant$ 10 were considered as high-quality studies[12]) and Jadad scale for randomized clinical trials ($\geqslant$ 3 were considered as high-quality ones[13]).

RESULTS

Comparison between INF-based and IFN-free regimens

We evaluated four studies that met the selection criteria and that were identified using the search strategy described. Studies characteristics are shown in Table 1. Pooled data included 807 patients. The meta-analysis demonstrated that triple therapy including SOF + RBV + PEG-IFN was able to achieve higher SVR rates (92.5%; 236/255) than SOF + RBV (75.2%; 415/552), using fixed effects model [OR = 3.51 (95%CI: 2.08-5.92)] (Figure 2A). We found neither heterogeneity between these studies [(Cochran-*Q* = 0.94; *df* = 3, *P* = 0.8157); inconsistency I^2 = 0%, and τ^2 = 0.0000)] nor publication bias [(Begg test: Kendall' s tau 1.70, *P* = 0.1); (Egger test: -1.14, *P* = 0.37)].

Course of SOF + RBV treatment

We included four studies involving 850 patients. The meta-analysis demonstrated that a 24 wk-course of SOF + RBV (85.5%; 501/586) combination was better than 12 wk-16 wk (70%; 185/264) in terms of SVR rates, using random effects model [OR = 3.51 (95%CI: 1.59-7.70)] (Figure 2B). We found a moderate heterogeneity between these studies [(Cochran-Q = 7.77, *df* = 3, *P* = 0.0511); inconsistency I^2 = 61%, and τ^2 = 0.3718], but no publication bias [(Begg test: Kendall's tau 0.34, *P* = 0.73); (Egger test: 0.81, *P* = 0.50)]. Three of these studies evaluated SVR rates according to the presence of cirrhosis. In non-cirrhotic patients, longer therapy of SOF + RBV (89.7%; 218/243) achieved higher SVR rates than shorter one (78.2%; 144/184) using random effects model (OR 2.44 (95%CI: 1.41-4.23). We did find a moderate heterogeneity between these studies [(Cochran-*Q* = 4.42; *df* = 2, *P* = 0.11); inconsistency I^2 = 55%, and τ^2 = 0.3987], with no publication bias. Similarly, this effect was observed in cirrhotic population (78.5%; 73/93 *vs* 55%; 38/69) using the random effects model [OR = 2.79 (95%CI: 1.34-5.78)].

Role of RBV in SOF + DCV and SOF + LDV combinations

Additionally, we assessed the role of adding RBV in

HCV: Hepatitis C virus; HIV: Human immunodeficiency virus; SOF: Sofosbuvir; DCV: Daclatasvir; LDV: Ledipasvir; PEG-IFN: Polyethylene glycol interferon.

IFN-free regimens. Four studies have evaluated this point regarding the combination treatment of SOF + DCV. Pooled data included 502 patients. The meta-analysis demonstrated that adding RBV was not essential to achieve optimal SVR rates (83%; 173/209 *vs* 86.3%; 253/293), using fixed effects model [OR = 1.09 (95%CI: 0.35-3.40)] (Figure 2C). We did not find heterogeneity between these studies [(Cochran-Q = 2.38; df = 3, P = 0.4981); inconsistency I^2 = 0%, and τ^2 = 0.0000], and did not seem to have publication bias. On the other hand, two studies have evaluated the role of adding RBV in SOF + LDV combination. Pooled data included 169 patients. The meta-analysis demonstrated that adding RBV was important to achieve better SVR rates (81%; 111/137 *vs* 62.5%; 20/32), using fixed effects model [OR = 3.30 (95%CI: 1.35-8.04)] (Figure 2D). We did not find heterogeneity between these studies [(Cochran-Q = 0.61, df = 1, P = 0.4335); inconsistency I^2 = 0%, and τ^2 = 0.0000], and no publication bias was found [(Begg test: Kendall's tau 0.01, P = 0.99)].

DISCUSSION

New challenges have emerged in the evolving era of HCV therapy, particularly with genotype 3, and these

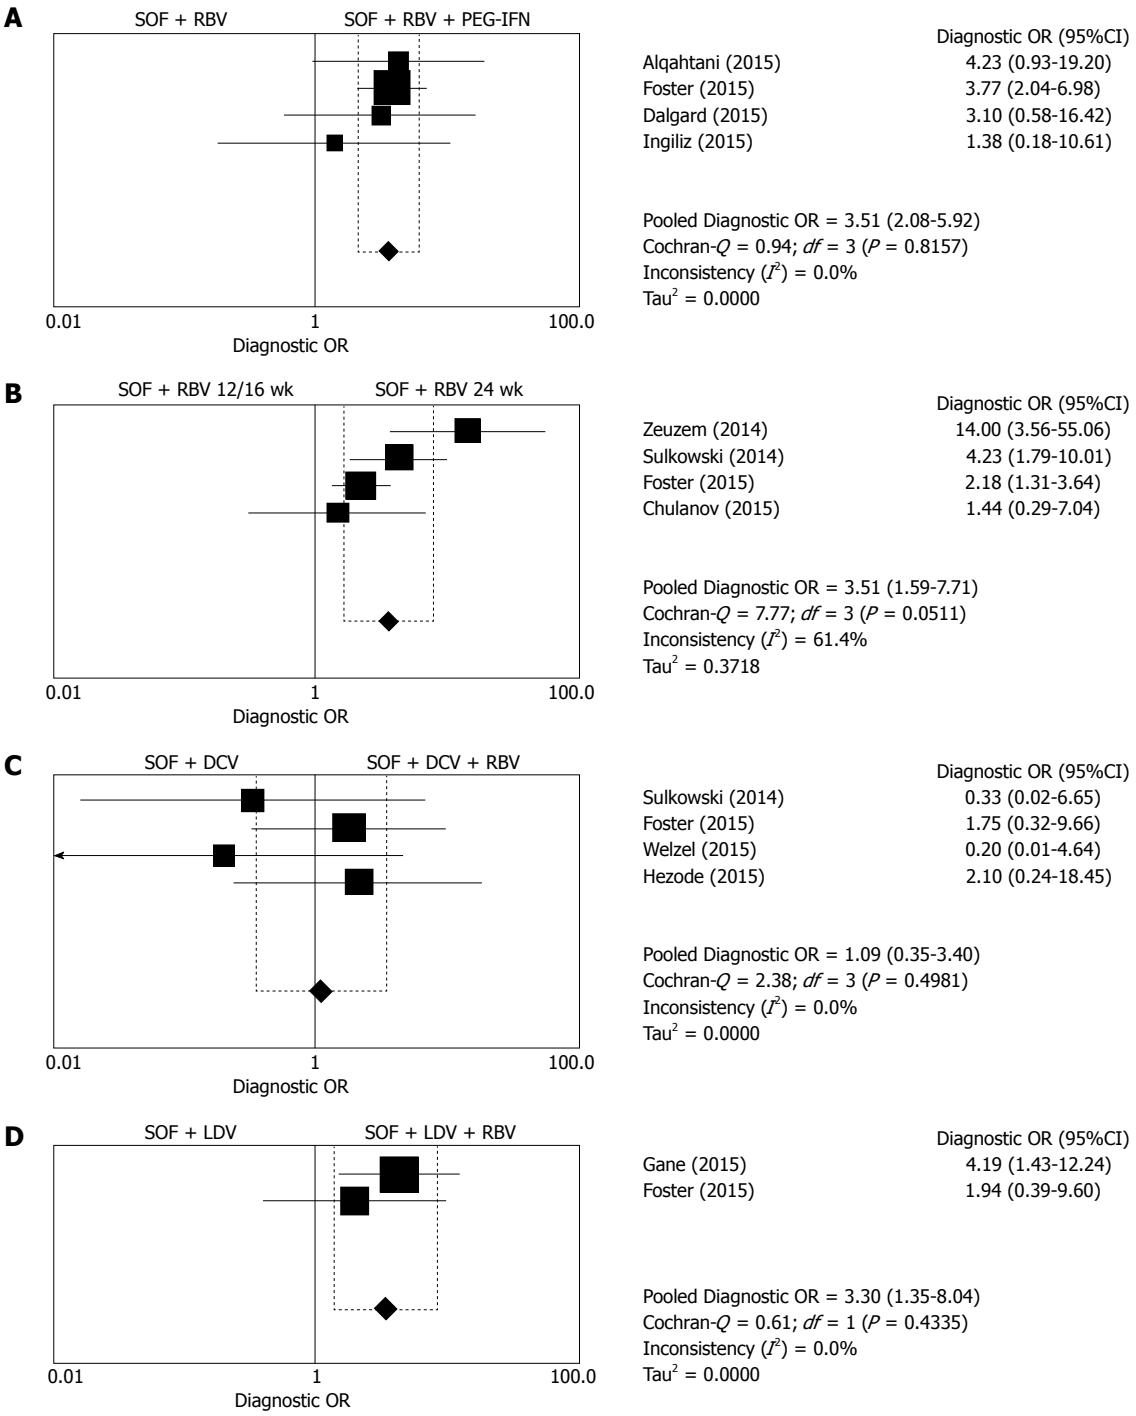

Figure 2 Odds ratio (95%CI) and Forest plot for SVR rates. A: SOF + RBV + PEG-IFN *vs* SOF + RBV combinations; B: SOF + RBV 12 wk/16 wk *vs* SOF + RBV 24 wk combinations; C: SOF + RBV 12 wk/16 wk *vs* SOF + RBV 24 wk combinations; D: SOF + LDV *vs* SOF + LDV + RBV combinations.

include the ongoing role of PEG-IFN, the addition of RBV and the adequate duration of the therapy[13]. The rapid development and use of DAAs in several heterogeneous studies including small number of patients has made robust guideline development and recommendation rather challenging. Thus, a meta-analysis is needed pooling all patients to address these questions.

In this new era, PEG-IFN is being abandoned as part of standard HCV therapy because of the association with serious adverse effects (and the parenteral administration)[14]. From now on, PEG-IFN will not be used for genotypes 1, 2 or 4 anymore. For genotype 3, there are only two DAAs (SOF and DCV) with a significant inhibitory activity *in vitro*[15]. In this context, PEG-IFN could potentially play a role in HCV treatment and could be the last such indication for its use. We demonstrated that the addition of PEG-IFN to SOF + RBV 12 wk was superior to only SOF + RBV combination (92% *vs* 75%, OR = 3.51). BOSON study

represents the main study evaluating this comparison, and it included nearly two hundred patients per arm[16]. Additionally, DCV has been evaluated in combination with PEG-IFN + RBV, although SVR rates were not higher than those patients treated with dual standard therapy (65% *vs* 59%)[17]. Both EASL and AASLD recommend SOF + RBV + PEG-IFN as a good alternative in non-cirrhotic and compensated-cirrhotic patients[18]. On the other hand, no data is available evaluating SOF + RBV + PEG-IFN *vs* SOF + DCV.

We analyzed the combination of SOF + RBV, in terms of duration of therapy. To date, this combination has been evaluated for 12, 16 and 24 wk duration. We compared SOF + RBV 12 wk/16 wk *vs* SOF + RBV 24 wk, and the latter achieved higher SVR rates (89% *vs* 70%, OR = 3.51). Furthermore, SOF + RBV 12 wk (56%) was associated with poorer SVR rates than dual standard therapy with PEG-IFN + RBV 24 wk (63%) in FISSION study[19], and showing similar results than POSITRON study (61%)[20]. Both studies demonstrated that SOF + RBV combination 12 wk was suboptimal, especially in the cirrhotic population. In FISSION study, a longer course of therapy (16 wk) with SOF + RBV showed better results than a shorter one (62% *vs* 30%)[21]. Overall SVR rates with SOF + RBV 12/16 wk were about 60%, which is considered suboptimal in the evolving era of hepatitis C therapy where response rates far below 90% are considered suboptimal. We included four studies that evaluated the course of 24 wk of SOF + RBV and noted an overall SVR rate around 90%. In addition, PHOTON study confirmed the extrapolation of these results in HIV-co-infected patients[22]. Taking into account all of these results, EASL and AASLD guidelines recommend extending SOF + RBV treatment to 24 wk (especially indicated in non-cirrhotic population).

In this meta-analysis, we demonstrated that SOF + LDV combination needs the addition of RBV to achieve optimal SVR rates in patients with genotype 3 (81% *vs* 62%, OR = 3.30). In contrast, RBV did not play any role in the combination of SOF + DCV because it did not improve SVR rates. DCV and LDV are HCV NS5A inhibitors[23], although DCV shows a pangenotypic activity[24] while LDV has a low activity in genotypes 2 and 3[25]. Currently, SOF + DCV combination is the first option to treat patients with genotype 3 in EASL guidelines, 12 wk in non-cirrhotic and 24 wk (with RBV) in cirrhotic patients. This recommendation is mainly based on ALLY-3 study in which SOF + DCV 12 wk achieved 97% and only 58% SVR in non-cirrhotic and cirrhotic population respectively[26]. The UK Early Access Program did not show any impact of adding RBV to SOF + DCV 24 wk in cirrhotic patients (70% *vs* 71%)[27], as well as the European Compassionate Use Program in patients at high risk of hepatic decompensation or death within 12 mo (100% *vs* 85%, *P* = NS)[28]. In a relatively small study, ELECTRON-2 trial, SOF + LDV for 12 wk achieved suboptimal SVR rates while the addition of RBV substantially increased it (100% in non-cirrhotic naïve patients, and 89% in non-cirrhotic and 73% in cirrhotic treatment-experienced patients)[29]. However, this trial should be interpreted with caution because it has very limited data from a phase Ⅱ single-center study and comprising a homogenous population which could limit the generalizability of the results. This, together with the high EC50 of LDV for genotype 3[30], has lead EASL and AASLD to not recommend SOF + LDV±RBV combination for genotype 3.

Recommendations made by EASL and AASLD guidelines were based on few data derived from randomized clinical trials and, due to the rapid and wide use in clinical practice, modified by prospective national cohorts. This meta-analysis provides solid and robust information to address several important questions, regarding the treatment of HCV genotype 3. First, combination including SOF + RBV + PEG-IFN shows better results than only SOF + RBV, although its association with adverse effects may limit the use (*i.e.,* cirrhotic population). Second, longer therapies including SOF + RBV (24 wk) have higher SVR rates than shorter ones (12 or 16 wk). Therefore, SOF + RBV for 24 wk are ideal. Third, SOF + LDV should not be used in genotype 3 and, if so, necessarily with RBV. Lastly, SOF + DCV combination is probably the best option and the addition of RBV does not appear to be needed to increase substantially the SVR rates.

COMMENTS

Background

The advent of direct acting antivirals has not solved all questions of successfully and effectively treating all hepatitis C virus (HCV) genotypes. Genotype 3, a common genotype globally, remains the last challenge.

Research frontiers

Nowadays, it remains unclear if Peg-IFN and RBV are still required to treat HCV genotype 3 effectively. The worldwide research is directed towards a more suitable combination of DAA.

Innovations and breakthroughs

In the present study, the authors investigated the SVR rates of different DAA combinations. This is the first report of a meta-analysis including sofosbuvir, daclatasvir, ledipasvir, peginterferon and ribavirin showing the eradication of the HCV infection.

Applications

The present report allows understanding the role of DAAs in the treatment of HCV genotype 3.

Peer-review

This systematic review and meta-analysis adds useful information for clinical practice and research.

Abstract

We report on a patient diagnosed with Peutz-Jeghers syndrome (PJS) with synchronous rectal cancer who was treated with laparoscopic restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA). PJS is an autosomal dominant syndrome characterized by multiple hamartomatous polyps in the gastrointestinal tract, mucocutaneous pigmentation, and increased risks of gastrointestinal and nongastrointestinal cancer. This report presents a patient with a 20-year history of intermittent bloody stool, mucocutaneous pigmentation and a family history of PJS, which together led to a diagnosis of PJS. Moreover, colonoscopy and biopsy revealed the presence of multiple serried giant pedunculated polyps and rectal adenocarcinoma. Currently, few options exist for the therapeutic management of PJS with synchronous rectal cancer. For this case, we adopted an unconventional surgical strategy and ultimately performed laparoscopic restorative proctocolectomy with IPAA. This procedure is widely considered to be the first-line treatment option for patients with ulcerative colitis or familial adenomatous polyposis. However, there are no previous reports of treating PJS patients with laparoscopic IPAA. Since the operation, the patient has experienced no further episodes of gastrointestinal bleeding and has demonstrated satisfactory bowel control. Laparoscopic restorative proctocolectomy with IPAA may be a safe and effective treatment for patients with PJS with synchronous rectal cancer.

Key words: Peutz-Jeghers syndrome; Laparoscopy; Ileal pouch-anal anastomosis; Restorative proctocolectomy; Multiple polyps in gastrointestinal tract

Core tip: Few options currently exist for the therapeutic management of Peutz-Jeghers syndrome with synchronous rectal cancer. Here, we present a patient diagnosed with Peutz-Jeghers syndrome with synchronous rectal cancer treated with laparoscopic restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA). The patient has experienced no further episodes of gastrointestinal bleeding and has demonstrated satisfactory bowel control. To our knowledge, this is the first report on laparoscopic restorative proctocolectomy with IPAA performed for the treatment of Peutz-Jeghers syndrome with synchronous rectal cancer.

Laparoscopic restorative proctocolectomy with ileal pouch-anal anastomosis for Peutz-Jeghers syndrome with synchronous rectal cancer. *World J Gastroenterol* 2016; 22(22): 5293-5296 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5293.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5293

INTRODUCTION

Peutz-Jeghers syndrome (PJS) is a rare, hereditary, autosomal dominant disorder characterized by multiple hamartomatous polyps in the gastrointestinal tract (mainly in the jejunoileum but also in the stomach and colon) and mucocutaneous pigmentation. It has also been reported to be associated with a high risk of malignancy, with a lifetime cancer risk of up to 93%, and it is caused by a germline mutation in the STK11 gene[1,2].

Few options currently exist for the therapeutic management of PJS with synchronous rectal cancer. Surgical strategies are commonly used to treat the sequelae of PJS, such as small bowel intussusception or neoplastic lesions, which may require enterectomy. To date, no studies have focused on PJS patients treated with laparoscopic restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA).

Here, we present a patient diagnosed with PJS with synchronous rectal cancer that was treated with laparoscopic restorative proctocolectomy with IPAA.

CASE REPORT

A 42-year-old female patient presented with a 20-year history of intermittent bloody stool, poor appetite, abdominal pain and body-weight loss. Twenty years prior, she had experienced occasional abdominal pain, which subsided without treatment. Her family history confirmed that her father and children had similar symptoms. She had presented to our emergency department one month prior with acute gastrointestinal hemorrhaging.

Physical examination showed scattered, punctate, dark-blue areas of pigmentation on her lips (Figure 1) and the distal parts of her fingers. The patient was pale and extremely emaciated. Her body mass index (BMI) was 16. Rectal examination (in the knee-chest position) revealed the presence of a soft mass in the rectal lumen that was 6 cm from the anal verge, approximately 3 cm in diameter, located at nine o' clock, and difficult to move.

Figure 1 Scattered, punctate, dark blue macules on the mucosa of the lips.

Laboratory tests revealed that she had iron deficiency anemia (69 g/L hemoglobin). Her serum CA125 and serum CEA levels were within the normal limits. A computed tomography scan of the abdomen and pelvis revealed the presence of multiple polyps in the ileum and colorectum. Colonoscopy revealed the presence of multiple serried giant pedunculated polyps, with involvement of the rectum, sigmoid colon, descending colon, transverse colon and part of the ascending colon. In addition, a large cauliflower-like mass was identified at 7 cm from the anal verge (Figure 2). Biopsy of the tumor was performed, which revealed that the cauliflower-like mass was rectal adenocarcinoma (Figure 3A).

Finally, PJS with synchronous rectal adenocarcinoma was diagnosed. Surgical intervention consisting of laparoscopic restorative proctocolectomy and IPAA with a covering ileostomy was performed. During the operation, the patient was noted to have areas of intussusception of the small bowel secondary to the giant polyps. Several adenomatoid polyps were found at locations 30, 50 and 70 cm from the Treitz ligament, and consequently, enterotomy and polypectomy were performed.

The final pathological examination confirmed the diagnosis of moderately differentiated rectal adenocarcinoma (Figure 3B). Of the 37 lymph nodes examined, metastatic adenocarcinoma was detected in 3, and hamartomas with atypical hyperplasia were identified in the polyps, thereby confirming the diagnosis of PJS.

The patient underwent ileostomy closure 6 mo later. After 14 mo of follow-up, no further episodes of gastrointestinal bleeding occurred. This patient has demonstrated satisfactory bowel control to date. Her Wexner incontinence score is zero, indicating that she has no fecal incontinence. Her defecation frequency

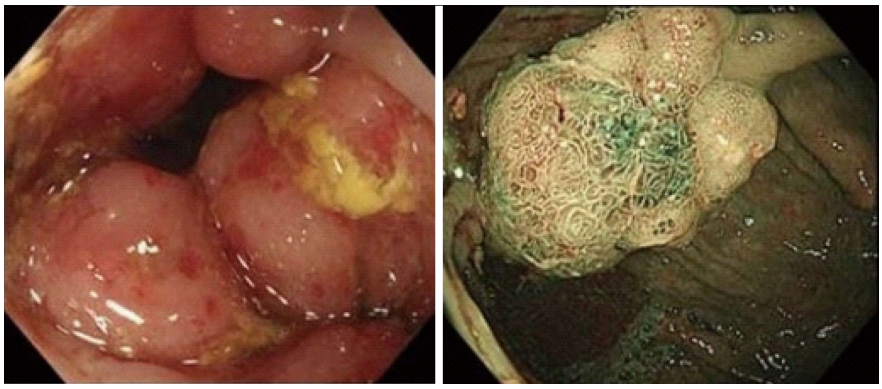

Figure 2 Colonoscopy revealed the presence of multiple polyps and a rectal cauliflower-like mass.

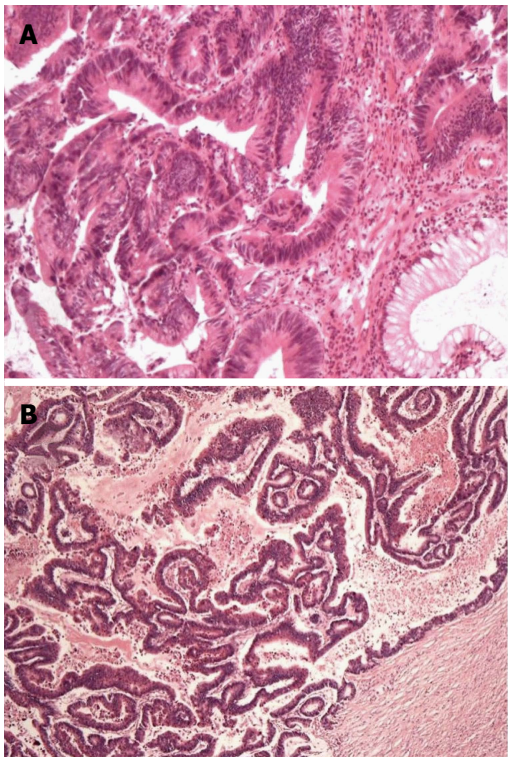

Figure 3 Biopsy revealed that the rectal mass was rectal adenocarcinoma (A) and postoperative pathological examination showed moderately differentiated rectal adenocarcinoma (B).

is 1-2/d. In addition, she is very satisfied with the cosmetic results.

One month ago, this patient underwent gastroenterography, and several polyps were found in the small bowel. As a result, double balloon enteroscopy (DBE) was performed. The ileal polyps were removed using an endoscopic snare.

DISCUSSION

PJS is an inherited, autosomal dominant disorder with variable inheritance and is characterized by hamartomatous polyps in the gastrointestinal tract, mainly in the small bowel, as well as pigmented mucocutaneous lesions. It is also characterized by increased risks for gastrointestinal and nongastrointestinal cancer. The prevalence of PJS is estimated to be between 1 in 50000 and 1 in 200000 individuals[2].

In this case, the patient had typical manifestations and a family history of PJS. Thus, it was not difficult to diagnose her. In addition, colonoscopy and biopsy revealed the presence of synchronous midrectal cancer.

Few options currently exist for the therapeutic management of PJS with synchronous rectal cancer. Surgical strategies are commonly used to treat the sequelae of PJS, such as small bowel intussusception or neoplastic lesions. Enterotomy and polypectomy or limited resection is considered to be the procedures of choice. Polypectomy using DBE is now recommended for small bowel polyps[3]. DBE is well recognized as a new enteroscopic method that allows for the examination and treatment of the jejunum and ileum in almost all patients. However, it cannot completely replace the surgical treatment of malignancies.

In the present case, we adopted an unconventional surgical strategy and performed laparoscopic restorative proctocolectomy and IPAA with a covering ileostomy.

Laparoscopic restorative proctocolectomy with IPAA is generally considered to be the first-line treatment option for patients with ulcerative colitis or familial adenomatous polyposis (FAP)[4]. However, no previous reports have focused on treating PJS patients with laparoscopic IPAA.

This report describes a patient who presented with severe gastrointestinal hemorrhage. Multiple polyps were found in her gastrointestinal tract, most of which were located in the colorectum and not the small bowl. Giant pedunculated polyps covered the patient's rectum, sigmoid colon, descending colon, transverse colon and part of the ascending colon, and surgery was necessary. In addition, colonoscopy and biopsy indicated the presence of a midrectal malignancy. Due to the locations of the giant polyps and the midrectal malignancy, restorative proctocolectomy with IPAA was considered. This procedure effectively minimizes

the risk of recurrence through the maximal removal of the involved bowel tissue while maintaining bowel continence. A large, retrospective cohort study from the Cleveland Clinic has shown that IPAA is a relatively safe and effective procedure with a low perioperative mortality rate of 0.1%[5]. Compared to conventional laparotomy, laparoscopic restorative proctocolectomy with IPAA is associated with less blood loss, fewer respiratory complications, a faster return of bowel function and a shorter hospital stay[6,7]. In addition, patients are satisfied with laparoscopic surgery[5], which significantly improves cosmesis and quality of life. In this case, the patient has not suffered from further episodes of gastrointestinal bleeding or fecal incontinence since the operation, and she is satisfied with the cosmetic results and the therapeutic effects.

We suggest that laparoscopic restorative proctocolectomy with IPAA may be a safe and effective treatment for PJS with synchronous rectal cancer in patients similar to the one presented in this report. However, this procedure cannot be applied to all patients with PJS. Polyps in the small intestine still require endoscopic polypectomy or resection of the involved regions of the small intestine.

COMMENTS

Case characteristics

A 42-year-old female patient presented with a 20-year history of intermittent bloody stool. Physical examination showed areas of pigmentation on the lips and extremities.

Clinical diagnosis

Peutz-Jeghers syndrome (PJS) with synchronous rectal cancer.

Differential diagnosis

Familial adenomatous polyposis.

Laboratory diagnosis

The hemoglobin level was 69 g/L, CEA, CA19-9 levels and metabolic panel and liver function test results were within the normal limits.

Imaging diagnosis

CT scan revealed the presence of multiple polyps in the ileum and colorectum.

Pathological diagnosis

Colonoscopy and biopsy revealed that the rectal mass was an adenoma with high-grade intraepithelial neoplastic changes. The final pathological examination confirmed the diagnosis of moderately differentiated rectal adenocarcinoma.

Treatment

The patient was treated with laparoscopic restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA).

Experiences and lessons

The authors suggest that laparoscopic restorative proctocolectomy with IPAA may be a safe and effective treatment for treating patients with PJS with synchronous rectal cancer, with the advantage of minimal invasiveness.

Peer-review

In this manuscript, the authors reported a patient with PJS with synchronous rectal cancer who was treated with laparoscopic restorative proctocolectomy with ileal pouch-anal anastomosis. Overall, this case report is very interesting, and worthy to be published.

Abstract

Development of portal vein tumor thrombus deteriorates the prognosis of hepatocellular carcinoma, while surgical treatment can offer a promising prognosis for selected patients. However, the possibility of residual lesions in portal vein after conventional thrombectomy is a main risk factor leading to postoperative recurrence. Therefore, ensuring the complete removal of tumor thrombus during operation is critical to improve prognosis. For the first time, we report here one case of hepatocellular carcinoma with portal vein tumor thrombus in which cystoscope was successfully applied as a substitute of intravascular endoscope to visualize the cavity of the portal vein. The patient was a 61-year-old man with a 7-cm tumor in the right lobe of the liver, with tumor thrombus invading the right branch and adjacent to the conjunction of the portal vein. After removal of the tumor, the Olympus CYF-VA2 cystoscope was used to check the portal vein from the opening stump of the right branch of the portal vein. In this case, residual thrombus tissue was found near the opening stump and the conjunction of the portal vein. The residual lesion was carefully retrieved from the stump after retraction of the cystoscope. The procedure was repeated until no residual lesion was found. The whole duration time of thrombectomy was 22.5 (15 + 7.5) min. The patient was free from recurrence at 8 months after the procedure. Our work indicated that the cystoscope is a suitable substitute, with a proper size and function to check the portal vein system and ensure the curability of thrombectomy. Although well-designed clinic trails are still needed, this procedure may further improve the postoperative prognosis of hepatocellular carcinoma with portal vein tumor thrombus.

Key words: Hepatocellular carcinoma; Portal vein tumor thrombus; Surgical treatment; Thrombectomy; Cystoscope

Core tip: Inability to ensure the curability of the thrombectomy has been a main obstacle to improving postoperative prognosis of hepatocellular carcinoma with portal vein tumor thrombus, especially for cases with invasion in the main trunk of the portal vein. In this report, we firstly applied the cystoscope as an intravascular endoscope to investigate the cavity of the portal vein after primary tumor removal. The cystoscope offered a clear view of the portal vein cavity from the main trunk to the secondary branch, indicating its suitability as a substitute with a proper size and function to check the portal vein system.

Li N, Wei XB, Cheng SQ. Application of cystoscope in surgical treatment of hepatocellular carcinoma with portal vein tumor thrombus. *World J Gastroenterol* 2016; 22(22): 5297-5300 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i22/5297.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i22.5297

INTRODUCTION

Hepatocellular carcinoma (HCC) has a propensity to invade the intrahepatic vasculature, especially the portal vein system, leading to the formation of portal vein tumor thrombus (PVTT). PVTT is the most important significant factor for a poor prognosis, with a median survival of only 2.7 mo if patients are untreated[1]. Although sorafenib was recommended by the Barcelona Clinic Liver Cancer (BCLC) guideline as the only therapy for these patients, recent studies have demonstrated that surgical resection may offer a more promising prognosis for selected HCC patients with PVTT[2,3].

In the surgical operation, when the PVTT and tumor could not be resected *en-bloc*, thrombectomy was carried out after the removal of tumor. Theoretically, when thrombectomy was performed, squeezing or fragmenting the tumor thrombus could not be avoided, which would increase the risk of scattering tumor tissue within the portal vein cavity. What's more, there will be a possibility of residual PVTT tissues adhering to the inner wall of the portal vein even after careful extraction[4-6]. Those factors may lead to the early intrahepatic recurrence of tumor or PVTT[6]. Therefore, ensuring the complete removal of PVTT during operation is critical to improving the prognosis. With the development of endoscopy, it is theoretically ideal to achieve this goal by direct visual observation under intravascular endoscope. However, to the best of our knowledge, there is currently no angioscope specially designed for the portal vein system. Here, we describe one case of an HCC patient with PVTT in which the cystoscope was successfully applied as a substitute to the intravascular endoscope to visualize the cavity of the portal vein.

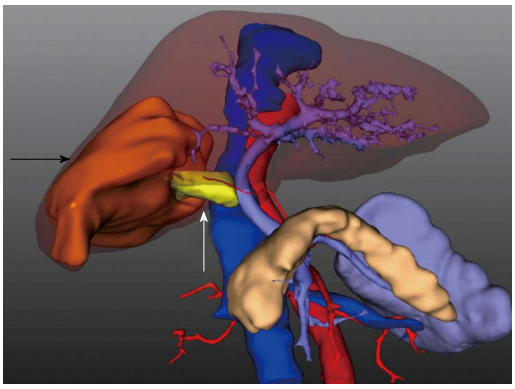

Figure 1 3D reconstruction of the tumor and portal vein tumor thrombus. A 7-cm hepatocellular carcinoma (white arrow) was located in segments Ⅴ, Ⅵ and Ⅶ. The tumor thrombus (black arrow) extended into the right branch and was adjacent to the conjunction of the portal vein.

CASE REPORT

This study was approved by our Institutional Review Board and written informed consent was obtained from the patient for this research. A 61-year-old man with hepatitis B virus infection presented to our department with a 7-cm HCC in the right lobe of the liver, with tumor thrombus that had invaded the right branch and was adjacent to the conjunction of the portal vein. Figure 1 shows a 3D reconstruction of the tumor and PVTT. The patient had Child-Pugh class A liver function and the other laboratory tests were normal. Intraoperative assessment confirmed the preoperative diagnosis. During operation, Pringle's maneuver was applied distal to the PVTT to occlude the blood inflow using a clamp/unclamp cycle of 15 min/5 min. According to characteristics of the tumor and the PVTT, a right semi-hepatectomy was carried out with a clamp crushing method.

After removal of the tumor, the Olympus CYF-VA2 cystoscope was used to check the portal vein. First, the streamlined tip was inserted into the opening stump on the right branch of the portal vein. The function of flush-and-suction was used to keep the field of view clear. In this case, scattered PVTT tissue was found near the opening stump. Further inspection revealed a residual lesion near the conjunction of the portal vein (Figure 2A and B). Then, the cystoscope was retracted from the stump and the residual PVTT was carefully retrieved using a clamp. After that, the portal vein cavity was reexamined meticulously from the main trunk to the left secondary branch by bending the flexible tip and drawing the insertion tube in and out. The procedure was repeated until no residual lesion was found (Figure 2C and D). Then, the stump was closed using a continuous suture. The whole duration time of the thrombectomy was 22.5 (15 + 7.5) min. The patient was discharged home without

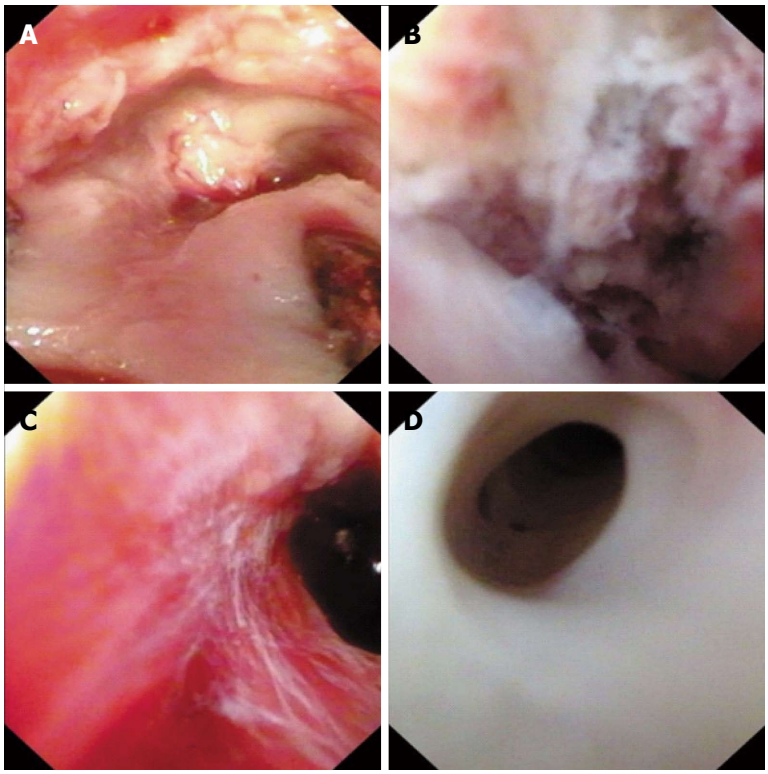

Figure 2 Endoscopic images of portal vein before and after thrombectomy. A: Before thrombectomy, endoscopy revealed scattered tissue of tumor thrombus near the opening stump; B: Residual tumor thrombus was adhered to the inner wall of the portal vein near the conjunction; C: After repeated retraction of the residual tumor thrombus, endoscopy revealed a clean inner wall of the portal vein with no macroscopic thrombus remaining; D: The left secondary branch of the portal vein was clean with no scattered thrombus.

complications on postoperative day 7 and was free from recurrence at 8 mo after the procedure when the last follow-up was attended.

DISCUSSION

Curative resection of tumor and complete removal of PVTT is essential to improve the oncological prognosis of HCC patients with PVTT. For PVTT confined to the ipsilateral branch of the portal vein, *en-bloc* resection of the ipsilateral portal vein branch containing the tumor thrombus has been recommended, whenever the liver remnant is sufficient[4,7]. However, for patients with PVTT extending to the main portal trunk, or patients with insufficient liver remnant after en-bloc resection, thrombectomy would be inevitably carried out after resection of the primary tumor. Patients who underwent thrombectomy have been reported to have a poor prognosis, with a 6-mo PVTT recurrence rate of 63.8% and the 1-year intrahepatic recurrence rate of 78.8%[4]. For these patients, residual or disseminated tumor thrombus in portal vein may be a significant risk factor leading to the high recurrence rate[6]. Therefore, it is crucial to eliminate the risk of residual thrombus while performing thrombectomy. Fortunately, the portal vein has no blood flow inside during the application of Pringle's maneuver, allowing the possibility of endoscopic inspection. In this case, the cystoscope we used could view the portal vein cavity clearly from the main trunk to the secondary branch, indicating it is a suitable substitute with a proper size and function to check the portal vein system. Despite the possibility that a microscopic lesion may still exist, this procedure theoretically eliminated the possibility of a residual and scattered macroscopic tumor thrombus in the portal vein and further ensured curability of the thrombectomy. This procedure may further improve the postoperative prognosis of HCC with PVTT**.** It will also be worthwhile to carry out a well-designed clinical trail to measure the significance of intravascular endoscopy to prove the postoperative prognosis of HCC with PVTT.

COMMENTS

Case characteristics

A 61-year-old man presented to our department with a 7-cm hepatocellular carcinoma (HCC) in the right lobe of the liver, with tumor thrombus invading the right branch and adjacent to the conjunction of the portal vein.

Treatment

Using a cystoscope to check the portal vein cavity after removal of the tumor in surgical treatment of HCC with portal vein tumor thrombus (PVTT).

Term explanation

PVTT means "portal vein tumor thrombus".

Experiences and lessons

The cystoscope we used could view the portal vein cavity clearly from the main trunk to the secondary branch, indicating it is a suitable substitute with a proper size and function to check the portal vein system in the surgical treatment of HCC with PVTT.

Peer-review

This is a novel idea to ensure the curability of hepatectomy for HCC with PVTT. The effectiveness of the treatment will require a well-designed clinical trail to further confirm.

Abstract

Tumor microenvironments have a crucial role in cancer initiation and progression, and share many molecular and pathological features with wound healing process. Unless treated, tumors, however, do not heal in contrast to wounds that heal within a limited time framework. Wounds heal in coordination of a myriad of types of cells, particularly endothelial cells, leukocytes, and fibroblasts. Similar sets of cells also contribute to cancer initiation and progression, and as a consequence, anti-cancer treatment strategies have been proposed and tested by targeting endothelial cells and/or leukocytes. Compared with endothelial cells and leukocytes, less attention has been paid to the roles of cancer-associated fibroblasts (CAFs), fibroblasts present in tumor tissues, because their heterogeneity hinders the elucidation on them at cellular and molecular levels. Here, we will discuss the origin of CAFs and their crucial roles in cancer initiation and progression, and the possibility to develop a novel type of anti-cancer treatment by manipulating the migration and functions of CAFs.

Key words: Angiogenesis; Drug resistance; Extracellular matrix; Immune evasion; Transforming growth factor-β; Invasion; Metastasis

Core tip: Tumor microenvironments have a crucial role in cancer initiation and progression, and consist of various types of cells, such as endothelial cells, leukocytes, and fibroblasts. Compared with endothelial cells and leukocytes, less attention has been paid to the roles of cancer-associated fibroblasts (CAFs), fibroblasts present in tumor tissues, because their heterogeneity hinders the elucidation on them at cellular and molecular levels. Here, we will discuss the origin of CAFs and their crucial roles in cancer initiation and progression, and the possibility to develop a novel type of anti-cancer treatment by manipulating the migration and functions of CAFs.

INTRODUCTION

Dvorak proposed that tumors are wounds that do not heal[1], based on his discovery of vascular endothelial growth factor (VEGF), which is produced in wound healing sites as well as tumor sites[2] and can account for chronic hyperpermeability-mediated fibrin deposition in solid tumors and in early stages of wound healing[3]. Moreover, solid tumors and wound healing process share many pathological and molecular features.

Irrespective of the causes and the severities of wounds, healing proceeds to repair the structure and functions of injured organs and tissues, through a series of processes; hemostasis, humoral inflammation with microvascular permeability and extravascular clotting, cellular inflammation with inflammatory cell infiltration, angiogenesis, and generation of mature connective tissue stroma[4]. These steps proceed through the interaction between the parenchymal cells and the stroma, a complex mixture of inflammatory cells, matrix proteins, and tissue cells such as fibroblasts and endothelial cells. Injured organs and tissues are completely replaced by proliferating parenchymal cells in the case of acute and mild wound, but if not replenished completely, they are filled with connective tissue. Tumor cells, regardless of their site of origin, behave like parenchymal cells in normal tissues and proliferate by interacting with the stroma[4].

Fibroblasts are a major cell type within the stroma and contribute to tissue remodeling in development and tissue homeostasis, by providing structural scaffolding and growth regulatory mediators. Moreover, following tissue injury, fibroblasts exhibit an activated and contractile phenotype with enhanced expression of α-smooth muscle actin (α-SMA) and are referred to as myofibroblasts[5]. Myofibroblasts synthesize increased amount of various types of collagens and extracellular matrix proteins (ECM) to provide scaffold and to eventually aid in wound repair[5]. Furthermore, the cells are important sources of many growth factors and cytokines that regulate wound healing processes[6].

Primary normal fibroblasts isolated from various human tissues, can restrict the *in vitro* cell proliferation of various types of human cancer cell lines, under co-culture condition[7]. Indeed, if Nod-like receptor pyrin domain-containing protein 6 (NLRP6) is absent in fibroblasts within the stem cell niche in the colon, regeneration of the colonic mucosa and processes of epithelial proliferation and migration are impaired and consequently, colitis-associated tumorigenesis is accelerated in mice[8]. Thus, under normal conditions, fibroblasts work as a sentinel cell to maintain epithelial tissue homeostasis and to prevent initiation of tumorigenesis in colon, in a NLRP6-dependent manner.

Like fibroblasts in wound healing process, fibroblasts present in tumor tissues exhibit an activated and a myofibroblast-like phenotype with α-SMA expression and are referred as cancer-associated fibroblasts (CAFs)[9]. In contrast to fibroblasts in normal tissues, CAFs in most solid tumors are presumed to promote tumor development and progression by providing cancer cells with a myriad of growth factors[9,10]. However, in pancreatic ductal cancer, CAFs can deliver immune stimulating signals. As a result, depletion of CAFs induces immunosuppression with increased intra-tumoral regulatory T cells (Tregs) and eventually accelerates tumor progression with reduced survival[11]. Hence, it still remains elusive on the pathophysiological roles of CAFs in the development and progression of solid tumors.

We will herein discuss the pathophysiological roles of CAFs and their clinical relevance mainly in colorectal cancer (CRC), but will mention CAFs in other types of cancer if necessary.

CAFS IN COLITIS-ASSOCIATED COLON CARCINOGENESIS MODEL

Accumulating evidence indicates the crucial contribution of chronic inflammation to tumor development and progression[12]. Colitis-associated colon carcinogenesis (CAC) is one typical example of this pathological process. CAC frequently ensues from chronic intestinal inflammatory changes observed in patients with inflammatory bowel diseases such as ulcerative colitis (UC), particularly those with a long duration, extensive involvement, and severe inflammation[13]. Pathological features of UC include mucosal damage and ulceration with prominent leukocyte infiltration, and these changes involve rectum at first and extend proximally.

Oral administration of dextran sulfate sodium (DSS) solution to rodents can cause acute inflammatory reaction and ulceration in the entire colon, similar to that observed in human UC patients, and therefore, is widely used to reproduce human UC[14]. Moreover, repeated DSS ingestion alone can cause a small number of colon carcinomas in about a half of mice[15], suggesting that inflammatory response alone can cause colon carcinoma. The incidence of DSS-induced colon carcinogenesis is accelerated and increased by a prior administration of azoxymethane (AOM)[16], which can alone cause colon cancer by inducing O^6-methyl guanine formation and mutations of the *β catenin* gene[17]. Thus, the combined treatment with AOM and DSS is used frequently to recapitulate the molecular mechanisms underlying CAC.

A transcription factor, NF-κB, is a key player in

Table 1 Pathological changes in various mice after azoxymethane/dextran sulfate sodium treatment

	Ingested DSS concentration	Body weight loss (> 20%)	Granulocyte infiltration (> 400/field)	Fibroblast accumulation (> 20% type I collagen$^+$ areas)	Tumor numbers
Wild-type mice	3.0%	+	+	+	> 20
CCR1-deficient mice	3.0%	-	-	-	< 5
	4.5%	+	+	+	> 20
CCR5-deficient mice	3.0%	-	-	-	< 5
	4.5%	+	+	-	< 7
CCL3-deficient mice	3.0%	-	-	-	< 5
	4.5%	+	+	-	< 5

Table is prepared according to Sasaki *et al*[22]. DSS: Dextran sulfate sodium.

inflammation and its activity is triggered by IκB kinase (IKK) complex, in response to a wide variety of pro-inflammatory stimuli such as infectious agents and pro-inflammatory cytokines[18]. Greten *et al*[19] demonstrated that IKKβ has crucial roles in AOM/DSS-induced CAC by two distinct pathways; prevention of apoptosis of epithelial cells and enhancement of growth factor expression by myeloid cells. Thus, these observations would indicate the crucial involvement of inflammatory cell infiltration in CAC development. Given the crucial roles of NF-κB in regulation of gene expression and biological functions of pro-inflammatory cytokines such as tumor necrosis factor (TNF)-α and chemokines[18], we examined the AOM/DSS-induced colon carcinogenesis process by using mice deficient in the tumor necrosis factor receptor (*TNF-R*)*p55* gene[20]. We revealed that genetic ablation of the *TNF-Rp55* gene in myeloid cells resulted in reduction in intracolonic infiltration of inflammatory cells, particularly macrophages, and neovascularization, and subsequent tumor formation. Moreover, a TNF inhibitor reduced tumor progression even when it was administered after multiple tumors developed in colon. Similar phenotypes were observed by genetic inactivation of a macrophage-tropic chemokine receptor, the *CCR2* gene, in myeloid cells or the administration of CCR2 inhibitors after multiple colon tumors developed[21].

These observations prompted us to further examine the roles of another macrophage-tropic chemokine, CCL3, and its receptors, CCR1 and CCR5[22]. Mice deficient in *CCL3*, *CCR1*, or *CCR5* gene, did display marginal inflammatory reactions and subsequently develop few colon tumors when AOM was administered together with 3% DSS ingestion. All wild-type (WT) mice failed to survive 4.5% DSS ingestion, whereas CCL3-, CCR1-, or CCR5-deficient mice survived this high concentration of DSS solution with a prominent mucosal damage and leukocyte infiltration in colon. Interestingly, CCR1-deficient mice developed multiple colon tumors, whereas the same treatment caused only a small number of colon tumors in CCL3- or CCR5-deficient mice (Table 1)[22]. These observations would indicate that inflammatory cell infiltration is necessary but not sufficient for the development of CAC in this model.

The most prominent difference in pathological change is that CCL3- or CCR5-deficient mice exhibited reduced accumulation of CAFs in colon, which was evident in the later phase of CAC in this model, compared with WT or CCR1-deficient mice (Table 1). Several groups including ours further demonstrated that CAFs expressed abundantly growth factors such as hepatocyte growth factor (HGF)[23], epiregulin[24], and heparin-binding epidermal growth factor-like growth factor (HB-EGF)[22] to promote tumor cell proliferation in the later phase of this CAC model. Moreover, the deficiency of the *CCR5* gene results in reduced growth of the tumors arising from either subcutaneous or orthotopic intracecum injection of a syngeneic mouse colon adenocarcinoma cell line, colon 26. Furthermore, this attenuated tumor growth was associated with a reduction in type I collagen-positive fibroblast numbers but not inflammatory cell infiltration[22]. These observations would indicate the crucial involvement of CAFs in rather progression of CAC than its development.

ORIGINS OF CAFS

The lack of a specific marker to identify CAF[25] hampers the precise identification of the origin of CAF. α-SMA, a robust CAF marker, is also expressed by normal colonic fibroblasts under *in vitro* culture conditions[26] and other cell types such as pericytes and smooth muscle cells surrounding vasculature, and cardiomyocytes[27]. There are several additional candidate CAF markers including fibroblast activation protein (FAP)-α[28,29], S100A4/fibroblast specific protein-1[30,31], neuron-glial antigen-2, platelet-derived growth factor (PDGF) receptor-β, and prolyl 4-hydroxylase[32]. However, these molecules can be expressed by other cell types than CAFs and therefore, are not specific to CAFs. The lack of a definitive maker for CAFs, imply the phenotypical and functional heterogeneity of CAFs in CRC and this assumption is further strengthened by global gene expression profiles[33] (Figure 1).

The most possible cellular source of CAFs in CRC is resident fibroblasts in colon tissues. Supporting this notion, CAFs in liver metastatic foci of CRC exhibit the

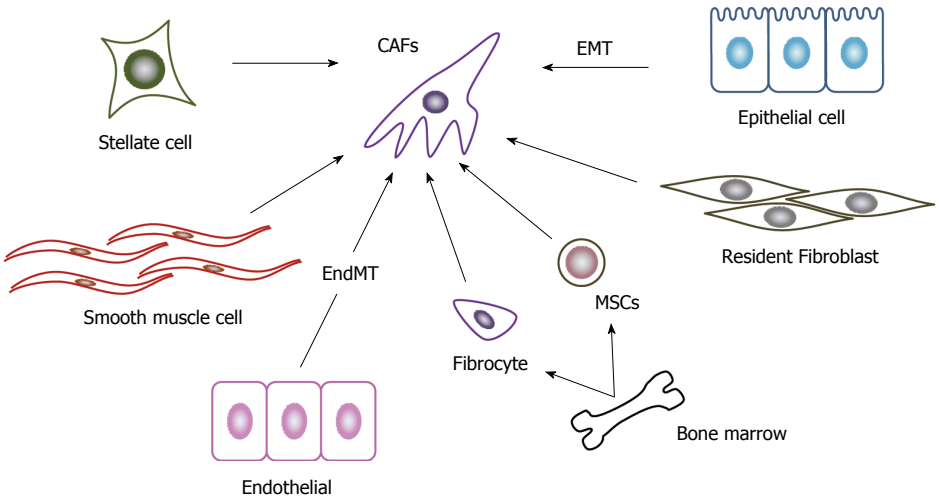

Figure 1 Origin of cancer associated fibroblasts. A variety of cells can generate to CAFs. The most important cellular source of CAFs in CRC is presumed to be resident fibroblasts. Stellate cells in intestine may be able to transform into CAFs similarly as stellate cells in liver and pancreas do. Other potential sources include epithelial cells undergoing EMT, endothelial cells undergoing EndMT, smooth muscle cells, and bone marrow-derived cells including fibrocytes and MSCs. CAFs: Cancer associated fibroblasts; CRC: Colorectal cancer; EMT: Epithelial-mesenchymal transition; EdnMT: Endothelial-mesenchymal transition; MSCs: Mesenchymal stem cells.

similar protein expression pattern as liver resident fibroblasts[34]. Kojima and colleagues demonstrated that resident human mammary fibroblasts progressively convert into CAF-like cells with enhanced α-SMA expression and pro-tumorigenic capacity, during the course of tumor progression in a breast tumor xenograft model[35]. Moreover, these cells express transforming growth factor (TGF)-β and a chemokine, stromal-derived factor (SDF)-1/CXCL12, the molecules which further initiate and maintain the differentiation of fibroblasts into CAF-like and the concurrent tumor-promoting phenotype in an autocrine and amplifying manner[35].

Stellate cells are vitamin A-containing and lipid droplet-containing cells in their quiescence state and are present in various tissues including liver, pancreas, kidney, and intestine[36]. These cells activate α-SMA expression under inflammatory and oncogenic conditions and acquire myofibroblast-like phenotypes as CAFs do. Most of hepatocellular carcinomas arise in a cirrhotic liver with prominent fibrosis. Activated hepatic stellate cells are the major source of extracellular proteins during fibrogenesis. Moreover, they can induce hepatocellular carcinoma cell growth, neovascularization, and immune evasion, to promote tumor progression[37]. Similar to hepatocellular carcinoma, pancreatic cancer is characterized by a prominent desmoplastic/stromal reaction. Like hepatic stellate cells, activated pancreatic stellate cells can produce abundantly the collagenous stroma of pancreatic cancer. Moreover, these cells can also interact closely with cancer cells to facilitate local tumor growth and distant metastasis, to mediate angiogenesis, and to induce immune evasion[38]. However, it has to be yet determined whether stellate cells in intestine, can also behave in a similar manner in the course of colon carcinogenesis, as those in liver and pancreas do.

Other types of cells are proposed to be a cellular source of CAFs, based on the analyses on other types of cancers than CRC. Accumulating evidence indicates that under chronic inflammatory conditions, epithelial cells can undergo epithelial-mesenchymal transition (EMT) to acquire myofibroblast-like phenotypes and to participate in the synthesis of the fibrotic matrix[39]. A breast carcinoma biopsy provided evidence to indicate the occurrence of EMT and a coincidental α-SMA-positive stromal reaction[40]. Moreover, when a mouse breast cancer cell line, MCF-7, was injected into nude mice, together with HBFL-1, a mammary gland epithelial cell line without tumorigenicity, HBFL-1 cells acquired myofibroblast-like phenotypes and conferred a significant 3.5- to 7-fold increase in MCF-7 tumor size in nude mice. Thus, breast cancer can transform its own nonmalignant stroma to facilitate its own growth[40]. Furthermore, when human epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (EGFR-TKI)-resistant lung cancer cells were used as a xenograft model, EMT-derived tumor cells give rise to about a quarter of CAFs, which provide cancer cells with resistance to EGFR-TKI[41]. Meanwhile, several independent groups argue against EMT as the origin of CAFs[42,43].

Bone marrow-derived mesenchymal stem cells (MSCs) are proposed to be an another origin of CAFs, because MSCs and CAFs exhibit similar immunophenotypes and share the potential to differentiate to various types of cell lineages such as adipocytes, chondrocytes, and osteoblasts[44]. Bone marrow-derived and circulating fibroblast progenitors, fibrocytes, also exhibit similar phenotypic and functional characteristics in chemically induced rat breast carcinogenesis model[45], suggesting that fibrocytes can be an origin of CAFs.

TGF-β1 can induce proliferating endothelial cells to undergo a phenotypic conversion into fibroblast-like cells with the emergence of mesenchymal markers

and the reciprocal down-regulation of CD31[46]. Moreover, when endothelial cells were irreversible tagged by crossing Tie2-Cre mice with R26Rosa-lox-Stop-lox-LacZ mice, endothelial-to-mesenchymal transition (EndMT) was evident at the invasive front of the tumors in the B16F10 melanoma model and the Rip-Tag2 spontaneous pancreatic carcinoma model[46]. Choi and colleagues further demonstrated that endothelial heat shock protein (a synonym of HSP27 in humans and HSP25 in rodents) has a crucial role in the maintenance of endothelial phenotypes and that its deficiency mediates the EndMT to accelerate fibrosis and eventually tumorigenesis in lungs[47]. Smooth muscle cells can be another source of CAFs in several cancers, particularly prostate cancer. Normal prostate stroma is enriched in smooth muscle cells, but during prostatic carcinogenesis in rats and humans, smooth muscle cells disappear with reciprocal appearance of CAFs, which can promote carcinogenesis in genetically abnormal but non-tumorigenic epithelial cells[48]. Thus, smooth muscle cells may be a source of CAFs in prostate cancer but it remains to be clarified whether CAFs originate from this population in other types of cancer, particularly CRC.

Evidence is accumulating to indicate functional heterogeneity of CAFs in various types of cancers including colon cancer[33]. This heterogeneity may arise from the differences in the origin of CAFs. Alternatively, CAFs are generated by the intricate interactions with tumor microenvironments consisting of cancer cells and other resident cells[10,25]. Thus, the heterogeneity of tumor microenvironments can induce a wide variation in CAFs. Nevertheless, this heterogeneity of CAFs can affect the clinical course of colon cancer patients[49].

RECRUITMENT AND ACTIVATION OF CAFS

Among chemokines, CCL2 and CCL3 can recruit fibroblasts[50], while CXCL12[51], CCL21[52], and CCL3[53] can recruit fibrocytes in chronic inflammation. We proved that CCL3 is produced locally at tumor sites and is associated with CAF accumulation[22,54]. Moreover, in a mouse gastric cancer model, a substantial proportion of CAFs originate from bone marrow-derived mesenchymal stem cells, which are recruited to tumor site in a TGF-β and CXCL12-dependent manner[55]. Thus, CAF accumulation may be regulated by the cooperation with chemokines and other fibroblast-tropic factors such as TGF-β.

Normal fibroblasts can inhibit *in vitro* cell proliferation of cancer cells[7]. Moreover, normal intestinal fibroblasts can maintain epithelial homeostasis to prevent carcinogenesis[23]. Thus, malignant cells must reprogram normal fibroblasts into CAFs with protumorigenic activity. This process is mediated by cancer cell-derived factors including TGF-β, CXCL12[35], PDGF[56], and interleukin (IL)-6[57]. On the contrary, several lines of evidence indicate that CAF phenotype can persist in the absence of continued exposure to cancer cell-derived factors[58]. This may be explained by the observation that CAFs increasingly acquire the capacity to express TGF-β and CXCL12, the cytokines which can act to initiate and maintain the differentiation into CAFs in auto-stimulatory and cross-communicating manner[35]. Alternatively, CAF may acquire irreversible genetic and/or epigenetic changes during the course of the differentiation, as similarly observed on tumor endothelial cells[59].

CAFS IN CARCINOGENESIS

Cancer cell growth and stemness

Human pre-malignant prostatic epithelial cells can transform to neoplastic cells when they are *in vitro* co-cultured with CAFs derived from human prostate cancer tissues[60]. Secreted factors from CAFs are believed to be responsible for this tumor-initiating capacity. Indeed, when human mammary epithelial cells are grafted into immunodeficient mice, together with fibroblasts overexpressing TGF-β and/or HGF, the engrafted cells develop into a proliferating tissue that closely resembles human ductal carcinomas[61]. These observations raise the possibility that CAFs can initiate malignant transformation of epithelial cells by secreting these growth factors (Figure 2).

Under the influence of cancer cell-derived IL-6, CAFs can secrete metalloproteinases, to stimulate EMT and cancer stem cell phenotypes in prostate cancer[62]. CAFs in colon cancer secrete HGF, activate β-catenin-dependent transcription and subsequently induce cancer stem cell clonogenicity[63]. Moreover, CAF-derived HGF also restores the cancer stem cell phenotype in more differentiated tumor cells both *in vitro* and *in vivo*. Furthermore, human colon cancer-derived and chemotherapy-treated CAFs produce abundantly interleukin-17A (IL-17A), which increases chemotherapy-resistant cancer stem cells[64].

CAFs produce various growth factors and cytokines, which can promote cancer cell proliferation; HGF[23], EGF[65], epiregulin[24], HB-EGF[22], insulin-like growth factor (IGF)[66], TGF-β[35] connective tissue growth factor[67], and CXC12[58]. Actually, most of these growth factors can be produced by cancer cells and can enhance the growth of CAFs. Moreover, CAF-derived TGF-β and CXCL12 affect CAF proliferation in an autocrine manner[35]. Thus, these growth factors form a vicious positive feedback loop between cancer cells and CAFs, and may eventually accelerate tumor progression.

Thus, CAFs can contribute to tumor development and progression by initiating malignant transformation, enhancing the proliferation of cancer cells, and inducing the cancer stem cell phenotype.

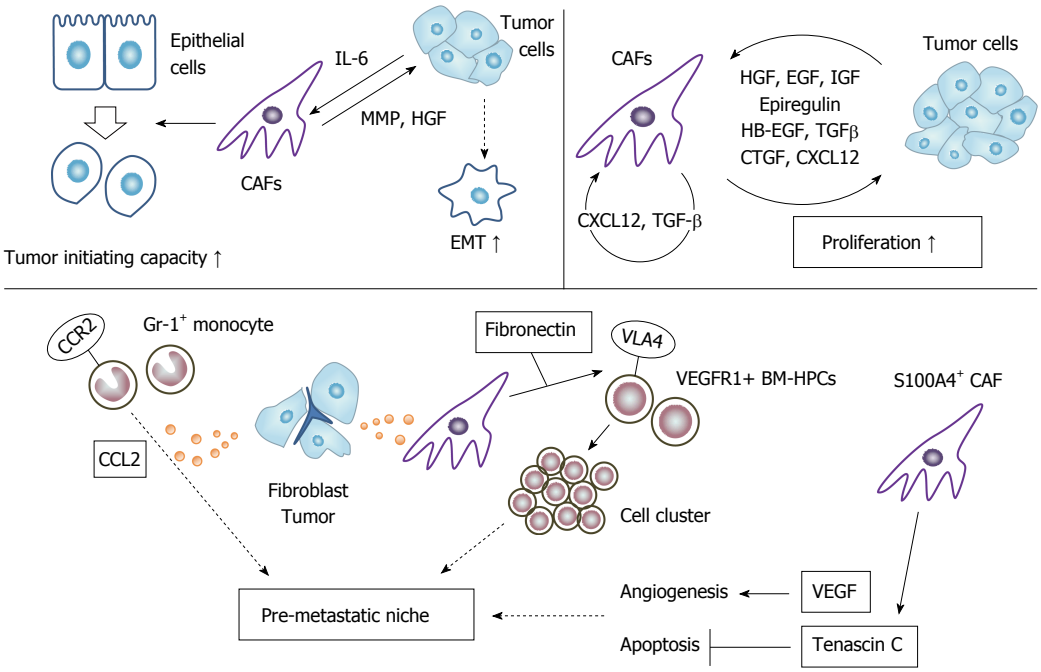

Figure 2 Action of cancer associated fibroblasts on tumor cells. CAF can induce tumor cells to enhance their tumor initiating capacity (stemness), and to undergo EMT. CAFs provide tumor cells with various growth factors to promote their growth. CAFs can also instigate pro-metastatic niche by inducing tumor cell cluster and angiogenesis, and suppressing tumor cell apoptosis. CAFs: Cancer associated fibroblasts; EMT: Epithelial-mesenchymal transition; VEGF: Vascular endothelial growth factor.

Cancer cell migration, invasion, and metastasis

Colon cancer cell lines exhibit enhanced migratory ability in a wound healing assay and increased clonogenic capacity in the presence of CAF-derived conditioned media, compared with normal fibroblast-derived conditioned media[26]. Moreover, co-injection of CAFs with a human colon cancer cell line into nude mice, significantly enhances tumor growth with increased tumor cell proliferation, compared with normal fibroblasts[26]. Gene ontology analysis further reveals that genes overexpressed in CAFs are associated with biological processes such as development (*TGFB2, PDGFC, cMET, CADM1, WNT1*) and cell-cell signaling (*TFAP2C, NTF-3, SEMA5A, EFNB2, INHBA*)[26]. These gene products can modulate the functions of cancer cells to promote their invasion and metastasis (Figure 2).

CAFs expressed various matrix metalloproteinases (MMPs) and MMP-mediated ECM degradation results in proteolytic destruction of basement membrane and aids tumor cells to invade surrounding tissues[68]. Moreover, MMP-mediated enhanced invasiveness also involves proteinase-activated receptor 1 (PAR1) expressed on cancer cell surface. CAF-derived MMP-1 cleaves PAR1 at its proper site to deliver PAR1-mediated signaling pathway in cancer cells, which is associated with cancer cell migration and invasion[69].

Fibroblasts as well as tumor cells produce abundantly CCL2, which recruits Gr-1-positive, CCR2-expressing inflammatory monocytes into lung[70]. Recruited inflammatory monocytes subsequently instigate a pre-metastatic niche, which favors lung metastasis of mouse mammary cancer. A pre-metastatic niche can be formed by direct actions by CAFs[71]. S100A4-positive CAFs produce abundantly VEGF-A, which plays an important role in the establishment of an angiogenic microenvironment at the metastatic site to facilitate colonization. Moreover, S100A4-positive CAFs produce tenascin-C to provide cancer cells with protection from apoptosis.

Gene expression-based classification systems have identified an aggressive colon cancer subtype with mesenchymal features, possibly reflecting EMT of tumor cells. Comparative analysis of stroma^{high} and stroma^{low} CRC shows that the neoplastic cells in stroma^{high} tumors express specific EMT drivers including ZEB2, TWIST1, and TWIST2[72]. Moreover, type Ⅰ collagen dominates the extracellular matrix in these aggressive colon cancer with EMT markers. Mimicking the tumor microenvironment, Matrigel enriched with type Ⅰ collagen can induce colon cancer cells to express tumor-specific mesenchymal gene, to suppress gene expression of hepatocyte nuclear factor 4, a transcriptional activator of epithelial differentiation, and its target genes, and to invade collectively patient-derived colon tumor organoids[72]. Thus, CAF-derived type Ⅰ collagen can induce EMT in cancer cells to promote their invasion.

Bone marrow-derived hematopoietic progenitor cells expressing VEGF receptor 1 (VEGFR1) home to tumor-specific pre-metastatic sites[73]. Primary tumor-derived factors induce resident fibroblast in pre-metastatic sites to express fibronectin, which interacts with VLA-4 on VEGFR1-positive cells to induce cell clusters and to promote subsequently pre-metastatic

niche formation. Fibronectin expression in fibroblasts is regulated by sphingosine-1-phosphate (SIP)-SIP receptor-STAT3 pathway[74].

CAFs can activate STAT3 pathway in cancer cells to promote malignant progression. CRCs frequently display mutational inactivation of the TGF-β pathway with elevated TGF-β production. Actually, cancer cell-derived TGF-β stimulates CAFs to secrete IL-11, which triggers gp130/STAT3 signaling in tumor cells[75]. This cross-talk can provide metastatic cells with a survival advantage.

Drug resistance

CAF-derived ECM has profound impact on cancer chemotherapy[76]. ECM forms a physical barrier and as a consequence, most anti-cancer drugs show limited penetration into solid tumors[77]. Moreover, cancer cells acquire chemoresistance through the activation of various pro-survival signal pathways including PI3K/Akt, Erk, Rho/Rock, and p53 after binding to ECM[76]. Adhesion of small cell lung cancer cells to ECM confers resistance to chemotherapeutic agents because the adhesion activates β1 integrin-stimulated tyrosine kinase to eventually suppress chemotherapy-induced apoptosis[78]. Similar mechanisms may also work in the case of resistance to radiotherapy in glioma cells[79].

In addition to ECM, CAF-derived soluble factors have been demonstrated to be involved in drug resistance. CAF-derived CXCL12 mediate drug resistance to conventional chemotherapeutics[80]. This resistance can arise from the ability of CXCL12 to promote cancer cell survival by activating focal adhesion kinase, Erk, and Akt, β-catenin and NF-κB, in CXCR4-expressing cancer cells[81].

The presence of driver mutations in receptor tyrosine kinase (RTK) pathways positions RTKs for potential targets for cancer therapy and accordingly, many anti-cancer drugs have been developed by targeting these RTKs[82]. However, RTK-mediated signals converge on common critical downstream cell-survival effectors such as PI3K and Erk, and consequently, most cells can be rescued from drug sensitivity by simply exposing them to one or more other unrelated RTK ligands. Among these RTK ligands, HGF confers resistance to the BRAF inhibitor in BRAF-mutant melanoma cells[83]. Likewise, CAF-derived HGF can confer the resistance to EGF-receptor inhibitors to human non-small cell lung cancer cells which is otherwise sensitive to the inhibitors[84].

CRC initiating cells (CICs) are resistant to conventional chemotherapy in cell-autonomous assays, but CIC chemoresistance is also increased by CAFs. Comparative analysis of matched CRC specimens from patients before and after cytotoxic treatment revealed a significant increase in CAFs after cytotoxic treatment[64]. Chemotherapy-treated human CAFs promoted CIC self-renewal and *in vivo* tumor growth associated with increased secretion of specific cytokines and chemokines, including IL-17A. Exogenous IL-17A increased CIC self-renewal and invasion, and targeting IL-17A signaling impaired CIC growth. Notably, IL-17A was overexpressed by colorectal CAFs in response to chemotherapy and this observation was validated directly in patient-derived specimens without culture[64]. These data suggest that chemotherapy induces remodeling of the tumor microenvironment through activating CAFs to secrete cytokines such as IL-17.

Tumor microenvironments

Inflammation, particularly chronic one, is closely associated with tumorigenesis of various types of cancer[12,85]. CAFs, as a major cellular component of cancer-associated inflammation, mediate tumor-enhancing inflammation by expressing a proinflammatory gene signature in an NF-κB-dependent manner[86]. NF-κB activation enhanced the expression of several chemokines such as CCL2 and proinflammatory genes such as cyclooxygenase 2 (COX-2) in CAFs. CAF-derived CCL2 mediates the recruitment of blood monocytes to tumor sites[87], favoring the generation of tumor-associated macrophages with a potent pro-tumorigenic activity. Simultaneously, COX-2 generates prostaglandin E2, which can promote both normal and malignant colonic epithelial cell proliferation[88,89] (Figure 3).

Another prominent feature of CAFs is their ability to synthesize ECM, which can serve as a reservoir for various growth factors such as TGF-β, bFGF, PDGF, HGF, and IGF-1[90]. In response to mechanical stress present in tumor tissues, CAFs exhibit an increase in contractility, which can augment the production of collagen[91]. Moreover, CAFs synthesize the specific ECM including type Ⅰ collagen, oncofetal nectin splice variants, periostin, and hyaluronan, and as a consequence, remodel ECM to promote tumor growth[90]. CAFs also express abundantly lysyl oxidase (LOX), an enzyme responsible for cross-linking type Ⅰ collagen. LOX-mediated cross-linking and the resultant tumor tissue stiffness are associated with tumorigenesis[92]. Mechanical stress activates CAFs to express members of MMPs, which regulate the degradation of ECM[90]. MMP-mediated ECM degradation can also promote cancer cell invasion[68].

Tumor microenvironment is characterized by abundant neovascularization, and this process can be induced by CAFs. CAF-induced MMP activation degrades ECM and eventually causes neovascularization[68]. Moreover, CAFs, particularly those in invasive margins, are a rich source of a CXC chemokine, SDF-1/CXCL12[58], which mediates the recruitment of endothelial progenitor cells and subsequent tumor neovascularization. Furthermore, hypoxia can induces CAFs to express a transcription factor, hypoxia-inducible factor (HIF)-1α, which in turn induces the expression of VEGF, a potent angiogenic factor[93]. VEGF production by CAFs can be further enhanced by CAF-derived IL-6, whose expression can

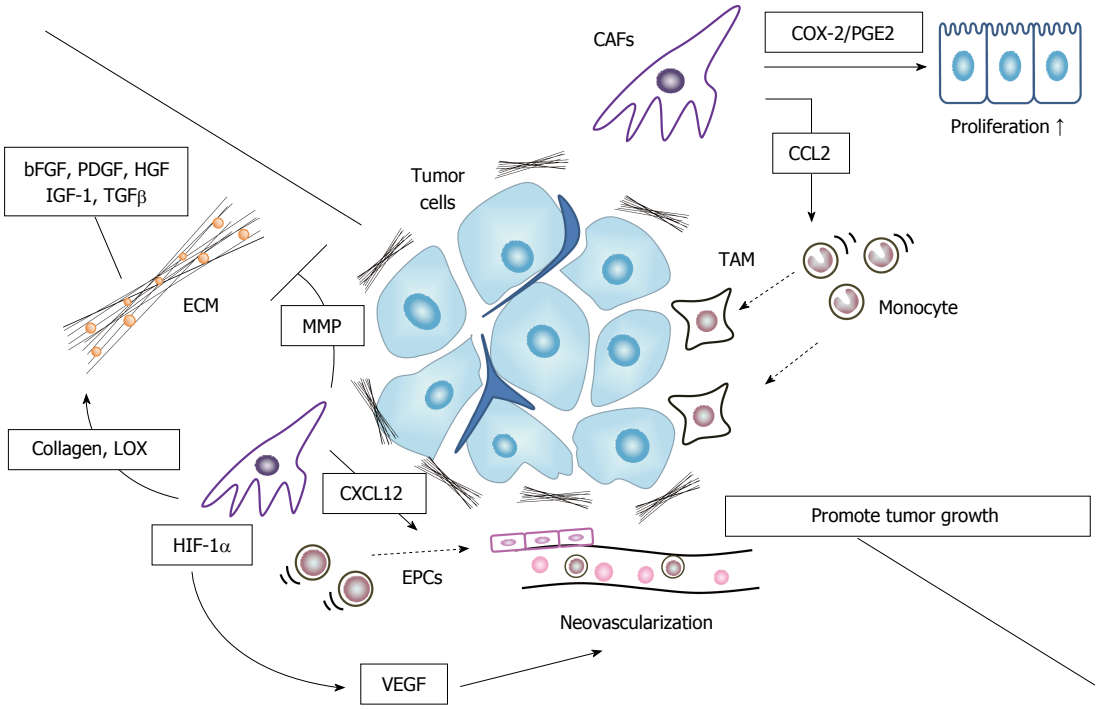

Figure 3 Cancer associated fibroblasts in tumor microenvironment formation. CAFs promote pro-tumorigenic microenvironment by producing extracellular matrix to provide tumor cells with a growth advantage, recruiting tumor-associated macrophages (TAMs) to foster tumor cell growth, and inducing neovascularization. CAFs: Cancer associated fibroblasts; EMT: Epithelial-mesenchymal transition; VEGF: Vascular endothelial growth factor; ECM: Extracellular matrix proteins; EPCs: Endothelial progenitor cells; MMP: Matrix metalloproteinase; HIF-1α: Hypoxia-inducible factor 1α.

be augmented in the presence of colon cancer cells[94].

Tumor immunity

Direct evidence on the involvement of CAFs in suppressed tumor immunity, comes from the study, which revealed that deletion of FAP-positive stromal cells enhances tumor immunity[28]. This study, however, did not clarify the cellular and molecular mechanisms in detail, but several candidate mechanisms have been proposed. CAF-derived prostaglandin E2 and indoleamine 2,3-dioxygenease can inhibit natural killer cell functions, thereby contributing to immune escape and subsequent tumor progression[95]. CAF-derived tenascin also contributes to immune suppression at tumor sites. Soluble tenascin inhibits proliferation of human T cells induced by the combination of anti-CD3 antibody and fibronectin. Tenascin further attenuates T cell proliferation driven by IL-2, while it prevents high level induction of IL-2 receptor[96]. Prostate cancer stem-like cells present in the draining lymph nodes use tenascin-C to inhibit T-cell receptor-dependent T-cell activation, proliferation, and cytokine production, and as a consequence, cancer stem-like cells are protected from T cell-mediated immune surveillance[97] (Figure 4).

CAFs abundantly express TGF-β1, which can suppress the functions of various immune cells, particularly effector T cells and natural killer cells[98]. TGF-β regulates Treg maturation and thereby suppresses immune responses. VEGF is also produced by CAFs and exhibits immunosuppressive effects[99]. VEGF can suppress the maturation of dendritic cell precursors, promote the proliferation of Tregs, and the accumulation of myeloid-derived suppressor cells (MDSC) in peripheral immune organs, and thereby inhibits T-cell immune responses.

In vivo vaccination with a DNA vaccine against FAP eliminates CAFs and eventually causes a shift of the immune microenvironment from a Th2 to Th1 polarization. This shift is characterized by increased protein expression of IL-2 and IL-7, suppressed recruitment of tumor-associated macrophages (TAMs), MDSCs, and Tregs, and decreased tumor angiogenesis and lymphangiogenesis[100]. These observations suggest the roles of CAFs in intratumor Th2 polarization and subsequent depression of tumor immunity. This Th2 polarization is mediated by CAF-derived thymic stromal lymphopoietin (TSLP), which induces *in vitro* myeloid DCs to up-regulate the TSLP receptor, secrete Th2-attracting chemokines, and acquire TSLP-dependent Th2-polarizing capability *in vitro* and *in vivo*[101]. Moreover, CD90-positive CAFs in colon cancer produce IL-6, which induces the polarization of tumor promoting inflammatory T helper 17 cells in infiltrating lymphocytes as well as the expression of cancer stem cell markers in colon cancer cells[102].

CAFs can produce a myriad of chemokines, which can attract and activate immunosuppressive cells, such as M2-polarized TAMs, MDSCs, and Tregs, thereby suppressing tumor immunity[103]. Simultaneously, CAFs can produce chemokines that promote the

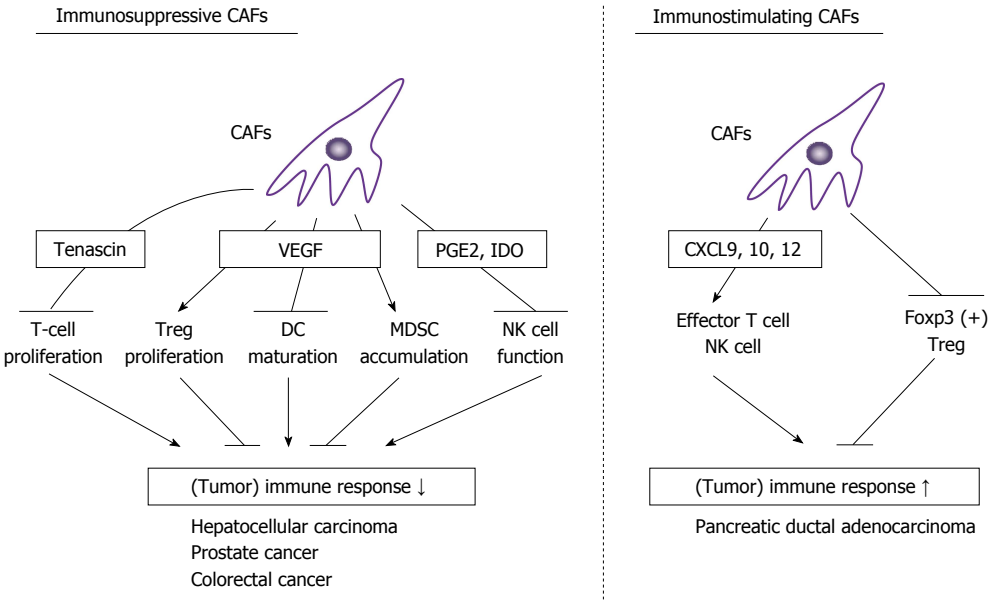

Figure 4 Double-edged actions of cancer associated fibroblasts in tumor immunity. CAFs exhibit double-edged actions in tumor immunity. In most types of cancers, CAFs can dampen tumor immunity by suppressing T cell proliferation, NK cell activity, and DC maturation, and inducing Treg proliferation and MDSC accumulation. In some types of cancers such as pancreatic ductal adenocarcinoma, CAFs can enhance tumor immunity by enhancing effector T cell and NK cell functions and depressing Treg activities. CAFs: Cancer associated fibroblasts; VEGF: Vascular endothelial growth factor; MDSC: Myeloid-derived suppressor cells; NK: Natural killer.

recruitment of effector T cells and natural killer cells, including CXCL9, CXCL10, and CXCL12[103]. If the latter chemokines are predominant chemokines produced by CAFs, they can enhance specific tumor immunity instead of suppressing it. Indeed, depletion of CAFs induces immunosuppression and accelerates pancreas cancer with reduced survival in a mouse pancreatic ductal adenocarcinoma (PDAC) model[11]. The immunosuppression is associated with increased Foxp3-positive Treg numbers and can be reversed by the immune checkpoint therapy using anti-CTLA4 antibody. Thus, in this model, CAFs restrain Tregs from expansion to keep tumor cells under immune surveillance.

CAFS AS A PROGNOSIS MARKER IN CRC

CAFs can be a useful marker to predict disease recurrence in patients with various type of cancer[10]. Similar observations are obtained on CAFs in CRC. Tumors with abundant α-SMA-positive CAFs are associated with shorter disease-free survival for stage Ⅱ and Ⅲ CRC after curative CRC surgery[104]. Likewise, high intra-tumor stroma proportion was associated with shorter overall and disease-free survival in stage Ⅱ and stage Ⅲ CRC patients after curative surgery[105]. CAFs express abundantly FAP-α and SDF-1/CXCL12. Colon cancer patients with high intra-tumor stromal FAP-α expression tend to have more aggressive disease progression and experience metastasis or recurrence[106]. Similarly, intra-tumor FAP-α and SDF-1 expression is shown to be involved in tumor re-growth and recurrence in rectal cancer patients treated with pre-operative chemo-radiation therapy[107].

The analysis was conducted on CAFs established from primary human colon cancer and revealed that CAFs exhibit significant differences in their promigratory effects on cancer cells upon co-culture with cancer cells[33]. Moreover, CAFs' promigratory effects on cancer cells are associated with fibroblast activation and stemness markers. CAF signature is identified from the gene expression signature derived from the most protumorigenic CAFs and shows a remarkable prognostic value for the clinical outcome of patients with CRC. Berdiel-Acer and colleagues conducted a transcriptomic profile of normal colonic fibroblasts, CAFs at primary tumor and CAFs at liver metastasis sites, and they identified 19-gene classifier that can predict recurrence with high accuracy in patients with CRC and correlates with fibroblast migratory potential[108]. Moreover, this 19-gene classifier can identify low-risk patients very accurately, and this identification is of particular importance for stage Ⅱ patients, especially T4N0 patients clinically classified as being at high risk, who would benefit from the omission of chemotherapy. The same group further developed a 5-gene classifier for relapse prediction in Stage Ⅱ/Ⅲ CRC by analyzing gene expression patterns in CAFs[109]. The 5-gene classifier in CAFs was significantly associated with increased relapse risk and death from CRC among stage Ⅱ/Ⅲ patients. These studies also proved the existence of heterogeneity in CAFs in terms of gene expression signatures.

Molecular classification of CRC based on global gene expression profiles have defined three subtypes;

chromosomal-instable tumor (CCS1), microsatellite-instable/CpG island methylator (CIMP)-positive tumor (CCS2), microsatellite-stable/CIMP-positive tumor (CCS3)[110]. CCS3 subtype exhibits upregulation of genes involved in matrix remodeling and EMT and has a very poor prognosis. However, a more detailed analysis revealed that their predictive power arises from genes expressed by stromal cells rather than epithelial tumor cells[111]. Moreover, functional studies indicate that CAFs can increase the frequency of tumor-initiating cells and that this enhancing effect is further augmented by TGF-β signaling. Furthermore, poor-prognosis CRC displays a gene program induced by TGF-β in tumor stromal cells. These observations would indicate that CAF-mediated gene expression profiles can be used to predict the prognosis of colon cancer patients.

CAF AS A TARGET FOR CANCER TREATMENT

Kraman and colleagues demonstrated that genetic depletion of FAP-expressing cells causes rapid hypoxic necrosis of both cancer and stromal cells in Lewis lung carcinoma-bearing mice depending on interferon-γ and TNF-α. They also demonstrated that depleting FAP-expressing cells allows immunological control of tumor[28]. However, the same group demonstrated that FAP-positive cells of skeletal muscle are the major local source of follistatin and that those in bone marrow express CXCL12 and kit ligand. As a consequence, experimental ablation of these cells causes loss of muscle mass and a reduction of B-lymphopoiesis and erythropoiesis[29]. Thus, it is probable that depletion of FAP-positive cells in tumor tissue can cause cachexia and anemia, and as a consequence, it may be difficult to target FAP to deplete CAFs.

We demonstrated the crucial involvement of the CCL3-CCR5 axis on AOM/DSS-induced colon carcinogenesis by recruiting and activating CAFs. Systemic delivery of a CCR5-antagonist-expressing vector is well tolerated by tumor-bearing mice and reduces significantly tumor mass together with decreased CAFs, when it is given even after multiple tumors develop[22]. An antagonist to another chemokine, CXCL12, inhibits CAF-mediated integrin β1 clustering at the cell surface and eventually the invasive ability of gastric cancer cells, suggesting that the inhibition of CXCL12/CXCR4 signaling in gastric cancer cells may be a promising therapeutic strategy against gastric cell invasion[112]. Moreover, CAF-derived CXCL12 can provide prostate cancer cells with the chemoresistance to a cytotoxic drug, docetaxel, and a CXCR4 antagonist can sensitize cancer cells to this drug in a subcutaneous xenograft model of prostate cancer[80]. PDAC-bearing mice frequently does not respond to immune checkpoint therapy with anti-programmed cell death ligand 1 (PD-L1) antibody despite the presence of tumor-specific CD8-positive cells, but depletion of FAP-positive CAFs uncovers the antitumor effects of anti-PD-L1 antibody and inhibits tumor growth[113]. Moreover, FAP-positive CAFs express CXCL12 and as a consequence, a CXCR4 antagonist also induces rapid T-cell accumulation among cancer cells and acts synergistically with anti-PD-L1 to greatly diminish cancer cells in pancreatic cancer model[113].

Normalization of CAFs is proposed as the strategy targeting CAFs. CAFs in prostate cancer exhibit reduced miR-15 and miR-16 expression, which is associated with the reduced post-transcriptional repression of Fgf-2 and its receptor Fgfr1[114]. The Fgf-2-Fgfr1 axis acts on both stromal and tumor cells to enhance cancer cell survival, proliferation, and migration. Moreover, reconstitution of miR-15 and miR-16 impairs considerably the tumor-supportive capability of stromal cells *in vitro* and *in vivo*[114]. Downregulation of miR-31 and miR-214 is observed in CAFs in ovarian cancer and the expression of these miRNAs induces a functional conversion of CAFs into normal fibroblasts[115]. Similar observations were also obtained on miR-31 and miR-148a expression in CAFs[116,117]. Phosphatase and tensin homolog deleted on chromosome 10 (Pten) expression in stromal fibroblasts suppresses epithelial mammary tumors. Pten-deficient mammary fibroblasts exhibit reduced miR-320 expression and reciprocally enhanced ETS2 expression, and can accelerate tumorigenicity when co-injected into mice with mouse mammary cancer cells[118]. miR-320 overexpression in fibroblasts reduces their tumorigenic activity upon co-injection with cancer cells[118]. These observations would indicate that the modulation of miRNA expression can reduce the protumorigenic capacity of CAFs, by dedifferentiating CAFs into normal fibroblasts.

Nintedanib is a broad spectrum tyrosine kinase inhibitor, with the VEGF receptor, FGF receptor, and PDGF receptor as target by binding the ATP pocket in a competitively reversible manner and is used as monotherapy for the treatment of idiopathic lung fibrosis (IPF)[119]. Nintedanib reduces lung inflammation and fibrosis in IPF as evidenced by the reduced deposition of type Ⅰ collagen and the inhibition of fibroblast activation. VEGF, FGF, and PDGF are secreted by CAFs as well as cancer cells and TAMs, and their receptors are expressed by CAFs, cancer cells, and endothelial cells[120]. Moreover, the mechanism of fibroblast activation in IPF closely resembles that in cancer[121]. Hence, nintedanib is proposed to be used as a second line therapy for non-small cell lung cancer in combination with docetaxel[122]. Another anti-fibrotic agent, pirfenidone, is used for the treatment of IPF although its exact molecular mechanisms remain enigmatic[123]. The combination of pirfenidone and cisplatin leads to increased CAF cell death and decreased tumor progression in a human non-small cell lung cancer xenografted model[124]. These observations would indicate that these anti-fibrotic

agents may be used for the treatment of cancer with abundant fibrotic changes.

Given the capacity of TGF-β as a potent fibrotic molecule[98], anti-TGF-β monoclonal antibody was developed and tested in clinical trials for several types of cancer. It can induce anti-tumor effects but simultaneously cutaneous keratoacanthomas/squamous cell carcinomas[125]. This may arise from double-edged activities of TGF-β; a tumor suppressor for normal epithelial cells and a tumor driver in tumor microenvironments[98].

FUTURE PERSPECTIVES

Accumulating evidence indicates the crucial involvement of inflammation in cancer development and progression[12]. Inflammation is a dynamic host response, wherein various types of cells participate in a concerted manner[4]. However, until recently, much attention has been focused on two processes involved in inflammation; neovascularization and inflammatory cell infiltration. Various agents have been developed as anti-cancer drugs, by targeting neovascularization, but with limited success[126]. Despite the remarkable successes of immunotherapies that modulate the adaptive immune system consisting of lymphocytes and dendritic cells[127], the plasticity and the heterogeneity of inflammatory leukocytes, monocytes/macrophages and granulocytes, have hindered the elucidation of the precise roles of these cells in carcinogenesis, and eventually the development of anti-cancer agents targeting inflammatory leukocytes[128]. Under these circumstances, fibroblasts, another type of cells in inflammation, have emerged as an important player in cancer-related inflammation[10,25,129].

CAFs express a NF-κB-dependent gene signature in mouse tumor models of skin, pancreatic and breast cancer[86]. These observations incited two independent groups to conduct fibroblast-specific deletion of the gene of *IKKβ*, which is indispensable to NF-κB activation and to examine the effects of the gene deletion on AOM/DSS-induced colon carcinogenesis[130,131]. However, the results are completely opposite to each other; Koliaraki *et al*[130] demonstrated a pro-tumorigenic activity of IKKβ whereas Pallangyo identified IKKβ as a tumor suppressor. A remarkable difference between these two groups seems to arise from the use of the different gene promoters to delete the *IKKβ* gene. Koliaraki *et al*[130] used type Ⅵ collagen gene promoter whereas Pallangyo and colleagues used type Ⅰ collagen gene promoter. The *IKKβ* gene deletion in type Ⅵ collagen-positive CAFs, decreased IL-6 production associated with decreased inflammation and suppressed tumor formation[130]. On the contrary, the *IKKβ* gene deletion in type Ⅰ collagen-positive CAFs, resulted in enhanced HGF production and subsequent tumor growth promotion[131]. Thus, CAFs as a whole may act to promote carcinogenesis but a part of them, particularly type Ⅰ collagen-positive ones, may still retain normal fibroblast-like phenotypes and functionality to suppress carcinogenesis, because normal intestinal fibroblasts can regulate intestinal homeostasis to suppress colitis-associated tumorigenesis[23].

Targeting CAFs can be a novel strategy to treat cancer, particularly inflammation-related cancer. In order to advance this strategy, however, more detailed and precise understanding of phenotypical and functional heterogeneity in CAFs is required to identify the CAF subpopulation and/or the molecules, which have crucial roles in cancer development and progression.

ACKNOWLEDGMENTS

We would like to express our sincere appreciation to Dr. Tomohisa Baba (Cancer Research Institute, Kanazawa University) for his critical comments on the manuscript.

Abstract

Colorectal carcinoma (CRC) is one of the most common types of cancer worldwide and the prognosis for CRC patients with recurrence or metastasis is extremely poor. Although chemotherapy and radiation therapy can improve survival, there are still numerous efforts to be performed. Immunotherapy is frequently used, either alone or in combination with other therapies, for the treatment of CRC and is a safe and feasible way to improve CRC treatment. Furthermore, the significance of the immune system in the biology of CRC has been demonstrated by retrospective assessments of immune infiltrates in resected CRC tumors. MicroRNAs (miRNAs) are short, non-coding RNAs that can regulate multiple target genes at the post-transcriptional level and play critical roles in cell proliferation, differentiation and apoptosis. MiRNAs are required for normal immune system development and function. Nevertheless, aberrant expression of miRNAs is often observed in various tumor types and leads to immune disorders or immune evasion. The immunomodulatory function of miRNAs indicates that miRNAs may ultimately be part of the portfolio of anti-cancer targets. Herein, we will review the potential roles of miRNAs in the regulation of the immune response in CRC and then move on to discuss how to utilize different miRNA targets to treat CRC. We also provide an overview of the major limitations and challenges of using miRNAs as immunotherapeutic targets.

Key words: Colorectal carcinoma; microRNAs; Tumor microenvironment; Immunotherapy; Inflammation; Inflammatory bowel disease; Immune response

Core tip: Colorectal carcinoma (CRC) is one of the most common tumor types worldwide. Immunotherapy has been used to treat advanced CRC and has the

potential to eradicate the disease by activating immune responses. MicroRNAs play critical roles in regulating anti-tumor immune responses. There is a need to summarize the current understanding of the diverse roles of microRNAs in the regulation of immune responses and their clinical applications for CRC immunotherapy.

INTRODUCTION

Colorectal carcinoma (CRC) is the third most common malignancy in males and the second in females, posing a serious demographic and economic burden worldwide[1,2]. Although surgical resection for patients with localized disease has dramatically improved 5-year survival rates, more than half of all patients diagnosed with CRC eventually develop recurrence and metastasis[3,4]. Current strategies such as chemotherapy are approved for the treatment of CRC; however, these non-surgical therapeutics have only modest efficacy and are ineffective against distant metastasis[5]. Moreover, traditional strategies generate reverse events, such as cytotoxicity, that limit their use[6]. Therefore, the prognosis of CRC patients remains poor and presents an opportunity to study future therapeutic approaches to improve clinical outcomes. Recently, immunotherapy has been used to treat advanced CRC and has the potential to eradicate the disease by activating immune responses[6]. Some clinical trials utilizing immunotherapy have demonstrated objective responses in CRC patients[7,8]. Moreover, immunotherapy, such as monoclonal antibody cetuximab, has immune-modulating effects in combination with traditional approaches, such as chemotherapy, thus resulting in an increase of circulating dendritic cells (DCs), natural killers (NK), central memory T cells and T-helper 1 (Th1) cells[9]. However, CRC is able to evade detection and elimination by the immune system, and the objective responses have been manifested in only a small fraction of patients with CRC[6]. For example, the lack of CRC-associated antigens limits the development of immunotherapy[6]. The important role of the immune system in the biology of CRC has been emphasized by retrospective assessments of immune infiltrates, affecting all aspects of CRC from tumorigenesis to treatment. Within the tumor microenvironment (TME), immune infiltrates can act as suppressors of tumor initiation and progression, as well as promote the proliferation, infiltration and metastasis of CRC[10]. The presence of tumor infiltrating lymphocytes, including CD8+ T cells, in the TME is strongly associated with a better prognosis[11]. Regulatory T cells (Tregs) suppress the proliferation and activation of CD4+ and CD8+ T cells and increased Tregs activation is correlated with poorer prognosis[12]. However, higher Tregs infiltration scores are correlated with overall survival, treatment-relative survival and progression-free survival. Therefore, higher Tregs infiltration score is a favorable prognostic factor in advanced colon cancer patients undergoing chemo or chemoimmunotherapy[13]. The immune evasion of CRC has complex mechanisms. The induction of immune tolerance and resistance to activated immune effectors are two important mechanisms of immune evasion[14]. Programmed death 1 (PD-1) is an inhibitory receptor that is overexpressed in nonfunctional and exhausted T cells in cancers[15]. PD-1 and the ligands for PD-1 (PD-L1) have been implicated in escape from the immune system by directly suppressing antitumor CD8+ T cells[16]. Furthermore, the recognition of tumor-associated antigens by immune effectors is one of the most important steps in antitumor immune responses. Thus, the dysregulation of antigens limits specific immune responses. For example, NY-ESO-1 is silenced in many tumor types. As a result, the immune system cannot attack cancer cells through the recognition of the antigen[17].

MicroRNAs (miRNAs) are approximately 19 to 25 nt in length and post-transcriptionally regulate gene expression in a sequence-specific manner by binding to the 3'-untranslated region, leading to either degradation of mRNA or a translation blockade[18,19]. MiRNAs have emerged as crucial modulators in various biological processes such as proliferation, tumor initiation and development[20]. Global dysexpression of miRNAs has been identified in tumors and has become a potential biomarker for tumor diagnosis, therapy and prognosis[19,21]. MiRNAs were displayed to function as oncogenes or tumor suppressors according to their target mRNAs. For example, miR-484 is significantly decreased in microsatellite instability (MSI) CRC and functions as a tumor suppressor to inhibit MSI CRC cell viability[22]. MiR-21 is upregulated in several tumors such as lung cancer, which promotes tumor cell growth and metastasis[20]. Recent studies have demonstrated that miRNAs are coming to light as a critical regulator of immune responses and its aberrant expression or dysfunction in the immune system has been associated with cancers[23-25]. MiRNAs can either inhibit or enhance immune signals by regulating the expression of the positive or negative components of immune signaling pathways. MiR-181a expression appears to control T cell sensitivity to antigens during T cell development and maturation by repressing the expression of multiple phosphatases in the TCR signaling pathway[26]. Signal transducer and activator of transcription 3 (STAT3) has been shown to play an important role in tumor-mediated mechanisms of immunosuppression[27]. MiR-124 was

found to target the STAT3 signaling pathway and exert potent therapeutic effects by enhancing immune effector responses in cancer[28]. Emerging evidence has demonstrated that immune-associated miRNAs are dysregulated in both tumor cells and immune cells, which suggests that miRNAs could be involved in communication between tumor cells and immune cells. MiR-124 is absent in all types of gliomas, and its upregulation in glioma cancer stem cells inhibits the STAT3 pathway and reverses stem cell-mediated immune suppression of T cell proliferation and Treg activation[28]. MiR-23a is upregulated in tumor-infiltrating cytotoxic T lymphocytes (CTLs) and impairs antitumor potential of patient CTLs by repressing the transcription factor B lymphocyte-induced maturation protein-1, which promotes CTL cytotoxicity and effector cell differentiation[29]. In addition to CTLs, miRNAs can regulate other immune cells, such as Th1 cells and NK cells. The members of miR-17-92 cluster miR-17 and miR-19b are the important regulators modulating Th1 responses through multiple coordinated biologic processes[30]. Moreover, miR-29 suppresses Th1 responses through the combined direct suppressive effect on T-bet, eomesodermin and interferon γ (IFN-γ)[31,32]. NK cells play critical roles in the innate immune system, contributing to the early detection and destruction of transformed cells[33]. MiRNAs have critical roles in controlling NK cell activation, survival and function[34]. Recent report has demonstrated that ovarian tumor-associated miR-20a decreases NK cell cytotoxicity by directly repressing MHC class I chain-related molecules A and B expression[35]. However, the immunomodulatory roles of miRNAs in CRC still need to be further explored. Therefore, in this review, we summarize the current understanding of the diverse roles of miRNAs involved in immune responses in CRC. We also discuss the clinical applications of miRNAs in CRC immunotherapy and the limitations and challenges in future use.

REGULATION OF IMMUNE-RELATED MIRNA BIOGENESIS IN CRC

Primary miRNAs are processed into mature miRNAs through multiple biochemical steps. Our previous review[18] and other excellent reviews[19,20,36] have illustrated the mechanism of miRNA biogenesis. Thus, we will not discuss it further here. In the process of miRNA biogenesis, the RNase III endonuclease Dicer plays a critical role in the generation of miRNAs[37]. Dicer has been reported to regulate miRNA biogenesis in Tregs[38]. Depleting miRNAs by silencing Dicer generates functional miRNAs, reduces Treg cell numbers and results in immune pathology[38]. Previous studies have found that Dicer is required, in a cell-autonomous fashion, for the development of Tregs in the thymus[38]. However, the mechanism by with the expression of Dicer in tumor cells regulates immune surveillance through miRNA processing needs to be deeply explored. Indeed, Dicer depletion upregulates intercellular cell adhesion molecule 1 (ICAM-1) and enhances the susceptibility of CRC cells to antigen-specific lysis by CTLs[39]. ICAM-1 plays an important role in physical and functional interactions between cancer cells and CTLs[40]. Furthermore, Dicer-disrupted CRC cells have downregulated expression of miR-222/339, which directly target ICAM-1 mRNA. Upregulation of ICAM-1 by repressing Dicer or miR-222/339 in CRC cells contributes to increased susceptibility of tumor cells to antigen-specific CTLs[39]. Thus, Dicer is responsible for the generation of the mature miR-222/339, which repress the expression of ICAM by binding to the 3'UTR, thereby reducing the susceptibility of tumor cells to CTL-mediated cytolysis. These findings indicate the viability of the development of novel miRNA-targeted therapy to promote cytolysis of tumor cells in tumor immunotherapy.

MIRNAS REGULATE IMMUNE RESPONSES IN THE CRC TME

MiRNAs involved in immunotherapy in CRC cells

Multiple studies have demonstrated that miRNAs play key roles in CRC tumor biology including tumor initiation, progression, invasion and metastasis, and immune responses[41-43] (Figure 1). Several miRNAs have been found to directly regulate the primary pathways of CRC initiation and development. The development of CRC follows the sequential progression from adenoma to malignant adenocarcinoma[44]. Tumor protein 53 (TP53) is frequently lost during the progression of adenoma to adenocarcinoma[45]. TP53 loss mediates apoptosis and cell cycle arrest through the inhibition of a direct downstream target, miR-34a[46]. Increased miR-17-92 cluster expression from adenoma to adenocarcinoma is associated with the transcriptional activity of c-myc, which induces the expression of miR-17-92[47]. Uncontrolled growth and proliferation are key components in the colorectal tumorigenesis. The dysfunction of the PI3K pathway and its associated proteins plays important roles in the cell cycle regulation of CRC. MiR-144 has been found to inhibit the PI3K pathway by negatively regulating mTOR[48]. Emerging evidence has demonstrated that miRNAs are most frequently associated with the invasion and metastasis of CRC. Upregulation of miR-21 positively regulates invasion and metastasis by directly targeting several tumor suppressor genes, including programmed cell death 4 (PDCD4)[49] and phosphatase and tensin homolog (PTEN)[50] in CRC. MiRNAs could regulate CRC cell invasion and metastasis through the epithelial to mesenchymal transition (EMT). Activation of EMT allows CRC cells to migrate and metastasize to distant organs. Recent studies suggested that miRNAs are new EMT regulators and regulate CRC metastasis.

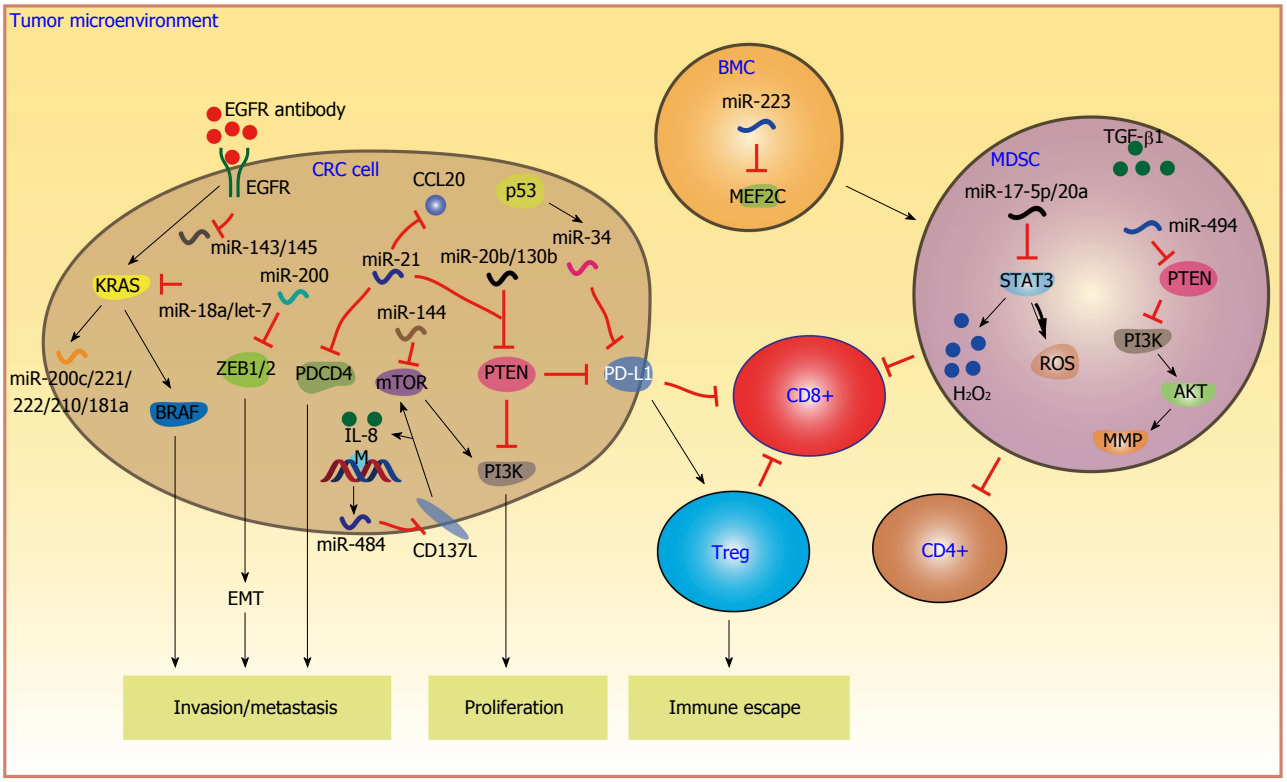

Figure 1 MicroRNAs control colorectal carcinoma progression through modulating anti-tumor immune responses in tumor microenvironment. MiRNAs play important roles in colorectal carcinoma (CRC) biology, including tumor proliferation, invasion/metastasis and immune responses. For example, miR-20b and miR-130b repress the expression of PTEN and increase the activity of PI3K, leading to the increased viability of CRC cells. MiR-21 promotes CRC invasion and metastasis by directly targeting PDCD4. Furthermore, miR-34a enhances CD8+ T cells cytotoxicity by repressing the expression of PD-L1, contributing to the elimination of CRC cells by CTLs.

Downregulation of the miR-200 family has been found to induce EMT by targeting zinc finger E-box binding homeobox 1/2 (ZEB1/2) in CRC cells, which results in the development of CRC metastasis[51-53]. Therefore, the dysregulation of miRNAs is involved in the full range of CRC development.

According to previous reports, the immune system plays complex and multi-faceted roles in CRC, affecting all aspects of CRC initiation and metastasis[10]. The body's immune system can act both to suppress tumor initiation and progression, as well as promote malignancies. During tumorigenesis, normal cells transform into neoplastic cells through multifactorial processes that involve genetic and epigenetic factors, leading to the immune escape of tumor cells. Immune escape plays a key role for the success of tumor cell growth and survival through developing multiple suppressive mechanisms in the TME[54]. More recently, miRNAs have been observed to play important regulatory roles in the immune system. The abnormal expression of co-inhibitory molecules of PD-L1 in the TME has been identified as an important immunosuppressive mechanism in many tumor types, and contributes to tumor immune escape by inhibiting T cell activation and proliferation[55]. Furthermore, PD-L1 expression in tumor cells may be associated with the expansion of Tregs in the TME, which suppresses the activation and proliferation of effector T cells[16,56,57]. MiR-20b, -21 and -130b are upregulated in advanced CRC and inhibit PTEN expression, resulting in PD-L1 overexpression[58]. PTEN, a famous tumor suppressor gene, plays a critical role in CRC cell growth, proliferation and the occurrence of CRC[59]. This study revealed a novel mechanism of PD-L1 protein expression mediated by miRNAs indirectly, which leads to the immune escape of CRC. Moreover, miR-34 has been found to modulate tumor escape by directly targeting PD-L1 in lung cancer[60]. MiR-34a therapy elicits the activation of tumor-infiltrating immune cells (CD8+ T cells) and decreases exhausted tumor-infiltrating immune cells (PD1/CD8+), indicating an active immune response and reduced tumor tolerance[60]. These results suggest that the miRNA-PD-L1 axis may be a therapeutic target for CRC immunotherapy and miRNAs may be implicated in checkpoint blockade therapy.

Cancer immunotherapy has the potential role to eliminate tumor cells by eliciting immune responses through the recognition of tumor-specific antigens on tumor cells. Numerous studies have reported that monoclonal antibody (mAb)-based immunotherapy against tumor antigens is a promising strategy and has been clinically effective as CRC therapeutics[54]. Antibodies targeting tumor antigens block major

pathways central to tumor cell proliferation and survival. Anti-human epidermal growth factor (anti-EGFR) antibodies, such as cetuximab and panitumumab, have been approved and routinely used for the treatment of CRC[54]. EGFR, commonly overexpressed in CRC, leads to the stimulation of the oncogene KRAS that subsequently activates BRAF, which contributes to the promotion and progression of a broad spectrum of CRC[61]. These two antibodies can trigger tumor antigen-specific cellular immunity to eliminate CRC cells. Recent studies have demonstrated that miRNAs could serve as predictive or prognostic biomarkers for anti-EGFR therapy in patients with wild-type KRAS (wt-KRAS) metastatic CRC (mCRC). Anti-tumor immune responses of antibody and EGFR signaling pathway have been shown to be regulated by miRNAs. MiR-31-3p/5p have been confirmed to be strongly associated with time to progression in wt-KRAS mCRC patients treated with cetuximab but not panitumumab, suggesting that miR-31-3p/5p should not be used as a predictor of response to panitumumab[62]. Two reasons could explain the predictive role of miR-31-3p/5p for cetuximab: one associated with concomitant chemotherapy, and the other with different immune responses linked to cetuximab and panitumumab[54]. Furthermore, the expression level of miR-31-3p is associated with progression-free survival, indicating that miR-31-3p seems to be a new mCRC biomarker for anti-EGFR therapy[63]. Significant miR-31* upregulation and miR-592 downregulation show a marked difference in progressive disease compared to disease control[64]. Moreover, the upregulation of some miRNAs, such as let-7 and miR-140-5p, as well as the downregulation of miR-1224-5p are significantly associated with poor overall survival, revealing that in mCRC patients with wt-KRAS/BRAF, miRNA profiling can efficiently predict the prognosis after anti-EGFR treatment[64]. Interestingly, miRNAs can also directly or indirectly target EGFR signaling pathway and its signaling components. Therefore, miRNAs-EGFR signaling has been validated as a therapeutic target in CRC. EGFR has been found to control and negatively regulate the expression of miR-143 and miR-145 in CRC cell lines, two famous tumor suppressive miRNAs, which suggests that inhibition of EGFR may upregulate the expression of these two miRNAs and suppress tumor growth and progression[65]. According to previous reports, wt-KRAS, a major factor that drives CRC progression, is a necessary condition for anti-EGFR treatment and it can be activated by the stimulation of EGFR[66]. Several miRNAs, miR-143, miR-145, let-7 and miR-18a*, act as tumor suppressors and repress the expression of KRAS[61]. In contrast to targeting KRAS, KRAS can regulate the expression of miRNAs. Recent studies have demonstrated that KRAS upregulates the expression of some oncogenic miRNAs, including miR-200c, miR-221/222, miR-210 and miR-181a[67]. These miRNAs act as oncogenic miRNAs and promote CRC progression. Therefore, the extensive involvement of miRNAs in regulating EGFR signaling pathway and its components suggests that miRNAs could serve as promising predictive biomarkers and therapeutic targets for anti-EGFR therapy in CRC.

MiRNAs regulate stromal cells

Tumor tissues have two distinct regions: the tumor bed and TME. TME comprises fibroblasts, various immune cells and endothelial cells, along with extracellular matrix, proteases and cytokines[68]. TME represents an integral part of tumors and establishes dynamic interactions with tumor cells that influence tumor growth, metastasis and immune tolerance. Stromal cells, including cancer-associated fibroblasts (CAFs), myeloid-derived suppressor cells (MDSCs) and mesenchymal stem cells (MSCs), are important components of TME and can shape anti-tumor immunity and responsiveness to immunotherapy[68]. MDSCs are a heterogeneous group of myeloid cells in early differential stages and one of the major elements of the immunosuppressive network responsible for effector T cell defective response in cancer[69]. A previous report has found that the number of blood MDSCs correlates with the stage and metastasis in many tumor types, including CRC[70-72]. MDSCs could inhibit the host immune response in tumor cells by interfering with immune cell responsiveness to interferons α and γ in CT26 bearing mice[70]. Although MDSCs contribute to immune invasion *via* suppression of anti-tumor functions of CD4+ and CD8+ T cells, the molecular mechanisms involved in the expansion, function and infiltration of MDSCs are not fully understood. Numerous studies have demonstrated that miRNAs play key regulatory roles in MDSC development, expansion and function. Recently, miR-17-5p and miR-20a have been found to alleviate the suppressive potential of MDSCs in the CT26 colon carcinoma model[73]. The overexpression of miR-17-5p and miR-20a remarkably reduces the expression of reactive oxygen species (ROS) and the production of H_2O_2 by modulating the expression of STAT3. Furthermore, MDSCs transfected with miR-17-5p and miR-20a are less able to suppress antigen-specific CD4+ and CD8+ T cells. Thus, the modulation of miR-17-5p and miR-20a expression may play important roles for the process by which patients with a tumor can overcome the immune tolerance mediated by MDSCs and could potentially be applied in immunotherapy against CRC. Increased expression of miR-17-5p and miR-20a, which are members of the miR-17-92 cluster, can promote tumor development in cancer cells. However, miR-17-92 members block the immunosuppressive function of MDSCs by silencing STAT3 expression. These studies indicate that the functional diversity of miR-17-92 cluster may result from the different targets subjected to miR-17-92

post-transcriptional silencing in different cell types, different developmental or physiological contexts[73]. MiR-494, whose expression is mainly upregulated by TGF-β1, has been identified as an essential player in the regulation of the accumulation and activity of MDSCs by targeting PTEN and activating the PI3K/AKT pathway[74]. Upregulation of miR-494 represses PTEN expression, resulting in increased activity of AKT pathway, and facilitates tumor cell invasion and metastasis by upregulating of MMPs in murine breast and colon cancers. These findings revealed that TGF-β1-induced miR-494 expression in MDSCs plays a critical role in regulating the accumulation and functions of MDSCs and may be identified as a potential target in cancer immunotherapy. Emerging studies have demonstrated that CD11b+Gr1+ MDSCs play an important role in the suppression of T cell responses and the induction of T cell tolerance in tumors[75]. MiR-223 has been identified to be related to myeloid development in myeloid expansion and differentiation[76]. The expression of miR-223 was downregulated during the differentiation of CD11b+Gr+ MDSCs from bone marrow cells (BMCs) upon exposure to tumor-associated factors. Moreover, overexpression of miR-233 remarkably inhibits differentiation of BMCs into MDSCs by targeting myocyte enhancer factor 2c, which promotes the accumulation of MDSCs.

In addition to regulating stoma cells, miRNAs also play key roles in modulating the expression of cytokines or chemokines in TME. Chemokines, which are chemo-attractant cytokines and are primarily known as critical regulators of the immune system, have been implicated in malignant transformation and tumor progression[77]. In the TME, specific chemokines have been found to be responsible for the recruitment of leukocytes into tumor sites[78]. In addition, chemokines also play an important role in the functionally of tumor cells and other cells in TME, which together modulate the processes of tumor development and progression[79]. Emerging evidence has demonstrated that various miRNAs can regulate different chemokines in the TME of CRC. Chemokine CCL20 was shown to regulate CRC progression and metastasis through binding to its receptor CCR6[80]. Moreover, CCL20 and its receptor CCR6 are significantly increased in CRC[81]. Interestingly, miR-21, a well-known oncomiR, has been identified to target CCL20 in CRC cells[82,83]. Ectopic expression of miR-21 downregulates CCL20 gene expression in different cell lines. These results seem to indicate that miR-21 acts as a tumor suppressor in this situation. However, for functional interaction of miR-21 with CCL20, both the two molecules must be present in the same cell. Furthermore, miR-21 and CCL20 are both significantly upregulated in CRC tissues. It is well-known that TME is composed of tumor cells and various types of stromal cells, such as fibroblasts and endothelial cells, as well as various immune cells. Thus, this suggests that miR-21 and CCL20 may not be expressed in the same cell in the TME of CRC. Actually, CCL20 expression found in CRC tissues is largely restricted to mesenchymal cells, such as macrophage and lymphocytes, in the TME[83]. Likewise, miR-21 expression is primarily detected in stromal cells, such as CAFs, and immune cells, such as macrophages, but not within tumor cells and lymphocytes in the TME of CRC tissues[83]. These data clearly exclude the chance of miR-21 and CCL20 being expressed in the same cell of TME. It may also be speculated that CCL20 secreted by infiltrated-immune cells affects miR-21 expression in CAFs through the CCR6 signaling pathway. In our recent report, we found that methylation-induced loss of miR-484 in MSI CRC promotes both cell viability and IL-8 (also known as CXCL8) production by targeting CD137L[22]. CD137, a member of the TNF superfamily, can induce cell viability by triggering the activation of the PI3K and mTOR signaling pathways[84]. Moreover, CD137L can signal back to tumor cells and induce the production of IL-8, which can promote tumor invasion by the recruitment of tumor-associated macrophages and neutrophils. However, CD137L expressed in CRC cells also functions as a co-stimulatory molecule for the production of IFN-γ by human T cells. Thus, these results may indicate that miR-484 can play a suppressive role in anti-tumor immune responses in MSI CRC through repressing the expression of CD137L. It seems to suggest that MSI is detrimental to immunotherapy for CRC treatment. MSI is the molecular feature of a mismatch repair deficient (dMMR) system[85]. Interestingly, the immunotherapy PD-1 blockade is more effective against dMMR tumors[86]. The reason may be that the increased number of mutation-associated neoantigens in dMMR tumors stimulated antitumor immune responses.

INFLAMMATION-RELATED MIRNAS IN CRC TUMORIGENESIS

Unique miRNA profiles

Chronic inflammatory disorders are often associated with an increased risk of CRC tumorigenesis[87,88]. CRC is preceded by clinically detectable inflammatory bowel disease (IBD), such as Crohn's disease (CD) and ulcerative colitis (UC)[88]. Because of chronic damage to the colon and rectum in IBD, these patients are at increased risk for CRC. Increasing evidence has demonstrated that miRNA dysregulation is an important pattern in IBD. Elevated miR-150 was found in UC and reduced the expression of c-myb, a transcription factor known to regulate the anti-apoptotic protein, BCL-2[89]. Several studies have found that increased cytokines, such as TNF, IL and interferon, cause apoptosis and play important roles in intestinal epithelial cells[90]. Apoptosis can interrupt intestinal mucosal integrity and barrier function and eventually result in inflammation[91]. MiR-29a has been

found to promote intestinal epithelial apoptosis in UC by directly targeting myeloid cell leukemia 1, which is an anti-apoptotic BCL-2 family member and essential for the survival of multiple cell lineages[92]. Although both CD and UC are subtypes of IBD, the expression patterns of miRNAs show region-specific differences and are expressed differently. Eight different miRNAs could be used to distinguish active CD from active UC[93]. Moreover, the expression of miR-23b/106/191 was increased in active UC tissues, while miR-19b/629 were decreased in Crohn's colitis patients[94]. Given these common changes in miRNA expression profiles in IBD, these miRNAs may be involved in regulating central components of the immune system.

MiRNAs regulate inflammatory signaling pathways

Numerous studies have demonstrated that miRNAs can regulate many inflammation associated pathways in IBD. The IL-6-STAT3 signaling pathway plays an important role in IBD and specifically STAT3 is up-regulated in UC[95,96]. This pathway regulates the development of UC and has been implicated in the progression of UC to CRC[97]. Recently, miRNAs have been identified as a potent regulator of STAT3 activity in human colonocytes. MiR-124 is downregulated in children with active UC, resulting in increased levels of STAT3 expression and the transcriptional activation of its downstream targets, which could promote inflammation and the pathogenesis of UC in children[98]. The vitamin D receptor (VDR) is highly expressed in the epithelial cells of the gut mucosal epithelial barrier and plays a critical role in maintaining the integrity of the mucosal epithelial barrier by suppressing inflammation-induced intestinal epithelial cell apoptosis[99]. Epithelial VDR levels are reduced by more than 50% in IBD and promote colitis[99]. MiRNAs have been identified to be involved in the downregulation of VDR. Pro-inflammatory cytokine TNF-α suppresses epithelial VDR expression through induction of miR-346[100]. TNF-α is one of the most important cytokines in regulating the development of colitis, and anti-TNF therapy is a standard therapy in the management of IBD[101,102]. Thus, the use of TNF-α, which as an inflammatory mediator inhibiting VDR, will have promising clinical applications. Further, TNF-α is markedly increased and may serve as an objective index of inflammatory activity in human UC. A recent report has found that miR-19a, which is downregulated in UC, directly targets the expression of TNF-α, and induces the expression of downstream inflammation targets IL-8 and granulocyte-macrophage colony-stimulating factor[103]. Immune dysregulation is thought to play a critical role in the pathogenesis of CD[104]. Cytokines are involved in immune regulation and the dysregulation of cytokines contributes to heightened inflammation[105]. Therefore, cytokine signaling pathways may be useful targets for CD treatment. MiR-19b has been reported to regulate cytokine signaling by directly targeting suppressors of cytokine signaling[106]. SOCS proteins are important physiological regulators of immune responses and negatively regulate cytokine expression through the JAK/STAT pathway[107]. Thus, this study will provide potential evidence for the development of miR-19b-based anti-inflammation therapies for CD treatment. Neurotensin (NT) is a neuropeptide expressed in the central nervous system and the intestine, while NT receptor 1 (NTR1), the high-affinity receptor of NT, is expressed in neurons and colonic epithelial cells[108]. In the colon, the NT/NTR1 signaling pathway can promote inflammation in acute colitis and their expression increases in patients with UC[109]. NT induces miR-133a expression in colonic epithelial cells[110]. Moreover, miR-133a modulates NT-induced MAP kinase and NF-κB activation, as well as transcription of pro-inflammatory cytokines, such as IL-6/8/1β, by inhibiting aftiphilin (AFTPH) expression[110]. This study may represent a promising strategy to inhibit miR-133a and restore AFTPH expression for the treatment of IBD.

MiRNAs regulate immune responses

Immune responses play important roles in connecting inflammation and CRC. IBD has been connected to predisposing genetic factors that contribute to abnormal immune responses. For example, adaptive immune system related genes that have been linked to IBD include components of the IL-23 signaling pathway, which are required for induction of Th17 cells[111,112]. Interestingly, a recent study has found that the intracellular sensor nucleotide-binding oligomerization domain protein 2 (NOD2) can induce miR-29 expression in human DCs to limit IL-23 release[113]. NOD2 is required for the induction of miR-29; miR-29 downregulates IL-23 and attenuates Th17 cell responses in CD. Activation of NOD2 has a key role in influencing the release of pro-/anti-inflammatory cytokines, particularly IL-1belta/6/8/23[114,115]. Furthermore, activation of NOD2-dependent pathways contributes to the induction of NF-κB, as well as the activation of JNK and p38 MAPK[116,117]. NOD2 not only induces miRNA expression but also has been identified as a functional downstream target of several miRNAs. MiR-122[118] and miR-192[119] can directly target NOD2 and suppress the expression of NOD2. Ectopic expression of these two miRNAs inhibits NOD2 expression, NF-κB activation and immune responses. Furthermore, miRNAs are also pivotal regulators of Th17 cells differentiation and function. MiR-210 has a particularly important role in regulating Th17 cell lineage, and is a signature miRNA of hypoxia[120]. The expression of miR-210 increases rapidly in hypoxia-challenged Th17 cells[120]. Hypoxic conditions inhibit degradation of the subunits of hypoxia-inducible factor 1 (HIF-1) and lead to their stabilization[121,122]. HIF-1 plays important roles in regulating Th17 differentiation[123].

Intriguingly, miR-210 directly targets HIF-1α, reduces HIF-1α transcript abundance and the proportion of cells that produce inflammatory cytokines, and controls IBD severity[120]. In addition to regulating Th cell differentiation, miRNAs can regulate leukocyte migration by targeting chemokines. MiR-141 regulates colonic leukocyte trafficking *via* directly targeting CXCL12β during intestinal inflammation of CD[124]. The miR-141-CXCL12β pathway contributes significantly to the development of CD, likely by affecting the recruitment of immune cells into the inflamed colonic tissue. Therefore, repressing colonic CXCL12β and immune cell recruitment with miRNAs represents a feasible and promising strategy that may be valuable for the treatment of CD. Moreover, the expression of a number of intestinal epithelial cell-derived chemokine is regulated by miRNAs. MiR-192 was dramatically upregulated in UC and regulated the expression of macrophage inflammatory peptide-2α (MIP-2α), which is a chemotactic chemokine secreted by colonic epithelial cells and macrophages[125]. Recently, miRNAs have been found to regulate gut mucosal immunity *via* epithelium-T-cell crosstalk. MiR-375 regulates gut mucosal immunity by modulating the differentiation of goblet cells, and targets the expression of thymic stromal lymphopoietin and resistin-like molecule-β, a Th-2-facilitating epithelial cytokine and an important goblet cell effector, respectively[126].

IBD and CRC are related to dysregulation of the intestinal immune system and of the microbiota[127]. The gut microbiota provides constant immunological signals to intestinal tissues, thus a variety of regulatory mechanisms have evolved to ensure proper development and function of the intestinal immune system. MiRNAs have been demonstrated to regulate expression of genes involved in microbial recognition and downstream immune activity. Thus, miRNAs play a key role within the intestinal immune system during its interactions with the gut microbiota[128]. Nine miRNAs are differentially expressed in the colon of germ-free mice colonized with the microbiota; the upregulation of miR-665 significantly downregulates the ATP-binding cassette sub-family C member 3[129], which belongs to the multidrug resistance-associated protein family[130]. MiR-146a represses a subset of gut barrier and inflammatory genes and restricts the expansion of intestinal T cell populations, including Tregs, Th17 and T follicular helper cells[131]. Furthermore, the regulatory effect of microbiota on miRNA expression and on the maintenance of intestinal homeostasis has been investigated. The expression of miR-10a and its targets IL-2/IL-23p40 play important roles in regulating innate immune responses to commensal bacteria in DC[132]. These studies open new perspectives for the investigation of miRNA regulation in intestinal diseases and microbiota. Furthermore, a variety of bacterial infection can trigger inflammasome formation and activation[133]. Inflammasomes are large cytosolic protein complexes that promote immediate inflammatory responses and regulate intestinal homeostasis through its effects on the intestinal microbiota[134,135]. The inflammasomes have potentially critical roles in the development and pathogenesis of IBD, because of their important role in intestinal immunity[135]. Emerging evidence has demonstrated that inflammasomes can influence intestinal microbiota. Some reports have exhibited that mice lacking various components of the inflammasome showed prototypical alterations in their microbiota, predisposing these mice to the development of IBD[136]. Inflammasomes have important roles in IBD, whereas the mechanisms of inflammasome formation and activation in the onset of intestinal diseases have not yet been fully established. MiRNAs may be regulators in inflammasomes formation and activation. Although only few reports explore the role of miRNAs in modulating inflammasomes in intestinal diseases, some works have been carried out in other disease types[137,138]. In the future, more investigations should illustrate novel understandings on miRNA and inflammasome interactions, which will potentially lead to the discovery of new treatment approaches for intestinal disease or CRC.

PERSPECTIVES AND CHALLENGES

The limitations of surgery and chemo/radio therapies to treat CRC patients necessitate the development of novel strategies, including immunotherapy. Tremendous progress has been made in understanding the role of the immune system in driving the development of CRC. Immune cell markers could be used to predict CRC outcomes[11], while targeting various aspects of the immune system could be used to generate anti-tumor immune responses. Unfortunately, effective immunotherapy in CRC treatment remains elusive. The ultimate goal of immunotherapy is to recruit the immune effectors to destroy cancer cells. However, immune escape leads to the failure of immunotherapy. It has been proposed that cancer cells use immune escape to evade the recognition and killing by the host immune system. For example, the expression of B7, a co-stimulatory molecule, has been found to be involved in CRC progression and immune escape mechanism[139]. Furthermore, STAT3 regulates key pathways that mediate immune escape in the TME[140,141]. Therefore, novel approaches need to be identified to overcome immune escape. Although several trails utilizing cancer vaccines or immune-checkpoint therapies have demonstrated objective responses in immunized patients with mCRC, more work is needed.

MiRNAs are deregulated and play critical roles in CRC. Initially, miRNAs have been found to act as oncogenic or tumor suppressor genes and regulate tumorigenesis, angiogenesis, progression, invasion and metastasis. The discoveries of miRNAs have

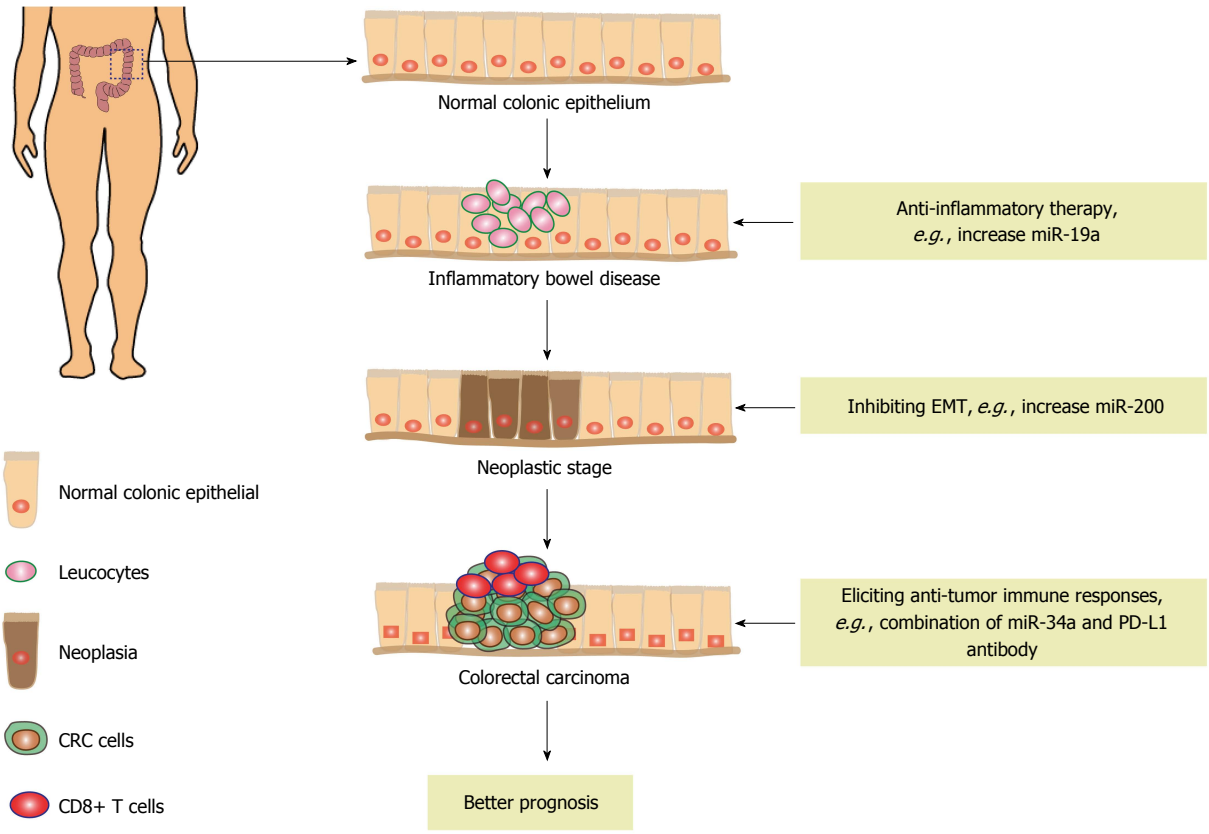

Figure 2 MiRNA-based immunotherapy in multi-steps colorectal carcinoma tumorigenesis. Various immune-related miRNAs have been identified that are dysregulated during colorectal carcinoma (CRC) tumorigenesis. These findings can be used to prevent and treat CRC in different pathological stages. In IBD stage, miRNAs and their specific targets are ideally anti-inflammatory targets. For example, overexpression of miR-19a inhibits inflammatory response through targeting TNF-α. During the stage that normal colonic epithelium transforms to neoplasia, miRNA can be utilized to suppress EMT. For example, increased miR-200 reverses EMT and represses the neoplastic cells. In the CRC stage, in addition to traditional approaches, combination of immune-related miRNAs and existing immunotherapeutic strategies can elicit anti-tumor immune responses. For example, combination of miR-34a and PD-L1 antibody can eliminate tumor cells through eliciting tumor-infiltrating CD8+ T cells. The patients with CRC receiving miRNA-based immunotherapy will have better prognosis.

opened a new era of CRC research and the potential of novel therapies for CRC treatment (Figure 2). Recently, miRNAs have been identified to regulate immune responses in CRC. The fact that miRNAs regulate tumor behaviors through targeting multiple genes, including immune associated genes, makes them excellent candidates for gene therapy. Therefore, the ability to use miRNA-based therapy to restore a dysfunctional immune system to a healthy state needs to be deeply studied. Generally, restoring the expression of tumor suppressor miRNAs or inhibiting the expression of oncogenic miRNAs has been employed for the development of miRNA-based therapeutics. In this regard, an example such as inducing miR-34a expression has been found to elicit tumor-infiltrating CD8+ T cells activation by targeting PD-L1[60]. Actually, an miR-34 mimic (MRX34) has become the first miRNA to enter phase I clinical trial (NCT01829971). The study was started to evaluate the safety of MRX34 in patients with unresectable primary liver cancer or other selected solid tumors, such as renal cell carcinoma, non-small cell lung cancer and melanoma. Targeted therapy and immunotherapy, such as PD-1 antibodies, in melanoma have led to a marked improvement in patients' survival and their quality of life[142]. Therefore, the miRNA-target mRNA axis may be another novel immunotherapeutic target for cancer treatment. For example, STAT3 has been identified to play a pivotal role in a wide variety of tumor-mediated immunosuppression and is one of the first candidates that researchers assessed for potential miRNA binding. MiR-124 can enhance immune effector responses by directly inhibiting the activation of the STAT3 signaling pathway[28]. Because aberrant activation of STAT3 pathway occurs in each stage of CRC tumorigenesis, including inflammation, adenoma and carcinogenesis, targeting diverse miRNA-STAT3 axes in specific pathological stages may improve therapeutic efficacy. In addition, combinational therapies are promising approaches for CRC immunotherapy. As shown above, PD-L1 is the target of miR-34. MiR-34 therapy and PD-L1 monoclonal antibody therapy combinations will elicit stronger anti-tumor immune responses. Furthermore, miRNAs are known to target networks of genes and this may provide a unique therapeutic advantage. Therefore, altering the expression of multiple miRNAs simultaneously by repressing distinct targets is a potential approach for CRC treatment.

MiRNAs exhibit diverse immunomodulatory effects through their action on multiple mRNA species because they control many important immunological processes. Although great efforts have been made to discover the precise role of miRNAs in anti-tumor immune response regulations, there are many challenges for the development of miRNA-based immunotherapy. These challenges include screening tissue-specific profiles, target identification, safe delivery to specific tissue, off-targets and biological safety. According to previous reports, miRNA expression is deregulated in tumor tissues compared to normal tissues and each patient has specific miRNA profiles. Thus, the ability to identify distinct miRNAs to treat CRC needs to be deeply explored. Moreover, although many computational algorithms have been developed to identify potential targets, many critical functional miRNA targets could not be identified due to the inability of bio-informatics predictions to find miRNA binding sites with seed mismatches[143]. Fortunately, novel approaches have been developed to overcome these limitations. The major challenge in miRNA-based immunotherapy is the safe delivery to specific tissues without side effects. Moreover, there are challenges to ensure miRNAs to reach the TME rather than other organs. To overcome these delivery and biological safety hurdles, some effective and marketable strategies, such as viral and non-viral strategies, have been developed[144,145]. However, novel approaches are needed to determine the efficacy of immune responses in clinical applications. In addition, another obstacle faced is whether exogenous miRNAs can precisely regulate their appeal targets in tumor cells. Therefore, there is a long way to go before we resolve many technical and biological challenges. Nevertheless, the successful development of miRNA-based immunotherapy has attracted the attention of many researchers.

Abstract

Although monoclonal antibodies (mAbs) against epidermal growth factor receptor (EGFR) have largely enriched the available therapeutic choices for colorectal cancer (CRC), the understanding and management of their associated clinical toxicities are limited. In addition, the combined strategies of administering EGFR mAbs and traditional cytotoxic agents, such as 5-fluorouracil, oxaliplatin and irinotecan, have resulted in a more complicated management of CRC treatment-related side effects compared with EGFR mAb monotherapy. We believe that a thorough recognition of the toxicities of EGFR mAb drugs is essential for physicians to increase the therapeutic index in the treatment of CRC. This review aims to summarize the existing information regarding the treatment dilemmas of cetuximab combined with chemotherapy in the management of metastatic CRC.

Key words: Cetuximab; Colorectal cancer; Metastatic; Toxicity; Chemotherapy

Core tip: The advent of epidermal growth factor receptor monoclonal antibodies (EGFR mAbs), especially cetuximab, has provided a meaningful transformation in the available treatment options for advanced colorectal cancer (CRC). Nevertheless, their efficacy is accompanied by some undesired complications. Additionally, combination treatments comprising EGFR mAbs and traditional cytotoxic agents have resulted in a more complex management of CRC treatment-related side effects. Therefore, it is imperative to understand and appropriately address the treatment dilemmas of cetuximab combined with chemotherapy for the management of metastatic CRC.

INTRODUCTION

Colorectal cancer (CRC), one of the most commonly diagnosed malignancies, is the third leading cause of cancer-related deaths, with more than 600000 worldwide[1]. It is predicted that nearly 123 million new cases are diagnosed yearly, although the incidence has declined in long-term records[1]. Nevertheless, approximately 50% of patients have metastatic disease when first diagnosed, and among the 60% of patients with an initial curative intent, approximately 25%-40% will suffer from disease recurrence or progression[2,3]. Hence, the treatment of metastatic disease plays a key role in the management of advanced CRC, the cost of which accounts for an appreciable global healthcare burden.

Notably, with the advent of new biologic drugs during the last decade, an unprecedented surge of new treatment strategies for the management of advanced CRC has been witnessed. Consequently, the overall survival of patients with advanced CRC has been extended and their quality of life has improved significantly. According to reviews of institutional databases since 2004, which is when novel therapeutic drugs became available, the median overall survival of patients with advanced CRC has recently increased from 18 mo (95%CI: 15.8-20.2 mo) to almost 29.2 mo (95%CI: 24.3-34.2 mo)[4,5]. Moreover, the 5-year relative survival rates have changed significantly from 51% of patients diagnosed during 1975-1977 to 65% of patients treated from 2004 to 2010[1]. Therefore, considerable pharmacological advancements in recent years have transformed CRC from a disease that is rapidly lethal to one that can be managed chronically for 2-3 years (Figure 1).

Most of these new biologics should work effectively in combination with at least one of the chemotherapy regimens. The combination of 5-fluorouracil (5-Fu) plus leucovorin (LV) with the addition of irinotecan (iri) or oxaliplatin (oxa) is recommended as the primary backbone chemotherapy for advanced CRC[6,7]. Despite extensive chemotherapy treatments, even including the new biological agents, the clinical outcomes in CRC remain limited, and increasing severity of toxicity is often observed. Therefore, there is an urgent need to improve the accurate selection of treatment strategies for individuals based on the expected clinical outcomes and accompanied toxicities. Ultimately, advanced knowledge of molecular medicine might guide clinicians to select the right treatment regimen for individual patients[8]. This review aims to summarize the existing information regarding the treatment dilemmas of cetuximab (Cmab), one of the epidermal growth factor receptor (EGFR) monoclonal antibodie (mAb), combined with chemotherapy, including 5-Fu, oxa and iri, for the management of metastatic CRC.

MECHANISM OF CETUXIMAB EFFICACY

Targeting EGFR and its ligands' pathways is a promising treatment strategy because it is reported that approximately 25%-77% of CRC cases exhibited overexpression of EGFR as well as its ligands, including EGF and transforming growth factor α (TGF-α)[9,10]. Notably, mAbs targeting EGFR have had a profound beneficial effect in the treatment of CRC since the clinical application of Cmab was approved by the United States Food and Drug Administration in 2004 followed by the authorization of panitumumab (Pmab) two years later[11]. Significant improvement was achieved in the CALGB80405 trial, which showed that the OS of CRC patients reached 29.93 mo with Cmab treatment combined with chemotherapy; in particular, the OS was 30.1 mo for the Cmab and mFOLFOX6 (oxaliplatin/5-FU/leucovorin) combination[12].

Cetuximab is a human/mouse recombinant immunoglobulin G1 mAb that has a higher affinity for the extracellular domain of EGFR than other ligands, such as EGF and TGF-α. The binding of Cmab to EGFR prevents intracellular ligand-mediated receptor-related tyrosine kinase phosphorylation, resulting in the inhibition of downstream signaling pathways, including the RAS-RAF-MAPK and PI3K-Akt/mTOR pathways[13]. Consequently, the antitumor effects of Cmab are due to multiple mechanisms: (1) cell proliferation suppression: Cmab arrests the cell cycle in G1 phase and, consequently, the number of S-phase cells is decreased. This effect is a result of the increased expression of p27KIP1, a CDK2 inhibitor, and the over phosphorylation of Rb protein[14]. Then, apoptosis-associated proteins are activated, including the induction of BAX, the release of Smac and the activation of caspase 8. As a result, the number of cells arrested in G1 declines; (2) antiangiogenesis: the production of angiogenic factors is reduced by the inhibition of EGFR pathways; for example, the production of vascular endothelial growth factor (VEGF), basic fibroblast growth factor, and interleukin-8 (IL-8) is decreased, which contributes to a decline in microvessel density and enhanced endothelial cell apoptosis[15]; (3) antibody-dependent cellular cytotoxicity might be induced[16]; and (4) cancer metastasis-related matrix metalloproteinases are decreased by the inactivated EGFR. Hence, cell adhesion is reduced and metastasis is further down-regulated. The anti-tumor effect has been demonstrated in EGFR-expressing CRC cells and nude mice *in vivo*. Additionally, the combination of Cmab and chemotherapy drugs or radiotherapy exhibits significant tumor inhibition in nude mice bearing CRC cell xenografts[17].

MECHANISM OF CETUXIMAB TOXICITY

Notably, Cmab has achieved demonstrable clinical anti-cancer efficacy, and awareness of the underlying mechanism is essential in the management of advanced CRC. Cmab is a chimeric mAb against EGFR, namely, the immunoglobulin's constant region

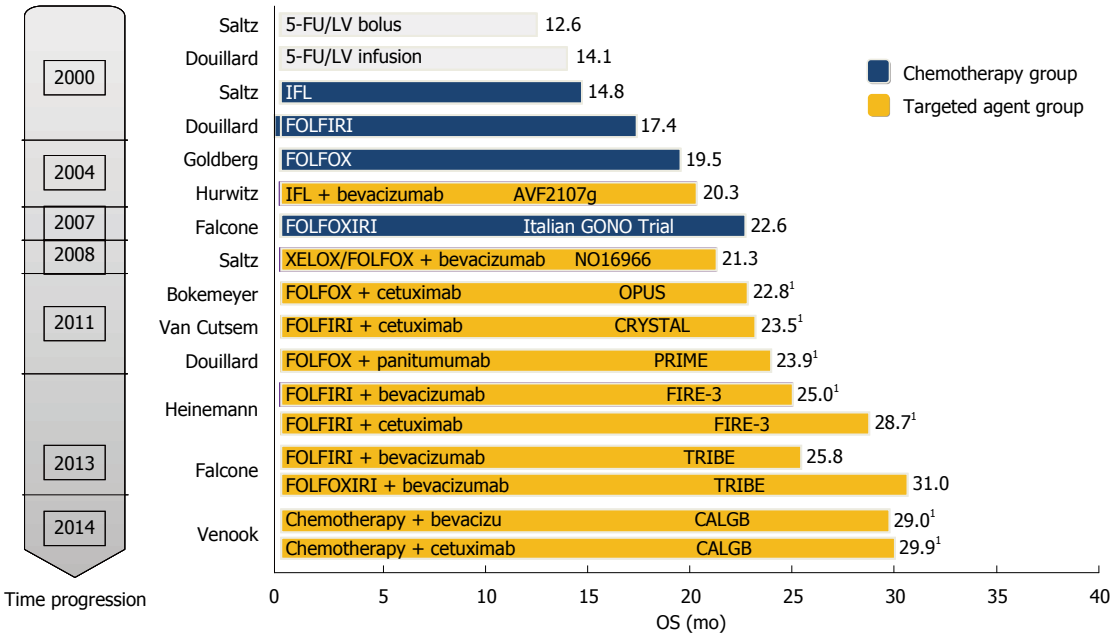

Figure 1 Development of cytotoxic and targeted agents for the treatment of colorectal cancer. [1]KRAS wide-type patients. CRC: Colorectal cancer; 5-FU: 5-fluorouracil; LV: Leucovorin; IFL: Irinotecan + 5-fluorouracil + leucovorin; FOLFOXIRI: Leucovorin + 5-fluorouracil + oxaliplatin + irinotecan.

is derived from humans, but the variable domain is derived from mice[18]. Hence, the nonhuman nature of these early antibodies leads to inflammatory reactions with repeated administrations, which might be related to the increasing immunogenicity of recipients[19,20].

According to Lee *et al*[21], to better understand of the toxicity-associated mechanism, adverse events should be distinguished into two categories: target-related (on target) and agent-related (off-target) toxicities. Generally, on-target adverse events cannot be avoided because of the specific target the agent inhibited, and they should be managed proactively. By contrast, off-target toxicities are the result of the cross-inhibition of unintended targets or cross-interaction with undesired pathways, and they are related to the specificity of the targeted agents. In addition, the pharmacokinetics are closely related to the toxicities and are determined by the inter-individual variations of drug absorption, distribution and metabolism. Consequently, ABC drug transporter polymorphisms and the cytochrome P450 genotype of the patient could be pharmacogenetic contributors to adverse events[22,23]. Importantly, it has been suggested that the mAbs could induce immune activity indirectly in a known non-allergic, cytokine-associated process of infusion reaction[24]. Chung *et al*[25] found that a high frequency of infusion reactions was significantly related to elevated circulating anti-cetuximab IgE levels pretreatment.

RECIPROCAL INTERACTIONS BETWEEN CETUXIMAB AND CYTOTOXIC CHEMOTHERAPEUTIC REGIMENS

With the increasing emergence of targeted agents, optimization of therapeutic drugs has received widespread attention, especially the choice of chemotherapy backbone and mAbs or antiangiogenic regimens. Until now, the combination of 5-Fu or oral capecitabine (cap) with either oxa (FOLFOX), XELOX, iri (FOLFIRI) or XELIRI (cap and iri) has been recommended as the standard treatment combined with targeted agents for patients with advanced CRC[7]. Hence, there is an urgent need to determine how best to integrate these regimens to achieve clinical outcomes with a high efficacy but low toxicity. To better understand the reciprocal interactions between chemotherapy regimens and targeted agents, the current study reviewed clinical trials from January 2002 and March 2015 collected from the PubMed, American Society of Clinical Oncology annual meeting, gastrointestinal cancer symposium and European Society for Medical Oncology databases; the clinical trials were phase 3 or multicenter, randomized phase 2 trials studying the FDA recommended target drugs combined with cytotoxicity chemotherapies for the first-line treatment of CRC. Research studies involving adjuvant, neo-adjuvant and maintenance regimens of CRC were excluded. Moreover, incomplete studies without safety results were also excluded.

It must be noted that Cmab has contributed greatly to improving the clinical outcome of CRC, with a prolonged OS of more than 30 mo (Figures 2 and 3, and Table 1). Of the multi-chemotherapies, FOLFIRI and FOLFOX are the most commonly used. Nevertheless, some unpredictable toxicity related to the combination occurred (Figures 2 and 3). An overview of the figures showing the adverse events of Cmab and chemotherapies reveals that the incidence of grade 3/4 hand-foot syndrome was 13%-35%,

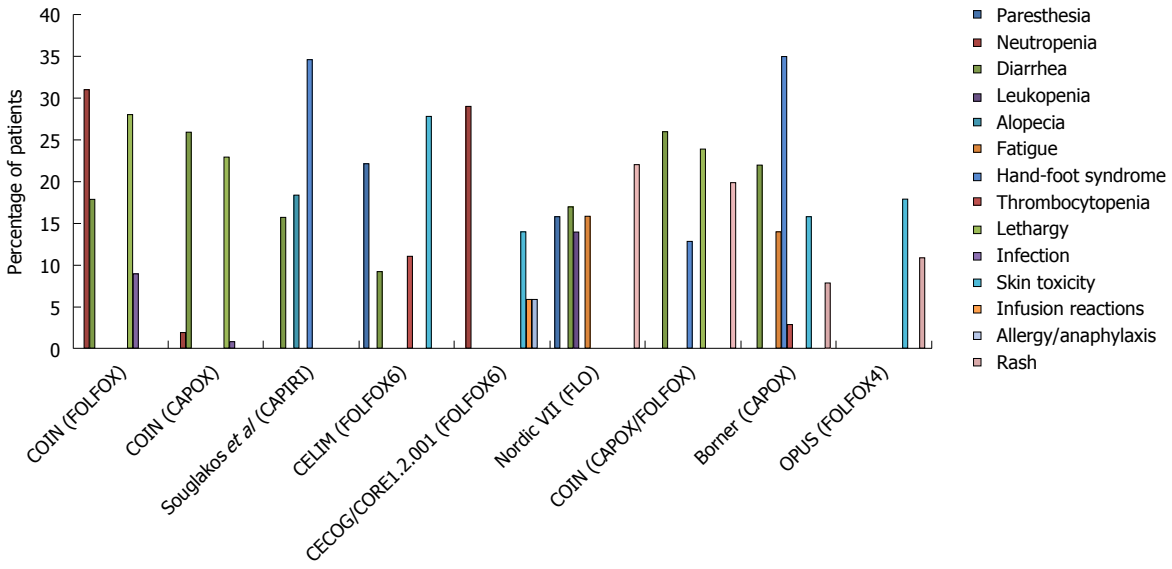

Figure 2 Toxicity of cetuximab combined with oxaliplatin-based chemotherapy summarized from the published clinical trials. FOLFOX: Leucovorin + 5-fluorouracil + oxaliplatin; CAPOX: Capecitabine + oxaliplatin; CAPIRI: Capecitabine + irinotecan; FLOX: 5-fluorouracil/leucovorin bolus + oxaliplatin.

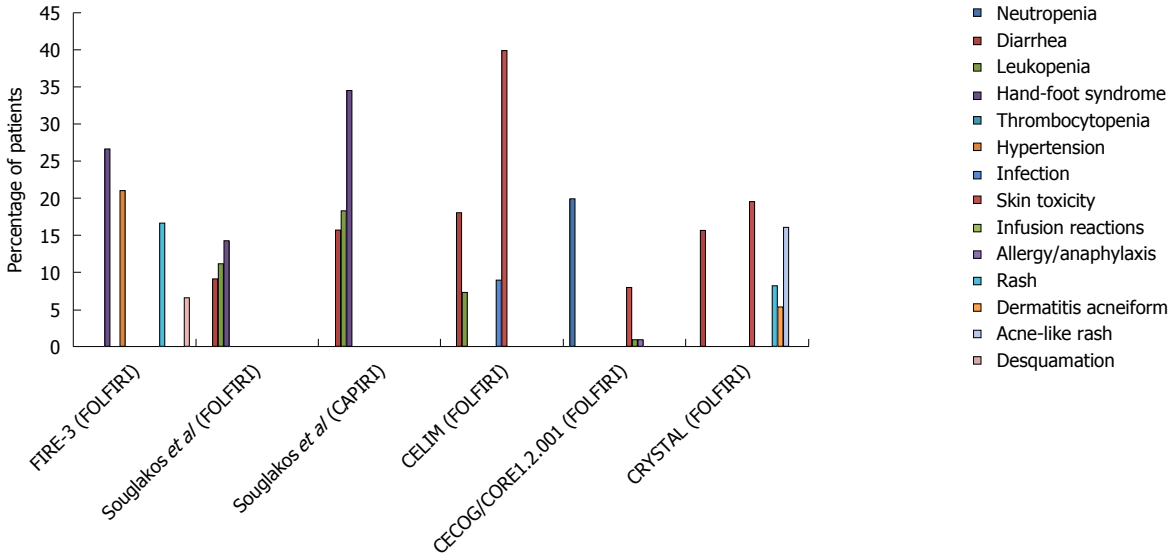

Figure 3 Toxicity of cetuximab combined with irinotecan-based chemotherapy summarized from the published clinical trials. FOLFIRI: Leucovorin + 5-fluorouracil + irinotecan; CAPIRI: Capecitabine + irinotecan.

followed by skin toxicity (8%-40%); diarrhea, neutropenia and lethargy were also common.

The efficacy and toxicity mechanism of Cmab and oxa-based chemotherapies is perplexing. In 2001, oxa was recommended as a cytotoxicity backbone for the treatment of adjuvant and advanced chemotherapy settings by the United States Food and Drug Administration[26,27]. As a conventional partner of Cmab, the regular regimens were FOLFOX in the PRIME, OPUS, and COIN trials; FLOX in the NORDIC VII trial; and XELOX in the COIN trial. However, the outcomes were distinctly different. The outcomes become more confusing when considering the results of CALGB80405, which added another layer to the already puzzling situation.

The interaction of Cmab and oxa is a double-edged sword - the interaction has shown both synergistic and antagonistic effects *in vitro*. First, the combined administration enhanced cell cycle arrest and induced cell apoptosis by elevating pro-apoptotic proteins, such as Bax and Caspase 8; meanwhile, it reduced the expression of anti-apoptotic proteins, for example, Bcl-2, and NF-κB was also decreased[28]. Second, the level of AKT phosphorylation, a target of the EGFR downstream pathway, was increased after the administration of oxa, which was apparently inhibited by Cmab[28]. Third, Cmab promoted the oxa anti-tumor efficacy by suppressing the DNA repair system, which involves increasing platinum-DNA adducts; inducing apurinic or apyrimidinic sites; and

Table 1 Cetuximab combined with cytotoxic chemotherapeutic regimens for the first-line treatment of advanced colorectal cancer

Name of study	Clinical trial phase	*n*	Chemotherapy	OS (mo)	PFS (mo)
FIRE-3[55-57]	3	171	Cmab + FOLFIRI	33.1	10.2

OS: Overall survival; PFS: Progression-free survival; Cmab: Cetuximab; N: Number of patients analyzed in the study; CRC: Colorectal cancer; WT: Wild type; CT: Chemotherapy treatment; FOLFIRI: Leucovorin + 5-fluorouracil + irinotecan; FOLFOX: Leucovorin + 5-fluorouracil + oxaliplatin; CAPOX: Capecitabine + oxaliplatin; CAPIRI: Capecitabine + irinotecan; Nordic FLOX: 5-fluorouracil/leucovorin bolus + oxaliplatin.

decreasing Claspin, CDC45 and CDC6 levels expressed at the beginning of DNA replication[29]. Prewett *et al*[30] found that Cmab decreased the phosphorylation of ERK1/2 and AKT, resulting in the inhibition of ERCC1 and XPF. Additionally, Balin-Gauthier *et al*[29] reported that the mRNA level and protein expression of ERCC1 and XRCC1 declined after treatment with Cmab[31]. Last, EGFR expression in CRC cells increased when stimulated by oxa, which sensitized the treatment with Cmab[32,33]. By contrast, Cmab inhibited NOX1 expression, which assisted NADPH, as a coenzyme, to produce ROS. When the levels of ROS produced by the cell was reduced, the anti-tumor effect induced by oxa was also reduced[34,35].

It is known that oxa alone has little efficacy, and its activation requires fluoropyrimidine as a partner. Moreover, the toxicity of oxa-based chemotherapy and Cmab combination was different (Figure 2), varying with the mode of administration of fluoropyrimidine (infusional 5-Fu, bolus 5-Fu, and cap). Preclinical research studies addressing the question of the optimal administration method of 5-Fu are rare. One study showed that the longer the infusion time, the more significant the suppression of thymidylate synthase (TS)[11,36]. In that study, three different 5-Fu-sensitive human cancer cell lines, gastric cancer, colorectal cancer and breast cancer, were exposed to 5-Fu for either one hour or 24 h repeatedly. The 5-Fu concentration was fixed, and the two treatments had equivalent effective doses. The results showed that cells exposed to one-hour of 5-Fu developed resistance more rapidly than those exposed to 24 h of 5-Fu. Additionally, only a small fraction of one-hour exposed cells was cross-resistant to a 24-h treatment, whereas obvious cross-resistance was seen for 24-h exposed cells to a one-hour schedule. Moreover, increasing TS expression was observed in all of the 24-h exposed cells, but in only one cell line treated with one-hour 5-Fu. Hence, the author concluded that the effect of 5-Fu was determined by the mode of application because the inhibition of TS was more significant with a prolonged infusion time. Although the preclinical data are limited, the efficacy of 5-Fu infusion application has been demonstrated by clinicians. Aschele *et al*[37] suggested that the application schedule and biochemical modulators of 5-Fu-based chemotherapy determine the relationship between intratumoral TS levels and clinical outcomes.

Meanwhile, Cmab promotes 5-Fu activity by inhibiting TS[36,38]. Skvortsov *et al*[39] illustrated that in EGFR-overexpressed CRC cell lines, such as Caco-2, HRT-18, HT-29, WiDr and SW-480, TS expression were suppressed, whereas in the EGFR-negative cell line SW-620, inhibition disappeared. Additionally, the combined treatment of 5-Fu and Cmab was related to a synergistic activation of the MAPK pathway. The *in vitro* results were consistent with a meta-analysis showing that the efficacy of oxa and Cmab combination was optimized by infusional 5-Fu[40].

The efficacy and toxicity mechanisms of Cmab and iri-based chemotherapies are quite clear compared with those of the oxa and Cmab combination. According to clinical trial results, iri is the only cytotoxic agent combined with all targeted drugs that is recommended in the first-line treatment of CRC. The reciprocal interactions of Cmab and iri result in reduced DNA damage repair, increased SN-38 plasma concentration and enhanced suppression of the EGFR signaling pathway. Chu *et al*[41] found that the EGFR inhibitor could reduce SN-38 excretion by suppressing ABB1 *in vivo*. The researcher studied the influence of Cmab on the iri concentration and its effective metabolite SN-38 in mice *via* HPLC analysis. Human CRC xenografted nude mice were generated and treated with oral iri alone or with iri following pretreatment with Cmab. They found that the AUC of SN-38 in the plasma and tumors of mice given the combined treatment was nearly 1.7-fold higher than that in mice treated with iri alone, which demonstrated that Cmab was associated with the distribution of iri into tissues. In addition, Yashiro *et al*[42] suggested that EGFR inhibitors decreased the expression of uridinediphosphoglucuronate glucuronosyltransferase 1A1 (UGT1A1) and ABCG2 to prolong the active ingredient concentration. However, the improved

efficacy did not occur without toxicity. The common adverse events of the combination treatments include hand-foot syndrome, which occurs at a rate as high as 34.6%; diarrhea, which occurs at a rate of approximately 15%; and skin toxicity (Figure 3).

COMMON ADVERSE EVENTS AND SUGGESTED MANAGEMENT

Dermatologic

Of particular note, dermatologic toxicities have received considerable attention in clinical practice because of their prognostic role in Cmab treatment[23,43,44]. As the most common side effect related to anti-EGFR therapy, the incidence of all grades of rash is as high as 45%-95%, of which 5%-18% are grades 3 or above[43]. Papulopustular eruption, also known as acneiform rash, is the most common dermatologic adverse event induced by EGFR inhibitor treatment. In addition, nail changes, ocular changes, hair changes, pruritis, photosensitivity, xerosis and erythema also appear during Cmab treatment[44]. Usually, the rash occurs within two to three days following initiation of Cmab treatment, and it worsens within one to three weeks. Although not life threatening, the dermatologic toxicities are significantly related with impaired quality of life, especially in younger patients because of the discomfort and detriment in some obvious locations, such as the face[45,46].

Indeed, oral minocycline or doxycycline is suggested as a prophylactic treatment during Cmab treatment. In addition, broad-spectrum sunscreen should be applied to reduce sunshine exposure, and alcohol-containing skin products should be avoided. For dry skin, emollients and mild topical steroids, such as 1% hydrocortisone cream twice or three times a day, are suggested. For papulopustular eruptions, topical antibiotics should be administered. For moderate pruritus or tender skin rashes, 0.1% triamcinolone or 2.5% hydrocortisone cream is recommended. The Cmab treatment should be adjusted once a grade 3 rash appears, and oral corticosteroids or even oral antibiotics are administered to these patients.

Gastrointestinal/hepatobiliary

Gastrointestinal toxicities are common adverse events for traditional chemotherapy regimens and are also a common toxic effect of targeted therapies. The frequency of diarrhea and colitis of all grades is 20%-66%, and it is 2%-16% for grade 3 or above. In addition, 38%-43% of patients exhibit elevated transaminase elevation and 7% to 32% from mucositis/stomatitis[43]. The appearance of diarrhea is due to widespread mucosal inflammation, from oropharyngolaryngeal inflammation to frank stomatitis. It is reported that the mechanism of this diarrhea is associated with Notch signaling pathway inhibition, which results from the transformation of proliferative undifferentiated intestinal crypt cells into secretory goblet cells[47-49]. Regarding the elevated transaminase levels, this increase might be associated with the inhibition of UGT1A1, the polymorphic variants of which contribute to isolated hyperbilirubinemia in Gilbert's syndrome[50,51].

To treat diarrhea and colitis, the cause of diarrhea should be determined along with the administration of anti-motility agents, for example, loperamide and diphenoxylate/atropine, especially for patients who have received chemotherapy combined therapy. Alcohol- or peroxide-based mouthwashes should be avoided in the management of mucositis and stomatitis, and anesthetic mouthwashes should be administered at the same time. If infection is found, antifungal agents should be applied. Liver function laboratory investigations should be taken at baseline and at least once monthly if transaminase is elevated during treatment. If the aspartate aminotransferase (AST) or alanine aminotransferase (ALT) levels are above 53 upper limits of normal (ULN), treatment should be withheld. If the AST or ALT levels are less than 33 ULN, treatment can be resumed at a reduced dose.

Hypomagnesemia

Hypomagnesemia often occurs as a metabolic abnormality during Cmab treatment, and the frequency of all grades is 11%-38%, of which 4%-5% is grade 3 or 4[43]. A positive association has been demonstrated between total treatment duration and defective renal magnesium reabsorption, and the age and baseline serum magnesium concentrations are negatively associated with hypomagnesemia[52]. The activity and distribution of the transepithelial magnesium channel TRPM6 is regulated by EGF, resulting in excretion of renal magnesium. In addition, Thebault *et al*[53] and Groenestege *et al*[54] discovered an *EGFR* gene point mutation that contributes to isolated hypomagnesemia.

The suggested management is the optimal management of diarrhea. Significant QT-prolongation potential medications should be avoided. Oral supplementation should be used if necessary. Patients with grade 2 hypomagnesemia should be given a weekly intravenous infusion of replacement magnesium. Treatment should be initiated for patients with grade 3/4 or symptomatic hypomagnesemia, and intravenous magnesium should be increased to every 2-3 d.

Ocular

Corneal abnormalities (keratoconjunctivitis, corneal ulceration) and corneal epithelium are the direct ocular toxicity effects of Cmab, and Cmab indirectly affects the associated glands and appendages, resulting in indirect adverse effects (meibomitis, cicatricial ectropion, dry eye). The incidence of all-grade ocular toxicity is reported to be 4%-18%, of which less than

1% is above grade 3[43].

The advised management of ocular toxicity is to continue the treatment. Artificial tears are applied if necessary, and antibacterial ointment should be used if infection is confirmed. Ophthalmologic evaluation is recommended for patients with vision changes, persistent eye pain, photosensitivity or presence of other drug-induced ocular anomalies, such as trichiasis. For patients with grade 3 symptoms, treatment should be withheld.

CONCLUSION

The advent of EGFR mAbs, especially Cmab, has provided a meaningful transformation in the available treatment options for CRC. Nevertheless, although the application of these targeted drugs has yielded a tremendous benefit for patients with advanced CRC and although these drugs have even outperformed conventional chemotherapies, their efficacy is accompanied by some undesired complications. In addition, combination treatments comprising EGFR mAbs and traditional cytotoxic agents, such as 5-fluorouracil, oxa and iri, have resulted in a more complex management of CRC treatment-related side effects compared with EGFR mAb monotherapy. We believe that a thorough recognition of the toxicities from EGFR mAbs is essential for physicians to evaluate the potential risks into the correct context of clinical benefit. Therefore, it is imperative to understand and appropriately address the treatment dilemmas of cetuximab combined with chemotherapy for the management of metastatic CRC.

Currently, investigations of precise drug mechanisms are needed to refine existing drugs, to develop new targeted therapies and to optimize amenable therapeutic settings for personalized medicine. However, the existing research to precisely guide regimen and dose selection and to better reveal the mechanisms of interactions related to efficacy and toxicity is limited. Hence, more information is needed, especially for the reciprocal interactions between iri/oxa-based chemotherapies and mAbs. Additionally, a better understanding of the mechanisms of targeted agents regarding their activity, metabolism and resistance is also urgently needed to employ these combined therapies most effectively. Finally, an improved knowledge of robust markers of prognosis and toxicity is vital to implement treatment strategies and accurately select patients. Consequently, emerging molecular technologies will result in a definitive treatment for colorectal cancer.

Abstract

AIM: To develop a potent and safe gene therapy for esophageal cancer.

METHODS: An expression vector carrying fusion suicide gene (yCDglyTK) and shRNA against vascular endothelial growth factor (VEGF) was constructed and delivered into EC9706 esophageal cancer cells by calcium phosphate nanoparticles (CPNP). To achieve tumor selectivity, expression of the fusion suicide gene was driven by a tumor-specific human telomerase reverse transcriptase (hTERT) promoter. The biologic properties and therapeutic efficiency of the vector, in the presence of prodrug 5-fluorocytosine (5-FC), were evaluated *in vitro* and *in vivo*.

RESULTS: Both *in vitro* and *in vivo* testing showed that the expression vector was efficiently introduced by CPNP into tumor cells, leading to cellular expression of yCDglyTK and decreased VEGF level. With exposure to 5-FC, it exhibited strong anti-tumor effects against esophageal cancer. Combination of VEGF shRNA with the fusion suicide gene demonstrated strong anti-tumor activity.

CONCLUSION: The shVEGF-hTERT-yCDglyTK/5-FC system provided a novel approach for esophageal cancer-targeted gene therapy.

Key words: Esophageal cancer; Suicide gene; RNA interference; Vascular endothelial growth factor; Nanoparticles

Core tip: Esophageal cancer is a highly aggressive neoplasm with poor prognosis and low survival rates. In this study, an expression vector carrying a fusion suicide gene (yCDglyTK) and shRNA against vascular endothelial growth factor (VEGF) was constructed and delivered into EC9706 esophageal cancer cells by calcium phosphate nanoparticles (CPNP). To achieve tumor selectivity, the expression of the fusion suicide gene was driven by a tumor-specific human telomerase reverse transcriptase promoter. Our results showed that the novel expression vector was efficiently introduced into EC9706 cells by CPNP, leading to cellular expression of yCDglyTK and decreased VEGF level. With exposure to 5-fluorocytosine, it exhibited strong anti-tumor effects against esophageal cancer both *in vitro* and *in vivo*. Combination of VEGF shRNA with the fusion suicide gene demonstrated strong anti-cancer effects. Our study provides a novel approach for esophageal cancer-targeted gene therapy.

Tumor-specific expression of shVEGF and suicide gene as a novel strategy for esophageal cancer therapy. *World J Gastroenterol* 2016; 22(23): 5342-5352 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5342.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5342

INTRODUCTION

Esophageal cancer is one of the most prevalent cancers in the world. It has high incidence and mortality rates, especially in Africa, East Asia, and North America[1]. Histologically, the most common type of esophageal cancer is esophageal squamous cell cancer (ESCC), which accounts for more than 90% of all cases[2]. Despite advances in diagnosis and treatment of ESCC during recent years, postoperative survival rates have not improved in the last decade. The 5-year overall survival rate is still less than 20%[3,4]. Novel and effective treatments are urgently needed for esophageal cancer.

Gene therapy has been recognized as a promising strategy for cancer treatment[5]. Among various gene therapy approaches, suicide gene therapy holds great promise since suicide gene expression can be manipulated to a particular tissue[6]. It transfers prodrug-activating enzyme genes into cancer cells. These genes encode enzymes that can catalyze non-toxic prodrugs into cytotoxic agents to confer drug sensitivity to certain types of cells[7]. Cytosine deaminase (CD) and herpes simplex type I thymidine kinase are the two most intensively studied suicide genes. Previous studies showed that a fusion gene (CDglyTK) of yeast cytosine deaminase (yCD) and thymidine kinase (TK) was more effective than either single suicide gene[8]. In addition, suicide gene expressed in localized areas of tumor can produce high local concentration of cytotoxic agent [*e.g.*, 5-fluorouracil (5-FU)], thus killing the neighboring tumor cells[9]. Expression of yCDglyTK, together with the treatment of prodrug 5-fluorocytosine (5-FC) exhibited targeted therapeutic effects[10-12].

A major limitation for the clinical use of suicide gene therapy for cancer is its proneness to cause side effects due to a lack of tumor specificity. The tissue-specific expression of suicide genes in tumor cells could be achieved by taking advantage of certain tumor-specific transcription regulatory elements, such as promoters and enhancers[13]. A number of tumor-specific promoters were employed in previous studies[14,15], and among them, the human telomerase reverse transcriptase (hTERT) promoter demonstrated the greatest tumor specificity[10]. The hTERT promoter is inactive in normal somatic cells[16,17] and may enable tumor-selective pharmaceutical effects of therapeutic genes.

Angiogenesis plays a vital role in the process of growth and metastasis of solid tumors[18]. Vascular endothelial growth factor (VEGF) has been found to be an important angiogenesis factor in cancer development[19]. It exerts various biological effects on the growth and spread of tumors, including induction of proteinases, cell mitogenesis, cell migration, increase of vascular permeability, and survival maintenance of newly formed blood vessels. Overexpression of VEGF

has been found in about 60% of esophageal carcinoma cases[20,21]. Downregulating VEGF may be a potential targeted treatment strategy for esophageal cancer[22].

Another key consideration for developing a successful gene therapy system is improving transfection efficiency while minimizing toxicity and enhancing stability[23,24]. A number of viral vectors and non-viral plasmids have been developed for gene therapy. However, viral vectors have some serious drawbacks, such as triggering immune response[25], severe hepatic inflammation[26], random chromosomal integration[27], and cytotoxicity to host cells[28]. Non-viral vectors are considered more promising as gene delivery vehicles because they are safe, easy to synthesize, cost-effective, and have a low degree of immunogenicity[29]. In our previous work, we developed the calcium phosphate nanoparticle (CPNP) as a novel non-viral tool for efficient gene delivery[11,12,30]. CPNP-delivered suicide genes mediated tumor specific cytotoxicity in gastric cancer and colon cancer[11,12].

In this study, tumor-specific shVEGF-yCDglyTK expression cassette was delivered using CPNP into human esophageal cancer cells and xenograft esophageal carcinoma. The therapeutic efficacy of this novel gene therapy system was evaluated, and the results suggest it was specific and effective for esophageal carcinoma.

MATERIALS AND METHODS

Cell lines and cell culture

Human esophageal squamous cell cancer cell line EC9706 and normal human lung fibroblast cell line HLF were obtained from the Central Laboratory of Xiangya Hospital, Central South University. A human cervical adenocarcinoma cell line HeLa was acquired from the Cancer Research Institute, Central South University. Cells were cultured in Roswell Park Memorial Institute 1640 medium (Hyclone, Logan, UT, United States) supplemented with 10% heat-inactivated fetal bovine serum and maintained in a humidified atmosphere of 5% CO_2 and 95% air at 37 ℃.

Construction of tumor-specific shVEGF-yCDglyTK expression cassette

Human hTERT promoter was amplified by polymerase chain reaction (PCR) from HeLa genomic DNA by using the following primers: forward primer 5′-GCGACGCGTGATTCGCGGGCACAGACG-3′and reverse primer 5′- AAACTCGAGCCACGTGCGCAGCAGGAC-3′. The product was cloned into the Mlu I and Xho I sites of the pGL3-Basic vector. pcDNA3.1(-)-CV-yCDglyTK[11] and pGenesil-shVEGF[31] were constructed in previous studies. pcDNA3.1(-) hTERT-yCDglyTK was made by replacing the carcinoembryonic antigen (CEA) promoter with the hTERT promoter. An expression cassette pcDNA3.1(-)-shVEGF-hTERT-yCDglyTK, which expressed shVEGF and yCDglyTK, was constructed as shown in Supplementary Figure 1. All constructs were confirmed by sequencing.

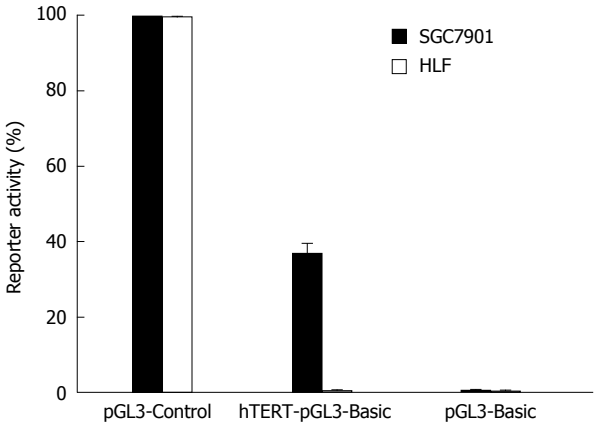

Figure 1 Human telomerase reverse transcriptase promoter activities in cancerous and normal cells. EC9706 and HLF cells were transfected with hTERT reporter vector (hTERT-pGL3 basic). pGL3-Control and pGL3 basic were transfected as positive and negative controls, respectively. hTERT: Human telomerase reverse transcriptase.

Transcriptional activity analysis of the hTERT Promoter

EC9706 and HLF cells were seeded in 24-well plates with 1 × 10^5 cells per well. Three plasmids, hTERT-pGL3 Basic, pGL3-Basic, and pGL3-control, were transfected when the cell monolayer reached 80%-85% confluence. The activities of luciferase and beta-galactosidase (β-gal) were detected 48 h post transfection. The luciferase activity was normalized against β-gal activity and expressed as relative luciferase activity.

Transfection efficiency of CPNP-DNA complexes

CPNP was produced according to previous studies[11,12,30]. The characteristics of CPNP have been described previously[11]. Two micrograms of pEGFP-N1 DNA were mixed with 20 μg of CPNP to generate the CPNP-pEGFP-N1 complexes. EC9706 cells were seeded in 12-well plates at a density of 2 × 10^5 cells per well. When the cell monolayer reached 80%-85% confluence, the CPNP-pEGFP-N1 complexes were added to the cells. The pEGFP-N1 DNA-liposome complexes (10 μg:2 μg) were used as a positive control. Transient transfection efficiency after 48 h was determined by examining GFP expression using flow cytometry and fluorescence microscopy.

Stable transfection

EC9706 cells were seeded in 6-well plates at a density of 2 × 10^5 cells each well. When the cell reached 70%-80% of confluence, pcDNA3.1(-) null, pGenesil-shVEGF, pcDNA3.1(-)-hTERT-yCDglyTK, and pcDNA3.1(-)-hTERT -shVEGF-yCDglyTK were mixed with CPNP (2 μg of DNA: 20 μg of CPNP), respectively[30]. At 48 h after transfection, G418 was added to cell culture medium, the final concentration

of which was 600 μg/mL. The G418-resistant colonies were picked 16 d later and kept in 96-well plates. These cells were maintained in selective medium containing 200 μg/mL of G418.

Reverse transcription-PCR and Western blot analysis

Total RNA from parental EC9706 cells and stable transfected cells was prepared by using TRIzol reagent (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's protocol. Reverse transcription (RT)-PCR of yCDglyTK and VEGF were carried out with AMV reverse transcription kit (Promega, Madison, WI, United States). Primers for yCDglyTK were: forward primer 5'-GGGAGATTAGAGGGCAAAGTGT-3', reverse primer5'-ACGGCGTCGGTCACGGCATAA-3'. The yCDglyTK PCR product was 707 bp. A VEGF PCR product of 112 bp was produced by forward primer 5'-TCTTCAAGCCATCCTGTGTG-3'and reverse primer 5'-ATCCGCATAATCTGCATGGT-3'. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as the internal control, and a PCR product of 101 bp was produced by forward primer 5'-CCTGTTCGACAGTCA GCCG-3'; reverse primer 5'-CGACCAAATCCGTTGACTCC-3'. The amplified fragments were separated in 2% agarose gels for visualization.

For Western blot assay, 30 μg protein from each sample was loaded for 10% sodium dodecyl sulfate gel electrophoresis and transferred to polyvinylidene fluoride membrane. The membranes were blocked with 5% (w/v) non-fat dry milk in Tris-buffered saline with tween (TBST) buffer at room temperature for 1 h. The membranes were then incubated overnight at 4℃ with anti-CD antibody (QED Bioscience Inc., San Diego, CA, United States). After washing three times with TBST buffer, blots were incubated for 2 h at room temperature with horseradish peroxidase-conjugated rabbit anti-mouse secondary antibody (Sigma, St. Louis, MO, United States). Signals were detected by enhanced chemiluminescence with Western blot detection system (Amersham, Piscataway, NJ, United States). GAPDH was used as a control to ensure equal protein loading.

Cytotoxicity assay

Parental and stable EC9706 cells were seeded at a density of 5000 cells per well in 96-well plates and incubated at 37℃ for 24 h. 5-FC was added into the culture medium, and the final concentration was 200 μg/mL. Methylthiazole tetrazolium (MTT) assays were conducted after incubation for 24, 48, 72, and 96 h, respectively. At the end of the incubation period, 20 μL of MTT stock solution (5 mg/mL, Sigma) was added per well, and the supernatant was carefully removed 4 h later. The formazan crystals were dissolved in dimethyl sulfoxide (DMSO, Promega). Optical density (OD) was determined by using a multi-well plate reader by measuring absorbance at 570 nm with a 690 nm reference wavelength. The background absorbance of medium was subtracted. All samples were assayed in triplicate, and the mean value for each experiment was analyzed. Cell growth curves were plotted with culture time on the horizontal axis and OD570 values on the vertical axis.

Hoechst staining

Nuclear morphology changes of apoptotic cells were detected by staining with Hoechst 33258. Parental EC9706 cells and stable cells transfected with empty vector, shVEGF, yCDglyTK, and shVEGF-yCDglyTK were cultured in complete medium supplemented with 5-FC (200 μg/mL). After 48 h, cells were washed three times with phosphate buffered saline (PBS) and stained with 5 μg/mL Hoechst 33258 for 30 min in the dark. Stained nuclei were visualized using a fluorescence microscope with a wavelength of excitation at 355 to 366 nm.

Flow cytometry analysis of cell apoptosis

Flow cytometry was performed as previously described[11]. EC9706 cells stably expressing shVEGF, yCDglyTK, and shVEGF-yCDglyTK and untransfected EC9706 cells were seeded in 10 cm dishes, respectively. 5-FC was added to the culture medium at a concentration of 200 μg/mL when the cells reached 90%-95% confluence. Cells were pelleted after 48 h, washed with PBS, and then resuspended in staining buffer (HEPES supplemented with 2.5 mmol/L $CaCl_2$). Flow cytometry was employed for detecting cell apoptosis after addition of fluorescein isothiocyanate-labeled annexin V and incubation for 15 min at 4℃.

Animal experiments

The animal use protocol was reviewed and approved by the Institutional Animal Care and Use Committee of Central South University. Twenty-five female BALB/c nude mice (4-6 wk old, 18-20 g) were acquired from Slac Laboratory Animal of Shanghai Co. Ltd, China. A suspension of 5×10^6 EC9706 cells was inoculated subcutaneously into the right flank of nude mice. After 10 d, when transplanted tumors reached a volume of 100-200 mm^3, the mice were randomized into five groups, named A, B, C, D, and E, with five mice in each group. Group A was the non-treating control group; Group B received intratumoral injection of the CPNPs/pcDNA3.1(-)null complex; Group C received intratumoral injection of the CPNPs/pGenesil-shVEGF complex; Group D received intratumoral injection of the CPNPs/pcDNA3.1(-)-hTERT-yCDglyTK complex; and Group E received intratumoral injection of the CPNPs/pcDNA3.1(-)shVEGF-hTERT -yCDglyTK complex.

The intratumoral injections of CPNP/DNA complexes were carried out every other day and repeated three times in total. One day after the first intratumoral injection, mice in groups B, D, and E received daily

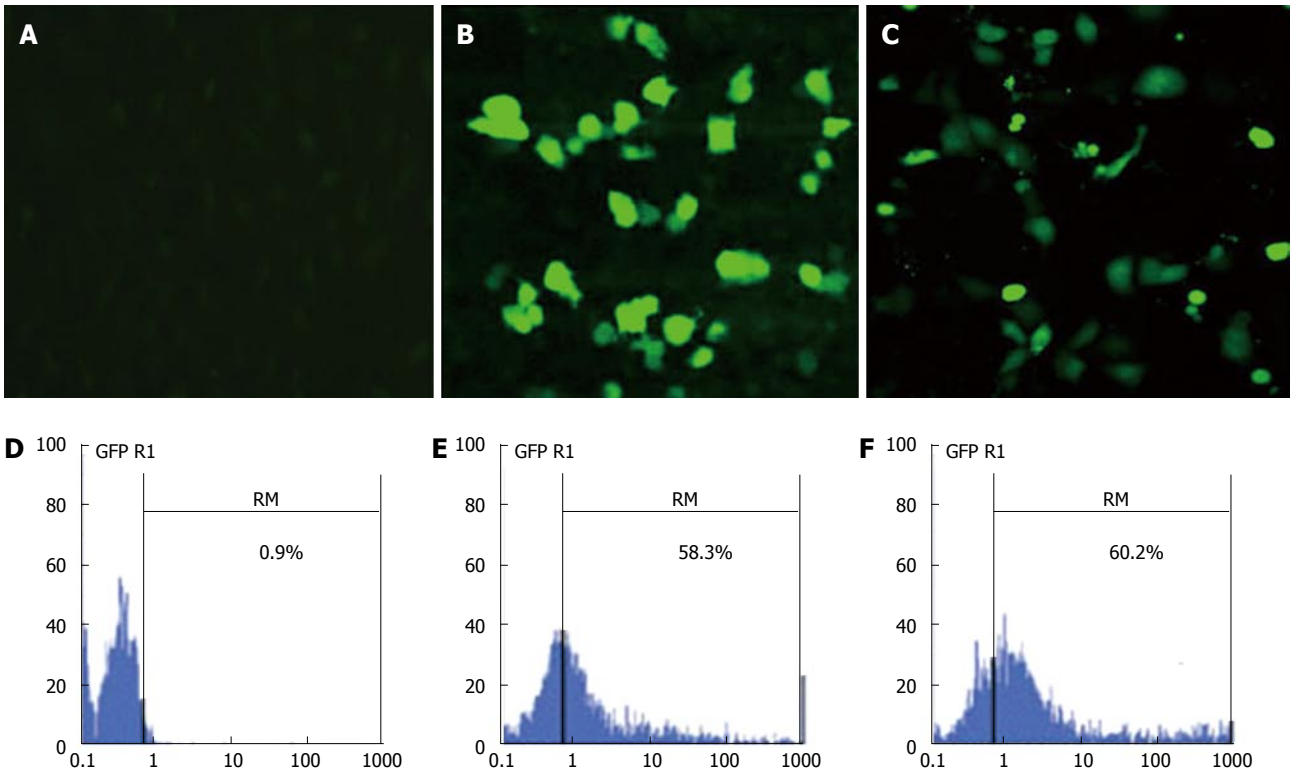

Figure 2 Transfection efficiency of calcium phosphate nanoparticles. A-C: Images of transfected EC9706 cells acquired by fluorescence microscope at magnification × 200 after 48 h of transfection. Negative control (A), CPNP-GFP complex (B), Liposome/GFP complex (C); D-F: Qualitative analysis of transfection efficiency by flow cytometric assay. Negative control (D), CPNP-GFP complex (E), Liposome/GFP complex (F). CPNP: Calcium phosphate nanoparticles; GFP: Green fluorescent protein.

intraperitoneal injection of 5-FC (500 mg/kg) for 14 consecutive days. The body weights of mice were recorded twice every week, and symptoms of side effects including change in behavior and food withdrawal were closely monitored. The longest (L) and shortest (W) perpendicular tumor diameters were measured every 3 d with calipers. To estimate the tumor volume; the following formula: $V = (1/2)W^2 \times L$ was used to calculate the three-dimensional volume of the xenograft. The growth curve was drawn according to the tumor volume. Animals were euthanized if the tumor diameter reached 1.5 cm or weight loss was more than 20% during the experiment. All surviving mice were euthanized by CO_2 inhalation and cervical dislocation at the end of the experiment.

Immunohistochemistry assays

The esophagus cancer xenograft tissue was cut at 4-μm thickness. The sections were incubated overnight at 4 ℃ with primary polyclonal antibody (anti-CD). The anti-rabbit antibody (Abgent, San Diego, CA, United States) was used as secondary antibody and incubated with sections for 30 min at 37 ℃. Color development was performed with the streptavidin-peroxidase system (Sigma-Aldrich). The chromogen was 3,3-diaminobenzidine tetrahydrochloride. Nuclei were lightly counterstained with hematoxylin. Microvessel counts (MVC) were analyzed to evaluate the degree of angiogenesis. Sections were immunostained with anti-CD34 antibody and examined at 200 × magnification. At least three microscopic images were collected and further analyzed with Axion Vision Rel 4.6 software to obtain MVC.

RESULTS

Assembly of tumor-specific shVEGF-yCDglyTK expression vector

In order to develop a more effective treatment for esophageal cancer, a novel expression plasmid, which could express a shRNA for VEGF and a fusion suicide gene yCDglyTK (Supplementary Figure 1), was constructed. The expression of shVEGF was under the control of the U6 promoter, a pol Ⅲ promoter; the expression of yCDglyTK was controlled by the tumor-specific hTERT promoter.

Specific transcriptional activities of the hTERT promoter in esophageal carcinoma cells

Activities of the hTERT promoter were determined by luciferase assay in EC9706 esophageal cancer cells and HLF normal lung fibroblast cells. The pGL3-Control vector containing SV40 promoter and enhancer sequences was used as a positive control. Luciferase activity driven by the hTERT promoter was much higher in EC9706 cells than in the HLF cells (Figure

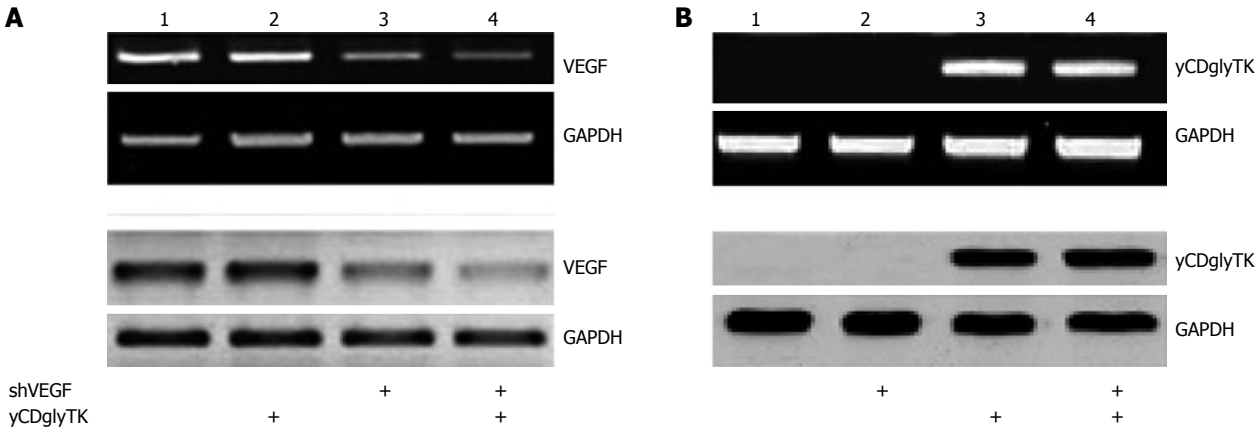

Figure 3 Changes of vascular endothelial growth factor and yCDglyTK expression in established stable cell lines. A: Representative VEGF mRNA and protein expression were analyzed by RT-PCR (top panel) and western blot (bottom panel), respectively. GAPDH was used as an internal control. Lane 1, EC9706/null; lane 2, EC9706/yCDglyTK; lane 3, EC9706/shVEGF; lane 4, EC9706/shVEGF-yCDglyTK; B: Representative yCDglyTK mRNA and protein expression were analyzed by semiquantitative RT-PCR (top panel) and western blot (bottom panel), respectively. GAPDH was used as an internal control. Lane 1, EC9706/null; lane 2, EC9706/shVEGF; lane 3, EC9706/yCDglyTK; lane 4, EC9706/shVEGF-yCDglyTK. 1). The results indicated that tumor specificity driven by the hTERT promoter could be achieved in EC9706 esophageal carcinoma cells.

Transfection efficiency of CPNP on esophageal cancer cells

EC9706 cells were transiently transfected with CPNP/green fluorescent protein (GFP) complex to evaluate the transfection efficiency of CPNP. EC9706 cells were assessed 48 h after transfection for GFP expression by using fluorescence microscopy and flow cytometry analysis. As shown in Figure 2, the proportion of GFP expressing cells transfected with CPNP was 58.3%, similar to that in liposome-medicated transfection group (60.2%). These data suggested that CPNP is an efficient strategy to deliver DNA into EC9706 esophageal cancer cells.

MTT assay was carried out to test the toxicity. Compared to the control group, liposome inhibited the cell growth by about 21%, while CPNP-DNA group had little effect on the cell growth (Supplementary Figure 1).

Changes in expression of VEGF and yCDglyTK by introducing the expression construct

RT-PCR and western blot were used to determine the expression of VEGF and yCDglyTK. Compared with cells transfected with pcDNA3.1(-), EC9706 cells transfected with pcDNA3.1(-)-shVEGF-hTERT-yCDglyTK showed significantly decreased expression of VEGF at both the mRNA and protein levels. No significant changes of VEGF expression were observed in EC9706 cells transfected with pGenesil-shVEGF and pcDNA3.1(-)-shVEGF- hTERT-yCDglyTK (Figure 3A). yCDglyTK expression was not present in cells transfected with pcDNA3.1(-). Its expression was substantially increased at both the mRNA and protein level by introduction of pcDNA3.1(-) -shVEGF-hTERT-yCDglyTK into EC9706 cells (Figure 3B).

Effects of shVEGF-yCDglyTK/5-FC system on cell growth and apoptosis in EC9706 cells

MTT assay was performed to assess cytotoxicity of the shVEGF-yCDglyTK/prodrug system in EC9706 cells. Parental and stable EC9706 cells were treated with 200 μg/mL of 5-FC. Cells were harvested at 24, 48, 72, and 96 h after 5-FC administration and subjected to MTT assay. As shown in Figure 4A, 96 h after 5-FC treatment, cells growth in the shVEGF group, yCDglyTK group, and shVEGF-yCDglyTK group was inhibited by 36%, 85%, and 94%, respectively.

Forty eight hours after 5-FC exposure, cell apoptosis were determined by Hoechst staining and flow cytometry, respectively. Hoechst staining showed that 5-FC induced a significant increase in apoptosis in EC9706 cells stably modified with the pcDNA3.1(-)-shVEGF-hTERT-yCDglyTK (Figure 4B). In contrast, apoptotic cells were barely found in parental EC9706 cells and cells carrying empty vector. Consistent results were found by the flow cytometry analysis (Figure 4C). Apoptotic population (early and late apoptotic) in EC9706 cells expressing shVEGF, yCDglyTK, and shVEGF together with yCDglyTK were 24.96%, 48.06%, and 62.9%, respectively. The percentage of apoptotic cells in untransfected EC9706 cells and EC9706 null cells transfected with an empty vector was only 0.97% and 1.3%, respectively. These results showed that both shVEGF and yCDglyTK expression could induce apoptosis and that combining them had the strongest effect on apoptosis induction.

Anti-tumor activity of shVEGF-yCDglyTK/5-FC system in vivo

The anti-tumor activity of the shVEGF-yCDglyTK/5-FC system was investigated with EC9706 xenograft

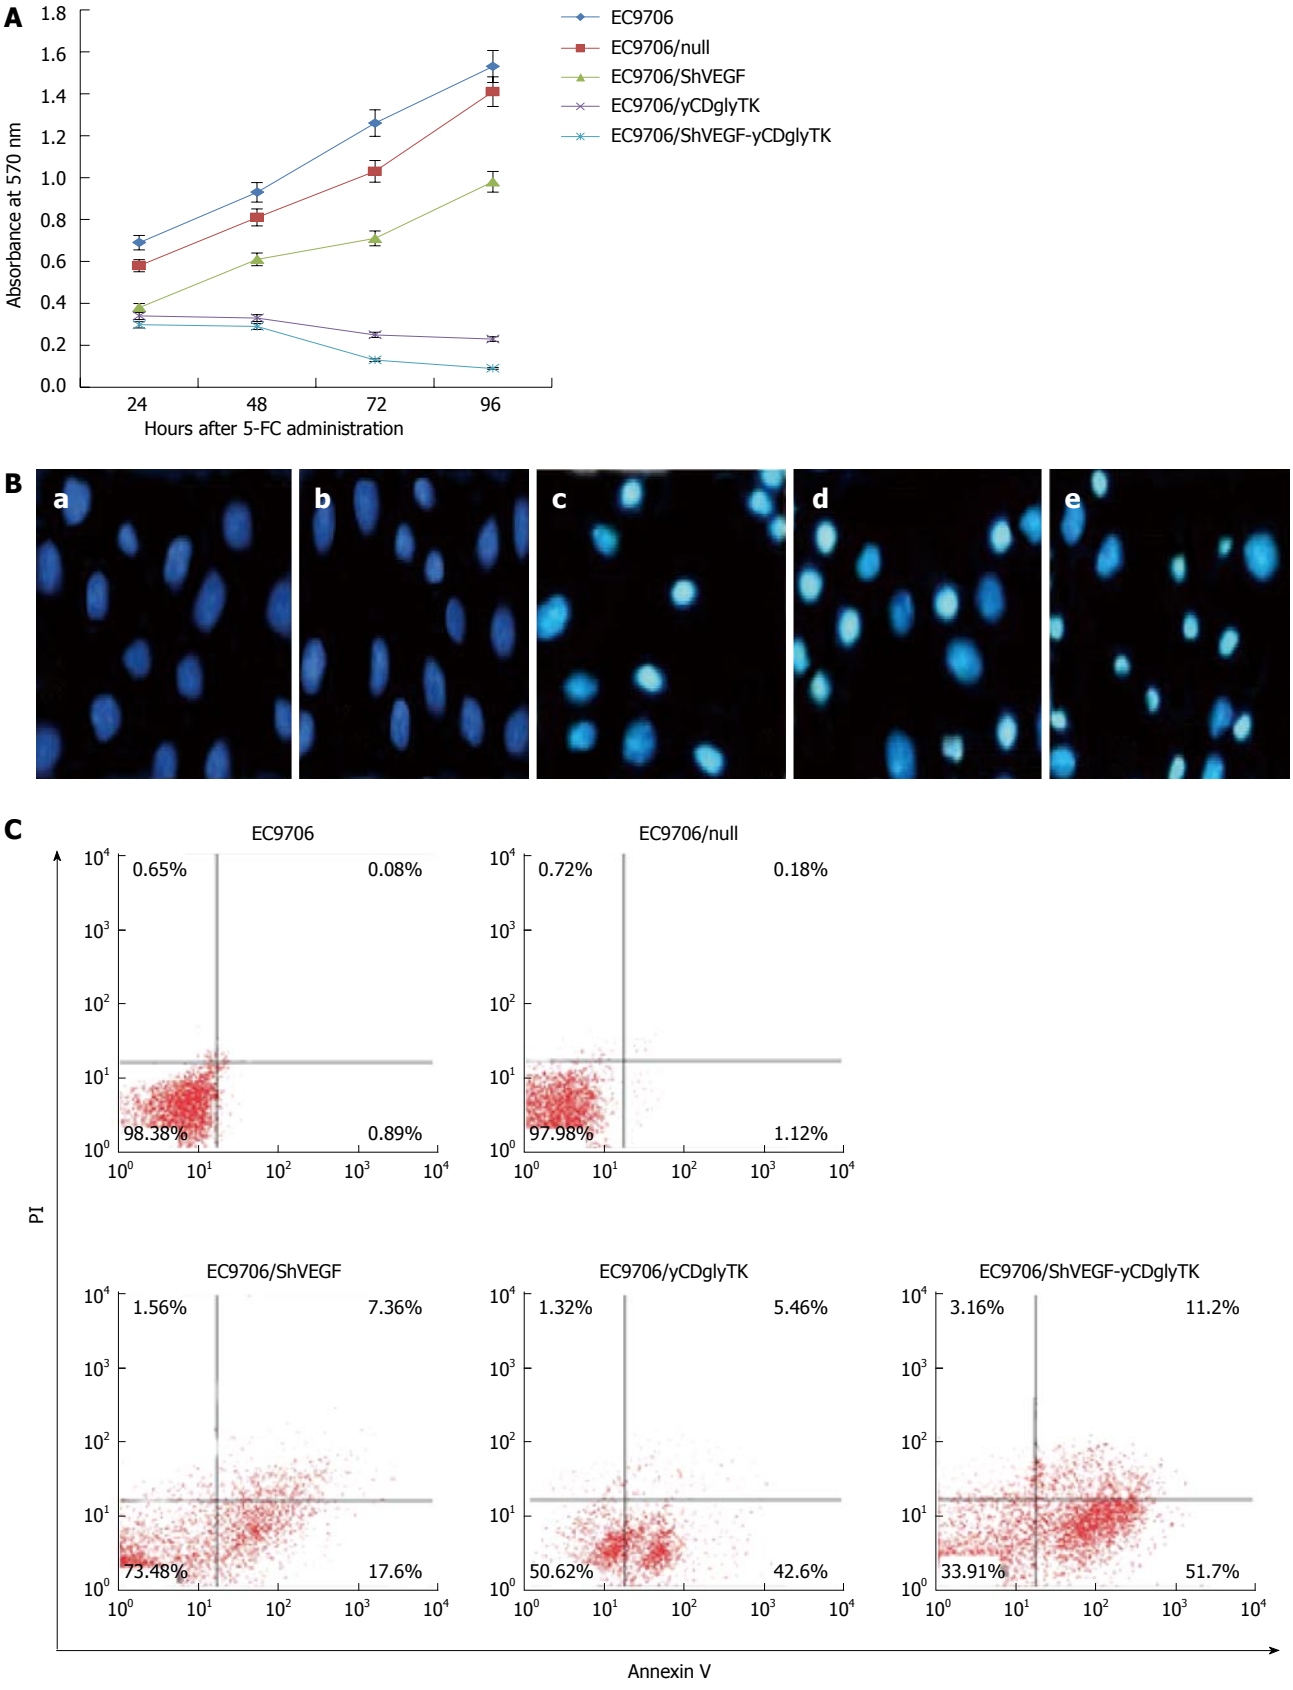

Figure 4 Effects of shVEGF-yCDglyTK/5-FC system on EC9706 cells. A: Cell viability of parental and stable EC9706 cells were determined with MTT assay at various time points after 5-FC treatment. The results shown are representative of three independent experiments; B: Representative images of Hoechst 33258-stained nuclei at magnification × 200. Apoptotic nuclei are condensed or fragmented; parental EC9706 cells (a); EC9706/null (b); EC9706/shVEGF (c); EC9706/yCDglyTK (d); EC9706/shVEGF-yCDglyTK (e); C: Representative dot plots of flow cytometry analysis. The numbers represent the percentage (%) of cells. Upper right quadrant, late apoptosis; lower right quadrant, early apoptosis; lower left, live cells. 5-FC: 5-fluorocytosine.

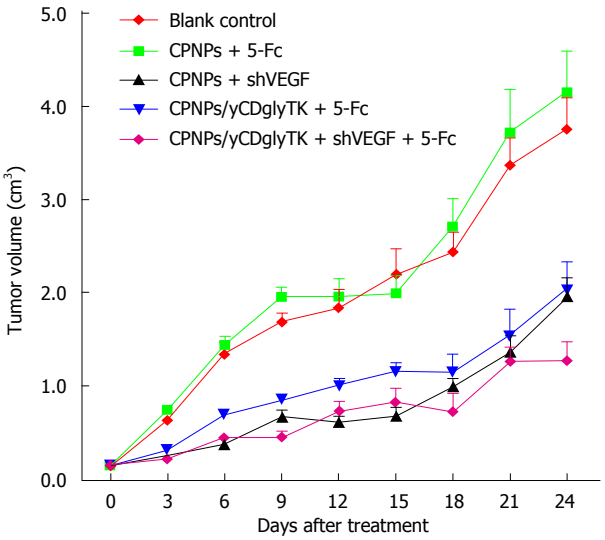

Figure 5 shVEGF-yCDglyTK/5-FC system inhibited tumor growth in the EC9706 xenograft model. Twenty-five BALB/C nude mice bearing EC9706 xenografts were randomized into five groups. The CPNPs/null, CPNPs/shVEGF, CPNPs/yCDglyTK or CPNPs/shVEGF-yCDglyTK complexes were delivered by intratumoral injection every other day, and the injection was repeated three times in total. 5-FC (500 mg/kg) was administered daily for 14 consecutive days. Tumors were measured every 3 d. All of the mice were scarified at day 36 after inoculation.

models. Tumors receiving CPNPs/null injection grew at a similar rate to that of the blank control group. On day 24, when compared with blank control group, CPNPs/yCDglyTK + 5-FC group and CPNPs + shVEGF group showed about 46% and 48% tumor growth inhibition. When combining CPNPs/yCDglyTK + 5-FC and shVEGF, the tumor growth was inhibited by 66% at day 24. These results demonstrated the potential benefit of the shVEGF-yCDglyTK/5-FC system for treating esophageal cancer (Figure 5).

Immunohistochemistry staining for yCDglyTK and VEGF

The expression and distribution of yCDglyTK and VEGF in the tumor xenograft were visualized by using immunohistochemistry staining. As shown in Figure 6A, tumor tissue expression of yCDglyTK was detected in mice injected with CPNPs/yCDglyTK or CPNPs/shVEGF-yCDglyTK. Meanwhile, it was not present in other groups, including non-treatment, sham control, and CPNPs/shVEGF groups. VEGF expression was quantified and represented by integrated optical density (IOD) values (Figure 6B). VEGF levels were significantly decreased in tumor tissues receiving injection of CPNPs/shVEGF or CPNPs/shVEGF-yCDglyTK, when compared with those of other groups ($P < 0.01$). No significant difference in VEGF expression was found between these two groups ($P > 0.05$). Since VEGF is an important angiogenesis factor, neovascularization was assessed by quantification of MVD. CPNPs/shVEGF and CPNPs/shVEGF-yCDglyTK groups showed lower MVD as compared to other groups (Figure 6C). The results suggested that the intratumoral injection of CPNPs/shVEGF-yCDglyTK could effectively inhibit neovascularization by down-regulating VEGF expression.

DISCUSSION

Esophageal carcinoma is a common cause of death globally. Traditional remedies for esophageal cancer, such as surgery, chemotherapy, and radiotherapy, all have drawbacks. For example, surgery is applicable only if the tumor is diagnosed at an early stage. Chemotherapy and radiotherapy have serious side effects as a result of lacking tumor specificity. Therefore, novel methods are required for the treatment of esophageal cancer. Gene therapy, especially suicide gene therapy, has been studied extensively for cancer treatment[32]. For suicide gene therapy, the therapeutic transgenes can convert a non-toxic pro-drug, which easily penetrates the tumor cell membrane, into a cytotoxic drug[33]. However, present suicide gene therapies have limited success due to lack of tumor specificity and an effective gene delivery tool.

One key point for successful gene therapy is the development of a safe and effective gene delivery system. Viral vectors are the most widely investigated delivering system because of their high transfection efficiency. However, viral vectors have some serious drawbacks, such as triggering immune response, severe hepatic inflammation, and random chromosomal integration[25-27]. Among non-viral vectors, cationic lipids could cause toxic effects when repeatedly used and induce potent anti-inflammatory activity *in vivo*; calcium phosphate precipitation had low transfection efficiency. The use of nanoparticles has become one of the most promising vectors because of their high transfection efficiency and low toxicity. In previous studies, we developed a new gene delivery system using either CPNP or calcium carbonate nanoparticles (CCNP)[11,12,30,31,34]. In this study, CPNP successfully delivered the suicide gene into EC9706 esophageal cells, with low toxicity.

Inserting a tumor-specific promoter upstream of suicide genes has been proven to be a successful strategy to achieve targeted expression of suicide genes in tumor tissues. Previously, we successfully used CEA promoter for targeting gastric cancer and colon cancer[11,12]. In this study, the specificity against esophageal cancer cells was achieved using the hTERT promoter.

VEGF stimulates tumor cell proliferation and angiogenesis in tumor tissue, and overexpression of VEGF has been found in the majority of human cancers[35,36]. Silencing VEGF with RNA interference (RNAi) could inhibit tumor growth and metastasis[37,38]. In this study, a novel fusion gene vector carrying a suicide gene (yCDglyTK) and a VEGF shRNA was developed. This expression vector was transfected into EC9706 esophageal cells by CPNP. Increased

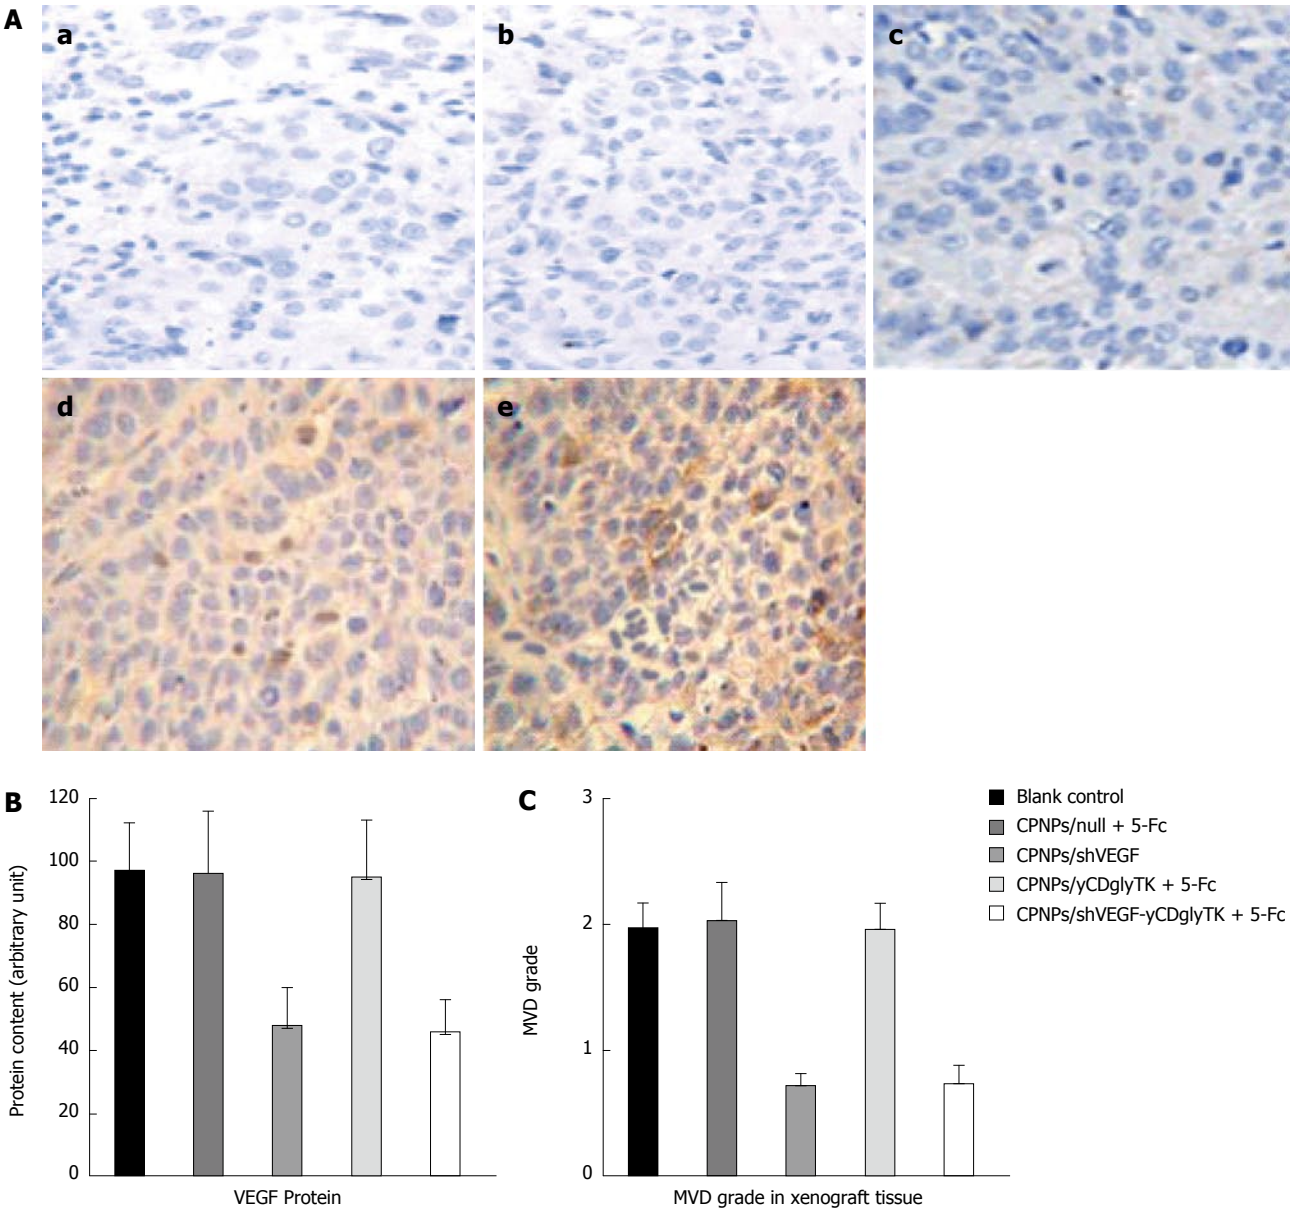

Figure 6 Immunohistochemistry analysis for yCDglyTK and vascular endothelial growth factor in EC9706 xenograft sections. A: Histological expression and distribution of yCDglyTK at magnification × 200; no-treatment control group (a); CPNPs/null + 5-FC (b); CPNPs/shVEGFX (c); CPNPs/yCDglyTK+5-FC (d); CPNPs/shVEGF-yCDglyTK +5-FC (e); B: Integrated optical density (IOD) values of VEGF expression in EC9706 xenografts. Anti-VEGF antibody was used for immunohistochemistry assay; C: Quantification of angiogenesis by microvessel counts (MVC) in EC9706 xenografts. Anti-CD34 was used for microvessel staining. CPNPs: Calcium phosphate nanoparticles; VEGF: Vascular endothelial growth factor; 5-FC: 5-fluorocytosine.

expression of yCDglyTK and decreased expression of VEGF were confirmed at both the mRNA and protein level in EC9706 cells.

In vitro antitumor activity of this novel system in the presence of prodrug was tested by MTT assay, Hoechst staining, and flow cytometry. The antitumor effect of the CPNP/shVEGF-yCDglyTK/5-FC system was further evaluated *in vivo* by using EC9706 cell xenograft model. Both yCDglyTK/5-FC and shVEGF successfully inhibited the tumor growth, and the combination of the two showed the strongest anti-tumor activity. Subsequent immunohistochemistry staining confirmed the expression of yCDglyTK, the knockdown of VEGF, and decreased neovascularization in the cancer tissue.

In summary, the CPNP/shVEGF-hTERT-yCDglyTK/5-FC system developed in this study may overcome several challenges for cancer gene therapy. The use of CPNP increased delivery efficiency, and insertion of hTERT promoter improved tumor specificity. VEGF-targeted shRNA further enhanced the anti-tumor effect. This combination of gene therapies exerted more potent anti-esophageal cancer activity *in vitro* and *in vivo*. The present study provides a novel and promising strategy for esophageal cancer treatment. We will try to optimize this approach to make it more feasible in the future clinical trials.

COMMENTS

Background

Esophageal cancer is one of the most prevalent cancers in the world. It has high incidence and mortality rates. Novel and effective treatment options are urgently needed for esophageal cancer.

Research frontiers

In recent years, gene therapy, especially suicide gene therapy, has been recognized as a promising strategy for cancer treatment.

Innovations and breakthroughs

In this study, tumor-specific shVEGF-yCDglyTK expression cassette was delivered using calcium phosphate nanoparticle (CPNP) into human esophageal cancer cells. The therapeutic efficacy of this novel gene therapy system was evaluated *in vitro* and *in vivo*, and results showed that it was an effective strategy for esophageal carcinoma treatment.

Applications

The present study provides a novel and promising strategy for esophageal cancer treatment.

Terminology

CPNP is a novel non-viral tool for efficient gene delivery.

Peer-review

This study investigated a novel technique for targeted gene therapy in an esophageal cancer model. The authors report transfection rates and altered gene expression profiles. The study is well conducted and well described. The techniques are appropriate and the experiments are clearly written. The study topic is interesting and relevant.

Abstract

AIM: To investigate the effects of different parameters of gastric electrical stimulation (GES) on interstitial cells of Cajal (ICCs) and changes in the insulin-like growth factor 1 (IGF-1) signal pathway in streptozotocin-induced diabetic rats.

METHODS: Male rats were randomized into control, diabetic (DM), diabetic with sham GES (DM + SGES), diabetic with GES1 (5.5 cpm, 100 ms, 4 mA) (DM + GES1), diabetic with GES2 (5.5 cpm, 300 ms, 4 mA) (DM + GES2) and diabetic with GES3 (5.5 cpm, 550 ms, 2 mA) (DM + GES3) groups. The expression levels of c-kit, M-SCF and IGF-1 receptors were evaluated in the gastric antrum using Western blot analysis. The distribution of ICCs was observed using immunolabeling for c-kit, while smooth muscle cells and IGF-1 receptors were identified using α-SMA and IGF-1R antibodies. Serum level of IGF-1 was tested using enzyme-linked immunosorbent assay.

RESULTS: Gastric emptying was delayed in the DM group but improved in all GES groups, especially in the GES2 group. The expression levels of c-kit, M-SCF and IGF-1R were decreased in the DM group but increased in all GES groups. More ICCs (c-kit$^+$) and smooth muscle cells (α-SMA$^+$/IGF-1R$^+$) were observed in all GES groups than in the DM group. The average level

of IGF-1 in the DM group was markedly decreased, but it was up-regulated in all GES groups, especially in the GES2 group.

CONCLUSION: The results suggest that long-pulse GES promotes the regeneration of ICCs. The IGF-1 signaling pathway might be involved in the mechanism underlying this process, which results in improved gastric emptying.

Key words: Long-pulse gastric electrical stimulation; Interstitial cells of Cajal; Gastric emptying; IGF-1 pathway; Diabetes mellitus; Gastrointestinal motility disorders

Core tip: Gastric electrical stimulation (GES) regulates gastric motility and protects the interstitial cells of Cajal (ICCs). However, the mechanisms underlying these processes have not been determined. In this study, we report that long-pulse GES with three different parameters protected ICCs and that the insulin-like growth factor 1 signaling pathway is probably involved in this process. One GES parameter (5.5 cpm, 300 ms, 4 mA) showed immense potential as a clinical application for applying long-pulse GES as the optimal parameter.

Long-pulse gastric electrical stimulation protects interstitial cells of Cajal in diabetic rats *via* IGF-1 signaling pathway. *World J Gastroenterol* 2016; 22(23): 5353-5363 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5353.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5353

INTRODUCTION

Gastrointestinal motility disorders (such as early satiety, bloating and vomiting) often plague patients with long-standing diabetes. However, the pathogenesis of these disorders remains unclear, and effective pharmacological management is limited for these symptoms. Fortunately, a few recent non-pharmacological treatments, including gastric electrical stimulation (GES), have renewed the hope for achieving new management strategies, but the mechanisms underlying their efficacy remain unclear.

Recently, a number of studies have indicated that interstitial cells of Cajal (ICCs) may play an important physiological role in coordinating gastric contractile activity and gastric motility[1,2]. C-kit protein is known to localize on the surface of ICCs and to be activated by interactions between kit receptors and stem cell factor (SCF). SCF/c-kit signaling is important for maintaining the ICC phenotype and ICC proliferation, differentiation and survival[3,4]. Furthermore, some studies have suggested that damage to or the loss of ICCs leads to gastrointestinal motility disorders in diabetic models[5-7] and that decreases in the levels of SCF and insulin-like growth factor 1 (IGF-1) are involved in ICC deficiency[8]. According to the results of recent studies, SCF and IGF-1, which are necessary for the differentiation and maintenance of the ICC phenotype, are derived from smooth muscle cells (SMCs), and IGF-1 increases the expression of SCF[9]. Moreover, the IGF-1 receptor (IGF-1R) appears to be lacking in mature ICCs, and IGF-1 is likely to directly interact with receptors on SMCs to enhance SCF synthesis, resulting in a protective effect in ICCs[8]. Based on a recent study, the levels of serum IGF-1 and its binding protein 3 are altered in type 1 diabetes and that circulating IGF-1 and its binding protein 3 control colonic stem cell function and gastrointestinal complications of diabetes[10].

Generally, GES is classified into three categories according to the length of the pulse and the energy that is applied: the short-pulse GES, the long-pulse GES and the dual-pulse GES. The effects of GES varied with the parameters. In refractory gastroparesis patients who cannot undergo drug therapy due to serious side effects or who are unable to undergo surgical treatment, GES is an alternative option. Our previous study indicated that GES might increase the expression of membrane stem cell factor (M-SCF) in streptozotocin (STZ)-induced diabetic rats[11]. However, the mechanism by which GES affects gastric motility and the involvement of IGF-1 signaling remain unknown. The aim of this study was to: (1) systematically assess the effects of applying GES with different parameters on gastric emptying; (2) ascertain the effects of GES on ICCs in diabetic rats; and (3) determine whether the IGF-1 pathway is involved in the regeneration of ICCs.

MATERIALS AND METHODS

Animal subjects

Adult male Sprague-Dawley rats (250-300 g) obtained from the Experiment Animal Center of Tongji Medical College were used in this study. All appropriate measures were adopted to minimize discomfort or pain to the animals. The rats were housed in standardized laboratory conditions (a 12/12 h light/dark cycle at 22 ℃) and allowed free access to standard solid food and sterile water. The rats were formally enrolled after they were adapted to the laboratory conditions for one week. All experiments were reviewed and approved by the Institutional Animal Care and Use Committee of Tongji Medical College.

Experimental protocols

The animals were randomized into one of six equal groups (6 rats/group): control, diabetic (DM), diabetic and sham GES (DM + SGES), diabetic and GES parameter 1 (5.5 cpm, 100 ms, 4 mA) (DM + GES1), diabetic and GES parameter 2 (5.5 cpm, 300 ms, 4 mA) (DM + GES2), and diabetic and GES parameter 3 (5.5 cpm, 550 ms, 2 mA) (DM + GES3). Diabetes was

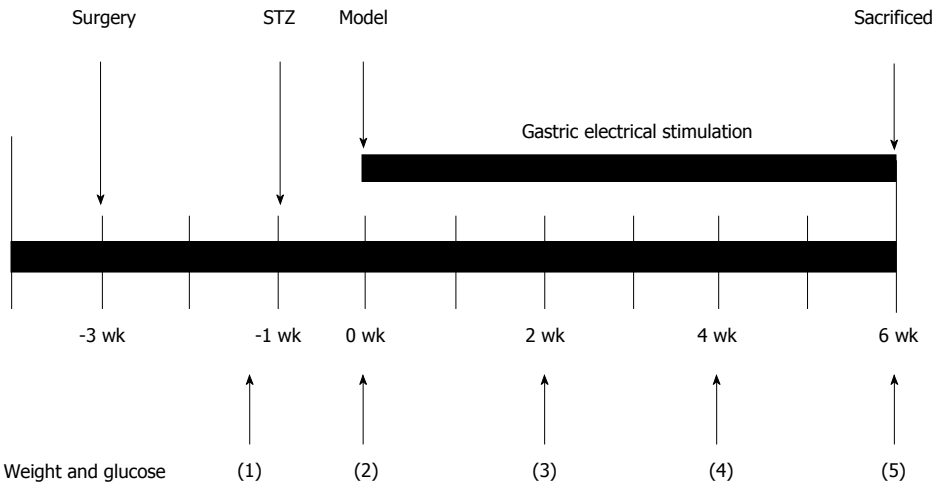

Figure 1 Schematic representation of the gastric electrical stimulation study protocol. After surgery of electrode implantation, the rats had 2 wk to recover from the surgery. After streptozotocin injection, the diabetic rats were randomized into four large groups depending on the parameter of gastric electrical stimulation (GES): DM (diabetic group) + SGES (diabetic with sham GES), DM + GES1 (GES parameter 1), DM + GES2 and DM + GES3 groups for 6 wk. GES was adopted for 30 min/d, 7 d/wk during the whole process of the experiment. The body weights and blood glucose levels were measured before the injection of STZ and during weeks 0, 2, 4, and 6 after the induction of diabetes.

induced using STZ (60 mg/kg, ip, Alexis Biochemical, United States). Rats in the control group were injected with equal volume of diluent. Blood glucose concentrations were measured one week after the injection. The rats were considered diabetic if their blood glucose level increased and was maintained at equal to or more than 16.7 mmol/L. Body weight and blood glucose levels were also tested before the rats were injected and during weeks 0, 2, 4, and 6 after the induction of diabetes. After sequential GES intervention was performed for 6 wk, gastric emptying was measured in all groups. Serum samples were collected for enzyme-linked immunosorbent assay (ELISA), and the rats were sacrificed and the specimens of the antrum were acquired. Each antrum specimen was separated into two pieces. One of these was stored at -80 ℃ for Western blot analysis, and a relatively large piece was fixed in Zamboni's fixative [1.5% saturated picric acid solution and 2% paraformaldehyde in 0.1 M phosphate buffer solution (PBS, pH = 7.4)] for the immunofluorescence study.

Gastric electrical stimulation

Rats in the GES and sham GES groups were anesthetized using pentobarbital sodium (30 mg/kg, ip, Sigma, United States). A midline laparotomy was performed, and stimulating electrodes were pierced the subserosa of the stomach and placed on the serosal surface along the greater curvature. The distal pair of electrodes was about 0.5 cm away from the pylorus and the proximal pair was approximately 1.5 cm away from the distal pair. The electrodes of the proximal pair were placed 0.3 cm apart. The wires were tunneled through the anterior abdominal wall and led out of the skin so they could be connected to the stimulator (G6805-2A; Shanghai Huayi Medical Instrument Factory, China). The abdominal wall was closed using a simple interrupted suture. After the rats recovered from the surgery completely (usually 2 wk), they continuously received GES intervention for 30 min/day for 6 wk (Figure 1). The following respective long-pulse GES frequencies, pulse widths and amplitude parameters were used: GES1, 5.5 cycles/min (cpm), 100 ms and 4 mA; GES2, 5.5 cpm, 300 ms and 4 mA; and GES3, 5.5 cpm, 550 ms and 2 mA. These parameters were shown to be effective and representative in previous experiments[11-13]. Rats in the DM + SGES group were connected only to the stimulator and were not stimulated with an electric current.

Measurement of gastric emptying

The test meals, including carboxymethylcellulose (15 mg/mL) and phenol red (0.5 mg/mL), were continually stirred and maintained at 37 ℃. After the rats were deprived of food overnight, the animals were fed 2 mL of the test meal using a straight gavage needle. After 30 min, the rats were quickly sacrificed using cervical dislocation. The stomach was acquired after it was ligated at the pylorus and cardia, and then it was opened. The gastric contents were placed into a test tube and then washed using distilled water. A NaOH solution (20 mL, 1 mol/L) was placed in each test tube. Absorbance at 560 nm was read using a spectrophotometer (U-2900, Hitachi, Japan) to determine the quantity of remained phenol red.

Gastric emptying was calculated using the following formula: gastric emptying (%) = 100 × (1-X/Y), where X is the absorbance of phenol red measured at 30 min after the test meal, and Y is the absorbance of phenol red in the control rats that were sacrificed immediately after they were fed the test meal[14].

Immunofluorescence studies

The gastric antrum tissues were rapidly fixed in Zamboni's fixative for 24 h at room temperature. They were then dehydrated, embedded in paraffin and cut at a thickness of 5-7 μm. The paraffin sections were deparaffinized and hydrated before antigen retrieval was performed. Endogenous peroxidase was controlled using 3% hydrogen peroxide (H_2O_2) for 30 min. The sections were then microwaved (750 W) for 5 min, and nonspecific reactions were inhibited using normal goat serum for 20 min. The primary antibodies, including IGF-1R (1:200; Santa Cruz Biotechnology, Inc), c-kit (1:150; Santa Cruz Biotechnology, Inc) and α-SMA (1:500; Santa Cruz Biotechnology, Inc), were added dropwise to the paraffin sections which were placed at 4 ℃ overnight. The sections were then rinsed three times using PBS (PH 7.4) and incubated in secondary antibodies for 60 min at 37 ℃, followed by incubation with DAPI (Sigma, United States) for 30 min. The sections were then counterstained and dehydrated. The specimens were observed using a laser scanning confocal microscope (Olympus, Tokyo, Japan).

Western blot analysis

The antrum specimens were homogenized in RIPA buffer (Upstate, United States) containing protease inhibitor (Beyotime, China) and incubated for 30 min on ice. The liquid was centrifuged at 12000 *g* at 4 ℃ for 8 min, and the supernatant containing the total extracted proteins was then collected. BCA reagent (Pierce, Rockford, IL, United States) was used to analyze the protein concentration of each sample. Total proteins were separated using 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and then transferred to PVDF membranes (Millipore, United States). The membranes were immersed in 5% skim milk solution for 1 h and then incubated with primary antibodies against c-kit (1:200, Sigma-Aldrich, United States), SCF (1:200, Abcam, United Kingdom), IGF-1R (1:200, Boster, China) or β-actin (1:1000, Beyotime, China) at 37 ℃ with gentle shaking for 1 h, followed by maintenance at 4 ℃ overnight. After incubation with secondary antibodies for 1 h, the bands on the PVDF membranes were visualized using enhanced chemiluminescence (Amersham Pharmacia, United States). A densitometry analysis was conducted using AlphaView software.

ELISA

For this experiment, approximately 2 mL of blood was obtained from each rat to study differences in serum IGF-1 levels. The concentration of IGF-1 was quantified using rat IGF-1 ELISA kits (RayBiotech, United States). A standard curve was established for IGF-1 by testing the standard with a spectrophotometer at 450 nm, and the concentration of IGF-1 in the serum was then determined by comparing the optical densities of the study samples to those of the standard samples.

Electron microscopy

The gastric antrum was immersed in fixative solution (2.5% glutaraldehyde) for 2 h at 4 ℃. Tissue samples (approximately 1 mm × 5 mm) were separated from the gastric antrum and soaked in 1% OsO_4 for 60-120 min. They were then rinsed with 0.1 mol/L phosphate buffer and dehydrated in ethanol. The tissue samples were immersed in propylene oxide followed by mixtures of Epon Resin and propylene oxide for 2 h, and then embedded in Epon. An ultramicrotome was used to identify the regions of interest in the study and to section them into ultrathin sections (70 nm). The sections were visualized using a transmission electron microscope (Tecnai G212, FEI, The Netherlands).

Statistical analysis

The data are presented as the mean ± SEM. One-way analysis of variance was used to evaluate differences among groups. The least significant difference post hoc test was applied to compare differences between groups. A P value < 0.05 was considered statistically significant. Statistical analyses were performed using SPSS 17.0 software.

RESULTS

Weight and blood glucose level

Baseline weight did not markedly differ between the groups (Figure 2A). The weights of the rats in the DM group were markedly lower at the end of weeks 2, 4 and 6 (P = 0.013, P = 0.005 and P < 0.0001, respectively) than the weights of the controls. The weights of the DM + GES1, DM + GES2 and DM + GES3 groups were significantly higher at the 6th week than the weights in the DM group (P = 0.035, 0.028 and 0.031, respectively).

As shown in Figure 2B, baseline blood glucose levels were not significantly different between the groups. After the induction of diabetes, the blood glucose levels were higher in the DM group than in the control group for the remainder of the experiment (P < 0.0001). After long-pulse GES intervention was applied, blood glucose levels were not markedly different between the DM + GES1, DM + GES2 or DM + GES3 group and the DM group (P = 0.332, 0.281 and 0.416, respectively).

Electron microscopy

In the control group, ICCs showed higher electron-dense cytoplasm than SMCs and were abundant in the endoplasmic reticulum, mitochondria and basal lamina (Figure 3A). In addition, they showed a close connection with SMCs and enteric nerves. However, in the DM group, ICCs were seriously impaired (Figure 3B): swollen endoplasmic reticulum and mitochondria, extensive vacuolization, cytoplasmic depletion and lamellar bodies were frequently observed in their cell bodies. The intercellular spaces were dilated,

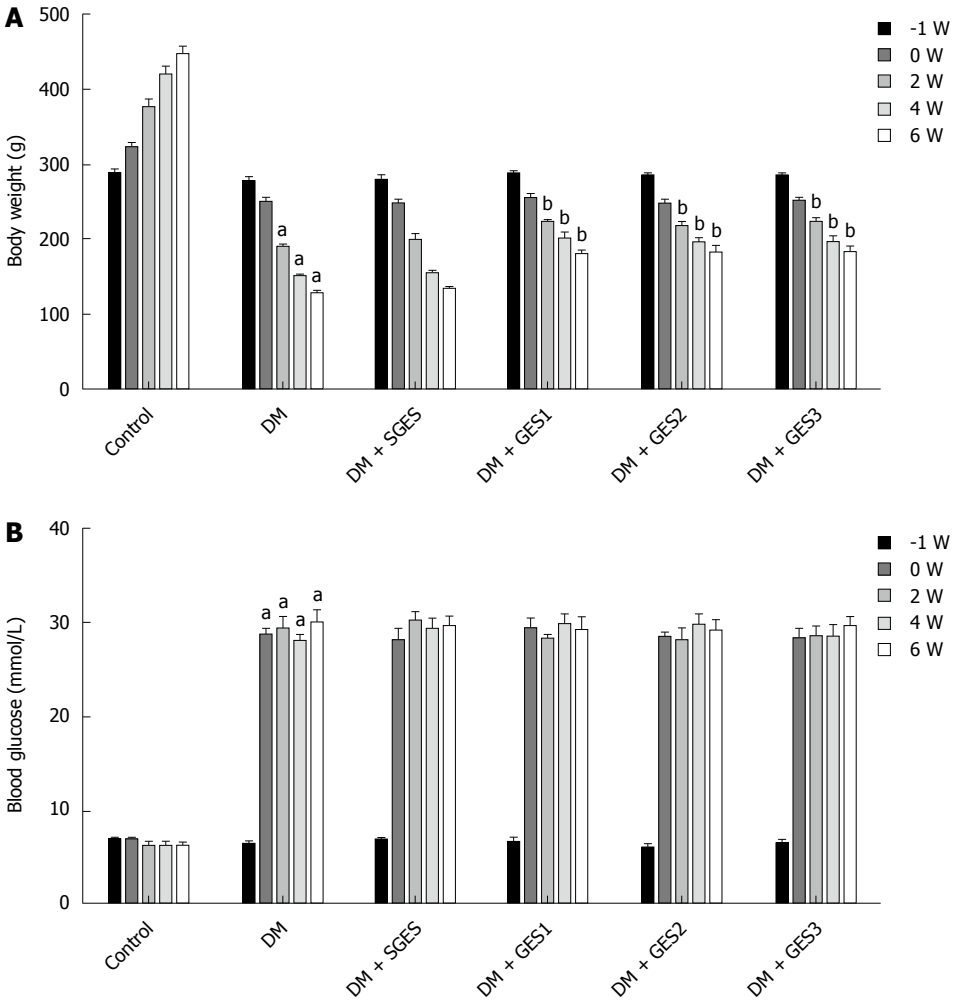

Figure 2 Body weights and blood glucose levels at different time points in different groups. A: The body weights of the diabetic rats were obviously decreased compared with the controls at 6 wk ($P < 0.05$). The weights in all GES groups were increased compared with the DM (diabetic group) ($P < 0.05$). There was no significant difference between the DM and DM + SGES groups ($P > 0.05$); B: Compared with the control group, the blood glucose level of the DM group was significantly increased at weeks 0, 2, 4 and 6 ($P < 0.05$ for all). [a]$P < 0.05$ *vs* control; [b]$P < 0.05$ *vs* DM group.

gap junctions between ICCs and enteric nerves were reduced and exudation of fibrin was occasionally observed. ICCs in the DM + SGES group displayed ultrastructural changes that were similar to those in the ICCs in the DM group (Figure 3C). However, most of the ICCs in the DM + GES1 (Figure 3D), DM + GES2 (Figure 3E) and DM + GES3 (Figure 3F) groups were repaired, and minor damage (the structure of the cytomembrane was relatively complete, organelles were abundant, there were slight cytoplasmic depletion, slightly swollen endoplasmic reticulum and mitochondria and limited vacuolization, there were few denuded ribosomes and a small number of lysosomes, and there was little heterochromatin.) was occasionally observed.

Gastric emptying

Figure 4 shows the effect of GES on gastric emptying. Gastric emptying in the DM group was slower than that in the control group ($P < 0.0001$). SGES did not markedly affect gastric emptying compared to the DM group ($P = 0.573$), but GES1, GES2 and GES3 significantly improved the delayed gastric emptying from 35.89% ± 4.43% to 48.27% ± 2.20%, 61.84% ± 4.87 and 53.34 ± 2.26%, respectively ($P = 0.03$, 0.0028 and 0.0041, respectively). These improvements were significantly different between the DM + GES1 group and the DM + GES2 group ($P = 0.029$), indicating that the effect of GES2 on gastric emptying was stronger than that of GES1.

Western blot analysis of c-kit, SCF and IGF-1R

As shown in Figure 5A and B, the expression of c-kit was evaluated in the antrum. The level of c-kit was markedly lower in the DM group than in the control group ($P < 0.0001$). Conversely, the expression of c-kit was dramatically higher in the DM + GES1, DM + GES2 and DM + GES3 groups than in the DM group ($P = 0.0004$, $P < 0.0001$ and $P = 0.0027$, respectively). The expression of M-SCF (Figure 5C and D) was lower in the DM group than in the control group ($P < 0.0001$). However, GES1, GES2 and GES3 resulted in a higher

Table 1 Serum levels of IGF-1 in each group

	Control	DM	DM + SGES	DM + GES1	DM + GES2	DM + GES3
IGF-1 (ng/mL)	281.22 ± 9.75	31.27 ± 5.61[a]	29.18 ± 5.02	90.88 ± 6.74[c]	121.62 ± 9.97[c,e]	113.97 ± 9.37[c]

Data are given as mean ± SEM. [a]$P < 0.05$, Control *vs* DM group; [c]$P < 0.05$ *vs* DM group; [e]$P < 0.05$, DM + GES2 *vs* DM + GES1 group.

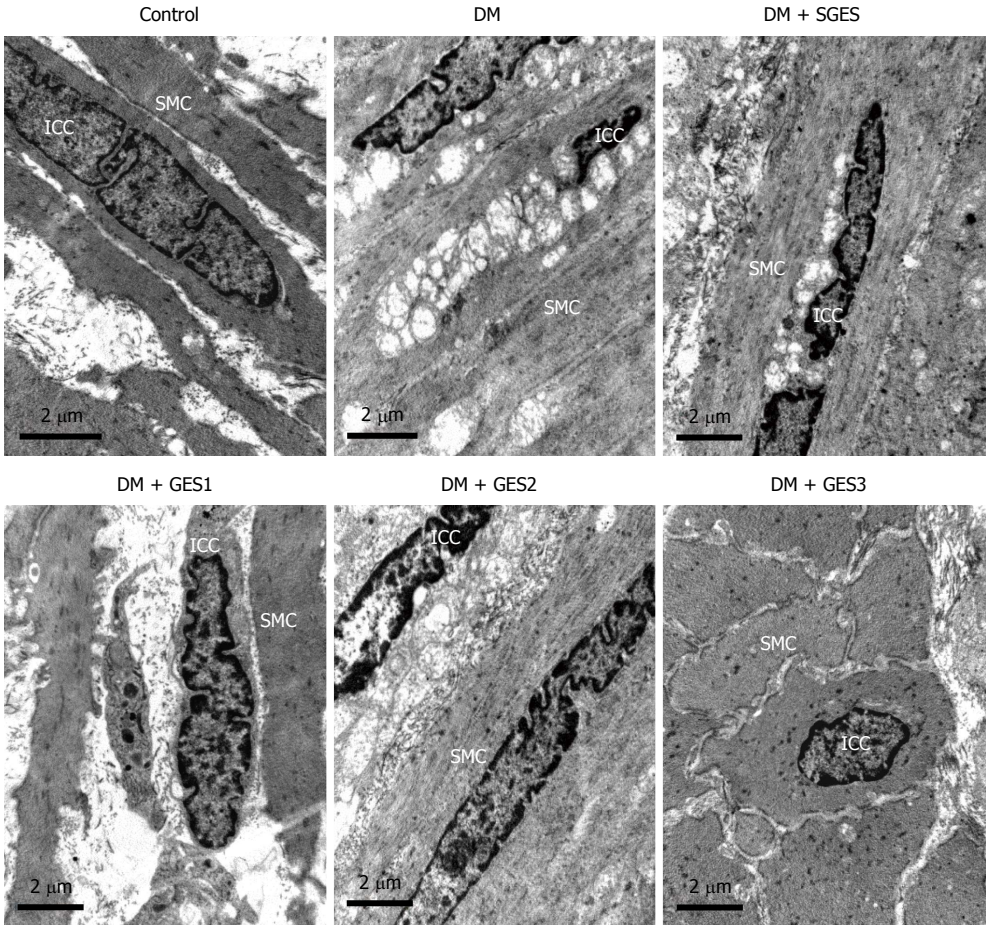

Figure 3 Electron microscopy of interstitial cells of Cajal in each group. In the DM (diabetic) and SGES (diabetic with sham GES) groups, interstitial cells of Cajal (ICCs) were markedly affected compared with the control group, while they appeared to be almost normal in structure or had minor damage in the DM (diabetic group) + GES1 (GES parameter 1), DM + GES2 and DM + GES3 groups. Scale bars = 2 μm.

level of expression of M-SCF than was observed in the DM group ($P = 0.001$, $P < 0.0001$ and $P < 0.0001$, respectively). The effect of GES2 was stronger than that of GES1 ($P = 0.028$).

Compared to the control, the expression of IGF-1R (Figure 5E and F) was markedly lower in the DM group ($P < 0.0001$), whereas the level of IGF-1R in the DM + GES1, DM + GES2 and DM + GES3 groups was significantly higher than the level in the DM group ($P = 0.004$, $P < 0.0001$ and $P = 0.001$, respectively). This effect was stronger in the GES2 group than in the GES1 group ($P = 0.039$).

Serum IGF-1 levels

Table 1 shows the levels of IGF-1 in the serum in each group. The IGF-1 levels in the Control, DM, DM + SGES, DM + GES1, DM + GES2 and DM + GES3 groups were 281.22 ± 9.75, 31.27 ± 5.61, 29.18 ± 5.02, 90.88 ± 6.74, 121.62 ± 9.97 and 113.97 ± 9.37 ng/mL, respectively. The average IGF-1 level in the DM group was lower than that in the control group ($P < 0.0001$). However, the IGF-1 level was higher in the DM + GES1, DM + GES2 and DM + GES3 groups than in the DM group ($P < 0.0001$ for all). The level of IGF-1 was not markedly different between the DM + SGES and the DM groups ($P = 0.794$).

Immunofluorescence studies of c-kit and IGF-1R

As shown in Figure 6, c-kit immunoreactivity revealed the distribution of ICCs in the gastric antrum of each group. There were a number of c-kit$^+$ cells in the control group. However, few ICCs were observed in the DM group. Similar results were found in the DM + SGES group, and long-pulse GES interventions

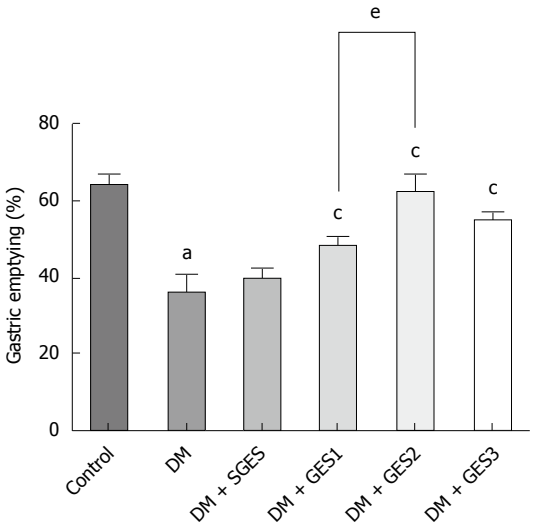

Figure 4 Effects of gastric electrical stimulation on gastric emptying. Compared with the control group, gastric emptying in the DM group was significantly delayed ($P < 0.01$). However, gastric electrical stimulation (GES) significantly improved the delayed gastric emptying ($P < 0.01$ for all). Meanwhile, significance was found between the DM (diabetic group) + GES1 (GES parameter 1) group and DM + GES2 group ($P = 0.0275$). $^{a}P < 0.05$ *vs* control; $^{c}P < 0.05$ *vs* DM group; $^{e}P < 0.05$, DM + GES1 *vs* DM + GES2 group.

markedly increased the expression of c-kit in the DM + GES1, DM + GES2 and DM + GES3 groups.

In Figure 7, α-SMA and IGF-1R immunoreactivity reflects the distribution of smooth muscle cells and IGF-1 receptors, respectively, in the gastric antrum of each group. In the control group, a large number of IGF-1R^{+} cells was observed in the intramuscular layer, whereas few IGF-1R^{+} cells were observed in the DM group. Analogously, few IGF-1R^{+} cells were observed in the DM + SGES group. However, IGF-1R expression was markedly increased in the DM + GES1, DM + GES2 and DM + GES3 groups after treatment with long-pulse GES.

DISCUSSION

In the current study, applying GES using various settings increased the expression of M-SCF and IGF-1/IGF-1R and improved the regeneration of ICCs in diabetic rats, which ameliorated delayed gastric emptying in these rats.

In recent years, GES has been proposed as a therapeutic option for patients suffering from refractory gastroparesis. Some studies have demonstrated that the effects of GES depend on the GES parameters. Short-pulse GES improved dyspeptic symptoms, while long-pulse GES normalized gastric dysrhythmia and regulated gastric slow waves, and dual-pulse GES reduced dyspeptic symptoms and gastric dysrhythmia[15-20]. Because in some instances, long-pulse GES re-establishes normal slow wave activity and improves gastric emptying, it is usually applied to treat gastroparesis. Based on the results of previous studies, a frequency of 5.5 cpm, a pulse width ranging from 100 ms to 300 ms and an amplitude of 4 mA are frequently used and have been shown to be effective in regulating gastric dysrhythmia and gastric slow waves[21,22]. In this study, we selected representative widths of 100 ms (GES1: 5.5 cpm, 100 ms, and 4 mA) and 300 ms (GES2: 5.5 cpm, 300 ms, and 4 mA) for further study. Additionally, GES3 (5.5 cpm, 550 ms, 2 mA) was also demonstrated to be effective in our previous study[11], and that setting was consequently also used in this study. Bellahsène *et al*[23] demonstrated that long-pulse GES (7 cpm, 300 ms, 4 mA) accelerated gastric emptying in a canine model of gastroparesis. Moreover, McCallum *et al*[24] discovered that long-pulse GES (at a frequency that was 10% higher than the intrinsic slow-wave frequency, 300 ms, 4 mA) accelerated gastric emptying in gastroparesis patients. However, Xing *et al*[20] found that long-pulse GES (6 cpm, 375 ms, 4 mA) did not significantly influence gastric emptying in a canine model. In the present study, delayed gastric emptying was accelerated after GES intervention, especially in the GES2 group (5.5 cpm, 300 ms, 4 mA), which supports the findings of most studies in this field. Our results showed that long-pulse GES improved delayed gastric emptying in diabetic rats, and the effect of GES2 (5.5 cpm, 300 ms, 4 mA) was more pronounced than those of GES1 and GES3. Thus, the GES2 protocol should potentially be applied in the clinic, but further studies are needed to explore this issue.

The mechanisms by which long-pulse GES affects gastric emptying remain unclear. ICCs have been shown to play an important role in the regulation of gastric peristalsis, which significantly affects gastric emptying[1,25]. However, few studies have examined the involvement of ICCs in the effect of long-pulse GES on gastric emptying. We conducted related experiments in which we examined the effect of GES on ICCs. The results revealed that long-pulse GES (5.5 cpm, 550 ms, 2 mA) resulted in ICC remodeling in diabetic rats. Furthermore, our previous study showed that both low- and high-frequency electroacupuncture at ST-36 increased the number of ICCs[14]. In the present study, GES intervention also markedly recovered the ultrastructure of ICCs to a minor injury or normal state[26] and increased the number of ICCs in the antrum in diabetic rats, indicating that long-pulse GES might induce ICC remodeling and further contribute to improved gastric emptying.

The c-kit/SCF pathway is one of the most important regulators of ICCs. As the ligand of c-kit, SCF exists in both a soluble form (S-SCF) and a transmembrane form (M-SCF). M-SCF may play a more important role than S-SCF during the differentiation, survival and maintenance of the ICC phenotype[27]. Thus, we focused on M-SCF in our evaluation of c-kit/SCF signaling and our goal of identifying the mechanisms by which GES results in ICC remodeling. Horváth *et al*[8] linked reduced SCF to an ICC deficiency in diabetic gastroparesis and found that the level of M-SCF was

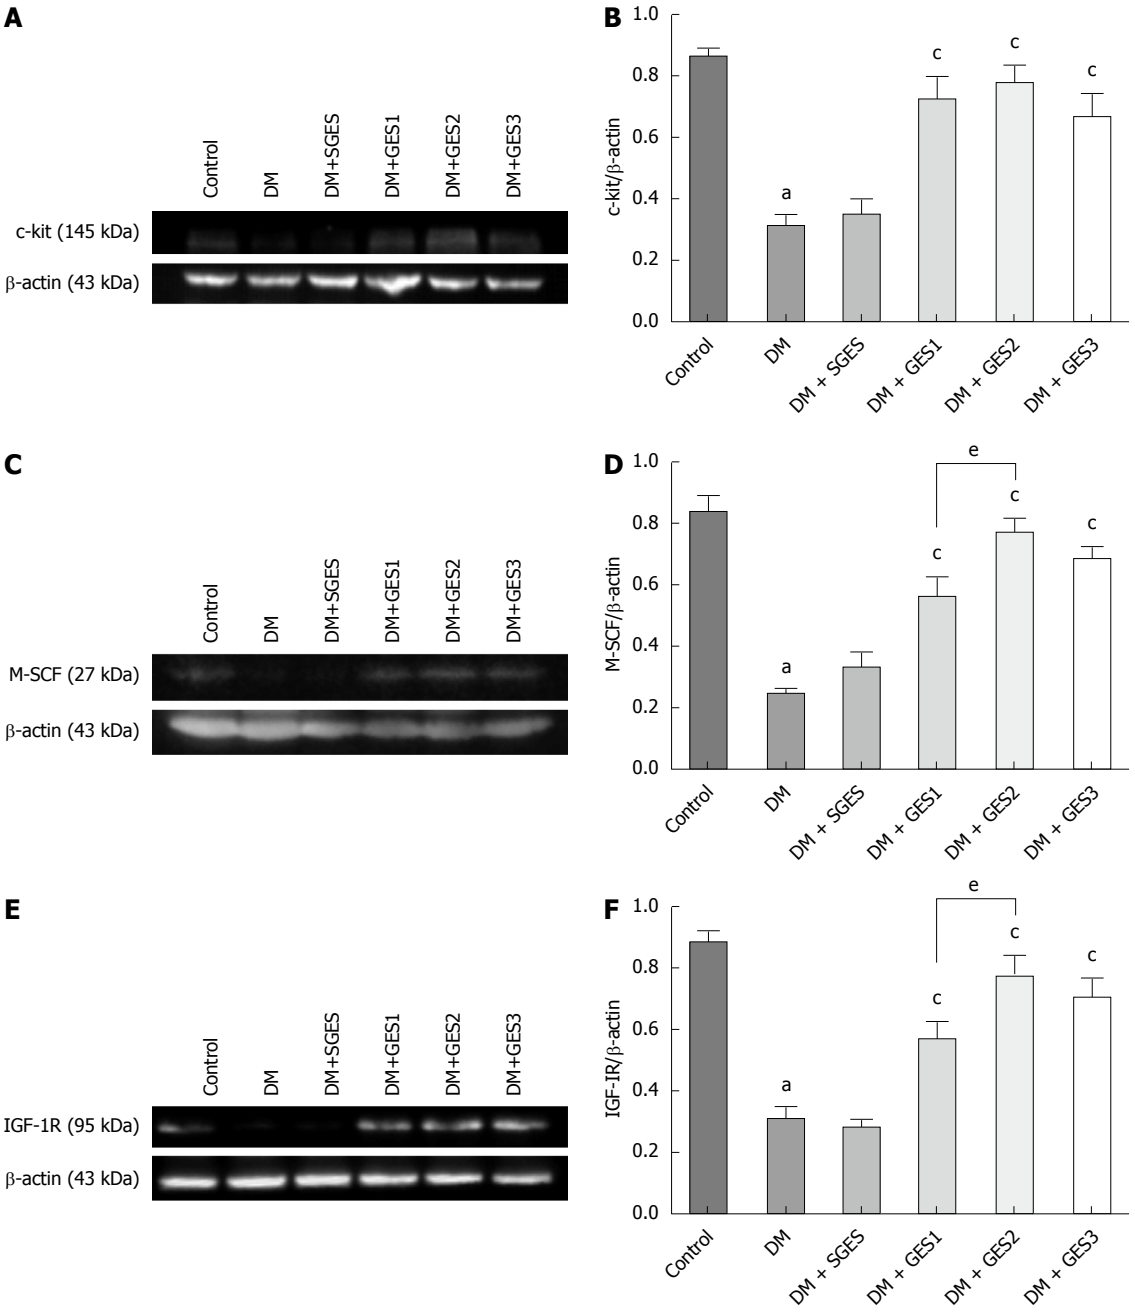

Figure 5 Expression levels of related proteins quantified by Western blot. A, B: The expression of c-kit in different groups; C, D: The expression of M-SCF in different groups; E, F: The expression of IGF-1R in different groups. $^{a}P < 0.05$ *vs* control; $^{c}P < 0.05$ *vs* DM (diabetic group) group; $^{e}P < 0.05$, DM + GES1 (GES parameter 1) *vs* DM + GES2 group. GES: Gastric electrical stimulation.

decreased in the gastric antrum in diabetic mice. Our results also indicate that the expression of M-SCF is markedly decreased in diabetic rats. However, the effects of GES on the expression of M-SCF have rarely been investigated. In a previous study, we showed that both low- and high-frequency electroacupuncture at ST-36 increased the expression of M-SCF in diabetic rats[14]. In the present study, we found that GES treatment also increased the expression of M-SCF, and this increase was stronger when GES2 (5.5 cpm, 300 ms, 4 mA) was applied. Therefore, M-SCF is likely to be involved in ICC remodeling as a result of long-pulse GES.

IGF-1 signaling is one of the main factors that regulate the expression of M-SCF. IGF-1R, which is necessary for the differentiation and maintenance of ICC phenotype, is located on smooth muscle cells but not on ICCs[8,28]. Horváth *et al*[29] showed the first *in vitro* evidence that IGF-1 signaling was responsible for maintaining the ICC network. In their subsequent study, they suggested that endogenous IGF-1 expression was decreased in the diabetic group and that adding IGF-1 to the medium improved the expression of M-SCF[9]. The results of the present study show that the expression of IGF-1R in gastric antral SMCs was markedly decreased in the DM group,

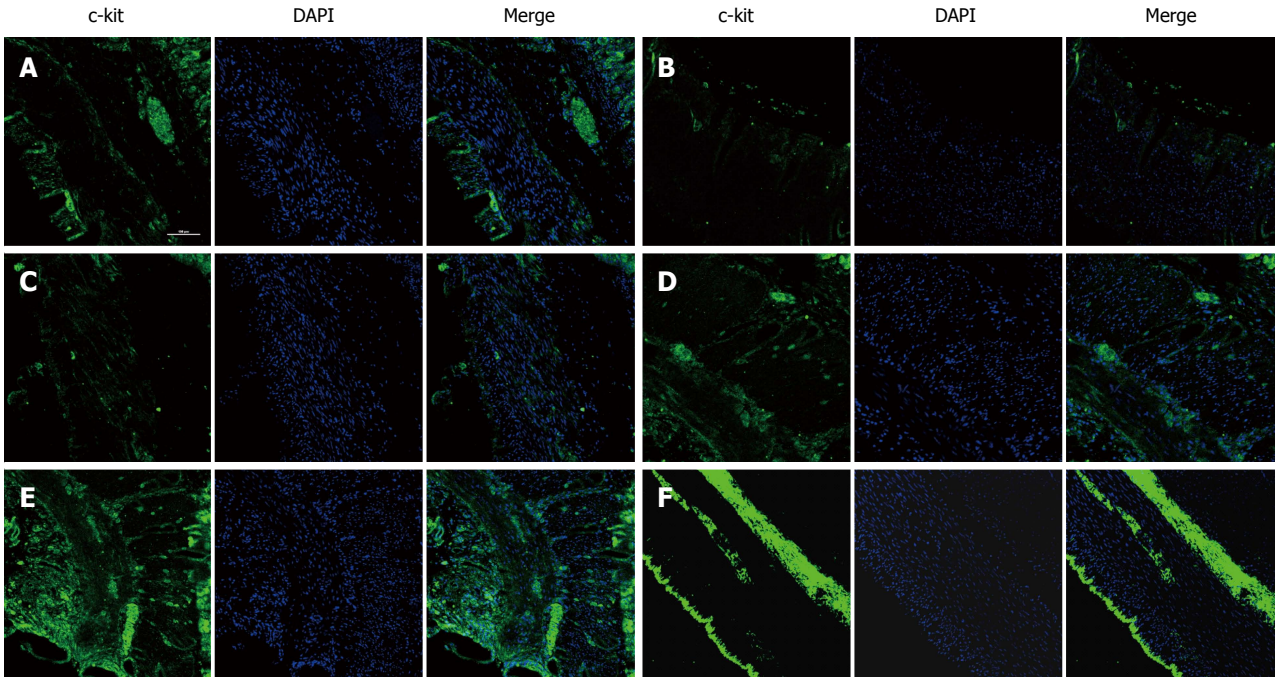

Figure 6 Confocal micrographs of interstitial cells of Cajal. Interstitial cells of Cajal (ICCs) were labelled with c-kit (green) and DAPI (blue). ICCs were abundant in the control group (A). Few ICCs were observed in the DM group (B). Similar changes in ICCs were found in the SGES (diabetic with sham GES) group (C). However, numerous ICCs were observed in the DM (diabetic group) + GES1 (GES parameter 1) group (D), DM + GES2 group (E) and DM + GES3 group (F). Scale bars = 100 μm. GES: Gastric electrical stimulation.

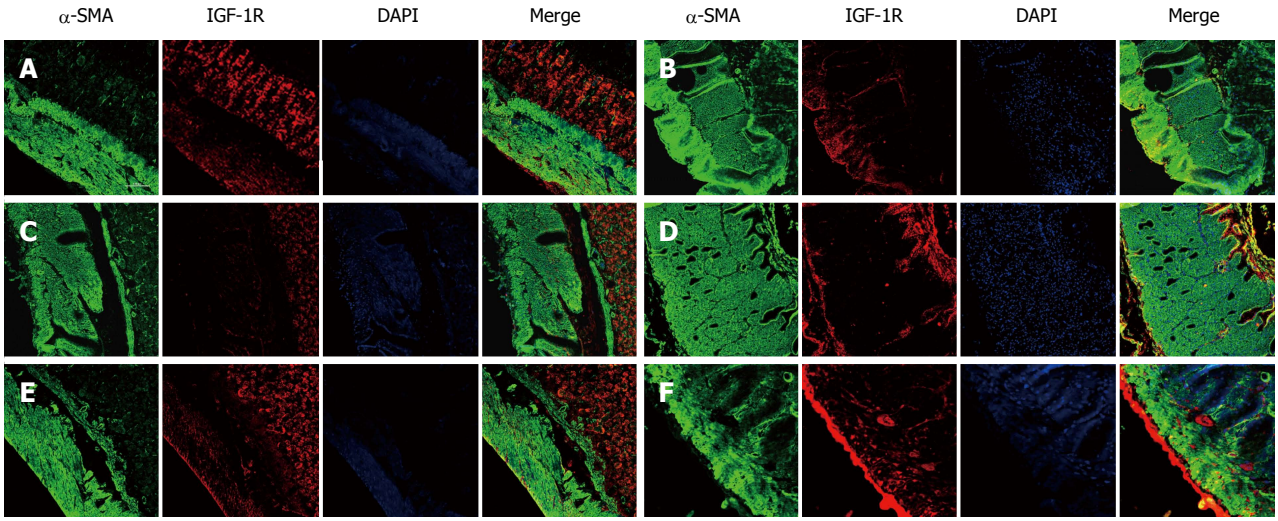

Figure 7 Confocal micrographs showing the distribution of insulin-like growth factor 1 receptor. The smooth muscle cells were labelled with α-SMA (green), IGF-1R (red) and DAPI (blue). IGF-1R expression was high in the control group (A). Weak IGF-1R signals were found in the DM group (B), and similar changes appeared in the SGES group (diabetic with sham GES) (C). Strong IGF-IR signals were captured in the DM (diabetic group) + GES1 (GES parameter 1) group (D), DM + GES2 group (E) and DM + GES3 group (F). Scale bars = 100 μm. DM: and GES parameter 1. GES: Gastric electrical stimulation; IGF: Insulin-like growth factor.

which supports the findings of previous studies[8,9]. Moreover, serum IGF-1 levels were also decreased in the DM group. However, few studies have examined the effects of GES on IGF-1 and IGF-1R levels or the involvement of IGF-1 signaling in the induction of ICC remodeling by GES. In our study, the levels of both IGF-1 and IGF-1R were significantly increased following GES treatment, which mirrored the changes we observed in M-SCF. Additionally, GES2 (5.5 cpm, 300 ms, 4 mA) was more effective in improving the expression of IGF-1 and IGF-1R. These results indicate that improvements in IGF-1 signaling might be involved in the up-regulation of M-SCF expression and that it might also contribute to ICC remodeling in response to long-pulse GES in diabetic rats.

Xing *et al*[30] reported that the total area under the curve for blood glucose in healthy dogs was markedly decreased by long-pulse GES (10 cpm, 300 ms, 8 mA). In the present study, GES did not significantly affect blood glucose levels. We speculate that the

difference between these effects might be associated with differences in the parameters, animal models and physical states that were used, and that the effect of GES on the blood glucose levels in diabetic models might therefore require further study. Yan *et al*[31] reported that pulse-train GES (0.3 ms, 3 mA, 20 Hz for 2 s on and 3 s off) reduced body weight in obese rats. Our results show that long-pulse GES treatment markedly increased body weight in diabetic rats. Therefore, the effects of GES on body weight might depend on the parameters and physical states that are used. Broadly, our results suggest that GES increased the body weight but did not significantly affect blood glucose levels in STZ-induced diabetic rats.

In summary, our results reveal that the expression levels of M-SCF, IGF-1 and IGF-1R are significantly lower and that the number of ICCs is markedly decreased in the gastric antrum of diabetic rats. These characteristics likely contribute to delayed gastric emptying. Following long-pulse GES intervention, ICCs remodeled and gastric emptying was improved. The IGF-1 signaling pathway might participate in this process by enhancing the expression of M-SCF on SMCs and then protecting ICCs. Furthermore, the effects of GES2 (5.5 cpm, 300 ms, 4 mA) on the expression of M-SCF and IGF-1/IGF-1R appeared to be stronger than those of GES1 and GES2. Long-pulse GES involves low-frequency/high-energy stimulation; its frequency is slightly higher than the intrinsic slow wave and requires a high amount of energy. This stimulus could directly activate ICCs and/or SMCs without involving cholinergic nerves[21], and the magnitude of energy is probably responsible for the effects of long-pulse GES. In our study, GES2 (5.5 cpm, 300 ms, 4 mA) afforded higher energy than did GES1 (5.5 cpm, 100 ms, 4 mA) and GES3 (5.5 cpm, 550 ms, 2 mA), and this might partly explain why GES2 had a more significant effect on gastric emptying and the IGF-1 signaling pathway. Thus, this parameter should be used in clinical applications involving long-pulse GES. However, further studies into the mechanisms underlying these processes are needed to ensure the safety and clinical efficacy of using long-pulse GES as a treatment for refractory functional gastric disorders.

COMMENTS

Background

Gastric electrical stimulation (GES) regulates gastric motility and promotes the renovation of interstitial cells of Cajal (ICCs). However, the mechanisms underlying this effect remain unclear. Previous studies demonstrated that ICCs are damaged and the insulin-like growth factor 1 (IGF-1) pathway is down-regulated in diabetic models. In this study, the authors report that applying long-pulse GES using three different parameters promoted the regeneration of ICCs and that the IGF-1 signaling pathway is likely to be involved in this process.

Research frontiers

Experiments have shown that ICCs are damaged in diabetic models. The c-kit/SCF pathway is one of the most important regulators of ICCs. M-stem cell factor (SCF) may play a more important role than S-SCF in the differentiation, survival and maintenance of the ICC phenotype. IGF-1 signaling is one of the main factors that regulate the expression of M-SCF.

Innovations and breakthroughs

This study provides evidence showing that long-pulse GES protects the ICCs in diabetic rats and that the IGF-1 signaling pathway is involved in this effect. The effects of one GES parameter (5.5 cpm, 300 ms, 4 mA) were stronger.

Applications

One GES parameter (5.5 cpm, 300 ms, 4 mA) showed greater potential for being used in clinical application involving long-pulse GES, and the IGF-1 signaling pathway may be a possible therapeutic target in gastroparesis.

Terminology

ICCs, as the gastrointestinal pace-making cells, play an important physiological role in coordinating gastric contractile activity and gastric motility. Long-pulse GES restores injured ICCs. SCF and IGF-1 are regulatory proteins that protect ICCs.

Peer-review

An interesting paper! The paper by Li and colleagues describes the effect of different timing pulse GES (gastric electrical stimulation) on gastric emptying in a rat diabetic model. In particular, the authors demonstrate that long-term pulsing GES protects ICCs located in the gastric antrum and this is associated with an improvement of gastric emptying delay during diabetes. Interestingly, the authors also suggest that the IGF-1 signaling pathway may be involved.

Abstract

AIM: To investigate whether Tg737 is regulated by microRNA-548a-5p (miR-548a-5p), and correlates with hepatocellular carcinoma (HCC) cell proliferation and apoptosis.

METHODS: Assays of loss of function of Tg737 were performed by the colony formation assay, CCK assay and cell cycle assay in HCC cell lines. The interaction between miR-548a-5p and its downstream target, Tg737, was evaluated by a dual-luciferase reporter assay and quantitative real-time polymerase chain reaction. Tg737 was then up-regulated in HCC cells to evaluate its effect on miR-548a-5p regulation. HepG2

cells stably overexpressing miR-548a-5p or miR-control were also subcutaneously inoculated into nude mice to evaluate the effect of miR-548a-5p up-regulation on *in vivo* tumor growth. As the final step, the effect of miR-548a-5p on the apoptosis induced by cisplatin was evaluated by flow cytometry.

RESULTS: Down-regulation of Tg737, which is a target gene of miR-548a-5p, accelerated HCC cell proliferation, and miR-548a-5p promoted HCC cell proliferation *in vitro* and *in vivo*. Like the down-regulation of Tg737, overexpression of miR-548a-5p in HCC cell lines promoted cell proliferation, increased colony forming ability and hampered cell apoptosis. In addition, miR-548a-5p overexpression increased HCC cell growth *in vivo*. MiR-548a-5p down-regulated Tg737 expression through direct contact with its 3′ untranslated region (UTR), and miR-548a-5p expression was negatively correlated with Tg737 levels in HCC specimens. Restoring Tg737 (without the 3′UTR) significantly hampered miR-548a-5p induced cell proliferation, and rescued the miR-548a-5p induced cell proliferation inhibition and apoptosis induced by cisplatin.

CONCLUSION: MiR-548a-5p negatively regulates the tumor inhibitor gene Tg737 and promotes tumorigenesis *in vitro* and *in vivo*, indicating its potential as a novel therapeutic target for HCC.

Key words: microRNA-548a-5p; Tg737; Proliferation; Apoptosis; Hepatocellular carcinoma cells

Core tip: Tg737 gene functions as a tumor suppresser in hepatocellular carcinoma (HCC). However, studies based on regulation of Tg737 were rare. MiR-548a-5p is a novel miRNA which negatively regulates Tg737 and promotes tumorigenesis *in vitro* and *in vivo*, indicating its potential as a novel therapeutic target for HCC.

Zhao G, Wang T, Huang QK, Pu M, Sun W, Zhang ZC, Ling R, Tao KS. MicroRNA-548a-5p promotes proliferation and inhibits apoptosis in hepatocellular carcinoma cells by targeting Tg737. *World J Gastroenterol* 2016; 22(23): 5364-5373 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5364.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5364

INTRODUCTION

Primary hepatocellular carcinoma (HCC) is currently one of the most common and lethal malignancies, and the leading cause of death among patients with cirrhosis[1]. Despite advances in surgical therapies, the reason for frequent recurrence remains mostly obscure. Several studies showed that some genes may play a major role in cell proliferation and migration in HCC cells[2]. However, little information is available about the regulation of these genes.

The Tg737 gene, first found in algae[3], is now identified as a tumor suppressor gene in multiple cancers, including cancers of the liver, kidney and pancreas[4-5]. In liver tissues from HCC patients, a 59% down-regulation of the Tg737 was observed[6]. This gene may participate in alterations in a series of human or rodent liver tumors and tumorigenic cell lines[7]. In the previous investigation, we found that Tg737 contributed to hypoxia-induced invasion and migration in HepG2 and MHCC97H cells[8], and that Tg737 inhibition resulted in malignant transformation in fetal liver stem/progenitor cells by promoting cell-cycle progression and differentiation arrest[9]. However, the regulatory factor for Tg737 is not yet clear.

In recent years, microRNAs (miRNAs) emerged as a group of important endogenous modulators of gene function at the posttranscriptional level. It has been revealed that many miRNAs are underscored by the promotion of tumorigenesis and cancer progression[10-11]. More importantly, in HCC, several miRNAs have been demonstrated to contribute to the tumor regulation, including, but not limited to, migration, invasion and proliferation[12-13]. Multiple miRNAs have been identified as down-regulated tumor-suppressing genes involved in cellular processes, including miR-34a[14], miR-122[15], miR-199a[16] and miR-200[17]. Contrarily, miR-21[18], miR-148a[19] and miR-221[20], as oncogenic miRNAs, showed up-regulated expression which potentially targeted many tumor-suppressive genes. These results suggest the involvement of miRNAs in HCC.

MiR-548 is a big, poorly conserved primate-specific miRNA family. There are 68 members of the hsa-miR-548 family recorded in the miRBase database[21]. The products of miR-548c-5p and miR-548c-3p show discrepant evolutionary patterns, which brings about great genetic distances between pre-miRNAs to some extent and might contribute to dynamic expression profiles and regulatory network[22]. MiR-548c-3p was identified as a source of functional biomarkers for the primary prostate cancer progression[23]. It also significantly increased in *Helicobacter pylori*-negative cancer tissues[24]. In addition, our previous studies found the high expression of miR-548c-3p and miR-548c-5p in side population cells from HCC[25]. However, like the homologous gene, the exact effect of miR-548a-5p on HCC is still unknown. The direct aim of this study was to investigate whether Tg737 is regulated by miR-548a-5p, and correlates with HCC cell proliferation and apoptosis.

MATERIALS AND METHODS

Cell lines and culture

HCC cell lines HepG2 and MHCC97-H were maintained in DMEM medium (Invitrogen, United States) sup-

plemented with 10% fetal bovine serum (FBS, Invitrogen, United States), 100 IU/mL penicillin, and 100 μg/mL streptomycin. Cells were cultured in a humidified cellular incubator (Thermo Fisher, United States) supplemented with 5% CO_2 at 37 ℃.

RNA isolation, reverse transcription and quantitative real-time polymerase chain reaction

Total RNA was extracted using RNAiso Plus (Takara, Japan) according to the manufacturer's instructions. Reverse transcription was carried out using the PrimeScript RT Reagent Kit Perfect Real Time (Takara, Dalian, China) or the miScript II RT Kit (Qiagen, Germany). Quantitative polymerase chain reaction (qPCR) was used to detect the miRNA expression levels. The SYBR Green dye (Takara, Dalian, China) was used according to the manufacturer's protocol. The following primers were used for analysis: TG737: forward primer, 5'-GTGCCAGTAGTAAAGGTG-3' and reverse primer, 5'-GGTCGTTCTATTTGAGGG-3'; β-actin: forward primer, 5'-TCACCAACTGGGACGACA-3' and reverse primer, 5'-ACAGCACCGCCTGGATAG-3'; miR-548a-5p: forward primer, 5'-AAAAGTAATTGCGAGTTTACC-3' and reverse primer, Universal Primer (Qiagen, Germany). The CFX96 real-time PCR detection system (Bio-Rad, United States) was used to perform real-time PCR and the $2^{-\Delta\Delta CT}$ method was used to determine the relative gene expression. Mature miRNA was normalized to U6-snRNA.

Plasmid construction

MiR-548a-5p was obtained from Gene Pharma (Shanghai, China). The miR-548a-5p and 150 bp of flanking sequence was amplified with forward primer, 5'-CAGCTGGGTGCTCAGCCAGG-3', reverse primer, 5'-GGCAACTTAATGTTTCTTGC-3'. A PCR fragment was inserted into the pENTRTM3C vector (Invitrogen, United States) using EcoR I and Xho I sites. The pLenti6.3-miR-548a-5p vector was constructed using Gateway LR Clonase II Enzyme Mix (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's instructions. The constructs were sequenced for verification. Overexpression and RNAi vectors were determined by Gene Pharma (Shanghai, China). The target sequence of sh-Tg737 was 5-'GTTACATACTTGAGACAAA-3'. Tg737 and Tg737-3'UTR overexpression vectors were also designed.

Western blot

Proteins were extracted from cells with a RIPA buffer purchased from Beyotime with 1 mmol/L PMSF and a cocktail of protease inhibitors. The proper amount of loading buffer was added into cell lysis, followed by a BCA protein determination. SDS-PAGE was performed according to Genshare's instructions (Genshare, Xi'an, China). The results were analyzed using Image J 5.0 software. Anti-Tg737 antibody (13967-1-AP) and anti-β-actin antibody (14395-1-AP) were purchased from Proteintech (Proteintech, Wuhan, China). Goat anti-rabbit IgG HL (HRP) (ab6721) was supplied by Abcam (United States).

Colony formation assay

Two hundred cells were seeded into a 6 cm dish and cultured in a complete medium for 10 d. Cells were fixed in methanol and stained with crystal violet, washed with PBS three times before fixing and staining. Colonies were washed with ddH_2O after 30-min staining. The number and area of the colonies were calculated with Image J 5.0 software.

Cell viability assay

Cells were seeded in 96-well plates (2.0×10^3 cells/well). The cells were incubated for 0, 1, 2, 3 and 4 d using three replicates. Cell Counting Kit-8 (CCK-8) (7Sea Pharmatech, China) was used for cell proliferation analysis according to the manufacturer's protocol. The Bio-Rad iMARK™ microplate reader was used to detect the optical density at 450 nm.

Cell cycle and apoptosis assay

Cells were seeded in 6-well plates with 2.0×10^5 cells in each well. After 48 h, flow cytometry was performed to detect cell cycle analysis and the percentage of dying cells. The annexin V-FITC/PI apoptosis detection kit (Biovision, Palo Alto, CA, United States) was used according to the manufacturer's protocol. Flow cytometry was performed with the Epics XL-MCL (BECKMAN coulter, United States). The results were analyzed using ModFit LT V3.1 (BECKMAN coulter).

Luciferase reporter assays

HepG2 and MHCC97H cells were seeded in 48 well plates and allowed to be adherent for 24 h. The cells were then co-transfected with a mixture of 100 ng pGL3-Tg737-3'UTR, 20 μmol miR-548a-5p mimic or antisense-miR-548a-5p, and 5 ng pRL-TK using Lipofectamine 2000 reagent and performed in three independent experiments. Firefly and Renilla luciferase activities were detected using the Dual-Glo luciferase assay system (Promega, United States) following the manufacturer's instructions.

Tumor xenograft

HepG2 cells (2×10^6) stably overexpressing miR-548a-5p or miR-control were injected subcutaneously into the flank site of male Balb/c nude mice (Fourth Military Medical University, Xi'an, China). Tumor volume was measured with calipers every 5 d[26]. On day 30, mice were killed by cervical dislocation. All animal procedures were performed in accordance with a protocol approved by the Fourth Military Medical University Animal Care and Usage Committee.

Statistical analysis

Sample capacity for each experiment was adjusted according to the variance obtained. All experiments were performed in triplicate. In graphs, all data are

presented as mean ± SD and were evaluated by the Student's *t*-test. Statistical analyses were carried out using SPSS 16.0 software. Differences were considered significant at $P < 0.05$.

RESULTS

Down-regulation of Tg737 promotes HCC cell proliferation in vitro

To illuminate the role of Tg737 in HCC cell proliferation, HCC cell lines HepG2 and MHCC97H were transfected with a si-Tg737 sequence or negative control (Figure 1A). Down-regulation of Tg737 significantly promoted the proliferation of HepG2 and MHCC97H cells and enhanced colony forming capability (Figure 1B and C). The distribution of HepG2 and MHCC97H cell cycles showed that the percentage of cells in G0/G1 phase significantly decreased in Tg737 down-regulated cells compared with their counterparts, while the cells in S phase increased sharply (Figure 1D). In all cases, down-regulation of Tg737 promoted cell proliferation and inhibited G0/G1 phase arrest in HCC cells.

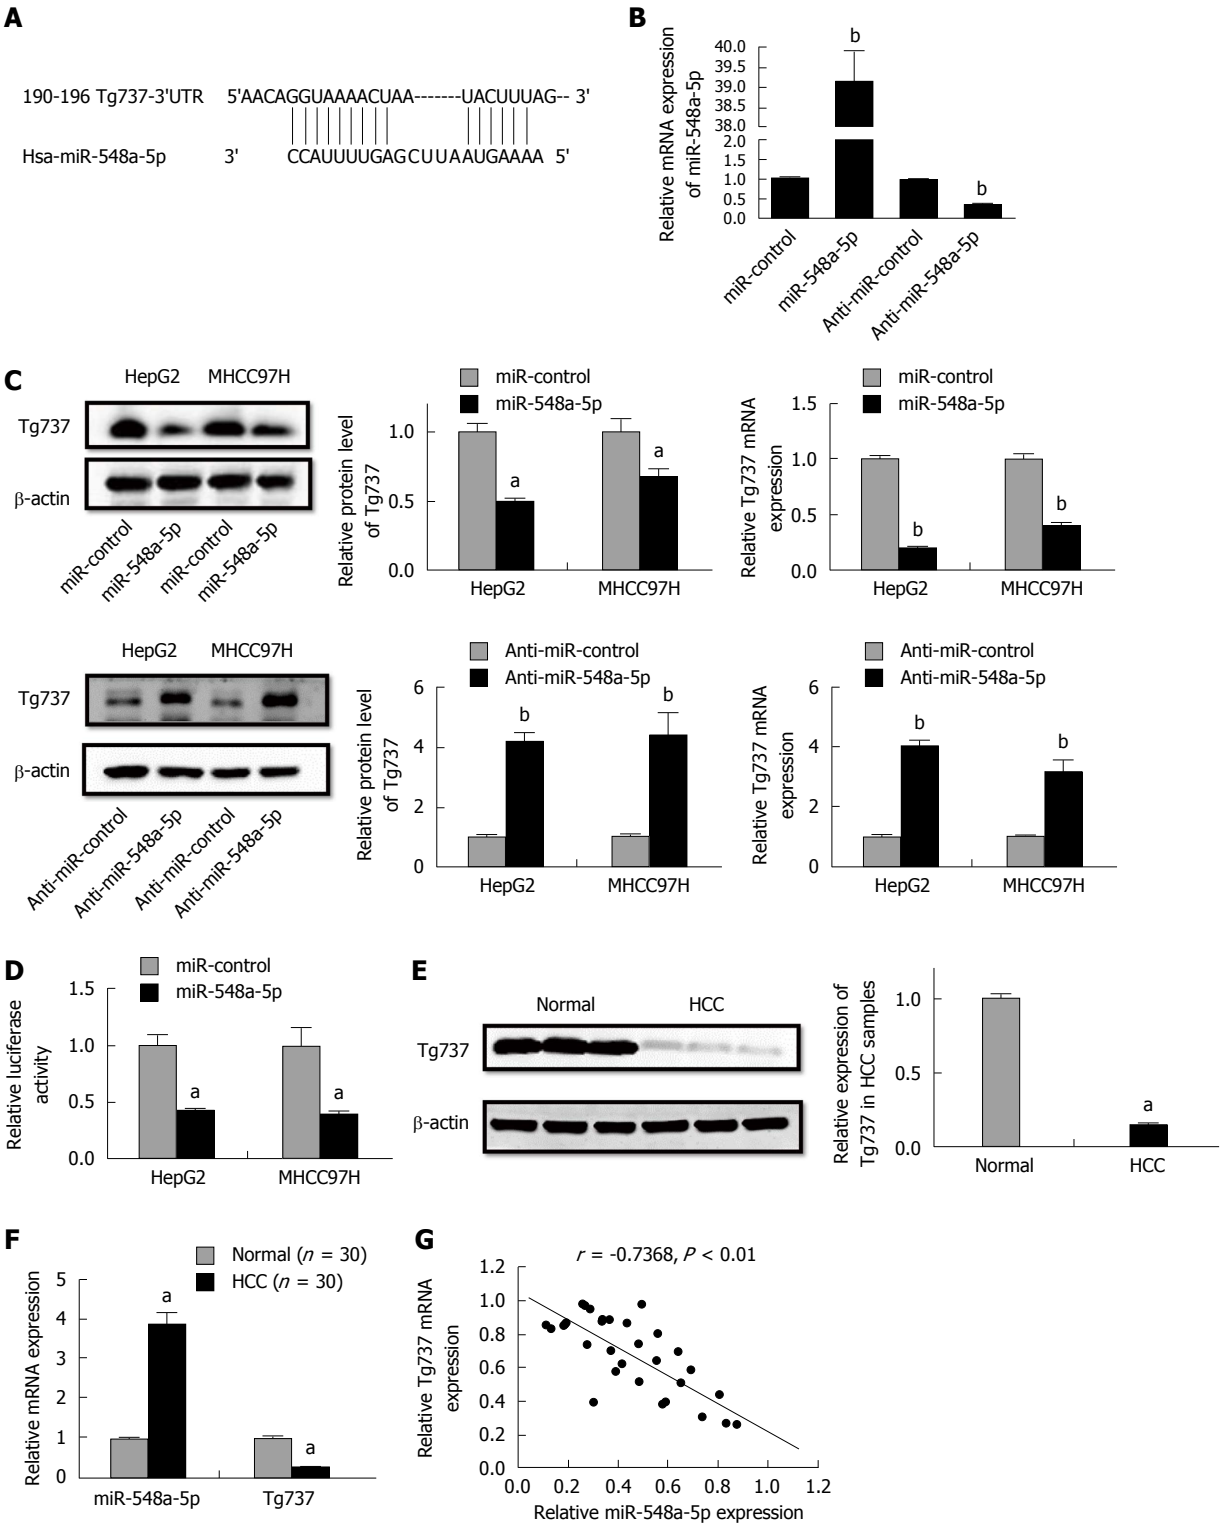

Figure 2 Tg737 is a target gene of miR-548a-5p. A: MiR-548a-5p and its deductive binding domain in the 3'UTR of Tg737; B: Relative expression of miR-548a-5p; C: qRT-PCR and Western blot analysis demonstrated that miR-548a-5p overexpression significantly decreased Tg737 mRNA expression and miR-548a-5p knockdown significantly increased Tg737 mRNA expression in HepG2 and MHCC97H cells; D: Luciferase reporter assay of the connection between the 3'UTR of Tg737 and miR-548a-5p in HepG2 and MHCC97H cells; E: Western blot analysis demonstrated higher miR-548a-5p and lower Tg737 expression in human HCC specimens compared to normal liver tissue; F: qRT-PCR demonstrated higher miR-548a-5p and lower Tg737 expression in human HCC specimens compared to normal liver tissue; G: Spearman's correlation assay showed that miR-548a-5p was negatively correlated with Tg737 mRNA expression in HCC specimens. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control.

MiR-548a-5p down-regulates Tg737 by interacting with its 3'UTR

A bio-informatics assay with TargetScan demonstrated that Tg737 is a potential target of miR-548a-5p (Figure 2A). To illuminate whether miR-548a-5p acts on Tg737, we transfected miR-548a-5p as well as anti-miR-548a-5p to HCC cells. Relative miR-548a-5p levels are shown in Figure 2B. MiR-548a-5p overexpression decreased

mRNA and protein levels of Tg737, while miR-548a-5p inhibition increased mRNA and protein levels of Tg737 in HepG2 and MHCC97H cells (Figure 2C). To confirm whether Tg737 acts as a molecular target regulated by miR-548a-5p, we constructed luciferase reporter vectors containing Tg737-3'UTR. The reporter vectors were co-transfected into HepG2 and MHCC97H cells. Up-regulation of miR-548a-5p expression significantly decreased the luciferase activity of Tg737 containing 3' UTR (Figure 2D). Further, to illuminate whether miR-548a-5p inhibits Tg737 in patients diagnosed with HCC, we detected the expression of miR-548a-5p and Tg737 in 30 HCC specimens as well as 30 normal ones. Compared with normal liver tissues, the HCC specimens showed higher miR-548a-5p and lower Tg737 expression (Figure 2E and F). In addition, a statistically significant correlation was revealed by Spearman's correlation analysis between mRNA levels of miR-548a-5p and Tg737 (r = -0.7368, P < 0.01; Figure 2G). Together, these data suggest that Tg737 is a target of miR-548a-5p in HCC.

MiR-548a-5p promotes HCC cell proliferation in vitro and in vivo

Continuing our analysis, we detected the impact of miR-548a-5p on HCC cell proliferation. Similar to the effect of Tg737 knockdown, miR-548a-5p overexpression in HepG2 and MHCC97H cells significantly accelerated cell proliferation, promoted colony forming capacity, and inhibited cell arrest in G0/G1 phase (Figure 3A-C). To investigate the relationship between miR-548a-5p and its tumor promoting characteristics *in vivo*, HepG2 cells exhibiting sustained expression of miR-548a-5p or control cells were injected into the subcutaneous skin layer of nude mice. Tumor size was detected every 5 d from the injection. The mice were killed 30 d after implantation. As shown in Figure 3D, tumors in those specimens with miR-548a-5p overexpression were larger significantly than those in the control group. The average size and weight of miR-548a-5p overexpressing tumors were increased significantly (Figure 3D and E). Collectively, miR-548a-5p may have a vigorous ability to enhance HCC cell proliferation *in vivo* and *in vitro*.

Restoration of Tg737 inhibits miR-548a-5p-mediated HCC cell proliferation inhibition and protects against cisplatin induced apoptosis

We further traced whether the restoration of Tg737 could arrest the HCC cell proliferation induced by miR-548a-5p overexpression in HepG2 and MHCC97H cells. A Western blot technique was performed 48 h after transfection of control, Tg737 and Tg737-3' UTR overexpression vectors into miR-548a-5p overexpressing HepG2 and MHCC97H cells (Figure 4A). Tg737 up-regulation significantly decreased the capacity of cell proliferation and colony formation (Figure 4B). Up-regulation of Tg737 rescued miR-548a-5p induced inhibition in cell cycle arrest (Figure 4B-D). However, overexpression of Tg737-3'UTR in miR-548a-5p overexpressing HepG2 and MHCC97H cells had no significance (Figure 4B-D). These results again illustrate that Tg737 is a functional target of miR-548a-5p. We evaluated the impact of miR-548a-5p on apoptosis by flow cytometry. Cell apoptosis increased in anti-miR-548a-5p transfected HCC cells (Figure 4E). Meanwhile, the cell apoptosis ratio decreased in miR-548a-5p transfected HCC cells (Figure 4F).

DISCUSSION

To our knowledge, this is the first report describing the effects of miR-548a-5p on HCC cell proliferation and apoptosis and the relationship with the Tg737 protein. In this study, we showed that Tg737 was the key regulator of the proliferation of human HCC cell lines. Overexpression of miR-548a-5p observably increased oncogenesis in nude mice. Moreover, when the expression of Tg737 was inhibited through interaction with its 3'UTR, HCC cells grew quickly when induced by miR-548a-5p. These findings suggest that miR-548a-5p acts as a novel tumor promoter in HCC cells and contributes to the tumor behavior by targeting the Tg737 gene.

MiR-548 was identified as a large human gene family with 69 members, which are mainly expressed in primates and play a key role in multiple biological processes[22]. The miR-548 family possesses the most abundant primate-specific miRNA common seed (5'-AAAGUA-3') detected by computational characterization[27] and the signatures were identified to be down-regulated in peripheral blood mononuclear cells from heart failure patients. This information suggests that miR-548 level could be used as a potential biomarker specific for cardiac dysfunction[28]. In addition, endogenous miR-548 levels were suppressed during viral infections. MiR-548 shows significant identity to three viruses (HCV, HBV and HIV-1)[29], and regulated the host antiviral response *via* direct targeting interferon[30]. The marked up-regulation of miR-548ah-5p suggests that it might be related to the transition from the immune tolerance phase to the immune activation phase in chronic hepatitis B[31]. Such evidence makes miRNA a valuable therapeutic agent for patients diagnosed with multiple virus infection. Regarding the relationship of miR-548 with tumors, an analysis of the expression profiles and functional affinities of 3500 putative target genes of miR-548 suggested its cancer-related regulatory role[32]. A recent study found that miR-548d-3p, another miR-548 family member, is usually overexpressed in numerous types of cancer and affects tumorigenesis[33]. Overexpression of the miR-548 family, especially miR-548a-5p and miRNA-548d-5p, could play a complementary role in supporting the oncogenicity in cervical carcinogenesis[34]. Similar results were obtained in our study. MiR-548a-5p

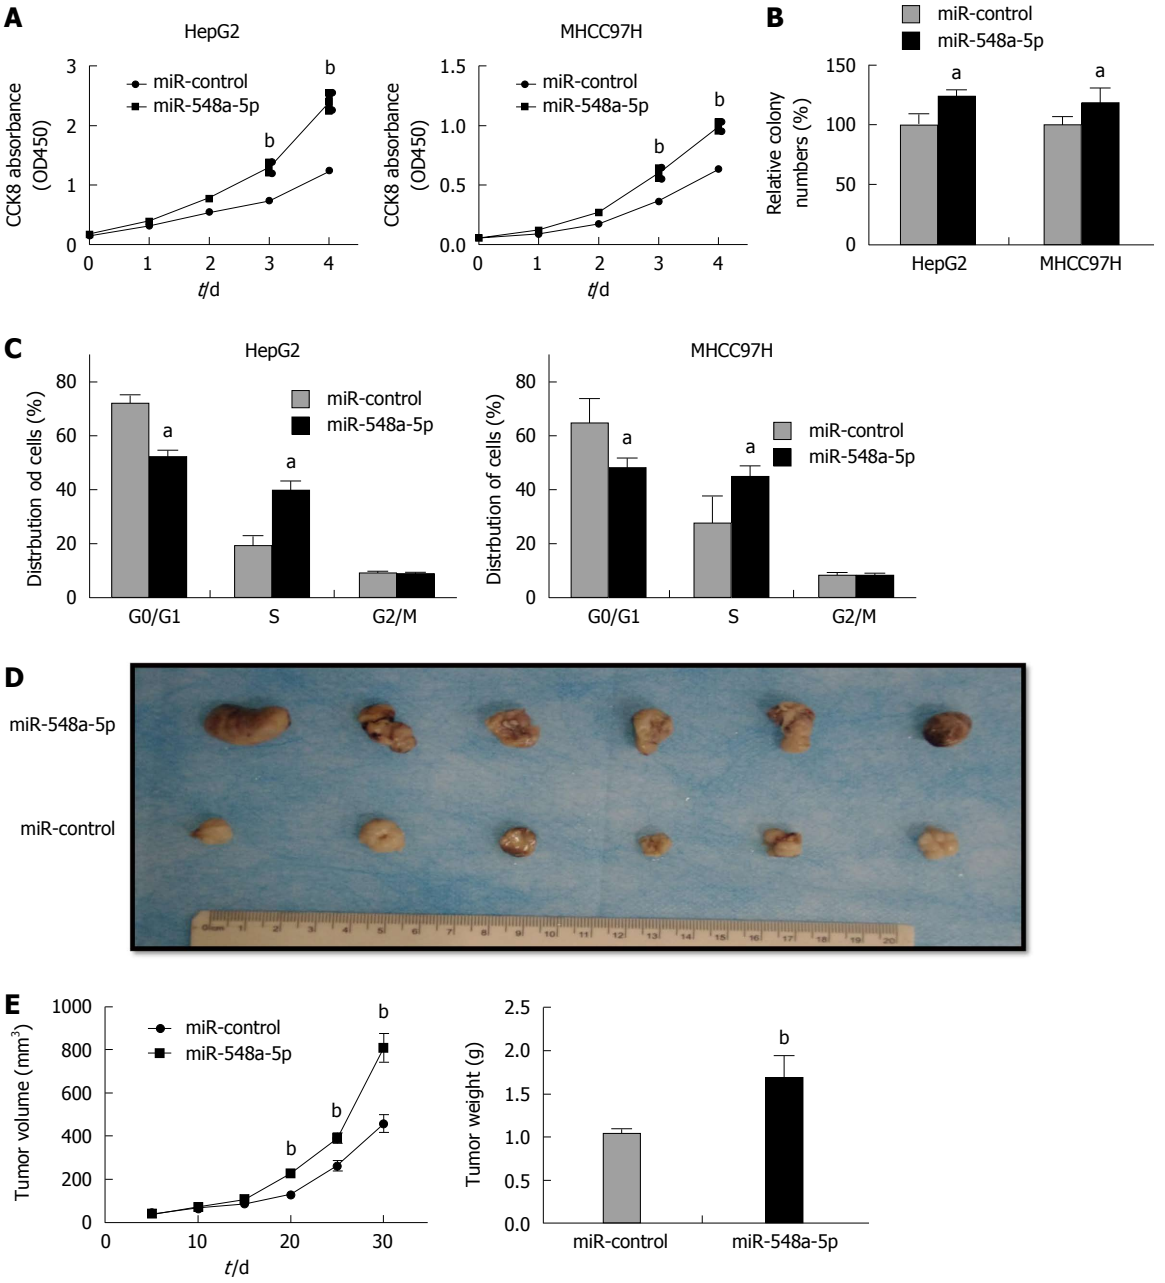

Figure 3 miR-548a-5p promotes hepatocellular carcinoma cell proliferation *in vitro* and *in vivo*. A: CCK-8 assays of HepG2 and MHCC97H cells constantly expressing miR-548a-5p or miR-control; B: Colony forming assays of HepG2 and MHCC97H cells constantly expressing miR-548a-5p or miR-control; C: Cell cycle assays of HepG2 and MHCC97H cells constantly expressing miR-548a-5p or miR-control; D: MiR-548a-5p or miR-control overexpressing HepG2 cells were injected into the subcutaneous layer of nude mice. overexpression accelerated HepG2 and MHCC97H cell proliferation *in vitro* and increased the tumor size and weight *in vivo*, which indicates that miR-548a-5p promotes hepatic neoplasia.

Tg737 has attracted much attention because its functional inactivation by regulation of its expression is relevant to the formation of many solid tumors, such as those in the liver, kidney, and pancreas[4-5]. As a liver tumor suppressor gene, it has been implicated to be important for cell proliferation and apoptosis[35], because it is found deficient in HCC samples from chemical-induced rats and clinical patients[7,36]. In our previous research, Tg737 was found to be remarkably decreased in gene expression in side population cells of HCC, and the loss of heterozygosity of Tg737 was markedly associated with a poor prognosis in patients with HCC after curative liver resection[37]. In the present study, we confirmed these results and found that a loss of Tg737 function showed growth promotion in HepG2 and MHCC97H cells, which corresponds to the results of miR-548a-5p overexpression. Furthermore, miR-548a-5p knockdown rescued the effects caused by Tg737. There was a significant inverse correlation between miR-548a-5p expression and Tg737 mRNA and protein levels in hepatocellular carcinoma tissue and cell specimens. Thus, all these

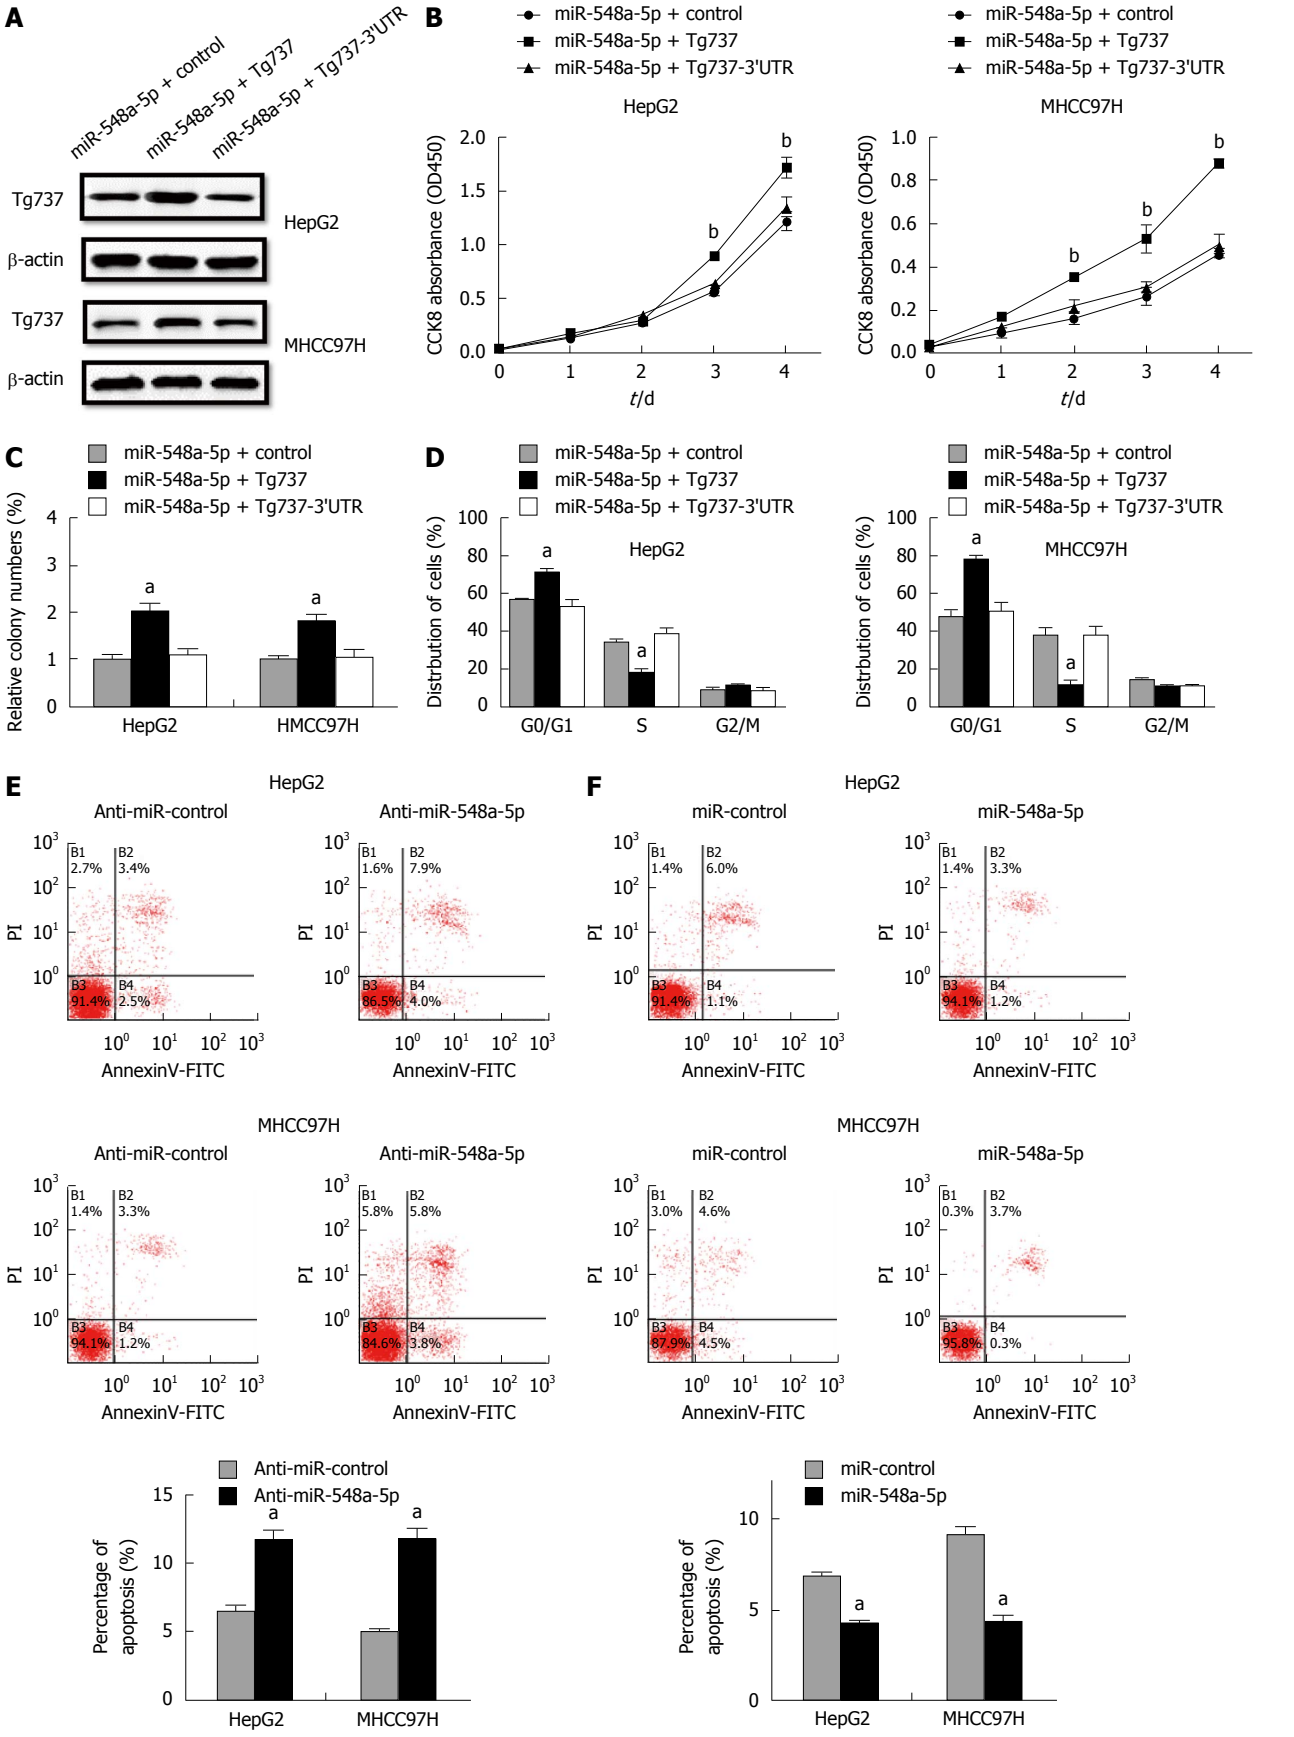

Figure 4 Restoration of Tg737 rescues the miR-548a-5p induced cell proliferation inhibition and apoptosis induced by cisplatin. A: Western blot was performed 48 h after transfection of pc CON, pc Tg737 and plasmid with 3'UTR of Tg737 into miR-548a-5p overexpressing HepG2 and MHCC97H cells; B: CCK-8 assay; C: Colony forming assay; D: Cell cycle assay; E: Cell apoptosis increased in anti-miR-548a-5p transfected HepG2 and MHCC97H cells; F: Cell apoptosis decreased in miR-548a-5p transfected HepG2 and MHCC97H cells. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control.

results support the hypothesis that miR-548a-5p functions in HCC by targeting the 3'UTR of Tg737.

In summary, our observations provide novel evidence that miR-548a-5p negatively regulates the tumor inhibitor gene Tg737 and promotes tumorigenesis *in vitro* and *in vivo*, adding to our understanding of the biological function of miR-548a-5p, as well as its relationship with Tg737. Therapeutic strategies to inhibit miR-548a-5p therefore potentially may be useful in limiting HCC growth and metastasis. A practical application of our findings could be the use of miR-548a-5p expression as a potential predictor of tumors that may be more likely to respond to Tg737-targeting therapies.

COMMENTS

Background

Primary hepatocellular carcinoma (HCC) is one of the most common and lethal malignancies. Despite advances in the surgical therapies, the reason of frequent recurrence remains mostly unclear. Several studies show that some genes may have good roles in cell proliferation and migration in HCC cells. The Tg737 gene is now identified as a tumor suppressor gene in multiple cancers, including those of the liver, kidney, and pancreas. In liver tissues from HCC patients, a 59% down-regulation of the Tg737 was observed. This gene may participate in alterations in a series of human or rodent liver tumors and tumorigenic cell lines. Nevertheless, the regulatory factor for Tg737 is not fully clear.

Research frontiers

In recent years, microRNAs (miRNAs) emerged as a group of important endogenous modulators of gene function at the posttranscriptional level. It has been revealed that many miRNAs are underscored by the promotion of tumorigenesis and cancer progression. More importantly, in HCC, several miRNAs have been demonstrated to contribute to the tumor regulation, including, but not limited to, migration, invasion, and proliferation. Multiple miRNAs have been identified as down-regulated tumor-suppressing genes involved in cellular processes, as oncogenic miRNAs, showed up-regulated expressions which potentially targeted many tumor-suppressive genes. MiR-548 is a large and poorly conserved primate-specific miRNA family. The authors previous studies have found high expression of miR-548c-3p and miR-548c-5p in side population cells from HCC. However, like the homologous gene, the exact effect of miR-548a-5p on HCC is still unknown. The direct aim of this study was to investigate whether Tg737 is regulated by miR-548a-5p, and correlates with HCC cell proliferation and apoptosis.

Innovations and breakthroughs

MiR-548a-5p negatively regulates the tumor inhibitor gene Tg737 and promotes tumorigenesis *in vitro* and *in vivo*. The novelty of the research represents the idea that the inhibition of miR-548a-5p may limit HCC growth, and miR-548a-5p expression may be the potential predictor of tumors that respond to Tg737-targeting therapies.

Applications

In summary, this observations provide novel evidence that miR-548a-5p negatively regulates the tumor inhibitor gene Tg737, and promotes tumorigenesis *in vitro* and *in vivo*, which adds to the authors understanding of the biological function of miR-548a-5p, as well as the relationship with Tg737. Therapeutic strategies to inhibit miR-548a-5p therefore potentially may be useful to limit HCC growth and metastasis. A practical application of the authors findings could be the use of miR-548a-5p expression as a potential predictor of tumors that may be more likely to respond to Tg737-targeting therapies.

Peer-review

The study by Zhao Ge *et al* on microRNA-548a-5p and its role in hepatocellular carcinoma *via* Tg737 is very interesting. The authors show that miR-548a-5p regulates negatively the tumor suppressor gene Tg737 and promotes tumorigenesis *in vitro* and *in vivo*. The authors suggest that therapeutic strategies to inhibit miR-548a-5p in the future may prove useful in limiting HCC growth and metastasis.

Abstract

AIM: To explore the probable pathway by which curcumin (Cur) regulates the function of Treg cells by observing the expression of costimulatory molecules of dendritic cells (DCs).

METHODS: Experimental colitis was induced by administering 2, 4, 6-trinitrobenzene sulfonic acid (TNBS)/ethanol solution. Forty male C57BL/6 mice were randomly divided into four groups: normal, TNBS + Cur, TNBS + mesalazine (Mes) and TNBS groups. The mice in the TNBS + Cur and TNBS +Mes groups were treated with Cur and Mes, respectively, while those in the TNBS group were treated with physiological saline for 7 d. After treatment, the curative effect of Cur was evaluated by colonic weight, colonic length, weight index of the colon, and histological observation and score. The levels of $CD4^+CD25+Foxp3^+$ T cells (Treg cells) and costimulatory molecules of DCs were measured by flow cytometry. Also, related cytokines were analyzed by enzyme-linked immunosorbent assay.

RESULTS: Cur alleviated inflammatory injury of the colonic mucosa, decreased colonic weigh and histological score, and restored colonic length. The number of Treg cells was increased, while the secretion of TNF-α, IL-2, IL-6, IL-12 p40, IL-17 and IL-21 and the expression of costimulatory molecules (CD205, CD54 [ICAM-1], TLR4, CD252[OX40 L], CD256 [RANK] and CD254 [RANK L]) of DCs were notably inhibited in colitis mice treated with Cur.

CONCLUSION: Cur potentially modulates activation of DCs to enhance the suppressive functions of Treg cells and promote the recovery of damaged colonic mucosa in inflammatory bowel disease.

Key words: Curcumin; Regulatory T cells; Dendritic cells; Costimulatory molecules

Core tip: The low level of regulatory T (Treg) cells plays an important role in pathogenic process of inflammatory bowel disease (IBD). In our and other previous studies, curcumin (Cur) can effectively attenuate inflammation in humans and animals with colitis. However, whether Cur can improve the level of Treg cells and the pathway by which Cur regulates Treg cells are unclear. In the present study, we have shown that Cur potentially modulates activation of dendritic cells to enhance the suppressive functions of Treg cells and promote the recovery of damaged colonic mucosa in IBD.

Curcumin improves regulatory T cells in gut-associated lymphoid tissue of colitis mice. *World J Gastroenterol* 2016; 22(23): 5374-5383 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5374.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5374

INTRODUCTION

Since 1995, regulatory T (Treg) cells as a particular lineage of $CD4^+$T cells have been found to play a central role in the effective control of self-tolerance and maintenance of immune homeostasis[1,2]. Insufficient quantity or dysfunction of Treg cells invariably leads to inflammatory diseases, autoimmune diseases or lymphoproliferative syndrome including inflammatory bowel disease (IBD), rheumatoid arthritis and systemic lupus erythematosus in humans and animals[3-6]. Many previous studies have demonstrated that the suppressive function of Treg cells limits convincingly favorable host effector responses and restrains inflammatory responses in diverse anatomical locations as mucosal barriers against chronic inflammations and tumors[7-10]. Distinct Treg subsets coexist in the intestinal mucosa and mesenteric lymph nodes. Some studies have demonstrated that the suppressive function of Treg cells is partly implemented *via* modulation of dendritic cells (DCs)[11-13]. Usually, the transfer of Treg cells leads to the development of colitis *via* accumulation of T cells and DCs[14]. However, adequate Tregs or transfusion of Treg cells maintains mucosal tolerance to prevent and cure experimental colitis by directly inhibiting the expression of costimulatory molecules (such as CD40, CD154, CD134 and CD134L) of DCs or the migration of DCs to the MLNs, or by reducing DC activation[15,16]. These findings indicate that the interactions of DCs and Treg cells are closely related to the pathogenesis of IBD, and probably become a target for treatment of IBD.

Curcumin (Cur), a major active component of the rhizome of Curcuma longa (turmeric), has been used widely to treat cardiovascular disease, diabetes mellitus and IBD for several centuries in China[17,18]. Cur is known for its low toxicity and a wide range of reported pharmacological effects, which include antioxidant, anti-inflammatory, antiplatelet, hypoglycemic, cholesterol-lowering, anti-bacterial, wound-healing and anti-fungal effects[19-21]. Several studies have demonstrated that Cur can effectively attenuate inflammation in humans and animals with colitis[19-21]. Although anti-inflammatory actions of Cur in IBD may be associated with the inhibition of nuclear factor κB (NF-κB) pathway, such as p38 mitogen-activated protein kinases, and the reduction of pro-inflammatory cytokine response[22,23], its exact mechanisms remain unclear. In the present study, we explored the pathway by which Cur regulates function of Treg cells by observing the expression of costimulatory molecules of DCs in an animal model of colitis.

MATERIALS AND METHODS

Animals

Male C57BL/6 mice (9-12-wk-old) were purchased from the Animal Center of Peking University Health Science Center (Animal certificate number: SCXK 2012-0001). They were housed at 23 ± 2 ℃ with a humidity of 50% ± 5% in a 12 h light/dark cycle and provided with standard diet and water ad libitum. Mice

were randomly divided into four groups: normal, TNBS, TNBS + Cur, and TNBS + mesalazine (Mes) groups. Each group contained ten mice. The experimental protocol (JZ2015-016) was approved by Institutional Animal Care and Use Committee of Jiangxi University of Traditional Chinese Medicine.

Induction of colitis

Colitis was induced with 2, 4, 6-trinitrobenzene sulfonic acid (TNBS; batch number: p2297, Sigma, United States) as described by previous studies[24,25]. Except for mice in the normal group, mice in other groups were mildly anesthetized with pentobarbital sodium (40 mg/kg) *via* intraperitoneal injection before 100 mg/kg TNBS dissolved in 0.3 mL of 50% ethanol was instilled into the colon approximately 2 cm to the anus. Equal volume of physiological saline was given in the normal group.

Treatment protocol

Twenty-four hours after colitis was induced, the mice in the TNBS+Cur and TNBS+Mes groups were, respectively, administered with Cur (200 mg/kg) (purity > 95% by HPLC, batch number: GR-133-140421, GANGRUN Biotechnology, Nanjing, China) and Mes (300 mg/kg) (batch number: 130407, Sunflower Pharma Jiamusi, China) intragastrically for 7 d. The mice in the normal and TNBS groups received equal volume of physiological saline every day until the end of the experiment. All the mice were sacrificed on the 8^{th} day.

Histological evaluation

The whole colon (n = 10) was separated rapidly, and its length was measured. After clearing its contents, the colon was weighed and then divided into two parts. The weight index of the colon was calculated as colonic weight/body weight × 100%. The colonic segments were fixed in 4% paraformaldehyde solution, cut into sections, and stained with hematoxylin and eosin (HE). According to the previous study reported by Nicole and his colleagues[26], the criterion of the histological damage score (n = 10) was implemented to evaluate colonic injury. Histological score was calculated based on inflammatory cell infiltration and tissue damage. Scores for infiltration are as follows: 0: no infiltration; 1: increased number of inflammatory cells in the lamina propria; 2: inflammatory cells extending into the submucosa; and 3: transmural inflammatory cell infiltration. Scores of tissue damage are as follows: 0: no mucosal damage; 1: discrete epithelial lesions; 2: erosions or focal ulcerations; and 3: severe mucosal damage with extensive ulceration extending into the bowel wall.

Isolation of lymphocyte from gut-associated lymphoid tissue

Gut-associated lymphoid tissue (GALT) was separated and collected from the whole small intestine to the terminal rectum. GALT was triturated in 3% fetal calf serum (FCS)/PBS solution on ice cake, and filtrated *via* 300 section stainless steel cell cribble. The cell suspensions were centrifuged at 1500 rpm/min at 4 ℃ for 5 min and suspended in 3% FCS/PBS solution at 1 × 10^6-1 × 10^7/mL.

Assay of $CD4^+CD25^+Foxp3^+$ T cells by flow cytometry

The cell suspensions (n = 8) were incubated for 30 min with V450 -anti-mouse $CD4^+$Ab (0.125 μg/100 μL, BD Bioscience) and PerCP/Cy5.5 anti-mouse $CD25^+$Ab (0.25 μg/100 μL, Biolegend) at 37 ℃ in the dark. Cells were centrifuged at 1500 rpm/min and 4 ℃ for 5 min, fixed in Fix/Perm Buffer (eBioscience, San Diego, CA) for at least 1 h at 37 ℃, and then incubated with APC -anti-mouse $Foxp3^+$Ab (0.5 μg/100 μL; eBioscience) for 30 min at 37 ℃ in the dark. Cells labeled with PE rat IgG2a were used as the isotype negative control. Fluorescence-activated cell sorting analysis was performed on a FACSCalibur (BD Biosciences).

Measurement of costimulatory molecules by flow cytometry

Data acquisition was performed using a flow cytometer (FACSCalibur, BD-Pharmingen, San Diego, CA, United States) by collecting a minimum of 10000 events per sample. The frequency of positive cells was analyzed using the program Cell Quest in two regions. The lymphocyte region was determined using granularity (SSC) and size (FSC) plot. DCs were identified as a MHC^+ [$CD205^+$, CD54 (ICAM-1)$^+$, $TLR4^+$, CD252 (OX40 L)$^+$, CD256 (RANK)$^+$ and CD254 (RANK L)$^+$] population, and within this gate the $CD11c^+$ population was assessed. The following mAbs were used: APC/Cy7 anti-mouse CD11c, PerCP/Cy5.5 anti-mouse CD205, FITC anti-mouse CD54, PerCP-Cy™5.5 anti-mouse I-A/I-E (MHC-II), PE-cyanine7 anti-mouse TLR4, APC anti-mouse CD252, PE anti-mouse CD256 and PE rat anti-mouse CD254 (eBioscience, San Diego, CA). Limits for the quadrant markers were always set based on negative populations and isotype controls.

Enzyme-linked immunosorbent assay

The colonic mucosa was separated from all mice to prepare tissue homogenate. After centrifugation at 5000 rpm/min for 10 min, the supernatant was collected and used for testing the levels of cytokines by enzyme-linked immunosorbent assay (ELISA). The levels of TNF-α, IL-2, IL-6, IL-12 p40, IL-17 and IL-21 (n = 8) were determined using commercial ELISA kits according to the manufacturer's instructions (eBioscience, San Diego, CA).

Statistical analysis

Data are expressed as mean ± SE. The statistical significance was evaluated by one-way analysis of

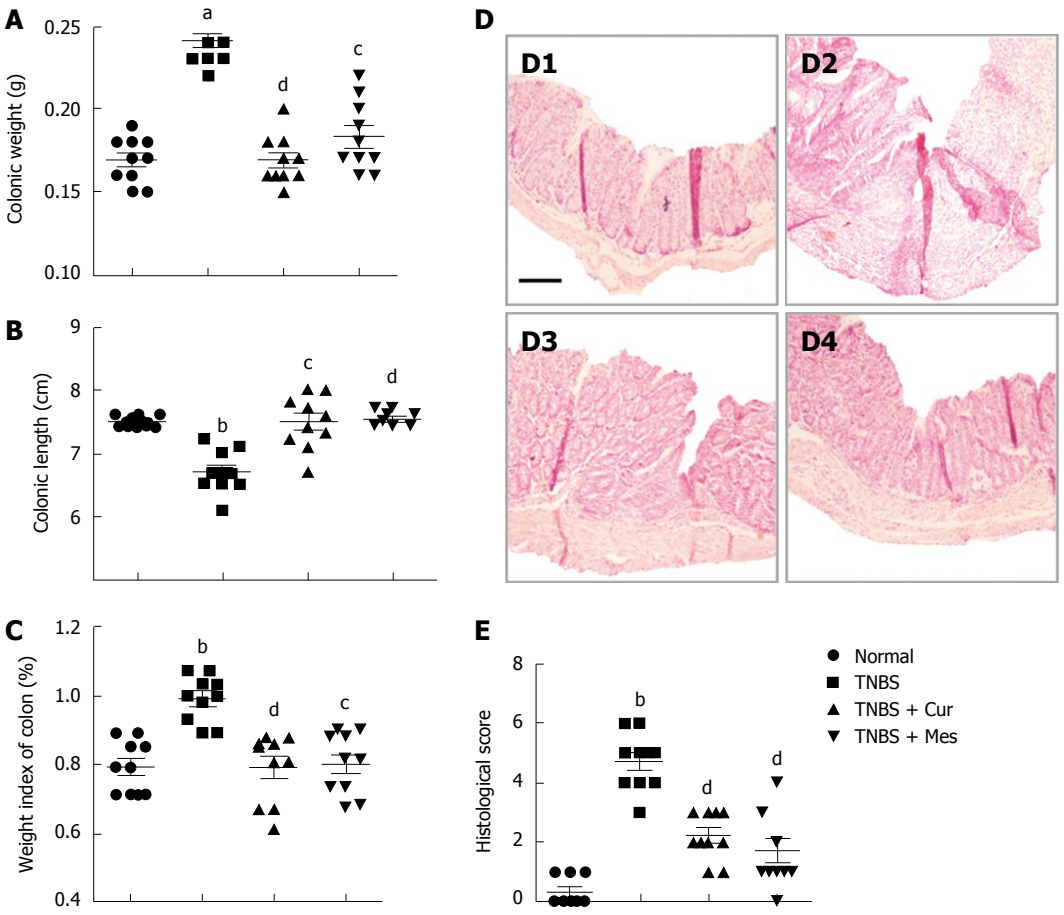

Figure 1 Histological evaluation. A: Colonic weight; B: Colonic length; C: Weight index of the colon; D: Typical histological images stained with HE. D1, D2, D3 and D4, respectively, represent the normal, TNBS, TNBS + Cur and TNBS + Mes groups. Bar = 200 μm; E: Histological scores. Data are presented as mean ± SE (n = 10). $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* normal group; $^{c}P < 0.05$ and $^{d}P < 0.01$ *vs* TNBS group.

variance, and statistical analyses were performed with Prism 4.0 (GraphPad Software, La Jolla, CA). P values less than 0.05 were considered statistically significant.

RESULTS

Cur effectively alleviates inflammatory injury of the colonic mucosa in colitis mice

Administration of TNBS led to a severe illness that was characterized by damaged colonic mucosa, increased colonic weight and so on. As shown in Figure 1, compared with mice in the TNBS group, the colonic weight (Figure 1A) and weight index of the colon (Figure 1C) were significantly decreased in the TNBS + Cur and TNBS + Mes groups, while the colonic length (Figure 1B) was lengthened. Pathological observation found that mucosal architecture was damaged, the colon wall was thicken, ulcers formed, and extensive inflammatory cells infiltrated in the colonic mucosa of colitis mice, while its histological score was increased (Figure 1D-2 and E). However, the extent of damaged colonic mucosa was alleviated in the TNBS + Cur and TNBS + Mes groups (Figure 1D-3 and D-4) as revealed by decreased histological scores (Figure 1E). These results suggest that Cur alleviates inflammatory injury of the colonic mucosa effectively.

Cur improves levels of Treg cells in GALT

As shown in Figure 2, the total number of $CD4^+$ T cells in GALT decreased in the normal, TNBS + Cur, and TNBS + Mes groups compared with the TNBS group. However, the number of $CD4^+CD25^+Foxp3^+$ T cells (Treg cells), which is a marker of Treg cells, increased in the three groups compared with the TNBS group.

Cur inhibits secretion of related cytokines in the colonic mucosa of mice with colitis

Significant increases in the secretions of TNF-α, IL-2, IL-6, IL-12 p40, IL-17, and IL-21, as assessed by ELISA in Figure 3, were observed in the TNBS group compared to the normal group. Notably, the increased expression of TNF-α, IL-2, IL-6, IL-12 p40, IL-17, and IL-21 was remarkably reduced in the TNBS + Cur group after treatment with Cur compared to the TNBS group.

Cur reduces expression of costimulatory molecules in GALT

Figure 3 shows the expression of CD205 (Figure 4A), CD54 (ICAM-1) (Figure 4B), TLR4 (Figure 4C), CD252

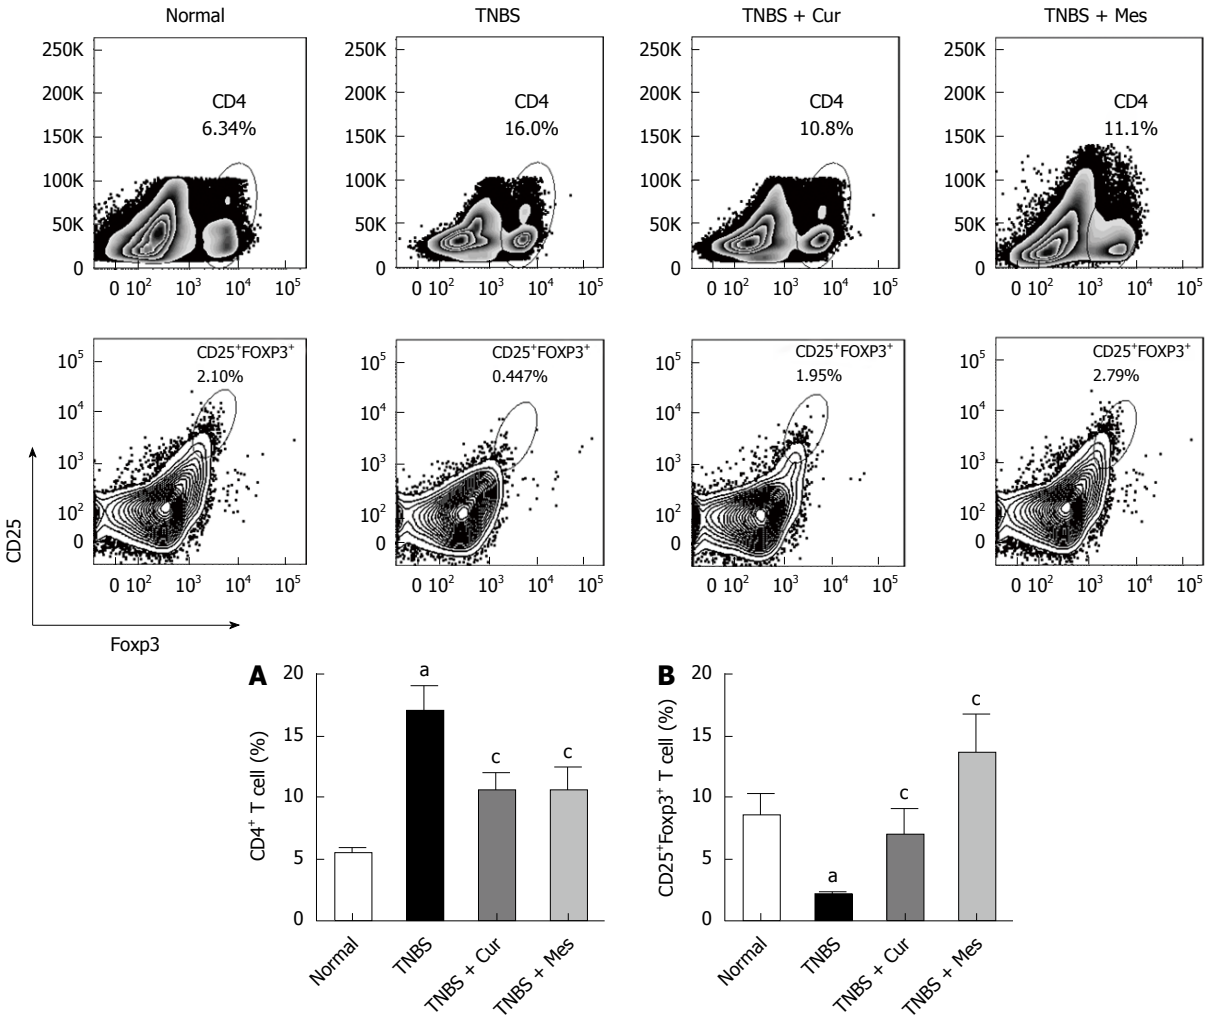

Figure 2 Typical graphs and levels of CD4$^+$ and CD25$^+$Foxp3$^+$ T cells. Lymphocytes were isolated from GALT of normal mice or mice with TNBS-induced colitis, and analyzed by flow cytometry. A: Typical graphs and levels (MFI) of CD4$^+$ T cells; B: Typical graphs and levels (MFI) of CD25$^+$Foxp3$^+$ T cells. Data are expressed as mean ± SE (n = 8). $^aP < 0.05$ *vs* normal group; $^cP < 0.05$ *vs* TNBS group.

(OX40 L) (Figure 4D), CD256 (RANK) (Figure 4E) and CD254 (RANK L) (Figure 4F) in GALT. The expression of these costimulatory molecules was increased in the TNBS group compared with the normal group. Interestingly, after 7 d treatment the increased levels of costimulatory molecules were coincidently inhibited or down-regulated in the TNBS + Cur and TNBS + Mes groups compared with the TNBS group.

DISCUSSION

Many studies have indicated that IBD is usually characterized by inflammatory injury of the colonic mucosa and disorder immune responses in inflamed mucosa, along with the dominance of IL-17-producing cells and deficiency of Treg cells[27-29]. In the present study, the results showed that Cur repaired colonic structure, decreased colonic weigh and histological injury score, recovered colonic length, indicating that Cur effectively restored damaged colonic mucosa in mice with TNBS-induced colitis. The overexpression of IL-17 and decreased Treg cells in the development of TNBS-induced colitis in our experiments were in agreement with those previous studies. After treatment with Cur, the level of IL-17 decreased, and Treg cells increased, indicating that the protective effect of Cur against TNBS-induced colitis is closely associated with decreased IL-17 expression and recovered levels of Treg cells. Also, we found that the production of related cytokines (as TNF-α, IL-2, IL-6, IL-12 p40 and IL-21) and expression of costimulatory molecules were suppressed by treatment with Cur. It is known that these inhibitory cytokines are secreted by DCs. Therefore, the effect of Cur in experimental colitis is closely with the suppressive function of Treg cells and activation of DCs.

Treg cells, also known as CD4$^+$CD25$^+$Foxp3$^+$T cells, are involved in the maintenance of peripheral tolerance and control of the immune response by initiating suppressive effects on activated immune cells[30,31]. Treg-mediated suppression can be regulated primarily by the four broad categories of mechanisms including suppression by inhibitory cytokines (IL-10, IL-35 and TGF-β), cytolysis, metabolic disruption, or

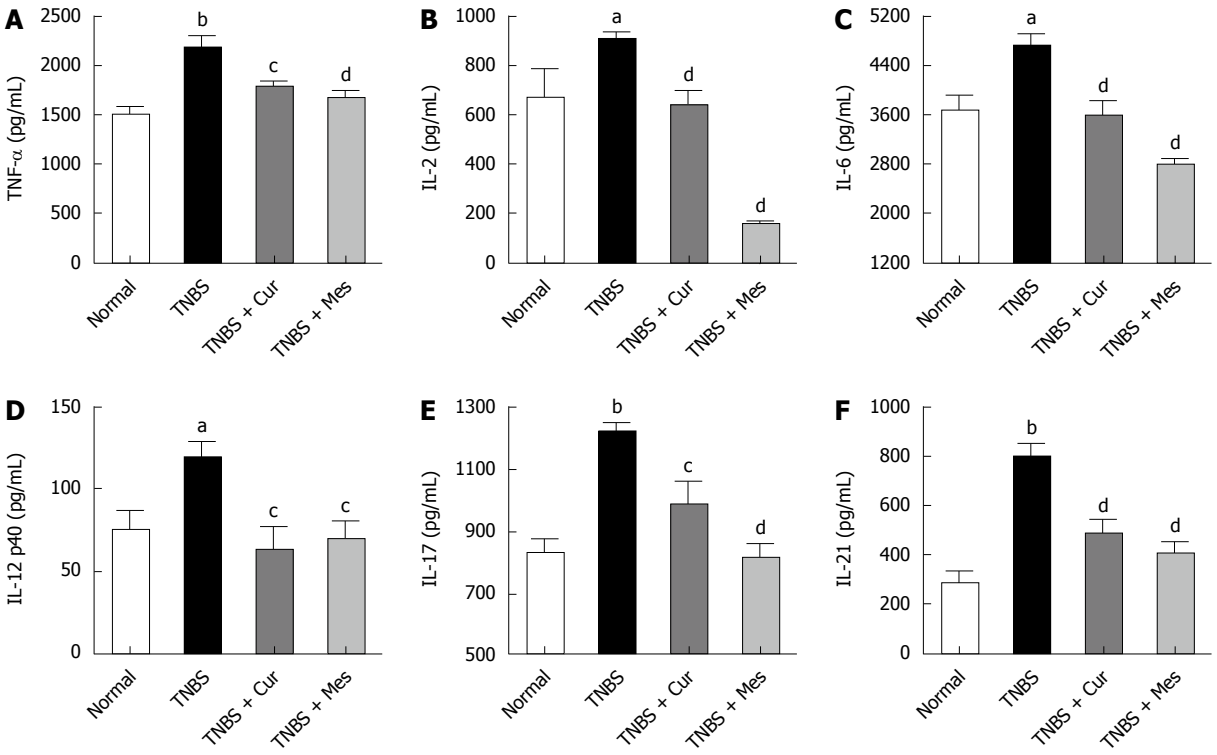

Figure 3 Concentrations of cytokines in the colonic mucosa. The tissue supernatant was prepared from the colonic mucosa in all mice. The levels of cytokines were analyzed by ELISA. A: Concentrations of TNF-α in the colonic mucosa from different groups; B: Concentrations of IL-2 in the colonic mucosa from different groups; C: Concentrations of IL-6 in the colonic mucosa from different groups; D: Concentrations of IL-12 p40 in the colonic mucosa from different groups; E: Concentrations of IL-17 in the colonic mucosa from different groups; F: Concentrations of IL-21 in the colonic mucosa from different groups. Data are expressed as mean ± SE (n = 8). $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* normal group; $^{c}P < 0.05$ and $^{d}P < 0.01$ *vs* TNBS group.

modulation of DC maturation or function[11-13]. One of mechanisms of Treg-mediated suppression is realized by anti-inflammatory cytokines (IL-10, IL-35) and TGF-β, which are in balance with pro-inflammatory cytokines such as TNF-α, IL-1, IL-6, IL-12, and IL-21. These pro-inflammatory cytokines are inhibited by anti-inflammatory cytokines, and as a result, Th17 cells are promoted to secrete IL-17 and eventually induce inflammatory damage. IL-17 is overwhelmingly produced by Th17 cells[12,32], and is expressed extensively in the mucosa and serum of IBD patients and TNBS-induced colitis mice[33]. This suggests that the balance of Treg cells and Th17 cells was possibly broken in GALT of mice with colitis.

Foxp3, a forkhead/winged helix transcription factor, can maintain the generation, function, and stabilization of Treg cells[12]. Hence, the level of Treg cells is usually evaluated by the expression of Foxp3 in the nucleus of Treg cells. High expression of Foxp 3 is essential for effector cytokines of T helper (Th) 1, Th2, and Th17 lineages[34,35]. For example, IL-2 can maintain the stable Foxp3 expression in Treg cells *via* STAT5 phosphorylation[36,37]. Moreover, IL-6 may cause Treg cells to transfer into Th17 cells and secrete abundant IL-17 and IL-21. IL-21 combined with IL-23 induces signal transducer and activator of transcription-3 expression, promotes retinoid-related orphan receptor-γt activation, and finally improves secretion of IL-17[38-40]. In our study, down-regulation of Treg cells led to an imbalance of Treg and Th17 cells and also an imbalance of Th1 and Th2 cells, and thus induced strong expression of pro-inflammatory cytokines that resulted in inflammatory damages in the colonic mucosa.

As the uppermost part, DCs can modulate Treg-mediated suppressive function *via* expression of costimulatory molecules[41,42]. DCs are critical for regulation of intestinal immunity and mucosal immune tolerance to commensal microorganisms, which is one of the pivotal etiologies of IBD[41]. Maturation and migration of DCs in lymph nodes are "danger" signals that induce inflammatory injuries in the intestinal mucosa[42,43]. Mature DCs with expression of costimulatory molecules can regulate the balance between Th1 and Th2 cells, and the balance of Treg and Th17 cells. Misra and colleagues have demonstrated that low expression of costimulatory molecules of DCs can induce immature and limited antigen presentation of DCs, which will ineffectively stimulate T cell responses and then induce an increase in the number of Treg cells[44]. Certainly, Treg cells can secrete inhibitory cytokines to repress activation of MHC-II and costimulatory molecules of DCs *via* negative feedback to suppress the antigen presentation of DCs[45,46]. Furthermore, DCs can induce the differentiation of Th17 cells to regulate the balance of Treg cells and Th17 cells by secreting IL-6 or IL-12 p40 and producing more pro-inflammatory cytokines (such

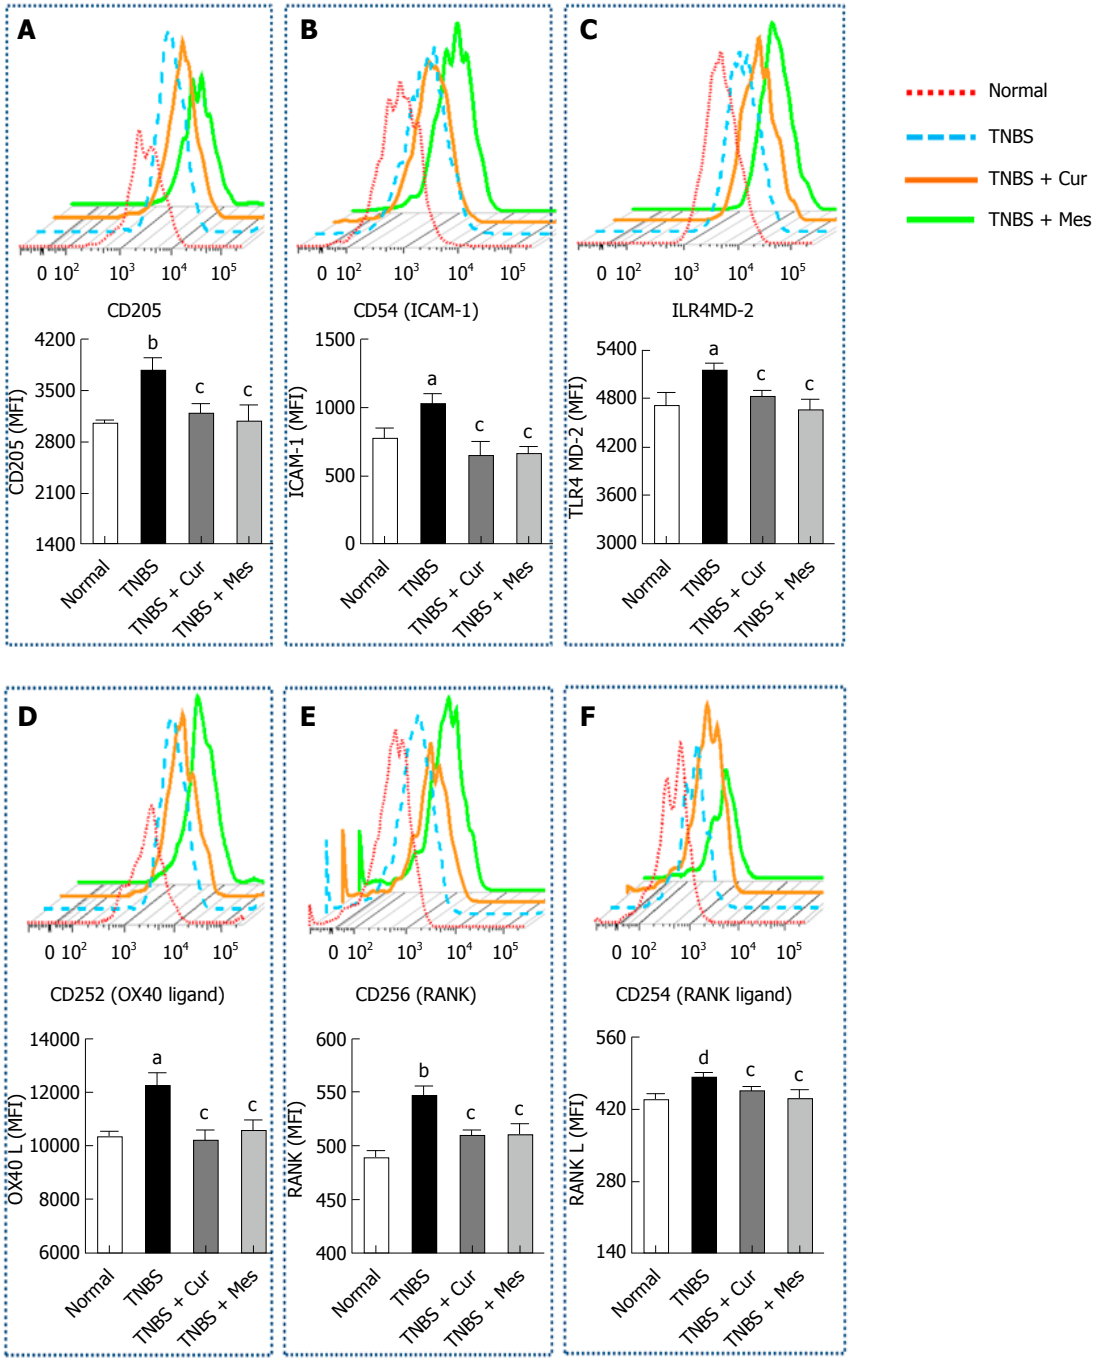

Figure 4 Typical curves and levels of costimulatory molecules in dendritic cells. Lymphocytes were isolated from GALT of normal mice or mice with TNBS-induced colitis, and analyzed by flow cytometry. A: Typical pseudocolor and level (MFI) of CD205; B: Typical pseudocolor and level (MFI) of CD54(ICAM-1); C:Typical pseudocolor and level (MFI) of TLR4; D: Typical pseudocolor and level (MFI) of CD252 (OX40 L); E: Typical pseudocolor and level (MFI) of CD256 (RNAK); F: Typical pseudocolor and level (MFI) of CD254 (RNAK L). Data are expressed as mean ± SE (n = 8). $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* normal group; $^{c}P < 0.05$ and $^{d}P < 0.01$ *vs* TNBS group.

as TNF-α, IL-6, and IL-15) that mediate inflammatory injury[47,48]. Meanwhile, costimulatory molecules of DCs, which include TNF/TNF receptor protein families (CD40/CD40L, OX40/OX40L, TNFR/TNF and so on) and immune globulin superfamily (ICAM-1/LAF-1, CD28/CTLA4/B7, *etc.*), participate in the polarization of Th1 and Th2 cell responses. As an example, receptor activator of NF-κB (RANK)/receptor activator of NF-κB ligand (RANKL) signal is an important costimulatory factor that activates DCs and prolongs their lifespan. This is achieved by activating *Bcl-XL* gene and cooperating with other costimulatory molecules (ICAM-1, TLR4, OX40 L, *etc.*) and some cytokines (IL-6 and IL-12) to activate NF-κB and induce the secretion of pro-inflammatory cytokines (TNF-α, IL-6, IL-17, and IL-21)[49]. The ICAM-1/LFA-1 signal and B7-1 molecule (B7/CD28 signal) can activate DCs to induce Th1 cell response *via* secretion of IL-12. However,

B7-2 molecule and OX40/OX40L signal promote the polarization of Th2 cells. These costimulatory molecules of DCs were highly expressed in human and animal colitis[50,51]. Thus, DCs are closely related to the development of IBD, suppression of Treg cells and balance of Treg/Th17 cells. In the present study, Cur noticeably inhibited the expression of costimulatory molecules of DCs that ineffectively stimulated T cell response to increase the suppression or number of Treg cells, and maintain Treg-mediated suppression. Also, Cur down-regulated the secretion of cytokines including IL-6 and IL-12 p40 by inhibiting DCs to prevent Treg cells from transferring into Th17 cells, inhibit the production of pro-inflammatory cytokines (TNF-α, IL-2, and IL-6) and decrease the destructive effects of IL-17 and IL-21. The mechanisms by which Cur maintains Treg-mediated suppression were only partly revealed in the present study. Therefore, further study is needed to determine whether cytolysis of Treg cells and metabolic disruption of Treg cells are also mechanisms through which Cur maintains Treg-mediated suppression.

In conclusion, Cur potentially modulates activation of DCs to enhance the suppressive functions of Treg cells and promote the recovery of damaged colonic mucosa in IBD.

COMMENTS

Background

Regulatory T cells (Treg) play a crucial role in the maintenance of self tolerance and the prevention of inflammatory bowel disease. Treg-mediated suppression can be implemented primarily by the four broad categories of mechanisms including suppression by inhibitory cytokine, cytolysis, metabolic disruption, or *via* modulation of dendritic cells (DCs) maturation or function. In these four facts, the activation of DCs is thought as the main role to maintain the suppression of Treg cells.

Research frontiers

The mature DCs with an expression of costimulatory molecules can regulate the balance between balance of Treg and Th17 cells. The previous had demonstrated that higher level expression of costimulatory molecules of DCs can lead to a decreased numbers of Treg cells to induce IBD.

Innovations and breakthroughs

The present study is firstly shown that curcumin (Cur) potentially modulated activation of DCs to enhance the suppressive functions of Treg cells and restore damaged colonic mucosa of inflammatory bowel disease (IBD).

Applications

It is known that Cur effectively treated experimental colitis by many pathway including the inhibition of nuclear factor κB pathway and reduction of pro-inflammatory cytokine response. However the level and pathway are ambiguous that Cur can or not regulate Treg cell. In the present study, our results had hinted that Cur can height the suppressive function of Treg cells *via* inhibiting the activation of DCs. The results are favorable to explore the mechanism of Cur treated chronic colitis.

Terminology

These costimulatory molecules of DCs, which include TNF/TNF receptor protein families (CD40/CD40L, OX40/OX40L, TNFR/TNF and so on) and immune globulin superfamily (ICAM-1/LAF-1, CD28/CTLA4/B7, *etc.*), are marker of activation of DCs, and decreased to inhibit the suppressive function of Treg cells in many previous documents .

Peer-review

This is a well-designed and well-presented study for examining the anti-inflammatory potential of curcumine in TNBS colitis of mice. The authors found that curcumine modulates the action of dendritic cells to enhance suppressive Treg functions, leading to an accelerated mucosal healing.

Abstract

AIM: To investigate the efficacy and safety of adjuvant sorafenib after curative resection for patients with Barcelona Clinic Liver Cancer (BCLC)-stage C hepatocellular carcinoma (HCC).

METHODS: Thirty-four HCC patients, classified as BCLC-stage C, received adjuvant sorafenib for high-risk of tumor recurrence after curative hepatectomy at a tertiary care university hospital. The study group was compared with a case-matched control group of 68 patients who received curative hepatectomy for HCC during the study period in a 1:2 ratio.

RESULTS: The tumor recurrence rate was markedly lower in the sorafenib group (15/34, 44.1%) than in the control group (51/68, 75%, P = 0.002). The median disease-free survival was 12 mo in the study group and 10 mo in the control group. Tumor number more than 3, macrovascular invasion, hilar lymph nodes metastasis, and treatment with sorafenib were

significant factors of disease-free survival by univariate analysis. Tumor number more than 3 and treatment with sorafenib were significant risk factors of disease-free survival by multivariate analysis in the Cox proportional hazards model. The disease-free survival and cumulative overall survival in the study group were significantly better than in the control group (P = 0.034 and 0.016, respectively).

CONCLUSION: Our study verifies the potential benefit and safety of adjuvant sorafenib for both decreasing HCC recurrence and extending disease-free and overall survival rates for patients with BCLC-stage C HCC after curative resection.

Key words: Hepatectomy; Hepatocellular carcinoma; Sorafenib; Survival; Tumor recurrence

Core tip: Hepatocellular carcinoma (HCC) has a 5-year recurrence rate reaching 80%-90% even after potentially curative treatment. Therefore, it is extremely important to prevent recurrence for the prognosis of HCC patients. Sorafenib is the only approved treatment for patients with advanced HCC. Thus, based on the action of sorafenib, namely inhibition of tumor cell proliferation and angiogenesis, there is rationale for the study of sorafenib as an adjuvant therapy in HCC. It is essential to investigate the efficacy and safety of adjuvant sorafenib administered following curative resection in patients with Barcelona Clinic Liver Cancer-stage C HCC.

Adjuvant sorafenib after heptectomy for Barcelona Clinic Liver Cancer-stage C hepatocellular carcinoma patients. *World J Gastroenterol* 2016; 22(23): 5384-5392 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5384.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5384

INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) is increasing globally in conjunction with increasing prevalence of hepatitis C virus infection in the West and of both hepatitis B and C in Asia[1]. Surgical resection remains the mainstay of treatment for HCC, according to guidelines and consensus coming from all over the world[2-4]. Most HCC patients are in the advanced stage of disease on initial diagnosis[5,6]. According to the Barcelona Clinic Liver Cancer (BCLC) staging system, surgical resection should only be used on a very small population of patients with very early staged HCC, while sorafenib, a multi-kinase inhibitor, is recommended as the treatment for advanced HCC. However, patients with advanced HCC who receive sorafenib achieve a median gain in overall survival (OS) of around 3 mo[7-9]. Therefore, additional management strategies need to be identified to improve therapeutic benefits. Hepatectomy for advanced HCC patients remains controversial, although previous studies showed survival benefit in patients with more advanced HCC[10]. However, early tumor recurrence is common after hepatectomy for HCC with macrovascular invasion, multinodular or large HCC. There is still no acknowledged adjuvant therapy for HCC after radical surgery, and tumor recurrence is still the main cause of death for these patients. It has been reported that sorafenib can be used as an adjuvant therapy to reduce the risk of recurrence after potentially curative treatment in animal research and in pilot clinical studies[10-13]. Feng *et al*[12] reported that sorafenib suppressed development of postsurgical intrahepatic recurrence and abdominal metastasis, which consequently led to prolonged postoperative survival, in an orthotopic xenograft model of HCC. Saab *et al*[13] demonstrated the safety and potential benefit of sorafenib, in both reducing HCC recurrence and extending disease-free survival (DFS) and OS rates, in their study of eight high-risk liver transplant recipients. Thus, further research on the efficacy of sorafenib in decreasing HCC recurrence after liver resection in high-risk patients is urgently needed. In this study, sorafenib was used as an adjuvant therapy to decrease the risk of tumor recurrence following potentially curative resection in patients with HCC of BCLC-stage C. The efficacy and safety of this modality were evaluated in this case-matched comparative study.

MATERIALS AND METHODS

Patient selection

From September 2010 to September 2013, 41 HCC patients classified as BCLC-stage C received adjuvant sorafenib after curative liver resection. This is a retrospective study on data that were prospectively collected and entered into a computer database. All patients were histologically confirmed to have HCC in the resected specimens. The definition of BCLC-stage C was: any tumor with radiological and histological evidence of macrovascular invasion (portal vein, hepatic vein, inferior vena cava). Patients with lymph nodes (Hilar lymph nodes excluded) and/or distant metastases[2,8], tumor recurrence diagnosed within 2 mo of operation, or who had received any other forms of adjuvant or neoadjuvant therapy were excluded. Patients in the sorafenib group were recruited if they agreed to take adjuvant sorafenib. Each patient in the study group was matched, as closely as possible, with two BCLC-stage C patients for tumor size (± 1 cm in diameter), tumor number, tumor location, type of operation and Child-Pugh grading from a prospectively maintained database of 1335 patients who received R0 liver resection for stage BCLC A/B/C HCC during the study period (the control group). The demographics,

blood biochemistry, tumor characteristics, surgical variables, length of hospital stay, and postoperative complications were compared. This study was approved by the Ethics Committee of the Southwest Hospital before the study began; it conformed to the ethical guidelines of the 1975 Helsinki Declaration. Written informed consent was obtained from all patients for their data to be used for research purposes.

Preoperative assessments

The patients were evaluated pre-operatively according to the routine procedure of our institute, as previously reported[14]. All patients underwent the same preoperative evaluation protocol that included percutaneous ultrasonography (US), spiral computed tomography (CT) of the thoraco-abdomen (from March 2010 in our institute), CT angiography of hepatic artery/hepatic vein/portal vein, electrocardiogram and blood biochemistry. Liver function was assessed by the Child-Pugh grading system (A or B) and indocyanine green clearance test at 15 min (ICG_{15}; less than 10%). The Eastern Cooperative Oncology Group performance status was 0 or 1 in this study. The liver volume to be resected and the future liver remnant volume (FRLV; more than 50% in cirrhosis and 40% in normal) were calculated using computed tomographic volumetry (UniSight, China), according to the method described by Urata *et al*[15].

Partial hepatectomy

The operation was performed as previously reported using a right subcostal or a midline incision with a right horizontal extension[16]. After excluding any unexpected intraperitoneal metastasis, intraoperative ultrasonography was used routinely to clarify the extent of tumor, detect tumor nodules in the contralateral hemiliver and invasion of tumor into major blood vessels, and to plan and mark the plane of liver transection. An intermittent Pringle's maneuver with clamp/unclamp times of 15/5 min by a tourniquet was used during liver transection using a clamp crushing technique. A low central venous pressure was applied routinely. The extent of hepatic resection was defined anatomically according to Couinaud's liver segmentation. Major hepatectomy was defined as resection of three or more liver segments. Blood transfusion was only given when the hemoglobin fell below 8.0 g/L. All patients received the same postoperative care by the same team of surgeons and were nursed in the surgical intensive care unit during the early postoperative period. Parenteral nutritional support was provided for patients with cirrhosis. All intra- and post-operative complications were recorded prospectively. Biliary leakage was diagnosed when the total bilirubin level in the drainage fluid exceeded the upper normal limit of serum bilirubin (21 μmol/L) on or after postoperative day 7.

Conventional surveillance strategy and sorafenib

After hepatectomy, patients were routinely monitored with thoraco-abdominal CT scans once every 2 mo for the first 6 mo, and then alternating between abdominal US and CT scan every 2 mo thereafter. Blood for α-fetoprotein (AFP) and hepatitis B virus (HBV) load were also checked at each of the follow-up visits. For patients with a high viral load (HBV DNA > 1×10^3 copies/mL), nucleoside analogues were given. Intrahepatic tumor recurrence was confirmed with imaging, AFP and/or histology. Whole-body positron emission tomography/computed tomography with ^{18}F-fluorodeoxyglucose (^{18}F-FDG PET/CT) was used to assess extra-hepatic metastasis. Recurrence time was calculated from the date of operation to the date of diagnosis of tumor recurrence or the date of censor of this study on June 31, 2014. The start point of survival analysis is the day of liver resection.

Sorafenib treatment would be initiated in the first month after surgery following receipt of formal consent from the patient, which was given as free choice by himself/herself. Patients in the sorafenib group were given sorafenib at a dose of 400 mg twice daily. Patients treated with sorafenib were followed-up closely for any adverse effects on an outpatient basis, with reduction in dosage or discontinuation when the drug was poorly tolerated according to the commonly used criteria for adverse events 3.0. Monitoring of complete blood count, blood biochemistry, contrast CT scan or magnetic resonance imaging were performed for evaluation of tumor recurrence every two months, similar to the control group of patients.

Statistical analysis

Statistical analyses were performed using the χ^2 test, the Fisher's exact test or the generalized linear model to compare discrete variables, and the Mann-Whitney test was used to compare continuous variables. DFS and OS rates were determined using the Kaplan-Meier method and the log-rank test. A $P < 0.05$ was considered as statistically significant. Potential factors associated with DFS after resection were analyzed using univariate and multivariate analyses. Univariate analysis was performed for 21 risk factors, and significant risk factors were subsequently analyzed by multivariate analysis using a stepwise Cox's proportional hazard regression model to identify independent prognostic factors for predicting DFS. Statistical analyses were performed with SPSS 13.0 for Windows computer software (SPSS Inc., Chicago, IL, United States).

RESULTS

The patient demographics and tumor characteristics are shown in Table 1. There were no significant differences between the two groups of patients. The median follow-

[1]Value expressed in median with range in parentheses; [2]Study group compared with control group; [3]Major hepatectomy was defined as resection of three or more segments.

up was 26 mo and 25 mo for the sorafenib group and the control group, respectively.

Surgical variables and outcomes are shown in Table 2. Postoperative aspartate aminotransferase (AST) on day 3 was significantly lower in the sorafenib group than in the control group (P = 0.042). There were no marked differences between the two groups for the types of resection, intraoperative blood loss/transfusion and postoperative total bilirubin levels on postoperative day 3. The main complications were summarized as infectious and noninfectious morbidity. There was no in-hospital or 90-d mortality in this study. There was no significant difference in the overall morbidity rates (P = 0.853). All patients with pleural effusion and bile leakage recovered after percutaneous drainage.

Table 3 Type of recurrence

Type of recurrence	Sorafenib	Control	*P* value[1]
Hepatic	8	28	0.079
Extrahepatic	5	12	0.707
Hepatic + extrahepatic	2	11	0.142
Overall hepatic recurrence	10	39	0.008
Overall extrahepatic	7	23	0.167
Total recurrence	15 (44.1%)	51 (75.0%)	0.002

[1]Study group compared with control group.

The type of recurrence was divided into hepatic lesion and extrahepatic lesion (Table 3). The total recurrence was significantly lower in the sorafenib group (15/34, 44.1%), as compared to the control group (51/68, 75%, P = 0.002). The overall hepatic recurrence was also markedly lower in the sorafenib group (P = 0.008).

Table 4 shows the results of the univariate and multivariate analyses for the 21 selected variables. Of these variables, tumor number more than 3, presence of macrovascular invasion, positive hilar lymph nodes metastasis and treatment with sorafenib were significantly correlated to DFS. Multivariate analysis by Cox's proportional hazard model showed that tumor number more than 3 and treatment with sorafenib were independent significant risk factors of DFS.

The DFS and cumulative OS rates in the sorafenib group were significantly better than those in the control group (P = 0.034 and 0.016, respectively) (Figure 1). The median DFS was 12 mo for the sorafenib group and 10 mo for the control group. Meanwhile, the median cumulative OS was 25 mo for the sorafenib group and 18 mo for the control group.

Sorafenib was generally safe and well tolerated, with only grades 1 and 2 drug-related adverse events (14 patients, 41.2% in this study). Overall, 9 of 34 patients (26.5%) required a dosage reduction for adverse effects of sorafenib, and most patients recovered (n = 6). The remaining 3 patients were kept on half dose. The mean duration of sorafenib treatment was 22.9 mo. Viral loads were controlled satisfactorily with nucleoside analogues in most of the patients. However, 5 patients required a combination of antiviral drugs (lamivudine + adefovir dipivoxil) to control the viral load.

DISCUSSION

Since tumor recurrence remains a major obstacle

[1]The number of patients forin each risk factor analyzed = 102.

to good survival for HCC patients following curative resection for locally advanced HCC, an effective adjuvant therapy becomes important. Recently, sorafenib has been shown to be effective for patients with advanced HCC with Child-Pugh class A cirrhosis[9]. The present study showed that sorafenib prolonged DFS and OS by reducing tumor recurrence after curative resection for locally advanced HCC in BCLC-stage C patients.

The role of liver resection for patients with locally advanced HCC has remained controversial until now. The BCLC classification has been endorsed by the European Association for the Study of Liver Disease and the American Association for the Study of Liver Disease as the best staging system and treatment algorithm for HCC[2,4]. Patients with BCLC-stage C HCC are recommended to receive sorafenib only. However, there have been many retrospective studies in which aggressive surgical therapy was shown to improve long-term survival in the selected patients with locally advanced HCC[10]. The main arguments against resectional surgery for these patients are early recurrence and metastases. Llovet *et al*[9] and Bruix *et al*[5] advocated that research efforts should be focused on adjuvant setting of resection, local ablation or combination therapy. Animal studies have indicated sorafenib inhibited tumor growth and prevented tumor recurrence after resection of HCC[12,17]. Feng *et al*[12] used a luciferase labeled orthotropic xenograft model of HCC to examine the role of sorafenib in prevention of HCC recurrence and demonstrated that sorafenib suppressed development of postsurgical intrahepatic recurrence and abdominal metastasis, which led to prolonged postoperative survival in mice. Wang *et al*[17] demonstrated that sorafenib inhibited tumor growth and prevented metastatic recurrence after resection of HCC in nude mice. There were also a few clinical reports on the effect of sorafenib in prevention of tumor recurrence[13,18]. A group from the University of California Los Angeles performed a retrospective case-matched study that included eight HCC patients who tolerated adjuvant sorafenib after orthotopic liver transplantation. This study demonstrated the safety and potential benefit of sorafenib in both reducing HCC recurrence and extending DFS and OS for high-risk liver transplant recipients[13]. Recently, a pilot study was conducted on adjuvant sorafenib for HCC patients (31 patients) who underwent curative liver surgery and had high-risk factors for tumor recurrence[18]. The time to recurrence and disease recurrence rate were assessed and showed that adjuvant sorafenib for HCC prevented early recurrence after hepatic resection. The significantly lower cumulative recurrence-free survival rate also demonstrated the preventive effectiveness of sorafenib. All these data strongly suggest that sorafenib has a potential role to play in patients with locally advanced HCC after hepatectomy with curative intention. A phase Ⅲ randomized controlled trial to evaluate whether sorafenib could be used as an effective adjuvant therapy after resection or ablation (STORM trial, NCT00692770) was reported by Bruix *et al*[19] recently. The study showed the trial did not meet its main endpoint of improving recurrence-free survival. Nevertheless, the inclusion criteria of the STORM trial was very narrow (for surgical resection: single tumor of ≥ 2 cm without microscopic vascular

invasion, without tumor satellites and histologically well- or moderately-differentiated, or any size single lesion but must be ⩾ 2 cm if well-differentiated; for local ablation: single tumor > 2 cm or ⩽ 5 cm, or 2-3 lesions with each ⩽ 3 cm in size). As all these patients were classified as BCLC early stage (A), the impact of sorafenib on these patients after curative hepatectomy may have been insufficiently robust to be demonstrated in that study. On the contrary, there is a recently published review in which a meta-analysis confirmed that the combination therapy of transcatheter arterial chemoembolization plus sorafenib in patients with intermediate or advanced stage HCC can improve OS, time to progression and objective response rate[20].

In our study, tumor number more than 3, presence of macrovascular invasion and positive hilar lymph nodes metastasis were identified as factors with the highest risk of tumor recurrence. Sorafenib was well tolerated in most of our patients. A literature review was conducted on the prognosis of BCLC-stage C HCC patients treated with either sorafenib or liver resection

[1]Including patients with BCLC-stage B. DFS: Disease-free survival; OS: Overall survival; TACE: Transarterial chemoembolization.

alone (Table 5). The median overall survival was better in the groups treated with liver resection in selected patients than with sorafenib only. In our study, when liver resection was combined with sorafenib, there was significantly better OS than for liver resection alone. To the best of our knowledge, our study is the first to evaluate adjuvant sorafenib for BCLC-stage C patients after curative resection. Adjuvant systemic treatment is the most promising of all adjuvant therapies for locally advanced HCC, as this disease is likely to be systemic at this stage.

PET/CT was used for the diagnosis of extrahepatic metastasis in this study, as ^{18}F-FDG PET/CT is currently the most sophisticated technique to detect metastases, despite the possibility of false positivity. A systematic review and meta-analysis published recently reported the pooled estimates of sensitivity, specificity, positive likelihood ratio and negative likelihood ratio of ^{18}F-FDG PET/CT in the detection of metastatic HCC were 76.6%, 98.0%, 14.68 and 0.28, respectively[21]. This study has the limitations of small case number and the study came from a single institute; also, the median follow-up was not long enough. As a retrospective study, the selection bias was fully considered and treated by matching and statistic analysis. Future prospective clinical randomized controlled trials are warranted to confirm our results.

In conclusion, this study demonstrates the safety and potential benefits of sorafenib in both decreasing the incidence of HCC recurrence and extending the DFS and OS rates for patients with locally advanced HCC after curative resection.

ACKNOWLEDGMENTS

We are grateful to Miss Shu Chen, a research assistant, for her help with data collection and statistical analyses.

COMMENTS

Background

To investigate the efficacy and safety of adjuvant sorafenib after potentially curative resection for patients with Barcelona Clinic Liver Cancer-stage C hepatocellular carcinoma (BCLC-stage C HCC).

Research frontiers

Hepatocarcinogenesis is a complex process including many signaling cascades. Currently, there is no standard of care for adjuvant therapy because no treatment has a proven benefit in randomized studies in patients with HCC after potentially curative treatment. Sorafenib is approved for use in patients with unresectable HCC based on two phase 3 randomized trials, and is the recommended treatment in patients with advanced HCC. Animal studies and a few retrospective clinical studies published recently have indicated sorafenib inhibited tumor growth and prevented tumor recurrence after resection of HCC.

Innovations and breakthroughs

Based on the mechanism of sorafenib, inhibition of tumor cell proliferation and angiogenesis, in addition to it's proven efficacy in advanced HCC, there is rationale for the study of sorafenib as an adjuvant therapy in HCC.

Applications

It is worthwhile to investigate the efficacy of adjuvant sorafenib after potentially curative resection for BCLC-stage C HCC patients with the prospective clinical randomized controlled trials in future.

Terminology

Thirty-four HCC patients received adjuvant sorafenib after curative liver resection and were compared with a case-matched control group of 68 HCC

patients who underwent hepatectomy.

Peer-review

This case-control study proves the important clinical role of sorafenib as an adjuvant treatment after R0 resection of BCLC-stage C HCC patients. It would be worth using sorafenib not just in advanced but in early stages of HCC.

Abstract

AIM: To determine the genomic changes in hepatitis B virus (HBV) and evaluate their role in the development of hepatocellular carcinoma (HCC) in patients chronically infected with genotype C HBV.

METHODS: Two hundred and forty chronic hepatitis B (CHB) patients were subjected and followed for a median of 105 mo. HCC was diagnosed in accordance with AASLD guidelines. The whole X, S, basal core promoter (BCP), and precore regions of HBV were sequenced using the direct sequencing method.

RESULTS: All of the subjects were infected with genotype C HBV. Out of 240 CHB patients, 25 (10%) had C1653T and 33 (14%) had T1753V mutation in X region; 157 (65%) had A1762T/G1764A mutations in BCP region, 50 (21%) had G1896A mutation in precore region and 67 (28%) had pre-S deletions. HCC occurred in 6 patients (3%). The prevalence of T1753V mutation was significantly higher in patients who developed HCC than in those without HCC. The cumulative occurrence rates of HCC were 5% and 19% at 10 and 15 years, respectively, in patients with T1753V mutant, which were significantly higher than 1% and 1% in those with wild type HBV ($P < 0.001$).

CONCLUSION: The presence of T1753V mutation in HBV X-gene significantly increases the risk of HCC development in patients chronically infected with genotype C HBV.

Key words: Hepatocellular carcinoma; Chronic hepatitis B; Genomic change; Hepatitis B virus; Genotype C

Core tip: In the present study, we determined the genomic changes in the X, S, basal core promoter (BCP), and precore regions of hepatitis B virus (HBV), and evaluate their role in the development of hepatocellular carcinoma (HCC) in chronic hepatitis B (CHB) patients with genotype C HBV. As the results, it was suggested that T1753V mutation in X region might significantly increase the risk of HCC development in CHB patients with genotype C HBV. Also, the BCP mutations might act in synergy with T1753V or G1896A mutation, and with pre-S deletion to promote the development of HCC in these patients.

Genomic change in hepatitis B virus associated with development of hepatocellular carcinoma. *World J Gastroenterol* 2016; 22(23): 5393-5399 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5393.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5393

INTRODUCTION

Worldwide, hepatocellular carcinoma (HCC) is one of the most common malignant tumors[1]. One of the major risk factors closely associated with HCC development is chronic hepatitis B virus (HBV) infection, which in combination with the hepatitis C virus accounts for more than 80% of HCC worldwide[2]. The specific details of the hepatocarcinogenesis from the initial HBV infection is still unclear, although it has been suggested that many factors including but not limited to sex, age, viral genotype environmental factors, and genetic susceptibility all play an important role in the multistage process of HCC development[3].

Due to the high degree of genetic heterogeneity of the virus, there may be multiple mechanisms by which HBV causes HCC. Some studies have found that HBV can directly provoke hepatocarcinogenesis through chromosomal integration or transactivation of cellular genes[3,4]. Regardless, many of these molecular changes indirectly or directly leading to the development of HCC can be linked to genomic changes within the virus.

Various mutations in the HBV genome have been strongly associated with the development of HCC. A significant amount of evidence points to specific genetic mutations as essential viral factors contributing to the development of HCC that could serve as important prognostic biomarkers of the disease. The substitution of A by T at nucleotide 1762 (A1762T) and of G by A at nucleotide 1764 (G1764A) in the basal core promoter (BCP) region is the most common mutation in the HBV genome. This BCP mutation has been associated with higher occurrence of HCC[5,6]. In addition, it has been reported that other mutations of HBV such as G to A transition at nucleotide 1896 (G1896A) in the precore (PC) region, substitution from C to T at nucleotide 1653 (C1653T) and from T to either C/A/G at nucleotide 1753 (T1753V) in the X region, and the deletion in the pre-S region, may be associated with HCC, although their exact roles are still unknown[7-12].

Moreover, it has been demonstrated that genotype C HBV is strongly associated with mutations in the core promoter region and these particular mutations have been shown to be independent risk factors for HCC development[6,13,14]. Consequently, those infected with genotype C HBV may have a poorer prognosis with more aggressive liver disease[11].

Individual mutations within the HBV genome have been studied in order to prove their role in HCC development in chronic hepatitis B patients. Nevertheless, combined mutations in the HBV genome must also be recognized to have the potential to serve as predictive markers for HCC due to the potential ability of the virus to acquire mutations over time. Although there are few reports about the effects of combined mutations of HBV on HCC development, these results are still controversial.

Therefore, in this study, we intended to investigate the genomic changes in the X, S, BCP, and PC regions of HBV. And also we aimed to evaluate their roles in the development of HCC in patients chronically infected with genotype C HBV.

MATERIALS AND METHODS

Subjects

This study included 240 patients with chronic hepatitis B (CHB) diagnosed at Asan Medical Center, Seoul, Korea, between 1991 and 1998. All patients fulfilled

Table 1 Baseline characteristics of patients with chronic hepatitis B

Variables	*n* = 240
Age, yr[1]	48 (27-86)
Gender, M/F	201/39 (84/16)
[1]Platelet, × 10^3/mm^3	176 (62-556)
Prothrombin time, %[1]	87 (30-147)
ALT, IU/L[1]	149 (10-2170)
Total bilirubin, mg/dL[1]	0.8 (0.3-15.4)
Albumin, g/dL[1]	4.1 (2.2-5.2)
Serum AFP, ng/mL[1]	5.9 (1-2150)
Child-Pugh class, A/B/C	216/15/0 (94/6/0)
HBeAg positivity	195 (81)
Serum HBV DNA, copies/mL[1]	4.2×10^6 (ND-1.1×10^9)
Presence of HBV genotype C	240 (100)
Follow-up periods, mo[1]	105 (1-237)

[1]Median (range). ALT: Alanine aminotransferase; AFP: α-fetoprotein; HBeAg: Hepatitis B e antigen; ND: Not-detected.

the following requirements: (1) seropositivity for hepatitis B surface antigen for at least 6 mo; (2) age > 20 years; and (3) diagnosis with genotype C HBV. The exclusion criteria were as follows: (1) co-infection with hepatitis C virus, hepatitis D virus or human immunodeficiency virus; or (2) diagnosis with HCC at the time of screening.

The patients were followed up regularly at 3-6 month intervals. Serum biochemistry, hematology, HBV DNA titers, hepatitis B e antigen (HBeAg), and anti-HBe, were obtained at each visit. Serum alpha-fetoprotein (AFP), and imaging studies such as ultrasonography or dynamic computed tomographic scan were also performed for the surveillance of HCC development during follow-up. The diagnosis of HCC was determined using AASLD guidelines requiring typical imaging patterns on dynamic CT scan or MRI or pathologic findings[15]. This study was approved by the Institutional Review Board of Asan Medical Center.

HBV genotyping and detection of HBV mutations

HBV DNA was extracted from patient's serum or liver tissue samples using QIAmp DNA extraction kit (Qiagen K.K., Tokyo, Japan). The HBV genotypes were determined by polymerase chain reaction-restriction fragment length polymorphism of the surface gene of the HBV genome. False positives were avoided by preventing cross-contamination and duplicating the tests in order to validate the results.

The sequence was analyzed by amplifying the entire X, S, PC/core, and BCP regions of the HBV genomes. These regions of HBV genome were then sequenced using a direct sequencing method. The methods used for the genotyping and sequencing of the HBV genome were detailed in our previous study[6]. The sequencing conditions, including A1762T or G1764A in the BCP region, G1896A in the PC region, C1653T or T1753V in the region encoding HBx, and the pre-S deletion mutation were specified in the protocol for the Taq DyeDeoxy Terminator Cycle Sequencing Kit (ABI).

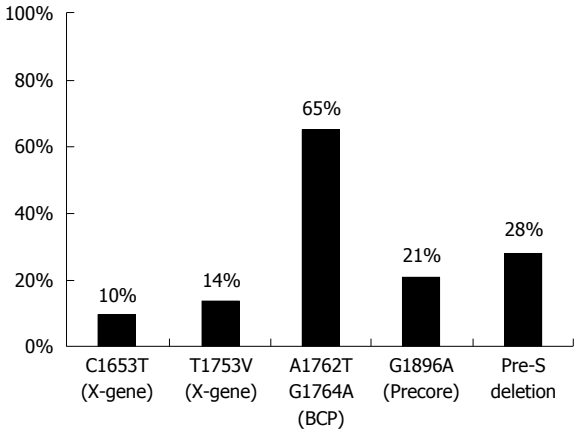

Figure 1 Prevalence of genomic changes in genotype C hepatitis B virus.

Statistical analysis

All variables are expressed as the median (range) or number (percentage). Follow-up duration was calculated from the date of enrollment to the last visit and time to recurrence was defined as the duration from enrollment to HCC diagnosis. To identify factors predisposing the development of HCC, the Kaplan-Meier method and log-rank test were used. And also multivariate analysis was performed using the Cox proportional hazards model. All significance tests were two-tailed, and $P < 0.05$ was considered to be statistically significant. All statistical analyses were performed using the SPSS statistical software package (version 20; SPSS Inc., Chicago, IL).

RESULTS

Baseline characteristics

The demographic data of the 240 patients with CHB are summarized in Table 1. All of the patients had a genotype C HBV infection. About 84% of the patients were male and the median age was 48 years (range, 27-86 years). More than 90% of the patients had relatively well-preserved liver function with Child-Pugh Class A and the median serum alanine aminotransferase (ALT) level was 149 IU/L (range, 10-2170 IU/L). Over 80% of the study subjects were positive for HBeAg. The median follow-up period was 105 mo (range, 1-237 mo).

Prevalence of HBV genomic mutations in CHB patients

The frequencies of genomic mutations in HBV are shown in Figure 1. The C1653T mutation in the X region was found in 10% of the study cases (n = 25). Another mutation in the X region, T1753V, was seen in 14% (n = 33). The BCP double mutation, A1762T/G1764A was detected in 65% (n = 157). The G1896A

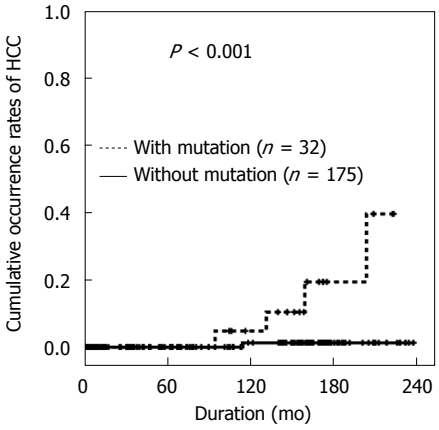

Figure 3 Cumulative occurrence rates of hepatocellular carcinoma in relation to the T1753V mutation in the X region. HCC: Hepatocellular carcinoma.

Table 2 Univariate analysis of risk factors for hepatocellular carcinoma development

Variables	RR (95%CI)	*P* value
Genomic changes		
C1653T in X region	1.583 (0.176-14.210)	NS
T1753V in X region	17.565 (1.956-157.737)	< 0.01
A1762T/G1764A in BCP	30.512 (0.004-230706)	NS
G1896A in PC	5.765 (0.519-64.076)	NS
Pre-S deletion	2.491 (0.502-12.370)	NS
Clinical characteristics		
Age > 50 yr	57.5 (0.035-93428)	NS
Male	27.3 (0.001-547718)	NS
ALT > 80 IU/L	0.55 (0.091-3.29)	NS
PT ⩽ 70 %	4.12 (0.682-24.845)	NS
Serum AFP > 200 ng/mL	0.044 (0.00-209046)	NS
HBeAg positive	0.034 (0.00-360.724)	NS
HBV DNA > 10^5 copies/mL	0.741 (0.123-4.452)	NS

RR: Relative risk; CI: Confidence interval; NS: Not significant; BCP: Basal core promoter; PC: Precore; ALT: Alanine aminotransferase; PT: Prothrombin time; AFP: α-fetoprotein; HBeAg: Hepatitis B e antigen.

mutation in the PC region was seen in 21% (*n* = 50) and the pre-S deletion was found in 28% (*n* = 67).

Overall occurrence rates of HCC in CHB patients

During follow-up, 6 of 240 patients with CHB (3%) newly developed HCC. The 5-, 10-, and 15-year overall cumulative occurrence rates of HCC were 0%, 1.8% and 4.1%, respectively (Figure 2).

Development of HCC in relation to individual genomic mutations in HBV

The presence of the T1753V mutation in the X region was significantly associated with the development of HCC (Figure 3). The 10- and 15-year cumulative occurrence rates of HCC were 5% and 19%, respectively, in patients with the T1753V mutation, which were significantly higher than the 1% 10- and 15-year rates seen in those with wild-type HBV ($P < 0.001$). However, other point mutations, such as C1653T in the X region, the BCP double mutation A1762T/G1764A, G1896A in the PC region, and the pre-S deletion, did not affect HCC occurrence (Table 2).

Effects of combined mutations in HBV genome on HCC development

The occurrence rates of HCC were assessed in relation to the presence of combined mutations to evaluate the synergic effects of genomic changes in HBV. The combination of the BCP double mutations A1762T/G1764A and the T1753V mutation had a close association with HCC development ($P < 0.01$) (Figure 4A). Patients with both BCP A1762T/G1764A mutations and the G1896A mutation also had a significantly higher occurrence rate of HCC ($P < 0.05$) (Figure 4B). In addition, coexistence of BCP double mutations and pre-S deletion showed the higher HCC occurrence rates ($P < 0.05$) (Figure 4C). However, the combination of BCP double mutations and C1653T in the X region was not significantly associated with HCC development (Figure 4D).

Predisposing factors of the development of HCC in patients with CHB

The occurrence rates of HCC in relation to baseline characteristics were also evaluated (Table 2). Age and gender did not showed significant association with the occurrence of HCC in univariate analysis. In addition, other clinical characteristics, such as serum ALT level, prothrombin time, serum AFP level, HBeAg positivity, and HBV DNA titers, did not affect HCC development. In multivariate analysis, the presence of the T1753V mutation in the X region was an independent risk factor for the development of HCC (relative risk 14.03, $P < 0.05$) (Table 3).

DISCUSSION

The impact of genomic changes in HBV on the clinical course of the infection-from the initial viral infection to HCC development-has been of great interest due to the unclear nature of the relationship between

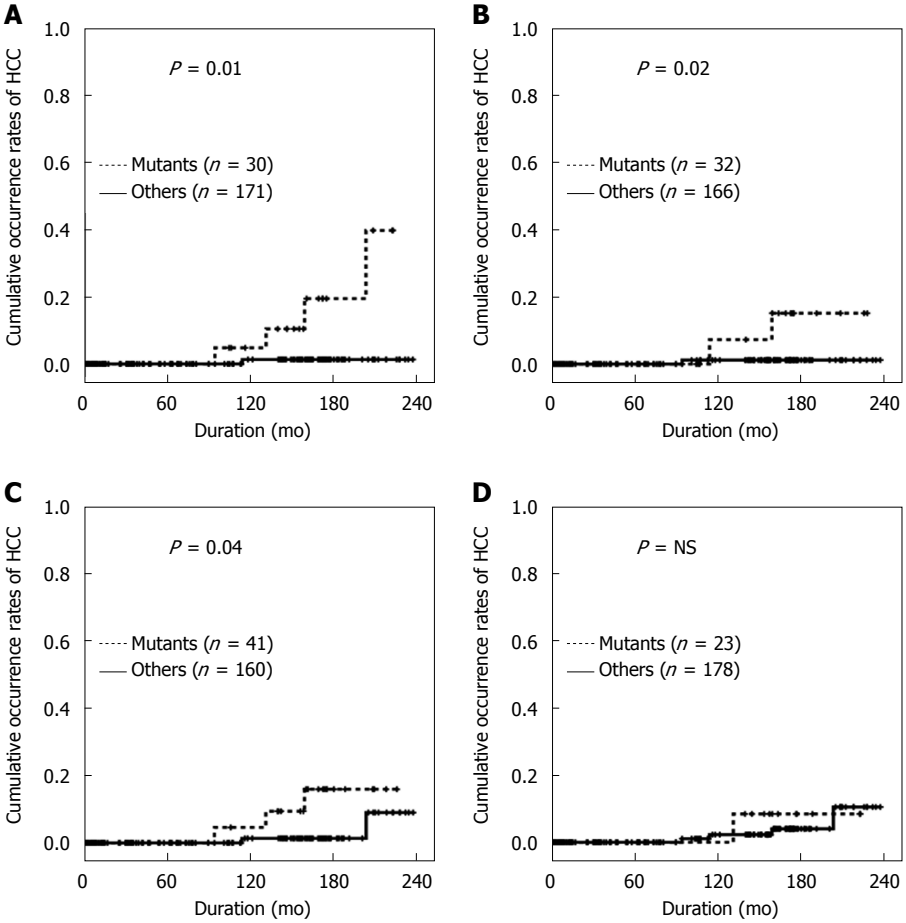

Figure 4 Cumulative occurrence rates of hepatocellular carcinoma in relation to the combination. A: The BCP A1762T/G1764A double mutation and with the T1753V mutation in the X region; B: The BCP A1762T/G1764A double mutation and the G1896A mutation in the PC region; C: The BCP A1762T/G1764A double mutation and the pre-S Deletion; D: The BCP A1762T/G1764A double mutation and the C1653T mutation in the X region. T1753V in X region	14.029 (1.568-125.550)	< 0.05

NS: Not significant.

the two components. Our work clarifies some of the uncertainty because our results suggest that patients with the T1753V mutation in the X region of the HBV genome are more likely to develop HCC as a result of their chronic HBV infection, especially that of genotype C. The HBx, a nonstructural regulatory protein of HBV, may play an essential role in hepatocarcinogenesis in the context of HBV. Studies of HBx transgenic mice have provided limited results regarding the role of the X-gene in live tumor formation[3,7,11]. Moreover, the exact role of the genomic mutations in the X region is still unclear. However, the present findings indicated that the T1753V mutation in the X region is an independent risk factor for the development of HCC in patients with CHB. Our results thus suggest that an amino acid change at nucleotide 1753 in the X region can affect the function of the HBx protein and thereby contribute to the process of hepatocarcinogenesis[7,11,16]. Therefore, it seems likely that mutations in the X region resulting in the translation of a truncated HBx protein contribute to the initiation of tumor formation in the liver[3,17].

The BCP double mutation A1762T/G1764A is one of the most common mutations in the HBV genome. The current study also showed high prevalence (65%) of A1762T/G1764A in patients with CHB of genotype C. However, the BCP double mutation was not significantly associated with HCC development. Nevertheless, we found that A1762T/G1764A tended to have high occurrence rates of HCC, although the results were not statistically significant. Interestingly, the BCP double mutation A1762T/G1764A significantly contributed to HCC development when it was combined with other individual mutations such as T1753V in the X region, G1896A in the PC region, or the pre-S deletion. Thus, the BCP mutations may also be associated with hepatocarcinogenesis[13,18]. The BCP mutations may change the viral pre-genomic secondary structure or increase the transcription of the pre-genomic RNA, consequently, the BCP mutations

can increase viral replication[14,19].

The PC mutation terminates the translation of HBeAg by creating a premature stop codon in the PC gene[6,7,20]. However, the exact role of this mutation is unclear because, although the mutation has been demonstrated to cause more severe liver disease, it was frequently detected in HBeAg-negative asymptomatic carriers[9,21,22]. In particular, one study has shown that the PC 1896 mutation alone appears to have no direct pathogenic role in HBV genotype C[21]. Our results also showed that the PC G1896A mutation alone was not significantly associated with HCC development, but a combination of the PC mutation and the BCP double mutation significantly influenced HCC occurrence.

Truncated pre-S2/S sequences can often be found in HBV DNA integration sites in HCC[3,23]. As in our present results, a recent study in Taiwan showed that the combination of the pre-S deletion mutation and the BCP double mutation was significantly associated with the development of HCC[6,24]. It is possible that hepatocytes expressing altered large and middle surface proteins encoded by the mutated S gene have a potential growth advantage[10,25]. Moreover, the pre-S mutant has been found to upregulate cyclin A expression and induce nodular proliferation of hepatocytes[10,17]. The modified surface antigen may induce oxidative DNA damage and mutations in hepatocytes in the late stages of a chronic HBV infection[10,26].

One limitation of our present study was the small number of newly developed HCC cases during follow-up. Out of 240 patients with CHB, only 6 patients developed HCC. However, most subjects had CHB, not liver cirrhosis. In addition, the median follow-up duration was about 9 years, which may be insufficient duration for HCC development, especially in patients with CHB. Nevertheless, our current study is one of the largest of its kind to date and had a longer follow-up period than other similar reports.

In conclusion, the presence of the T1753V mutation in the X region significantly increases the risk of HCC development in patients with genotype C CHB. The BCP mutations may act in synergy with the T1753V mutation in the X region, G1896A in the PC region, and with the pre-S deletion to significantly increase the occurrence of HCC in CHB patients with genotype C HBV.

COMMENTS

Background

Hepatitis B virus (HBV) is the most common risk factor for hepatocellular carcinoma development. Especially, among the various characteristics of HBV, genomic variation of the virus may effect on hepatocellular carcinoma (HCC) development directly. However, the exact role of the genomic mutation of HBV is still controversial for hepatocarcinogenesis. Thus, it is very important to clarify obvious function of the genomic mutation for the development of HCC in patients with HBV infection.

Research frontiers

The authors are part of the leading group in the studies of carcinogenesis for HBV associated HCC. The authors believe that some mutations in the basal core promoter, the precore, and the X regions may be associated with HCC development. We provide reasonable evidence to support the hypothesis which we have made from this paper.

Innovations and breakthroughs

Generally agreed by the most researchers on genomic changes of HBV are able to effect on the development of HCC. However, their opinions are far from being unanimous as to obvious role of each mutation for the development of HCC. This paper shows that the T1753V mutation in X region plays an important role as the risk factor for HCC development. Moreover, combined mutations of the basal core promoter mutation and other mutations such as T1753V, G1896A, and the pre-S deletion are also the risk factors for the development of HCC in patients with genotype C HBV infection.

Applications

High risk group for HCC development can be identified among the patients infected with genotype C HBV. Furthermore, the authors can establish efficient process to detect HCC earlier and also the authors may prevent the development of HCC ultimately.

Terminology

HBV is a member of hepadnaviridae family, and it can cause acute hepatitis, fulminant hepatitis, asymptomatic carrier state, chronic hepatitis, cirrhosis, and HCC. Especially, HBV is the most common risk factor for HCC development. Because HBV has the high degree of genetic diversity, it is considered that the genomic changes of HBV can influence on the carcinogenesis of HCC, although the exact role of each genomic mutation is not obvious. HCC is a primary cancer of the liver and usually occurs in patients with chronic liver disease, especially chronic hepatitis B. Multiple mechanisms impact on the development of HCC and some of mechanisms has not been fully verified as yet.

Peer-review

Excellent study has been performed by Danbi Lee *et al* reporting about the association between genomic changes of genotype C HBV and HCC development. This study definitely help to verify mechanism of HCC development. Congratulation to authors for the valuable results for role of genetic mutation of HBV for the hepatocarcinogenesis.

Abstract

AIM: To analyze the efficacy of last line sorafenib treatment in colorectal cancer patients.

METHODS: All patients receiving chemotherapy for colorectal cancer in the outpatient clinic of the University of Mainz since 2006 were retrospectively analyzed for last line sorafenib exposure. Charts of identified patients were analyzed for clinic-pathological parameters, like data on gender, age, date of initial diagnosis, UICC stage, number and kind of the pre-therapies, therapy start and end of sorafenib, sorafenib mediated treatment cessation, side effects, response rates, time to progression and overall survival.

RESULTS: Ten patients with a median of 3.0 prior chemotherapy lines had received a last line sorafenib therapy either alone (10%) or in combination with

5-fluorouracil derivates (90%). All patients suffered from colorectal cancer stage UICC 4 and were routinely seen in 2-wk intervals in the oncology outpatient clinic. Median duration of treatment was 142.0 d. At 8 wk 80% of patients showed stable disease but we did not observe any remissions. Median time to progression was 140.5 d (4.7 mo), while median overall survival reached 176.5 d. One patient ceased treatment due to side effects. Reason for treatment stop was bleeding complication in one case and non-specified sorafenib intolerance in another case. Due to the retrospective approach we did not further quantify side effects.

CONCLUSION: This retrospective analysis encourages further investigation of sorafenib in colorectal cancer last line therapy.

Key words: Colorectal cancer; Sorafenib; Regorafenib; Chemotherapy; Last line

Core tip: In this restrospective analysis we demonstrate that sorafenib monotherapy or in combination with 5-fluorouracil derivates seems to be feasible. Eighty percent of the patients showed stable disease with a median time to progression of 140.5 d and acceptable toxicity profile. In our eyes, the reported overall as well as progression free survival under sorafenib treatment are of clinical and financial interest.

Last line therapy with sorafenib in colorectal cancer: A retrospective analysis. *World J Gastroenterol* 2016; 22(23): 5400-5405 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5400.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5400

INTRODUCTION

Colorectal cancer ranges among the most frequent malignancies in Western countries[1,2]. Annually, more than 1.2 million patients are diagnosed with colorectal cancer resulting in more than 600000 death each year (1 Sora). Survival is delineated by local recurrence and tumor dissemination[3]. Noteworthy, 50% of patients develop metastases in the due course of the disease (2 Sora).

Due to improved therapeutic strategies, the overall survival in metastatic stage Ⅳ colorectal cancer has increased from eight months to more than two years during the last decade. Chemotherapeutics, such as platinum derivates (oxaliplatin) or topoisomerase Ⅱ inhibitors (irinotecan) as well as the introduction of biologicals targeting tumor neo-vascularisation (anti-VEGF: bevacizumab and aflibercept) or growth-signaling (anti-EGFR: cetuximab and panitumumab) have significantly augmented response rates and prognosic parameters[4-10].

Those new strategies have resulted in an unexpected dilemma: Numerous patients in good condition have experienced progression following treatment with all available agents. This therapeutic gap has recently been targeted by the multi-tyrosine kinase inhibitor regorafenib[11]. Last line treatment with regorafenib resulted in a progression free survival of 1.9 mo (*vs* 1.7 mo in the placebo arm) and an overall survival of 6.4 mo (*vs* 5.0 mo in the placebo arm). Receptor tyrosine kinases (RTKs) are transmembrane-receptors containing extracellular ligand-binding domains connected to intracellular catalytic domains[12]. The growth factors VEGF/PDGF/EGF and their receptors VEGFR1-3, PDGFRα/β and EGFR are critical in the process of (lymphatic) neo-angiogenesis and dissemination in human cancer[13-17].

Inhibition of RTKs with sorafenib has been successful in renal and hepatocellular cancer[18,19]. Two phase I studies revealed a disease stabilization in pretreated colorectal cancer patients receiving sorafenib in combination with either irinotecan or oxaliplatin[20,21]. Therefore, the impact of combinational therapies (sorafenib + chemotherapy) remains controversial.

However due to a lack of treatment options in the augmenting number of colorectal cancer patients pretreated with all available chemotherapeutic and biological options, we identified 10 patients which had received off-label sorafenib within a risk sharing program of Bayer Healthcare. The current publication reports on the results of those patients in a retrospective approach.

MATERIALS AND METHODS

Analyses

We retrospectively analyzed all medical records of colorectal cancer patients which received any treatment in the outpatient clinic of the university if Mainz between January 1, 2007 and December 31, 2011 in order to identify patients that had received sorafenib as last line treatment. We then retrospectively collected and analyzed data from the medical records. In particular we collected data on gender, age, date of initial diagnosis, UICC stage, number and kind of the pre-therapies, therapy start and end of sorafenib, sorafenib mediated treatment cessation, progression free survival (PFS), overall survival (OS) and relative risk.

RESULTS

Patient characteristics

We identified 10 patients, which had received off-lable sorafenib after entering a risk sharing program of Bayer Healthcare. All patients were routinely seen

in 2-wk intervals in the oncology outpatient clinic. At visits following assessments were done: general condition of the patients, blood counts, side effects. Staging analyses (CT scan abdomen and thorax) were done every 8 wk. All patients (100%) suffered from colorectal cancer stage UICC 4. Eighty percent of patients were male, while 20% were of female gender. Average patient age was 65 years. One hundred percent of patients were in good condition as indicated by an ECOG of 0-1. Patients had received an average of 3 prior chemotherapy regimens prior to treatment with sorafenib (Tables 1 and 2).

Treatment characteristics

One patient (10%) had received a sorafenib monotherapy, while 9 patients (90%) had had a combination of sorafenib with different 5-fluorouracil (5-FU) derivates. 5-FU derivates applied were intravenous 5-FU (*n* = 2; folinic acid 400 mg/qm d1, 5-FU 400 mg/q.m. bolus d1, 2400 mg/q.m. d1 and d2), capecitabine (*n* = 4; dose 2000 mg/q.m. d1-d14) or Tegafur-Uracil (*n* = 3; 300 mg/q.m. and Calciumfolinat 90 mg/d d1-d28). All patients were initially administered a reduced dose of sorafenib of 400 mg/d (200 mg b.i.d.). The dose was adjusted to 800 mg/d (400 mg b.i.d.) after 1 to 2 wk. Treatment duration was 142 d in median. Maximal treatment duration was 176 d. Eighty percent of patients (8/10) received treatment until progression, while 20% (2/10) ceased treatment due to side effects after average treatment duration of 56 d. Reason for treatment stop was bleeding complication in one case and non-specified sorafenib intolerance in another case. Due to the retrospective approach we did not further quantify side effects (Table 3).

Survival and response parameters

At the first staging at treatment week 6, 80% of patients (8/10) revealed stable disease (SD) as compared to progressive disease (PD) in 20% (2/10; one of both patients had died after 21 d of treatment due to clinical progress). No partial or complete responses were observed. At week 12 only six patients were evaluable. Of those 50% (3/6) revealed stable disease and 50% (3/6) progressive disease. Median PFS was 140 d, median OS was 176 d (Figures 1 and 2).

Adverse events

The most frequent sorafenib-related adverse events of grade 3 or higher were fatigue (30%), anemia (20%), emesis (10%), mucositis (10%), pain (10%), leucocytopenia (10%) and thrombocytopenia (10%; Table 4). Relevant sorafenib-related adverse events grade 1 or 2 were fatigue (70%), diarrhea (40%), anemia (40%), mucositis (30%), hand foot syndrome (30%) and thrombocytopenia (30%) among others (Table 4).

DISCUSSION

As to our best knowledge, this is the first retrospective study investigating last line sorafenib in colorectal cancer patients. Prospective studies have not been performed or published, so far.

Due to augmented therapeutic options, the overall survival in metastatic stage Ⅳ colorectal cancer has increased from eight months to more than two years during the last decade[4-7]. Those new strategies have resulted in an unexpected dilemma: Numerous patients in good condition have experienced progression following treatment with all available agents. This therapeutic gap has recently been targeted by the multi-tyrosine kinase inhibitor regorafenib[11]. Last line treatment with regorafenib resulted in a progression free survival of 1.9 mo (*vs* 1.7 mo in the placebo arm) and an overall survival of 6.4 mo (*vs* 5.0 mo in the placebo arm). In the light of the regorafenib approval in 2013 we decided to analyze the efficacy of sorafenib in a retrospective approach. Diverse colorectal cancer patients in good condition had previously received sorafenib in a last line approach over the recent years prior to admission of regorafenib.

Our retrospective data must be handled with care due to their limitation by the retrospective approach and the small number of patients. All patients were UICC stage Ⅳ, in good condition and had received an average of 3 prior chemotherapy regimens. However, the majority of patients were of male gender, thus not representing the normal distribution of colorectal cancer among genders.

Tolerability of last line sorafenib was generally good: 30% of patients developed a grade 3/4 fatigue, 20% a grade 3/4 anemia and respectively 10% a grade 3/4 emesis, mucositis, leucocytopenia or thrombocytopenia. Thus grade 3/4 fatigue, anemia and thrombocytopenia seems to occur more often than

Table 2 Detailed description of patients at therapy start

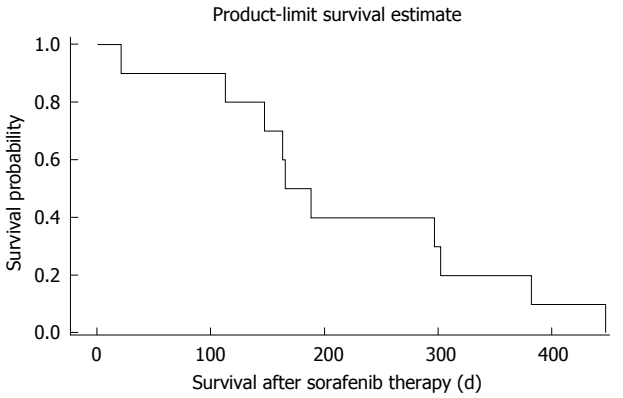

Figure 2 Overall survival. Kaplan-Meier analysis, retrospective population. Median progression free survival 176.5 d.

under regorafenib (10%, 3% and 4%, respectively)[11]. However, due to the low number of cases this data is at best descriptive.

We were surprised to find a median PFS of 4.7 mo (140 d) among our patients as compared to 1.9 mo under regorafenib treatment as reported by Axel Grothey and coauthors. In addition our retrospective analysis revealed an overall survival of 5.9 mo (176 d) and thus is in line with the reported overall survival of last line regorafenib (6.4 mo *vs* 5.0 mo in the placebo arm). As to be expected we did not observe any remissions but found an interesting effect in disease stabilization (80% at week 8). Noteworthy, the majority of patients (90%) had received a combination of sorafenib with 5-FU (or its pro-drugs) and only one patient had ceased treatment due to side effects.

However, the combination of sorafenib with 5-FU might not explain the observed effects. As reported by our own group, we previously studied the combination of sorafenib with 5-FU *in vitro* as well as *in vivo* in xenograft models[22]. We demonstrated that a sorafenib-monotherapy (5 mg/kg; approximately 400 mg in an 80 kg patient) was equally effective as a combination therapy of both sorafenib and 5-FU. Thus,

Table 4 Adverse events (CTC AE3.0)

Patient	Ⅰ°-Ⅱ°	Ⅲ°-Ⅳ°	Total
Fatigue	70% (7/10)	30% (3/10)	100%
Nausea	20% (2/10)	0% (0/10)	20%
Emesis	20% (2/10)	10% (1/10)	30%
Diarrhea	40% (4/10)	0% (0/10)	40%
Mukositis	30% (3/10)	10% (1/10)	40%
Rash	20% (2/10)	0% (0/10)	20%
HFS	30% (3/10)	0% (0/10)	30%
PNP	20% (2/10)	0% (0/10)	20%
Pain	20% (2/10)	10% (1/10)	30%
Weight loss	10% (1/10)	0% (0/10)	10%
Infection	20% (2/10)	0% (0/10)	20%
Anemia	40% (4/10)	20% (2/10)	60%
Thrombopenia	30% (3/10)	10% (1/10)	40%
Leucopenia	20% (2/10)	10% (1/10)	30%

a combination therapy did not result in any additive effects, but might add adverse events. However, these data became available only after the off-label treatment of colorectal cancer patients.

In our eyes, the reported overall as well as progression free survival under sorafenib treatment are of clinical and financial interest, as treatment costs of regorafenib sum up to €5573 per 28-d-cycle as compared to €2611 for its predecessor sorafenib. Therefore a trial focusing on non-inferiority for sorafenib *vs* regorafenib might be feasible.

COMMENTS

Background

Improved therapeutic strategies have resulted in an unexpected dilemma: Numerous patients in good condition have experienced progression following treatment with all available agents. This therapeutic gap has recently been targeted by the multi-tyrosine kinase inhibitor regorafenib. Last line treatment with regorafenib resulted in a progression free survival of 1.9 mo (*vs* 1.7 mo in the placebo arm) and an overall survival of 6.4 mo (*vs* 5.0 mo in the placebo arm). Receptor tyrosine kinases (RTKs) are transmembrane-receptors containing extracellular ligand-binding domains connected to intracellular catalytic domains. The growth factors VEGF/PDGF/EGF and their receptors VEGFR1-3, PDGFRα/β and EGFR are critical in the process of (lymphatic) neo-angiogenesis and dissemination in human cancer. Inhibition of RTKs with sorafenib has been successful in renal and hepatocellular cancer. Two phase I studies revealed a disease stabilization in pretreated colorectal cancer patients receiving sorafenib in combination with either irinotecan or oxaliplatin. Therefore, the impact of combinational therapies (sorafenib + chemotherapy) remains controversial.

Research frontiers

Due to novel therapeutic approaches patients with stage IV colorectal cancer show an improvement in overall survival. In this palliative setting it remains a major goal to reduce therapy induced toxicity and still preserve improvement of progression free survival or overall survival.

Innovations and breakthroughs

Ten patients with a median of 3.0 prior chemotherapy lines had received a last line sorafenib therapy either alone (10%) or in combination with 5-fluorouracil derivates (90%). All patients suffered from colorectal cancer stage UICC 4 and were routinely seen in 2-wk intervals in the oncology outpatient clinic. Median duration of treatment was 142.0 d. At 8 wk 80% of patients showed stable disease. Therefore sorafenib could be a very efficient and cost effective therapeutic last line approach to compared to regorafenib.

Applications

The authors evaluate a cost effective last line therapeutic approach for colorectal cancer patient with a favorable toxicity profile.

Terminology

Receptor tyrosine kinases (RTKs), are transmembrane-receptors containing extracellular ligand-binding domains connected to intracellular catalytic domains. The growth factors VEGF/PDGF/EGF and their receptors VEGFR1-3, PDGFRα/β and EGFR are critical in the process of (lymphatic) neo-angiogenesis and dissemination in human cancer. Sorafenib and regorafenib are inhibitors for these RTKs.

Peer-review

The retrospective study in order to analyze the efficacy of sorafenib treatment in colorectal cancer present a small number of patients, but the results are valuable.

Abstract

AIM: To determine whether the positive status of human epidermal growth receptor 2 (HER2) can be regarded as an effective prognostic factor for patients with gastric cancer (GC) undergoing R0 resection.

METHODS: A total of 1562 GC patients treated by R0 resection were recruited. HER2 status was evaluated in surgically resected samples of all the

patients using immunohistochemical (IHC) staining. Correlations between HER2 status and clinicopathological characteristics were retrospective analyzed. Hazard ratios (HRs) and 95% confidence intervals (CIs) were estimated using Cox proportional hazard model, stratified by age, gender, tumor location and tumor-node-metastasis (TNM) stage, with additional adjustment for potential prognostic factors.

RESULTS: Among 1562 patients, 548 (positive rate = 35.08%, 95%CI: 32.72%-37.45%) were HER2 positive. Positive status of HER2 was significantly correlated with gender (P = 0.004), minority (P < 0.001), tumor location (P = 0.001), pathological grade (P < 0.001), TNM stage (P < 0.001) and adjuvant radiotherapy (74.67% *vs* 23.53%, P = 0.011). No significant associations were observed between HER2 status and disease free survival (HR = 0.19, 95%CI: 0.96-1.46, P = 0.105) or overall survival (HR = 1.19, 95%CI: 0.96-1.48, P = 0.118) using multivariate analysis, although stratified analyses showed marginally statistically significant associations both in disease free survival and overall survival, especially among patients aged < 60 years or with early TNM stages (Ⅰ and Ⅱ). Categorical age, TNM stage, neural invasion, and adjuvant chemotherapy were, as expected, independent prognostic factors for both disease free survival and overall survival.

CONCLUSION: The positive status of HER2 based on IHC staining was not related to the survival in patients with GC among the Chinese population.

Key words: Human epidermal growth receptor 2; Gastric cancer; R0 resection; Chinese population; Prognostic factors

Core tip: The study retrospectively analyzed the associations between the positive status of human epidermal growth receptor (HER) 2 and survival of patients with gastric cancer (GC) undergoing R0 resection among the Chinese population, and found that the positive status of HER2 based on immunohistochemical staining was not related to survival in GC patients.

INTRODUCTION

The human epidermal growth receptor 2 (HER2) is now well recognized as a key factor in the development of certain solid human tumors[1], most notably in breast cancer[2]. It activates numerous downstream pathways in response to extracellular ligands, regulating diverse processes that include differentiation, migration, proliferation and survival[3,4]. Over the last few years, HER2 has been the most frequently studied molecular biological prognostic factors in various tumors[5-7].

In gastric cancer (GC), the ToGA trial was the first study showing the clinical benefit of trastuzumab in combination with chemotherapy for HER2 positive advanced GC patients[8,9]. That is to say, HER2 status is thought to be an important prognostic factor and biologic agent[10-12]. However, a post-hoc subgroup analyses failed to show survival benefits of trastuzumab therapy in Asian populations[8]. Although several studies have evaluated the poor prognosis of GC with HER2 overexpression recently[13,14], the clinical significance of such association remains controversial[14-16]. Therefore, we conducted this retrospective study to examine whether the positive status of HER2 can be regarded as an effective prognostic factor for patients with GC undergoing R0 resection among the Chinese population.

MATERIALS AND METHODS

Ethical statement

All procedures performed in the study involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. This study was also approved by institutional review board of Qinghai University Affiliated Hospital and National Cancer Center/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College. Additional informed consent was obtained from all individual participants for whom identifying is included in this article.

Patients

In this retrospective study, 1562 patients with GC who underwent R0 resection between December 2009 and December 2011 at Qinghai University Affiliated Hospital, Xining, or National Cancer Center/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, or People's Hospital of Qinghai province, Xining, were recruited. Patients were treated exclusively by total or subtotal gastrectomy with lymphadenectomy according to tumor location; neoadjuvant chemotherapy or radiotherapy was not administered to any patients. Patients' characteristics regarding age (categorical age: <60 years *vs* ⩾ 60 years), gender, minority, family history, tumor location, histological grade, tumor stage, tumor embolus, neural invasion and adjuvant chemotherapy and radiotherapy are listed in Table 1. Each cases was staged according to the tumor-node-metastasis (TNM) cancer staging system of malignant tumors 7th edition advocated by the American Joint Committee on Cancer (AJCC)[17].

Table 1 Baseline and clinicopathological characteristics among gastric cancer patients with different human epidermal growth receptor 2 status *n* (%)

[1]The parametric *P* value is calculated by t-test for numerical covariates and χ^2 test for categorical covariates. Number of observations in the original data set = 1562. Number of observations used = 1313, owing to the missing value occurring in family history of cancer (249). HER2: Human epidermal growth receptor 2.

All patients were evaluated for disease recurrence and survival status by clinical examinations, upper gastrointestinal endoscopic assessment, and diagnostic imaging (chest radiograph, ultrasonography, computed tomography, or magnetic resonance imaging) every 3 mo during the 1st year and once 6 mo thereafter until death or the last time of follow-up.

Tissue processing

Samples were removed from tumors; grossly necrotic tissue was avoided. Immediately after surgical resection, samples were processed for pathological examination while the remainder was washed with a cold saline solution, divided into aliquots, rapidly transported on ice to the laboratory, and stored at -70 ℃ pending biochemical studies.

Specimens from neoplastic tissues were processed at the same time. They were fixed in buffered 10% formalin, embedded in paraffin, and 4-μm thick sections were cut from the paraffin block of each specimen and applied to slides for immunohistochemical (IHC) staining.

IHC staining and HER2 status

The IHC analysis with the Herecp test was performed according to the manufacturer's instructions. In brief, heat-induced epitope retrieval was performed on the deparaffinized sections in advance by immersing the slides in Epitope Retrieval Solution (10 mm citrate buffer; pH = 6.0), which had been preheated to 95 ℃. They were then placed in a water bath at 95 ℃ for 40 min, followed by incubation for 20 min at room temperature, then endogenous peroxidase was quenched with Peroxidase Blocking Reagent. Next, the slides were incubated at room temperature for 30 min with a ready-to-use rabbit polyclonal antibody to HER,

and the primary antibody was detected by incubation at room temperature for 30 min with Visualization Reagent (dextran polymer conjugated with horseradish peroxidase and goat anti-rabbit immunoglobulin). After washing, slides were developed with Substrate Chromogenic Solution at room temperature for 10 min. The results were scored following the HER2 scoring scheme (scores 0, 1+, 2+ and 3+) in accordance with DFA-approved system for breast cancer[18] and interpreted by two independent pathologists who were blinded to the clinical information, and the inconsistent results were also judged by the third pathologist. Positivity status of HER2 was defined as IHC 3+, and the others were considered as negative.

Statistical analyses

Pearson χ^2 tests or Fisher exact tests were used to explore the correlation between HER2 status and clinicopathological characteristics. Kaplan-Meier method was performed to calculate the disease free survival (DFS) rate and overall survival (OS) rate, and survival curves were compared using log-rank test. Hazard ratios (HRs) and 95% confidence intervals (CIs) were estimated using Cox proportional hazard regression model with and without additional adjustment for potential prognostic factors. The proportional hazard assumption was examined using models that allowed time-dependent HRs combined with curve of log[-log (t)].

All *P*-values were two-sided and *P*-values less than 0.05 were considered statistically significant. All analyses were conducted using SAS version 9.1.3 service pack 4 (SAS Institute, Inc., Cary, NC).

RESULTS

Patients and baseline characteristics

A total of 1562 patients with a median age of 59 years (range: 20-84 years) were recruited and screened for HER2 status by IHC staining, of whom 548 were considered HER2 positive. Baseline and clinical pathological characteristics are outlined in Table 1. Of these 1562 patients, 1176 (75.29%) were male, 1505 (96.35%) were Chinese Han, 157 (11.96%) were reported with a positive history of familial cancer, and 1006 (64.40%) with primary tumor located in gastric were verified by pathology. All the patients were treated by R0 resection, with 389 (24.90%) patients developing tumor embolus. Therefore, all patients in this study had enough tumor samples to conduct the IHC analysis. Poorly differentiated tumors were observed in 71.32% of patients, and 54.99% of patients had pTNM stage Ⅲ disease. Besides, 886 (56.72%) and 102 (6.53%) patients accepted the adjuvant chemotherapy and radiotherapy, respectively, after the surgical treatment owing to the neural invasion (229, 14.66%) or other reasons.

HER2 status and clinicopathological characteristics

Table 1 shows the HER2 status and clinicopathological characteristics between HER2 positive and negative patients. Of all the patients, 548 tested positive for HER2, with a positive rate of 35.08% (95%CI: 32.72-37.45%). No significant differences were observed for categorical age (<60 years *vs* ⩾ 60 years), familial cancer, tumor embolus, neural invasion or adjuvant chemotherapy. We found that the following factors were statistically associated with the HER2 status. Compared with negative status of HER2, patients with positive status had a significantly lower proportion of male gender (62.93% *vs* 37.07%, $P = 0.004$), Chinese Han population (65.71% *vs* 34.29%, $P < 0.001$), GC (62.03% *vs* 37.97%, $P = 0.001$), pTNM stages (Ⅰ: 55.20% *vs* 44.80%, Ⅱ: 65.55% *vs* 34.45% and Ⅲ: 68.92% *vs* 31.08%, respectively, $P < 0.001$) and adjuvant radiotherapy (74.67% *vs* 23.53%, $P = 0.011$). In contrast, compared with patients with positive status of HER2, patients with negative status had a lower proportion of high differentiation (40.79% *vs* 59.21%), whereas a higher proportion of moderate differentiation (38.11% *vs* 61.89%) and low differentiation or signet-ring cell cancer (31.63% *vs* 68.37%) with *P*-values less than 0.001.

HER2 status and DFS

Because of the potential differences in DFS among the patients with negative or positive status of HER2, we estimated the HRs and adjusted HRs. There were no statistically significant associations between the status of HER2 and DFS in GC, regardless of additional adjustment of potential prognostic factors (Table 2).

In stratified analyses, we observed that the risk of disease progression was marginally significantly increased for GC patients in both younger population and older population (⩾ 60 years), although the HR reached statistical significance only in the older group (HR = 1.32, 95%CI: 1.02-1.71, $P = 0.032$). Results were also marginally significant for risk of disease progression in pTNM stage, especially in stage Ⅰ (HR = 1.86, 95%CI: 0.99-3.50, $P = 0.056$) and stage Ⅱ (HR = 1.55, 95%CI: 0.94-2.55, $P = 0.089$) according to the AJCC-TNM Cancer Staging 7th edition (Tables 2 and 3, and Figure 1).

HER2 status and OS

No significant association was observed between HER2 status and OS rate. Further stratified analyses showed marginally statistically significant associations in both the older patients (HR = 1.28, 95%CI: 0.98-1.68, $P = 0.070$) and patients with early pTNM stage (Ⅱ *vs* Ⅰ: HR = 2.03, 95%CI: 0.97-4.23, $P = 0.061$; Ⅲ *vs* Ⅰ: HR = 1.75, 95%CI: 1.04-2.94, $P = 0.035$) (Tables 2 and 3, and Figure 2).

Other prognostic factors

As expected, the estimated parameters of categorical

[1]Adjusted HRs and 95%CIs are calculated using models stratified by age, gender, location and TNM stage, with additional adjustment for ethnic, history of family cancer, tumor embolus, neural invasion, adjuvant chemotherapy and adjuvant radiotherapy. Number of observations in the original data set = 1562. Number of observations used = 1313, owing to the missing value occurring in family history of cancer (249). DFS: Disease free survival; OS: Overall survival; TNM: Tumor-node-metastasis.

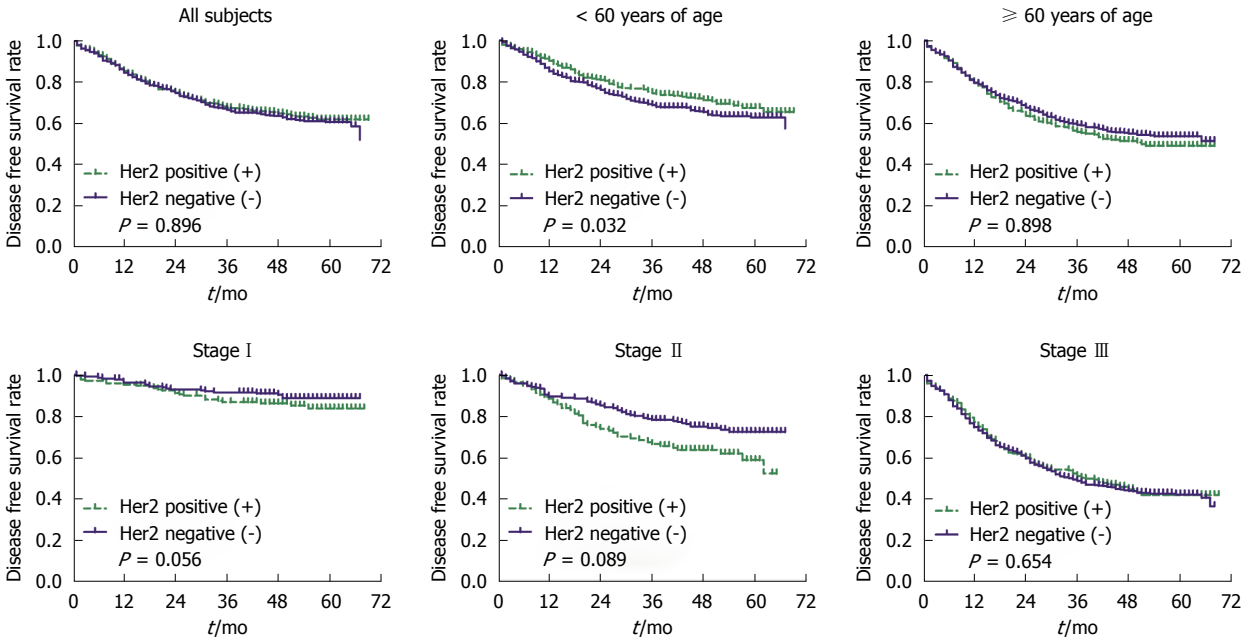

Figure 1 Kaplan-Meier survival curves for disease free survival rate stratified by categorical age (< 60 year *vs* ⩾ 60 year) and pTNM stage without adjustment, respectively. The green dash with plus indicates the positive status of HER2, and the blue solid with plus indicates the negative status of HER2. HER2: Human epidermal growth receptor 2.

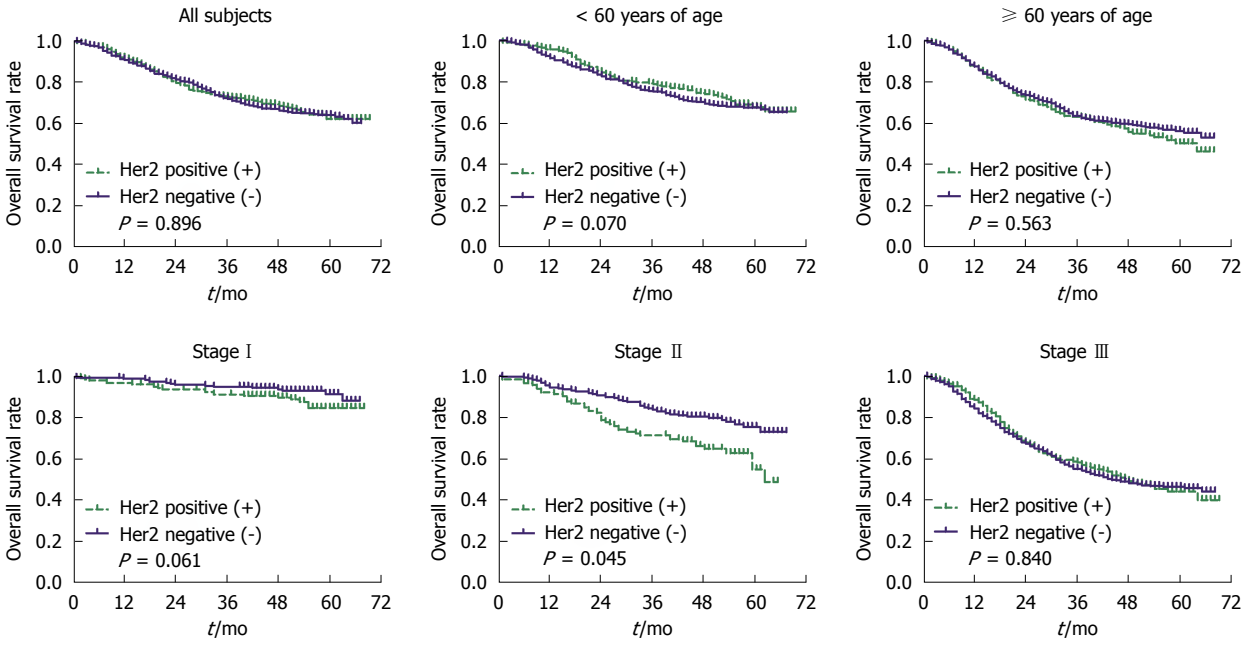

Figure 2 Kaplan-Meier survival curves for overall survival rate stratified by categorical age (< 60 year *vs* ⩾ 60 year) and pTNM stage without adjustment, respectively. The green dash with plus indicates the positive status of HER2, and the blue solid with plus indicates the negative status of HER2. HER2: Human epidermal growth receptor 2.

age (HR = 1.42, 95%CI: 1.18-1.71, $P < 0.001$), pTNM stage (Ⅱ *vs* Ⅰ: HR = 2.61, 95%CI: 1.76-3.87, $P < 0.001$; Ⅲ *vs* Ⅰ: HR = 6.50, 95%CI: 4.57-9.23, $P < 0.001$), neural invasion (HR = 1.51, 95%CI: 1.21-1.89, $P < 0.001$), and adjuvant chemotherapy (HR = 0.79, 95%CI: 0.65-0.95, $P = 0.015$) statistically significantly affected DFS in both univariate and multivariate analyses, that is to say, these factors were independent prognostic factors for DFS among GC patients. Furthermore, categorical age (HR = 1.39, 95%CI: 1.15-1.70, $P < 0.001$), pTNM stage (Ⅱ *vs* Ⅰ: HR = 3.33, 95%CI: 2.14-5.18, $P < 0.001$; Ⅲ *vs* Ⅰ: HR = 8.70, 95%CI: 5.83-12.98, $P < 0.001$), neural invasion (HR = 1.68, 95%CI: 1.33-2.12, $P < 0.001$), and adjuvant chemotherapy (HR = 0.73, 95%CI: 0.60-0.90, $P = 0.002$) were also independent

prognostic factors for OS (Table 2).

DISCUSSION

GC is the fourth most frequently diagnosed cancer and the second leading cause of cancer-related mortality worldwide[19]. However, China accounts for approximately 45% of world's GC cases with an estimated 420489 new cases and 330010 deaths in 2012, and GC remains the second most common GC in both urban and rural areas in China[20]. To date, treatment outcomes for GC remain poor, particularly in patients with inoperable or metastatic disease[21]. Therefore, there is a clear need for effective therapeutic regimes for GC patients. HER2 cancer biomarker testing in GC has been a highly controversial subject, with huge clinical advances taking place in this field while major biomarker mythology discrepancies have persisted[8,22]. HER2 positive GC patients tended to have a more aggressive disease[12,23,24].

Previous studies reported that the prevalence of HER2 amplification is rare and highly heterogeneous in GC with an estimated rate ranging from 4% to 53% owing to the different techniques, methodologies, and scoring systems applied in the studies[4,25-27]. To avoid potential pitfalls in our results, we applied the scoring system approved by the Food and Drug Administration for breast cancer[18] and found that the positive rate of HER2 was approximately 35.08% (95%CI: 32.72-37.45%), which is consistent to the previously reported rates. Although recent studies have been conducted to validate the HER2 scoring system for GC in both IHC analysis and fluorescence in situ hybridization (FISH) analysis, the concordance between FISH and IHC ranged from 88.5% to 93.5%[2,28-30]. In addition, previous reports have demonstrated that a higher rate of HER2 expression is more frequently in intestinal-type than in diffuse-type according to Lauren's classification[8,31] and more common in gastroesophageal junction cancer than in GC[32], but this is not the case in our study.

The role of HER2 as a prognostic factor in GC has been controversial and some initial studies failed to find an association with prognosis[15,26], as in our results. In the post-hoc subgroup analysis of ToGA (Trastuzumab for GC) trial, HER2 positive patients from the Asian population did not reveal a statistically significant improvement of DFS or OS[8]. However, several studies have reported a direct correlation between HER2 expression or HER2 amplification and poorer survival, especially in patients with surgical treatment, gastroesophageal junction cancer and intestinal-type cancer[22,23,33-35]. Even in the Chinese population, Liang *et al*[36] and Zhang *et al*[37] have demonstrated a strong association between HER2 expression and unfavorable survival. In our study, we retrospectively analyzed 1562 patients with GC, all of whom were treated by R0 resection and 35.60% of whom had cardia GC, and found that positive status of HER2 did not affect DFS or OS among the Chinese population. Furthermore, we also conducted subgroup analyses stratified by categorical age, gender, tumor location and pTNM stage. Marginally statistically significant associations were observed between HER2 overexpression and GC in younger patients ($P_{DFS\ Interaction} < 0.001$, $P_{OS\ Interaction} = 0.003$, respectively) and patients with early pTNM stage ($P_{DFS\ Interaction} = 0.037$, $P_{OS\ Interaction} = 0.041$, respectively). Owing to the post-hoc defined group the difference was found by exploratory but not by preplanned analysis, and unrestricted subgroup analysis generates multiple comparisons that dramatically increase the likelihood of detecting a probability value of nominal statistical significance ($P < 0.05$) by chance alone[38]. Therefore, further study should be conducted to confirm these associations in the future.

On the other hand, several limitations should be notable. First and foremost, status of HER2 was tested using IHC analysis only, which may be prone to false negative results especially for IHC 2+ cases, and then lead to bias eventually. Second, sampling errors in specimens of biopsy size may be caused by heterogeneous overexpression of HER2 in GC, which should also be taken into consideration. Third, Lauren classification was also reported to be an important pathological feature of GC patients combined with HER2 status, which indicated a better prognostic factor, while we failed to test the Lauren classification. Finally, 886 (56.72%) and 102 (6.53%) patients received subsequent adjuvant chemotherapy and radiotherapy, respectively, which may lead to a protective effect for patients with GC, despite additional adjustments in this study (Table 2).

In summary, our study provides evidence that HER2 expression was correlated with clinicopathological features of patients with GC undergoing R0 resection, but not associated with unfavorable DFS and OS among the Chinese population.

COMMENTS

Background

Recently, several studies have evaluated the poor prognosis of gastric cancer (GC) with human epidermal growth receptor 2 (HER2) overexpression, whereas the clinical significance of such association remains controversial, especially in the Chinese population. Therefore, we conducted this retrospective study to examine whether the positive status of HER2 can be regarded as an effective prognostic factor for patients with GC undergoing R0 resection among the Chinese population.

Research frontiers

Over the last few years, HER2 has been the most frequently studied molecular biological prognostic factor in various tumors. In GC, the ToGA trial was the first study showing the clinical benefit of trastuzumab in combination with chemotherapy for HER2 positive advanced GC patients. However, a post-hoc subgroup analysis failed to show survival benefits of trastuzumab therapy in Asian populations. Besides, several studies have evaluated the poor prognosis of GC with HER2 overexpression recently, but the clinical significance of such association remains controversial.

Innovations and breakthroughs

The authors conducted this retrospective study to examine whether the positive status of HER2 can be regarded as an effective prognostic factor for patients with GC undergoing R0 resection among the Chinese population, and found the positive status of HER2 based on IHC staining was not related to the survival in patients with GC among the Chinese population.

Applications

In this study, we failed to show survival benefits of trastuzumab therapy in Chinese populations. Therefore, it should be more prudent to use trastuzumab in combination with chemotherapy for HER2 positive GC patients undergoing R0 resection.

Peer-review

The manuscript is very interesting and well written. Considering that the results were retrospectively analyzed, the authors should use the score matched analysis in HER2 positive patients to better explore the prognostic significance of HER2 status in the Chinese population.

Abstract

AIM: To evaluate the effect of oral *Escherichia coli* (*E. coli*) Nissle application on the outcome of intestinal-borne dermatoses.

METHODS: In a randomized, controlled, non-blinded prospective clinical trial 82 patients with intestinal-borne facial dermatoses characterized by an erythematous papular-pustular rash were screened. At the initiation visit 37 patients entered the experimental arm and 20 patients constituted the control arm. All 57 patients were treated with a vegetarian diet and conventional topical therapy of the dermatoses with ointments containing tetracycline, steroids and retinoids. In the experimental arm patients received a one month therapy with oral *E. coli* Nissle at a maintenance dose of 2 capsules daily. The experimental group was compared to a non-treatment group only receiving the diet and topical therapy. The primary outcome parameter was improvement of the dermatoses, secondary parameters included life quality and adverse events. In addition the immunological reaction profile (IgA, interleucin-8 and interferon-α) was determined. Furthermore the changes of stool consistency and the microbiota composition over the time of intervention were recorded.

RESULTS: Eighty-nine percent of the patients with acne, papular-pustular rosacea and seborrhoic dermatitis responded to *E. coli* Nissle therapy with significant amelioration or complete recovery in contrast

to 56% in the control arm ($P < 0.01$). Accordingly, in the *E. coli* Nissle treated patients life quality improved significantly ($P < 0.01$), and adverse events were not recorded. The clinical improvement was associated with a significant increase of IgA levels to normal values in serum as well as suppression of the proinflammatory cytokine IL-8 ($P < 0.01$ for both parameters). In the *E. coli* Nissle treated group a shift towards a protective microbiota with predominance of bifidobacteria and lactobacteria ($> 10^7$ CFU/g stool) was observed in 79% and 63% of the patients, respectively ($P < 0.01$), compared to no change in the control group without *E. coli* Nissle. Moreover, the detection rate of a pathogenic flora dropped from 73% to 14 % of the patients in the experimental arm ($P < 0.01$) with no significant change in the control arm (accounting 80% before and 70% after the observation period, $P > 0.05$). Accordingly, stool consistency, color and smell normalized in the *E. coli* Nissle treated patients.

CONCLUSION: *E. coli* Nissle protects the mucus barrier by overgrowth of a favorable gut microbiota with less immunoreactive potential which finally leads to clinical improvement of intestinal borne dermatoses.

Key words: Intestinal-borne dermatoses; *Escherichia coli* Nissle 1917; Immunological response; IgA; Interleukin-8; Interferon-α; Gut microbiota

Core tip: The occurrence of facial dermatoses with erythematous papular-pustular exanthemas is often linked to intestinal inflammation. However, the underlying mechanism remains unclear, and innovative treatment options are missing. Here we show that patients with these dermatoses carry a more aggressive microbiota associated with suppressed serum IgA levels, but increase of the proinflammatory cytokines interleukin-8 and interferon-α. Clinical manifestation, microbiota and inflammatory parameters are significantly improved by application of *Escherichia coli* Nissle. It indicates the usefulness of this probiotic therapy in a neglected patient population in desperate need for effective help.

Manzhalii E, Hornuss D, Stremmel W. Intestinal-borne dermatoses significantly improved by oral application of *Escherichia coli* Nissle 1917. *World J Gastroenterol* 2016; 22(23): 5415-5421 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5415.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5415

INTRODUCTION

Gastrointestinal diseases are often associated with facial dermatoses including acne, rosacea or seborrhoic dermatitis which impair the quality of life of these patients[1-3]. Common feature of these manifestations is an erythematous papular-pustular rash. The digestive system reveals in these cases often infections or an altered microbiota[1,4-8]. Some bacterial genera or species, *e.g.*, bacteroides, firmicutes or bifidobacteria, are predominant in comparison to others like *Escherichia coli* (*E. coli*), lactobacilli and enterococci[4,5,9-13]. Staphylococci, proteus and candida belong to the transient microflora[14]. The composition of the intestinal microbiota is mainly determined by dietary patterns[12]. The function of the microbiota has recently been the focus of scientific interest because it is not only responsible for maintaining a physiological immune response, but also for metabolic processes connected with insulin resistance, obesity and manifestation of fatty liver disease[1,2,8,15-17]. It has also been suggested that an intestinal micro-ecologic imbalance may cause dermatoses induced by an overstimulated immune system[17-19]. This could have therapeutic implications by changing the microbiota towards less aggressive bacterial colonization. One example is the oral application of the *E. coli* strain Nissle 1917 (EcN). By means of special adhesive organelles (by the type F-1A, F-1C and curly fimbriae), the strain has an ability to attach to the mucus membrane of the large intestine and to arrange as microcolonies, forming of a biofilm[20]. Due to the presence of flagella, the bacteria are also mobile, which gives them the advantage of colonizing the colon[21,22]. Therefore, these bacteria were shown to strengthen the mucosal barrier also by interacting with immune modulatory and anti-inflammatory mechanisms[23,24]. *E. coli* Nissle inhibits the growth of Gram-negative anaerobic bacteria by its secretion of antimicrobial substances (microcins) and by siderophores which capture iron and, thus, prevent the growth of certain pathological bacterial strain[16,25]. A postulated overstimulation of the immune system in intestinal disease-related dermatoses by a pathologic microbiota could be identified by elevation of cytokines and chemokines in the circulation[18,26]. Central players are interleukin-8 (IL-8) and α-interferon, which attract mononuclear cells to the site of inflammation to destroy pathogens by activation of the immune system[3]. Before a pathological microbiota invades the organism it has to pass the mucosal barrier. There are several lines of defense which have to be broken[3,26]. The mucus is the first hurdle which has to be taken. Within the mucus there is IgA which is known to inactivate invading bacteria. Since it is secreted from systemic sources, patients with IgA deficiency are prone to intestinal-borne infections[27].

Accordingly, in this study we evaluate the role of IL-8, interferon (INF)-α and IgA as players in the pathogenesis of intestinal disease related dermatoses and the effect of oral administration of *E. coli* Nissle in these conditions.

Table 1 Baseline characteristics of the study population

Characteristic	Experimental arm (n = 37)	Control arm (n = 20)
Sex (women)	63%	61%
Sex (male)	37%	39%
Age (yr)	29 ± 3.1	28 ± 2.5
Smoker	34%	36%
Oral contraception (women)	4%	5%

MATERIALS AND METHODS

In the randomized, controlled, non-blinded, prospective clinical trial 82 patients met the criterion of papular-pustular exanthema with facial manifestation. They were instructed to participate in a clinical trial, informed about the nature of the study and randomized by a closed envelope drawing to the experimental (EA) or control (CA) arm population. Between the evaluation and initiation visit (up to 4 wk interval), 4 and 21 of the participants in the EA and CA groups, respectively, were lost for the study population. The high loss of patients in the control arm was due to the information of the patients that they did not participate in active treatment protocol with *E. coli* Nissle. Thus, finally 37 patients entered the EA and 20 patients constituted the CA group. All included patients underwent physical examinations including the consultation of a dermatologist to verify the diagnosis of the skin dermatoses.

For basic treatment of chronic dermatoses, a diet with predominance of vegetable products was prescribed for all patients. The patients of the control arm (CA) only received standard topical therapy prescribed by a dermatologist, consisting of ointments containing tetracycline, steroids and retinoids (Kremgen® and Lokoid®). The patients of the experimental arm (EA) received a combination treatment which included the standard topical therapy of the dermatoses in combination with oral administration of *E. coli* Nissle 1917 (Mutaflor®): 1 capsule daily for 4 d, then 2 capsules daily for the following month. One capsule of the *E. coli* Nissle 1917 contained 2.5 - 25 × 10^9 live bacteria (CFU). The capsules are resistant to gastric juice and do not disintegrate before they reach the terminal small intestine. The patients were informed about the need to store the medication at a cool place. Follow-up examinations of the dermatoses were performed after a month. The therapeutic effect was estimated according to the dynamics of improvement of the dermatological manifestations. Another criterion was the subjective evaluation of the patients in regard to tolerability and adverse events. Life quality was measured by a scale of 4 index points including: good, acceptable, impaired and not acceptable. For testing of the immunological response in blood, a white blood cell (WBC) differentiation was performed, and the concentration of IL-8 and INF-α was determined by an immunoassay. IgA was quantified by an immunoassay method. The stool of the patients was evaluated in regard to its consistency, color, smell, mucus content and WBC.

Furthermore the stool neutral fat, fatty acid, starch content and presence of muscle fibers were determined[14]. Quantification of bacterial strains was performed by standard techniques[14]. The trial was approved by the local ethical committee.

Ethical permission

All study participants were informed about the study nature and signed a written consent form. The study protocol was approved by the regional committee for research ethics.

Statistical analysis

Statistical analysis performed by using SPSS-20 software. All data in this study were expressed as mean ± SD or percent. The Kolmogorov-Smirnov normality test was used for data distribution analysis. All the values had parametric distribution. Analysis of Variance was applied for multiple comparisons and if the results were significant, a post-hoc Turkey's test was performed. The comparison of the connected values namely the data from the same patient before and after treatment was done using the Student's *t*-test for paired samples. The differences between groups were considered significant at $P < 0.05$.

RESULTS

Out of 123 patients with dermatoses primarily evaluated, 82 patients revealed a papular-pustular exanthema with facial manifestation. Of these, 57 patients agreed to participate in the study and were finally included in the trial with an age range from 18 to 42 years, a disease duration range from 1 to 10 years, and a gender distribution of 35 women and 22 men. The experimental arm (EA) consisted of 37 and the control arm (CA) of 20 patients (Table 1).

All patients revealed the predominant feature of erythema in conjunction with papular-pustular elements. Twenty-two percent out of the patients were diagnosed with acne, 36% with papular-pustular rosacea and 57% with seborrhoic dermatitis. In 10% of the cases the entire facial skin was involved. Concerning the primary end point of the trial, the improvement of the dermatologic features was significantly greater in the EA compared to the CA group ($P < 0.01$). After one month, in the EA group 32% showed recovery and 57% significant amelioration (11% simple amelioration), whereas in the CA group only 17% revealed recovery and 39% significant amelioration (32% simple amelioration and 12% no change) (Figure 1).

The resolution of clinical manifestations of the inflammatory process of the facial skin occurred in

Table 2 Interferon-α, interleukin-8 and IgA in serum before and after treatment

Arms of the patients	INF-α, pg/mL		IL-8, pg/mL		IgA, g/L	
	Before treatment	After treatment	Before treatment	After treatment	Before treatment	After treatment
Experimental arm (n = 37)	8.07 ± 2.97	3.73 ± 2.88[d, f]	30.8 ± 4.42	17.1 ± 0.65[d, f]	0.45 ± 0.05[b]	0.71±0.22[d, f]
Control arm (n = 20)	6.88 ± 1.77	6.12 ± 1.53	27.0 ± 2.72	25.2 ± 1.23[b]	0.35 ± 0.9	0.54 ±0.05[d]

[b]P < 0.01 and [d]P < 0.001 significant difference before *vs* after treatment; [f]P < 0.01 *vs* control arm after treatment. INF: Interferon; IL: Interleukin.

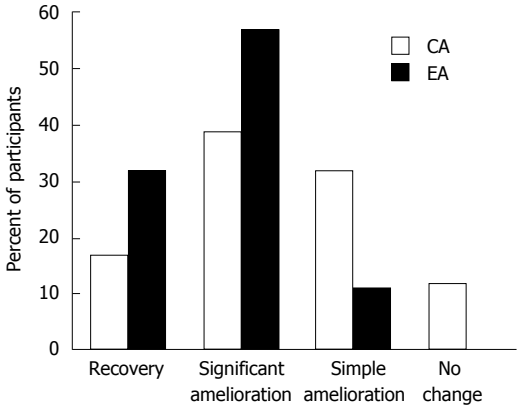

Figure 1 Improvement of dermatological features in both groups after 1 mo. Illustrated are the percentages of patients with facial dermatoses in the control arm (CA) and experimental arm (EA) over the time of the trial. They are categorized according to the degree of change in clinical manifestation.

the reversed order of their development. Initially, edema and swelling decreased, later papular rush and erythema faded as well as the formation of new papulae and pustulae discontinued. This was followed by disappearance of crusts in the area of the lesions, and nodular eruptions gradually flattened (Figure 2 as an example).

All patients in both groups tolerated the treatment very well, and adverse events were not recorded. All patients in the EA showed an increase of life quality by 1.7 ± 0.6 index points (< 0.01) revealing an acceptable or good condition in all patients of the EA group in contrast to the CA group with an overall unchanged impaired life quality (P > 0.05). Accordingly, *E. coli* Nissle showed high therapeutic efficacy in addition to good tolerability and absence of serious adverse reactions reported by the patients.

Elevated INF-α values showed a trend towards reduction in the EA patient population after therapy, but did not reach statistical significance. Low serum IgA levels were initially recorded in the EA and CA group. After treatment, the IgA level was normalized only in the EA arm (Table 2 and Figure 3). The same is true for the elevation of IL-8 cytokine levels which were normalized after treatment in the EA patient group. This is probably due to the immunomodulatory properties of *E. coli* Nissle 1917 which decreases the level of newly activated T-lymphocytes migration into the focus of inflammation. Accordingly, also the lymphocytosis disappeared in 78% of the EA group, whereas it improved in the CA group only in 42 % of the patients (Table 2 and Figure 3).

In regard to stool appearance, 82% of the patients initially had loose stools of grey color, sticky consistency with strong smell and mucus in large amounts. After treatment, 71% of participants in the EA had a formed stool of typical color and smell, and only small amounts of mucus.

Before treatment, bacteriological stool culture showed a decrease in the number of bifidobacteria and lactobacteria in both patient groups but an increase in potential pathogenic bacteria, *i.e.,* staphylococci, yeasts, bacteroides, proteus, citrobacter and klebsiellae (Table 3).

After therapy with *E. coli* Nissle (EA), an increase of bifidobacteria and lactobacteria in stool cultures was noted (P < 0.01 for both species). There was a significant decrease recorded in the number of staphylococci, yeasts, bacteroides, proteus, citrobacter, klebsieallae in 59% of the EA-patients as compared to no change in the CA-group (P < 0.01) (Table 3).

DISCUSSION

The mechanism by which intestinal diseases induce related dermatoses is obscure. Here we show that intestinal-borne dermatoses are accompanied by a shift towards a more aggressive intestinal microbiota spectrum. Due to their potential to invade the mucosal barrier, they activate the immune system with elevation of IL-8 and interferon-α. This could be the reason for induction of dermatoses because they attract mononuclear cells to preformed lesions of the skin, leading to inflammation. The dermatoses are significantly improved after oral application of *E. coli* Nissle. Whether the low IgA levels initially recorded in the patient population are the consequence or origin of invasion of pathogenic bacteria remains to be determined. However, the consumption of IgA within the mucus seems more likely because it returns to normal values after the treatment course.

In addition to the observed changes of the microbiota distribution, the biofilm of *E. coli* Nissle per se may also have an impact on stool consistency. It may be due to an effect on motility as well as the

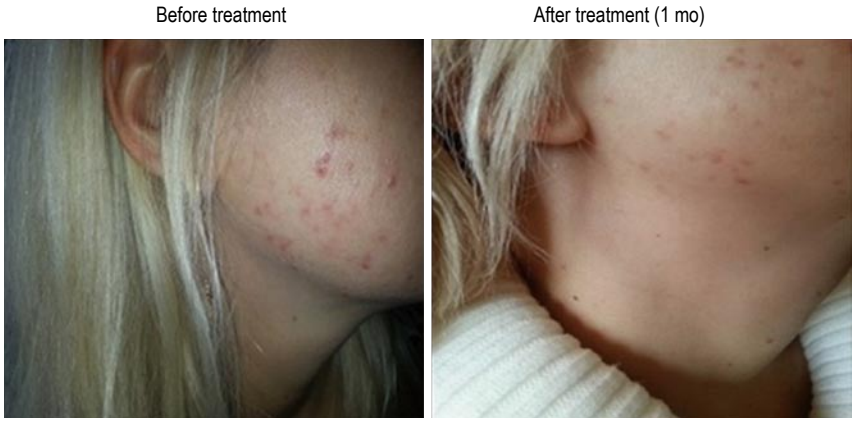

Figure 2 Female patient; EA group before and one month after treatment. Clinical example of a patient treated with *E. coli* Nissle. The facial popular-pustular exanthema was significantly improved over the 1 mo treatment period.

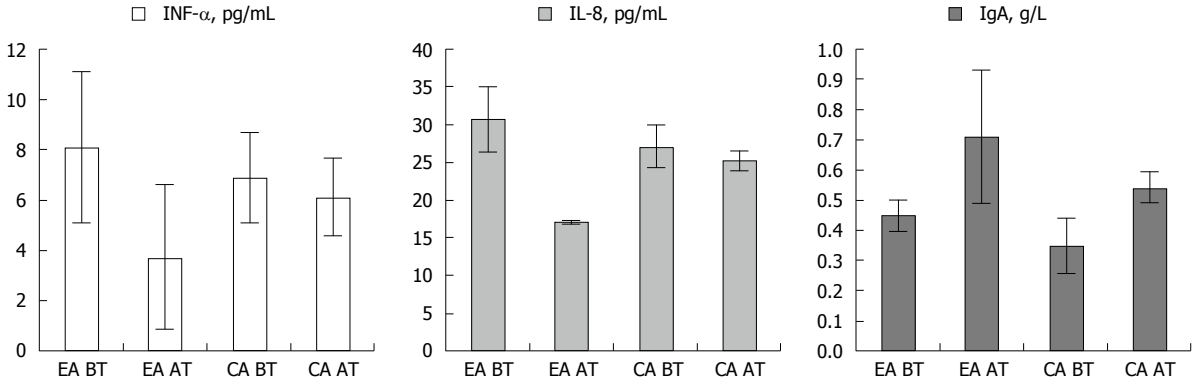

Figure 3 Improvement of serum levels of INF-α, IL-8 and IgA in experimental arm before (EA BT) and after treatment (EA AT), and control arm before (CA BT) and after treatment (CA AT). Serum INF-α, IL-8 and IgA levels over the trial course. Illustrated are the values of INF-α , IL-8 and IgA in the experimental arm before (EA BT) and after treatment (EA AT) and the control arm before (CA BT) and after treatment (CA AT).

Table 3 Changes of the flora after treatment with *E. coli* Nissle *n* (%)

Microflora characteristics	Experimental arm (n = 37)		Control arm (n = 20)	
	Before treatment	After treatment	Before treatment	After treatment
Bifidobacteria > 10^7 CFU/g	5 (14)	29 (79)[b]	3 (15)	3 (15)
Normal < 10^7 CFU/g	26 (70)	7 (19)[b]	15 (75)	14 (70)
Below normal absent	6 (16)	1 (2)[b]	2 (10)	3 (15)
Lactobacteria > 10^7 CFU/g	3 (8)	23 (63)[b]	3 (15)	2 (10)
Normal < 10^7 CFU/g	27 (73)	13 (35)[b]	15 (75)	15 (75)
Below normal absent	7 (19)	1 (2)[b]	2 (10)	3 (15)
Pathogenic microflora	27 (73)	5 (14)[b]	16 (80)	14 (70)

[b]$P < 0.01$ significant difference before *vs* after treatment.

functionality of the mucus barrier. The production of short-chain fatty acids increases the nutritional state of the mucus and thus its capability to absorb water[14,20]. This improves the motility as well as the absorption of water and sodium. All of this helps to form a more consolidated stool. More importantly, because the mucosal barrier is strengthened, pathogens cannot easily penetrate and, thus, the *E. coli* Nissle application prohibits systemic activation of the immune system eventually inducing intestinal-borne dermatoses.

In conclusion, we report that *E. coli* Nissle is very effective to treat intestinal-borne chronic dermatoses. It shows good tolerability and no adverse events. The mode of action relates to change of the intestinal microbiota towards less aggressive bacteria. This in turn ameliorates the immune response characterized by a normalization of IgA and IL-8. Thus, it represents a treatment option for patients with intestinal borne dermatosis.

COMMENTS

Background

Intestinal-borne dermatoses have unknown etiology and there is a medical need for their therapy. The recent observation that the gut microbiota has impact on the immune system guided us to the question whether this induces

dermatoses and whether microbiota modulation may be of therapeutic use.

Research frontiers

The present study focuses on etiology and therapy of intestinal dermatoses as a neglected field in gastroenterology, although a large number of patients suffer from this entity. It covers the areas of microbiota and the associated systemic immune response.

Innovations and breakthroughs

It is an innovative approach to link the gut microbiota to the pathogenesis of intestinal-borne dermatoses. The fact that modulation of the microbiota by application of *Escherichia coli* (*E. coli*) Nissle 1917 improves the dermatoses was unexpected and opens a new avenue of therapy for these patients in need.

Applications

The study provides a rationale for the therapy of intestinal-borne dermatoses. Indeed it is shown that *E. coli* Nissle 1917 improves these dermatoses by suppressing the intestinal microbiota-triggered immune response. It will open avenues of new therapies also with other microbiota-modulating regimens. The study may also stimulate basic research to unravel the interaction of the gut microbiota and the immune system.

Terminology

The paper deals with different intestinal-borne dermatoses, the adaptive immune response mechanism, the composition of the gut microbiota in regard to protective and aggressive bacterial colonization and the biological activity of *E. coli* Nissle 1917.

Peer-review

The manuscript is very interesting for the readers.

Abstract

AIM: To investigate the expression of endocan in tumour vessels and the relationships between endocan and the expression of vascular endothelial growth factor (VEGF) and prognosis in gastric cancer.

METHODS: This study included 142 patients with confirmed gastric cancer in a single cancer centre between 2008 and 2009. Clinicopathologic features were determined, and an immunohistochemical analysis of endocan-expressing microvessel density (MVD) (endocan-MVD), VEGF and vascular endothelial growth factor receptor 2 (VEGFR2) was performed. Potential relationships between endocan-MVD and clinicopathological variables were assessed using a Student's t-test or an analysis of variance test. Spearman's rank correlation was applied to evaluate the relationship between endocan-MVD and the expression of VEGF/VEGFR2. Long-term survival of these patients was analysed using univariate and multivariate analyses.

RESULTS: Positive staining of endocan was observed in most of the gastric cancer tissues (108/142) and in fewer of the normal gastric tissues. Endocan-MVD was not associated with gender or histological type ($P > 0.05$), while endocan-MVD was associated with tumour size,

Borrmann type, tumour differentiation, tumour invasion, lymph node metastasis and TNM stage ($P < 0.05$). According to the Spearman's rank correlation analysis, endocan-MVD had a positive correlation with VEGF ($r = 0.167$, $P = 0.047$) and VEGFR2 ($r = 0.410$, $P = 0.000$). The univariate analysis with a log-rank test indicated that the patients with a high level of endocan-MVD had a significantly poorer overall survival rate than those with a low level of endocan-MVD (17.9% *vs* 64.0%, $P = 0.000$). The multivariate analysis showed that a high level of endocan-MVD was a valuable prognostic factor.

CONCLUSION: Endocan-MVD significantly correlates with the expression of VEGF and VEGFR2 and is a valuable prognostic factor for survival in human gastric cancer.

Key words: Endocan; Microvessel density; Vascular endothelial growth factor; Gastric cancer; Survival

Core tip: Angiogenesis plays an important role in the progression of gastric cancer. In the present study, we first found that endocan-expressing microvessel density (MVD) (endocan-MVD) had a positive correlation with vascular endothelial growth factor (VEGF) and VEGFR2 in gastric cancer tissues. Patients with a high level of endocan-MVD had a significantly poorer overall survival rate than those with a low level of endocan-MVD. Based on our research, we suggest that endocan-MVD may act as a valuable prognostic factor for survival in patients with gastric cancer.

INTRODUCTION

Gastric cancer, a malignancy that remains the second leading cause of cancer-related deaths worldwide and causes high morbidity and mortality, is one of the most common malignancies in the world[1]. Compared to developed countries, developing countries have higher morbidity and mortality rates. Worldwide, more than 70% of new cases of gastric cancer and related deaths occur in developing countries, such as in Eastern Europe, East Asia and South America[2]. In particular, in China, there are approximately 400000 new cases annually, which account for 42% of the total global cases, and the death toll in China is 300000[3]. Therefore, identifying a new potential therapeutic target can benefit diagnosis and treatment. It is critical to investigate new factors that are closely associated with the initiation and development of gastric cancer.

Endocan, previously called the endothelial cell specific molecule-1, which is a new member of the proteoglycan family, plays an extremely important role in the transformation, survival, proliferation, invasion, angiogenesis and metastasis of tumours[4-7]. Previous *in vivo* and *in vitro* studies have demonstrated that endocan is overexpressed in human tumours, such as in colon cancer, kidney cancer and prostate cancer[8-10]. Consistently, elevated blood levels of endocan have also been observed in patients with lung cancers[11]. In particular, in liver cancer and gastric cancer[12,13], serum levels of endocan are significantly changed after treatment; thus, endocan is a biomarker of tumour progression as well as a validated therapeutic target.

It has been extensively reported that the secretion of endocan by cultured endothelial cells is strongly upregulated in the presence of proangiogenic molecules such as vascular endothelial growth factor (VEGF)[14]. Endocan has been shown to be activated by VEGF through the PKC and PI3K signalling pathways in human umbilical vein endothelial cells, and this process can be inhibited by PI3K pathway blockers[15]. Furthermore, the blockade of VEGFR2 by specific antibodies completely prevented VEGFC-mediated induction of endocan expression in endothelial cells[16]. Data obtained from cancer tissue samples have shown that endocan can be visualized in newly growing tumour vessels of endothelial cells. Thus, endocan-expressing microvessel density (MVD) is likely to be valuable for assessing the prognosis of malignancy. Vascular endocan, as a biomarker of neoangiogenesis, is found inside the vessels in different types of tumours, such as colon, kidney, prostate and brain cancers, but not in gastric cancer[8-10,17]. Thus, endocan immunolabelling was explored in this study to understand the progression of gastric cancer.

The aim of this study was to examine the expression of endocan in gastric cancer vessels, to investigate the relationship between endocan-MVD and the expression of VEGF and VEGFR2, and to determine whether endocan-MVD could be used to predict the outcomes of patients with gastric cancer.

MATERIALS AND METHODS

Patients

A total of 142 patients with gastric cancer who had undergone gastrectomy were enrolled in this study between January 2008 and April 2009 at the Qilu Hospital of Shandong University. All patients had undergone primary curative gastrectomy, and none of them had received chemotherapy or radiotherapy before surgery. Meanwhile, 142 specimens of adjacent tissues were obtained from these patients to serve as the paired controls. The tissues were embedded in paraffin after 16 h of formalin fixation. Of the patients

enrolled in this study, 93 (65.4%) were male and 49 (34.5%) were female, with a median age of 56.8 years (ranging from 24 to 79 years). The cut-off date for follow-up was April 2015, and the median follow-up duration was 39 mo (ranging from 6 to 72 mo). The clinicopathological features of the patients examined included gender, age, Borrmann type, tumour size, tumour histological morphology, tumour differentiation (according to the WHO classification for gastric cancer in 2000), tumour invasion, lymph node metastasis, TNM stage (TNM 7th edition by the American Joint Committee on Cancer) and vascular invasion. This study was approved by the Ethics Committee of Qilu Hospital, Shandong University, and all study participants signed an informed consent form. The clinicopathological characteristics of the patients are summarized in Table 1.

Immunohistochemistry

Paraffin-embedded tissues containing primary tumours and paired controls were obtained from the archives of the Department of Pathology of our hospital. Successive sections at 1 mm intervals from each paraffin block were used for evaluation. Anti-endocan mouse monoclonal antibody (ab56914, Abcam, Cambridge, MA, United States), anti-VEGF mouse monoclonal antibody (sc-7269, Santa Cruz Biotechnology Inc., Santa Cruz, CA, United States) and anti-VEGFR2/Flk-1 mouse monoclonal antibody (sc-6251, Santa Cruz Biotechnology Inc., Santa Cruz, CA, United States) were used for the immunohistochemical staining of endocan, VEGF and VEGFR2, respectively.

The immunohistochemical staining was performed using the streptavidin peroxidase complex method. The slides were deparaffinized with xylene and washed with PBS. After antigen retrieval, the slides were incubated with 0.3% blocking serum for 30 min at 37 ℃ to reduce nonspecific binding. The sections were incubated overnight at 4 ℃ with primary antibody against endocan (dilution: 1:100), VEGF (dilution: 1:150) or VEGFR2 (dilution: 1:150). The tissue sections were rinsed in TBS and then detected using biotinylated goat anti-mouse immunoglobulin as secondary antibody. After rinsing with TBS, the sections were incubated with 3,3'-diaminobenzidine solution until the desired staining was achieved. The slides were counterstained with haematoxylin, dehydrated, cleared and mounted. Negative controls were created by omitting the primary antibodies.

The immunohistochemical staining was evaluated independently by two pathologists who were blinded to the clinical information and the nature of the specimens. Quantitative analysis of MVD was performed in the sections that were stained for endocan. The most vascularized areas within the tumours ("hot spots") were chosen at low magnification (× 40), and the vessels were counted at representative high magnification (× 400). All brown-stained endothelial cells that were clearly separated from connective tissue elements were considered microvessels. MVD was counted in three fields and was recorded as a total number per unit area. Endocan-MVD was divided into four groups (0, 1, 2 and 3) based on quartiles of endocan-MVD numbers, which were 12.51, 18.86 and 25.88, respectively. For all cases, the scores (0) and (1) were defined as a low level of endocan-MVD, and (2) and (3) as a high level of endocan-MVD.

The immunohistochemical results of VEGF and VEGFR2 were classified according to the number of positive cells as follows: (-), no cell was stained; (+), < 25% of cells were stained; (++), 25%-50% of cells were stained; and (+++), > 50% of cells

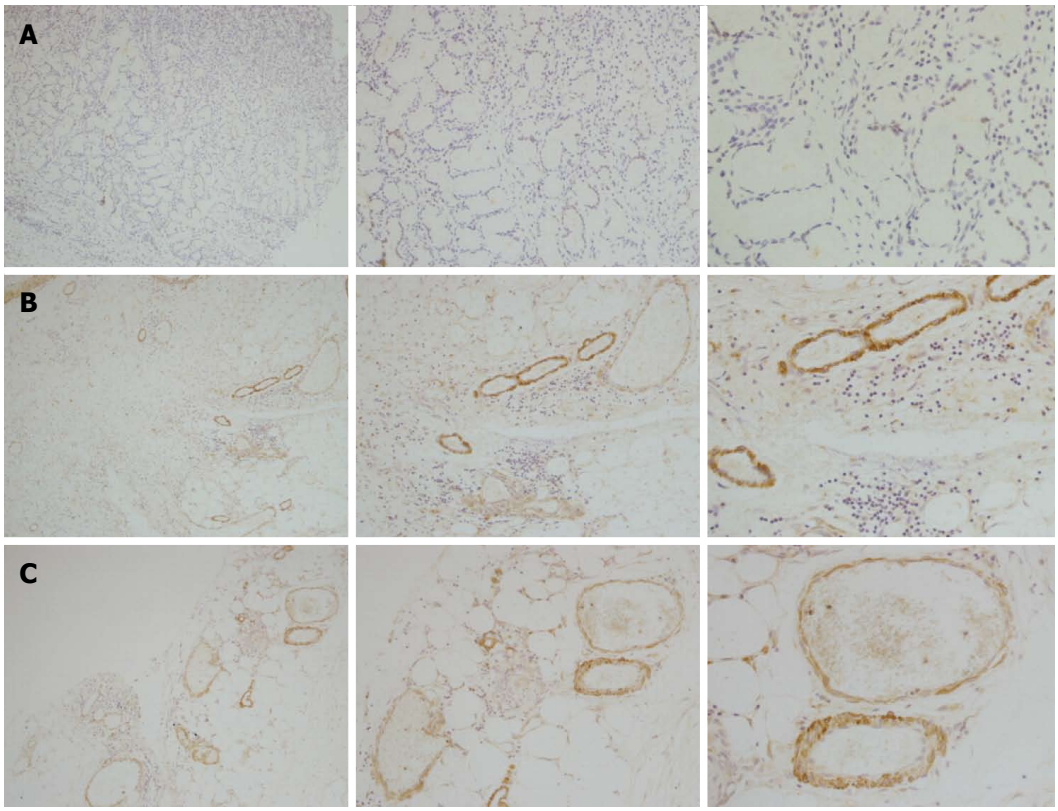

Figure 1 Immunohistochemical staining of endocan in gastric cancer. Positive staining of endocan was observed in most of the endothelial cells of the tumour vessels, but less staining was observed in normal gastric tissues (A); In the peritumour vascular endothelium (B); positive endocan was more compact than that in the tumour centres (C).

were stained. For all cases, the scores (-) and (+) were defined as the negative expression of VEGF and VEGFR2, and (++) and (+++) as positive expression.

Statistical analysis

The SPSS program (version 16, SPSS Inc., Chicago, IL, United States) was used for the statistical analyses. Continuous quantitative data with a normal distribution are expressed as the mean ± SD. Potential relationships between endocan-MVD and clinicopathological variables were assessed using a Student's *t*-test or an analysis of variance test, as appropriate. Spearman's rank correlation was applied to evaluate the relationship between endocan-MVD and the expression of VEGF/VEGFR2. A Kaplan-Meier analysis was used to assess patient survival. We conducted a univariate analysis of the prognostic factors with a log-rank test and a multivariate analysis with a Cox's regression model. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of endocan in gastric cancer tissues

Positive staining of endocan was observed in most of the gastric cancer tissues (108/142) and in fewer of the normal gastric tissues (Figure 1A and B). The expression of endocan was also found in the endothelial cells of tumour vessels. In tumour centres, endocan-expressing endothelial cells of tumour vessels were observed in 78% (85/108) of the gastric cancer tissues stained with the endocan antibody (Figure 1C). In the peritumour vascular endothelium, positive endocan staining was more compact and was observed in most cases of gastric cancer tissues stained with the endocan antibody (100/108; Figure 1B). The endocan-MVD in gastric cancer tissues was 18.8 ± 8.1 and ranged from 4 to 44.

Relationship between endocan-MVD and clinicopathological features

Endocan-MVD was significantly correlated with tumour size, Borrmann type, tumour differentiation, tumour invasion, lymph node metastasis, TNM stage and the expression of VEGF and VEGFR2, whereas it was not correlated with gender, age or histology. These data are summarized in Table 1.

Relationship between endocan-MVD and the expression of VEGF and VEGFR2

VEGF and VEGFR2 were dispersed granularly within the cytoplasm of the tumour cells (Figure 2). Among the total 142 gastric cancer specimens, VEGF overexpression was detected in 84 (59.1%), and VEGFR2 was overexpressed in 76 (53.5%). A

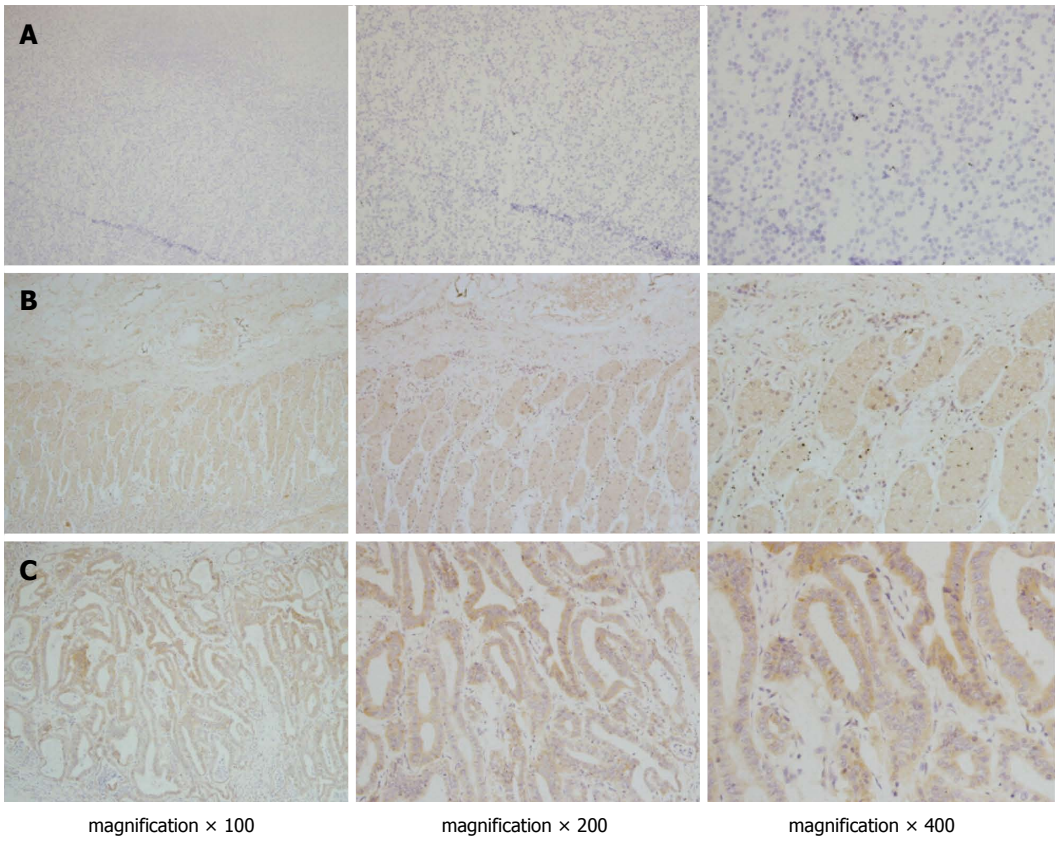

Figure 2 Immunohistochemical staining of vascular endothelial growth factor and vascular endothelial growth factor receptor 2 in gastric cancer. Positive staining of VEGF (B) and VEGFR2 (C) was observed in most gastric cancer tissues, but less staining was observed in normal gastric tissues (A). VEGF: Vascular endothelial growth factor; VEGFR2: VEGF receptor 2.

Table 2 Correlation between endocan-microvessel density and vascular endothelial growth factor expression in gastric cancer (r = 0.167, P = 0.047), and between endocan-microvessel density and vascular endothelial growth factor receptor 2 expression in gastric cancer (r = 0.410, P = 0.000)

[1]Endocan-MVD was divided into four groups (0, 1, 2, and 3) based on quartiles of Endocan-MVD number, which were 12.51, 18.86 and 25.88, respectively; [2]VEGF and VEGFR2 were divided as follows: (-), no cell stained; (+), < 25% of cells stained; (++), 25%-50% of cells stained; (+++), > 50% of cells stained. VEGF: Vascular endothelial growth factor; VEGFR2: VEGF receptor 2; MVD: Microvessel density.

significant association was found between endocan-MVD and the expression of VEGF or VEGFR2 (Spearman's rank correlation analysis, r = 0.167, P = 0.047 and r = 0.410, P = 0.000, respectively; Table 2).

Univariate and multivariate analyses of prognosis variables

The 142 patients were divided into a low endocan-MVD group (75/142) and a high endocan-MVD group (67/142) using the median value of endocan-MVD (*i.e.*, 18.8). The univariate analysis with a log-rank test indicated that the patients with a high endocan-MVD had a significantly poorer overall survival rate than those with a low endocan-MVD (17.9% *vs* 64.0%, P = 0.000; Figure 3). Tumour size, Borrmann type, differentiation, tumour invasion, lymph node metastasis, TNM stage and the expression of VEGF and VEGFR2 were significantly associated with the overall survival rate, whereas the other clinicopathologic features were not (Table 3).

Parameters with P values < 0.05 in the univariate analysis were included in the multivariate analysis using a Cox proportional hazards model. It was revealed that differentiation, TNM stage, endocan-MVD and the expression of VEGF and VEGFR2 were significant prognostic factors in these patients (Table 4).

DISCUSSION

Angiogenesis plays an important role in the invasion, growth and metastasis of most tumours in which a number of cytokines are now known to be involved[18]. Among these cytokines is an essential factor for angiogenesis, which is known as VEGF. VEGF not only stimulates the division and migration of vascular

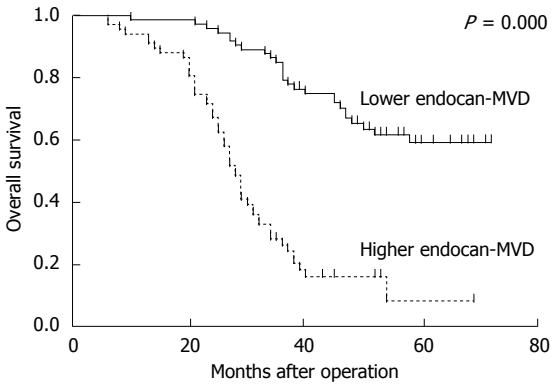

Figure 3 Overall survival curves of the patients in the high and low endocan-microvessel density groups. Patients with high endocan-MVD had a significantly poorer overall survival rate than those with low endocan-MVD (17.9% *vs* 64.0%, *P* = 0.000). MVD: Microvessel density.

endothelial cells but can also induce new vessels, which are thin and susceptible to the invasion of cancer, leading to distant metastases[19]. Microvascular density is used as an objective evaluation index for tumour angiogenesis. Previous studies have shown that endocan is expressed in endothelial cells in colon cancer and kidney cancer, and endocan-MVD is associated with the prognosis of tumours[8-10]. Therefore, in this paper, we performed further research on the relationship between endocan-MVD and VEGF/VEGFR2 and the prognosis of patients with gastric cancer to provide a new therapy for patients with gastric cancer.

Endocan is the product of a gene that is located in the proximal region of the long arm of chromosome 5 (5q11.2)[4]. Recent evidence has implied that endocan plays important roles in several pathophysiological processes, including inflammatory disorders and tumour progression, and in the regulation of major cellular processes, such as adhesion, migration and angiogenesis[4-7]. Numerous studies have focused on endocan expression in tumour tissues, and it is deemed as a new tumour prognostic marker because of its expression in serum[20,21]. However, our studies paid more attention to the expression of endocan in tumour vessels, as well as the relationship between the expression of endocan and tumour clinical features. We have confirmed the expression of endocan in the endothelial cells of tumour centre vessels, and positive endocan showed denser expression in the peritumour vascular endothelium. This showed that endocan is crucial in gastric cancer angiogenesis.

To test whether endocan-MVD can predict the prognosis of gastric cancer after resection, we used immunohistochemical staining to determine endocan expression in tumour specimens and correlated our findings with available follow-up information. We found that positive staining of endocan was preferentially detected in gastric cancer vessels but not in normal gastric tissues. Endocan-MVD in the peritumour vascular endothelium was higher than that in the tumour centre. The data from the current study

indicated that endocan-MVD in gastric cancer was significantly associated with tumour size, Borrmann type, differentiation, tumour invasion, lymph node metastasis, TNM stage and the expression of VEGF and VEGFR2. By analysing the potential relationship between endocan-MVD and survival time, we found that patients with high endocan-MVD had a significantly poorer overall survival rate, which is consistent with the results for non-small-cell lung cancer and hepatocellular carcinoma[11,22]. With the Cox proportional hazards regression model, we found that endocan-MVD was an ideal marker to predict the prognosis in patients with gastric cancer.

The expression of endocan is regulated by a number of cytokines and growth factors, such as tumour necrosis factor-α, transforming growth factor-β1 and VEGF[23,24]. Among them, VEGF, as a major proangiogenic factor, has attracted the most attention. Recent studies have suggested that VEGF can induce the expression of endocan *in vitro*, and the VEGF-mediated induction of endocan mRNA was blocked by BIM (a PKC inhibitor) but not by PD98059 (an MEK1/2 inhibitor)[15]. However, endocan was reported less often in gastric cancer tissues and cells. In this study, we found that endocan-MVD was closely related to the expression of VEGF and VEGFR2 in gastric cancer tissues, which suggested that VEGF and VEGFR2 might induce the expression of endocan. The size of samples enrolled in our study was not large enough, and a subsequent study will employ larger samples based on a multicentre survey for further intervention. Despite this, analysing endocan-MVD might be useful in predicting prognoses and in choosing appropriate therapeutic modalities for patients with gastric cancer.

In conclusion, endocan had a high expression level in the endothelial cells of tumour vessels, and a significant association was found between endocan-MVD and the expression of VEGF or VEGFR2. The patients with high endocan-MVD had a significantly poorer overall survival rate than those with low endocan-MVD. This shows that endocan-MVD may play an important role in the processes of tumour therapy, which can be used as a critical factor for prognosis.

COMMENTS

Background

Endocan plays an extremely important role in the angiogenesis of tumours, and endocan-expressing microvessel density (MVD) (endocan-MVD) is likely to be valuable for the prognosis of malignancy. It has been reported that the secretion of endocan is strongly upregulated in the presence of vascular endothelial growth factor (VEGF). The exact relationship between endocan-MVD and the expression of VEGF and the value of endocan-MVD as a prognostic factor in patients with gastric cancer have not yet been defined.

Research frontiers

Vascular endocan, as a biomarker of neoangiogenesis, is found inside the vessels in different types of tumours, but not in gastric cancer. The exact relationship between endocan-MVD and the expression of VEGF in gastric cancer remains unclear. The research hotspot is to further clarify these issues.

Innovations and breakthroughs

Based on the investigation of clinical characteristics and endocan expression in 142 patients with gastric cancer, we first found that endocan-MVD had a positive correlation with VEGF and vascular endothelial growth factor receptor 2 (VEGFR2) in gastric cancer tissues. Patients with a high level of endocan-MVD had a significantly poorer overall survival rate than those with a low level of endocan-MVD.

Applications

The results of this study may clarify the role of endocan-MVD in the tumour neoangiogenesis in patients with gastric cancer, and provide strategies for the treatment of patients with advanced gastric cancer. Endocan-MVD may act as a valuable prognostic factor for survival in patients with gastric cancer.

Terminology

Endocan, previously called the endothelial cell specific molecule-1, which is a new member of the proteoglycan family, plays an extremely important role in the transformation, survival, proliferation, invasion, angiogenesis and metastasis of tumours. Microvascular density (MVD) is used as an objective evaluation index for tumour angiogenesis.

Peer-review

This is an interesting study about the expression of endocan in cancer vessels and the relationships between endocan and the expression of VEGF and prognosis in gastric cancer.

Abstract

AIM: To compare the clinical efficacy of the second-generation H2RA lafutidine with that of lansoprazole in Japanese patients with mild gastroesophageal reflux disease (GERD).

METHODS: Patients with symptoms of GERD and a diagnosis of grade A reflux esophagitis (according to the Los Angeles classification) were randomized to receive lafutidine (10 mg, twice daily) or lansoprazole (30 mg, once daily) for an initial 8 wk, followed by maintenance treatment comprising half-doses of the assigned drug for 24 wk. The primary endpoint was the frequency and severity of heartburn during initial and maintenance treatment. The secondary endpoints were the sum score of questions 2 and 3 in the Gastrointestinal Symptom Rating Scale (GSRS), and the satisfaction score.

RESULTS: Between April 2012 and March 2013, a total of 53 patients were enrolled, of whom 24 and 29 received lafutidine and lansoprazole, respectively. After 8 wk, the frequency and severity of heartburn was significantly reduced in both groups. However, lafutidine was significantly inferior to lansoprazole with regard to the severity of heartburn during initial and maintenance treatment (P = 0.016). The sum score of questions 2 and 3 in the GSRS, and satisfaction scores were also significantly worse in the lafutidine group than the lansoprazole group (P = 0.0068 and P = 0.0048, respectively).

CONCLUSION: The clinical efficacy of lafutidine was inferior to that of lansoprazole, even in Japanese patients with mild GERD.

Key words: Gastroesophageal reflux disease; Proton pump inhibitors; Histamine receptor-2 antagonists; Los Angeles classification

Core tip: The clinical efficacy of the second-generation H2RA lafutidine was inferior to that of lansoprazole, particularly during maintenance therapy, even in Japanese patients with mild gastroesophageal reflux disease.

Randomized study of lafutidine *vs* lansoprazole in patients with mild gastroesophageal reflux disease. *World J Gastroenterol* 2016; 22(23): 5430-5435 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5430.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5430

INTRODUCTION

Gastroesophageal reflux disease (GERD) is characterized by symptoms of heartburn and acid regurgitation. It is extremely common and has a chronic, relapsing disease course[1]. Standard pharmacological treatments for GERD comprise proton pump inhibitors (PPIs) and histamine receptor-2 antagonists (H2RAs), which act by suppressing gastric acid secretion. Of the two drug classes, PPIs are considered to be more cost-effective as initial treatment for GERD[2,3]. However, the cost-effectiveness of pharmacotherapy in Japanese patients with mild GERD has not been evaluated.

Lafutidine is a second-generation H2RA that has a potent and sustained anti-acid secretory effect. It acts by increasing plasma concentrations of calcitonin gene-related peptide and somatostatin, resulting in inhibition of postprandial acid secretion and gastroprotective activity[4]. In contrast to other H2RAs, the therapeutic action of lafutidine involves esophageal host-defense *via* capsaicin-sensitive afferent nerves[5]. The LAFORE trials conducted in Japanese patients with mild GERD (grade A in the Los Angeles classification) indicated that healing rates at 8 wk were 79.4% in the lafutidine groups and 68.3% in the famotidine group[6]. The cost of lafutidine treatment is 41.3 yen per day, and cheaper than half doses of PPIs (95.2 yen).

The aim of this study was to compare the clinical efficacy of lafutidine with that of lansoprazole as initial and maintenance treatment in Japanese patients with mild GERD.

MATERIALS AND METHODS

Study design

This was a phase Ⅲ, controlled study performed in 4

university hospitals and 11 of their affiliated hospitals in Japan between April 2012 and March 2013. The study was approved by the institutional review board of each participating hospital and was conducted in accordance to Good Clinical Practice guidelines. Written informed consent was obtained from all patients. The study is registered in the University Hospital Medical Network Clinical Trials Registry (unique trial number UMIN000006162).

Subjects

Inclusion criteria: Patients who were ⩾ 20 years old with symptoms of heartburn or regurgitation and a diagnosis of grade A reflux esophagitis according to the Los Angeles classification, as confirmed by endoscopic examination at least 1 wk prior to the observation period, were eligible for enrollment. Both the frequency and severity of symptoms were required to be ⩾ 3 on question 2 or 3 of the Gastrointestinal Symptom Rating Scale (GSRS).

Exclusion criteria: Patients with any of the following conditions were excluded: (1) gastric or duodenal ulcers (excluding ulcer scars); (2) esophageal, gastric or duodenal cancer; (3) the concurrent presence of Barrett's esophagus; (4) a history of upper gastrointestinal resection; (5) a history of receiving PPIs or H2RAs within the 2 wk prior to endoscopic examination; (6) comorbidity with severe cardiovascular, hepatic, or renal disease; (7) a history of allergy to lafutidine or lansoprazole; and (8) other conditions considered unsuitable for study participation by the attending physician.

Study methods

Eligible patients were randomized in a 1:1 ration to receive lafutidine (10 mg, twice daily) or lansoprazole (30 mg, once daily) for an initial 8 wk according to assignment lists generated by a permuted-block procedure. Patients were questioned on the frequency of heartburn during the week prior to initial treatment. After initial treatment, the frequency of heartburn was recorded daily for 2 wk. The number of episodes and the severity of heartburn were also assessed using the visual analog scale (VAS) and GSRS until 24 wk after the initial treatment-period. During initial treatment, concomitant administration of the following drugs was not permitted: (1) PPI; (2) H2RA; (3) prostaglandins; (4) mucosal protection drugs; (5) antacids; and (6) drugs that may affect upper gastrointestinal symptoms. Unless symptoms became worse, the allocated drug was administrated as initial treatment for 8 wk, followed by maintenance treatment for 24 wk. In the lafutidine group, a half dose was selected for maintenance treatment if symptoms had improved or disappeared at the first assessment, whereas the full dose was continued if symptoms had not improved. An asymptomatic state was defined as ⩽ 2 for both questions 2 and 3 on the GSRS. In the lansoprazole group, a half dose was administrated irrespective of symptoms, but was changed to the full dose if symptoms worsened. If symptoms had not improved at the first maintenance assessment, the attending physician was permitted to consider other treatment strategies. Patients underwent symptomatic evaluation every 8 wk for the duration of 32 wk. During the study, the number of episodes of heartburn was evaluated by reviewing patients' diaries. In addition to endoscopy, physical examinations and laboratory tests were performed to confirm the eligibility and safety of the patients.

Evaluation of symptoms

Patients' diaries were used to assess the frequency and severity of heartburn. The severity of heartburn and patient satisfaction were graded with VAS scores.

Endpoints

The primary endpoint was the frequency and severity of heart burn. The secondary endpoints were the sum score of questions 2 and 3 of the GSRS, and the patient satisfaction score, during initial and maintenance treatment.

Statistical analysis

Statistical differences between the two groups were determined with the chi-squared test or Fisher's exact test for discontinuous variables and the Mann-Whitney *U* test or Wilcoxon rank sum test for continuous variables. Repeated measures such as VAS and GSRS scores were analyzed by ANOVA. Statistical analyses were performed with the JMP (version 7) software package (SAS Institute, Cary, North Carolina, United States). *P* values ⩽ 0.05 were considered to denote statistically significant differences between groups. The statistical methods of this study were reviewed by Ryuta Takenaka from Tsuyama Chuo Hospital.

RESULTS

Patients flow

Between April 2012 and March 2013, the study enrolled 53 patients with heartburn or regurgitation who underwent upper gastrointestinal endoscopy. Among the 53 patients, 24 and 29 were randomized to the lafutidine and lansoprazole group, respectively. There were no significant differences between the two groups in background characteristics, except for gender distribution (Table 1).

During initial treatment, 8 patients discontinued the study, with the most common reasons being withdrawal of informed consent. Of the 45 patients assigned to receive maintenance treatment, 22 were excluded from the final analysis, primarily because of missing to follow-up (Figure 1).

Clinical outcomes during treatment

questionnaires was lower after initial treatment in both groups (Figure 2). However, the change in heartburn frequency was not statistically significantly different in either group (Figure 3). The severity of heartburn, evaluated using VAS, was also significantly reduced after initial treatment in both groups. Worsening of symptom during maintenance treatment did not occur in either group. However, lafutidine was significantly inferior to lansoprazole in reducing heartburn severity (Figure 4). Similarly, the sum score of questions 2 and 3 in the GSRS and the satisfaction score were both significantly worse in the lafutidine group than those in the lansoprazole group, particularly during maintenance therapy (Figures 5 and 6, respectively).

DISCUSSION

GERD is a chronic disorder and long-term acid-suppression therapy is necessary in most cases[7].

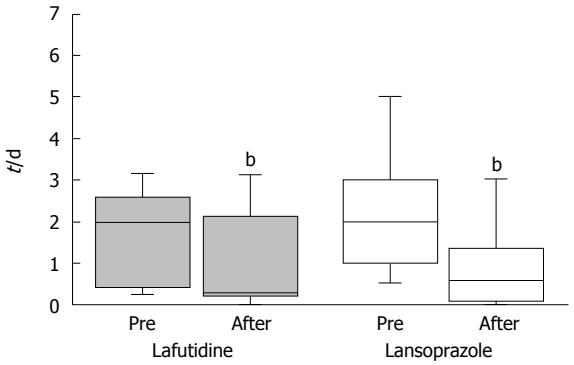

Figure 2 Frequency of heartburn evaluated using patient' questionnaires. Data are shown as a boxplot. In both groups, the frequency of heartburn was reduced after initial treatment, $^{b}P < 0.01$.

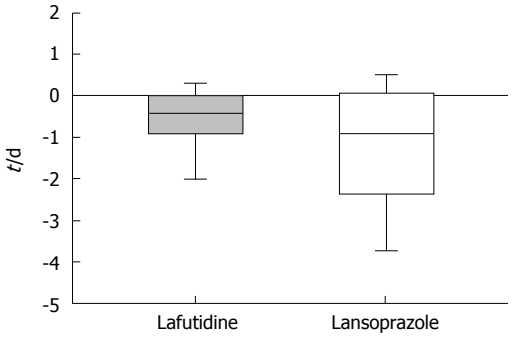

Figure 3 Change in heartburn frequency after initial treatment. Data are shown as a boxplot. There were no significant difference between the lafutidine group and the lansoprazole group ($P = 0.26$).

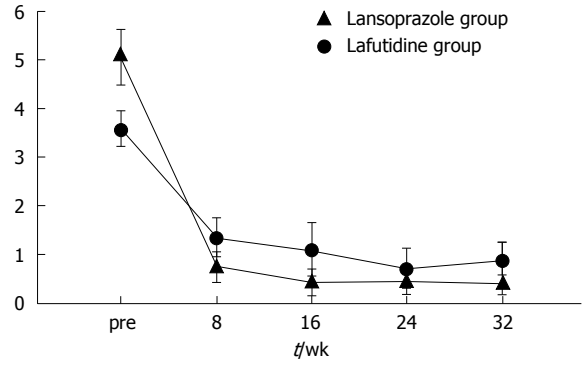

Figure 4 Severity of heartburn evaluated using visual analog scale scores. Data are expressed as means ± SE. VAS scores in the lafutidine group were significantly worse than in the lansoprazole group ($P = 0.016$, ANOVA for repeated measures). VAS: Visual analog scale.

A meta-analysis of 34 trials that included 1,314 individuals demonstrated that PPIs were significantly more effective than H2RAs in relieving heartburn in GERD (RR = 0.66, 95%CI: 0.60-0.73) as well as in patients with non-erosive reflux disease on upper endoscopy (RR = 0.78, 95%CI: 0.62-0.97)[8]. Because no reports have been published concerning the cost-effectiveness of pharmacotherapy in Japanese patients with mild GERD, which is a common condition in Japan, the present study was designed to evaluate

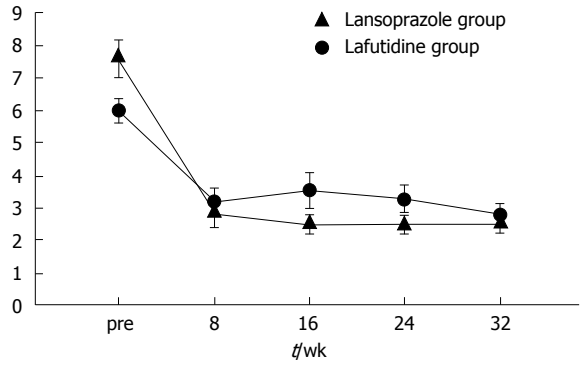

Figure 5 Sum score of question 2 and question 3 in the GSRS score. Data are expressed as means ± SE. VAS scores in the lafutidine group were significantly worse than in the lansoprazole group (P = 0.0068, ANOVA for repeated measures). VAS: Visual analog scale.

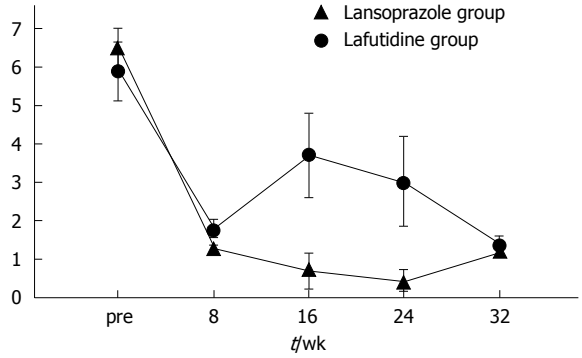

Figure 6 Satisfaction score evaluated using visual analog scale scores. Data are expressed as means ± SE. VAS scores in the lafutidine group were significantly worse than the lansoprazole group (P = 0.0048, ANOVA for repeated measures). VAS: Visual analog scale.

the efficacy of the second-generation H2RA lafutidine. However, lansoprazole was superior to lafutidine in Japanese patients with mild GERD, not only with respect to lowering the severity of heartburn, but also the satisfaction score. The GSRS score was also better in the lansoprazole than the lafutidine group. Thus, the hypothesis that lafutidine has similar efficacy and superior cost-effectiveness compared with lansoprazole in Japanese patients with mild GERD was not confirmed.

Limitations of PPIs include a higher cost than H2RAs, and potential side effects such as hypochlorhydria and hypergastrinemia. In particular, PPI-related hypochlorhydria is concern because it may increase susceptibility to infections, for example Clostridium difficile-associated diarrhea[9-11], as well as malabsorption leading to hypomagnesemia[12]. Hypochlorhydria may theoretically reduce calcium absorption[13]. A meta-analysis that included 11 cohort and case-control studies examined the risk of fractures associated with PPI use, and showed that the risk of hip fracture, spine fracture, and any-site fracture was increased among PPI users compared with nonusers (RR = 1.30, 95%CI: 1.19-1.43; RR = 1.56, 95%CI: 1.31-1.85; and RR = 1.16, 95%CI: 1.02-1.32, respectively)[14]. Therefore, once an asymptomatic state has been attained, tapering or cessation of medication should be considered in patients with GERD.

In the present study, initial therapy improved clinical outcomes such as heartburn and patient satisfaction score in both the lafutidine group and the lansoprazole group. However, the satisfaction score and GSRS score became worse during maintenance therapy in the lafutidine group. The effect of acid suppression in the lafutidine group was weak during the maintenance therapy. Two possible mechanisms may explain this observation. Firstly, patients may develop tolerance to lafutidine during maintenance therapy. As previously reported in a study assessing ranitidine and famotidine, the development of tachyphylaxis within 2 to 6 wk of initiation of H2RAs limits their use as maintenance therapy for GERD[15]. Secondly, the dose of lafutidine during maintenance therapy was low for symptomatic relief. If a 10-mg dose of lafutidine was administered twice daily during maintenance therapy, symptomatic severity may have been similar to that in the lansoprazole group. The costs of 10 mg of lafutidine twice daily and a half dose of lansoprazole were 82.6 yen and 95.2 yen, respectively. Therefore, future studies are planned to evaluate 10 mg of lafutidine twice daily for maintenance therapy, with the aim of proving our hypothesis that lafutidine has similar efficacy and superior cost-performance to lansoprazole in Japanese patients with mild GERD.

This study has some limitations. The sample size was relatively small. Furthermore, a substantial number of patients discontinued the study although the proportion of patients lost to follow-up was similar in the two treatment groups. In addition, the male/female ratio was significantly smaller in the lafutidine than the lansoprazole group, which may have had an influence on clinical outcomes.

In conclusion, the efficacy of a second-generation H2RA over a PPI in Japanese patients with mild GERD was not demonstrated, most notably during maintenance therapy.

COMMENTS

Background

Proton pump inhibitors (PPIs) are considered to be more cost-effective for patients with gastroesophageal reflux disease (GERD) than first-generation histamine receptor-2 antagonists (H2RAs). Lafutidine is a second-generation H2RA that has a potent and sustained anti-acid secretory effect. In LAFORE trials conducted in Japanese patients with mild GERD, lafutidine was superior to first-generation H2RA (famotidine). The aim of this study was to compare the clinical efficacy of lafutidine with that of PPI (lansoprazole) as initial and maintenance treatment in Japanese patients with mild GERD.

Research frontiers

GERD is a chronic disorder and long-term acid-suppression therapy is necessary in most cases. Limitations of PPIs include a higher cost than H2RAs, and potential side effects related to hypochlorhydria and hypergastrinemia.

Innovations and breakthroughs

Lansoprazole was superior to lafutidine in Japanese patients with mild GERD, not only with respect to lowering the severity of heartburn, but also the satisfaction score. The hypothesis that lafutidine had similar efficacy and superior cost-effectiveness compared with lansoprazole in Japanese patients with mild GERD was not confirmed.

Applications

The efficacy of a second-generation H2RA over a PPI in Japanese patients with mild GERD was not demonstrated, most notably during maintenance therapy.

Terminology

Lafutidine is a second-generation H2RA and shown to be superior to first-generation H2RA (famotidine).

Peer-review

Interesting and well written study.

Abstract

AIM: To compare previously reported randomized controlled studies (RCTs) of cold and hot polypectomy, we systematically reviewed and clarify the utility of cold polypectomy over hot with respect to efficacy and adverse events.

METHODS: A meta-analysis was conducted to evaluate the predominance of cold and hot polypectomy for removing colon polyps. Published articles and abstracts from worldwide conferences were searched using the keywords "cold polypectomy". RCTs that compared either or both the effects or adverse events of cold polypectomy with those of hot polypectomy were collected. The patients' demographics, endoscopic procedures, No. of examined lesions, lesion size, macroscopic and histologic findings, rates of incomplete resection, bleeding amount, perforation, and length of procedure were extracted from each study. A forest plot analysis was used to verify the relative strength of the effects and adverse events of each procedure. A funnel plot was generated to assess the possibility of publication bias.

RESULTS: Ultimately, six RCTs were selected. No significant differences were noted in the average lesion size (less than 10 mm) between the cold and hot polypectomy groups in each study. Further, the rates of complete resection and adverse events, including

delayed bleeding, did not differ markedly between cold and hot polypectomy. The average procedural time in the cold polypectomy group was significantly shorter than in the hot polypectomy group.

CONCLUSION: Cold polypectomy is a time-saving procedure for removing small polyps with markedly similar curability and safety to hot polypectomy.

Key words: Cold polypectomy; Hot polypectomy; Colon adenoma; Conventional polypectomy; Colon neoplasm; Endoscopic mucosal resection; Bleeding

Core tip: We conducted a meta-analysis to evaluate the predominance of cold and hot polypectomy for removing colon polyps. The patients' demographics, endoscopic procedures, No. of examined lesions, lesion size, macroscopic and histologic findings, rates of incomplete resection, bleeding, and perforation, and length of procedure were extracted from six randomized controlled studies. The rates of complete resection and adverse events did not markedly differ between cold and hot polypectomy. However, the procedural time was significantly shorter in the cold polypectomy group. These results suggest that cold polypectomy is a time-saving procedure for removing small polyps with similar curability and safety to hot polypectomy.

Efficacy and adverse events of cold *vs* hot polypectomy: A meta-analysis. *World J Gastroenterol* 2016; 22(23): 5436-5444 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5436.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5436

INTRODUCTION

Colon cancer is an extremely common cancer with high mortality in both Asia and the West. Because colon cancer develops due to an accumulation of genetic alterations prompting the transformation of the normal colon epithelium to adenoma and subsequently adenocarcinoma[1,2], removal of colon adenomas is considered crucial for preventing the development of cancer[3]. Indeed, several trials have demonstrated that removal of colon adenoma successfully decreases the mortality rate of colon cancer[3,4].

Polypectomy is a minimally invasive and easy-to-learn procedure for removing colon adenomas, particularly elevated-shaped ones. The polypectomy procedure for colon neoplasms generally uses a snare to enclose the lesion, which is then cut using a high-frequency generator. This procedure is known as hot polypectomy. Cutting and coagulation of the lesion with a high-frequency generator is generally believed to help prevent bleeding after polypectomy, although this procedure can occasionally cause perforation after lesion removal due to the burning of the intestinal wall.

An alternative procedure, known as cold polypectomy, simply removes lesions using a snare with no high-frequency generator and is believed to be as effective as hot polypectomy for removing colon neoplasms, but with lower risk of complications, such as perforation. In their examination of 210 constitutive patients after cold polypectomy for polyps 5 mm or less in size, Tappero *et al*[5] observed no adverse effects, including immediate or delayed bleeding or perforation. In addition, several uncontrolled studies have further confirmed the safety of cold polypectomy for removing small polyps[5-8]. However, 2 uncontrolled studies reported incomplete resection rates of 5% and 11% for cold polypectomy[9,10], which could still allow for progression to colon cancer. Any advantages of cold polypectomy over hot with respect to efficacy and adverse events therefore remain unclear.

To clarify the utility of cold polypectomy concerning efficacy and adverse events, we systematically reviewed previously-reported randomized controlled studies (RCTs) comparing cold and hot polypectomy procedures.

MATERIALS AND METHODS

Retrieval strategy and quality assessment

Articles posted on PubMed (as of March 2015) and abstracts of worldwide conferences described in *Gastrointestinal Endoscopy and Gut* were searched using the keywords "cold polypectomy". The language was limited to studies published in English.

The results were reviewed by two evaluators. The abstracts were not blinded for authors, institutions, or journals during review. All studies comparing the effects and adverse events of cold polypectomy with those of hot polypectomy were collected, regardless of whether or not the data were part of the primary or secondary endpoint. When multiple articles were published from the same institution or study group, the most recent one was selected for our analysis. Even if the study group was included in multiple articles, the data were applied when the study population was different in each study. Reviews, case reports, abstracts, and presentations from meetings were excluded.

The risk of bias was evaluated in accordance with the Cochrane Handbook for Systematic Reviews of Interventions using the following parameters: adequacy of random sequence generation; allocation concealment; blinding of the participants, personnel and outcome assessors; incomplete outcome data and selective outcome reporting. The Jadad score was used to evaluate the quality of each study[11]. Briefly, the details of the randomization and blinding procedures

and information regarding withdrawals were first evaluated. One or two points were then awarded for specifying the randomization and blinding procedures and one point for a statement of information regarding withdrawals (Table 1). A funnel plot was generated to assess the possibility of any publication bias[12].

Data collection and bias assessment

The patients' demographics, endoscopic procedures, No. of examined lesions, lesion size, macroscopic and histologic findings, rates of incomplete resection, occurrence of immediate or delayed bleeding and perforation, and procedure duration were extracted from each study. The macroscopic and histologic findings were assessed based on Paris classification[13] and Vienna classification[14], respectively. Incomplete resection was defined as the clear presence of tumor cells in the margin of the removed specimen on histologic examination. The procedure duration was defined as the total time elapsed during the procedure. A forest plot analysis was used to verify the relative strength of the effects and adverse events of each procedure in multiple quantitative scientific studies. The between-study heterogeneity was tested and quantified using the Cochran Q statistic and the I^2 statistic, respectively.

Statistical analysis

The relative risk (RR) and 95% confidence interval (CI) were calculated for each variable based on the data. Statistical analyses were performed using the Cochrane Collaboration's Revman 5.0 software program (The Cochrane Collaboration, Oxford, Oxfordshire, United Kingdom). The inter-study heterogeneity was assessed using the Cochran Q test, with the significance level set at $P = 0.1$, and was quantified using the I^2 statistic. If any obvious inter-study heterogeneity was noted ($I^2 > 50\%$), the random effects model was chosen; otherwise, the fixed effects model was chosen.

RESULTS

Evaluation and details of the selected studies

A total of 131 reports were initially retrieved (Figure 1). After screening the titles, abstracts, or full text and excluding reviews, case reports, uncontrolled tests, and basic research studies, seven studies were selected[15-21]. Of these seven, one study was

NA: Data not available.

excluded because some of the enrolled cases were believed to overlap with those of other reports[21]. The risk of bias was then assessed for the remaining six studies in accordance with the Cochrane Handbook for Systematic Reviews of Interventions (Table 1).

All six included studies were published from 2010 to 2014 (Table 2). The mean or median age of patients treated with cold polypectomy ranged from 59.4 to 67.0 years old, while those of patients treated with hot polypectomy ranged from 58.3 to 67.3 years old, which were described in 4 studies. The ratio of males to females in all described cases was 1.06 to 2.50 among cold polypectomy cases and 1.54 to 3.00 among hot polypectomy cases. Cold polypectomy with a snare only was used in 5 studies, while both snare and forceps were used in 1 study. The macroscopic appearances of the lesions in 2 studies were 0-I in 89 and 55 lesions and 0-Ⅱ in 12 and 23 lesions among cold polypectomy cases, and 0-I in 95 and 62 lesions and 0-Ⅱ in 9 and 19 lesions among hot polypectomy cases. The histologic diagnoses of the lesions in these 2 studies were 187 and 142 low-grade adenomas, 2 and 4 high-grade adenomas, and 16 and 13 hyperplastic polyps.

Tumor size

Two and four studies investigated lesions measuring 10 mm or less[18,19] and 8 mm or less in diameter[15-17,20], respectively, indicating that all studies investigated the effect of cold and hot polypectomy on the treatment of small polyps. Four studies described the average size and standard deviation (SD) of the examined lesions[16-19], and no significant difference was noted in the average size (less than 10 mm) between the cold and hot polypectomy groups in each study (Table 2).

Incomplete resection

Three studies described the rate of curative resection[16,17,19]. These reports included a total of 815 lesions removed by cold polypectomy and 804 removed by hot polypectomy. Total rates of curative resection by cold and hot polypectomy were 98.5% and 97.8%, respectively. Because the between-study heterogeneity of these 3 studies was low (P = 0.5134, I^2 = 0%), a fixed-effects model was used to analyze the rate of curative resection. The RR for all lesions was 0.68, and the 95%CI ranged from 0.33 to 1.38 (Figure 2A), findings which indicate that the rate of complete resection did not markedly differ between cold and hot polypectomy groups. Evaluation

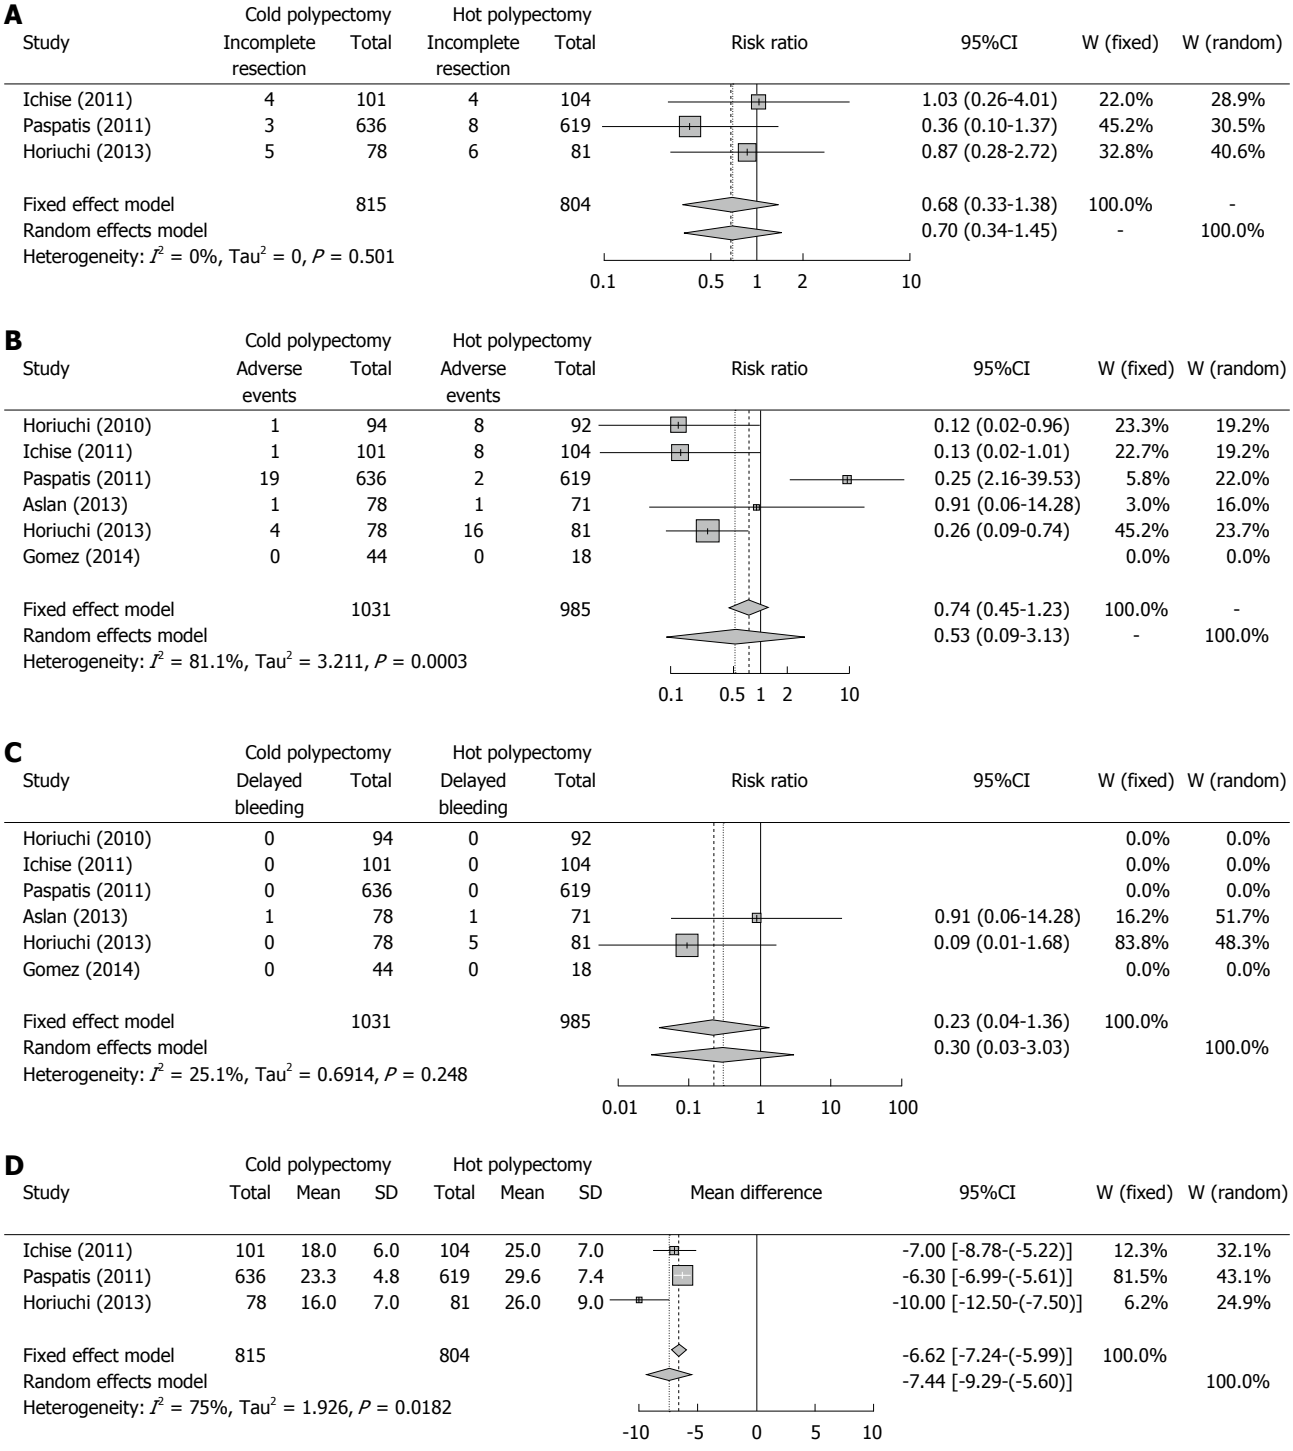

Figure 2 Forest plots were used to verify the relative strength of the diagnostic value of each procedure. The results regarding the rates of incomplete resection (A), adverse events (B), delayed bleeding (C), and procedure duration (D) are shown. ESD: Endoscopic submucosal dissection; MD: Mean difference; SD: Standard deviation; CI: Confidence interval; W: Weight; OR: Odds ratio.

of publication bias was difficult due to the small No. of studies, as shown in the funnel plot (Figure 3A).

Adverse events

All six studies reported the rate of adverse events, including bleeding and abdominal pain or discomfort[15-20]. These six reports included a total of 1031 lesions removed by cold polypectomy and 985 removed by hot polypectomy. Total rates of adverse events by cold and hot polypectomy were 2.5% and 3.6%, respectively. Because the between-study heterogeneity of these six studies was high (P = 0.0002, I^2 = 81.8%), a random-effects model was used to analyze the rate of adverse events. The RR for all lesions was 0.53, and the 95%CI ranged from 0.09 to 3.13 (Figure 2B), findings which indicated that the rate of adverse events did not

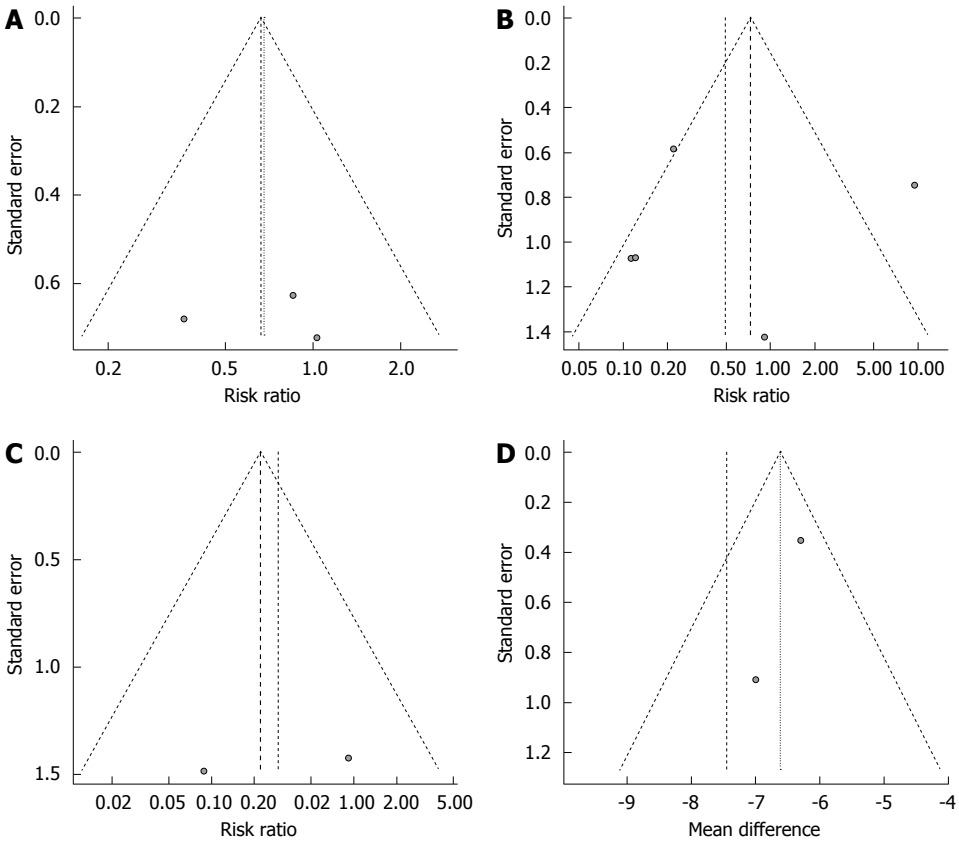

Figure 3 Funnel plots were used to clarify any publication bias. The results regarding the rates of incomplete resection (A), adverse events (B), delayed bleeding (C), and procedure duration (D) are shown.

markedly differ between cold and hot polypectomy procedures. An evaluation of publication bias was difficult to carry out due to the small No. of studies, as shown in the funnel plot (Figure 3B).

Delayed bleeding was observed in only two studies, with conflicting findings in both[18,19]. While Aslan *et al*[18] noted no marked differences in the rate of bleeding between cold and hot polypectomy groups, Horiuchi *et al*[19] observed a higher bleeding rate in the hot polypectomy group than in the cold procedure group among patients given anticoagulants. Total rates of delayed bleeding by cold and hot polypectomy were 0.1% and 0.6%, respectively. Because the between-study heterogeneity of these six studies was high (P = 0.2427, I^2 = 26.7%), a fixed-effects model was used to analyze the rate of bleeding. The RR for all lesions was 0.23, and the 95%CI ranged from 0.04 to 1.36 (Figure 2C). An evaluation of publication bias was difficult to carry out due to the small No. of studies, as shown in the funnel plot (Figure 3C).

Perforation

No perforation occurred in any of the six studies investigated.

Procedure duration

Three studies described the average and SD of procedure duration[16,17,19]. The average durations for these three studies ranged from 16.0 to 23.3 min in the cold polypectomy group and from 25.0 to 29.6 min in the hot polypectomy group. The cold polypectomy procedures were significantly shorter in duration than those using hot polypectomy in all three studies. Because the between-study heterogeneity of these three studies was high (P = 0.0182, I^2 = 75.0%), a random-effects model was used to analyze the length of the procedure. The mean difference for all lesions was -7.44, and the 95%CI ranged from -9.29 to -5.60 (Figure 2D), findings which indicate that the cold polypectomy procedure was shorter than the hot polypectomy procedure. An evaluation of publication bias was difficult to carry out due to the small No. of studies, as shown in the funnel plot (Figure 3D).

DISCUSSION

To our knowledge, the present systematic review is the first meta-analysis to compare the efficacy and safety of cold polypectomy for removing colon tumors with those of hot polypectomy procedures based on previously published RCTs. In our analysis, the rates of incomplete resection and adverse events in the cold polypectomy group were not significantly different from those in the hot polypectomy group, suggesting that cold polypectomy possesses the same efficacy and safety as hot polypectomy. Further, the procedural

time was significantly shorter in the cold polypectomy group, suggesting that cold polypectomy is also a time-saving procedure compared to hot polypectomy.

The present analysis also investigated the sizes of polyps encountered in the six RCTs and confirmed a lack of any marked difference in size between the two polypectomy groups, which indicates low bias associated with tumor size. However, all polyps encountered in these RCTs were 10 mm or less in diameter, and most were 8 mm or less. The findings from the present analysis therefore apply only with respect to removal of small polyps, and the risks of incomplete resection and adverse events with cold polypectomy for removing large polyps remains unclear. Previous studies have reported that rates of incomplete resection and adverse events of endoscopic resection are proportional to polyp size[22,23]. Recently, Tribonias *et al*[24] developed a new method for removing flat polyps measuring larger than 10 mm in size using a pulling technique and proposed the potential utility of cold polypectomy in removing large polyps. Further analysis of studies involving patients with large polyps using novel methods will be needed to determine whether or not cold polypectomy is a practical option for removing polyps larger than 10 mm in size.

Cold polypectomy can be performed *via* two methods: cold snare polypectomy and cold forceps polypectomy. The cold snare procedure uses snares to encircle and cut polyps, while the cold forceps procedure uses large forceps to "bite" polyps. While cold forceps polypectomy is easier to perform than cold snare polypectomy, the rate of incomplete resection is believed to be higher for cold forceps polypectomy[25], coming in at approximately 20% even when using jumbo-sized forceps[26]. In the RCTs retrieved in the present meta-analysis, only one study used the cold forceps procedure (and only for a portion of cases)[20], while other five studies used only the cold snare procedure[15-19]. Because the RCT using the cold forceps procedure did not describe the rate of incomplete resection, our meta-analysis of the rate of incomplete resection was not influenced by any bias related to cold polypectomy procedure.

Lee *et al*[27] showed in their RCT that the rate of incomplete resection for cold snare polypectomy was significantly lower than that in the cold forceps polypectomy group (93.2% *vs* 75.9%). Similarly, Kim *et al*[28] showed in their RCT that the rate of incomplete resection for cold snare polypectomy removing 5- to 7-mm-sized adenomatous polyps was significantly lower than that for cold forceps polypectomy (93.8% *vs* 70.3%). These findings suggest that the cold snare procedure is indeed superior to the cold forceps procedure for removing colon polyps.

Several limitations to the present meta-analysis warrant mention. First, the rates of recurrence after cold and hot polypectomies were not investigated, although histological margins were assessed. Because histological findings do not always predict future recurrence, a true rate of incomplete resection should be assessed through follow-up studies. Second, the difference in the mortality rates of colon cancer in populations with and without cold polypectomy was not investigated. Because the goal of polypectomy for removing colon adenoma is to reduce risk of colon cancer-associated death, the efficacy of cold polypectomy should be assessed based on improvement in colon cancer-related mortality. Long-term follow-up studies are therefore needed to clarify whether or not cold polypectomy does indeed reduce the mortality of colon cancer. Third, the skill and experience of each physician is believed to be another source of bias affecting the rates of incomplete resection and adverse events as well as the procedural time, which should be resolved by future studies.

In conclusion, we conducted the first meta-analysis concerning the efficacy and adverse events of cold polypectomy in comparison to hot polypectomy. Our findings demonstrate that cold polypectomy possesses similar curability and safety to hot polypectomy. Further, cold polypectomy is a time-saving procedure compared to hot polypectomy and is thus recommended for use over the hot procedure in removing small polyps. However, further analyses are needed to assess the feasibility of cold polypectomy for removing large polyps as well as to evaluate any bias associated with the skill and experience of each physician and the type of endoscopic device used.

COMMENTS

Background

Interest in cold polypectomy for removing small polyps is growing among endoscopists worldwide. In several prospective randomized trials, cold polypectomy has been proven effective in removing colon polyps less than 10 mm in diameter. However, no systematic review concerning the efficacy and safety of cold polypectomy, versus conventional hot polypectomy, has been published.

Research frontiers

Polypectomy is an easy-to-learn, minimally invasive procedure for removing colon polyps. Cold polypectomy is believed to be a safer procedure with fewer complications than hot polypectomy.

Innovations and breakthroughs

To confirm the safety and efficacy of cold polypectomy for removing colon polyps, the authors evaluated the findings from six prospective randomized controlled trials (RCTs). This is the first meta-analysis of RCTs comparing cold and hot polypectomy outcomes.

Applications

The present findings support the safety and efficacy of cold polypectomy for removing colon polyps less than 10 mm in diameter.

Terminology

Cochrane Handbook for Systematic Reviews of Interventions: This book is an official guide describing in detail the process of preparing and maintaining Cochrane systematic reviews on the effects of healthcare interventions. Adequacy of random sequence generation: A simple statement such as 'we randomly allocated' or 'using a randomized design' is often insufficient to prove that the allocation sequence was genuinely randomized. Authors commonly use

the term 'randomized' even when it is not justified, and many trials with declared systematic allocation are described by the authors as being randomized. When in doubt, the adequacy of sequence generation should be considered unclear. Allocation concealment: Proper allocation sequence concealment secures strict implementation of an allocation sequence without foreknowledge of intervention assignments. Methods for allocation concealment refer to techniques used to implement the sequence, not to generate it. However, most allocation sequences that are deemed inadequate, such as allocation based on day of admission or case record number, cannot be adequately concealed, and so fail on both counts. It is theoretically possible, yet unlikely, that an inadequate sequence is adequately concealed. However, it is not uncommon for an adequate allocation sequence to be inadequately concealed, such as if the sequence is posted on a staff room wall. Blinding of the participants, personnel, and outcome assessors: Study reports often describe blinding in broad terms, such as 'double-blinded'. This term makes it impossible to know who was blinded. Such terms are often used inconsistently, and the frequency of explicit reporting of the blinding status of study participants and personnel remains low. A review of methods used for blinding highlights the variety of methods used in practice. The following may help review authors assess whether or not any blinding of participants and personnel in a study was likely to be sufficient to protect against bias when using the Collaboration's tool: When considering the risk of bias from lack of blinding of participants and personnel, consider specifically (1) who was and was not blinded; and (2) risk of bias in actual outcomes due to lack of blinding during the study. Incomplete outcome data and selective outcome reporting: The risk of bias arising from incomplete outcome data depends on several factors, including the amount and distribution across intervention groups, the reasons for outcomes being missing, the likely difference in outcome between participants with and without data, what study authors have done to address the problem in their reported analyses, and the clinical context. Therefore, it is not possible to formulate a simple rule for judging a study to be at low or high risk of bias. The following may help review authors assess whether or not incomplete outcome data can be addressed in a way that protects against bias when using the Collaboration's tool. Jadad score: The Jadad score assesses the quality of published clinical trials based on methods relevant to random assignment, double blinding, and the flow of patients. The score is assigned based on four items. Forest plot: A forest plot is a graphic display of estimated results from a No. of scientific studies addressing the same question, along with the overall results. This plot was developed for use in medical research as a means of graphically representing a meta-analysis of the results of RCTs. Funnel plot: A funnel plot is a graph designed to check for the existence of publication bias; funnel plots are commonly used in systematic reviews and meta-analyses.

Peer-review

This systematic review and meta-analysis of six RCTs provides valuable information supporting cold polypectomy as a safe and time-saving procedure for removing small polyps with no risk of additional complications.

Abstract

AIM: To evaluate the applicability of nonbismuth concomitant quadruple therapy for *Helicobacter pylori* (*H. pylori*) eradication in Chinese regions.

METHODS: A systematic review and meta-analysis of randomized controlled trials was performed to evaluate the efficacy of nonbismuth concomitant quadruple therapy between sequential therapy or triple therapy for *H. pylori* eradication in Chinese regions. The defined Chinese regions include China, Hong Kong, Taiwan, and Singapore. The primary outcome was the *H. pylori* eradication rate; the secondary outcome was the compliance with therapy. The PubMed, Embase, Scopus, and Cochrane databases were searched for studies published in the period up to March 2016 with no language restriction.

RESULTS: We reviewed six randomized controlled trials and 1616 patients. In 3 trials comparing concomitant quadruple therapy with triple therapy, the *H. pylori* eradication rate was significantly higher for 7-d

nonbismuth concomitant quadruple therapy than for 7-d triple therapy (91.2% *vs* 77.9%, risk ratio = 1.17, 95%CI: 1.09-1.25). In 3 trials comparing quadruple therapy with sequential therapy, the eradication rate was not significant between groups (86.9% *vs* 86.0%). However, higher compliance was achieved with concomitant therapy than with sequential therapy.

CONCLUSION: The *H. pylori* eradication rate was higher for nonbismuth concomitant quadruple therapy than for triple therapy. Moreover, higher compliance was achieved with nonbismuth concomitant quadruple therapy than with sequential therapy. Thus, nonbismuth concomitant quadruple therapy should be the first-line treatment in Chinese regions.

Key words: *Helicobacter pylori* eradication; Nonbismuth concomitant quadruple therapy; Peptic ulcer; Chinese region

Core tip: *Helicobacter pylori* (*H. pylori*) infection is highly prevalent in Chinese regions and associated with peptic ulcers. Currently, triple and sequential therapies have been widely used to eradicate *H. pylori*. Nonbismuth concomitant quadruple therapy is an alternative treatment with high efficacy. Our meta-analysis revealed that a higher *H. pylori* eradication rate was achieved with 7-d concomitant therapy than with 7-d triple therapy. The eradication rates of concomitant and sequential therapies were similar. However, the compliance with concomitant therapy was higher. Therefore, nonbismuth concomitant quadruple therapy should be the first-line treatment for *H. pylori* infection.

Nonbismuth concomitant quadruple therapy for *Helicobacter pylori* eradication in Chinese regions: A meta-analysis of randomized controlled trials. *World J Gastroenterol* 2016; 22(23): 5445-5453 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5445.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5445

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection has been proven to be the major cause of chronic gastritis, gastric and duodenal ulcers, gastric adenocarcinoma, and gastric mucosa-associated lymphoma[1-3]. Moreover, *H. pylori* eradication has become the standard and most widely adopted therapy for curing peptic ulcers[4-6].

According to most international guidelines, conventional triple therapy, involving the use of a proton pump inhibitor (PPI) with amoxicillin and clarithromycin for 7-10 d, is the first-line therapy for *H. pylori* eradication[7-10]. However, the eradication rate of triple therapy has decreased to 80% in many countries worldwide[11-14]. By contrast, studies have shown a high eradication rate for sequential therapy, which entails administering a PPI and amoxicillin for 5 d, followed by a PPI, clarithromycin, and metronidazole (or tinidazole) for another 5 d[15-18]. However, compliance may be poor because of the complexity of sequential therapy[19]. In addition, nonbismuth concomitant quadruple therapy, involving the simultaneous administration of a PPI, amoxicillin, clarithromycin, and metronidazole for 7 or 10 d, is more convenient than sequential therapy, although its efficacy is yet to be determined[20-26].

Peptic ulcer is a common disease in Chinese regions. In Taiwan, the overall prevalence of *H. pylori* infection is 54%, and it increases with age[27]. However, the infection rate of *H. pylori* is only 31% in Singapore[28]. Because antibiotic resistance is a critical reason for *H. pylori* eradication failure, studies on *H. pylori* eradication are needed within specific region[14]. However, most meta-analyses of *H. pylori* eradication have been performed in Europe and Korea, and the optimal treatment for *H. pylori* eradication in Chinese regions is still unknown[29,30]. Therefore, we conducted a systematic review and meta-analysis of randomized controlled trials (RCTs) to evaluate whether nonbismuth concomitant quadruple therapy is the first-line therapy for *H. pylori* eradication in Chinese regions.

MATERIALS AND METHODS

Data sources

The PubMed, Embase, Scopus, and Cochrane databases were searched for studies published in the period up to March 2016 without language restrictions. The following medical search heading terms, words, and combinations of words were used in the systematic search: *Helicobactor pylori* or *H. pylori, eradication, peptic* or *gastric* or *duodenal ulcer, concomitant* or *quadruple, and China* or *Chinese* or *Hong Kong* or *Taiwan* or *Singapore*. All included studies were also entered into the PubMed "similar articles" function and the science citation index. Moreover, we identified additional studies by manually searching the reference sections of these papers and by contacting known experts in the field. Finally, unpublished trials were retrieved from the ClinicalTrials.gov registry (http://clinicaltrials.gov/). The systematic review described herein was accepted by the online PROSPERO international prospective register of systematic reviews of the National Institute for Health Research (CRD42016-032668).

Study selection

The following studies were selected for analysis: RCTs evaluating the efficacy of nonbismuth concomitant quadruple therapy versus standard triple or sequential for *H. pylori* eradication; those performed in Chinese regions including China, Hong Kong, Taiwan, and Singapore; patients aged 18 years or over; those

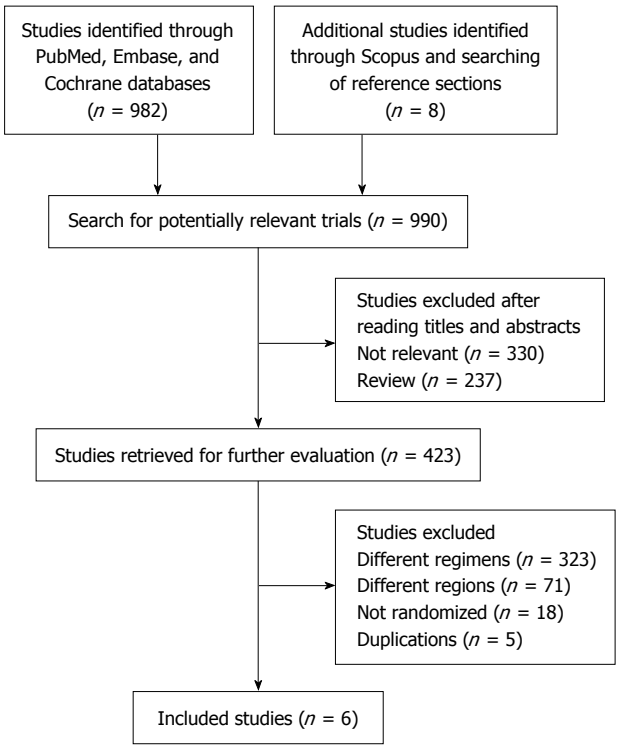

Figure 1 Flowchart for study selection.

clearly describing the inclusion and exclusion criteria used for patient selection; those adequately describing the administration of antibiotics and PPIs; and trials that precisely defined and evaluated *H. pylori* infection. Triple therapy was defined as a PPI plus amoxicillin and clarithromycin given for 7-14 d. Sequential therapy was defined as a PPI plus amoxicillin given for the first 5-7 d, followed by a PPI plus nitroimidazole derivatives and clarithromycin for the next 5-7 d. Nonbismuth concomitant quadruple therapy was defined as a PPI plus amoxicillin, clarithromycin, and nitroimidazole derivatives given for 7-14 d. The Studies were excluded from the analysis if one or both of the following criteria were present: patients enrolled in the trials who were proven to have had previous *H. pylori* infection with a history of bacterial eradication, and an overlap occurred between patient cohorts evaluated in two or more studies.

Data extraction and quality assessment

Two independent reviewers (Lin LC and Hsu TH) extracted the data of the trials, including the participants, inclusion and exclusion criteria, administration of experimental drugs, prevalence and assessment of *H. pylori* infection, and complications. Discrepancies and any disagreements were resolved through discussion with a third reviewer (Tam KW). The authors of the studies were contacted for additional information when necessary.

The risk of bias in the included trials was assessed using the following domains: adequacy of the randomization, allocation concealment, blinding, duration of follow-up, numbers of drop-outs, and performance of intention-to-treat (ITT) analysis.

Data synthesis and analysis

The *H. pylori* eradication rate was the primary outcome used to evaluate the efficacy of nonbismuth concomitant quadruple therapy. The occurrence of *H. pylori* infection was determined using assessments of histology, culture, rapid urease tests, or breath tests. The secondary outcome was the compliance with treatment.

The analysis was performed using the statistical package Review Manager, version 5.3 (Cochrane Collaboration, Oxford, England). The meta-analysis was performed according to the recommendations of the PRISMA statement[31]. For dichotomous data, the results were summarized as risk ratios (RRs) with 95%CIs. A pooled estimate of the RR was calculated using the DerSimonian and Laird random effect model[32]. This approach provides a more appropriate estimate of the average treatment effect when trials are statistically heterogeneous and usually yields wider CIs, thereby resulting in a more conservative statistical claim. χ^2 statistics tests (Q statistics) and the I^2 test were used to test for heterogeneity among controlled trials.

RESULTS

Characteristics of the trials

The review process is outlined in Figure 1. The initial search yielded 990 studies, 567 of which were deemed ineligible through screening of titles and abstracts. Subsequently, the full text of 423 studies was screened. Of these, five did not meet the eligibility criteria because of duplicate publication, 18 were not randomized studies, 71 evaluated *H. pylori* eradication in different regions, and 323 included different comparisons. Thus, only six eligible trials were included in this meta-analysis[20,22,33-36].

The main characteristics of the studies are listed in Table 1. Four of the six studies were performed in Taiwan, and the remaining two were conducted in China and Singapore. The publication dates of the studies were between 2012 and 2015, and the sample sizes ranged from 169 to 462. All trials evaluated patients diagnosed with *H. pylori* infection. In our included studies, three indicated that their patients had gastritis or peptic ulcers[33-35]. Only one study did not report the tests for diagnosing *H. pylori* infection[34], and other studies reported the following diagnostic tests: rapid urease test, histology, urea breath test, and culture. The timing of evaluation for the *H. pylori* infection status ranged from 4 to 12 wk after the treatment course. Treatment strategies for *H. pylori* eradication varied among the studies. Regarding the PPIs administered, three studies used esomeprazole[20,34,35], one used pantoprazole[33], one used lansoprazole[22], and one

Table 1 Characteristics of included studies

Ref.	Inclusion criteria	Region	Diagnostic test	No. of patients (male %)	Age, yr (mean ± SD)	Intervention
Ang *et al*[36] (2015)	Age > 21 yr	Singapore	RUT, H, UBT	C10: 153 (47.1)	C10: 46.9 ± 14.8	10-d concomitant therapy
				S10: 154 (59.7)	S10: 47.5 ± 12.7	10-d sequential therapy
				T10: 155 (58.1)	T10: 49.8 ± 14.6	10-d triple therapy
Hsu *et al*[33] (2014)	Age ≥ 20 yr, PU or gastritis	Taiwan	RUT, Cu, H	C7: 102 (59.8)	C7: 53.9 ± 12.3	7-d concomitant therapy
				S10: 102 (50.9)	S10: 55.0 ± 12.0	10-d sequential therapy
				T7: 103 (60.2)	T7: 56.1 ± 14.0	7-d triple therapy
Huang *et al*[22] (2012)	Dyspepsia or epigastric discomfort	Taiwan	RUT, Cu, H	C10: 84 (57.1)	C10: 53.8 ± 15.2	10-d concomitant therapy
				S10: 85 (56.7)	S10: 51.3 ± 15.0	10-d sequential therapy
Tai *et al*[34] (2015)	Age ≥ 20 yr, PU or gastritis	Taiwan	Not reported	C7: 92 (50.0)	C7: 47.8 ± 11.6	7-d concomitant therapy
				T7: 92 (49.0)	T7: 52.8±12.8	7-d triple therapy
Wang *et al*[35] (2014)	PU and gastritis	China	UBT	C7: 81 (45.7)	C7: 51 ± 13	7-d concomitant therapy
				T7: 82 (42.7)	T7: 51 ± 15	7-d triple therapy
				T10: 83 (45.8)	T10: 52 ± 14	10-d triple therapy
Wu *et al*[20] (2010)	Patients visited GI clinics with HP infection	Taiwan	RUT, Cu, H	C10: 115(52.2)	C10: 51.8 ± 11	10-d concomitant therapy
				S10:117(52.1)	S10: 51.7 ± 12	10-d sequential therapy

Concomitant therapy: PPI, amoxicillin, clarithromycin, and metronidazole for 7-10 d; sequential therapy: PPI and amoxicillin for 5 d, followed by PPT, clarithromycin, and metronidazole (or tinidazole) for 5 d; triple therapy: PPI, amoxicillin, and clarithromycin for 7-10 d. PPI: lansoprazole, pantoprazole, or esomeprazole; GI: Gastrointestinal; PU: Peptic ulcer; C7: 7-d concomitant therapy; C10: 10-d concomitant therapy; S10: 10-d sequential therapy; T7: 7-d triple therapy; T10: 10-d triple therapy; Cu: Culture; H: Histology; RUT: Rapid urease test; UBT: Urea breath test.

did not control the choice of the PPI[36]. Regarding concomitant and sequential regimens, all studies used metronidazole, except for Wang *et al*[35], who substituted metronidazole with tinidazole. In all included studies, a PPI, amoxicillin, and clarithromycin were administered as triple therapy for 7 d[33-35] or 10 d[35,36]. Regarding sequential therapy, all treatment regimens entailed administering a PPI and amoxicillin for 5 d, followed by a PPI, clarithromycin, and metronidazole for another 5 d[20,22,33,36]. Finally, concomitant therapy involved administering a PPI, clarithromycin, amoxicillin, and metronidazole for 7 d[33-35] or 10 d[20,22,36]. Huang *et al*[22] prolonged PPI maintenance therapy to 10 wk. Baseline characteristics were balanced and similar between groups in the six included RCTs.

Table 2 presents the details of the six included RCTs. The use of random allocation was clearly documented in all studies. The treatment group allocation was concealed from the patients in three studies[33,34,36]. Only one reported the blinding of the investigators who assessed the outcomes[20]. In all studies, outcomes were evaluated using both ITT and per-protocol analyses. The percentage of patients lost to follow-up was acceptable (< 20%) in all studies. All studies had a bias attributable to insufficient data on antibiotic susceptibility[20,22,33,36].

H. pylori eradication rate

Nonbismuth concomitant quadruple therapy *vs* triple therapy: Three studies compared the *H. pylori* eradication rates of 7-d nonbismuth concomitant quadruple and triple therapies[33-35]. The timing of *H. pylori* infection status assessment was different among these studies: 4[35], 6[33], and 8 wk[34] after treatment. A significant difference was observed in the overall *H. pylori* eradication rate of nonbismuth concomitant quadruple and triple therapies (91.2% *vs* 77.9%). Fewer patients receiving nonbismuth concomitant quadruple therapy experienced *H. pylori* infection after treatment (RR = 1.17, 95%CI: 1.09-1.25) (Figure 2). The results demonstrated low heterogeneity among the studies (I^2 = 0%).

One study compared the *H. pylori* eradication rates of 10-d nonbismuth concomitant quadruple and triple therapies[36]. The timing of *H. pylori* infection status assessment was 4 wk after treatment. No significant difference was observed in the *H. pylori* eradication rates of nonbismuth concomitant quadruple and triple therapies (81.7% *vs* 83.2%, RR = 0.98, 95%CI: 0.89-1.09) (Figure 2).

Nonbismuth concomitant quadruple therapy *vs* sequential therapy: Three studies compared the *H. pylori* eradication rate of 10-d nonbismuth concomitant quadruple and sequential therapies[20,22,36]. The timing of *H. pylori* infection status assessment was different among the studies: 4[36], 6[20], and 12 wk[22] after treatment. No statistically significant difference was observed in the overall *H. pylori* eradication rates of nonbismuth concomitant quadruple and sequential therapies (86.9% *vs* 86.0%, RR = 1.01, 95%CI: 0.95-1.07) (Figure 2).

Compliance

Nonbismuth concomitant quadruple therapy *vs* triple therapy: Three studies compared the compliance with 7-d nonbismuth concomitant quadruple and triple therapies[33-35]. No statistically significant difference was observed in the compliance with these therapies (100% *vs* 99.3%, RR = 1.01, 95%CI: 0.99-1.02) (Figure 3).

Nonbismuth concomitant quadruple therapy *vs* sequential therapy: Three studies compared

Table 2 Assessment of methodological quality of included studies

Ref.	Region	Allocation generation	Allocation concealment	Blinding of patients and assessors	Data analysis	Loss to follow up	Selective reporting	Other bias
Ang *et al*[36] (2015)	Singapore	Sealed envelope	Adequate	Open-label	ITT/PP	10.0%	Low risk	Not all patients underwent antibiotic susceptibility testing
Hsu *et al*[33] (2014)	Taiwan	Compute generated	Adequate	Open-label	ITT/PP	0.3%	Low risk	Not all patients underwent antibiotic susceptibility testing
Huang *et al*[22] (2012)	Taiwan	Computer generated	Unclear	Open-label	ITT/PP	6.5%	Low risk	No patient underwent antibiotic susceptibility testing
Tai *et al*[34] (2015)	Taiwan	Computer generated	Adequate	Unclear	ITT/PP	8.0%	Low risk	Not all patients underwent antibiotic susceptibility testing
Wang *et al*[35] (2014)	China	Computer generated	Unclear	Unclear	ITT/PP	1.2%	Low risk	No patient underwent antibiotic susceptibility testing
Wu *et al*[20] (2010)	Taiwan	Computer generated	Unclear	Outcome assessor blinded	ITT/PP	0.4%	Low risk	Not all patients underwent antibiotic susceptibility testing

Risk of bias was assessed according to the method recommended by the Cochrane Collaboration. ITT: Intention-to-treat; PP: Per-protocol.

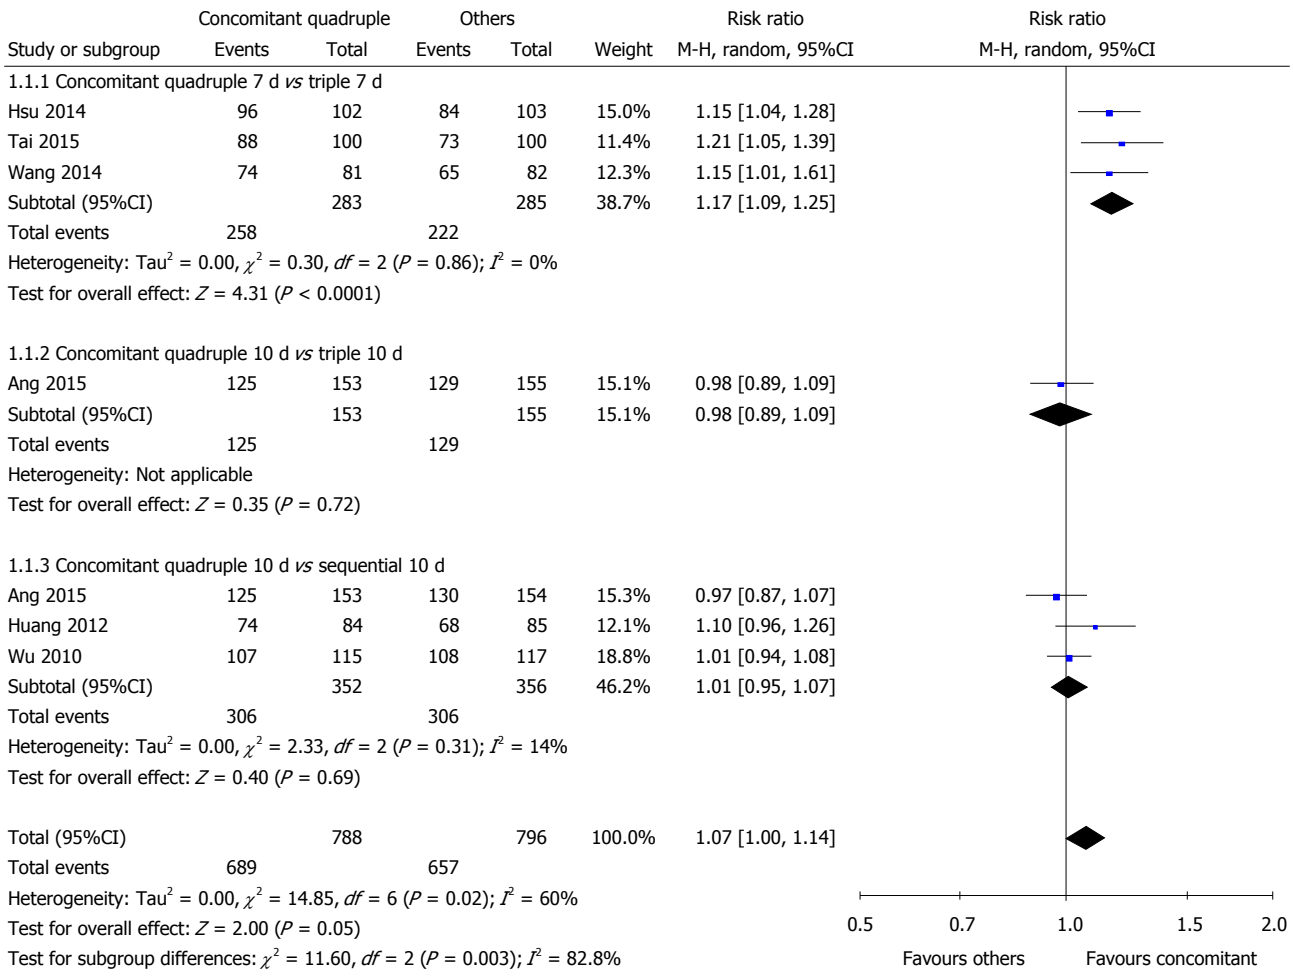

Figure 2 Forest plot for comparison of concomitant quadruple therapy with other therapies. Outcome: *Helicobacter pylori* eradication rate.

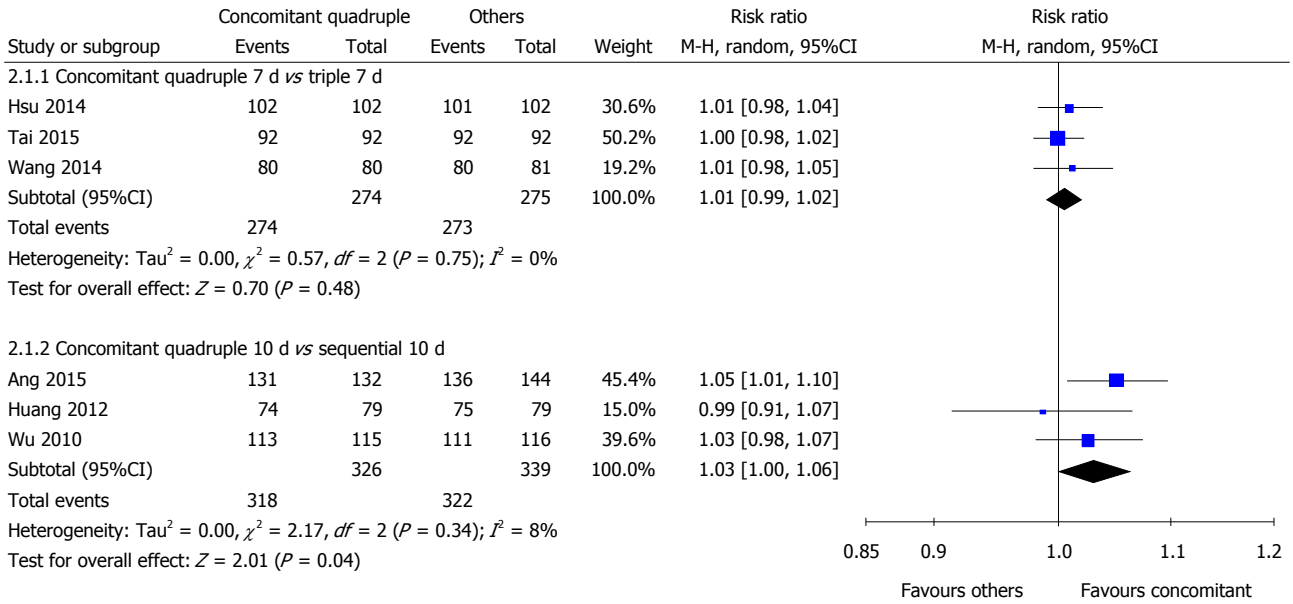

Figure 3 Forest plot for comparison of concomitant quadruple therapy with other therapies. Outcome: Compliance.

the compliance with 10-d nonbismuth concomitant quadruple and sequential therapies[20,22,36]. Although no significant difference was observed in the compliance with these therapies (97.5% *vs* 95.0%, RR = 1.03, 95%CI: 1.00-1.06), more patients tended to comply with nonbismuth concomitant quadruple therapy (Figure 3).

Adverse events

Two studies compared adverse events including abdominal pain, gastrointestinal disturbance, nausea and vomiting, skin rash, dizziness, and fatigue between 10-d nonbismuth concomitant quadruple and sequential therapies[20,22]. Patients receiving these two therapies showed a similar adverse event rate. Moreover, three studies compared the adverse event rate between 7-d nonbismuth concomitant quadruple and triple therapies[33-35]. Among two studies, patients receiving these two therapies showed a similar incidence of adverse events[33,35]. One study reported more adverse events after 7-d nonbismuth concomitant quadruple therapy than after triple therapy[34]. However, these effects were mild and did not markedly interfere with the patients' daily activities.

DISCUSSION

Because antibiotic resistance is a critical reason for *H. pylori* eradication failure, we conducted a systematic review and meta-analysis of RCTs to evaluate whether nonbismuth concomitant quadruple therapy is the optimal first-line therapy for *H. pylori* eradication in Chinese regions. Our meta-analysis revealed that a higher *H. pylori* eradication rate was achieved with 7-d concomitant therapy than with 7-d triple therapy. The eradication rates of concomitant and sequential therapies were similar. However, the compliance with concomitant therapy was higher. Therefore, nonbismuth concomitant quadruple therapy should be the first-line treatment for *H. pylori* infection.

Recently, Li *et al*[37] conducted a network meta-analysis of treatment for *H. pylori* infection. They showed that nonbismuth concomitant quadruple treatment is effective in *H. pylori* eradication. However, ethnicity and region play pivotal roles in antibacterial treatments; thus, investigating *H. pylori* eradication in different regions is necessary[38]. In South Korea, two RCTs showed that a much higher *H. pylori* eradication rate was achieved with nonbismuth concomitant quadruple therapy than with standard triple therapy or sequential therapy[26,39]. In Japan, an RCT also reported a higher eradication rate for nonbismuth concomitant quadruple therapy than that for triple therapy[40]. Our study revealed a similar outcome in Chinese regions.

Although the included studies used different PPIs, the same PPI was administered to the experimental groups in all studies, except for Ang *et al*[36]. Nevertheless, a meta-analysis revealed that different PPI types did not have different efficacies for *H. pylori* eradication[41]. Moreover, regarding concomitant therapy, Wang *et al*[35] substituted metronidazole with tinidazole; the eradication rate of that study is similar to that of other studies using metronidazole. These results are compatible with the trial that compared the efficacy of tinidazole and metronidazole for *H. pylori* eradication[42].

The optimal dosage of metronidazole remains undetermined. All RCTs used 500 mg of metronidazole twice daily, except for Ang *et al*[36], who used 400 mg twice daily. Nevertheless, Ang *et al*[36] still obtained a high eradication rate; this finding indicated that metronidazole doses from 400 to 500 mg are acceptable for *H.*

pylori eradication.

To determine the effectiveness of the treatments in practice, we considered the compliance rate. Although the eradication rates of nonbismuth concomitant and sequential therapies were not statistically different, higher compliance was achieved with nonbismuth concomitant therapy than with sequential therapy. Generally, the compliance rate may be higher in RCTs than in clinical settings. Thus, nonbismuth concomitant therapy may be a superior choice for *H. pylori* eradication because higher compliance was achieved with this therapy than with sequential therapy.

The value of I^2 was 0%-14% for each therapy, revealed that mild heterogeneity existed among our selected studies. This could be attributed to heterogeneity among patients' demographics and characteristics and the inclusion and exclusion criteria, dose and route of administration of *H. pylori* treatment, and time of outcome assessment.

Our study has several limitations. First, all our studies were open label, except for the study of Wu *et al*[20], which was outcome assessor blinded. However, we believe that this is not a major concern because the treatment outcomes were mainly objective. Second, not all trials evaluate antibiotic susceptibility. Third, because China has the highest population globally, more RCTs conducted in China may be required to determine the optimal treatment for *H. pylori* infection in Chinese regions.

In conclusion, the evidence reviewed in the present meta-analysis indicated that nonbismuth concomitant quadruple therapy achieved a higher *H. pylori* eradication rate than that of standard triple therapy and higher compliance than that of sequential therapy. Therefore, nonbismuth concomitant quadruple therapy should be the first-line treatment for *H. pylori* infection in Chinese regions.

COMMENTS

Background

Peptic ulcer is a common disease in Chinese regions, and *Helicobacter pylori (H. pylori)* eradication has become the standard and most widely adopted therapy. However, eradication rate of standard triple therapy has decreased to 80% in many countries worldwide, and compliance of sequential therapy may be poor due to the complexity. Therefore, there is a need to evaluate whether nonbismuth concomitant quadruple therapy is the first-line therapy for *H. pylori* eradication in Chinese regions.

Research frontiers

Due to increasing antibiotic resistance, current *H. pylori* eradication therapies may be poor. In this study, the authors compared eradication rate and compliance rate of three different types of therapies in Chinese region.

Innovations and breakthroughs

This study is the first meta-analysis to compare nonbismuth concomitant quadruple therapy with triple therapy and sequential therapy in Chinese region. Based on this study, nonbismuth concomitant quadruple therapy showed high *H. pylori* eradication rate and good compliance rate in Chinese region.

Applications

This study showed high efficacy and compliance in nonbismuth concomitant quadruple therapy. Thus, nonbismuth concomitant quadruple therapy is a good choice for first-line *H. pylori* eradication therapy in Chinese region.

Terminology

Nonbismuth concomitant quadruple therapy consist of proton pump inhibitor plus amoxicillin, clarithromycin, and nitroimidazole derivatives given for 7-14 d. Chinese regions in this study included China, Hong Kong, Taiwan, and Singapore.

Peer-review

The results of this meta-analysis showed that treatment with nonbismuth concomitant quadruple therapy resulted in high *H. pylori* eradication rate in Chinese region. In addition, good compliance rate and mild adverse effects were also noted in this study. Consequently, the study provided a better choice for first-line eradication therapy of *H. pylori* in Chinese region.

Abstract

Here, we report the first successful endoscopic resection of an exophytic gastrointestinal stromal tumor (GIST) using a novel perforation-free suction excavation technique. A 49-year-old woman presented for further management of a gastric subepithelial tumor on the lesser curvature of the lower body, originally detected *via* routine upper gastrointestinal endoscopy. Abdominal computed tomography and endoscopic ultrasound showed a 4-cm extraluminally protruding mass originating from the muscularis propria layer. The patient firmly refused surgical resection owing to potential cardiac problems, and informed consent was obtained for endoscopic removal. Careful dissection and suction of the tumor was repeated until successful extraction was achieved without serosal injury. We named this procedure the suction excavation technique. The tumor's dimensions were 3.5 cm × 2.8 cm × 2.5 cm. The tumor was positive for C-KIT and CD34 by immunohistochemical staining. The mitotic count was 6/50 high-power fields. The patient was followed

for 5 years without tumor recurrence. This case demonstrated the use of endoscopic resection of an exophytic GIST using the suction excavation technique as a potential therapy without surgical resection.

Key words: Gastrointestinal stromal tumor; Endoscopic resection; Submucosal tumor; Subepithelial tumor; *En bloc* resection

Core tip: Most small gastrointestinal stromal tumor (GISTs) are treated surgically, and endoscopic resection is contraindicated as the risk of perforation and incomplete resection is high. However, several authors recently reported successful results with endoscopic resection of a subepithelial tumor originating from the muscularis propria layer, including GISTs. A GIST with exophytic growth was previously considered a contraindication for endoscopic resection. In cases of exophytic GISTs, surgical or endoscopic full-thickness resection with laparoscopic support is generally indicated. However, this case shows that even exophytic GISTs can potentially be endoscopically resected without perforation using the suction excavation method.

Endoscopic *en bloc* resection of an exophytic gastrointestinal stromal tumor with suction excavation technique. *World J Gastroenterol* 2016; 22(23): 5454-5458 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i23/5454.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i23.5454

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumor of the gastrointestinal tract, especially of the stomach. Most small GISTs are treated surgically, and endoscopic resection was previously contraindicated as the risk of perforation and incomplete resection is high. Recently, however, several authors have reported successful results using endoscopic resection for subepithelial tumors (SETs) originating from the muscularis propria layer, including GISTs[1-3]. However, GISTs with exophytic growth have been considered a contraindication for endoscopic resection. Few studies on endoscopic resection of an extragastric bulging SET have been published, and the procedure reported previously was full-thickness resection of the gastric wall with laparoscopic support. In cases of exophytic GISTs, surgical or endoscopic full-thickness resection with laparoscopic support is usually indicated. However, the case presented here shows that even exophytic GISTs can potentially be endoscopically resected without perforation. We report the first successful endoscopic resection of a GIST with exophytic growth using a suction excavation technique.

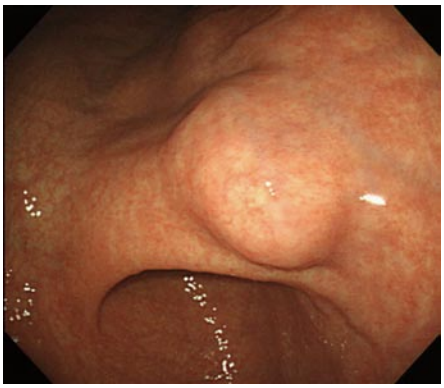

Figure 1 Endoscopic view of the lesion.

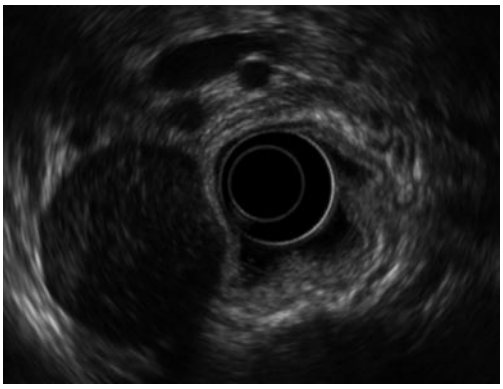

Figure 2 Endoscopic ultrasound. Endoscopic ultrasonography showed a heterogenic hypoechoic mass with extraluminal growth originating from the muscularis propria layer.

CASE REPORT

A 49-year-old woman visited our hospital for further evaluation and management of a gastric SET, detected *via* routine upper gastrointestinal endoscopy at a private health clinic. The esophagogastroduodenoscopy performed outside the hospital showed a 4-cm mass with a smooth tapered margin located in the lower body, on the side of lesser curvature (Figure 1). The mass was hard and immovable upon palpation with biopsy forceps. Endoscopic ultrasound showed a heterogeneous hypoechoic mass with extraluminal growth, originating from the muscularis propria layer (Figure 2). An abdominal CT scan showed a 4-cm extraluminally protruding mass compressing the gastric wall (Figure 3). Our initial treatment plan was surgical resection owing to the tumor's extraluminal growth pattern. However, the patient resolutely refused surgical resection and we therefore chose to attempt an endoscopic removal of the tumor. The endoscopic submucosal dissection procedure was performed using a cap-fitted gastroscope (GIF-Q260; Olympus, Tokyo, Japan). The endoscopic procedure is clearly illustrated and presented in Figure 4. Marking was done along

Figure 3 Abdominal computerized tomography scan showing the 3.5 cm × 2.5 cm tumor with exophytic growth.

the tumor's margin using an argon plasma coagulation probe. After submucosal injection of sodium hyaluronate, a circumferential incision was made along the marking line using a hook knife (KD-620Q; Olympus). After the circumferential incision, the overlying mucosa was removed by snare resection and dissection of the muscular tissue between the tumor and the serosa (Figure 5). Muscular dissection was carefully performed using a hook knife. Shortly after muscular dissection, suction was applied to the tumor using the end of the cap-fitted gastroscope. This careful dissection and suction of the tumor was repeated until, finally, the tumor was successfully extracted without serosal injury (Figure 6). The procedure time was approximately 1 h. Propofol was initially injected intravenously to induce sedation (0.5 mg/kg), and additional propofol was administered repeatedly during the endoscopic procedure (10-20 mg per each injection). Supplemental oxygen was administered nasally throughout sedation.

The tumor dimensions were 3.5 cm × 2.8 cm × 2.5 cm (Figure 7). Immunohistochemical staining showed that the tumor was positive for C-KIT and CD34. It was diagnosed as GIST. The mitotic count was 6/50 high-power fields. Although the patient had a high risk of recurrence according to risk stratification analysis, further surgery could not be performed owing to the patient's unwillingness to undergo surgical resection. No tumor recurrence occurred during the 5-year follow-up period (Figure 8).

DISCUSSION

The number of clinical trials investigating endoscopic resection of SETs originating from the muscularis propria layer has recently increased. These trials have reported that some SETs originating from the muscularis propria layer can be safely resected by using gastrointestinal endoscopy without perforation or any other serious complications. However, it is not yet known which of these tumors is an appropriate indication for endoscopic resection. Appropriate indications for endoscopic resection should be based on low complication and recurrence rates. A previous study showed that a positive rolling sign and a small tumor size are appropriate indications for endoscopic removal. In addition, successful endoscopic resection of GISTs depends on their location in the gastric wall[4]. Submucosal tumors that protrude mainly into the serosal side of the gastric wall are not easy to resect completely using an endoscopic method. Nevertheless, further studies are required to verify these findings. In cases of exophytic GISTs, surgical or endoscopic full-thickness resection with laparoscopic support is generally indicated. However, this case shows that even exophytic GISTs can potentially be endoscopically resected without perforation.

Previous endoscopic therapy did not emphasize the suction concept, but we showed that suction excavation is useful for SET removal. Full endoscopic suction can move SETs in an endoluminal direction, so our technique has the advantage of reducing perforation risk compared with previous endoscopic submucosal dissection techniques. However, the suction excavation technique has its own limitations. If the SETs do not move inward by endoscopic suction, this technique cannot be used for endoscopic resection. Therefore, it is difficult to apply our suction excavation technique to all exophytic SET resections. The use of the suction excavation technique to remove exophytic SETs has limited indications, such as a positive rolling sign, small tumor size, and moving sign by endoscopic suction. However, the suction excavation technique can be useful for removing simple SETs as well as exophytic SETs in clinical practice.

Most cases of recurrence after surgical resection of a GIST involve intraperitoneal or hepatic recurrence. Local recurrence itself is very rare. The risk factors of GIST recurrence include not only tumor size and the number of mitoses but also exposure of tumor cells in the abdominal cavity after the capsule of the tumor is ruptured[5]. If gastric perforation can be avoided during endoscopic resection, the risk of tumor cell exposure in the abdominal cavity could be lower than that of surgical resection and the frequency of intra-abdominal recurrence would decrease accordingly. As such, avoidance of gastric perforation during endoscopic resection is critical. In this case, the patient was followed for 5 years without tumor recurrence. A recent study comparing the results of endoscopic versus surgical resection of a GIST in the upper gastrointestinal tract found that endoscopic resection could be an alternative therapeutic modality in selective cases[5]. In our subject's case, the tumor showed

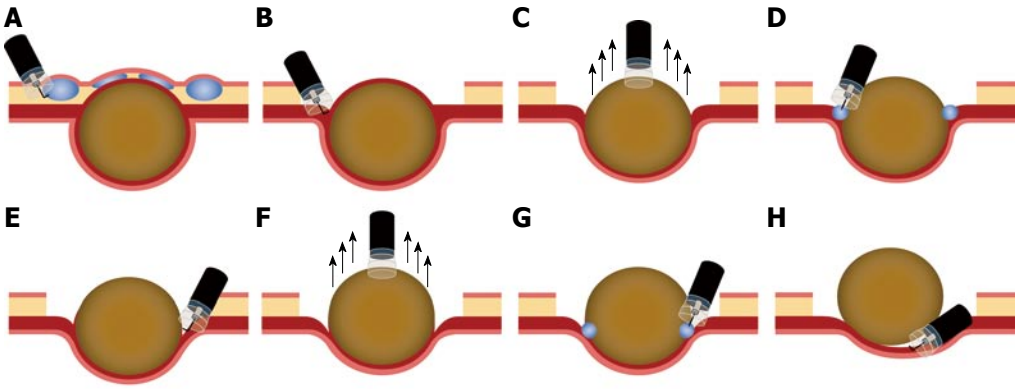

Figure 4 Illustration of the endoscopic suction excavation technique. A: After submucosal injection of sodium hyaluronate, a circumferential incision and removal of the overlying mucosa were performed; B, E: Careful muscular dissection between the tumor and serosa with a hook knife; C, F: Endoscopic suction using the end of a cap-fitted endoscope attached to the tumor; D, G: Submucosal injection of sodium hyaluronate; H: Tumor fully extracted after repeated careful dissection and endoscopic suction.

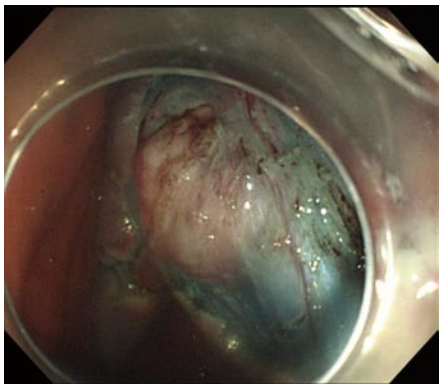

Figure 5 Tumor was exposed after removing the overlying mucosa.

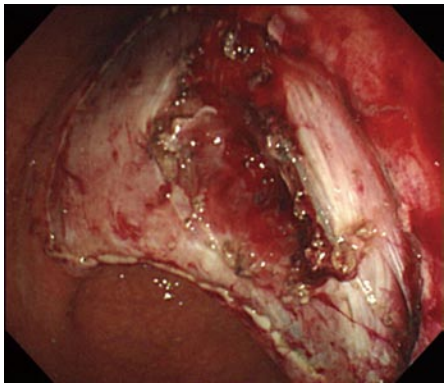

Figure 6 Extraction showing no perforation.

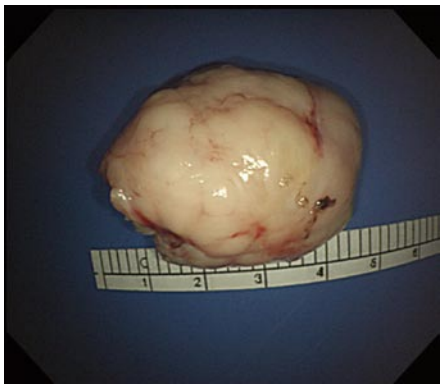

Figure 7 Extracted tumor after repeated muscular dissection and endoscopic suction.

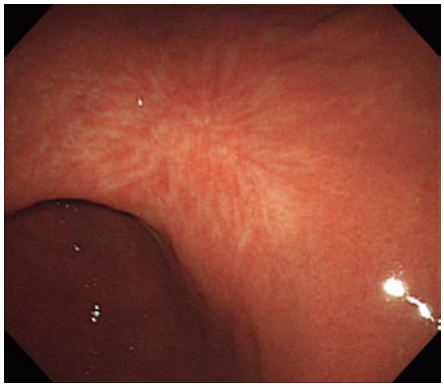

Figure 8 Endoscopic submucosal dissection scar after 5 years.

extraluminal bulging or exophytic growth, and thus, the risk of perforation during endoscopic resection was very high. This suction excavation method can be safer than endoscopic submucosal dissection. Although this method does require physician experience, it can be helpful in difficult cases of endoscopic GIST removal.

In the case presented here, a full-thickness resection with laparoscopic support followed by laparoscopic gastroparietal suture, as opposed to an endoscopic-only procedure, is usually indicated. In this case, endoscopic resection of the extraluminal bulging SET using a suction excavation technique without laparoscopic support was successfully performed for the first time. Although not all exophytic GISTs can be resected endoscopically using this excavation technique, we do hope that this method may aid in the removal of tough submucosal tumors using gastrointestinal endoscopy.

COMMENTS

Case characteristics

A 49-year-old woman presented for further management of a gastric subepithelial tumor on the lesser curvature of the lower body, originally detected *via* routine upper gastrointestinal endoscopy.

Clinical diagnosis

The esophagogastroduodenoscopy performed outside the hospital showed a 4-cm mass with a smooth tapered margin located in the lower body, on the side of lesser curvature. The mass was hard and immovable upon palpation with biopsy forceps.

Differential diagnosis

Subepithelial tumor: Gastrointestinal stromal tumor, leiomyoma, granular cell tumor, ectopic pancreas.

Laboratory diagnosis

All labs were within normal limits.

Imaging diagnosis

Endoscopic ultrasound showed a heterogeneous hypoechoic mass with extraluminal growth, originating from the muscularis propria layer. An abdominal CT scan showed a 4-cm extraluminally protruding mass compressing the gastric wall.

Pathological diagnosis

Immunohistochemical staining showed that the tumor was positive for C-KIT and CD34. It was diagnosed as gastrointestinal stromal tumors (GISTs). The mitotic count was 6/50 high-power fields.

Treatment

Endoscopic resection of an exophytic GIST using the suction excavation technique.

Related reports

Most GISTs are treated surgically, and endoscopic resection was contraindicated as the risk of perforation and incomplete resection is high. However, several authors have recently reported successful results using endoscopic resection of a subepithelial tumor (SET) originating from the muscularis propria layer, including GISTs. A GIST with exophytic growth was previously considered a contraindication for endoscopic resection. In cases of exophytic GISTs, surgical or endoscopic full-thickness resection with laparoscopic support is generally indicated. However, this case shows that even exophytic GISTs can potentially be endoscopically resected without perforation using the suction excavation method.

Term explanation

GISTs are the most common mesenchymal neoplasms of the gastrointestinal tract that arise in smooth muscle pacemaker cells such as interstitial cells of Cajal.

Experiences and lessons

The suction excavation technique described here is a helpful technique to remove exophytic SETs. Previous endoscopic therapy did not emphasize the suction concept, but we showed that suction excavation is useful for SET removal.

Peer-review

The paper is well written.

Abstract

The fibrosis of liver cirrhosis was considered to be irreversible before the anti-viral drugs showed that it is reversible when they lead to continuous suppression of viral replication and inflammation. However, several reports previously showed that fibrosis of type B liver cirrhosis was almost completely absorbed after the natural remission of chronic inflammation. This phenomenon might not be limited to exceptional patients, but rather occur commonly, considering the dynamic clinical features of chronic hepatitis B (CHB), where inactive carrier stage normally follows aggravation of hepatitis and progression of fibrosis at the time of HBeAg seroconversion. Thus, fibrosis levels of CHB as a hepatocellular carcinoma (HCC)-surveillance marker, particularly those of the inactive stage, could be underestimated, because some of them might have been (pre)cirrhotic in the past and recovered with the natural regression of fibrosis. We argue that cirrhosis-induced HCC mechanisms, rather than direct action of viral genome, may be more common than generally considered in CHB patients. This may have some impact on reconsidering the surveillance rationale for HCC in CHB, from where advanced HCCs tended to be missed. In addition, a molecular marker to assess the cancer-prone characteristics of the liver will definitely be needed to resolve the issue.

Key words: Chronic hepatitis B; Cirrhosis; Spontaneous remission; Regression of fibrosis; Occult hepatitis B infection; Hepatocellular carcinoma surveillance of hepatitis B virus

Core tip: The fibrosis of liver cirrhosis may be reversible. Regression of fibrosis in hepatitis B virus (HBV) patients with (pre)cirrhosis might be a more common phenomenon than generally considered. This might cause the underestimation of fibrosis levels in chronic hepatitis B, suggesting a difficulty with the surveillance system of HBV-hepatocellular carcinoma (HCC). That is, some HCC patients with non-cirrhotic liver might have been cirrhotic in the past, after which spontaneous regression of fibrosis occurred. Cirrhosis-HCC mechanisms, compared to the direct action of the viral genome, might be more prevalent than generally considered in HBV patients.

Ohkoshi S, Hirono H, Watanabe K, Hasegawa K, Kamimura K, Yano M. Natural regression of fibrosis in chronic hepatitis B. *World J Gastroenterol* 2016; 22(24): 5459-5466 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5459.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5459

INTRODUCTION

Continuous inflammation of the liver induces deposition of extracellular matrix (ECM) and results in liver cirrhosis. Although several reports showed regression of fibrosis in animal models with liver cirrhosis[1,2], and in human case reports[3-5], established fibrosis of cirrhosis was generally considered to be irreversible[6,7]. However, reversibility of fibrosis in the liver became commonly-known recently because elimination of viruses with anti-hepatitis B virus (HBV) or hepatitis C virus (HCV) drugs caused regression of fibrosis even in cirrhotic cases[8,9].

The natural history of chronic HBV infection pursues a dynamic process caused by the conflict between virus and immune system, which results in the seroconversion of HBeAg to anti-HBe, followed by that of HBsAg to anti-HBs[10]. Long-standing liver injury in the process of HBeAg-seroconversion induces particularly rapid progression of fibrosis that frequently results in cirrhosis. However, due to the dynamic course of the disease, stable clinical remission with low HBV DNA and transaminase levels follows, and the majority of patients become inactive carriers. Natural regression of fibrosis induced by this clinical remission has been reported[3,11].

In general, hepatocellular carcinoma (HCC) with HBV arises more frequently in non-cirrhotic liver than in HCV infection[12,13]. This is considered mainly due to the direct mutagenesis effect of the HBV genome that integrates into the host genome or the direct hepatocarcinogenic action of viral genes such as hepatitis B virus X (HBx)[14]. However, if HCCs have arisen in the liver in which fibrosis naturally regressed from advanced liver fibrosis, they might be misinterpreted as having arisen from a non-cirrhotic liver.

Consequently, it should always be kept in mind that fibrosis levels of chronic hepatitis B (CHB) always have the possibility of being underestimated in terms of HCC-risk, because they might have regressed from a more advanced stage of fibrosis[15]. We attempt to spotlight the natural regression of fibrosis in chronic HBV infection and re-evaluate the clinical background of HBV-induced HCC in this review.

CHRONIC HBV DISEASE AND PROGRESSION OF FIBROSIS

About 350 million people in the world have chronic HBV infection[16]. Chronic HBV infection is a significant cause of liver cirrhosis, which bears a high risk of HCC. The annual rate of development of HCC has been reported to be 10% to 17% in HBV-induced liver cirrhosis[17]. In general, fibrosis levels correlate well with the risk of HCC, as in the case with HCV infection.

The immunological attack against hepatocytes infected with HBV induces a dynamic clinical course which is represented by seroconversion of HBeAg to anti-HBe. Almost no or very mild liver injury is observed in the HBeAg-positive immunotolerant phase[18]. The severity of liver injury and the progression of fibrosis depend on how long and severe the immunological attacks continue in the phase of HBeAg seroconversion. A rapid transition to anti-HBe normally results in a silent clinical course, referred to as the inactive carrier state, while a difficult transition that is accompanied by aggravation of chronic hepatitis result in liver cirrhosis or HBeAb-positive chronic active hepatitis, which frequently bears core-promoter mutations. Importantly, the majority of patients become inactive carriers afterwards, irrespective of their clinical course[10,19].

MECHANISM OF HBV-INDUCED HCC AND CLINICAL BACKGROUND CHARACTERISTICS

Chronic inflammation induces a progression of fibrosis resulting in liver cirrhosis in which HCC frequently develops. This cirrhosis-HCC mechanism is common to both HBV and HCV infections and is considered to play the main role in hepatocarcinogenesis, to which a process of accumulation of genetic mutations and epigenetic events contributes. In addition to this common carcinogenetic mechanism, each virus infection has its own carcinogenic mechanism.

On the other hand, HBV, which is related to retroviruses, integrates into the host genome during the process of replication and acts as a mutagen. In addition, the *HBx* gene, which is a pleiotropic transactivator of many genes, has been known to be directly involved in hepatocarcinogenesis[20]. Because "cirrhosis to HCC" (indirect) and these

Table 1 A comparison of clinic-pathological data between type-B and type-C hepatocellular carcinoma

	Type B (*n* = 97)	Type C (*n* = 81)	*P* value

direct mechanisms are not mutually exclusive, it is unknown how much a role each mechanism plays in real hepatocarcinogenesis, especially in individual HCC patients with variable clinical backgrounds.

DIFFICULTY OF HCC SURVEILLANCE IN CHRONIC HBV PATIENTS

Because the carcinogenic processes of HBV and HCV are different, the rationale to perform effective cancer surveillance should be confirmed based on the difference in the specific clinical courses of these infections. Age, sex, fibrosis levels, the presence of HBeAg, HBV viral load, HBsAg levels accounts for the risks of HBV-HCC[21]. In reports from Japan, HCC patients with HBV tended to be younger and have advanced tumor when diagnosed, as well as lower fibrosis levels with good liver function when compared to those with HCV[22,23]. Our result also showed that patients with HBV were younger, with lower fibrosis levels and higher platelet counts than those with HCV (Table 1). Notably, the clinical stages of HBV-HCC were more advanced. These clinical features suggest that cancer surveillance of HBV is much more difficult than that of HCV infection, where continuous elevation of transaminase values induces gradually increasing fibrosis levels, and a low platelet count may be associated with advanced fibrosis levels[24]. In general, a direct hepatocarcinogenic mechanism of HBV, such as the integration of the genome or a direct role of an HBV gene such as HBx, may be considered to be involved in the occurrence of HCC in these "unexpected" patients. However, our question is "Is this the full explanation?"

It seems very paradoxical that HBeAg-positive carriers in the immunotolerant phase with high viral loads and little inflammation, who are supposed have abundant viral gene expression and integration event, seldom suffer from HCC[18]. On the other hand, most HCC patients who were younger than 20 years old were already seroconverted to anti-HBe, and the majority of them were cirrhotic[25-27]. Thus, the cirrhosis to HCC mechanism might play a central role even in these young HCC patients. These facts render the HCC surveillance system for HBV more complex.

REVERSIBILITY OF FIBROSIS WITH LIVER CIRRHOSIS WITH ANTI-HBV TREATMENT AND NATURAL COURSE

The generally accepted idea was that the fibrosis of liver cirrhosis is an irreversible process, and established fibrosis could not regress. However, the development of innovative anti-viral drugs for HBV and HCV changed this long-lasting concept[8]. Fibrosis is reversed when inflammation is suppressed by effective anti-viral agents, and even cirrhosis can be cured. Dienstag *et al*[28] reported that the fibrosis of cirrhosis was reversed during 3.5 years lamivudine treatment. Several reports also confirmed the improvement of fibrosis levels with anti-HBV drugs[29,30].

However, the regression of fibrosis occurs even in the natural course of CHB, where remission of inflammation usually follows the aggravation of hepatitis and progression of fibrosis that occurred during the HBeAg-positive stage[31]. In the past, several reports showed the improvement of fibrosis during the natural course of CHB. Fong *et al*[3] showed the improvement of histology comparing before and after the seroclearance of HBsAg. Waneless *et al*[32] reported that most cirrhotic livers showed some findings indicating the regression of fibrosis, irrespective of etiology. Natural regression of fibrosis consists of three steps, that is, thinning of fibrous septa, regeneration of hepatocytes and recovery of acinal structure. The regression of fibrosis occurs at a particularly early stage of improvement[6].

Recently, Jang *et al*[33] reported improvement of the long-term prognosis with anti-HBV drugs for patients with HBV-cirrhosis. However, suppression of HCC development was not observed in these cirrhotic patients, while it has been confirmed in patients with chronic hepatitis[8]. These results strongly suggest that liver cirrhosis still provides a strong risk for HCC, even after the eradication of virus and suppression of

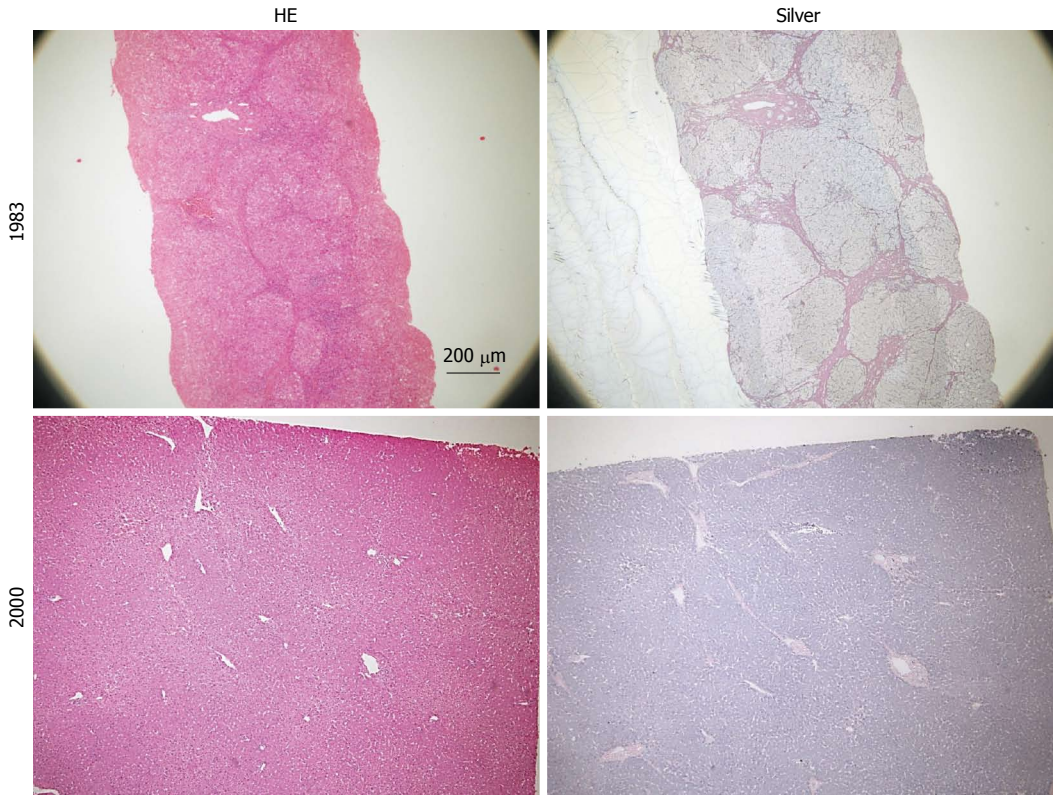

Figure 1 Liver histology of a patient obtained in 1983 (58 year old, needle biopsy) and 2000 (surgical resection of hepatocellular carcinoma). Slides stained with hematoxylin-eosin are shown on the left and those stained with silver are on the right. Marked reduction of fibrosis with improvement of inflammation is observed (This patient was patient 1 in our previous report[4]).

inflammation.

THE LESSONS FROM THE HCC CASES THAT OCCURRED AFTER HBSAG SEROCLEARANCE

We previously reported several cases with HCC that developed after seroconvesion from HBsAg to anti-HBs[4,34]. They progressed to liver cirrhosis or precirrhosis when they had HBeAg-positive chronic hepatitis several decades earlier and became inactive carriers with low viral load and long-standing normal transaminase levels after the seroconversion to anti-HBe. HCC developed further after the seroconversion to anti-HBs. Hepatic fibrosis was dramatically reversed and found to become only thin septa. Changes in liver histology of one patient[4] are shown in Figure 1. Similarly, Bortolotti *et al*[5] reported 2 pediatric patients with HBV-induced liver cirrhosis, whose fibrosis was almost completely resolved after normalization of transaminase levels. Similar to our cases, these results suggested that fibrosis of cirrhosis could be dramatically resolved when viral replication and inflammation were suppressed[31,35]. These cases, considering the dynamic natural course of HBV infection, give us some important suggestions about the clinical background characteristics of HBV-induced hepatocarcinogenesis.

First, as with anti-HBV treatment, these cases are typical examples showing that advanced fibrosis could be absorbed even in the natural course of CHB. After HBeAg-positive chronic hepatitis progresses to liver cirrhosis, the majority of patients follow the clinical course of long-standing remission with a low viral load. Considering this typical clinical course of CHB, natural regression of fibrosis might not be an exceptional phenomenon limited to these case reports, but it might occur commonly. This also suggests that some population of HBV-HCC patients with non-cirrhotic liver might have regressed fibrosis that was once cirrhotic or pre-cirrhotic. Consequently, our hypothesis is that the incidence and role of cirrhosis-derived HCC might be underestimated in HBV-HCC, and the roles of direct carcinogenesis due to HBV integration or viral gene function with a slight involvement of necroinflammation in non-cirrhotic HCC are overestimated.

HBV-cirrhosis is "macronodular" and has thinner septa than HCV[32]. Micronodular cirrhosis changes to macronodular with the suppression of inflammation[36]. This morphological observation might reflect the clinical course of these viruses, where HCV takes a continuous progressive course, and HBV is characterized by the alternating increases and normalization of transaminase levels.

Another important suggestion relates to the assess-

ment of fibrosis in CHB patients for the establishment of an effective HCC surveillance system. Recently, not only liver biopsy which is a gold standard for the evaluation of fibrosis, but a handful of methods to assess fibrosis levels have been used clinically. However, these methods may not discriminate these cases of "regressed fibrosis from cirrhosis", which might have more risk of HCC than "ongoing fibrosis". Thus, it might be possible to underestimate the risk of HCC in these patients with regressed fibrosis levels using these current methods. Indeed, needle biopsy might give the diagnosis of an almost normal liver with completely regressed fibrosis[32].

Cirrhosis-HCC mechanisms can be glimpsed in studies that examined the incidence of HCC after the seroclearance of HBsAg, which normally has a good prognosis[10,37,38]. Yuen *et al*[39] reported that the risk factors of HCC at this stage were the presence of liver cirrhosis and old age. Liver cirrhosis was also counted as a significant factor for the seroclearance of HBsAg[40]. This indicates that the strong immune reaction that caused liver cirrhosis eventually contributed to the seroclearance of HBsAg, providing some risk of HCC.

Similar suggestions could be applied to HCC cases with occult HBV infection (OHB). Some patients might have overt chronic HBV infection before entering the stage of OHB[41]. These patients might have "regressed fibrosis from advanced fibrosis" during the process of becoming seronegative for HBsAg. They can easily be missed during clinical surveillance of HCC, unless they were recognized as HBV carriers, possibly in early life[15]. Integration of HBV DNA or the direct action of an HBV gene such as HBx from long-standing viral replication is considered to play a role in the occurrence of HCC with OHB[42]. However, cirrhosis-HCC mechanism might play a central role in more number of patients with OHB-HCC than generally considered.

Liver biopsy has been a gold standard of evaluation for liver fibrosis[43]. Non-invasive methods for evaluation of fibrosis are widely used in clinical settings. They have been primarily used for the assessment of HCV-related fibrosis, and their application to HBV-induced fibrosis has always been under constant debate[44]. Transient elastography (TE) is one of the most reliable recent modalities to assess the fibrosis level without biopsy[45]. Several reports evaluated the efficacy of TE in both CHB and CHC patients and reported that diagnostic accuracy was almost equal between them[46,47]. However, a lower liver stiffness (LS) cut-off in CHB than in CHC in the advanced fibrosis stage was reported[48]. The interpretation of this was that fibrous septa were thinner in CHB than in CHC. Moreover, because CHB tended to have macronodular cirrhosis, TE waves go through liver parenchyma and produce a low stiffness value[49]. Likewise, Castéra *et al*[50] reported that the cut off values of TE in cirrhosis were higher in HCV-LC than that of HBV-LC and this difference came from the high prevalence of macronodular LC in HBV. Thus, although fibrosis markers are considered to be useful in the evaluation of fibrosis levels of CHB in general[49], there have been no studies attempting to assess the fibrosis levels following CHB patients from aggravation of hepatitis to the inactive stage.

APPLICATION OF MOLECULAR ANALYSIS TO THE "HCC FROM REGRESSED FIBROSIS"

Innovative advances of molecular analysis recently allow comprehensive cancer genome analysis in a short time, resulting in the accumulation of an overwhelming body of information about the cancer genome[51]. Schulze *et al*[52] analyzed the whole exon of 243 HCC tissues and reported that genomic pathways centered on three signaling abnormalities, β-catenin (CTNNB1), TP53, and AXIN1-related. They also suggested that they can distinguish HCC that arose from cirrhosis from those derived from non-cirrhosis using the difference in incidence of CTNNB1 TP53, a mutation of telomerase reverse transcriptase (TERT). In addition, mutations of TERT promoter have been noted as a characteristic genomic change of HBV-HCC, in which integration of the HBV genome frequently occurs[53,54]. It is interesting to know whether HCC that arose from "liver with regressed fibrosis from cirrhosis" is close to a cirrhotic or a non-cirrhotic pattern.

Telomere shortening is a general genetic marker of liver cirrhosis causing senescence of hepatocytes that is associated with the development of HCC[55-57]. Recently, TERT promotor mutations were observed already in premalignant nodules in cirrhotic liver[58]. In addition, Hartmann *et al*[59] reported that TERT gene mutations were frequently detected in liver cirrhosis irrespective of etiology, suggesting that they may be used to evaluate cancer-prone characteristics of liver. This result might be applicable in the evaluation of whether the liver with regressed fibrosis has oncogenic potential close to that of real cirrhosis, helping the understandings of the carcinogenic potential of that state. Such molecular markers that can assess cancer-prone characteristics of cirrhotic or non-cirrhotic liver are much needed to prove that a cirrhosis-HCC mechanism might be involved in the development of HCC than currently considered, even in low-fibrosis cases.

CONCLUSION

The clinical course of chronic HBV infection is dynamic and complex, with changes of serological markers, which is distinct from HCV infection that takes a more continuous clinical course. Because of this clinical profile, long-standing remission after established cirrhosis, result in the regression of fibrosis, where only thin septa are recognized. On the other hand, the integration of

the HBV genome or a direct gene function, such as HBx, may play an important role in so-called direct hepatocarcinogenesis. HCCs from regressed fibrosis and those *via* direct hepatocarcinogenesis might be categorized together into "HCC from non-cirrhotic liver". Thus, these mechanisms render the assessment of fibrosis as a risk factor for HCC very complex. Therefore, there is an urgent need to establish effective cancer surveillance system that addresses these complex issues. In addition, molecular markers to evaluate the risk of HCC in non-cirrhotic as well as cirrhotic liver should be clarified in a future analysis.

Abstract

Chronic hepatitis B virus (HBV) infection remains a major health problem, with more than 240 million people chronically infected worldwide and potentially 650000 deaths per year due to advanced liver diseases including liver cirrhosis and hepatocellular carcinoma (HCC). HBV-X protein (HBx) contributes to the biology and pathogenesis of HBV *via* stimulating virus replication or altering host gene expression related to HCC. The HBV X region contains only 465 bp encoding the 16.5 kDa HBx protein, which also contains several critical cis-elements such as enhancer Ⅱ, the core promoter and the microRNA-binding region. Thus, mutations in this region may affect not only the HBx open reading frame but also the overlapped cis-elements. Recently, several types of HBx mutations significantly associated with clinical severity have been described, although the functional mechanism in most of these cases remains unsolved. This review article will mainly focus on the HBx mutations proven to be significantly related to clinical severity *via* epidemiological studies.

Key words: Hepatitis B virus infection; Hepatitis B virus-X protein mutation; Hepatocellular carcinoma; Clinical severity

Core tip: Of hepatitis B virus (HBV)-X protein (HBx) mutations related to clinical severity, the A1762T/G1764A BCP mutation is one of the most frequently

encountered HBx mutations and plays a significant role in liver disease progression in chronic patients with HBV infections. It also further contributes to disease progression by inducing mutations of other HBx mutations related to clinical severity, such as G1386A/C (V5M/L), C1653T (H94Y), T1753V (I127V) and HBx C-terminal deletion or insertion. Moreover, T1753V (I127L,T,N,S) and C1653T (H94Y) mutations in the enhancer Ⅱ/BCP region and A1383C, G1386A/C (V5M/L) and C1485T (P38S) in the negative regulation domain are significantly related to severe types of liver diseases, including hepatocellular carcinoma. Furthermore, deletions or insertions affecting the C-terminal region of HBx may also contribute to the severity of the clinical outcome in chronic patients. In addition, our recent study indicated that a novel mutation type (X8Del) composed of an 8-bp deletion in the C-terminal region of the HBx could contribute to occult HBV infection in vaccinated Korean individuals *via* a reduced secretion of HBsAg and virions. Therefore, several distinct types of HBx mutations may contribute to HBV pathogenesis by regulating HBV replication or host genes related to cell homeostasis.

INTRODUCTION

Chronic hepatitis B virus (HBV) infection remains a major health problem with more than 240 million people chronically infected worldwide, which potentially causes 650000 deaths per year due to advanced liver diseases including liver cirrhosis and hepatocellular carcinoma (HCC), particularly in endemic areas such as China and South Korea[1,2]. It is generally accepted that HBV infection accounts for approximately 50% of the HCC cases worldwide and even 80%-90% in highly endemic areas[1].

HBV is an enveloped Hepadnavirus belonging to the *Hepadnaviridae* family, with an incomplete double-stranded DNA genome of approximately 3.2 kb in length with four overlapping open reading frames (ORFs) encoding the polymerase (P), core (C), surface antigen (S), and X protein[3]. The S gene encodes a family of surface antigen polypeptides embedded within the viral envelope, which is a major target for diagnosis and protective vaccines. The C gene encodes the core antigen, which forms the nucleocapsid, within which reverse transcription of pre-genomic RNA occurs. The P gene encodes the virus reverse transcriptase, which also has RNase H and DNA polymerase activities[4-6]. Transcription of HBV proteins is controlled under four promoters (preS1, preS2, core and X) and two enhancers (EnhI and EnhII) in the viral genome, which overlap with those ORFs. Because it contains a polymerase without proofreading activity and uses an RNA intermediate (pgRNA) during its replication, the HBV genome has a higher mutation ratio than other DNA viruses[7-11]. Moreover, host immune pressures and interventions such as antiviral drugs and vaccines make the viral mutations more complicated[12-18].

Based on an intergroup divergence of > 8% in its complete genome sequence, the HBV strains are classified into eight genotypes, which are designated A-H, with a distinct ethnic and geographical distribution[1,19-21]. Different genotypes have distinct geographical distributions and usually induce various clinical outcomes. For instance, genotype C, the most prevalent genotype in Asia, is more prone to mutations and is associated with more severe liver diseases and lower antiviral responses compared with genotype B[3,22,23]. In particular, genotype C2 is reportedly responsible for the most chronic infections in South Korea. Indeed, several types of HBV mutations that are never or rarely encountered in other areas have been found in South Korea and have been proven through molecular epidemiologic or functional studies to be related to disease progression in chronic patients[24-44].

HBV X PROTEIN STRUCTURE AND FUNCTION

The HBV X protein (HBx) is a multifunctional non-structural protein that contributes to HBV biology and pathogenesis by stimulating virus replication or altering host gene expression related to HCC. HBx contains only 465 bp encoding the 16.5 kDa protein, which also contains several critical cis-elements such as EnhII, the core promoter and the microRNA-binding region[45-47] (Figure 1).

HBx plays a significant role in sustained HBV replication, which is a major risk factor for HCC development *via* proteasome inhibition[48,49], transactivation of HBV enhancer or promoters[50], autophagy induction[51,52], or polymerase activation by Ca^{2+}-dependent signaling[53-55]. HBx can also regulate HBV replication through epigenetic modifications, by being recruited onto the viral minichromosome in the nuclei of infected hepatocytes along with cellular histone acetyltransferases such as CREB-binding protein (CBP)/p300[56,57] and histone deacetylases such as HDAC1 and hSirt1[58]. HBx can help establish and maintain chronic infection by altering the patterns of host innate immunity, which causes the development and progression of chronic liver diseases in the absence of virus elimination[59,60]. HBx blocks apoptotic signaling and activates signaling pathways (such as NF-κB and PI3K) that override apoptotic signals from extrinsic ligands such as Fas or TNF-alpha[61,62]. HBx also plays an important role in hepatocarcinogenesis by inactivating the tumor suppressor p53[63], promoting Rb inactivation by

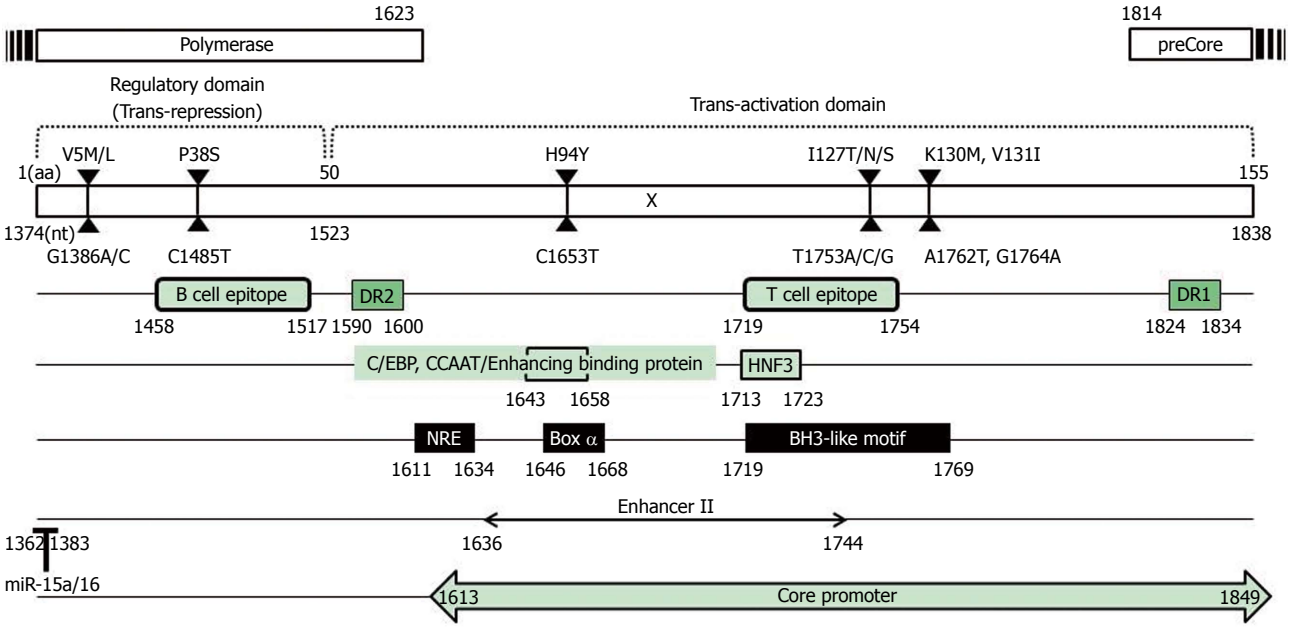

Figure 1 Hepatitis B virus-X protein genome structure. The HBV X region contains 465 bp (nt 1374 to 1838) encoding the 16.5 kDa HBx protein composed of 154 aa, which also contains several critical cis-elements such as EnhII (nt 1636 to 1744), the core promoter (nt 1613 to 1849) and the microRNA-binding region (nt 1362 to 1383). Thus, HBx mutations affected not only the HBx open reading frame but also the overlapped cis-elements. HBx: Hepatitis B virus-X protein.

phosphorylation[64], and compromising DNA repair mechanisms[65]. Consequently, mutations in the HBx ORF region may affect not only the HBx ORF and the overlapped cis-elements but also its binding capacity for host proteins. Recently, several types of HBx mutations significantly associated with clinical severity have been described mainly from chronic patients infected with genotype C[28,31,39,66-83], although the functional mechanism in most of these cases remains unsolved. This review article will mainly focus on the HBx mutations that have been proven to be significantly related to clinical severity *via* epidemiological studies (Table 1).

HBx MUTATIONS RELATED TO CLINICAL SEVERITY

Mutations in EnhII and (or) the core promoter region (BCP mutation, T1753V, and C1653T)

In general, 3 types of mutations in the EnhII/BCP region [one mutation in EnhII (H94Y: C→T of nt 1653) and two mutations in BCP (I127L,T,N,S: T→V of nt 1753, K130M and V131I: A→T of nt 1762 and G→A of nt 1764)] are mutational "hot spots", namely, the most frequently encountered among naturally occurring HBx mutations related to clinical severance from chronic hepatitis B patients, irrespective of genotype or geographical distributions (Table 1). The A1762T/G1764A BCP mutation leading to two overlapped HBx amino acid changes, K130M and V131I, is the most frequent HBV DNA mutation identified in many studies as being associated with HCC risk and outcomes[72,74,84-87]. The exact mechanism underlying the role of this mutation in hepatocarcinogenesis is still unknown. However, some underlying mechanisms have been recently elucidated. The mutation can cause a substantial decrease in HBeAg expression and enhancement of viral genome replication, which contribute to the liver disease progression *via* increased inflammation and viral invasion[88,89]. The mutation also leads to a truncated HBx protein, which not only promotes hepatocellular proliferation but also enhances HCC cell invasion and metastasis[90,91]. In particular, in chronic patients infected with genotype C2, this mutation is reported to be related to HBV genome deletion[26,31] or to be positively correlated with HBx M5V/L or H94Y mutations[28,37]. In addition, it may also contribute to hepatocarcinogenesis *via* reduced p21 expression, leading to rapid and uncontrolled cell proliferation[92]. A recent meta-analysis by Yang *et al*[82] revealed that the BCP mutation is present at significantly higher frequencies in HCC patients than in non-HCC controls, including patients with liver cirrhosis, chronic hepatitis and asymptomatic carriers. Our previous data using a Korean cohort with genotype C2-infected chronic patients also showed that the BCP mutation was the most frequently encountered mutation related to clinical severity (66.1%, 123/184 strains) and was significantly related to HCC [HCC (86.7%) *vs* chronic hepatitis (61%), $P = 0.017$; HCC (86.7%) *vs* asymptomatic carrier (24.4%), $P < 0.001$][28]. Our data also showed that during the natural course of HBV chronic infection, the most significant rise in the rate of the BCP mutation was found during the progression from asymptomatic carrier to chronic hepatitis (24.4%-61.0%), suggesting that the BCP mutation may play a major role in liver

Table 1 Mutations in the hepatitis B virus X region as related to clinical severity

disease progression, especially in the progression from asymptomatic carrier to chronic hepatitis in chronic patients infected with genotype C2[28]. This finding has also been confirmed by a recent meta-analysis[82]. Yang *et al*[82] also demonstrated that HBV-infected patients with genotype C, including HCC patients, have a significantly higher risk of BCP mutation compared with those with genotype B, suggesting that the BCP mutation can increase the risk of HBV-related hepatocellular carcinoma, particularly in an HBV genotype C population.

An HBV genome transfection-based experiment indicated that the BCP mutation can reduce the synthesis of HBeAg and enhance viral replication. However, a meta-analysis and our previous report also showed that there is no significant difference in BCP mutation prevalence between HBeAg-positive and HBeAg-negative chronic HBV-infected patients[28,82], suggesting that BCP mutation may occur in the HBeAg-positive immune tolerance phase earlier than in the HBeAg-negative immune clearance phase, at least in chronic patients infected with genotype C2.

The other HCC-associated T1753V mutation (I127L,T,N,S: T→V of nt 1753) was also shown to affect HCC survival[93,94]. The mutations in the HBx protein, which include an I127L,T,N,S amino acid substitution, can change the HBx binding affinity to BCL2, thereby affecting HBx-induced apoptosis[95]. Our previous data using Korean HBV-infected patients with genotype C2 showed that the prevalence of this mutation was also significantly higher in chronic patients with severe liver disease, HCC or liver cirrhosis than in patients who had milder types of diseases, were carriers or had chronic hepatitis [HCC and LC (34.3%) *vs* chronic hepatitis and carrier (13.4%), $P < 0.001$][28]. The other study using chronic patients from India who had genotype A or D revealed that this mutation is also usually associated with advanced forms of liver disease and had an increased risk of HCC[69], suggesting that the T1753V mutation may play a significant role in liver disease progression. Our previous report showed that the T1753V mutation is significantly related to the BCP double mutation [patients with the BCP mutation (31.7%) *vs* patients without the BCP mutation (11.5%), $P = 0.003$], but not to HBeAg serostatus[28]. A recent multivariate survival analysis by Xie *et al*[66] showed that the T1753V mutation is an independent predictor of HCC survival.

The C1653T mutation, leading to a simultaneous H94Y amino acid change in HBx, is located in box α, which is a strong activation element of the EnhII/core promoter, can enhance the box α binding affinity and EnhII/core promoter activity[96,97]. Because many trans-regulated nuclear factors bind HBV at the 1653 site, this mutation can alter the binding affinity of these nuclear factors. The C1653T mutation has been recently reported to be a predictive factor for HCC in Japan[75,98] and is associated with fulminant hepatitis and the acute exacerbation of HCC[99,100]. A recent multivariate survival analysis by Xie *et al*[66] showed that the C1653T mutation together with the T1753V mutation is also an independent predictor of HCC survival. Furthermore, our previous report showed that the C1653T mutation is significantly related to advanced liver diseases in Korean patients with genotype C2 infections [patients with HCC or LC (36.3%) *vs* patients who have chronic hepatitis or are carriers (12.2%), $P < 0.001$]. It has been reported that the C1653T mutation, together with 1762T/1764A mutations, can reduce the pre-C mRNA level (to approximately 55%) and HBeAg secretion in a transient transfection system using Huh7 cells[101]. Our previous study also demonstrated that this mutation tended to be related to an HBeAg-negative serostatus ($P = 0.087$) and was significantly related to the BCP mutation [patients with the BCP mutation (35.0%) *vs* patients without the BCP mutation (6.6%), $P < 0.001$].

Mutation in the negative regulation domain of HBx (aa 1-50) (A1383C, G1386A/C-V5M/L, C1485T-P38S)

The A1383T synonymous mutation, which does not cause an amino acid change in the HBx protein, is located in the negative regulation domain of HBx (aa 1-50), and this mutation was first found to be associated with HCC in a Korean cohort[28]. In one clinical study using Chinese cohort mostly infected with genotype B and C, this mutation was also associated with a worse prognosis in patients after liver transplantation[66]. Recently, a comprehensive analysis study based on global data by Li *et al*[67] showed that A1383T is one of the HBx mutations identified as independent risk factors for genotype C HBV-related HCC. It has also been reported that tumor suppressor microRNA 15a/16 (miR-15a/16) can directly target the wildtype HBx RNA sequence (nt1362-1383), inducing Bcl-2 expression by acting as a sponge to bind and sequester endogenous miR-15a/16. Consequently, this mutation can lead to a reduced binding capacity of miR-15a/16 to the HBx protein[47], which can prevent the infected cell from apoptosis by altering critical cell signal pathways and thereby contributing to hepatocarcinogenesis.

The G1386A/C mutation leading to a simultaneous V5M/L amino acid change at codon 5 of the HBx protein was first introduced by our previous study using a Korean cohort with genotype C2 infections[28]. Our data showed that this mutation was significantly more frequently found in HCC patients than in patients in other disease groups. Notably, the prevalence of this mutation was abruptly increased in HCC patients rather than in liver cirrhosis patients during disease progression (HCC *vs* liver cirrhosis; 49.2% *vs* 25.6%, $P = 0.024$), strongly suggesting that this mutation is a genuine HCC-specific mutation that possibly plays a pivotal role in the progression from liver cirrhosis to HCC[28]. Recently, the combination of both BCP double

mutations and both types of the V5M mutation, V5M and V5L, has also been reported to increase the HCC risk by 5.34 times compared with the wild type by inducing a higher NF-κB activity in transformed cells[86]. Our previous report showed that this mutation is significantly related to an HBeAg-negative serostatus [HBeAg-negative patients (40%) *vs* HBeAg-positive patients (19.1%), $P = 0.004$], suggesting that it may be generated from the immune clearance phase[28]. This mutation was also significantly related to the BCP mutation [patients with the BCP mutation (36.6%) *vs* patients without the BCP mutation (9.2%), $P < 0.001$]. To date, its clinical relevance has not been introduced except for a Korean cohort with genotype C2 infections. It is tempting to speculate that this mutation may play a pivotal role in hepatocarcinogenesis during the HBeAg-negative immune clearance phase during the natural course of genotype C2 HBV infection.

The C1485T mutation, leading to simultaneous P38S in the HBx protein, were first introduced as an independent risk factor for HCC development in a study by Muroyama *et al*[70] using a Japanese cohort with genotype C infections. Both studies using Korean cohorts with genotype C2 infections[28,68] and a recent investigation based on global data by Li *et al*[67] also revealed that this mutation is significantly related to HCC. A functional study supporting the relationship between the mutations with HCC still remains to be conducted. However, given that its mutation site is located at the B cell epitope region (Figure 1), this mutation may lead to persistent infection by providing a mechanism of evading the humoral immune response of the host.

Deletions or insertions in the C-terminal region of HBx

The C-terminal region of HBx plays a key role in controlling cell proliferation, viability, and transformation[102-105]. Therefore, C-terminally deleted or inserted HBx has reduced transactivation activity and inhibitory effects on cell proliferation and thus may contribute to HCC generation[106]. Moreover, its reduced transacting capacity might reduce HBV replication[107]. The C-terminal deletion or insertion is one of the most frequently reported mutations of HBx and has been frequently detected in tissues and serum samples from HCC patients, irrespective of genotype or geographical distribution[24,108,109]. Our previous report using a Korean cohort with genotype C2 infections showed that the prevalence of deletions or insertions was significantly higher in patients with severe liver disease, HCC, or cirrhosis of the liver (7.2%, 10/132), compared with patients who were carriers or had chronic hepatitis (1.5%, 2/135) ($P = 0.017$)[31]. All deletions in six strains were concentrated at the C-terminal end of HBx, encompassing the 113th to 154th codons. Four types of insertions (PKLL, GM, FFN, and tt) were observed in six patients. Notably, all insertions were accompanied by a BCP double mutation[31] (Figure 2). Furthermore, we first introduced a novel HBxAg vaccine escape mutation, X8Del with an 8-bp deletion in the C-terminal region of the HBx gene from 6 vaccinated Korean subjects[38]. Our *in vitro* and *in vivo* studies showed that this mutation causes a reduced secretion of HBsAg and HBV virions compared with the wild type, suggesting that the X8Del mutation may contribute to occult HBV infection in vaccinated individuals *via* the reduced secretion of HBsAg and virions, possibly by compromising the transacting capacity of HBxAg[38].

Other HBx mutations related to clinical severity

Recently, Xie *et al*[66] have reported 8 HBx mutational sites identified as significant independent risk predictors of HCC survival: 1383, 1461, 1485, 1544, 1613, 1653, 1719, and 1753 from a Chinese cohort mostly infected with genotype B and C. Despite the fact that the G1461V mutation is located at the B cell epitope, it (as a synonymous mutation) did not cause any simultaneous amino acid change in the HBx protein. Its regulatory modification in host cell or virion replication remains to be solved. The T1544V mutation also did not cause an amino acid change in the HBx protein. The G1613A mutation in the core promoter region is also a synonymous mutation, and its relationships with HCC have been reported in other previous studies.

Mutations in the BH-3-like motif of HBx can interfere with its interaction with two other Bcl-2 family members (Bcl-2 and Bcl-xL, which are critical for HBx to increase the intracellular calcium concentration), playing a significant role in viral replication and cell death[110]. Previous studies have reported that several types of mutations in the BH-3-like motif, T/G1719G/T, T1724C, and T1741C, were also significantly related to HCC[66,67,79].

The T1800C mutation leading to a simultaneous C143R amino acid change in the HBx protein is a novel genotype C HCC risk mutation identified by the Li *et al*[67] study, based on global data. To date, the function of this mutation in HCC remains unclear. However, of note, a recent study regarding HBV integration sites in 88 Chinese HCC patients showed that almost 40% of the integrated HBV genomes were cleaved at approximately nt1800, suggesting a potential role of this site in carcinogenesis, given that HBV genome integration has long been considered an important factor in HCC development.

CONCLUSION

In conclusion, HBx mutations may affect not only the HBx ORF but also the overlapped cis-elements. Considering all the HBx mutations related to clinical severity, the A1762T/G1764A BCP mutation is one of the most frequently encountered HBx mutations and plays a significant role in liver disease progression in

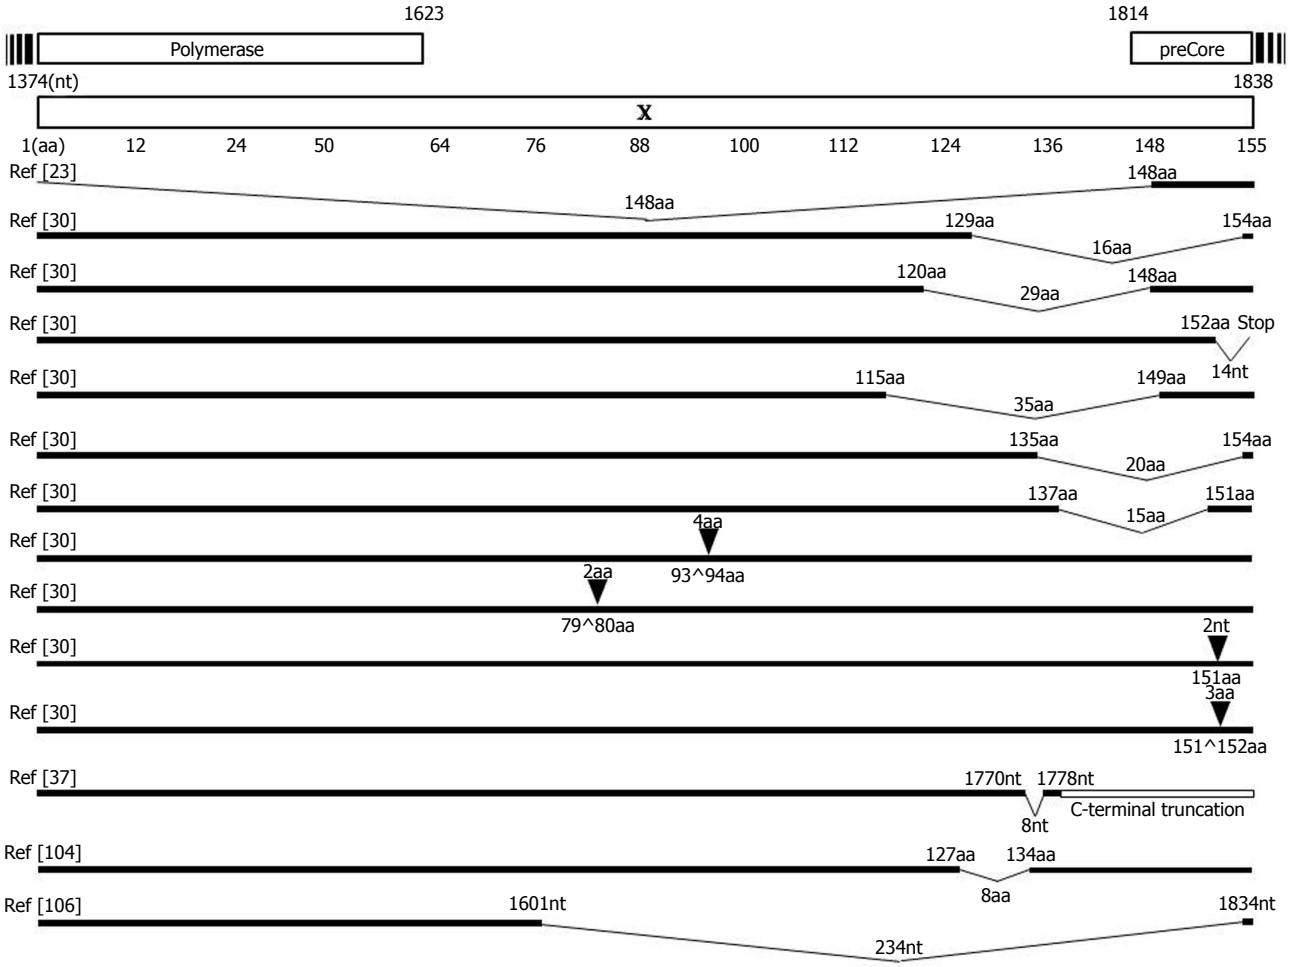

Figure 2 Mapping of deletions or insertions in the hepatitis B virus-X protein region. Deletions or insertions in the HBx region mainly occur in the C-terminal region of HBx, which may also contribute to the clinical outcome severity in chronic patients. HBx: Hepatitis B virus-X protein.

chronic patients with HBV infections. It also further contributes to disease progression by inducing mutations of other HBx mutations related to clinical severity, such as G1386A/C (V5M/L), C1653T (H94Y), T1753V (I127V) and HBx C terminal deletion or insertion. Moreover, T1753V (I127L,T,N,S) and C1653T (H94Y) mutations in the EnhII/BCP region and A1383C, G1386A/C (V5M/L) and C1485T (P38S) in the negative regulation domain were significantly related to severe types of liver diseases, including HCC. Furthermore, deletions or insertions affecting the C-terminal region of HBx can also contribute to the clinical outcome severity in chronic patients. In addition, our recent study indicated that a novel mutation type (X8Del) composed of an 8-bp deletion in the C-terminal region of the HBx contributes to occult HBV infection in vaccinated Korean individuals *via* a reduced secretion of HBsAg and virions. Thus, several distinct types of HBx mutations may contribute to HBV pathogenesis by regulating HBV replication or host genes related to cell homeostasis.

Abstract

Much has been written about hepatic metastasis and animal models abound. In terms of the human experience, progress in treating this final common pathway, a terminal event of many human malignancies has been relatively slow. The current thinking is that primary prevention is best served by early detection of cancer and eradication of early stage cancers by screening. Some cancers spread early in their course and the role of screening may be limited. Until relatively recently there has not been a pathfinder model that makes the evasion of this unfortunate event a reality. This review discusses such an animal model and attempts to relate it to human disease in terms of intervention. Concrete proposals are also offered on how scientists may be able to intervene to prevent this deadly progression of the cancer process.

Key words: Cotton top tamarin; Hepatic metastasis; Carcinoembryonic antigen; Fibulin-5; Common marmoset

Core tip: Hepatic metastasis is a terminal event. Avoiding this complication would prolong life and current understanding of inflammatory mediators allows possible secondary intervention. The cotton top tamarin (CTT), like humans develops inflammatory bowel disease complicated by colorectal cancer but avoids liver metastasis. We suggest 5 mechanisms by which CTT avoid liver spread. They involve changes in ICAMs and their receptors, carcinoembryonic antigen (CEA) family mediators of angiogenesis, post translational modifications of molecules like CEA, and increased expression of anti-proliferative agents such as fibulins. This changes our perception from "monkey

see, monkey do" to "see what the monkeys do and do the same". Possible avenues of intervention are suggested.

INTRODUCTION

There are many animal models for human cancer and most of these do not occur naturally but are designed to mimic human disease by introduction of mutagen and may also employ promoters. Natural models lack this human "design" element but historically the differences may enhance understanding of disease causality and management for example, the Roux Sarcoma virus in the Plymouth Barred Rock fowl (chickens) and Bittner milk factor in murine mammary carcinoma among others. It is however unusual for a single animal to provide more than 1 natural model for disease[1].

Enter the cotton top tamarin (CTT), a pint-sized lower order, New World primate of the order Callitrichidae[2]. This remarkable monkey provides a model for human disease in inflammatory bowel disease and potential mechanisms[3,4], cancer of the lymphatic system[5], large bowel cancer[6], and immune-altered states[7], and recently liver metastases[8]. While a review of these models apart from the latter is beyond the scope of this review, it is significant that the example of the liver metastasis model could best be described as a "negative" or "avoidance model" in that the CTT with colon cancer avoids liver metastasis with an estimated frequency of 97.2%.

The hypotheses of how the CTT achieves this are open for discussion and debate has been ongoing since the first symposium, reported in 1985[9] where anatomical blood vessel variance was advanced as an explanation. This was refuted by veterinarians since the anatomy is similar to most mammals including humans (N. Clapp- personal communication). Our group has been exploring hypotheses based on adhesion molecules known to be important in human liver metastasis. While the article will focus on these molecular families in tamarins, it is important to first discuss our understanding of their importance in human "metastogenesis" as the findings in the CTT may enable intervention in the human where over 70% of GI cancer victims succumb to death caused by hepatic metastases.

Hypotheses of hepatic metastases in humans

Cancers of the colon and rectum comprise 14.5% of all cancers diagnosed in the United States (149880) and 11.1% of cancer deaths (51710) each year[10]. The primary treatment for large bowel cancer is surgery. Patients who recur do so largely in the liver, lung or peritoneum. While combination chemotherapy can increase survival even in advanced disease it is rarely long term. Metastatic colorectal cancer is therefore a major public health problem. Colorectal cancer is associated with chronic inflammation[11-13]. Inflammatory cytokines can be induced by interaction of terminally differentiated macrophages with the cancer associated glycoprotein carcinoembryonic antigen (CEA)[14]. CEA (CEACAM5) is a large heavily glycosylated glycoprotein of indeterminate function in the normal tissue in which it is expressed[15,16]. Discovered in 1965 by Gold and Freedman[17] it has become the most used tumor marker for colorectal cancers but failed to live up to the early expectations for use as an early detector of cancer[15,18]. It is a glycoprotein that is a member of a large gene family that consists of 29 genes divided into three subgroups that include the CEA-like glycoproteins and the pregnancy-specific glycoproteins (PSGs)[19]. These CEA like proteins are members of the much larger immunoglobulin supergene family[15]. The nomenclature for the entire CEA and PSG families is published in Beauchemin *et al*[20].

CEA

CEA is a GPI anchored glycoprotein with an average MW of 180 kDa this varies depending on the degree of glycosylation of the native protein. CEA contains 651 amino acids and these are found in 7 immunoglobulin like domains, an IgV domain at the N-terminus and six disulfide bridge linked IgC domains[15,16]. There are 29 possible sites for N-linked glycosylation and they tend to be of the complex tetra antennary type[15]. Recently a large number of functions in cancer cells have been attributed to CEA. These include a role in cell-cell adhesion[21,22], apoptosis (anoikis)[23], inflammatory responses leading to increased hepatic and possibly lung metastasis[14] and angiogenesis[24].

CEA AND ITS IMPACT ON LIVER METASTASIS: INDUCTION OF INFLAMMATORY RESPONSES IN THE LIVER

Liver metastasis is the major cause of death in patients with colorectal cancers. There is good evidence that cytokines play a major role in preparing the liver for implantation and subsequent growth of cancer cells[14]. It appears that a relationship exists between the colon cancer derived glycoprotein CEA and macrophage related cytokine production particularly associated with CEA Kupffer cell interactions in metastasis of colorectal

cancers to the liver. The discovery of CEA in 1965[17] marked a turning point in the study of cancer and led what might be called the age of tumor markers. CEA was the first commercially available tumor marker and may be considered the prototype[25]. Serum elevations of CEA (above 3 ng/mL) are seen in about 60% of colorectal cancer patients at presentation[26] and elevated levels are also seen in a number of other cancers including breast, gastric, lung and pancreas. Unfortunately, the early premise that CEA levels could be used as a screening test for colorectal cancer was not fulfilled. CEA was found not to be cancer specific and high false positive and false negative rates precluded its use in early detection of cancer. However, CEA is a useful marker in the determination of prognosis[27] and for detection of recurrence in the post-surgical follow up of colorectal cancer patients[28]. CEA has also been used for the detection of occult tumor by radioimmuno-detection[29] and as a target for treatment using radioimmuno-therapy[30]. In addition a number of studies have used CEA as the target antigen for immunotherapy[31]. Clinically CEA is very well understood, but its biological role is not clear and its function in the normal colonocyte still evades us. However over the years a number of functions mostly associated with tumor cell behavior have been attributed to CEA. We focused on the molecular interactions between CEA and its receptor CEAR in colorectal cancer cells and how disruption of these interactions and inhibition of cytokine production will affect the spread and growth of colorectal cancers. Designing an effective mimetic-based therapy requires the identification of the responsible molecules, mechanisms of action and regulation.

The most important functions of CEA are the effects associated with tumor cell survival whether it is at the primary site or at a distant metastasis. High levels of CEA are also associated with malignant ascites from colorectal cancer (CRC)[32]. CEA interacts with liver Kupffer cells through a cell surface receptor (CEAR) that we have identified as the heterogeneous RNA binding protein (hnRNP) M4[33]. The hnRNP group of proteins are multifunctional and are involved in many cellular events including alternative splicing, translational regulation and packaging of transcripts[34]. These proteins have also been implicated in the regulation of mRNA stability and translation in many cancers[35]. CEAR is a highly conserved protein that can bind both RNA and DNA and can transport mature RNA to the cytoplasm as well as acting as a splicing factor[36]. It can also be expressed both on the cell surface, in the cytoplasm and in the nucleus where it is most commonly found[37]. There are 4 isoforms of hnRNP M known[38]. Two of which we have shown bind CEA[33]. One form (hnRNP M4) which we originally identified as the CEA receptor has a 38 amino acid deletion between the first and second RNA binding domains. The longer form also binds CEA[33]. The two other forms have not been identified other than as proteins on 2D gels. CEAR will also bind to CEA in HT-29 colon cancer cells although the functional significance of this is not known. It has been suggested that it may be involved with the resistance afforded to anoikis[39,40]. Binding to CEAR occurs *via* a penta-peptide motif (PELPK) located at the hinge region between the CEA's N-terminal and first immunoglobulin loop domain. This interaction produces cytokines by activating a signaling cascade and these cytokines alter the liver microenvironment such that it becomes more hospitable to the implantation and growth of the cancer cells[41,42]. Production of both IL-6 and IL-10 by CEA stimulated Kupffer cells improves the survival of highly metastatic human colorectal cancer cells in the nude mouse intra-splenic injection model for liver metastasis[43] (see Figure 1).

CEA AS AN ADHESION MOLECULE

In 1989 Benchimol *et al*[22] demonstrated the first potential function for CEA. By transfecting tumor cells with the CEA gene they showed increased cell to cell adhesion and demonstrated that this could be inhibited using anti CEA antibodies. Adhesion was due to interactions between the N-terminal and the 5th and 6th (A3B3) immunoglobulin domains[44]. This suggested that these interactions may play a role in tumor cell behavior and in the development of metastases.

CEA AND ANOIKIS

Another important function that has been attributed to CEA expression is inhibition of apoptosis in particular the apoptosis caused by absence of attachment of cells to a substratum (anoikis)[23,40]. This would play an important role in metastases formation to a distant organ as unattached tumor cells in the circulation would be more susceptible to anoikis.

CEA AND ANGIOGENESIS

Here, we suggest a relationship between CEA, its receptor CEAR and angiogenesis. Others have also suggested a relationship between CEA and angiogenesis though they did not establish it as causal or identify potential mechanisms[45,46]. Recently, however they showed that secreted (soluble) CEA can directly activate endothelial cells *via* integrin β3 signaling[24,47]. We suggest that an alternate mechanism may also exist involving the relationship between CEA and its receptor CEAR. Interaction of CEAR with CEA in tumor associated stromal cells particularly macrophages is important. Disrupting that relationship may affect tumor growth and progression

It is significant that Low-Marchelli *et al*[48] have shown that CCL2 recruits macrophages to promote angiogenesis. We therefore suggest that colon cancer cells recruit macrophages by secreting MCP-1 and these macrophages are activated by tumor derived

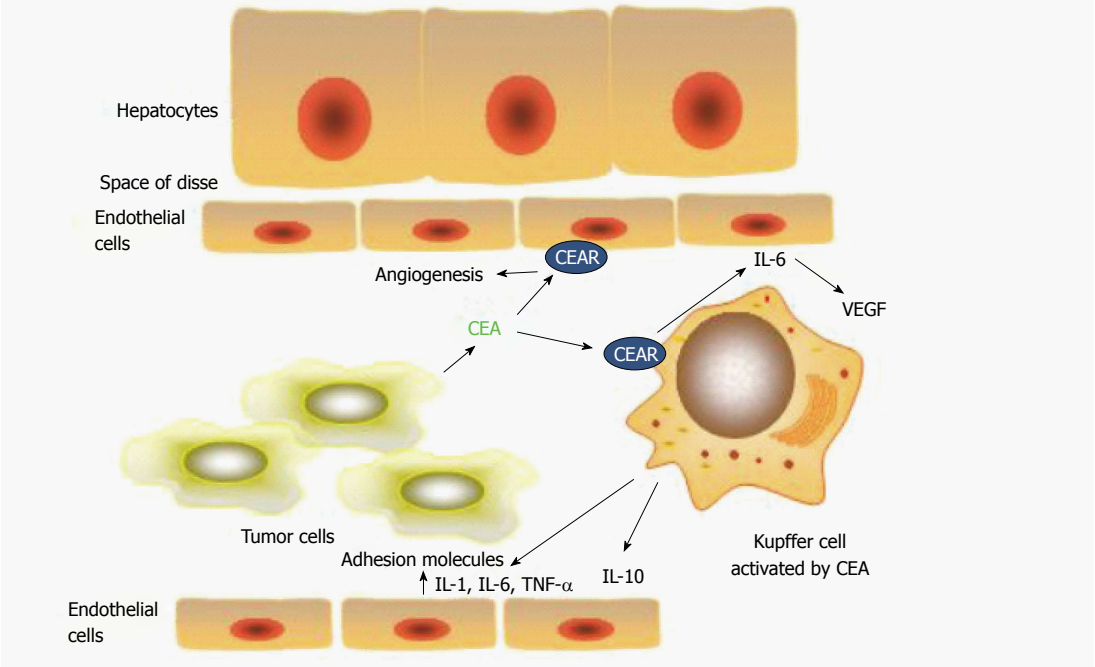

Figure 1 Schematic of the interactions of carcinoembryonic antigen in the hepatic sinusoid. Interactions of carcinoembryonic antigen (CEA) in the hepatic sinusoid. CEA released by the tumor cell binds with hnRNP M (CEAR) on the Kupffer cell surface resulting in release of the cytokines interleukin (IL)-1, IL-6, IL-10 and TNF-α. Effect of CEA induced cytokines on tumor cell interactions in the hepatic sinusoid. Cytokines IL-1, IL-6, IL-10 and TNF-α produced by Kupffer cells have a number of effects on the tumor cell microenvironment. These include up-regulation of adhesion molecules on hepatic sinusoidal endothelial cells. The most important of these seem to be E-selectin and ICAM-1. Cytokines such as IL-6 and IL-8 are pro-angiogenesis and they may also effect growth at the distant site[14,42].

CEA to secrete IL-6 and IL-8 both known pro-angiogenic factors[49]. Anti angiogenic factors are also produced (IL-10) and an imbalance between these two competing factions will tend towards pro-angiogenesis.

TARGETING CEA/CEAR INTERACTIONS AS A MEANS OF INHIBITING CYTOKINE PRODUCTION AS AN ANTI-METASTATIC THERAPY IN COLORECTAL CANCER

Because transformed cells home into tissues from the circulation in a highly selective way through complex molecular mechanisms, it provides a template for targeted therapy. Designing an effective mimetic-based therapy requires the identification of the responsible molecules and their mechanisms of action along with their regulation. The investigation of methods to block or modulate CEAR function *in vitro* and *in vivo* and relating this to tumor growth and development will increase our understanding of the molecular and biological mechanisms involved in the progression of gastrointestinal cancers. The investigation of methods to block or modulate CEAR function *in vitro* and *in vivo* and relating this to tumor growth and development has increased our understanding of the molecular and biological mechanisms involved in the progression of colorectal cancers. We have shown that the binding peptide YPELPK will induce cytokine responses in macrophages activated by CEA[50]. We have shown that the binding peptide YPELPK will induce cytokine responses in PMA activated THP-1 macrophages. These types of study are important for the development of rational therapies that will enhance those currently available.

OTHER POTENTIALLY PRO/ANTI-METASTATIC MOLECULES STUDIED

Fibulin-5

During the initial development of metastasis, the adhesion of tumor cells is mainly mediated through binding of extracellular matrix components to cell surface receptors[51]. Interestingly, one study[52] found an association of fibulin-5, the newest member of the fibulin family of extracellular matrix glycoproteins, with hepatic metastasis of colorectal carcinoma. Since fibulin-5 plays an important role in antagonizing angiogenesis[51-53] in humans, we sought to confirm the expression of fibulin-5 expression level in the CTT.

Avoidance hypotheses in the CTT

Our understanding of cancer and metastases in primates began when colon cancer was described in old world monkeys as early as 1914 and then in the new world in inter alia, Goeldi's monkey in the early 1960s. The latter, *Callimico goeldii* shares the Colombian habitat with the CTT and is a small black-furred New World lower order primate. At that time tens of thousands of CTT were imported by the pharmaceutical industry utilizing the "tamarin alarm reaction" to test the efficacy of anxiolytics although literature to document

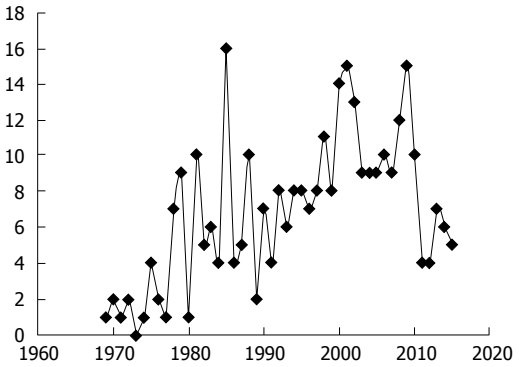

Figure 2 Graphic representation of published cotton top tamarin articles by year as estimated by a typical online search. The line chart is not necessarily inclusive of all cotton top tamarin (CTT) articles but merely confined to the search terms used. It is therefore used mainly to demonstrate the overall trends in annual publications devoted to this animal "CTT supermodel".

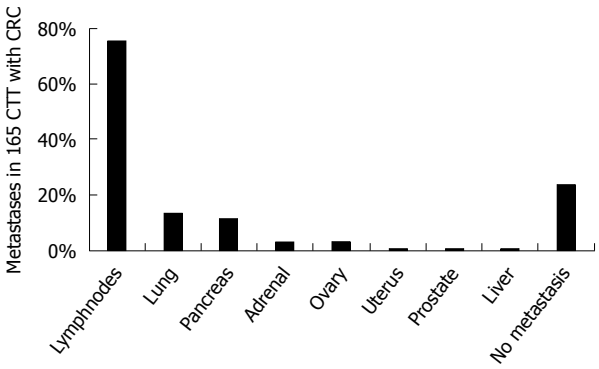

Figure 3 Schematic bar diagram depicting proportion of metastases in cotton top tamarin with colorectal cancer. The bar diagram shows the distribution of metastasis based on the ORAU colony cancer statistics. The paucity of liver metastases is remarkable. CTT: Cotton top tamarin; CRC: Colorectal cancer.

this is difficult to come by utilizing electronic search methods. Problems of CTT husbandry arose when the animals developed the "wasting marmoset syndrome"[54] postulated to be caused by a coronavirus but later effectively countered by improving the nutritional intake. The major challenge facing the CTT is the reduction of its numbers in its shrinking natural habitat in northwestern Colombia and most CTT are today found in zoos. As a result the species was listed as endangered in 1973 by the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES)[55]. Since that time, the numbers of articles on the CTT had increased exponentially. This attests to the interest of the scientific community in the CTT specifically. Despite this interest, primate research in the United States is in decline with the closures of the ORAU (Oak Ridge Associated Universities) facility and that of the NEPC (New England Primate Center) which housed a significant proportion of CTT. The waning of public support and therefore funding opportunities combined with the expense of operations has largely been the cause of this decline. This is regrettable as it is generally not appreciated that monkey publication numbers are an extensive part of the scientific literature (678000 Medline™-listed publications) attesting to their usefulness and their command of the attention of the scientific community. Now, specifically CTT publications which were formerly about one tenth of non-human primate-themed publications (398 total CTT per National Library of Medicine ticket 28045-54653), are in decline in the example depicted graphically (Figure 2).

In view of the importance of this animal model applicable to many models of human disease, a CTT symposium was convened resulting in the publication of numerous articles in a supplement published in the journal Digestive Diseases and Sciences in 1985[9]. Thereafter a comprehensive book on the CTT was edited by Dr. Neil K. Clapp and published in 1993 by CRC Press[2]. This review seeks to build on that experience specifically focusing on the ability of the CTT to avoid hepatic metastases even though a large proportion of the animals develop advanced colorectal cancer. This is a unique feature of the CTT not typically found in other marmosets. It would appear that CTT peritoneal metastasis and ascites is also not common as it is with terminal human disease.

CTT MODEL FOR HEPATIC METASTASIS

The CTT develops colitis in the juvenile years and about one third (34.5%) go on to develop colon cancer and die of the disease. An observational study showed only 1.2% of animals had hepatic metastases[56] (Figure 3).

The etiology of the cancer seems to be the de novo inflammation-dysplasia-cancer variety although animals with adenomas have been described[56]. The risk of cancer deaths shows an increase from 3-8 years and then a gradual decline after age 12 similar to the recently described risk in humans with positive family history of CRC[57]. The etiology is still unknown but stress and micro-organisms may play a role[3,4]. Over half have multiple primaries diffusely distributed but the descending colon has the greatest proportion similar to the rectosigmoid colon predominance in ulcerative colitis cancer location.

CTT COLON CANCER BIOLOGY VIS A VIS HUMAN

Despite similarities in cancer biology between CTT and humans it can be seen from Table 1 that the anticipated mutations are either not described or characterization has not been attempted.

When considering changes associated with metastases[63] no CXC, CXCR4, CXCL12 (fusins), CCR7 (chemokine receptor 7) chemokines thought to be important in metastases have been described as yet in the CTT. Interestingly CXCL12 has been described in the common marmoset[64] and thus likely to be expressed in the CTT but is not necessarily a given.

Table 1 Comparison of cancer genetics in the cotton top tamarin and human

Stage of neoplasia	Sporadic human CRC	Human IBD-associated CRC	CTT colitis-CRC
Normal-appearing mucosa	*APC* initiator	Inflammation leading to mutations listed below	No cell line mutations in APC exon 4 and 15[58]
Early adenoma/indefinite dysplasia	Aneuploidy, methylation, Sialyl Tn	Aneuploidy, methylation, Sialyl Tn, MSI	90%diploid; no methylation[59]
Early promotor	MSI; *kRAS*, COX-2	DCC	kRAS absent[60]
Intermediate adenoma/low-grade dysplasia	c-src	c-src	c-src ND
Intermediate promoter	DCC/DPC4	*kRAS*	DCC/DPC4 ND; kRAS absent[60]
Late promoter	p53	*APC*	p53 ND; as above for APC exon 4 and 15[58]

Adapted from Itzkowitz and Harpaz 2004[61]; and Mattar MC, Lough D, Pishvaian MJ, Charabaty A[62]. APC: Adenomatous polyposis coli gene; MSI: Microsatellite instability; DCC: Deleted in colon cancer; *kRAS*: V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; COX-2: Cyclooxygenase 2 gene; c-src: Rous sarcoma gene that encodes for usual C-terminal inhibitory phosphorylation site (tyrosine-527); DPC4: Deleted in pancreatic carcinoma, locus 4; p53: Protein 53 kilodaltons; ND: Not done.

The human kallikrein zymogens (hK2) closely related to prostate specific antigen (PSA) have been studied in the CTT[65]. They concluded that the CTT has no functional hK2 or PSA. Since these moieties regulate cancer cell survival and growth the CTT may be a natural knock-out model for the study of this topic. We see in these findings yet another potential mechanism by which the CTT impedes cancer proliferation. Likely Toll-like receptors (TLR) also remain to be discovered in the CTT and may have likely similar functions to the human.

Since lectins[66] and adhesion molecules have been described in the CTT we have focused our attention on these molecules, particularly CEA. We also explored extracellular matrix proteins as the interaction between these proteins and cells play an important role in tumorigenesis and metastases. One such protein, fibulin-5[51-53] has calcium-binding EGF-like domains and associate with vascular and vascular structures. It is thought therefore to have anti-angiogenic actions and be an inhibitor of metastasis. It has not as yet been studied in the CTT.

CEA HOMOLOGUES IN THE CTT AND HUMAN

Cross reactive CEA species in monkeys were known when we published our seminal paper in 1994[67]. Haagensen *et al*[68] had reported CEA in higher order non-human primates, including the chimpanzee and gorilla. A mouse analogue had also been described by Abraham Fuks' group in 1989[69]. Our initial experiments used a number of antibodies to CEA including the T84.66 antibody developed by Dr. J. Shively's laboratory group at the Beckman Institute at the City of Hope which was used in the CEA kit commercialized by Roche™. This antibody when used in immunohistochemistry produced consistently negative results when using colon CTT fixed tissues and later native antigen in CTT colon tissue extracts in early experiments[70]. We tested other antigens such as organ specific neoantigen[71], thought to be the mediator of the lymphocyte adherence inhibition test for cancer and found reactivity[72]. In the early 1990's Karel Kithier of the Department of Pathology at Wayne State University was beta-testing a CEA kit produced by Tosoh Medics (CEA-AIA PACK kit™) which seemed to have a greater proportion of positive results when compared to another CEA kit marketed by Abbot. These results were expanded and confirmed and found to yield similar levels in CTT and humans with IBD[60,73] which opened a pathway to possible intervention[33] in addition to other cancer related moieties such as telomerase[60]. In order to show the CEA molecular moieties recognized by the kit we obtained both solid phase and tracer antibodies from Hybritech Inc., from Dr. Harry Rittenhouse. The resultant Western blotting[67] showed a specific 50 kDa band shared by CTT and humans (Figure 4).

A control blot using T84.1EC monoclonal which reacts with both NCA and CEA did not recognize the 50 kDa shared antigen in the same samples. Based on the known epitopes on the antibodies concerned we were able to speculate that the shared antigen included the Ig-like loop domains however the exact structure of this moiety remains unknown. In this publication we did hypothesize that "the smaller CTT CEA molecule might lack the critical peptides necessary for uptake and hence explain the paucity of liver involvement in CTTs with CRC".

EXPRESSION OF THE CEA GENE FAMILY OF PROTEINS IN THE CTT AND HUMANS

The next question we needed to answer was if an entire repertoire of CEA-family adhesion molecules were expressed by the CTT and if this subspecies was unique in this respect in the *Callitrichidae* family. In a later paper in 2000[73] we explored these questions by expanding the repertoire of antigens and extending our observations to include a close cousin of the CTT, the common marmoset (Callithrix jacchus - CM) which is

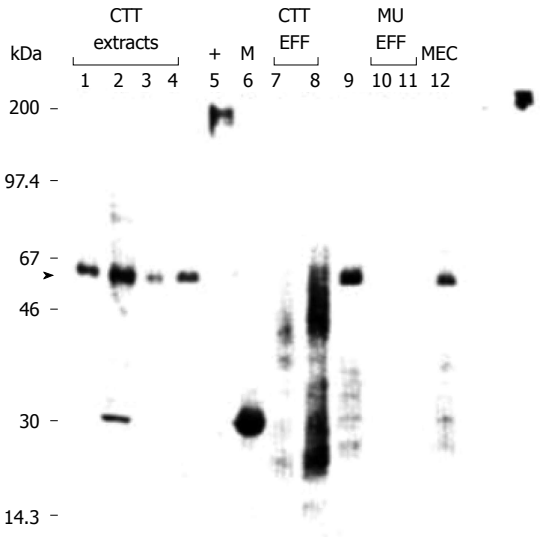

Figure 4 Specific carcinoembryonic antigen bands shared by cotton top tamarin and humans. Western blot using solid phase anti-CEA monoclonal antibody. Immunoblotting was performed using 5.6 pg protein/ml antibody after electrophoresis of a 12% SDS-polyacrylamide gel run under reducing conditions. Relative mobility (M) is shown on the left, and the type of samples loaded at 10 pg protein/lane are shown above the numbered lanes. Cotton-top tamarin extracts are in lanes 1 to 4 and effluent samples in 7 and 8. An extract from a patient with histologically proven rectal cancer and IBD is in lane 9, with human effluent samples in lanes I0 and 11 and human meconium in lane 12. Lane 5 contains the positive human CEA control, and the M, markers (M) are in lane 6. An arrow indicates the M, - 50000 band evident also in human extract (lane 5) likely a deglycosylated moiety. (Published with permission of Elsevier[67] and modified). CEA: Carcinoembryonic antigen.

not endangered but does develop colitis uncomplicated by cancer. Aware that the changes likely to influence CEA uptake were at the N-terminal end of the CEA molecule we used antibodies directed at epitope in that region, including the aforementioned Tosoh Medics™ kit and T84.66 antibody to quantify the CEA in colonic washings.

We found that the concentration of CEA in washings was sevenfold times higher than in washings from humans with IBD. T84.66 antibody was able to demonstrate a faint high MW band in a specimen of colonic washing from a CTT by immunoblot. In the Western blot using T84.66 we could now also demonstrate specific bands (immunohistochemistry had been consistently negative) in CTT washings and tissue extract of Mr $\geqslant$ 90 kDa which is the size of the non-glycosylated protein core of the CEA molecule[74]. CEA levels assayed by the Tosoh™ kit in CTT extracts were significantly higher than those from CM extracts ($P < 0.005$). Consistent with this finding was a high mean value in sera of CTT (134 ng/mL) compared to undetectable levels in the CM. NCA levels tended to be the lowest in the CTT as compared to humans and CM. Both animals' samples were low when reacted with a CEA-family antibody. In contrast binding with the anti-BGP was seen in both animals. We concluded that the similarity between human and tamarin native CEA is greater than previously believed and that it was likely that the N-terminal epitopes were conserved in the tamarins.

OTHER ANTIGENS SHARED BY CTT AND HUMANS

By the end of 2000 we published an expanded group of antibody assays involving 7 additional common epitopes representing most colonic cell types and blood group/carbohydrate antigens, some of them accepted tumor markers[60,70-76]. Mucin antigens, epidermal growth factor (EGFR) and telomerase were shared by CTT and humans but *k-ras* p21 and adenoma antigen (Adnab-9) were not. This supported the notion that carcinogenesis was likely de novo and did not progress through the adenoma-carcinoma sequence. Our finding of EGFR reactivity in the CTT provided a basis[76] for fibulin-5 role in the anti-metastatic armamentarium and OSN (by reactivity of BAC 18 monoclonal) suggesting similarities in anti-cancer immune responsiveness *via* the lymphocyte migration reaction. We were able to demonstrate also significant levels of EGFR epitope in the urine of 5 CTT (0.152 ± 0.053 absorbance OD-background at 405 μm) by ELISA. CEA reactivity with various antibodies in these samples were low (mean < 0.05). Blood Group Substances (BGS) were detectable [Span 0.063; FBB 0.103; CaCo 0.054) as were Bac18.1 (anti-OSN antibody) at 0.06]. Wild-type (Table 1) Ras p21; src, common membrane antigen (CMA), were negative corresponding to the data derived from CTT tissue. The only pieces of the puzzle missing were the questions of CEA molecular homology and how to tie the available data together to explain how the CTT dodges liver metastases.

DEFINITIVE STUDIES ON THE HOMOLOGY OF THE CEA MOLECULE

A comparative study of the C-terminus of the CEA molecule by the Stanners' group looked at multiple primate and prosimian species. The membrane linkage in CTT and other monkeys was found to be GPI anchorage rather than transmembrane (TM) seen in mice and rats[77]. This paper showed that the more versatile glycophosphatidyl inositol (GPI) linkage with a greater functionality constellation likely confers a tendency to tumorigenesis. Mutational packages evolved over time, one applicable to most primates including humans, and the second confined to the Cebidae radiation of New World monkeys leading to inhibition of cell differentiation. The rate of Ka (indicator of selective pressure acting on a protein-coding gene) nonsynonymous mutations for this radiation is 7X higher than the average Ka in primates. This led us to postulate that if such mutations occur at the C-terminus, it is quite feasible that similar mutations occur at the N-terminus where they may affect uptake of CEA, inhibiting hepatic metastases. Having

also found common CEA-family and fibulin-5 ligand antigens we resolved to also investigate for parallel pathways of metastasis inhibition.

SUMMARY: SPECIFIC METASTASIS-TARGETED STUDIES IN CTT AND HUMANS

Using DNA extracted from the CTT tissues a Hot start PCR was performed and (1) sequences around the hinge region between the N-terminal and the first loop domain of CEA obtained using a Big Dye Terminator™ sequencing kit. We also immunolabeled human and CTT liver tissue using: (2) BGP (CEACAM1) antibody kindly supplied by Christophe Wagener (University of Freiberg, Germany); (3) CEAR (CEA receptor) polyclonal antibody; and (4) an antibody directed to fibulin-5 supplied by W. P. Schiemann (Department of Pharmacology, University of Colorado, Aurora, CO, United States). Finally, (5) we deglycosylated CTT CEA to determine the degree of N-glycosylation, as glycosylation may correlate with hepatic metastases. We thus examined 5 potential ways in which the CTT may evade hepatic metastases in 10 CTT and 25 humans.

To briefly summarize the observed[8] results (Table 2) we enumerate: (1) 63% of the CTT had non-synonymous PELPK pentapeptide mutations shown to be essential for hepatic uptake of numerous groups of protein including CEA and stromelysin, laminin, complement protein *etc.* CM had the PELPK mutations

Table 3 Biological attributes of the fibulin family[51-53]

Attribute	Fibulin-1	Fibulin-2	Fibulin-3	Fibulin-4	Fibulin-5
Invasion of endothelium	Decrease	Increase	Decrease	Unknown	Decrease
Binding of tropoelastin	Moderate	High	low	Moderate	High
Effect on angiogenesis	Unknown	Unknown	Reduced	Unknown	Reduce
MMP/ fibronectin change	Increase	Unknown	Reduced	Unknown	Reduced

to a lesser extent (73% *vs* 29%, $P < 0.05$). Sequence changes in the PELPK binding motif are found in the CTT that prevent binding to CEAR and do not allow activation of Kupffer cells and thus secretion of pro-inflammatory cytokines.

This could account for the high CEA serum levels in the CTT as compared to CM and humans and contribute to the lack of liver metastasis. Zimmer and Thomas in 2001 showed in a minority of patients with advanced colon cancer all of whom had high CEA levels, changes in the PELPK sequence. CEA from these patients could not bind to Kupffer cells. These patients did not have liver metastasis though peritoneal carcinomatosis was common[78]. Serendipitously: (2) Normal sections of human livers bearing metastatic disease (our intended "negative" controls) showed translocation of the BGP to the cytosol of the hepatocyte whereas CTT livers did not have detectable BGP except in the gallbladder wall. BGP is usually a structural protein found in the bile canaliculus but conceivably, if translocated to the cytosol, may act as a downstream mediator of VEGF, facilitating the progression of liver metastasis. Human cirrhotic and hepatitis livers demonstrated orthotopic BGP compared to human livers bearing metastases ($P < 0.02$) where the BGP had translocated to the cytoplasm (Figure 5).

This may answer the age-old clinical question as to why patients with cirrhosis rarely get hepatic metastases from extrahepatic primary cancers.We also observed: (3) a diminution of CEAR staining (Figure 6) in the CTT liver sections compared to humans ($P < 0.02$), a further barrier to CEA hepatic uptake in the CTT as compared to the human liver. Surprisingly: (4) Extremely robust fibulin-5 hepatocyte labeling was detected in CTT livers (Figure 7) and finally: (5) Minimal glycosylation of CTT CEA was demonstrated as opposed to human CEA. 80% of CTT *vs* 60% of CM were positive for fibulin-5 binding with functions of the various fibulins contrasted in Table 3.

Hepatocytes were the predominant cell types expressing fibulin-5 in both types of animals but tended to be more intense (Figure 6) in the CTT (0.75 ± 0.289 and 0.4 ± 0.418 respectively) and also seen to be of the same distribution and intensity in the human liver controls. Kupffer cells did not stain ($P = 0.033$ CTT and $P = 0.09$ CM) but occasional bile duct

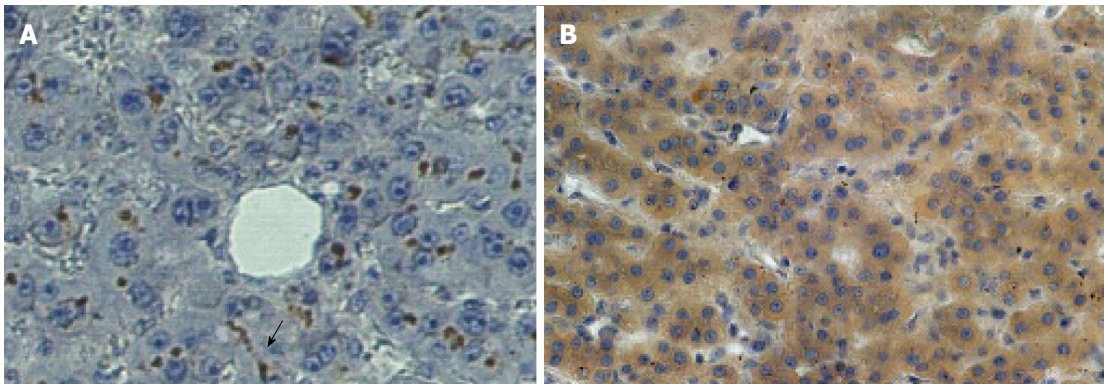

Figure 5 Distribution of CEACAM1 (BGP) in human liver. Photomicrographs of CEACAM1 staining with monoclonal antibody 4D1/C2 showing very intense brown staining mainly in the distribution of the biliary canaliculus in normal human liver (A).In contrast, in the normal portion of a liver from a patient with hepatic metastasis (B), dark staining is seen in the cytoplasm of the hepatocytes with no canalicular staining evident. Published with permission of Springer[8]. The arrow points to the typical distribution of bound ant-BGP in the bile canaliculus in the normal liver (A) at center, bottom.

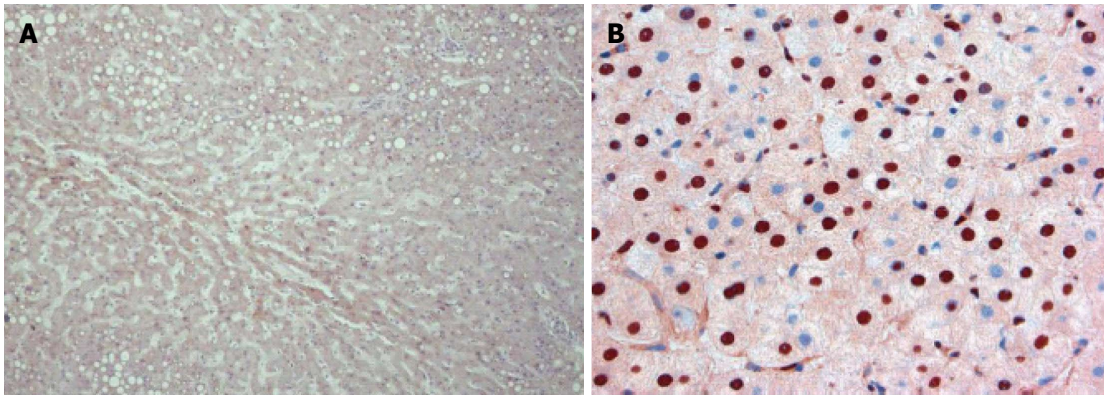

Figure 6 Distribution of carcinoembryonic antigen receptor in cotton top tamarin and human. The distribution of CEAR in the CTT (A) at low power can be seen in the cytoplasm of the hepatocyte by the light brown stain. In humans (B) at a higher power the increased intensity of staining in hepatocyte nuclei can be clearly seen. Published with permission of Springer[8]. CEA: Carcinoembryonic antigen; CTT: Cotton top tamarin; CEAR: Carcinoembryonic antigen receptor.

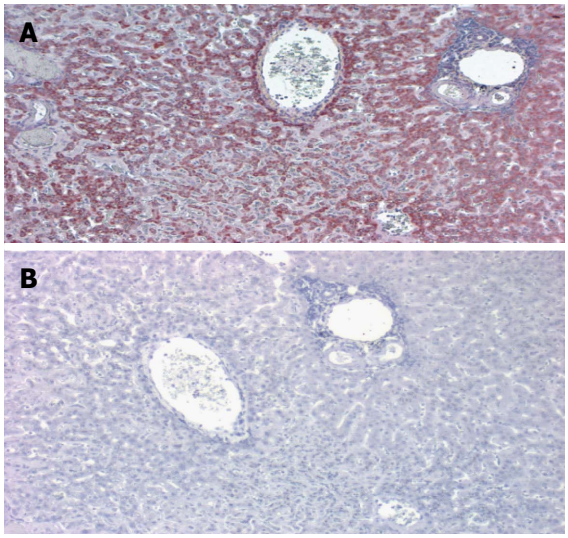

Figure 7 Immune labeling of CTT liver by anti fibulin-5 monoclonal antibody (A) and corresponding negative control (B). A: A central vein is seen in the upper center and a portal triad to the right. The dark red staining denotes the distribution of the antibody which is particularly intense surround the central vein. This is a low power magnification; B: In the negative control no staining is evident.

cells were positive but of lesser intensity in the CTT (0.125 ± 0.25 and 0.375 ± 0.479 respectively - Figure 8). Vascular staining was seen only in 2/5 CTT sections at a mean intensity of (0.3 ± 0.447). No appreciable uptake was noted in white blood cells in CTT and minimal in CM.

We therefore postulate 5 possible pathways of spontaneous hepatic metastasis evasion in the CTT, 4 of which we have previously reported[8], summarized in Table 4.

OTHER POTENTIAL ANTI-METASTATIC AND METASTOGENIC MOIETIES IN THE CTT

Lastly using the Gelco Diagnostics antibody kit to POA we determined a low level of POA[79] in extracts from CTT non-cancerous tissues 1.603 ± 1.656 μg/mL (mean ± SD). In contrast to serum in 13 humans with pancreatic cancer (9.622 ± 6.424) these levels were modest.Since normal serum levels in humans are < 15 U/mL even an order of magnitude increase in the

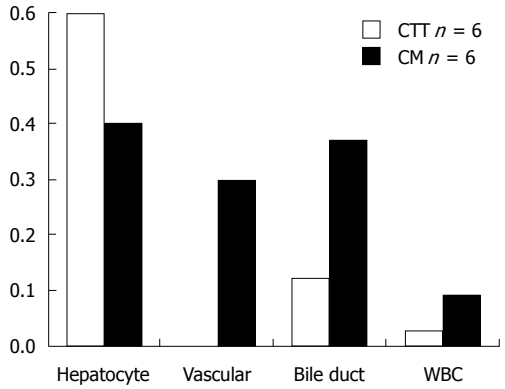

Figure 8 Summary of fibulin-5 immune labeling in cotton top tamarin, common marmoset and humans. Intensity of labeling: CTT and CM of Hepatocyte, Bile Ducts, Vascular Cells and White Blood Cells with Anti-fibulin-5. CTT: Cotton top tamarin; CM: Common marmoset.

CTT is unlikely to increase levels where they might influence the tumor invasiveness. In the study cited, a significant correlation was found between POA and CEA levels classified by stage of CRC (P = 0.003). Although further study is required it would appear that POA is not a major determinant in the CTT of the metastatic process to the extent that it is in humans making this another potential discouraging factor for the development of hepatic metastasis.

Ultimately, we would need to show that the cytokine environment milieu is similar in the CTT as described above for humans. Wilson *et al*[80] using 32 monoclonal antibodies has shown MHC Class 1 and Ⅱ proteins on lymphocytic B cells (CD20-21, 23) and CD16-56 on NK cells; CD2 and CD3 and CD4/8 helper T cells. In addition IL-2 receptor CD25 receptor is present as well as B chain LFA-1 CD 18. There was however poor reactivity for CD11a; and ICAM-1 (CD54) was negative. 14 years later with more reagents available, Kap *et al*[81] confirmed much of the above findings with IL1, 2, 4, 6, 10, 12, and 17a found. In addition they found all 4 clones against CD11a to be positive in contrast to the above paper. CD11a and CD18 and CD29 are important factors for adhesion and are expressed in the CTT. In addition, CD40 of the TNF family is present thus demonstrating that the CTT has almost all the necessary repertoire of proteins as is present in humans to develop hepatic metastasis. Although ICAM-1 was not included in the repertoire, by virtue of CTT colitis to respond to an anti-integrin monoclonal[82], we can conclude that selectins adhesion molecules are also likely expressed. This being the case, it would appear that the aforementioned inhibitory mechanisms are sufficient to abrogate this phenomenon almost completely.

We cannot rule out additional mechanisms and would encourage such research efforts. While ICAM1 may not have been confirmed in the above review (because it does not seem that it was included in the battery of monoclonals described above), E-selectin and integrins certainly have been convincingly demonstrated to be actionable by therapeutic intervention in the CTT[80-82].

Table 4 Summarization of our findings in this study

Parameter	CTT	CM	Human
PELPK Change	+ + + +	+ +	-
CEAR expression	±	±	+ + + +
CEA glycosylation	±	±	+ + + +
CEACAM1 expression	-	-	+ + + +
Fibulin-5 expression	+ + +	+ + +	+ +[1]

[1]Human data have limited staining data; Modified from and published with permission of Springer[8]. CTT: Cotton top tamarin; CM: Common marmoset; CEA: Carcinoembryonic antigen.

Certainly, the above hypotheses are not established scientific facts but they are testable and applicable to a particularly vexing problem presented by hepatic metastases. The ability to intervene using novel approaches based on these ideas will constitute the final section of this review and may represent an encouraging future vision of hope for myriads of "terminal" cancer patients.

In quoting the final chapter of the late Neal K. Clapp's book on this topic: "Our research opportunities using the cotton-top tamarins to study colonic diseases are truly only limited by our ingenuity".

HOW MIGHT WE EXPLOIT THESE ADVANCES FOR THE BETTERMENT OF THE CANCER PATIENT?

Hepatic metastasis of CRC is a very common clinical situation in oncology with prevalence at the time of diagnosis of approximately 20%-25%. The liver has been shown to be the most common site of metastatic spread of colorectal cancer. The prognosis of colorectal hepatic metastases has improved in the last few years owing to surgical resection of liver metastases for patients with no extrahepatic disease; however, liver metastases are resectable in only 15% of the cases[83,84]. Often, factors such as location, size and number of hepatic metastases make it difficult to resect these tumors[83,85]. Thus early prevention of metastasis is crucial in improving the prognosis of patients diagnosed with primary colorectal cancer. As earlier documented by Smedsrød *et al*[86] colorectal hepatic metastasis involve four steps which are interrelated; the cancer cells must establish micrometastasis in the liver by passing through microvasculature which is guarded by Kupffer acting in concert with NK cells. To ensure nutritional supply and establish clinically evident metastatic disease, these cells engage growth factors and adhesion molecules such as VEGF, VCAMs *etc.* As can be appreciated from both clinical and experimental evidence, Kupffer cells are involved with all the rate

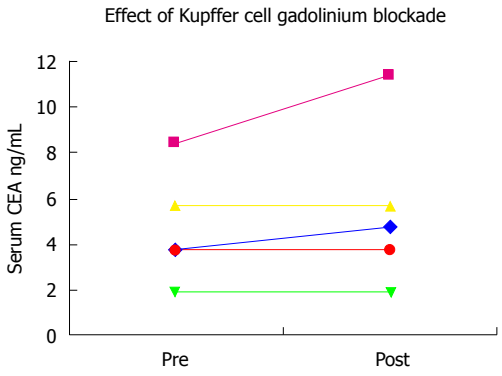

Figure 9 Carcinoembryonic antigen concentrations before and after gadolinium injection for magnetic resonance imaging. Five human patients had serial CEA levels measured before and after MRI with gadolinium contrast administration. No significant changes are seen after gadolinium for patients with normal or near-normal baseline levels. However the patient with a baseline CEA elevation showed a sizeable increase in the CEA level designated by the pink line. CEA: Carcinoembryonic antigen.

limiting step of this macrometastatic disease process which has been established in experimental systems but this role is not proven in human cancers[86]. These phases represent target points of recent therapeutic interventional designs.

USE OF GADOLINIUM BLOCKADE TO DEPLETE KUPFFER CELLS

In our earlier study using CTT[8], we showed that although they have CEA receptors similar to humans, they are able to evade CRC hepatic metastasis *via* two possible means; defective CEA receptors with much reduced receptor capacity or by sequence changes in the PELPK binding motif that is required for receptor activation (Table 2). We hypothesize exploiting methods to prevent CEA/CEAR binding in humans may prove effective in reducing the occurrence of hepatic and possibly lung metastasis. This hypothesis was tested earlier using gadolinium to block uptake of CEA by sinusoidal cells. Although the result was promising, only a transient blockage of CEA was achieved mostly due to the short wash out period for gadolinium (Figure 9). Therefore, using animal models this approach can be refined to optimize our earlier findings using gadolinium as blocking agent for Kupffer cells and the CEA/CEAR interaction.

As a novel approach to anti-metastatic therapy, gadolinium may be encapsulated in smart nano-devices that will prolong the residence time significantly. Using PEGylated-gellan-gum as the polymer of choice, gadolinium can be encapsulated in nanoparticles with average size of 250 nm[87].

Gellan gum is an exocellular microbial polysaccharide with a natural propensity to absorb biological fluid *in vivo* thus regulating the rate of drug/agent release. It consists of repeating tetrasaccharide units of glucose, glucuronic acid and rhamnose in a molar ratio of 2:1:1[88,89]. In addition to being used as a food additive, gellan gum has a wide range of applications in the pharmaceutical industry. In this area, its use has been mainly concentrated in ophthalmic drug delivery and oral sustained-release preparations, in which its ability to undergo cation-induced gelation is utilized as the main fabrication platform[87]. Gellan gum has a number of advantages as it can undergo temperature-dependent as well as cation-induced gelation, which may be of importance for *in vivo* slow release of encapsulated gadolinium. It also has proven non-toxicity in humans[90]. The FDA has also approved gellan gum as a food additive for human consumption[90], thus, its safety in humans is established. To improve the effectiveness of this targeting system, a three-dimensional matrix *via* covalent crosslinking with an end-reactive polyethylene glycol (PEG) through amide linkage can be used. Such modification provides a stronger gellan gum matrix that is nontoxic to normal cells and possesses the ability to deliver biological molecules such as gadolinium to target cells[91] in a controlled manner as illustrated in Figure 10. There is some experimental animal model work that suggests that gadolinium in the form of metallofullerenol nanoparticles inhibit cancer metastases[92] but the metastases observed were mainly pulmonary.

FIBULIN AS A TREATMENT FOR HEPATIC METASTASIS

The process of nanoprecipitation described by the schematics in Figure 10 can potentially be applied to protein encapsulation provided the formulation parameters are optimized as described earlier by our group[91]. Fibulin-5 plays an important role in antagonizing angiogenesis in humans; furthermore its overexpression has been shown to inhibit HCC cell migration and invasion *in vitro*[93], thus fibulin-5 could also be encapsulated in gellan gum nanoparticles to increase their *in vivo* residence time. Nanoparticles formulation should be optimized as described earlier[91] prior to encapsulation of fibulin-5. We would expect fibulin-5 to be the most effective of the fibulins in reducing angiogenesis but fibulin-3 may also be considered (Table 3). While fibulin-5 has been shown to suppress metastasis to the liver and lung[94], it has yet to be used directly in a nanotechnology formulation as we propose. A report that human oncogenic fibulin-5 may promote nasopharyngeal cancer metastasis[95] would suggest that we proceed cautiously with this approach with both agents.

TARGETING CEA/CEAR INTERACTIONS AS A THERAPEUTIC APPROACH TO LIVER METASTASIS

CEA has been shown to be a mediator of metastasis for colorectal cancer by causing changes in the tumor microenvironment that increase the potential for tumor

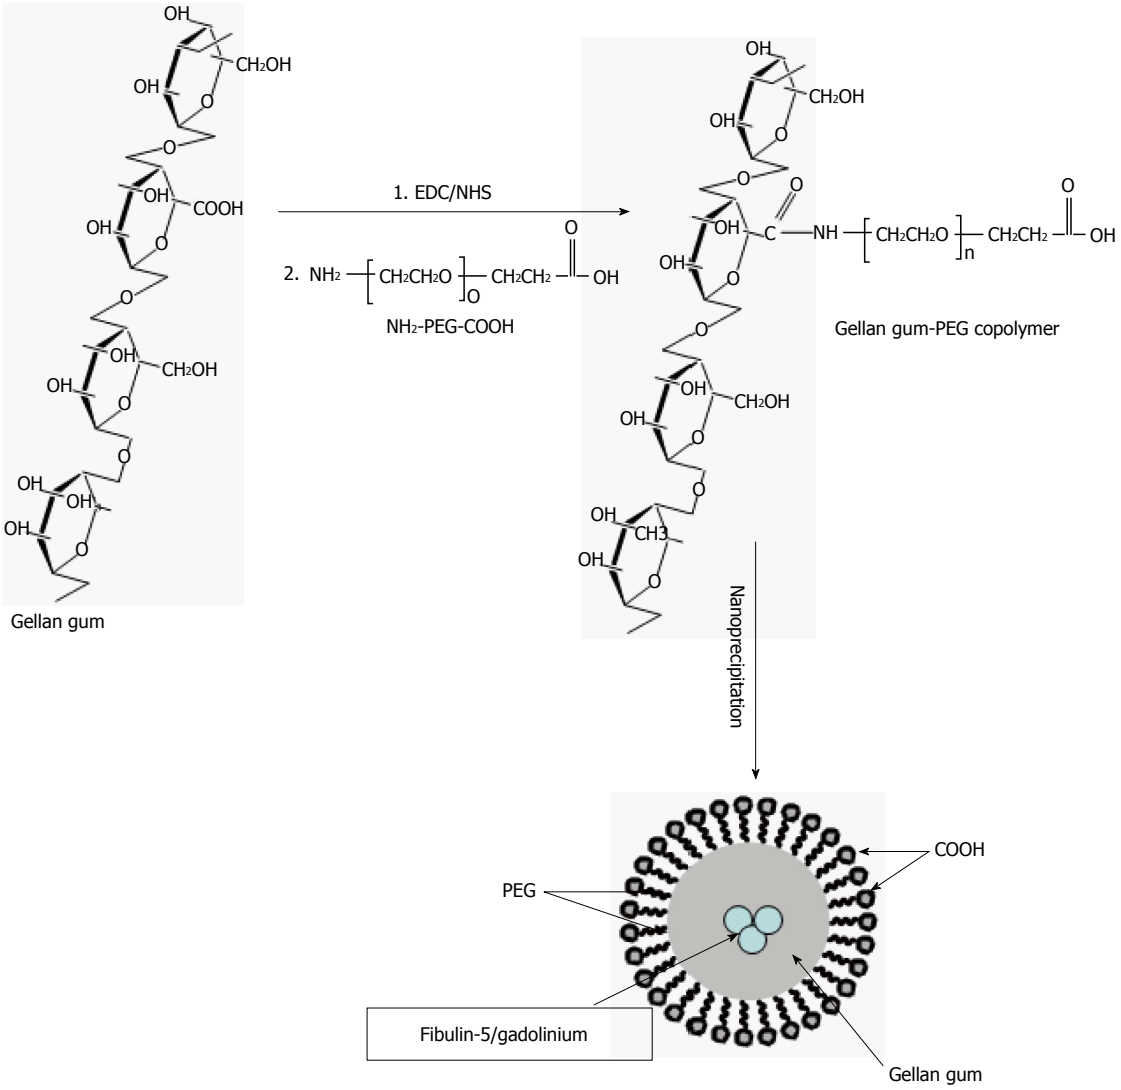

Figure 10 Schematic representation of the technique used for the synthesis of gadolinium encapsulated Gellan-gum-block-Polyethylene glycol co-polymeric nanoparticles. The above figure is a representation of the technical steps to generate nanoparticles of gadolinium encapsulated by Gellan-gum-block-Polyethylene glycol copolymeric micelle nanoparticles. This should ensure delivery and advantageous dwell time in order to block Kupffer functions of uptake of CEA and reduce the pro-metastogenic role of these cells. CEA: Carcinoembryonic antigen.

cell implantation and growth[14]. CEA interaction with its receptor therefore suggests a targeted approach to therapy. A number of methods could be used to achieve disruption of CEA/CEAR including the use of antibodies specific for CEA or its receptor. In general this type of approach has worked well against various cancers and growth receptors *e.g.*, EGFR. Other approaches using small molecule inhibitors of ligand receptor interactions are also being used, In particular RNA aptamers hold great promise as therapeutic agents[96]. These aptamers are now being used in studies involving CEA[97]. Lee *et al*[98] have described the use of a RNA aptamer directed against the PELPK motif of CEA to prevent liver metastasis from the mucinous colon cancer cell line LS174T. They suggest this occurred by disruption of CEA/CEAR interaction. LS174T produces large amounts of CEA and has a high metastatic potential to the liver[99]. Recently, aptamers have also been used against the homotypic adhesion sites of CEA to block tumor cell/cell interactions[100] further emphasizing the feasibility of this approach[101]. Aptamers are also being used for radiolocalization of CEA producing tumors and may even supplant the use of antibodies for this purpose[102]. The use of CEA antagonists to reduce the metastatic potential has now become feasible especially with the advent of small molecule inhibitors. More pre-clinical trials are needed before these approaches can be used in cancer patients at high risk for metastases.

CONCLUSION

We thus have the means to potentially interfere with the uptake of CEA from the hepatic sinusoid Kupffer cell receptor and hopefully disrupt the inflammatory cascade and well as intervening in the fibulin pathways in delivery of fibulin-5 to shore up hepatic defenses against tumor spread to the liver. In time, additional

interventions will be designed to make this a reality based on the lessons learned from the cotton top tamarin- the artful liver metastasis dodger.

ACKNOWLEDGMENTS

Were we to mention every contributor to this substantial body of work this section would undoubtedly be the most extensive.We hope that the names listed in the references will be a curtain call for us to applaud their hard work and sincere efforts. At the same time there were a number of individuals without whom this work would not have been done. We recognize our mentors Norman Zamcheck and Neil Clapp of blessed memory. The guidance and generosity of Phil Gold, Abraham Fuks, Jack Shively, Young S Kim, Jim Fox and Sen-Itoh Hakamori, Clifford Stanners, Zvi Bentwich, Steven Itzkowitz and James Allard was peerless. Their mention here should not be construed to imply their approval of this work but we hope that they do. The tenacity and attention to detail by Karel Kithier and James Hatfield were legend. To the many students, resident and Fellows who appear in many meeting abstracts we are most grateful. Our work could not have progressed without various grants from National Institute of Health, Veterans Health Administration, Kaiser Permanente and Hybritech™ Inc. Thanks also to S. Jatczak and the library staff at the Saginaw VAMC. All previously published material that is used in this manuscript by the principal author emanates from work done as a US Government employee and is therefore in the public domain. However, this work does not necessarily reflect the views of the US Government. As a courtesy, permissions were sought from the relevant publishing houses and graciously granted. This paper is dedicated to the memory of Mendel Tobi whose love for the animal world was boundless.

Abstract

Endoscopic bariatric therapy may be a useful alternative to pharmacological treatment for obesity, and it provides greater efficacy with lower risks than do conventional surgical procedures. Among the various endoscopic treatments for obesity, the intragastric balloon is associated with significant efficacy in body weight reduction and relief of comorbid disease symptoms. Anatomically, this treatment is based on gastric space-occupying effects that increase the feeling of satiety and may also affect gut neuroendocrine signaling. The simplicity of the intragastric balloon procedure may account for its widespread role in obesity treatment and its applicability to various degrees of obesity. However, advances in device properties and procedural techniques are still needed in order to improve its safety and cost-effectiveness. Furthermore, verification of the physiological outcomes of intragastric balloon treatment and the clinical predictive factors for treatment responses should be considered. In this article, we discuss the types, efficacy, safety, and future directions of intragastric balloon treatment.

Key words: Intragastric balloon; Obesity; Bariatric; Metabolic; Endoscopy

Core tip: Obesity is a complex metabolic illness that is associated with several comorbid diseases. There has been a constant demand for safe and more effective weight reduction interventions to fill the gap in the treatment of obesity. The intragastric balloon is a fascinating intermediate alternative solution between

medical obesity treatment and bariatric surgical procedures for obese patients that may provide better efficacy and have a more favorable risk profile.

INTRODUCTION

Obesity is a complex metabolic illness that results from excess accumulation of body fat and may lead to negative health consequences. Obesity increases the prevalence of various diseases, including diabetes mellitus, hypertension, coronary heart disease, sleep apnea, stroke, gastroesophageal reflux disease, gall bladder disease, certain types of malignancy, and non-alcoholic fatty liver disease[1]. Moreover, it is also a major avoidable health detriment. Current therapeutic approaches to obesity are lifestyle changes, pharmacologic treatment, and bariatric surgery. Although intensive lifestyle modification was reportedly associated with only limited weight reduction[2-4], when it is combined with weight-loss drugs approved for long-term use, an additional weight reduction of 3%-9% can occur within 1 year[5]. Such drugs are said to improve several cardiometabolic risk factors, but they are also related to harmful adverse effects[5]. Although new obesity medications have recently been approved and introduced[6-8], they are associated with issues of safety and high costs. Weight-loss surgery provides the most sustained and effective therapeutic choice for obesity. Accessible methods include the adjustable gastric band, Roux-en-Y gastric bypass, or sleeve gastrectomy[9,10]. Regardless of its proven effectiveness, only 1% of obese patients eligible for the surgical procedure choose to undergo it[11]. The major issues with surgery are difficult accessibility, high costs, patient non-preference, and significant morbidity and mortality. Although its associated mortality has decreased considerably, the complication rate in the early and late stages of the bariatric procedure persist at 17% (95%CI: 11%-23%)[10].

Therefore, minimally invasive and effective methods are needed for the treatment of obesity. As such, endoscopic bariatric treatment was recently introduced. It includes intragastric balloons, gastroplasty techniques, aspiration therapy, and gastrointestinal bypass sleeves. Among them, the intragastric balloon has been the most frequently used in practice and the most studied for obesity treatment.

INTRAGASTRIC BALLOON

In 1985, the Garren-Edwards gastric bubble (GEGB) was the first intragastric balloon approved for obesity treatment and was introduced in the United States market. It was made of polyurethane, had a cylindrical design, and was filled with 200-220 mL of air[12]. However, several adverse events were associated with its use, including small bowel obstruction associated with spontaneous deflation and gastric mucosal injury. Although the GEGB is no longer used, considerable advancements to its design have led to the development of a more effective and safer intragastric balloon. It is now being used in numerous countries. Additionally, the United States Food and Drug Administration (FDA) recently approved two new intragastric balloons.

The increased prevalence of obesity has motivated experts in bariatric medicine to advance minimally invasive endoscopic treatment for obesity management as well as innovative techniques that address important features of treatments, such as their efficiency and safety. A new meta-analysis showed that endoscopic obesity treatment could be effective and of substantial value if combined with a multidisciplinary and comprehensive treatment plan[13].

The intragastric balloon technique has become an effective method of achieving significant weight reduction in obese people (Figure 1). One or more intragastric balloons can be placed in the stomach using endoscopic procedures under mild sedation in an outpatient setting. Intragastric balloons allow patients to sense fullness and ultimately reduce their food intake. It is hypothesized that the intragastric balloon facilitates satiety peripherally by being an obstacle to food consumption, decreasing intragastric volume, and delaying gastric emptying[14]. Additionally, signals transmitted centrally through the vagal nerves by activated gastric stretching receptors could affect satiety[14]. The intragastric balloon permits an early feeling of satiety, which is thought to be a consequence of gastric distention. The mechanical intragastric distention to a meaningful volume during mealtime significantly decreases the amount of food eaten[15,16].

The intragastric balloon may also act *via* its relationship with various neurohumoral factors. It affects hunger control and gastric emptying by altering gut hormones and peptides such as ghrelin, leptin, cholecystokinin, and pancreatic polypeptide[17,18] and may also be related to physiological adaptation to weight loss.

The intragastric balloon may play diverse roles in obesity treatment as a preemptive therapy, a metabolic therapy, or a primary therapy.

TYPES OF INTRAGASTRIC BALLOONS

Orbera intragastric balloon

The most frequently used balloon is the Orbera Intragastric Balloon (Apollo Endosurgery, Austin, TX, United States), which was known previously as the BioEnterics Intragastric Balloon (BIB). It is an elastic

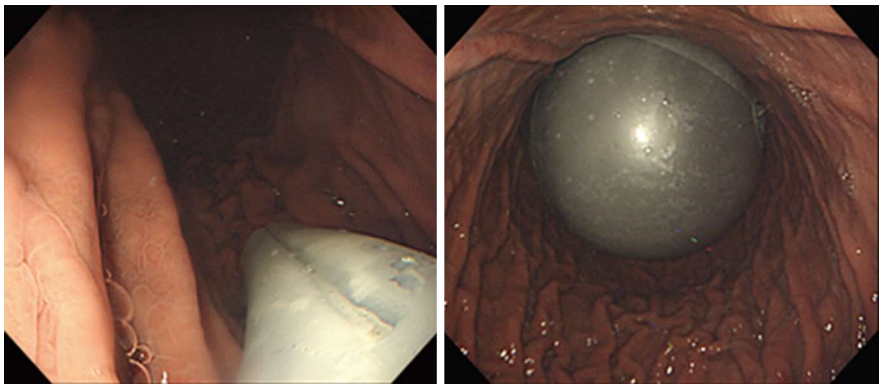

Figure 1 Intragastric balloon placement.

Table 1 Types of intragastric balloons

Balloon	Material	Volume	Weight loss[1]	Note
Fluid-supplied				
Orbera (Apollo Endosurgery)	Silicone	400-700 mL (saline)	16.9 ± 0.9 kg (at 6 mo)[58]	Most widely used and studied intragastric balloon Volume adjustment at the time of placement
Spatz Adjustable Balloon system (Spatz FGIA)	Silicone	400-600 mL (saline)	24 kg (at 12 mo)[64]	Totally adjustable balloon Approved for 12 mo of implantation
ReShape Duo® Integrated DualBalloon System (ReShape medical)	Silicone	900 mL (450 mL × 2) (saline)	25.1 ± 1.6 %EWL (at 6 mo)[62]	Two independent balloons connected to silicone shaft
The Elipse™ (Allurion Technologies)	N/A	450-550 mL (filling fluid)	2.4 kg (at 6 wk)[19]	Naturally swallowed, self-emptying, and naturally excreted
Air-supplied				
Obalon® Gastric Balloon (Obalon Therapeutics)	N/A	250 mL (air, nitrogen)	5 kg (at 12 wk)[66]	Can be swallowed A second or a third balloon can be swallowed depending on patient's progress
Heliosphere BAG® (Helioscopie)	Polyurethane and silicone	950 mL (air)	16 ± 7 kg (at 6 mo)[23]	Less than 30g

[1]Values extrapolated from representative reviews and clinical trials of each intervention. N/A: Not available; %EWL: Percentage of excess weight loss.

silicone balloon containing saline (450-700 mL) (Table 1). The positioning assembly, which comprises a balloon-filling tube and a catheter with the deflated balloon, is blindly advanced to the gastro-esophageal junction. An endoscopic device is inserted to ensure the precise deployment of the intragastric balloon, which is then filled with methylene-mixed saline under direct observation *via* the catheter. If an unexpected balloon rupture occurs, the methylene blue turns the urine green. The Orbera balloon is usually implanted for 6 mo, removed endoscopically by needle aspiration of the intragastric fluid, and retrieved with a snare or grasper. The FDA approved the use of the Orbera balloon on August 6, 2015. It is expected that the Orbera balloon could provide a valuable and less invasive therapeutic approach to bariatric treatment.

ReShape duo

The ReShape Duo® (ReShape Medical, San Clemente, CA, United States) aims to improve the space-occupying effects of intragastric balloons. This non-invasive device is delivered *via* the mouth through a 30-min endoscopic procedure. It is inflated with 900 mL of saline, which is equally distributed to each of two balloons. The balloon is inflated by a controller with methylene blue-mixed saline. This dual balloon system may reduce deflation-associated complications. If one of the balloons ruptures, the other balloon could sustain the location of the device in the stomach. It is recommended that the balloon be retrieved 6 mo after placement. The ReShape Duo was also approved by the FDA, on July 29, 2015.

Spatz

The Spatz Adjustable Balloon System (Spatz Medical, Great Neck, NY, United States) is a silicone balloon that is inflated with saline. It includes a filling catheter, which is extractable endoscopically, that permits an intragastric volume adjustment of 400-800 mL. The volume of the intragastric balloon can be modified to improve the patient's tolerance and increase weight reduction. The Spatz Adjustable Balloon System is allowed to be implanted in the stomach for 12 mo in locations outside the United States.

Elipse

The Elipse™ (Allurion Technologies, Wellesley, MA, United States) is a swallowable, self-draining, and naturally expelled intragastric balloon device for weight reduction. It is covered with a vegetarian shell and fixed to a flexible, slim tube. A resorbable substance inside the balloon degrades, allowing the balloon to empty naturally after a certain period. The deflated intragastric balloon is devised to be excreted *via* the digestive tract[19]. It is inflated with 550 mL of fluid and can be placed in the stomach for 4 mo. Endoscopic procedures are not needed for Elipse™ placement or removal.

Obalon

The Obalon Gastric Balloon® (Obalon Therapeutics Inc, Carlsbad, CA, United States) is a balloon filled with 250 mL of air. It has a self-sealing valve linked to a catheter and is set inside a gelatin capsule. The balloon is packaged in the capsule and swallowed, and the thin catheter is extended alongside the esophagus into the stomach. Fluoroscopy is used to define the location of the intragastric balloon, and the gelatin capsule disintegrates and releases the balloon. The balloon is then inflated using a gas-contained canister. The catheter is separated from the balloon and removed after balloon inflation.

Heliosphere bag

The Heliosphere Bag® (Helioscopie, Vienne, France) comprises a double-bagged polymer covered with an external silicone pouch. It is slowly filled with 960 mL of air for a final inflation volume of 700 mL[20,21]. The weight of the Heliosphere Bag is less than 30 g[22,23].

Silimed balloon

The Silimed Gastric Balloon is a spherical silicone balloon set inside a thin silicone sheath[24]. It is attached to the endoscope by a snare, advanced by an endoscope, and placed in the gastric fundus. It is filled with 650 mL of saline solution mixed with contrast dye and 10 mL of methylene blue.

Adjustable totally implantable intragastric prosthesis

The adjustable totally implantable intragastric prosthesis (ATIIP) is a polyurethane intragastric balloon that is rugby-shaped, 12 cm long, and has a volume of 300 mL when inflated with air[25]. This balloon is placed with an endoscopic percutaneous gastrostomy technique followed by the deployment of a subcutaneous totally implantable system through a surgical procedure. This method may reduce the likelihood of device dislocation and allows for balloon volume adjustment. The proximal balloon position in the gastric fundus-corpus lesion could affect gastric accommodation, neurohormonal process, and electrical action, thus modifying various control processes related to satiety[14].

INTRAGASTRIC BALLOON TREATMENT FOR OBESITY

Indications

The intragastric balloon may offer a minimally invasive and valuable method for managing obesity and related conditions. It is used to achieve weight loss in obese people, generally those with a body mass index (BMI) > 35 kg/m^2, or 30 kg/m^2 with certain comorbidities. Intragastric balloon treatment may play a different role in bariatric treatment based on the grade of obesity.

Preemptive therapy

Early intervention and preemptive therapy for weight reduction can be performed in obese patients (BMI $\geqslant$ 30 kg/m^2) at risk for disease development, at high risk for all-cause mortality, and with a high cardiovascular risk profile[26].

The objective of preemptive treatment is to achieve modest weight reduction, and, therefore, the overall risk/benefit ratio could validate the standards for procedures with this indication. Depending on the circumstances, indications for placement of intragastric balloons could also be extended to manage overweight people with a BMI < 30 kg/m^2 who desire weight reduction but who cannot achieve body weight loss with a controlled dietary program or with pharmacotherapy[27].

Metabolic therapy

Body weight loss achieved with intragastric balloon placement is associated with improvements in obesity-related metabolic illness. The intragastric balloon for metabolic therapy may be performed in patients with mild obesity (BMI $\geqslant$ 30 kg/m^2), where recovery from metabolic disease is the primary concern[28]. Co-existing illnesses, such as hyperlipidemia, type Ⅱ diabetes mellitus, and hypertension, could be particularly improved or resolved with even a modest reduction in body weight[29,30]. Treatment for metabolic issues should be relatively low-risk and have superior stability.

Primary therapy

The goal of intragastric balloon treatment is to achieve weight reduction in severely obese people, generally those with a BMI > 35 kg/m^2 with or without comorbidities, and who could not achieve long-term weight loss with a weight-control regimen. In addition, intragastric balloon therapy could be performed in patients with a BMI $\geqslant$ 40 kg/m^2, primarily as a preparation for bariatric treatment or in patients with increased surgical risks. Obese patients who reject bariatric surgical procedures or who do not have an approach for surgery can also opt for it. Intragastric balloon therapy used as a primary therapy could induce weight reduction and improve obesity-related comorbidities with a level of safety and efficiency

comparable to that of bariatric surgery[28]. However, lower efficiency is also acceptable because of the lower risk profile of intragastric balloon therapy.

Exclusion criteria

Exclusion criteria include any situation that could increase the risks related to intragastric balloon insertion, such as a large hiatal hernia (> 5 cm), active ulcer in the stomach or duodenum, previous surgical resection of the stomach, inflammatory bowel disease, gastrointestinal neoplasm, oropharyngeal abnormalities, active gastrointestinal bleeding, coagulative disorder, variceal disease, alcoholic disease or drug abuse, psychiatric disease, pregnancy, use of anti-coagulants or anti-inflammatory drugs, and cardiovascular, pulmonary or cerebrovascular diseases[31].

EFFECTS OF INTRAGASTRIC BALLOONS

The purpose of intragastric balloon treatment is to stimulate weight loss and assist with recovery from associated comorbidities with adequate safety. Gastric capacity restriction is an essential factor in surgical bariatric management.

Surgical gastric restriction could induce early satiety and potentiate gastric mechanical and chemical stimulation through a relationship with various gastric or exogenic factors. It affects hunger control and gastric emptying through alterations in gut hormones and peptides[32-34]. The intragastric balloon attempts to mimic surgical weight loss procedures by restricting the effective gastric volume.

Body weight loss

Results from previous studies indicated that the mean weight loss associated with intragastric balloon therapy ranged between 10.5 and 13.7 kg after 3 mo and between 12 and 26.3 kg after a 6-mo placement of the Orbera intragastric balloon[22,23,35-49]. After balloon removal at 6 mo, the achieved weight reduction endured to some extent. The excess weight loss (EWL) at the 12-mo implantation mark (6 mo after removal) was 14% to 50.9%[37,40,42,44,50-54]. The EWL at 12 mo after balloon extraction ranged from 14.2% to 27.2%[51,55-57]. The Orbera intragastric balloon was most effective during the first 3 mo of therapy. During that time, average weight loss of obese patients was 12.9 kg, or 80% of the total achieved weight reduction[58]. Additionally, the initial body weight loss (BWL) following intragastric balloon placement was associated with significant long-term weight maintenance. The percentage of BWL 1 mo after intragastric balloon placement was significantly associated with weight loss after 6, 12, and 18 mo (Pearson correlation coefficient = 0.77, 0.65, and 0.62, respectively, $P < 0.001$ for all)[59].

A study reported that insertion of a second balloon is not difficult and achieved good results. The mean %EWL was 31.5 ± 23.2 after the second balloon removal[43]. Some studies showed long-term results after intragastric balloon placement. A multi-center European study presented results for weight loss 3 years after balloon removal, which accounted for 29.1% of mean EWL[54]. A study that included 195 patients who were followed up for 5 years after intragastric balloon insertion demonstrated a %EWL of 12.97 ± 8.54[44].

Additional limited studies have utilized other intragastric balloons. A Spanish study with 60 patients showed a total body weight reduction of 16.6 ± 9.33 kg 6 mo after implantation of the ReShape Duo double-balloon system[60]. A prospective study with a double-balloon system showed a mean EWL of 18.3% in the control group compared to 31.8% in the treatment group 6 mo post-balloon implantation[61]. Furthermore, 64% of the reduced body weight was maintained at 12 mo post-implantation (6 mo after removal). In the REDUCE Pivotal Trial, a prospective randomized trial with 326 patients, patients assigned to the double-balloon system plus exercise and diet showed significantly superior EWL compared to the sham endoscopy plus exercise and diet alone group at 6 mo post-implantation (25.1% *vs* 11.3%, $P < 0.05$) in an intent-to-treat analysis[62].

A pilot trial showed 15.6 kg of mean weight loss at 24 wk and 24.4 kg at 52 wk after Spatz adjustable balloon placement[63]. A small observational investigation in 73 obese patients showed 45.7% of EWL 12 mo after deployment of the Spatz adjustable balloon[64].

Two preliminary studies with the Silimed Gastric Balloon reported results after the completion of 6 mo of treatment. The mean weight loss was 11.3 kg[24] and 8.1 kg[65]. A total of 57 morbidly obese patients underwent ATIIP placement. Mean EWL was 28.7% at 6 mo (38 patients) and 39.2% at 12 mo (20 patients)[25]. The Obalon (orally ingestable intragastric balloon) showed median weight losses after 4 weeks, 8 weeks, and 12 wk as 2.2 kg, 4.0 kg, and 5 kg, respectively[66]. A prospective study with 50 obese patients compared the effects of intragastric balloon therapy or pharmacotherapy on weight reduction. At 6 mo, patients in the intragastric balloon group had lost more weight than had patients in the pharmacotherapy group (percent of initial weight lost, %IWL = 14.5 ± 1.2; percent of excess BMI lost, %EBL = 37.7 ± 3.2 *vs* %IWL = 9.1 ± 1.5, %EBL = 25.3 ± 4.1, respectively, $P < 0.005$)[67].

Although the intragastric balloon has been shown to be effective in causing a meaningful weight loss, several studies have reported that the results were short-lasting, with most patients regaining weight following intragastric balloon removal[31,36,51,55,68-72].

Improvement in metabolic diseases

Obesity in patients is related to several comorbidities that are significant targets for obesity treatment. A

study with 143 obese patients described the effects of the Orbera intragastric balloon at the 12-mo follow-up[51]. The incidence of metabolic syndrome declined from 34.8% (before balloon insertion) to 14.5%, 13%, and 11.6% at the time of removal, at the 6-mo follow-up, and at the 1-year follow-up, respectively. The incidence of type 2 diabetes mellitus decreased from 32.6% to 20.9%, 22.5%, and 21.3%, respectively. Likewise, the occurrence of hyperuricemia, hypertriglyceridemia, and hypercholesterolemia decreased from 26.1%, 37.7%, and 33.4% to 25.4%, 14.5%, and 16.7%, respectively, at the time of removal, 25.9%, 15.2%, and 16.7%, respectively, at the 6-mo follow-up, and 26.4%, 17.4%, and 18.9%, respectively, at the 1-year follow-up. A multi-center study presented data following treatment with the Orbera intragastric balloon in overweight populations[54]. The percentage of patients with co-morbidities at baseline and at the 3-year follow-up was 29% and 16% for hypertension, 15% and 10% for diabetes mellitus, 20% and 18% for dyslipidemia, 32% and 21% for hypercholesterolemia, and 25% and 13% for osteoarthropathy, respectively. A study with 119 obese patients assessed the effects of the Orbera intragastric balloon on obesity-associated diseases and quality of life[42]. Six months after placement of the intragastric balloon, the rate of metabolic syndrome in the patients decreased from 42.9% to 15.1% (P < 0.0005). Cholesterol, triglycerides, fasting glucose, C-reactive protein levels, and blood pressure also improved after balloon treatment (P < 0.005). In patients with diabetes mellitus, the HbA1c level was decreased at 6 mo compared to that at baseline (7.4% to 5.8%; P < 0.0005). In addition, the quality of life of patients increased.

Obesity is one of the risk factors for nonalcoholic fatty liver disease (NAFLD). About 27% of patients with NAFLD can develop fibrosis, and 19% can develop cirrhosis[73]. A randomized controlled study showed that intragastric balloon therapy improved the histology of nonalcoholic steatohepatitis[74]. Six months after implantation, a significant reduction in the median NAFLD activity scores was observed in the intragastric balloon-treated group (2 *vs* 4, P = 0.030) compared to that in the control group. Additionally, the median steatosis scores displayed a trend toward improvement in the balloon-treated group compared to those in the control group (1 *vs* 1, P = 0.075).

Alterations in gastrointestinal hormones

Body weight is controlled by multifaceted coordination of both central and peripheral factors. It is now obvious that a physiologic change in gut neurohumoral signaling is one important contributor to weight reduction and improvement in related diseases obtained by anatomic surgical manipulation of the gastrointestinal tract[75]. Moreover, intragastric balloon treatment may affect weight changes through an interaction of gastric neurohumoral factors (Table 2). These factors include several gut peptides and hormones, such as ghrelin, leptin, cholecystokinin, peptide YY, pancreatic polypeptide, and glucagon-like peptide-1.

These factors are interrelated and participate in the peripheral mediation of satiety[76,77]. Ghrelin is a hormone that has been known to influence energy balance. However, several studies presented varying results regarding ghrelin concentrations after balloon treatment. A study with 40 obese patients who underwent balloon placement indicated no effect on ghrelin levels when patients were fasting or meal-suppressed[17]. In another study, 17 patients with non-morbid obesity underwent balloon placement, and fasting plasma ghrelin concentrations significantly decreased (3.2 to 1.9 ng/mL; P = 0.021) as a result[78]. Martinez-Brocca *et al*[79] reported that fasting and meal-suppressed plasma ghrelin levels did not

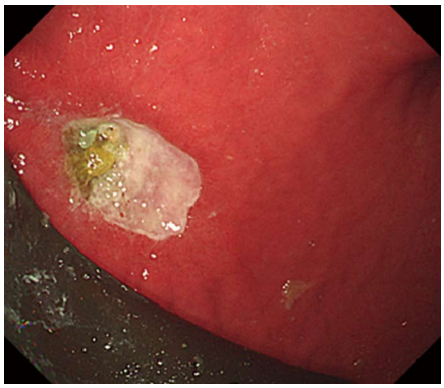

Figure 2 Gastric ulcer induced by intragastric balloon placement.

differ significantly between groups in morbidly obese patients. Konopko-Zubrzycka *et al*[39] reported that body weight reduction after balloon treatment is related to a transient elevation in plasma ghrelin levels and a decrease in plasma leptin levels.

Another study evaluated fasting and postprandial cholecystokinin and pancreatic polypeptide secretion after 13 wk of balloon treatment in obese patients. Baseline and meal-stimulated cholecystokinin levels were decreased[18].

Maintenance of weight loss is controlled by the collaboration of several processes, including environmental, behavioral, and homeostatic factors[80]. Physiological adaptation to weight reduction and weight regain show interplaying alterations in the stability of the levels of hunger hormones and energy homeostasis, in addition to changes in subjective appetite and nutrient metabolism. Appetite-related gastrointestinal hormones may play a crucial function in body weight regain after weight reduction[81]. Bariatric procedures may prove to be effective methods to aid in altering obese patients' physiology and may provide a good opportunity for long-term maintenance. Procedures that affect the physiology of weight loss and regain may eventually fortify future approaches for obesity treatment.

COMPLICATIONS OF THE INTRAGASTRIC BALLOON

Adverse events rates following Orbera intragastric balloon placement showed pooled incidences of pain (33.7%) and nausea (29%) as common adverse side effects[82]. The incidence of GERD, gastric ulcers (Figure 2), and balloon migration was 18.3%, 2%, and 1.4%, respectively. Serious adverse events with the Orbera balloon are uncommon, with prevalences of small bowel obstruction, perforation, and death as 0.3%, 0.1% and 0.08%, respectively[82]. Similarly, the REDUCE pivotal trial (n = 264), which evaluated the efficacy and safety of the ReShape Duo intragastric balloon, showed that symptoms such as nausea, abdominal pain, and vomiting were common, but decreased rapidly with medical management. Spontaneous intragastric balloon deflation occurred in 6% of patients, but balloon migrations did not occur concurrently. Early balloon removal occurred in 9.1% of study participants for non-ulcer-related intolerance. In 35% of the study participants, a gastric ulcer presented initially, but ulcer incidence and size decreased following subsequent device modification[62].

FUTURE DIRECTIONS FOR THE INTRAGASTRIC BALLOON

New emerging technology trends in endoscopic treatment for obesity require an extensive and meticulous research plan to promote finding and recognize their optimal role in managing obese patients and their applications for clinical practice[83]. Intragastric balloon placement can be performed through a simple endoscopic method and is easily reversible. This simplicity offers an expansive role in obesity treatment based on the degree of obesity. It is important to establish an appropriate method for intragastric balloon treatment by classifying the degree of obesity. Although serious complications with intragastric balloon treatment are rare, safety is an issue that cannot be overlooked. Various factors are associated with balloon safety, such as its durability and the simplicity of the procedure. Advances in device properties and procedural techniques could offer more cost-effectiveness with this outpatient procedure[84]. There is also uncertainty about the ideal filling medium and content. A preference for fluid other than air has been mentioned[14], but a debate still exists, with no established guidelines to date. There is a need to establish standards of intragastric balloon treatment practice, which could comprise pre- and post-procedural guidelines and long-term schedule management. In addition, collaboration with dietary counseling and an exercise program could offer quality assurance with intragastric balloon treatment.

Intragastric balloon treatment might produce only short-lasting effects in obesity treatment. Thus, it is important to maintain weight loss following intragastric balloon removal. Long-term management for weight reduction after intragastric balloon removal can also comprise intensive lifestyle modification, alone or with pharmacotherapy, and could be suggested to protect against weight regain.

Material and safety issues regarding the intragastric balloon should be further investigated. More research should be performed to investigate a pathophysiologic pattern of obesity, the uncertain role of gut hormones, potential predictive factors for the efficacy of the intragastric balloon in obesity treatment, and individualized treatment-induced changes.

CONCLUSION

Effective and safe weight reduction is very important

for the treatment of obesity, which is responsible for about 5% of all obesity-related deaths globally. Intragastric balloon treatment is more than just a transient curiosity. It shows promise in improving the quality of life and health status for obese patients. It offers a minimally invasive and effective method for managing obesity and associated conditions. Although there remains the possibility of improvement with research and development, gastroenterologists should maintain attention and interest in determining satisfactory outcomes and verifying standards of intragastric balloon treatment for the obesity epidemic.

Abstract

Ulcerative colitis (UC) is a chronic inflammatory disease, whose etiology is still unclear. Its pathogenesis involves an interaction between genetic factors, immune response and the "forgotten organ", Gut Microbiota. Several studies have been conducted to assess the role of antibiotics and probiotics as additional or alternative therapies for Ulcerative Colitis. *Escherichia coli* Nissle (EcN) is a nonpathogenic Gram-negative strain isolated in 1917 by Alfred Nissle and it is the active component of microbial drug Mutaflor® (Ardeypharm GmbH, Herdecke, Germany and EcN, Cadigroup, In Italy) used in many gastrointestinal disorder including diarrhea, uncomplicated diverticular disease and UC. It is the only probiotic recommended in ECCO guidelines as effective alternative to mesalazine in maintenance of remission in UC patients. In this review we propose an update on the role of EcN 1917 in maintenance of remission in UC patients, including data about efficacy and safety. Further studies may be helpful for this subject to further the full use of potential of EcN.

Key words: Ulcerative colitis; *Escherichia coli* Nissle; Metanalysis; Probiotic; Randomized trial; Inflammatory bowel disease

Core tip: *Escherichia coli* (*E. coli*) Nissle is a nonpathogenic Gram-negative strain used as a probiotic with very good quality paper assessing its bio-equivalence to mesalazine in maintaining remission in ulcerative colitis. Mechanisms of actions of this compound include immune-modulatory properties, reinforcement of intestinal barrier and inhibitory effect towards other pathogenic *E. coli*.

INTRODUCTION

Ulcerative colitis (UC) is a chronic remitting and relapsing disease, characterized by a continuous inflammation which can stretch from the rectum up to the entire colon, often resulting in mucosal ulceration, rectal bleeding, diarrhea, abdominal pain. Its etiology is still unclear, and it is multifactorial. Several factors have been identified as major determinants for induction or relapses and, among these, the imbalanced gut microbiota has become more crucial in recent years. The main hypothesis is that it is due to an excessive immune response to endogenous bacteria, in genetically predisposed individuals[1].

The human microflora, known as "microbiota", includes more then thousand different species and higher than 15000 different bacterial strains, for an average total weight of 1 kg. In recent years several studies investigated the correlation between dysbiosis and intestinal and extra-intestinal diseases, including inflammatory bowel disease (IBD) and so UC[2].

Probiotics are viable agents conferring benefits to the health of the human host[3]. They can provide a beneficial effect on intestinal epithelial cells in numerous ways. Some strains can block pathogen entry into the epithelial cell by providing a physical barrier or by creating a mucus barrier; other probiotics maintain intestinal permeability acting on tight junctions. Some probiotic strains produce antimicrobial factors, other strains modulate the immune response[4].

The role of microbiota in UC was supported by several evidences: inflammation is greatest in intestinal tracts with high concentration of bacteria, surgical reduction of the bacterial load is associated with improvement of inflammation and inflammation does not occur in germ free animals[5].

The treatment goal of UC is the induction and the maintenance of remission. 5-aminosalicylic acid (ASA) compounds, azathioprine/6 mercaptopurine, corticosteroids, cyclosporine, methotrexate, and anti-TNFα agents are conventional therapies used to control the disease. There are also other therapies, used as addition or alternative to conventional therapies in UC, in particular antibiotics and probiotics, which modulate gut microbiota.

Escherichia coli (*E. coli*) Nissle (EcN) 1917 is a non-pathogenic Gram-negative strain used in many gastrointestinal disorder including diarrhea[6], uncomplicated diverticular disease[7] and IBD, in particular UC[8].

STRUCTURE AND MECHANISMS OF ACTION OF EcN 1917

EcN 1917 (O6:K5:H1) was isolated by Prof. Alfred Nissle from Freiburg, Germany, in 1917 from the intestinal microflora of a young soldier. This soldier - unlike his comrades - did not develop infectious diarrhea, when stationed during World War I in Southeastern Europe (Dobrudja/Balkan peninsula), endemic for Shigella at that time. The strain was named *E. coli* strain Nissle 1917.

Using this *E. coli* strain Prof. Nissle developed the probiotic drug Mutaflor® and introduced it into medical practice in the same year. Since 1917, Mutaflor® is available in the German pharmaceutical market without interruption and recently also in Italy as EcN (cadigroup).

The lack of defined virulence factors (alpha-hemolysin, P-fimbrial adhesins, *etc.*) combined with the expression of fitness factors such as microcins, different iron uptake systems (enterobactin, yersiniabactin, aerobactin, salmochelin, ferric dicitrate transport system, and the *chu* heme transport locus), adhesins, and proteases may support its survival and efficacious colonization of the human gut, and contribute to the probiotic character of EcN 1917.

It exhibits a semi-rough lipopolysaccharide (LPS) phenotype and serum sensitivity and does not produce known toxins[9]. EcN colonizes the intestine within few days and it remains as colonic flora for months after administration[10].

EcN has an intestinal anti-inflammatory effect, but also systemic effects[11], and there are many theories about its mechanism of action (Figure 1): (1) It has direct antimicrobial effects: it inhibits EHEC (*E. coli* EDL933) colonization in animal models[12] and synthesis of Shiga-Toxins in co-cultivation experiment with STEC (Shiga-Toxin producing *E. coli*)[13]. (2) It is involved in the bacterial-epithelial crosstalk ("Host cell signaling") by biofilm formation: it expresses F1C Fimbria. This is very important in the formation of biofilm, adherence to epithelial cells and persistence in infant mouse colonization[14]. Its flagellum is the major "propulsor" *in vivo*, which allow this probiotic strain to efficiently compete with pathogens for binding sites on host tissue[15]. It directly stimulates

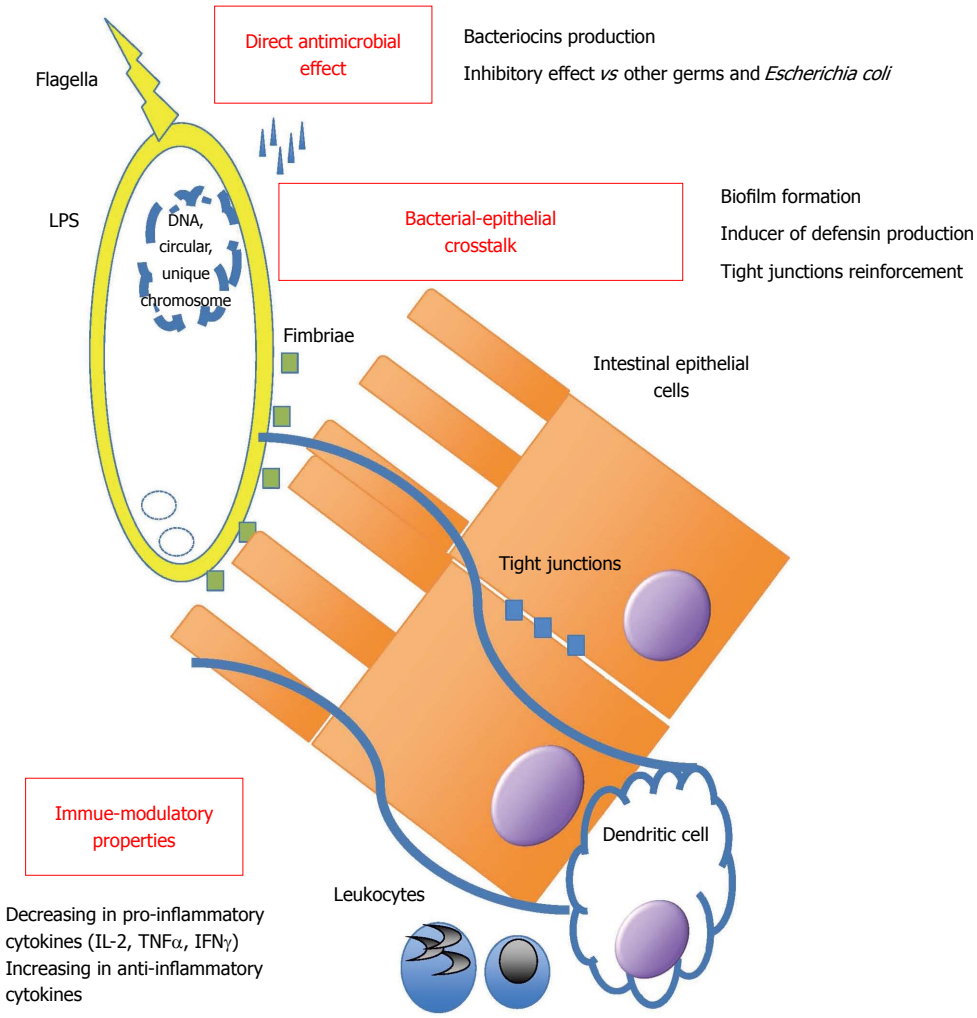

Figure 1 Structure and mechanisms of action of *Escherichia coli* Nissle 1917. LPS: Lipopolysaccharide; IL-2: Interleukin-2; TNF: Tumor necrosis factor; IFN: Interferon.

defensin production by intestinal epithelial cells, such as the human beta-defensin that inhibits adhesion and invasion of intestinal cells by pathogenic adherent invasive *E. coli*, which play a key role as trigger in immune response in IBD patients[16-18]. It strengthens tight junctions of intestinal epithelial cells, by up-regulating the expression of the mRNA for the zonula occludens proteins ZO-1 and ZO-2, so it has an effect on the repair of the "leaky gut"[19-21]. (3) It interacts with immune system by causing decreasing in pro-inflammatory cytokines (IL-2, TNF-α, IFNγ) and increasing in anti-inflammatory cytokines by peripheral blood mononuclear cells *in vitro*. It may reduce the expansion of newly recruited T cells into the intestinal mucosa and decrease intestinal inflammation, but it doesn't affect activated tissue-bound T cells, which may eliminate deleterious antigens in order to maintain immunological homeostasis[22,23]. Furthermore EcN has a specific LPS that is responsible for its immunogenicity, without major immunotoxic properties at doses suggested and that provide, together with the other described features, a powerful effect on intestinal immune function[24].

Efficacy of EcN in animal models of colitis

Schultz *et al*[25] conducted a study on animal models of acute and chronic colitis. Acute colitis was induced by administration of dextran-sodium sulfate (DSS) in drinking water and chronic colitis was induced by transferin $CD4^+$ $CD62L^+$ T lymphocytes from BALB/c mice in SCID mice. These studies have shown that administration of EcN ameliorates intestinal inflammation (measured by histological scores) in chronic models but not in acute models, in accordance with clinical observations. Therefore, it was shown that EcN reduced secretion of pro-inflammatory cytokines, measured by enzyme-linked immune-sorbent assay[25].

Grabig *et al*[5] demonstrated that EcN ameliorates experimental colitis induced by administration of 5% DSS in mice *via* TLR-2 and TLR-4 dependent pathway.

Decreasing of symptom scores and differences in body mass loss were shown in animal models of DSS colitis in BALB/c mice treated with EcN in the study conducted by Kokesová *et al*[26].

Table 1 Main results from trials on *Escherichia coli* Nissle on ulcerative colitis

Efficacy of EcN 1917 in maintanance of UC remission
Results from major randomized controlled clinical trials
EcN 200 mg/d is equivalent to Mesalazine 1000 mg/d in mantainance of UC remission[27]
EcN 400 mg/d is equivalent to to Mesalazine 2400 mg/d in maintanance of UC remission following an acute flare[28]
EcN 200 mg/d is equivalent to Mesalazine 1500 mg/d in mantainance of UC remission[10]
Results from minor studies
Rectal admistration of EcN 40 mL/d is effective in moderate distal active UC[30]
EcN 200 mg/d is equivalent to Mesalazine 1500 mg/d in maintanance of UC remission[6]

EcN: *Escherichia coli* Nissle; UC: Ulcerative colitis.

CLINICAL ROLE OF EcN 1917 IN MAINTANANCE OF UC

There are three major double-blind RCTs (Table 1), which compare EcN to mesalazine in prevention of relapse in UC patients, all of them designed to demonstrate equivalence of two treatment according to Schuirmann's two-one side test or "non inferiority trials".

The first trial was conducted by Kruis *et al*[27] in 1997. It was a randomized, double-blind, double-dummy study conducted on 120 out-patients in Germany, Czech Republic and Austria. Patients had a confirmed diagnosis of ulcerative colitis in remission. In particular patients had to be in remission for a maximum of 12 mo, with clinical activity index (CAI) < 4, no endoscopic or histological signs of acute inflammation. Each patient had to have had at least 2 relapses prior inclusion.

Patients received 500 mg mesalazine t.d.s. and a placebo form of EcN preparation or 200 mg/d of a preparation containing EcN in a single dose ("Mutaflor", Ardeypharm GmbH, Herdecke, Germany. 100 mg contains 25×10^9 viable *E. coli* bacteria) and a placebo form of mesalazine. The duration of the study was 12 wk. Study objectives included the assessment of the equivalence of the CAI under the two treatment modalities and the comparison of the relapse rates, relapse-free times and global assessment.

Study population was homogeneous into the two groups, with a prevalence in left sided colitis and small prevalence of active use of steroids (less then 25 % in both groups).

From the results of this study, no significant difference was observed between the two groups, although a low statistical power and a minor trend towards a slightly higher CAI in the EcN group. No serious adverse events reported for both groups.

The second trial was conducted by Rembacken *et al*[28] in 1999. This was a single-center, randomised, double-dummy study involving 116 patients, which were treated with mesalazine 800 tds (Asacol formulation) or EcN 2 cp per 2 times daily ("Mutaflor", Ardeypharm GmbH, Herdecke, Germany. 100 mg contains 25×10^9 viable *E. coli* bacteria).

Inclusion criteria were: 18-80 years of age, clinical active (mild-moderate and severe) ulcerative colitis ("Leeds-Index") defined by number of 4 or more liquid stools/day for the last 7 d, with or without blood, erythema on sigmoidoscopy and histological confirmation of active ulcerative colitis.

The study populations were comparable. In particular: the median clinical activity index on study entry was 11 in the mesalazine group and nine in the EcN group (up to 30% of patients had a severe disease). The median sigmoidoscopy score was four in both groups. All patients received rectal or oral steroids at different doses together with a 1-wk course of oral gentamicin. At baseline both groups had an high active usage of steroids, around for 50% of the cases; furthermore, 2% in mesalazine group and 18% in EcN. In both groups the proportion between proctitis, left sided and pancolitis was similar (1/3 per each condition). No significant differences between the 2 groups were found.

Active treatment, started at the enrolment, was hydrocortisone enema twice daily, prednisolone 30 mg a day in moderate colitis and prednisolone 60 mg a day in severe colitis (according to Truelov Witts criteria). Only people in remission at 12 wk were enrolled in the follow up part of the trial assessing maintenance of remission.

Starting from remission, patients were maintained on either mesalazine or *E. coli* but the doses were reduced respectively at 1.2 g per day for the mesalazine group and 2 capsules per day for the EcN group. The follow up was at 12 mo. 59 were randomised to mesalazine and 57 to EcN. Of them 75% and 68% reached remission. Of those in remission, 73% of patients in the mesalazine group and 67% in the EcN group, relapsed by 12 mo. In the mesalazine group, the mean duration of remission was 206 d (median 175) compared with 221 (median 185) in the group given *E. coli*, ($P = 0.0174$). The treatment with EcN was proved safe, acceptable, and clinically equivalent to mesalazine in maintaining remission after an acute relapse of ulcerative colitis. Finally, this study is characterized by a very high rate of relapse: this is however not un-expected as the study population comprehends moderate and also severe patients.

The third trial was conducted by Kruis *et al*[10] in 2004. This was a double-blind, double dummy study in which 327 patients affected by ulcerative colitis in remission phase were recruited. 162 patients received Mutaflor 200 mg/d and 165 received Mesalazine 500 mg three times daily for 12 mo. Inclusion criteria were: age between 18-70 years, diagnosis of UC in remission [CAI $\leqslant$ 4, endoscopic index (EI) $\leqslant$ 4, and no signs of acute inflammation on histological examination]. Furthermore, within inclusion criteria there was at

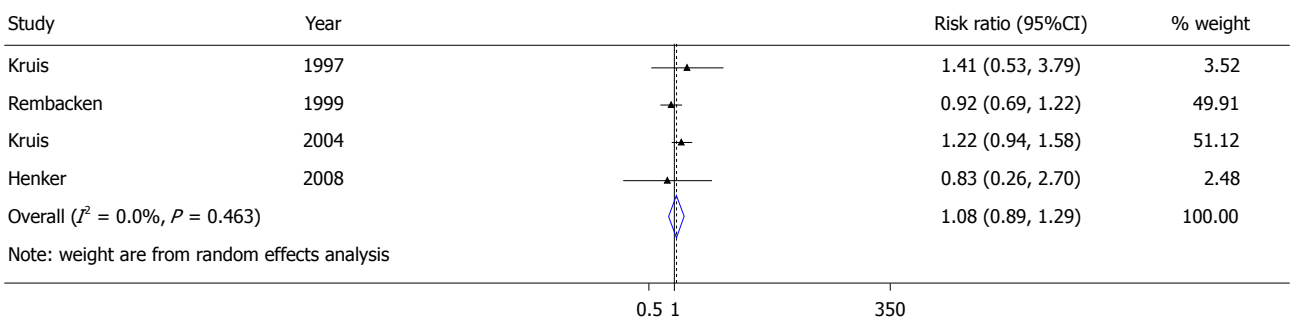

Figure 2 Metanalysis on randomized controlled trials assessing role of *Escherichia coli* Nissle on maintenance of remission in ulcerative colitis.

least two acute attacks of UC prior to the study and duration of the current remission of no longer than 12 mo. Primary objective of the study was meant to compare the number of patients experiencing a relapse during the 12 mo observation time between the two treatment groups. Secondary aims included efficacy variables like physician's and patient's assessment of general well being and calculation of a quality of life index. Additionally, time to relapse, CAI, EI, and histological findings were also evaluated. In the EcN group 36.4% of patients relapsed compared to 33.9% in the mesalazine group and statistical tests showed equivalence of the two treatments. A subgroup analyses showed no difference in terms of duration and localization of disease or pre-trial treatment. No difference of quality of life was shown in the two groups.

Overall same results on tolerance were found: it was very good or good in the EcN group in 80.0% and in the mesalazine group in 86.0%. According to the physician's assessment, the respective values were 85.1% and 90.3%. No unexpected drug reactions occurred during the study.

This is perhaps the best study based on the quality of data and also the large number of patients enrolled. Furthermore clinical outcomes were assessed by well-established endoscopic and histological activity indices, like in modern trials for more powerful drugs.

In addition to the above-described trials, there is a multicentric placebo-controlled study on 90 patients with moderate distal active UC conducted by Matthes *et al*[29] Patients in EcN groups received EcN 40, 20 or 10 mL (amount of bacteria 10E8/mL) enema once daily for at least 2 wk. A clinical DAI was recorded after 2, 4 and/or 8 wk.

The majority of patients also received concomitant medical treatment such as oral mesalazine. Remission rates and improvement of the histological score was showed particularly in the EcN 40 mL group, but further studies on largest population are required.

This study has shown that rectal administration of EcN is an effective treatment, with a dose dependent efficacy as shown in the Per Protocol analysis. Unfortunately the ITT analysis did not show significant results[29].

Many meta-analysis present in the literature support the role of ECN in the therapy of ulcerative colitis[6,10,27,28,30]. In particular, a very recent published meta-analysis, performed by Losurdo *et al*[31] (Figure 2), showed a non-significant inferiority of EcN in relapse prevention compared to mesalazine in preventing disease relapse, thus confirming current guideline recommendations[31], despite a novel randomized double-blinded placebo controlled trial conducted in Denmark and published very recently[32], with negative results. One hundred patients with active UC defined by CAI-score $\geqslant$ 6 and with calprotectin higher than 50 mg/kg, were enrolled and randomized into four groups of treatment: Ciprofloxacin (for 1 wk) followed by EcN (for 7 wk), Ciprofloxacin (for 7 wk) followed by placebo (for one week), placebo (for one week) followed by EcN (for 7 wk) and placebo (for one week) followed by placebo (for 7 wk). Aim of the study was the induction of the remission in ulcerative colitis and Kaplan-Meier curves were used to compare groups. In this study, the 54% of patients in the placebo/EcN group reached remission, compared to 89% of patients in the placebo/placebo group (P < 0.05), 78% of Ciprofloxacin/placebo group and 66% Ciprofloxacin/EcN group. Furthermore, the placebo/EcN group had the largest number of withdrawals. These impressive results, which would exclude a role of EcN in treatment of active ulcerative colitis, display several limitations, which make this study really weak. First of all this is a monocenter study, with a very not homogeneous population as showed in the table of patients characteristics. Mean CAI score at baseline was 10.5, 8.9, 9.3 and 8.9 in the Cipro/EcN, Cipro/placebo group, placebo/EcN group, placebo/placebo group, respectively. Furthermore patients clearly differed in concomitant medications use, in particular for use of active use of topical drugs and steroids as well as immunosuppressant. Taken together, these data suggest that this trial display major limitations regarding groups homogeneity. We confirmed the data from the published metanalysis, which we performed independently before discovering that it was just published. In the present paper we report an extract of the recent published metanalysis on the equivalence of the treatment between ECN and mesalazine[31],

Table 2 Main potential clinical indications for *Escherichia coli* Nissle in gastroenterology

Maintenance of remission in ulcerative colitis[6,10,27,28]
Irritable bowel syndrome[34-37]
Constipation[38,39]
Acute diarrhea[6,40]
Collagenous colitis[41]
Uncomplicated diverticular disease[7]

starting from the major trials available. An equivalence between EcN and mesalamine on maintenance of remission in UC is still detectable (Figure 2).

Other studies assessing the use of EcN in ulcerative colitis

There is also an open-label multicenter pilot study that investigate the clinical benefit of EcN 1917 for maintenance therapy in young patients with UC. In this study 34 patients with UC in remission aged between 11 and 18 years were allocated either to EcN (2 capsules daily n = 24) or 5-ASA (median 1.5 g/d, n = 10), and observed over one year[33]. Inclusion criteria were: 11-18 years of age, ulcerative colitis in remission for a maximum of 12 mo, at least 2 relapses prior inclusion, active therapy with mesalazine. Taking into account the low statistical power of the study, relapse rate was 25% (6/24) in the EcN group and 30% (3/10) in the 5-ASA group. Data on the patients' global health and development were favorable and no serious adverse events were reported[33].

CONCLUSION

EcN is a well known probiotic, used in several countries for GI diseases (Table 2)[6,10,27,28,34-41], registered as a drug in certain European countries, and it is the only one approved for maintenance of remission in UC patients by ECCO guidelines, based on data discussed also in the present paper. Trials designed to be non-inferiority/equivalence trials, comparing EcN to mesalazine, have reported equivalent rates of relapse between the two treatments, demonstrating that EcN is equivalent to mesalazine in the maintenance of remission in UC. Of the 3 major trials demonstrating these findings, the best and larger trial is the one conducted by Kruis *et al* and published on 2004. Finally, EcN showed a robust safe profile in UC patients. Further studies may be helpful to further dissect mechanisms of actions and perhaps optimize dose and newer indication of EcN.

Abstract

AIM: To explore the expression of transient receptor potential vanilloid 4 (TRPV4) and its physiological meaning in mouse and rat gastric epithelia.

METHODS: RT-PCR and immunochemistry were used to detect TRPV4 mRNA and protein expression in mouse stomach and a rat normal gastric epithelial cell line (RGE1-01), while Ca^{2+}-imaging and electrophysiology were used to evaluate TRPV4 channel activity. ATP release was measured by a luciferin-luciferase assay. Gastric emptying was also compared between WT and TRPV4 knockout mice.

RESULTS: TRPV4 mRNA and protein were detected in mouse tissues and RGE1-01 cells. A TRPV4-specific agonist (GSK1016790A) increased intracellular Ca^{2+} concentrations and/or evoked TRPV4-like current activities in WT mouse gastric epithelial cells and

RGE1-01 cells, but not TRPV4KO cells. GSK1016790A or mechanical stimuli induced ATP release from RGE1-01 cells while TRPV4 knockout mice displayed delayed gastric emptying *in vivo*.

CONCLUSION: TRPV4 is expressed in mouse and rat gastric epithelium and contributes to ATP release and gastric emptying.

Key words: Transient receptor potential vanilloid 4; Stomach; Gastric emptying; ATP

Core tip: A mechano-sensitive ion channel, transient receptor potential vanilloid 4 (TRPV4), is expressed in gastric epithelium and contributes to ATP release and gastric emptying. These findings suggest that gastric distension stimulates TRPV4 on gastric epithelium and released ATP stimulates sub-epithelial nerve fibers or acts on visceral smooth muscles. TRPV4 might be a promising novel diagnostic and therapeutic target for functional gastric disorders.

Transient receptor potential vanilloid 4-dependent calcium influx and ATP release in mouse and rat gastric epithelia. *World J Gastroenterol* 2016; 22(24): 5512-5519 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5512.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5512

INTRODUCTION

The transient receptor potential vanilloid 4 channel (TRPV4) is a non-selective cation channel that is involved in various cellular functions[1] and is activated by several physical and chemical stimuli, including mechanical stimuli, endogenous arachidonic acid metabolites (epoxyeicosatrienoic acids)[2], and heat. TRPV4 is also activated by the specific agonist GSK1016790A that elicits whole-cell currents in mouse and rat TRPV4-expressing cells with EC_{50} values of 18.5 and 10 nmol/L, respectively[3]. TRPV4 is widely expressed throughout the body, including gastrointestinal tract epithelium and the esophagus[4]. Although the physiological function of TRPV4 expression in intestinal epithelial cells is unknown, TRPV4 activation in these cells causes increases in intracellular calcium concentrations, chemokine release, and incidence of colitis[5], as well as increased paracellular permeability[6]. Furthermore, TRPV4 antagonists are promising therapeutic options for colitis[7,8]. However, TRPV4 expression in the gastric epithelium awaits evaluation.

In addition to its function as an intracellular energy donor, ATP is recognized as an important signaling molecule that mediates diverse biological effects *via* cell surface receptors: the purinergic receptors[9]. ATP is released by neurons of the central, peripheral, and enteric nervous system[10,11], and acts as a non-adrenergic non-cholinergic (NANC) neurotransmitter that causes different responses or effects (either excitatory or inhibitory depending on the P2 receptor subtype upon which they act as well as the animal species under study). Several studies showed that purinergic neurotransmission (assuming that gut neurons are the sole source of released ATP) affects gastric motility[12]. Recent reports showed that ATP is also released from non-neuronal tissues and has an effect on tissue function. Moreover, we found that ATP release in the esophagus and urothelium was mediated by TRPV4 stimulation[4,13,14]. However, there are no data concerning whether TRPV4 is expressed in the stomach and, if so, whether TRPV4 stimulation plays a role in mediating ATP release. Therefore, this study explored the morphological (RT-PCR and immunostaining) and functional (Ca^{2+}-imaging, patch clamp and gastric emptying) expression of TRPV4 in mouse and rat stomach with special focus on gastric epithelium.

MATERIALS AND METHODS

Animals

Eight week-old male C57BL/6NCr (SLC) and TRPV4-knockout (TRPV4KO) mice[15] weighing between 23 and 25 g were housed in a controlled environment (12-h light/12-h dark cycle; room temperature, 22-24 ℃; 50%-60% relative humidity) with free access to food and water. All procedures involving the care and use of animals were approved by The Institutional Animal Care and Use Committee of the National Institutes of Natural Sciences.

Cell lines

RGE1-01 is an immortalized rat gastric mucosal cell line that shows distinct cell differentiation types and preserves some epithelial cell characteristics. RGE1-01 cells were maintained at 34 ℃ in Dulbecco's modified Eagle medium supplemented with 10% heat-inactivated fetal bovine serum, 100 μg/mL streptomycin and 100 U/mL penicillin with the addition of ITES (see reference[16] for details).

Acute isolated mouse gastric epithelium

WT and TRPV4KO mice were sacrificed by cervical dislocation. The stomachs were washed in cold (4 ℃) PBS (-) and then incubated in trypsin solution (Invitrogen) at 4 ℃ for 1 h. Gastric epithelial cells were harvested and plated on CELL-TAK (BD Biosciences)-coated glass cover slips and used for Ca^{2+}-imaging and patch clamp experiments.

Reverse transcription PCR analysis

RT-PCR was performed as previously described[4,17]. Total RNA (1 μg) was isolated using the RNeasy Mini

Table 1 Primer sequences for RT-PCR

Primer name	Sequence (5'→3')
mTRPV4-F	ACAACACCCGAGAGAACACC
mTRPV4-R	CCCAAACTTACGCCACTTGT
mGAPDH-F	TGAAGGGTGGAGCCAAAAGG
mGAPDH-R	GGAAGAGTGGGAGTTGCTGTTG
rTRPV4-F	CCTGGCAGGGATCGAGGCCT
rTRPV4-R	GGATGGTGGTGGCCCACTGC
rGAPDH-F	GCCAAGGCTGTGGGCAAGGT
rGAPDH-R	GAGCAATGCCAGCCCCAGCA

Kit (Qiagen, Courtaboeuf, France) and measured with a NanoDrop device (Thermo Fisher Scientific Inc., Wilmington, United States). Genomic DNA was eliminated in the process of reverse transcription (QuantiTect Reverse Transcription Kit, QIAGEN). PCR was performed using rTaq DNA polymerase (TaKaRa) in an iCycler (Bio-Rad) with specific primer sets (Table 1).

Immunochemistry

Immunochemistry was performed as previously described[4] using the antibodies summarized in Table 2. For section preparation, mouse stomachs were fixed at 4 ℃ for 6 h. Tissues were placed in PBS-sucrose and embedded in OCT compound (Tissue Tek, Elkhart, IN, United States). Non-specific antibody binding was reduced by incubation in BlockAce (Yukijirushi, Sapporo, Japan) for 1 h at room temperature prior to antibody exposure. Preparations were analyzed using a confocal laser scanning microscope (LSM 700, Carl Zeiss). For immunocytochemistry, RGE1-01 cells were fixed at 4 ℃ for 20 min with the same fixative. Bovine serum albumin (3% BSA; Sigma) was used as a blocking solution.

Ca^{2+}-imaging

Fura-2 fluorescence was measured in primary mouse gastric epithelial cells and RGE1-01 cells with a standard bath solution containing 140 mmol/L NaCl, 5 mmol/L KCl, 2 mmol/L $MgCl_2$, 2 mmol/L $CaCl_2$, 10 mmol/L HEPES, and 10 mmol/L glucose at pH 7.4 (adjusted with NaOH) at 25 ℃. Results are presented as ratios of fluorescence intensities obtained with fura-2 emissions at 340 nm and 380 nm. GSK1016790A[3] and ionomycin (both from Sigma) were used as a TRPV4 agonist and a positive control, respectively. F_{340}/F_{380} was calculated and acquired with an image processing system (IP-Lab, Scanalytics Inc., Rockville, MD or AQUA COSMOS, Hamamatsu Co., Japan) and ImageJ software (http://rsb.info.nih.gov/ij/). Changes in ratio (Δ) were calculated by subtracting the mean basal values from peak values. Since the degree of responses (strong, weak, or no response) to GSK varied from cell to cell in WT gastric epithelial cells, we expressed the observed changes in all ionomycin-responsive cells as a ratio between WT and TRPV4 knockout mice (Δ). We evaluated 53 and 41 ionomycin-responsive cells from six WT mice and five TRPV4 knockout mice, respectively. Given the variations in response times, and that some WT cells responded 30 s after GSK application, we decided to incubate cells with GSK for 90 s.

Table 2 Primary and secondary antisera for immunochemistry

Tissue antigen/host	Dilution	Source
TRPV4/rabbit	1:500	B. Nilius, or Abcam
Goat anti-rabbit IgG-Alexa488	1:1500	Invitrogen, Inc.

Electrophysiology

The standard bath solution was the same as that used in the Ca^{2+}-imaging experiments. Pipette solutions for whole-cell recordings contained 140 mmol/L KCl, 5 mmol/L EGTA and 10 mmol/L HEPES, pH 7.4. Whole-cell recording data on primary gastric epithelial cells three hours after insolation and RGE1-01 were sampled at 10 kHz and filtered at 5 kHz for analysis (Axon 200B amplifier with pCLAMP software, Molecular Devices, Foster City, CA, United States). Voltage ramp-pulses from -100 mV to +100 mV (500 ms) were applied every 5 s to generate an I-V curve.

ATP release measurement

ATP concentrations released from RGE1-01 rat gastric epithelial cells cultured in 12-well plates or stretch silicon chambers (STB-10-04 from STREX Inc., Osaka, Japan) were measured by a luciferin-luciferase assay (ATP Bioluminescence assay kit CLS II, Roche Diagnostics) and a luminometer (Lumat LB 9507, Berthold Technologies, Japan), using a previously described method that was slightly modified[4]. For chemical stimuli, cells cultured to 70%-80% confluence and incubated in 500 μL bath solution for 30 min at room temperature (25 ℃) were used to measure basal ATP release. The superfusate was collected and replaced gently with another 500 μL of bath solution with or without the TRPV4 agonists GSK1016790A or 5,6-EET. The superfusate was collected after 15 min and the ratio of released ATP (15 min stimulation/30 min basal condition) was calculated. An aliquot (200 μL) of superfusate was then mixed with 200 μL luciferin-luciferase reagent for luminometric ATP measurements. For mechanical stimuli, stretching was quantitatively applied with a STB-10 stretch machine (STREX Inc.) to RGE1-01 cells cultured on a silicon chamber. Three minutes after chamber placement in the stretch machine, the superfusate was washed away to exclude artificial ATP release and replaced with 500 μL of bath solution for basal ATP measurement. After a further 3 min, the superfusate was collected and replaced, whereupon mechanical stimuli was applied for 3 min and the ratio of released ATP (3 min stimulation/3 min basal condition) was calculated. To block TRPV4 channels, cells were pre-treated with the specific TRPV4 antagonist HC 067047 (Sigma, 1 μmol/L) for 3 min[18].

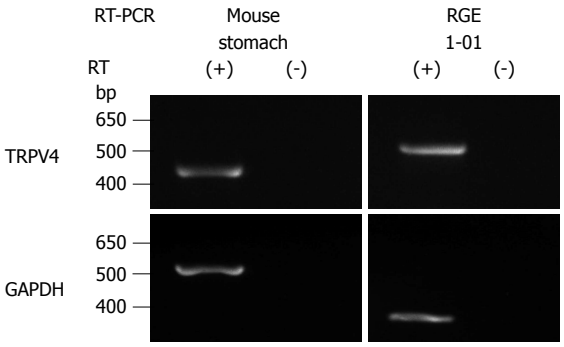

Figure 1 *TRPV4* mRNA expression in mouse stomach and RGE1-01 cells. *TRPV4* and *GAPDH* mRNA levels were examined with (+) and without (-) RT reaction. The expected sizes of the amplified fragments for *TRPV4* and *GAPDH* were 404 and 545 bp for mouse and 524 and 268 bp for rat, respectively. *TRPV4* mRNA was detected in mouse stomach and RGE1-01 cells (RGE1-01: normal rat gastric epithelial cell line). Band positions differed due to the use of different primers.

Gastric emptying

Eight-week-old WT and TRPV4KO male mice were used with a modified version of previously reported methods[17]. Gastric emptying was determined by transit of a test meal containing phenol red. Mice were fasted for 14 h with *ad libitum* water before the experiment. Five mg/kg (200 μL) of the test meal was administered into the stomach using a feeding needle. Fifteen minutes later, the mice were euthanized by cervical dislocation and the gastrointestinal tract was removed. The stomach was minced and the remaining phenol red concentration was measured. Gastric emptying was expressed as mean ± SEM for each group.

Data analysis

Values for Ca^{2+}-imaging, patch-clamp experiments, ATP measurements, and gastric emptying are presented as mean ± SEM from three or more independent experiments. A Student's *t*-test or non-parametric Bonferroni-type multiple comparison was used. Significance was accepted for $P < 0.05$.

RESULTS

TRPV4 expression in mouse and rat gastric epithelia

Given that TRPV4 was shown to be expressed in the esophagus and intestinal epithelia[4-6,19,20], we examined *TRPV4* mRNA expression in mouse stomach and a rat gastric epithelial cell line, RGE1-01. *TRPV4* mRNA was detected in mouse stomach and RGE1-01 cells (Figure 1). We next examined TRPV4 protein expression in mouse and the RGE1-01 cells. A strong homogenous immunofluorescent signal was confined to the epithelial cell layer of the WT mouse gastric corpus and antrum but not in cells from TRPV4KO mice (Figure 2A). Meanwhile, Z-stack images obtained by confocal microscopy of RGE1-01 cells displayed apical TRPV4 expression (Figure 2B).

TRPV4-mediated increase in cytosolic Ca^{2+} ($[Ca^{2+}]_i$) in mouse primary gastric epithelial cells

To confirm functional TRPV4 expression in primary gastric epithelial cells and RGE1-01 cells, we examined the response to the reported specific TRPV4 agonist, GSK1016790A (GSK)[3], using a fluorescent Ca^{2+}-imaging system (10 μmol/L, fura-2/AM). Response traces of $[Ca^{2+}]_i$ for WT and TRPV4KO gastric epithelial cells in the presence of GSK (100 nmol/L) showed that almost all cells isolated from WT stomach responded to GSK (Figure 3A) and the $[Ca^{2+}]_i$ increases were significantly larger in WT cells compared to TRPV4KO cells (Figure 3B). This finding suggests that the majority of gastric epithelial cells expressed TRPV4 and $[Ca^{2+}]_i$ responses to GSK were TRPV4 specific.

TRPV4-mediated current responses in mouse primary gastric epithelial cells and RGE1-01 cells

We next performed patch-clamp experiments with acute isolated mouse gastric epithelial cells in the presence of GSK (300 nmol/L) and observed inward current responses with an outwardly rectifying IV-relationship in WT but not TRPV4KO cells (Figure 4A)[3]. Current responses were observed in all 5 trials with WT gastric epithelial cells but were completely absent with TRPV4KO cells, which indicates that the majority of gastric epithelial cells expressed TRPV4. Similar chemical stimulation with GSK (300 nmol/L) induced TRPV4-like current responses in the rat gastric epithelial cell line, RGE1-01 (Figure 4B). These data strongly indicated functional expression of TRPV4 in mouse and rat gastric epithelial cells.

TRPV4 activators induced ATP release from RGE1-01 cells

Mechanical stimuli reportedly activate TRPV4 expressed in esophageal keratinocytes that in turn leads to increased ATP release[4]. To examine whether TRPV4 stimulation has a similar effect in gastric epithelium, we measured ATP release in chemically- or mechanically-stimulated RGE1-01 cells using a luciferin-luciferase assay. TRPV4 agonists GSK1016790A (GSK, 100 nmol/L) or 5,6-EET (500 nmol/L)[2] significantly increased ATP release in RGE1-01 cells (Figure 5A, 2- to 3-fold higher *vs* control, $P < 0.05$). Additionally, 120% lateral stretch applied for 3 min to RGE1-01 cells cultured on a silicon chamber induced significantly higher amounts of ATP release (Figure 5B, about 2-fold *vs* without stretch (control), $P < 0.05$), and these responses were inhibited by the specific TRPV4 inhibitor HC 067047 (1 μmol/L) (stretched cells showed no detachment over the 3-min stretch period). These results suggested that chemical and mechanical stimuli-induced ATP release in RGE1-01 cells was mediated by TRPV4 channel activation.

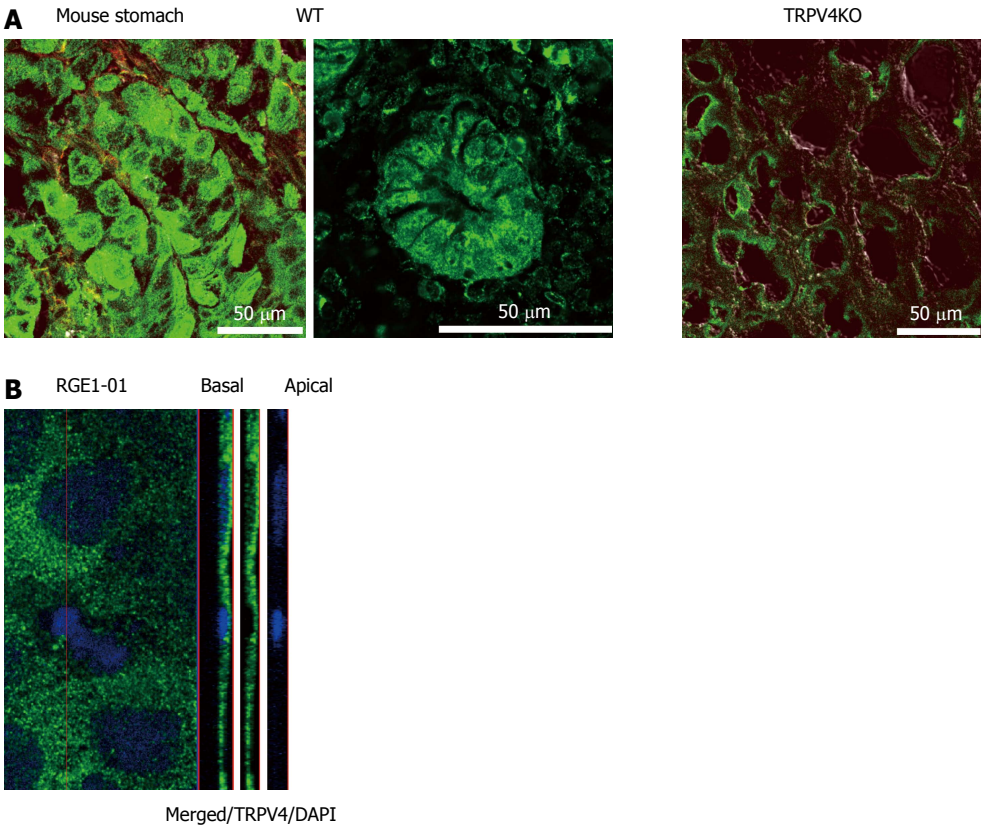

Figure 2 TRPV4 protein expression in mouse stomach and RGE1-01 cells. A: TRPV4 expression was homogeneously observed in WT but not TRPV4KO mouse gastric epithelium. Bars indicate 50 μm; B: Z-stack image of RGE1-01 cells demonstrated apical TRPV4 expression.

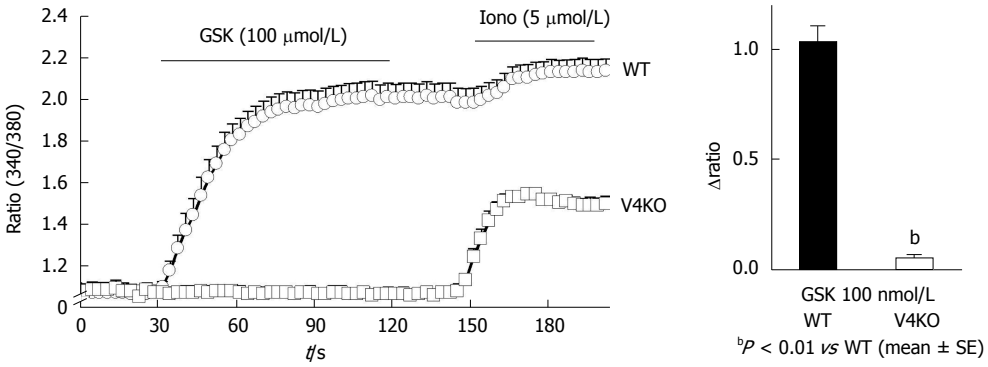

Figure 3 TRPV4-mediated increases in cytosolic Ca^{2+} ($[Ca^{2+}]_i$) in mouse primary gastric epithelial cells. A: $[Ca^{2+}]_i$ changes (340/380 ratio) in response to the TRPV4 specific agonist GSK1016790A (GSK, 100 nmol/L) in WT or TRPV4KO (V4KO) primary gastric epithelial cells (mean ± SEM). Ionomycin (iono, 5 μmol/L) was used as a positive control. Bars indicate the period of chemical application; B: GSK significantly increased $[Ca^{2+}]_i$ in WT cells (means ± SD; 1.03 ± 0.07, n = 20) compared to TRPV4KO cells (0.05 ± 0.01, n = 20) ($^bP < 0.01$ *vs* WT).

Delayed gastric emptying in TRPV4KO mice

Since TRPV4 has been shown to sense chemical and mechanical stimuli and contribute to ATP release from gastric epithelial cells, we hypothesized that TRPV4KO mice would exhibit altered gastric motility. To evaluate the physiological role of TRPV4 expressed in the gastric epithelium, we performed an *in vivo* experiment to compare gastric emptying rates of WT and TRPV4KO mice. Gastric emptying rates in TRPV4KO mice were about 2/3 of those in WT (Figure 6), suggesting that TRPV4 contributes to gastric motor function.

DISCUSSION

We identified morphological and functional TRPV4 expression in mouse gastric epithelial cells as well as the rat gastric epithelial cell line RGE1-01 (Figures 1-4). Furthermore, we demonstrated that chemical and mechanical stimuli can induce TRPV4-dependent ATP release from RGE1-01 cells (Figure 5), and that stimulation of gastric epithelial TRPV4 enhances gastric emptying *in vivo* (Figure 6). Using immunohistochemistry, Ca^{2+} imaging,

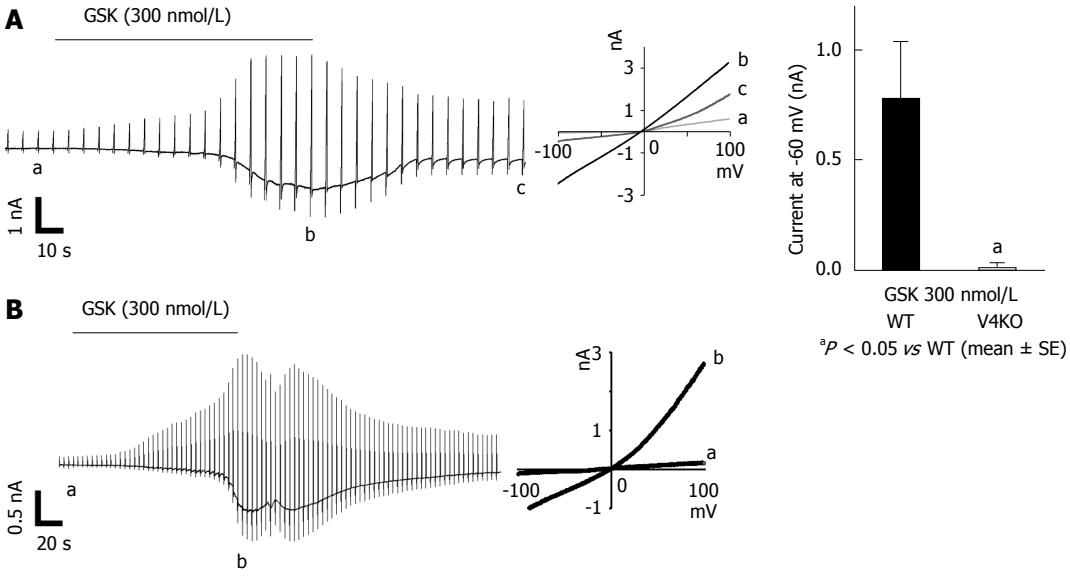

Figure 4 TRPV4-mediated current responses in mouse primary gastric epithelial cells and RGE1-01 cells. A: GSK (300 nmol/L) evoked inward current responses in WT primary gastric epithelial cells. Currents in response to ramp-pulses at points a, b and c (left in panel B) are shown (middle), with a strongly outwardly rectifying current-voltage relationship. Significantly larger inward currents at -60 mV were obtained from WT cells (means ± SEM; 0.76 ± 0.27 nA, n = 5) than in TRPV4KO cells (0.01 ± 0.00 nA, n = 5) ([a]P < 0.05 *vs* WT). B: Similar current responses were also obtained in RGE1-01 cells.

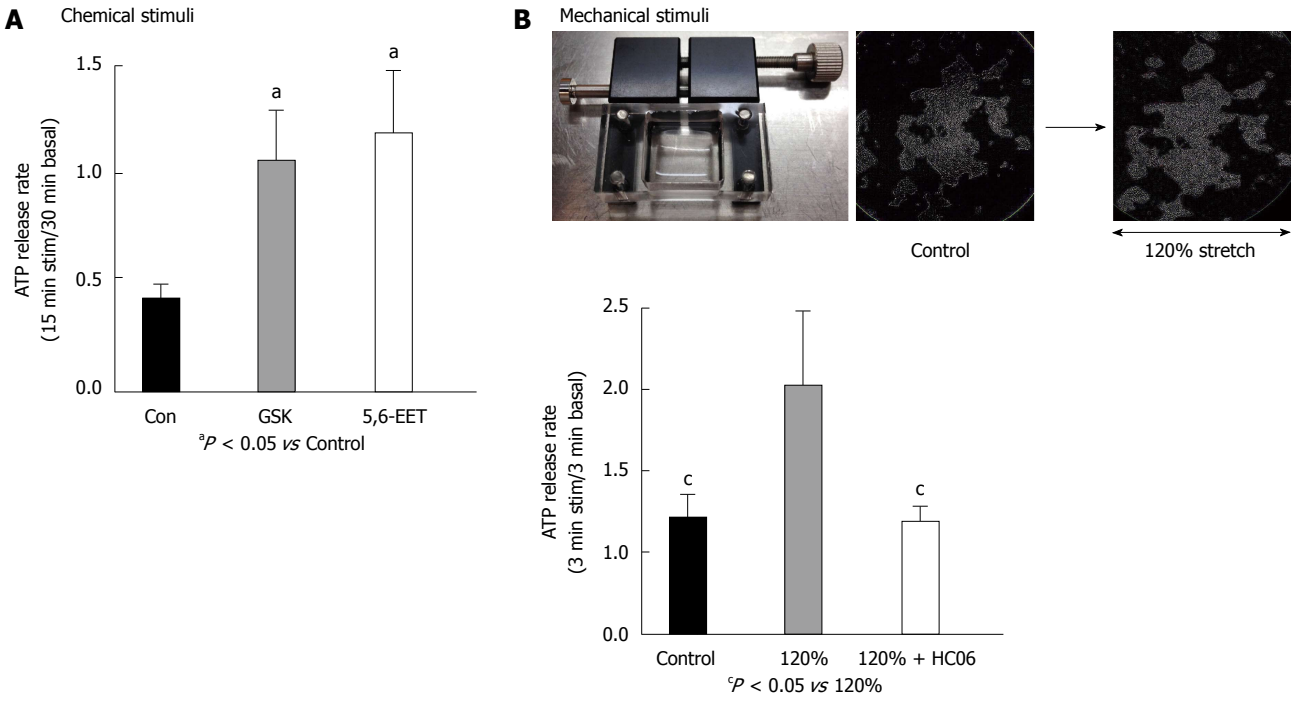

Figure 5 TRPV4 activator-induced ATP release in the RGE1-01 cells. A: GSK1016790A (GSK, 100 nmol/L) or 5,6-EET (500 nmol/L) induced significantly higher ATP release in RGE1-01 cells ([a]P < 0.05 *vs* Control). B: Mechanical stimuli were quantitatively applied with a stretch apparatus. Microscopy images demonstrated that cells were stretched laterally without detachment. A 120% stretch induced significantly higher amounts of ATP release from RGE1-01 cells [[c]P < 0.05 *vs* 0% stretch (control)] that could be inhibited by pre-treatment with specific TRPV4 antagonist HC 067047 (1 μmol/L). TRPV4: Transient receptor potential vanilloid 4.

and electrophysiology, we found that the majority of mouse gastric epithelial cells exhibited abundant TRPV4 expression and responded to TRPV4 agonists, suggesting that TRPV4 is a candidate mechanoreceptor in gastric epithelial cells. In fact, ATP release was several hundred nmol/L in our *in vitro* study, suggesting that the corresponding ATP concentration *in vivo* might be estimated to be several μmol/L, which would be sufficient to activate the P2 receptor present in the wall of mouse stomach[21,22]. These results suggested the hypothesis that luminal distension stimulates TRPV4 on gastric epithelial cells that in turn release ATP. The released ATP either stimulates subepithelial sensory nerve fibers that form the afferent limb of short or long gastrointestinal reflex arcs or acts directly on visceral smooth muscles expressing

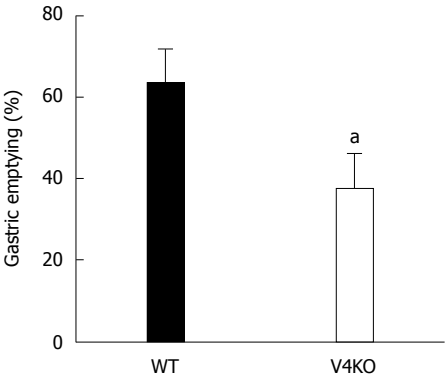

Figure 6 Delayed gastric empting in TRPV4 knockout mice. Gastric emptying rates *in vivo* in TRPV4KO mice were significantly delayed relative to WT mice ($^{a}P < 0.05$, *vs* WT, $n = 7$-9).

purinergic receptors. The first possibility is supported by morphological evidence showing that purinergic receptors, mainly P2X2 and P2X3, were identified on putative gastric mechanosensing structures, including the vagal afferent intraganglionic laminar endings that are located in close proximity to the epithelium[23,24]. These vagal afferents form the afferent limb of the central vago-vagal reflex (long reflex arc) and are known to increase gastric motility following stimulation[25]. The hypothesis is also supported by findings from a previous study wherein P2X3-knockout mice show a blunted neural response to gastric distension and no differences in distension-evoked ATP release between knockout and control mice[26]. The released ATP could also trigger a local reflex arc intrinsic to the stomach wall, which is supported by results from a previous study wherein ATP was shown to induce tetrodotoxin-sensitive contraction responses mediated by neuronal P2X receptors in an *in vitro* whole-stomach preparation[27].

The possibility that ATP released from gastric epithelium could directly stimulate purinergic receptors expressed on gastric visceral smooth muscles is rather unlikely considering the short half-life of ATP and the distance that ATP must cross while diffusing from the gastric epithelium to visceral smooth muscles. Moreover, gastric smooth muscles are known to functionally express P2Y receptors that mediate relaxation in response to ATP[27] and would be expected, upon stimulation, to delay gastric emptying, which is opposite to our current findings. This outcome further decreases the likelihood of a direct effect for ATP released from gastric epithelium on smooth muscles. However, the purinergic signaling pathway that mediates gastric distension-induced epithelial TRPV4 stimulation requires further future characterization.

In conclusion, TRPV4 is morphologically and functionally expressed in mouse and rat gastric epithelia and contributes to ATP release and gastric emptying. Our results suggest that TRPV4 could be a promising novel diagnostic and therapeutic target for functional gastrointestinal disorders.

COMMENTS

Background

The transient receptor potential vanilloid 4 channel (TRPV4) is a non-selective cation channel that is activated by mechanical stimuli. ATP has been recognized as an important signaling molecule *via* cell surface ATP receptors. This study explored TRPV4 expression in mouse and rat stomach and whether the stimulation mediated ATP release.

Research frontiers

The authors have reported that ATP release in the esophagus and urothelium is mediated by TRPV4 stimulation.

Innovations and breakthroughs

This is the first study showing TRPV4 expression and ATP release by its stimulation in the mouse stomach and/or rat gastric epithelial cells.

Applications

These data suggested the hypothesis that luminal distension stimulates TRPV4 on gastric epithelial cells that in turn release ATP. However TRPV4 expression in human gastric epithelium and the purinergic signaling pathway requires further evaluation.

Terminology

TRPV4 is a non-selective cation channel, that is activated by several physical and chemical stimuli, including mechanical stimuli. The channel activation increases intracellular Ca^{2+} concentration and elicits whole-cell currents in TRPV4-expressing cells.

Peer-review

The manuscript describes an original research performed in mouse stomach and in rat epithelium cell line focusing on the expression and function of TRPV4 ion channels. The study concept is based on previous findings of the authors regarding TRPV4-mediated ATP release on the esophasgus. The series of experiments in this manuscript demonstrated delayed gastric emptying in TRPV4 knockout mice compared to their WT littermates, as well as TRPV4 expression in mRNA and protein levels in both mouse and rat gastric epithelial cell line. In general, the idea is interesting, the various morphological and functional methods are sophisticated, the figures are demonstrative.

Abstract

AIM: To assess intravoxel incoherent motion diffusion-weighted imaging (IVIM-DWI) for monitoring early efficacy of chemotherapy in a human gastric cancer mouse model.

METHODS: IVIM-DWI was performed with 12 *b*-values (0-800 s/mm^2) in 25 human gastric cancer-bearing nude mice at baseline (day 0), and then they were randomly divided into control and 1-, 3-, 5- and 7-d treatment groups (n = 5 per group). The control group underwent longitudinal MRI scans at days 1, 3, 5 and 7, and the treatment groups underwent subsequent MRI scans after a specified 5-fluorouracil/calcium

folinate treatment. Together with tumor volumes (TV), the apparent diffusion coefficient (ADC) and IVIM parameters [true water molecular diffusion coefficient (D), perfusion fraction (f) and pseudo-related diffusion coefficient (D^*)] were measured. The differences in those parameters from baseline to each measurement (ΔTV%, ΔADC%, ΔD%, Δf% and ΔD^*%) were calculated. After image acquisition, tumor necrosis, microvessel density (MVD) and cellular apoptosis were evaluated by hematoxylin-eosin (HE), CD31 and terminal-deoxynucleotidyl transferase mediated nick end labeling (TUNEL) staining respectively, to confirm the imaging findings. Mann-Whitney test and Spearman's correlation coefficient analysis were performed.

RESULTS: The observed relative volume increase (ΔTV%) in the treatment group were significantly smaller than those in the control group at day 5 ($\Delta TV_{treatment}$% = 19.63% ± 3.01% and $\Delta TV_{control}$% = 83.60% ± 14.87%, P = 0.008) and day 7 ($\Delta TV_{treatment}$% = 29.07% ± 10.01% and $\Delta TV_{control}$% = 177.06% ± 63.00%, P = 0.008). The difference in ΔTV% between the treatment and the control groups was not significant at days 1 and 3 after a short duration of treatment. Increases in ADC in the treatment group ($\Delta ADC\%_{treatment}$, median, 30.10% ± 18.32%, 36.11% ± 21.82%, 45.22% ± 24.36%) were significantly higher compared with the control group ($\Delta ADC\%_{control}$, median, 4.98% ± 3.39%, 6.26% ± 3.08%, 9.24% ± 6.33%) at days 3, 5 and 7 (P = 0.008, P = 0.016, P = 0.008, respectively). Increases in D in the treatment group ($\Delta D\%_{treatment}$, median 17.12% ± 8.20%, 24.16% ± 16.87%, 38.54% ± 19.36%) were higher than those in the control group ($\Delta D\%_{control}$, median -0.13% ± 4.23%, 5.89% ± 4.56%, 5.54% ± 4.44%) at days 1, 3, and 5 (P = 0.032, P = 0.008, P = 0.016, respectively). Relative changes in f were significantly lower in the treatment group compared with the control group at days 1, 3, 5 and 7 follow-up (median, -34.13% ± 16.61% *vs* 1.68% ± 3.40%, P = 0.016; -50.64% ± 6.82% *vs* 3.01% ± 6.50%, P = 0.008; -49.93% ± 6.05% *vs* 0.97% ± 4.38%, P = 0.008, and -46.22% ± 7.75% *vs* 8.14% ± 6.75%, P = 0.008, respectively). D* in the treatment group decreased significantly compared to those in the control group at all time points (median, -32.10% ± 12.22% *vs* 1.85% ± 5.54%, P = 0.008; -44.14% ± 14.83% *vs* 2.29% ± 10.38%, P = 0.008; -59.06% ± 19.10% *vs* 3.86% ± 5.10%, P = 0.008 and -47.20% ± 20.48% *vs* 7.13% ± 9.88%, P = 0.016, respectively). Furthermore, histopathologic findings showed positive correlations with ADC and D and tumor necrosis (r_s = 0.720, P < 0.001; r_s = 0.522, P = 0.007, respectively). The cellular apoptosis of the tumor also showed positive correlations with ADC and D (r_s = 0.626, P = 0.001; r_s = 0.542, P = 0.005, respectively). Perfusion-related parameters (f and D^*) were positively correlated to MVD (r_s = 0.618, P = 0.001; r_s = 0.538, P = 0.006, respectively), and negatively correlated to cellular apoptosis of the tumor (r_s = -0.550, P = 0.004; r_s = -0.692, P < 0.001, respectively).

CONCLUSION: IVIM-DWI is potentially useful for predicting the early efficacy of chemotherapy in a human gastric cancer mouse model.

Key words: Gastric cancer; Microvessel density; Nude mouse model; Intravoxel incoherent motion diffusion-weighted imaging; Terminal-deoxynucleoitidyl transferase mediated nick end labeling

Core tip: Intravoxel incoherent motion diffusion-weighted imaging (IVIM-DWI) is useful for monitoring changes of molecular diffusion and microcirculation in gastric cancer at the early stage of chemotherapy. The apparent diffusion coefficient (ADC) and IVIM parameters of true water molecular diffusion coefficient (D) could be reliable marker to detect the necrosis and cellular apoptosis, while perfusion-related IVIM parameters of perfusion fraction (f) and pseudo-related diffusion coefficient (D^*) are capable of noninvasive assessment of angiogenesis activity in gastric cancer undergoing chemotherapy.

Intravoxel incoherent motion diffusion-weighted imaging for monitoring chemotherapeutic efficacy in gastric cancer. *World J Gastroenterol* 2016; 22(24): 5520-5531 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5520.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5520

INTRODUCTION

Gastric cancer (GC) remains the fourth most common malignancy and the second-leading cause of cancer deaths in the world[1]. Despite many advances in cancer diagnosis and treatment, approximately two-thirds of patients are diagnosed with advanced gastric cancer (AGC) in many countries, excluding some trial results in Japanese and South Korean patients[2,3]. For many years, 5-fluorouracil (5-FU)-based chemotherapy has been considered a standard chemotherapy regimen for AGC[2-4]. Unfortunately, not all patients benefit from this regimen. If an ineffective therapy can be identified at an early stage of treatment, there will be an opportunity to change the therapy approach and clinical management in the individual patient quickly. The response evaluation criteria in solid tumors (RECIST) is widely adopted standard for evaluating therapy response based on the change in tumor size in clinical practice. However, this often takes several weeks to months to develop, and its evaluation period is too long to adjust patient management[5]. Therefore, increasing demands are being placed on imaging modalities to identify early

and reliable surrogate markers for the evaluation of therapeutic effect in patients with GC[6].

Diffusion-weighted magnetic resonance imaging (DWI) is capable of providing an apparent diffusion coefficient (ADC), which is a measure magnitude of diffusion (of water molecules) within tissue, and has become a favorite choice for oncologic studies[7]. It is well known that a lower ADC is a characteristic of most tumors compare with native tissues because of their high cellularity. An increase in tissue diffusivity, which is induced by an enlarged extracellular space, cell swelling or a loss of membrane integrity under an effective therapy, makes it possible to use ADC to identify the treatment response[8-11]. However, the ADC value derived from DWI based a mono-exponential model does not sufficiently demonstrate the characteristics of tissue behavior. The *b*-value, which represents the strength and timing of the gradients, determines DWI sensitivity to water motion. When a lower *b*-value is applied ($\leqslant$ 100 s/mm^2), microcirculation related protons have relative large diffusion distances, and are capable of changing diffusion signal intensities. In 1986, Le Bihan *et al*[12] first described the concept of intravoxel incoherent motion (IVIM), which can be used to estimate molecular diffusion and microcirculation in the capillaries separately through bi-exponential fitting of the DWI data using multiple *b*-values. In recent years, there has been increasing interests in IVIM-DWI, which allows acquisition of quantitative parameters that reflect tissue diffusivity and microcirculation perfusion simultaneously. The true water molecular diffusion coefficient (D), perfusion fractional (f) volume reflective of capillary blood volume and pseudo-related diffusion coefficient associated with capillary network blood flow (D*) can be measured using IVIM-DWI. The blood microcirculation within capillaries can be considered as a type of "pseudo-diffusion" because it has no specific orientation[13].

It has been determined that IVIM-DWI can provide a new opportunity to gain an insight into the perfusion of a tumor without contrast agent administration for preclinical and clinical applications[12,14,15]. Koh *et al*[16] reported that the calculated f values were lower in colorectal liver metastases, which are characterized by their hypovascular nature, than in the normal liver. In addition, DWI with 10 *b*-values between 0 and 700 s/mm^2 enables the measurement of diffusion and microcirculation contributions in renal allografts as early as 5-d after transplantation[17]. Moreover, IVIM-DWI has been used to evaluate the treatment responses to radiofrequency ablation[18] or a vascular disrupting agent of CKD-516[19] in rabbit model with VX2 liver tumors, and to neoadjuvant chemotherapy in human locoregionally advanced nasopharyngeal carcinoma. Although DWI is increasingly being applied in the body, few studies have focused on gastric lesions due to the limitations of modality of the gastric[20]. Recently, Cheng *et al*[21] applied IVIM with *b*-values of up to 1500 s/mm^2 to evaluate chemotherapeutic efficacy in a gastric cancer xenograft model. In that study, f increased after chemotherapy treatment, which refutes currents theories regarding angiogenesis activity within tumors after treatment[22]. A previous IVIM study in prostate cancer also found that f in tumors significantly increased compared to that in normal prostate tissue when a *b*-value of less than 750 s/mm^2 was used, while f decrease or became indistinguishable from the normal prostate tissue when high *b*-values were employed[23]. This phenomenon could be explained by the following theory: The departure of molecular diffusion at very high *b*-values may have an influence on perfusion-related parameters because both water diffusion and microcirculation contribute to the signal attenuation observed at lower *b*-values ($\leqslant$ 100 s/mm^2)[13,15]. It should be noted that higher b values may affect the accuracy of the IVIM-derived parameters, which depend heavily on the *b*-value selection.

Here, we investigate IVIM-DWI with *b*-values below 800 s/mm^2 as a potential imaging marker for assessing the early chemotherapy response in term of tissue diffusion and microvascular perfusion, by comparing the tissue cellularity and microvascular density (MVD) properties revealed by histopathological analysis during the full course of treatment using a mouse human gastric cancer xenograft model.

MATERIALS AND METHODS

Animal model

This study included 25 male adult (6 weeks old) nude mice (BALB/c-nu/nu, Orient Bio, Gwangju, South Korea), each weighing 20-25 g. All mice, fed with a standard diet with water ad libitum, were maintained in appropriate laboratory conditions (a photoperiod of 12 h light and darkness, 50% humidity, 23 ℃). After a two-week adaption period, 1 × 10^7 human gastric adenocarcinoma AGS cells (ATCC®, CRL-1739™) suspended in 100 μL cold PBS were subcutaneously injected into the lower right hind limbs of the nude mice with a 31 gauge syringe. To evaluate the therapeutic response, the tumor growth curves in each group were estimated based on the morphologic T2-weighted images by using the following formula: TV = π/6 × L × W × H (L, length, W, width, H, height of the tumor).

Study design

Following a baseline (day 0) MRI examination, human gastric cancer-bearing mice were randomly divided into control and 1-d, 3-d, 5-d, and 7-d treatment groups (n = 5 per group). 5-fluorouraci (5-FU) (15 mg/kg)/calcium folinate (5 mg/kg) was used for chemotherapy in the treatment groups, while same volume of saline was administered in the control group. 5-FU/calcium folinate was intraperitoneally injected on a bi-daily basis. Mice in the control group underwent longitudinal MRI at days 1, 3, 5 and 7. Each

treatment group underwent a second scan with same MRI protocol at days 1, 3, 5, or 7 after treatment. After the MRI examination, mice were euthanized by an overdose of isoflurane, and the tumor was stripped for further analysis. The short-term 7-d 5-FU treatment was performed, because this study was aimed to investigate the potential of IVIM-DWI for monitoring the early tumor diffusion and perfusion response to treatment.

MRI protocol

All MRI scans were performed using 3T MRI (GE Healthcare, Waukesha, WI, United States) with a wrist coil. Mice were placed on a heated pad and anesthetized with 2% isoflurane in oxygen (at a rate of 1.0 L/min) to void movement during imaging. After acquisition of the routine images for localization, a transverse T2-weighted image was obtained using fast spin echo (FSE) sequence [repetition time/echo time (TR/TE), 2000/99.6 ms; section thickness, 3 mm; matrix, 512 × 358; number of excitations (NEX), 4]. Subsequently, IVIM-DWI with 12 *b*-values (0, 10, 15, 20, 25, 30, 60, 75, 100, 200, 400 and 800 s/mm^2) were acquired using a free-breathing single-shot echo-planar imaging (EPI) sequence with application of three diffusion-gradients directions (TR/TE, 2500/66.5; section thickness, 3 mm; number of sections, 8; field of view, 10 × 10 cm^2; matrix, 128 × 128; NEX, 4) with an acquisition time of 7 min and 30 s for each study.

MR imaging analysis

The acquired datasets were transferred to a GE workstation (Advance Workstation 4.6) and analyzed using an in-house software. The ADC value was calculated by using a liner fit (least-squares fit) mono-exponential model based on the following equation: $S_b/S_0 = \exp(-b \times ADC)$[15], where S_0 is the signal intensity at a *b* value of 0 and S_b is the signal intensity at higher *b* values. IVIM parameters was calculated by a nonlinear fit (Levenberg-Marquardt fit)bi-exponential model, and the equation is shown as follow: $S_b/S_0 = (1\text{-}f) \times \exp(-bD) + f \times \exp[-b(D + D^*)]$[15], where D represents true water molecular diffusion coefficient, f and D* represent perfusion fraction and pseudo-related diffusion coefficient, respectively. A technician with 8 years of experience in MRI measured the tumor sizes and values of ADC, D, f, and D*. The technician was blinded to the information regarding the treatment and control groups.

Regions of interest (ROIs) were drawn by outlining the tumor border on ADC maps, which showed the largest cross-section of the tumor. The ROIs on ADC map were copied and pasted on the corresponding D, f, and D* maps. In each mouse, the change in tumor volume (TV) relative to the baseline was quantified to determine the treatment response as follows: $\Delta TV\% = [(TV_{given\ time} - TV_{baseline})/TV_{baseline}] \times 100$, where $TV_{given\ time}$ is the tumor volume on day 1, 3, 5, or 7 and $TV_{baseline}$ is the tumor volume on day 0. For the ADC and IVIM parameters, the percentage changes in values compared to the baseline were recorded by using the following formula: $\Delta Value\% = [(Value_{given\ time} - Value_{baseline})/Value_{baseline}] \times 100$, where $value_{given\ time}$ is the value on day 1, 3, 5, or 7 and $Value_{baseline}$ is the value on day 0.

Histopathological analysis

The tumor tissue was paraffin-embedded, and sliced in the transverse plane at 0.6 μm intervals to match the corresponding MR image, was selected. The necrotic fraction (NF) of the tumor was evaluated through hematoxylin-eosin (HE) staining. CD31 (Dako, Carpinteria, CA, United States; mouse anti-human; used at 1:200) staining was carried out on pathological specimens by immunohistochemical methods, to analyze the angiogenesis activity of the tumor. The paraffin-embedded sections were incubated with the primary antibody at 4 ℃ overnight. Secondary antibody (Stem cell Technologies; rabbit anti-mouse; used at 1:300) was applied at room temperature for 1 h and then sections were rinsed with PBS. Positive reaction was visualized by DAB chromogen (Dako, Carpinteria, CA, United States) according to standard methods. Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) (Roche Applied Science, Penzberg, Germany) was performed to evaluate cellular apoptosis of the tumor by following the manufacturer's instructions.

Histopathological analysis was performed by using Image J software (http://rsb.info.nih.gov/ij). Tumor necrosis was scored according to the following formula: $NF = Area_{necrosis}/Area_{total\ tumor}$. Cellular apoptosis of the tumor was defined as the percentage of positive TUNEL-stained cells among 200 nuclei from five randomly selected fields at a high magnification (× 200). The mean MVD of the tumor was defined by the CD31-stained vessels[24], where any distinct area of positive for CD31 staining was defined as a single vessel, from five hot spots with higher vascular density compared to the remaining tissue in a high-power field (× 200; 0.578 mm^2).

Statistical analysis

SPSS 21.0 (SPSS, Chicago, IL, United States) was used for statistical analysis. The differences in relative changes in the ADC and IVIM parameters, and tumor volumes between the control and treatment groups were determined by the Mann-Whitney test. Spearman's correlation coefficient was used to determine the correlations between histological features, including NF, MVD and TUNEL and the corresponding ADC and IVIM parameters. Spearman's coefficient was considered to be satisfactory with a critical value of $r_s = 0.415$ at P value < 0.05 (two-tailed test). A spearman's coefficient of 0.90-1.00 indicated almost perfect agreement; 0.70-0.90 indicated high

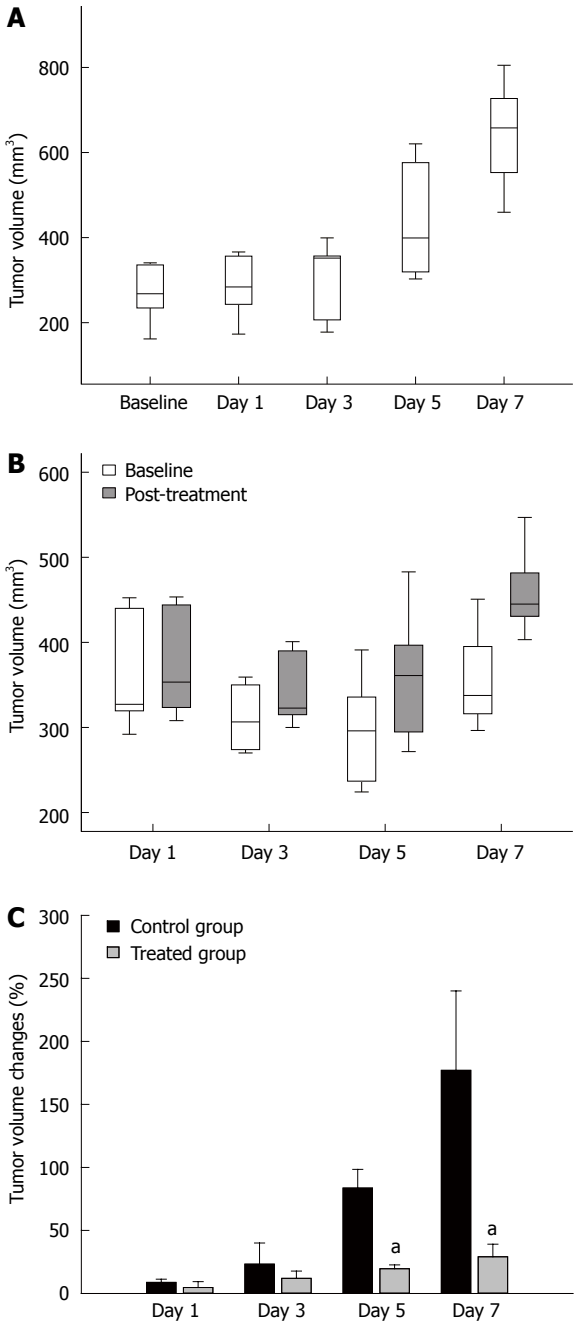

Figure 1 Anti-tumor effects of 5-fluorouracil therapy in mouse gastric cancer xenografts. A: Actual tumor volume changes in the control group; B: Actual tumor volume changes in the treatment groups; C: The comparison of the change in tumor volumes relative to baseline (day 0) between the control and treatment groups. The control group showed increases in tumor volume, while the treatment group showed as significant tumor growth delay from day 5. Center line = median; upper and lower margins of the box = 25th to the 75th percentile, respectively; whiskers = data from the minimum to the maximum. Error bars denote standard errors. $^{a}P < 0.05$ *vs* control group, $n = 5$ in each group.

agreement; 0.50-0.70 indicate moderate agreement; 0.30-0.50 indicate low agreement; and 0.00-0.30 indicate negligible agreement[25]. A two-tailed *P* value < 0.05 was considered as significant difference.

RESULTS

Effects of chemotherapy on tumor growth

Twenty-five tumors with a mean volume of 298.07 ± 103.44 mm^3 (range: 194.32-432.34 mm^3) before treatment were analyzed 20 to 25 d of implantation. The tumor volume in the control and treatment groups is shown in Figure 1A and B. 5-FU induced a significant growth delay, as assessed by the MRI-derived tumor volume measurements in comparison with that in the control group from day 5. As shown in Figure 1C, the observed relative volume increase (ΔTV%) in the therapy groups were significantly lower than in the control group at day 5 ($\Delta TV_{treatment}\%$ = 19.63% ± 3.01% and $\Delta TV_{control}\%$ = 83.60% ± 14.87%, $P = 0.008$) and day 7 ($\Delta TV_{treatment}\%$ = 29.07% ± 10.01% and $\Delta TV_{control}\%$ = 177.06% ± 63.00%, $P = 0.008$). The difference in ΔTV% between the treatment and the control groups was not significant at day 1 ($\Delta TV_{treatment}\%$ = 4.97% ± 4.59% and $\Delta TV_{control}\%$ = 8.08% ± 2.47%, $P = 0.841$) or day 3 ($\Delta TV_{treatment}\%$ = 15.36% ± 5.75% and $\Delta TV_{control}\%$ = 23.28% ± 16.76%, $P = 0.310$) after a short treatment duration.

IVIM-DWI assessment of a human gastric cancer xenograft

Table 1 summarizes the ADC, D, f, and D* values of the tumors in the control and treatment groups, that were measured at baseline and at days 1, 3, 5 and 7. Figure 2 shows the mean percentage changes in the DWI parameters relative to baseline at each time point in each group. In the control group, all ADC values and IVIM parameters of the tumor remained relatively constant over the 7-d experiment. ADC increases in the treatment group ($\Delta ADC\%_{treatment}$, median, 30.10% ± 18.32%, 36.11% ± 21.82%, 45.22% ± 24.36%) were significantly higher compared with the control group ($\Delta ADC\%_{control}$, median, 4.98% ± 3.39%, 6.26% ± 3.08%, 9.24% ± 6.33%) at days 3, 5 and 7 ($P = 0.008$, $P = 0.016$, $P = 0.008$, respectively) (Figure 2A). Increases in D in the treatment group ($\Delta D\%_{treatment}$, median 17.12% ± 8.20%, 24.16% ± 16.87%, 38.54% ± 19.36%) were higher than in the control group ($\Delta D\%_{control}$, median -0.13% ± 4.23%, 5.89% ± 4.56%, 5.54% ± 4.44%) at days 1, 3, and 5 ($P = 0.032$, $P = 0.008$, $P = 0.016$, respectively) (Figure 2B). The relative changes in f were significantly lower in the treatment group than in the control group at days 1, 3, 5 and 7 follow-up (median, -34.13% ± 16.61% *vs* 1.68% ± 3.40%, $P = 0.016$; -50.64% ± 6.82% *vs* 3.01% ± 6.50%, $P = 0.008$; -49.93% ± 6.05% *vs* 0.97% ± 4.38%, $P = 0.008$, and -46.22% ± 7.75% *vs* 8.14% ± 6.75%, $P = 0.008$, respectively) (Figure 2C). D* in the treatment group decreased significantly compared with the control group at all time points (median, -32.10% ± 12.22% *vs* 1.85% ±

ADC: Apparent diffusion coefficient; IVIM: Intravoxel incoherent motion.

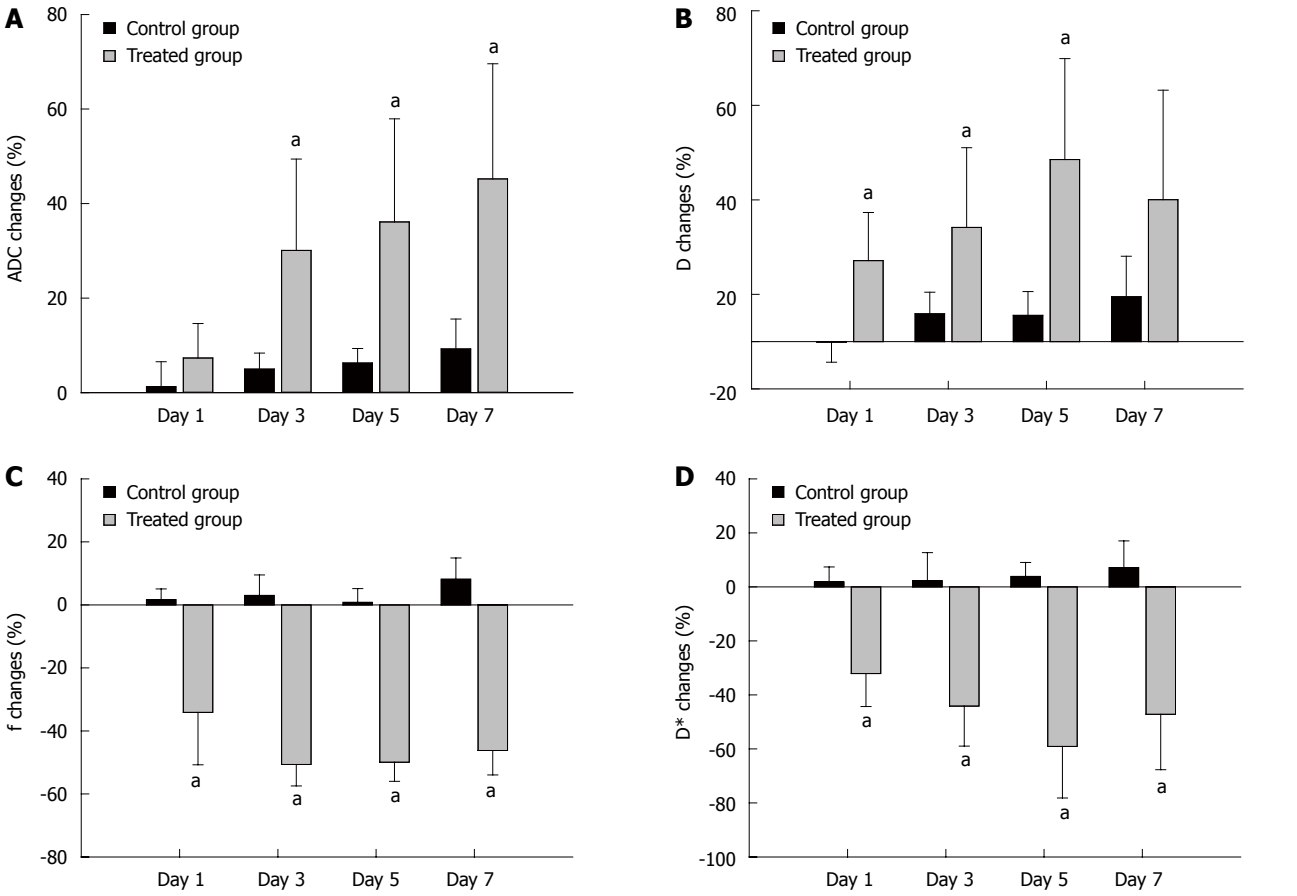

Figure 2 Comparison of the mean percentage changes from baseline in the intravoxel incoherent motion diffusion-weighted imaging derived values between the control (dark) and the 1-, 3-, 5- and 7-d treatment groups (grey). A: ADC value; B: D value; C: f value; D: D* value. Standard deviations are represented by vertical bars. Relative changes were determined by comparing the values at baseline and those in follow-up. $^aP < 0.05$ *vs* control. n = 5 in each group. ADC: Apparent diffusion coefficient.

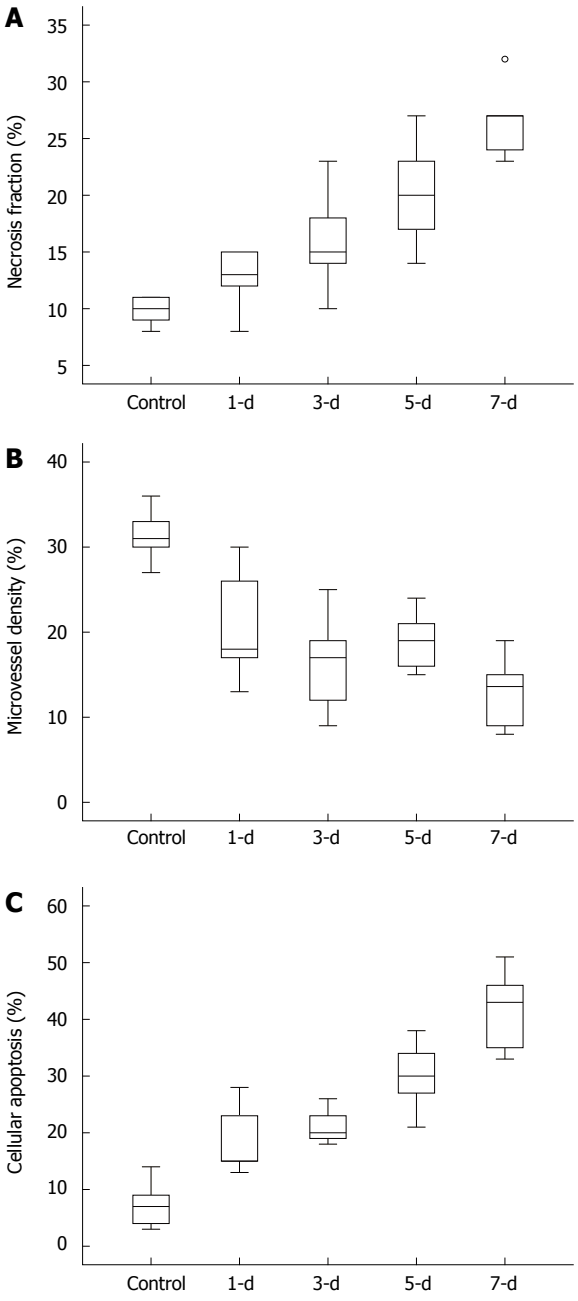

Figure 3 Box-and-Whisker plots show the results of histopathological analysis in the control and the 1-, 3-, 5- and 7-d treatment groups, respectively (*n* = 5 per group). A: Necrosis fraction of tumor; B: Microvessel density of tumor; C: Cellular apoptosis of tumor. Center line = median; upper and lower margins of box = 25th to the 75th percentile, respectively; whiskers = data from the minimum to the maximum; ○ = outlier.

5.54%, P = 0.008; -44.14% ± 14.83% *vs* 2.29% ± 10.38%, P = 0.008; -59.06% ± 19.10% *vs* 3.86% ± 5.10%, P = 0.008, and -47.20% ± 20.48% *vs* 7.13% ± 9.88%, P = 0.016, respectively) (Figure 2D).

Histopathological assessment of tumor response and its correlation with MR images

HE, CD31 and TUNEL staining were performed to confirm the tissue and vessel changes in the tumor. Figure 3 shows the quantification of the NF, MVD, and cellular apoptosis in all animals of the control and the treatment groups (n = 5 per group). The MVD scores in 5-FU treatment tumors decreased significantly compared with the control group. The 5-FU treated tumors displayed a time-dependent increase in NF and cellular apoptosis compared to those in the control group, indicating an effective therapeutic response.

Table 2 summarizes the relationship among ADC, the IVIM parameters, MVD, cellular apoptosis and necrosis of tumors (n = 25) determined by Spearman's correlation coefficient analysis. ADC and D were positively correlated with NF (r_s = 0.720, P < 0.001; r_s = 0.522, P = 0.007, respectively) (Figure 4A, B) and the cellular apoptosis of the tumor (r_s = 0.626, P = 0.001; r_s = 0.542, P = 0.005, respectively) (Figure 4E, F).There is no significant correlation among ADC, D, and MVD. Perfusion-related parameters f and D* shows positive correlations with MVD (r_s = 0.618, P = 0.001; r_s = 0.538, P = 0.006, respectively) (Figure 4C, D), and a negative correlation with the cellular apoptosis of the tumor (r_s = -0.550, P = 0.004; r_s = -0.692, P < 0.001, respectively) (Figure 4G, H). There is no significant correlation between the perfusion parameters and NF. Figure 5 shows the calculated ADC, D, f, and D* maps and the correspondent histopathologic images from the control and 3 d treated mice.

DISCUSSION

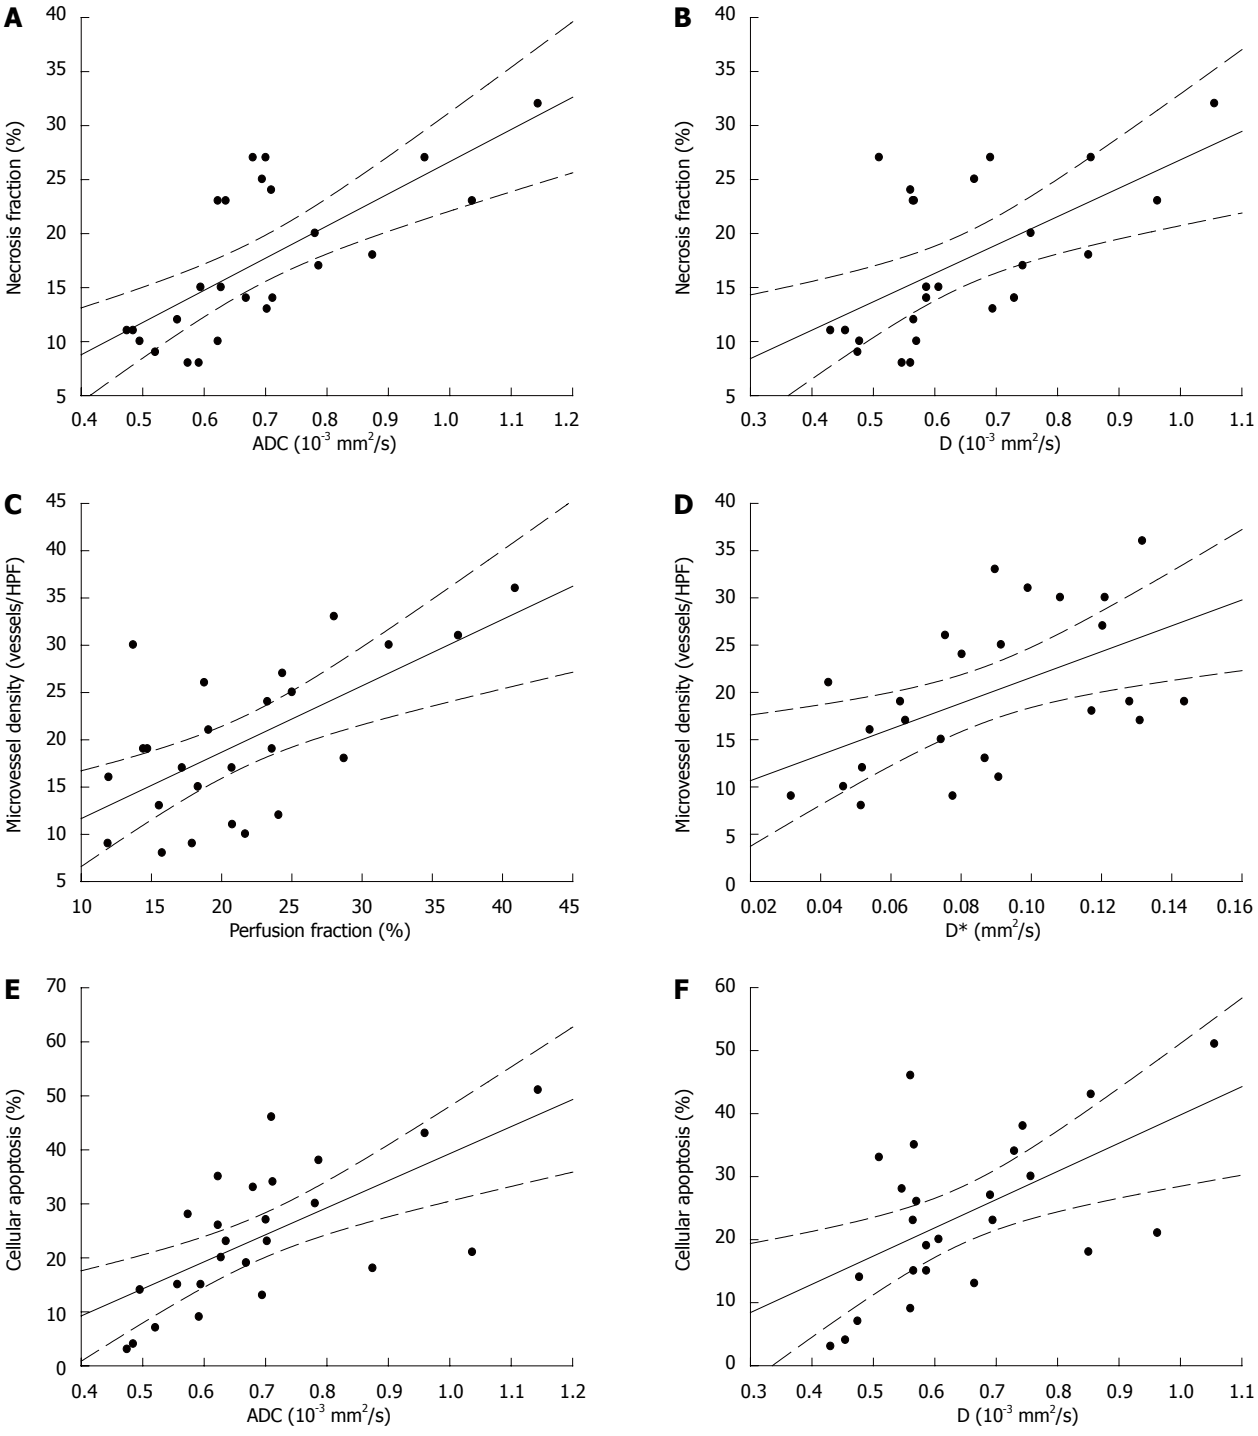
The ADC obtained from conventional DWI has been widely accepted as a marker to monitor the therapeutic efficacy of chemotherapy, radiotherapy or combined therapy with target medicine[26,27]. In recent years, there has been a resurgent interest in IVIM studies, which allows to measure tissue diffusion and perfusion simultaneously. In this study, we performed IVIM-DWI using 12 *b*-values less than 800 s/mm^2 to monitor the efficacy of chemotherapy in a mouse model of human gastric cancer. A histopathological analysis was carried out to evaluate the tissue cellularity and MVD properties of the tumor.

Our results demonstrated that conventional ADC significantly increased after 3-d of treatment and it showed a positive correlation with the 5-FU induced intratumoral necrosis and cellular apoptosis of the tumor. Papaevangelou *et al*[28] found that ADC changes in the tumor were associated with the induction of a mixture of necrosis and apoptosis after irinotecan treatment. Therefore, ADC could be a reliable marker for detecting the necrotic and apoptotic cell death in gastric cancer patients during treatment. IVIM derived D values that showed a similar trend to ADC, were significantly increased as early as after one day treatment compared with the baseline values. Moreover, HE and TUNEL stain showed that D values were positively correlated with intratumoral necrosis and cellular apoptosis, indicating the possibility of

Table 2 Correlation between apparent diffusion coefficient and intravoxel incoherent motion parameters, microvessel density, cellular apoptosis and necrosis fraction of tumors (n = 25)

	NF (%)		MVD (vessels/HPF)		Apoptosis (%)	
	r_s	*P* value	r_s	*P* value	r_s	*P* value
ADC ($\times 10^{-3}$ mm^2/s)	0.720	< 0.001	-0.395	0.051	0.626	0.001
IVIM parameters						
D ($\times 10^{-3}$ mm^2/s)	0.522	0.007	-0.201	0.335	0.542	0.005
f (%)	-0.347	0.089	0.618	0.001	-0.550	0.004
D^* ($\times$ mm^2/s)	-0.378	0.062	0.538	0.006	-0.692	< 0.001

P < 0.05 is considered to be statistically significant. ADC: Apparent diffusion coefficient; IVIM: Intravoxel incoherent motion; MVD: Microvessel density; NF: Necrosis fraction.



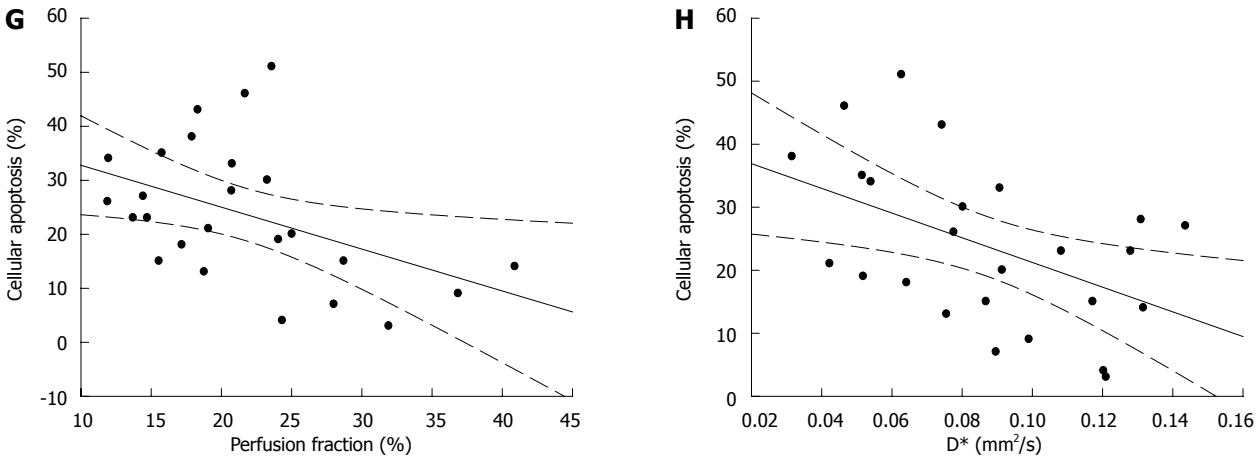


Figure 4 Representative scatter diagrams showing the relationships between intravoxel incoherent motion diffusion-weighted imaging derived parameters and the histological features (*n* = 25). A and B: ADC and D were positively correlated with tumor necrosis fraction; C and D: f and D* were positively correlated with microvascular density of tumor; E and F: ADC, D were positively correlated with tumor cellular apoptosis; G and H: f and D* were negatively correlated with tumor cellular apoptosis. *P* values are shown in Table 2. ADC: Apparent diffusion coefficient.

a noninvasive evaluation of necrosis or apoptotic. Our finding regarding the D value is consistent with previous studies which showed that an increase in D value can predict chemotherapeutic responsiveness in locoregionally advanced nasopharyngeal carcinoma[20] and advanced cervical cancer[29]. There is no denying that accurate quantification of the D value, which associates with the intra-to-extracellular spaces ratio and represents the true molecular diffusion, would eventually translate into a reliable marker to evaluate the tumor therapy response.

The f and D* significantly decreased during the early phase of chemotherapy. In addition, the f and D* were well correlated with the decrease in MVD revealed by the endothelial cell marker CD31 staining, which indicated that f and D* have the potential to assess tumor angiogenesis activity noninvasively. There are experimental and clinical dates in body tissues with IVIM-DWI which support the claim that the signal attenuation is related to microcirculation in tissue when *b*-values less than 100 s/mm^2 were applied. Wang *et al*[30] found an increase in the tumor blood flow induced by IV hydralazine injection was accompanied by an increase in the IVIM-derived D* in a mammary adenocarcinoma rat model. In a human brain study, f and D* were correlated separately with the relative blood volume and blood flow derived from dynamic susceptibility contrast enhancement imaging[31]. Joo *et al*[19] reported that IVIM-DWI has the potential to evaluate the early therapeutic effect induced by a vascular disrupting agent named CKD-516 in rabbit VX2 liver tumors. In addition, f and D* also showed a weak negative correlation with the cellular apoptosis of the tumor, indicating that the decreased cellularity also contributed to the changes in f and D*. This may reconfirm the finding that tissue water diffusion also contributes to the observed signal attenuation at low *b*-values. After effective chemotherapy, extracellular spaces would expand, resulting in less restriction of migration of water molecules and weakening the process of pseudo-diffusion. This would then yield a higher D value and lower f and D* than those obtained pre-treatment. Our results and the conclusions from previous studies[13,32] indicated the usefulness of IVIM-DWI for depicting the therapeutic efficiency in gastric cancer before changes in tumor size are evident.

The option of a bi-exponential model for extracting molecular diffusion and microcirculation perfusion information from DWI remains controversial. A previous IVIM study with the *b*-values up to 1500 s/mm^2 found that f increased after treatment, which contradicts our finding[21]. Pang *et al*[23] found that f obtained from *b*-values below 750 s/mm^2 is more in keeping with the increased perfusion in prostate cancer tissue, while f decrease or became indistinguishable from the normal level of prostate tissue when high *b*-values employed. Both tissue microcirculation and water diffusion in the tissue contributed to signal attenuation at a low *b*-value; hence, departure of molecular diffusion at very high *b*-values may influence the perfusion-related parameters[33,34]. Moreover, the IVIM method suffers significantly from the variations in the signal-to-noise ratio and is prone to generate measurement errors when *b*-values are lower than 100 s/mm^2[13]. To date, no consensus has been reached on the magnitude and number of *b*-values that ought to be applied in preclinical and clinical studies. Therefore, more studies are required to optimize the process of image collection and image post-processing for deriving sufficiently accurate parameters based on the original IVIM model.

There are limitations to this study. First, the observation endpoint in this study is too short. Secondly, because of the small sample sizes, serial relative changes in ADC and the IVIM parameters of the tumor were not evaluated in the treatment groups. Therefore, we need further studies with larger sample size and long-term observations to clarity the limitation of this study.

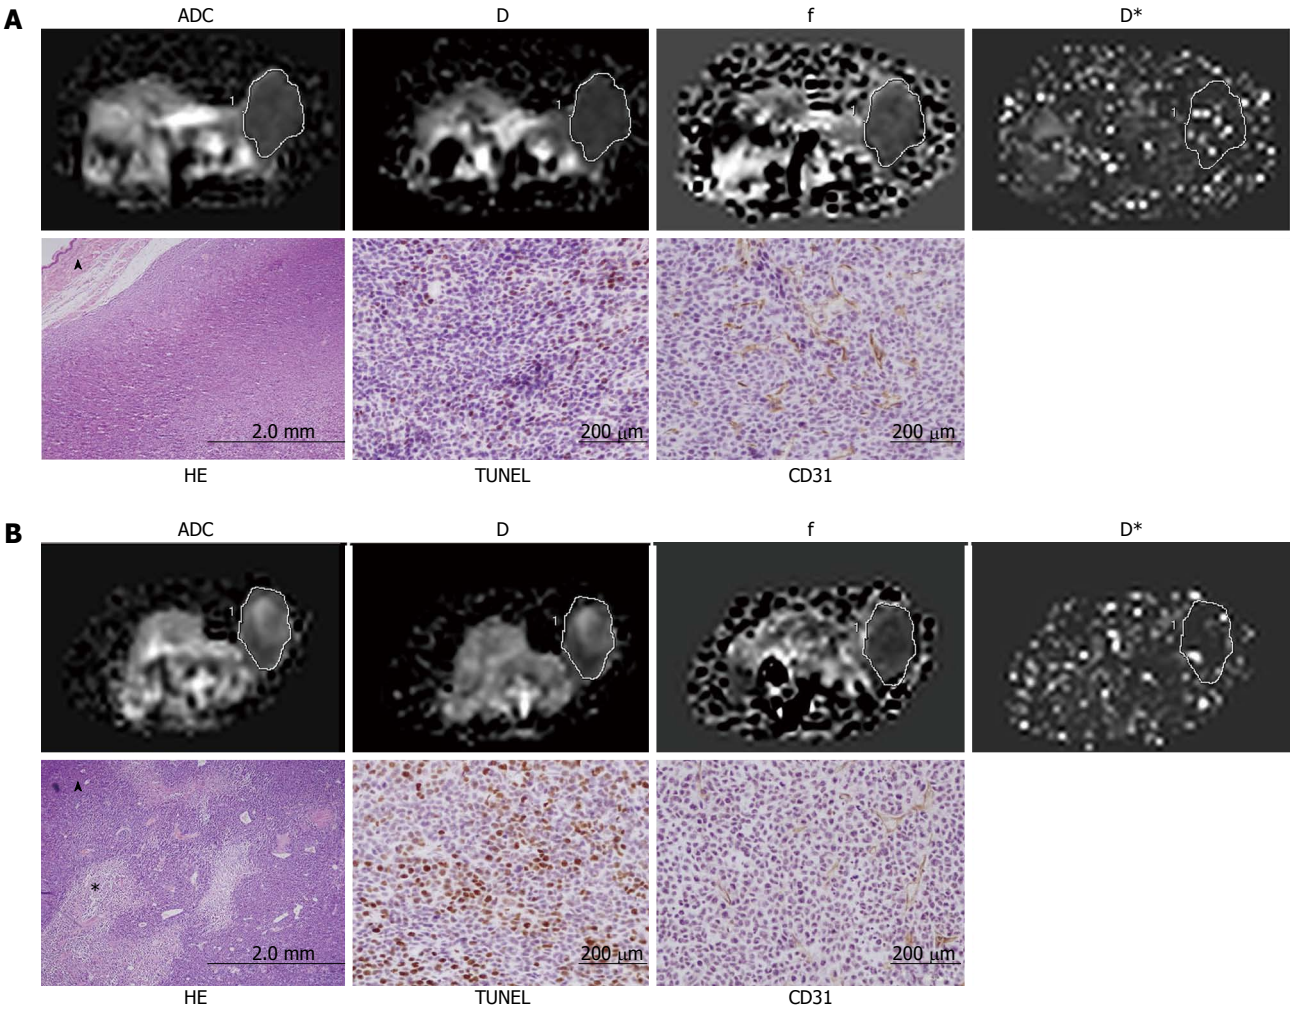

Figure 5 Calculated maps of intravoxel incoherent motion diffusion-weighted imaging parameters and the histopathological images. A: The lower ADC (0.521 × 10^{-3} mm^2/s) and D values (0.475 × 10^{-3} mm^2/s) and the higher f (40.92%) and D* (0.131 mm^2/s) values, which correspond to low necrosis (10%) and cellular apoptosis (7%) and high MVD (36) in the control group; B: Increased ADC (0.875 × 10^{-3} mm^2/s) and D (0.851 × 10^{-3} mm^2/s) values and reduced f (17.20%) and D* (0.098 mm^2/s) values, which correspond to the increased necrosis (18%) and cellular apoptosis (23%) and decreased MVD (17) in the 3-d treatment group. Note high signal intensity within tumor suggesting necrosis. asterisk means necrosis area; The triangle symbol means skin of the mouse. ADC: Apparent diffusion coefficient; MVD: Microvessel density.

In conclusion, IVIM-DWI raises the possibility of an effective, multi-parametric (D, f, D*) imaging method without requirement of gadolinium enhancement. The IVIM method could potentially be used to assess tissue diffusivity changes in addition to evaluate the microcirculatory perfusion of gastric cancer in response to chemotherapy.

COMMENTS

Background

Chemotherapy is a standard treatment for advanced gastric cancer. Imaging modalities that help to identify early and reliable surrogate markers for the evaluation of chemotherapy response are important in patients with gastric cancer. Intravoxel incoherent motion diffusion-weighted imaging (IVIM-DWI), which allows acquisition of quantitative parameters that reflect tissue diffusivity and tissue microcapillary perfusion, maybe a useful tool that can monitor the early chemotherapy response in terms of gastric cancer tissue diffusion and microvascular perfusion.

Research frontiers

IVIM-DWI has been used to monitor the treatment responses to radiofrequency ablation or a vascular disrupting agent of CKD-516 in rabbit model with VX2 liver tumors, and the response of human locoregionally advanced nasopharyngeal carcinoma to neoadjuvant chemotherapy. DWI is increasingly being applied in the human body, but few studies focused on the gastric lesions due to the limitation of the modality.

Innovations and breakthroughs

In this study, IVIM-DWI with 12 *b*-values less than 800 s/mm^2 was performed to avoid the potential impact of higher *b*-values on the accuracy of the IVIM-derived parameters.

Applications

IVIM-DWI raises the possibility of an effective, multi-parametric (D, f, D*) imaging method that does not require gadolinium enhancement. The IVIM

method could potentially be used to assess tissue diffusivity changes in addition to measuring the microcirculatory perfusion of gastric cancer in response to chemotherapy.

Terminology

DWI is capable of providing a parameter of apparent diffusion coefficient (ADC). The measured ADC, which represents tissue diffusivity, has become a favorite choice in oncologic studies. IVIM-DWI allows acquisition of multi-quantitative parameters that reflect tissue diffusivity and microcirculation perfusion.

Peer-review

The authors have demonstrated the usefulness of IVIM-DWI for monitoring early chemotherapeutic efficacy in a human gastric cancer xenograft model with nude mouse. The manuscript presents interesting and novel findings. The data are well presented and important. However, noted by the authors, the limitation of this study is the short observation endpoint.

Abstract

AIM: To explore the regulatory mechanism of the target gene of microRNA-21 (miR-21), phosphatase gene (PTEN), and its downstream proteins, protein kinase B (AKT) and phosphatidylinositol 3-kinase (PI3K), in colorectal cancer (CRC) cells.

METHODS: Quantitative real-time PCR (qRT-PCR) and Western blot were used to detect the expression levels of miR-21 and PTEN in HCT116, HT29, Colo32 and SW480 CRC cell lines. Also, the expression levels of PTEN mRNA and its downstream proteins AKT and PI3K in HCT116 cells after downregulating miR-21 were investigated.

RESULTS: Comparing the miR-21 expression in CRC cells, the expression levels of miR-21 were highest in HCT116 cells, and the expression levels of miR-21 were lowest in SW480 cells. In comparing miR-21 and PTEN expression in CRC cells, we found that the protein expression levels of miR-21 and PTEN were inversely correlated ($P < 0.05$); when miR-21 expression was reduced, mRNA expression levels of PTEN did not significantly change ($P > 0.05$), but the expression levels of its protein significantly increased ($P < 0.05$). In comparing the levels of PTEN protein and downstream AKT and PI3K in HCT116 cells after downregulation of miR-21 expression, the levels of AKT and PI3K protein expression significantly decreased ($P < 0.05$).

CONCLUSION: PTEN is one of the direct target genes

of miR-21. Thus, phosphatase gene and its downstream AKT and PI3K expression levels can be regulated by regulating the expression levels of miR-21, which in turn regulates the development of CRC.

Key words: MicroRNA-21; Protein kinase B; Colorectal cancer; Phosphatidylinositol 3-kinase; Phosphatase and tensin homolog

Core tip: RT-PCR and Western blot were applied to detect the expression level of microRNA-21 (miR-21) and Phosphatase gene (PTEN), including its downstream proteins protein kinase B (AKT) and phosphatidylinositol 3-kinase (PI3K) in colorectal cancer (CRC) cell lines, and to explore the regulatory mechanism of the expression of miR-21 in inhibiting CRC, respectively. Their associations were investigated to clarify whether one of the direct target genes of miR-21 is PTEN. The expression levels of miR-21, PTEN and its downstream proteins AKT and PI3K are regulated and controlled to manage the occurrence and progression of CRC.

MicroRNA-21 promotes phosphatase gene and protein kinase B/phosphatidylinositol 3-kinase expression in colorectal cancer. *World J Gastroenterol* 2016; 22(24): 5532-5539 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5532.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5532

INTRODUCTION

MicroRNA (miRNA) is a kind of non-coding macromolecule RNA that includes nearly 22 nucleotides, and it is able to conjugate the 3'UTR of mRNA to facilitate target mRNA degradation and inhibition of the translation process by virtue of lowering gene expression[1-4]. The research of Calin *et al* indicated that approximately 50% of miRNA was located in tumor-related genomic regions. This work also revealed aberrant expression levels in a number of tumors, which was probably on account of the oncogenic and tumor suppressing gene functions of miRNA molecules. In addition, miRNA is involved in the occurrence and progression of human tumors[5-8]. Phosphatase gene (PTEN) is a phosphatase and tensin homologue gene derived from chromosome ten, which is associated with phosphohydrolase; its inactivation induces tumor occurrence in the human body[9-11]. In recent years, the protein kinase B/phosphatase gene/phosphatidylinositol 3-kinase (AKT/PTEN/PI3K) signaling pathway has raised increasing concern, and a number of studies found that the atypical AKT/PTEN/PI3K signaling pathway was intimately linked with numerous tumor occurrences and progression, immunity, drug resistance, metastasis, angiogenesis, *etc.*[12-16]. In addition, the AKT/PTEN/PI3K signaling pathway has been reported in pulmonary, nasopharyngeal, gastric and renal tumors, as well as in neuroglioma[17-21]. However, literature with regard to colorectal cancer (CRC) is rare. Moreover, there were reports that revealed that microRNA-21 (miR-21) could regulate the AKT/PTEN/PI3K signaling pathway to promote tumor occurrence and progression, and even tumor invasion[22-25]. Hence, quantitative real-time PCR (qRT-PCR) and Western blot were applied to detect the expression level of miR-21 and PTEN, including its downstream proteins AKT and PI3K, in CRC cell lines. Furthermore, the mechanism of miR-21 expression in inhibiting CRC and their correlations were also explored. This study will provide a theoretical and experimental basis for the early diagnosis and therapy of CRC.

MATERIALS AND METHODS

Experimental materials

Primary reagents and equipment: PTEN antibody, PI3K mouse anti-human monoclonal antibody, immunohistochemistry (IHC) kit and AKT rabbit anti-human polyclonal antibody were purchased from Beijing Zhongshan Golden Bridge Biotechnology Company. Quantitative RT-PCR kit and miR-21 primer were purchased from Takara. Fluorescent quantitative PCR detection system was purchased from ABI (United States). The PCR instrument was purchased from Bio-Rad (United States). The inverted microscope was purchased from Olympus (Japan). The refrigerated centrifuge was purchased from Thermo Scientific (United States). HCT116, HT29, Colo32 and SW480 CRC cell strains were all purchased from the Cell Bank of the Chinese Academy of Sciences.

Preparation of primary reagents: Requisite reagents: phosphate buffer solution (PBS), bovine serum albumin (BSA) solution, Tris-buffered saline and Tween-20 (TBST) buffer, BSA blocking buffer, 0.25% trypsin solution, sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) electrophoresis buffer, transmembrane buffer, SDS-PAGE separation and stacking gel.

Experimental methods

CRC cell culture and transfection: A Dulbecco's modified Eagle's medium (DMEM) high glucose medium with 10% calf serum was used to culture HCT116, Ht29, Colo32 and SW480 CRC cell strains in 5% CO_2 at 37 ℃. Cells in the logarithmic phase were used in experiments. All cells were sorted into three groups: miR-21 inhibition group (IG), negative control (NC) and blank control (BC). HCT116 cells were inoculated in 500 μL of medium (no antibiotics) to 30%-60% degree to spare. Then, 20 pmol/L of miR-21 inhibitor was

diluted with 50 mL of DMEM medium (no serum) and incubated for five minutes at room temperature after mixing. Next, 1 μL of mixing Lipofectamine 2000 was diluted in 50 μL of DMEM (no antibiotics and serum) and incubated at room temperature for 5 min. The diluted miR-21 inhibitor was mixed with Lipofectamine 2000 and incubated at room temperature for 20 min. Then, a 100-μL transfection buffer was added, mixed and incubated for six hours in an incubator (5% CO_2 at 37 ℃). Afterward, the medium was changed to normal medium and cells were incubated for another 48-72 hours for detection.

Transwell assay: Pre-cooling non-serum DMEM was used to dilute the Matrigel matrix gel. Then, it was paved on the chamber of the polycarbonate filtering membrane followed by inoculation of diluted HCT116 cells (100 μL). Afterwards, 10% fetal calf serum was added to the lower chamber. After 24 h of culture in 5% CO_2 at 37 ℃, the chamber was washed twice, stained with 0.1% crystal violet for five minutes, and washed again. Cells were randomly counted in five views at 100 × objective and the average was calculated. This was performed in three replicates for each group.

Real-time quantitative RT-PCR to detect miR-21 and PTEN mRNA levels: Total RNA was extracted using Trizol RNA extraction methods, based on the Molecular Clone Technique Experimental Manual. One mL of Trizol reagent could be added to approximately 100-mg tissues. A mortar was used to grind the tissues to powder, which eventually reached complete decomposition. The lysate was drawn into a 1.5-mL tube and incubated for 10 min on ice. After centrifuging at 12000 rpm for 10 min at 4 ℃, the supernatant was drawn into a new 1.5-mL tube. Isopropanol in equal volume was added and mixed, plated on ice for 10 min, and centrifuged at 12000 rpm for another 10 min at 4 ℃. The supernatant was discarded, 1 mL of 75% ethanol was added, the precipitate was washed, and centrifuged for another five minutes. Afterwards, the supernatant was discarded, placed into a tube in room temperature for 10 min, waited until the residue entirely volatilized, then 100 μL of diethyl pyrocarbonate H_2O was added to dissolve the precipitate, and it was stored in liquid nitrogen for use. Extracted RNA purity and concentration was detected using a spectrophotometer. The normal value of optical density (OD) OD_{260}/OD_{280} was between 1.8 and 2.1, respectively. Then, cDNA was synthesized by reverse transcription reaction. RT-PCR was used to detect miR-21 reaction conditions: 95 ℃ for 10 s, one cycle, 95 ℃ for 5 s, 60 ℃ for 34 s, 45 cycles; computational formula: relative amount = $2^{-\Delta\Delta CT}$, where -ΔΔCT = (CTmiR-21-CTu6) tumor-(CTmiR-21-CTu6) normal tissue. RT-PCR was used to detect PTEN mRNA reaction conditions: 95 ℃ for 10 s, one cycle, 95 ℃ for 5 s, 60 ℃ for 20 s, 45 cycle; and PTEN mRNA expression level was calculated on the basis of ΔCt = Ct(PTEN) - Ct(β-actin), where Folds = $2^{-\Delta\Delta CT}$, and the average result was used with three repeats.

Western blot: After 48-72 h of transfection, the medium was discarded and 100 μL of RIPA lysate was added into each well. The lysate was mixed for 5 min, centrifuged at 12000 rpm for 15 min at 4 ℃, and the supernatant was stored for use. Samples mixed with 5 × loading were boiled for 10 min at 95 ℃ and loaded after centrifugation. Eight μL of purified and desalted antibody was loaded, and 2-3 μL of the marker was loaded. The antibody was confirmed according to the marker position. Electrophoresis: stacking gel in 80 V for 20-30 min, and separation gel in 120 V for 40 min. Transmembrane: 300 mA for 90 min. After transmembrane, the membrane was blocked with non-fat milk, washed with PBS for three times, and incubated with the primary antibody (PTEN antibody, PI3K antibody, AKT antibody and β-actin antibody; 1:500 dilution) overnight at 4 ℃. On the next day, cells were washed with TBST for seven times and incubated with the secondary antibody (horseradish peroxidase-labeled goat-anti rabbit secondary antibody, 1:2500 dilution) for one hour. Then, cells were washed with TBST for another six times. Chemiluminescence reagent A and B solutions were mixed and added on the membrane based on a 1:1 proportion, and β-actin protein was used as an internal reference.

Statistical analysis

SPSS 19.0 was used to analyze all data; measurement data were presented as mean ± SD. The *t*-test was used to compare miR-21 and PTEN expression levels, and the variance analysis method was used to compare the mean value of transfection in the IG, NC and BC groups. $P < 0.05$ was considered statistically significant.

RESULTS

miR-21 and PTEN expression in CRC cells

miR-21 had the highest protein expression in HCT116 cells, but had the lowest expression in SW480 cells (Figure 1). In contrast, PTEN protein expression was the lowest in HCT116 cells, but had the highest expression in SW480 cells (Figure 2). The protein expression level between miR-21 and PTEN was inversely related, and the difference was statistically significant ($P < 0.01$).

Invasive ability changes in cells after transfection

In counting the cells that crossed after transfection in the Transwell assay, we found that cells transfected with miR-21 in IG were reduced by 39.1% compared to BC and 36.9% compared to NC. However, the difference between BC and NC was not statistically significant (Figure 3).

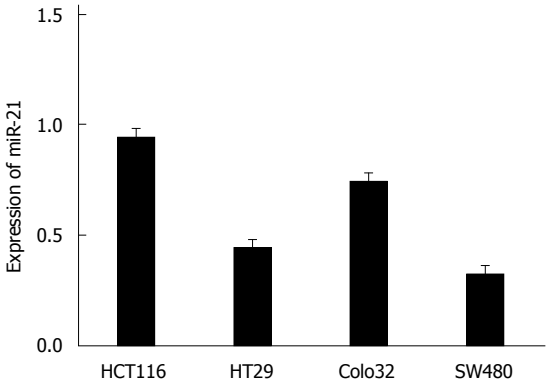

Figure 1 Expression of miR-21 in colorectal cancer cell lines (*n* = 3).

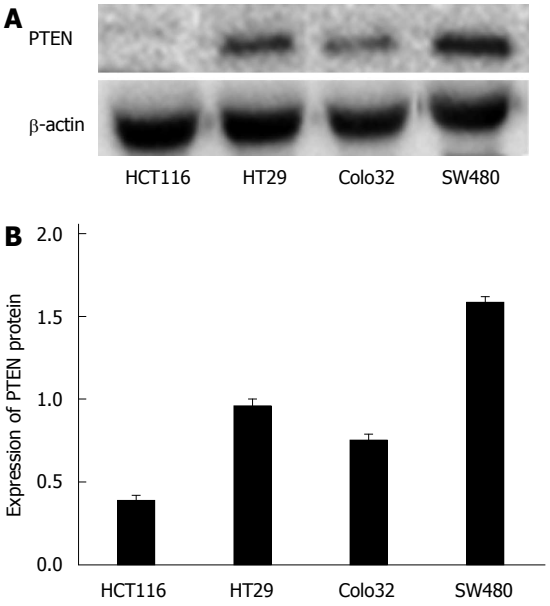

Figure 2 Expression of PTEN protein in colorectal cancer cell lines. A: Western blot assay; B: the expression of PTEN in colorectal cancer cell lines (*n* = 3).

RT-PCR detection of miR-21 expression after transfection

miR-21 expression levels after transfection in IG, NC and BC are shown in Figure 4. It can be observed that miR-21 expression levels in BC and NC were higher than in IG, and the difference was statistically significant ($P < 0.05$).

PTEN mRNA and protein expression in HCT116 cells after downregulation of miR-21

As shown in Figure 5A, after reducing the expression of miR-21, PTEN mRNA expression levels in HCT116 cells revealed no statistical significance after transfection in IG, NC and BC ($P > 0.05$). As illustrated in Figure 5B, when miR-21 was downregulated, PTEN protein expression levels were markedly elevated, and the difference was statistically significant ($P < 0.05$). The difference between BC and NC was not statistically significant ($P > 0.05$)

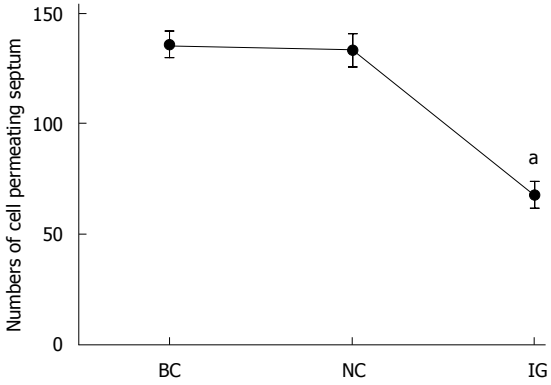

Figure 3 Changes in cell invasion ability after transfection ($^aP < 0.05$, $n = 3$). IG: Inhibition group; NC: Negative control; BC: Blank control.

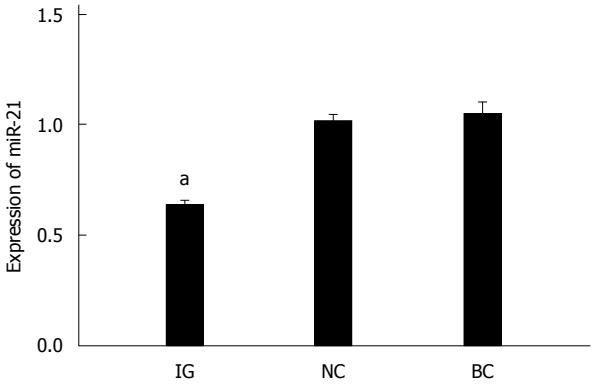

Figure 4 Effect of the miR-21 inhibitor on miR-21 expression in HCT116 cells ($^aP < 0.05$, $n = 3$). IG: Inhibition group; NC: Negative control; BC: Blank control.

PTEN and its downstream proteins AKT and PI3K expression in HCT116 cells after downregulating miR-21

As shown in Figure 6, PTEN protein expression levels in HCT116 cells were elevated in IG, and the difference was statistically significant ($P < 0.05$). However, AKT and PI3K expression levels in HCT116 cells in IG decreased; and the difference was statistically significant ($P < 0.05$).

DISCUSSION

Much research has indicated that CRC occurrence in patients is a complicated process, which consists of multiple stages and factors. One momentous feature is its oncogenic activation and tumor-suppressing gene expression dysregulation or absence[26,27]. In recent years, it has been found miRNA possesses oncogenic and tumor suppressing gene functions[22]. One representative miRNA, miR-21, possesses a crucial oncogenic function and exhibits high expression levels in a number of tumors; it is closely associated with tumor occurrence and chemotherapy sensitivity[28,29]. PTEN is derived from chromosome ten, and acts as a tumor-suppressing gene. PTEN exerts vital effects on cell growth, proliferation, migration, signal transmission,

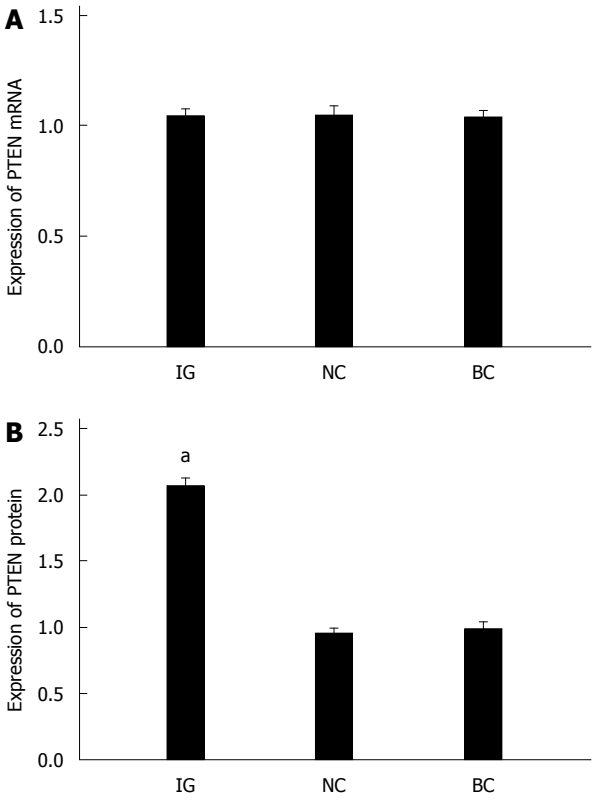

Figure 5 Effect of the miR-21 inhibitor on PTEN mRNA (A) and protein (B) expression in HCT116 cells ($^aP < 0.05$, $n = 3$). IG: Inhibition group; NC: Negative control; BC: Blank control.

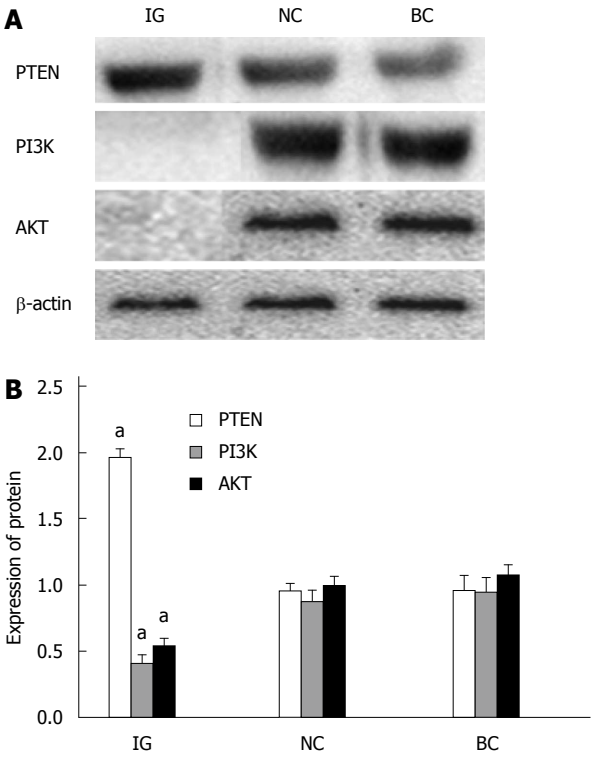

Figure 6 Protein expression of PTEN/AKT/PI3K in colorectal cancer HCT116 cell lines. A: Western blot assay; B: Protein expression in HCT116 cell lines ($^aP < 0.05$, $n = 3$). IG: Inhibition group; NC: Negative control; BC: Blank control.

invasion and apoptosis; it has an inhibitory role on tumor cell growth, invasion, proliferation, metastasis and apoptosis[30]. The AKT/PTEN/PI3K signaling pathway plays a significant part in regulating cell growth, metabolism, differentiation and apoptosis; it is closely associated with tumor occurrence and progression[31-36]. PTEN protein phosphatase activity (dephosphorylation) can inhibit AKT function, leading to cell apoptosis. Furthermore, the deletion or mutation of PTEN is able to enhance AKT activity to increase PI3K expression[37]. AKT/PTEN/PI3K signaling pathway activation is capable of inhibiting cell apoptosis to facilitate cell differentiation and proliferation. This also exerts a crucial role in tumor occurrence and progression, and participates in tumor metastasis and invasion[38-44].

miR-21 and PTEN expression in CRC cells

miR-21 and PTEN protein expression was detected in HCT116, HT29, Colo32 and SW480 CRC cell lines through RT-PCR and Western blot. Results revealed that miR-21 expression level was highest in HCT116 cells and lowest in SW480 cells. Furthermore, PTEN expression level was lowest in HCT116 cells and highest in SW480 cells. The protein expression level between miR-21 and PTEN was inversely correlated. These results indicate that miR-21 could be involved in the regulation of PTEN protein expression. In addition, due to the high expression level of miR-21 in HCT116 cells, HCT116 cells were selected for this study. Transwell invasion assay revealed that the invasive capacity of tumor cells was obviously reduced after inhibiting CRC cell miR-21 expression, which in turn indicates that miR-21 probably plays a promoting role in cell malignancy transformation.

miR-21 and PTEN mRNA and protein expression in HCT116 cells after downregulating miR-21

After downregulating the expression of miR-21, the expression level of miR-21 in HCT116 cells in IG was obviously lower compared to NC and BC, which illustrates the successful inhibition of miR-21. As a known miR-21 target gene, PTEN has been verified to be a target gene of miR-21 by Western blot. When we inhibited the expression of miR-21, PTEN mRNA expression levels did not reveal apparent change, but protein levels were obviously elevated; which indicates that miR-21 could regulate PTEN expression at the post-transcriptional level and that PTEN was a target gene for miR-21. Meng *et al*[45] recently found that miR-21 targeted tumor-suppressing gene PTEN in liver and bile duct cancer cells to promote tumor growth, invasion and migration, manifesting that PTEN was a target gene of miR-21.

PTEN and its downstream AKT and PI3K expression in HCT116 cells after reducing miR-21 expression

After inhibiting the expression of miR-21, PTEN protein

level was significantly elevated, but its downstream AKT and PI3K expression obviously decreased, indicating that miR-21 could regulate and control PTEN and the expression level of downstream AKT and PI3K in terms of its effects on tumor cell invasion and migration. Certain studies have shown that change in miR-21 expression level is able to induce PTEN downstream molecule AKT phosphorylation, metalloproteinase 2 and focal adhesion kinase expression; these are altered to restrain tumor cell invasion and migration[45-50].

In conclusion, our study revealed that PTEN is one of the direct target genes of miR-21. By altering miR-21 expression, downstream AKT and PI3K expression levels could be regulated and controlled, in order to control CRC occurrence and progression. Nevertheless, the mechanisms of miR-21 and PTEN function, as well as their effects in tumors, need to be further investigated. As more in-depth research on miRNA is being undertaken, especially regarding tumor cell regulatory mechanisms, more roles and targets of miR-21 will probably be unraveled.

COMMENTS

Background

Colorectal cancer (CRC) is complicated and combines multiple stages and factors. In recent years, we have found that miRNA possesses oncogenic and tumor-suppressing gene functions. One representative miRNA, microRNA-21 (miR-21), possesses a crucial oncogenic function that shows high expression levels in a number of tumors; this is closely associated with tumor occurrence and chemotherapy sensitivity. PTEN acts as a tumor-suppressing gene derived from chromosome ten. PTEN exerts vital effects in cell growth, proliferation, migration, signal transmission, invasion and apoptosis; it has an inhibitory role in tumor cell growth, invasion, proliferation, metastasis and apoptosis. The AKT/PTEN/PI3K signaling pathway plays a significant part in regulating cell growth, metabolism, differentiation, and apoptosis; it is closely associated with tumor occurrence and progression.

Research frontiers

In addition, the AKT/PTEN/PI3K signaling pathway has been reported in pulmonary, nasopharyngeal, gastric and renal tumors, as well as in neuroglioma; however, literature with regard to CRC is rare. Moreover, there have been reports that revealed that miR-21 could regulate the AKT/PTEN/PI3K signaling pathway, in order to promote tumor occurrence and progression, and even tumor invasion. Hence, RT-PCR and Western blot were applied to detect the expression levels of miR-21 and PTEN, including its downstream proteins AKT and PI3K in CRC cell lines, as well as the inhibition of miR-21 expression in CRC cell lines. Furthermore, their association was also explored. This study hopes to provide a theoretical and experimental basis for the early diagnosis and therapy of CRC.

Innovations and breakthroughs

RT-PCR and Western blot were applied to detect the expression level of miR-21 and PTEN including its downstream proteins AKT and PI3K, and the inhibition of miR-21 expression in CRC cell lines, respectively. This association was also investigated to demonstrate that PTEN was one of the direct target genes of miR-21. Through regulating and controlling the expression level of miR-21, PTEN and its downstream proteins AKT and PI3K expression level are regulated to control the occurrence and progression of CRC.

Applications

This study revealed that PTEN was one of the direct target genes of miR-21, and that its downstream AKT and PI3K expression levels could be regulated and controlled through altering miR-21 expression, in order to control CRC occurrence and progression. Nevertheless, the mechanisms of miR-21 and PTEN function, as well as their effects in tumors, need to be further investigated. As in-depth research on mRNA is currently being implemented, particularly regarding the regulatory mechanism of tumor cells, more roles and targets of miR-21 will probably be unraveled.

Peer-review

This is an interesting manuscript about the miR-21 promotion of PTEN and its downstream proteins AKT and PI3K in CRC. Over all, this study is well designed and the manuscript is well written.

Institutional review board statement: The study was reviewed and approved by the Provincial Hospital Affiliated to Shangdong University Institutional Review Board.

Institutional animal care and use committee statement: The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimatized to laboratory conditions (room temperature 23 ℃, 12-h light and dark cycle, 50% humidity, ad libitum access to food and water) for two weeks prior to experimentation. All animals were euthanized by barbiturate overdose (intravenous injection, 150 mg/kg pentobarbital sodium) for tissue collection.

Conflict-of-interest statement: The authors declare there is no conflict of interest related to this study.

Data sharing statement: Technical appendix, statistical code, and dataset available from the corresponding author at zhangzhenhai410@126.com. Participants gave informed consent for data sharing.

Abstract

AIM: To investigate the mechanisms and effects of sphincter of Oddi (SO) motility on cholesterol gallbladder stone formation in guinea pigs.

METHODS: Thirty-four adult male Hartley guinea pigs were divided randomly into two groups, the control group (n = 10) and the cholesterol gallstone group (n = 24), which was sequentially divided into four subgroups with six guinea pigs each according to time of sacrifice. The guinea pigs in the cholesterol gallstone group were fed a cholesterol lithogenic diet and sacrificed after 3, 6, 9, and 12 wk. SO manometry and recording of myoelectric activity were obtained by a multifunctional physiograph at each stage. Cholecystokinin-A receptor (CCKAR) expression levels in SO smooth muscle were detected by quantitative real-time PCR (qRT-PCR) and serum vasoactive intestinal peptide (VIP), gastrin, and cholecystokinin octapeptide (CCK-8) were detected by enzyme-linked immunosorbent assay at each stage in the process of cholesterol gallstone formation.

RESULTS: The gallstone formation rate was 0%, 0%, 16.7%, and 83.3% in the 3, 6, 9, and 12 wk groups, respectively. The frequency of myoelectric activity in the 9 wk group, the amplitude of myoelectric activity in the 9 and 12 wk groups, and the amplitude and the frequency of SO in the 9 wk group were all significantly decreased compared to the control group. The SO basal pressure and common bile duct pressure increased markedly in the 12 wk group, and the CCKAR expression levels increased in the 6 and 12 wk groups compared to the control group. Serum VIP was elevated significantly in the 9 and 12 wk groups and gastrin decreased significantly in the 3 and 9 wk groups. There was no difference in serum CCK-8 between the groups.

CONCLUSION: A cholesterol gallstone-causing diet can induce SO dysfunction. The increasing tension of the SO along with its decreasing activity may play an important role in cholesterol gallstone formation. Expression changes of CCKAR in SO smooth muscle and serum VIP and CCK-8 may be important causes of SO dysfunction.

Key words: Cholesterol gallstone; Sphincter of Oddi; Manometry; Myoelectric activity; Cholecystokinin-A receptor

Core tip: This study investigated the role of sphincter of Oddi (SO) motility in cholesterol gallstone formation in a guinea pig model. The myoelectric activity and manometry of SO were measured at different stages of stone formation. As SO motility is controlled by neurological and hormonal factors, we detected the expression of serum vasoactive intestinal peptide (VIP), gastrin, cholecystokinin octapeptide (CCK-8), and CCK-A receptor (CCKAR) in the SO at different stages of stone formation. We found that a cholesterol gallstone-causing diet can induce SO dysfunction and expression changes of CCKAR in SO smooth muscle and serum VIP and CCK-8 may be important causes of SO dysfunction.

Effects of sphincter of Oddi motility on the formation of cholesterol gallstones. *World J Gastroenterol* 2016; 22(24): 5540-5547 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5540.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5540

INTRODUCTION

Gallstone disease is one of the most common digestive disorders requiring hospital admission in Western countries, with a morbidity of 10%-15% in adults[1]. In China, the incidence of cholesterol gallstones has been increasing in the past few decades due to changing lifestyles[2]. Cholesterol gallstone formation is a complicated process and is still not fully understood. Cholesterol supersaturation of bile, biliary stasis, and mucus hypersecretion are universally known to be important factors in the process of cholesterol gallstone formation[3,4]. Among them, biliary stasis is thought to be a key factor because it allows time for cholesterol nucleation and then retention of the precipitated microcrystals[4,5]. The sphincter of Oddi (SO) may play an important role in gallstone formation because it is the only way by which bile is discharged into the duodenum. There are very few reports investigating the relationship between SO motility and cholesterol gallstone formation, and the conclusions are controversial[6-8].

It is well-established that cholecystokinin (CCK) is one of the major gastrointestinal hormones responsible for gallbladder contraction and SO relaxation[9]. The biological actions of CCK in the alimentary tract are mediated by the CCK-A receptor (CCK-AR)[10]. A series of studies focused on the expression level of CCK-AR in the gallbladder in the pathogenesis of cholesterol gallstone disease[5,11]. However, no report on CCK-AR expression in the SO in animals with gallstones is available yet.

The aim of this study was to investigate the role of SO motility in cholesterol gallstone formation in a guinea pig model. The myoelectric activity and manometry of SO were measured at different stages of stone formation in this model. As SO motility is controlled by neurological and hormonal factors, we detected serum vasoactive intestinal peptide (VIP), gastrin, CCK-8, and CCK-AR expression in the SO at different stages of stone formation.

MATERIALS AND METHODS

Experimental animals

Thirty-four adult male Hartley guinea pigs, weighing between 230 g and 270 g, were purchased from Huishan Jiangnan Laboratory Animal Company (License SCXK SU: 2009-0005). The animals were housed in climate-controlled rooms under an alternating 12-h light and dark cycle and permitted continuous access to food and water. After a 2-wk equilibration, the animals were divided randomly into two groups (control and cholesterol stone groups): the control group (n = 10) was fed a normal diet, and the cholesterol stone group (n = 24) was sequentially divided into four subgroups with six guinea pigs each according to time of sacrifice, fed a cholesterol lithogenic diet[6], and sacrificed after 3, 6, 9, and 12 wk. The lithogenic diet consisted of 1% cholesterol[10] (purchased from Trophic Animal Feed High-Tech Co. Ltd., Nantong, China). Gallstones were defined as macroscopically visible sediment. The calculi were tested by infrared spectrometry to verify the sample as cholesterol gallstones. SO manometry and myoelectric activity of the guinea pigs were determined at 3, 6, 9, and 12 wk.

Table 1 Primer sequences of *CCKAR* and *GAPDH*

Genes	Forward primer (5′-3′)	Reverse primer (5′-3′)
CCKAR	ACGGAGGGTAGTGAACTCCA	TCGCAGGCAGAAGTGATGTT
GAPDH	GCACCGTCAAGGCTGAGAAT	CATCACGAACATAGGGGCATC

CCKAR: Cholecystokinin-A receptor; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

Measurement of myoelectric activity of the SO

At the end of the feeding period, the animals were anesthetized by injecting pentobarbital sodium (45 mg/kg) into the peritoneal cavity. The guinea pigs were fixed in the supine position, and the skin of the superior abdomen was prepared and sterilized. A longitudinal incision was made and the papilla determined. Details of the myoelectric system were described previously[12]. In brief, two polar hook metal electrodes were inserted 0.2 mm into the subserosa of the SO by megaloscope (× 10 magnification). The fan-out of the two signals was connected with the two polars of the physiological recorder (BL-420 F; Chengdu Taimeng Software, Chengdu, China), and a piece of metal needle was inserted into the legs of the animals to connect with the earth pole of the recorder. The myoelectric signal was collected by the electrode, imported into the computer, and stored after processing by a physiological recorder and the software system specialized in electromyographic signals. The setup parameters were as follows: scanning speed, 500 ms/div; sensitivity, 200 μV; time parameter, 1 s; and frequency filtering, 10 Hz. Finally, the myoelectric figure was dealt with by digital filtering of 10-30 Hz.

SO manometry

Details of manometry were described previously[12]. In brief, a manometry catheter was modified from a pedo bi-lumen central venous catheter (4F and 30 cm long). The catheter was inserted into the common bile duct (CBD) and SO through the duodenal ampulla. The pressure transducer was used for receiving the dynamic pressure change from the manometric lumen. The frequency of SO phasic contraction, SO amplitude, SO basal pressure, and CBD pressure were measured and recorded. A physiological recorder and relevant manometry program were used to record and analyze the tracings.

Detection of serum VIP, gastrin, and CCK-8

Four milliliters of venous blood were obtained from the guinea pigs in the early morning before they were sacrificed and placed in a test tube. The blood was centrifuged at 1500 r/min for 15 min, and serum was isolated, placed in Eppendorf tubes and stored at -70 ℃. Serum VIP, gastrin, and CCK-8 were measured by enzyme-linked immunosorbent assay (ELISA). The ELISA testing kit was supplied by USCN Life Science Inc. (Houston, TX, United States).

Quantification of CCKAR mRNA in SO tissues

The SO of each animal was quickly removed and transferred to normal saline after animals were euthanized. The smooth muscle was removed carefully using sharp dissection. Total RNA from SO tissue samples was extracted using TRIzol reagent (Invitrogen, Carlsbad, CA, United States). Every 50 mg of SO tissue sample was extracted with 1 mL of TRIzol reagent according to the manufacturer's protocol. One microgram of total RNA was used for the synthesis of cDNA using a FastQuant RT Kit and target genes were assayed using SYBR Green Real-time PCR Master Mix (*via* Roche Light Cycler, Roche, Basel, Switzerland) with their respective primers. The PCR conditions were as follows: 95 ℃ for 30 s; 40 cycles of 95 ℃ for 5 s, 57 ℃ for 10 s, and 72 ℃ for 15 s. Transcription levels of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were used as an internal control to calculate fold induction, and the fold changes in transcription levels were calculated using the $2^{-\Delta\Delta Ct}$ method. Primer sequences of CCKAR and GAPDH are shown in Table 1.

Statistical analysis

Statistical analysis was performed using Student's *t* test. Data were analyzed with software SPSS 17.0 (SPSS Inc. Chicago, IL, United States), and $P < 0.05$ was set as the level of significance. The results are expressed as mean ± SE.

RESULTS

Gallstone formation rate

No gallstone was found in guinea pigs in the control group. In contrast, the gallstone formation rate in the cholesterol stone group fed with a cholesterol lithogenic diet was 0%, 0%, 16.7%, and 83.3% in the 3, 6, 9, and 12 wk groups, respectively.

SO myoelectric activity analysis

Compared with the control group, the frequency of myoelectric activity decreased markedly in the 9 wk group (Figure 1A and B, Table 2). The amplitude of myoelectric activity decreased significantly in the 9 and 12 wk groups (Figure 1A-C, Table 2).

SO manometry analysis

Compared with the control group, the amplitude and frequency of SO decreased significantly in the 9 wk group (Table 3), and SO basal pressure and common

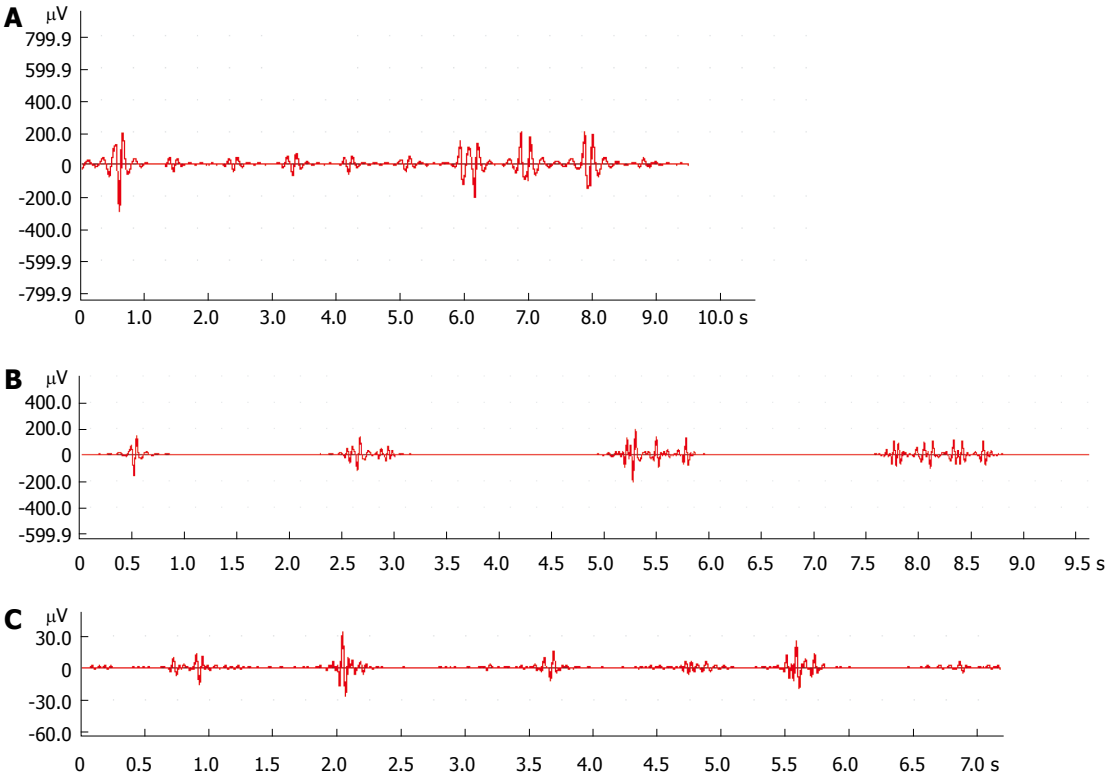

Figure 1 Sphincter of Oddi myoelectric activity analysis. A: The frequency and amplitude of myoelectric activity in the control group; B: The frequency and amplitude of myoelectric activity in the 9 wk group; C: The frequency and amplitude of myoelectric activity in the 12 wk group.

Table 2 Changes of sphincter of Oddi myoelectric activity in the process of gallstone formation

Group	Amplitude	Frequency
Control group	142.45 ± 71.25	16.56 ± 4.05
3-wk group	125.06 ± 59.76	13.70 ± 2.88
6-wk group	152.96 ± 81.05	15.10 ± 4.13
9-wk group	100.27 ± 50.42[a]	8.68 ± 2.35[a]
12-wk group	40.60 ± 15.03[c]	13.80 ± 3.79

[a]$P < 0.05$, [c]$P < 0.01$ *vs* the control group.

bile duct pressure increased significantly in the 12 wk group (Figure 2, Table 3).

Changes in serum VIP, gastrin and CCK-8

Compared with the control group, serum VIP was elevated significantly in the 9 and 12 wk groups (Table 4), and serum gastrin was decreased significantly in the 3 and 9 wk groups (Table 4). There was no difference in serum CCK-8 between the groups (Table 4).

Quantitative expression of CCK-AR mRNA

Compared with the control group, expression levels of the CCK-A receptor mRNA were increased significantly in the 6 and 12 wk groups (Figure 3).

DISCUSSION

Gallstone disease is one of the most common and most expensive digestive disorders requiring admission to the hospital[13-15], with a prevalence of 10%-15% in adults in Europe and the United States. In Western countries, cholesterol gallstones account for 80%-90% of gallstones at cholecystectomy[15], but the mechanism underlying the pathogenesis of cholesterol gallstone disease is not completely understood.

Epidemiological evidence indicates that multiple environmental factors and genetic elements are involved in cholesterol gallstone formation. Among them, biliary stasis is thought to be an important factor. A series of studies in human and animal models have shown that formation of cholesterol gallstones is causatively related to decreased gallbladder contractility[16]. Since SO is the only gate through which bile is discharged into the duodenum, bile filling and excretion of the gallbladder are closely related to the motility state of the SO[17]. However, there is limited research on the role of SO motility in the process of cholesterol gallstone formation. SO manometry (SOM) is the only method that can assess directly the motor function of the SO and is considered the gold standard for assessing SO dysfunction (SOD)[18]. However, manometry changes of the SO in cholelithiasis are controversial. Research by Pang *et al*[19] indicated that the base pressure of the SO was significantly increased in rabbits fed a cholesterol lithogenic diet. On the other hand, a study in prairie dogs showed that SO resistance remained normal throughout the period of gallstone formation. These completely different results may be species dependent. Meanwhile, the mechanical activity recorded may not represent the features of

Table 3 Sphincter of Oddi manometry in the process of gallstone formation

Group	SO basal pressure	CBD pressure	Amplitude of SO	Frequency of SO
Control group	26.59 ± 8.16	23.25 ± 8.35	8.72 ± 2.05	11.27 ± 3.74
3-wk group	21.25 ± 1.38	18.48 ± 1.94	8.33 ± 3.85	11.50 ± 1.64
6-wk group	27.57 ± 8.67	25.82 ± 8.26	8.03 ± 3.15	9.33 ± 3.27
9-wk group	34.11 ± 11.56	32.15 ± 11.64	5.89 ± 1.41[a]	7.67 ± 3.44[a]
12-wk group	52.38 ± 12.84[c]	50.11 ± 12.59[e]	6.82 ± 1.34	10.60 ± 3.51

[a]$P < 0.05$, [c]$P < 0.01$, [e]$P < 0.001$ *vs* the control group. SO: Sphincter of Oddi; CBD: Common bile duct.

SO activity, especially in the relaxed SO. Another measurement reflecting SO function is recording the myoelectric activity of the SO[20].

In this study, we investigated whether SOD was present and what role it played in the process of cholesterol gallstone formation in guinea pigs. SOM and myoelectric activity of SO were investigated simultaneously at different stages of stone formation. We found that gallstones did not occur until 9 wk, with an incidence rate of 16.7%, increasing to 83.3% after 12 wk. SO myoelectric activity analysis indicated that the frequency and amplitude of myoelectric activity decreased significantly in the 9 wk group compared to control. Subsequent SO manometry analyses showed the same result: both SO amplitude and SO frequency decreased significantly in the 9 wk group, and the most important indications, the SO basal pressure and common bile duct pressure, increased significantly in the 12 wk group. All these findings are consistent with weakening of the myoelectric activity of SO and gradual increasing of SO tension in the process of gallstone formation. Disturbance of SO motor function impedes the flow of bile into the duodenum, and biliary stasis occurs.

Table 4 Changes in VIP, gastrin and CCK-8 in the process of cholesterol stone formation (pg/mL)

Group	3-wk	6-wk	9-wk	12-wk
VIP

The mechanism of cholesterol gallstone-causing diet-induced SOD has not been fully elucidated. Pang *et al*[19] considered that the potential mechanisms of hypercholesterolemia (HC)-induced SOD were the intracellular calcium overload and calcium oscillation abnormality. Szilvassy *et al*[21] suggested that the impairment of the SO relaxation function was related to the alteration of the nitric oxide signal caused by hypercholesterolemia and hypertriglyceridemia. SO motility was controlled by numerous neurotransmitters and gastrointestinal hormones[22]. The most important hormone in the regulation of SO function is CCK[23]. In normal conditions, CCK can contract the gallbladder smooth muscle and reduce tone in the SO to regulate bile flow from the liver through the bile duct into the duodenum. During fasting, hepatic bile enters the gallbladder for storage. Eating initiates gallbladder emptying by neural and hormonal (predominantly CCK) influences. We found serum CCK-8 level was not increased in the 9 and 12 wk groups, meaning that the gallbladder evacuation resistance increased during eating in these groups. Decreases in serum CCK-8 level can cause gallbladder bile stasis, increase the volume of the gallbladder, and induce SOD by increasing the tension of SO.

CCK modulates SO motility mainly *via* excitatory receptors on the smooth muscle and inhibitory receptors in the neural endings[24]. A study in cats[24] showed that the SO relaxation by CCK was abolished by complete denervation induced by tetrodotoxin. Beagle dogs after cholecystectomy[25] showed an increased CBD pressure, and SO relaxation response to CCK was weakened. These findings were thought to be due to destruction of neural pathways with the operation. In our study, we examined the expression of CCK-AR in the SO using quantitative real-time PCR for the first time. We found that the expression levels of *CCK-AR* mRNA increased in SO in the 6 and 12 wk groups. The increase in CCK-AR may result in changes in tension of SO, and, therefore, the excreting resistance of the bile may be enhanced significantly.

VIP, an alkaline intestinal peptide composed of 28 amino acids, can relax gallbladder smooth muscle and decrease gallbladder pressure. In the present study, serum VIP level in the 9 and 12 wk groups was higher than that of the control group. We restated the role of VIP in the formation of cholesterol gallstones that had been stressed in our previous study[12]. We found that the frequency of myoelectric activity decreased markedly in the 9 wk group, the amplitude of myoelectric activity decreased in the 9 and 12 wk groups, and the SO basal pressure and common bile duct pressure increased significantly in the 12 wk group. Elevation of VIP may play an important role in the mechanism of SOD.

Gastrin can increase the SO basal pressure amplitude[12]. Elevation of serum gastrin may be related to SOD with characteristics of high tension in patients with post-cholecystectomy pain[26]. However, we found that serum gastrin was decreased significantly in the 3 and 9 wk groups. This effect may have resulted from changes in diet and may not necessarily be related to the formation of gallstones.

In conclusion, we have indicated that a cholesterol gallstone-causing diet may induce SOD, the increasing tension of SO along with its decreasing activity may play an important role in cholesterol gallstone formation, and expression changes in CCK-AR in SO smooth muscle and serum CCK-8 and VIP may be important causes of SOD. The exact mechanism of cholesterol gallstone-causing diet-induced SOD needs further study. Control

of a cholesterol diet and regulation of SO motility are important in the prevention of cholesterol gallstone formation.

COMMENTS

Background

The sphincter of Oddi (SO) may play an important role in gallstone formation because it is the only way by which bile is discharged into the duodenum. However, there is limited research on how the motor function of the SO works and what mechanism by which stones are formed in the process of cholesterol gallstone formation.

Research frontiers

SO manometry is the only method to directly assess the motor function of the SO and is considered the gold standard for assessing SO dysfunction (SOD). However, manometry changes of SO in cholelithiasis are quite controversial. Another measurement reflecting SO function is recording the myoelectric activity of the SO.

Innovations and breakthroughs

This study showed that a cholesterol gallstone-causing diet can induce SOD. The increasing tension of the SO along with its decreasing activity may play an important role in cholesterol gallstone formation. Expression changes of cholecystokinin-A receptor in SO smooth muscle, serum vasoactive intestinal peptide, and cholecystokinin-octapeptide may be important causes of SOD.

Applications

The study results suggest that a cholesterol gallstone-causing diet can induce SOD, and disturbance of SO motility may play a role in gallstone formation. Control of a cholesterol diet and regulation of SO motility are important in the prevention of cholesterol gallstone formation.

Peer-review

This is an interesting paper. The authors describe the results of a basic study in a guinea pig model to investigate the role of SO motility in cholesterol gallbladder stone formation. They concluded that a cholesterol gallstone causing diet may induce increasing tension and decreasing activity of SO, and these effects could play an important role in cholesterol gallstone formation. This work represents a well-conducted basic study that contributes useful information about the role of SO motility in the process of cholesterol gallstone formation and confirms previous limited data that indicated a significant increase in the base pressure of the SO in rabbits with a cholesterol lithogenic diet.

Abstract

AIM: To determine risk factors for early neurologic complications (NCs) after liver transplantation from perspective of recipient, donor, and surgeon.

METHODS: In all, 295 adult recipients were enrolled consecutively between August 2001 and February 2014 from a single medical center in Taiwan. Any NC in the first 30 d post-liver transplantation, and perioperative variables from multiple perspectives were collected and analyzed. The main outcome was a 30-d NC. Generalized additive models were used to detect the non-linear effect of continuous variables on outcome, and to determine cut-off values for categorizing risk. Risk factors were identified using multiple logistic regression analysis.

RESULTS: In all, 288 recipients were included, of whom 142 (49.3%) experienced at least one NC, with encephalopathy being the most common 106 (73%). NCs prolonged hospital stay (35.15 ± 43.80 d *vs* 20.88 ± 13.58 d, $P < 0.001$). Liver recipients' age < 29 or ⩾ 60 years, body mass index < 21.6 or >

27.6 kg/m^2, Child-Pugh class C, history of preoperative hepatoencephalopathy or mental disorders, day 7 tacrolimus level > 8.9 ng/mL, and postoperative intra-abdominal infection were more likely associated with NCs. Novel risk factors for NCs were donor age < 22 or ⩾ 40 years, male-to-male gender matching, graft-recipient weight ratio 0.9%-1.9%, and sequence of transplantation between 31 and 174.

CONCLUSION: NCs post- liver transplantation occurs because of factors related to recipient, donor, and surgeon. Our results provide a basis of risk stratification for surgeon to minimize neurotoxic factors during transplantation.

Key words: Risk; Liver transplantation; Neurotoxicity syndromes; Donor; Learning curve

Core tip: The study uses generalized additive models and logistic regression in statistics to control confounders in the case-control study. We identified 11 risk factors for early neurologic complication after transplantation. From liver recipients' perspective, age < 29 or ⩾ 60 years, body mass index < 21.6 or > 27.6 kg/m^2, Child-Pugh class C, history of preoperative hepatoencephalopathy or mental disorders, day 7 tacrolimus level > 8.9 ng/mL, and postoperative intra-abdominal infection were at risk. From donors' perspective, age < 22 or ⩾ 40 years, male-to-male gender matching, graft-recipient weight ratio 0.9%-1.9% was at risk. From surgeons' perspective, sequence of transplantation between 31 and 174 were at risk.

Comprehensive risk assessment for early neurologic complications after liver transplantation. *World J Gastroenterol* 2016; 22(24): 5548-5557 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5548.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5548

INTRODUCTION

Neurologic complications (NCs) are common after solid organ transplantation, especially liver transplantation[1]. While mortality rates decreased with advances in surgical technique and postoperative care in recent years, NCs continue to affect more than one-third of transplanted patients and cause significant morbidity, mortality, and prolonged hospital stay[2,3]. The liver recipient is vulnerable to NCs since many patients have preoperative hepatic encephalopathy, which is a well-known risk factor[3-6]. Moreover, the unfavorable condition of recipients including metabolic, nutritional, and electrolyte imbalances may predispose them to NCs[7,8]. Generally, NCs develop early, with more than 80% of patients developing NCs within 30 d after liver transplantation[6,9]. Encephalopathy is the most frequent etiology[3,5,9-12]. As it is multifactorial in nature, the transplant team should identify patients at risk and avoid predisposing variables during the perioperative period to minimize its incidence.

In the last decade, the risk factors and mechanism of NCs have been investigated in several studies, most of which were retrospective[3,6,9-12]. The majority of these focused on recipients' factors depending on timing of transplant, such as presence of hepatic encephalopathy, etiology of cirrhosis before transplant, hyponatremia, cerebrovascular insult during transplant, immunosuppressant toxicity and central nervous system infection after transplant. However, the nature of liver graft, donor-recipient matching, and experience of surgeon and transplant team also impact outcome, and few studies have investigated NCs after liver transplantation from these perspectives. No study showed how the accumulated experience of the transplant team influences NC development. Besides, the non-linear effect of certain continuous variables, such as age, body mass index (BMI) and graft-recipient weight ratio (GRWR), was not considered in the statistical analysis of prior studies. Our study aimed to identify new risk factors of 30-d NCs after liver transplantation from multiple perspectives. In particular, we performed statistical analyses to explore how the non-linear effect of certain continuous variables increase NC risk.

MATERIALS AND METHODS

Patients

From August 2001 to February 2014, 295 consecutive adult liver transplantation surgeries were performed in the Tri-Service General Hospital (Taipei, Taiwan). All causes of mortality were included in the study except for surgical mortality unrelated to NCs. All procedures were performed after approval of the Ethics Committee. The transplant team included 2 qualified transplant surgeons, 2 fellows and 2 senior residents. The immunosuppressant induction protocol consisted of intravenous methylprednisolone, starting with a large bolus dose during the anhepatic phase, followed by daily tapering off until postoperative day 5, and triple oral immunosuppressants (tacrolimus, mycophenolate mofetil, steroids). Serum trough levels of tacrolimus were checked daily in the first postoperative week to maintain a level of 6-10 ng/mL. If basiliximab was included, the first 20 mg were given during anhepatic phase and the second dose on postoperative day 4, along with halving the steroid dose. Diagnoses of NCs were primarily made by the transplant team based on clinical examination, and ancillary examinations such as computed tomography, magnetic resonance imaging, and electroencephalography. Neurologists were consulted for major NCs. Only new onset of

postoperative neurologic disorders was regarded as NCs. The clinical data and patients' outcomes were retrospectively reviewed from medical charts. The final follow-up was conducted until March 31, 2014.

Data collection

The medical records and transplant database were reviewed after approval of the Institutional Review Board I of Tri-Service General Hospital, National Defense Medical Center (TSGHIRB No.100-05-220). Data were collected from 4 major perspectives: recipient, donor, donor-recipient match, and surgeon. The recipient-related variables were demographic details, comorbidities other than liver diseases, primary liver disease requiring liver transplantation, preoperative Child-Pugh and Model for End-Stage Liver Disease (MELD) scores, any complications of end-stage liver disease, such as ascites, hepatic encephalopathy, variceal bleeding and hepatorenal syndrome. In addition, any mental disorders related to alcoholism or encephalopathy were recorded. The perioperative variables included intraoperative blood loss, length of the procedure, complex vascular anatomy, and splenectomy. The postoperative variables included dose and serum level of tacrolimus, inclusion of basiliximab, and blood chemistry parameters (ammonia, sodium, and magnesium) on postoperative day 7. In addition, any postoperative complications as acute rejection, intra-abdominal infection, or kidney injury requiring dialysis were recorded. The donor and donor-recipient matching-related variables were graft's type and weight, gender match, GRWR, and ABO compatibility. The surgeon variables were surgeon in charge, and the chronological sequence of transplantations.

Outcomes' evaluation

The primary outcome was occurrence of any NCs within 30 d after liver transplantation. We adapted the NC classification from Dhar *et al*[3] as follows: (1) encephalopathy: delirium, psychosis, or alteration of conscious level diagnosed after excluding specific lesions of the central nervous system; (2) seizures; (3) drug neurotoxicity: symptoms subsiding after reduction or discontinuation of immunosuppressants, with severity varying from tremors to imaging-confirmed posterior reversible encephalopathy syndrome; (4) cerebrovascular insults; (5) central nervous system infection; and (6) central pontine myelinolysis: acute para- or quadriparesis, dysphagia, dysarthria, diplopia, loss of consciousness with evident change in serum sodium levels. Patients experiencing "locked-in syndrome", that is, awake but unable to move or communicate, were categorized into "central pontine myelinolysis" if rapid changes in serum sodium level coexisted. If the definite etiology could not be determined, they were recorded separately.

Other outcome data were hospital days and complications other than NCs during the first month. In addition, the complications were classified into minor and major according to the clinical finding and its severity. Minor complications included those that improved spontaneously without sequela within 1 mo, while the others causing functional deficit, brain damage or death were considered as major complications.

Statistical analysis

Statistical analysis was performed using the R 3.1.0 software (R Foundation for Statistical Computing, Vienna, Austria). A P-value of < 0.05 was considered statistically significant.

Descriptive statistics were used to express data as mean ± SD for continuous variables, and frequency and percentage for categorical variables. Differences between the two groups, patients developing NCs and those who did not, were analyzed using Wilcoxon's rank-sum test for continuous variables, and Fisher's exact test for categorical variables.

Some continuous variables had non-linear effect, such as age and BMI. The regression model may have described poor correlation between these variables and the outcome since linearity was usually assumed during the analysis. Generalized additive models (GAMs)[13] for binary response (patients developing NCs and those who did not) were fitted to detect the potential nonlinear effects of continuous covariates; if nonlinearity existed, appropriate cut-off point(s) for discretizing the continuous covariate were selected in the GAM plots. This procedure was carried out using the vgam function (with the default values of smoothing parameters) of the VGAM package in R.

Multiple logistic regression analysis was conducted by fitting a generalized linear model to estimate the effects of predictors on the occurrence of NCs. First, all variables, donor-recipient gender match combinations, and new categorical variables obtained from previous cut-off points for discretizing continuous variables by GAM were selected. Next, a step-wise variable selection procedure went through iteration between the forward and backward steps with both the significant levels for entry and for stay set to 0.15 for being conservative. Then, the best candidate final logistic regression model was identified manually by dropping the covariates with P value > 0.05 one at a time until all regression coefficients were significantly different from 0. The final fitted logistic model was assessed with 3 goodness of fit measures: the estimated area under the receiver operating characteristic curve ($\geqslant$ 0.7 acceptable), adjusted generalized R^2 ($\geqslant$ 0.30 acceptable), and the Hosmer-Lemeshow test ($P \geqslant$ 0.05, larger means better fit). In addition, the variance inflation factor was checked for multicollinearity (no more than 10 for continuous covariates and 2.5 for categorical covariates).

RESULTS

Among the 295 patients, 7 with surgical mortality

Total complications	85	

The outcome data are shown in Table 2. One hundred and forty two patients experienced 145 events of NCs, with an overall incidence of 49.3%. The most frequent events were encephalopathy (n = 106, 73%), including delirium (n = 75, 52%), conscious change (n = 26, 18%) and psychosis (n = 5, 4%). The average hospital stay was significantly longer in those with postoperative NCs (35.15 ± 43.80 d *vs* 20.88 ± 13.58 d, P < 0.001).

Variables associated with NCs

The differences between the patients with NC or not are shown in Table 3. Both groups were similar in demographics of recipient and donor, liver graft type, surgeon and sequence of transplantation. For primary diagnosis, alcoholic liver cirrhosis was more common in the NC group (P = 0.001), while hepatocellular carcinoma was prevalent in the control group (P < 0.001). The NC group included patients with more severe liver disease before transplant, more preoperative mental disorders and hepatic encephalopathy, more intraoperative complex vascular anatomy, higher day 7 tacrolimus level, more postoperative complications of acute rejection, intra-abdominal infection, and kidney injury requiring dialysis.

GAMs were fitted to continuous variables with potential non-linear effect on outcome. The selected GAM plots for continuous variables on the NC group are shown in Figure 1. According to the GAM plots, the following scales of variables were associated with higher probability of NCs: age < 29 or ⩾ 60, recipient BMI < 21.6 or > 27.6 kg/m^2, Child-Pugh score >

NCs: Neurologic complications; HCC: Hepatocellular carcinoma; MELD: Model for end-stage liver disease; GRWR: Graft-recipient weight ratio; BMI: Body mass index.

9, MELD score between 11 and 20, serum glucose > 8 mmol/L, serum albumin between 2.9 and 4.2 g/dL, serum creatinine between 0.6-1.6 mg/dL, the logarithm of INR > 0.3, platelet count < 70 × 10^3/μL, serum ammonia > 268 μg/dL, day 7 tacrolimus level > 9 ng/mL, day 7 serum ammonia level > 98 μg/dL, day 7 serum sodium level > 143 mmol/L, day 7 serum magnesium level > 1.8 mEq/L, donor age < 22 or ⩾ 40 years, GRWR between 0.9% and 1.9%, and sequence of transplantation between 31 and 174. New categorical variables for regression analysis were obtained after grouping these continuous variables.

After stepwise multiple logistic regression analysis, 12 independent variables were identified as significant in the final logistic regression model (Table 4). Eleven positive predictors of NCs were: recipient age < 29 or ⩾ 60 years, BMI < 21.6 or > 27.6 kg/m^2, Child-Pugh score > 9, preoperative hepatic encephalopathy, history of mental disorder, day 7 tacrolimus level > 8.9, postoperative intra-abdominal infection, donor age < 22 or ⩾ 40 years, male-to-male gender match, GRWR between 0.9% and 1.9%, and sequence of transplantation between 31 and 174. On the other hand, recipients with history of variceal bleeding were less likely to develop NCs (OR = 0.431; 95%CI: 0.221-0.821). The assessment of final logistic regression model showed fair goodness-of-fit (area under the receiver operating characteristic curve = 0.8553 > 0.7 with 95%CI: 0.8119-0.8988; adjusted R^2 = 0.471 > 0.3; Hosmer-Lemeshow goodness-of-fit test P = 0.1446 > 0.05). Furthermore, variance inflation factors for each covariate in the selected final logistic regression model were between 1.075 and 1.582, indicating no multicollinearity.

DISCUSSION

Our results confirmed the prevalence of NCs following liver transplantation, with three-quarters of patients developing encephalopathy. The risk factors were not only from recipient's perspective, but also from perspectives of donor, donor-recipient match and surgeon. Since randomization of subjects is hardly possible in critical conditions as those requiring liver transplantation, studies in this area almost have case-control design. The novelty we have in this study came from better control of confounding effects by flexible statistical tools. The GAM plots enabled more proper stratification of continuous variables on outcome, and the regression analysis controlled the confounding bias by considering multiple covariates all at a time.

The incidence of NCs in the study was relatively higher than in other reports (49.3% *vs* 20%-30%) because of more diagnoses of minor encephalopathy (88/145, 60.7% of overall NC events). In fact, the diagnostic criteria for encephalopathy are not universal among physicians, especially for minor degrees. In our institution we tend to broaden the diagnostic criteria to include any transient delirium, psychosis or consciousness' level change. This enables us to correct metabolic disorders and use immunosuppressants more properly. Our categorical system here is limited by not differentiating anoxic, septic or metabolic etiologies[14] accounting for intra-abdominal infection as an independent risk factor (OR = 5.193, 95%CI: 2.114-13.67).

Preoperative hepatic encephalopathy and mental disorders significantly increased the risk of NCs, with an OR 2.432 and 2.517, respectively. Hepatic encephalopathy, both episodic and active before the operation, is a well-known risk factor[3,4,6,12,14]. It is hypothesized that excess serum ammonia in end stage liver disease interferes with cerebral metabolism, and the condition is not immediately reversed after

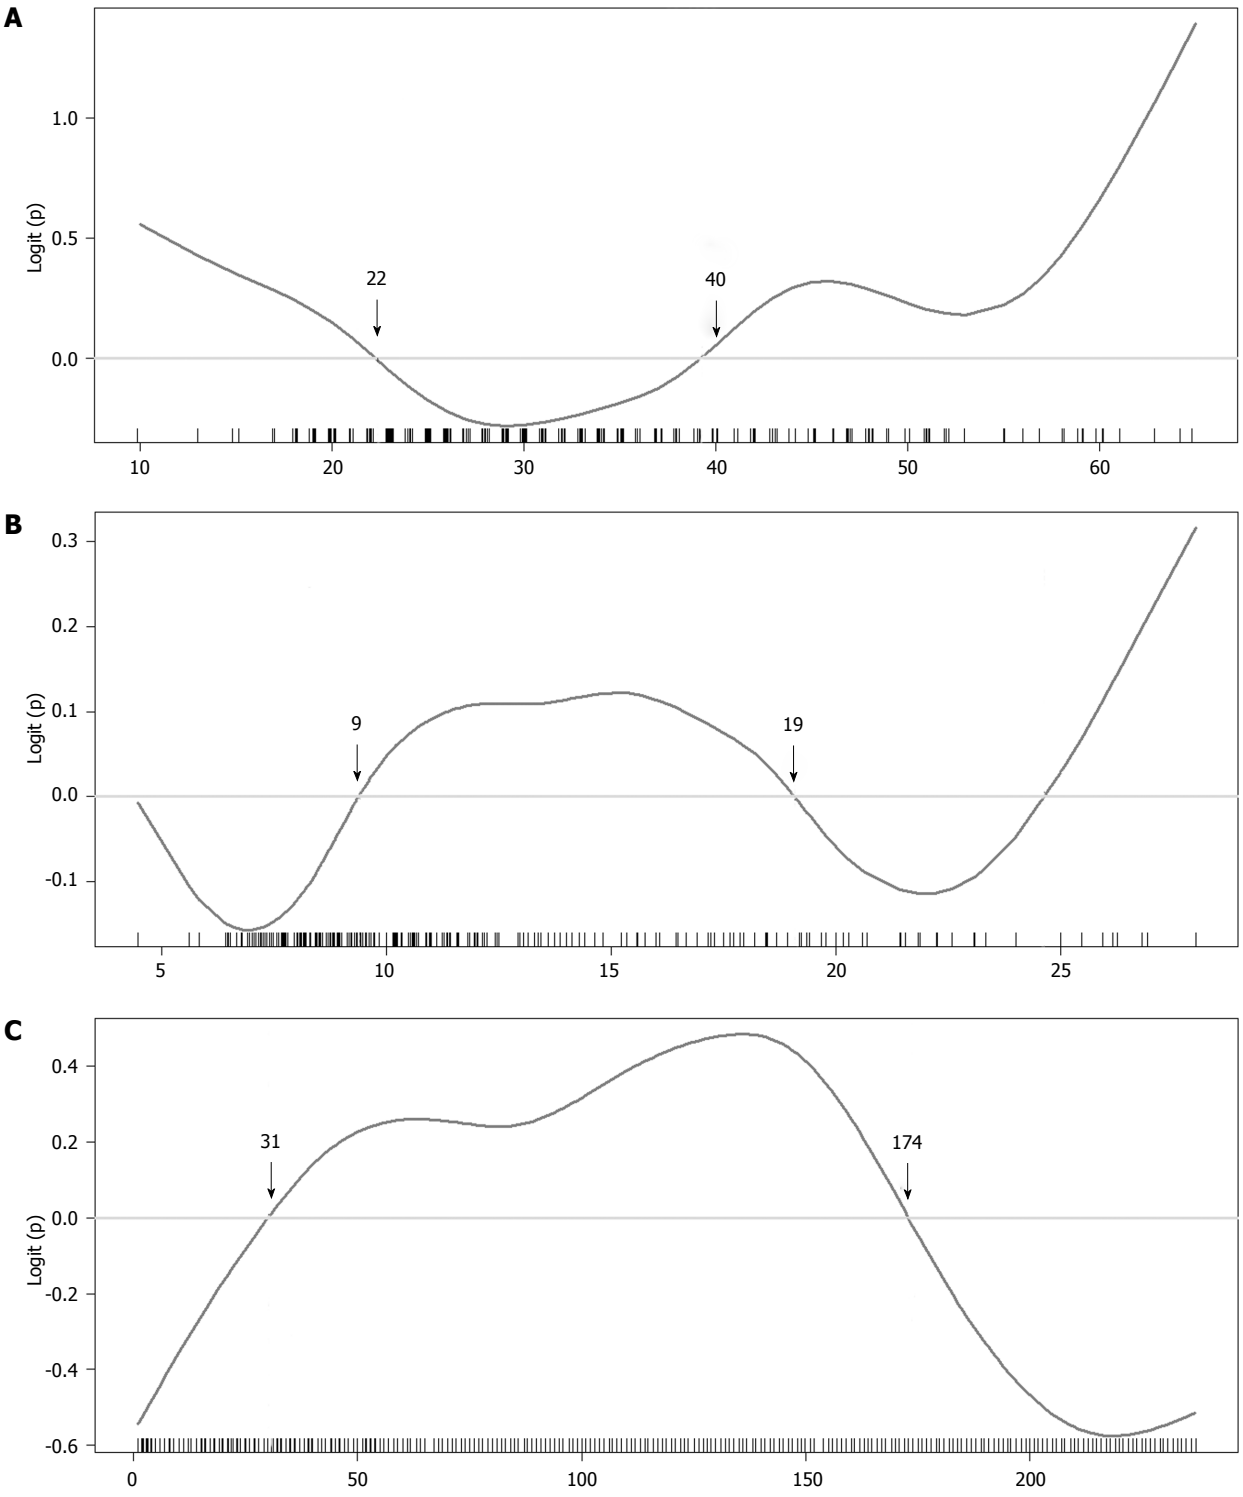

Figure 1 Influence of continuous covariates on neurologic complications resulting from fitting a generalized additive model to the data. A: Donor age; B: Graft-recipient weight ratio; C: Sequence of transplantation.

transplantation. Several investigators have emphasized the importance of comprehensive preoperative neurologic examinations including neuropsychiatric and neuromuscular assessments.

In addition to hepatic encephalopathy, chronic alcohol abuses also contribute to neurotoxicity, which impairs cognitive function especially memory. Alcoholism also renders patients at risk for thiamine deficiency. A prospective study that performed neuropsychological assessments before and after liver transplantation found that recipients with alcoholic etiology had poorer cognitive indexes in memory; in addition, a multivariate analysis determined that alcohol etiology, diabetes mellitus, and hepatic encephalopathy were predictors of poor global cognitive function after transplantation[15]. However,

NCs: Neurologic complications; BMI: Body mass index; MELD: Model for end-stage liver disease; GRWR: Graft-recipient weight ratio.

in line with the result of recent studies on LDLT[10,14,16], the current study, using regression analysis adjusted by other covariates, did not find alcoholic liver disease to be a predictor of NCs. The discrepancy may be related to the multifactorial nature of neurologic complications, and it is difficult to attribute to a specific cause of NC in patients with alcoholic liver disease. As a result, clinicians believe that hepatic encephalopathy, which is prevalent in cirrhotic patients, could be the most common cause of NC. A controlled study with the exact definition of alcohol abuse, complete neurologic examination before and after transplantation, standard postoperative care, and exclusion of postoperative complications confounding the result is needed to answer the question.

On the other hand, recipients with history of variceal bleeding were not likely to have NCs after controlling of potential confounders in the regression model. It was somewhat difficult to explain. One possible reason was that our recipients with variceal bleeding tended to receive living donor liver transplantation earlier than those without did, which enabled transplant proceeding under less severe liver disease. Another reason might be related to the shunt ligation procedure which we often done during transplantation blocking portosystemic encephalopathy.

Moreover, patients with NCs had more severe liver disease before transplant. Child-Pugh class C was an independent risk factor, with an odds ratio of 1.509 (95%CI: 1.288-1.790), while MELD score was not when adjusted by serum creatinine level and other factors in regression analysis. These results were consistent with data obtained in previous studies. In a retrospective study by Dhar *et al*[3] investigating factors associated with NCs, preoperative Child-Pugh Class C was a significant variable in the univariate analysis, while only active preoperative hepatic encephalopathy was significant in the multivariate analysis. Another retrospective study by Kanwal *et al*[17] used age, sex and era-matched control group to identify risk factors of post-transplant mental status change. MELD score > 15 was an independent risk factor in both univariate and multivariate analyses and was one of the four factors included in the prediction model. These results are likely to be related to encephalopathy precipitated by higher serum level of endogenous neurotoxic substances (including ammonia) in patients with severe liver disease. Besides, the frequent changes in electrolyte levels, malnutrition and metabolic disorders in decompensated cirrhosis may result in an unfavorable postoperative environment, rendering liver recipients vulnerable to postoperative neurologic disorders.

Age < 29 or ⩾ 60 years and BMI < 21.6 or ⩾ 27.6 kg/m^2 showed increased probability of NCs in the GAM plot, and both were independent predictors in multiple logistic regression model, with odds ratios of 2.071 and 1.877, respectively (Table 4). Advanced age, preoperative cognitive impairment and multiple medical comorbidities were known risk factors for postoperative delirium after various procedures in several studies[18-20]. We believe that age ⩾ 60 years had greater impact on NCs since the mean recipients' age in our study was 52.3 ± 9.81 years, without pediatric recipients.

Underweight and overweight liver recipients had a significant risk for NCs. Extreme BMI values (< 18.5 and ⩾ 40 kg/m^2) are known risk factors for mortality after liver transplantation[21]. Patients are also more likely to develop infectious complications owing to malnutrition, as well as prolonged treatment time, and NCs secondary to of vitamins' and trace elements' deficiencies[22]. Early diagnosis and prompt treatment of nutritional deficits before transplantation may ameliorate encephalopathy and optimize transplant outcome[22,23].

In the GAM plot for postoperative variables, we found that day 7 tacrolimus level > 8.9 ng/mL, serum ammonia level > 98 μg/dL, serum sodium level > 143 mmol/L, serum magnesium level > 1.8 mEq/L were associated with higher probabilities for NCs. In the final logistic regression model, only day 7 tacrolimus level was an independent variable. This is in line with prior study[3].

Neurotoxicity during induction of immunosuppressants, mostly induced by calcineurin inhibitors (CNIs), is common in the early postoperative period. Clinical manifestations may vary from tremors, headache, and visual disturbances to altered mental status. In addition, seizures after transplantation are most often caused by drug neurotoxicity. The incidence is associated with high serum levels of CNIs while the occurrence is not excluded by normal serum CNI level. Coexisting hypomagnesemia and hypocholesterolemia

are risk factors. Rarely, patients using CNIs have posterior reversible encephalopathy syndrome, a radiographic diagnosis characterized by reversible vasogenic edema of the white matter involving the posterior circulation territory on serial magnetic resonance imaging. It is likely to occur in patients with concomitant alcoholic liver disease and infection/sepsis. Management is mainly dose reduction and shift to an immunosuppressant with another mechanism of action; however, these patients may be at risk of acute rejection from the lower maintenance dose[24]. The process of optimizing immunosuppression, aiming to minimize graft rejection and avoid neurotoxicity, may need multidisciplinary teamwork and accumulated experience.

From the donor perspective, variables of graft type, donor age, donor gender, and GRWR were not significantly different between the NC and control groups. While age and GRWR had a biphasic effect on the GAM plots (Figure 1), we adjusted the cut-off values (donor age < 22 or > 40 years, and 0.9% < GRWR < 1.9%) and found that both variables were predictors in the regression analysis. In the literature, few studies investigated the influence of donor and donor-recipient match factors on NCs. Study from the SRTR database have shown an increased risk of graft failure with donor age > 40 years[25]. Prior studies on NC risk factors including donor age and GRWR showed no significant difference of these variables[5,11]. In contrast, our study indicated that risk of NC depends on either extreme donor age, or improper GRWR. In the GAM plots, we could see the probability of NCs decreasing when GRWR was above 1.9, which could suggest better detoxification capabilities of larger grafts. Besides, small size grafts are not likely to increase NC risk, suggesting non-inferiority of small graft when graft inflow is properly controlled[26].

Male-to-male gender match was another independent risk factor for NCs in this study. The association between donor-gender match and neurologic complications has not been reported previously. The impact of gender mismatch on the outcome of liver transplantation is still controversial. Several studies demonstrated that female-to-male gender match is associated with negative outcomes in kidney, heart, lung, and liver transplantations, possibly due to the effect of estrogen and the relative small-for-size of female grafts[27-30]. It is unclear whether other confounding variables specific to male gender play a role, such as prevalent alcoholic liver diseases. Further prospective, controlled studies are needed to confirm the gender match effect on NCs.

The sequence of transplantation was a notable finding. The risk of NCs decreased after 174 transplantations by the team, and the order between 31 and 174 was an independent risk factor for NC development. The lower risk in the first 30 cases could be related to strict patient selection and relatively conservative strategy of immunosuppression. Learning curve effect in liver transplantation has been described, which is affected by the volume of the center or the year of transplant[31-34]. For successful liver transplantation, multidisciplinary team work is needed. The improvement is important, not only in the surgical technique but also in donor selection, timely decision for surgery, standardized postoperative care and optimal immunosuppression. Compared to graft survival rate commonly used in studies with a learning curve, NCs are more likely to be related to non-operative factors[35,36]. It is the environment influenced by perioperative risk factors from all perspectives that results in complications. To avoid NCs, the transplant team may need risk stratification during patient selection and donor matching, correcting risk factors before the operation as much as possible, and should remain watchful during the perioperative period. Ideal immunosuppression aims at minimizing acute rejection and avoids neurotoxicity. It is crucial for the transplant surgeon to recognize this process of development and to conduct interdisciplinary learning as well as continuously improving the patient care quality of the team.

This study has limitations owing to its retrospective design. First, the complications included were those that were identified and reported by the clinician. While serious complications are rarely excluded, clinicians may have missed minor complications that resolved spontaneously without treatment. Second, NCs often manifests as one or more signs, but it is possible that only the most serious ones were documented, leading to misclassification. Third, patients in the control group might have shared features and exposures with those in the NC group. Even if we have considered as many potential important variables as we could, residual confounders are still possible. Despite these limitations, the risk factors identified in the study could be subjective for validation in further prospective, randomized studies.

In conclusion, NCs after liver transplantation occur frequently and affect almost half of liver recipients, with encephalopathy being the most common (73%). In this study, we identified 11 risk factors for neurologic complications. From the recipient's perspective, age < 29 or ⩾ 60 years along with BMI < 21.6 or > 27.6 kg/m^2 significantly increased NC risk, and Child-Pugh score > 9, hepatic encephalopathy, mental disorder, 7-d tacrolimus level > 8.9 ng/mL, intraabdominal infection were complementary to previous studies. Patients with history of variceal bleeding were less likely to develop NCs. Novel risk factors from donor's and surgeon's perspective were donor age < 22 or ⩾ 40 years, male-to-male gender match, GRWR between 0.9 and 1.9 and sequence of transplantation between 31 and 174. Our results provide a basis for risk stratification, which would enable transplant surgeons to weigh the risk during patient selection, control unfavorable factors before operation, avoid neurotoxicity during perioperative period, and perform active surveillance

after operation. The manner in which the experience of transplant team influences NCs should also be taken into account by the team leader or health care manager who would allow the conduction of interdisciplinary education as well as strategies for continuous quality improvement.

The authors are grateful for the statistical support provided by Dr. Fu-Chang Hu.

COMMENTS

Background

Neurologic complications (NCs) are common after liver transplantation and result in significant morbidity and mortality. Encephalopathy, the most frequent etiology, is multifactorial in nature. Surgeons should identify patients at risk and avoid predisposing variables during the perioperative period to minimize their incidence. However, known risk factors have been mainly investigated from the recipient's perspective.

Research frontiers

The authors have considered various factors from recipient, donor, donor-recipient matching, and surgeon perspectives that had potential impact on early NC after liver transplantation. They had better control of confounders from the case-control study design using more flexible statistical tools, including generalized additive models for variables, which had a nonlinear effect on outcome.

Innovations and breakthroughs

In addition to risk factors from the recipient perspective that were complementary to those in the literature, novel risk factors discovered in this study were donor age (< 22 or ⩾ 40 years), male-to-male gender matching, graft-recipient weight ratio 0.9%-1.9%, and sequence of transplantation between 31 and 174.

Applications

The results provide a basis for risk stratification for surgeons to minimize neurotoxic factors during transplantation. In addition, the transplant team leader should be aware of the higher risk of neurologic complication during the team's earlier experiences to conduct interdisciplinary education and quality improvement program.

Peer-review

The manuscript is clearly written to describe the results with pretty good discussion. The method section is really well written as a clinical report and can be one of the greatest examples for physician-scientists.

Abstract

AIM: To investigate the associations between the polymorphisms of cell cycle pathway genes and the risk of hepatocellular carcinoma (HCC).

METHODS: We enrolled 1127 cases newly diagnosed with HCC from the Tumor Hospital of Guangxi Medical University and 1200 non-tumor patients from the First Affiliated Hospital of Guangxi Medical University. General demographic characteristics, behavioral information, and hematological indices were collected by unified questionnaires. Genomic DNA was isolated

from peripheral venous blood using Phenol-Chloroform. The genotyping was performed using the Sequenom MassARRAY iPLEX genotyping method. The association between genetic polymorphisms and risk of HCC was shown by *P*-value and the odd ratio (OR) with 95% confidence interval (CI) using the unconditional logistic regression after adjusting for age, sex, nationality, smoking, drinking, family history of HCC, and hepatitis B virus (HBV) infection. Moreover, stratified analysis was conducted on the basis of the status of HBV infection, smoking, and alcohol drinking.

RESULTS: The HCC risk was lower in patients with the *MCM4* rs2305952 CC (OR = 0.22, 95%CI: 0.08-0.63, *P* = 0.01) and with the *CHEK1* rs515255 TC, TT, TC/TT (OR = 0.73, 95%CI: 0.56-0.96, *P* = 0.02; OR = 0.67, 95%CI: 0.46-0.97, *P* = 0.04; OR = 0.72, 95%CI: 0.56-0.92, *P* = 0.01, respectively). Conversely, the HCC risk was higher in patients with the *KAT2B* rs17006625 GG (OR = 1.64, 95%CI: 1.01-2.64, *P* = 0.04). In addition, the risk was markedly lower for those who were carriers of *MCM4* rs2305952 CC and were also HBsAg-positive and non-drinking and non-smoking (*P* < 0.05, respectively) and for those who were carriers of *CHEK1* rs515255 TC, TT, TC/TT and were also HBsAg-negative and non-drinking (*P* < 0.05, respectively). Moreover, the risk was higher for those who were carriers of *KAT2B* rs17006625 GG and were also HBsAg-negative (*P* < 0.05).

CONCLUSION: Of 12 cell cycle pathway genes, *MCM4*, *CHEK1* and *KAT2B* polymorphisms may be associated with the risk of HCC.

Key words: Cell cycle pathway genes; Hepatocellular carcinoma; Single nucleotide polymorphism; Case-control study; Genetic susceptibility

Core tip: We analyzed the effects of polymorphisms of 12 cell cycle pathway genes on the risk of hepatocellular carcinoma (HCC) in a large population of 1019 HCC cases and 1138 controls. The results suggest that *MCM4* rs2305952 CC and *CHEK1* rs515255 TC, TT, TC/TT may be significantly associated with a decreased risk of HCC. *KAT2B* rs17006625 GG may increase the risk of HCC.

Relationships between cell cycle pathway gene polymorphisms and risk of hepatocellular carcinoma. *World J Gastroenterol* 2016; 22(24): 5558-5567 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5558.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5558

INTRODUCTION

Hepatocellular carcinoma (HCC) is a serious threat to human health worldwide. It is the fourth most common cancer and the second leading cause of cancer death, with nearly 746000 deaths per year[1]. The incidence of this fatal disease continues to increase. HCC occurrence and development are related to environmental factors, such as infection with hepatitis B virus (HBV) or hepatitis C virus (HCV), cigarette smoking, and alcohol consumption, as well as genetic susceptibility[2-4]. Many studies strongly support that single nucleotide polymorphisms (SNPs) of a variety of genes are associated with HCC[5-7]. However, the genetic mechanism underlying the inherited component of HCC is still not fully understood.

The cell cycle comprises the events that result in the formation of two daughter cells through division of the parent cell. Cell cycle progression, including cell division, is influenced by three different types of molecules: cyclin, cyclin-dependent kinases, and cyclin kinase inhibitors[8]. The associations between the genetic susceptibility of genes which regulate the cell cycle and the risk of cancer are well known. For instance, a polymorphism of the *p27* generates an increased risk of squamous cell carcinoma of the head and neck[9], while polymorphisms of *p27* and *p21* are associated with a significantly increased risk of HCC[10]. Other cell cycle pathway genes implicated in cancer include *cyclinD1*[11], *p53*[12], *CHEK2*[13] and *P21*[14].

During the last several decades, an increasing number of studies have shown an association between genetic variants, mainly in the form of SNPs, and the risk of cancer, including breast[15], colorectal[16], cervical, and vulvar cancers[17], and HCC[18]. Despite investigations into the association of polymorphisms in cell cycle pathway genes with cancer susceptibility[19,20], in the case of HCC this association remains unclear. Therefore, in this hospital-based study we investigated the associations between the polymorphisms of SNPs in cell cycle pathway genes and the risk of HCC.

MATERIALS AND METHODS

Study population

For this case-control study, 2327 subjects were consecutively recruited from June 2007 to December 2013. The 1127 HCC patients were from the Tumor Hospital of Guangxi Medical University and were newly diagnosed with HCC based on biochemical (α-fetoprotein > 20 μg/L) and histopathological examinations. None had undergone radiotherapy or chemotherapy before blood sampling. The 1200 controls from the First Affiliated Hospital of Guangxi Medical University consisted of non-tumor patients admitted within the same period of time. Informed

Table 1 Summarized information of selected single nucleotide polymorphisms in cell cycle pathway genes

Genes	SNPs	Chromosome (position)	Allele	MAF (hapmap-HCB)
MCM4	rs2305952	8 (47962049)	C/T	C = 0.18
YWHAB	rs2425675	20 (44906293)	A/G	A = 0.20
CDKN2A	rs3088440	9 (21968160)	A/G	A = 0.08
TGFB3	rs3917148	14 (75980178)	A/C	C = 0.10
RBL2	rs3929	16 (53490396)	C/G	C = 0.20
RAD21	rs6987652	8 (116870042)	A/G	A = 0.12
SMAD3	rs11556090	15 (67194045)	A/G	G = 0.09
	rs8025774	15 (67190938)	C/T	C = 0.45
KAT2B	rs17006625	3 (20119604)	A/G	G = 0.14
	rs4858770	3 (20152931)	C/T	T = 0.47
MCM7	rs2070215	7 (100099174)	A/G	G = 0.29
	rs2261360	7 (100095370)	A/C	A = 0.37
CDKN1A	rs3176320	6 (36679011)	A/G	G = 0.17
CDC25C	rs3734166	5 (138329634)	A/G	G = 0.38
CHEK1	rs515255	11 (125627250)	C/T	T = 0.44

MAF (minor allele frequency) was derived from HCB population in HapMap website (http://hapmap.ncbi.nlm.nih.gov/). SNPs: Single nucleotide polymorphisms.

consent was obtained from all participants, who also agreed to truthfully complete the questionnaires.

Information and sample collection

General demographic and behavioral information, hematological indices, and data on the patients' age, sex, nationality, drinking habit, smoking habit, HBV infection, and family history of HCC were obtained in face-to-face interviews by trained investigators. Peripheral venous blood was collected in a vacuum EDTA anticoagulant tube from each participant. Genomic DNA was extracted using a standard phenol-chloroform extraction method and stored at -80 ℃.

SNP selection

From the GEO database (https://www.ncbi.nlm.nih.gov/geo/), we found three sets of whole genome expression microarray data which were related to HCC (GSE14520, GSE25097, and GSE12941). A total of 3826 different genes were selected using SPSS 16.0 software (SPSS Inc., Chicago, IL, United States) ($P < 0.05$). Gene ontology classification and pathway enrichment analysis were performed by blast2GO and DAVID (https://david.ncifcrf.gov/) and 40 cell cycle pathway genes involved in the cellular process were chose. The genotype information was downloaded from Hapmap website (http://hapmap.ncbi.nlm.nih.gov/), and functional SNPs were selected using Haploview 4.2 software (Cambridge, MA o2141, United States) based on a function prediction website (http://snpinfo.niehs.nih.gov/snpfunc.htm). Referring to the existing literature on these SNPs with HCC, 15 SNPs in 12 genes (*MCM4* rs2305952, *YWHAB* rs2425675, *CDKN2A* rs3088440, *TGFB3* rs3917148, *RBL2* rs3929, *RAD21* rs6987652, *SMAD3* rs11556090, rs8025774, *KAT2B* rs17006625, rs4858770, *MCM7* rs2070215, rs2261360, *CDKN1A* rs3176320, *CDC25C* rs3734166, and *CHEK1* rs515255) were selected in this study. Information of selected SNPs is shown in Table 1.

SNP genotyping

Before genotyping, each DNA sample was quantified using a UV-Vis spectrophotometer Q5000 (Quawell Technology, Inc., United States) and diluted to a final concentration of 50 ng/μL. SNP genotyping was performed using a MassARRAY system (Sequenom, San Diego, CA, United States) and a matrix-assisted laser desorption ionization-time of flight mass spectrometry method according to the manufacturer's instructions. Primers for PCR and extension were designed using the Assay Designer software package (Sequenom). For quality control, 5% of the samples were randomly chosen and genotyped twice for each locus. Among the 1127 patient samples and 1200 control samples, genotyping was successful for all 15 SNPs in both groups, with a success rate of 92.7%. Thus, all 1019 HCC patients and 1138 controls were included in the final analysis.

Statistical analysis

Statistical analyses were performed using the SPSS 16.0 software (SPSS Inc., Chicago, IL, United States). Continuous variables were evaluated using the two-sample *t*-test. Categorical variables and genotype frequencies between the HCC patients and controls were compared using the Pearson's χ^2 and Fisher's exact test. Hardy-Weinberg equilibrium (HWE) was evaluated by a goodness-of-fit χ^2 test to compare the observed genotype frequencies with the expected ones. The association between SNP genotypes and HCC risk was estimated using unconditional logistic regression analysis and an odds ratio (OR) with 95% confidence interval (CI). All statistical tests were two-sided. A P-value < 0.05 was considered to indicate statistical significance.

RESULTS

Characteristics of the participants

The 2157 unrelated Chinese subjects enrolled in this study included 881 (86.5%) males and 138 (13.5%) females with HCC. The mean age of these patients was 48.54 ± 11.44 years. The control group consisted of 982 (86.3%) males and 156 (13.7%) females, with a mean age of 48.01 ± 11.5 years. The general demographic characteristics and behavior information on the patients and controls are provided in Table 2. There were no significant differences between the HCC patients and the controls in terms of age, sex, and nationality; however, HCC patients had a significantly higher rate of a positive history of HBV infection, a family history of HCC, smoking, and drinking.

Table 2 General demographic characteristics and behavioral information among hepatocellular carcinoma patients and controls

HCC: Hepatocellular carcinoma.

Allele frequencies and genotype distribution

In the control group, the genotype frequencies of the 15 SNPs, all but *CDKN1A* rs3176320, were in line with the HWE ($P > 0.05$), which indicated that these study participants were from a homogeneous group. The allele frequencies and genotype distribution of SNPs among the HCC patients and controls from this study are listed in Table 3.

Association analysis of genetic polymorphisms and HCC

The association between SNPs and the risk of HCC was examined using unconditional logistic regression analysis. According to the crude ORs and their 95%CIs, *SMAD3* rs11556090 AG or AG/GG and *MCM7* rs2070215 GG carried an increased risk of HCC when compared with the wild genotype *SMAD3* rs11556090 AA and *MCM7* rs2070215 AA, respectively. Individuals with *CDC25C* rs3734166 GG or GA/GG and *KAT2B* rs4858770 TT had a lower risk of HCC than those with the wild genotype *CDC25C* rs3734166 AA and *KAT2B* rs4858770 CC, respectively. However, the association disappeared after adjusting for age, sex, nationality, smoking, drinking, family history of HCC, and HBV infection. Using individuals with the wild genotype AA as the reference, individuals carrying the GG variant of *KAT2B* rs17006625 had a higher risk of HCC (adjusted OR = 1.64, 95%CI: 1.01-2.64, $P = 0.04$) after adjusting for confounding factors. In addition, compared with the wild genotypes *MCM4* rs2305952 TT and *CHEK1* rs515255 CC, individuals carrying the CC variant of *MCM4* rs2305952 or the TC, TT, TC/TT variants of *CHEK1* rs515255 had a significantly lower risk of HCC (adjusted OR = 0.22, 95%CI: 0.08-0.63, $P = 0.01$; adjusted OR = 0.73, 95%CI: 0.56-0.96, $P = 0.02$; adjusted OR = 0.67, 95%CI: 0.46-0.97, $P = 0.04$; adjusted OR = 0.72, 95%CI: 0.56-0.92, $P = 0.01$, respectively). The associations are shown in Table 4.

[1]OR and 95%CI after adjusting for age, sex, nationality, smoking, family history of hepatocellular carcinoma, and hepatitis B virus infection. [a]$P < 0.05$ was considered statistically significant. OR: Odds ratio; CI: Confidence interval; SNPs: Single nucleotide polymorphisms.

= 0.004; adjusted OR = 0.17, 95%CI: 0.05-0.56, *P* = 0.004, respectively). The variant genotypes TC, TT, and TC/TT of *CHEK1* rs515255 were associated with a significantly lower risk of HCC in HBsAg-negative individuals (adjusted OR = 0.64, 95%CI: 0.46-0.89, *P* = 0.01; adjusted OR = 0.69, 95%CI: 0.36-0.96, *P* = 0.03; adjusted OR = 0.63, 95%CI: 0.46-0.86, *P* = 0.003) and in non-drinkers (adjusted OR = 0.73, 95%CI: 0.54-0.99, *P* = 0.05; adjusted OR = 0.56, 95%CI: 0.36-0.86, *P* = 0.01; adjusted OR = 0.69, 95%CI: 0.52-0.92, *P* = 0.01, respectively). Among smokers, those with the TC variant genotype of *CHEK1* rs515255 had a significantly lower risk of HCC (adjusted OR = 0.54, 95%CI: 0.32-0.93, *P* = 0.03), while among non-smokers the risk was significantly lower in those with the TT variant genotype (adjusted OR = 0.60, 95%CI: 0.39-0.94, *P* = 0.03). In addition, the variant genotype GG of *KAT2B* rs17006625 was shown to carry a significantly higher risk of HCC among HBsAg-negative individuals (adjusted OR = 1.79, 95%CI: 1.02-3.12, *P* = 0.04). These findings are summarized in Tables 5-7 (only significant SNPs are shown).

DISCUSSION

We performed this case-control study to investigate the associations between the 15 SNPs in 12 cell cycle pathway genes and the risk of HCC. The *KAT2B* rs17006625 GG was associated with an increased risk of HCC. Furthermore, this harmful effect was more marked in HBsAg-negative carriers. Conversely, the *CHEK1* rs515255 TC, TT, TC/TT and the *MCM4* rs2305952 CC were associated with a decreased risk of HCC. In addition, the risk was markedly lower for those who were carriers of *MCM4* rs2305952 CC and were also HBsAg-positive and non-drinking and non-smoking and for those who were carriers of the TC,

TT, TC/TT genotype of *CHEK1* rs515255 and were also HBsAg-negative and non-drinking. No significant associations were observed between other 12 SNPs and HCC risk.

The cell cycle pathway is one of the most important cellular signaling pathways, as it regulates both cell division and apoptosis. DNA damage readily leads to dysregulation of the cell cycle, which is an essential step in the initiation and development of human malignancies[21-23]. In the present study, we reported that three SNPs in cell cycle pathway genes (*MCM4*, *CHEK1*, and *KAT2B*) were significantly associated with the risk of HCC.

MCM4, a member of the mini-chromosome maintenance family of proteins, which interact with cell cycle checkpoints and recombinant proteins to stabilize the S phase, is essential for the initiation of eukaryotic genome replication[24,25]. Several reports have shown that MCM4 protein is overexpressed in esophageal carcinomas[26], cervical cancer[27], and cervical squamous cell carcinoma[28]. In our study, we found that the polymorphism of *MCM4* rs2305952 was associated with a lower risk of HCC. However, the mechanism of *MCM4* polymorphisms in HCC development remains unclear. Ishimi *et al*[29] found that MCM4 is one of the crucial targets of DNA replication checkpoint and the phosphorylation of MCM4, which is caused by the activation of ATR-CHK1 pathway and CDK2, results in the DNA replication through the inactivation of the MCM4/6/7 complex. It is also found that *MCM4* mutations may cause tumors by affecting the formation of the MCM4/6/7 complex[30,31].

CHEK1 is a mediator of cell cycle arrest in response to DNA damage. In addition to controlling cell cycle progression[32], it regulates DNA repair[33] and coordinates cell survival and death[34,35]. It is reported that CHEK1 plays an important role in the checkpoint of DNA damage and DNA replication through the ATR-CHK1 pathway[36-38]. Lin *et al*[39] performed a meta-analysis to explore the association of *CHEK1* SNPs with breast cancer in patients registered in the database of the Utah Breast Cancer Study. They found that *CHEK1* polymorphisms are significantly associated with the risk of breast cancer. However, in that study common alleles of *CHEK1* are not implicated in breast cancer risk or in the survival of breast cancer patients after meta-analysis. Our results showed an association between the *CHEK1* rs515255 genetic variant and a decreased risk of HCC, after adjusting for age, sex, nationality, smoking, drinking, family history of HCC, and HBV infection. The conflicting results may reflect the different cancers evaluated and/or differences in the study population. This remains to be clarified in further investigations.

KAT2B, also known as *PCAF*, encodes the cofactor PCAF (P300/CBP associated factor) of activated nucleoprotein that is important in cell cycle regulation. KAT2B induces cell cycle arrest and/or apoptosis by regulating p53 and affects the acetylation and stability of E2F1 in the presence of DNA damage[40,41]. Overexpression of PCAF was reported in samples of both central nervous system tumors and Wilm's tumors[42]. In addition, an association between *KAT2B* gene polymorphisms and several human diseases and behaviors has been reported. For example, the *KAT2B* SNP rs9829896 is associated with drug abuse in African Americans[43]. We also found that the risk of HCC was higher in individuals with the *KAT2B* rs17006625 GG genotype than with the AA genotype, after adjusting for age, sex, nationality, smoking, drinking, family history of HCC, and HBV infection.

HBV infection status, drinking status, and smoking status are well known to influence the occurrence and development of HCC[44-47]. Moreover, some genotypes have no effect on HCC risk when considered within a population as a whole, but the subgroup analysis may show an effect on HCC risk among alcohol drinkers and/or smokers[48,49]. Therefore, in our study, we evaluated the role of risk factors such as drinking status and smoking status in a stratified analysis and

found that these environmental factors may interact with the analyzed SNPs.

Our study had several limitations. First, the research population was drawn only from the Guangxi Zhuang Autonomous Region. Whether the results apply to the Chinese population as a whole or to other ethnic groups remains to be seen. Second, because our study used a case-control format, recall bias was difficult to avoid. However, we sought to minimize recall bias by choosing patients newly diagnosed with HCC. Finally, the functional influence of the examined SNPs and the potential mechanisms need to be determined in functional validation tests.

In conclusion, *MCM4* rs2305952 CC and *CHEK1* rs515255 TC, TT, TC/TT may decrease the risk of HCC and *KAT2B* rs17006625 GG may increase the risk of HCC. In addition, we observed an increased risk associated with *KAT2B* rs17006625 GG in HBsAg-negative patients. Furthermore, we also observed a decreased risk associated with *MCM4* rs2305952 CC in HBsAg-positive patients and in also non-drinking patients and non-smoking patients, and with *CHEK1* rs515255 TC, TT, TC/TT in HBsAg-negative patients and in also non-drinking patients. Our results suggest that the genetic variants in the cell cycle pathway genes affect the risk of HCC, however, further studies are needed to confirm the findings.

ACKNOWLEDGMENTS

We sincerely thank the staff of the First Affiliated Hospital of Guangxi Medical University and the Tumor Hospital of Guangxi Medical University for their support in recruiting the study participants. We also thank Da-Fang Chen and his students at the Peking University Health Science Center for technical help.

COMMENTS

Background

The uncontrollable proliferation of cancer cells is a crucial mechanism in cancer development and progression. Previous studies have shown that polymorphisms of cell cycle pathway genes are associated with cancer. However, their relationship with hepatocellular carcinoma (HCC) is unclear.

Research frontiers

Despite reports of an association between polymorphisms in cell cycle pathway genes and cancer risk, little is known about the relationship between these polymorphisms and HCC risk.

Innovations and breakthroughs

This study enrolled 1127 cases newly diagnosed with HCC and 1200 non-tumor patients. It comprehensively investigated the relationship between 15 SNPs in 12 cell cycle pathway genes and HCC risk.

Applications

Since individuals with the *KAT2B* rs17006625 GG genotype may have an increased risk of HCC, they should be carefully monitored to reduce the occurrence and development of HCC.

Terminology

A single nucleotide polymorphism (SNP) is a variation in the genomic DNA sequence. SNPs in some genes may cause an increased or decreased risk of HCC.

Peer-review

The manuscript is interesting and provides relevant information. The study is a descriptive paper analyzing the polymorphism in HCC in a wide number of patients. The analyses are consistent with the results and the conclusions asserted in the manuscript.

Abstract

AIM: To investigate the epidemiology, risk factors and clinical course of acute hepatitis E virus (HEV) infection in Israel, an industrialized country.

METHODS: A retrospective analysis of acute HEV cases diagnosed in Israel from 1993 to 2013. Acute HEV was defined by ALT/AST elevation and a positive HEV PCR test or positive anti-HEV-IgM serology. HEV RNA was tested by quantitative reverse transcription PCR. Antibodies to HEV were tested retrospectively using an ELISA assay. HEV-RNA was sequenced using RT-PCR of ORF1 and ORF2 regions to diagnose genotype of the virus. Epidemiologic and clinical data were collected by reviewing the clinical files and through a telephone interview according to a structured questionnaire.

RESULTS: Acute HEV was diagnosed in 68 patients. Among the 59 patients who gave an informed consent and were interviewed, 41% of infections were autochthonous (acquired in Israel), 44% travel-related and 15% imported by foreign workers. Autochthonous patients were mainly females (62.5%), more than half of them pregnant, 26% recalled consuming food or water in areas with poor sanitation, 44% ate non-kosher meat. Fulminant hepatitis developed in 3 patients (5%), all of them were females, two of them with post-partum infection, all acquired the disease in Israel (autochthonous). Israeli travelers with imported infection were predominantly males (73%), acquired the disease in the Indian subcontinent (81%), with 100% reporting having consumed fresh vegetables and drinks with ice cubes abroad. Six patients' sera were tested for genotype and revealed HEV genotype 1 (all cases acquired in the Indian subcontinent).

CONCLUSION: This is the first report which highlights the existence of hepatitis E as an autochthonous infection in Israel. Imported HEV originates mostly from the Indian subcontinent.

Key words: Hepatitis E; Autochthonous; Travel; Foreign workers; Pregnancy; Post-partum; India; Nepal; Indian subcontinent; Israel

Core tip: This is the first epidemiologic report on hepatitis E virus (HEV) in Israel. This report demonstrates the significant presence of autochthonous acute HEV in Israel, serving as an example of occurrence in an industrialized country. Suspected risk factors in Israel include consumption of water and food in areas with poor sanitation, exposure to animals and eating a non-Kosher meat. The high risk group for fulminant hepatitis was pregnant women in their final trimester. Additionally, imported HEV, originating mainly from the Indian subcontinent, is also seen in Israel. Awareness of this disease is important both among physicians in Israel as well as those in other industrialized countries.

Erez-Granat O, Lachish T, Daudi N, Shouval D, Schwartz E. Hepatitis E in Israel: A nation-wide retrospective study. *World J Gastroenterol* 2016; 22(24): 5568-5577 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5568.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5568

INTRODUCTION

Hepatitis E virus (HEV) infection is currently one of the leading causes of viral hepatitis worldwide[1]. The first epidemic of HEV infection was recognized in India, by a retrospective epidemiologic and serologic survey performed in India and the United States in the early 1980s. This led to the recognition of HEV as a water-borne associated hepatitis. Similar epidemics were subsequently identified in Central and Southeast Asia, the Middle East and North Africa[2-4]. The viral genome was later cloned and sequenced using samples of bile obtained from experimentally infected macaques, and the virus was named Hepatitis E[5-8].

HEV is a single strand RNA virus classified in the genus Hepevirus, family Hepeviridae[9]. Identification of four HEV genotypes has subsequently been used to study the molecular epidemiology of HEV infection worldwide. Genotypes 1 and 2, restricted to humans, are mostly seen in developing countries causing large waterborne outbreaks of hepatitis. Genotype 1 is mostly associated with outbreaks in Asia and Africa, whereas genotype 2 has been detected in Mexico and some African countries[10]. In recent years there has been increasing evidence of an autochthonous HEV infection in industrialized countries, contrasting with previous reports of HEV as only an imported infection from endemic, developing countries. In these cases, genotypes 3 and 4 have been identified, and found to be responsible for sporadic cases of autochthonous hepatitis E in industrialized countries[11-15]. In contrast to genotypes 1 and 2, genotypes 3 and 4 infect not only humans but also other mammalian species such as pigs, boars, and deer[11].

HEV is transmitted predominantly *via* the fecal-oral route, causing a self-limiting disease which resolves spontaneously within 4-6 wk[6]. Occasionally, in immune-suppressed patients and in pregnant women, a fulminant form of hepatitis develops[16]. Chronic infection has been identified almost exclusively among immunocompromised persons, including organ-transplant recipients, patients receiving cancer chemotherapy, and HIV-infected persons[17].

Israel is an industrialized country located amid HEV endemic countries and home to immigrants and refugees from African countries (such as Egypt, Sudan and Ethiopia, all endemic for genotype 1 of the virus). Furthermore, since a portion of Israel's population eats only kosher food (*i.e.,* avoiding pork, game meat or seafood), the index of suspicion for autochthonous cases has been low. Data obtained through old and non-validated immune-assays regarding sero-epidemiology of hepatitis E in Israel revealed a seroprevalence of 2.81% and 1.81% in the Jewish and Arab population, respectively[18]. However, data regarding acute HEV revealed only one case report of acute HEV infection acquired in Israel[19] while the remaining published cases were travel-related[20,21].

The aim of this study was to identify whether there is a change in the epidemiology of acute HEV in Israel, with cases acquired in Israel (autochthonous cases) and to characterize the epidemiology, risk factors and clinical presentation of all documented acute HEV infections in patients diagnosed in Israel.

MATERIALS AND METHODS

Study design

A descriptive, retrospective, nation-wide study.

Patient population

The study included all patients diagnosed with acute HEV infection in Israel from October 1993 to 2013 at the laboratory of the Liver Unit at the Hadassah Medical Center in Jerusalem. During the study period, this laboratory was the only reference laboratory in Israel for HEV detection. Epidemiologic and clinical data were collected by reviewing the clinical files and through telephone interviews in accordance with a structured questionnaire. The study was approved by the Sheba-Medical Centers' institutional review board.

Case definitions

"*Definite acute HEV*" was defined as acute hepatitis manifested by ALT/AST elevation and a positive HEV PCR (polymerase chain reaction) test or positive anti-HEV-IgM serology. "*Probable acute HEV*" was defined as acute non-A, non-B, non-C hepatitis with negative HEV PCR and negative anti-HEV-IgM serology but positive for anti-HEV-IgG serology, where serum samples were taken later in the course of the disease, and with a clinical course that fit HEV infection, and no other proven etiology. "*Fulminant hepatitis*" was defined as a rapid development of acute liver injury with evidence of coagulation abnormality, an international normalized ratio (INR) > 1.5, and any degree of hepatic encephalopathy in a patient without pre-existing liver disease; and after exclusion of the conventional etiologies for acute liver failure[22].

Laboratory tests

Serologic detection of anti-HEV antibodies: Antibodies to HEV (IgG and IgM) were tested using an ELISA micro-titer plates assay [DS-EIA-anti-HEV-G, DS-EIA-anti-HEV-M, DSI S.R.L. Serronno (VA), Milan, Italy] according to the manufacturer's instructions. Micro-titer plates were coated with HEV peptides able to detect all four genotypes of HEV. Ten μL serum samples were diluted 1:10 with 90 μL diluent and incubated for 30 min at 37 ℃ and rinsed three times, followed by a second incubation with 100 μL conjugated antibodies for another 30 min at 37 ℃. After rinsing three times, 100 μL substrate was incubated for 30 min at room temperature. Finally, 100 μL stop solution was added followed by reading the plates at a 450 nm wave length. Sample reading > 0.2 OD were considered as positive.

A pangenotypic evaluation by CDC of 6 serologic assays for IgM against HEV identified the assay manufactured by diagnostic systems, which was used in this study, as having the best performance characteristics. Its diagnostic sensitivity and specificity were 98% and 95.2%, respectively[23].

We used an assay for the detection of IgG against HEV from the same manufacturer, with a sensitivity of 100% and specificity of 97.5%[24].

Detection of HEV-RNA by Taqman real time PCR: Detection of HEV RNA was performed by quantitative reverse transcription PCR (qRT-PCR)[25]. RNA was extracted from 200 μL serum with TRI reagent (Bio Lab), then diluted in 10 μL DEPC water. A 10 μL RNA aliquot was used for one step RT-PCR assay in a final volume of 20 μL. The region used for the real time assay is a highly conserved region, junction of ORF's 2/3 of HEV: HEV Forward primer GGTGGTTTCTGGGGTGAC, HEV Reverse primer AGGGGTTGGTTGGATGAA, HEV Probe FAM-TGATTCTCAGCCCTTCGC-BHQ.

HEV sequence: To define HEV genotype in the sera samples, we ran reverse transcription polymerase chain reaction (RT-PCR) of two regions of the virus: ORF1 and ORF2. PCR products were sent for cleaning and sequencing in a service laboratory (HY-lab). We used the programs CHROMAS and CLUSTAL in order to analyze the sequences.

Statistical analysis

Quantitative variables are presented as mean ± SD or as medians and range. Qualitative variables are presented as frequencies and ratios (percent). The χ^2 and the Fisher's exact tests were applied to assess associations between two qualitative variables. The comparison of quantitative variables between two independent groups was carried out using the two-sample *t*-test or the non-parametric Mann-Whitney test. All tests applied were two-tailed, and a *P*-value of 5% or less was considered statistically significant.

RESULTS

During the years 1993 to 2013, 651 patients with presumed acute non-A, non-B, non-C hepatitis were tested for HEV in Israel. Acute HEV was diagnosed in 68/651 patients (10.45%). Among them, 61 patients (90%) were classified as having "definite acute HEV" confirmed by a positive HEV-RNA PCR result (n = 50) or positive anti-HEV-IgM serology (n = 10). One patient had a positive PCR result from a stool sample taken abroad. Probable acute HEV was diagnosed in 7 patients.

Altogether the cohort of acute HEV infection included 68 patients, 58.8% male, with a mean age of 39.4 years. The greatest number of patients were between the ages of 17-40 years (63.5%). Comparing acute HEV positive patients with non-A-non-B-non-C-non-E acute hepatitis patients revealed no significant differences in gender or age distribution (Table 1).

Among this cohort of 68 patients with a history of acute HEV, 59 patients gave an informed consent and

were further evaluated. Thirty five patients (35/59, 59%) had "imported" HEV; among them 26 cases (26/59, 44%) were travel-related HEV infections in Israeli patients and 9 cases (9/59, 15%) were diagnosed in foreign workers from HEV endemic countries (Figure 1). The majority (80%) of travel-related HEV cases were acquired in the Indian subcontinent. Finally, 41% of the patients (24/59) did not travel abroad and had no contact with people from endemic areas, and are therefore defined as "autochthonous HEV".

There was a trend of an increasing number of cases diagnosed with acute hepatitis E throughout the study years in both the travel-related and autochthonous groups (Figure 2).

Autochthonous HE

This group consisted of 24 patients, predominantly female (15/24, 62.5%), with a mean age of 42 years old (SD-15, range: 15-69 years old) and without any contact with a foreign worker in Israel. There were, however, 26% (5/19) who recalled consuming food or water from rural settlements and areas of low sanitation (the West Bank, Bedouin villages) during the 6 wk before the onset of symptoms. Other probable risk factors for HEV infection are summarized in Table 2; 44%, (8/18) ate non-kosher meat (14% ate raw meat, 10% consumed sea food); 40% (8/20) reported contact with animals (cats, dogs, chicken, parrots, geese, fish, guinea pigs, horses or a monkey). Five out of the 24 with autochthonous infections (21%) had chronic liver disease before acquiring HEV (chronic HCV, HBsAg carrier, cystic fibrosis of liver or autoimmune hepatitis). Four of them were diagnosed by positive molecular test (PCR), and one by positive anti-IgM serology for HEV. Eight percent (2/24) received immune suppressing medications (Corticosteroids, Azathioprine, Mycophenolate Moftil and Tacrolimus). Among the female patients, 53% (8/15) were pregnant or post-partum at the time of clinical presentation.

Fifteen of the patients with autochthonous HEV infection (15/24, 62.5%) were diagnosed by detection of HEV-RNA in their serum. Unfortunately, we were unable to retrospectively test for the genotype in this group of autochthonous patients due to a breakdown in refrigeration.

Travel related HEV

This group consisted 26 patients, predominantly male (19/26, 73%), with a mean age of 37.38 years, SD-16.7. Among the females, 1 out of 7 was pregnant (14.3%). Sixty four percent (16/25) developed symptoms after returning to Israel, with a mean time elapsing before symptoms of 16 d (range: 2-28 d). Duration of travel was on average 62.5 d (range: 3-240 d). Thirty six percent (9/25) were symptomatic before flying back to Israel, and among those patients, the average duration of travel was 6.5 mo (range: 1-24 mo).

Behavior during travel, possibly contributing to risk of infection is summarized in Table 3. As described, the vast majority had contact with suspected contaminated water and raw vegetables. The entire group consisted

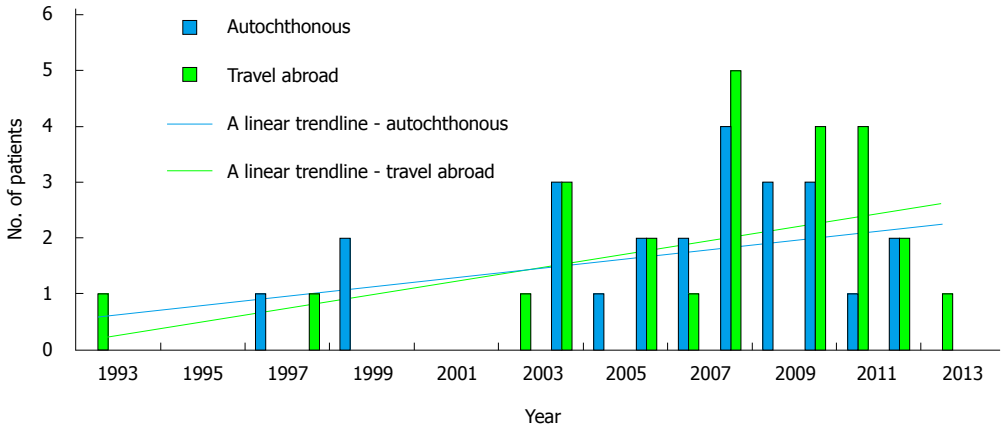

Figure 2 Number of cases of acute hepatitis E virus infection in travel related and autochthonous cases.

Table 2 Clinical characteristics and potential risk factors for hepatitis E virus in patients with autochthonous and travel-related hepatitis E virus infection[1]

Character		Autochthonous infection (n = 24)	Travel related (n = 26)	P value[2]
Demography	Gender: M	9 (37.5)	19 (73.1)	0.011

[1]Excluding foreign workers with acute HEV; [2]Mann-Whitney *U* Test, the χ^2 and the Fisher's exact tests were applied as detailed in the text (Methods); [3]Contact with animals *i.e.,*: cats, dogs, chicken, parrots, goose, fish, guinea pigs, horses, and monkeys; [4]Immune-suppressed patients: (1) Forty five years old woman treated with immune-suppressed therapy (Imuran) for autoimmune hepatitis; and (2) 19 years old woman treated with immune suppressed therapy after liver and kidney transplantation due to cystic fibrosis.

of healthy travelers, none took immunosuppressive drugs or had a known systemic disease associated with immunosuppression, with the exception of one patient who had chronic hepatitis B, diagnosed in the past. Foreign workers from endemic countries (n = 9) were not included in the travel-related HEV group.

Twenty of the patients with travel-related HEV (20/26, 77%) were diagnosed by detection of HEV-RNA in their serum. Among them, we were able to sequence the HEV genome in six of the patients with available sera. All cases revealed genotype 1.

Comparing patients with travel-related infection and autochthonous infection revealed that the autochthonous patients were predominantly female (62.5% *vs* 27%, $P < 0.05$), had lower levels of alanine aminotransferase on presentation (mean 1169 U/L *vs* 2446 U/L, $P < 0.05$) and the time from onset of symptoms to diagnosis was more than twice as long (59 d *vs* 25 d; $P < 0.01$) (Table 2). Although there was no significant statistical difference in outcome between the two

Table 3 Potential risk factors for travel-related hepatitis E virus infection

Risk factor	No. of patients (total: n = 26)	Incidence
Gender - M	19/26	73.07%
Pregnancy	1/7	14.28%
Chronic liver disease[1]	1/23	4.30%
Immunosuppression	0/23	0.00%
Eating non-kosher meat	18/22	81.81%
Eating raw meat	3/23	13.04%
Eating sea-food	6/21	28.57%
Drinking tap water abroad	8/23	34.78%
Consuming drinks with ice cubes	23/23	100.00%
Brushing teeth with tap water	20/23	86.95%

Bath in fresh water	15/23	65.21%
Contact with animals[2]	8/23	34.78%
Contact with travelers having similar symptoms	2/25	8.00%

[1]Chronic hepatitis B virus; [2]Contact with animals *i.e.*,: cat, dog, chicken, parrot, goose, fish, guinea pig, horse and monkey.

groups (due to small sample size), the results may indicate that patients with autochthonous HEV are more prone to fulminant hepatitis than patients with travel-related HEV infection (13% *vs* 0% respectively). There were no significant differences in age, hospitalization rate and symptom duration between the groups.

Pregnant women

In this study, there were nine cases of HEV in pregnant women (9/28 women in the study, 32%). Only one of the women was a returning traveler from India, while the rest were diagnosed with autochthonous infection (8/9, 88.9%). Fulminant hepatitis occurred in two of the pregnant women (2/9, 22%), without fatality or vertical transmission. A detailed description of this cohort, together with other cases of acute HEV in pregnant women from Western countries, was published recently[26].

In the entire cohort of the Israeli patients, the most common signs and symptoms were fatigue and non-obstructive-jaundice in 84% (26/31) and 78% (40/51) of patients respectively; 61% (11/18) of patients developed abdominal pain and 41% (19/46) had fever (> 37.5 ℃). Other complaints were nausea (40%, 19/48), diarrhea (21%, 10/48) and headache (24%, 11/45). Nine percent (4/43), developed neurologic abnormalities including epilepsy, encephalopathy or loss of consciousness. Admission to hospital in Israel was reported by 78% of patients, for a mean duration of 15.6 d (range: 1-84 d, SD-19.4). One Israeli traveler was admitted to an Indian hospital while abroad where HEV-RNA was identified in a stool sample by PCR.

Results of conventional liver tests and INR at presentation or later were retrieved in only 22 patients (Table 2). The rate of bilirubin level varied between 0.39 to 27.9 mg/dL. No clinically significant bleeding disorders were reported although coagulopathy was recorded in 41% of the patients (7/17), who presented with prolonged INR up to 3.49. Hepatocellular injury manifested in ALT elevation was significantly higher in patients with travel-related hepatitis compared to autochthonous infection (mean 2246.4 U/dL *vs* 1169.3 U/dL respectively, $P < 0.05$).

Ninety four percent (46/49) of the patients with HEV infection had self-limiting disease (Table 2). Among the travelers, none of the patients had a chronic or fulminant course of infection. This included a pregnant woman with HEV infection in her third trimester, who had a self-limiting infection, without any pregnancy or fetal related complications. In contrast, among the patients with autochthonous infection, three patients (3/23, 13%) developed fulminant hepatitis. All three were females in their reproductive years, two of them post-partum and the third had cystic fibrosis.

DISCUSSION

The current study was designed to review retrospectively the epidemiology and clinical outcome of acute HEV cases diagnosed in Israel in the past 20 years. During this period, 68 patients were diagnosed with acute HEV infection, and from those patients, 59 gave their consent for evaluation. In this cohort, 44% were travel related, 15% affected foreign workers and surprisingly 41% were autochthonous infection. This is the first study which recognizes the existence of a relatively large cohort of autochthonous HEV infections in Israel, while previous reports suggest that almost all cases of hepatitis E were travel related as summarized in Table 4.

Recently, reports on autochthonous HE in industrialized countries have become more frequent. The distribution of autochthonous *vs* travel-related cases varies widely between different countries[13,14,27-30], as can be seen in Table 5. In Israel about half of the cases are autochthonous.

As shown in this report (Figure 2), the number of HEV cases increased during the study years in both travelers and the autochthonous groups. This may reflect an increase in infection rates, but may also be the consequence of improved diagnostic tools and growing awareness among physicians in Israel of HEV infection.

Previous studies in industrialized countries linked sporadic cases of HEV to consumption of undercooked pork[1,12,31], raw game meat, shellfish[32] and to blood transfusions[33,34]. In autochthonous HEV in Israel, the most frequent risk factors included eating non-kosher meat and being exposed to animals. Furthermore, about a quarter of the patients reported that during the 6 wk that preceded the symptoms, they consumed food and/or water from the West Bank or other rural areas in Israel known to have relatively lower hygienic standards as compared to the rest of the country.

Table 4 Summary of the published case reports of acute hepatitis E virus in Israeli patients

Ref.	Year of follow-up	No. of patients	Travel related/autochthonous	Diagnosis
Schwartz *et al*[20]	1992-1998	5	Travel related (all cases acquired in the Indian subcontinent)	Serology tests (Abbott Laboratories, Abbott Park, IL, United States)

[1]A Literature review of the prevalence of HEV infection in industrialized countries[13,14,27-30]; [2]the rest 15% were foreign workers. HEV: Hepatitis E virus.

The other major risk group susceptible to HEV was the Israeli travelers (44% of acute HEV in Israel). In a prospective observational study from Israel, 1% of ill-returning Israeli travelers were diagnosed with acute hepatitis (1997-2012), while HEV has become the most common hepatitis, with a prevalence of 39%, of all hepatitis cases. In the aforementioned study, 84% of the travel-related HEV cases were "imported" from the Indian subcontinent[21]. In this study, 80.7% of travel associated cases were acquired in the Indian subcontinent. In travel-related HEV, in contrast to autochthonous HEV, the majority of patients were young adult males (73% male, average age of 37 years). Only a minority of patients had chronic liver disease (3.8%). Regarding risk behaviors during travel in this population, although the majority of patients followed pre-travel instructions and did not drink tap water abroad, all patients ate raw vegetables, used ice cubes, brushed their teeth with tap water and bathed in fresh water (Table 3). A control group of travelers without HEV was not available for this study.

The comparison of characteristics of autochthonous and travel-related acute HEV infection, revealed significant differences between the two groups (Table 2); the majority of infected travelers were male, while in the autochthonous group, the majority were female. Time to diagnose was significantly longer in the autochthonous group (on average, more than twice longer), suggesting a delay in diagnosis. ALT levels were significantly higher in infected travelers than in patients with autochthonous infection.

HEV is generally a self-limiting disease, although on rare occasions it can be fulminant[6,16]. In the present study, most of the patients with acute HEV infection had a self-limited disease. Patients who had fulminant hepatitis reported one of the following risk factors: pregnancy (including post-partum women), immune-suppression or chronic liver disease.

There is scarce evidence about the mortality of pregnant women with acute HEV infection in industrialized countries[35-38]. Our previous report indicated that in an industrialized country such as Israel, pregnant women had a high risk of fulminant hepatitis during their final trimester (2/9, 22.2%), though with no mortality or vertical transmission[26].

Patients with underlying chronic liver disease who develop hepatitis E have a poor prognosis, as they frequently develop acute or sub-acute liver failure[17]. In a study of a large cohort of patients in India with chronic liver disease, patients who developed HEV associated liver failure had a significantly worse prognosis than patients who decompensated due to other causes. In this cited cohort, the 12-mo mortality with HEV infection reached 70%[39]. In industrialized countries, smaller studies have also shown a poor prognosis for HEV infected patients with underlying chronic liver disease[40,41]. In our current study, evaluation of the entire group of 69 patients with acute HEV infection, revealed 7 patients with underlying chronic liver disease (chronic HCV, chronic HBV, cystic fibrotic liver, autoimmune hepatitis, idiopathic cirrhosis). Six of the patients survived and were interviewed and only one patient with chronic HBV infection and cirrhosis died 4 years after the diagnosis of chronic hepatitis B and 3 years after the diagnosis of acute HEV infection.

The differential diagnosis of autochthonous HEV infection includes drug induced liver injury (DILI). Two reports from the United Kingdom and the United States revealed that 21.4% and 3%, respectively, of the patients with an initial diagnosis of DILI, had autochthonous HEV. Such misdiagnosis is particularly common in elderly populations with autochthonous HEV taking various potentially hepato-toxic medications and herbs[42,43]. In the present cohort, two patients treated with Isoniazide and Ketoconazole who presented with acute hepatitis, were initially misdiagnosed as DILI and subsequently were found positive for HEV RNA by PCR.

In the industrialized world, HEV genotypes 3 and 4 are responsible for sporadic cases of autochthonous HEV infection, where the disease is zoonotic. Imported,

travel related, cases are usually genotypes 1 and 2. In this study, genotyping of 6 travel-related cases with available serum revealed genotype 1 in all cases, a genotype which is prevalent in India where all cases were acquired. One case of hepatitis E in a foreign worker from Nepal who spent one month in Israel, revealed genotype 1 as well.

Israel is located amid countries endemic for HEV, with evidence for genotype 1 in most of the cases reported from those countries. For example, isolation of HEV circulating in Egypt, a country with HEV seroprevalence among the highest in the world, revealed HEV genotype 1 in acute HEV cases, both from rural and urban areas[44-46]. Studies of North African countries revealed autochthonous infection with genotype 1 as well[2]. Data on the HEV-genotype circulating in Lebanon, Syria, and Jordan is lacking.

Unfortunately, we were unable to retrospectively test for the genotype in the autochthonous group of patients. The cause included the retrospective design of this study which did not enable storage of large volumes of suspected sera and the physical state of some of the stored sera which were thawed and frozen several times prior to an attempt of sequencing.

However, a recent Israeli study confirmed the presence of HEV in 8.2% of the 169 sewage samples tested throughout the country during 2013-2015[47]. Sequencing revealed genotype 3 in all sewage samples positive for HEV. These data along with the evidence for acute autochthonous HEV in Israel shown in the present study, suggest autochthonous infection with HEV genotype 3, as seen in Europe and in contrast to the circulating HEV genotype in Israel bordering countries.

The present study has several limitations. The information of exposure related to different risk factors, was based on patients' recollections of events that happened years before the survey, and consequently might be biased. And as mentioned, we were unable to retrospectively test for the HEV genotypes in the autochthonous group of patients. Thus phylogenetic analysis of HEV confirmed autochthonous cases in Israel remains an undertaking for the future.

This report, along with previous reports from Western countries mentioned above, provides evidence for the presence of sporadic autochthonous or travel-related acute HEV cases in the industrialized world. At present, treatment of active HEV infection with viremia with an effective anti-viral agent remains an elusive goal[48].

To date, two types of recombinant HEV vaccine have been developed[49-51], but neither of them is commercially available in the Western countries. Additionally both vaccines are genotype 1-based, and although they would be very useful in pregnant women and travelers to endemic regions, their efficacy in preventing HEV infection in non-endemic areas (where other genotypes predominate) needs to be investigated.

COMMENTS

Background

Hepatitis E virus (HEV), one of the leading causes of viral hepatitis worldwide, is transmitted predominantly *via* the fecal-oral route and responsible for epidemics of acute hepatitis in developing countries. However studies have shown that HEV is an emerging infection in industrialized countries as well, with increasing evidence of autochthonous cases (contracted locally) in addition to imported infection among immigrants and travelers from endemic countries. Israel is an industrialized country located amid endemic countries and absorbs immigrants from African countries, however a significant portion of Israel's population eats only kosher food (*i.e.*, do not eat pork, game meat or seafood), therefore the existence of autochthonous cases is not obvious.

Research frontiers

This study is a nation-wide epidemiological study of acute HEV cases diagnosed in Israel between the years 1993-2013. The aim of this manuscript was to identify whether there is any evidence of acute autochthonous HEV in Israel and to characterize the epidemiology, risk factors and clinical presentation of all documented acute HEV infection in Israel.

Innovations and breakthroughs

This report demonstrates, for the first time, the significant presence of autochthonous acute HEV in Israel (41% of all cases were autochthonous). Additionally, the imported HEV cases were from travelers and foreign workers acquiring the disease mainly in the Indian subcontinent.

Applications

The presence of autochthonous cases in Israel highlights the need for medical practitioners to be acquainted with the disease, even in non-endemic countries, and accurate diagnostic means should be easily accessible.

Terminology

"Autochthonous infection" is an infection contracted in the area where reported. Autochthonous HEV infection in Israel relates to patients with acute hepatitis E, with no history of travel during the last six months before disease onset, and who are not immigrants. In contrast, imported infection is one contracted in a country endemic for HEV, and occurs among travelers and immigrants.

Peer-review

The manuscript represents an interesting study of the etiology of acute hepatitis HEV in Israel reporting well documented data of interest to the scientific community.

Abstract

AIM: To perform sequencing analysis in patients with very early-onset inflammatory bowel disease (VEO-IBD) to determine the genetic basis for VEO-IBD in Chinese pediatric patients.

METHODS: A total of 13 Chinese pediatric patients with VEO-IBD were diagnosed from May 2012 and August 2014. The relevant clinical characteristics of these patients were analyzed. Then DNA in the peripheral blood from patients was extracted. Next generation sequencing (NGS) based on an Illumina-Miseq platform was used to analyze the exons in the coding regions of 10 candidate genes: *IL-10*, *IL-10RA*, *IL-10RB*, *NOD2*, *FUT2*, *IL23R*, *GPR35*, *GPR65*, *TNFSF15*, and *ADAM30*. The Sanger sequencing was used to verify the variations detected in NGS.

RESULTS: Out of the 13 pediatric patients, ten were diagnosed with Crohn's disease, and three diagnosed with ulcerative colitis. Mutations in *IL-10RA* and *IL-10RB* were detected in five patients. There were four patients who had single nucleotide polymorphisms associated with IBD. Two patients had *IL-10RA* and

FUT2 polymorphisms, and two patients had *IL-10RB* and *FUT2* polymorphisms. Gene variations were not found in the rest four patients. Children with mutations had lower percentile body weight (1.0% *vs* 27.5%, P = 0.002) and hemoglobin (87.4 g/L *vs* 108.5 g/L, P = 0.040) when compared with children without mutations. Although the age of onset was earlier, height was shorter, and the response to treatment was poorer in the mutation group, there was no significant difference in these factors between groups.

CONCLUSION: *IL-10RA* and *IL-10RB* mutations are common in Chinese children with VEO-IBD. Patients with mutations have an earlier disease onset, lower body weight and hemoglobin, and poorer prognosis.

Key words: Pediatric inflammatory bowel disease; Very early-onset inflammatory bowel disease; Interleukin 10 receptor; *NOD2* gene; *FUT2* gene

Core tip: In this small-sample size study, we performed next generation sequencing for 10 candidate genes in Chinese pediatric patients with very early onset inflammatory bowel disease. We found that *IL-10RA* and *IL-10RB* mutations were common. There were five patients harbouring mutations in these two genes and accounted for 38.5% of all samples. Besides, there were four patients who had single nucleotide polymorphisms associated with inflammatory bowel disease. Pediatric patients with mutations had an earlier disease onset, lower body weight, markedly lower hemoglobin, and poorer prognosis.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic and recurrent gastrointestinal inflammatory disease in children. Based on clinical characteristics, laboratory tests, and endoscopic and pathological presentations, IBD can be subdivided into Crohn's disease (CD), ulcerative colitis (UC), and IBD-unclassified (IBD-U)[1]. Our previous study showed that the annual incidence of IBD in the 0- to 14-year age group of Shanghai residents steadily increased from 2000 to 2010[2]. Although pediatric IBD mainly occurs in adolescence[2], approximately 15% of IBD pediatric patients have very early-onset IBD (VEO-IBD) that begins before 6 years of age, and 1% of children develop this disease before reaching 1 year of age[3,4]. The majority of VEO-IBD cases have clinical characteristics that are distinct from those of classic IBD with adult and adolescent onset. VEO-IBD has more severe clinical symptoms, resistance to a variety of immunosuppressive therapies, and a poor prognosis after conventional treatments. Some scholars even consider VEO-IBD to be a completely different disease from classic IBD[5].

Previous studies suggested that persistent intestinal immune dysfunction in a genetically susceptible individual exposed to adverse environmental factors is an important mechanism for IBD development. Genome-wide association studies (GWAS) have discovered a total of 163 loci associated with the risk for IBD development[6]. However, disease onset at an early stage of life suggests a leading role for rare gene variations in VEO-IBD patients, especially in children with a disease onset before the age of 1 year. These low frequency mutations are difficult to detect using GWAS. Next generation sequencing technology allows for the high-throughput sequencing of exons in a series of genes concurrently; therefore, rare gene variations can be discovered[7]. Since Glocker *et al*[8] first discovered in 2009 that mutations in genes encoding the α subunit (IL-10R1, encoding gene *IL-10RA*) and the β subunit (IL-10R2, encoding gene *IL-10RB*) of the interleukin-10 (IL-10) receptor could induce VEO-IBD development, a few studies have continuously discovered mutations in genes encoding IL-10R1, IL-10R2, and IL-10[5,9-12]. However, current reports are limited, and the majority of studies are small-size case studies. Reports on the Han Chinese population are scarcer[13,14].

This study used the Illumina-Miseq platform to sequence candidate genes in Han Chinese children diagnosed with VEO-IBD. The candidate genes included genes involved in the IL-10 signaling pathway, such as *IL-10*, *IL-10RA*, and *IL-10RB*, and genes highly associated with the development of CD in previous studies, including *NOD2, FUT2, IL-23R, GPR35, GPR65, TNFSF15,* and *ADAM30*. This study furthers our understanding of the genetic factors associated with VEO-IBD development in Han Chinese children.

MATERIALS AND METHODS

Patient consent and ethic committee approval

Verbal and written consent was obtained from the parents of all of children included this study. Ethic committee approval for the study was granted by Institutional Review Boards of Ruijin Hospital affiliated to Shanghai Jiao Tong University School of Medicine.

Study subjects

A total of 13 pediatric patients with repeated diarrhea, mucus and bloody stool, or abdominal pain who were diagnosed by laboratory tests and digestive endoscopy with VEO-IBD in the Pediatric Department of Ruijin

Hospital of Shanghai Jiao Tong University School of Medicine between May 2012 and August 2014 were included in this study. All of the patients were Han Chinese. VEO-IBD was defined as IBD onset before the age of 6 years, and a disease onset before 2 years of age was called infantile-onset IBD[15,16]. The clinical characteristics of these pediatric patients, including gender, age of disease onset, body height, body weight, family history, clinical symptoms, complications, major laboratory examinations, endoscopic presentations, and therapeutic effects, were retrospectively analyzed.

Laboratory and digestive endoscopic examinations

Relevant laboratory examinations, including complete blood count (CBC), C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), tumor necrosis factor α (TNF-α) level, immunoglobulins G, A, M, and E, vitamin D, human Immunodeficiency virus (HIV) and human cytomegalovirus (CMV) antibody detection in serum, T lymphocyte flow cytometry sorting, stool parasite tests, stool culture, and stool *Clostridium difficile* toxin detection, were performed when the patients were admitted to the hospital. Common infectious diseases and primary immunodeficiency diseases were excluded.

All patients received a colonoscopy under general anesthesia. A biopsy of the colonic mucosa under endoscopy was performed for pathological examination.

Illumina-Miseq platform sequencing

Genomic DNA extraction: After obtaining verbal and written informed consent from the patients' parents, genomic DNA in the peripheral blood from 13 pediatric patients was extracted using a FlexiGene DNA Kit (Qiagen Inc., Germany). Another 100 copies of DNA extracted from patients suffering from idiopathic short stature (ISS) in previous research were used to test frequency of mutant sites which were newly detected in our study.

Multiplex PCR primer design: Based on the stability of the Illumina-Miseq experiment and the operability of subsequent steps, the length requirement of target fragments for sequencing was < 400 bp. If the length of an exon was longer than 400 bp, an additional pair of primers was designed with overlapping bases of adjacent fragments. To avoid a high number of non-target fragment products, primers were grouped and suspended in a primer mix before the multiplex PCR was performed. The concentration of each primer in the primer mix was 10 mmol/L. The basic requirement for grouping was the lack of matching sequences between two of the amplified products. Oligo 7 software was used to design primers for exons of the encoding region of the 10 candidate genes: *IL-10, IL-10RA, IL-10RB, NOD2, FUT2, IL23R, GPR35, GPR65, TNFSF15,* and *ADAM30*. A total of 86 pairs of primers were designed. The sequences are shown in supplementary Table 1.

Multiplex PCR amplification of candidate genes: A Qiagen Multiple PCR Kit was used in this study. The PCR amplification reaction system had a total volume of 21 μL, including 4 μL of ddH_2O, 2 μL of Q-solution (5 ×), 4 μL of 10 mmol/L primer mix, 10 μL of buffer mix, and 1 μL of the DNA template (20 ng/μL). The reaction procedure consisted of pre-denaturation at 94 ℃ for 15 min, denaturation at 94 ℃ for 40 s, annealing at 63 ℃ for 1 min, and extension at 72 ℃ for 40 s. After each cycle, the annealing temperature was reduced by 0.5 ℃ for 10 cycles until the annealing temperature reached 58 ℃. Next, the amplification was continued for 30 cycles with a constant annealing temperature of 58 ℃. The final extension at 72 ℃ lasted for 10 min. The PCR products were stained with 100 × GelRed and subjected to 1% agarose electrophoresis (120 V for 60 min).

The purified multiplex PCR products were sent to Shanghai South Gene Technology Co., Ltd. for sequencing analysis with the Illumina-Miseq platform. After sequencing, the nucleotide sequence information was compared with the standard gene sequences available in GenBank. The obtained gene mutation sites were compared with information in the dbSNP, HGMD, and OMIM databases to determine if the mutations had been previously reported.

To confirm the accuracy of the results, the corresponding gene sequences for the mutations discovered using the Illumina-Miseq platform were sequenced again using the Sanger sequencing method.

The newly discovered gene variation sites were analyzed to predict their influence on protein functions using two online databases: SIFT (http:// http://sift.jcvi.org/) and PolyPhen 2 (http://genetics.bwh.harvard.edu/pph2/).

Statistical analysis

According to the sequencing results, the 13 pediatric patients were divided into two groups. The patients who harboured pathogenic mutations were in group 1. Those without pathogenic mutations (including presence of polymorphisms only or wild type) were in group 2. The differences in diagnosis, age of disease onset, growth indicators (percentiles of body weight and height were calculated according to WHO standards), complications (perianal diseases and recurrent infection), and therapeutic effects among all groups were compared. Because the sample size was small, quantitative and ranked ordinal data were subjected to nonparametric statistics. The Mann-Whitney Test was performed, and the difference was statistically analyzed using exact probability. SPSS13.0 for Windows software was used for the statistical analysis. $P < 0.05$ indicated a significant difference.

Table 1 Genotypes of 13 patients diagnosed with very early-onset inflammatory bowel disease

Patient	Gene	Variation	Homo/Heterozygote	Function defect
1	*IL-10RA*	p.R101W	Homozygote	Yes
2	*IL-10RA*	p.R101W	Compound	Yes
		p.V100G (novel mutation)	heterozygote	Pathogenic supporting by Polyphen 2 and SIFT
3	*IL-10RA*	p.R101W	Compound	Yes
		p.Y64C (novel mutation)	heterozygote	Pathogenic supporting by Polyphen 2 and SIFT
4	*IL-10RA*	p.R117H (rs199989396)	Heterozygote	Yes
	NOD2	p.R703C (rs5743277)	Heterozygote	Susceptibility to CD recorded in HGMD
	FUT2	p.I140F (rs1047781)	Heterozygote	Susceptibility to CD in Chinese population reported by Hu *et al*[31]
5	*IL-10RB*	p.K47E (rs2834167)	Homozygote	SNP in a VEO-UC child reported by Galatola *et al*[29]
		p.E141K (rs387907326)	Heterozygote	Pathogenic supporting by Polyphen 2 and SIFT
	IL-10RA	p.P115P (rs22280554)	Homozygote	Susceptibility to VEO-IBD reported by Moran *et al*[30]
		p.I224V (rs22280555)	Homozygote	
	FUT2	p.I140F (rs1047781)	Heterozygote	Susceptibility to CD in Chinese population reported by Hu *et al*[31]
6	*IL-10RA*	p.P115P (rs22280554)	Homozygote	Susceptibility to VEO-IBD reported by Moran *et al*[30]
		p.I224V (rs22280555)	Homozygote	
	FUT2	p.I140F (rs1047781)	Homozygote	Susceptibility to CD in Chinese population reported by Hu *et al*[31]
7	*IL-10RA*	p.P115P (rs22280554)	Homozygote	Susceptibility to VEO-IBD reported by Moran *et al*[30]
		p.I224V (rs22280555)	Homozygote	
	FUT2	p.I140F (rs1047781)	Heterozygote	Susceptibility to CD in Chinese population reported by Hu *et al*[31]

	FUT2	p.I140F (rs1047781)	Heterozygote	Susceptibility to CD in Chinese population reported by Hu *et al*[31]
9	*IL-10RB*	p.K47E (rs2834167)	Heterozygote	SNP in a VEO-UC child reported by Galatola *et al*[29]
	FUT2	p.I140F (rs1047781)	Heterozygote	Susceptibility to CD in Chinese population reported by Hu *et al*[31]

Patients 10, 11, 12 and 13 were wild types in all these genes. CD: Crohn's disease; UC: Ulcerative colitis; VEO-IBD: Very early-onset inflammatory bowel disease; VEO-UC: Very early-onset ulcerative colitis; SNP: Single nucleotide polymorphism; HGMD: The Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/index.php).

RESULTS

Genotyping in VEO-IBD patients

_IL-10RA_, _IL-10RB_, and _IL-10_ mutations: *IL-10RA* mutations were detected in four patients, an *IL-10RB* mutation was detected in one patient, and an *IL-10* mutation was not detected in any of the 13 patients.

The detected *IL-10RA* mutations were all in exon 3: c.A191G (p.Y64C), c.T299G (p.V100G), c.C301T (p.R101W), and c.G350A (rs199989396) (p.R117H). The p.R101W mutation was the most common and was detected in three patients (patients 1-3). The other mutations were detected in only one patient. Patient 1 had a homozygous mutation, patients 2 and 3 had compound mutations, and patient 4 had a heterozygous mutation (Table 1 and Figure 1).

Among detected *IL-10RA* mutations, p.Y64C and p.V100G were new mutations that were predicted to be deleterious by SIFT and Polyphen 2. These novel mutant sites were not found in 100 ISS children. The other two mutations had been confirmed to be deleterious in several studies[5,12,14,17].

An *IL-10RB* heterozygous mutation was detected in one patient (patient 5) (Table 1 and Figure 1). This c.G421A (p.E141K) (rs387907326) mutation was located in exon 4 and was also predicted as a deleterious mutation by SIFT and Polyphen 2. A nonsense mutation in the same site was detected in previous studies[11,18].

Candidate gene polymorphisms

After the sequence analysis of the coding regions of 10 candidate genes, we found that six patients (patient 4, 5, 6, 7, 8 and 9) had many IBD-associated single nucleotide polymorphisms (SNPs) in *IL-10RA*, *IL-10RB*, *NOD2*, and *FUT2*. The SNP loci in *IL-10RA* were rs22280554: c.G525A, p. P175P and rs22280555: c.A670G, p.I224V; the SNP locus in *IL-10RB* was rs2834167: c.A139G, p.K47E; the SNP locus in *NOD2* was rs5743277: c.C2107T, p.R703C; and the SNP locus in *FUT2* was rs1047781: c.A418T, p.I140F (Table 1).

In addition to the detected p.R117H heterozygous mutation in *IL-10RA*, patient 4 also had heterozygous SNPs in *NOD2* and *FUT2*.

Patient 5 had a heterozygous p.E141K mutation (rs387907326) in *IL-10RB* and SNPs in *IL-10RA, IL-10RB,* and *FUT2*. The SNP loci in *IL-10RA* were rs22280554 and rs22280555. The homozygous SNP loci for *IL-10RB* were rs2834167. The SNP in *FUT2* was heterozygous.

Patients 6 and 7 had SNPs in *IL-10RA* and *FUT2*. Patients 8 and 9 had SNPs in *IL-10RB* and *FUT2*.

Four patients did not show any IBD-associated variations in the coding regions of the 10 candidate genes.

There was no IBD-associated variation discovered in the coding regions of six genes: *IL-10, IL-23R*, *GPR35*, *GPR65*, *TNFSF15*, and *ADAM30*.

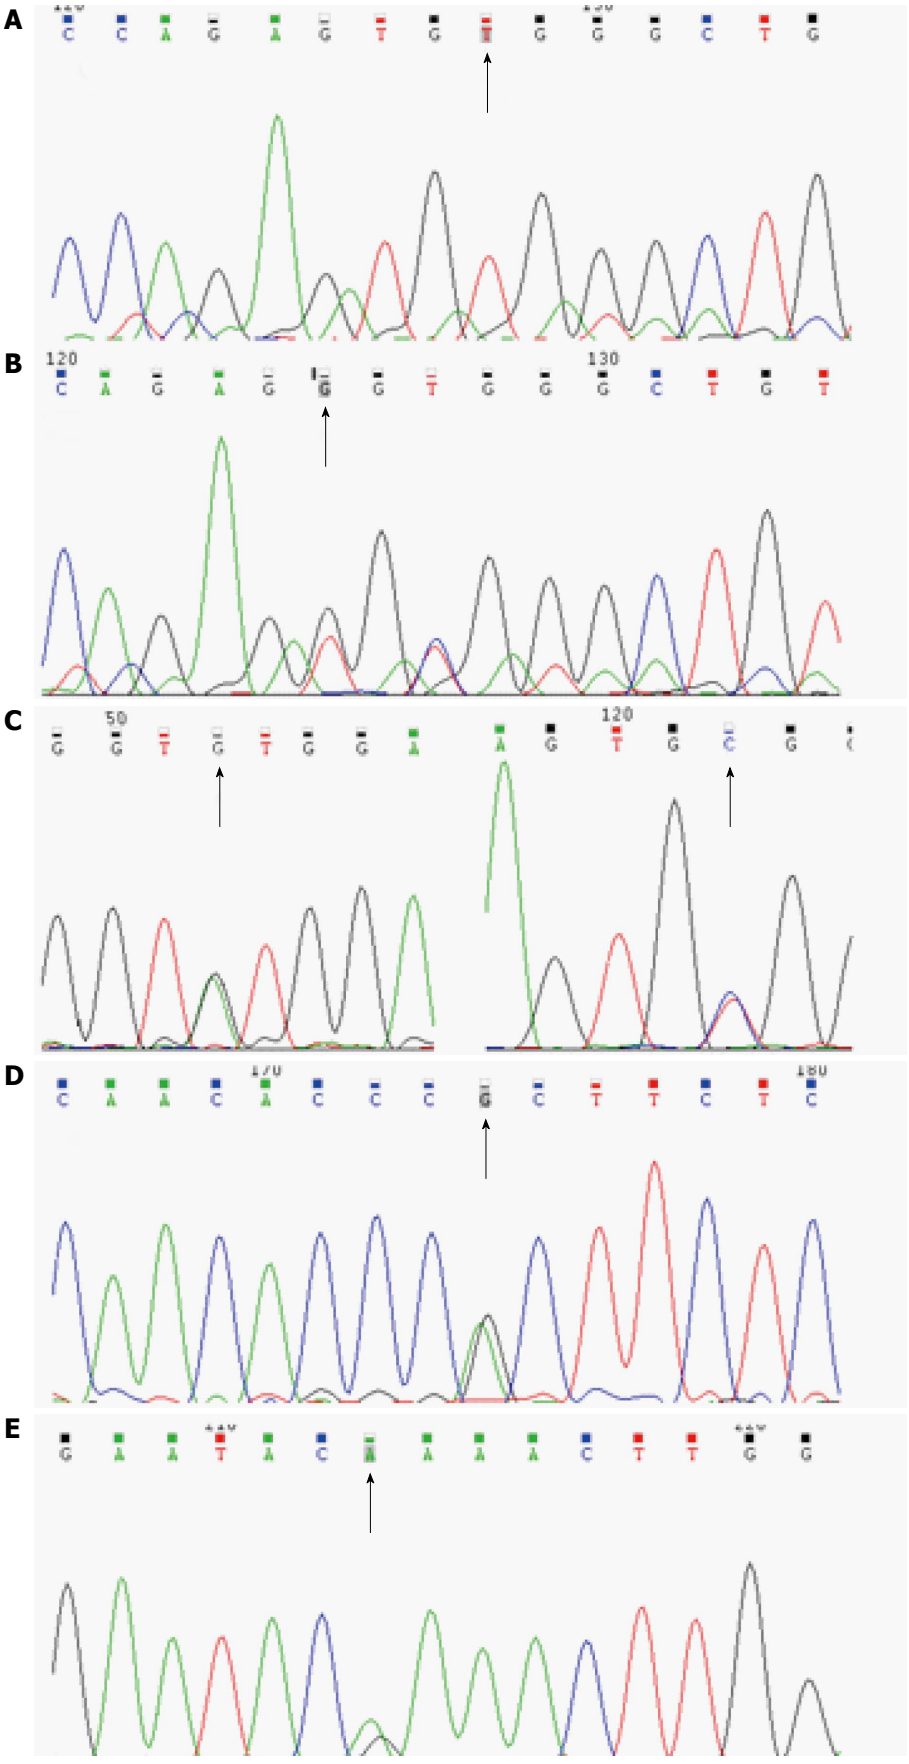

Figure 1 Causative mutations in *IL-10RA* (A-D) or *IL-10RB* (E). A: Patient 1, c.C301T, p.R101W, homozygote; B: Patient 2, c.T299G, p.V100G and c. C301T, p.R101W, compound heterozygote; C: Patient 3, c.A191G, p.Y64C and c. C301T, p.R101W, compound heterozygote; D: Patient 4, c.G35A, p.R117H (rs199989396), heterozygote; E: Patient 5, c.G421A, p.E141K (rs387907326), heterozygote.

Clinical characteristics of VEO-IBD pediatric patients

Out of the 13 VEO-IBD pediatric patients in this study, ten were diagnosed with CD (M:F = 9:1) and three had UC (M:F = 1:2). The mean age of disease onset was 5.8 ± 9.7 mo (range: birth to 3 years of age). None of the parents of the patients had a consanguineous marriage. Patient 8 had a brother that died as a neonate because of repeated diarrhea after birth. There was no clear diagnosis made at that time. The clinical symptoms of the pediatric patients included repeated abdominal pain (13/13), diarrhea (11/13), mucus and bloody stool (11/13), failure to thrive (8/13), recurrent infection (7/13), and perianal fistulas and abscesses (5/13). The colonoscopic presentation of patients with causative mutations showed pancolitis, cobblestone-like changes in mucosa, and deep and large ulcers (Figure 2). All patients received immunosuppressive treatment with glucocorticoids, 6-mercaptopurine and/or infliximab, and thalidomide; however, varying therapeutic effects were observed. Two patient died from severe sepsis or intestinal failure, 2 patients showed no change, 4 patients showed a partial alleviation of symptoms, and 5 patients showed complete clinical remission (Table 2).

Clinical characteristics of different genotypes

Based on the presence of causative mutations in *IL-10RA* and *IL-10RB*, 13 patients were divided into two groups for analysis (group 1: causative mutations in *IL-10RA* or *IL-10RB*; group 2: polymorphisms and no causative mutations). The five patients in group 1 were all diagnosed with CD (100%). Four of these patients had recurrent infections (80%), and three patients had perianal diseases (60%). In group 2 (eight patients), five patients were diagnosed with CD (62.5%), and the other three patients were diagnosed with UC (37.5%). There were only three (37.5%) and two (25%) patients that had recurrent infections and perianal diseases, respectively. Patients in group 1 had lower body weight percentile (1.0% *vs* 27.5%, $P = 0.002$) and hemoglobin concentrations (87.4 g/L *vs* 108.5 g/L, $P = 0.040$) when compared with group 2. Although patients in group 1 had a younger age of disease onset (2.7 mo), lower body height percentile (5.0%), and higher CRP (60.7 mg/L), there were no significant differences when compared with group 2 (Table 3).

DISCUSSION

The currently recognized pathogenetic mechanism of IBD is the involvement of many environmental triggers and genetic susceptibility that causes intestinal immune dysfunction. However, the influence of genes are likely more important than environmental factors for VEO-IBD patients with a disease onset prior to 6 years of age, especially for patients with an infantile onset prior to 1 year of age[19]. GWAS studies suggested that SNPs of *IL-10* and *STAT3* were associated with IBD[20-23]. Previous studies confirmed that IL-10 or IL-10 receptor gene knockout mice had severe chronic inflammation of the intestinal tract[24]. IL-10 forms a complex with two molecules of IL-10R1 and two molecules of IL-10R2 to activate Janus kinase 1 (Jak1) and tyrosine kinase 2 (Tyk2). This activation results in the phosphorylation of signal transducer and activator of transcription 3 (STAT3), which regulates the transcription of specific genes. Studies suggested that IL-10-mediated signals effectively reduced the number of Th17 cells and relieved intestinal inflammation in CD[25]. These data indicated that the anti-inflammatory IL-10 signaling pathway plays a critical role in the regulation of intestinal immune homeostasis.

Since Glocker *et al*[8] first reported in 2009 that gene mutations in *IL-10RA* and *IL-10RB* caused infantile onset IBD[8], studies have continuously reported mutations in *IL-10*, *IL-10RA*, and *IL-10RB* in patients with infantile onset IBD[9-12,18,26]. In these limited data, the majority of patients were Arabian or Caucasian and the offspring of a consanguineous marriage. There are few reports on the Han Chinese population, which included only three pediatric patients to date[13,14].

In this study, we used high-throughput next generation sequencing technology to sequence 10 IBD-associated genes, *IL-10*, *IL-10RA*, *IL-10RB*, *NOD2*, *FUT2*, *IL-23R*, *GPR35*, *GPR65*, *TNFSF15*, and *ADAM30*, in 13 Han Chinese children diagnosed with VEO-IBD. A total of four mutations were discovered in *IL-10RA*, including two novel mutations. There was one mutation in *IL-10RB*. These pathogenic mutations were found in five patients, which accounted for 38.5% of all VEO-IBD cases. Among these patients, one had an *IL-10RA* homozygous mutation, two had *IL-10RA* compound heterozygous mutations, one had an *IL-10RA* heterozygous mutation, and one had an *IL-10RB* heterozygous mutation. All *IL-10RA* mutations were in exon 3, and c.C301T (p.R101W) showed the highest frequency. The c.C301T (p.R101W) and c.G350A (p.R117H) mutations in *IL-10RA* were previously reported in similar pediatric patients. These mutations may disrupt signal transduction after activation of the IL-10 receptor; therefore, STAT3 is not phosphorylated and intractable inflammatory reactions in the intestinal tract of pediatric patients develop[5,12]. The two novel mutations in *IL-10RA* discovered in this study were c.A191G (p.Y64C) and c.T299G (p.V100G). Because of condition limitations, we did not perform functional studies on these mutations. However, the SIFT prediction results for these two mutations were deleterious (scores of 0 and 0.002, respectively), and the Polyphen 2 prediction results were probably damaging (both scores were 1.000). These predictions suggest that these two mutations are pathogenic. According to the recommendation of the American College of Medical Genetics and Genomics and the Association for Molecular Pathology[27], these two

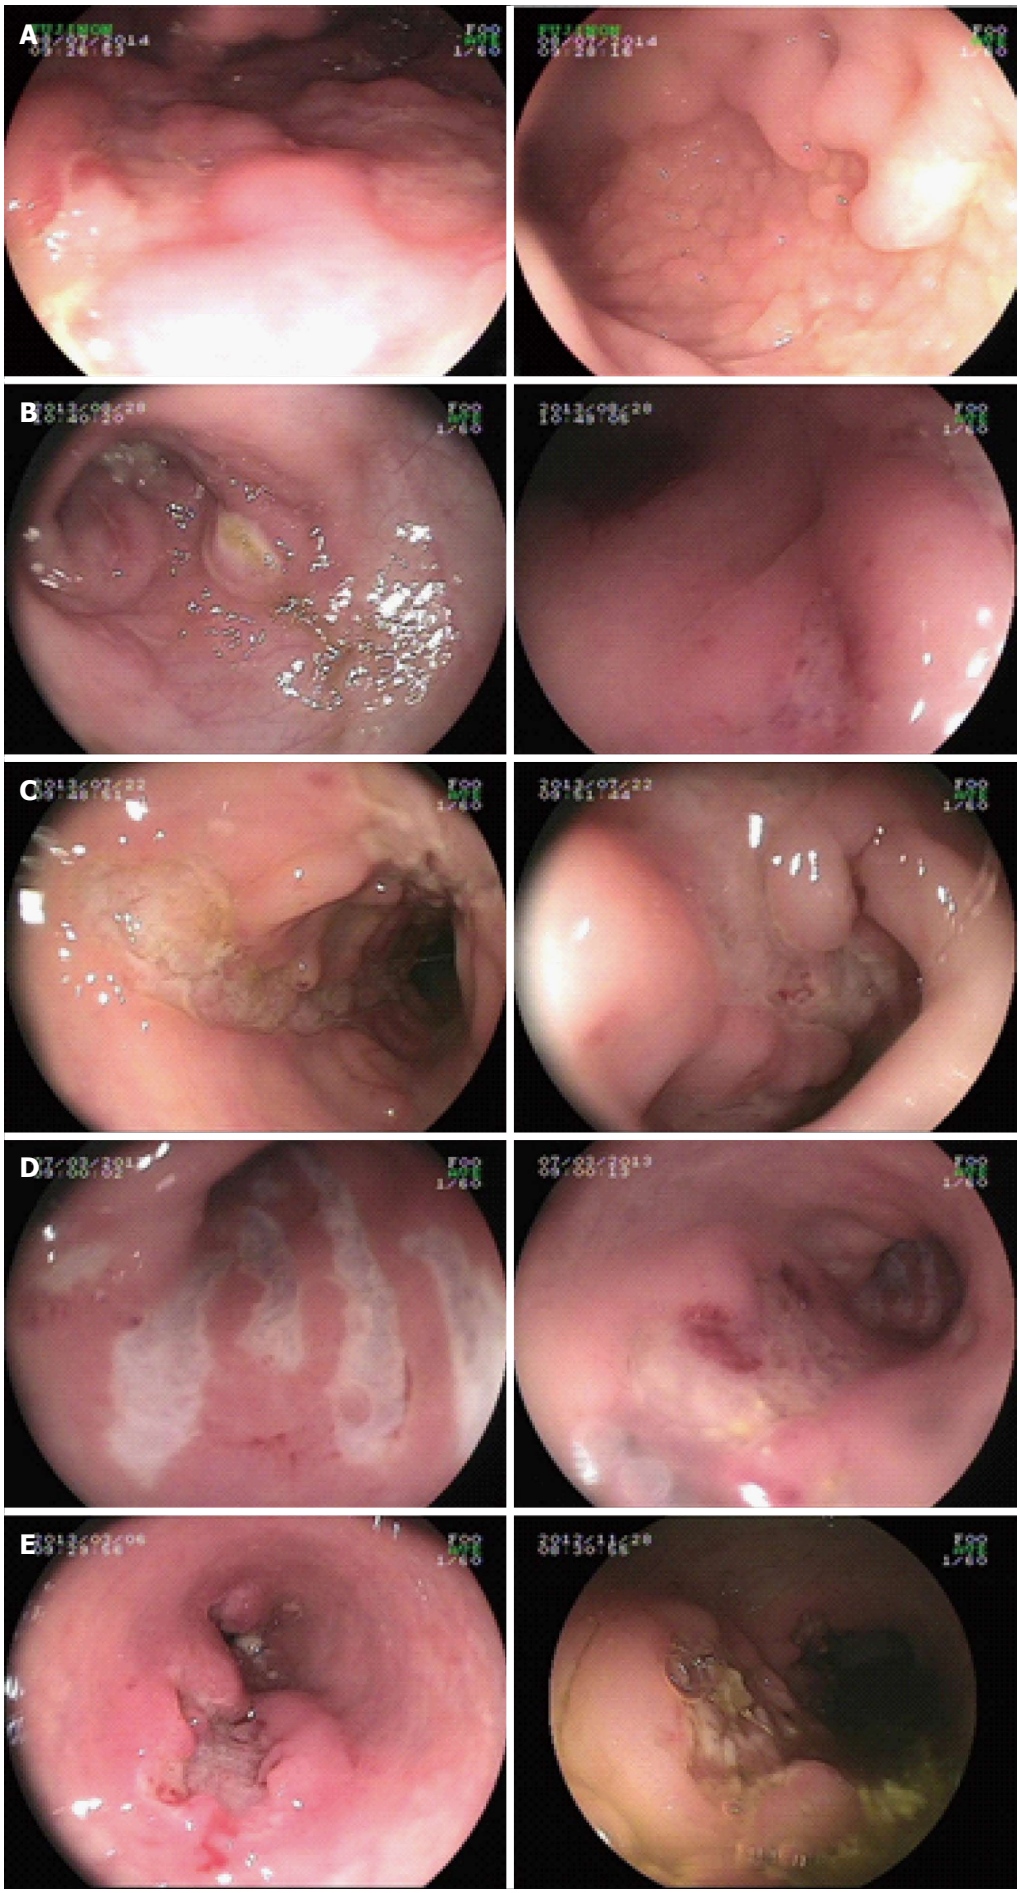

Figure 2 Colonoscopic presentation of patients with causative mutations showed pancolitis, cobblestone-like changes in mucosa, and deep and large ulcers. A to E presents patient 1 to patient 5, respectively.

mutations were defined as pathological supporting. Therefore, we speculate that these two novel mutations individually formed compound heterozygotes with the c.C301T (p.R101W) mutation to cause the disease symptoms observed in patients 2 and 3.

Previous analyses showed that the colitis caused by gene mutations in IL-10 and its receptor exhibited an autosomal recessive inheritance pattern. In the current study, patients 4 and 5 were carriers of heterozygous mutations in *IL-10RA* and *IL-10RB*, respectively. The c.G350A (p.R117H) mutation in *IL-10RA* carried by patient 4 was a pathogenic mutation[5,12,17]. The c.G421A (p.E141K) mutation in *IL-10RB* carried by patient 5 may affect protein function as predicted by SIFT (score = 0.026) and Polyphen 2 (score = 0.946). However, the clinical presentation of these two patients was similar to the symptoms of patients with other IL-10 receptor mutations: disease onset within 1 year of age, the presence of perianal diseases and recurrent infection, and resistance to conventional medication treatment. Based on currently available knowledge, there are at least 50 single-gene genetic conditions that induce IBD-like diseases, and the majority of conditions are related to immunodeficiency[4,6]. Therefore, the two patients that did not conform to a Mendelian genetic pattern might also carry abnormal sites on other genes that cause the disease symptoms. In addition to carrying a pathogenic mutation in *IL-10RA*, patient 4 also had a non-synonymous SNP (nsSNP): rs5743277 in *NOD2*. SIFT prediction results suggest that the nsSNP is deleterious (score = 0), and the Polyphen 2 prediction results suggest the nsSNP is probably damaging (score = 0.999). This polymorphism was already present in the HGMD database and has been considered to cause susceptibility to CD[28]. Patient 5 had a similar condition. In addition to carrying an *IL-10RB* mutation, patient 5 also had multiple polymorphisms: rs22280554 (homozygous) and rs22280555 (homozygous) in *IL-10RA*,

Table 3 Comparison of features between patients with mutations and polymorphisms

	Group 1	Group 2
Size of sample	5	8
Age of onset (mo)	2.7	7.7

[a]$P < 0.05$. All measurement data are expressed as mean. Group 1: Mutations in *IL-10RA* or *IL-10RB*; Group 2: Polymorphisms. Height and weight percentile was calculated according to WHO charts. WBC: White blood cell; ESR: Erythrocyte sedimentation rate; TNFα: Tumor necrosis factor alpha; CD: Crohn's disease.

rs2834167 (homozygous) in *IL-10RB*, and rs1047781 (heterozygous) in *FUT2*. There are previous reports on the pathogenicity of these SNPs. For example, Galatola *et al*[29] reported that the heterozygous rs2834167 in *IL-10RB* and the heterozygous mutation in the promoter region of *IL-10RA* caused the development of UC in an 18-month-old patient. Although rs22280554 did not cause a change in the amino acid sequence of IL-10R1, a study by Moran *et al*[30] showed that rs22280554 and rs2228055 in *IL-10RA* may increase the risk for VEO-IBD, especially VEO-UC. Furthermore, in the Han Chinese population, the rs1047781 polymorphism in *FUT2* may increase the risk for CD development[31]. The above SNPs were also detected in four patients in this study. Therefore, their disease development may be due to "trans-heterzygous": the collective effects of a variety of detected mutations. Another possible cause is that the pathogenic genes were not detected in this study.

When genotypes and phenotypes were combined for analyses, the results showed that the disease phenotype in patients with mutations were more severe. The age of disease onset was earlier, the patients were more likely to have combined recurrent infections and perianal diseases, their body weight and height were low, anemia was more severe, inflammatory indicators were high, and the prognosis was much poorer. These results are in accordance with previous studies[5,8-14,18,32]. However, the sample size of this study was small, and significant differences were only found in body weight and hemoglobin parameters. Because of the influence of cultural ideas, family members find difficulty in accepting an ileostomy as a disease treatment. Past literature reported that pediatric patients with *IL-10RA* and *IL-10RB* mutations could be cured through hematopoietic stem cell transplantation[4,6,8,17]; therefore, some patients are waiting for a donor match.

In this study, we found that mutations in *IL-10RA* and *IL-10RB* were more common in Han Chinese VEO-IBD patients and accounted for 38.5% of all VEO-IBD cases. The high percentage is probably due to the small number of patients in the cohort as most of our patients who were referred by other clinical IBD centers were very ill. There was a selection bias. Because VEO-IBD is relatively rare, multi-center studies on the relationship between genotypes and phenotypes in VEO-IBD patients in China are necessary. The implementation of hematopoietic stem cell transplantation therapy is the focus in research agenda.

COMMENTS

Background

Very early-onset inflammatory bowel disease (VEO-IBD) may have stronger genetic contribution. Recently, a few studies on genetic defects in the IL-10 signaling pathway have provided new insights into IBD, especially in VEO-IBD. Furthermore, a lot of genes associated with IBD were identified, such as *NOD2*, *FUT2*, *IL-23R*, *GPR35*, *GPR65*, *TNFSF15*, and *ADAM30*. Because of different genetic background, this study was set to disclose whether mutations in these genes contributed to VEO-IBD in Chinese children.

Research frontiers

In addition to the polygenic variants associated with IBD, there are rare monogenic disorders, including many immunodeficiencies that can present with IBD-like intestinal inflammation, especially in early life.

Innovations and breakthroughs

To our knowledge, this is the first cohort study to apply NGS in 13 Chinese pediatric patients with VEO-IBD to discover gene variations in these children. The result revealed that IL-10RA and IL-10RB mutations were common in Chinese VEO-IBD, especially in infantile IBD. These monogenic IBD patients had more severe clinical features.

Applications

According to the results of this study and previous studies of VEO-IBD, the authors suggest that screening for gene mutations in IL-10 signaling pathway is necessary.

Peer-review

The clinical study is focused on gene mutation analysis in VEO-IBD by NGS. The authors conclude that mutations in the IL-10 pathway are common in VEO-IBD.

Abstract

AIM: To determine the expression of miR-422a in colorectal cancer (CRC) tissues and to further explore the prognostic value and function of miR-422a in CRC carcinogenesis.

METHODS: miR-422a expression was analyzed in 102 CRC tissues and paired normal mucosa adjacent to carcinoma by quantitative real-time PCR. The relationship of miR-422a expression with clinicopathological parameters was also analyzed. Kaplan-Meier analysis and Cox multivariate analysis were performed to estimate the potential role of miR-422a. Cell proliferation, migration, and invasion were used for *in vitro* functional analysis of miR-422a.

RESULTS: The levels of miR-422a were dramatically reduced in CRC tissues compared with normal mucosa ($P < 0.05$), and significantly correlated with local invasion ($P = 0.004$) and lymph node metastasis ($P < 0.001$). Kaplan-Meier survival and Cox regression multivariate analyses revealed that miR-422a expression (HR = 0.568, $P = 0.015$) and clinical TNM stage (HR = 2.942, $P = 0.003$) were independent prognostic factors

for overall survival in CRC patients. Furthermore, *in vitro* experiments showed that overexpression of miR-422a inhibited the proliferation, migration, and invasion of SW480 and HT-29 cells.

CONCLUSION: Down-regulation of miR-422a may serve as an independent prognosis factor in CRC. MiR-422a functions as a tumor suppressor and regulates progression of CRC.

Key words: Colorectal cancer; MicroRNA; miR-422a; Prognosis; *In vitro* function

Core tip: In the present study, we found that miR-422a was dramatically reduced in colorectal cancer (CRC) tissues, and significantly correlated with local invasion and lymph node metastasis. miR-422a expression and clinical TNM stage were independent prognostic factors for overall survival in CRC patients. Furthermore, *in vitro* experiments showed that overexpression of miR-422a inhibited the proliferation, migration, and invasion of SW480 and HT-29 cells. These results indicated that down-regulation of miR-422a might serve as an independent prognosis factor in CRC, and miR-422a functions as a tumor suppressor and regulates progression of CRC.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignant tumors with increasing incidence and mortality over the past several decades[1]. Despite the significant progress made in diagnostic methods and improved treatment strategies, the prognosis of CRC patients remains poor, especially in those with advanced CRC[2,3]. CRC carcinogenesis is associated with multiple alterations in oncogenes and tumor suppressor genes. A growing number of studies have revealed that microRNAs (miRNAs) might regulate up to 30% of human genes and play a pivotal role in various cellular processes including proliferation, differentiation, apoptosis, migration, and invasion[4-8]. While the functional mechanisms of miRNAs remain largely unknown in the pathogenesis of CRC, dysregulated expression of miRNAs can serve as potential biomarkers for the diagnosis and prognosis of cancer[9-11].

Several studies have determined the importance of miR-422a in human diseases such as cancer, multiple sclerosis, and postmenopausal osteoporosis. Gougelet *et al*[12] reported that miR-422a could inhibit signaling pathways regulating tumor cell proliferation in osteosarcoma. A study by Mao *et al*[13] demonstrated that miR-422a targeted key mismatch repair protein (MutLα) by suppressing MLH1 expression, resulting in genome instability and tumorigenesis. Faltejskova *et al*[14] reported that dysregulation of miR-378, miR-375, miR-422a, miR-215 and miR-135b in CRC patients played an important role in CRC pathogenesis. However, further study is needed to confirm whether miR-422a is an independent predictive factor in patients with CRC. Moreover, the functional mechanism by which miR-422a regulates CRC progression and whether it can serve as a prognostic biomarker in CRC remain largely unknown.

Previously, we have identified a serum 4-miRNA panel that included miR-19a-3p, miR-92a-3p, miR-223-3p, and miR-422a. This miRNA panel served as biomarkers for early diagnosis of colorectal adenocarcinoma[15,16]. In this study, we showed that the expression of miR-422a is dysregulated in CRC tissues. The correlation between miR-422a and certain clinical characteristics, as well as its potential as a prognostic marker for CRC, was also investigated. The effects of miR-422a on CRC cell proliferation, invasion, and migration were also assessed.

MATERIALS AND METHODS

Study population and sample collection

All written informed consent was obtained from every participant for use of tissue samples. This project was approved by the Clinical Research Ethics Committee of Qilu Hospital of Shandong University. All CRC patients were recruited from the Department of General Surgery, Qilu Hospital of Shandong University between November 2004 and December 2013. The diagnosis of CRC was confirmed by histopathology or histobiopsy. A total of 102 CRC tissues were collected and the adjacent normal mucosa tissues were used as controls since CRC is a malignant epithelial tumor and originates from glandular epithelium of the colorectal mucosa. All tissues were immediately frozen in liquid nitrogen and stored at -80 ℃ until RNA extraction. The median follow-up period for patients enrolled in this study was 63 mo (range, 14-78 mo).

Cell culture

SW480 and HT29 cells were purchased from the Type Culture Collection of the Chinese Academy of Sciences (Shanghai, China). The two cell lines were cultured in DMEM medium supplemented with 10% fetal bovine serum (Gibco, Carlsbad, CA, United States) at 37 ℃ in an incubator containing 5% CO_2.

Table 1 Relationship between miR-422a and clinical parameters in colorectal cancer tissues

Clinical parameter	Number of cases (n = 102)	miR-422a expression, median (min-max)	P value
Gender			0.704
Male	63	1.446 (0.074-130.774)

Values are median (IQR: Inter-quartile range). TNM: Tumor node metastasis.

Cell transfection

CRC cells were seeded at 2 × 10^5 cells/well in 6-well plates until 30%-50% confluency and then were transfected with miR-422a mimics or negative control mimics (RiboBio, Guangzhou, China) using Lipofectamine 2000 (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's introduction. The transfected cells were normalized and used in subsequent assays. The transfection efficiency was determined by RT-qPCR to verify the success of transfection.

RNA preparation, cDNA synthesis and RT-qPCR

Total RNA from cell lines, CRC tissues and normal mucosa was extracted using Trizol reagent (Invitrogen, Carlsbad, CA, United States). The cDNA was reverse-transcribed at 65 ℃ for 5 min in a 12 μL reaction system including 1 μg RNA, 1 μL reverse transcription primer (RiboBio, Guangzhou, China), 1 μL U6 reverse transcription primer and 1 μL dNTP. Then, 4 μL buffer, 2 μL DTT and 1 μL RNase inhibitor were added and incubated at 37 ℃ for 2 min followed by adding 1 μL MMLV and incubating at 37 ℃ for 50 min and 70 ℃ for 5 min. The PCR reaction was performed as follows: 95 ℃ for 1 min, and 45 cycles of 95 ℃ for 15 s, 60 ℃ for 30 s, and 72 ℃ for 45 s. U6 was used as a reference gene and each test was performed in triplicate in this study. RT-qPCR reactions were carried out on ABI Prism 7500 System (Applied Biosystems, Foster City, CA, United States).

Cell proliferation assay

miR-422a mimics and control mimics were transfected into SW480 and HT29 cells, then cultured for another 24, 48, 72, or 96 h. Cell proliferation rates was measured with CCK-8 reagent (Beyotime, Hangzhou, China) following the manufacturer's protocol. A microplate photometer (Multiskan FC, Thermo scientific, Shanghai, China) was used to determine the optical density at 450 nm.

Transwell migration and invasion assays

Transwell migration assay was performed using transwell chambers (Corning Costar, United States). After transfection for 24 h, cells were transferred into the upper chamber. RPMI 1640 medium containing 10% FBS functioning as a chemoattractant was added to matched lower chamber. SW480 and HT29 cells unable to migrate were removed from the upper surface of the transwell membrane after incubation for 48 h. Cells that were able to invade on the lower membrane surface were fixed in methanol, stained with 0.1% crystal violet, and counted using an inverted microscope (Olympus, Tokyo, Japan). For invasion assay, the inserts were pre-coated with matrix gel (BD Biosciences, Franklin Lakes, NJ, United States).

Statistical analysis

Data were analyzed using SPSS 17.0 software (IBM Corporation, Armonk, NY, United States). The expression of miR-422a between groups was compared using Mann-Whitney U test. Kaplan-Meier method was used for overall survival analysis. The Cox regression model was used for univariate and multivariate analyses to estimate the prognostic factors.

RESULTS

Expression of miR-422a in CRC tissues and correlative analysis with clinicopathological parameters

We detected the expression of miR-422a in 102 pairs of CRC tissues and normal mucosa adjacent to carcinoma using RT-qPCR. The results indicated that miR-422a levels were significantly lower in CRC tissues compared with normal mucosa (P < 0.05) (Figure 1A). Moreover, 65.7% (67 of 102) of CRC tissues had at least 2-fold down-regulated expression of miR-422a compared with normal mucosa (Figure 1B). The levels of miR-422a in stages Ⅰ and Ⅱ samples were significantly higher than those in stage Ⅲ samples (P < 0.05). There was no significant difference in miR-422a expression between stages Ⅰ and Ⅱ samples (P

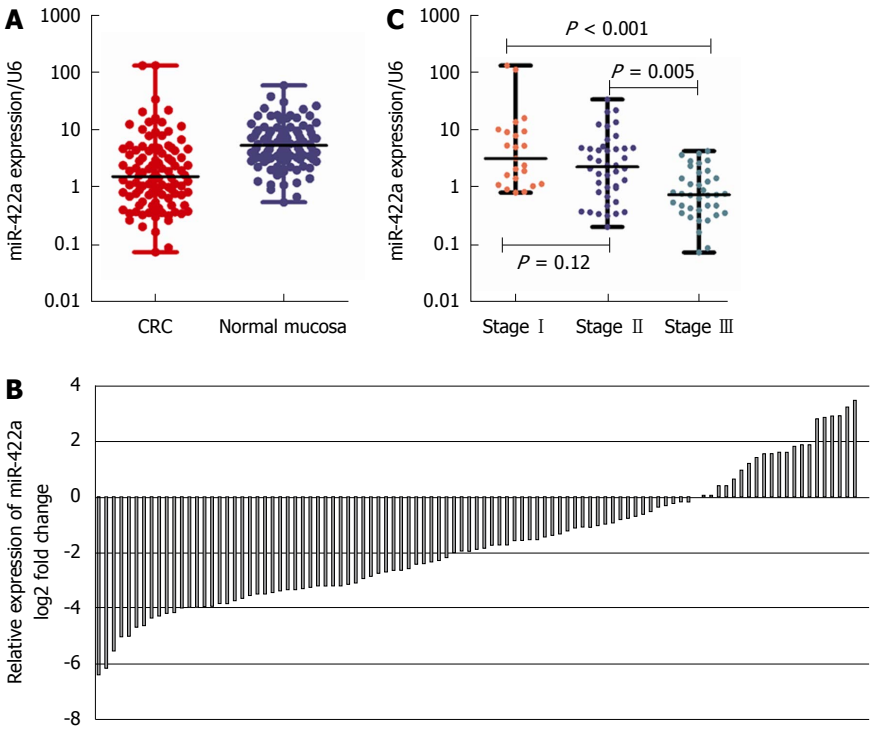

Figure 1 Expression of miR-422a in colorectal cancer and its association with TNM stage. A: Levels of miR-422a were determined in 102 colorectal cancer (CRC) tissues and their corresponding normal mucosa (NC); B: The fold changes of relative miR-422a level (CRC/NC) in each matched samples, with "< -1" defined as under-expression, "-1-1" as unchanged, and "> 1" as overexpression; C: Levels of miR-422a in stages Ⅰ/Ⅱ/Ⅲ CRC.

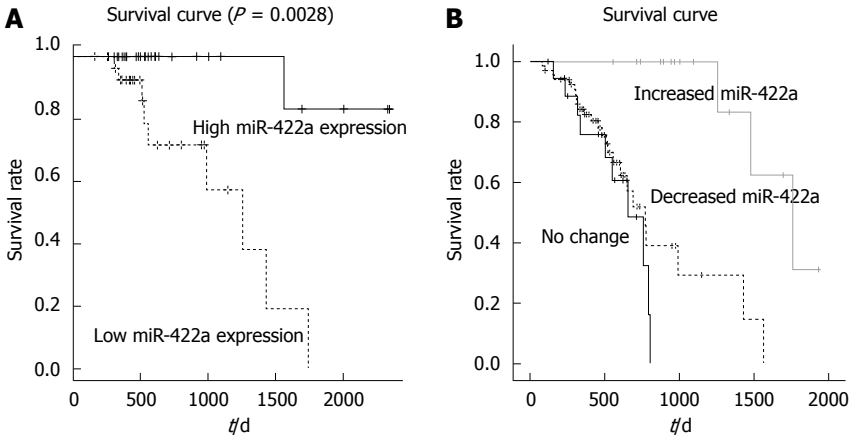

Figure 2 Kaplan-Meier curves for overall survival in 102 colorectal cancer patients based on miR-422a expression and the change of miR-422a expression compared to adjacent normal mucosa, respectively. Results showed that patients with low miR-422a expression had a significantly poorer prognosis than those with high miR-422a expression (A) (P = 0.0028), and patients with decreased miR-422a expression compared to adjacent normal mucosa had a significantly poorer prognosis than those with increased miR-422a expression (B) (P < 0.001).

> 0.05) (Figure 1C).

The association between miR-422a level and clinicopathological parameters of CRC patients is showed in Table 1. Our data showed that the level of miR-422a significantly correlated with local invasion (P = 0.004), lymph node metastasis (P = 0.002), and TNM stage (P < 0.001). However, there were no significant correlations between miR-422a level and gender, age, tumor location, differentiation or tumor size (P > 0.05).

miR-422a is an independent prognostic factor for overall survival in CRC patients

Our results demonstrated that 42 of 102 CRC patients died during the follow-up period. The 5-year overall survival rate was 58.8%. Patients were divided into high miR-422a expression and low miR-422a expression groups based on the median level. The prognosis was analyzed by Kaplan-Meier survival analysis, which revealed that patients with low miR-422a expression had a significantly poorer prognosis

Table 2 Univariate and multivariate analyses of overall survival in colorectal cancer patients

Variable	Category	Univariate analysis			Multivariate analysis		
		HR	95%CI	*P* value	HR	95%CI	*P* value
Gender	Male *vs* Female	0.943	0.493-1.872	0.810			
Age	≤ Median *vs* > Median	1.436	0.528-3.157	0.148			
Tumor location	Colon *vs* Rectum	0.862	0.484-1.706	0.603			
Tumor size	≤ 5 cm *vs* > 5 cm	1.093	0.568-2.194	0.873			
Differentiation	Well and moderate *vs* Poor	1.018	0.462-2.180	0.160	0.986	0.486-2.006	0.074
Local invasion	T1-T2 *vs* T3-T4	1.682	1.020-2.628	0.01[1]	1.460	0.746-2.632	0.482
Lymph node metastasis	Yes *vs* No	1.182	0.634-2.530	< 0.001[1]	1.262	0.584-2.680	0.306
TNM stage	Ⅰ and Ⅱ *vs* Ⅲ	2.738	1.509-4.265	< 0.001[1]	2.942	1.426-4.378	0.003[1]
MiR-422a level	Low *vs* High	0.306	0.108-0.763	0.001[1]	0.568	0.245-1.082	0.015[1]

[1]There was a significant difference between the two groups ($P < 0.05$).

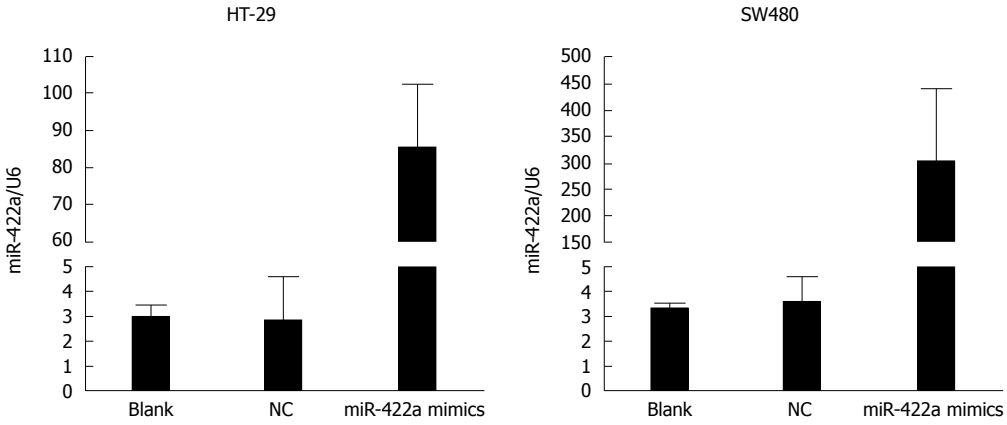

Figure 3 Transfection efficiency assays. The expression of miR-422a in HT-29 and SW480 cells was significantly increased after transfection with the mimics. All experiments were performed in triplicate.

than those with high miR-422a ($P = 0.0028$; Figure 2A). Furthermore, patients were divided into three groups (decreased, no change, and increased) based on the change of miR-422a expression compared to adjacent normal mucosa. Kaplan-Meier survival analysis showed that patients with decreased miR-422a expression had a significantly poorer prognosis than those with increased miR-422a expression ($P < 0.001$; Figure 2B). There was no significant difference between the decreased miR-422a group and no change group. In addition, Cox regression multivariate analysis was performed to determine whether miR-422a was an independent factor of overall survival in CRC patients. The analysis revealed that miR-422a expression (HR = 0.568, 95%CI: 0.245-1.082; $P = 0.015$) and clinical TNM stage (HR = 2.942, 95%CI: 1.426-4.378; $P = 0.003$) were independent prognostic factors for overall survival in CRC patients (Table 2).

Overexpression of miR-422a inhibits CRC cell proliferation

In our preliminary experiments, we detected the expression levels of miR-422a endogenously in several CRC cell lines, including HT-29, SW480, SW620 and HCT-116. The results showed that the levels of miR-422a were quite low in these CRC cells, and there were no significant differences in the expression level of miR-422a among these cell lines (data not shown). To measure the biological properties of miR-422a in CRC cells, miR-422a mimics were transiently transfected into HT-29 and SW480 cells, respectively. Subsequently, real-time RT-qPCR was performed, which showed high transfection efficiencies in both cell lines (Figure 3). The results of MTT assay showed that transfection of miR-422a mimics could significantly decrease cell number in SW480 and HT29 CRC cells ($P < 0.05$; Figure 4). It means that overexpression of miR-422a can inhibit the proliferation potential of SW480 and HT29 CRC cells.

Effect of miR-422a overexpression on cell migration and invasion

The transwell assays with and without Matrigel were performed to determine the effects of miR-422a on the migration and invasiveness of CRC cells. Overexpression of miR-422a significantly inhibited the migration of SW480 (P = 0.017; Figure 5A and B) and HT-29 cells ($P = 0.007$; Figure 5C and D). Furthermore, transwell assay with Matrigel showed that the invasiveness of these cells was significantly suppressed in cells transfected with miR-422a compared with miR control (Figure 6A-D).

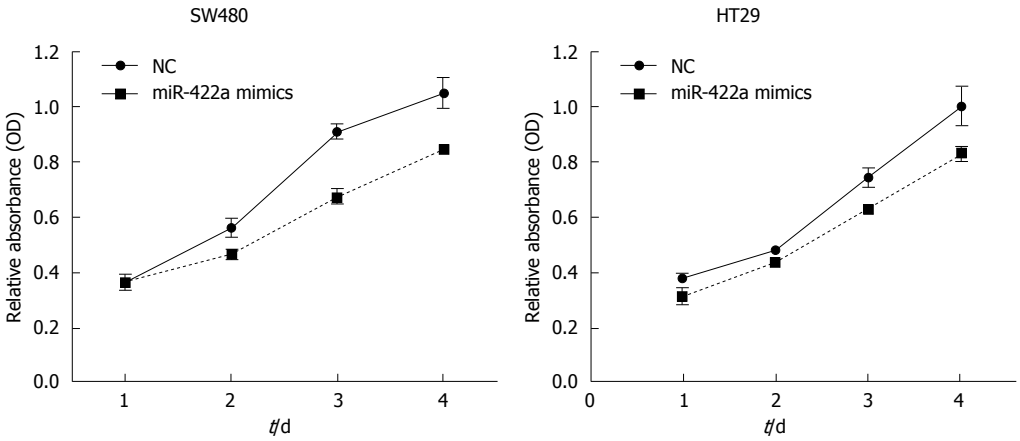

Figure 4 Overexpression of miR-422a inhibits colorectal cancer cell proliferation. Growth curves of miR-422a mimics and negative control mimics-transfected CRC cells were plotted after CCK-8 assay in SW480 and HT29 cells. All experiments were performed in triplicate. NC: Negative control.

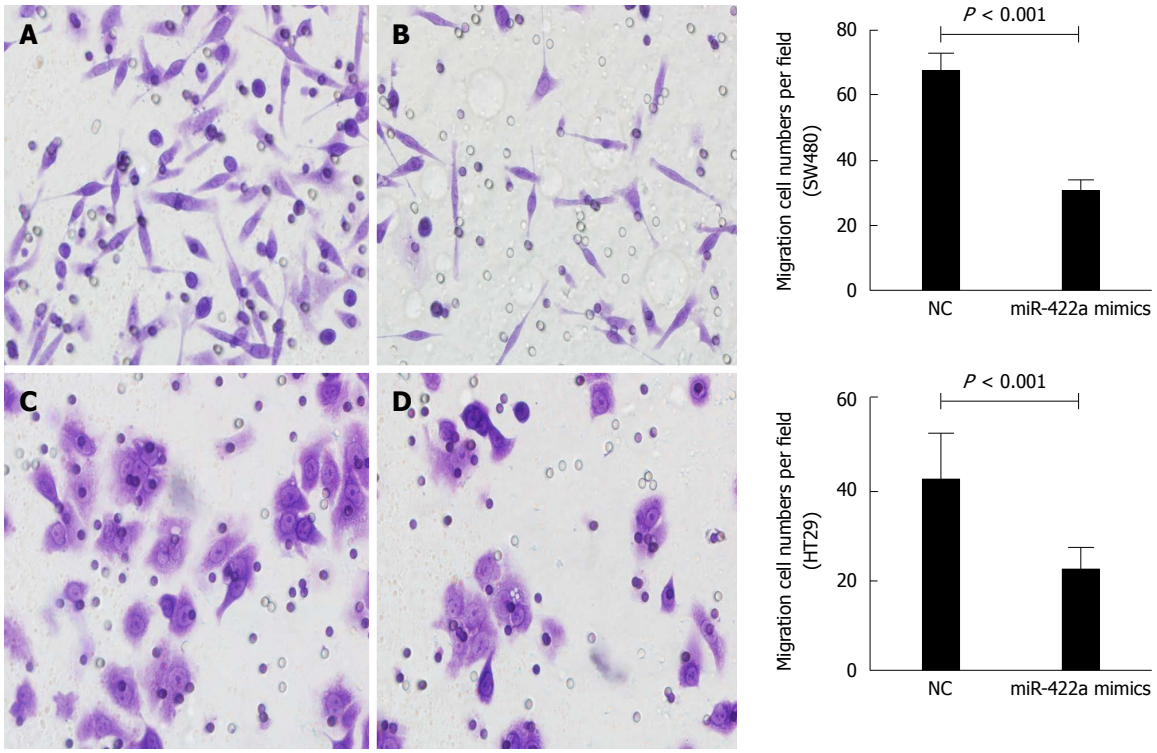

Figure 5 Effect of miR-422a overexpression on cell migration. Overexpression of miR-422a significantly inhibited the migration of SW480 (A and B) and HT29 (C and D) cells after transient transfection with miR-422a mimics. Stained cells were counted in five randomly selected fields under a light microscope. Representative photographs (left) and quantification (right) are shown. Magnification: × 400. All assays were performed in triplicate to derive the confidence intervals.

DISCUSSION

Tumor progression in CRC is a multi-step process involving a large number of genetic and epigenetic alterations[17-19]. Numerous studies have showed that miRNA target genes are involved in CRC tumorigenesis[6-8,20]. Currently, there is an ongoing effort to elucidate new deregulated miRNAs and their roles in CRC progression.

miR-422a is encoded by gene MIR422A on 15q22.31 (64, 163, 129-64, 163, 218bp). Recently, several studies have studied the functional role of miR-422a in osteosarcoma, osteoporosis, HIV infection, and other tumor types[21-25]. Our previous study demonstrated that serum miR-422a was significantly downregulated in CRC patients and is a potential biomarker with a high diagnostic accuracy[15]. However, the expression and role of miR-422a in CRC tissues, as well as its clinicopathological and prognostic value in CRC tumorigenesis remain undefined. In this study, our results demonstrated that miR-422a was down-regulated in CRC tissues compared with normal mucosa, which is consistent with a previous study[14]. We also found that the expression of miR-422a was significantly associated with lymph node metastasis and clinical stage in CRC

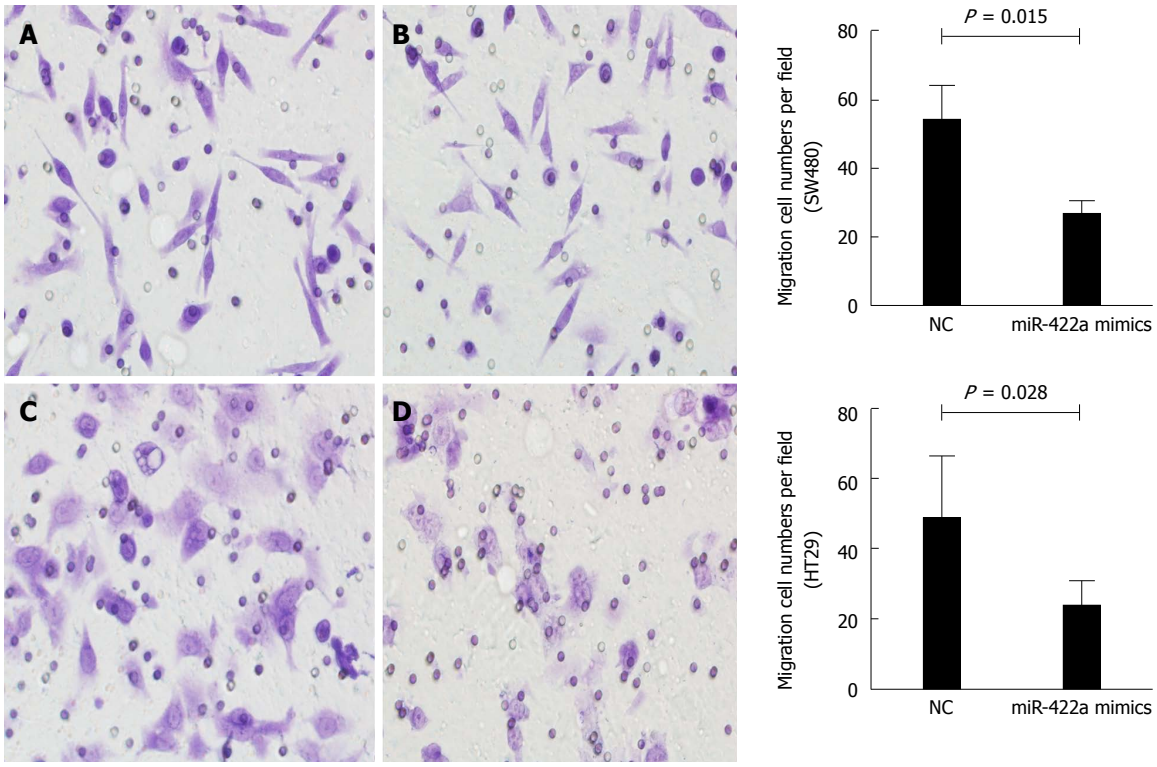

Figure 6 Effect of miR-422a overexpression on cell invasion. Overexpression of miR-422a significantly inhibited the invasiveness of in SW480 (A and B) and HT29 (C and D) cells after transient transfection with miR-422A mimics. Stained cells were counted in five randomly selected fields under a light microscope. Representative photographs (left) and quantification (right) are shown. Magnification: × 400. All assays were performed in triplicate to derive the confidence intervals.

patients, suggesting that down-regulation of miR-422a might participate in CRC progression. To further explore the value of miR-422a as a prognostic factor, we investigated the correlation between miR-422a and overall survival in CRC patients. Our results showed that patients with low expression of miR-422a and decreased miR-422a expression compared with normal mucosa had poorer survival, suggesting that miR-422a could serve as an independent prognostic factor in CRC patients. Overall, these results suggest that miR-422a plays a protective role against CRC and could be used to evaluate prognosis in CRC patients.

Until now, few studies have described the function of miR-422a[13,22,26]. A study has demonstrated that miR-422a and the mismatch repair protein Mutlα (MLH1) are involved in a feedback loop, leading to genome instability and tumorigenesis[13]. Another study showed that miR-422a significantly modulated the efficacy of IFN-α/RBV treatment *in vivo*. Exogenous IFN-α treatment led to decreased miR-422a and likely contributed to the IFN-mediated suppression of HIV-1, suggesting that restoring miR-422a treatment could be a potential therapeutic strategy for HIV-1 infection[26]. Moreover, overexpression of human telomerase reverse transcriptase (hTERT) has been associated with the invasion and metastasis of CRC cells. miR-138-5p and miR-422a were found to be hTERT-targeting miRNAs, potentially inhibiting hTERT expression[26]. Invasion and migration are required for tumor cells to spread from the primary site to lymph or blood vessels. In the present study, we found that miR-422a expression was associated with lymph node metastasis and overexpression of miR-422a inhibited CRC cell proliferation, migration and invasion. These results suggest that multiple signaling pathways regulating different aspects of tumorigenesis may be regulated by miR-422a expression, suggesting that miR-422a may be a new therapeutic target to repress cancer progression.

COMMENTS

Background

A growing number of studies have shown that deregulated miRNAs play critical roles in tumorigenesis and progression of colorectal cancer (CRC). Nevertheless, an ongoing effort to elucidate new deregulated miRNAs and their roles in CRC is still urgently needed. Several studies have demonstrated the importance of miR-422a in different types of human diseases. In our previous study, miR-422a was found to be down-regulated in serum and could be used as a potential biomarker for CRC. Therefore, it is necessary to further determine the expression of miR-422a in CRC tissues and to explore its clinicopathological, prognostic value and role in CRC carcinogenesis.

Research frontiers

Several studies have determined the importance of miR-422a in human diseases such as cancer, multiple sclerosis, and postmenopausal osteoporosis. miR-422a could inhibit signaling pathways regulating tumor cell proliferation in osteosarcoma. It was also shown that miR-422a targeted key mismatch repair protein (MutLα) by suppressing MLH1 expression, resulting in genome instability and tumorigenesis. Previously, we identified a serum 4-miRNA panel that included miR-19a-3p, miR-92a-3p, miR-223-3p, and miR-

422a. This miRNA panel served as biomarkers for early diagnosis of colorectal adenocarcinoma.

Innovations and breakthroughs

The present study indicated that down-regulation of miR-422a might serve as an independent prognosis factor in CRC. miR-422a functions as a tumor suppressor and regulates progression of CRC.

Applications

By understanding the differential expression of miR-422a in CRC patients and its relationship with clinicopathological characteristics, prognosis and *in vitro* function, the present study may provide a new prognostic factor of CRC and further reveal the mechanism of miR-422a participating in CRC carcinogenesis.

Terminology

MicroRNAs are a class of short non-coding RNAs that regulate up to 30% of human genes and play a pivotal role in various cellular processes. A growing number of miRNAs have been implicated in the initiation and progression of tumors including miR-422a. miR-422a is encoded by gene *MIR422A* on 15q22.31 (64,163,129-64,163,218bp), which has been found to be important in human diseases such as cancer, multiple sclerosis, and postmenopausal osteoporosis.

Peer-review

The authors presented a study analyzing the prognostic value and function of miR-422a in CRC carcinogenesis. The results demonstrated that miR-422a was dramatically reduced in CRC tissues and significantly correlated with local invasion and lymph node metastasis. miR-422a expression was an independent prognostic factor for overall survival. *In vitro* experiments showed that overexpression of miR-422a inhibited the proliferation, migration, and invasion of SW480 and HT-29 cells. These data indicated that miR-422a might serve as an independent prognosis factor and regulate progression of CRC by functioning as a tumor suppressor.

Abstract

AIM: To assess the efficacy and safety of diverting colostomy in treating severe hemorrhagic chronic radiation proctitis (CRP).

METHODS: Patients with severe hemorrhagic CRP who were admitted from 2008 to 2014 were enrolled into this study. All CRP patients were diagnosed by a combination of pelvic radiation history, clinical rectal bleeding, and endoscopic findings. Inclusion criteria were CRP patients with refractory bleeding with moderate to severe anemia with a hemoglobin level < 90 g/L. The study group included patients who were treated by diverting colostomy, while the control group included patients who received conservative treatment. The remission of bleeding was defined as complete cessation or only occasional bleeding that needed no further treatment. The primary outcome was bleeding remission at 6 mo after treatment. Quality of life before

treatment and at follow-up was evaluated according to EORTC QLQ C30. Severe CRP complications were recorded during follow-up.

RESULTS: Forty-seven consecutive patients were enrolled, including 22 in the colostomy group and 27 in the conservative treatment group. When compared to conservative treatment, colostomy obtained a higher rate of bleeding remission (94% *vs* 12%), especially in control of transfusion-dependent bleeding (100% *vs* 0%), and offered a better control of refractory perianal pain (100% *vs* 0%), and a lower score of bleeding ($P < 0.001$) at 6 mo after treatment. At 1 year after treatment, colostomy achieved better remission of both moderate bleeding (100% *vs* 21.5%, $P = 0.002$) and severe bleeding (100% *vs* 0%, $P < 0.001$), obtained a lower score of bleeding (0.8 *vs* 2.0, $P < 0.001$), and achieved obvious elevated hemoglobin levels ($P = 0.003$), when compared to the conservative treatment group. The quality of life dramatically improved after colostomy, which included global health, function, and symptoms, but it was not improved in the control group. Pathological evaluation after colostomy found diffused chronic inflammation cells, and massive fibrosis collagen depositions under the rectal wall, which revealed potential fibrosis formation.

CONCLUSION: Diverting colostomy is a simple, effective and safe procedure for severe hemorrhagic CRP. Colostomy can improve quality of life and reduce serious complications secondary to radiotherapy.

Key words: Chronic radiation proctitis; Rectal bleeding; Diverting colostomy; Quality of life; Serious complication

Core tip: The study describes the efficacy and safety of diverting colostomy in treating severe hemorrhagic chronic radiation proctitis. The procedure focuses on improving the severe refractory bleeding and reducing severe complications. The advantages of diverting colostomy are as follows: it acts effectively and rapidly in controlling severe bleeding that does not respond to conservative treatment; it is a simple procedure that can be conducted in many medical centers; and it can improve quality of life dramatically and reduce serious complications that occur secondary to radiotherapy.

Yuan ZX, Ma TH, Wang HM, Zhong QH, Yu XH, Qin QY, Wang JP, Wang L. Colostomy is a simple and effective procedure for severe chronic radiation proctitis. *World J Gastroenterol* 2016; 22(24): 5598-5608 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5598.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5598

INTRODUCTION

Chronic radiation proctitis (CRP) is a common complication after radiotherapy of pelvic malignancies, accounting for 5%-20% of cases[1]. The onset of RP can be delayed for several months to years after radiotherapy. CRP develops as a result of ischemic lesions due to obliterative endarteritis and progressive fibrosis[2,3]. Rectal bleeding is the most common symptom, which accounts for > 80% of CRP patients[4]. Acute and mild CRP is usually self-limiting and easy to manage, but moderate to severe CRP is difficult to treat; especially those cases requiring blood transfusions and that are life threatening[1,5].

Various treatment modalities have been tried. Medical agents include topical sucralfate, steroids[6], sulfasalazine[7], metronidazole[8], rebamipide[9] and short-chain fatty acid[10]. Other treatment options include topical formalin[11,12], endoscopic argon plasma coagulation (APC)[13], laser therapy[14], and hyperbaric oxygen therapy[15]. However, most of these treatments are only useful for mild to moderate bleeding, and severe and refractory bleeding is still problematic[16]. Furthermore, endoscopic treatments can bring severe side effects and multiple treatment sessions are needed for severe CRP[17]. In addition, accompanying symptoms such as intractable perianal pain, urgency and tenesmus in CRP are usually hard to manage.

Diverting colostomy has been reported previously, mainly for severe CRP complications[18,19]. Colostomy can reduce the irritation injury of fecal stream to the irradiated tissues and thus decrease rectal bleeding. However, unlike formalin or APC, colostomy is now not widely used. The issue of colostomy is not well studied to date. To the best of our knowledge, no study has compared diverting colostomy to conservative treatment. The aim of this study was to assess the efficacy and safety of diverting colostomy in severe CRP. The indications, quality of life, severe CRP complications, and stoma reversals after colostomy were also investigated, when compared to conservative treatment.

MATERIALS AND METHODS

Patients and ethical statements

Hemorrhagic CRP patients who were treated at the Sixth Affiliated Hospital of Sun Yat-Sen University (SYSU) from March 2008 to October 2014 were retrospectively enrolled in this study. Electronic files and medical records were both carefully collected to extract clinicopathological data. This study was approved by the Ethical Committee of the Sixth Affiliated Hospital of SYSU and the study was conducted in accordance with the provisions of the World Medical Association's Declaration of Helsinki in 1995 (revised in Tokyo, 2004). Due to the nature of

Table 1 Modified subjective objective management analysis system to assess the severity of bleeding in radiation proctitis

Grade	Bleeding	Severity	Anemia (Hb, g/L)
1	Mild bleeding	Occasionally or occult	Mild anemia (Hb: ≥ 90 g/L)
2	Moderate bleeding	Persistent	Moderate anemia (Hb: 70-90 g/L)
3	Severe bleeding	Gross	Severe anemia, transfusion needed (Hb: < 70 g/L)

Hb: Hemoglobin.

the retrospective study, informed consent was waived.

Inclusion and exclusion criteria

Inclusion criteria were CRP patients with refractory bleeding with moderate to severe anemia with a hemoglobin level < 90 g/L. Refractory bleeding was defined as no response to conservative treatment. Patients who were treated with diverting stomas were enrolled in the study group, while those who continued to non-surgical treatment were enrolled in the control group. Patients with tumor relapses, loss to follow-up, or who underwent rectal resection with preventive colostomy were excluded.

Diagnosis, scores and definitions

All patients were diagnosed by combination of pelvic radiation history, clinical rectal bleeding, and endoscopic findings of injured rectal mucosa. Flexible colonoscopy was performed in all patients to rule out other causes of bleeding, such as recurrent tumors, inflammatory bowel disease and anal benign hemorrhagic diseases. The Vienna Rectoscopy Score[20] system was used to assess endoscopic severity.

Current scores to evaluate the severity of bleeding included Common Terminology Criteria for Adverse Events[21], Radiation Therapy Oncology Group/European Organization for Research and Treatment of Cancer (EORTC) score[22]. However, most of them are based on subjective complaints of patients, instead of accurate laboratory tests. Because the severity of bleeding was mainly reflected by a decrease in hemoglobin level, we designed a modified Subjective Objective Management Analysis (SOMA) system reported in a previous study[23], to assess the severity of bleeding, included both subjective complaints of bleeding and objective hemoglobin level. All patients were scored by the system (Table 1). The remission of bleeding was defined as complete cessation of bleeding or only occasional bleeding that needed no further treatment. Failure in the conservative treatment group was defined as no improvement or even worse bleeding and decreased hemoglobin level 6 mo after treatment.

Indications of diverting colostomy

All patients, except those with fistulas, were initially treated with medical agent enemas including almagate (one mucosa-protector like sucralfate), corticosteroids, and metronidazole. Topical formalin (details listed in our previous study)[24] or endoscopic APC were suggested when they experienced recurrent bleeding. As for refractory and transfusion-dependent CRP after these conservative measures, physicians suggested a diverting stoma. If patients refused a colostomy and demanded to continue conservative treatment, they were enrolled in the control group. Other indications of diverting colostomy were as follow: (1) fistula, perforation or stricture; and (2) deep ulcer with refractory perianal pain.

Diverting loop colostomies were conducted under general anesthesia in the operating room. The transverse colon was pulled out through a small incision, then a soft catheter of a stent was inserted to prevent stoma retraction, and a double-cavity stoma of the transverse colon was then created. The catheter was removed postoperatively. Classical images of a double-cavity colostomy and a "gunsight" of stoma closure were shown (Figure 1). This technique of stoma closure can simplify wound care, decrease surgical site infection, and give a neat cosmetic result[25,26].

Follow-up

Follow-up was scheduled through outpatient visits or telephone questionnaires at 6 mo and 1 year after treatment. The quality of life before treatment and at follow-up was evaluated according to EORTC QLQ C30[27]. The primary outcome was the remission rate of bleeding at 6 mo after treatment. The secondary outcomes included hemoglobin level, remission rate of bleeding at 1 year after treatment, quality of life, stoma-related complications, severe CRP complications, and stoma reversal rate.

Statistical analysis

Comparisons of characteristics were made by Student's *t* test analysis for continuous variables. For categorical variables, the χ^2 test was used. Fisher's exact test was adopted when appropriate. For non-parameter variables, the Wilcoxon rank sum test was used. All statistical analyses were performed by SPSS version 17.0 (Chicago, IL, United States). $P < 0.05$ (two-tails) was considered to be statistically significant.

RESULTS

Demographics and characteristics

A total of 47 patients were analyzed. Twenty-two (46.8%) were treated by diverting colostomy, and 27 (53.2%) were managed by conservative treatment (Figure 2). Forty-three (91.5%) were women, and 40 (85.1%) primary malignancies were cervical cancer. Cumulative radiation dosage of one patient was about 80 Gy, which included the radiation for both sites

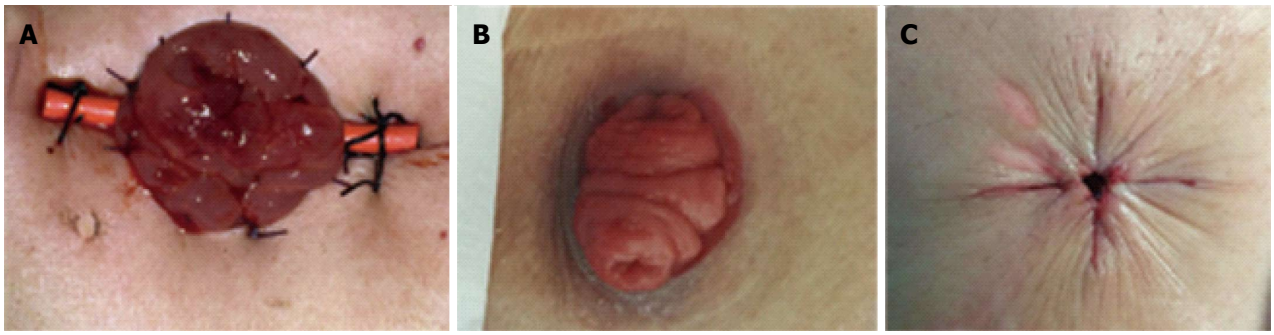

Figure 1 Classic representative images of a double-cavity colostomy. A: A double-cavity colostomy with a soft catheter as a stent; B: A colostomy after during follow-up; C: A "gunsight" skin incision and closure for stoma reversal.

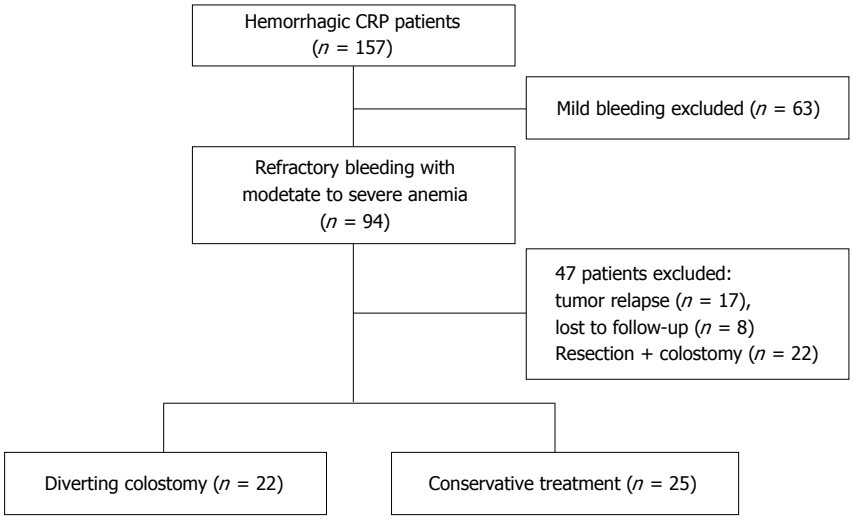

Figure 2 Flow chart of patient selection.

of primary malignancy and invasive lymph nodes. The detailed radiotherapy for those patients with gynecological cancers, especially cervical cancer, was 25 rounds (2 Gy/round) of external beam radiation and five or six episodes (6 Gy/episode) of intra-cavity brachytherapy. Patients with prostate or rectal cancers received only external beam radiation. When comparing demographics prior to treatment between the two groups, there were no significant differences in age, gender, type of primary malignancy, cumulative radiation dosage, latency period, duration from treatment to end of radiotherapy, duration of bleeding, albumin level, body mass index (BMI), concomitant radiation uropathy, radiation enteritis, and associated risk factors of CRP such as previous history of abdominal surgery, diabetes mellitus and hypertension (Table 2). Thus, these above characteristics were comparable between the two groups. However, the colostomy group had a higher score of bleeding (2.7 *vs* 2.0, $P < 0.001$) and a lower hemoglobin level (60.8 g/L *vs* 88.2 g/L, $P < 0.001$), when compared to the conservative treatment group, respectively. These results indicated that the colostomy group had more serious bleeding before treatment (Table 2).

Treatment

The indications for colostomy were as follows: (1) severe bleeding in eight (36.4%) cases; (2) fistulas in 11 (50%), including nine (40.9%) rectovaginal fistulas and two (9.1%) sigmoid-vesical-vaginal fistulas; (3) deep ulcer + refractory perianal pain in two (9.1%) cases; and (4) severe bleeding + deep ulcer + anal stricture in one (4.5%) case. Among these 11 patients with fistulas, five also had concomitant severe bleeding. Among these nine recto-vaginal fistulas, one had concomitant recto-urethral fistula, and another had concomitant recto-vesical fistula and small bowel fistula.

In the conservative treatment group, seven patients received topical formalin irrigation and one received APC treatment after enrollment. All eight (32%) cases transiently obtained bleeding remission, but only two (25%) obtained long-term remission of bleeding. The other six patients experienced recurrent bleeding and developed severe anemia. Repeat topical formalin achieved only limited efficacy in these patients with severe anemia (average 2 sessions of formalin at 2-4-wk intervals). The remaining 17 patients refused formalin treatment, and thus continued retention

Table 2 Comparisons of patient demographics between the colostomy group and conservative group before treatment *n* (%)

Characteristics	Diverting colostomy (*n* = 22)	Conservative treatment (*n* = 25)	*P* value

enemas and transfusions when needed.

Outcomes

During a mean 22 (range: 6-77) mo of follow-up, eight (17%) patients died. The cause of death was recurrent malignancy in seven cases. The other one died of bladder perforation and sepsis that occurred secondary to radiation recto-vesical-vaginal perforation. At 6 mo after treatment, colostomy offered higher remission of bleeding (94% *vs* 12%, $P < 0.001$), higher remission of refractory perianal pain (100% *vs* 0%, $P < 0.001$), decreased scores of bleeding (1.1 *vs* 2.2, $P < 0.001$), and obvious increased hemoglobin levels (34.1 g/dL *vs* -12.3 g/dL, $P < 0.001$), compared to the conservative treatment group. At 1 year after treatment, colostomy achieved still higher remission of both moderate bleeding (100% *vs* 21.5%, $P = 0.002$) and severe bleeding (100% *vs* 0%, $P < 0.001$), acquired lower score of bleeding (0.8 *vs* 2.0, $P < 0.001$), and obviously elevated hemoglobin levels (40.3 g/dL *vs* -1.9 g/dL, $P = 0.003$), than those cases in the conservative treatment group. In addition, three recto-vaginal fistulas were found in the conservative treatment group during follow-up, but no new fistula occurred after the operation in the colostomy group. Patients who did not have bleeding remission continued conservative treatment at home (Table 3).

Stoma closure and complications

Of the eight patients who received colostomy to control severe bleeding, three (37.5%) underwent stoma closure (2 cases at 9 mo and 1 at 10 mo after colostomy). All three had no bleeding and remained well after stoma reversal. Of the remaining five, all obtained bleeding remission and improved hemoglobin levels. However, among these five, one had grade IV New York Heart Association heart failure and could not risk stoma closure. Four were unsuitable for closure

[1]Wilcoxon rank-sum test; [2]Point (follow-up) - point (pre-treatment).

because of erythema and telangiectasia at 6 mo after colostomy, and two of these four had not yet reached 1 year follow-up to assess the lesion by colonoscopy.

Stoma complications were found in seven (31.8%) cases, which contained six stoma prolapses and one stoma stricture. Of these six stoma prolapses, four were managed with conservative measures by manual repositions (Grade Ⅱ by Clavien-Dindo classification[28]), and two required stoma rebuilding (Grade Ⅲ). One stoma stricture occurred in a stoma of the descending colon, instead of the transverse colon, and stoma stricture was managed by finger dilatation (Grade Ⅱ).

Quality of life

The quality of life was evaluated in 41 (87.2%) patients by the EORTC QLQ-C30 questionnaires. Because there were no similar reports in the Chinese population, the values were referred to the normal German population. Osoba *et al*[29] suggested that a difference of ⩾ 20 points in global health was considered to be clinically relevant. In this study, when compared to pre-treatment, diverting colostomy improved quality of life, including improved global health (difference = 42, $P < 0.001$), improved functions like physical function ($P < 0.001$), role function ($P < 0.001$), emotional function ($P < 0.001$), social function ($P < 0.001$), and improved symptoms like fatigue ($P < 0.001$), pain ($P = 0.001$), dyspnea ($P = 0.003$), insomnia ($P = 0.026$), and diarrhea ($P = 0.018$). However, conservative treatment did not significantly improve quality of life at follow-up compared with before treatment (Table 4).

Endoscopic and pathological features

Classical endoscopic images prior to colostomy and at stoma closure from three patients with stoma closures were collected (Figure 3). After a mean 9.3 (range: 9-10) mo after colostomy, endoscopic lesions of active bleeding, multiple confluent telangiectasia, congested mucosa, or even ulcer were greatly improved and reached the criteria of stoma closure.

Pathological evaluation of endoscopic biopsy from rectal lesions was conducted at 31 mo after colostomy in Case 3. This patient obtained complete remission of bleeding and the biopsy sites were fully healed according to endoscopic observation at follow-up. Pathologically, diffuse chronic inflammatory cells were observed in the mucosa and sub-mucosa layers. In addition, massive fibrotic collagen depositions were found in the sub-mucosa layer, which revealed fibrosis formation (Figure 4).

DISCUSSION

Endoscopic treatments, such as topical formalin or APC, are extensively used for mild to moderate hemorrhagic CRP worldwide[14,16]. However, these treatments show only limited long-term efficacy for severe CRP[17]. It is also unclear how many patients have received these treatments for serious transfusion-dependent bleeding in previous studies[17]. Meanwhile, serious complications can be caused by these endoscopic treatments[5,17]. Our previous study also suggested that topical formalin should not be applied in CRP with ulcer because of the risk of fistula[24]. In the present study, patients in the conservative treatment group received more topical formalin or APC treatment and developed more fistulas later, than patients in the colostomy group. Therefore, we suggest topical formalin or APC should be selected cautiously for patients with severe CRP. Recently, radiofrequency ablation (RFA) in treating CRP has been introduced, with improvement in hemoglobin level and decrease in clinical symptoms[30,31]. Most RFA studies are based

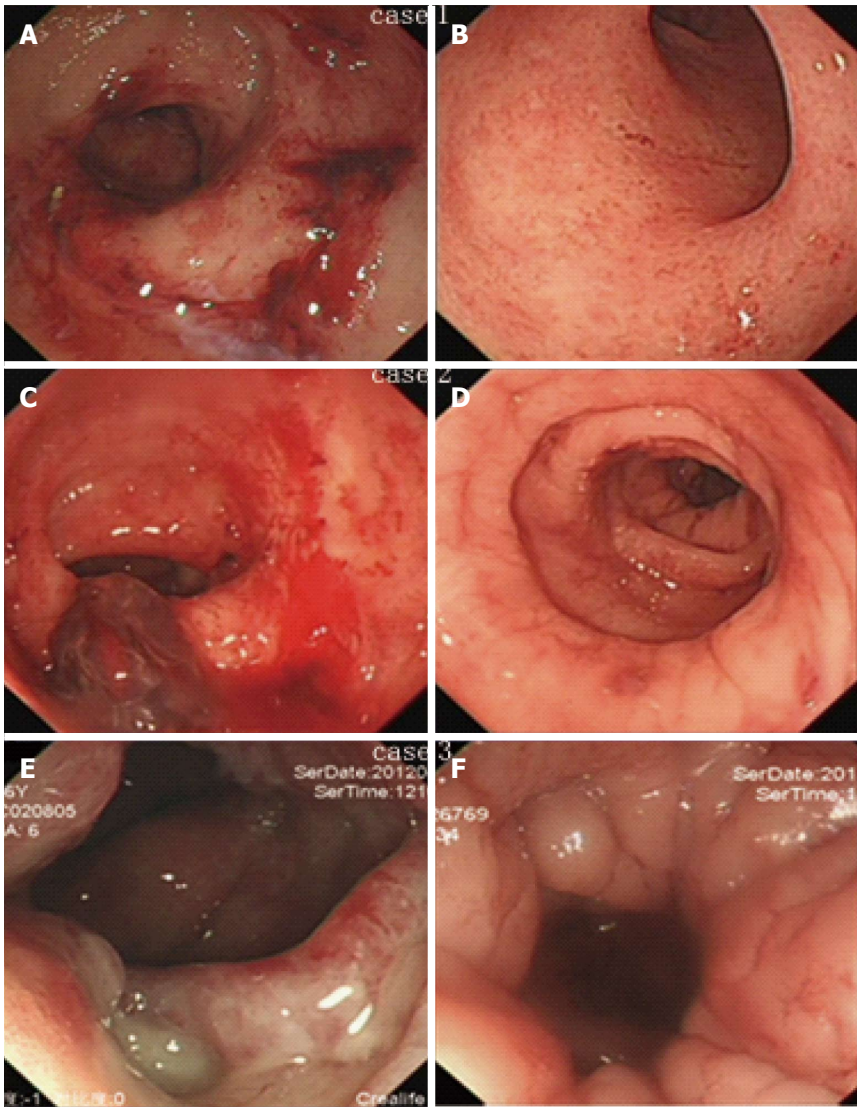

Figure 3 Classical endoscopic images before colostomy and at stoma reversal. Severe active bleeding (A and C), or confluent telangiectasia, edema and ulcer (E) were observed in cases 1-3 before colostomy, while these lesions was greatly improved at stoma reversal (B, D, F).

on retrospective case series without controls and current data are scare, therefore, prospective trials of RFA should be conducted in the future to validate its efficacy and application in severe CRP.

Surgical intervention is often the last resort for severe CRP[3,19]. Rectal resection is controversial, because it is difficult to perform a safe anastomosis in the radiation-injured tissue, and high risks of anastomotic leak and death from postoperative peritonitis are reported[19]. Therefore, a simple and safe procedure to save life and relive symptoms is mandatory. Theoretically, diverting colostomy can reduce bacterial contamination and decrease irritation injury by fecal stream, and colostomy can gain time to subside any radiation reaction to protect injured tissue[32]. Thus, severe bleeding and refractory perianal pain can be controlled. Colostomy can also accelerate the course of fibrosis and relieve severe proctitis rapidly, which may prevent deep ulcers progressing to fistulas. In our recent study[33], we reported typical histopathological features of CRP: telangiectasia, abnormal hyaline-like wall vessels and sporadic radiation fibrocytes in the submucosal layer. In this study, consistently, massive fibrotic collagen depositions were observed in irradiated tissue after colostomy. Collectively, the nature of CRP is a progressive fibrosis course[7]. The efficacy and safety of colostomy have been reported in previous studies[18,19,34]. However, most previous studies did not contain controls, which could not discriminate the efficacy of interventions from the self-remission course. To the best of our knowledge, no previous study has reported quality of life after colostomy. It is also not clear whether colostomy can reduce serious CRP complications.

In this study, diverting colostomy resolved most cases of severe bleeding. No recurrent bleeding and no colostomy-related death were observed. Colostomy

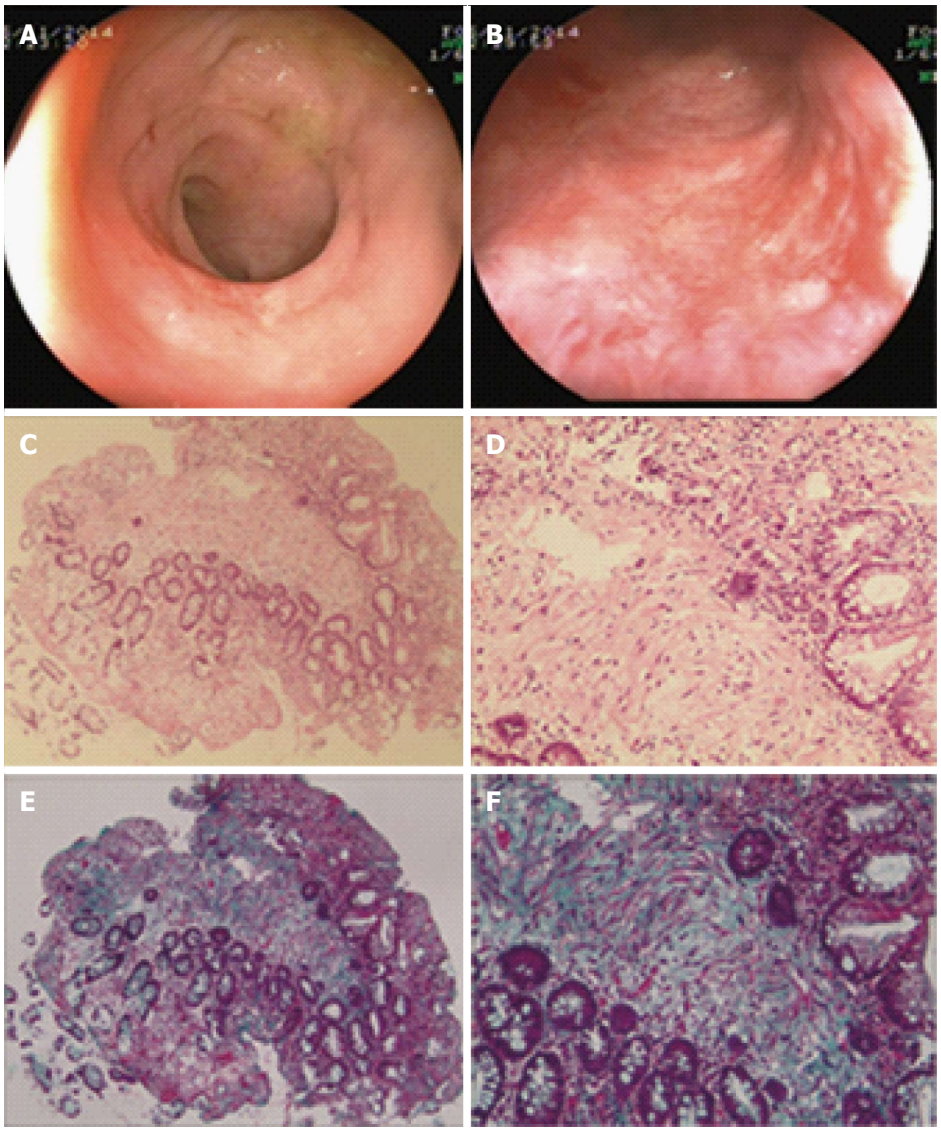

Figure 4 Histo-pathological features after colostomy in case 3. Complete remission of confluent telangiectasia, edema and ulcer were observed 31 mo after colostomy (A and B). Diffused chronic inflammatory cells and rebuilt of mucosal integrity were seen in hematoxylin and eosin-stained slides (C: × 100; D: × 400). Massive fibrotic collagen depositions were observed in the sub-mucosa layer, with green color by Masson staining (E: × 100; F: × 400).

can also decrease serious complications, including remission of long-term perianal pain, transfusion-dependent bleeding and fistula. Deep ulcer with severe bleeding is a contraindication to endoscopic treatment, because it is easy to progress to fistula, due to the poor-healing capacity and impaired blood supply of friable intestinal wall[17,19]. We have previously tried topical revision and skin flap transplantation for some CRP fistulas. However, the efficacy was limited and new fistulas can occur rapidly, due to poor healing capacity of irradiated mucosa and bacterial infection from the fecal stream, which leads to treatment failure. In this study, two patients with deep ulcer and severe bleeding were successfully controlled by colostomy, and no fistula was found at follow-up.

Transverse colostomy is preferred because it provides a greater blood supply by preserving superior rectal and left marginal vessels, and provides more options for later possible recto-sigmoid resection than sigmoid colostomy does, and transverse colostomy is easier to be closed and is more effective[32,34]. In addition, the recto-sigmoid colon is expected to receive a higher radiation dose for pelvic malignancy, while the transverse colon receives the least radiation and damage, because it is located far from pelvic tumors, and thus causes the fewest complications[19,32,35]. Loop ileostomy is not widely used because of the risk of high-volume fluid discharge. Colostomy-related complications were reported, ranging from 21.8% to 40%[19,35]. Consistent with previous studies, colostomy-related complications in this study were 31.8%, including six (85%) cases of Grade Ⅱ and one (15%) case of Grade Ⅲ complications. Among them, stoma prolapse was a common complication.

Colostomy for recto-vaginal fistula and rectal stricture is permanent. However, colostomy for patients

unresponsive to medical treatment can be closed when severe proctitis improves sufficiently. Anseline *et al*[19] reported six (43%) colostomy reversals in 14 CRP patients, who were unresponsive to medical treatment. A similar result was observed in the present study. Three (38%) of eight patients with severe bleeding were closed successfully in a mean 9 mo after colostomy. Because the duration of follow-up after fecal diversion was short, many patients who obtained long-term remission of bleeding after colostomy had great potential to reverse the stoma.

In this study, we used a modified SOMA system, which coordinates subjective bleeding symptoms and objective accurate hemoglobin level. According to the system, we suggest that mild to moderate hemorrhagic CRP can be managed by medical or endoscopic treatment. However, for severe refractory bleeding colostomy should be considered to prevent development of serious complications. The scoring system will guide physicians in primary care to evaluate patient condition according to hemoglobin level, and then choose the appropriate treatment. Having a routine and easy protocol can reduce treatment-related delays and avoid unnecessary morbidity[7].

In this study, 44 (94%) CRP patients enrolled had gynecological cancers, so most fistulas were documented in women. In western countries, patients with prostate cancer are the dominant population receiving pelvic radiation, and CRP is mainly reported in prostate cancer[4,12]. However, prostate cancer receives only external beam radiation such as 3D conformal radiotherapy or intensity-modulated radiotherapy, and it does not receive intra-cavity brachytherapy, thus, fewer fistulas are observed. According to our clinical practice, intra-cavity radiation can result in more fistulas and other severe adverse radiation-related symptoms than external beam radiation can.

Although the colostomy group had more severe bleeding than the conservative treatment group, which could have resulted in selection bias, it achieved dramatically better control of bleeding, higher increased hemoglobin level, and improved quality of life compared with the conservative treatment group. These results have shown the advantages of diverting colostomy in treating severe CRP bleeding. Topical formalin or APC was not used in all the patients in the conservative treatment group, because some patients in China have not sufficient knowledge of CRP, poor compliance with physicians' advice, and poor economic status. Thus, they choose to continue self-enemas at home, when recurrent bleeding occurs. In addition, this study was limited by its non-randomized, retrospective design and small sample size. Additional randomized prospective studies of diverting colostomy are needed to confirm our findings.

ACKNOWLEDGMENTS

The authors thank Jie Zhao, Li-Li Chu for the contributions in the collection of stoma pictures and providing stoma cares. We also thank Yan-Qi Liu for the contribution in patient follow-up.

COMMENTS

Background

Chronic radiation proctitis (CRP) occurs in 5%-20% of patients receiving radiotherapy for pelvic malignant tumors. Mild to moderate CRP is usually self-limiting and easy to manage, but severe and refractory bleeding is still problematic, especially in cases requiring blood transfusions and that are life threatening. Furthermore, endoscopic treatment can cause severe side effects and only limited efficacy can be obtained for severe CRP. Thus, a simple and safe treatment with fewer complications to save life and relive symptoms is mandatory.

Research frontiers

Diverting colostomy has been reported previously, mainly for severe CRP complications. However, unlike formalin or argon plasma coagulation, colostomy is now not widely used for severe bleeding in CRP patients. The issue of colostomy is not well studied to date. To the best of our knowledge, no study has compared diverting colostomy to conservative measures in treating severe hemorrhagic CRP.

Innovations and breakthroughs

In this series, the authors reported their experience that diverting colostomy was a simple, effective and safe procedure for severe hemorrhagic CRP. Furthermore, they found that colostomy improved quality of life and reduced serious complications secondary to radiotherapy, while conservative medical and endoscopic treatments did not show efficacy in severe CRP patients.

Applications

Diverting colostomy is a simple and safe procedure that can be performed in most medical centers. The authors also developed a modified Subjective Objective Management Analysis system, which coordinates subjective bleeding symptoms and objective accurate hemoglobin level, to guide physicians in primary care to evaluate patient condition according to hemoglobin level, and then choose the appropriate treatment. Having a routine and easy protocol can reduce treatment-related delays and avoid unnecessary morbidity.

Terminology

The underlying causes of CRP are endarteritis obliterans and progressive submucosal fibrosis due to radiotherapy. Diverting colostomy can reduce bacterial contamination and decrease irritation injury by the fecal stream, and can gain time to reduce any radiation reaction to protect injured tissue. Colostomy can also accelerate the course of fibrosis and relieve severe proctitis rapidly, which may prevent deep ulcers progressing to fistulas.

Peer-review

This is a single center, controlled, and retrospective case series of severe CRP patients who received diverting colostomy. Colostomy can relieve most of severe bleeding rapidly and unexpected, colostomy can also reduce serious CRP complications, including remission of long-term perianal pain, transfusion-dependent bleeding and fistula.

Abstract

AIM: To assess the use of dezocine combined with propofol for the anesthetization of patients undergoing indolent colonoscopy.

METHODS: A cross-sectional survey of patients undergoing indolent colonoscopy in the Xinjiang People's Hospital was conducted from April 1 to April 30, 2015. The survey collected patient general information and anesthesia data, including overall medical experience and pain management. Thirty minutes after colonoscopy surgery, samples of venous blood were collected and the biochemical indicators of gastrointestinal function were analyzed.

RESULTS: There were 98 female and 62 male respondents. Indolent colonoscopy was found to be more suitable for mid to older-aged patients. The necessary conditions for the diagnosis of digestive diseases were required in 65 of the 73 inpatients. Adverse reactions to the intraoperative process included two cases of body movement and two cases of respiratory depression. Gastrin and vasoactive intestinal peptide levels were slightly increased. However, somatostatin and endothelin levels were slightly decreased.

CONCLUSION: This study revealed that dezocine combined with propofol can be successfully used for the anesthetization of indolent colonoscopy patients without pain and should be widely used.

Key words: Dezocine; Propofol; Colonoscopy; Patient

assessment; Anesthetization; Cross-sectional

Core tip: A cross-sectional survey of patients undergoing indolent colonoscopy was carried out to study the clinical effect of anesthetization by dezocine combined with propofol. Thirty minutes after colonoscopy surgery, samples of venous blood were collected and the biochemical indicators of gastrointestinal function were analyzed. Indolent colonoscopy was found to be more suitable for mid to older-aged patients. Gastrin and vasoactive intestinal peptide levels were slightly increased. However, somatostatin and endothelin levels were slightly decreased. This study revealed that dezocine combined with propofol can be successfully used for the anesthetization of indolent colonoscopy patients without pain and should be widely used.

INTRODUCTION

Colonoscopy is an endoscopic examination of the large intestine and the distal part of the small intestine. It provides a diagnosis and therapeutic opportunity for colorectal lesions[1-4]. At present, colonoscopy remains the gold standard investigation for inspecting colorectal lesions such as adenomas, cancer or inflammation. In many situations, it remains preferable to other imaging examinations such as computed tomography (CT) colonography or barium enema due to the capacity to intervene and sample or remove the pathology encountered.

Unlike sigmoidoscopy which can get to the distal portion (about 600 mm) of the colon, colonoscopy provides an investigation of the full colon (1200-1500 mm)[5,6]. The pain is not caused by the scope of the insertion but rather by the inflation of the colon to allow the inspection. The scope itself is essentially a long, flexible tube about a centimeter in diameter, *i.e.*, around the diameter of the little finger, which is less than the diameter of an average stool[7-9].

Increasingly, doctors like to operate on totally anesthetized patients because it allows for a calmer examination without perceived pain or discomfort. Compared with general anesthesia, twilight sedation is safer and it also allows the patient to follow simple commands and even to watch the operation on a monitor. Therefore, twilight sedation is generally best and the operator should not rush, even although the examination may cause discomfort. Tens of millions of people need colonoscopies annually and yet many of them refuse because of concerns about the procedure[9]. Propofol is a short-acting, intravenously administered hypnotic/amnestic agent. It is usually used in the induction and maintenance of general anesthesia, sedation for mechanically ventilated adults and procedural sedation. Propofol is also used in veterinary medicine[9-11].

Recently, propofol has replaced sodium thiopental for the induction of anesthesia in many hospitals because anabiosis is faster and "clearer" using propofol. Propofol is not a pain medication so it may be combined with opioids such as fentanyl to alleviate pain. Whether this is always necessary is unclear.

Propofol has been known as "milk of amnesia" (a play on milk of magnesia) because the intravenous preparation has a milk-like appearance. It is on the World Health Organization Model List of Essential Medicines. More than 50 countries have approved it for use and generic versions are available[11-15]. Some patients may develop propofol infusion syndrome (PRIS), a rare syndrome that affects patients who undergo long-term treatment with high doses of propofol (> 4 mg/kg per hour for more than 24 h). It can result in cardiac failure, kidney failure, metabolic acidosis and rhabdomyolysis and is often fatal. High blood potassium, high blood triglycerides and liver enlargement, possibly caused by either direct mitochondrial respiratory chain inhibition or impaired mitochondrial fatty acid metabolism, are also key features. Children are more likely to develop PRIS and critically ill patients who receive glucocorticoids and catecholamines are at high risk. The main treatment is supportive therapy[9,16,17]. Early recognition of the syndrome and discontinuation of the propofol infusion reduces morbidity and mortality.

Dezocine is an opioid analgesic which was first synthesized in 1970. It is a mixed agonist/antagonist of opioid receptors and has the effects of analgesic action and euphoria. However, it is a silent antagonist of the κ-opioid receptor and thus has no side effects such as hallucinations or dysphoria[18]. Dezocine was patented by the American Home Products Corp. in 1978. Clinical trials ran from 1979 to 1985 before its approval by the United States Food and Drug Administration in 1986. The use of dezocine was discontinued in the United States in 2011 but it is commonly used after surgery in China.

This study analyzed the clinical manifestations after the administration of dezocine combined with propofol in the anesthetization of indolent colonoscopy patients to assess its effects on gastrointestinal function. The incidence of adverse reactions and improvement of patient tolerance were also studied.

A cross-sectional survey was used to collect epidemiological evidence. The use of regularly collected data provides large cross-sectional studies at little or no expense[19-21], which is an important advantage

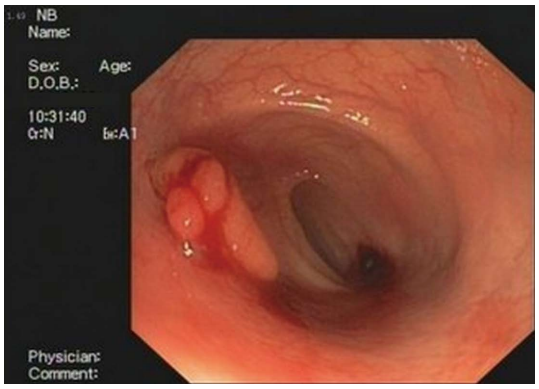

Figure 1 Colonoscopy image.

over other styles of epidemiological studies. A natural progression has been suggested from cheap cross-sectional studies of regularly collected data that can put forward hypotheses. However case-control studies test more specific hypotheses, cohort studies and trials cost much more and take much longer but provide stronger evidence. A cross-sectional survey is conducted to examine a specific group to determine whether alcohol consumption is correlated with cirrhosis being investigated. If alcohol is related to cirrhosis, this would support the hypothesis that alcohol may induce cirrhosis.

MATERIALS AND METHODS

General information

After obtaining institutional review board approval and informed consent from the participants or their guardians, 160 consecutive eligible patients previously diagnosed with indolent colonoscopy were enrolled in the study. All the patients had an ASA physical status of Ⅰ or Ⅱ and were aged between 1 and 68 years old.

All the experiments were performed under the supervision of the Patients' Experimental Ethics Committee of the Beijing Army General Hospital (Beijing, China). The cross-sectional survey, conducted from April 1 to April 30, 2015, recruited patients undergoing indolent colonoscopy in the Xinjiang People's Hospital. Patients with severe organ damage and drug allergies were excluded. This department does not operate on patients aged over 70 or under 1 year, or with a body mass index over 28 or under 18.

General epidemiological data and a history of neurological anesthetic drugs, including intravenous injection or oral drugs, were recorded.

Anesthesia methods

After identification of the patients, intravenous access to the appropriate area was established. All patients received 5 mg of anisodamine, avoiding microvascular spasm. Baseline hemodynamic data were recorded on arrival in the operating room after placement of routine monitors.

Anesthesia was induced with an intravenous injection of 5 mg of dezocine. Ten minutes later, 1.5-2.0 mg/kg of propofol was administered intravenously to induce anesthesia. The dose of propofol was adjusted to maintain the heart rate and blood pressure within 20% of the pre-induction values. No opioids were given intraoperatively. All patients received standardized colonoscopy by a practicing physician.

Evaluation index

The intraoperative index included the time the patient took to lose consciousness (from the induction of anesthesia until the eyelash conditioned reflex disappeared) and the total dosage of propofol.

The postoperative index included the length of time from the end of the colonoscopy surgery to the patient waking up and the patient's pain score in the observation room 30 min after surgery. Adverse reactions were investigated during two phases: the incidence of body movements and respiratory depression in the intraoperative phase and the incidence of vomiting and dizziness or headache in the postoperative phase.

Laboratory testing

Samples of venous blood were collected thirty minutes after the colonoscopy surgery. The biochemical indicators gastrin, vasoactive intestinal peptide, somatostatin and endothelin were tested using the radioimmunoassay (RIA) method. The RIA kits were purchased from the Chinese People's Liberation Army General Hospital, RIA Technology Development Center Institute (East Immunity Institute of Technology).

Statistical analysis

All data are represented as the means x ± SD (x ± s) of three or more independent experiments. Data with a positively skewed distribution were logarithmically transformed into a normal distribution. If the data were homogenous, analysis of variance, the Student-Newman-Keuls test and Pearson's correlation were used. If the data were not homogenous, the Kruskal-Wallis test, Games-Howell test and Spearman's correlation analysis were used. All the analyses were carried out using SPSS17.0 software (SPSS Inc., Chicago, IL, United States). Values below 0.05 were considered to be statistically significant.

RESULTS

Population investigation

From April 1 to April 30, 2015, 160 patients who had undergone dezocine combined with propofol in the anesthetization of indolent colonoscopy took part in the cross-sectional survey. Table 1 summarizes the patients' characteristics. There were 98 females and 62 males; therefore, there were more than 1.6 times

Table 1 Sample characteristics of patients receiving dezocine combined with propofol

as many females as males. They ranged from 1 to 68 years of age, with a median of 43, an average of 48 and a mode of 52 years. These figures indicate that indolent colonoscopy was more common among mid to older-aged patients.

There were 87 outpatients and 73 inpatients. For the purpose of health screening, more people chose indolent colonoscopy, especially the older patients. The necessary conditions for a diagnosis of digestive disease were required in 65 of the 73 inpatients (89.04%).

The patients' feedback about their overall medical experience indicated that 92 had a good medical experience, 58 had an average experience, but 9 had a bad experience and 1 had a very bad experience, which was concentrated in the younger age group. Only one child had no statistical significance.

Management survey for operation

According to the American Society of Anesthesiologists (ASA) grading, 89 patients were classified as P1, 62 as P2, and 9 as P3, but no patient was classified as P4, 5 or 6. All diagnoses met the standard clinical symptoms of the ASA.

The ASA physical status class risk stratification system is dependent on comorbid conditions that are a threat to life or limit activity, thus helping to predicting preoperative risks. They are as follows: (1) P1 - normal healthy patient; (2) P2 - patient with mild systemic disease; (3) P3 - patient with severe systemic disease; (4) P4 - patient with severe systemic disease that is a constant threat to life; (5) P5 - moribund patient who is not expected to survive without the operation; and (6) P6 - declared brain-dead patient whose organs are being removed for donor purposes. All the patients were assessed by the anesthetist before surgery and not by self-reporting.

Among the 160 anesthetized patients, two episodes of postoperative emesis were recorded which occurred after propofol anesthesia. No patient required additional medication for pain in the post-anesthesia care or normal unit. The anesthesia experience perceived by the parents of the children was more appropriate for dezocine combined with propofol. However, three patients reported dizziness 30 min after the operation.

Intraoperative adverse reactions included two cases of body movement and two cases of respiratory depression. The assessment and pain management methods were based on the World Health Organization classification. One hundred and thirty-two patients reported a pain level under 3. No patients reported a higher level of pain; however, 12 patients reported feeling exhausted and fatigued. These results are shown in Table 2.

Length of operation

The mean duration of surgery was 52 ± 24 min, the induction time was 10 ± 4 min and the duration of maintenance was 60 ± 23 min.

Laboratory results

Thirty minutes after the colonoscopy surgery, samples of venous blood were collected and four meaningful biochemical indicators of gastrointestinal function were assessed, as shown in Table 3. The results showed that gastrin and vasoactive intestinal peptide levels were slightly increased, whereas somatostatin and endothelin levels were slightly decreased.

Gastrin can increase gastric mucosal blood flow and protect the gastric mucosa. Vasoactive intestinal peptide can cause the relaxation of the pyloric sphincter. The decrease in somatostatin and endothelin levels helped to inhibit the relaxation of the smooth gastric muscles.

DISCUSSION

General anesthesia refers to a medically induced coma

Table 3 Biochemical indicators of gastrointestinal function

	Detection value	Reference value	Comparison
Gastrin (μg/mL)	88.94 ± 18.77	63.12 ± 28.71	Up
Vasoactive intestinal peptide (pg/mL)	58.33 ± 4.22	35.25 ± 3.12	Up
Somatostatin (pg/mL)	79.42 ± 4.26	108.25 ± 5.12	Down
Endothelin (pg/mL)	36.77 ± 9.12	48.91 ± 10.1	Down

with the lack of protective reflexes caused by one or more general anesthetic agents[1,12,21]. Various kinds of medications may be administered, with the aim of amnesia, analgesia, ensuring unconsciousness, relaxing the skeletal muscles and loss of control of the autonomic nervous system reflexes[9]. The optimal combination of these agents for any given patient and operation is usually chosen by the anesthesiologist or another provider, such as an anesthesiology assistant or nurse anesthetist, in consultation with the patient and the doctor conducting the operation.

Colonoscopy is the standard procedure for the diagnosis, screening, treatment and follow-up of many colorectal diseases[22,23]. Although some patients can tolerate the colonoscopy procedure without sedation or analgesics, the use of drugs in some patients is associated with stress. There are difficulties in determining an optimal dose for sedation and monitoring patients adequately during the procedure[24-27]. Many patients require intravenous benzodiazepines and opiates, which are associated with amnesic, anxiolytic and sedative properties. Combined administration of benzodiazepines and opioids has several undesirable effects, including a delay of several minutes from the time of injection before the drugs exert their effects, amnesia and the risk of respiratory depression[7,28,29].

Hospitals increasingly prefer to use fospropofol for colonoscopy. Fospropofol (trade name Lusedra) is an intravenous sedative-hypnotic agent. It is currently used for the sedation of adult patients undergoing diagnostic or therapeutic operations such as endoscopy. Some water-soluble prodrugs of propofol have been developed, of which fospropofol is known as the most fit for clinical development to date. Fospropofol is often administered combined with an opioid such as fentanyl. As a prodrug of propofol, it is metabolized into propofol by alkaline phosphatases. Theoretically, one millimole (mmol) of propofol may be generated for each mmol of fospropofol sodium administered; 1.86 mg of fospropofol sodium is the molar equivalent of 1 mg propofol[30-33].

Dezocine can be administered intravenously or intramuscularly. Dezocine is an effective painkiller compared with meperidine (pethidine) and a more effective analgesic than pentazocine but may cause greater respiratory depression. It is an effective drug for the treatment of pain but side effects such as dizziness restrict its clinical use and it also causes opioid withdrawal syndrome in patients already using other opioids[34].

A study conducted by the Department of Anesthesia, Xishan People's Hospital of Wuxi City in Jiangsu province explored the clinical effect of dezocine combined with propofol in the anesthetization of 60 patients undergoing indolent enteroscopy between July 2012 and June 2014. The patients were randomly divided into a research group that received dezocine combined with propofol and a control group that received fentanyl combined with propofol[33-36]. The total dosage of propofol in the research group was less than that in the control group ($P < 0.05$), the awakening time in the research group was shorter than in the control group ($P < 0.05$) and the number of adverse effects during and after surgery was lower in the research group than in the control group ($P < 0.05$). Dezocine combined with propofol applied in the anesthetization of indolent enteroscopy can have a remarkable effect, improve operational safety and decrease the occurrence of adverse reactions. Our results were consistent with those of this study.

According to the results of a study by the Department of Anesthesiology at the First Hospital of Quanzhou, age was an important influence on the pharmacodynamics of propofol in patients receiving propofol combined with dezocine while undergoing colonoscopy[37]. However, the results from the Department of Gastroenterology at the Second People's Hospital of Fujian province showed that endoscopic mucosal resection under painless colonoscopy shortened the recovery time, increased the success rate and improved the satisfaction rate of older patients who received propofol and fentanyl. Endoscopic mucosal resection under painless colonoscopy is an easy, safe and effective therapy for colorectal polyps.

Thirty minutes after colonoscopy surgery, samples of venous blood were collected and the biochemical indicators gastrin, vasoactive intestinal peptide, somatostatin and endothelin were tested. There was an increase in the plasma contents of gastrin and vasoactive intestinal peptide ($P < 0.05$) and a decrease in somatostatin and endothelin ($P < 0.05$) compared with the standard reference values[38-40].

Anesthesia with dezocine combined with propofol evidently increases gastric mucosal blood flow, suggesting that it has a regulative effect on gastrointestinal function. The use of dezocine combined with propofol might change plasma brain-gut peptides levels and may be useful.

COMMENTS

Background

Increasingly, doctors like to operate on totally anesthetized patients because it allows for a calmer examination without perceived pain or discomfort. Twilight sedation is safer than general anesthesia and allows the patient to follow simple commands and even to watch the operation on a monitor. Therefore,

twilight sedation is generally best and the operator should not rush, even although the examination may cause discomfort. Tens of millions of adults need colonoscopies annually and yet many refuse because of concerns about the procedure.

Research frontiers

This study assessed the use of dezocine combined with propofol for the anesthetization of patients undergoing indolent colonoscopy for the assessment of gastrointestinal function. A cross-sectional survey of patients undergoing indolent colonoscopy in the Xinjiang People's Hospital was conducted from April 1 to April 30, 2015. The survey collected general information and anesthesia data, including overall medical experience and pain management.

Innovations and breakthroughs

Indolent colonoscopy was found to be more suitable for mid to older-aged patients. Somatostatin and endothelin levels were slightly decreased and patients had a good medical experience.

Applications

Gastrin and vasoactive intestinal peptide levels were slightly increased. However, somatostatin and endothelin levels were slightly decreased. This clinical study of dezocine combined with propofol indicates that it is a successful method for the anesthetization of indolent colonoscopy patients without pain and should therefore be widely used.

Peer-review

In this study, the authors assessed the use of dezocine combined with propofol for the anesthetization of patients undergoing indolent colonoscopy for the assessment of gastrointestinal function. The study collected general information and anesthesia data, including overall medical experience and pain management. This clinical study of dezocine combined with propofol indicates that it is a successful method for the anesthetization of indolent colonoscopy patients without pain and should therefore be widely used.

Abstract

Although gastroduodenal ulcers are common in solid organ transplant patients, there are few reports on multiple giant ulcers in the distal ileum and ileocecal valve caused by immunosuppressants Herein, we report on a liver transplant recipient and a renal transplant recipient with multiple large ulcers in the distal ileum and ileocecal valve who rapidly achieved ulcer healing upon withdrawal of sirolimus or tacrolimus and administration of thalidomide. In case 1, a 56-year-old man with primary hepatocellular carcinoma had received a liver transplantation. Tacrolimus combined with sirolimus and prednisolone was used as the anti-rejection regimen. Colonoscopy was performed because of severe abdominal pain and diarrhea at post-operative month 10. Multiple giant ulcers were found at the ileocecal valve and distal ileum. The ulcers healed rapidly with withdrawal of sirolimus and treatment with thalidomide. There was no recurrence during 2 years of follow-up. In case 2, a 34-year-old man with end-stage kidney disease received kidney transplantation and was put on tacrolimus combined with mycophenolate mofetil and prednisolone as the anti-rejection regimen. Twelve weeks after the operation, the patient presented with hematochezia and severe anemia. Colonoscopy revealed multiple large ulcers in the ileocecal valve and distal ileum, with massive accumulation of fresh blood. The bleeding ceased after treatment with intravenous somatostatin and oral thalidomide. Tacrolimus was withdrawn at the same time. Colonoscopy at week 4 of follow-up revealed remarkable healing of the ulcers, and there was no recurrence of bleeding during 1 year of follow-up. No lymphoma, tuberculosis, or infection of cytomegalovirus, Epstein-Barr virus, or fungus was

found in either patient. In post-transplantation cases with ulcers in the distal ileum and ileocecal valve, sirolimus or tacrolimus should be considered a possible risk factor, and withdrawing them or switching to another immunosuppressant might be effective to treat these ulcers.

Key words: Ileal ulcers; Liver transplantation; Kidney transplantation; Sirolimus; Tacrolimus

Core tip: There are few reports available on ileal ulcers caused by immunosuppressants. Herein, we report a liver transplant recipient and a renal transplant recipient who had multiple large ulcers in the distal ileum and ileocecal valve. Ulcers rapidly healed after withdrawal of sirolimus or tacrolimus and administration of thalidomide. No lymphoma, tuberculosis, or infection of cytomegalovirus, Epstein-Barr virus, or fungus was found in either patient. There was no recurrence of ulcers or organ rejection. In some post-transplantation cases with ileal ulcers, sirolimus or tacrolimus should be considered as a risk factor because of their inhibitory effects on wound healing. Withdrawing them or switching to other immunosuppressants might be effective.

Guo YW, Gu HY, Abassa KK, Lin XY, Wei XQ. Successful treatment of ileal ulcers caused by immunosuppressants in two organ transplant recipients. *World J Gastroenterol* 2016; 22(24): 5616-5622 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i24/5616.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i24.5616

INTRODUCTION

Solid organ transplant recipients are susceptible to a variety of gastrointestinal (GI) complications, one of which is ulcer disease[1-5]. Most of these ulcers are located at the anastomotic stoma or gastroduodenum; ulcers at the intestine or colon are rare. In addition to *Helicobacter pylori* infection and ischemia, infection with cytomegalovirus (CMV), Epstein-Barr virus (EBV), mycobacteria, and fungus can contribute to ulcer disease in transplant recipients[1-5]. A few reports suggest that the use of immunosuppressants, especially high-dose immunosuppression after transplantation, might correlate with impairment of the gastrointestinal tract[6,7]. Herein, we report a liver transplant recipient and a renal transplant recipient with multiple large ulcers in the distal ileum and ileocecal valve who rapidly achieved ulcers healing upon withdrawal of sirolimus or tacrolimus and administration of thalidomide.

CASE REPORT

Case 1

A 56-year-old man with primary hepatocellular carcinoma received orthotopic liver transplantation in our hospital. Prior to the transplantation, he was diagnosed with chronic hepatitis B virus (HBV), Child-C liver function, and elevated blood glucose. No history of renal or cardiac disease or mycobacterium tuberculosis (TB) infection was noted. He denied smoking and drinking. Tacrolimus combined with sirolimus and prednisolone was used as the anti-rejection regimen. The dose of tacrolimus and sirolimus was adjusted according the drug serum concentration. The patient recovered and liver function improved to normal level. Entecavir was prescribed to prevent HBV reinfection.

After administration of the immunosuppressants, the patient began to develop mild peri-umbilical pain and diarrhea, which were tolerable at the time. Probiotics and antispasmodic treatment seemed not so effective. At 10 mo post-operation, he was admitted to our hospital because of severe diarrhea and abdominal pain. There were 7-10 bowel movements per day, with mucous blood stool. On physical examination, blood pressure, heart rate, and temperature were normal. There was slight tenderness on the peri-umbilicus area without rebound tenderness. Complete blood count revealed a leukocyte count of 11.50 × 10^9/L, erythrocyte count of 4.50 × 10^{12}/L, hemoglobin level of 121 g/L, platelet count of 295 × 10^9/L, neutrophils of 76.4%, and lymphocytes of 16.3%. Leukocytes and erythrocytes were found in the stool. The ratio of coccus to bacillus in stool was 1:9. Serum glutamic-oxaloacetic transaminase, glutamic-pyruvic transaminase, total bilirubin, BUN, creatine, and electrolytes were within normal range. Serum 1-3-β-D dextran was < 10 pg/mL. Blood and stool cultures for fungus and bacteria showed no growth. Chest computed tomography (CT) scan revealed no lesions and serum T-SPOT.TB was negative. Immunoglobulin (Ig)M and IgG of the EB virus were negative. Abdominal enhanced CT scan showed thickening of the distal ileum and ileocecal region, suggesting inflammatory lesions. The spleen was slightly enlarged, muddy stones were found in the common bile duct, and no enlarged lymphonodus was noted. Chronic erosive gastritis with negative *Helicobacter pylori* infection was confirmed through esophagogastroduodenoscopy. Colonoscopy revealed multiple giant and deep ulcers in the ileocecal valve and distal ileum, with polypoid hyperplasia. The length of the largest ulcer was up to 5.0 cm (Figure 1A-C). Histopathology of biopsy specimens revealed benign ulcers and chronic inflammation with non-caseous granulomas (Figure 2A and B), without signs of fungus and parasites infection. The immunohistochemical study was negative for CMV infection. EBV encoded

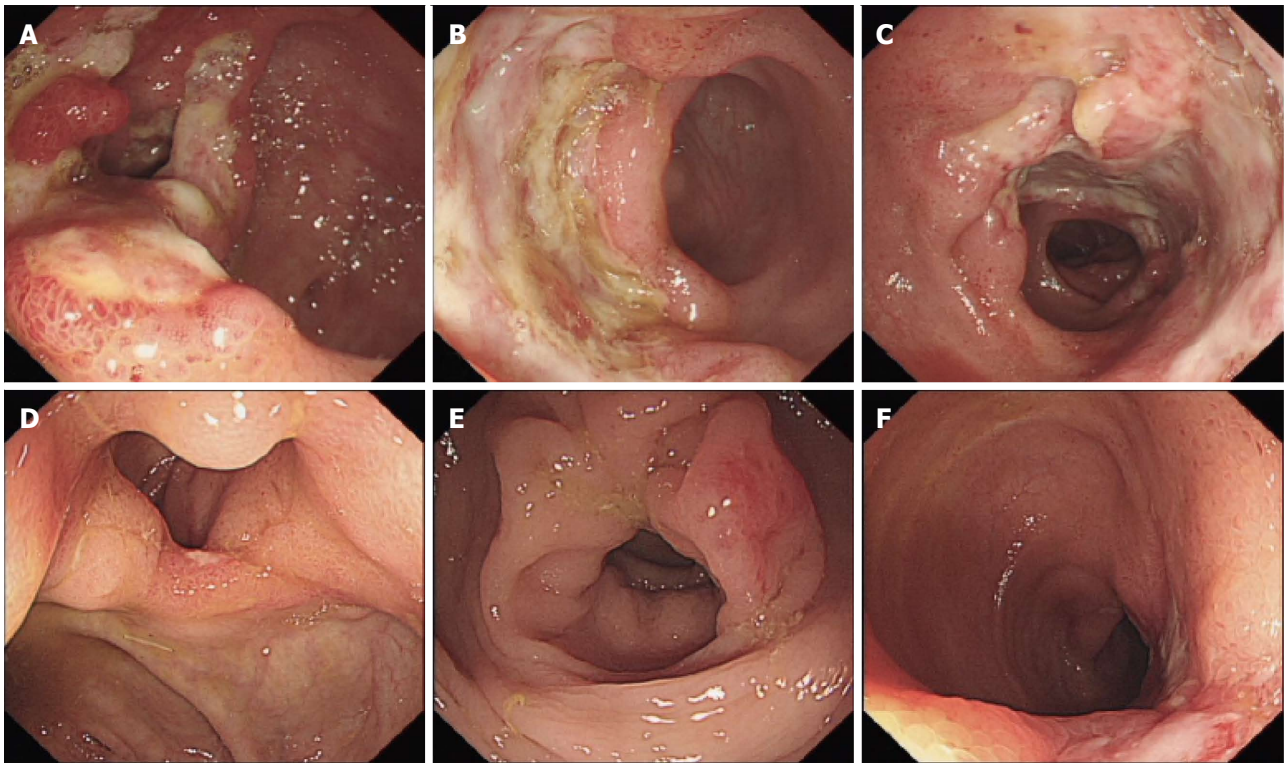

Figure 1 Colonoscopic images of case one. A-C: Multiple giant and deep ulcers in the ileocecal valve and distal ileum, with polypoid hyperplasia; D-F: Rapid healing of the ulcers in the ileocecal valve and distal ileum and only two healing 2 stage ulcers left.

early small RNA (EBER) was negative by *in situ* hybridization.

Considering sirolimus to have more gastrointestinal complications than tacrolimus in clinical application,

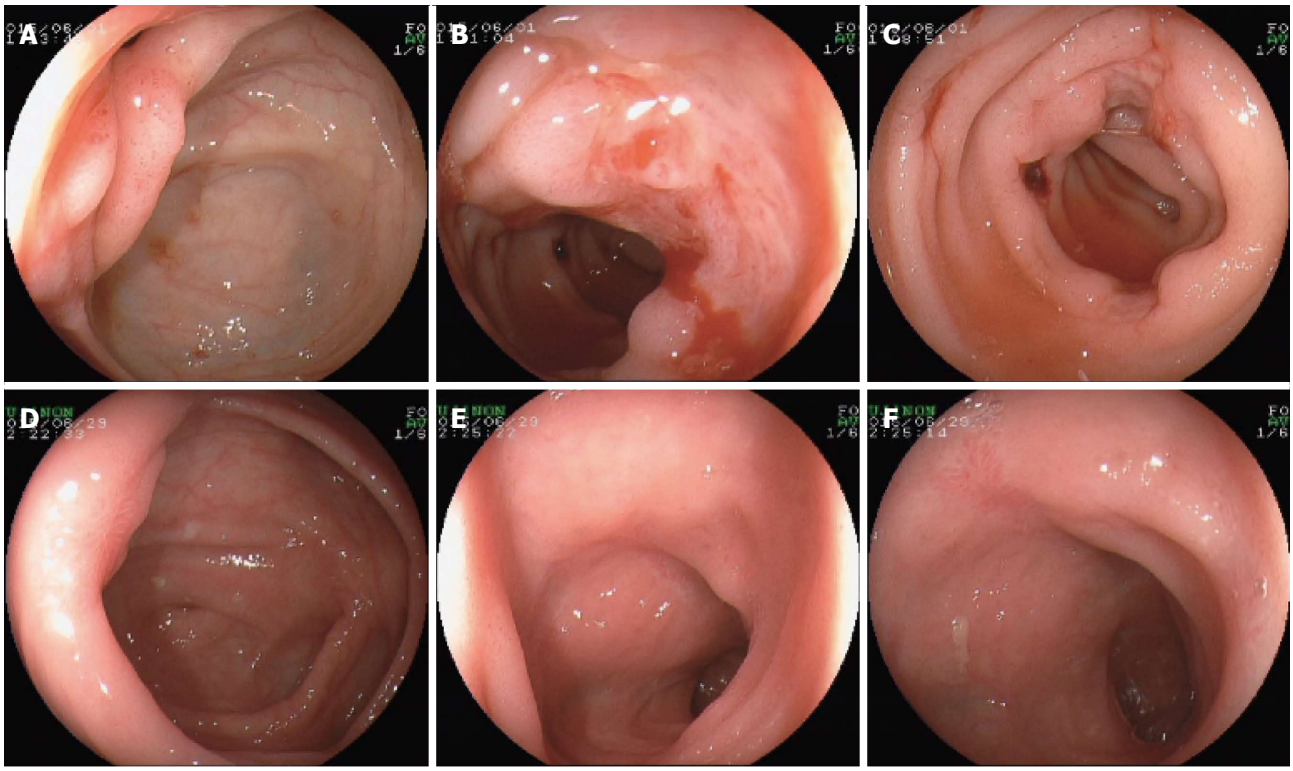

Figure 3 Multiple ulcers in ileocecal valve and distal ileum, with massive fresh blood accumulation (A-C); rapid healing of the ulcers with scar tissue in ileocecal valve and distal ileum (D-F).

sirolimus was withdrawn first. The patient was also put on oral thalidomide at a dose of 100 mg/d for 2 wk and intravenous antibiotics for one week. Diarrhea and abdominal pain were gradually relieved and subsided. Colonoscopy at week 6 of follow-up revealed remarkable healing of the ulcers in the ileocecal valve and distal ileum, and only two healing 2 stage ulcers were found (Figure 1D-F). No organ rejection was noted after withdrawing sirolimus. No recurrence of diarrhea and abdominal pain was noted during the 2 years of follow-up.

Case 2

A 34-year-old man with end-stage kidney disease was admitted to the department of renal transplantation for living-donor kidney transplantation. Except for kidney disease, he had no history of primary liver, heart, or head disease. He denied smoking and drinking. Tacrolimus combined with mycophenolate mofetil and prednisolone was applied as the anti-rejection regimen. The dose of tacrolimus was adjusted according to the drug serum concentration. At the same time, oral ganciclovir, voriconazole, and esomeprazole were used to prevent CMV and fungus infection and esophagogastroduodenal complications. The patient recovered smoothly. Serum creatinine level decreased to 152.0 μmol/L, and urine output was normal.

At postoperative week 12, the patient was admitted to our department because of repeated hematochezia for 2 wk, which was accompanied by dizziness and weakness. No abdominal pain, nausea, or vomiting was observed. On physical examination, blood pressure, heart rate, and temperature were 95/55 mmHg, 102 beats/min, 37.5 ℃, respectively. There was mild tenderness at the peri-umbilicus area and the lower right abdomen, without rebound tenderness. Complete blood count revealed a leukocyte count of 7.45 × 10^9/L, erythrocyte count of 2.05 × 10^{12}/L, hemoglobin level of 57 g/L, and platelet count of 241 × 10^9/L. Mild elevated serum creatinine level of 168.0 μmol/L was noted, with a normal BUN level of 6.8 mmol/L. Prothrombin time, apartprothrombin time, and thrombin time were within the normal range. Laboratory indices about hepatic, cardiac, and respiratory function were all normal. Blood and stool cultures for fungus and bacteria showed no growth. Chest CT scan revealed some pulmonary lesions of previous tuberculosis, and serum T-SPOT.TB was negative. There were no abnormal findings in the abdominal doppler ultrasound. Esophagogastroduodenoscopy was performed first, and only mild gastritis was observed, with negative rapid urease test for *Helicobacter pylori* infection. Colonoscopy revealed multiple ulcers in the ileocecal valve and distal ileum, with massive accumulation of fresh blood. These ulcers were oval and deep, covered with white fur or a blood scab, and the biggest had a diameter of 2.0 cm (Figure 3A-C). Histopathology revealed chronic inflammation with a large number of lymphocytes infiltration (Figure 2C

and D), without signs of fungus or parasite infection. Immunohistochemistry stain for CMV was negative. EBER was also negative by *in situ* hybridization.

The bleeding lessened and eventually ceased after treatment with intravenous somatostatin (1.2 mg/d) and oral thalidomide (100 mg/d) for 5 d. At the same time, because the multiple intestinal ulcers may be due to immunosuppressors, tacrolimus was withdrawn, and cyclosporine combined with mycophenolate mofetil and prednisolone were administered. Additionally, the patient was put on oral thalidomide at a dose of 100 mg/d for 4 wk. Colonoscopy at week 4 of follow-up revealed remarkable healing of the ulcers with scar tissue in the ileocecal valve and distal ileum (Figure 3D-F). There was no recurrent bleeding during the 1 year of follow-up. In addition, no organ rejection was found after withdrawing tacrolimus.

DISCUSSION

It is well known that solid organ transplantation patients are particularly at risk for GI complications. Severe GI complications such as GI bleeding and GI perforation may negatively influence long-term outcome and become deadly. It had been reported that GI bleeding occurred in 2.3%-6.4% patients after liver transplantation[8,9] and GI perforation in 2.9% patients after renal transplantation[7]. Ulcer diseases are an important cause of GI bleeding, and perforation can manifest with symptoms of abdominal pain or diarrhea. Most of these ulcers are located at the anastomotic stoma or gastroduodenum, whereas ulcers at the intestine or colon are rare. In the two cases described here, deep and large ulcers were located in the ileocecal valve and distal ileum with no lesions in the gastroduodenum. In case 1, there was a longer period of diarrhea and abdominal pain, while case 2 mainly presented with acute and massive GI bleeding.

Differentiation of ulcer diseases in post-transplantation patients is always difficult. Common and uncommon pathogenesis such as *Helicobacter pylori* infection, ischemia, infection of CMV, EBV, mycobacteria, and fungus, and post-transplant lymphoproliferative disorders (PTLDs) should be considered. In the present two cases, ulcers were in the ileocecal valve and distal ileum, and *Helicobacter pylori* infection was ruled out as the pathogen. Clinical manifestation and endoscopic characteristics of ulcers were not consistent with a pathogenesis of ischemia. Because of negative the findings on chest CT scan, serum T-SPOT.TB, and histopathology of ulcers, mycobacteria and fungus infection were also excluded. CMV infection is common in patients with solid organ transplantation, and attention should be paid in cases of gastrointestinal ulcers. In a study of renal transplant patients susceptible to a variety of GI complications, such as infections, ulcer disease, and malignancies, CMV infection occurred in 11% of all patients[1]. Although oral ganciclovir preventive strategy was used in case 2, this treatment might be inefficient in some patients, and atypical symptoms might be present[10,11]. Decreased leukocyte count and interstitial pneumonitis are always found in CMV infection, but in both of our cases, no positive signs about CMV infection were noted in leukocyte count or chest CT scan. More importantly, immunohistochemistry stain for CMV of ulcer biopsy tissue was negative, and both patients recovered without further anti-CMV therapy. Therefore, CMV infection was not considered the cause of ulcers in these two cases.

PTLD was most difficult to be excluded in both patients. This was especially true in case 1, where the ulcers in the ileocecal valve and distal ileum appeared deeper and larger, with surrounding proliferative tissue. PTLD is a severe complication after organ transplantation with a cumulative incidence of 1.1% at 18 mo and 4.7% at 15 years, and it is always associated with EBV infection[12]. Lymph nodes, GI tract, and graft liver are the most common sites of involvement[13]. The involvement of the GI tract could result in deadly perforation and hemorrhage. In both patients, no persistent fever, palpable superficial lymph nodes, enlarged liver, or lymph nodes were found on chest and abdominal CT scan or ultrasound; EBER was negative by *in situ* hybridization. Pathology was also not consistent with the characteristics of PTLD. Furthermore, PTLD usually deteriorates quickly and is difficult to treat. However, the present two patients were stable within 1-2 wk, and the ulcers healed rapidly in 4-6 wk. Taken together, the evidence did not support the diagnosis of PTLD.

Finally, we considered that ulcer development was related to the use of immunosuppressants. Current studies have shown that some immunosuppressants, such as mammalian target of rapamycin inhibitors, had inhibitory effects on wound healing. Sirolimus is the most common drug that can lead to impairment of wound healing, and the most common wound complication is skin or dermal eruption[14-17]. Therefore, the immunosuppressant use was considered to be a possible cause of GI epithelium impairment. Fortunately, both patients recovered quickly after withdrawing sirolimus and tacrolimus, supporting our speculation. In Smith *et al*[6], three liver transplant patients taking sirolimus suffered from gastrointestinal hemorrhage due to complications of gastroduodenal ulcers. The ulcers in two patients healed only after discontinuation of sirolimus, and the third patient died of massive gastrointestinal bleeding[6].

Thalidomide has anti-angiogenic properties and seems effective in some cases of GI bleeding, especially angiodysplasia-related bleeding[18-20]. It is also used in some inflammatory and ulcerative diseases like inflammatory bowel disease and some skin and oral ulcers, because of its anti-inflammatory and immunomodulatory effects[20-22]. In our clinical practice, thalidomide is effective in some unexplained

and refractory multiple ulcers of intestine and related GI bleeding. It also seemed to work in our present two patients. Thalidomide was administrated at a dose of 100 mg/d for 2 wk and 4 wk respectively, and no severe side effects were found.

In summary, some types of immunosuppressants, such as sirolimus and tacrolimus, can lead to impairment of the GI track and sometimes to the development of severe ulcers. Withdrawing them or switching to other immunosuppressants might be effective to treat these ulcers.

COMMENTS

Case characteristics

A 56-year-old man presented with severe diarrhea and abdominal pain after orthotopic liver transplantation, and a 34-year-old man presented with hematochezia and severe anemia after living-donor kidney transplantation.

Clinical diagnosis

Multiple giant ulcers in the distal ileum and ileocecal valve were caused by immunosuppressants.

Differential diagnosis

Common and uncommon pathogenesis of gastrointestinal (GI) ulcers in solid organ transplant recipient, such as *Helicobacter pylori* infection, ischemia, infection of cytomegalovirus (CMV), Epstein-Barr virus (EBV), mycobacteria and fungus, and post-transplant lymphoproliferative disorders (PTLDs), should be considered.

Laboratory diagnosis

Blood and stool cultures for fungus and bacteria showed no growth, and serum T-SPOT.TB was negative.

Imaging diagnosis

Computed tomography (CT)scan revealed no current tuberculosis, and there were no abnormal findings on abdominal enhanced CT or doppler ultrasound.

Endoscopic diagnosis

Colonoscopy revealed multiple giant and deep ulcers in the ileocecal valve and distal ileum.

Pathological diagnosis

Histopathology revealed chronic inflammation without signs of fungus or parasite infection, negative immunohistochemistry stain for CMV, and negative stain for EBV encoded early small RNA by *in situ* hybridization.

Treatment

Sirolimus or tacrolimus was withdrawn, and thalidomide was administrated.

Related reports

Most GI ulcers are located at the anastomotic stoma or gastroduodenum in post-transplant recipients, and ulcers at the intestine or colon are rare. Besides ischemia and infection of CMV, EBV, mycobacteria, and fungus, use of immunosuppressants might contribute to the impairment of gastrointestinal tract.

Term explanation

PTLDs are a severe complication of solid organ and hematopoietic stem cell transplantation, including lymphoproliferative entities varying from reactive hyperplasia to malignant lymphoma. EBV is the main pathogen of PTLD.

Experiences and lessons

In some post-transplantation cases with ileal ulcers, sirolimus or tacrolimus should be considered as a risk factor, and withdrawing them or switching to other immunosuppressants might be effective.

Peer-review

This article is very interesting for those in the field of liver and kidney transplantation. Since ulcers in the distal ileum in solid organ transplant recipients are very rare, experience about the management of these patients is very useful.
