Abstract

Colorectal cancer (CRC) is one of the most common cancers and a leading cause of cancer-related mortality worldwide. Although systemic therapy is the standard care for patients with recurrent or metastatic CRC, the prognosis is extremely poor. The optimal sequence of therapy remains unknown. Therefore, alternative strategies, such as immunotherapy, are needed for patients with advanced CRC. This review summarizes evidence from dendritic cell-based cancer immunotherapy strategies that are currently in clinical trials. In addition, we discuss the possibility of antitumor immune responses through immunoinhibitory PD-1/PD-L1 pathway blockade in CRC patients.

Key words: Colorectal cancer; Dendritic cell; Cancer immunotherapy; Cytotoxic T lymphocyte; Immune-checkpoint inhibitors

Core tip: Dendritic cell (DC) is potent antigen-presenting cells that play a pivotal role in the induction of antitumor immune responses. Strategies for delivering antigens to DCs have been developed and used in clinical trials

in cancer patients, including colorectal cancer (CRC). Numerous reports indicate that the use of DC-based immunotherapy for CRC patients is promising to induce antigen-specific CTL responses. However, the immune suppression induced through CRC and the tumor microenvironment continues to be a major hurdle. Thus, the combination of DC-based immunotherapy with immune-modulating agents may be necessary to maximize antitumor immunity. These combinatorial therapies may have the potential for clinical benefit.

Kajihara M, Takakura K, Kanai T, Ito Z, Saito K, Takami S, Shimodaira S, Okamoto M, Ohkusa T, Koido S. Dendritic cell-based cancer immunotherapy for colorectal cancer. *World J Gastroenterol* 2016; 22(17): 4275-4286 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4275.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4275

INTRODUCTION

Colorectal cancer (CRC) is a common cancer and remains one of the leading causes of cancer-related deaths worldwide. Although surgery is the only curative treatment available for localized disease, more than 20% of CRC patients are not eligible for surgery due to liver metastases at the time of diagnosis[1]. To date, surgery, neoadjuvant radiotherapy and adjuvant chemotherapy have improved the outcome of CRC patients; however, 50% of patients still die from recurrent or metastatic disease[1,2]. Indeed, the treatment of CRC patients with distant metastases or recurrence through surgery or chemotherapy currently remains limited. Therefore, alternative strategies, including immunotherapy, for treating advanced CRC have been considered[3].

Recent studies have suggested that CRC is a good candidate for immunotherapy. As potential targets for cancer immunotherapy, human CRC cells express numerous numbers of tumor-associated antigens (TAAs), such as carcinoembryonic antigen (CEA)[4-6], Wilms' tumor gene 1 (WT1)[7,8], mucin 1 (MUC1)[4,9], melanoma-associated antigen gene (MAGE)[10-12], or p53[13]. Moreover, CRC is a heterogeneous disease with genetic and epigenetic characterizations, such as the mutation of oncogenes, microsatellite instability (MSI) phenotype, chromosomal instability (CIN) pathway, CpG island methylator phenotype (CIMP), and DNA hypomethylation[14]. For example, the MSI phenotype reflects various deficiencies in the DNA mismatch-repair system, leading to an increased mutation rate of oncogenes[15]. The CIN pathway in cancers reveals aneuploidy and chromosomal rearrangements[15]. Cancers with the CpG island methylator phenotype (CIMP) exhibit DNA methylation associated with the transcriptional inactivation of tumor-suppressor genes[15]. These genetic and epigenetic characterizations lead to multiple mutations of oncogenes, resulting in immunogenic CRC. Therefore, some patients with CRC may be effective candidates for immunotherapy. Moreover, immunotherapy mediates a potent antitumor effect when combined with chemotherapy and/or radiotherapy[16-18]. Indeed, cancer immunotherapy targeting these TAAs can be combined with surgery, radiotherapy, and conventional chemotherapy for treating patients with CRC. Interestingly, given the success of immune-checkpoint inhibitors in several tumors, we believe that cancer immunotherapy may also be combined with immune checkpoint blockade agents to induce efficient antitumor immunity in CRC patients.

ANTITUMOR IMMUNITY

T cells with the αβ T cell receptor (TCR) generally express $CD4^+$ or $CD8^+$ lineage markers and have primarily been classified as helper or cytotoxic subsets, respectively[19]. Major histocompatibility complex (MHC) class Ⅰ molecules on cancer cells bound to antigenic peptide derived from tumor-associated antigens (TAAs) are recognized by the TCR of $CD8^+$ T cells. However, $CD4^+$ T cells recognize peptides in association with MHC class Ⅱ molecules on antigen-presenting cells (APCs)[3,19]. The goal of cancer immunotherapy is to induce efficient antigen-specific cytotoxic $CD8^+$T cells (CTLs). The induction of efficient $CD8^+$ CTLs requires helper functions mediated through $CD4^+$ T cells *via* the production of cytokines, such as interleukin (IL)-2 and interferon (IFN)-γ, resulting in the maintenance of antigen-specific $CD8^+$ CTLs[20,21]. Therefore, the simultaneous interaction of the TCR of T cells with antigenic peptides/MHC class Ⅰ and class Ⅱ complexes on APCs is essential for the induction of $CD4^+$ and $CD8^+$ T cell-mediated antitumor immune responses. Moreover, antigen-specific $CD8^+$ CTLs respond to antigenic peptides presented by MHC class Ⅰ molecules on cancer cells and identify and kill TAA-expressing cancer cells.

Dendritic cells (DCs) are potent APCs that play a pivotal role in the initiation, programming, and regulation of antitumor immune responses[20]. DCs capture antigens, resulting in a mature phenotype and the release of IL-12 from DCs. The exogenous antigens are processed by DCs, and antigenic peptides are presented on MHC class Ⅰ molecules, a process known as antigen cross-presentation[20]. In addition, DCs also process endogenously synthesized antigens into antigenic peptides, presented to MHC class Ⅰ molecules. However, exogenous antigens are also processed to antigenic peptides and complexed with MHC class Ⅱ molecules[20,21]. Antigen presentation primarily occurs in the draining lymph node, where antigenic peptides are presented by DCs, resulting in the simultaneous activation of $CD4^+$ and $CD8^+$ T cells. Moreover, interactions between DCs and innate and innate-like immune cells, such as natural killer (NK), invariant natural killer T (iNKT), and γδ T cells,

can bypass the T helper arm in CTL induction[22,23]. NK, iNKT, and γδ T cells also have the ability to attack tumor cells directly[23]. Therefore, efficient induction of antitumor immunity *via* DC-based cancer vaccines may require interaction between DCs and innate and innate-like immune cells with central roles in DC-based cancer immunotherapy[23,24].

Cancer immunotherapy, including peptide vaccines, whole tumor cell vaccines, viral vector vaccines, and adopted cell transfer therapy, have been developed to treat CRC patients[3]. In particular, peptide vaccines have been widely tested in clinical trials, reflecting the simple, safe, stable, and economical features of these vaccine types. However, there are several drawbacks to the peptide vaccines, including: (1) limitations due to the MHC type; (2) limited numbers of identified epitopes; and (3) impaired DC function in cancer patients[3,25]. Therefore, DCs have been loaded with multiple antigenic peptides[26-28], whole tumor cell-mRNA[29], whole tumor cell lysates[30], and whole tumor-derived apoptotic bodies[31] or fused with whole tumor cells to form hybrid cells (DCs-tumor fusions)[32]. DC-tumor fusion cells process a broad array of TAAs, including both known and unidentified, and present these molecules by MHC class Ⅰ and class Ⅱ pathways in the context of co-stimulatory molecules[32,33]. In our laboratory, patient-derived DCs are generated through adherent mononuclear cells from a single leukapheresis collection after culture in the presence of granulocyte macrophage colony-stimulating factor (GM-CSF) and IL-4. Immature DCs are matured with penicillin-killed and lyophilized preparations of a low-virulence strain (Su) of *Streptococcus pyogenes* (OK-432) and with prostaglandin E2 (PGE2). Subsequently, a large number of DCs can be cryopreserved in ready-for-use aliquots for immunotherapy[27].

IMMUNOSUPPRESSION MECHANISMS

Although antigen-specific CTLs are induced in cancer patients, cancer cells often escape immune surveillance through several mechanisms, including (1) the down-regulation of certain antigens, TAP-1/2, MHC class Ⅰ, or peptide-processing machinery in tumor cells[34,35]; (2) the induction of regulatory T cells (Tregs) producing proinflammatory and immunosuppressive cytokines, such as IL-10 and TGF-β[36]; (3) the presence of immunosuppressive cells (*e.g.,* cancer-associated fibroblasts (CAFs), M2 macrophages, myeloid-derived suppressor cells (MDSCs), immunosuppressive tumor-associated macrophages (TAMs), tolerogenic DCs, and Tregs) in the tumor microenvironment[36]; (4) the production of multiple immune suppressive factors from tumor cells[37]; and (5) the expression of immune checkpoint blockade between tumor cells and activated T cells[38,39]. Although, activated $CD8^+$ T cells associated with clinical prognosis often infiltrate in CRC[40], this benefit is controlled through immune suppressive cell populations in the tumor microenvironment, promoting tumor escape from immune surveillance[14,41,42]. The direct production of immune suppressive factors, such as IL-6, IL-10, TGF-β, vascular endothelial growth factor (VEGF), soluble Fas ligand (Fas-L), and indolamine-2,3-dioxygenase (IDO), by tumor cells also promotes the accumulation of heterogeneous populations of CAFs, M2 macrophages, TAMs, MDSCs, tolerogenic DCs, and Tregs[37]. These immunosuppressive cells in the tumor microenvironment inhibit antitumor immunity through various mechanisms, including the elaboration of arginase (Arg), nitrogen oxide (NO), and reactive oxygen species (ROS) from immunosuppressive cells[37]. Indeed, the tumor microenvironment is extremely complex and suppresses antitumor immunity, thus explaining why cancer immunotherapy is occasionally unsuccessful[41]. Therefore, the functional inhibition of Arg, NO, or ROS in immunosuppressive cells may augment antitumor immunity.

Programmed death 1 (PD-1) is expressed on the surface of activated T cells and inhibits T cell activation upon binding to the associated ligands PD-L1/PD-L2[3]. Moreover, cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) is another mechanism that inhibits T cell activation upon binding CD80/CD86 on DCs. CTLA-4 is expressed on naive or memory T cells. PD-1 is highly expressed in antigen-specific CTLs and activated DCs. PD-L1 is not constitutively expressed in some tumors but is induced in response to inflammatory signals, such as IFN-γ, produced by antigen-specific CTLs. In contrast, the CTLA-4-mediated immune checkpoint is induced in T cells during the initial response to antigen. Therefore, antibodies can be used to block inhibitory ligand-receptor interactions by acting on tumor cells and DCs (*e.g.*, anti-PD-L1) or T cells (*e.g.*, anti-CTLA-4 or anti-PD1). Indeed, CRC cells express PD-L1 associated with CTL inactivation and Treg development in the tumor microenvironment, resulting in worse survival[43-45]. Combining the blockade of multiple immune inhibitory pathways may synergistically activate antitumor immunity.

DC-BASED PASSIVE IMMUNOTHERAPY

DC-based cancer immunotherapy has been developed to induce TAA (*e.g.,* CEA, WT1, MAGE, or MUC1)-specific CTLs in patients with CRC. To date, various strategies for delivering TAAs to DCs have been developed and tested in clinical trials in cancer patients, including CRC (Table 1). In particular, as most CRC cells express CEA, CEA-targeted DC-based CRC immunotherapy has been reported.

CEA

CEA is a so-called onco-fetal antigen abundantly present in a majority of CRC cases. Importantly, the elevated expression of CEA is associated with adenocarcinoma, particularly CRC. Therefore, CEA-

Table 1 Clinical trials of dendritic cell-based cancer immunotherapy in patients with colorectal cancer

Targets	Immunotherapy	Phase	Patients	Results	Ref.	Year
CEA	DCs loaded with CEA peptide (HLA-A2 restricted)	I	21 advanced CEA-expressing malignancies including 11 CRC	Skin punch biopsy at DC injection sites demonstrated pleomorphic, perivascular infiltration of cells consistent with a DTH response	Morse *et al*[46]	1999
	DCs loaded with CEA mRNA	I	13 patients with resected hepatic metastases of CRC	9 of the 13 CRC patients relapsed at a median of 122 d	Morse *et al*[47]	2003
	DCs modified with a recombinant fowlpox vector encoding CEA and a triad of costimulatory molecules [rF-CEA(6D)-TRICOM]	I	14 patients with HLA-A2 (11 CRC and 3 non-small cell lung cancer)	CEA-specific T cells responses were detected in 10 patients; 5 patients were stable through at least 1 cycle of immunization (3 mo)	Morse *et al*[48]	2005
	Fowlpox vector encoding CEA	I	14 patients (5 CRC, 3 lung cancer, and 1 urachal adenocarcinoma)	Of the 9 patients analyzed, all with stable disease (n = 5) displayed increased NK activity	Osada *et al*[49]	2006
	Mature DCs induced by activation with a combination of OK-432, low-dose prostanoid, and IFN-α and loaded with CEA peptide		10 CRC patients	CRC patients with stable disease (n = 8) exhibited increased levels of NK cell frequency and CEA-specific CTL activity with a central memory phenotype. Lack of CTL activity was found in 2 CRC patients with progressive disease, but NK cell proliferation was detected	Sakakibara *et al*[51]	2011
	DCs loaded with altered CEA peptide (HLA-A2 restricted) with Flt3 ligand	I	12 patients with HLA-A2$^+$ malignancies (10 CRC and 2 non-small cell lung cancer)	CEA-specific CD8$^+$ CTLs were detected in 7 patients; 1 patient with progressive metastatic CRC had a complete resolution of pulmonary metastasis and malignant pleural effusion at 4 mo after vaccination, and 1 patient with CRC developed a mixed response after vaccination, with regression of some but not all liver metastases	Fong *et al*[52]	2001
	DCs loaded with CEA peptide (HLA-A24 restricted)	I	10 advanced CEA-expressing malignancies including 7 CRC	2 patients (CRC and lung cancer) exhibited positive DTH reactions against CEA and remained stable for 6 and 9 mo, respectively	Itoh *et al*[53]	2002
	DCs loaded with CEA peptides (HLA-A2- or HLA-A24-restricted)	I	10 CRC patients (6 HLA-A24 and 4 HLA-A2) who had failed standard chemotherapy	CEA-specific CTLs were detected in 7 patients; 2 patients exhibited stable disease for at least 12 wk	Liu *et al*[54]	2004
	DCs loading with CEA peptide (HLA-A24 restricted)	I	8 patients with advanced CEA-expressing gastrointestinal malignancies (7 CRC and 1 gall bladder cancer)	4 patients developed CEA-specific CTL responses; a DTH reaction was observed in 1 patient, with skin biopsy at the injection site showing lymphocyte infiltration, and 3 patients, including 2 CRC, exhibited stable disease after vaccination	Matsuda *et al*[55]	2004
	DCs loaded with CEA peptide (HLA-24 restricted)	I	8 patients with CEA-expressing metastatic gastrointestinal or lung adenocarcinoma	Long-term stable disease or marked decreases in the serum CEA level was observed in some patients. CEA-specific immune responses were demonstrated in most of the patients in whom treatment was clinically effective	Ueda *et al*[56]	2004
	DCs loaded with CEA peptide (HLA-2 restricted)	I	10 CRC patients with resection of liver metastases	CEA-specific CTLs were demonstrated in 7 patients; CEA-specific CTLs were detected in a resected lymph node in 1 patient	Lesterhuis *et al*[57]	2006
	DCs loaded with CEA altered peptide	I	9 patients with CEA-expressing malignancies (7 CRC and 2 lung cancer)	5 patients exhibited CEA altered peptide-specific CTL responses, and 3 patients exhibited CEA-specific CTL responses	Babatz *et al*[58]	2006
WT1	DCs loaded with WT1 peptide (MHC class Ⅰ and class Ⅱ restricted)	I	3 advanced CRC	WT1-specific CTLs were detected and persisted for 2 yr with prolonged disease-free and overall survival	Shimodaira *et al*[8]	2015

MAGE	DCs loaded with MAGE-3 peptide (HLA-A2 or A24 restricted)	I	12 patients with advanced gastrointestinal carcinoma (6 stomach, 3 esophagus, and 3 CRC)	MAGE-3-specific CTL responses were observed in 4 patients. Tumor markers were decreased in 7 patients, and evidence of minor tumor regression was detected in 3 patients	Sadanaga *et al*[65]	2001
	DCs loaded with MAGE-3 or MAGE-1 peptides (HLA-A2 0r A24 restricted)	I	28 patients with advanced gastrointestinal carcinoma, including 7 CRC	Peptide-specific CTL responses, tumor marker decreases, and minor tumor regressions were observed in some patients after vaccination	Tanaka *et al*[66]	2008
CEA and MUC1	DCs modified with CEA/MUC1 (PANVAC)	II	74 patients, disease free after CRC metastasectomy and perioperative chemotherapy	CEA-specific CTLs were detected	Morse *et al*[67]	2013
CEA, MAGE, and HER2	DCs loaded with CEA/MAGE/HER2/neu/pan-DR peptides (HLA-A2 restricted) and keyhole limpet hemocyanin (KLH) protein	I	13 advanced CRC	All patients exhibited progressive disease. CEA-specific CTLs were detected in 3 of 11 evaluated patients. Multiple TAAs-specific CTLs were induced	Kavanagh *et al*[70]	2007
Autologous whole tumor mRNA	DCs transfected with whole-tumor mRNA	I	15 advanced CRC received the immunotherapy and KLH intravenously	11 of the 13 CRC patients evaluated developed a positive KLH skin test, and 7 CRC patients exhibited CEA-specific responses	Rains *et al*[75]	2001
Autologous whole tumor cells	DCs-autologous whole-tumor fusion cells and IL-12	I	5 gastrointestinal tumors, including CRC	Among the 3 patients evaluated, 1 exhibited stable disease, and 2 exhibited progressive disease. No DTH-positive patients were detected in this trial. Good therapeutic responses in some patients with brain tumors were detected	Homma *et al*[78]	2005
Allogeneic whole tumor cell lysate	DCs loaded with allogeneic tumor cell lysate	I	6 advanced CRC (HLA-A2)	Antitumor immune responses in some patients and transient stabilization or even reduction of CEA levels were detected	Tamir *et al*[82]	2007
	DCs loaded with allogeneic melanoma cell lysate expressing at least one of six MAGE-A antigens	II	20 advanced CRC	1 patient experienced a partial response, 7 patients achieved stable disease, and 5 patients exhibited prolonged progression-free survival	Toh *et al*[83]	2009

DC: Dendritic cell; CRC: Colorectal cancer; DTH: Delayed-type hypersensitivity; CTL: Cytotoxic T lymphocyte.

targeted cancer immunotherapy has been developed. Morse *et al*[46] first conducted a phase I study using DCs loaded with an HLA-A2-restricted CEA peptide for the treatment of patients with 21 advanced CEA-expressing malignancies, including 11 CRC cases. One patient with ovarian cancer had a minor response, and one patient with breast cancer exhibited stable disease. Skin punch biopsy at DC injection sites demonstrated the pleomorphic, perivascular infiltration of cells consistent with a delayed-type hypersensitivity (DTH) response. This group also reported a phase II study of 13 patients with resected hepatic metastases of CRC, who received DCs loaded with CEA mRNA (DC/CEA mRNA). The administration of DC/CEA mRNA to CRC patients was feasible and safe. Nine of the 13 patients relapsed at a median of 122 days[47]. Furthermore, DCs modified with a recombinant fowlpox vector encoding CEA and a triad of costimulatory molecules [rF-CEA(6D)-TRICOM] was developed from the same group[48]. In this trial, 14 patients with HLA-A2 (11 with CRC and 3 with non-small cell lung cancer) were enrolled. CEA-specific T cells responses were detected in 10 patients. Five patients were stable through at least one cycle of immunization (3 mo)[48]. As recent reports indicate that DC-NK cell interaction plays a critical role in the induction of antitumor immunity[23,24], the same group conducted a phase I clinical trial of a vaccine consisting of autologous DCs loaded with a fowlpox vector encoding CEA[49]. Fourteen patients (5 CRC, 3 lung cancer, and 1 urachal adenocarcinoma) were enrolled in the trial; of the 9 patients analyzed, all with stable disease (n = 5) exhibited increased NK activity. Therefore, NK responses following DC vaccination may correlate with clinical benefit, and evaluation of NK responses should accordingly be included as a biomarker for DC-based cancer vaccines in clinical trials[49,50]. Another recent clinical trial also supports the importance of NK activity in CEA peptide-loaded DC-based cancer vaccines. In this trial, mature DCs activated by a combination of OK-432, low-dose prostanoid, and IFN-α were used[51], loaded with the CEA peptide and administrated to 10 CRC patients. Interestingly, the CRC patients with stable disease (n = 8) exhibited increased levels of NK cell frequency and CEA-specific CTL activity with a central memory phenotype. Conversely, a lack of CTL activity was observed in those with progressive disease, even though NK cell proliferation was detected. To induce efficient CEA-specific CTL responses, another study developed altered CEA peptides restricted with HLA-

A2-loaded DCs, which were administered along with Flt3 ligand, a hematopoietic growth factor, to 12 patients with CRC (n = 10) or non-small cell lung cancer (n = 2)[52]. After vaccination, the expansion of CEA-specific $CD8^+$ CTLs was detected in 7 out of 12 patients. Interestingly, 2 out of 12 CRC patients experienced dramatic tumor regression. One patient with progressive metastatic CRC had a complete resolution of pulmonary metastasis and malignant pleural effusion at 4 mo after vaccination, and one patient with CRC developed a mixed response after vaccination, with the regression of some but not all liver metastases. Clinical trials of DCs loaded with HLA-A24 restricted CEA peptides have also been reported. The vaccines were injected with adjuvant cytokines, such as natural human interferon alpha (IFN-α) and natural human tumor necrosis factor alpha (TNF-α), in patients with 10 advanced CEA-expressing metastatic malignancies, including 7 CRC cases[53]. Two patients (CRC and lung cancer) exhibited positive DTH reactions against CEA remained stable for 6 mo and 9 mo, respectively. Therefore, HLA-A24 and A2-restricted CEA peptide might be useful for inducing CEA-specific immune responses. Liu *et al*[54] immunized 10 metastatic CRC patients (6 patients with HLA-A24 and 4 with HLA-A2) who failed standard chemotherapy with DCs loaded with HLA-A2- or HLA-A24-restricted CEA peptides. In this clinical trial, the DC vaccine was injected into one inguinal lymph node under sonographic guidance. After vaccination, CEA-specific T cells were detected in 7 out of 10 patients. Two patients exhibited stable disease for at least 12 wk. Matsuda *et al*[55] also conducted a pilot study of DCs loaded with HLA-A24-restricted CEA peptide for 8 patients with advanced CEA-expressing gastrointestinal malignancies (7 CRCs and 1 gall bladder cancer). Four out of 7 patients developed CEA-specific CTL responses after vaccination. A DTH reaction was observed in 1 patient. Skin biopsy at the injected site showed the infiltration of lymphocytes. Three patients, including 2 CRCs, exhibited stable disease after vaccination. Reports from clinical trials using DCs loaded with HLA-restricted CEA peptide vaccines have also been reported in Japan, as 60% of the Japanese population and some Caucasians express HLA-A24. Ueda *et al*[56] injected the vaccines into 8 patients with CEA-expressing metastatic gastrointestinal or lung adenocarcinomas positive for HLA-A24. In this trial, no definite tumor shrinkage was observed; however, long-term stable disease or marked decreases in the serum CEA level was observed in some patients after therapy. CEA-specific immune responses have also been demonstrated in most of the patients in whom treatment was clinically effective. Another study examining the vaccination of patients with resectable liver metastases from CRC using mature DCs loaded with HLA-A2-restricted CEA-peptide has been reported in the Netherlands[57]. A total of 10 CRC patients with resection of liver metastases were treated, and the induction of CEA-specific T cells was demonstrated in 7 out of 10 patients. Interestingly, CEA-specific CTL responses were detected in a resected lymph node in one patient. CEA altered peptide (CEAalt) was also administered with DCs to induce antitumor immunity in patients with CEA-positive CRC (n = 7) or lung cancer (n = 2)[58]. In this trial, 5 out of 9 patients exhibited CEAalt-specific CTL responses, and 3 of 9 patients exhibited CEA-specific CTL responses[58]. As CEA is typically produced in gastrointestinal tissue during fetal development, the immune system exhibits some degree of tolerance. Therefore, a break in tolerance is required to induce efficient CEA-specific immunity.

WT1

The *WT1* gene possesses oncogenic functions and is highly expressed in various types of malignancies, including CRC[59]. Moreover, WT1 expression in CRC is significantly associated with tumor progression, lymph node metastasis, distant metastasis and clinical stage[60]. Therefore, the WT1 protein may be one of the most promising cancer antigens. Indeed, the National Cancer Institute (NCI) has ranked WT1 as the number 1 target for cancer immunotherapy based on several factors[61]. Moreover, *WT1* expression may be essential for maintaining the transformed characteristics of cancer cells. Tumor escape from immune surveillance, reflecting the downmodulation of WT1, is unlikely to occur[62,63]. Therefore, WT1-specific immune responses for the elimination of tumors may be induced in many types of cancers. Shimodaira *et al*[8] conducted a phase Ⅰ study to investigate the safety and immunogenicity of DCs loaded with WT1 peptides restricted by MHC class Ⅰ and class Ⅱ (DC/WT1-I/Ⅱ) for advanced CRC patients. Standard treatment comprising surgical resection and chemotherapy was followed by 1 course of 7 biweekly administrations of DC/WT1-I/Ⅱ with OK-432 in 3 CRC patients. Importantly, WT1-specific CTLs were detected after the first vaccination and persisted for two years with prolonged disease-free and overall survival (OS)[8]. The maintenance of long-term WT1-specific memory $CD8^+$ T cells through DC/WT1-I/Ⅱ may be associated with clinical benefits in cancer patients[64].

MAGE

MAGE is a cancer-testis antigen aberrantly expressed in various types of human malignancies, including CRC. MAGE is not expressed in normal tissues except the testis. Thus, MAGE has been developed as a cancer immunotherapy target[10-12]. Sadanaga *et al*[65] initially examined DCs loaded with MAGE-3 peptide in patients with gastrointestinal carcinomas, depending on the HLA haplotype (HLA-A2 or A24). Twelve patients with advanced gastrointestinal carcinoma (six stomach, three esophagus, and three colon) were enrolled. After vaccination, MAGE-3-specific CTL responses were

observed in 4 out of 8 patients. Tumor markers were decreased in 7 patients, and importantly, evidence of minor tumor regression was detected in 3 patients. This group also conducted clinical trials for CRC patients using MAGE-3 or MAGE-1 peptide[66]. Twenty-eight patients with advanced gastrointestinal carcinoma, including 7 CRCs, were administered mature DCs loaded with MAGE-3 or MAGE-1 peptide, depending on the HLA haplotype (HLA-A2 or A24). Peptide-specific CTL responses, tumor marker decreases and minor tumor regressions were observed in some patients after vaccination.

CEA and MUC1

A recent report from a randomized phase Ⅱ clinical trial also indicated the clinical benefits of TAA-targeted DC-based cancer immunotherapy for CRC patients[67]. The aim of this trial was to determine whether 1 of 2 vaccines based on DCs and poxvectors encoding CEA and MUC1 (PANVAC)[68] would lengthen the survival of patients with resected CRC metastases. A total 74 patients, disease-free after CRC metastasectomy and perioperative chemotherapy, were randomized to injections of DCs modified with MUC1 PANVAC (DC/PANVAC) or PANVAC with per injection GM-CSF. The results indicated no differences in the clinical outcomes [progression-free survival (PFS) or OS] between the 2 vaccine strategies. Although CEA-specific T cell responders after DC/PANVAC were more frequently detected compared with PANC, the clinical benefits were not significant[67].

CEA, MAGE, and HER2

HER2/neu is a proto-oncogene product overexpressed in CRC cells[69]. Therefore, Kavanagh *et al*[70] conducted a phase Ⅰ/Ⅱ clinical trial administering a DC-based cancer immunotherapy targeting multiple TAAs, including CEA, MAGE, and HER2/neu, to patients with advanced CRC. The DCs were loaded with HLA-A2-restricted peptides derived from CEA, MAGE, and HER2/neu, pan-DR non-natural peptide optimized for both HLA-DR binding and TCR stimulation, and keyhole limpet hemocyanin (KLH) protein[71]. In this trial, 13 HLA-A2$^+$ advanced CRC patients received the immunotherapy. Although, all patients exhibited progressive disease, CEA-specific T cell responses were detected in 3 out of 11 evaluated patients. Moreover, this pilot study demonstrated the induction of immune responses to multiple TAAs in patients with advanced CRC.

DCs loaded with whole tumor cell-derived antigens

DCs can present TAA-derived epitopes in various manners. Unlike antigenic peptide-loaded DCs, other strategies, such as DCs loaded with whole tumor cells (DC/whole tumor) through whole tumor lysates, apoptotic whole tumor cells, DNA, mRNA, or fusion with whole tumor cells, have been developed[72]. DC/whole tumor cells simultaneously induce numerous TAA-specific CD4$^+$ and CD8$^+$ T cell responses that are at least theoretically more effective than antigenic peptide-loaded DCs[72]. Moreover, for DC/whole tumor-based immunotherapy, allogeneic tumor cell lines can also be used instead of autologous tumor cells to induce autologous tumor specific antitumor immunity. However, unlike defined antigenic peptides, whole tumor cell-based therapy is applicable to all patients, regardless of HLA type.

DCs transfected with mRNA

We have previously reported that murine DCs transfected with MUC1 mRNA exhibited MUC1 expression on DCs in the context of co-stimulatory molecules, resulting in the induction of MUC1-specific CTL responses against CRC cells *in vivo* and *in vitro*[73]. Comparative studies have suggested that mRNA-transfected DCs are superior to other antigen-loaded DCs in inducing CTL responses[29,74]. In a clinical trial, DCs were transfected with whole tumor mRNA to induce antitumor immunity in CRC patients[74]. Fifteen patients with advanced CRC received the immunotherapy and KLH intravenously[75]. As a result, 11 out of the 13 CRC patients evaluated developed a positive KLH skin test, and 7 CRC patients exhibited CEA-specific responses.

Fusion of DCs with whole tumor cells

The fusion of DCs with whole tumor cells generates a heterokaryon expressing DC-derived co-stimulatory molecules and a broad array of TAAs, including both known and unidentified molecules. Thus, this method offers several advantages for presenting antigenic peptides and subsequently inducing polyclonal antigen-specific CD4$^+$ cells and CD8$^+$ T cell-mediated antitumor immune responses, resulting in long-term antitumor immunity activation without inducing tolerance[76]. Moreover, this strategy circumvents the daunting task of identifying TAAs for individualized immunotherapy. Interestingly, DC-tumor fusion cells are potent immune stimulators compared with DCs loaded with either apoptotic tumor-cell fragments or tumor lysates in mice studies[77]. In DC-tumor fusion cells, TAAs access the endogenous antigen-processing pathway, whereas DCs loaded with apoptotic tumor-cell fragments or tumor lysates rely on the cross-presentation of the antigen, which is typically not efficient[33]. In a phase Ⅰ study, DC-tumor fusion cell vaccines were also administered with IL-12 in 5 gastrointestinal tumors, including CRC[78]. Among the 3 patients evaluated, 1 patient exhibited stable disease, and 2 patients exhibited progressive disease. Moreover, no DTH-positive patients were detected in this trial. Immunotherapy through DC-tumor fusion cells with IL-12 induced no serious adverse events and provided good therapeutic responses in some patients with brain tumors. In addition, patients with elevated serum levels of anti-nuclear antibody (ANA) had significantly longer treatment periods than those without treatment in these trials[79].

Table 2 Clinical trials of immune checkpoint therapy in patients with colorectal cancer

Target	Immunotherapy	Phase	Patients	Results	Ref	Year
PD-1	Pembrolizumab, anti-PD-1 immune checkpoint inhibitor	Ⅱ	11 MMR-deficient CRC, 21 MMR-proficient CRC, and 9 MMR-deficient non-CRC	The immune-related objective response rate and immune-related progression-free survival rate were 40% (4 of 10 patients) and 78% (7 of 9 patients), respectively, for MMR-deficient CRC and 0% (0 of 18 patients) and 11% (2 of 18 patients) for MMR-proficient CRC	Le *et al*[89]	2015

PD-1: Programmed death 1; CRC: Colorectal cancer; MMR: DNA mismatch repair.

Allogeneic whole tumor cell lysate-loaded DCs

The use of autologous whole tumor cell lysates as a potential source of TAAs for DC loading has several potential advantages compared with defined antigenic peptides. DC-loaded whole tumor cell lysates and DC-tumor fusion cells express both known and unidentified TAAs, circumventing the daunting task of identifying TAAs. Moreover, DC-loaded whole tumor cell lysates also induce the simultaneous activation of polyclonal $CD8^+$ and $CD4^+$ T cells[80,81]. The activation of $CD4^+$ and $CD8^+$ T cells can provide robust assistance for the induction and maintenance of $CD8^+$ CTLs. However, autologous whole tumor cell-based immunotherapy is often limited by the availability of sufficient numbers of autologous tumor cells, which may not be obtained when surgery is not a component of the treatment. Therefore, an alternative approach involves a use of allogeneic tumor cell lines instead of autologous tumor cells. This approach is based on the fact that some TAAs, such as CEA, WT1 and MUC1, are shared among most tumors. We demonstrated that allogeneic CRC cell-loaded autologous DCs induce antigen-specific CTL responses in CRC patients *in vitro*[4].

In clinical settings, autologous tumor lysate-loaded DC vaccines were used in advanced patients with CEA-positive CRC cells[82]. Six HLA-$A2^+$ CRC patients received the immunotherapy and tetanus toxoid antigen, hepatitis B, and influenza matrix peptides. The results revealed antitumor immune responses in some patients, and the transient stabilization or even reduction of CEA levels were also detected. Moreover, DCs loaded with allogeneic melanoma cell lysate expressing at least one of six MAGE-A antigens were examined in this phase Ⅱ study[83]. Twenty patients with advanced CRC received a total of 161 vaccinations. One patient experienced a partial response. Seven patients achieved stable disease. Five patients exhibited prolonged PFS.

IMMUNE CHECKPOINT THERAPY

DNA mismatch repair (MMR) is a group of genes encoding four proteins that play a key role in repairing mistakes and maintaining genomic stability[84]. Deficiencies in MM lead to MSI; thus, CRCs with MSI contain 10- to 100-fold more somatic mutations than metastatic CRC without MSI[85-87]. MSI reflects defective MMR in 15% to 20% of CRC patients[88]. Accumulating evidence indicates that the neoantigens produced from mutated proteins in tumors with MSI are recognized by the immune system, inducing CTL infiltration in tumors[87]. In addition, $CD8^+$ CTL infiltration in CRC has a well-supported prognostic value[42]. However, the tumor microenvironment comprises not only $CD8^+$ CTLs but also immune regulatory cell populations. Recent evidence indicates that $CD8^+$ CRLs infiltration in tumors is associated with the therapeutic effects of immune checkpoint strategies[42]. Le *et al*[89] conducted a phase Ⅱ trial to evaluate the clinical benefit of an anti-PD-1 immune checkpoint inhibitor, pembrolizumab, in 41 patients (11 MMR-deficient CRC, 21 MMR-proficient CRC, and 9 MMR-deficient non-CRC) (Table 2). Most patients (40 of 41) had previously received treatment of two or more lines of therapy; all patients then received pembrolizumab until either disease progression or unacceptable toxicity occurred. Pembrolizumab was well tolerated, and the immune-related objective response rates for MMR-deficient CRC and MMR-proficient CRC were 40% (4 of 10 patients) and 0% (0 of 18 patients), respectively. Moreover, the 20-wk immune-related progression-free survival rates were 78% (7 of 9 patients) and 11% (2 of 18 patients) for MMR-deficient CRC and MMR-proficient CRC, respectively. Additionally, patients with MMR-deficient non-CRC displayed responses similar to those of patients with MMR-deficient CRC[89]. Importantly, PD-1 blockade in patients with tumors with MSI has exhibited dramatic and durable responses, even in patients with colon cancer[89,90].

CONCLUSION

The goal of CRC immunotherapy is to induce efficient antigen-specific polyclonal $CD4^+$ and cytotoxic $CD8^+$ CTLs in patients. DCs are potent APCs that play a pivotal role in the induction of antitumor immune responses. Therefore, the use of DC-based immunotherapy for CRC patients is promising. However, the immune suppression synergistically generated from CRC and the tumor microenvironment continues to be a major hurdle. Here, we described the ability of DC-based therapeutic immunotherapies to activate antitumor immune responses in CRC patients. However, these strategies may require combination with immune-modulating agents to maximize antitumor immunity. The induction of antigen-specific polyclonal T cell activation may be

associated with the success of immune checkpoint therapeutic strategies. The combination of DC-based immunotherapy and simultaneous blockade of multiple immune checkpoints may have the potential for clinical benefit and should be evaluated[91].

Abstract

Despite the availability of an effective vaccine, hepatitis B virus (HBV) infection remains a major health problem, with more than 350 million chronically infected people worldwide and over 1 million annual deaths due to cirrhosis and liver cancer. HBV mutations are primarily generated due both to a lack of proofreading capacity by HBV polymerase and to host immune pressure, which is a very important factor for predicting disease progression and therapeutic outcomes. Several types of HBV precore/core (preC/C) mutations have been described to date. The host immune response against T cells drives mutation in the preC/C region. Specifically, preC/C mutations in the MHC class Ⅱ restricted region are more common than in other regions and are significantly related to hepatocellular carcinoma. Certain mutations, including preC G1896A, are also significantly related to HBeAg-negative chronic infection. This review article mainly focuses on the HBV preC/C mutations that are related to disease severity and on the HBeAg serostatus of chronically infected patients.

Key words: Hepatitis B virus infection; Precore/core mutations; Hepatocellular carcinoma; HBeAg serostatus; Disease severity

Core tip: The presence of several distinct types of mutations in HBV infections has been shown to contribute to the progression of liver disease in chronically infected patients. Although the relationships between single mutation types in the preC/C region and clinical severity have rarely been studied to date,

it was recently reported that some preC/C mutations, particularly in the MHC class Ⅱ restricted region, are significantly correlated with hepatocellular carcinoma. Several preC/C mutations, including preC G1896A, are also related to HBeAg sero-negative status, which can affect the disease progression of chronic patients. Mutations such as I97F/L or P135Q, which inhibit core nucleocapsid formation, also contribute to disease progression by evading host innate immunity. In addition, the P5H/L/T mutation may lead to hepatocarcinogenesis by inducing the ER stress-ROS axis. In this review, we mainly focus on the clinical implications of the reported preC/C mutations.

INTRODUCTION

Despite the availability of an effective vaccine, hepatitis B virus (HBV) infection remains a major public health concern in most countries, but particularly in endemic areas such as China and South Korea. Globally, there are more than 350 million people who are chronically infected with HBV, which annually causes over 1 million deaths due to serious liver diseases, such as cirrhosis and hepatocellular carcinoma (HCC)[1].

HBV is an enveloped Hepadnavirus belonging to the *Hepadnaviridae* family. HBV has an incomplete double-stranded DNA genome that is approximately 3.2 kb in length and contains 4 overlapping open reading frames (ORFs) encoding the polymerase (P), core (C), surface antigen (S), and X protein[2,3]. Based on an intergroup divergence of > 8% in its complete genome sequence, HBV strains are classified into 8 genotypes, designated A-H, which correlate strongly with the ethnicity of infected patients[4-8]. There is increasing evidence that specific HBV genotypes may play significant roles in causing different disease profiles during chronic hepatitis B (CHB) infection[9-12]. Notably, an extraordinary prevalence of the C2 genotype has been reported in South Korea[13-15]. This genotype is more prone to mutations and is associated with more severe liver disease and poorer antiviral responses compared to genotype B[16,17]. In actuality, several types of HBV mutations that are rarely, if ever, encountered in other areas have been found in South Korea. These mutations were demonstrated *via* molecular epidemiologic and functional studies to be related to the disease progression of chronic patients[14,15,18-34].

Over the past decade, increasing attention has been focused on variant HBV strains that contribute to the clinical severity of liver diseases, especially HCC. To date, certain mutation patterns of HBV, such as the precore (preC) mutation at nucleotide 1896 (G1896A) or the double mutation in the basal core promoter (BCP) region at nucleotides 1762 (A→T) and 1764 (G→A), have been widely studied in the context of clinical severity[35-42]. Recently, several types of naturally occurring mutations in the pre-surface antigen (preS), S and X regions (*i.e.*, the preS1 start codon deletion[28,43], the preS2 deletion[28], W4P/R in preS1[29,32], sW182* in S[28,31,44], and V5M in X[23]), which are related to clinical severity, have also been described.

HBcAg AND HBeAg STRUCTURE AND THEIR VARIANTS

The HBV C protein antigen (HBcAg), the major structural protein of the nucleocapsid, is 183 residues long, of which the N-terminal 149 residues are the assembly domain[45-47]. The preC/C ORF is transcribed and translated into a precore/core fusion protein. During entry into the endoplasmic reticulum (ER), 19 residues of the 29-residue preC region are cleaved off by a signal peptidase, generating a 22-kDa protein. When transported into the Golgi compartment, additional amino acids are removed from the C-terminus by intra-Golgi proteases to form the HBe antigen, leading to a final, heterogeneous secreted protein of 15-18 kDa[48-50]. The secreted HBeAg is regarded as a marker of productive infection in clinical practice. Although the biological function of the HBeAg remains unsolved, it has been suggested that the HBeAg may contribute to HBV replication and modulate the host immune system as a type of tolerogen[51-53].

Most preC/C mutations are generated during HBeAg seroconversion in chronic HBV infections[54-56]. Such mutations can affect HBeAg serostatus and antigenicity, HBV nucleocapsid structure and stability, and the packaging of pregenomic RNA into the nucleocapsid[57]. HBcAg is the principal target of the host immune response and especially of CD4 and CD8 T cell attack[58,59]. Thus, mutations in the preC/C region are mainly distributed in the MHC-restricted region and can induce persistent HBV infections[27,60,61].

Several mutations in the preC/C region have been described, and the most frequently reported mutations in the literature are listed in Table 1[27,61-80]. Except in cases of nucleotide deletions, most mutations in the preC/C region are point mutations[65,80]. Most of the reported mutations in the preC region are associated with reduced HBeAg levels or reduced HBV replication in patient sera. In the C region, mutations are mainly located in immuno-active regions (MHC class Ⅰ + Ⅱ) rather than in immuno-inactive regions.

preC/C MUTATIONS RELATED TO CLINICAL SEVERITY OR HBeAg SEROSTATUS

Certain preC/C mutations have been associated with significant virological or clinical events, such as the

failure to form a nucleocapsid, liver disease progression, or HBeAg seroconversion.

preC/C mutations related to HBeAg serostatus

As patients with HBeAg-negative CHB respond poorly to conventional interferon-alpha therapy, they should be treated differently from those with HBeAg-positive CHB[81-83]. Thus, preC/C mutation analysis can provide valuable information for the management of patients with HBeAg-negative CHB. Basal core promoter mutations (BCP, nt1742-1849) that suppress the production of preC mRNA at the transcriptional level may contribute to the defective synthesis of HBeAg *in vivo*[35]. However, the most frequently occurring mutations that are responsible for an HBeAg-negative hepatitis B profile are mutations that occur within the preC region and that inhibit translation of the protein due to frameshift mutations or premature stop codons (Table 1). Among the mutations reported thus far (Table 1), the mutation that is most often responsible for defective HBeAg secretion is a point mutation, namely a G to A transition at nucleotide 1896 (G1896A) that changes the 28th codon of preC from tryptophan (UGG) into a translational stop codon (UAG). The reduced HBeAg level can also have an important effect on HBV replication and can thereby influence liver disease progression, particularly in fulminant hepatitis and acute exacerbation of CHB[66]. Several studies have reported a positive association between the severity of liver disease and the occurrence of G1896A mutations[27,41,70]. However, it has also been reported that there is no correlation between this mutation and liver disease[72-74]. The discrepancy between different findings may be due to various factors, including HBV genotype, the geographical location or race/ethnicity of patients, host immune competence, and co-infection with other viruses, such as HIV or HCV[5,30,84-86].

Most published studies have reported that HBeAg-negative CHB due to the preC G1896A mutation is only common in non-A genotypes. In patients with genotype A, preC start codon mutations (A1814C/T, T1815C/A) that lead to a failure of HBeAg production have been frequently found[87], but such mutations are very rare in those infected with non-A genotypes. Recently, Mayaphi *et al*[61] reported that 24% of patients with sub-genotype A1 had preC start codon mutations, suggesting that this mutation, rather than the G1896A mutation, may contribute to HBeAg-negative CHB infection in patients with sub-genotype A1.

The G1862T mutation, which leads to a valine-to-phenylalanine amino acid substitution at residue 17 of the preC region, can affect the expression of HBeAg by interfering with signal peptidase cleavage[88]. This mutation prevails in HBV genotype A and particularly in sub-genotype A1; together with preC start codon mutations, G1862T is responsible for the HBeAg-negative serostatus and much lower viremia titers in patients infected with HBV genotype A. Moreover, Saha *et al*[77] recently reported that all tested HBV/A1 isolates from Eastern India harbored the G1862T mutation irrespective of HBeAg status, supporting the idea that this mutation might represent a natural variation in HBV/A1 rather than an adaptive mutation.

Mutations in the C-terminus of the preC/C region alter the biosynthesis, transportation, and secretion of HBeAg[73,79,89]. Such mutations lead to the cytoplasmic accumulation of the HBeAg proprotein (p22) in hepatocytes, resulting in decreased HBV replication in patient sera due to down-regulated HBV DNA replication and HBcAg capsid polymerization[73]. Recently, Wu *et al*[73] reported that, together with the G1896A mutation, the C2304A mutation, which causes a glutamine-to-proline substitution at residue 135 of HBcAg (P135Q), is a predictor of spontaneous HBeAg seroconversion following long-term immune-tolerance development

Table 2 Mutations in the hepatitis B virus preC/C region leading to change of HBeAg serostatus in chronic patients

MHC: Major histocompatibility complex; N: Negative; P: Positive.

within chronic HBV genotype B-infected subjects. Based on a functional study, this mutation was significantly associated with increased cytoplasmic accumulation of the 22-kDa HBeAg proprotein (p22), decreased mature 17-kDa HBeAg (p17) secretion, and a decreased number of HBV capsid particles in Huh7 hepatoma cells, suggesting that this mutation may be associated with spontaneous HBeAg seroconversion in chronic HBV genotype B-infected patients *via* the decreased secretion of the 17-kDa mature HBeAg (p17)[57,90-92].

Recently, we reported that a total of 5 preC/C mutations (G1896A in preC plus 4 in the C region, namely E43K, P50A/H/Y, A131G/N/P and S181H/P) were found to be significantly related to HBeAg serostatus in chronic patients infected with sub-genotype C2[27]. Of those, interestingly, 2 mutations (D32N/H, and E43K) were related to the HBeAg-positive serostatus that was first introduced in the report. These 2 mutations were not located in the regions encoding T or B cell epitopes, suggesting that they may be induced by mechanisms other than immune evasion. Notably, none of the above-described 5 preC/C mutations that were related to HBeAg-negative serostatus was significantly related to HCC, although the G1896A mutation tended towards association with HCC (P = 0.093). These findings raise questions regarding the actual pathogenetic implications of HBeAg-defective mutants. Prospective studies on mutations in the preC/C region and their molecular mechanisms as they relate to the progression of liver disease would provide a better understanding of the clinical relevance of preC/C mutations in relation to HBeAg-negative serostatus. The preC/C mutations that have been reported to cause a change in the HBeAg serostatus of CHB patients are summarized in Table 2.

HBcAg mutations related to clinical severance

As HBcAg is the principal target of the host immune response and particularly of CD4 and CD8 T cell attack, the mutations in this region are mainly distributed in the MHC restricted region and may induce persistent HBV infection[58,59,78]. Indeed, a positive relationship between the frequency of HBcAg and the progression of liver disease has been reported[93-96]. We recently reported that the mutation rate in the MHC class Ⅱ restricted region (M2RR) (2.7% *vs* 1.9%, P = 0.024), but not in the MHC class I restricted region (M1RR) (2.4% *vs* 1.8%, P = 0.3), was significantly higher in HCC patients infected with sub-genotype C2 than in non-HCC patients with the same HBV genotype[27]. Furthermore, the difference between HCC and non-HCC patients with respect to the hotspot region in the M2RR (residues 81-105) was also pronounced (5.6% *vs* 2.6%, P = 0.002). In genotype A1-infected patients, HBcAg mutations were also most commonly found in the M2RR, suggesting that mutations in the M2RR of HBcAg that aid in immune escape can contribute to persistent HBV infection and influence disease progression[97].

We recently introduced 5 mutations in the HBcAg region (P5H/L/T, E83D, I97F/L, L100I and Q182K/Stop) that have been significantly associated with HCC patients compared to patients at other stages of the disease, such as liver cirrhosis (LC) and chronic hepatitis (CH)[27]. Notably, 4 of the 5 HCC-related HBcAg mutations, namely P5H/L/T, E83D, I97F/L and L100I, were located in the M2RR. I97F/L, which was previously known to lead to defects in HBcAg assembly[98,99], was most frequently found in HCC patients (13/35 HCC patients, 37.1%). The frequency of this mutation (16%) was also higher among sub-genotype A1 variants in South Africa[61]. Intrahepatic

Table 3 Mutations in the hepatitis B virus preC/C region related to clinical severance

ASC: Asymptomatic S antigen carrier; AVH: Acute viral hepatitis; CHB: Chronic hepatitis B; FHF: Fulminant hepatic failure; HCC: Hepatocellular carcinoma; LC: Liver cirrhosis; MHC: Major histocompatibility Complex; NC: No change.

expression of HBcAg induced a robust IFN response in mice that facilitated control of the viral infection[100]. However, a recent study reported that the majority of mice that received a capsid assembly-deficient HBV mutant with the Y132A mutation in HBcAg failed to elicit the appropriate HBV-specific immune responses for eliminating hepatitis B surface antigenemia, suggesting that nucleocapsid formation is important for triggering a proper antiviral immune response, perhaps *via* the induction of innate immunity against HBV[101]. Thus, the I97F/L mutation, which is responsible for defective nucleocapsid assembly, may partially contribute to the progress of severe liver disease by failing to elicit a proper host immune response against HBV infection. We have previously reported that the lower level of HBV DNA in patients infected with mutated strains in preC/C region than in those with wild strains were found[27], suggesting preC/C mutations could lead to inhibition of HBV replication, generally. But, the identification of mutation types affecting HBV replication should also be done *via* functional study in the future.

Mutations in residue 5 of HBcAg (P5H/L/T or P5R) are reported to be significantly more frequent in HCC patients relative to a reference group, not only in Korean patients infected with sub-genotype C2[27] but also in Indian patients infected with genotypes A or D[72]. Recently, we demonstrated that P5H/L/T mutations in HBV genotype C2 can elicit the ER stress-ROS axis in hepatocytes[75]. This response then leads to inflammatory cytokine production, TGF-β secretion, apoptosis and HBsAg secretion, all of which are related to liver disease progression. The resulting prolonged inflammation, liver damage and increased HBsAg secretion induced by these mutations may contribute to the progression of liver disease in chronic patients.

Xie *et al*[70] recently reported that 5 mutation sites in the preC/C region, namely 1915, 2134, 2221, 2245, and 2288, were identified as statistically significant independent predictors of HCC survival by multivariate survival analysis. Of these, only the C2288A mutation in HBcAg (P130T) results in an amino acid change, while the other 4 mutations are silent. However, further validation in other populations and functional studies will be required to elucidate the mechanism by which these mutations, particularly the 4 silent mutations, affect HCC progression. The preC/C mutations that have been previously reported as associated with liver disease progression in chronic patients and particularly in HCC patients are summarized in Table 3.

CONCLUSION

Mutations in the preC/C region can affect HBeAg serostatus, HBV replication, nucleocapsid formation, and even pgRNA encapsidation[27,45,48,49,74]. Despite disparities in the infecting genotypes and in patient factors such as co-infection with HIV and patient ethnicity and geographical location, several preC/C mutation types that affect disease progression in chronic patients have been identified[61,77,78,87]. In general, mutations such as G1896A, which decrease or cause a loss of HBeAg, may contribute to disease progression *via* persistent

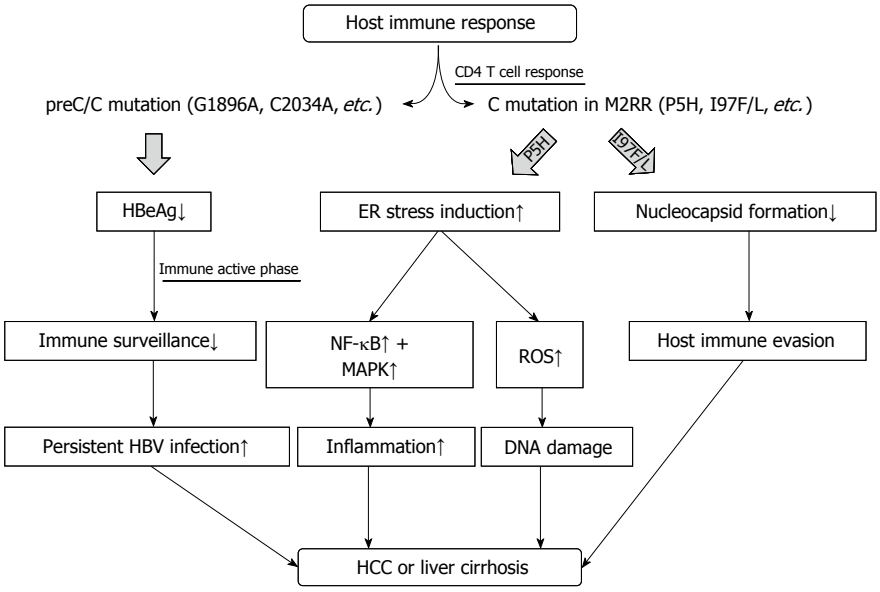

Figure 1 Schematic representation indicating role of mutations in the hepatitis B virus preC/C region in the disease progression of chronic patients. HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma; ER: Endoplasmic reticulum; NF-κB: Nuclear factor kappa B.

HBV infection[21,102,103]. Immune-escape mutations in the M2RR of HBcAg, particularly in the hotspot region comprising amino acid residues 81-105, may contribute to persistent HBV infection that is related to disease progression[53,73,79,104]. Mutations such as I97F/L and P135Q, which inhibit core nucleocapsid formation, may also contribute to disease progression by evading host innate immunity[27,73,98,99]. The P5H/L/T mutation was shown to lead to hepatocarcinogenesis by inducing the ER stress-ROS axis (Figure 1). However, to better understand the clinical relevance of preC/C mutations, large, worldwide prospective studies on the clinical relevance of the different types of preC/C mutations are required, as are functional studies that relate the mutations to liver disease progression.

Abstract

Barrett's esophagus (BE) is a pre-malignant condition affecting up to 15% of patients with gastroesophageal reflux disease. Neoplastic Barrett's mucosa is defined as harboring high grade dysplasia or intra-mucosal cancer, and carries a high risk of progression to esophageal adenocarcinoma. The rising incidence of Barrett's lesions along with the high morbidity of surgical approaches has led to the development of numerous validated endoscopic techniques capable of eradicating neoplastic mucosa in a minimally invasive manner. While there has been widespread adoption of these techniques, less is known about optimal surveillance intervals in the post-therapy period. This is due in part to limitations in current surveillance methods, questions about durability of treatment response and the risk of subendothelial progression. As we are now able to achieve organ sparing eradication of superficial neoplasia in BE, we need to also then focus our attention on how best to manage these patients after eradication is achieved. Implementing optimal surveillance practices requires additional understanding of the biology of the disease, appreciation of the limits of current tools and treatments, and exploration of the role of adjunctive technologies. The aim of this article is to provide a comprehensive review of current literature surrounding post-ablation surveillance in neoplastic BE.

Key words: Barrett's esophagus; Endotherapy; Post-ablation surveillance; Neoplastic; Radiofrequency ablation; Endoscopic mucosal resection

Core tip: Hybrid endotherapy has become common practice for neoplastic Barrett's esophagus with many studies supporting its efficacy. There are limited data and recommendations on appropriate intervals of endoscopic surveillance in the post-therapy period. The purpose of this paper is to review the literature regarding

endoscopic surveillance following current endotherapy strategies for neoplastic Barrett's esophagus, discuss the deficiencies of current surveillance protocols, as well as to comment on the potential role of emerging modalities for monitoring disease progression in the post treatment setting.

INTRODUCTION

In the United States, Barrett's esophagus (BE) is currently defined as the presence of endoscopically recognizable columnar mucosa in the esophagus, which is confirmed to have intestinal metaplasia in mucosal biopsy specimens that should be designated as at or above the gastroesophageal junction (GEJ). This definition has evolved in the guidelines over time as more data regarding risk for cancer progression has been discovered[1-5]. It is a condition that affects 5%-15% of patients with gastroesophageal reflux disease and approximately 2% of the total population[5,6]. It is believed to develop partly in response to acid exposure in the distal esophagus causing cellular changes that have the potential to form dysplasia or even cancer. Non-dysplastic BE progresses to cancer at a rate of 0.18%-0.3% per person per year based on robust population and cohort studies[7-10]. In the presence of high grade dysplasia (HGD), this risk of cancer is increased to the order of 15% per year[3,6,11]. While it has been demonstrated that non-dysplastic lesions can be safely monitored with surveillance endoscopy, the presence of neoplastic lesions hastens the need for interventions that eradicate dysplasia and lower both mortality and progression to cancer[4,11-14]. The rise in the incidence of esophageal adenocarcinoma in recent decades without significant improvement in patient outcomes has prompted the development of an array of endoscopic therapies for neoplastic BE. Following endoscopic therapy however, a paucity of guidelines exist for post-treatment surveillance and the optimal follow up interval is unknown[1-5]. The purpose of this paper is to review the literature regarding endoscopic surveillance following current endotherapy strategies for neoplastic BE, discuss the deficiencies of current surveillance protocols, as well as to comment on the potential role of emerging modalities for monitoring disease progression in the post treatment setting.

DYSPLASIA, ENDOTHERAPY, AND RECURRENCE

Dysplasia in BE is classified into non-dysplastic BE, low grade dysplasia (LGD), indeterminate for dysplasia, HGD, and intra-mucosal cancer (IMC). Often times HGD and IMC are combined into a category of neoplastic BE, with further sub-classifications based on depth of invasion. Recent analyses have concluded that endotherapy is equally as effective at achieving remission in high grade mucosal lesions as esophagectomy, but with less morbidity and fewer complications[4,14,15]. In the realm of endotherapy, both tissue acquiring and tissue damaging modalities exist and are often used in concert. Visible lesions are an indication for endoscopic mucosal resection (EMR) which can be used to confirm a diagnosis and allow appropriate staging[1-2,16-18]. Radical EMR has also been associated with higher complication rates, with strictures occurring in up to 37% in one cohort[16,18]. Photodynamic therapy was initially utilized to ablate Barrett's neoplasia based on early randomized trials demonstrating a reduction in cancer progression and elimination of dysplasia *vs* proton pump inhibitor alone[1,19]. However, this technique has also been shown to yield higher rates of residual buried metaplasia, recurrence of dysplasia, inability to ablate non-dysplastic lesions, and more frequent adverse effects[3,15,20]. Cryotherapy is a technique that has been used in smaller cohorts, however longitudinal randomized controlled data regarding outcomes are still needed[1-4,21]. In the last decade, circumferential radiofrequency ablation (RFA) has become one of the most commonly used endoscopic ablative therapies[4]. RFA is typically combined with focal EMR of visible lesions, and this hybrid method has produced high (> 90%) rates of eradication and a durable response up to 5 years post-treatment[12,22-25]. There is also emerging data that hybrid therapy in patients with LGD can decrease rates of progression to HGD and IMC by up to 25% with an acceptable safety profile when compared to optimal surveillance alone[13]. Proton pump inhibitors remain the standard of care in medical management regardless of whether endotherapy is pursued[1-4]. Their use decreases acid exposure in the distal esophagus and is thought to prevent the cellular changes that lead to the development of dysplasia and cancer, although this relationship has never been definitively proven[5,26,27].

Despite its high rate of eradication of dysplasia, there remain concerns about durability of response and recurrence patterns following hybrid endotherapy[20,23,25,28,29]. Multiple studies have demonstrated that recurrence of intestinal metaplasia and progression to cancer still happen in the post-treatment period[30-33]. One meta-analysis quotes recurrence rates of 11% following endotherapy with complete eradication of neoplastic lesions[14]. Most gastroenterologists agree with continued surveillance, but there still remains significant variability among endoscopic follow up in practice due to both patient and physician factors[4,15,34]. Part of this has been due to rapid advances in technology causing a shifting landscape

of ablative therapies, and the lack of large, high quality randomized controlled trials. The adequacy of current surveillance methods has also been called into question on numerous fronts. Sampling error, inter-observer variability, biopsy depth, properties of neosquamous epithelium and buried metaplasia, and metachronous lesions all provide challenges to the standard of targeted and four quadrant biopsies. The cost-effectiveness of post-ablation surveillance and new imaging technologies to detect buried intestinal metaplasia are also items gaining attention in the literature, as the financial burden of healthcare continues to grow[6,12,35]. All of these reasons highlight the need for evidence based protocols to guide surveillance in the post-treatment period.

CURRENT GUIDELINES FOR DYSPLASIA SURVEILLANCE AND PRACTICE TRENDS IN THE POST-ABLATION PERIOD

Endoscopic surveillance with four quadrant biopsies and targeted sampling of visible irregularities is the current standard of practice for patients diagnosed with BE. This technique has been implemented largely based on the assumption that earlier detection of dysplasia and treatable cancers will reduce deaths from esophageal adenocarcinoma and prolong survival[2,5]. A majority of the available evidence suggesting decreased mortality from surveillance has been retrospective to date[1-3]. Guidelines suggest that non-dysplastic BE can be followed with surveillance endoscopy every 3-5 years and targeted four quadrant biopsies every two centimeters (low quality of evidence). Most professional organizations recommend more aggressive surveillance intervals immediately following a diagnosis of dysplasia, based on the accelerated risk of developing esophageal adenocarcinoma. The presence of indeterminate for dysplasia or LGD calls for repeat endoscopy after 6 mo and, if confirmed, surveillance annually with biopsies every 1-2 centimeters (moderate quality of evidence). HGD/IMC requires targeted four quadrant biopsies every centimeter (low quality of evidence) with repeat endoscopy at 3 mo provided no ablative therapies or resection are initially pursued, in concert with consideration of further imaging and possible surgical consultation[1-4].

However, the frequency and duration of optimal surveillance following endoscopic therapy is less clear. Post-ablation surveillance is not discussed in the most recent position statement from the American Gastroenterological Association on the management of BE[2]. The American College of Gastroenterology guidelines suggest (grade D recommendation) that patients should be followed with biopsies in the area of prior Barrett's mucosa at intervals appropriate for their prior grade of dysplasia until there is "reasonable certainty of complete ablation" on at least three consecutive endoscopies. They go on to say that periodic surveillance is then recommended but there is insufficient evidence to offer specific time intervals[1]. The American Society for Gastrointestinal Endoscopy (ASGE) guidelines state that optimal surveillance intervals after ablation are unknown, however their authors recommend endoscopy every 3 mo for the first year following ablation, every 6 months in the second year, and annually thereafter (no associated level of evidence)[3]. One recent survey of 42 expert endoscopists found that all are performing post-ablation surveillance, and most are following the intervals suggested by the ASGE guidelines, with only a minority routinely ordering other imaging studies such as endoscopic ultrasound (EUS) and computed tomography for further staging[15].

DEFICIENCIES OF CURRENT SURVEILLANCE PROTOCOLS

Defining recurrence

Even though most experts agree that surveillance is beneficial following endoscopic treatment of neoplastic BE, there are deficiencies in the current surveillance process that cast doubt on our ability to reliably detect recurrence and progression of disease. First there is a lack of standardization in terminology when discussing disease recurrence. Most studies on RFA acknowledge that it often takes multiple sessions to achieve complete eradication of dysplastic lesions, but there is variability in the definition of complete eradication. Some studies count a single endoscopy free of visible and histopathologic findings of dysplasia adequate for achieving remission, whereas others require multiple consecutive endoscopies[1,22,25,36]. Often times, intestinal metaplasia is found incidentally on random biopsy of neosquamous epithelium following circumferential RFA of high grade lesions, and its implication on prognosis and the need for maintenance RFA treatment is uncertain[12,29,37-39]. When such areas are found and touched up, it is unclear if this constitutes residual metaplasia that was insufficiently treated, if it represents true recurrence of the parent lesion, or if it is a metachronous lesion that may be genetically independent with unknown malignant potential.

Sampling error and white light endoscopy

Furthering the difficulty in characterizing recurrence, is the fact that studies to date have utilized traditional white light endoscopy to identify areas with visible changes for targeted forceps biopsy, along with random four quadrant biopsies most commonly following the Seattle protocol[3]. Unfortunately, a random biopsy approach can be tedious, and does not provide information from a significant portion of the esophageal mucosa. Visible detection of the recurrence of intestinal metaplasia following ablation may also be insufficient with current imaging techniques. It has

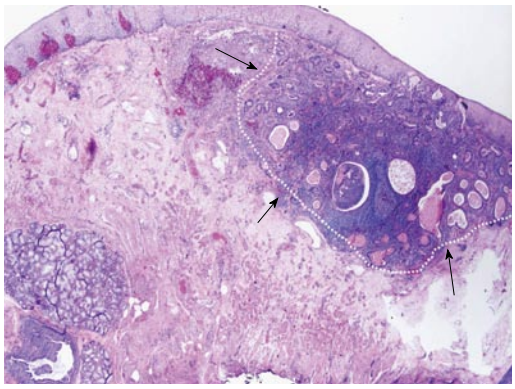

Figure 1 Subsquamous progression on endoscopic mucosal resection specimen. Outlined is an area of adenocarcinoma buried underneath squamous epithelium found on surveillance endoscopy, highlighting the potential danger of buried intestinal metaplasia.

been shown that endoscopic evaluation of the neo-squamocolumnar junction, even with the use of narrow band imaging, has limited sensitivity and specificity (sensitivity 65%-71%, specificity 37%-46%) for detecting biopsy confirmed intestinal metaplasia[40]. In addition, endoscopy and histology do not always tell the full picture of genetic changes that may be present in normal appearing neosquamous tissue, predisposing certain areas to tumorigenesis[33]. The heavy reliance upon visual inspection and random biopsies in our literature to date introduces inherent sampling bias, and has the potential for missing lesions not evident to the endoscopist, altering true rates of remission and recurrence[30]. The methodological weakness in this surveillance technique may in part limit our ability draw accurate conclusions on recurrence rates.

Buried metaplasia and adequacy of pinch biopsies

Buried intestinal metaplasia following ablation techniques has become recognized as an increasingly common phenomenon that may be underestimated by studies using pinch biopsies for surveillance. EMR and biopsy specimens can vary significantly in their final diagnosis, raising concern that surface biopsy findings do not accurately reflect the nature of a given lesion[18,32,37]. Unfortunately, EMR is not feasible in all areas where metaplasia is found on random sampling of the overlying neosquamous epithelium. Numerous studies have confirmed the existence of so-called subsquamous islands of intestinal metaplasia and dysplasia buried beneath normal and post-ablation epithelium[20,31-32,38,41]. Esophagectomy specimens have yielded rates of buried intestinal metaplasia as high as 71% confirmed by optical coherence tomography (OCT) and surgical pathology[42]. One study performing complete EMR for eradication of BE revealed subsquamous lesions with HGD or IMC in 21% of specimens prior to any tissue damaging therapy[32]. A systematic review of buried metaplasia following RFA yielded positive findings in only 0.9% of specimens on follow up biopsy, a rate much lower than for prior ablative techniques[20]. This is an encouraging finding for the use of RFA, but also raises concern over the adequacy of biopsy depth in post-RFA neosquamous epithelium. While it is known that the presence of lamina propria in a biopsy indicates adequate tissue purchase to sample the majority of mucosal lesions, this can often be difficult in the esophagus due to technical limitations[39]. Neosquamous epithelium may also be more fibrous, and limit the ability to achieve adequate biopsy depth. Three major studies looking at the depth of biopsies following photodynamic therapy or RFA ablation showed no difference between the number of pre-treatment and post-treatment biopsies containing lamina propria, despite their absolute percentages varying widely[29,43,44]. The clinical relevance of buried metaplasia remains in question due to a high prevalence and limited research into its malignant potential[38]. However, at least 8 cases of buried neoplasia have been reported in the literature to date, making the concept of subsquamous progression (Figure 1) a legitimate concern[31,38,42,45]. The possibility that endoscopically normal appearing mucosa may be harboring synchronous or metachronous lesions with cancerous potential beyond the reach of random biopsies creates a need for more precise methods of detection.

Histologic preparation and inter-observer variation

Appropriate post-ablation surveillance also relies on the proper handling and interpretation of biopsy specimens. The histopathological diagnosis of BE varies between American and British societies, with the American Gastroenterological Association still requiring goblet cell identification for confirming the diagnosis[2,37]. In practice, these stringent guidelines can be difficult to meet due to the small amount of tissue obtained and inability to sample the entire area of suspected Barrett's mucosa. Every step in biopsy processing is important to give the pathologist and endoscopist an accurate picture of the tissue they are sampling. The angle of the biopsy and how it is presented on the slide can impact whether glands appear buried or exposed to the surface, which has implications for their degree of acid exposure and malignant potential[29,37,38]. There is also a spectrum of dysplasia inherent in all biopsies that must be condensed into a single categorization, and this labeling has a large impact on surveillance intervals and therapy recommendations[37]. In the post-ablation population, regenerating tissue has a tendency to appear dysplastic due to inflammation and mesenchymal changes, and differentiating the level of dysplasia may be more difficult[37]. This can lead to over-calling of dysplasia, particularly in the community setting, to decrease the number of false negatives and prevent missing a cancer. Significant inter-observer variability also exists between pathologists, so confirmation with at least one expert gastrointestinal pathologist is recommended[1-4]. Research is ongoing to find supplemental genetic markers that can

reliably identify dysplastic changes that predispose an individual to developing cancer[33,46,47].

Durability of response and recurrence patterns

Effective eradication of intestinal metaplasia and IMC is believed to be possible by both tissue acquiring and tissue damaging methods[18,24,48-50]. Patient factors such as age and gender, characteristics of Barrett's lesions themselves, and the type and quality of endotherapy have been implicated in the ease of eradication and durability of response[27,36,51-53]. Effective post-therapy surveillance guidelines would require accurate information about durability of response, rates of recurrence, and patterns of recurrence for each available treatment option. Regarding hybrid EMR/RFA therapy, Shaheen *et al*[12] prospectively evaluated 127 patients with dysplastic BE demonstrating rates of eradication above 90% at 3 years based on white light endoscopy with targeted and surveillance biopsies. Even when factoring in patients lost to follow up, intestinal metaplasia was eradicated in 83% and dysplasia in 85% of cases. Phoa *et al*[23] looked at remission of neoplastic lesions 5 years following focal EMR and serial RFA in a 54 patient cohort using EUS and neosquamous resection to detect recurrence. They showed that 90% sustained complete eradication of neoplasia and intestinal metaplasia, with both neoplastic recurrences occurring near the 5 year cut off. In a multi-center review, Gupta *et al*[25] reported rates of recurrence using surveillance biopsies at 1 and 2 years as 20% and 33% respectively, with a majority being non-dysplastic. In general the literature supports a rate of recurrence between 5% and 30%, with high variability owing to differing methods for detecting recurrence, inclusion or exclusion of the GEJ, and different periods of follow up. Durability studies to date are limited by the methods used to evaluate for recurrence (*i.e.,* random biopsies) and likely underestimate its true prevalence, however the clinical relevance of buried intestinal metaplasia remains of some debate due to altered microenvironment and tissue properties[20,26,27,29,31].

Patterns and location of recurrence are another important factor surrounding the durability of endoscopic therapies that affects the need for surveillance. Studies have observed that synchronous and metachronous lesions are often present at various depths in the esophageal mucosa, and may not be adequately detected or treated by current techniques[6,28,32,37,41]. One study of EMR specimens found synchronous or metachronous lesions in as many as 28% of samples, and another using OCT found subsquamous metaplasia in 72% pre-RFA and 63% post-RFA[32,54]. The GEJ is a common culprit for harboring dysplastic lesions in patients with pre-existing BE. It has been speculated that this could be due to repeated acid exposure, difficulty in distinguishing the true location of the Z line on biopsy, and some feel that intestinal metaplasia represents a migration of cells from their origin at the GEJ. In one review of over 400 cases of BE following hybrid therapy with 37 recurrences, 19 involved the GEJ[25]. Vaccaro *et al*[6] also found that all cases of recurrent dysplasia in their cohort occurred at the GEJ in the absence of visible mucosal changes. For this reason, routine ablation of the GEJ has become a common practice and some also advocate surveillance and treatment of the superior gastric folds[40].

OTHER CONSIDERATIONS

Tissue acquiring vs non-tissue acquiring therapy

There is growing concern that tissue damaging therapies may select for dysplastic properties in the residual tissue and thereby predispose treated segments to the development of dysplasia over time. This may be related to certain clonal mutations being refractory to ablative therapy, and tissues containing these mutations would thereby be allowed to proliferate post-treatment creating a new, resistant dysplastic lesion[33,41]. Others have proposed that ablative therapies lead to *de novo* mutations in tumor suppressor genes p16 and p53 that can cause increased tumorigenesis[33]. Shaheen *et al*[48] showed that nearly 80% of post-RFA treated areas reverted to a neosquamous phenotype, however this does not account for genetic variants that may persist and predispose to neoplastic lesions buried under normal mucosa[31,41,45]. There has been some interest in more aggressive tissue acquiring therapies such as circumferential EMR and stepwise radical EMR to prevent these potential changes from occurring and propagating[18,50]. Epigenetic alterations are another area of evolving research into elucidating the genetic mechanism of BE progression and identifying at risk lesions. Loss of protection against hypermethylation of promoter regions around tumor suppressor genes is thought to play a role at multiple stages of tumorigenesis. These local hypermethylation events can vary in frequency across a neoplastic lesion, and less is known about their direct cause. It is unclear how various treatment strategies affect epigenetic modifications, but this area may evolve into one that can be applied clinically to identify patients at risk of recurrence after hybrid endotherapy[55-58]. Both genetic and phenotypic targets will likely be required in the future to truly understand a patient's risk profile[33,47]. Future research advances in the area of clonal mutations and epigenetics may support alterations in surveillance guidelines based on what type of therapy was rendered, however this remains controversial and requires additional research.

Complications of therapy and surveillance

As with any invasive procedure, complications of endoscopic surveillance and therapies must be considered when weighing risks and benefits in

discussion with patients. A recent meta-analysis comparing esophagectomy with endotherapy showed no difference in overall remission rate and mortality, with fewer major adverse events in the endotherapy group[14]. However, endotherapy also requires that the patient be willing to undergo some form of surveillance procedure(s), with the potential for additional therapies to be rendered on an as needed basis. Studies of decision-making have shown that patients' perceived risk of a procedure can vary widely based on their values, past experiences, personal relationships, baseline risk perception, mood, *etc*. When structuring the conversation of whether to treat endoscopically and how frequently to perform surveillance, providers must take into account the patient's subjective and objective risk perception, as some patients are willing to accept exceedingly high complication rates in order to have their disorder treated[34]. Alternatively, if a patient has an adverse event when therapy is rendered, they may be less amenable to post-treatment surveillance recommendations. Data on endoscopic complication rates and recommended surveillance intervals must be conveyed accurately to the patient using language they can easily comprehend. This can be difficult as these rates vary widely by institution, expertise of the endoscopist, and type of procedure. Pooled complication estimates for RFA or focal EMR followed by RFA vary from 5%-12% with the most common being esophageal stricture with or without dysphagia, bleeding, mucosal tears and dysrhythmias[13,25,48,49]. Some factors that have been associated with a higher risk of complications include length of BE segment, use of EMR in conjunction with RFA, and older age[25]. Reports on complete EMR also demonstrate rates of symptomatic strictures on the order of 37.8% and perforations around 1.9%[18]. Most adverse outcomes regardless of procedure type were easily treated endoscopically upon follow-up[13,25,48-50].

Cost effectiveness

In today's ever changing healthcare landscape, quality and cost control have become major considerations in population disease management. Endoscopic therapies have been found to be cost effective in patients with HGD compared to esophagectomy, and could add three quality-adjusted life years (QALY) at minimal cost[35,59]. In non-dysplastic BE or LGD, the cost-utility depends on the ability of endotherapy to durably eradicate the lesion. If an initial ablation could be definitive for these patients and obviate the need for further surveillance, then that could be considered cost-effective[25,35]. One analysis by Hur *et al*[59] compared different management strategies for patients with BE ranging from non-dysplastic to HGD. The model was based on a 50 year old individual being followed until age 80 or death, and compared surveillance with RFA once HGD developed *vs* initial RFA followed by surveillance endoscopy. For patients with no dysplasia, the incremental cost-effectiveness ratio for initial RFA *vs* surveillance was $205500 per QALY, assuming rate of progression of 0.12% per year. This was well above the study's willingness to pay threshold of $100000 per QALY. In patients with LGD, the incremental cost-effectiveness ratio for initial RFA *vs* a surveillance first strategy was $18231 per QALY assuming a rate of progression of 0.5% per year. Such complicated population modeling can be difficult to apply to individual patients, and there is inherent variation in the natural history of many LGD lesions[59]. Given the low rates of non-dysplastic progression, extended interval surveillance remains the recommended management strategy along with acid suppression at this time[1-4,11]. Unfortunately, over-surveillance is currently present in up to 2/3 of patients with non-dysplastic BE and presents a major area for improved health resource utilization[11]. Until further long term data are available, definitive cost-effective recommendations will remain difficult for the cohort of patients with indefinite for and LGD[11,13,35,59,60].

EMERGING SURVEILLANCE MODALITIES

Current surveillance recommendations remain dependent on biopsies of neosquamous epithelium as well as random mucosal sampling[1-4]. However, numerous advanced imaging modalities are now being applied to endoscopic techniques that have the potential for improving detection of recurrence and reducing sampling bias. Certain technologies show more progress than others in accomplishing this feat. In 2008, Savoy *et al*[61] showed that EUS provided little to no additional diagnostic value for patients with normal endoscopic biopsies and cross sectional imaging. It was primarily useful when abnormalities such as deeply invading tumors or extra-esophageal lymphadenopathy were found, and cannot differentiate between dysplastic and non-dysplastic mucosal lesions due to limited resolution[61,62]. Confocal laser microscopy (CLM), an endoscopic technique that allows real time microscopic analysis of surface features using fluorescent staining agents, has also been invoked to offer improvements in targeted biopsies during surveillance endoscopy[41,62-65]. It's diagnostic yield is limited to superficial lesions as deep as 250 μm, a depth insufficient to detect many sites of buried intestinal metaplasia, making its use in surveillance still incomplete[41,64,66]. Of note, one major randomized controlled trial adding CLM to standard white light imaging was stopped early due to a lack of difference between the experimental and control groups in detection of residual intestinal metaplasia, concluding that CLM did not add any additional diagnostic information[63]. Narrow band imaging (NBI) has also been touted as having the potential to detect patterns of intestinal metaplasia with reasonable

accuracy[67-69]. Many of the studies on NBI were unblinded and involved patients with long segment BE that was endoscopically easy to visualize. In patients with a normal appearing mucosa, particularly at the neo-squamocolumnar junction following RFA ablation, NBI showed a sensitivity of 71% and specificity of 37% for detecting residual intestinal metaplasia in one study. This same article also revealed that increasing confidence of the endoscopist in the diagnosis did not change the sensitivity and specificity values[40].

Of the emerging endoscopic techniques, OCT has shown promise for future diagnostic advancement. This ultra-high resolution device encompasses a fiber-optic probe that can be inserted into the accessory port of the endoscope with the ability to provide high quality volumetric images of the esophageal wall in real time using near infrared low coherence light[42,54,66,70]. It has the capacity to image to a depth of 1-3 mm with resolution on the scale of 3-5 μm[38]. One study by Cobb *et al*[42], utilized ultra high resolution OCT in fresh esophagectomy specimens of patients with HGD or esophageal adenocarcinoma. OCT was able to detect histologically confirmed subsquamous intestinal metaplasia, as well as differentiate between dysplasia and adenocarcinoma by imaging alone[42]. In another application of this technology, Tsai *et al*[66] performed OCT at the GEJ before and after RFA treatment and demonstrated that thinner lesions predicted higher success rates of ablative therapy. A depth of 333 μm or less was associated with a 92% sensitivity, 85% specificity, and 88% accuracy in predicting the absence of residual metaplasia at follow up endoscopy[38,66]. OCT has also been used to identify buried glands in pre and post-RFA specimens, demonstrating responses to treatment in real time[53]. It offers the potential for improved depth, a larger field of view, 3-D imaging, and reliable detection and differentiation of mucosal and submucosal abnormalities when compared to white light endoscopy with random biopsies[38,39,42,54,66]. Akin to other advanced imaging technologies, it is not immune to criticisms, including lack of standardized and validated criteria, added time to procedure, expense of the probes, variable endoscopic expertise, and limited speed of image processing[16,39,42,66].

Despite the fascination with endoscopic regression, many geneticists have argued for years that phenotype is only part of the story. Endoscopic improvement in the degree of visible abnormalities is no doubt important, but the genetic changes that underlie progression to cancer can persist in normal appearing mucosa[31,33,38,41,45]. The proportion of clonal abnormalities involving p16, p53 and chromosomal ploidy in a given lesion has been implicated in the genetic instability that causes progression to adenocarcinoma[47]. Some even feel these changes make mucosal segments inherently resistant to, and therefore clonally enhanced by, tissue damaging therapies[33,46,47]. Changes in such pro-tumorigenic loci have been implicated in both neosquamous epithelium as well as buried esophageal glands that may proliferate despite histologic normalization on biopsy in some cases[33,71]. We currently have limited ability to achieve real time molecular profiling that reliably detects mucosal genetic abnormalities during endoscopic intervention. It is hoped that with further study, novel genetic markers may become easier to detect in endoscopically normal mucosa, such that a hybrid genotypic and phenotypic approach to targeted surveillance and endotherapy might be achieved.

CONCLUSION

As we are now able to achieve organ sparing eradication of superficial neoplasia in BE, we need to also then focus our attention on how best to manage these patients after eradication is achieved. Implementing optimal surveillance practices requires additional understanding of the biology of the disease, appreciation of the limits of current tools and treatments, and exploration of the role of adjunctive technologies. Novel molecular targets combined with improvements in real time imaging of the epithelium and submucosal structures will likely continue to further our recognition of disease patterns and refine our understanding of recurrence. Patient centric models of surveillance and therapy may emerge as we learn more about the disease and inherent features that lead to increased morbidity and mortality. All of these advances must also be undertaken in a cost conscious way that will promote patient autonomy within the shared-decision making model. As we strive to reach a consensus on post-therapy surveillance guidelines, continued endoscopy with biopsies and vigilance of the endoscopist after eradication is paramount to achieving long term success of endotherapy in BE.

Abstract

Gastric cancer has an important place in the worldwide incidence of cancer and cancer-related deaths. It can metastasize to the lymph nodes in the early stages, and lymph node metastasis is an important prognostic factor. Surgery is a very important part of gastric cancer treatment. A D2 lymphadenectomy is the standard surgical treatment for cT1N+ and T2-T4 cancers, which are potentially curable. Recently, the TNM classification system was reorganized, and the margins for gastrectomy and lymphadenectomy were revised. Endoscopic, laparoscopic and robotic treatments of gastric cancer have progressed rapidly with development of surgical instruments and techniques, especially in Eastern countries. Different endoscopic resection techniques have been identified, and these can be divided into two main categories: endoscopic mucosal resection and endoscopic submucosal dissection. Minimally invasive surgery has been reported to be safe and effective for early gastric cancer, and it can be successfully applied to advanced gastric cancer with increasing experience. Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy were developed as a combined treatment modality from the results of experimental and clinical studies. Also, hyperthermia increases the antitumor activity and penetration of chemotherapeutics. Trastuzumab which is a monoclonal antibody interacts with human epidermal growth factor (HER) 2 and is related to gastric carcinoma. The anti-tumor mechanism of trastuzumab is not clearly known, but mechanisms such as interruption of the HER2-mediated cell signaling pathways and cell cycle progression have been reported previously. *H. pylori* is involved in 90% of all gastric malignancies and Japanese guidelines strongly recommend that all *H. pylori* infections should be eradicated regardless of the associated disease. In this review, we present innovations discussed in recent studies.

Key words: Gastric; Cancer; Endoscopic mucosal resection; Endoscopic submucosal resection; Minimally invasive surgery; Neoadjuvant chemotherapy; Human epidermal growth factor receptor 2

Core tip: Gastric cancers are distinguished from other cancers by their high mortality and morbidity. Many studies have been conducted to improve the quality of life and extend the survival rates of patients, and some of these studies are ongoing. Although promising developments have been made in recent years, the obtained results have limited reliability and benefits. We believe that significant improvements in the treatment of gastric cancer will be developed according to the long-term results of ongoing randomized clinical trials.

INTRODUCTION

Gastric cancer is in the fifth most common cancer worldwide but it has the third highest incidence of death[1]. Gastric cancer usually does not metastasize to the distant organs until the third stage, but it can metastasize to the lymph nodes during the early stages, which is an important prognostic factor. Metastatic lymph nodes are correlated with the depth (T level) of the cancer. The recurrence observed after a D2- lymph node dissection (LND) is different from the recurrence observed after limited surgery, and locoregional recurrence can occur in most patients who undergo limited surgery. In addition, a minority of patients without perigastric lymph node metastasis can skip metastasis to distant lymph nodes[2,3]. The CA19-9 value is associated with the number of metastatic lymph nodes, and elevated CA19-9 values are significantly correlated (P = 0.008) with the number of metastatic lymph nodes. This could be useful for selecting advanced gastric cancer[4]. Curative surgery for gastric cancer consists of the excision of the mesogastrium, which contains lymph nodes and the omentum, with adequate surgical margins. The Japanese Research Society for the Study of Gastric Cancer (JRSGC) standardized the lymph node dissection for gastric cancer.

According to the JRSGC, a gastrectomy without D2-LND can only provide palliation. D2-LND was used to extend the lymphadenectomy in the 1960's in Japan. Currently, a para-aortic lymphadenectomy is defined as an extended lymphadenectomy. However, a D2-LND is known as an extended lymphadenectomy in Western countries[5,6]. Innovations of gastric cancer therapies include revising the gastrectomy and lymphadenectomy margins; reorganization of the TNM classification; developments in the endoscopic, laparoscopic and robotic treatment of gastric cancer; and innovations in cytoreductive, neoadjuvant and targeted therapies.

REVISIONS FOR GASTRECTOMY AND LYMPHADENECTOMY FOR GASTRIC CANCER

The classifications of lymph nodes have been upgraded intermittently since their first publication in 1962. Lymph node groups were classified as N1-N2-N3-N4, according to cancer location, in the first English edition[7]. The groups were formed based on the incidence of lymph node metastasis and according to the cancer location and the survival rate. The lymph nodes in the "N" groups were upgraded periodically. For example lymph node "7" was originally located in the "N2" group. However, in the third English edition, it was included in the "N1" group. The lymph nodes were grouped into 4 main groups (N1-3 and M1) in the second English edition[8]. This classification was misunderstood such that "N1 and N2" lymph node dissections were thought to be equal to "D1 and D2" lymph node dissections in countries outside of Japan[9]. This definition did not fully coincide with the Japanese classification system determined according to tumor location. For example, if the cancer was located in the proximal part of the stomach, the left paracardial lymph node (No. 2) was defined as N1; if the cancer was located in the corpus of the stomach, the left paracardial lymph node (No. 2) was defined as N3, and if the cancer was located in the distal part of the stomach, the left paracardial lymph node (No. 2) was defined as M (metastatic). This confusion is based on the difficulty of defining the classification. This complex classification system changed in 2010[10]. "D" dissection types (D0, D1, D1+, D2) are defined according to the type of total or subtotal gastrectomy instead of the old classification system[11] (Table 1). This classification system was more practical and easier to understand than the others.

D0 dissection is performed less often than D1 dissection. D1 dissection is preferred for T1a cancers that are not suitable for endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). In addition, cT1bN0, well differentiated, $\leqslant$ 1.5 cm cancers are suitable for D1 dissection. D1+ dissection includes cT1N0 tumors that are not suitable for D1 dissection (> 1.5 cm, poorly differentiated cancers). D2 dissection is suitable for the gastric cancers consisting of potentially curable T2-T4 and/or cT1N+ tumors. D2+ dissection involves removing the para-aortic lymph nodes in addition to the D2 lymph nodes.

Mesenteric vein lymph node dissection (No. 14v) is described as a part of the D2 dissection for distal gastric cancers in the previous edition of the guidelines. However, in the current edition, these lymph nodes are removed from the classification. Furthermore, removing the No.14v lymph nodes can be useful if apparent metastasis to the subpyloric lymph nodes (No. 6) occurs, and this dissection is called D2+No.14v. According to the latest guidelines, lymph nodes behind

Table 1 Lymph node dissections according to gastrectomy type for gastric cancer

Type of gastrectomy	Type of disection	Retrieved lymph node stations
Total	D0	Less than D1
	D1	No. 1-7
	D1+	D1 + No. 8a, 9, 11p[1]
	D2	D1 + No. 8a, 9, 10, 11p, 11d, 12a[1]
Distal subtotal	D0	Less than D1
	D1	No. 1, 3, 4sb, 4d, 5, 6, 7
	D1+	D1 + No. 8a, 9
	D2	D1 + No. 8a, 9, 11p, 12a
Pylor preserving	D0	Less than D1
	D1	No. 1, 3, 4sb, 4d, 6, 7
	D1+	D1+ No. 8a, 9
Proximal	D0	Less than D1
	D1	No. 1, 2, 3a, 4sa, 4sb, 7
	D1+	D1 + No. 8a, 9,11p[2]

[1]If the cancer has invaded the esophagus, the No. 110 lymph node must be removed in addition to D1+ dissection, and the No. 19, 20, 110 and 111 lymph nodes must be removed in addition to D2 dissection; [2]The No. 110 lymph node must be removed in addition to D1+ dissection.

the pancreatic head (No.13) must be dissected if the cancer has invaded the duodenum, and this dissection is defined as D2+ No.13. A prophylactic para-aortic lymphadenectomy is not recommended due to the increased number of postoperative complications and the reduced survival, according to a Japanese randomized clinical trial (RCT) (JCOG 9501)[12]. In the absence of direct invasion of the spleen and macroscopic splenic hilar lymph node metastasis, a splenectomy for dissection the splenic hilum (No. 10) and splenic artery (No. 11) lymph nodes is controversial. The results of RCT JCOG 0110 will provide guidance[13] on this matter.

DEVELOPMENTS IN THE TNM STAGING SYSTEM FOR GASTRIC CANCER

The TNM staging system is the gold standard for staging of all types of cancers. The depth of the cancer and number of the metastatic lymph nodes are the most important prognostic factors for curative gastric cancer surgery. Two major staging systems exist for gastric cancer. The first system is the Japanese Gastric Carcinoma Classification (JGCC) which is based on the location of the metastatic lymph node, and the second is the Union Internationale Contre le Cancer/American Joint Committee Cancer (UICC/AJCC) TNM staging system, which is based on the number of metastatic lymph nodes[14].

The TNM classification system was adapted to the JGCC in 2009 and called the UICC/AJC TNM staging system in the 7th edition. This system can be effective for evaluating the clinical and pathological data and for minimizing the stage migration phenomenon. The main principles of pT and pN, according to this new staging system, are shown in Table 2.

Table 2 Comparison of the sixth and the seventh TNM staging systems for the pT and pN stages

Tumor localization	6th TNM staging system	7th TNM staging system
Lamina propria or muscularis mucosa	T1	T1a
Submukoza	T1	T1b
Muscularis propria	T2a	T2
Subseroza	T2b	T3
Serozal invasion	T3	T4a
Adjacent organ invasion	T4	T4b
1-2 lymp node metastasis	N1	N1
3-6 lymp node metastasis	N1	N2
7-15 lymp node metastasis	N2	N3a
⩾ 16 lymp node metastasis	N3	N3b

Another important difference between sixth and seventh TNM staging systems is that M0 patients could have been classified as stage Ⅳ in the sixth edition. However, in the seventh edition, only M1 patients (positive peritoneal fluid and liver, lung, bone, or brain metastasis) are classified as stage Ⅳ. In addition, a stage ⅢC sub-group has been added (T4aN3M0, T4bN2M0, and T4bN3M0). Esophagogastric cancers that have not invaded the esophagus and that are below the Z line are included in the gastric cancer TNM staging system. Esophagogastric cancers that are located in the proximal 5 cm area or that have invaded the esophagus are included in the esophageal cancer TNM staging system[1,15].

Some authors have suggested that the UICC/AJCC TNM staging system can cause stage migration phenomenon[16]. Patients with less than 15 lymph nodes removed were not included in the N3 classification in the sixth edition of the TNM staging system. Stage migration phenomenon can be prevented because the presence of 7 or more metastatic lymph nodes is classified as N3 in the seventh edition. However, this issue is still controversial. The reduction of the stage migration has not yet been shown in the seventh edition of the UICC/AJCC TNM staging system[17]. In clinical practice, especially when considering adjuvant treatment, the true staging of gastric cancer is very important[18]. Additionally, after removing an insufficient number of lymph nodes and staging the gastric cancer according to the UICC/AJCC TNM staging system of these lymph nodes, the prognosis of patient will be poorer than expected. A new classification system that is based on the ratio of metastatic lymph nodes to the total number of lymph nodes removed (N ratio) has been proposed for more accurate staging of gastric cancer and a more reliable prognostic assessment[19-21]. However, this classification system is in the hypothetical stage. Determining the cut-off value and the fact that this system is only useful for patients with less than 15 lymph nodes removed are the main problems for N ratio staging. The N ratio staging system requires further study.

ENDOSCOPIC INTERVENTIONS FOR EARLY GASTRIC CANCER

Surgical resection has long been the primary treatment for gastric cancers. Minimally invasive surgery and endoscopic treatment modalities have been used with increasing frequency to prevent the mortality and morbidity caused by conventional surgery. With these new interventions, less invasive and less costly treatment protocols that do not have any negative impact on oncologic outcomes, preserve physiological functions, and improve the quality of life after surgery have been developed.

Different endoscopic resection (ER) techniques have been identified, and these can be divided into two main categories: endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD)[22-24].

Patients with very low risk for lymph node metastasis and local recurrence are ideal candidates for ER. Early gastric cancer (EGC) is a limited malignant lesion in the gastric mucosa and submucosa, regardless of lymph node metastasis, and has excellent survival rates with curative treatment[25]. However, despite the reported high long-term survival rate, 3% of mucosal cancers and 20% of submucosal cancers exhibit lymph node metastasis[26]. The first indications for ER (differentiated cancer, < 2 cm tumor, and lesions with no ulceration or lymphovascular invasion that are limited to the mucosa) were determined empirically[27]. The extended indications for ER are still being discussed.

Japanese and South Korean gastric cancer treatment guidelines recommend that extended indications for ER should not be used for routine clinical practice, only for clinical research, due to the lack of high level evidence regarding the curative effect of ER[11,28]. In addition, the guidelines also suggest that ER should be applied according to standard indications. However, some gastric cancer treatment guidelines [National Comprehensive Cancer Network (NCCN), the European Society for Medical Oncology (ESMO), the European Society of Surgical Oncology (ESSO) and the European Society of Radiotherapy and Oncology (ESTRO)] have suggested that obtaining negative horizontal and vertical margins with ER is adequate for the treatment of gastric cancers that are < 2 cm, are well/moderately differentiated, have no lymphovascular invasion and are not located under the submucosa[29].

We can assess to the high level of evidence of the efficacy and safety of ER with the results of randomized clinical trials that compare gastrectomy and ER. However, no randomized clinical trials have compared ER and gastrectomy. The initial information generated by compiling data from 12 institutions in Japan indicates that if negative horizontal and vertical margins are present, EMR is an effective and safe treatment[30]. According to these results, EMR has a 75.8% *en bloc* resection rate, a 73.9% complete resection rate, a 1.9% recurrence rate after complete resection, and a 99% gastric cancer-specific survival rate. Recently, in a matched cohort study that compared EMR and gastrectomy, no difference was observed in the complication rates in terms of survival and recurrence between the groups. The risk of metachronous gastric cancer was higher in the EMR group, but shorter hospital stays and lower costs were reported as the benefits of the EMR procedure[31].

The use of ER increased when ESD was applied, and higher curative resection rates than those produced by EMR were obtained. Although different results from various clinical centers were obtained, rates of 65%-100% for unblocked resection, 68%-95% for complete resection, 94%-100% for 5-year recurrence-free survival and 95%-100% for 5-year survival have been reported for ESD[32,33]. According to a meta-analysis examining 3548 EGC cases and comparing EMR and ESD, ESD produced higher unblocked resection rates (odds ratio: 9.69; 95%CI: 7.74-12.13), higher complete resection rates (odds ratio: 5.66; 95%CI, 2.92-10.96) and lower recurrence rates (odds ratio: 0.10; 95%CI: 0.06-0.18)[34].

In another meta-analysis, standard ESD criteria were compared to the extended ESD criteria. No differences in the overall survival rates were found between the ESD and extended ESD groups. However, a higher rate of complications was observed in the extended ESD group[35]. In a retrospective study, ESD was compared to gastrectomy, and similar oncological results were obtained. However, lower complication rates were observed in the ESD group[36]. Although the ESD procedure is considered adequate for many EGC patients, histopathological examinations have shown that in 5%-20% patients, the procedure is non-curative[37]. Due to the risk of lymphatic metastasis and non-standard presentations (deep submucosal invasion and the presence of lymphovascular invasion), surgical resection with a lymphadenectomy should be performed. Surgery is suggested in the presence of positive lateral surgical margins; however, ER, endoscopic ablation therapy or close monitoring are also feasible[38,39]. The oncologic efficacy of ER has not been supported by a high level of evidence because most recent studies have consisted of retrospective comparisons of non-homogenous groups[36]. In addition, the clinical studies were performed mostly in the South Korea or Japan, which have a 50% rate of EGC. In Western countries, EGC is performed at lower rates; therefore, ER has been applied at lower rates than in Japan or South Korea. Due to these reasons, the applicability of ER by endoscopists is limited[40]. Detecting the early stages of gastric cancer and more widespread use of ER modalities for selected indications will be possible with the implementation of standardized training modules in Western countries[22,41].

MINIMALLY INVASIVE SURGERY FOR GASTRIC CANCER (LAPAROSCOPIC AND ROBOTIC SURGERY)

Laparoscopic surgery

Minimally invasive surgery (MIS) has been increasingly performed due to new surgical tools and the development of techniques for gastric cancer surgery. MIS has some short-term and long-term advantages. MIS has been reported to be safe and effective for EGC, and it can be successfully applied to advanced gastric cancer (AGC) with increasing experience[42-44]. T1 gastric cancer, which has clinically been shown to exhibit perigastric lymph node involvement, and gastric cancer, which has no serosal and lymph node involvement, are expanded indications for MIS[45]. The laparoscopic assisted distal gastrectomy (LADG) was described for EGC in 1991[46]. LADG for EGC has shown short-term benefits, such as reduced intraoperative blood loss and providing early postoperative mobilization, in a meta-analysis of RCTs[47]. The short-term results of laparoscopic gastrectomy (LG) are favorable, but the long-term results for gastric cancer are still controversial. Despite the increasing use of laparoscopic surgery for gastric cancer, a low level of evidence exists. Six RCTs have compared LG and open gastrectomy (OG)[48-53]. Recently, Chen *et al*[54] reported a meta-analysis that included 7336 patients and 23 studies. In this meta-analysis, the 5-year survival and death related to the gastric cancer rates were compared between the LG and OG groups. The 5-year overall survival, recurrence and gastric cancer-related death rates were comparable for LG and OG. The authors suggested that, based on current information at the end of the study, LG provided oncologic safety for early and advanced gastric cancer surgery. LADG has been compared with the open distal gastrectomy (ODG) in some studies, and no significant difference has been found in the 3-year survival rates[55-57]. Choi *et al*[58] reported no significant differences in the overall survival and disease free survival rates over a long period. Zhang *et al*[59] also found no significant differences in recurrence rates between LG and OG for EGCs. Tang *et al*[60] published a review consisting of 32 independent studies that compared LG and OG. They reported less intraoperative blood loss, less pain, earlier return to mobilization, earlier return of bowel sounds and shorter hospital stay as benefits of LG and found no difference in mortality between LG and OG. In addition, they stated that the increased operation time is the only disadvantage of LG, which can be solved by developing surgical techniques.

Fewer lymph nodes were removed during the first applications of MIS than by OG[61]. However, the number of the lymph nodes removed became similar to that of OG as surgeons gained experience[62]. LG is defined as a safe, feasible procedure, especially for EGC, in many studies, and this statement is widely accepted[42,63]. The success of this method depends on factors such as the experience of the surgeon, surgeon's experience with laparoscopy, hospital volume and gastric cancer volume of the surgeon, and preoperative diagnosis. These factors have been found in many studies[42].

With the development of surgical instruments and the increasing experience of surgeons, efforts have been made to decrease the number of ports used for MIS and to develop a single incision technique[64]. However, carbon dioxide pneumoperitoneum, increased intra-abdominal pressure, prolonged operative time, less lymph node removal, port site metastases and technical issues are still problems for laparoscopic gastric cancer surgery[47,65]. MIS does not increase peritoneal spread and port site metastasis according to many studies[66,67].

The short-term results of MIS applications for AGC have been described in the literature[42,68]. Authors report that MIS is a viable option compared to OG for selected cases. Son *et al*[43] reported similar survival and recurrence rates for MIS and GC for T4a cancers. In a meta-analysis that compared OG with D2 dissection and LG with D2 dissection, similar overall survival and major complication rates were observed. However, less blood loss, less pain, reduced minor postoperative complications and shorter hospital stays were reported for the LG patients[69]. However, some experienced surgeons have suggested that current surgical instruments are not sufficient for D2 dissection during MIS for AGC, and they have published their oncological results[48,68,70]. Some ongoing RCTs (JOCG-0912, JLSSG-0901, KLASS-01, KLASS-02, and CLASS-01) are being performed to assess the feasibility of MIS in Korea, Japan and China[71-75].

Robotic surgery

Robotic technology has developed new tools for use in MIS during the past decade[42]. The first robot-assisted gastrectomy (RAG) was reported by Hashizume and Sugimachi in 2003[76]. RAG has been used for gastric cancer surgery to overcome the technical difficulties of LG[77]. RAG has potential technical advantages such as providing a three-dimensional image, articulated instruments, and allowing for precise movement. In addition, RAG has spread rapidly[42]. Compared to the LG, RAG provides better images and movements. RAG is more effective and safe than LG according to many experienced surgeons[78,79].

In a meta-analysis by Xiong *et al*[80], LG and RAG were compared regarding their effects on gastric cancer treatment. RAG produced less intraoperative blood loss and comparable mortality and morbidity rates. However, the operation time was significantly longer than that for LG and OG.

The potential advantages of RAG include facilitation of intra-corporeal anastomosis and allowing extended

Table 3 Ongoing multicentric studies of minimally invasive surgery

Country	Study	Subject
Japan	JCOG 0912 Phase Ⅲ	LG *vs* OG
South Korea	KLASS 01 Phase Ⅲ	LG *vs* OG
South Korea	KLASS 02-NCT01456598	LG *vs* OG (for AGC)
Japan	JLSSG0901 Phase Ⅱ-Ⅲ	LG *vs* OG (for AGC)
China	CLASS 01-NCT01609309	LG *vs* OG (for AGC)
South Korea	KLASS 03-NCT01584336 Phase Ⅱ	LG *vs* OG (for TG)
South Korea	NCT01309256	LG *vs* RAG

AGC: Advanced gastric cancer; LG: Laparoscopic gastrectomy; OG: Open gastrectomy; RAG: Robot asisted gastrectomy; TG: Total gastrectomy.

lymph node dissection. However, inconsistent results have been presented in the literature regarding this subject[42]. RAG would be useful for overcoming the challenges of traditional LG, but it has not provided the theoretical advantages of lymph node dissection[42]. RCTs involving RAG have not been reported, However, the recent meta-analyses are weak and include few patients[80,81].

The overall and major complication rates were similar to the short-term surgical results of the multicenter NCT01309256 study from Korea (11.9 *vs* 10.3 and 1.1% *vs* 1.1%, respectively). However, the operation costs (US $13432 *vs* US $8090, $P < 0.001$) and time (221 min *vs* 178 min, $P < 0.001$) were significantly higher for RAG[82].

ONGOING MULTICENTRIC STUDIES OF MINIMALLY INVASIVE SURGERY

The final results of the KLASS 01 Phase Ⅲ study for stage Ⅰ gastric cancer patients are expected to show the oncologic safety of the treatments. In the early results of this study, no significant differences were found between the LG and OG groups regarding mortality and morbidity. No significant difference between the MIS and OG groups regarding 3-year overall survival rates were observed according to the first results of the multicentric KLASS 02-NCT01456598 study. Phase Ⅱ and Ⅲ studies (JLSSG0901 trial; UMIN-000003420) are being conducted by the Japanese Laparoscopic Gastric Surgery Study (JLSSG) group to investigate the technical and oncologic safety of laparoscopic treatment. The feasibility and the oncological safety of laparoscopic treatment of AGC are being investigated by the Chinese Laparoscopic Gastrointestinal Surgical Study Group (CLASS) in the CLASS 01-NCT01609309 study. The ongoing phase 2 KLASS 03-NCT01584336 study is investigating the feasibility and safety of laparoscopic and open gastrectomy for stage 1 gastric cancer patients in Korea. In addition, the NCT01309256 study continues to compare RAG and LG (Table 3).

INTRAPERITONEAL CHEMOTHERAPY

Gastric cancer is a biologically aggressive tumor. The prognosis is poor even if curative surgery can be performed. For higher stages of stomach cancer, the most common form of invasion is peritoneal metastasis[83]. Almost all patients with positive peritoneal cytology progress to peritoneal carcinomatosis and die within the first two years of the disease[84]. The peritoneum is supported by the basal membrane of mesothelial cells and connective tissue. The blood- peritoneal barrier is located between the mesothelial cells and mesothelial capillaries. Few systemic chemotherapeutic agents can pass through this barrier. Additionally, intraperitoneal chemotherapy has less adverse effects and produces a higher dose in the intraperitoneal regions than systemic chemotherapy[85]. Intraperitoneal chemotherapy can be given preoperatively and during the early postoperative period (EPIC). Intraperitoneal chemotherapy, given preoperatively, is aimed to prevent micro metastasis, increase the chance of curative resection and perform a complete cytoreduction. EPIC is given as soon as the general condition of the patient has recovered after surgery. It is started during the period in which the minimal residual tumor load is present and before the residual cancer cells become hidden between fibrin deposits[86].

EXTENSIVE INTRAOPERATIVE PERITONEAL LAVAGES

Kuramoto *et al*[87] developed a treatment modality called "extensive intraoperative peritoneal lavage treatment" (EIPL), which aims to destroy the free cancer cells spreading into the peritoneum. After a curative resection is performed, the abdomen is washed with 1 liter of isotonic saline and aspirated. Then, this procedure is repeated 10 times. The aim of this method, which is called "Limiting dilution method", is to remove the free cancer cells in the peritoneum by washing with isotonic saline. A prospective randomized controlled study was performed that included 1522 patients with higher stage stomach cancer who had undergone curative resection (R0) and D2 dissection. Then, 88 patients with positive cytology and without peritoneal invasion (CY+/P-) were divided into 3 groups. Surgery alone was performed on for the first group. The second group was treated with intraperitoneal chemotherapy, and the third group was treated with EIPL+intraperitoneal chemotherapy. In the group given prophylactic intraperitoneal chemotherapy and intraoperative peritoneal lavage, the 5-year survival rate was markedly increased compared to the other group. The 5-year survival rates of each of the three groups were 0%, 4.6% and 43.8%, respectively. Standard prophylactic treatment against peritoneal metastasis has been reported as an effective treat-

ment modality. It is practical, can be performed in any situation, and does not extend the operation time. In the reported studies, prophylactic treatments used to prevent peritoneal metastasis in the early period has been shown to be promising[84,87-89].

CYTOREDUCTIVE SURGERY AND HYPERTHERMIC INTRAPERITONEAL CHEMOTHERAPY

Cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) were developed as a combined treatment modality from the results of experimental and clinical studies[90]. In the 1990's Sugarbaker described the surgical method in detail. Complete cytoreduction must be performed before HIPEC is administered. Hyperthermia increases the antitumor activity and penetration of chemotherapeutics[91].

A meta-analysis of the results of 13 randomized studies (1648 cases) examined the benefits of adjuvant intraperitoneal chemotherapy after curative gastric cancer resection. It reported that patients who received intraperitoneal chemotherapy exhibited better survival[92]. Yang *et al*[93] reported median survival times of 11 and 6.5 mo, respectively, in their prospective randomized phase Ⅲ clinic study that compared the effects of CRS + HIPEC and CRS alone on 68 patients with gastric peritoneal carcinomatosis.

The survival time was increased to 13.5 mo after complete macroscopic cytoreduction (CC-0/1). Gill *et al*[94] summarized the data of 10 studies (n = 445), including one prospective controlled study, 3 retrospective case reports and 6 prospective case series, in which they found a median survival time of 15 mo (9.5-43.4 mo) for CC-0/1 patients. Additionally, the study results of pioneering authors such as Fujimoto, Sugarbaker, Glehen and Yonemura showed that the median survival time ranged between 11 and 16 mo in patients who underwent HIPEC with partial or complete cytoreduction[91,95]. Systemic chemotherapy produces a very limited survival benefit for patients who undergo CRS and HIPEC, increasing the life expectancy by 30%. This shows that systemic chemotherapy and HIPEC are more beneficial for patients who have been surgically treated. Koga *et al*[96] investigated the benefits of HIPEC as an adjuvant therapy for the prevention of peritoneal recurrence in a limited number of patients with gastric cancer and serosal invasion in a randomized clinical study. They found 3-year survival rates of 67.3% and 83% in patients with surgery plus HIPEC and in the control group.

Additionally, Hamazoe *et al*[97] found an increased survival rate in patients who underwent prophylactic HIPEC with high dose mitomycin C compared to the control group (64.2% *vs* 52.5% respectively). However, a randomized clinical study by Fujimoto, Fujimura and Yonemura showed that adjuvant HIPEC treatment decreased peritoneal recurrence and increased the survival rates of AGC patients[98-100]. Only one prospective randomized study showed that adjuvant HIPEC treatment produces no survival advantage[101]. The SRC and HIPEC multimodal combined treatment can only produce survival benefits for patients with gastric peritoneal carcinomatosis with well-defined boundaries. However, more detailed clinical studies are needed to determine the role of modern systemic chemotherapy[90].

NEO-ADJUVANT CHEMOTHERAPY FOR GASTRIC CANCER

Pre- and post-operative chemotherapy are accepted as the standard treatments for curable gastric cancers, except for the stage 1 gastric cancers, in Europe and England[102]. These results were concluded from the results of the Medical Research Council Adjuvant Gastric Infusion Chemotherapy (MAGIC) study[103]. In the USA and some Latin American countries, post-operative chemotherapy is the gold standard because it has narrower boundaries than D2 surgery in most patients. This result was concluded from the results of the Inter group 0116 study[104]. Adjuvant chemotherapy is used as the gold standard treatment in East Asian countries that typically perform standard D2 surgery[105-108]. Neo-adjuvant chemotherapy (NAC) indications are limited in these countries, and this method is accepted as an experimental treatment for most curable patients. NAC is typically only administered to patients with borderline resectable gastric cancer or a poor prognosis after R0 resection, even though evidence supported by phase 3 studies is lacking.

In a randomized controlled study of a large population in Europe, perioperative chemotherapy, including epirubicin cisplatin and 5-FU (ECF), significantly increased overall survival and cancer free survival compared to the surgery group alone (HR: 0.75, 95%CI: 0.60-0.93, P = 0.009)[103]. Other prospective studies of this procedure include the FFCD 9703 study and the EORCT 40954 study, which had relatively fewer participants. Less than 250 cases were reported in both studies, and they were ended before reaching the planned sample size[109,110]. The EORCT 40954 study does not include post-operative chemotherapy; therefore it only determines the effect of NAC compared to surgery alone. Though the FFCD 9703 study had completed data on 224 patients (the planned sample size had been 250), it was statically shown that NAC is significantly more beneficial than surgery alone (HR: 0.69, 95%CI: 0.50-0.95, P = 0.02). The EORCT study was ended due to a low enrollment rate after having recorded only 114 cases. No survival advantage was shown in this study. In the MAGIC study, the ECF regimen was used; in the FFCD 9703

study, a cisplatin regimen and 5-FU (CF) were used; in the EORCT study, cisplatin, leucovorin (FLC) and 5-FU (CF) regimens were used.

Recently, much attention has been focused on linitis plastica, which has a worse prognosis than other diseases that involve extensive lymph node invasion (either large sized lymph nodes surrounding the first branch of the celiac artery or para-aortic lymph node metastasis)[111,112]. Three phase Ⅱ clinical studies have reported a 5-year survival rate of 10% for diseases with extensive lymph node invasion. Most of these diseases have been classified as unresectable, and they are treated with palliative chemotherapy in Western countries. The survival rates were reported only in the first two studies[112,113]. Another area of focus is linitis plastica, which is accepted as inoperable by some surgeons[114].

Regarding ongoing studies, a Korean study is comparing S1 monotherapy following D2 lymphadenectomy to NAC with Docetaxel, S-1 and Oxaliplatin (PRODIGY study: NCT01515748). The RESONANCE study in China (NCT01583361) is testing the effectiveness of postoperative SOX treatment after D2 lymphadenectomy in addition to NAC with S1 and Oxaliplatin[102].

HER 2 IN GASTRIC CANCER AND TARGETED TREATMENT

Trastuzumab is a monoclonal antibody that interacts with human epidermal growth factor (HER) 2 and is related to gastric carcinoma[115]. The gene amplification and protein expression of HER2 were first reported in 1986[116,117]. Herceptin (trastuzumab) blocks HER2 function, and HER2 is a treatment option fort he breast cancer patients[118]. The anti-tumor mechanism of trastuzumab is not clearly known, but mechanisms such as blocking the cycle progression of the cell and cell signaling pathways; initiating the cell mediated cytotoxicity with antibodies; induction of anti-angiogenesis effects and increasing receptor turnover by endocytosis have been reported previously. Gene amplification of HER2 using fluorescence in situ hybridization (FISH) and protein overexpression with immunohistochemistry (IHC) have reported HER2 levels of 16%-27.1% and 8.2%-54%, respectively[119]. The trastuzumab for gastric cancer (ToGA) phase Ⅲ international multicenter RCT compared the clinical effect and safety of trastuzumab with that of standard chemotherapy (capecitabine or intravenous 5-fluorouracil and cisplatin). Survival after treatment with trastuzumab was significantly longer than that with only standard chemotherapy (13.8 mo *vs* 11.1 mo, respectively, $P = 0.0046$). Additionally, comparable toxicity and improvement of the time of progression and progression free survival were observed in the trastuzumab+ standard chemotherapy group[120]. Treatment with trastuzumab is standard for the HER2 (+) patients (IHC score +3 and/or FISH-) in the USA and Japan. Trastuzumab is recommended for patients with an IHC score of 2+/positive FISH or an IHC score of 3+ with high HER2 protein expression, according to the ToGA study in Europe. Evaluation of HER2 is essential for trastuzumab treatment[120]. The effect of trastuzumab on patients with low HER2 expression (IHC score 0/FISH positive or IHC score 1/FISH positive) is not clear according to the ToGA study. Interestingly, HER2 expression was higher in patients with gastroesophageal cancers than in those with other gastric cancers in this study (33.2% *vs* 20.9%, respectively, $P < 0.001$)[121].

In a observational, prospective, cohort, multicenter, study by Matsusaka *et al*[122], HER 2 expression and gene amplification were assessed, and the relationship between HER2 status and clinicopathological findings in Japanese gastric cancer patients with metastasis or recurrence was investigated. A total of 1461 patients in 157 centers were included in the study, and 1427 of 1461 patients were evaluated. The overall HER2 (+) patient rate was 21.2%. The rate of patients with high levels of HER2(+) (IHC score of 2+/FISH positive or IHC score of 3+) was 15.6%, and the rate of patients with low HER2 (+) levels was 7.0%. Multiple logistic regression analysis showed that an intestinal type of cancer, the absence of peritoneal metastasis and hepatic metastases are significant independent factors associated with the expression of HER2 positivity. An intestinal cancer type was associated with low HER2 expression. Factors such as the type specimen fixation, total fixation time, pH of the fixative and the time before the fixation affected the HER2 status according to this study. Additionally, the authors reported that HER2 has intratumoral heterogeneity and this rate is up to %70 in the HER2 (+) cancers. Because of that gastric biopsies can cause false negative or false positive results[122]. Therefore, endoscopists should consider conducting multiple biopsies. As a result, the intestinal type of gastric cancer is an independent factor for HER2 positivity and low HER2 expression.

The association between the HER2 gene amplification and protein expression and the clinicopathological findings of resectable gastric cancer patients were investigated in another study by He *et al*[119] A total of 197 patients who underwent curative resection were included in the study, and the survival rates were noted. The amount of HER2 gene amplification was 17.7% according to Hoffman's gastric cancer HER2 scoring system. Additionally, the HER2 (3+), HER2 (2+) and HER2 (0/1+) rates in all patients were 9.64%, 12.69% and 77.66%, respectively. The positivity of HER2 was higher in the intestinal type of cancer and well differentiated cancers than in the diffuse type and poorly differentiated cancers (28.57% *vs* 13.43%, $P = 0.0103$ and 37.25% *vs* 11.64%, $P < 0.0001$). The authors reported that gastric cancers that were well differentiated, of the intestinal type, and poorly differentiated with no metastasis to the lymph nodes

were suitable for the targeted therapy with Herceptin.

An ongoing RCT is examining the effect of trastuzumab on the HER2(+) gastric cancer patients who have undergone an extended lymphadenectomy. The results of this study will provide detailed information[123].

An accurate and standardized scoring system of HER2 is important for the Herceptin therapy and useful for the selection of gastric cancer patients.

HELICOBACTER PYLORI IN GASTRIC CANCER

Helicobacter pylori (*H. pylori*) which is involved in 90% of all gastric malignancies, infects nearly 50% of the world's population and it is the most crucial etiologic agent for gastric adenocarcinoma[124-126]. *H. pylori* infection causes some clinical manifestations such as; chronic gastritis, duodenal ulcer, gastric ulcer/adenocarcinoma and gastric mucosa-associated lymphoid tissue lymphoma (MALToma). The most important *H. pylori* releated predisposed factors for gastric carcinoma are bacterial virulence factors [cagA (cytotoxin-associated gene A) and its pathogenicity island (cag PAI) and vacA (vacuolating cytotoxin A)], host genetic factors (IL-1 gene cluster polymorphism, TNF-α and IL-10 gene polymorphism) and environmental factors (salt, smoking)[127]. *H. pylori* eradication can prevent the recurrence of peptic ulcers and MALToma of the stomach. Also recurrence rates after endoscopic resection of early gastric cancer is lower after *H. pylori* eradication. However, it is not clear that the eradication of *H. pylori* reduces the risk of gastric cancer directly. A randomized controlled trial concluded that the eradication of *H. Pylori* provided decline of gastric cancer risk significantly after 15 years of follow-up[128]. The well-known indications for *H. pylori* eradication are peptic ulcer, MALToma, and endoscopic treatment of early gastric cancer. However, Japanese guidelines strongly recommend that all *H. pylori* infections should be eradicated regardless of the associated disease[129].

The eradication of *H. pylori* varies by region. Recent Korean and Japanese guidelines still recommend Standard triple therapy (PPI + amoxicillin + clarithromycin or PPI + metronidazole + clarithromycin) as a first-line treatment[129-131]. However, recent European guidelines recommend that first-line treatment should be adjusted to clarithromycin resistance[132]. Standard triple therapy is recommended as a first-line treatment for the low-resistance (< 20%) regions, but bismuth quadruple therapy or sequential/concomitant therapy is recommended for the high-resistance (> 20%) regions[132].

Some authors suggested that, the process of *H. pylori*-related carcinogenesis is being inhibited by aspirin, NSAIDs, and COX-2 inhibitors and these can prevent the development of gastric cancer[133]. Vitamin C and antioxidants have also protective effects against *H. pylori*-induced gastric carcinogenesis[134]. In a recent meta-analysis which is including 45 randomized controlled trials, increased *H. pylori* eradication was associated with using of probiotics with standard triple therapy[135].

On the other hand, preoperative *H. pylori* infection is associated with increased survival after resection of gastric adenocarcinoma. In a multicenter retrospective study, *H. pylori* positivity was associated with longer overall survival (84.3 mo *vs* 44.2 mo, P = 0.008) for the 559 patients who had gastrectomy because of gastric cancer. *H. pylori* was not associated with recurrence free survival or disease spesific survival in all patients. Also, *H. pylori* infection showed no association with overall survival in stage 1 or stage 2 patients. But in the stage 3 patients, *H. pylori* was associated with longer overall survival (44.5 mo *vs* 24.7 mo, P = 0.018), longer recurrence free survival (31.4 mo *vs* 21.6 mo, P = 0.232), and longer disease spesific survival (44.8 mo *vs* 27.2 mo, P = 0.034)[136].

CONCLUSION

Gastric cancers are distinguished from other cancers by their high morbidity and mortality. Many studies have been conducted to improve the quality of life and extend the survival rates of patients, and some of these studies are ongoing. Although promising developments have been made in recent years, the obtained results have limited reliability and benefits. We believe that significant improvements in the treatment of gastric cancer will be developed according to the long-term results of ongoing randomized clinical trials.

Abstract

AIM: To investigate whether the simultaneous treatment with human growth hormone (hGH) abolishes the negative effects of everolimus on anastomotic healing.

METHODS: Forty-eight male Sprague-Dawley-rats were randomized to three groups of 16 animals each (Ⅰ: vehicle; Ⅱ: everolimus 3 mg/kg po; Ⅲ: everolimus 3 mg/kg po + hGH 2.5 mg/kg sc). Animals were pretreated with hGH and/or everolimus daily for seven days. Then a standard anastomosis was created in the descending colon and treatment was continued for another seven days. The anastomosis was resected in toto and the bursting pressure was assessed as a mechanical parameter of intestinal healing. Moreover, biochemical (Hydroxyproline, PCNA, MPO, MMP-2 and MMP-9) and histological (cell density, angiogenesis, amount of granulation tissue) parameters of intestinal healing were assessed.

RESULTS: Anastomotic bursting pressure was significantly reduced by everolimus and a simultaneous treatment with hGH resulted in considerably higher values (Ⅰ: 134 ± 19 mmHg, Ⅱ: 85 ± 25 mmHg, Ⅲ: 114 ± 25 mmHg; $P < 0.05$, Ⅰ *vs* Ⅱ; $P = 0.09$, Ⅰ *vs* Ⅲ and Ⅱ *vs* Ⅲ) Hydroxyproline concentration was significantly increased by hGH compared to everolimus alone (Ⅰ: 14.9 ± 2.5 μg/mg, Ⅱ: 8.9 ± 3.6 μg/mg, Ⅲ: 11.9 ± 2.8 μg/mg; $P < 0.05$, Ⅰ *vs* Ⅱ/Ⅲ and Ⅱ *vs* Ⅲ). The number of MPO-positive cells was reduced significantly by hGH

compared to everolimus alone (Ⅰ: 10 ± 1 n/mm², Ⅱ: 15 ± 3 n/mm², Ⅲ: 9 ± 2 n/mm²; $P < 0.05$, Ⅰ *vs* Ⅱ and Ⅱ *vs* Ⅲ), while the number of PCNA-positive cells were increased by hGH (Ⅰ: 28 ± 3 /mm², Ⅱ: 12 ± 3 /mm², Ⅲ: 26 ± 12 /mm²; $P < 0.05$, Ⅰ *vs* Ⅱ and Ⅱ *vs* Ⅲ). Corresponding to these biochemical findings, HE-histology revealed significantly increased amount of granulation tissue in hGH-treated animals.

CONCLUSION: Inhibition of intestinal wound healing by everolimus is partially neutralized by simultaeous treatment with hGH. Both inflammation as well as collagen deposition is influenced by hGH.

Key words: Wound healing; Everolimus; Human growth hormone; Immunosuppression; mTOR-inhibitor; Growth hormone; Anastomotic healing

Core tip: Patients undergoing transplantation are set onto immunosuppressive medication afterwards. One agent is everolimus out of the group of the mTOR-inhibitors. Everolimus has been shown to inhibit healing of intestinal anastomoses by influencing the inflammatory phase of wound healing. Human growth hormone (hGH) has been shown to improve wound healing by increasing the amount of collagen in the wound. In this animal study we could demonstrate for the first time that a combined perioperative treatment with everolimus and hGH results in improved intestinal wound healing compared with everolimus alone. These results might be a step towards safer immunosuppression in transplanted patients.

INTRODUCTION

Wound healing is a complex mechanism which is essential for tissue regeneration. The wound healing cascade includes three main phases, which partly overlap[1-5]. First of all there is the inflammatory phase, which lasts the first few days after wounding. In this phase, neutrophils and macrophages are attracted to the wound and produce among others proinflammatory cytokines and growth factors[6]. Thereafter, angiogenesis starts[7-11] and new collagen fibres are synthesized in the wounded area as main components of the granulation tissue representing the proliferation phase[12-17]. Simultaneously, old collagen fibres are degraded by collagenases namely the matrix metalloproteinases 2 and 9 (MMP-2/-9). Finally, there is the phase of remodeling and maturation of the formatted scar. As the proliferation phase is crucial for the stability of the wounds, impairment of the inflammatory or proliferation phases may result in severe conditions as anastomotic insufficiency.

The mammalian target of rapamycin (mTOR) is a protein kinase that regulates among others protein synthesis and cell proliferation. Its effects are mediated *via* two different complexes, the mTOR complex 1 (mTOR1) and the mTOR complex 2 (mTOR2). There are inhibitors of mTOR namely sirolimus and its derivate everolimus. *Via* inhibition of protein synthesis and cell proliferation they act as potent immunosuppressive drugs and are widely used both after bone marrow and solid organ transplantation to prevent graft rejection. However, impairment of wound healing is one major side effect of immunosuppressive drugs like tacrolimus, sirolimus or steroids[18-30]. Especially the mTOR-inhibitors have been shown to impair not only cutaneous wound healing but also have significant effects on the healing of enteral anastomoses[20,21,25-27]. These effects limit the use of the mTOR-inhibitors in the immediate postoperative period after solid organ transplantation as well as they force surgeons to switch immunosuppressive medication from mTOR-inhibitors to another, mTOR-inhibitor-free regimen prior to elective surgery. Recently, it has been demonstrated that the negative effects of everolimus on intestinal wound healing are characterized by a prolongation of the inflammatory phase of the wound healing cascade[31]. This prolongation leads to a delayed initiation of the proliferation phase of the wound healing cascade resulting in a decreased mechanical stability of the anastomoses.

On the other hand, human Growth Hormone (hGH) is an anabolic hormone produced in the pituitary gland. It has been shown previously that hGH improves intestinal wound healing[32-37]. Administration of hGH results in a 30% increase of wound collagen as well as an improved generation of granulation tissue in intestinal wounds[35]. These biochemical findings result in an enhanced intestinal wound healing under medication with hGH[32].

Aim of this animal study was to investigate whether simultaneous administration of hGH and the mTOR-inhibitor everolimus results in an improved intestinal wound healing.

MATERIALS AND METHODS

Animals

Fourty-eight male Sprague-Dawley rats (300-380 g; Harlan Winkelmann, Borchem, Germany) were kept under controlled conditions with constant temperature at 23 ℃, constant humidity of 50% and a 12 h light/12

h dark cycle. The animals were acclimatized to the laboratory conditions for at least to weeks prior to the beginning of the experiments. Water and standard rodent laboratory chow (Provimi Kliba SA, Kaiseraugst, Switzerland) were supplied ad libitum. The institutional guidelines of the University of Tübingen for care and use of laboratory animals were followed throughout the study.

Surgical procedure

Rats were anesthetized by an intraperitoneal injection of ketamine (Ketanest, 100 mg/kg; Curamed Pharma, Karlsruhe, Germany) and xylazine (Rompun, 15 mg/kg; Bayer, Leverkusen, Germany). A midline laparotomy was performed, and the descending colon was divided under protection of the mesenteric vessels. Continuity was restored with an end-to-end-anastomosis by using 10 all-layer single-stitch sutures (6/0-Prolene; Ethicon, Norderstedt, Germany). The abdomen was closed in two layers by running sutures (3/0-Ethilon; Ethicon). Postoperatively, all animals had free access to water and chow. All operations were performed by the same surgeon. Postoperative analgesia with carprofen sc twice daily (Rimadyl, 5 mg/kg; Pfizer Animal Health, New York, NY) was administered until the third postoperative day.

Study design

The study protocol was designed to minimize pain or discomfort to the animals. Animals were randomized in three groups with 16 animals each. Group Ⅰ received placebo, group Ⅱ received everolimus (RAD001; Novartis Pharma, Basel, Switzerland) in a dosage of 3.0 mg/kg alone and group Ⅲ received everolimus (3.0 mg/kg) plus human Growth Hormone (hGH, Somatropin, Novo Nordisk Pharma, Mainz, Germany) in a dosage of 2.5 mg/kg. Everolimus was administered daily by gastric gavage, while hGH was administered daily subcutaneously. The first dose was given 7 d prior to surgery, and the medication was continued over a period of 14 d. At day 7 after surgery, rats were sacrificed by intracardiac puncture under isoflurane anesthesia. Relaparotomy was performed and the anastomotic region was resected over a length of 40 mm with the suture line in the middle. Surrounding tissues or adhesions were resected with the anastomosis. The following parameters were assessed in the anastomotic region: anastomotic bursting pressure, histology [hematoxylin and eosin (HE) and Azan staining], quantification of hydroxyproline, immunohistochemical staining for proliferating cell nuclear antigen (PCNA) and for myeloperoxidase (MPO), and zymography for quantification of the matrixmetalloproteinases MMP-2 and MMP-9.

Anastomotic bursting pressure

The resected colon segment with the anastomosis in the middle was cleared carefully of mesenteric fat. Feces were removed, and the segment was washed gently in sterile saline. One end of the bowel was connected to an infusion pump; the other end was connected to a manometer, which registered the increasing intraluminal pressure graphically and numerically. The bowel lumen was then infused with sterile isotonic saline solution at an infusion rate of 1 mL/h. The bursting pressure was defined as the highest pressure that was resisted by the bowel segment[38].

Quantification of hydroxyproline

After the assessment of bursting pressure, the anastomotic segment was bisected longitudinally into two-third and one-third segments as previously described by Agren *et al*[39]. Punch biopsies (4 mm diameter) were taken from the sutured area of the two-third longitudinal segment and stored in liquid nitrogen or dried for 48 h at 37 ℃. Tissue dry weight (DW) was measured, and the content of hydroxyproline was then determined by the method of Woessner, modified by Stegemann and Stalder[40].

Histology and immunohistochemistry

For the histopathologic and immunohistochemical analyses, the one-third longitudinal segment was pinned to a cork plate and immersed into 4% paraformaldehyde overnight at 4 ℃, dehydrated in alcohol, and embedded in paraffin. Tissue was cut in 1mm serial cross sections, deparaffinized, and stained with H and E. Cell proliferation was assessed by proliferating cell nuclear antigen antibody (PCNA, Oncogene Science, Uniondale, NY) and inflammatory activity of neutrophil granulocytes by myeloperoxidase antibody (MPO, Dianova, Germany). These assays use the avidin-biotin complex method with 3,3′ diaminobenzidine serving as chromagen. Tissue sections were incubated overnight at 4 ℃ with PCNA or MPO antibody (1:75) followed by incubation with biotinylated secondary antibody as previously described[41].

The analysis of PCNA and MPO positive cells was performed in the granulation tissue of the anastomosis. In total, four high power fields (× 400) of granulation tissue (two at each margin) were examined in every anastomosis. Stainings were evaluated by positive stained cells per area using the Quantimet system (Leica, Jena, Germany). Anastomotic morphology was assessed in H and E-stained slides by standard light microscopy. Analysis was performed semiquantitatively (grade 0-3 for each parameter) under a binocular light microscope (× 400). Histologic parameters were defined as cell density and the amount of granulation tissue in the anastomotic region. Angiogenesis was quantified by the extent of vessel growth at the anastomotic site. Samples were analyzed by an independent blinded investigator.

For the visualization of the collagen fibers,

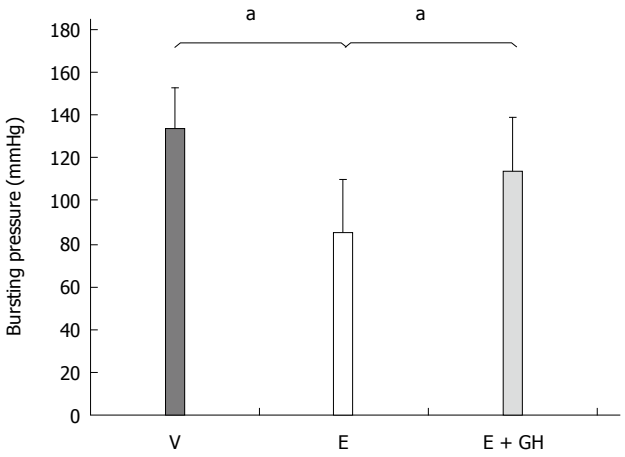

Figure 1 Bursting pressure of the colonic anastomosis (mmHg). Everolimus treatment decreased the bursting pressure significantly. Additional treatment with human growth hormone (hGH) partial antagonized this effect. V: Vehicle, E: Everolimus 3.0 mg/kg, E + GH: Everolimus 3.0 mg/kg + hGH 2.5 mg/kg; [a]*P* < 0.05, V *vs* E, E *vs* E + GH.

samples from the anastomosis were stained with the Azan method[42]. These samples were also analyzed semiquantitatively by an independent blinded investigator.

Zymography

Zymography was performed with equal amounts of pooled anastomotic protein samples from all animals of each group. The presence of MMP-2 and -9 activities was demonstrated by the use of 10% SDS-PAGE containing 10% gelatine (Ready Gel Zymogram; Bio-Rad Laboratories GmbH, Munich, Germany) under nonreducing conditions. Gels were washed twice with 2.5% Triton X-100 (Sigma-Aldrich, Seelze, Germany), incubated for 48 h at 37 ℃ in incubation buffer (50 mmol/L TRIS pH 7.0, 5 mmol/L $CaCl_2$, 200 mmol/L NaCl, 1 mmol/L $ZnCl_2$, 0.05% Brij35, 0.05% NaN_3), and stained with 0.1% Coomassie brilliant blue. Proteolytic activities were visualized by clear zones indicating the lysis of gelatine. The lytic zones on the zymograms were defined as MMP-2 or MMP-9 according to the size standard.

Statistical analysis

Data are expressed as mean ± SD unless otherwise stated. Differences between the groups were calculated by the Mann-Whitney-*U* test. For multiple comparisons, values were adjusted according to Bonferroni. A *P*-value < 0.05 was considered significant.

The statistical methods of this study were reviewed by the Institute of clinical epidemiology and applied biostatistics from the University of Tübingen.

RESULTS

All animals survived the procedure and no anastomotic dehiscence or peritonitis were found during re-laparotomy.

Bursting pressure

The anastomotic bursting pressure was significantly reduced by everolimus (Ⅰ: 134 ± 19 mmHg, Ⅱ: 85 ± 25 mmHg, *P* < 0.05) (Figure 1). Simultaneous treatment with hGH resulted in a higher bursting pressure (Ⅲ: 114 ± 25 mmHg). However, this increase was not statistically significantly both compared to groups Ⅰ and Ⅱ (*P* = 0.09, Ⅲ *vs* Ⅰ and Ⅲ *vs* Ⅱ each).

Histology

In the H and E stained samples there were significant changes in anastomotical architecture in everolimus-treated animals, which were reduced by simultaneous treatment with hGH (Figure 2A-C). Azan staining revealed a decreased arrangement of the collagen fibres under treatment with only everolimus compared to placebo and simultaneous treatment with hGH (Figure 3A-C).

Anastomotic hydroxyproline content

Everolimus significantly reduced the hydroxyproline content in the anastomotic region, while simultaneous treatment with hGH inverted this negative effect completely (Ⅰ: 14.9 ± 2.5 μg/mg DW, Ⅱ: 8.9 ± 3.6 μg/mg DW, Ⅲ: 11.9 ± 2.8 μg/mg DW, *P* < 0.05, Ⅰ *vs* Ⅱ and Ⅰ *vs* Ⅲ and Ⅱ *vs* Ⅲ; Figure 3D).

PCNA and MPO immunohistochemistry

Everolimus decreased PCNA expression significantly compared to placebo treatment (Ⅰ: 28 ± 3 n/mm², Ⅱ: 12 ± 3 n/mm², *P* < 0.05), while simultaneous treatment with hGH antagonized this effect completely (Ⅲ: 26 ± 12 n/mm², *P* < 0.05 Ⅱ *vs* Ⅰ and Ⅲ; Figure 4A). On the other hand hGH lead to normalization of the number of MPO-positive cells compared to only-everolimus-treated animals (Ⅰ: 10 ± 1 n/mm², Ⅱ: 15 ± 3 n/mm², Ⅲ: 9 ± 2 n/mm²; *P* < 0.05, Ⅱ *vs* Ⅰ and Ⅲ; Figure 4B).

Zymography

Everolimus-treated animals had significantly increased activity-levels of the pro-inflammatory zytokines MMP-2 and MMP-9 in the anastomotic region. Simultaneous treatment with hGH reduced these activity-levels to nearly-normal values (Figure 5A-C).

DISCUSSION

Wound healing is a complex biological process which is essential for healing of injured tissue. There are different phases of wound healing finally leading to a stable scar in the wounded tissue. After initial cleaning of the wound by macrophages and neutrophil granulocytes the white cell population shifts to predominantly macrophages, which consume large amounts of oxygen by their respiratory burst which produce proinflammatory cytokines, enzymes (*e.g.*, the matrix-metalloproteinases MMP-2 and MMP-9) and growth factors to remove destroyed collagen from the wounded tissue and to attract cells to the wound

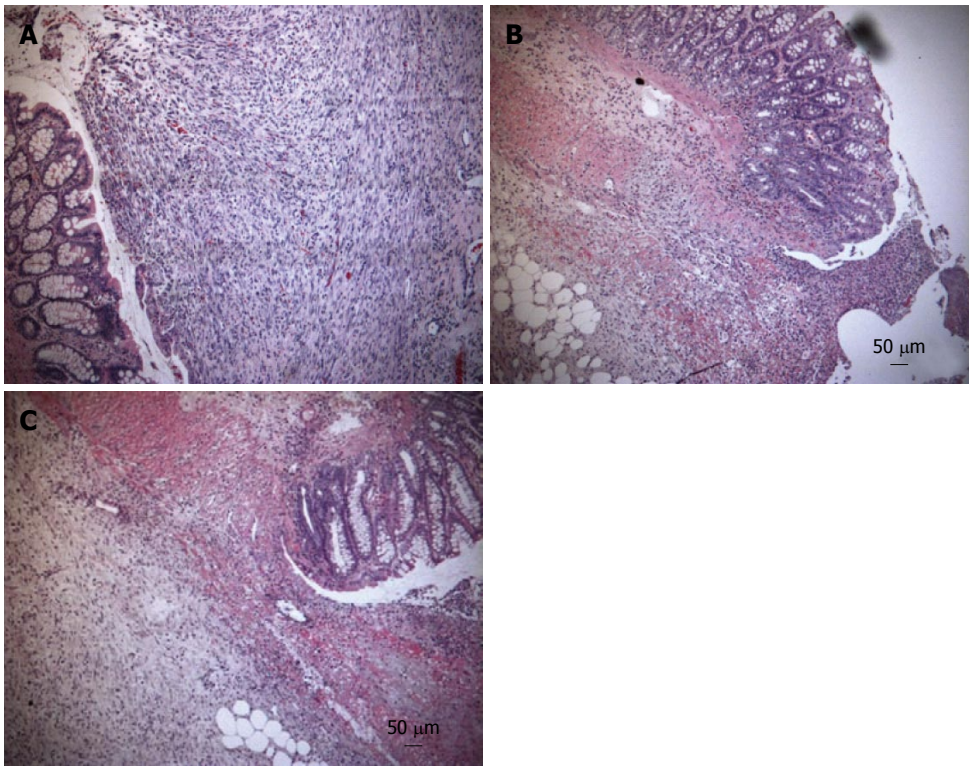

Figure 2 Hematoxylin and eosin staining from the anastomotic region. In the hematoxylin and eosin stained samples there were significant changes in anastomotical architecture in everolimus-treated animals, indicated by decreased cell density and reduced angiogenesis (B) which are indicators for granulation tissue. Simultaneous treatment with human growth hormone (hGH) showed more granulation tissue (C). A: Vehicle; B: Everolimus 3.0 mg/kg; C: Everolimus 3.0 mg/kg + hGH 2.5 mg/kg (magnification × 100).

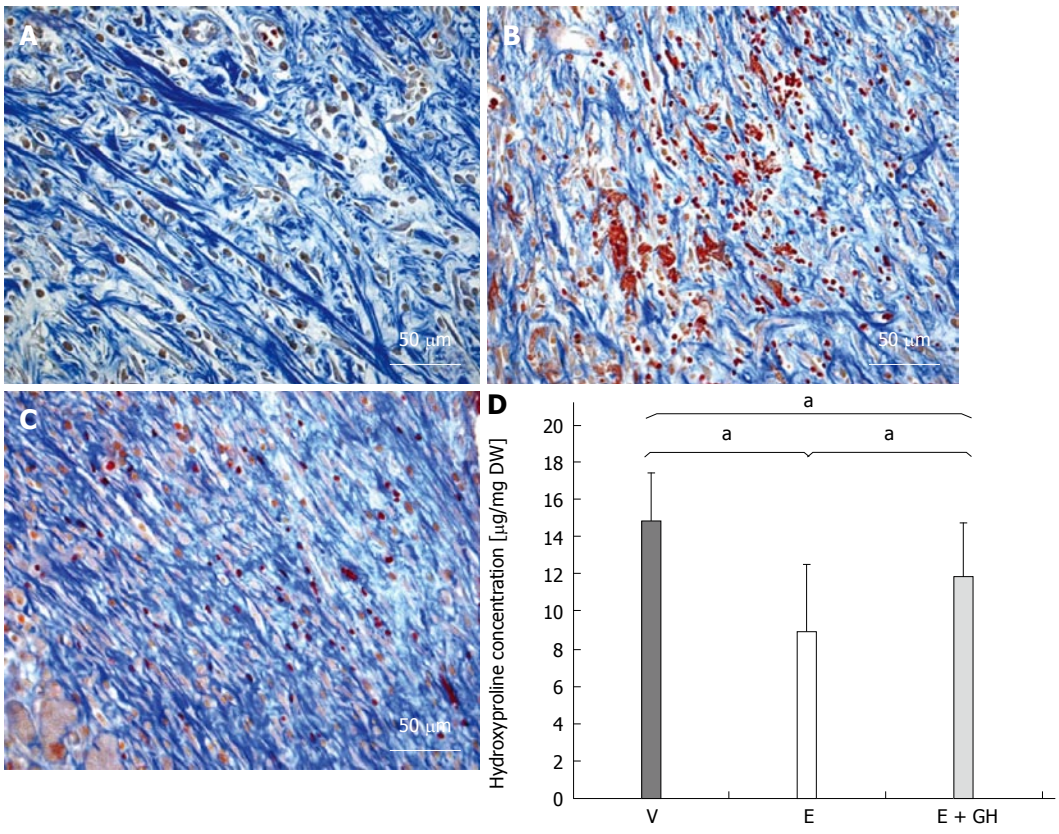

Figure 3 Azan staining from the anastomotic region. The collagen fibres appear blue. Everolimus treated animals show a disturbed arrangement of collagen fibres, which is antagonized by additional human growth hormone (hGH)-treatment (A-C). A: Vehicle; B: Everolimus 3.0 mg/kg; C: Everolimus 3.0 mg/kg + hGH 2.5 mg/kg. Hydroxyproline concentration in the anastomotic region in mg per mg dry weight (DW). The decrease of hydroxyproline under everolimus-treatment is reduced by additional hGH-treatment (D) (magnification × 400). V: Vehicle, E: Everolimus 3.0 mg/kg, E + GH: Everolimus 3.0 mg/kg + hGH 2.5 mg/kg; $^{a}P < 0.05$, *vs* E group, V *vs* E + GH group.

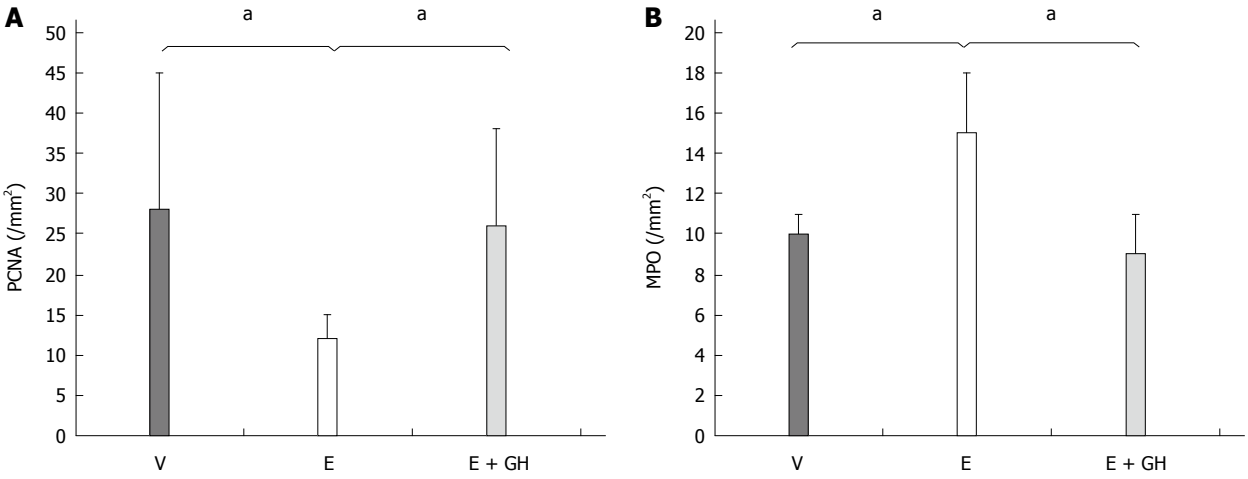

Figure 4 Immunohistochemistry for PCNA- (A) and MPO- (B) positive cells from the anastomotic region. Treatment with everolimus alone reduced significantly the amount of PCNA-positive cells in the anastomotic region while increasing the number of MPO-positive cells, indicating a prolonged inflammation. Simultaneous treatment with hGH led to nearly normal values for PCNA- and MPO-positive cells**.** V: Vehicle, E: Everolimus 3.0 mg/kg, E + GH: Everolimus 3.0 mg/kg + hGH 2.5 mg/kg; V *vs* E, E + GH *vs* E, $^{a}P < 0.05$.

which are essential for the proliferation phase[3,43]. This particular step of the healing cascade is defined as the so-called inflammatory phase; its activity peaks in the first 3 to 5 d after wounding[2,44]. Subsequently, healing progresses to the phases of proliferation and tissue remodeling, which are mainly characterized by collagen synthesis by the fibroblasts and new vessel growth to provide enough oxygen to the wound[3,44]. In this phase fibroblasts produce mainly collagen to repair the wound. Moreover, angiogenesis is started to provide enough oxygen to the wound. If these two phases of wound healing are disturbed, it may result in severe wound healing problems which can be devastating in cases of non-healing anastomoses in the gastrointestinal tract. mTOR is a key factor in the regulation of protein synthesis and cell proliferation. Its effects are mediated *via* complex building with two complexes being involved [mTOR-complex 1 (mTORC1) and mTOR-complex 2 (mTORC2)]. mTORC1 is essential in the regulation of protein synthesis, while the main function of mTORC2 is regulation of the actin cytosceleton. Both, mTORC1 and mTORC2 are activated amongst others by insulin-like growth factor 1 (IGF-1), a growth factor, which is stimulated by the human growth hormone (hGH). IGF-1 acts *via* the Protein-Kinase B (PKB), also known as Akt, and the corresponding Akt-pathway, resulting in complex-building of mTORC1 and thus activation of protein synthesis. This has been demonstrated in animal studies previously. Christensen *et al*[34] investigated the effects of hGH on the healing of rodent colon anastomoses in the 1990s[35,45-49]. They found an increased bursting pressure in the hGH-treated animals which showed a significantly increased amount of collagen in the anastomotic region compared to the control groups[35,45,46]. Beckert *et al*[32] demonstrated in another animal study that administration of hGH leads to increased healing of gastric ulcers in rats compared to the control groups. They showed an increased cell proliferation and angogenesis, both key factors of wound healing[3,44].

On the other hand, mTOR-inhibitors have been demonstrated to significantly disturbe wound healing. Initially there were clinical reports of patients after kidney transplantation who received sirolimus as immunosuppressant drug. These patients had significantly more wound complications than patients with a mTOR-inhibitor-free immunosuppressant regime[21,22,50]. The same was demonstrated later on after liver transplantation[19,20]. van der Vliet *et al*[27] then showed in 2011 that the hydroxyproline-content in healing colon anastomoses in rats was significantly decreased after treatment with everolimus. With hydroxyproline acting as a progenitor of collagen, this demonstrated for the first time, that mTOR-inihibtors result in a decreased wound strength by reducing protein synthesis. A similar way of action was shown in 2011, when it was demonstrated in the same experimental setting like in this study, that everolimus resulted in a decreased hydroxyproline-content in colonic anastomotic tissue. Furthermore, cell proliferation was reduced as well as angiogenesis while the inflammatory reaction in the anastomosis was increased by means of increased myeloperoxidase (MPO)-positive cells and increased activity of the matrix-metalloproteinases 2 and 9 (MMP2/9) indicating a delayed phase of proliferation[31].

The combination of hGH and everolimus resulted in an improved wound healing compared to everolimus alone. Bursting pressure, content and organization of collagen in the anastomotic tissue, as well as histological parameters like cell density and angiogenesis were significantly improved after combination treatment with hGH and everolimus compared to everolimus alone. All of these factors contribute the proliferation phase of wound healing and were increased, whilst

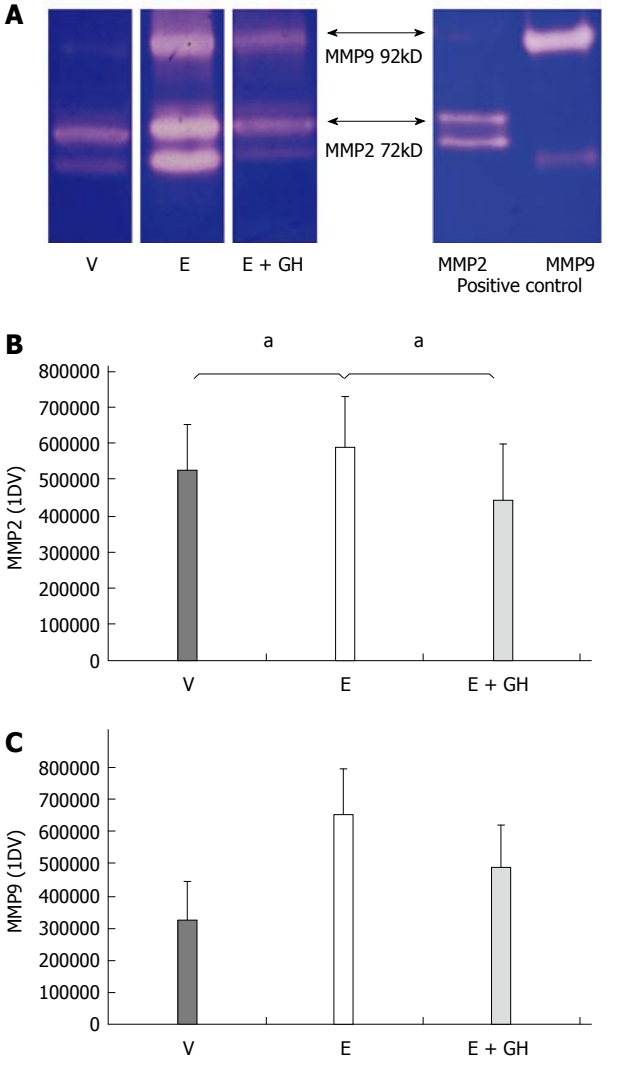

Figure 5 Zymographic activities of the pro-inflammatory matrix-metalloproteinases MMP2 and MMP9. Zymography gel showing increased proteolytic activity under treatment with everolimus which is reduced by simultaneous treatment with human growth hormone (hGH) (A). Numeric calculation of the proteolytic activity of MMP2 (B) and MMP9 (C). V: vehicle, E: everolimus 3.0 mg/kg, E+GH: everolimus 3.0 mg/kg + hGH 2.5 mg/kg; V *vs* E, E + GH *vs* E, $^{a}P < 0.05$.

MPO-positive cells and activity of MMP-2 and -9, both markers of the inflammatory phase of wound healing, were reduced by combination treatment of hGH and everolimus. This indicates a partial normalization of wound healing. However, all of these factors were still reduced compared to placebo treatment. One possible explanation is the activation of the Akt-pathway by an IGF-1 synthesis, which is stimulated by hGH. This Akt-pathway leads to an increased forming of the mTOR-complex 1 (mTORC1). On the other hand, everolimus binds to this mTORC1 with high affinity resulting in reduction of the mTORC1-mediated protein-synthesis and cell proliferation. With increased amounts of mTORC1 due to the hGH-treatment, higher doses of everolimus should be needed to produce the same effects as without simultaneous hGH-treatment. However, this has to be investigated in further studies.

In conclusion we could demonstrate for the first time that simultaneous treatment of everolimus and hGH can ameliorate the negative effects of everolimus on intestinal wound healing. However, the exact mechanisms of this partial antagonization remain unclear by now and have to be further investigated.

ACKNOWLEDGMENTS

We thank Dr. Dr. Frank Traub for the histopathological evaluation of the specimen. We thank Prof. Dr. Martin Eichner from the Institute of clinical epidemiology and applied biostatistics from the University of Tübingen for help with the biostatistics. We thank Mrs. Catharina Scheuermann-Poley for language editing.

COMMENTS

Background

Mammalian target of rapamycin (mTOR)-inhibitors are part of standard immunosuppressive medication after both solid organ and bone marrow or stem cell transplantation. The mostly used agents are sirolimus and its derivate everolimus. However, due to severe impairment of wound healing, the definitive mTOR-based immunosuppressive regime is often initiated weeks after transplantation. Moreover, in case of some medical interventions such as surgical procedures the regime has to been switched to an mTOR-inhibitor-free regime with an increased risk of adverse events like graft rejection. To reduce this risk we need to better understand the mechanisms of mTOR-inhibitor-induced impairment of wound healing. One aspect is the delayed inflammatory phase of wound healing resulting in a decreased deposition of wound collagen. So there might be a point of application to reduce this risk.

Research frontiers

The delayed inflammatory phase of wound healing probably is only one mechanism of action of impaired wound healing induced by mTOR-inhibitors as the exact working mechanisms are not known in detail yet. Moreover it is not known yet whether the immunosuppressive potential of the mTOR-inhibitors is caused by the same pathway.

Innovations and breakthroughs

This is the first study which evaluated an approach to counter the negative effects of everolimus on the wound healing and the first time that it was demonstrated that the negative effects of everolimus on wound healing can be antagonized at least partly by another agent.

Applications

The present results might be used to better understand the mechanisms of action of mTOR-inhibitors as well as the basis for further investigation of wound healing under mTOR-inhibitor medication. In the end there is the goal that changing of mTOR-inhibitor-based immunosuppressive regimes is not necessary any more in advance of a planned medical intervention or after an emergency surgical procedure.

Peer-review

The research topic has significant application for immunosuppressant medications in patients undergoing solid organ transplantation

Abstract

AIM: To determine the hypothesis that inflating the balloons in the duodenal papilla determines changes in the biochemical markers of pancreatitis.

METHODS: Four groups of pigs were used: Group papilla (GP), the overtube's balloon was inflated in the area of the papilla; GP + double balloon enteroscopy (GP + DBE), the overtube's balloon was kept inflated in the area of the papilla for 20 min before a DBE; Group DBE (GDBE), DBE was carried out after insuring the balloon's inflation far from the pancreatic papilla; and Group control (GC). Serum concentrations of amylase, lipase and C-reactive protein (CRP) were evaluated. Pancreases were processed for histopathology examination.

RESULTS: Main changes occurred 24 h after the procedure compared with baseline levels. Amylase levels increased significantly in GP (59.2% higher) and were moderately higher in groups GP + DBE and GDBE (22.7% and 20%, respectively). Lipase increased in GP and GP + DBE, whereas it hardly changed in GDBE

and in GC. CRP increased significantly in GP, GP + DBE and GDBE, while no changes were reported for GC. No statistically significant difference between groups GP and GP + DBE was found for the histopathological findings, except for vacuolization and necrosis of the pancreatic parenchyma that was higher in GP than in GP + DBE.

CONCLUSION: The manipulation of the duodenal papilla by the inflated overtube's balloon during DBE causes pancreatic structural damage and increased biochemical markers associated with pancreatitis.

Key words: Duodenal papilla; Double balloon enteroscopy; Pancreas; Animal model; Pancreatitis

Core tip: During double balloon enteroscopy (DBE) the manipulation of the duodenal papilla by the inflated balloons around the area of secretion of the pancreas determines structural damage in the organ and increased levels of biochemical markers of pancreatitis. Thus, the widely assumed recommendation of avoiding any contact of the balloons with the duodenal papilla so as to decrease post-DBE pancreatic risk is now supported by empirical results in an animal model.

Effect of the manipulation of the duodenal papilla during double balloon enteroscopy. *World J Gastroenterol* 2016; 22(17): 4330-4337 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4330.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4330

INTRODUCTION

Double balloon enteroscopy (DBE) is a variety of push and pull endoscopy which allows diagnostic and therapeutic actions deep in the small intestine[1]. Although DBE has been considered a reasonably safe technique[2], articles reviewing complications have been published recently[3]. Among the major complications (0.72%)[4] acute post-procedure pancreatitis is the most severe[5]. DBE can be done by oral or anal approaches but post-DBE pancreatitis is mainly related with the anterograde approach. The average incidence of this complication is not very high (0.3%)[6] however, it may be underestimated in previously published data[7]. With the use of the oral approach increases in the incidence of pancreatitis which may vary from 1%-3%[2,7,8] to 12.5[9].

There is some controversy about the etiology of acute pancreatitis after DBE but most opinions agree that the cause is related with the technique itself[2,10-13]. Ischemia of the pancreas from prolonged mechanical stress due to repeated stretching of the endoscope, reflux of duodenal content into the pancreatic duct consequent to overpressure in the intestinal compartment, and disturbance of the pancreatic secretion due to direct trauma to the papilla of Vater are the most plausible theories[6,7,11-13]. In order to avoid potential trauma in the ampullar zone some endoscopists recommend inflating the balloons after passing the ligament of Treitz[14,15], although no causal relationship has been found with a lower incidence of hyperamylasemia or reduction in pancreatitis rate[16]. However, precise control of this manoeuvre is not always guaranteed[2] and during the learning curve, unintentional shearing of the ampullary area is likely.

Post-DBE hyperamylasemia is the most frequent biochemical marker associated with suspicion of acute pancreatitis[10,11,13], however increased amylase levels after DBE are not always indicatory of pancreatic inflammation since asymptomatic hyperamylasemia is quite common in DBE procedures[2]. Lipase levels are more specific for the pancreatic function but post-DBE hyperlipasemia is not always accompanied by clinical signs of pancreatitis such as increased abdominal pain. Nevertheless, amylase and lipase levels together plus those of the reactive C-protein (CRP) are a valuable tool to diagnose post-DBE acute pancreatitis because they are commonly elevated soon after the procedure[2,9].

One major limitation for research in this field comes from the fact that DBE is mainly restricted to endoscopy procedures in humans, although the use of an appropriate animal model could help to overcome this limitation. The porcine model has been used both *ex vivo* and *in vivo* for DBE training and research, helping to improve the technique conditions in humans[17-19]. Pig and human pancreas are partially retroperitoneal, encircle the portal vein and have similar parenchyma firmness. Unlike humans, pigs have a unique pancreatic duct (accessory) which opens at a minor duodenal papilla located 8-10 cm distally from the major duodenal papilla and approximately 12-15 cm from the pylorus[20].

In the present work a pig model was used to test the hypothesis that the length of time the inflated balloons are kept in contact with the duodenal papilla determines changes in the pancreas structure, as well as the biochemical markers of pancreatitis. This study might help to reach a better understanding of the factors involved in the etiology of pancreatitis post-DBE.

MATERIALS AND METHODS

The experimental work was carried out at the Minimally Invasive Surgery Center Jesús Usón (CCMIJU) (http://www.ccmijesususon.com). All animals received humane care in compliance with the European Communities Council Directive (86/609/EEC) and protocols were approved by the Ethics Committee for Animal Research of the University of Murcia (Ref.452/2009). An EN-

450T5 enteroscope (Fuji Film) for exclusive use in animals was used in this work.

Thirty large white pigs (35-40 kg) were used in this study. Pigs were randomly assigned to one of the following groups: GP, GP + EDB and GC.

GP (Group papilla) (n = 10) aimed at evaluating the effect of shearing the minor duodenal papilla independently of DBE. In this group the overtube's balloon was inflated in the area of the papilla, kept there for 90 min and then removed without DBE exploration. GP + DBE (Group papilla + DBE) (n = 10) was designed to simulate a potential situation (beginner's scenario) where papilla compression might occur during the first manoeuvres of DBE exploration. In this group the overtube's balloon was kept inflated in the area of the papilla for 20 min before proceeding with a standard DBE exploration of 90 min. A control group GC (n = 10) for both papilla compression and DBE was used for comparison with GP, GP+DBE. In the control group a conventional esophagogastroduodenoscopy (EGD) was carried out. A forth group was considered GDBE (Group DBE), it represented the most common situation in conventional oral DBE (clinical situation). DBE was carried out for 90-140 min after insuring the balloon´s inflation occurred distal to the pancreatic papilla. The data from GDBE came from work previously published by our group[19].

Before procedure all pigs were fasted for 24 h and then intramuscularly pre-medicated with diazepam 0.1 mg/kg, ketamine 10 mg/kg and atropine 0.01 mg/kg. General anaesthesia was induced with propofol 2 mg/kg intravenously and maintained with Sevofluorane 1.8%-2% delivered *via* endotracheal tube. DBE were always performed by two of the authors (Pérez-Cuadrado E or Soria F) who have been routinely performing this technique for at least 9 years. During DBE exploration insertion depth was estimated according to the methodology established by May *et al*[17], which has also been validated in the pig model[21]. After anesthesia, recovering pigs were checked for 24 h for signs of decreased activity, irritability, vomiting or anorexia. Blood samples were taken before procedure (Basal), at the end of the procedure (End) and just before euthanasia (24 h). The serum concentrations of amylase, lipase and C-reactive protein (CRP) were evaluated. Euthanasia was performed by a pentobarbital overdose.

Immediately after death, pancreases were examined *in situ* and carefully removed from the abdominal cavity, and the left pancreatic lobe (tail) immersed in 10% buffered formaline. The samples for histopathology were systematically taken, making blocks of 1 cm^3 (8-12 blocks per pancreas). Tissues were embedded in paraffin, sectioned at 4 microns, and stained with hematoxylin and eosin. Histology sections were studied under light microscopy. The presence and distribution of lesions were evaluated for edema, vacuolization, necrosis, vascular congestion and inflammation. Histopathological findings were characterized and categorized by a pathologist (Candanosa E, author) as showed in Table 1. GDBE histopathology was not included because in this group euthanasia was performed 7 d after procedure[19].

The statistical analysis was carried out with the SPSS 19.0 (SPPS Inc) package. For the biochemical markers (amylase, lipase and CRP) descriptive statistics were calculated and the analysis of variance (ANOVA, linear model with repeated measures) performed considering the different timing of blood sampling as within-subject factors. To evaluate the significance of the histopathological findings the severity (graded 0-3) was compared between the experimental groups by the non-parametric Mann-Whitney test. In addition, the potential association between the histopathological features and the experimental groups was evaluated by contingency tables and the χ^2 test. All statistics were initially performed for a significance level of $P < 0.05$.

RESULTS

Pancreatic markers /Biochemical evaluation

The average serum concentrations of amylase, lipase and CRP at the different sampling periods (Basal, End of experiment and 24 h post-DBE) have been summarized in Table 2 (within groups comparison) and Figure 1 (between groups comparison).

Twenty four hours after the procedure the amylase levels increased quite significantly, such that compared to the basal situation it was 59.2% higher in group GP, and moderately higher in groups GP + DBE and GDBE (22.7% and 20% increases, respectively). However, the amylase levels in GC (control group) hardly changed from the basal levels throughout the experiment (Table 2).

Amylase levels ranged between a maximum in GP and minimum in GC with differences between

Table 2 Within group comparison of serum levels (mean ± SD) of biochemical markers (amylase, lipase and CRP) at different sampling points (Basal, End of endoscopy and 24 h later)

Group	Time	Amylase (IU/L)	Lipase (IU/L)	CRP (mg/L)
GP	Basal	2507.9 ± 553.6[1]	34.3 ± 19.26[1]	30.1 ± 43.3[1]
	End	2317 ± 523.5[2]	45.4 ± 33.6[1]	27.4 ± 41.7[1]
	24 h	3993.3 ± 2047.3[3]	444.6 ± 417.2[2,d]	182.3 ± 44.5[2,d]
GP + DBE	Basal	2214.9 ± 385.9[1]	19.6 ± 16.4[1]	20.6 ± 26.4[1]
	End	1920.2 ± 360.8[2]	37.1 ± 29.5[2,b]	16.2 ± 21.8[1]
	24 h	2717.2 ± 686.6[2]	146.8 ± 128.1[1,2]	117.3 ± 46.1[2,d]
GDBE	Basal	1968.1 ± 929.6[1]	17.7 ± 7.7[1]	39.1 ± 41.2[1]
	End	1850 ± 820.7[2]	8.8 ± 3.6[1]	37.2 ± 38.3[1]
	24 h	2487.2 ± 1093.4[2]	26.7 ± 20.9[1]	114.8 ± 100.7[2,d]
GC	Basal	1965.4 ± 856.4[1]	10.7 ± 3.1[1]	9.8 ± 8.8[1]
	End	1881.9 ± 839.5[1]	9.1 ± 2.32[1]	10.1 ± 8.3[1]
	24 h	2245.8 ± 995.9[1]	37.5 ± 23.6[1]	24.2 ± 17.4[1]

[1,2,3]Different superscripts within the same column of the same experimental group indicate significant differences at 95% confidence ($P < 0.05$). [b]$P < 0.01$, [d]$P < 0.0001$ *vs* basal. GP: Group papilla; GP + DBE: Group papilla + double balloon enteroscopy; GC: Group control; GDBE: Group DBE.

these two groups. Despite of the fact that the highest amylase levels were found in GP, no significant differences were found between GP, GP + DBE and GDBE at any of the three sampling points (Figure 1A).

The lipase concentration hardly changed throughout the procedure ranging between 8.8 and 45.4 IU/L. However, 24 h after the procedure lipase levels in the papilla-focused groups (GP and GP+DBE) were seen to rise sharply, while hardly changed in those groups where the papilla was not manipulated (GDBE and GC) (Figure 1B). Compared to the basal situation the lipase concentration was 11.4 and 7.5 times higher in GP and GP + DBE, respectively. Thus, inflation and maintenance of the balloons around the papillar area resulted in dramatic changes in the lipase levels one day after the procedure.

None of the procedures resulted in immediate changes in CRP levels (Table 2). The basal CRP range was 11-39.1 mg/L, which included the values observed at the end of the procedures. One day later CRP increased significantly in GP, GP + DBE and GDBE, with values of 5.5 and 6.3 and 3.6 times higher than basal levels, while no significant changes were reported in GC (Table 2).

From a clinical point of view it is important to note that none of the pigs showed significant alterations in the monitored parameters during the procedure (blood pressure, heart and respiratory rates and oxygen saturation). The pigs ate normally and showed no clinical signs of abdominal pain, vomiting, diarrhea or altered sensory behavior in the 24 h following endoscopies.

Histopathological findings

Results from the control group (GC) revealed the absence of edema, vacuolization, necrosis, vascular congestion and inflammation. However, all these pathological features were observed to a certain degree in pancreas samples from groups GP (Figure 2) and GP + EDB (Figure 3). No statistically significant differences between these two groups were found for edema, vessels congestion and inflammation, whereas vacuolization and necrosis of the pancreatic parenchyma was higher in GP than in GP + DBE (Table 3). This result was confirmed by the χ^2 test as the frequency of samples with vacuolization and necrosis was significantly different in GP and GP+DBE groups with a 90% of confidence ($P < 0.1$) (Table 4).

DISCUSSION

In this study the manipulation of the duodenal papilla by the inflated balloons during DBE was shown to cause pancreatic structural damage and concomitant increase of biochemical markers of pancreatitis. This direct association was experimentally demonstrated in a pig model using two experimental groups (GP and GP+DBE) with different time periods of contact between the balloons and the duodenal papilla. Results were conclusive, the longer the manipulation of the papilla the higher the changes in biochemical markers. Thus, the widely assumed recommendation of avoiding any contact of the balloons with the duodenal papilla so as to decrease post-DBE pancreatic risk[9,14] is now supported by empirical results in an animal model.

Contact between the duodenal papilla and the inflated balloon for 90 min resulted in a very significant increase in amylase (59.2%), lipase (11.4 times) and CRP (5.5 times) levels 24 h after endoscopy (Figure 1). This information gives a clear indication of how the manipulation of the duodenal papilla influences the pancreas independently of DBE. The combined effect of papilla manipulation and DBE was specifically monitored in GP + DBE. Although the results were less dramatic, GP + DBE procedure also resulted in significant increases of amylase (22.7%), lipase (7.5 times) and CRP (6.3 times) levels 24 h after the procedure. In contrast, in GDBE serum levels of amylase and lipase never reached twice the baseline levels (20% for amylase and 1.5 times for lipase), as

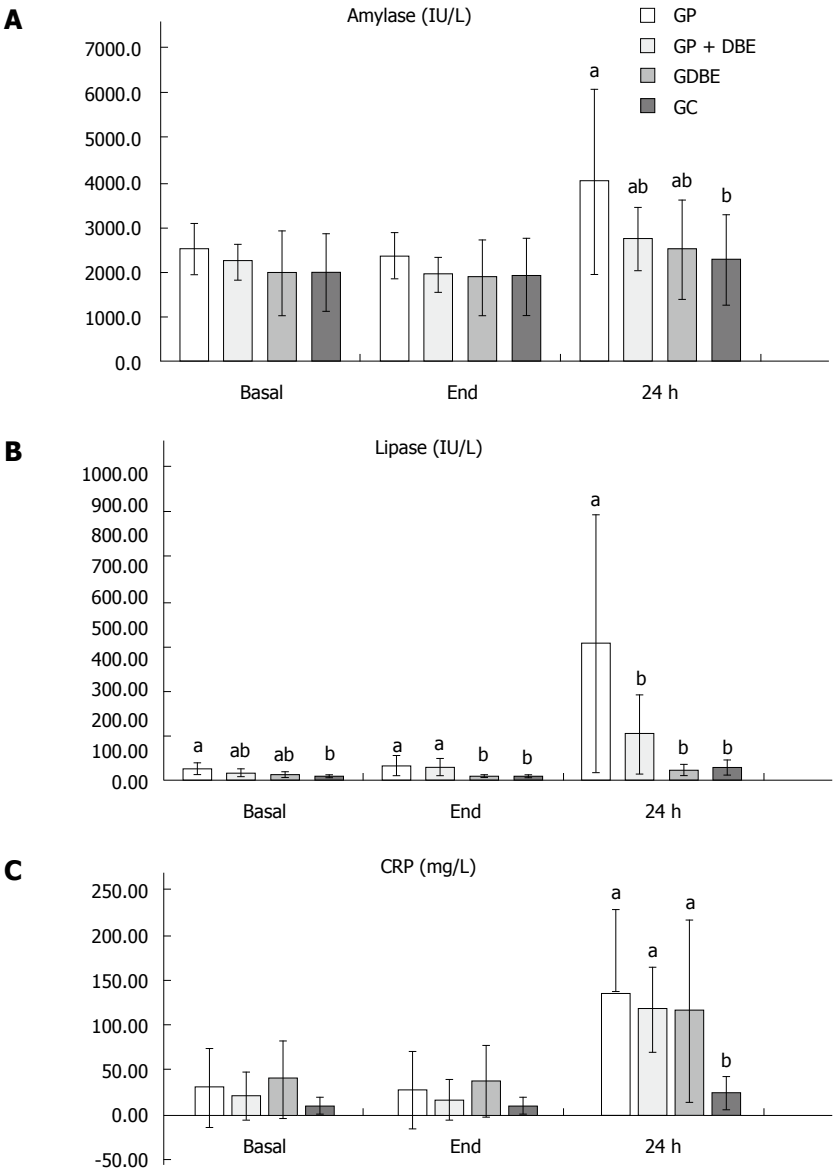

Figure 1 Between groups comparison of serum levels of amylase (A), lipase (B) and CRP (C) at different sampling times (Basal, End of endoscopy and 24 h later, mean ± SD). [a,b]Different superscripts over the bars within the same time interval indicate significant differences between GP, GP + DBE, GDBE and GC at 95% confidence ($P < 0.05$). GP: Group papilla; DBE: Double balloon enteroscopy; GC: Group control; GDBE: Group DBE.

Table 3 Comparison of histopathological features (mean ± SD) between the GP, GP + DBE groups according to the categorization scale given in Table 1

Group	Edema	Vacuolization	Necrosis	Vessels congestion	Inflammation
GP	3.38 ± 0.66	2.95 ± 0.83[1]	1.59 ± 0.75[1]	0.89 ± 0.44	0.21 ± 0.51
GP + DBE	3.29 ± 0.64	2.56 ± 0.97	1.32 ± 0.75	0.93 ± 0.41	0.21 ± 0.56

[1]The existence of significant differences at 95% significance level. Control group is not included, as it had no lesions. Group DBE (GDBE) is also not included because the histological assessment was performed at 7 d after procedure[19]. GP: Group papilla; DBE: Double balloon enteroscopy.

Table 4 Significance levels for the χ^2 test of association between the experimental procedures (GP, GP + DBE) and the frequency of damaged samples

Histopathological parameter	*P* value
Edema	0.73
Vacuolization	0.06[1]
Necrosis	0.09[1]
Vessels congestion	0.80
Inflammation	0.46

[1]The existence of a significantly different frequency of damaged samples in GP and GP + DBE for each histopathological parameter for a 90% confidence ($P < 0.1$).

has been observed in previous studies examining the iatrogenic effects of experimental oral DBE[19]. The differences between groups GP and GP + DBE could be a consequence of the fact that in group GDBE during the oral insertion the balloons were always inflated distally to the duodenal papilla where the pancreatic duct opens into the duodenum, as recommended by some authors[9,22].

The protocol used to monitor post-DBE pancreatitis coincides with the most common protocol in human medicine[2,10,13,22], and was also used in our previous paper[19]. It involves the serological measurement of amylase, lipase and the C-reactive protein (CRP). As a general rule, an increase of amylase and/or lipase higher than twice their basal levels, together with a significant increase of CRP is enough to suspect pancreatitis. There are many potential mechanisms that could hypothetically induce a rise of serum amylase after DBE and some of them have been discussed in previous studies[10,11,13]. For instance, hyperamylasemia has been suggested to occur by the smooth shearing involved while sliding the endoscope and overtube[23] due to its influence in the permeability of the intestine[24]. Thus, in routine DBE in humans amylase levels 24 h after procedure commonly increases up to a bit less than twice baseline levels in a high proportion of patients, 39%[8] 46%[13] and 58%[10]. However, when a relationship between serum amylase and post-endoscopy pancreatitis is suspected, amylase can reach three times the basal levels[25]. Regarding the lipase levels significant increases have also been described in patients at 4 h[9,10,24], 12 h[9] and 24 h[9,10,24] after procedure. It has been suggested that during pancreatic acinar cells injury the sensibility of lipase activity is 82%-100% much better than that amylase activity. Thus, serum lipase activity can increase 2 to 50 times of its upper limit of reference range and remain at such a high level for a longer time than amylase. In previous studies more than 65% of normoamylasemic patients with acute pancreatitis were found to have high lipase activity[26]. Finally, CRP is an indicator sensitive to inflammation but very non-specific regarding the origin of the inflammation. The increased CRP after DBE represents inflammation that could either be mucosal irritation or a clue for suspicion of pancreatitis when combined with hyperamylasemia and hyperlipemia[2,9].

Vacuolization and moderate necrosis in acinar cells was observed in groups GP and GP + DBE, this indicating a relationship between the histological

damage and the degree of manipulation of the duodenal papilla during the procedures. As a general rule, the longer the papilla was in direct contact with the inflated balloons the higher the structural changes found in the pancreas (Tables 3 and 4). From an ethiopatological point of view our histology results may resemble those described in experimental models of pancreatic duct obstruction. These studies showed that pancreatic outflow obstruction alone is sufficient to induce necrotizing pancreatitis[27,28] throughout a sequence of events including acinar cell swelling, vacuole formation, swelling and breakdown of mitochondria, nuclear condensation and rupture of the membranes of organelles[29]. As cell vacuolization may be reversible if the cause is removed this may help to explain the lack of clinical symptoms even in pigs of the GP group[29]. On other hand, in previous experimental studies from our group, where the major and minor duodenal papilla were avoided during DBE oral insertion, no vacuolization was observed in acinar cells. The only injures observed in those animals were related to an ischemic process in the vascular supply to the tail of the pancreas[19].

Regarding the experimental model, it might be argued a probably too long contact time between the overtube's balloon and the papilla in GP and GP + DBE. However, some authors refer to a significant learning curve in acquiring the skills necessary to perform DBE. The results of those authors showed for the first 10 oral-DBE a mean (SD) procedural time of 109 ± 44.6 min[30] or 92.3 ± 38.6 min[31], with a range distance examined between 0 and 665 cm[30] or with a mean speed of less than 1 cm/min for some cases[31]. That indicates that some procedures conducted during the DBE's learning curve have a very low or even null range of explored distance[30,31] without a clear awareness of the position of the inflated overtube's balloon. Other authors also correlate the oral-DBE learning curve with the incidence of hyperamylasemia and pancreatitis[10,23]. In DBE, a gripping force by the overtube balloon is used to support endoscopic insertion, and when an untrained endoscopist applies too much insertion force to the endoscope, the forceful insertion causes slippage of the overtube's balloon and ineffective advancement of the endoscope tip. Finally, in the opinion of several groups DBE should only be performed by an endoscopist with adequate training[15], technical skills and patient volume to maintain their skills[32], a minimum of between 10[31] and 50[33] procedures are required.

In conclusion, during DBE the persistence of the inflated balloon around the area of secretion of the pancreas determines structural damage in the organ and increased levels of biochemical markers (amylase, lipase and CRP). This study in the porcine animal model may help to further understand the potential etiology of post-DBE pancreatitis in humans.

COMMENTS

Background

Disturbance of the pancreatic secretion due to direct trauma to the papilla of Vater is one of the most plausible theories about the etiology of acute pancreatitis after double balloon enteroscopy (DBE).

Research frontiers

In order to avoid potential trauma in the ampullar zone some endoscopists recommend inflating the balloons after passing the ligament of Treitz, although no causal relationship has been found with a lower incidence of hyperamylasemia or reduction in pancreatitis rate.

Innovation and breakthroughs

This is the first study evaluating the manipulation of the duodenal papilla by the inflated balloons during DBE.

Applications

The results of this work support the recommendation of avoiding any contact of the balloons with the duodenal papilla so as to decrease post-DBE pancreatic risk.

Terminology

DBE is a variety of push and pull endoscopy which allows diagnostic and therapeutic actions deep in the small intestine. Although DBE has been considered a reasonably safe technique, articles reviewing complications have been published recently. Among the major complications acute post-procedure pancreatitis is the most severe. Post-DBE pancreatitis is mainly related with the anterograde approach, it may vary from 1%-3% to 12.5%.

Peer-review

Very interesting paper, well designed, dealing with an important clinical problem.

Abstract

AIM: To evaluate the correlation of shear wave elastography (SWE) results with liver fibrosis histology and quantitative function reserve.

METHODS: Weekly subcutaneous injection of 60% carbon tetrachloride (1.5 mL/kg) was given to 12 canines for 24 wk to induce experimental liver fibrosis, with olive oil given to 2 control canines. At 24 wk, liver condition was evaluated using clinical biochemistry assays, SWE imaging, lidocaine metabolite monoethylglycine-xylidide (MEGX) test, and histologic fibrosis grading. Clinical biochemistry assays were performed at the institutional central laboratory for routine liver function evaluation. Liver stiffness was measured in triplicate from three different intercostal spaces and expressed as mean liver stiffness modulus (LSM). Plasma concentrations of lidocaine and its metabolite MEGX were determined using high-performance liquid chromatography repeated in duplicate. Liver biopsy samples were fixed in 10% formaldehyde, and liver fibrosis was graded using the modified histological activity index Knodell score (F0-F4). Correlations among histologic grading, LSM, and MEGX measures were analyzed with the Pearson linear correlation coefficient.

RESULTS: At 24 wk liver fibrosis histologic grading

was as follows: F0, *n* = 2 (control); F1, *n* = 0; F2, *n* = 3; F3, *n* = 7; and F4, *n* = 2. SWE LSM was positively correlated with histologic grading (*r* = 0.835, *P* < 0.001). Specifically, the F4 group had a significantly higher elastic modulus than the F3, F2, and F0 groups (*P* = 0.002, *P* = 0.003, and *P* = 0.006, respectively), and the F3 group also had a significantly higher modulus than the control F0 group (*P* = 0.039). LSM was negatively associated with plasma MEGX concentrations at 30 min (*r* = -0.642; *P* = 0.013) and 60 min (*r* = -0.651; *P* = 0.012), time to ½ of the maximum concentration (*r* = -0.538; *P* = 0.047), and the area under the curve (*r* = -0.636; *P* = 0.014). Multiple comparisons showed identical differences in these three measures: significantly lower with F4 (*P* = 0.037) and F3 (*P* = 0.032) as compared to F0 and significantly lower with F4 as compared to F2 (*P* = 0.032).

CONCLUSION: SWE LSM shows a good correlation with histologic fibrosis grading and pharmacologic quantitative liver function reserve in experimental severe fibrosis and cirrhosis.

Key words: Liver fibrosis; Histologic grading; Shear wave elastography; Monoethylglycinexylidide test; Experimental study

Core tip: Non-invasive evaluation of liver histology and function reserve is critical for determination of treatment option and prognosis in severe fibrosis and cirrhotic patients. Shear wave elastography (SWE) is a newly emerging elastrographic modality with relatively high resolution and good reproducibility for liver imaging. Lidocaine/monoethylglycinexylidide is also an advanced, laboratory dynamic liver function assay with good diagnostic sensitivity, specificity, and accuracy. This study sheds light on the correlation of SWE imaging results with pharmacologic quantitative liver function for disease severity and function reserve evaluation in patients with severe fibrosis/cirrhosis scheduled for major hepatectomy or liver transplantation.

INTRODUCTION

Liver fibrosis is a progressive liver disease characterized by replacement of normal liver parenchymal tissue by fibrotic nonparenchymal tissue with or without concomitant abnormal regenerative nodules[1]. The etiologies of liver fibrosis vary among populations worldwide and mainly include viral hepatitis, especially chronic hepatitis B and C in Eastern and Southeastern Asians, alcoholic liver disease in Westerners, and nonalcoholic fatty liver disease[2]. Aside from portal hypertension, reduced or absent liver function reserve is the major pathophysiologic impairment in severely fibrotic and cirrhotic patients. Diagnosis and severity grading of liver fibrosis, especially the evaluation of liver function reserve, are clinically significant for determining the appropriate treatment modality, such as prioritization of liver transplantation and prediction of prognosis in patients with cirrhosis.

Liver ultrasonography is an non-invasive imaging modality most frequently used for routine liver fibrosis screening but suffers from a low sensitivity and specificity, especially for early liver disease or that complicated by another non-fibrotic disease[3]. A variety of elastrographic techniques, including quasistatic elastrography, transient elastography, acoustic radiation force impulse imaging, shear wave elastography (SWE), and magnetic resonance elastography, have been applied or investigated for quantitative evaluation of liver fibrosis[4]. SWE, also called supersonic shear imaging, is a newly emerging elastrographic modality[5] that has been shown to be clinically beneficial for breast[6], thyroid gland, prostate, musculoskeletal, and liver[7] imaging with relatively high resolution and good reproducibility.

Routine liver function biochemistry assays cannot detect compensated liver insufficiency, and thus, liver-based metabolism tests are normally performed for this purpose. The indocyanine green elimination test is a dynamic, liver metabolism-based function assay mainly used for preoperative bedside evaluation of a patient scheduled for liver resection[8] or transplantation[9]. Lidocaine/monoethylglycinexylidide (MEGX) is also an advanced, laboratory dynamic liver function assay based on the metabolization of lidocaine into MEGX by abundant cytochrome P450 in hepatocytes, with good diagnostic sensitivity, specificity, and accuracy, especially for critically ill patients[10].

The primary objective of this study was to assess the correlation of SWE imaging results and liver histology and MEGX liver function test results in an experimental canine model of liver fibrosis. Specifically, the investigation into the correlation of SWE imaging results with pharmacologic quantitative liver function might aid in the evaluation of the liver function reserve in patients with severe fibrosis/cirrhosis scheduled for major hepatectomy or liver transplantation using a bedside, noninvasive modality rather than an invasive laboratory diagnostic modality.

MATERIALS AND METHODS

Laboratory animals

The study protocol was approved by the Animal Research Committee of Beijing Friendship Hospital, Capital Medical University, in accordance with the

National Institute of Health Guidelines for Laboratory Animal Care and Use. Fourteen healthy laboratory Beagles (Rixin Technology Co., Ltd., Beijing; license No. SCXK[BJ]2011-0007) weighing 6-8 kg, including 6 males and 8 females, were bred at the Center of Laboratory Large Animal in Jilin Sino-Japan Friendship Hospital and housed in individual cages with free access to high-lipid canine feed and tap water containing 1:10 (v/v) ethanol. Under general anesthesia by subcutaneous injection of 3% phenobarbital (1 mg/kg), 12 animals were given a subcutaneous injection of 60% carbon tetrachloride (1.5 mL/kg; Shanghai Chemical Co., Ltd, China) diluted in commercially available olive oil, at a weekly interval for 24 consecutive weeks after the initial injection to induce experimental liver fibrosis[11]. Two animals were given 1.5 mL/kg olive oil alone using the same protocol as controls.

Liver SWE imaging

At 24 wk, the animals were anesthetized and positioned supine with the anterior abdominal wall shaved on the operating table. An Aixplorer color Doppler ultrasound system (SuperSonic Imagine, Aix-en-Provence, France), equipped with a 4-15 MHz probe, was operated by an independent ultrasound technician for SWE imaging. An appropriate right-side intercostal space was located for identifying the optimal liver parenchymal window with gray scale ultrasound imaging. The SWE module was subsequently switched on for elastography of the right lobe parenchyma approximately 1 cm below the liver capsule. Liver stiffness was measured in triplicate from three different intercostal spaces and expressed as the mean elastic modulus (kPa)[12].

Clinical biochemistry assays and MEGX liver function tests

Clinical biochemistry assays were performed at the institutional central laboratory for routine liver function evaluation, including serum total protein, albumin, alanine aminotransferase, asparate aminotransferase, gamma glutamyltransferase, alkaline phosphatase, and bilirubin (total, unconjugated, conjugated). After blood sampling for clinical biochemistry assays, lidocaine hydrochloride (1 mg/kg) was injected through the cephalic vein into the anesthetized animals. The femoral vein was punctured for venous blood sampling (2 mL) at 0, 5, 10, 15, 20, 30, 40, 50, and 60 min after lidocaine injection. Plasma concentrations of lidocaine and its metabolite MEGX were determined using high-performance liquid chromatography repeated in duplicate[13]. A plasma MEGX concentration curve was plotted against time.

Liver biopsy

Percutaneous liver biopsy was performed using an 18-gauge needle by an independent, board-certified interventional ultrasound physician under B-mode ultrasound guidance. Liver biopsy samples were fixed in 10% formaldehyde, and liver fibrosis was graded using the modified histological activity index, *i.e.*, Knodell score (F0-F4), with a higher score indicating more serious liver fibrosis[14].

Statistical analysis

The statistical software package SPSS 11.0 (SPSS Inc., Chicago, IL, United States) was used for statistical analyses. All continuous data are expressed as median ± interquartile range (IQR), and the medians were compared using the Wilcoxon rank-sum test. Multiple comparisons were performed using the Fisher least significance difference test at an adjusted significance level. Correlations among histologic grading, LSM, and MEGX measures were analyzed with the Pearson linear correlation coefficient. A two-sided P value < 0.05 was considered statistically significant.

RESULTS

Correlation of clinical biochemistry with liver histology

All 14 animals survived at 24 wk, and liver fibrosis histologic grading was as follows: F0, n = 2 (control); F1, n = 0; F2, n = 3; F3, n = 7; and F4, n = 2. The liver biochemistry assay results are shown in Table 1. All biochemical measures remained similar among the four histologic groups (P > 0.05); however, the serum albumin level was significantly lower in the F4 group than in the F2 and F0 groups (P = 0.003 and P = 0.021, respectively) but not statistically different among the F3, F2, and F0 groups and between F4 and F3 groups (P > 0.05).

Correlation of SWE with liver histology

Representative SWE images for F0 and F2-F4 are shown in Figure 1A-D. SWE liver stiffness modulus data are shown in Table 2 and exhibited a significant positive correlation with histologic grading (r = 0.835, P < 0.001) (Figure 1E). Specifically, the F4 group had a significantly higher elastic modulus than the F3, F2, and F0 groups (P = 0.002, P = 0.003, and P = 0.006, respectively), and the F3 group also had a significantly higher modulus than the control F0 group (P = 0.039). However, the elastic modulus was similar between the F3 and F2 groups and the F2 and F0 groups (P > 0.05).

Correlation of plasma MEGX pharmacokinetics with liver histology

A plasma MEGX concentration *vs* time plot is shown in Figure 2, and the pharmacokinetics of plasma MEGX are described in Table 3. The four fibrosis grading groups showed no significant differences in all of the pharmacokinetic measures, although a declining trend was observed from F0 to F4, which was statistically significant for plasma MEGX concentrations at 30 min (P = 0.033) and 60 min (P = 0.020) as well as with respect to the area under the curve (P = 0.016).

Table 1 Liver biochemistry assays (median ± IQR) by fibrosis grade (*n* = 14)

Variable	F0 control (*n* = 2)	F2 (*n* = 3)	F3 (*n* = 7)	F4 (*n* = 2)	*P* value
Albumin (g/Dl)	3.9 ± 1.8[1]	3.1 ± 0.5[1]	2.6 ± 0.9[1,2]	1.8 ± 0.5[2]	0.021

AST (IU/L)	28 ± 14	21 ± 12	28 ± 15	60 ± 76	0.711
ALT (IU/L)	44 ± 17	43 ± 22	31 ± 28	58 ± 27	0.669
GGT (IU/L)	5.2 ± 2.1	5 ± 1.3	5.2 ± 2.6	6.3 ± 6.2	0.938
ALP (IU/L)	44 ± 25	49 ± 8	61 ± 19	74 ± 31	0.140
TBil (mg/dL)	0.27 ± 0.08	0.24 ± 0.07	0.25 ± 0.11	0.33 ± 0.21	0.865
UBil (mg/dL)	0.13 ± 0.05	0.13 ± 0.06	0.16 ± 0.10	0.17 ± 0.12	0.825
CBil (mg/dL)	0.15 ± 0.03	0.09 ± 0.05	0.10 ± 0.07	0.16 ± 0.09	0.318

[1,2]The two groups with no common letter have a statistically significant difference. ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Asparate aminotransferase; CBil: Conjugated bilirubin; GGT: Gamma-glutamyl transpeptadase; IQR: Interquartile range; TBil: Total bilirubin; UBil: Unconjugated bilirubin.

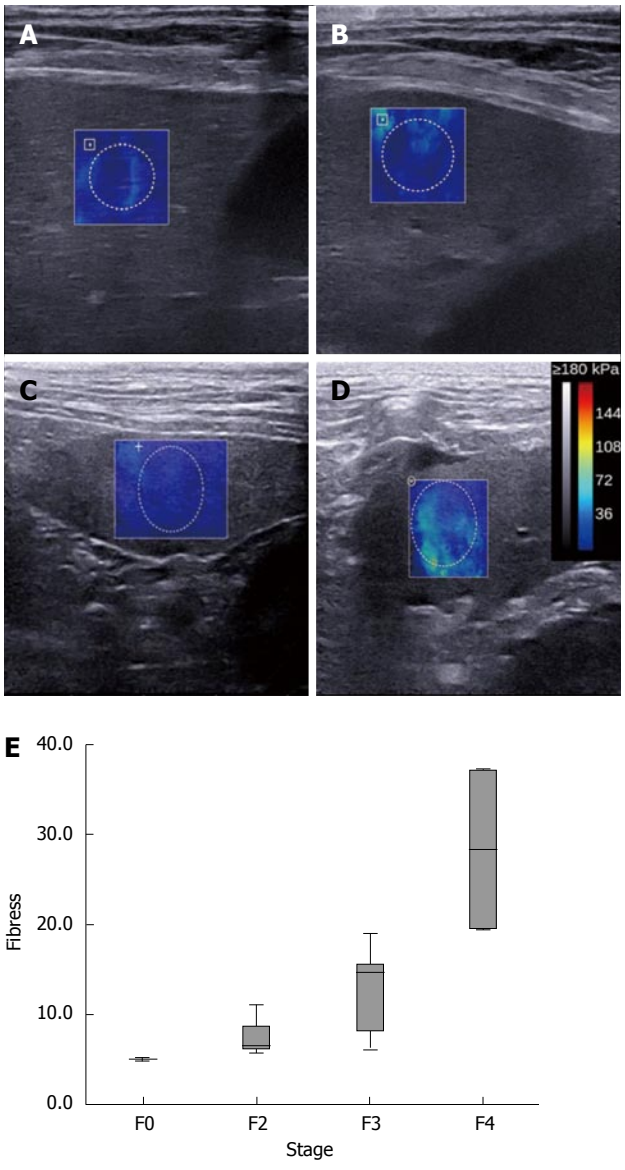

Figure 1 Correlation of shear wave elastography with fibrosis grading. A-D: Representative shear wave elastography images for F0, F2, F3, and F4, respectively; E: Box plot of the elastic modulus (kPa) expressed as median ± IQR against fibrosis grading. IQR: Interquartile range.

Table 2 Shear wave elastography elastic modulus (kPa, median ± IQR) by fibrosis grade (*n* = 14)

Variable	F0 control (*n* = 2)	F2 (*n* = 3)	F3 (*n* = 7)	F4 (*n* = 2)	*P* value
LSM	5.0 ± 0.4[1]	6.5 ± 5.4[1,2]	14.6 ± 9.4[2,3]	28.3 ± 17.8[4]	0.004

[1,2,3,4]The two groups with no common letter have a statistically significant difference. IQR: Interquartile range; LSM: Liver stiffness modulus.

Multiple comparisons showed identical differences in these three measures: significantly lower with F4 (*P* = 0.037) and F3 (*P* = 0.032) as compared to F0 and significantly lower with F4 as compared to F2 (*P* = 0.032), but similar between F3 and F2 and between F2 and F0 (both *P* values > 0.05). LSM was negatively associated with plasma MEGX concentrations at 30 min (*r* = -0.642, *P* = 0.013) and 60 min (*r* = -0.651, *P* = 0.012), time to ½ of the maximum concentration (*r* = -0.538, *P* = 0.047), and the area under the curve (*r* = -0.636, *P* = 0.014).

DISCUSSION

Liver biopsy, usually through the percutaneous approach, is the gold standard diagnostic modality for liver fibrosis/cirrhosis, but this procedure cannot be used and repeated as routine in general clinical practice due to low procedure-associated morbidities, such as bleeding, perforation, and infection[15]. Moreover, histologic grading of fibrosis does not necessarily correlate well with the underlying liver function reserve, but instead may over- or underestimate the disease severity due to the use of a limited liver tissue sample. As an alternative non-invasive diagnostic modality to liver biopsy, liver elastography is an advanced ultrasound or magnetic resonance imaging technique that quantifies liver stiffness by measuring liver tissue distortion (shear wave) and wave transition velocity upon mechanical vibration[16]. Among the elastographic techniques currently available, the

FibroScan using transient elastography has been well validated for fibrosis grading in liver fibrosis patients and the results show a good histologic correlation with liver biopsy findings; however, FibroScan measures liver stiffness on a one-dimensional ultrasonograph and also requires an additional designated probe for patients with a narrow rib cage or with complicating fatty liver disease[17]. In contrast, SWE offers a quantitative, real-time, two-dimensional elastography by incorporating an advanced ultrafast imaging technique[5] with a high correlation of histologic fibrosis staging comparable to transient elastography[18]. Our study results add new knowledge to current literature showing that the liver SWE elastic modulus also was well correlated with liver-based drug metabolism in addition to histologic grading. To the best of our knowledge, the present work is the first report regarding correlation of SWE results with fibrosis grading and cytochrome P450-based liver function reserve in experimental liver fibrosis.

Quantitative evaluation of liver function reserve can improve the predictive accuracy for chronic liver disease progression, including chronic hepatitis to liver fibrosis/cirrhosis[19]. The Child-Pugh score[20] and Model for End-Stage Liver Disease score[21] are most often used and based on clinical manifestations and laboratory biochemistry assays; however, these two scales have a variety of confounding factors and only represent a patient's pre-existing long-term liver function reserve rather than an acute change in liver function. The indocyanine green elimination test is the liver function reserve assay most frequently used in general clinical practice; however, its results may be affected by liver perfusion impairment, biliary obstruction, and complicating hypoalbuminemia[22]. MEGX test is a dynamic, quantitative liver function test that measures cytochrome P450 metabolism of lidocaine in metabolically active hepatocytes and is superior to the indocyanine green elimination test with respect to sensitivity, specificity, accuracy, and reproducibility. The MEGX level has been used for preoperative planning of liver resection[23], prediction of post-hepectomy acute liver failure[24], and survival of decompensated cirrhosis patients on the waiting list for liver transplantation[25]. Moreover, quantitative liver function tests including the MEGX test were reported as independent risk factors for improving the predictability of virologic response and disease progression of chronic hepatitis C virus with antiviral treatment[26]. Our results identified three potential measures, especially the area under the curve of the concentration *vs* time plot a sensitive and specific indicator of cytochrome P450 metabolic functionality, which could differentiate severe fibrosis or cirrhosis from mild disease.

SWE has been widely used for the evaluation of liver fibrosis/cirrhosis of multiple etiologies or with complicating comorbidities, including chronic hepatitis[27], liver cancer[28], steatohepatitis[29], and biliary atresia[30]. This two-dimensional elastographic technique offers better performance for assessing liver fibrosis as compared to conventional transient elastography, especially regarding the correlation of the LSM with histologic grading, with cutoff values of 8.0 kPa and 13.1 kPa for F2 and F4, respectively[31]. Our preliminary results demonstrated that severe fibrosis and especially cirrhosis had a higher LSM than moderate liver disease although no statistically significant difference was observed between F2 and F0

or between F3 and F2. Moreover, our results showed that the LSM on SWE was negatively correlated with MEGX test measures, including plasma concentrations at 30 min and 60 min, the time to ½ of the maximum concentration, and with respect to the area under the curve. Quantification of liver stiffness in patients with severe fibrosis or cirrhosis who are scheduled for major hepatectomy or liver transplantation may help estimate the risk of postoperative liver insufficiency with an advantage over pharmacologic liver function assays due to its non-invasiveness and technical reproducibility[32].

In conclusion, our results demonstrated that SWE results are well correlated with the histologic grading of experimental fibrosis. Moreover, SWE results also correlated well with quantitative liver function reserve measurements obtained by the lidocaine metabolite MEGX test. Therefore, it is beneficial to employ SWE for assessment of liver disease severity and function reserve in patients with severe fibrosis or cirrhosis as this modality is non-invasive and reproducible in the clinical setting.

COMMENTS

Background

Liver ultrasonography is a non-invasive imaging modality most frequently used for routine liver fibrosis screening but suffers from a low sensitivity and specificity, especially for early liver disease or that complicated by another non-fibrotic disease. Routine liver function biochemistry assays cannot detect compensated liver insufficiency, and thus, liver-based metabolism tests are normally performed for this purpose.

Research frontiers

Shear wave elastography (SWE) is a newly emerging elastrographic modality that has been shown to be clinically beneficial for liver imaging with relatively high resolution and good reproducibility. Monoethylglycinexylidide (MEGX) is also an advanced, laboratory dynamic liver function assay based on the metabolization of lidocaine into MEGX by abundant cytochrome P450 in hepatocytes, with good diagnostic sensitivity, specificity, and accuracy, especially for critically ill patients.

Innovations and breakthroughs

SWE results are well correlated with the histologic grading of experimental fibrosis and also with quantitative liver function reserve measurements obtained by the lidocaine metabolite MEGX test.

Applications

SWE is beneficial for assessment of liver disease severity and function reserve in patients with severe fibrosis or cirrhosis as this modality is non-invasive and reproducible in the clinical setting.

Peer-review

Interesting paper and topic. In the present study, the authors evaluated the correlation of shear wave elastrography results with liver fibrosis histology and liver function reserve. In general, the manuscript is well-written and the methodology is acceptable. Although the correlation of SWE in patients with various liver conditions have been extensively handled in the literature, this study throws light for the first time on its correlation with quantitative liver function reserve measurements obtained by the lidocaine metabolite MEGX test.

Abstract

AIM: To investigate the anti-apoptotic capability of the hepatitis B virus (HBV) in the HepG2 hepatoma cell line and the underlying mechanisms.

METHODS: Cell viability and apoptosis were measured by MTT assay and flow cytometry, respectively. Targeted knockdown of manganese superoxide dismutase (MnSOD), AMP-activated protein kinase (AMPK) and hepatitis B virus X protein (HBx) genes as well as AMPK agonist AICAR and antagonist compound C were employed to determine the correlations of expression of these genes.

RESULTS: HBV markedly protected the hepatoma cells from growth suppression and cell death in the condition of serum deprivation. A decrease of superoxide anion production accompanied with an increase of MnSOD expression and activity was found in HepG2.215 cells. Moreover, AMPK activation

contributed to the up-regulation of MnSOD. HBx protein was identified to induce the expression of AMPK and MnSOD.

CONCLUSION: Our results suggest that HBV suppresses mitochondrial superoxide level and exerts an anti-apoptotic effect by activating AMPK/MnSOD signaling pathway, which may provide a novel pharmacological strategy to prevent HCC.

Key words: Hepatitis B virus; Reactive oxygen species; Apoptosis; Manganese superoxide dismutase; AMP-activated protein kinase

Core tip: Hepatitis B virus markedly protected the cells from growth suppression and cell death in the condition of serum deprivation. A decrease of superoxide anion production accompanied with an increase of manganese superoxide dismutase (MnSOD) expression and activity was found in HepG2.215 cells. Moreover, AMP-activated protein kinase activation contributed to the up-regulation of MnSOD. Hepatitis B virus X protein was identified to promote the expression of AMPK and MnSOD.

Activation of AMPK/MnSOD signaling mediates anti-apoptotic effect of hepatitis B virus in hepatoma cells. *World J Gastroenterol* 2016; 22(17): 4345-4353 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4345.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4345

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most frequently diagnosed malignant cancers worldwide, while 50% of cases and deaths occurred in China[1]. Chronic hepatitis B virus (HBV) infection has been internationally recognized as one of the major risk factors for the development of HCC[2]. An estimated 350 million people were chronically infected and 600000 hepatitis B-related deaths occurred every year all over the world[3]. Accumulated evidence has shown that HBV proteins, particularly hepatitis B virus X protein (HBx) and surface protein (HBs), are implicated in hepatocyte carcinogenesis[4]. However, the mechanisms underlying HBV-induced malignant transformation remain ambiguous.

Apoptosis, also named programmed cell death, plays a crucial role in the development and homeostasis in normal tissue[5]. Recently, studies have indicated that defect or insufficient apoptosis may contribute to carcinogenesis, tumor progression and resistance of tumor cells to chemo-radiotherapy[6-8]. For that reason, escape of apoptosis has been identified as one of prominent hallmarks of cancer[9]. Reactive oxygen species (ROS), as toxic products of cell metabolism, can cause cell apoptosis by leading to cellular DNA damage and subsequently activating apoptotic signaling pathways[10]. In cancer, tumor niches characterized with poor nutrient and oxygen usually possess oxidative stress with excessive ROS formation[11,12]. Mitochondrial ROS (mtROS) especially superoxide anion, a natural by-product of electron transport chain activity, is the main source of cellular ROS[13]. Thus, decreasing mtROS production to relieve oxidative stress is very important for tumor survival and progression.

Manganese superoxide dismutase (MnSOD), a key antioxidant enzyme, is responsible for scavenging superoxide anion. Liver malignant tumors have been shown to express higher protein level and activity of MnSOD than their benign counterparts[14]. Aggressive tumors possessing invasive phenotype also have a high level of MnSOD, which can facilitate them to reach distant organs[15]. Therefore, increased MnSOD expression and activity may protect cells against apoptosis and offer a growth advantage, thereby acquiring a more aggressive phenotype.

The expression of MnSOD can be modulated by many molecular factors at transcription, translation and posttranslational modifications levels, for example, p53, Sp1, and NF-κB[16-18]. AMP-activated protein kinase (AMPK) is also reported to act as a new regulator of MnSOD expression in endothelial cells[19]. Moreover, AMPK activation is associated with protection of hepatocytes against oxidative stress[20].

Based on the aforementioned studies, we investigated the effect of HBV on the growth and survival of HepG2 cells, and explored the underlying molecular mechanisms. Herein, we demonstrated that HBV protected HepG2 cells from growth suppression and apoptosis in the condition of serum deprivation. Furthermore, AMPK activation-induced up-regulation of MnSOD contributed to the resistance of HBV-integrated HepG2 cells to apoptosis caused by superoxide, which could explain in part HBV-induced hepatocellular cell malignant transformation in the context of growth factor withdrawal.

MATERIALS AND METHODS

Cell culture

The human hepatoma cell line HepG2 was obtained from Cell Bank of Chinese Academy of Sciences where it was authenticated. HepG2.215 cell line, which was derived from HepG2 cells by integrating HBV genome and persistently produced HBV, was kindly provided by Prof. Erwei Song (Sun Yat-sen Memorial Hospital of Sun Yat-sen University, China). All of the cell lines were maintained in DMEM (Gibco, Gaithersburg, MD, United States) supplied with 10% fetal bovine serum and 1% penicillin/streptomycin, and incubated at 37 ℃ in a humidified incubator with 5% CO_2.

Regents

The HiPerFect transfection reagent was obtained from QIAGEN (QIAGEN, Carson City, CA). Antibodies of AMPKα and phospho-AMPKα (Thr^{172}) were purchased from Cell Signaling (Cell Signaling Technology, MA). Anti-MnSOD antibody was from BD (BD Pharmingen, San Diego, CA, United States). Antibody of HBx (anti-HBx) was obtained from Abcam (Abcam, Cambridge, UK). AICAR, Compound C and anti-β-actin were purchased from Sigma (Sigma-Aldrich, St. Louis, MO, United States).

Cell viability assay

Cells were seeded in 24-well plates in quadruplicate. After indicated treatments, cells viability was determined with 3-[4,5-dimethylthiazol-2-yl]-2,5-dephenyl tetrazolium bromide (MTT) (Sigma, MO) following the manufacture's protocol. Absorbance was measured at a wavelength of 570 nm.

Cell apoptosis assay

Cells were prepared as described elsewhere[21]. AnnexinV and propidium iodide (KeyGEN BioTECH, Nanjing, China) were added for incubation in the dark for 15 min at 4 ℃, and then cells were analyzed with a flow cytometer (Gallios, Beckman).

Mitochondrial superoxide anion detection

Measurements of mitochondrial superoxide anion formation in cells were performed as previously described[22]. In brief, HepG2 and HepG2.215 cells were incubated with 5 μmol/L MitoSOX (Invitrogen, Carlsbad, CA) for 20 min at 37 ℃. Cells were digested using EDTA (Invitrogen), and then washed three times using HBSS with Ca/Mg (Invitrogen). Mean fluorescent intensity was measured by flow cytometry (Gallios, Beckman).

MnSOD activity measurement

MnSOD activity was measured with a commercial SOD kit (Cayman Chemical) according to the manufacturer's protocol. Briefly, 1 mmol/L potassium cyanide was added in order to inhibit Cu/Zn-SOD and extracellular SOD, thus only MnSOD activity was detected. $O2^-$ was generated by adding hypoxanthine/xanthine oxidase and detected with tetrazolium salt through reading the absorbance at 450 nm.

RNA interference

The siRNAs for silencing AMPK, MnSOD and HBx genes as well as scrambled siRNA were purchased from Ribobio (Guangzhou, China). Transfection with synthetic siRNAs was performed with HiPerFect (QIAGEN, Carson City, CA) according to the manufacturer's instructions. The sense sequences of double-strand siRNA were as follows: siAMPK, 5'-UGCCUACCAUCUCAUAAUATT-3'; siMnSOD, 5'-GGAGAAUGUAACUGAAAGATT-3'; siHBx-1, 5'-CCGACCUUGAGGCAUACUUdTdT-3'; siHBx-2, 5'-UGUGCACUUCGCUUCACCUTT-3'.

Western blot analysis

Western blot analysis was performed as described previously[23]. Antibodies for MnSOD, AMPK, Phospho-AMPK and HBx were used at 1:1000 dilution. Antibody for β-actin was used at 1:10000 dilution. Bound antibody was visualized using HRP-conjugated secondary antibodies.

Statistical analysis

All data are expressed as mean ± standard deviation (SD). SPSS 13.0 software was used for one-way analysis of variance (ANOVA) and *t*-test in all statistical analyses (SPSS, Chicago, IL, United States). A *P* value less than 0.05 was considered statistically significant.

RESULTS

HepG2.215 is more tolerant to serum-deprivation environment

In order to assess the effect of HBV on the proliferation of HepG2 cells, we employed the HepG2.215 cell line which was derived from the HepG2 cell line and persistently produced HBV. We found that the HepG2.215 cell line showed faster growth kinetics compared with the HepG2 cell line on days 4 and 6 after serum depletion (Figure 1A). Moreover, the number of apoptotic HepG2 cells was significantly increased on days 4 and 6 compared with that of HepG2.215 cells. In contrast, the number of apoptotic HepG2.215 cells stayed at a much lower level at all testing time points (Figure 1B and C). These data suggest that HBV proteins may protect HepG2.215 cells against apoptosis induced by serum depletion.

Decreased mitochondrial superoxide level may be due to increased MnSOD expression and activity

To explain the different anti-apoptotic ability of the two cell lines, we investigated the production of mitochondrial superoxide which is a well-known killer of cells[10]. Decreased mitochondrial superoxide level was found in the HepG2.215 cell line (Figure 2A). Since MnSOD is the regulator of mitochondrial superoxide, we therefore detected the expression and activity of MnSOD in the two cell lines. As shown in Figure 2B and C, both the expression and activity of MnSOD in HepG2.215 cells were higher than those of HepG2 cells.

MnSOD mediates the apoptotic resistance of HepG2.215 cells

To further verify the role of MnSOD in the apoptotic resistance of HepG2.215 cells, the MnSOD siRNA was synthesized. Western blot analysis revealed that MnSOD siRNA specifically knocked down MnSOD in HepG2.215 cells (Figure 3A). Knockdown of MnSOD decreased cell viability and increased mitochondrial

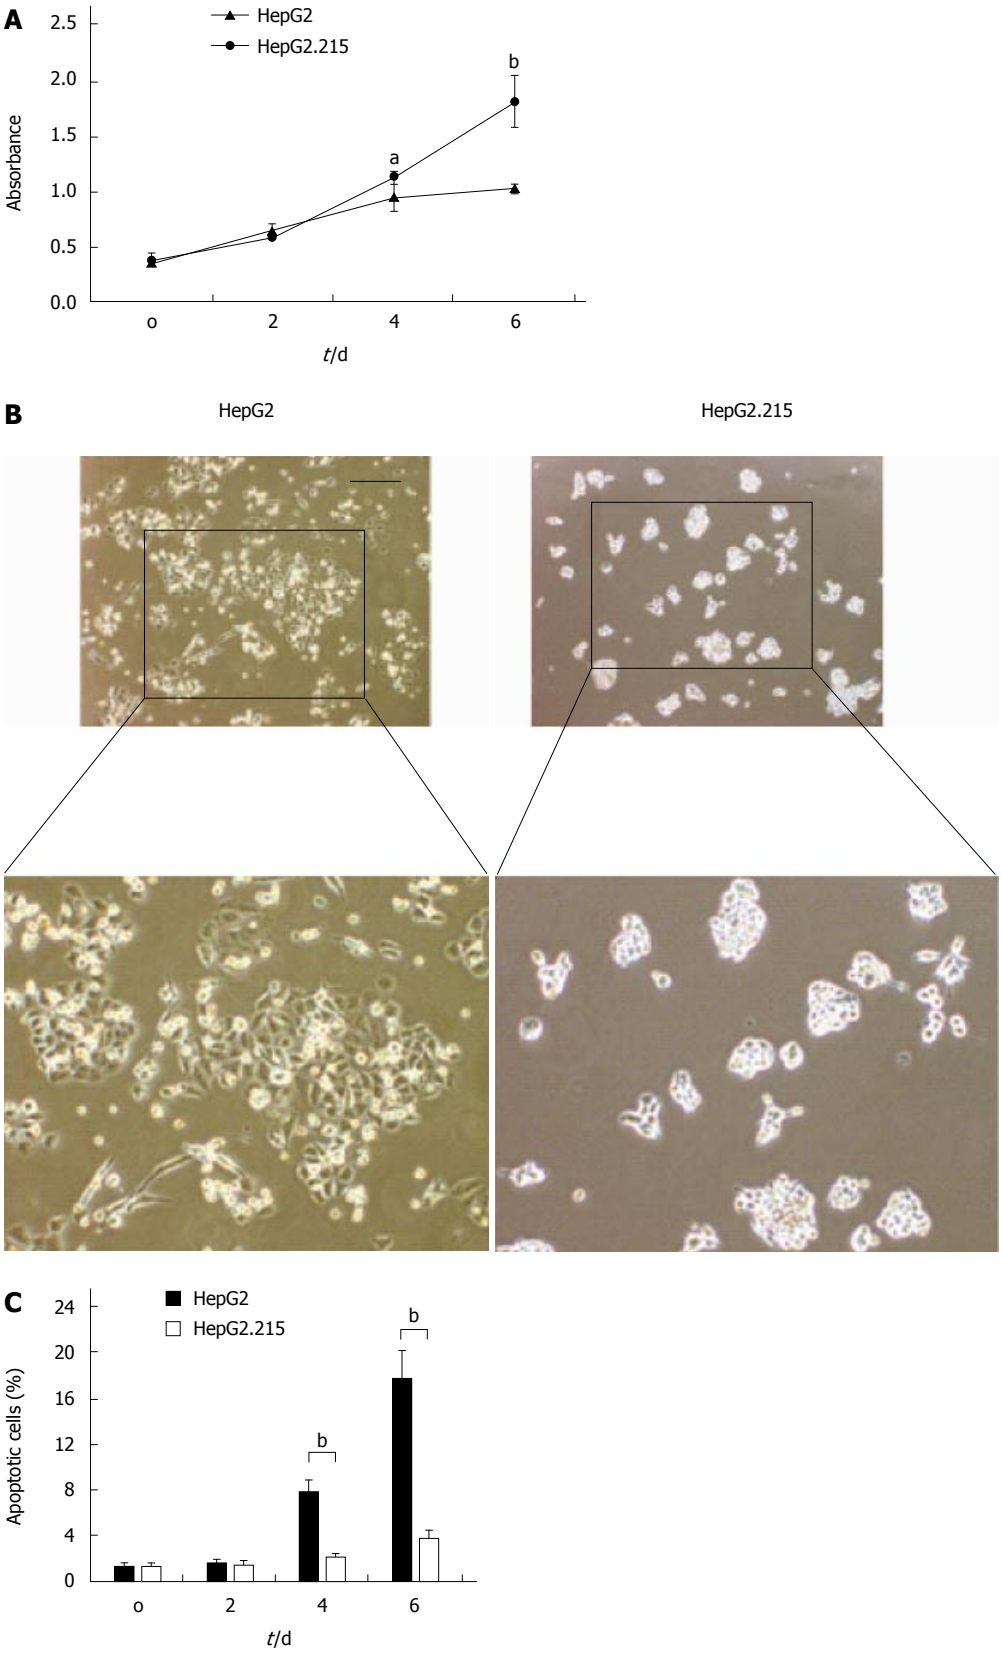

Figure 1 Resistance of HepG2.215 cells to apoptosis. A: Typical photographs of HepG2 and HepG2.215 cells cultured for 6 d after serum depletion. The data are representative of three independent experiments; B: MTT assay for the viability of cells cultured for 2, 4 and 6 d after serum depletion. Data represent absorbance at 570 nm and are shown as mean ± SD of quadruplicates. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* HepG2 cells group. The data are representative of three independent experiments; C: In parallel experiments, samples were subjected to FITC-Annexin V/propidium iodide staining and the quantitative analysis of apoptotic cells was performed using flow cytometry. Quantification of apoptotic cells is shown as mean ± SD of triplicates.

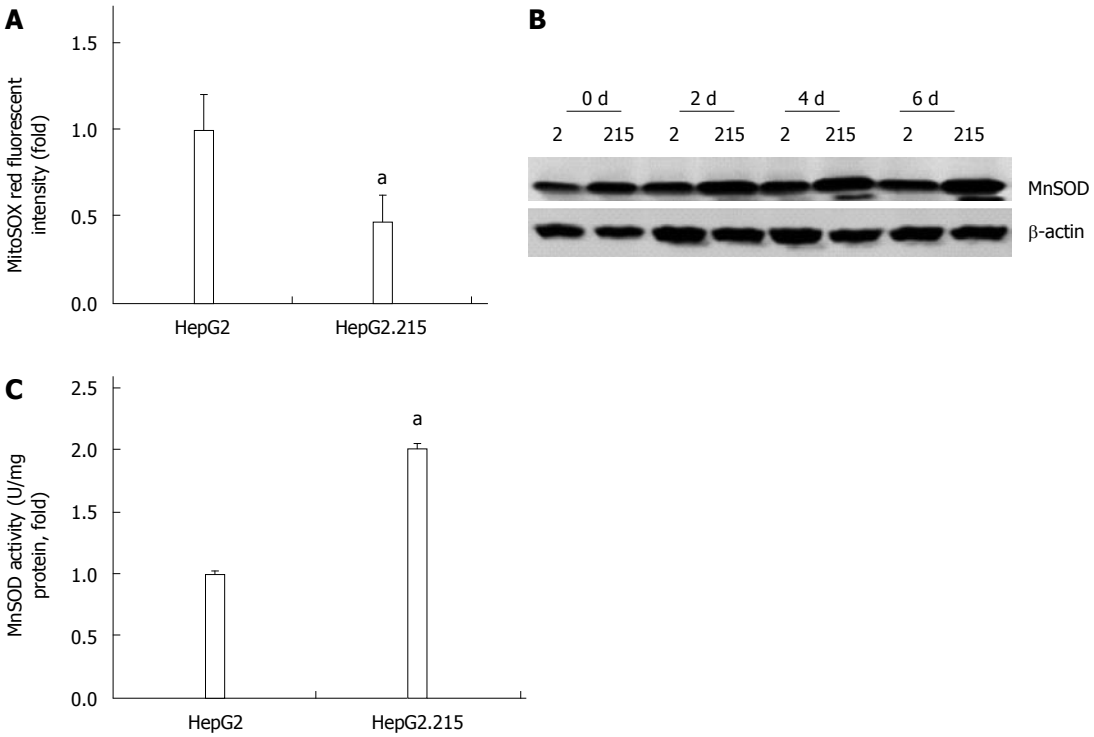

Figure 2 Decreased mitochondrial superoxide production is accompanied by increased MnSOD expression and activity in HepG2.215 cells. A: Mitochondrial superoxide level was decreased in HepG2.215 cells. Cells were cultured in serum-free medium for 6 d. Mitochondrial superoxide anion formation was measured by flow cytometry and MitoSOX. Quantification of mitochondrial superoxide anion is shown as mean ± SD of triplicates. $^{a}P < 0.05$ *vs* HepG2 cell group; B: Cell lysates were subjected to Western blot analysis. The protein level of MnSOD was detected; C: MnSOD activity was measured with a commercial SOD Assay Kit. Quantification of MnSOD activity is shown as mean ± SD of triplicates. $^{a}P < 0.05$ *vs* HepG2 cells group.

superoxide formation and the number of apoptotic HepG2.215 cells (Figure 3B-D), which suggests that MnSOD plays a critical role in apoptotic resistance of HepG2.215 cells.

AMPK activation contributes to up-regulation of MnSOD in HepG2.215 cells

To figure out the upstream factor involving the modulation of MnSOD, AMPK was investigated. We showed the protein levels of p-AMPK and AMPK were increased in HepG2.215 cells (Figure 4A). Both knockdown of AMPK and treatment with AMPK inhibitor Compound C reduced the expression of MnSOD (Figure 4B and C). Conversely, AMPK activator AICAR increased the expression of MnSOD (Figure 4C). Furthermore, the expression of p-AMPK, AMPK and MnSOD was inhibited by HBx knockdown (Figure 4D). These results suggest that HBV up-regulates MnSOD *via* AMPK.

DISCUSSION

As a major cause for HCC development, HBV can promote HCC in many ways, including enhancing host chromosomal stability, inducing inflammation-mediated immune escape, regulating epigenetic modification or altering the expression of oncogenes and tumor-suppressor genes[24]. Due to these internal changes, hepatoma cells acquire the capacity of fast growth, anti-apoptosis and metastasis[25,26]. In this study, we confirmed that HBV-integrated HepG2 cells exerted survival benefit compared with its parent cell line HepG2 in the serum-deprivation condition which can to some extent mimic the adapation of tumor cells to adverse growth conditions. In line with previous studies, we also found that HBV conferred HepG2 cells resistance to apoptosis[26,27]. Our data suggest that HBV apparently acts to promote the growth and viability of hepatoma cells in growth factor-restricted conditions.

An increased level of ROS by creating a potentially toxic environment to the cells represents a critical mechanism underlying cell death[28]. Superoxide anion is the precursor of other ROS such as H_2O_2 and peroxynitrite, and because of that the organelles most vulnerable to oxidative stress are the mitochondria[29]. MnSOD is an essential antioxidant enzyme in the mitochondrion that acts on superoxide anion[30]. Here, we showed that HBV reduced the level of superoxide anion. Consistently, the expression and activity of MnSOD were up-regulated in HBV-integrated HepG2 cells. This result was supported by the finding of a previous study that in patients with HBV infection, there was an average 5-fold rise of serum MnSOD[31].

The expression and activity of MnSOD are not static in different tumorigenesis stages. For transformed phenotype, MnSOD levels were maintained at a low level and could directly potentiate mitochondrial

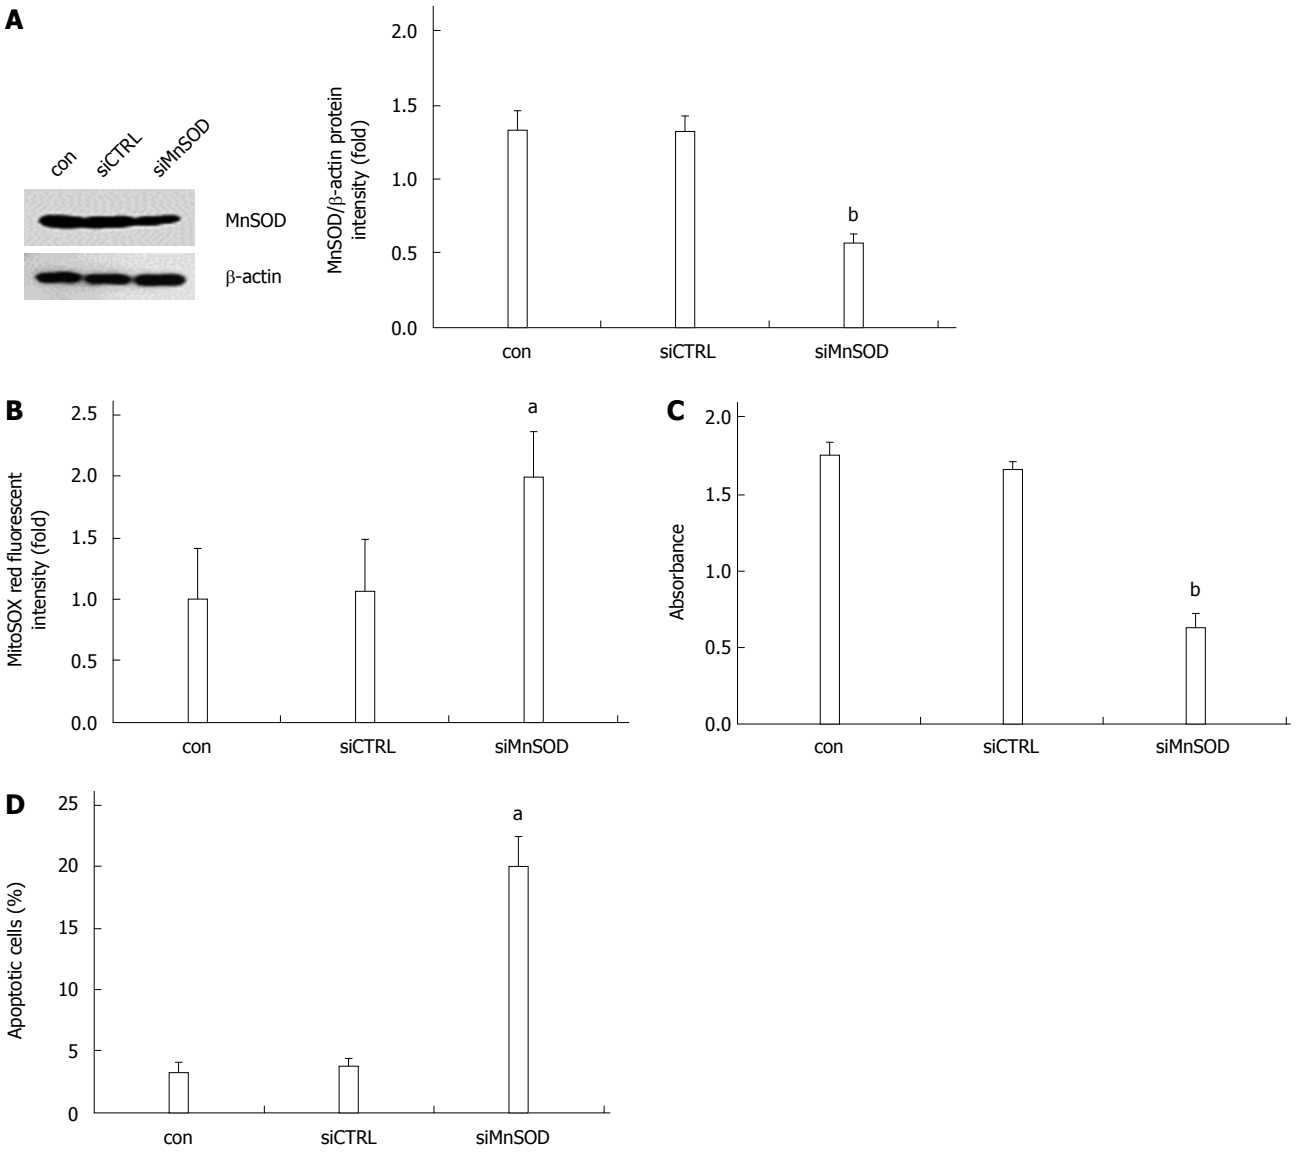

Figure 3 MnSOD contributes to decreased mitochondrial superoxide and apoptotic cells in HepG2.215 cells. A: After 6 d, the interference effect of MnSOD siRNA (siMnSOD) was analyzed by Western blot analysis. MnSOD siRNA (siMnSOD) or non-specific siRNA (siCTRL) was transfected into HepG2.215 cells for 12 h before serum depletion; B: After 6 d, cells were harvested for quantification of mitochondrial superoxide anion formation by flow cytometry. In parallel, (C) cell viability and (D) apoptotic cells were separately determined by MTT assay and flow cytometry. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* siCTRL group.

defects, leading to gene mutations. For acquiring a more aggressive phenotype, enhanced MnSOD activity may protect cells against mitochondrial injury, thereby conferring a growth advantage to the cancer cells[16]. The present study demonstrated that knockdown of MnSOD increased the production of superoxide anion and the apoptosis of HepG2.215 cells, which indicated that MnSOD protected hepatoma cells against apoptosis by detoxing superoxide anion, and conferred a growth advantage to those cells. However, since the function of MnSOD is to convert diffusion-restricted and mild-toxicant superoxide anion to freely diffuse and strong-toxicant H_2O_2, which means that increased MnSOD may enhance the production of more toxicant H_2O_2, the mechanism of modulation of tumor cell survival by MnSOD seems confusing. It has been reported that HBx expressing cell line showed significantly reduced sensitivity to H_2O_2-induced cell death, and the level of intracellular ROS did not elevate in HBx expressing cell line after exposure to H_2O_2 in the medium[32]. Based on these findings, we speculate that HBV-infected cells may express relatively high amounts of catalase, they would be able to counteract the cytotoxic effects of peroxide, and thus the outcome of increased MnSOD activity would more likely reflect the capacity of MnSOD to reduce levels of oxygen radicals. Unexpectedly, the level of catalase in HBV-related hepatocellular carcinoma specimens was lower than that of surrounding non-tumor tissues[33]. Thus, further investigation is required to explain the tolerance of HBV-infected cells to H_2O_2-induced cell apoptosis, which will be helpful for understanding the mechanism of MnSOD-modulated tumor cell survival.

AMPK, a serine/threonine protein kinase, is well

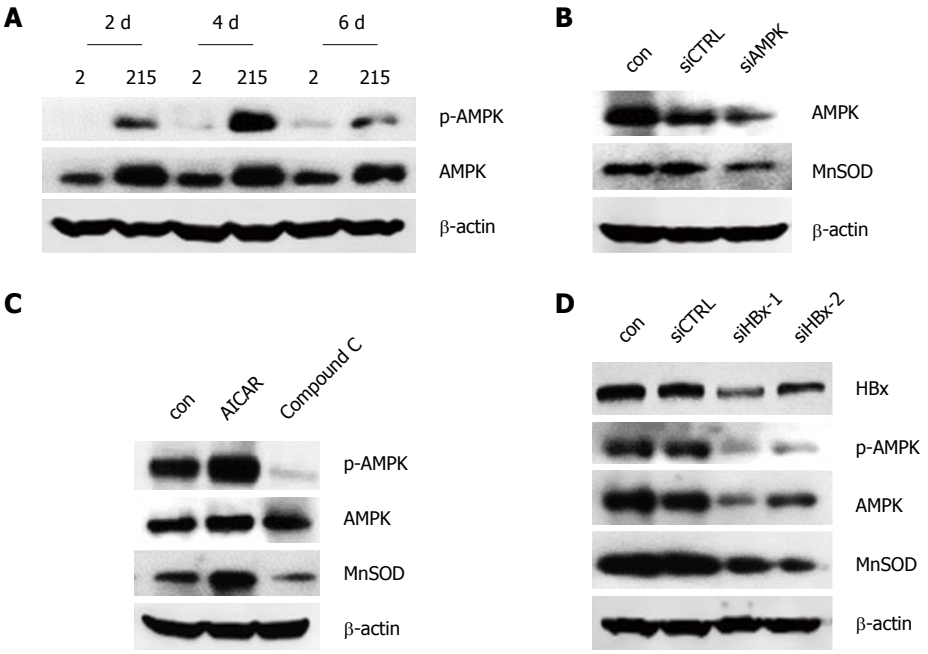

Figure 4 AMPK activation is required for MnSOD expression in HepG2.215 cells. A: Cell lysates were subjected to Western blot analysis. The protein levels of AMPK and p-AMPK were detected; B: Cells were transfected with AMPK siRNAs (siAMPK) or a nonspecific control siRNA (siCTRL) for 6 d. The protein levels of AMPK and MnSOD were detected by Western blot analysis; C: Cells were subjected to 1 mM AMPK activator AICAR or inhibitor compound C for 6 d. The protein levels of AMPK, p-AMPK and MnSOD were detected by Western blot analysis; D: Cells were transfected with HBx siRNAs (siHBx) or a nonspecific control siRNA (siCTRL) for 6 d. The protein levels of AMPK and MnSOD were detected by Western blot analysis.

known for its role in controlling energy metabolism. Recently, it comes into focus because of its potential roles in regulating other signaling pathways, such as regulating oxidative stress[34]. Studies have reported that activation of AMPK by AICAR, or overexpression of constitutively activated AMPK suppressed O_2^- production in human neutrophils or HUVECs[35,36]. A similar observation was also found in HepG2 cells, which showed that AA+ iron-induced reactive oxygen species generation was inhibited by isorhamnetin through AMPK activation[20]. These studies indicate that AMPK appears to be the key factor for cellular function protection in the presence of oxidative stress. Emerging evidence suggests that AMPK inhibits oxidant production by decreasing the expression of NADPH oxidases or increasing the expression of UCP-2 as well as MnSOD[19,35,36]. In the present study, HBV-integrated HepG2 cells displayed elevated AMPK protein level, which remains consistent with the expression of MnSOD. By utilizing a specific siRNA, or a selective agonist (AICAR) and antagonist (compound C) of AMPK, we observed that knockdown of AMPK and compound C resulted in the reduction of MnSOD protein level. Moreover, activation of AMPK by AICAR up-regulated the expression of MnSOD. Taken together, these findings demonstrate that AMPK is responsible for the up-regulation of MnSOD expression in HBV-integrated HepG2 cells.

Additionally, numerous studies have shown that HBx protein serves as a transactivator in the pathogenesis of HCC through regulating cell transformation, apoptosis and cellular immune system[37-39]. In our study, HBx was identified as the active ingredient of HBV proteins to promote the expression of AMPK and MnSOD. This is consistent with previous investigation reported by Severi *et al*[32] that HBx expressing cell line is more resistant to ROS-induced cell apoptosis than HBsAg expressing cell line. These data suggest that HBx may alleviate oxidative stress by up-regulating AMPK/MnSOD axis to maintain "normal" live cancer cell functions.

In summary, our current study demonstrates that HBV suppresses mitochondrial superoxide level and exerts an anti-apoptotic effect by activating AMPK/MnSOD signaling pathway in HBV-infected HepG2 cells. These findings may provide a novel mechanism involved in HBV-triggered carcinogenesis, and therefore might be useful in the design of new pharmacological approaches to prevent HCC.

COMMENTS

Background

Chronic hepatitis B virus (HBV) infection is one of the major risk factors for the development of hepatocellular carcinoma (HCC). However, the mechanisms

underlying HBV-induced HCC remain ambiguous. Recently, accumulated evidence has shown that escape of apoptosis may contribute to carcinogenesis.

Research frontiers

Previous experiments have revealed that liver malignant tumors and patients with HBV-infection express higher protein level of manganese superoxide dismutase (MnSOD) than their counterparts. Here, the authors showed that high expression of MnSOD protected hepatoma cells against apoptosis by detoxing superoxide anion, and conferred a growth advantage to those cells. These results explain how HBV offers a survival benefit to hepatoma cells.

Innovations and breakthroughs

This is the first study to demonstrate that HBV protects hepatoma cells against apoptosis *via* AMPK/MnSOD signaling pathway. HBV markedly protected the cells from growth suppression and cell death in the condition of serum deprivation. A decrease of superoxide anion production accompanied with an increase of MnSOD expression and activity was found in HepG2.215 cells. Moreover, AMPK activation contributed to the up-regulation of MnSOD. HBx protein was identified to promote the expression of AMPK and MnSOD. These results provide further evidence for the role of HBV as a major cause of HCC development *via* an anti-apoptosis mechanism involving activation of AMPK/MnSOD signaling pathway.

Applications

The present results suggest that HBV suppresses mitochondrial superoxide level and exerts an anti-apoptotic effect by activating AMPK/MnSOD signaling pathway, which may be useful in the design of new pharmacological approaches to prevent HCC.

Peer-review

In this study, Li *et al* aimed to investigate the anti-apoptotic capability of the hepatitis B virus in the HepG2 hepatoma cell line by suppressing mitochondrial superoxide levels. Generally, their findings seem to be interesting, anyway it should be validated in different cell lines, such as HepG2.117.

Abstract

AIM: To investigate the role of miR-125b in regulating monocyte immune responses induced by hepatitis C virus (HCV) core protein.

METHODS: Monocytic THP-1 cells were treated with various concentrations of recombinant HCV core protein, and cytokines and miR-125b expression in these cells were analyzed. The requirement of Toll-like receptor 2 (TLR2) or MyD88 gene for HCV core protein-induced immune responses was determined by the transfection of THP-1 cells with gene knockdown vectors expressing either TLR2 siRNA or MyD88 siRNA. The effect of miR-125b overexpression on TLR2/MyD88 signaling was examined by transfecting THP-1 cells with miR-125b mimic RNA oligos.

RESULTS: In response to HCV core protein stimulation, cytokine production was up-regulated and miR-125b expression was down-regulated in THP-1

cells. The modulatory effect of HCV core protein on cellular events was dose-dependent and required functional TLR2 or MyD88 gene. Forced miR-125b expression abolished the HCV core protein-induced enhancement of tumor necrosis factor-α, interleukin (IL)-6, and IL-10 expression by 66%, 54%, and 66%, respectively ($P < 0.001$), by inhibiting MyD88-mediated signaling, including phosphorylation of NF-κBp65, ERK, and P38.

CONCLUSION: The inverse correlation between miR-125b and cytokine expression after HCV core challenge suggests that miR-125b may negatively regulate HCV-induced immune responses by targeting TLR2/MyD88 signaling in monocytes.

Key words: miR-125b; Hepatitis virus C; Toll like receptor 2; Monocytes; Innate immunity

Core tip: Increasingly many studies have shown that microRNAs are critical regulators of the innate immune response. Many anti-pathogen pathways, including the pattern recognition Toll-like receptor (TLR)-mediated signaling pathway, are known to be regulated by a network of microRNAs. Here we investigated the possible role of miR-125b in regulating the monocyte immune responses induced by HCV core protein through TLR2/MyD88 signaling. Our findings indicated that miR-125b may function as a negative regulator of HCV-induced cellular events, which may provide insight into the role of miR-125b in the innate immune responses of monocytes to HCV.

INTRODUCTION

Hepatitis C virus (HCV), one of the primary causes of chronic hepatitis, end-stage cirrhosis, and hepatocellular carcinoma (HCC), contributes to an estimated 200 million chronic infections worldwide and 3-4 million or more each year[1]. HCV is a small enveloped RNA virus belonging to the Flavivridae family. The HCV genome encodes a polyprotein precursor of approximately 3000 amino acids that is processed by host and viral proteases into at least 10 different proteins. The viral core protein, a major cleaved product of HCV polyprotein by host peptidases, is known for its role in mediating HCV-induced pathogenesis. The RNA-binding HCV core protein is involved not only in the formation of the viral nucleocapsid but is capable of directly interacting with various host cell components, resulting in cellular dysfunction and carcinogenesis[2].

HCV not only infects hepatocytes, but it replicates in other immune cells, including B cells, T cells, NK cells and monocytes/macrophages[3,4]. It has been postulated that HCC is a consequence of prolonged liver injuries induced by chronic and persistent HCV infections. Numerous reports have indicated that defective host innate and adaptive immune systems are the major culprits facilitating the inability of the host to eradicate viruses[5]. While there is clear evidence that the synthesis of anti-viral cytokines, interferon (IFN)-α and IFN-γ were defective in chronic HCV infected patients[6], various others cytokines, such as tumor necrosis factor (TNF)-α, interleukin(IL)-6 and IL-10, were excessively expressed in patients with HCV viremia[7]. These skewed cytokine productions have been suggested to play a key role in liver injury, viral persistence and the progression to chronic HCV infection[8].

Monocytes/macrophages function as both innate immune cells by killing pathogens directly, and producing anti-pathogen cytokines and as adaptive immune cells by presenting antigens to other immune cells to produces antibodies. Although monocytes/macrophages dysfunction has been documented in patients with chronic HCV infection, particularly defective response to TLR ligand stimulation[9], the precise mechanism as how these cells are involved in the pathogenesis remains unclear.

MicroRNAs are highly conserved endogenous non-coding small RNAs that act as translational repressors to regulate a wide range of biological processes[10]. MicroRNAs have also been implicated in the pathogenesis, diagnosis and therapeutic aspects of HCV infections[11]. Recent studies have shown that several microRNAs, including miR-21, miR-146a and miR-155, were involved in regulation of virus-host interactions and may play important roles in the pathogenesis of HCV infection[12-14].

Since miR-125b is highly expressed in peripheral blood mononuclear cells, particularly in monocytes/macrophages[15], and its expression was found to be inversely associated with better treatment outcome of chronic HCV infection[16], we explored the role of miR-125b in modulating HCV-induced events in monocytic THP-1 cells. Here we show that miR-125b expression was negatively correlated with HCV core-induced cytokines expression in a TLR2/MyD88-dependent manner.

MATERIALS AND METHODS

Cell culture and reagents

The THP-1 human monocytic leukemia cell line was obtained from the Institute of Biochemistry and Cell Biology at the Shanghai Institute for Biological Sciences

and cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum, penicillin (100 IU/mL), and streptomycin (100 mg/mL). Bacterial HCV core recombinant protein was obtained from Immune Technology Co., China. Stability-enhanced miR-125b RNA oligonucleotide, miR-125b mimic (miR-125bM), and the control non-targeting RNA oligonucleotide were purchased from GenePharma.

RNA extraction and real-time quantitative reverse transcription-polymerase chain reaction analyses of cellular and miRNA genes

Total RNA (cellular and miRNA) was extracted from 1-3 × 10^6 THP-1 cells using TRIzol reagent (Life Technologies). For cellular gene expression, first strand cDNA and real-time quantitative polymerase chain reaction (RT-qPCR) analyses of TLR2 and MyD88 were performed according to the manufacturer's instructions (Kakara). The following PCR primers were used in this study: TLR2 (F: 5'-TGGCATGTGCTGTGCTCTGTT-3'; R: 5'-AGCTTTCCTGGGCTTCCTTTT-3'); MyD88 (F: 5'-CTCCTCCACATCCTCCCTTC-3'; R: 5'-GCTTGTGT-CTCCAGTTGCC-3'); internal control β-actin (F: 5'-CA-CGATGGAGGGGCCGGACTCATC-3'; R: 5'-TAAAG-ACCTCTATGCCAACACAGT-3'). The reaction conditions for PCR were 95 ℃ for 60 s, 53 ℃ for 60 s, and 72 ℃ for 60 s for 40 cycles, followed by an extension at 72 ℃ for 8 min. The relative gene expression of TLR2 and MyD88 was calculated using 2^{-ddCt}, where dd*Ct* = (*Ct*[gene]-*Ct*[β-actin]) and *Ct* is the crossing threshold value returned by the PCR instrument for each gene amplification.

To measure miRNA expression, total RNA was reversely transcribed at 16 ℃ for 30 min, 42 ℃ for 30 min and 85 ℃ for 5 min using miRNA gene specific primer (has-miR-125-5p and U6 snRNA NR_004394; Applied Biosystems). MicroRNA expression was determined by quantitative PCR using TaqMan Universal PCR System (Life Technologies) in 20 μL reactions, containing 1 μL TaqMan probes. The reaction was performed at 95 ℃ for 10 min, followed by 95 ℃ for 15 s and 60 ℃ at 60 s for 40 cycles. Expression of target genes was calculated as relative to that of the internal U6 snRNA.

Short interfering RNA knockdown vectors and transfections

TLR2-short interfering RNA (TLR2-siRNA) and MyD88-siRNA were constructed as previously described[12,13]. In brief, double-stranded oligonucleotides corresponding to the 164-182 position of TLR2 gene (NM_003264) or the 880-898 position of the MyD88 gene (NM_001172566) sequences were selected according to BLOCK-iT™ RNA Designer (Life Technologies) and cloned into Bsa I/Sac I sites of the pBSilence1.1 plasmid (Sirui Biologicl Co.). The recombinant plasmids were verified by sequencing from both ends. Silencing of TLR2 or MyD88 in THP-1 cells was performed using Lipofectamine 2000 (Life Technologies) and 50 nmol/L siRNA vector DNA according to the manufacturer's protocol. Cells transfected with empty pBSilence1.1 vector was used as a transfection control. Twenty-four hours after transfection, the cells were analyzed for RNA (by RT-qPCR) or protein (by Western blot) expression.

Transfection of miR-125b mimic or control RNA oligos was similarly performed using Lipofectamine 2000. Six hours post transfections, the cells were treated with 5 μg/mL HCV core protein and incubated for an additional 6 h at 37 ℃ prior to further assays.

Enzyme-linked immunosorbent assay

The levels of TNF-α, IL-6 and IL-10 in the supernatants were measured using a human ELISA kit (elabscience) according to the manufacturer's instructions. The detection ranges of TNF-α, IL-6 and IL-10 are > 8 pg/mL, > 4 pg/mL, and 7.813-500 pg/mL, respectively.

Western blot analysis

Cell lysates were prepared in a sodium dodecyl sulfate (SDS) sample buffer [62.5 mmol/L Tris-HCl (pH 6.8), 2% SDS, 10% glycerol, 50 mmol/L 1,4-dithiothreitol, and 0.1% bromophenol blue] containing a mixture of protease and phosphatase inhibitors. Lysates (25 μg) were separated on 12% acrylamide gels and transferred to a nitrocellulose membrane in Tris-glycine buffer containing 20% methanol. The membranes were then blocked with 5% milk in 1 × Tris-buffered saline and 0.1% Tween-20 for 1 h at room temperature and probed with various diluted primary monoclonal antibodies overnight at 4 ℃ with constant rocking. After extensive washing, the membranes were incubated with horseradish peroxidase-conjugated anti-mouse immunoglobulin G (Boster Biological Tech) at room temperature for 2 h. Protein expression was determined using a chemiluminesence method (Thermo Scientific). Antibodies recognizing TLR2, total NF-κBp65, phosphor-NF-κBp65 (Abcam), MyD88(Bioworld), phospho-ERK (Cell Signaling), and phospho-P38 (Santa Cruz Biotech) were used to probe the membranes. To control protein loading, the blots were stripped and re-probed with an anti-glyceraldehyde 3-phosphate dehydrogenase antibody (Xianzhi Lifescience).

Statistical analysis

Data are shown as mean ± SEM. Unpaired two-tailed Student's *t*-test was used to compare two independent groups. Graphpad 5.0 software (San Diego, CA) was used for all statistical analyses, and *P*-values < 0.05 were considered statistically significant.

RESULTS

HCV core protein up-regulates TNF-α, IL-6 and IL-10 expression and down-regulates miR-125b expression in THP-1 cells

We first tested whether treatment with HCV core protein regulates miRNA expression. THP-1 was

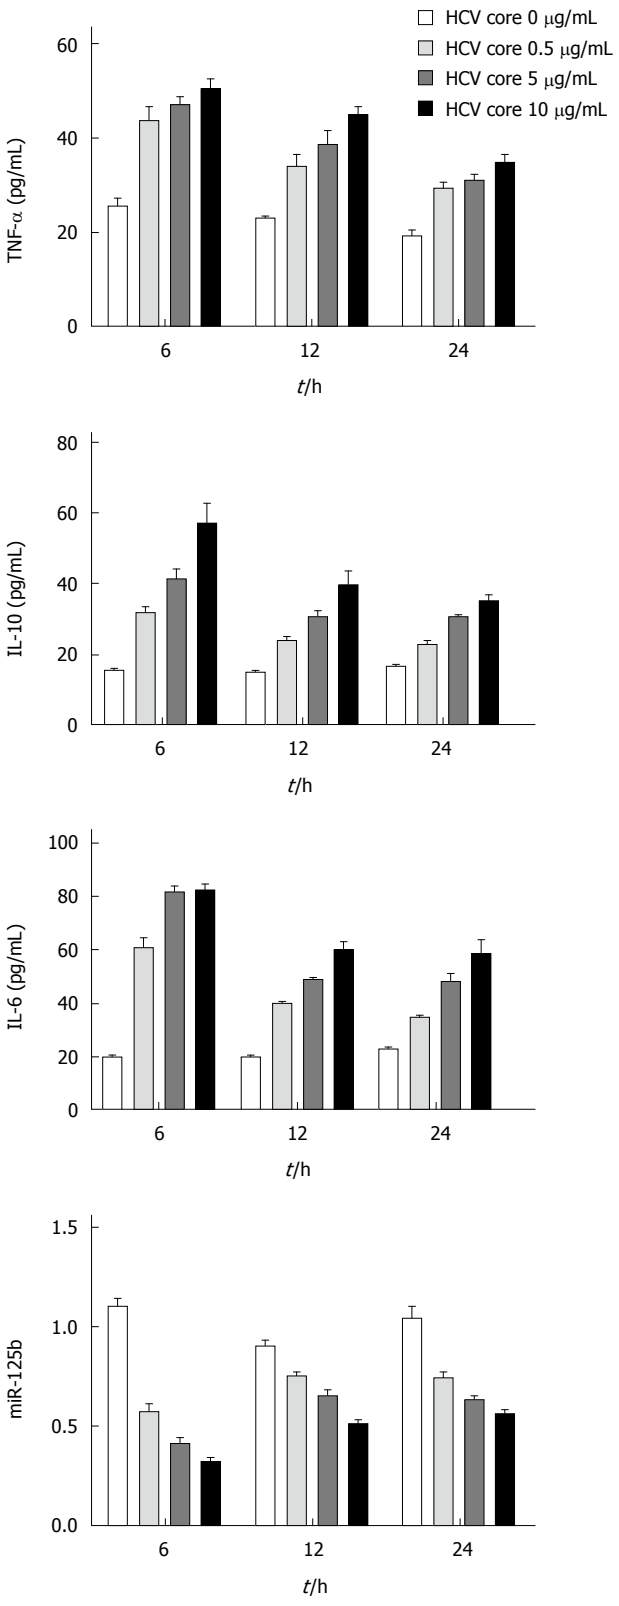

Figure 1 Increased cytokine expression and decreased miR-125b expression in hepatitis C virus core protein treated THP-1 cells. THP-1 cells were treated with HCV core recombinant protein at a final concentration of 0.5, 1.0 or 5.0 μg/mL and incubated for 6, 12 or 24 h. The levels of tumor necrosis factor (TNF)-α, interleukin (IL)-10, and IL-6 in culture supernatants were analyzed by enzyme-linked immunosorbent assay. The cellular miR-125b levels were determined by real-time quantitative polymerase chain reaction. The data are representative of three experiments and shown as mean ± SEM.

incubated with various concentrations (0.5, 1, 5 μg/mL) of HCV core protein for different time periods. Expression of miR-125b, miR-146 and miR-155, along with selected cytokine genes (TNF-α, IL-6 and IL-10) was examined by RT-qPCR analyses. Consistent with those of Yao *et al*[17], our results (Figure 1) showed that HCV core protein could directly stimulate THP-1 cells to express TNF-α, IL-6 and IL-10. The induction was dose-dependent; HCV core protein at 0.5 μg/mL significantly induced these cytokines more than two folds. The induction was also rapid; it peaked at 6 h after HCV core protein stimulation and slowly leveled off through the study period (24 h).

In parallel to the cytokine induction, miR-146 and miR-155 expression was also induced (data not shown)[12]. In contrast, miR-125 expression was down-regulated by HCV core stimulation in a dose-dependent manner. The miR-125b expression reached the lowest level (decreased by 68%) at 6 h with 5.0 μg/mL HCV core protein challenge. An inverse correlation between miR-125b expression and that of cytokines suggests that miR-125b may play a regulatory role in HCV-induced cellular responses.

TLR2 or MyD88 genes knockdown abolishes the suppressive effect of HCV core protein on miR-125b expression

TLR2 and its downstream signaling protein Myd88 play a prominent role in HCV core-induced inflammatory responses[18]. We employed a gene knockdown strategy to test if TLR2 or Myd88 could be directly involved in the repression of miR-125b. THP-1 cells were transfected with siRNA plasmids that could silence TLR2, MyD88 or the control plasmid for 24 h. The transfected cells were challenged with HCV core protein at 5 μg/mL for an additional 6 h. The miR-125b level was detected by RT-qPCR analysis. As shown in Figure 2A and 2B, we found that TLR2 and MyD88 mRNA and protein were reduced more than 2.5-fold when cells were transfected with these siRNA plasmids. When these transfected cells were exposed to HCV core protein, miR-125b expression was significantly restored compared to that of control-transfected cells. ($P < 0.05$, $n = 3$, Figure 2C). This result suggests that the suppression of miR-125b expression by HCV core treatment depends at least in part on the TLR2/MyD88 signaling.

Upregulation of cytokines by HCV core protein is abrogated by the miR-125b mimic

The inverse correlation noted between cytokine and miR-125b in HCV core protein-treated cells prompts us to examine whether miR-125b can directly participate in regulation of these HCV core protein-induced events. We transfected THP-1 cells with a chemically modified miR-125bM (miR-125b mimic) RNA oligos or the control RNA oligos for 24 h, followed by HCV core

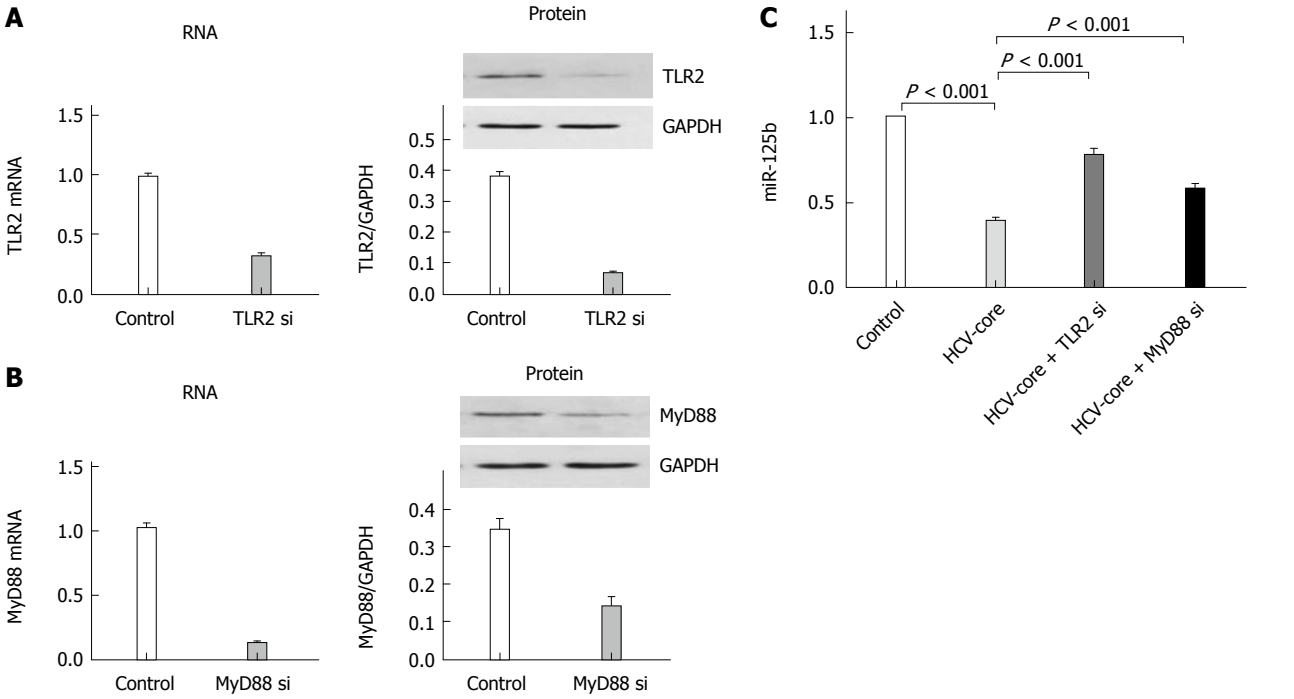

Figure 2 TLR2-MyD88 pathway dependent HCV core protein-induced miR-125b repression. TLR2 (A) or MyD88 (B) mRNA was analyzed by real-time quantitative polymerase chain reaction (RT-qPCR) and protein lysates were analyzed by Western blot at 6 h post transfection. The transfected cells were infected with HCV core protein at 5 μg/mL for 6 h and miR-125b expression was detected by RT-qPCR analysis (C). Cell data are representative of three experiments and are shown as mean ± SEM ($P < 0.001$ by unpaired two-tailed Student's *t*-test).

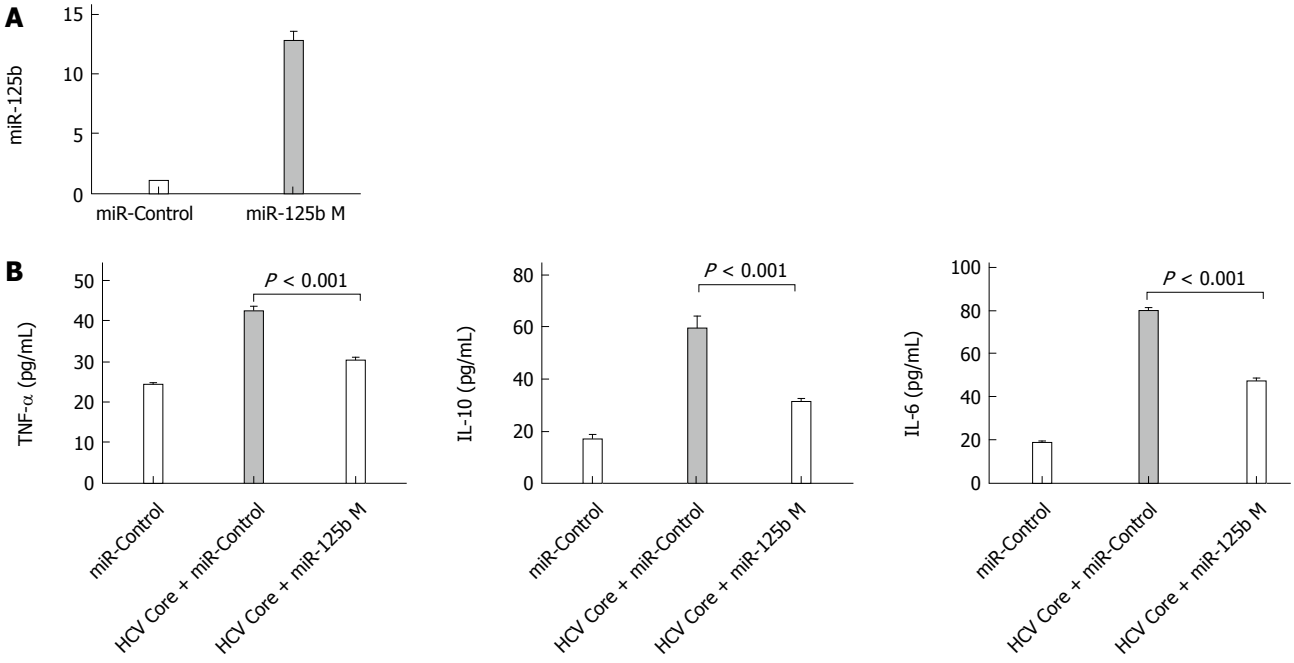

Figure 3 The miR-125b mimic abrogats hepatitis C virus core protein-induced upregulation of cytokines. A: Real-time quantitative polymerase chain reaction analysis of miR-125b levels in THP-1 cells transfected with 0.4 nmol/L miRNA negative control (miR-control) or miR-125b mimic (miR-125b M), respectively; B: Twenty four hours after transfection, cells were treated with 5.0 μg/mL HCV core protein for an additional 6 h. The concentrations of tumor necrosis factor (TNF)-α, interleukin (IL)-10 and IL-6 in culture supernatants were analyzed by enzyme-linked immunosorbent assay. These data are representative of three experiments and shown as mean ± SEM ($P < 0.001$ by unpaired two-tailed Student's *t*-test).

stimulation at 5.0 μg/mL for 6 h and examined the expression of TNF-α, IL-6 and IL-10. The effectiveness of miR-125b mimic transfection is shown in Figure 3A. In the experiment in which cells were treated with HCV core protein (Figure 3B), we found that transfection with control miRNA had no effect on the enhancement of cytokine expression by HCV core stimulation but that transfection with miR-125b mimic abrogated

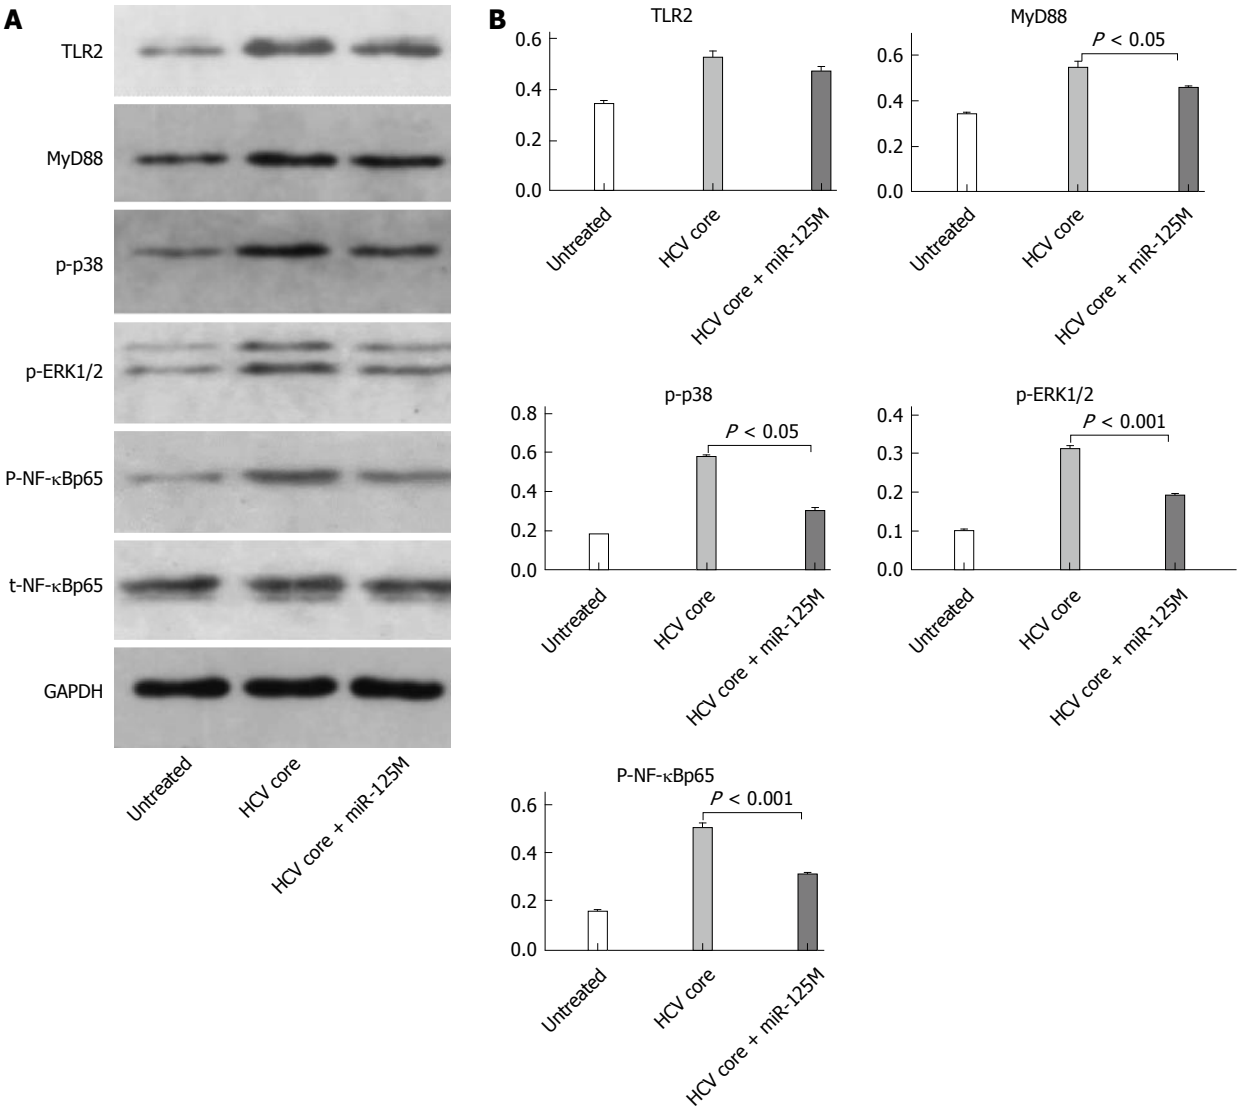

Figure 4 MiR-125b suppresses phosphorylation of NF-κBp65, ERK1/2 and p38. A: THP-1 cells were transfected with control or miR-125b mimic (miR-125bM) for 24 h, followed by incubation with hepatitis C virus (HCV) core protein at 5.0 μg/mL for 6 h. Western blot analysis of Toll-like receptor 2 (TLR2), MyD88, NF-κB, phosphorylated NF-κB, phosphorylated ERK1/2 and phosphorylated P38 in the collected cells; B: Densitometric quantification of the western blot data was performed using Quantity One Software. These data are representative of three experiments and shown as mean ± SEM ($P < 0.05$, $P < 0.001$ by unpaired two-tailed Student's *t*-test).

upregulated expression of TNF-α, IL-6 and IL-10 by 66%, 54% and 66%, respectively, compared with the control. These results indicate that overexpression of miR-125b down-regulates HCV-mediated cytokine induction.

MiR-125b mimic suppresses TLR2/MyD88 signaling

To understand the mechanism of miR-125b in regulating cytokine expression in HCV core protein-treated cells, we performed immunoblot analyses to determine the expression levels of the signaling molecules possibly involved in the TLR signaling pathways. THP-1 cells were transfected with or without miR-125b mimic and incubated with 5 μg/mL HCV core protein. The expression of various TLR signaling proteins was analyzed. As shown in Figure 4A, expression of TLR2 and MyD88 and the phosphorylation of their downstream signaling proteins ERK1/2, NF-κBp5 and p38 were up-regulated by HCV core treatments. The transfection of cells with the miR-125b mimic did not change the expression of TLR2 or NF-κBp65 but slightly down-regulated that of MyD88. In contrast, the phosphorylation of NF-κBp65, p38 and ERK1/2 was significantly down-regulated. Quantitation of three independent experiments showed two-fold down-regulation (Figure 4B).

DISCUSSION

In this study, we used recombinant HCV core protein-treated THP-1 cells as a model to investigate the interaction between HCV and monocytes. HCV core protein has been shown to be capable of directly interacting with various cellular proteins including

TLR2 and resulting in activation of TLR2-MyD88 signaling cascade in monocytes[18]. In agreement with these findings, our current findings indicate that HCV core protein can induce a similar profile of cytokine production in THP-1 cells. We further extended the study by demonstrating for the first time that treatment with HCV core protein suppressed the expression of miR-125b in a dose- and time-dependent manner (Figure 1). In addition, we demonstrated that this suppression was dependent on the TLR2/MyD88 pathway (Figure 2). However, the mechanism by which miR-125b expression is inhibited by HCV core protein treatment remains unknown.

MiR-125b has gained special interest in the field of cancer research because of its dysregulation in a broad variety of tumors[19]. Studing its role in tumorigenesis suggests that miR-125b could have the opposite effect depending on cellular context; miR-125b is upregulated in some tumors such as colon cancer and hematopoietic tumors, suggesting its oncogenic potential capability of facilitating cell proliferation and blocking apoptotic pathways[20,21]. On the other hand, miR-125b is down-regulated in other types of tumors, such as mammary tumors and HCC. The overexpression of miR-125b inhibits HCC cell proliferation *via* promoting apoptosis and other anti-tumor mechanisms[22].

Our finding that forced expression of miR-125b suppressed HCV core protein-induced cytokine production (Figure 3) and phosphorylation of the TLR/MyD88 signaling cascade (Figure 4) supports the notion that miR-125b suppresses HCV core protein-mediated events by inhibition of TLR2/MyD88 signaling. Although many receptors, signaling molecules, and transcriptional factors of the TLR signaling pathways have been verified to be regulated by various miRNAs[23], the molecules targeted by miR-125b in the TLR2/MyD88 signaling pathway remain unknown. Like other microRNAs, it is assumed that miR-125b exerts its biological function by directly targeting the 3′ untranslated (3′UTR) region of genes. Target site predictions using web-accessible miRNA database search programs (http://www.microrna.org,http://www.miRBase.org and http://www.targetscan.org) identified a miR-125b target site within the 1.3 kB 3′UTR of murine MyD88 mRNA. A study by Wang *et al*[24] indicated that the treatment of mouse macrophages with a miR-125b inhibitor induced MyD88 expression and that cellular transfection with a murine miR-125b mimic down-regulated the reporter gene activities mediated by 3′UTR MyD88 construct. These results provided clear evidence that murine miR-125b suppresses TLR/MyD88 by directly targeting MyD88 mRNA. We are currently testing this hypothesis by transfecting HCV core protein-treated THP-1 cells with the 3′UTR of MyD88 reporter construct.

In summary, our findings indicated that miR-125b may function as a negative regulator for HCV core protein-induced cellular events, which may provide insight into the role of miR-125b in the innate immune responses against HCV in monocytes. Our study may lay some groundwork for the development of a novel therapeutic approach for treating HCV core protein-induced inflammation and immune activation.

COMMENTS

Background

Macrophages/monocytes have been shown to be important immune cells mediating both innate and adaptive immunity in hepatitis C virus (HCV)-infected patients. Many anti-pathogen pathways, including pattern recognition Toll-like receptors (TLRs) mediating signaling, are known to be regulated by a network of microRNAs. MiR-125b is highly expressed in peripheral blood mononuclear cells, particularly monocytes/macrophages; however, its role in regulating monocyte immune responses induced by HCV has not yet been investigated.

Research frontiers

Recent studies have shown that several microRNAs, including miR-21, miR-146a and miR-155, are involved in regulation of virus-host interactions and may play important roles in the pathogenesis of HCV infection.

Innovations and breakthroughs

This is the first study to report that miR-125b may negatively regulate HCV core protein-induced host immune responses by targeting TLR2/MyD88 signaling in monocytes.

Applications

The present findings indicated that miR-125b may function as a negative regulator for HCV induced cellular events, which may provide insight into the role of miR-125b in the innate immune responses against HCV in monocytes. This study may lay some groundwork for the development of a novel therapeutic approach for treating HCV-induced inflammation and immune activation.

Terminology

MicroRNAs are highly conserved endogenous non-coding small RNAs that act as translational repressors to regulate a wide range of biological processes. They have also been implicated in the pathogenesis, diagnosis, and therapeutic aspects of HCV infections. miR-125b is highly expressed in peripheral blood mononuclear cells, particularly in monocytes/macrophages, and its expression is inversely associated with better treatment outcomes for chronic HCV infection.

Peer-review

The authors investigated the possible role of miR-125b in regulating monocyte immune responses induced by HCV core protein. This study found that cytokine production was up-regulated and miR-125b expression was down-regulated by HCV core protein treatment through TLR2/MyD88 signaling in THP-1 cells. Overexpression of miR125b resulted in suppressed MAPK and NF-κB activity and cytokine production. This research is novel and manuscript presentation and readability are good. Additionally, the manuscript is well organized and its results are sound with respect to the integrity of the paper.

Abstract

AIM: To examine the association between non-alcoholic fatty liver disease (NAFLD) and general health perception.

METHODS: This cross sectional and prospective follow-up study was performed on a cohort of a sub-sample of the first Israeli national health and nutrition examination survey, with no secondary liver disease or history of alcohol abuse. On the first survey, in 2003-2004, 349 participants were included. In 2009-2010 participants from the baseline survey were invited to participate in a follow-up survey. On both baseline and follow-up surveys the data collected included: self-reported general health perception, physical activity habits, frequency of physician's visits, fatigue impact scale and abdominal ultrasound. Fatty liver was diagnosed by abdominal ultrasonography using standardized criteria and the ratio between the median brightness level of the liver and the right kidney was calculated to determine the Hepato-Renal Index.

RESULTS: Out of 349 eligible participants in the first survey, 213 volunteers participated in the follow-up

cohort and were included in the current analysis, NAFLD was diagnosed in 70/213 (32.9%). The prevalence of "very good" self-reported health perception was lower among participants diagnosed with NAFLD compared to those without NAFLD. However, adjustment for BMI attenuated the association (OR = 0.73, 95%CI: 0.36-1.50, *P* = 0.392). Similar results were observed for the hepato-renal index; it was inversely associated with "very good" health perception but adjustment for BMI attenuated the association. In a full model of multivariate analysis, that included all potential predictors for health perception, NAFLD was not associated with the self-reported general health perception (OR = 0.86, 95%CI: 0.40-1.86, *P* = 0.704). The odds for "very good" self-reported general health perception (compared to "else") increased among men (OR = 2.42, 95%CI: 1.26-4.66, *P* = 0.008) and those with higher performance of leisure time physical activity (OR = 1.01, 95%CI: 1.00-1.01, *P* < 0.001, per every minute/week) and decreased with increasing level of BMI (OR = 0.91, 95%CI: 0.84-0.99, *P* = 0.028, per every kg/m^2) and older age (OR = 0.96, 95%CI: 0.93-0.99, *P* = 0.033, per one year). Current smoking was not associated with health perception (OR = 1.31, 95%CI: 0.54-3.16, *P* = 0.552). Newly diagnosed (naive) and previously diagnosed (at the first survey, not naive) NAFLD patients did not differ in their self-health perception. The presence of NAFLD at the first survey as compared to normal liver did not predict health perception deterioration at the 7 years follow-up. In terms of health-services utilization, subjects diagnosed with NAFLD had a similar number of physician's visits (general physicians and specialty consultants) as in the normal liver group. Parameters in the fatigue impact scale were equivalent between the NAFLD and the normal liver groups.

CONCLUSION: Fatty liver without clinically significant liver disease does not have independent impact on self-health perception.

Key words: Non-alcoholic fatty liver disease; Health perception; Quality of life; Fatigue; Health-care services utilization

Core tip: In recent years there is overwhelming evidence that non-alcoholic fatty liver disease (NAFLD) is a major public health concern; the most common chronic liver disorder globally and associated with hepatic and extrahepatic morbidity and mortality. However, this study demonstrates that NAFLD diagnosis among a general population is not independently associated with lower general health perception nor is it associated with higher health care utilization. Moreover, NAFLD does not seem to predict health perception deterioration over the years. These findings imply that in the general population, NAFLD is not considered a disease in the eyes of the NAFLD beholder, probably until an advanced stage.

Mlynarsky L, Schlesinger D, Lotan R, Webb M, Halpern Z, Santo E, Shibolet O, Zelber-Sagi S. Non-alcoholic fatty liver disease is not associated with a lower health perception. *World J Gastroenterol* 2016; 22(17): 4362-4372 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4362.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4362

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is defined as fat accumulation in the liver, in the absence of significant alcohol intake. NAFLD is the most common chronic liver disorder globally[1], with a worldwide prevalence estimated from 6.3% to 33% and a median of 20%[2]. Recently, the prevalence of NAFLD was shown to be increasing in developing countries due to adoption of a Western lifestyle, the estimated prevalence of NAFLD varies from 20%-30% in Western countries to 5%-18% in Asia[3].

NAFLD is associated with hepatic and extrahepatic morbidity. Moreover, patients with NAFLD have reduced survival compared with the general population, primarily due to cardiovascular disease followed by malignancy[4-7]. In a Swedish cohort of NAFLD patients with a median follow-up of 27 years, 25% were diagnosed with cirrhosis and 14% with hepatocellular cancer[8]. NAFLD patients do not usually present with symptoms directly attributable to their underlying liver disease[9]. However, some patients report non-specific symptoms, including fatigue or malaise, daytime sleepiness and discomfort in the right upper abdominal quadrant[10]. Fatigue is the most common symptom in NAFLD patients and leads to impaired quality of life[11]. Lifestyle modification is the only established treatment in NAFLD, nevertheless, patients have low level of readiness for change and motivation to adopt a healthier lifestyle (particularly in the area of physical activity). Furthermore, it was shown that the severity of liver disease or liver enzymes elevation, have almost no impact on motivation to change[12].

To date, only a few studies examined quality of life parameters[13,14] or evaluated the utilization of health-care services among NAFLD patients[11,15]. Moreover, self-rated general health perception, a frequently assessed parameter in epidemiological research[16] and a powerful predictor for morbidity and mortality[17], has not been tested in NAFLD patients. Therefore, the current study was aimed to examine the association between NAFLD and general health perception along with fatigue and utilization of health-care services in a sample of a general population screened for NAFLD.

MATERIALS AND METHODS

Study design and population

This cross sectional and prospective follow-up study was performed on a cohort of a sub-sample of the first Israeli national health and nutrition examination survey (the MABAT Survey)[18]. On the first survey, MABAT LIVER study, 2003-2004, 349 participants were included. In 2009-2010 participants from the baseline survey were invited to participate in a follow-up survey. No difference was observed between subjects that participated in the follow-up study compared to those who did not participate in any demographic, anthropometric or biochemical parameters as previously reported[19]. In both surveys, individuals with any of the following were excluded from the study: presence of HBsAg or anti-HCV antibodies, fatty liver suspected to be secondary to hepatotoxic drugs, inflammatory bowel disease, celiac disease and excessive alcohol consumption ($\geqslant$ 30 g/d in men or $\geqslant$ 20 g/d in women)[2,20].

Data collection

On both baseline and follow-up surveys the data collected included: measurements of weight, height, and waist circumference following a uniform protocol, interview, biochemical tests, and ultrasound for the diagnosis of NAFLD, all performed on the same day at the Gastroenterology department of the Tel-Aviv Medical Center. All blood samples were drawn at the morning hours after a fast of at least 12 h and assessed by the same laboratory of the Tel-Aviv Medical Center.

A face-to-face interview was carried out in both surveys using a structured questionnaire, assembled by the Ministry of Health and used in national surveys[18], that included demographic details, questions on health status, self-reported general health perception, alcohol consumption, smoking and physical activity habits, frequency of physician's visits and hospitalization. To avoid report bias, the participants were informed on their US and blood tests results only after filling in the questionnaires.

Fatigue was assessed by the fatigue impact scale (FIS)[21], including 7 questions regarding alertness, decreased work volume, less motivation for physical effort, difficulties in decision making or in thinking process and decreased activity[21]. The fatigue score represents the sum of questions with a positive response. Fatigue as a reason for physical inactivity was assessed by multi-choice question that evaluated the reasons for physical inactivity.

Self-reported general health perception was estimated with one simple question that was highly validated as an indication to general health status and is commonly used in surveys worldwide[17,22,23]. The question was "what is your general health status?" and the answers were: 1- "very good", 2- "good" 3- "not so good" 4- "poor".

Utilization of health service was estimated by a questionnaire assembled by the Israeli Center for Disease Control and used in the Israeli National Health Interview Survey[24]. Numbers of physician's visits (general physicians and specialty consultants) and hospitalization were assessed by a series of multi-choice questions.

Fatty liver was diagnosed by abdominal ultrasonography using standardized criteria[25]. Ultrasonography was performed in all subjects both at baseline and at follow up with the same equipment (EUB-8500 scanner Hitachi Medical Corporation, Tokyo, Japan) and by the same experienced radiologist (Webb M) as previously described[26-28]. The radiologist was blinded to the laboratory values and medical history of the participants. During the ultrasonography, a histogram of brightness levels, *i.e.*, a graphical representation of echo intensity within a region of interest was obtained. The ratio between the median brightness level of the liver and the right kidney was calculated to determine the Hepato-Renal Index (HRI). The HRI has been previously demonstrated to be highly reproducible and was validated against liver biopsy[29].

The study was approved by the institutional review board of Tel Aviv medical center and all participants signed an informed consent.

Statistical analysis

All statistical analyses were performed using SPSS version 22.0 for Windows (SPSS Inc., Chicago, IL, United States). Continuous variables are presented as mean ± SD, while categorical variables are presented in percentage. Univariate analyses were used for the comparison of variable's distribution between the study groups. To test differences in continuous variables between two groups the independent samples *t*-test (for normally distributed variables) or the Mann-Whitney *U* test (if non-parametric tests were required) were performed. To test differences in continuous variables between more than two groups the One-Way ANOVA was performed. To test the differences in categorical variables the Pearson χ^2 test was performed. The evaluation of the association between NAFLD and the prevalence of "very good" health perception, adjusting for potential confounders, was performed with multivariate logistic regression analysis, presenting odds ratio (OR) and confidence intervals (CI). The potential confounders included in the multivariate model were: gender, age, body mass index (BMI) and behavioral factors: current smoking and duration of performance of leisure time physical activity in the past year. $P < 0.05$ was considered statistically significant for all analyses. The statistical methods of this study were reviewed by Dr. Shira Zelber-Sagi, RD, PhD. Head of nutrition and behavior program, School of Public Health, the University of Haifa and Tel-Aviv Medical Center.

Table 1 Comparison between non-alcoholic fatty liver disease and normal liver groups in the follow-up survey (mean ± SD, unless otherwise stated)

Parameter (normal range)	Entire cohort (n = 213)	NAFLD (n = 70)	Normal liver (n = 143)	P value
Age (yr)	57.96 ± 9.58	57.87 ± 8.12	58.01 ± 10.25	0.917
Gender (% males)	54.0	58.6	51.7	0.348
BMI (kg/m^2) (20-25)	28.15 ± 4.59	31.20 ± 4.38	26.66 ± 3.92	< 0.001
Waist circumference men (< 102 cm)	94.21 ± 10.47	98.88 ± 9.01	91.66 ± 10.40	< 0.001
Waist circumference women (< 88 cm)	83.30 ± 11.01	93.49 ± 9.50	79.02 ± 8.55	< 0.001
Current smoker (%)	17.4	25.7	13.3	0.025
Leisure time physical activity (min/wk)	96.17 ± 144.97	63.00 ± 107.92	113.12 ± 158.32	0.008
Years of education (%)				0.333
< 12	43.4	38.0	45.9	
12	17.6	24.0	14.7	
> 12	39.0	38.0	39.4	
ALT (U/L) (5-39)	24.01 ± 8.60	28.31 ± 9.07	21.91 ± 7.53	< 0.001
Glucose (mg/dL) (70-110)	93.62 ± 25.02	101.21 ± 25.62	89.90 ± 23.95	0.002
Insulin (U/mL) (5-25)	20.39 ± 9.55	24.67 ± 11.22	18.33 ± 7.89	< 0.001
HbA1C (%) (3.9-6.0)	5.94 ± 0.75	6.27 ± 0.78	5.78 ± 0.68	< 0.001
Cholesterol (mg/dL) (150-200)	184.45 ± 34.91	185.51 ± 38.34	183.93 ± 33.24	0.757
Triglycerides (mg/dL) (50-175)	109.27 ± 55.39	133.36 ± 55.01	97.48 ± 51.81	< 0.001
Hepatorenal index	1.30 ± 0.35	1.70 ± 0.31	1.09 ± 0.10	< 0.001

NAFLD: Non-alcoholic fatty liver disease; BMI: Body mass index; ALT: Alanine aminotransferase; HbA1C: Glycosylated hemoglobin.

RESULTS

Characteristics of the study population and comparison between NAFLD and normal liver groups

Out of 349 eligible participants in the first survey, 213 volunteers participated in the follow-up cohort and were included in the current analysis (Figure 1), 54% were men, mean age was 57.96 ± 9.58 years and mean BMI was 28.15 ± 4.59 kg/m^2. According to abdominal US, NAFLD was diagnosed in 70/213 (32.9%) participants on the follow-up survey. There were no significant age and gender differences between subjects with and without NAFLD. BMI, waist circumference (women and men), serum ALT, blood glucose, serum insulin, HbA1C and triglyceride levels were all significantly higher in the NAFLD group (Table 1).

NAFLD and self- reported general health perception

Among the normal liver group, 46.9% reported their general health perception status as "very good" *vs* 31.4% of the subjects in the NAFLD group (P = 0.032). However, stratification by BMI indicating a clinically significant overweight and above (BMI > 27 kg/m^2)[30]

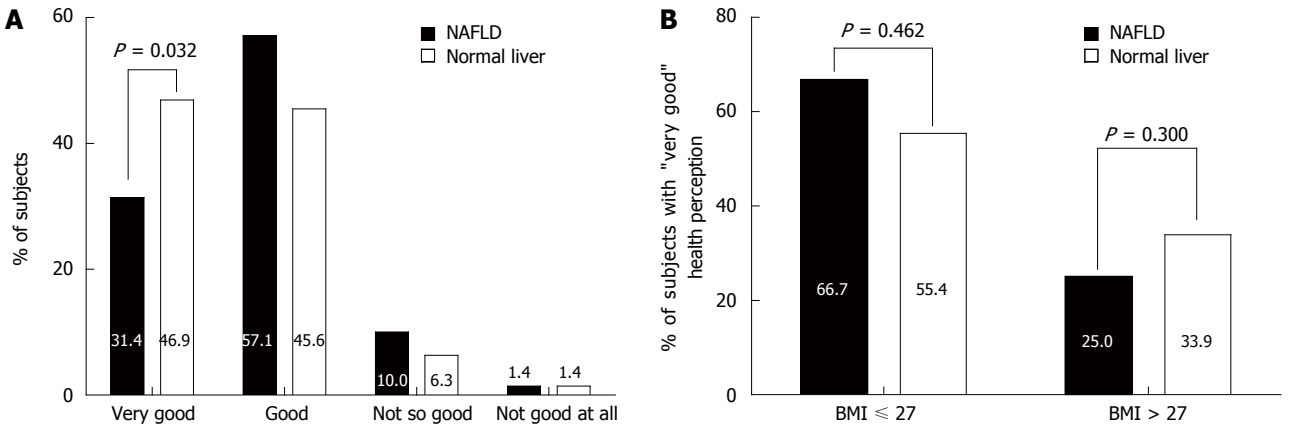

Figure 2 Distribution of self-rated health perception among non-alcoholic fatty liver disease and normal liver groups among the entire population (A), subjects with body mass index 27 and below (*n* = 95) and subjects with body mass index above 27 (*n* = 112) (B). *P* values represent the difference between NAFLD and normal liver groups in the distribution of "very good" health perception versus "else"- all other categories combined (Chi-square). NAFLD: Non-alcoholic fatty liver disease; BMI: Body mass index.

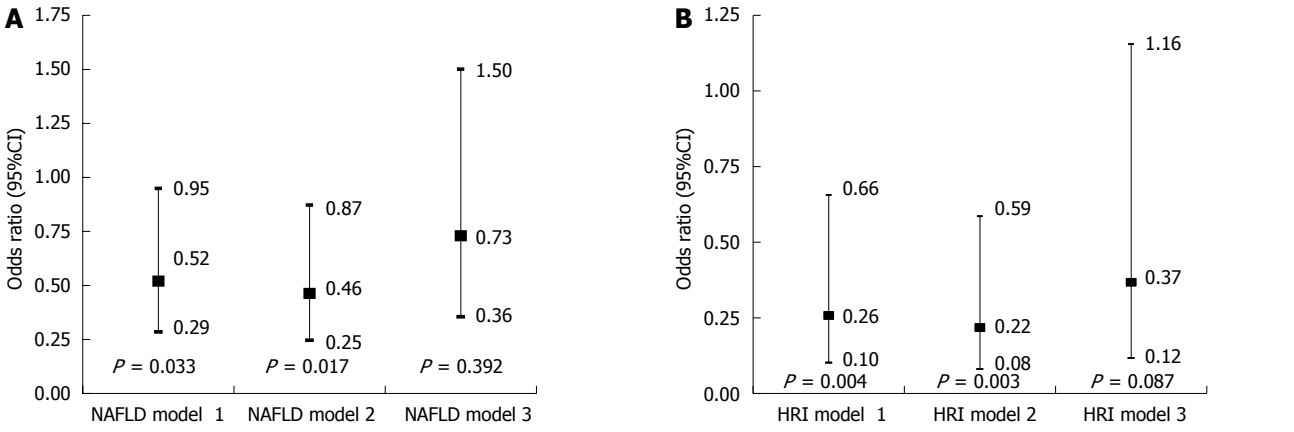

Figure 3 Univariate and multivariate association between non-alcoholic fatty liver disease and "very good" health perception (A) by non-alcoholic fatty liver disease diagnosed with regular US compared to normal liver (B) by hepato-renal index level (per one unit increase in the index) [odds ratio (95%CI)]. Model 1: Crude; Model 2: Adjusted for age and gender; Model 3: Adjusted for age, gender and BMI; NAFLD: Non-alcoholic fatty liver disease; BMI: Body mass index; HRI: Hepato-renal index.

eliminated this difference (Figure 2).

In a univariate analysis, the presence of NAFLD was associated with lower odds for a "very good" health perception (compared to "else") (OR = 0.52, 95%CI: 0.29-0.95, *P* = 0.033). This negative association remained significant with adjustment for age and gender (OR = 0.46, 95%CI: 0.25-0.87, *P* = 0.017). However, with farther adjustment for BMI the association with the presence of NAFLD was attenuated (OR = 0.73, 95%CI: 0.36-1.50, *P* = 0.392) (Figure 3). Similar results were observed for the hepato-renal index; it was inversely associated with "very good" health perception in the crude and in the age and gender adjusted model but not with further adjustment for BMI (Figure 3).

In a full model of multivariate analysis, that included all potential predictors for health perception (gender, age, BMI and behavioral factors: current smoking and duration of performance of leisure time physical activity in the past year), NAFLD was not associated with the self-reported general health perception (OR = 0.86, 95%CI: 0.40-1.86, *P* = 0.704). The odds for "very good" self-reported general health perception (compared to "else") increased among men (OR = 2.42, 95%CI: 1.26-4.66, *P* = 0.008) and those with higher performance of leisure time physical activity (OR = 1.01, 95%CI: 1.00-1.01, *P* < 0.001, per every minute/week) and decreased with increasing level of BMI (OR = 0.91, 95%CI: 0.84-0.99, P = 0.028, per every kg/m^2) and older age (OR = 0.96, 95%CI: 0.93-0.99, *P* = 0.033, per one year). Current smoking was not associated with health perception (OR = 1.31, 95%CI: 0.54-3.16, *P* = 0.552).

NAFLD dynamics and the association with health perception

All the participants in the study underwent two abdominal US evaluations with a 7 years interval. Forty-two (19.7%) participants were diagnosed with NAFLD in both US assessments, in 28 (13.1%) NAFLD

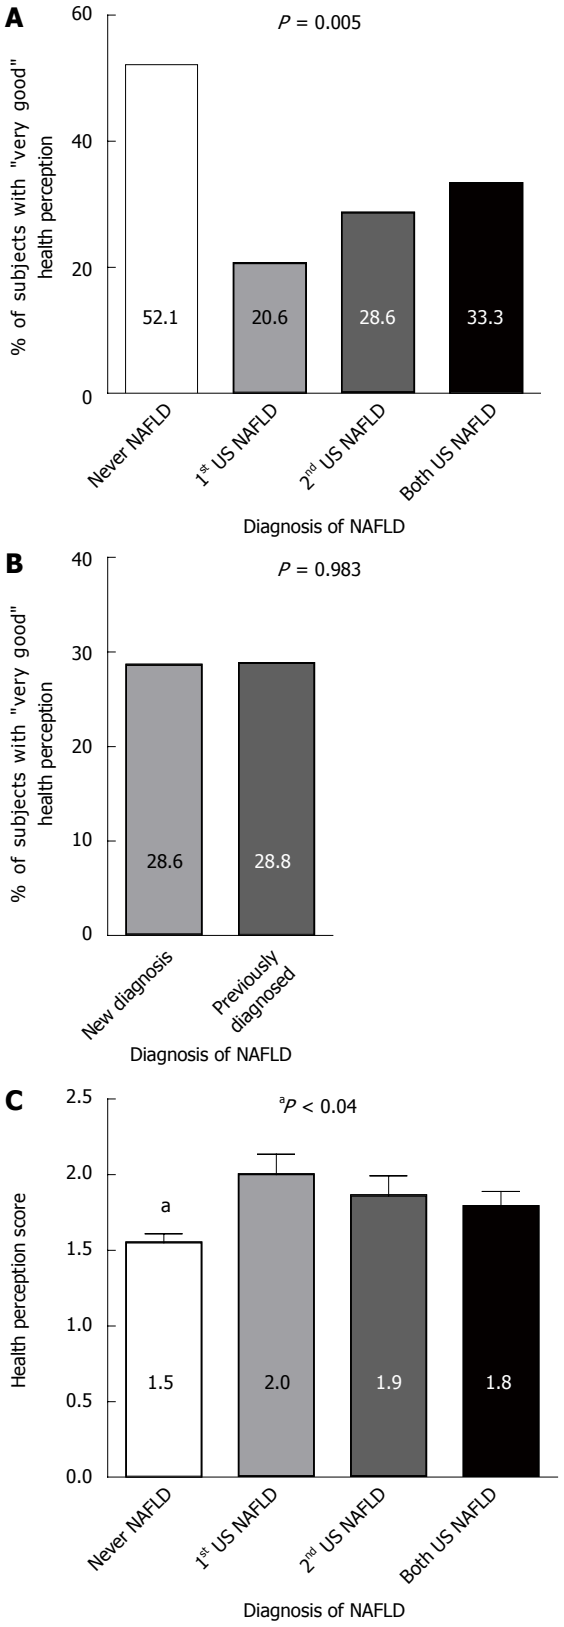

Figure 4 Health perception by past and present diagnosis of fatty liver on ultrasound (never NAFLD *n* = 119, 1st US NAFLD *n* = 24, 2nd US NAFLD *n* = 28, both US NAFLD *n* = 42). A: Percent of subjects with "very good" health perception by NAFLD dynamics; B: Percent of subjects with "very good" health perception by naive (newly diagnosed) and not naive (previously diagnosed) NAFLD status; C: The average score of health perception by NAFLD dynamics (the lower the score the higher the health perception; 1 = "very good", 4 = "not good at all") (a never NAFLD *vs* every other group). NAFLD: Non-alcoholic fatty liver disease.

was observed only in the latter US and in 24 (11.3%) NAFLD was diagnosed only in the first US but not in the second one, 119 (55.9%) participants had a normal liver in both US assessments.

The prevalence of "very good" health perception was higher among the subgroup that was never diagnosed with NAFLD (52.1%) compared to participates who were ever diagnosed with NAFLD during the study (only in the first evaluation, only in the second evaluation, or in both evaluations, 20.6%, 28.6% and 33.3%, respectively, P = 0.005), without significant difference between the "ever NAFLD" groups (Figure 4A). Furthermore, naive (newly diagnosed) and previously diagnosed NAFLD patients (who already knew they have NAFLD) did not differ in their prevalence of "very good" health perception (Figure 4B). Similarly, the average score of general health perception (1 = "very good", 4 = "poor") in patients who were never diagnosed with NAFLD was significantly lower than the score in patients "ever diagnosed" with NAFLD (P < 0.04 for all comparisons), but no significant differences were observed between all "ever diagnosed" with NAFLD groups (Figure 4C).

Health perception dynamics and the association with NAFLD

Among those diagnosed as normal liver at the first evaluation, 61/145 (42.1%) estimated their health as "very good" and among those with NAFLD at the first evaluation, 15/66 (22.7%) had "very good" health perception (P = 0.007). There was no difference between the NAFLD and the normal liver groups (as diagnosed at the first evaluation) in the dynamics of "very good" health perception between the first and follow-up surveys; 75.8% *vs* 70.3% retained, 9.1% *vs* 11.7% had a reduction and 15.2% *vs* 17.9% had improvement in health perception, respectively (P = 0.712).

Fatigue and avoidance from physical activity

The total time spent in all types of leisure time physical activity per week was twofold higher among subject without NAFLD as compared to those with NAFLD (113.12 ± 158.32 min/wk *vs* 63.00 ± 107.92 min/wk, P = 0.008).

In the entire cohort, 70/213 (32.9%) reported avoidance of physical activity. The main reason for avoidance was boredom (37.1%), followed by no available time (20.0%) and fatigue (12.9%). There was no significant difference between subjects with and without NAFLD in the main reason for avoidance from physical activity (P = 0.163). Only 2/26 (7.7%) in the NAFLD group *vs* 7/44 (15.9%) in the normal liver group reported fatigue as the main reason for avoidance from physical activity with no difference between groups (P = 0.321).

According to the FIS questionnaire, there was no significant difference between the NAFLD and the normal liver groups in any parameter of fatigue (data

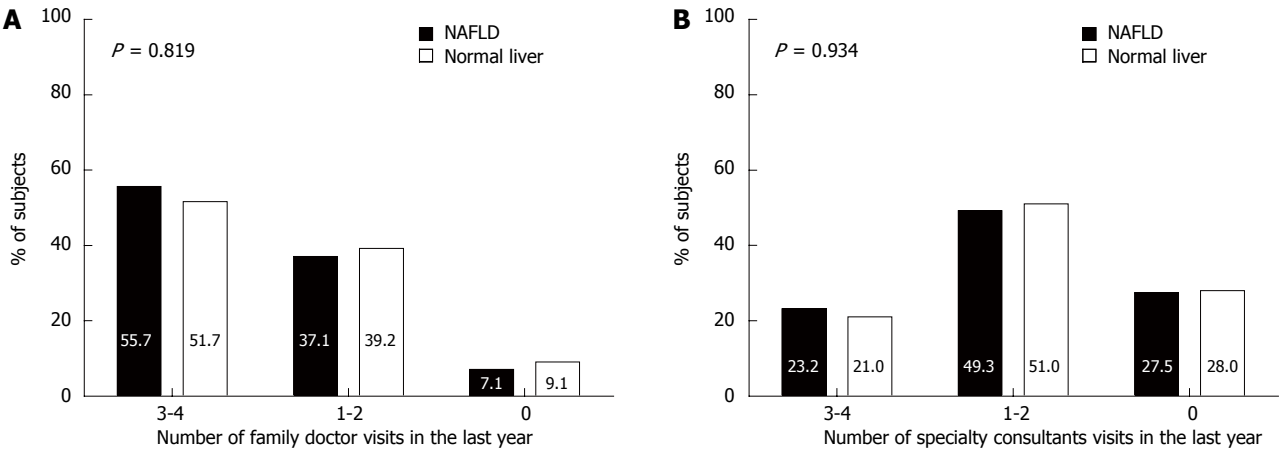

Figure 5 Comparison between non-alcoholic fatty liver disease and normal liver groups in the distribution of frequency of family doctor visits (A) and in the distribution of frequency of specialty consultants (B). NAFLD: Non-alcoholic fatty liver disease.

not shown, $P \geqslant 0.343$ for all) including the need to reduce daily activity due to fatigue (20.0% *vs* 19.6%, respectively, $P = 0.781$).

NAFLD and utilization of health-care services

There was no significant difference between subjects with and without NAFLD in the frequency of family doctor visits in the last year (Figure 5A). Furthermore, there was no difference between subjects with and without NAFLD in the frequency of specialty consultants in the last year (Figure 5B), in the occurrence of hospitalization in the last 5 years (28.6% *vs* 29.4%, respectively, $P = 0.904$) and in the number of hospitalization events (1.45 ± 0.99 *vs* 1.55 ± 1.47, respectively, $P = 0.789$).

DISCUSSION

NAFLD is emerging as a leading cause for chronic liver disease, cirrhosis and hepatocellular carcinoma[2], thus early diagnosis, life style modifications and treatment are essential. The association between NAFLD and general health perception is debatable. Perceived health status is a reflection of both physical and psychological self-perception and has a well-established association with adverse outcomes[31-33]. The question "How is your health in general?" is well validated and a good predictor of future health care utilization and mortality[34,35]. In this study, "very good" health perception was less prevalent among subject with NAFLD compared to subject with normal liver. However, controlling for BMI attenuated the association between both the presence of NAFLD and the amount of liver fat and self-reported health perception. We acknowledge that multicollinearity exists between NAFLD and obesity, the latter was associated with a lower health perception. However, we aimed to learn if NAFLD as a distinct entity is associated with a lower health perception and thus controlled for BMI. To do that, we not only controlled for BMI in a multivariate analysis, but also stratified on it and in both cases it attenuated the association between the presence of NAFLD and self-reported health perception. Moreover, deterioration of "very good" health perception with time could not be predicted by NAFLD. This finding indicates that despite the multiple negative health outcomes of NAFLD, patients don't feel or think of themselves as sick. This notion is also supported by other findings in our study. First, the NAFLD patients do not utilize more health services as measured by physician visits. Second, even though time spent in leisure time physical activity was lower among NAFLD subjects compared to normal liver controls, fatigue as an explanation for lack of physical activity was evenly reported between the groups. Furthermore, no difference in FIS was noted as well. Lastly, patients with a recent diagnosis of NAFLD (on the follow-up survey), who were unaware of the diagnosis at the time of the interview, had similar health perception as those with "long standing" NAFLD which was detected during the first survey, indicating that patients do not perceive NAFLD as a serious health threat.

Self-rated health has not been previously tested in NAFLD patients, but was tested in relation to diabetes mellitus indicating a greater chance for poor self-rated health among diabetic patients[36]. The difference between the perception of NAFLD and diabetes may stem from the "seniority" of diabetes in terms of disease recognition among physicians and public, the common use in medications in diabetes versus lack of medical treatment in NAFLD and additional diabetes-related complications related to a lower quality of life[37].

Significant positive predictors for "very good" health perception were male gender and regular performance of exercise and negative predictors were BMI and age. Similarly, according to the OECD cross-country comparisons of perceived good health status, in the vast majority of participating countries, men were more likely than women to report good health, and health perception tended to worsen with age[38].

As opposed to the scant data regarding health

perception, fatigue is more extensively investigated among NAFLD patients. In a cohort from Newcastle (United Kingdom) 44% of NAFLD patients experienced significant fatigue which was not correlated to thyroid function[39], insulin resistance or severity of liver disease[13]. Fatigue (assessed with FIS) among NAFLD patients was also significantly higher compared with age and sex matched controls[11,13]. The fatigue in NAFLD can be explained by lower blood pressure and autonomic dysfunction, but it may also be that relative hypotension is secondary to fatigue, reflecting the decreased amount of physical activity undertaken by patients who perceive themselves as fatigued[11,14]. Another explanation is excessive daytime sleepiness, the cardinal symptom of obstructive sleep apnea (OSA), commonly associated with obesity and NAFLD. OSA is well correlated with insulin resistance, but the correlation to NAFLD is debatable[40,41]. However, in a prospective cohort study, moderate to severe liver steatosis was associated with more severe obstructive sleep apnea. Continuous positive airway pressure (CPAP) therapy for 3 years partially reversed these changes in the majority of patients[42]. Our results may differ from other studies due to different study populations. In the current study the NAFLD subjects were sampled from the general population and not from a selected population of a liver clinic at a medical center.

If indeed fatigue is comparable among NAFLD and normal liver subjects, why do NAFLD subjects exercise less than normal liver subjects? Explanatory factors could be: reduced cardio-respiratory fitness, weight-related arthrosis, psychological factors and a tendency towards a sedentary lifestyle, all correlated with the metabolic syndrome[20, 43].

Only few studies evaluated the utilization of health services among NAFLD patients supporting the hypothesis that NAFLD patients have higher utilization of health services compared with the normal liver group[11,15,44]. In a 5-year population-based follow-up study in Germany, the presence of NAFLD, defined by both presence of a hyperechogenic pattern of the liver and elevated serum alanine aminotransferase (ALT) levels, was associated with a 26% increase of overall health care costs, after controlling for co-morbidities[45]. The current study results are inconsistent with the limited literature, perhaps since the NAFLD subjects in this study were sampled from the general population, most of them having liver enzymes within the normal range, thus it is very likely that their NAFLD is at a less progressive and symptomatic state compared with NAFLD patients referred for treatment at a medical center which have higher risk for having NASH.

In this study, the utilization of health services was not increased among the NAFLD diagnosed subjects. This finding combined with the equivalent health perception might point towards lack of awareness and understanding that NAFLD is in fact a progressive disease that requires a closer medical surveillance. The misperception of NAFLD as a non-significant disease may also be attributed to the way the health practitioners perceive NAFLD, perhaps not as a disease in itself with potentially severe outcomes, and as a consequence the information they provide to patients and their disease management. Several studies have demonstrated that hepatogastroenterologists[46], primary care practitioners[47] and hospital non-hepatologists specialists[48] do consider NAFLD as a disease and major health problem and follow NAFLD patients, but it is still unclear how firm is the message provided to the patients.

How can this obstacle to patient care be overcome? Health policy approach to improve the patient's perception and self-management of NAFLD may be an implementation of a "multidisciplinary team approach" in which patients will be followed by physicians, dietitians, psychologists and physical activity supervisors[49]. Furthermore, general practitioners and hepatologists treating NAFLD patients should provide information and refer the patients to appropriate resources about NAFLD implications and treatment and have training in behavioral therapy. Similarly to the treatment approach of other chronic diseases, healthcare providers need to talk with their NAFLD patients more about the broader picture of complications; hepatocellular cancer, increased risk of diabetes, heart attack or stroke, with the message that risk reduction is possible[50]. The 5 *A*'s model (ask, advise, assess, assist, and arrange) may be useful as a tool to assist clinicians advising NAFLD patients to modify their behavior, assessing their interest in doing so, assisting in their efforts to change, and arranging appropriate follow-up[51].

Our study has several limitations to consider. First, the diagnosis of NAFLD was established by using noninvasive methods of abdominal US and HRI and the histologic diagnosis of inflammation and fibrosis could not be obtained in a sample of the general population. However, with regard to the diagnosis of steatosis, using abdominal US is the most common and acceptable first-line screening procedure for NAFLD in clinical practice and in epidemiological studies[20,52,53].

Second, as mentioned above, the NAFLD subjects were sampled from the general population, thus our sample may not represent the more severe forms of the disease. Last, the utilization of health services was self-reported instead of objectively measured and thus prone to a report bias that may have weakened the observed associations.

In conclusion, NAFLD diagnosis among a general population is not independently associated with lower general health perception nor is it associated with higher health care utilization. Moreover, NAFLD does not seem to predict health perception deterioration over the years. These findings imply that in the general population, NAFLD is not considered a disease in the eyes of the NAFLD beholder, probably until the progressive state.

COMMENTS

Background

Non-alcoholic fatty liver disease (NAFLD) is defined as fat accumulation in the liver, in the absence of significant alcohol intake. It is the most common chronic liver disorder globally with significant hepatic and extrahepatic morbidity. Moreover, patients with NAFLD have reduced survival compared with the general population, primarily due to cardiovascular disease followed by malignancy.

Research frontiers

In recent years there is overwhelming evidence that NAFLD is a major public health concern. However, self-rated general health perception, a frequently assessed parameter in epidemiological research and a powerful predictor for morbidity and mortality, has not been tested in NAFLD patients.

Innovations and breakthroughs

This study demonstrates that NAFLD diagnosis among a general population is not independently associated with lower general health perception nor is it associated with higher health care utilization. Moreover, NAFLD does not seem to predict health perception deterioration over the years. These findings imply that in the general population, NAFLD is not considered a disease in the eyes of the NAFLD beholder, probably until the advanced stage.

Applications

More efforts should be directed to establish the acknowledgment of NAFLD as an independent clinical entity with a potentially progressive course. Such a firm and clear message from the treating physician to the patients may promote motivation and adherence to lifestyle changes and a wiser health care utilization for a closer medical surveillance.

Terminology

Self-reported general health perception was estimated with one simple question that was highly validated as an indication to general health status and is commonly used in surveys worldwide. The question was "what is your general health status?" and the answers were: 1- "very good", 2- "good" 3- "not so good" 4- "poor". Hepato-Renal Index (HRI) - during the ultrasonography, a histogram of brightness levels, *i.e.*, a graphical representation of echo intensity within a region of interest is obtained in the liver and in the right kidney. The brightness level for each organ is recorded and the ratio between the median brightness level of the liver and the right kidney cortex is calculated to determine the HRI.

Peer-review

This is a cross sectional study aimed at evaluating the self-rated general health perception in a cohort of 213 subjects form a health survey in Israel. The article is generally well-written and has scientific value, given the high prevalence of NAFLD and the potential implications of its findings in formulating health care policies.

Abstract

AIM: To evaluate the usefulness of the functional hepatic resection rate (FHRR) calculated using 3D computed tomography (CT)/^{99m}Tc-galactosyl-human serum albumin (GSA) single-photon emission computed tomography (SPECT) fusion imaging for surgical decision making.

METHODS: We enrolled 57 patients who underwent bi- or trisectionectomy at our institution between October 2013 and March 2015. Of these, 26 patients presented with hepatocellular carcinoma, 12 with hilar cholangiocarcinoma, six with intrahepatic cholangiocarcinoma, four with liver metastasis, and nine with other diseases. All patients preoperatively underwent three-phase dynamic multidetector CT and ^{99m}Tc-GSA scintigraphy. We compared the parenchymal hepatic resection rate (PHRR) with the FHRR, which was defined as the resection volume counts per total liver volume counts on 3D CT/^{99m}Tc-GSA SPECT fusion images.

RESULTS: In total, 50 patients underwent bisectionectomy and seven underwent trisectionectomy.

Biliary reconstruction was performed in 15 patients, including hepatopancreatoduodenectomy in two. FHRR and PHRR were 38.6 ± 19.9 and 44.5 ± 16.0, respectively; FHRR was strongly correlated with PHRR. The regression coefficient for FHRR on PHRR was 1.16 (P < 0.0001). The ratio of FHRR to PHRR for patients with preoperative therapies (transcatheter arterial chemoembolization, radiation, radiofrequency ablation, *etc*.), large tumors with a volume of > 1000 mL, and/or macroscopic vascular invasion was significantly smaller than that for patients without these factors (0.73 ± 0.19 *vs* 0.82 ± 0.18, P < 0.05). Postoperative hyperbilirubinemia was observed in six patients. Major morbidities (Clavien-Dindo grade ⩾ 3) occurred in 17 patients (29.8%). There was no case of surgery-related death.

CONCLUSION: Our results suggest that FHRR is an important deciding factor for major hepatectomy, because FHRR and PHRR may be discrepant owing to insufficient hepatic inflow and congestion in patients with preoperative therapies, macroscopic vascular invasion, and/or a tumor volume of > 1000 mL.

Key words: ^{99m}Tc-galactosyl human serum albumin; Single-photon emission computed tomography; Hepatectomy; Functional hepatic resection rate; Parenchymal hepatic resection rate

Core tip: We evaluated the usefulness of the functional hepatic resection rate (FHRR) calculated using 3D computed tomography (CT)/^{99m}Tc-galactosyl human serum albumin (GSA) single-photon emission computed tomography fusion imaging and found a strong correlation between FHRR and the parenchymal hepatic resection rate (PHRR). However, FHRR and PHRR were discrepant because of insufficient hepatic inflow and congestion in patients with preoperative therapies, macroscopic vascular invasion, or a tumor volume of > 1000 mL.

Significance of functional hepatic resection rate calculated using 3D CT/99mTc-galactosyl human serum albumin single-photon emission computed tomography fusion imaging. *World J Gastroenterol* 2016; 22(17): 4373-4379 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4373.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4373

INTRODUCTION

The development of postoperative liver failure (PHLF) is a major cause of morbidity and mortality after hepatectomy[1]. The mortality rate after major hepatectomy is reported as 2.0% to 6.8%[1-3]. A smaller remnant liver volume and an impaired hepatic functional capacity increase the risk of PHLF[4]. Preoperative estimation of the hepatic functional reserve is important for major hepatectomy[5]. Although the future remnant hepatic volume can be calculated by computed tomography (CT) volumetry[6], precise estimation of the future liver remnant function is difficult.

The asialoglycoprotein receptor is only expressed on the sinusoidal surfaces of mammalian hepatocytes. ^{99m}Tc-galactosyl human serum albumin (^{99m}Tc-GSA) was developed as a liver scintigraphy agent that binds to the asialoglycoprotein receptor on hepatocytes[7]. ^{99m}Tc-GSA scintigraphy is frequently used for evaluating the hepatic functional reserve, and several parameters for quantitative determination of hepatic function such as the hepatic uptake ratio to the liver plus heart at 15 min (LHL15)[8] and the maximum removal rate of ^{99m}Tc-GSA (Rmax)[9] have been reported. ^{99m}Tc-GSA single-photon emission computed tomography (SPECT) can acquire the regional distribution of hepatic function[10]. However, the spatial resolution of ^{99m}Tc-GSA SPECT is low. Furthermore, it is difficult to precisely estimate the functional reserve of the future liver remnant in patients requiring complicated resection. CT/^{99m}Tc-GSA SPECT fusion imaging has been reported to enable the precise evaluation of hepatic function distribution, given the high spatial resolution provided by CT[11]. Several parameters using CT/^{99m}Tc-GSA SPECT fusion imaging such as the preoperative total amount of receptor in the future remnant liver (R0-remnant)[12], the liver uptake value corrected for body surface area ($LUV_{(BSA)}$)[13] and the uptake index (UI)[14] have been reported to be useful for preoperative estimation of remnant hepatic function, but they were considerably complex. We considered hepatic resection rate is more intuitively usable.

In the present study, we calculated the functional hepatic resection rate (FHRR) using 3D CT/^{99m}Tc-GSA SPECT fusion imaging for patients undergoing major hepatectomy and determined its usefulness by correlation with the parenchymal hepatic resection rate (PHRR).

MATERIALS AND METHODS

Between October 2013 and March 2015, 57 patients who underwent bi- or trisectionectomy at the Department of Gastroenterological Surgery I, Hokkaido University Hospital were enrolled in this study. The baseline characteristics of the patients are shown in Table 1. All patients preoperatively underwent three-phase dynamic multidetector CT and ^{99m}Tc-GSA scintigraphy. Preoperative portal vein embolization (PVE) is performed for patients with a PHRR of > 60% at our institution[12]. Accordingly, 13 patients with a mean PHRR of 62.1% ± 7.9% (range, 47.0%-71.3%)

HCC: Hepatocellular carcinoma; ICGR$_{15}$: Indocyanine green retention at 15 min; LHL$_{15}$: The hepatic uptake ratio to the liver plus heart at 15 min of ^{99m}Tc-galactosyl human serum albumin; TACE: Transcatheter arterial chemoembolization; RFA: Radiofrequency ablation.

underwent preoperative PVE.

Hepatectomy

An algorithm (Hokkaido University Algorithm) incorporating the indocyanine green retention at 15 min and remnant liver volume is generally used to determine the nature of sectionectomy required, *e.g.*, bisectionectomy[15]. In the present study, FHRR and PHRR were used to determine the required procedure.

3D CT/^{99m}Tc-GSA SPECT fusion imaging

Three-phase dynamic CT was performed with a 320-row multidetector CT device (Aquilion ONE, Toshiba Medical Systems Co., Otawara, Japan). The obtained Digital Imaging and Communications in Medicine (DICOM) data were imported to the 3D image analysis system[16] (Volume Analyzer SYNAPSE VINCENT; Fuji Film Medical, Tokyo, Japan). 3D images were reconstructed from the DICOM data.

^{99m}Tc-GSA scintigraphy was performed separately from CT. Dynamic scanning was initially performed using a large-field view gamma camera (E.CAM; Siemens Japan, Tokyo) in an anterior view equipped with a low-energy high-resolution collimator, with the patient in the supine position after a bolus IV injection of 185 MBq of ^{99m}Tc-GSA. Dynamic planar images were obtained for 30 min by 147 serial frames (60 × 1 s, 87 × 20 s), with a matrix size of 128 × 128. Hepatic SPECT images were acquired after the dynamic study. The Digital Imaging and Communications in Medicine (DICOM) data obtained from SPECT were also imported to the SYNAPSE VINCENT and subsequently fused with the 3D CT images (Figure 1). PHRR and FHRR were calculated using the following formula:

Parenchymal hepatic resection rate (PHRR) (%) = liver resection volume/(total liver volume - tumor volume × 100)

Functional hepatic resection rate (FHRR) (%) = resection volume counts/total liver volume counts × 100

Statistical analysis

Statistical analyses were performed using JMP PRO version 11.2.0 (JMP statistical software; SAS Institute, Cary, NC, USA). The values are expressed as mean ± SDs. The correlation between PHRR and FHRR was assessed using Pearson's correlation product-moment coefficient. The ratio of FHRR to PHRR was calculated after stratifying the patients according to the presence or absence of preoperative therapies, macroscopic vascular invasion, and a tumor volume of 1000 mL. The ratio was derived by dividing the smaller value (PHRR or FHRR) with the larger value. The Wilcoxon signed rank test was used to compare data between groups.

RESULTS

Correlation between PHRR and FHRR

PHRR and FHRR were preoperatively calculated for all patients, and their correlation was determined (Figure 2). The mean PHRR and FHRR values were 44.5% ± 16.0% and 38.6% ± 19.9%, respectively. The FHRR value was approximately 10% smaller than the PHRR value, although there was a strong correlation between the two. The regression coefficient was 1.16 (P < 0.0001).

FHRR to PHRR ratio

There were 34 patients with preoperative therapies, including transcatheter arterial chemoembolization, radiation, radiofrequency ablation, chemotherapy, and partial resection), macroscopic vascular invasion, and/or a tumor volume of > 1000 mL, while 23 patients did not have any of these factors. The mean ratios for patients with and without these factors were 0.73 ± 0.19 and 0.82 ± 0.18, respectively (Figure 3). Thus, the ratio was significantly smaller for the former than for the latter (P < 0.05).

Surgical outcomes

Among the 57 patients, the most frequently performed procedure was right hepatectomy ± segment I (n = 18, 31.6%; Table 2). Biliary reconstruction was performed for 15 patients, including hepatopancreatoduodenectomy in two. Five patients exhibited Child-Pugh class B cirrhosis. These patients

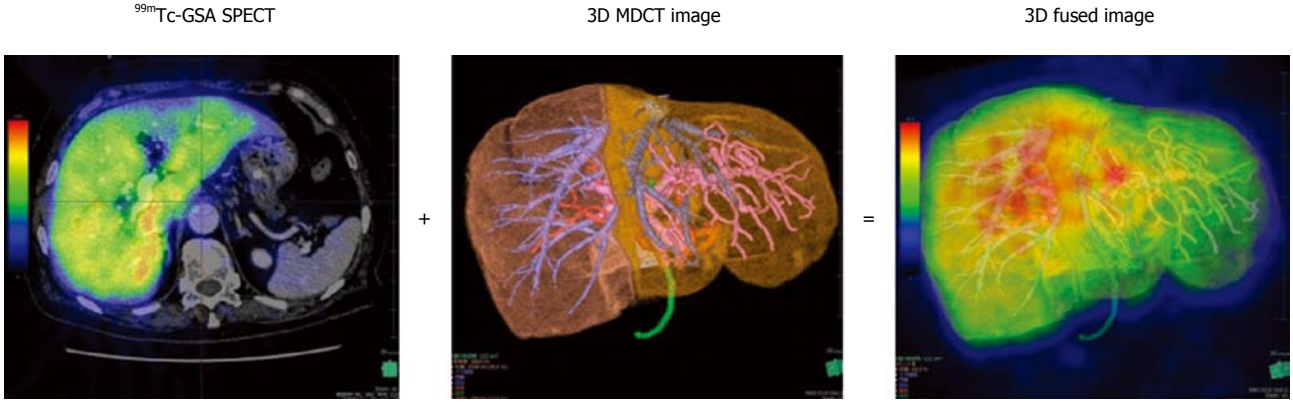

Figure 1 Creation of a 3D CT/^{99m}Tc-galactosyl human serum albumin single-photon emission computed tomography fusion image using the Volume Analyzer SYNAPSE VINCENT. The resection line is set using the 3D image reconstructed from Digital Imaging and Communications in Medicine (DICOM) data obtained from multidetector CT, following which the acquired ^{99m}Tc-GSA single-photon emission computed tomography (SPECT) image is fused with the 3D image. GSA: Galactosyl human serum albumin.

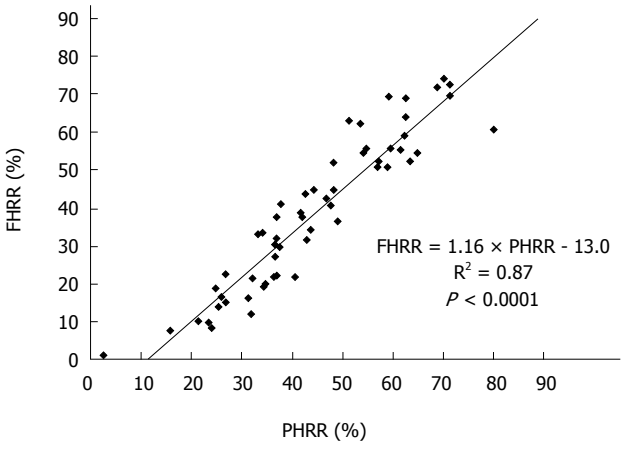

Figure 2 Correlation between the parenchymal hepatic resection rate and functional hepatic resection rate (calculated using 3D CT/^{99m}Tc-galactosyl human serum albumin single-photon emission computed tomography fusion imaging. Functional hepatic resection rate (FHRR) is strongly correlated with parenchymal hepatic resection rate (PHRR).

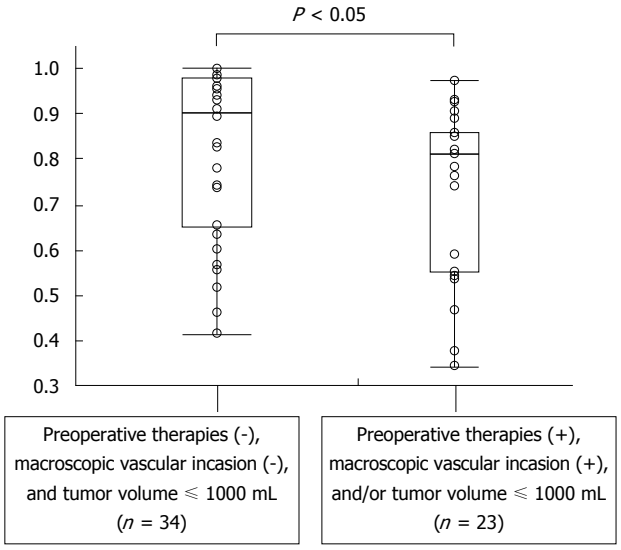

Figure 3 Comparison of the ratio of the functional hepatic resection rate to the parenchymal hepatic resection rate between patients with preoperative therapies, macroscopic vascular invasion, and/or a tumor volume of > 1000 mL and those without these factors. The ratio is significantly smaller for patients with preoperative therapies (transcatheter arterial chemoembolization, radiation, radiofrequency ablation, *etc.*), a tumor volume of > 1000 mL, and/or macroscopic vascular invasion than for those without these factors (0.82 ± 0.18 *vs* 0.73 ± 0.19, $P < 0.05$).

did not have chronic hepatitis, but they exhibited obstructive jaundice and malnutrition. Postoperative hyperbilirubinemia (serum total bilirubin ⩾ 5.0 mg/dL) was observed in six patients (10.5%). Five of these six patients underwent biliary reconstruction, and the remaining one exhibited preoperative cholangitis and underwent biliary drainage. PHLF, assessed according to the International Study Group of Liver Surgery definition, occurred in 12 patients (21.0%). Grade C liver failure was diagnosed in a patient who required repeat surgery because of portal vein thrombosis. Major morbidities (Clavien-Dindo grade ⩾ 3) occurred in 17 patients (29.8%). Bile leakage was a frequent occurrence (eight of 17 patients; 47.0%). There were no surgery-related deaths.

Representative case

A 34-year-old woman was diagnosed with a giant hemangioma (Figure 4). CT demonstrated that the posterior section was congested because of obstruction of the right hepatic vein by the giant hemangioma. Right trisectionectomy was planned. CT volumetry showed a tumor size of 2818 mL, a future remnant hepatic volume of 313 mL and a PHRR of 80.0%. 3D CT/^{99m}Tc-GSA SPECT fusion imaging showed an FHRR of 60.8%. She underwent right trisectionectomy without PVE and recovered without PHLF or any morbidity.

DISCUSSION

In the present study evaluating the significance of

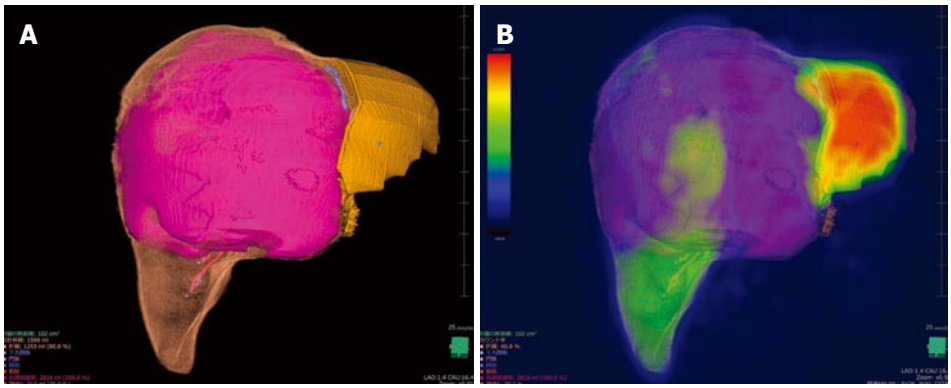

Figure 4 Representative case of a 34-year-old woman diagnosed with a giant hemangioma scheduled to undergo right trisectionectomy. A: CT volumetry showing the tumor volume as 2818 mL and parenchymal hepatic resection rate as 80.0%; B: 3D CT/^{99m}Tc-galactosyl human serum albumin single-photon emission computed tomography fusion image showing the functional hepatic resection rate as 60.8%. The patients underwent right trisectionectomy without preoperative portal vein embolization. She recovered without postoperative liver failure or any morbidity.

FHRR calculated using 3D CT/99mTc-GSA SPECT fusion imaging, we found a strong correlation between FHRR and PHRR. However, the ratio of FHRR to PHRR was significantly smaller for patients with preoperative therapies, a tumor volume of > 1000 mL, and/or macroscopic vascular invasion than for those without these factors.

^{99m}Tc-GSA scintigraphy is a well-accepted modality for assessment of the hepatic functional reserve, along with the indocyanine green clearance test[7,8,17]. We previously reported the conversion formula for ^{99m}Tc-GSA scintigraphy data to the indocyanine green retention at 15 min[18]. This is useful for estimating the functional reserve of the whole liver, although the function of the future liver remnant can only be estimated from the volume calculated by CT volumetry. The introduction of 3D CT/^{99m}Tc-GSA SPECT fusion imaging has enabled precise estimation of the function of the focal liver lesion[11-14,19,20].

In the present study, PHRR and FHRR were calculated using 3D CT/^{99m}Tc-GSA SPECT fusion imaging along the accurate cutting line. FHRR was strongly correlated with PHRR, although they were discrepant for patients with preoperative therapies, macroscopic vascular invasion, and/or a tumor volume of >1000 mL. Theoretically, the discrepancy cannot occur without any deflection in liver function. Akaki *et al*[10] suspected that the decrease in the portal venous flow caused by the tumor is a major factor for the discrepancy between CT and ^{99m}Tc-GSA SPECT data. Mitsumori *et al*[21] reported that ^{99m}Tc-GSA SPECT findings were better correlated with the remnant liver function than CT findings because of the following reasons. First, the degree of hepatic dysfunction in the segment or lobe containing the hepatocellular carcinoma is greater than that in the segment or lobe without cancer. Second, the liver parenchyma surrounding the tumor is damaged by mechanical compression. Third, secondary liver damage may occur because of compression of the vessels and bile ducts by the tumor. We also hypothesized that preoperative therapies such as transcatheter arterial chemoembolization, radiofrequency ablation, and radiation induce focal liver damage, and that macroscopic vascular invasion and large tumors cause insufficient inflow or congestion. To prove the hypothesis, we compared the ratio of FHRR to PHRR between patients with and without the abovementioned factors and found that it was significantly smaller for patients with these factors. Thus, PHRR and FHRR are likely to be discrepant for patients with these conditions.

Recent advances in surgical techniques and pre- and postoperative care, including the decision criteria for hepatectomy and indications for liver resection, have been applied to extended hepatectomy. However, the famous decision criteria of Makuuchi[22] do not include the future remnant liver volume. A smaller remnant liver volume and an impaired hepatic functional capacity increase the risk of PHLF[4]; therefore, calculation of the future remnant hepatic

volume using CT volumetry is important[6]. It was reported that the type of surgery (more than or equal to hemihepatectomy *vs* less than hemihepatectomy) was associated with in-hospital mortality, and, specifically, patients who underwent less than a hemihepatectomy exhibited a mortality rate of 4.1%, while those who underwent more than or equal to hemihepatectomy exhibited a mortality rate of 6.5%[23]. Therefore, major hepatectomy requires detailed preoperative evaluations and excellent techniques. When FHRR is larger than PHRR, surgical decision making should be more meticulous to prevent PHLF and postoperative morbidities. It was reported that preoperative functional assessment by ^{99m}Tc-GSA SPECT is more useful than volumetric assessments by CT for the prediction of surgical outcomes[21,24]. On the other hand, when FHRR is smaller than PHRR, the indications for hepatectomy may be expanded beyond the safe limits. The reported safe limit of PHRR for a normal liver is 75%[25,26]. In the present study, a 34-year-old woman with a giant hemangioma uneventfully underwent right trisectionectomy. Although her PHRR was 80.0%, right trisectionectomy was accomplished without PVE after referring to an FHRR of 60.8%. This was probably because the function of the posterior section may have been deteriorated by congestion caused by obstruction of the right hepatic vein by the giant hemangioma. She recovered without PHLF or any morbidity. Further studies are required to confirm the safety of giving more importance to FHRR over PHRR.

In conclusion, we found an overall strong correlation between FHRR calculated using 3D CT/^{99m}Tc-GSA SPECT and PHRR in our study. However, FHRR and PHRR were discrepant for patients with preoperative therapies, macroscopic vascular invasion, and/or a tumor volume of > 1000 mL. These findings suggest that FHRR is useful for accurate estimation of the future liver remnant function and an important deciding factor for major hepatectomy.

COMMENTS

Background

Preoperative estimation of the hepatic functional reserve is important for major hepatectomy. Precise estimation of the future liver remnant function is difficult. ^{99m}Tc-galactosyl human serum albumin (^{99m}Tc-GSA) is frequently used for evaluating the hepatic functional reserve. ^{99m}Tc-GSA single-photon emission computed tomography (SPECT) can show the regional distribution of hepatic function. However, it is difficult to precisely estimate the functional reserve of the future liver remnant in patients requiring complicated resection. CT/^{99m}Tc-GSA SPECT fusion imaging enables the precise evaluation of hepatic function distribution, given the high spatial resolution provided by CT. In the present study, the authors calculated the functional hepatic resection rate (FHRR) using 3D CT/^{99m}Tc-GSA SPECT fusion imaging for patients undergoing major hepatectomy and determined its usefulness by determining its correlation with the parenchymal hepatic resection rate (PHRR).

Research frontiers

Several parameters using CT/^{99m}Tc-GSA SPECT fusion imaging, such as the preoperative total amount of receptor in the future remnant liver (R0-remnant), the liver uptake value corrected for body surface area [LUV(BSA)], and the uptake index (UI), have been reported to be useful for the preoperative estimation of remnant hepatic function, although they are considerably complex.

Innovations and breakthroughs

In the present study, the authors calculated the FHRR using 3D CT/^{99m}Tc-GSA SPECT fusion imaging and determined its usefulness. They considered the hepatic resection rate to be more intuitively useful compared with former reported parameters. A strong correlation between FHRR and PHRR in the present study was found. However, FHRR and PHRR were discrepant for patients with preoperative therapies, macroscopic vascular invasion, and/or a tumor volume of > 1000 mL.

Applications

This study suggests that the measurement of FHRR is particularly useful for patients with preoperative therapies, macroscopic vascular invasion, and/or a tumor volume of > 1000 mL.

Terminology

^{99m}Tc-GSA scintigraphy: An image inspection used for evaluating the hepatic functional reserve. ^{99m}Tc-GSA SPECT: A procedure to obtain tomographic images of ^{99m}Tc-GSA scintigraphy.

Peer-review

The manuscript is well organized and developed. The study is inserted in the wide topic of selection of the patients for hepatic surgery, first of all based on the evaluation of the functions of the remnant liver.

Abstract

AIM: To identify prognostic factors and to correlate *APC* mutations with clinical features, including extracolic manifestations.

METHODS: One hundred thirty-five patients who underwent surgical procedures for familial adenomatous polyposis (FAP) were included. FAP was diagnosed when the number of adenomatous polyps was > 100. Data related to patient, extracoloic manifestations, cancer characteristics, operative procedure, follow up and surveillance were collected. *APC* mutation testing was performed in the 30 most recent patients. DNA was extracted from peripheral blood and polymerase chain reaction products using 31 primer pairs on *APC* gene were sequenced. A retrospective study was performed to investigate a causal relationship between prognosis and feature of patient.

RESULTS: The mean age of the 51 patients with colorectal cancer (CRC) was older than that of those without CRC (30.5 *vs* 36.9, P = 0.002). Older individuals were more likely to have colon cancer at the time of FAP diagnosis [odds ratio, 4.75 (95%CI: 1.71-13.89) and 5.91(1.76-22.12) for 40-49 years and age > 50 *vs* age < 30). The number of confirmed deaths was 13 and the median age at death was

40 years (range, 27 to 85 years). Ten of the deaths (76.9%) were from CRC. Another cause of two cases of death were desmoid tumors (15.4%). Development of cancer on remnant rectal or ileal mucosa after surgery was not observed. The *APC* mutation testing revealed 23 pathogenic mutations and one likely pathogenic mutation, among which were four novel mutations. The correlation between mutational status and clinical manifestations was investigated. Mutations that could prodict poor prognosis were at codon 1309 which located on mutation cluster region, codon 1465 and codon 1507.

CONCLUSION: Identification of *APC* mutations should aid in the diagnosis and counseling of family members in terms of early diagnosis and management of FAP.

Key words: Adenomatous polyposis coli; Colorectal neoplasms; *APC* gene; Prognosis; Survival

Core tip: Diagnostic delay to make adequate management harder, resulting in advanced colorectal cancer and accompanying morbidities, was not uncommon in patients with familial adenomatous polyposis. This study investigated prognostic factors and the correlation between *APC* mutations and clinical features, including extracolic manifestations. The present study revealed that early diagnosis and management of high-risk patients is essential and suggests the necessary *APC* mutations testing in the diagnosis and counseling of patients by informing on disease prognosis.

INTRODUCTION

Familial adenomatous polyposis (FAP) is an autosomal dominantly inherited cancer syndrome caused by germ-line mutation of the adenomatous polyposis coli gene (*APC*) and characterized by the development of 100 to 1000 colorectal adenomatous polyps in its classic form[1]. Subjects with FAP have a risk of almost 100% of developing colorectal cancer by 40-50 years of age[2]. The extracolic phenotype is characterized by the development of adenomatous polyps in the upper gastrointerstinal tract, gastric fundic polyps, desmoid tumors, osteomas, fibrous bone dysplasia, skin fibromas, pineal blastomas, brain cysts, papillary thyroid cancers (PTCs) and congenital retinal pigment epithelial hypertrophy (CHRPE). Colorectal cancer is the most common cause of death in FAP patients and desmoid tumors are the second[3]. To prevent the development of colon cancer, prophylactic removal of the entire colorectal mucosa is recommended for FAP patients.

The FAP registry was performed to improve the prognosis of FAP through early diagnosis and surgery before the development of colorectal cancer[4]. In addition, a recent molecular genetic test for *APC* mutations makes it possible to detect asymptomatic or not developing polyposis patients. *APC* mutations can be detected in 80%-90% of patients who have a valid indication for the test[5]. Since most families are managed through hospital-based registries and not by the nation wide registry, there are few investigations of integrative and continuous follow-up to provide treatment guidelines for Korean families. Patients' indifference and diagnostic delay appear to make adequate management harder, resulting in advanced colorectal cancers and accompanying morbidities.

The purpose of this study was to describe the clinicopathological features of the disease and the expression of extracolic manifestations, and to evaluate whether *APC* mutations have prognostic value in Korean patients. Finally, we propose management options for high-risk patients to improve outcome.

MATERIALS AND METHODS

Patient enrollment and eligibility

FAP was defined by the presence of more than 100 colorectal adenomatous polyps, according to intraoperative findings and pathologic reports. In this retrospective study, 135 consecutive patients who underwent surgical procedures for FAP at the Asan Medical Center (Seoul, Korea) between August 1991 and July 2014 were included with median follow-up periods of 54 mo. Patients with fewer than 100 adenomatous polyps and patients with hamartomatous polyposis were excluded. Demographics and length of follow-up were documented for each patient.

Work-up to surveillance

The extent of disease and developing cancer was assessed by colonoscopy, abdominopelvic computed tomography (CT) or magnetic resonance imaging (MRI). Positron emission tomography-computed tomography (PET-CT) was performed if advanced colorectal cancer was suspected. Investigation of extra-colonic manifestations was done when FAP was diagnosed or in the immediate postoperative period. Tests included physical examination for skin lesions and palpable masses, X-ray imaging for bone lesions, dental and ophthalmic examination and gastroduodenal endoscopy.

Patients were subjected to one of the following procedures: total proctocolectomy with ileal pouch anal anastomosis (TPC/IPAA) with hand sewn or

stapled anastomosis, TPC with end ileostomy, and total colectomy with ileorectal anastomosis (TC/IRA). The patients who underwent TPC/IPAA with mucosectomy with hand sewn anastomosis or TPC with end ileostomy did not have any remnant rectal mucosa. By contrast, the TPC/IPAA with stapled anastomosis or TC/IRA procedures left remnant rectal mucosa.

Annual colonic and gastric endoscopic surveillance is recommended after surgery. Colonoscopy was performed using a standard adult colonoscope or a gastroscope. Any lesion suspected to be an adenoma during endoscopic surveillance was biopsied. If the polyps could not be controlled by endoscopic procedures, surgical procedures were performed. Surveillance endoscopies and associated pathologic reports were reviewed including the incidence, timing and histology of the adenoma and cancer development. In patients with colon cancer, a follow-up assessment was performed every 3 to 6 mo for the first 2 years and annually thereafter.

APC mutation

In our institution, *APC* germ-line mutation testing has been performed since 2008 in the clinical setting to diagnosis FAP and counsel patients and their family members. The 30 most recent patients among 135 FAP patients underwent mutation tests. Genomic DNA was extracted from peripheral blood using a Qiagen DNA extraction kit (Qiagen, Hilden, Germany). Thirty-one primer pairs were used, including primer pairs covering exons 1-14 and 17 primer pairs covering exon 15 of the *APC* gene. Polymerase chain reaction (PCR) was performed using Accu-Power PCR premix (Bioneer, Daejeon, Korea). Each PCR product was sequenced using a 3130xl or 3730 genetic analyzer (Applied Biosystems, Foster City, CA). Sequences were aligned using the Sequencher 4.9 software (Gene Codes Corporation, Ann Arbor, MI).

Statistical analysis

Continuous variables were described as mean ± SD or median with ranges and categorical variables were expressed as numbers and percentages. Differences in characteristics of patients with or without colorectal cancer were calculated using *t*-tests for continuous variables and χ^2 tests or Fisher's exact tests for categorical variables. Survival curves were generated by the Kaplan-Meier method, and univariate survival distributions were compared with the use of the log-rank test.

All statistical analyses were carried out using SPSS version 20.0 (IBM Corp., Armonk, NY, United States) and R version 3.1.2 (The Comprehensive R Archive Network: http://cran.r-project.org). The level of significance was set at $P < 0.05$.

RESULTS

Characteristics of patients

The characteristics of the 135 patients are shown in Table 1. There was no significant difference in age at diagnosis between men and women ($P = 0.613$). The mean age of patients with cancer was significantly greater than that of patients without cancer ($P = 0.002$) and the mean age of the patients with cancer at an early stage (carcinoma *in situ* and carcinoma restricted to the submucosal layer), 32.7 years, was between the mean age of the patients with advanced cancer (38.7 years) and that of the patients without cancer. Thirty six of the 39 patients who had a family history of FAP also had a family history of colorectal cancer except three patients who only have a family history of FAP. The rates of familial history of FAP or CRC were significantly higher in patients without CRC than in patients with CRC. Only 12 of the 135 patients had been diagnosed with FAP prior to surgery and the median follow-up period was 5 years. TPC with end ileostomy was performed in patients with rectal cancer in 8 cases and total colectomy was performed in patients who presented a few rectal polyps (less than 5 and endoscopically removable) in 10 cases. There was no significant difference in operative procedure between patients with CRC and patients without CRC. Eighty-eight (65.2%) patients underwent a colonoscopy because of gastrointestinal

symptoms at the time of diagnosis and 47 patients (34.8%) underwent a colonoscopy because of positive stool occult blood test or health medical examination without specific symptom (Table 2).

Extra-colonic features in FAP

Extra-colonic manifestations are described in Table 2. Gastric polyps were found in 63 (46.7%) patients. The histological types of gastric polyps were fundic gland polyp in 57 patients (90.5%) and tubular adenoma biopsied from the antrum of the stomach in 16 patients (25.4%). Ten patients had both fundic gland polyps and tubular adenomas. Four cases of early gastric cancer were diagnosed and the median age was 41 (range, 34-51 years). Two of them were treated by endoscopic submucosal excision and two underwent distal gastrectomy. Among six patients with papillary thyroid cancer (PTC), two were diagnosed with PTC and underwent total thyroidectomy before receiving a diagnosis of FAP. Five patients (3.7%) underwent ampullectomy for polyps in the ampulla of vater in follow-up periods, and high-grade dysplasia was detected in one patient. Desmoid tumors were diagnosed at surgery in four patients and developed in 16 other cases during follow-up; the median age at diagnosis of desmoid tumors was 31 (range, 20-47 years). Desmoid tumors were mostly intra-abdominal in 19 cases, particularly mesenteric with one in the abdominal wall. The postoperative risk for desmoid tumors was not different between men and women (P = 0.625).

Colonic features and development of cancer

Clinicopathologic characteristics are shown in Table 3. The incidence of synchronous lesions and the rates of early colorectal cancer were relatively high. Odds ratio for having colon cancer at the time of FAP diagnosis for 40s and over 50s years were 4.75 (95%CI: 1.71-13.89) and 5.91 (95%CI: 1.76-22.12) when compared with under the age of 30 (Figure 1). Five cases of colorectal cancer were diagnosed in patients aged less than 20 years. Four of them had carcinoma *in situ* and one showed invasion to proper muscle of rectal wall without lymph node metastasis. Among 60 of *de novo* patients , who did not have a family history of colorectal cancer or FAP, 31 presented colorectal cancer

[1]*APC* mutation identified as novel mutations; [2]*APC* mutation located in MCR. CHRPE: Congenital retinal pigment epithelial hypertrophy; CRC: Colorectal cancer; PTC: Papillary thyroid cancer; DT: Desmoid tumor.

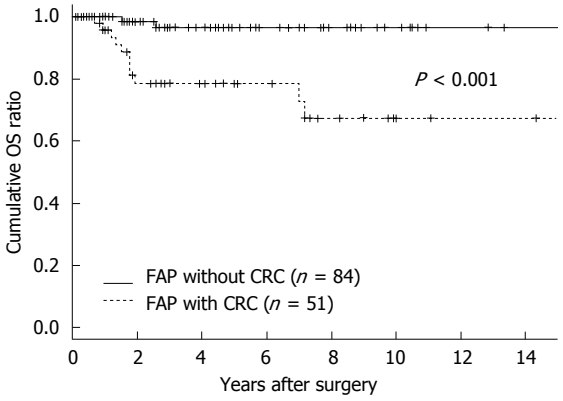

Figure 2 Overall survival of patients with familial adenomatous polyposis grouped by accompanying based on presence of colorectal cancer to none development of colorectal cancer. CRC: Colorectal cancer.

and it is significantly higher than that of patients with family history of FAP or CRC (51.7% *vs* 27.8%, P = 0.013), but there was no significant difference in mean age of development of CRC between the two groups (P = 0.265). Patients with gastrointestinal symptoms were more frequently diagnosed with cancer than patients without symptoms and the difference was statistically significant (P = 0.042). Cancer patients without symptoms at the time of diagnosis had a higher incidence of early stage cancer than those with symptoms at diagnosis (P = 0.041).

The patients who have remnant rectum after rectal excision (68.1%) presented a significantly higher incidence of adenomatous polyps in remnant rectal mucosa than other patients underwent TPC and mucosectomy (P < 0.001). Development of cancer on remnant rectal mucosa was not observed, but one patient who underwent TPC/IPAA with stapled anastomosis was diagnosed with villotubular adenoma with high-grade dysplasia and underwent trans-anal excision. There was no significant difference in the incidence of adenomatous polyps in pouch or ileum regardless of operative procedure (P = 0.465) and malignant change or dysplasia was not observed on any ileal adenomas.

Confirmed deaths were observed in 13 patients with a median age at death of 40 years (range, 27-85 years). Deaths from colorectal cancer accounted for 10 cases (76.9%). In these 10 patients, five cases had distant metastasis at the time of diagnosis. Comparison of postoperative survival between patients with colorectal cancer and patients without cancer is shown in Figure 2. In patients without CRC, only two deaths (15.4%) were observed in patients with desmoids tumor causing major complication and there was no death caused by desmoid tumors in the CRC group.

APC mutation test

The germ-line *APC* mutations that were detected in these patients are listed in Table 4 with clinical details.

Two of them was a sister relationship, so 29 unrelated patients were included. Testing revealed 23 pathogenic mutations and one likely pathogenic mutation. Five patients were negative for *APC* mutations. Of the 24 pathogenic or likely pathogenic mutations, frameshift, nonsense and splice-site mutations represented 54.2%, 33.3% and 12.5%, respectively. Sixteen of 24 mutations were localized within exon 15. Just one mutation in codon 1309 was located within the mutation cluster region (MCR, mutations from codon 1250 to 1464). The mutations on codons 1061, 1309 and 1465 were frequently observed in two cases, respectively. Four novel mutations were identified based on the Human Gene Mutation Database (www.hgmd.cf.ac.uk/ac): c.1378G>T, c.3709C>T, c.4519-4520insTGAGCTCA and c.1958+3A>T. A patient with a mutation on codon 461 (c.1378G>T) presented with a desmoid tumor and a upper gastrointerstinal (UGI) adenoma. A man with a novel mutation of codon 1507 (c.4519-4520insTGAGCTCA) was diagnosed with advanced synchronous colorectal cancer and had a family history of colorectal cancer; his father died of colon cancer with liver metastasis at 35 years of age. His older brother also died of colon cancer which was not indicated for surgery at 19 years of age. His younger brother was diagnosed with colon cancer and underwent surgery at age 19, but died of multiple liver metastases at 20 years of age. He presented with CHRPE, dental anomaly and adrenal adenoma.

DISCUSSION

While CRC is the inescapable fate of untreated FAP patients, few studies provide information on the age distribution at the time of diagnosis of CRC in FAP since most cases are diagnosed in a premalignant stage. In this study, CRC occurred in more than one-third of FAP patients. The prevalence of CRC in *de novo* patients was significantly higher than that of patients with a family history of FAP or CRC, but there was no significant difference in the mean age of development of CRC between the two groups. The mean age at diagnosis of FAP was significantly different between patients with CRC and those without CRC. In the present study, the prevalence of CRC in patients with a family history was more frequent than that of a previous study for call up patients who diagnosed FAP through family screening[6] since most patients underwent a colonoscopy after developing intestinal symptoms despite having a family history of CRC or FAP. This means that development of CRC in FAP patients depends more on the age at diagnosis than on family history and that we have the opportunity to reduce the frequency of CRC, especially in patients with a family history. We found that diagnosis of colorectal cancer exceeded 10% at the age of 26 and 50% at the age of 43 and that this age distribution was similar to that described in a previous Western report[7]. We also found that there were no cancer-specific deaths in early cancer cases (carcinoma *in situ* and cancer restricted to the submucosa). Even though some cases of CRC before 20 years of age were observed in this study, all were diagnosed earlier than stage Ⅰ and survived without recurrence. To improve survival, a reduction in the incidence of CRC at diagnosis should be achieved. These results suggest that a diagnosis of FAP should be obtained before the early twenties.

The standard prophylactic procedure for the majority of patients with FAP is TPC with IPAA. In selected patients, rectum-preserving surgery might be indicated. We performed TC with IRA in six patients who presented with a few rectal polyps. All of them developed adenomas on remnant rectal mucosa but did not develop any carcinomas. The cumulative risk of rectal cancer after IRA was reported to be about one-fourth of patients after 15-25 years despite surveillance[8]. Therefore continuing endoscopic surveillance is necessary for these patients. The incidence of developing adenomatous polyps after TPC in the anorectal transient zone was reported as 10%-15%[9]. There are several reports of adenomatous polyps and cancers arising from the ileal pouch mucosa as opposed to the anastomotic site[10]. We found nine cases of adenomatous polyps arising from the ileal pouch mucosa but did not observe cancer or dysplasia. Development of cancer on remnant rectal mucosa was also not observed, but one patient among 18 cases of adenomatous polyps arising from remnant mucosa was diagnosed with villotubular adenoma with high-grade dysplasia and underwent trans-anal excision. The incidence of tubular adenoma in remnant mucosa and ileal pouch increased over time, so periodical follow-up was necessary.

In the present study, gastric polyps were a common manifestation of FAP. The histological types of gastric polyps were mostly fundic gland polyps and secondary tubular adenomas biopsied from the antrum of the stomach. This is consistent with previous reports documenting that fundic gland polyps are the most common gastric polyps and that adenoma is the second most prevalent gastric lesion in individuals with FAP[11]. We observed that three patients had asymptomatic gastric carcinoma at their first gastroduodenal endoscopy while one developed carcinoma during the surveillance study 18 years after surgery and one developed TA with high-grade dysplasia (HGD) 10 years after surgery, which was treated with endoscopic submucosal dissection. All of these cancers and HGD developed in the antrum. The overall incidence of 3% for gastric carcinoma in this study is similar to the high prevalence of gastric cancer reported in previous study[12]. Nonetheless, the prevalence of gastric cancer in FAP was not reported to be higher than that in the general population in Western countries and the most common gastric cancer site in Western reports was the fundus of the stomach (fundic gland polyps)[11,13]. The high incidence

of gastric cancer and the different sites may indicate inter-ethnic differences in the presentation of FAP. In contrast to Western reports of a relatively high incidence of duodenal cancer, we did not observe any malignant neoplasms on the duodenum[14]; however, it is important to consider the possibility of malignancy on the duodenum, since duodenal adenomatous polyps occurred in one-third of patients and since one case of HGD was detected on the ampulla of vater in our study.

We found that desmoid tumor was the only cause of death associated with FAP except caused by CRC in this study. The incidence of 14.8% and location of intra-abdominal site, particularly small bowel mesentery, in the present study is consistent with previous studies[15]. In particular, mutation on codons 1445-1580 is associated with postoperative development of desmoid tumors and recommended to postpone elective colectomy[16], but this correlation does not always appear to be consistent. In our study, four of 20 desmoid tumors developed without any history of surgical trauma. Desmoid tumors unrelated to surgical trauma are a relatively poor prognostic factor[17]. In two of four synchronous desmoid tumors, the same *APC* mutation (codon 1465; c.4393-4394delAG), reported as a desmoid tumor-associated mutation[18], was detected in unrelated patients. The mutation at codon 1465 located in exon 15 may implicate progression, so patients having this mutation and desmoid tumors should be considered for permanent stoma at the time of primary surgery. Other mutations associated with desmoid tumors in our study were at codons 461 (c.1381G>T) and 1309 (c.3925-3928delGAAA). The incidence of desmoid tumors increased over time, so periodic follow-up is necessary.

Another feature of FAP is the variation in clinical course between patients, so prediction of the severity of the disease is important in the interest of effective cancer prevention. Correlation between mutation and the age at onset of intestinal symptoms and development of CRC was reported[19], but the manifestation may be variable even in patients with identical germ-line mutations. Tumors with mutations localized in exon 15 between codons 1250 and 1464 (mutation cluster region or MCR) have generally a worse prognosis with early onset of the disease and may be candidates for IPAA due to the high incidence of secondary protectomy after primary colectomy[19,20]. In the present study, two kinds of mutations at codon 1309 within the MCR were detected: c.3925-3928delGAAA and c.3927-3931delAAAGA. Deletion of 5 base pairs at codon 1309 (c.3927-3931delAAAGA), the most common mutation, was detected in a patient who presented with CRC at age 17. This finding corresponds with previous results showing that mutation at codon 1309 (c.3927-3931delAAAGA) is associated with early development of intestinal symptoms and death from colorectal cancer[19]. The incidence of this mutation was 4% in our study and 29% in a previous study[16] and its frequency varied. No other MCR mutation was observed in the present study (Table 4). These findings implicate the possibility of ethnic differences in *APC* mutations. We also observed one interesting novel mutation at codon 1507 within exon 15, c.4519-4520insTGAGCTCA, which was not located in the MCR but presented in a patient with early onset and poor prognosis of CRC. This information may help support surgical decisions of method and timing. In the present study, two-thirds of *APC* mutations were localized to exon 15. Two of the most common mutations were also identified in this study: at codon 1061 (c.3183-3187delACAAA) and codon 1465 (c.4393-4394delAG). Mutation at codon 1061 has not been reported in Korean patients even though it is one of the most frequently reported mutations.

Extracolic manifestations showed correlations with *APC* mutations. The expression of CHRPE is associated with a clearly distinct region of mutations located between codons 311 and 1445 of *APC*[20,21]. All mutations detected with CHPRE in this study were located on reported distinct region but one mutation was not located within this region (codon1507; c.4519-4520insTGAGCTCA). It is necessary to observe carefully the clinical manifestation of this novel mutation. PTC affects 1%-2% of patients with FAP. PTC is associated with a mutation located between codons 140 and 1309 of *APC*, and a strong association with CHRPE also exists[21]. In the present study, three mutations on codons 935, 1199 and 1309 were detected and all of them presented CHRPE, which is consistent with previous reports. The mutation detection rate in our study is consistent with previous reports[5]. None of the cases can be explained by large allelic deletions, promoter deletions, deep intronic base changes and chromothripsis in germline[22], reduced or absent expression from one allele of *APC* or bi-allelic germ-line mutation of *MYH*[23].

A major limitation of this study was the relatively small number of patients and the fact that the study was based on one medical center, so the result may not be generalizable. A multicenter or nationwide registry investigation is needed. Secondly, the retrospective nature of the study and use of medical records for data collection prevented knowledge about affected family members because of unclear medical records and low rates of hospital utilization in the previous two generations in Korea. A prospective cohort study using the FAP registry is required. Finally, the *APC* mutation test has been used only recently in suspected patients in the clinical setting since gene analysis only became available in 2008 at our institute. Mutation testing should be conducted in patients who do not know their family history of FAP to identify affected members.

In conclusion, we reported clinicopathologic features and prognosis of FAP in Korean patients. The

data suggest the necessity for early diagnosis and management of high-risk patients. *APC* mutations can inform on the severity of the disease and on prognosis and identify family members having the same mutation. The identification of *APC* gene mutations and the understanding of genotype-phenotype correlations should aid in the diagnosis and counseling of patients.

COMMENTS

Background

Familial adenomatous polyposis (FAP) have a risk of almost 100% of developing colorectal cancer by 40-50 years of age. Colorectal cancer is the most common cause of death in FAP patients and desmoid tumors are the second. A recent molecular genetic test for *APC* mutations makes it possible to detect asymptomatic or not developing polyposis patients. Studies on clinicopathological features of the disease and clinical availability of *APC* mutations testing were performed in order to improve the early detection and management. Diagnostic delay makes adequate management harder in patients with FAP. This study investigated prognostic factors and the correlation between APC mutations and clinical features.

Research frontiers

Diagnostic delay makes adequate management harder in patients with FAP. This study investigated prognostic factors and the correlation between *APC* mutations and clinical features.

Innovations and breakthroughs

The present study revealed that early diagnosis and management of high-risk patients is essential and suggests the necessary APC mutations testing in the diagnosis and counseling of patients by informing on disease prognosis.

Applications

The type of APC mutation was one indicator that could be used to evaluate the poor prognosis of patients with FAP. This finding suggested that APC mutation testing can inform on the severity of the disease and on prognosis and identify family members having the same mutation.

Terminology

APC gene located on chromosome 5q21-22 and found to be mutated in FAP patients. This gene encodes a tumor suppressor protein (APC protein, 2843 amino acids). APC protein acts as an antagonist of the Wnt signaling pathway and also play a role in process of cell migration and adhesion, transcriptional activation, and apoptosis.

Peer-review

It's a very nice and significant work. Congrats and thanks to authors for meaningful success. Congrats for authors for writing so much nice topic.

Abstract

AIM: To investigate efficacy and safety for granulocyte, monocyte apheresis in a population of pediatric patients with ulcerative colitis.

METHODS: The ADAPT study was a prospective, open-label, multicenter study in pediatric patients with moderate, active ulcerative colitis with pediatric ulcerative colitis activity index (PUCAI) of 35-64. Patients received one weekly apheresis with Adacolumn® granulocyte, monocyte/macrophage adsorptive (GMA) apheresis over 5 consecutive weeks, optionally followed by up to 3 additional apheresis treatments over 3 consecutive

weeks. The primary endpoint was the change in mean PUCAI between baseline and week 12; the secondary endpoint was improvement in PUCAI categorized as (Significant Improvement, PUCAI decrease of $\geqslant$ 35), Moderate Improvement (PUCAI decrease of 20 < 35), Small Improvement (PUCAI decrease of 10 < 20) or No change (PUCAI decrease of < 10).

RESULTS: Twenty-five patients (mean age 13.5 years; mean weight 47.7 kg) were enrolled. In the intention-to-treat set (ITT), the mean value for PUCAI improvement was 22.3 [95%CI: 12.9-31.6; *n* = 21]. In the per-protocol (PP) set, the mean improvement was 36.3 [95%CI: 31.4-41.1; *n* = 8]. Significant Improvement was recorded for 9 out of 20 patients (45%); 5 out of 20 patients (25%) had Moderate Improvement and one patient (5%) had No Change in PUCAI score at week 12. In the PP set, six out of eight patients (75%) showed Significant Improvement; and in two out of eight patients (25%) Moderate Improvement was recorded. The endoscopic activity index (EAI) decreased by 3 points on average. Seven (7) out of 21 (33%) patients in ITT and 4 out of 8 (50%) patients in PP have used steroids during the clinical investigation. The mean steroid dosage for these patients in the ITT set decreased from a mean 12.4 mg to 10 mg daily on average from Baseline to week 12.

CONCLUSION: Adacolumn® GMA apheresis treatment was effective in pediatric patients with moderate active Ulcerative Colitis. No new safety signals were reported. The present data contribute to considering GMA apheresis as a therapeutic option in pediatric patients having failed first line therapy.

Key words: Granulocyte-monocyte apheresis; Pediatric; Ulcerative colitis; Inflammatory bowel disease; Therapy; Steroids; Clinical trial

Core tip: For a considerable group of children with ulcerative colitis (UC), treatment options are limited especially after failure of conventional treatment. The ADAPT trial was designed to generate prospective cohort data on efficacy and safety levels in moderate active pediatric UC patients when treated with Adacolumn granulocyte, monocyte/macrophage adsorptive (GMA). The present data contribute to considering GMA apheresis as a therapeutic option in pediatric patients having failed first line therapy.

Efficacy and safety of granulocyte, monocyte/macrophage adsorptive in pediatric ulcerative colitis. *World J Gastroenterol* 2016; 22(17): 4389-4396 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4389.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4389

INTRODUCTION

Active ulcerative colitis is associated with extravasation of large numbers of activated granulocytes and monocytes into the colonic mucosa. This infiltration is promoted by potent pro-inflammatory cytokines such as tumor necrosis factor-α, interleukin-8, leukotriene B4 and platelet-activating factor. Activated leukocytes can cause extensive mucosal tissue injury through the release of degradative proteases, reactive oxygen derivatives and pro-inflammatory cytokines[1]. While pharmacologic approaches target the inflammatory messengers, an alternative option reducing the activated cells and also reducing the associated circulating cytokines implicated in the pathogenesis of ulcerative colitis (UC) is selective granulocyte, monocyte/macrophage adsorptive (GMA) adsorptive using Adacolumn®, a medical device (JIMRO Co. Ltd., Takasaki-shi, Gunma, Japan). The selective adsorption of predominantly old and activated CD10+ neutrophils to Adacolumn carrier beads is governed by opsonins C3b/C3bi, Fcγ receptors and the leukocyte complement receptors, while lymphocytes are spared[2]. Flow cytometry analyses during apheresis sessions have shown an initial drop in peripheral neutrophils and the emergence of naïve CD10 neutrophils from the bone marrow, which represents a qualitative change within the circulating neutrophil population[3].

To date published meta-analyses and systematic reviews favor Adacolumn® GMA over control therapy for inducing remission and response at 12 wk in adult moderate active adult UC[4-7].

Pediatric onset UC is more complex, extensive and severe compared to adult UC, and has a high rate of steroid dependency[8,9]. As for the data on Adacolumn use in children to date, there are limited small scale investigations and case reports which point to good response especially in the treatment of corticosteroid-dependent and corticosteroid-resistant pediatric UC patients, with good treatment tolerance, mild side-effects, and a comparable rate of relapses as seen with drug treatments[10].

MATERIALS AND METHODS

For a considerable group of children with UC, treatment options are limited especially after failure of conventional treatment. On the background of a retrospective on clinical results in children treated with GMA apheresis[11], the ADAPT trial was designed to generate prospective cohort data in order to report efficacy and safety levels in moderate active pediatric UC patients when treated with Adacolumn.

GMA procedures

Enrolled patients underwent apheresis treatment using the Adacolumn® GMA apheresis device (JIMRO, Japan; EU Authorized Representative: Otsuka Pharmaceuticals

Table 1 ADAPT trial key inclusion criteria

Children and adolescents < 18 yr and with a body weight ⩾ 30 kg
Ulcerative colitis documented by clinical symptoms, endoscopic findings and histology since at least 3 mo prior to inclusion
Moderate active ulcerative colitis at baseline, defined as a PUCAI score between 35 and 64
Pancolitis or left-sided colitis
Receiving or having received one or more of the following medicinal products before screening:
Sulfasalazine, mesalamine and other 5-aminosalicylic acid agents for 4 wk or more with a stable dose for the last 2 wk
0.5 mg/kg per body weight with a maximum of 20 mg per day of prednisone with a stable dose for the last 2 wk, or
6-mercaptopurine or azathioprine for 12 wk or more with a stable dose for the last 4 wk

PUCAI: Pediatric ulcerative colitis activity index.

Europe Ltd, UK), which is approved for clinical use in EU (CE-marked) and in Japan. Adacolumn is an adsorptive type, single-use column filled with cellulose acetate beads of 2 mm in diameter. The carriers adsorb leukocytes, mainly activated granulocytes and monocytes from peripheral venous blood, passing from one antecubital vein through the column at a flow rate of 30 mL/min and returned to the contralateral antecubital vein. One apheresis treatment usually lasted 60 min, during which a total of 1.8 L blood was exposed to the carriers[12]. In the present trial, all patients received one weekly Adacolumn® apheresis over 5 consecutive weeks. The investigator could decide to add up to three additional treatments in weekly intervals at his discretion.

Moderate improvement	⩾ 20
Small improvement	⩾ 10
No change	< 10

Trial design and efficacy assessment

This study used the PUCAI score[13] which encompasses abdominal pain, rectal bleeding, stool consistency, number of stools per 24 h, nocturnal stools and activity level; and the endoscopy activity index acc. to Rachmilewitz (EAI) comprising granulation, vascular pattern, vulnerability of mucosa and mucosal damage. Key inclusion criteria are listed in Table 1.

Steroid-resistance or -dependency, defined as inability to completely withdraw steroids without inducing a relapse or flare-up of the disease, was an exclusion criterion. The patients were not to have received a re-treatment of UC with drugs other than 5-ASA and derivatives, azathioprine and/or corticosteroids, *e.g.*, immunosuppressants and biologicals; or topical therapy for ulcerative colitis within the last 2 wk, or previous Adacolumn treatment.

At baseline, PUCAI was evaluated; flexible endoscopy (colonoscopy or sigmoidoscopy) for determination of EAI was performed, hematology and clinical chemistry tests were completed; vital signs, concomitant medication, and adverse events were recorded. During their treatment phase, patients were evaluated every week. Flexible endoscopy (colonoscopy or sigmoidoscopy) was performed at post screening unless there was one available from within 6 wk before and 5 d after screening. Endoscopy was optional at the evaluation visit in week 12 (Table 2).

The primary response variable was defined as the improvement in disease activity index (PUCAI) at week 12 (Visit 10) compared to Baseline (Visit 02). Key Secondary response variables were the proportion of significant improvement, moderate improvement, small improvement and no change as per PUCAI categories at week 12 (Table 3), the proportion of patients without disease activity (PUCAI < 10) at week 12, and the difference in EAI between week 12 and Baseline for those patients with pre- and post-treatment phase endoscopies available. Safety was assessed during the course of the clinical investigation by monitoring adverse events (AE), assessment of vital signs and collection of laboratory parameters.

Ethical considerations

This investigation was conducted in accordance with the Good Clinical Practice Guidelines according to CPMP/ICH/135/95, with the Declaration of Helsinki, ISO 14155:2003, and all relevant national guidelines. The Clinical Investigation Plan (CIP) was submitted

Table 4 Patient demography

to the structured Institutional Review Boards (ethics committees) of each investigational center and a positive vote was obtained prior to start of the enrolment, in accordance with local law. Hence, written informed consent was obtained from all patients and/or their legal guardians or representatives prior to participation in the clinical investigation.

Statistical analysis

Based on the assumption that the standard deviation of the primary response variable (change in PUCAI) is 20, we aimed at including a sample of 50 patients to ensure that the precision of the estimated mean change in PUCAI is ± 5 at $P > 0.95$. Where appropriate, data are presented as the average (mean ± SD) values. For efficacy response variables, 95% confidence intervals were provided. If the confidence interval was above 0 (*i.e.*, the lower limit of the confidence interval was greater than 0), then Improvement in PUCAI was considered as statistically significant. For efficacy analyses based on the ITT set, last observation carried forward (LOCF imputational method) was used in case of missing data. For all other analyses, no imputation was done. All statistical analyses were carried out using SAS® Version 9.2 under Windows® Server 2008. Statistical review of the study was performed by a biomedical statistician.

Datasets analyzed in this investigation were the Safety set, the intent-to-treat (ITT) and the per-protocol (PP) datasets. The Safety set included all enrolled patients, in whom at least one treatment was initiated. The primary efficacy endpoint was based on the ITT population, which was defined as all enrolled patients who received at least one treatment and for whom there was at least one valid post-baseline PUCAI measurement. The PP analysis set was defined as the subset of the ITT population who received the full course of assigned treatment and for whom there were valid efficacy values at week 12. All results are presented for the ITT population unless otherwise stated.

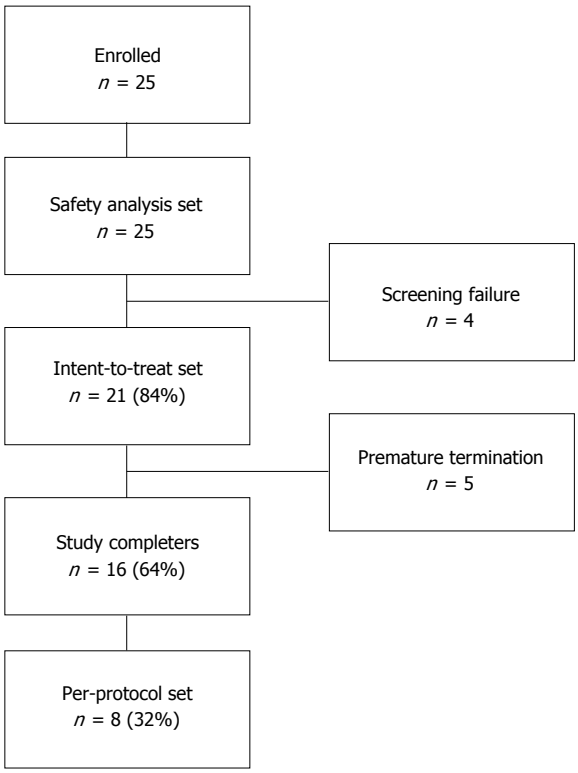

Figure 1 Patient disposition.

RESULTS

Patient demography

Twenty five children and adolescents with ulcerative colitis were enrolled (Figure 1, Table 4). All patients had at least one episode of active disease in the last 12 mo prior to enrollment in the clinical investigation.

Patient disposition

A total of 25 patients with moderate active UC (PUCAI score between 15 and 60) were screened and enrolled in the clinical investigation at 6 investigational centers. Twenty-five screened and enrolled patients entered the Safety Analysis set. There were four screening failures, one was due to detection of *Clostridium Difficile*, one was due to a diagnose change to Crohn's disease, and two patients with too low PUCAI scores were excluded from the trial. Twenty-one (84%) patients entered the ITT analysis set. Out of these, five patients prematurely terminated the clinical investigation due to adverse events (*n* = 2), intake of not permitted medication or physician's decision (*n* = 3). Sixteen patients (64%) completed the trial and 8 (32%) patients entered the Per-Protocol (PP) analysis set (Figure 1).

Concomitant medication

The most frequent used concomitant medication was Mesalazine, prescribed to 19 out of 25 patients (76%). Seven (7) of the 21 (33%) patients in ITT and 4 of the 8 (50%) patients in PP have used steroids during the clinical investigation. Fifteen out of 25 (60%) patients

PP	-2.8	2.5	-5.4-(-0.2)	6

ITT: Intention-to-treat; PP: Per-protocol.

have been prescribed immunosuppressants, 13 received Azathioprine, one patient Mercaptopurine and one patient Methotrexate.

Treatments administered

Nineteen out of 21 treated patients underwent at least 5 apheresis sessions, 17 patients received 6 treatments, 15 patients had 7 treatments, and 12 patients were treated with 8 Adacolumn aphereses.

Primary efficacy endpoint: The mean PUCAI improvement at week 12 was 22.3 (CI: 12.9-31.6) in the ITT population and 36.3 (CI 31.4-41.1) in PP analysis set (Table 5). Eight out of 15 patients (53%) in ITT and 4 out of 8 patients (50%) in PP were not on steroids. For these efficacy subsets, the PUCAI scores over time are depicted separately below (Figures 2 and 3).

Categorized PUCAI improvement: Defined as "significant improvement", "moderate improvement", "small improvement" and "no change" as per PUCAI categories at week 12 (Table 3), 70% of subjects had Significant improvement or moderate improvement; whereas a cumulated 30% of the patients experienced small improvement or no change comparing Visit 10 (week 12) *vs* baseline (Table 6).

EAI: At entry, the median EAI score was 7.5. Ten patients in the ITT dataset and six patients in the PP dataset had both endoscopies, at entry and at week 12. Calculated as per the available data, the mean change in EAI score was -3.0 for the ITT and -2.8 for the PP analysis set. Upper confidence intervals for both analysis sets were below zero (-1.2 for ITT and -0.2 for PP), indicating that EAI meaningfully decreased at week 12 compared to the screening visit (Table 7).

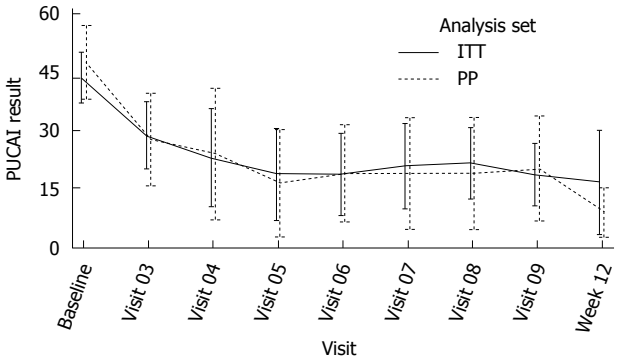

Figure 2 Pediatric ulcerative colitis activity index results over time by analysis set - Patients who received steroids.

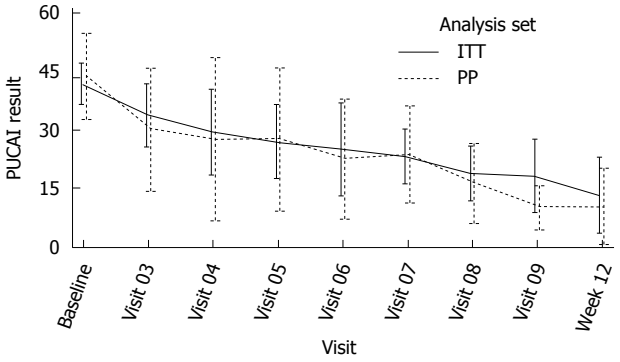

Figure 3 Pediatric ulcerative colitis activity index results over time by analysis set - Patients who did not receive steroids.

Disease activity: At Visit 03, Ulcerative Colitis disease activity of all patients (100%) was classified as "active". At week 12, 70% of the ITT and 50% of the PP analysis group were classified as active, reflecting a decrease in disease activity of 30% and 50% respectively.

High sensitive C - reactive protein (hsCRP): The mean change in hsCRP at Visit 10 was 0.6 for the ITT and -2.5 for the PP analysis set. The changes in hsCRP - levels were not significantly different between a specific visit and baseline visit in any direction. Similarly, no significant change was observed in hsCRP between baseline and the end of the follow-up phase in both ITT and PP analysis sets (mean changes were 0.9 and 0.5 mg/L respectively).

Further secondary endpoints: Seven (7) of the 21 (33%) patients in ITT and 4 of the 8 (50%) patients in PP have used steroids during the clinical investigation. The mean steroid dosage for steroid users in the ITT set from Baseline to Termination visit significantly decreased by 10.0 mg ($P < 0.04$)

Table 8 Adverse events, *n*

Relation	Severity	AEs; patients (safety set)
None	Mild	35; 12 (48%)
	Moderate	7; 4 (16%)
	Severe	0; 0 (0%)
	Total	42; 13 (52%)
Possibly or definitely related	Mild	15; 6 (24%)
	Moderate	6; 5 (20%)
	Severe	0; 0 (0%)
	Total	21; 8 (32%)

Clinical chemistry and hsCRP levels did not show any significant differences. Hematology, physical examination and vital signs did also not show any clinically significant changes throughout the clinical investigation.

Treatment safety and feasibility: During this clinical trial, up to week 12, no serious adverse event (SAE) occurred. Twenty one possibly or definitely related Adverse Events (AEs) were reported in 8 out of 25 (32%) patients, none of which was severe, 6 AEs were moderate, and 15 AEs were mild. Forty two unrelated AEs were furthermore recorded in 12 out of 25 (48%) patients. Unrelated mild transient headache, recorded for 6 patients, and procedural headache, recorded in 5 patients were the most prominent adverse events (Table 8).

Despite the additional challenges of venous access in pediatric patients, no more than 3 patients per visit experienced blood access problems, perfusions were stopped in no more than 4 patients per visit, and the flow rate was adjusted in no more than 4 patients per visit.

DISCUSSION

Therapeutic options in inflammatory bowel disease (IBD) continue to evolve. The Joint ECCO and ESPGHAN Evidence-based Consensus Guidelines aimed to develop guidelines for managing UC in children based on a systematic review (SR) of the literature and a robust consensus process of an international working group of specialists, also considering series on Adacolumn[10,11,14,15]. The overall number of pediatric UC patients in the literature is nevertheless still low and results confirm a persistent unmet medical need[16-19].

Infliximab is currently the only anti-TNFα approved in EU for pediatric UC patients for reducing signs and symptoms and inducing and maintaining clinical remission in moderately to severely active disease with a prior inadequate response to "conventional" therapy. In an overall pediatric UC cohort of 31 patients, the ratio of primary non-response to IFX was reported as 29% (9 out of 31 patients), and further 29% discontinued IFX after a median duration of treatment of 12.7 mo[17]. Data also lack for maintenance schemes with immunosuppressants alone or in combination with anti-TNFα[19].

The ADAPT trial endpoints and outcome parameters are in line with the recommendations published in the practical statement paper of the pediatric ECCO committee[8]. A limitation of our study is the low number of patients enrolled (n = 25): When designing the trial, the Standard Deviation estimate of the Primary Endpoint (mean change in PUCAI) was 20 points; hence a sample size of 50 subjects would have ensured that the precision of the estimated mean change in PUCAI is ± 5 (P > 0.95). ADAPT inclusion and exclusion criteria defined eligible patients to be on the one hand not treatment-naïve, and had on the other hand not (yet) steroid-resistant or steroid-dependent. Practically, this allowed only cases with ongoing steroid medication but not yet at the edge of treatment escalation or surgery. While this profile is not uncommon in adult UC, it turned out to be difficult to enroll pediatric patients, as there were fewer such patients than originally assumed, and their therapy is faster escalated nowadays.

Comparing the Safety to published results in pediatric and adult UC patients, there are two meta-analyses[4,5] and one systematic review[6]. The results all favor GMA apheresis over control therapy at week 12. Other groups (Tanaka *et al*[15]) communicated results from a series of 17 steroid-naïve consecutive pediatric UC patients over 5 years from a single center in Japan, having received Adacolumn treatment as monotherapy or in combination with low dose prednisolone after failure of first-line medication (sulphasalazine or mesalazine dosed at 2-4 g per day), and with a short duration of disease (median 6.5 mo). The group had used the adult CAI score. With 12 out of 17 patients responding to Adacolumn monotherapy in the Tanaka cohort, this reminds to some extent the subgroup of patients not having received steroids from our trial, and points to the favorable use of Adacolumn early in the course of the disease. The safety signals were transient mild headache in 8 patients, nausea and lightheadedness in 6 patients (35.3%), vomiting in 4 patients (23.5%). This compares quite well to the present ADAPT safety results; both as per profile and per occurrence rate. Looking to retrospective adult UC data as described in a large post-marketing surveillance study on GMA apheresis in 656 adult UC patients an overall positive outcome (remission or clinical response) was achieved in 77.3% of patients. The proportion of adverse effects in the adult population was only 2.3% (all mild and not requiring premature interruption of the procedure)[20].

The most common adverse event with Adacolumn GMA apheresis is headache, which is possibly due to transitory blood volume shifts while on extracorporeal circulation amounting to ca. 210 mL blood. The higher rate of transitory AEs like headache in the pediatric samples could hence be due to relatively

higher volume shifts and proportion of blood out in the extracorporeal system in pediatric patients, given their lower overall blood volume. On this background, it appears that the overall occurrence rate of adverse events is numerically less important in adult than in the pediatric patients of our cohort, but equal in nature and as mild and transient.

As for all induction treatments, transition to maintenance treatment and related compliance are a topic. Loss of response with or without antibody development seem to occur at least as often in pediatric patients as in adults, which is not the case with GMA maintenance schemes as published so far for adult UC patients: On-demand treatment with Adacolumn led to recurring remission, trend wise lasting longer than the prior remission phases[21].

Hematology and clinical chemistry tests did not show any treatment-related clinically significant changes throughout this clinical investigation, although the Adacolumn carriers deplete predominantly activated granulocytes and monocytes from the blood. The levels of these cells in the peripheral circulation are known to not be significantly lower after an apheresis session, which is due to a reactive influx of CD10 negative neutrophils from the bone marrow into the circulation ("pooling") within the first 20 min into an apheresis session[22].

Within the confidence interval boundaries calculated for the ADAPT trial at 25 patients, the outcomes in efficacy and safety levels at week 12 allow the assumption that Adacolumn treatment in a pediatric UC population yields comparable profiles of efficacy and safety as documented to date in adult UC treatment looking back on a decade of clinical experience.

In conclusion, GMA apheresis with Adacolumn® was safe and effective in pediatric patients with moderate active Ulcerative Colitis. The present data contribute to considering GMA apheresis as a therapeutic option in pediatric patients having failed first line therapy.

ACKNOWLEDGMENTS

Obituary: Sadly, Dr. Lena Grahnquist, Stockholm, passed away in January 2015 after long sickness. With the clinician's sharp eye, the researcher's intellect and her compassionate approach Lena Grahnquist combined the very best of what Pediatrics is about. We have lost a great person and colleague.

COMMENTS

Background

For a considerable group of children with ulcerative colitis (UC), treatment options are limited especially after failure of conventional treatment. The ADAPT trial was designed to generate prospective cohort data on efficacy and safety levels in moderate active pediatric UC patients when treated with Adacolumn granulocyte, monocyte/macrophage adsorptive (GMA) apheresis.

Research frontiers

Few therapeutic concepts in inflammatory bowel disease have a registered pediatric indication, and conducting clinical trials in children is particularly challenging.

Innovations and breakthroughs

The investigators report that the outcomes in efficacy and safety levels at week 12 allow the assumption that Adacolumn treatment in a pediatric UC population yields comparable profiles of efficacy and safety as documented to date in adult UC treatment looking back on a decade of clinical experience.

Applications

The present data contribute to considering GMA apheresis as a therapeutic option in pediatric patients having failed first line therapy.

Terminology

GMA apheresis is an extracorporeal, veno venous apheresis which selectively depletes neutrophils (granulocytes, monocytes) to adsorptive carriers in a single-use, sterile column. Adsorption to the carriers is governed by C3b/C3bi, FcgRs and the leukocyte complement receptors.

Peer-review

The authors aimed to investigate efficacy and safety of GMA prospectively in a population of pediatric patients with UC. In this study, significant improvement was detected in half of the patients who were treated. In adult patients with UC, surgery or anti TNF treatment might be considered. The present study suggests that Adacolumn treatment may be a useful option for pediatric patients in whom first line therapy has failed. Considering that GMA apheresis was well tolerated, this study provides useful new information.

Abstract

AIM: To evaluate the association between serum concentrations of S100β in patients with cirrhosis and the presence of low grade hepatic encephalopathy (HE).

METHODS: This was a cross-sectional study. The population was categorized into four groups healthy subjects, cirrhosis without HE, cirrhosis with covert hepatic encephalopathy (CHE) and cirrhosis with overt HE. Kruskal-Wallis, Mann Whitney's *U* with Bonferroni adjustment Spearman correlations and area under the ROC were used as appropriate.

RESULTS: A total of 61 subjects were included, 46 cirrhotic patients and 15 healthy volunteers. S100β values were different among all groups, and differences remained significant between groups 1 and 2 ($P < 0.001$), and also between groups 2 and 3 ($P = 0.016$), but not between groups 3 and 4. In cirrhotic patients with HE S100β was higher than in

patients without HE [0.18 (0.14-0.28) ng/mL *vs* 0.11 (0.06-0.14) ng/mL, $P < 0.001$]. There was a close correlation between serum concentrations of S100β and psychometric hepatic encephalopathy score in patients with cirrhosis without HE compared to the patients with cirrhosis with CHE ($r = -0.413$, $P = 0.019$). ROC curve analysis yielded > 0.13 ng/mL as the best cutoff value of S100β for the diagnosis of HE (sensitivity 83.3%, specificity 63.6%).

CONCLUSION: Serum concentrations of S100β are higher in patients with cirrhosis than in healthy volunteers, and are further increased in the presence of hepatic encephalopathy. The results suggest that serum biomarkers such as S100β could help in the correct characterization of incipient stages of HE.

Key words: Hepatic encephalopathy; S100β protein; Astrocyte; Psychometric hepatic encephalopathy score; Critical flicker frequency

Core tip: Hepatic encephalopathy is a complication present in 30%-80% of the patients with cirrhosis and it is associated with increased mortality, adverse clinical outcomes, and poor quality of life. An increased concern about early recognition of this complication has risen in recent years; however, no biochemical marker is available to date. In this paper we evaluated the performance of S100β as a biochemical marker to identify the early stages of HE, and its correlation with neuropsychometric tests.

Clinical scenarios for the use of S100β as a marker of hepatic encephalopathy. *World J Gastroenterol* 2016; 22(17): 4397-4402 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4397.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4397

INTRODUCTION

Hepatic encephalopathy (HE) reflects a spectrum of neuropsychiatric abnormalities seen in patients with liver dysfunction after exclusion of other brain diseases[1,2]. Covert hepatic encephalopathy (CHE) is the initial stage in the clinical spectrum of HE and involves subtle changes in cognitive and motor function, and electroencephalographic patterns. In contrast to patients with symptomatic HE, patients with CHE have no recognizable clinical symptoms of brain dysfunction and need to be diagnosed on the basis of neuropsychologic tests[3]. The prevalence of CHE in cirrhotics with good liver function (Child A) is 15%, while in those with advanced cirrhosis (Child B/C) it approaches 50%[4-6]. Multiple pathways are involved in the pathophysiology of HE, however, hyperammonemia plays a central role. Astroglial swelling in HE occurs if the load of glutamine accumulating during ammonia detoxification is not compensated by a decrease in other osmolytes like myo-inositol[7]. This is followed by development of low-grade cerebral edema, which is accompanied by an increased production of reactive oxygen and nitrogen species, triggering multiple protein and RNA modifications, thereby affecting brain function[8]. Associated abnormalities in the homeostasis of cerebral neurotransmitters and blood-brain barrier (BBB) disruption have not been well characterized yet. Different molecules have been addressed as markers of brain injury, some of them being linked to astrocyte damage, but to date there is no useful serologic marker that can aid the diagnosis of HE or CHE.

S100β is a 10.4 kDa protein that is primarily synthesized in the brain by the endfeet processes of the astrocytes, and it belongs to a superfamily of low molecular weight acidic calcium binding proteins of the EF-hand type[9]. This protein is primarily metabolized in the kidney and excreted in the urine, its expression across ethnic groups seems to be consistent, differences between genders are not found, and it does not seem to show circadian variation[10]. Although S100β is not entirely specific for the central nervous system (CNS), it is present in the brain at much higher concentrations than in other tissues (80%-90% of the total pool is found within the brain), and as such, this protein can be used as an early marker of brain damage[9].

Astrocytes are key in homeostasis regulation in the CNS, being activated after brain injury and releasing S100β[11]. Some studies have shown increased levels of S100β in patients with acute or chronic liver failure and HE which might reflect an early stage of intracerebral changes before the development of marked cerebral edema[12,13]. Moreover it has been proposed that increased serum concentrations of S100β could predict CHE[14]. However, evidence associating S100β levels and the presence of HE is scarce. The aim of this study was to evaluate the association between serum concentrations of S100β and the presence of low-grade HE in patients with cirrhosis.

MATERIALS AND METHODS

Patients

This was a cross-sectional analytic study. Healthy volunteers and ambulatory patients with cirrhosis were invited to participate. Cirrhosis was confirmed on the basis of liver biopsy, or presence of biochemical, ultrasonographic, and/or endoscopic features of portal hypertension and liver dysfunction. High-grade HE, use of psychoactive drugs, alcohol during the 3 mo prior to the start of the study, presence of renal failure, respiratory or central nervous system (CNS) disease, cardiac failure, or severe malnutrition

Table 1 Demographic characteristics of the study population

	Healthy subjects	C + non-HE	C + CHE	C + HE
n	**15**	**22**	**10**	**14**
Gender (M/F)	(8/7)	(11/11)	(6/4)	(9/5)
Age	51.5 (46-64.5)	53 (45-60)	65.5 (59-71.5)	66 (57-71)
Years of education	14 (6-19)	12 (6-16)	6 (4-9.7)	9 (6-16)
Main etiology (%)	--	HCV (34%)	HCV (40%)	HCV (66%)
MELD score	--	9.5 (8.5-11.5)	10 (7.7-15.2)	11.5 (10-17.5)
Child-Pugh (points)	--	7 (6-8)	7.5 (6-9)	10 (8-12)
Serum sodium	--	136 (129-143)	135 (126-139)	138 (122-141)
Ammonia	--	179 (113.5-224)	217 (194-250)	134 (95-277)
Total bilirubin	--	1.81 (1.11-2.48)	1.50 (1.26-2.58)	2.81 (2.09-5.94)
ALT	--	34 (28-55.2)	31 (24.5-95.5)	42.5 (32.2-65.5)

Albumin	--	2.9 (2.6-3.3)	2.9 (2.6-3.2)	2.2 (2.0-2.7)
Alkaline phosphatase	--	141.5 (89.7-211)	140 (85-184)	154 (100.5-80.5)
INR	--	1.1 (1.1-1.2)	1 (0.9-1.2)	1.2 (1.1-1.7)
Creatinine	--	0.82 ± 0.19	1.11 ± 0.38	0.92 ± 0.31

Data presented as absolute frequencies, median (IQR) and mean ± SD. C: Cirrhosis; CHE: Covert hepatic encephalopathy; HE: Overt hepatic encephalopathy.

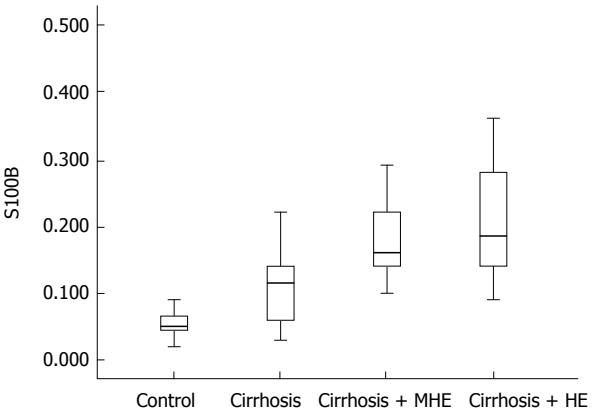

Figure 1 Serum concentrations of S100β (ng/mL) among groups. (1) Healthy subjects [0.05 (0.04-0.07)]; (2) Cirrhosis without HE [0.11 (0.06-0.14)]; (3) Cirrhosis with covert HE [0.16 (0.13-0.23)]; (4) Cirrhosis with overt HE [0.18 (0.14-0.28)]. Group 1 *vs* group 2, $P < 0.001$; Group 2 *vs* group 3, $P < 0.016$; Group 3 *vs* 4, $P = 0.508$. Healthy subjects *vs* all groups [0.14 (0.098-0.198)], $P < 0.001$.

were all considered exclusion criteria. History and physical examination, as well as psychometric hepatic encephalopathy score (PHES) test, and critical flicker frequency (CFF) analysis (Hepatonorm Analyzer; R&R Medi-Business Freiburg GMBH, Freiburg, Germany) were performed in all patients. Healthy volunteers did not show any neurologic abnormality on exam.

Methods

Overt HE was diagnosed on clinical grounds and classified according to West Haven criteria (all grade Ⅰ or Ⅱ). Covert HE (CHE)was identified in patients without overt manifestations of HE, when a PHES score was more than 4 SD below the Mexican population norms[15]. Using above criteria, 4 groups were formed: (1) healthy subjects; (2) cirrhosis without HE; (3) cirrhosis with CHE; and (4) cirrhosis with overt HE. Blood samples were drawn after an 8-h fasting period, and plasma collected and stored at -70 ℃ for further determination. S100β was measured using a human S100β enzyme-linked immunoassay (ELISA) according to manufacturer's instructions (BioVendor, Candler, United States). All tests were run in duplicate.

Statistical analysis

All results HE are expressed in medians and inter-quartile range, except for PHES, for which we used maximum and minimum values. The Kruskal-Wallis test was used to compare differences between groups for each of the variables of interest, while the *U* of Mann-Whitney with Bonferroni adjustment ($\alpha/\kappa = 0.016$) was used to evaluate differences between pairs of groups. Spearman test was used for bivariate correlations. ROC curve analysis was used to obtain a cutoff value for S100β. A P value < 0.05 was considered significant. SPSS version 21.0 was used for statistical analysis (IBM, Armonk, NY).

RESULTS

A total of 61 subjects were included, 46 cirrhotic patients and 15 healthy volunteers. The main characteristics of the population are shown in Table 1. Median age was higher in cirrhotics compared to the healthy subjects, most patients were males. The main etiology of cirrhosis was HCV and there was a stepwise increase in Child-Pugh and MELD score according to the presence and severity of HE.

The distribution of S100β serum values according from each group is shown in Figure 1. S100β values were different among all groups, and differences remained significant between groups 1 and 2 ($P < 0.001$), and also between groups 2 and 3 ($P = 0.016$),

Table 2 Psychometric evaluation

	Healthy subjects	C + non-HE	C + CHE	C + HE	*P* value
CFF	45.0 (43.0-48.6)	39.9 (39.2-41.4)	36 (33-39)	36 (35-40)	0.000
PHES	0 (-2 to 1)	-2 (-3 to -1)	-9 (-13 to -5)	-9.5 (-12 to –3)	0.000
Digit symbol	33.8 ± 18.3	28.91 ± 9.06	18.9 ± 8.8	13.4 ± 7.8	0.000
Number connection A	43.6 ± 21.1	49.5 ± 19.4	102.8 ± 66.5	148.8 ± 85.7	0.000
Number connection B	112.9 ± 39.1	147.2 ± 82.8	318.5 ± 153.03	435.7 ± 209.9	0.000
Serial dotting	62.3 ± 22.6	77.43 ± 18.1	127 ± 46.9	147.6 ± 64.3	0.000
Line tracing	95.2 ± 27.45	95.6 ± 28.6	193.8 ± 93.5	167.5 ± 37.8	0.000

Data presented as absolute frequencies, median (IQR) and mean ± SD. C: Cirrhosis; CHE: Covert hepatic encephalopathy; HE: Overt hepatic encephalopathy.

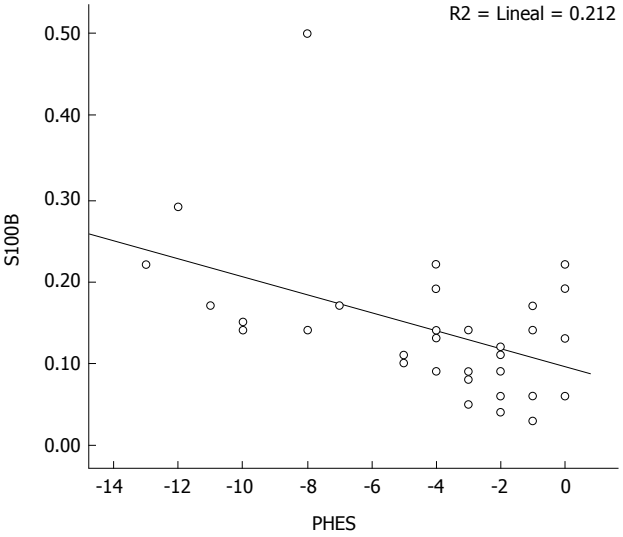

Figure 2 S100β and PHES correlations between patients with cirrhosis and covert HE and non-covert HE. *r* = -0.413, *P* = 0.019. HE: Hepatic encephalopathy; PHES: Psychometric hepatic encephalopathy score.

but not between groups 3 and 4. In cirrhotic patients with HE S100β was higher than in patients without HE [0.18 (0.14-0.28) ng/mL *vs* 0.11 (0.06-0.14) ng/mL, *P* < 0.001].

The results of the HE psychometric evaluation can be observed in Table 2. There was a clear deterioration in the performance of the CFF and PHES tests in the group with cirrhosis and cirrhosis with CHE or HE, as well as worsening in the individual PHES tests with a statistically significant difference.

In the total population, S100β was found to have a moderate correlation both with PHES (rho = -0.624, *P* < 0.001) and CFF (rho = -0.516, *P* < 0.001). In the subgroup of patients with cirrhosis, S100β showed moderate correlations with PHES (rho = -0.528, *P* < 0.001), as well as with CTP score (rho = -0.515, *P* < 0.001), and MELD score (rho = -0.440, *P* < 0.001), but not with CFF (rho = 0.240, *P* = 0.108) (Figure 2).

ROC curve analysis yielded > 0.13 ng/mL as the best cutoff value of S100β for the diagnosis of CHE and HE, with sensitivity of 83.3% and specificity of 63.6%. Area under the ROC curve (AUROC) was 0.801 (*P* < 0.0001).

DISCUSSION

HE and CHE are associated with decreased quality of life, impaired working performance, and patients become unfit to safely drive motor vehicles[16-21]. Cirrhotic patients with CHE are prone to develop episodes of overt HE when compared to those without CHE (incidence of 56% for those with CHE *vs* 8% for those without CHE at 3 years of follow up)[22]. Moreover, CHE is associated with a decreased survival, and thus it might be considered within the spectrum of complications definying advanced liver failure[23]. It is not known whether treatment of CHE may prevent overt HE or improve survival, but it is tempting to hypothesize that early identification of CHE followed by proper treatment should translate into improved quality of life, and have a favorable impact in prognosis. Psychometric tests are the preferred tool to diagnose CHE, and, since the final PHES score is adjusted to age and years of education, the differences of these two variables in our population did not have an impact in the results of our study.

S100β is not entirely specific for the CNS, but it is present in the brain at much higher concentrations than other tissues (80%-90% of the total pool is found within the brain), and as such, this protein can be used as a marker of brain damage[9]. Other places where S100β synthesis has been identified are adipose tissue[24], skin and melanoma tumors[25,26] and T-lymphocytes[27]. S100β protein is secreted by activated astrocytes and the mechanism of secretion remains unknown but astrocyte expression has been reported to be stimulated by interleukin-1 (IL-1) and by cyclic-AMP. The effects of secreted glial S100β depends on its concentration, being neurotrophic at low levels (nanomolar) and neurotoxic at high levels (micromolar)[9]. Nanomolar levels of S100β exert a stimulatory effect on astrocytes, causing glial proliferation *in vitro*[28]. S100β also accumulates in the extracellular space after astrocyte death or after cellular disintegration of the damaged parenchyma. Under these conditions, the S100β concentration may well be in the micromolar range and the protein may become toxic. This has originated the hypothesis that extracellular accumulation of S100β in ongoing brain

insults can, in combination with other unknown factors, cause a shift in its neuronal attributes from protective to hazardous[9].

We found significant differences in the serum concentrations of S100β between healthy volunteers and patients with cirrhosis. Moreover, in patients with cirrhosis, the levels of S100β increase in the presence of CHE and overt HE. The correlation between S100β and PHES indicates that at lower PHES scores, indicating a higher degree of HE, there is an increased concentration of S100β in serum. This suggests increased permeability of the BBB as the cognitive deterioration of HE progresses, what would determine not only leaking of S100β into the blood circulation, but increased ammonia delivery to the brain, leading to astrocyte activation and swelling. All of these changes (astrocyte activation and swelling, increased BBB permeability) seem to be present in patients with cirrhosis, and, moreover, seem to be more notorious in the presence of CHE and HE. However, our results would suggest that even in the absence of overt HE and CHE, the cirrhotic patient is at a state of astrocyte activation and swelling, and has increased BBB permeability. Brain adaptation to ammonia insults during early stages of cirrhosis and portal hypertension might consitute the counteracting condition preventing CHE or overt HE[29-31]. Our understanding of the cellular mechanisms leading to astrocyte dysfunction and neurotoxicity is limited, and it is unclear whether BBB disruption is crucial in the etiopathogenesis of HE, or an inevitable consequence of the disease itself. More studies are needed to better understand the role of S100β in the origin and perpetuation of HE in cirrhotic patients.

When we compared the cirrhotic patients without HE and CHE we found that S100β could differentiate both groups of patients with a fair accuracy, as shown by an AUROC curve of 0.801. Moreover, S100β correlated with the neuropsychometric tests (PHES and CFF), and with the hepatic functional status (MELD and CTP), attesting for its possible role in the evaluation of HE. Our results suggest that S100β can be useful in the diagnosis of HE, precisely in clinical scenarios where the diagnosis of HE remains unclear because behavior changes being subtle, evaluation of highly-educated patients, or when other psychiatric abnormalities (*i.e.*, depression) coexist or cannot be ruled out.

In conclusion, serum concentrations of S100β are higher in patients with cirrhosis when compared to healthy volunteers, and are further increased in the presence of CHE and overt HE. The results suggest the presence of astrocyte dysfunction, and maybe BBB disruption too, in patients with cirrhosis that seems to be more severe and progressive in the presence of HE. S100β showed significant differences between patients with cirrhosis but no encephalopathy at all, and the subgroup presenting with CHE, suggesting its usefulness to identify CHE. Although the AUROC curve was modest, S100β would potentially be useful in the diagnosis of low-grade HE whenever neuropsychometric tests are suboptimal, or when competing psychiatric differential diagnoses are in place.

The authors would like to thank Dr. Mick Frissen for IT support and Dr. Norberto Chavez Tapia for his assistance in the initial conceptualization of this project.

COMMENTS

Background

Hepatic encephalopathy (HE) is a frequent complication of cirrhosis, present in 30%-80% of patients. Covert HE has a profound impact in the quality of life of these patients, especially in daily functioning and driving ability, and it affects the sense of well-being. Thus, covert HE is very relevant to patients who suffer from it.

Research frontiers

The diagnosis and characterization of HE, especially in its low-grade forms, is difficult and requires specialized tests. Serum levels of ammonia were initially considered as a suitable marker of HE; however, they do not correlate with the degree of HE. Therefore, different serum markers for the diagnosis of HE, and particularly covert HE, are urgently needed.

Innovations and breakthroughs

Little attention has been paid to the use of biochemical markers as a means to detect early stages of HE. The data presented in the current study, indicate that S100β - a molecule released after astrocyte damage - might be a potential marker for covert HE in patients with cirrhosis. Interestingly, the association between high levels of S100β and presence of HE, as well as with the psychometric hepatic encephalopathy score, points towards a novel finding in the field.

Applications

The determination of S100β levels in serum, together with the standard clinical and psychometric evaluations, might help clinicians to establish the diagnosis of covert HE and therefore a timely treatment for these patients.

Terminology

S100β is a protein that is primarily synthesized in the brain by the processes of the astrocytes. Although S100β is not entirely specific to the central nervous system, it is present in the brain at much higher concentrations than in other tissues (80%-90% of the total pool is found within the brain), and as such, this protein could be used as an early marker of damage.

Peer-review

This manuscript mainly describes the association between serum concentrations of S100β and the presence of low-grade HE in patients with liver cirrhosis. The results suggest that S100β might help in the correct characterization of early stages of HE. The content is interesting and meaningful.

Abstract

AIM: To determine the efficacy of Mac-2 binding protein (Mac-2bp) for diagnosis of chronic pancreatitis.

METHODS: Fifty-nine healthy volunteers (HV), 162 patients with chronic pancreatitis (CP), and 94 patients with pancreatic ductal adenocarcinoma (PDAC) were enrolled in this study. We measured serum Mac-2bp using our developed enzyme-linked immunosorbent assay kit. Additional biochemical variables were measured using an automated analyzer (including aminotransferase, alanine aminotransferase, γ-glutamyltransferase, alkaline phosphatase, triglyceride, C-reactive protein, and amylase levels) or chemiluminescent enzyme immunoassay (carbohydrate antigen 19-9 and carcinoembryonic antigen). The ability of Mac-2bp to predict CP diagnosis accurately was assessed using receiver operating characteristic (ROC) analyses.

RESULTS: Serum Mac-2bp levels were significantly increased in CP patients compared to HV ($P < 0.0001$) and PDAC patients ($P < 0.0001$). Area under the ROC curve values of Mac-2bp for the discrimination of CP from HV and PDAC were 0.727 and 0.784, respectively. Multivariate analyses demonstrated that serum Mac-2bp levels were independent determinants for CP diagnosis from HV and PDAC patients. Immunohistological staining showed that Mac-2bp was expressed faintly in the pancreas tissues of both CP and PDAC patients. Serum aspartate aminotransferase, alanine aminotransferase, γ-glutamyltransferase, alkaline phosphatase, and triglyceride levels were significantly higher in patients with CP or PDAC. Serum Mac-2bp levels were highly correlated with protein levels of alanine aminotransferase, γ-glutamyltransferase, and C-reactive protein, but not amylase, suggesting that the damaged liver produces Mac-2bp.

CONCLUSION: Measurement of serum Mac-2bp may be a novel and useful biomarker for CP diagnosis as well as liver fibrosis in the general population.

Key words: Pancreatic ductal adenocarcinoma; Chronic pancreatitis; Biomarker; Steatopancreatitis; Mac-2 binding protein (LGALS3BP)

Core tip: Serum Mac-2 binding protein (Mac-2bp) levels were significantly increased in chronic pancreatitis patients compared to healthy volunteers and pancreatic ductal adenocarcinoma patients. Therefore, measurement of serum Mac-2bp is a novel method for diagnosing chronic pancreatitis.

Serum Mac-2 binding protein is a novel biomarker for chronic pancreatitis. *World J Gastroenterol* 2016; 22(17): 4403-4410 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4403.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4403

INTRODUCTION

Chronic pancreatitis (CP) is characterized by progressive destruction of the pancreas tissue and recurrent episodes of intractable abdominal pain accompanied by exocrine and endocrine pancreatic insufficiencies[1,2]. CP is morphologically defined as progressive pancreatic fibrosis and inflammation that is accompanied by atrophy of pancreatic parenchymal cells[1,2]. CP is a strong risk factor for pancreatic ductal adenocarcinoma (PDAC) occurrence[3-5]. Recently, we investigated 76 PDAC patients who underwent surgery and analyzed pancreatic histological changes in specimens of noncancerous lesions[6]. Interestingly, we found that pancreatic steatosis, inflammation, and fibrosis in noncancerous lesions were each significant and independent determinants for PDAC. These histological changes are known as steatopancreatitis, and exactly the same characteristics are observed in the nonalcoholic steatohepatitis (NASH) liver. NASH, a severe form of nonalcoholic fatty liver disease (NAFLD), is a growing medical problem in industrialized countries around the world, and can progress to liver cirrhosis and hepatocellular carcinoma (HCC). We hypothesized that steatopancreatitis-induced CP would exist in the pathological background of PDAC comparable to NASH-related HCC occurrence.

PDAC is one of the most fatal cancers with a poor prognosis[7-11]. Most patients with PDAC are diagnosed at an advanced stage when the tumors are unresectable[7]. Even in the resectable cases, the prognosis of patients with PDAC is very poor because of local recurrence or distant metastasis occurring within a short period after the operation[9-11]. In our previous report, we found none of the 76 PDAC patients had a past history of clinical CP[6]. Therefore, the diagnosis of subclinical CP should be an important predictive factor for the early detection of PDAC. However, no useful diagnostic methods for the clinical diagnosis of CP have been identified.

Recently, we identified Mac-2 binding protein (Mac-2bp) as a novel diagnostic serum biomarker for NASH and fibrosis[12,13]. Mac-2bp is a glycoprotein that has

seven potential *N*-glycosylation sites[14,15]. Serum Mac-2bp concentrations increase in patients with breast and lung cancers, viral hepatitis, and autoimmune diseases[14]. Mac-2bp is rarely detectable in normal liver, but strongly detected in hepatocytes from chronic hepatitis type C (CHC) patients as liver fibrosis progresses[16]. Using proteome analysis, serum Mac-2bp is reported as a potential fibrosis marker in CHC patients[17]. In addition, *Wisteria floribunda agglutinin* (WFA)-positive Mac-2bp was recently reported as a novel serum fibrosis biomarker for CHC[18,19] and NASH[12,13,20]. Now, serum Mac-2bp is recognized as a novel and useful liver fibrosis biomarker in the clinic.

Therefore, we hypothesized that serum Mac-2bp also would be increased in CP patients with pancreatic fibrosis progression, and could be a useful biomarker for CP diagnosis. In this study, we measured serum Mac-2bp in 59 healthy volunteers (HV), 162 patients with CP, and 94 patients with PDAC, and investigated the availability of serum Mac-2bp as a CP diagnostic biomarker in comparison with other biochemical data.

MATERIALS AND METHODS

Ethics committee approval

This study was approved by the ethics committee of Osaka University Hospital (No. 260), and the study was conducted in accordance with the Helsinki Declaration. Written informed consent was obtained from all subjects at the time of enrollment or blood sampling.

Study subjects

Fifty-nine HV subjects were enrolled in this study from the aMs New Otani Clinic. We defined HV as the subjects who revealed no abnormal values in their laboratory evaluation without ultrasound-diagnosed fatty liver in health check-ups. One hundred sixty-two clinically diagnosed CP patients and 94 PDAC patients were enrolled in this study from Ogaki Municipal Hospital, Japan Community Health Care Organization Osaka Hospital, and Osaka University Hospital. The diagnosis of CP was made according to the guidelines of the Japan Pancreas Society[21]. The exclusion criteria from this study included a history of hepatic disease, such as chronic hepatitis C, chronic hepatitis B (seropositive for hepatitis B surface antigen), autoimmune hepatitis, Wilson's disease, or hepatic injury caused by substance abuse. Sera from these subjects were collected and frozen at -80 ℃ until use. Study subjects in this study were enrolled from 2002 to 2013.

Laboratory measurements and Mac-2bp ELISA

Serum biochemical variables [aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyltransferase (GGT), alkaline phosphatase (ALP), albumin (Alb), total bilirubin (T-Bil), creatinine (Cr), total cholesterol (T-Chol), triglyceride (TG), C-reactive protein (CRP), amylase (AMY)] were measured with a conventional automated analyzer. Serum levels of carbohydrate antigen 19-9 (CA19-9) and carcinoembryonic antigen (CEA) were determined using a chemiluminescent enzyme immunoassay. We measured serum Mac-2bp using our developed ELISA kit (Immuno-Biological Laboratory Co., Ltd., Fujioka, Japan, code No. 27362) as previously reported[12].

Statistical analysis

Statistical analysis was conducted using JMP Pro 11.0 software (SAS Institute Inc., Cary, NC). Variables were expressed as the mean ± standard deviation (SD). Statistical analysis included descriptive statistics, analysis of variance, the Wilcoxon and Kruskal-Wallis tests, and Spearman R correlations. As Mac-2bp, AST, ALT, GGT, T-Bil, TG, AMY, CRP, CA19-9, and CEA did not show a Gaussian distribution, these parameters were common log-transformed before analysis. The diagnostic performances of the scoring systems were assessed by analyzing receiver operating characteristic (ROC) curves. The probabilities of true positive (sensitivity) and true negative (specificity) assessments were determined for selected cut-off values, and the area under the ROC curve (AUC) was calculated for each index. The Youden index was used to identify the optimal cut-off points. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Serum biochemical variables and Mac-2bp levels in study subjects

The descriptive characteristics of the study subjects are shown in Table 1. The average age and serum AST, ALT, GGT, ALP, TG, and CEA were significantly lower in HV subjects than in CP and PDAC patients. T-Chol, CRP, AMY, and platelet count were significantly higher in CP patients than in HV subjects and PDAC participants. Serum Alb was significantly lower and average age and CA19-9 were significantly higher in PDAC patients than in CP patients. Serum Mac-2bp levels were significantly higher in CP patients than in both HV subjects and PDAC patients (Table 1, Figure 1).

Relationships between serum Mac-2bp levels and other biochemical tests

The results of Pearson's correlations between serum Mac-2bp levels and other biochemical tests are summarized in Table 2. Mac-2bp levels showed significant positive correlations with AST, ALT, GGT, and CRP.

Ability of serum Mac-2bp levels to distinguish HV from CP patients

We investigated the ability of serum Mac-2bp levels to distinguish CP patients from HV subjects using the ROC curve (Figure 2A). The AUC value for Mac-2bp in distinguishing CP patients from HV subjects

[1]*P* values (Wilcoxon test) correspond to the comparison between HV and CP; [2]*P* values correspond to the comparison between PDAC and CP. HV: Healthy volunteers; CP: Chronic pancreatitis patients; PDAC: Pancreatic ductal adenocarcinoma patients; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: γ-glutamyltransferase; ALP: Alkaline phosphatase; Alb: Albumin; T-Bil: Total bilirubin; Cr: Creatinine; T-Chol: Total cholesterol; TG: Triglyceride; CRP: C-reactive protein; AMY: Amylase; CEA: Carcinoembryonic antigen; Mac-2bp: Mac-2 binding protein; NS: Not significant.

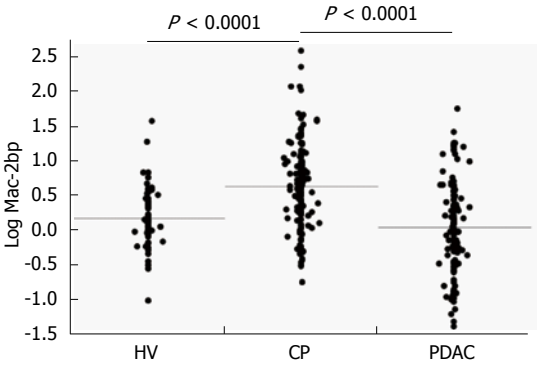

Figure 1 Serum Mac-2 binding protein levels were significantly elevated in chronic pancreatitis patients. Serum Mac-2 binding protein (Mac-2bp) levels in each group [healthy volunteer (HV), chronic pancreatitis patients (CP), pancreatic ductal adenocarcinoma patients (PDAC)]. Each dot on the graph is one individual. Horizontal gray lines indicate the mean values of common log-transformed Mac-2bp in each group.

was 0.727, and the cut-off value was 1.83 μg/mL with 87.9% sensitivity and 55.4% specificity. Multiple logistic analysis was performed to assess the CP diagnostic ability between HV subjects and CP patients (Table 3). Clinical variables that were significantly different between HV subjects and CP patients in univariate analysis were included except for ALT, which was strongly correlated with AST (Table 1). Age, TG, CRP, CEA, and Mac-2bp were significant independent variables for CP diagnosis. The odds ratio of Mac-2bp for the diagnosis of CP was 4.04.

Ability of serum Mac-2bp levels to distinguish CP patients from PDAC patients

We also investigated the ability of serum Mac-2bp levels to distinguish CP patients from PDAC patients

Table 2 Correlation coefficients for the relationships between Mac-2bp and various parameters

Factors	R	*P* value
Age (yr)	0.1	NS
AST (U/L)	0.22	< 0.0005
ALT (U/L)	0.15	< 0.05
GGT (U/L)	0.17	< 0.01

independent variables for CP diagnosis.

DISCUSSION

In the present study, we found that serum Mac-2bp levels were increased in CP patients compared with in HV subjects and PDAC patients. Multivariate analyses demonstrated that Mac-2bp was an independent and significant determinant for CP discrimination from HV subjects and PDAC patients. Mac-2bp levels are known to increase in chronic liver diseases such as chronic hepatitis type C[18,19] and NASH[12,13,20]. Our results indicate that increased serum Mac-2bp in subjects without liver diseases should be evaluated for CP.

PDAC is one of the most fatal cancers with a poor prognosis, and most PDAC patients are diagnosed at advanced stages[7,9,10]. In advanced stages, PDAC is usually unresectable, and in even resectable cases, the prognosis of PDAC patients is very poor because of local recurrence or distant metastasis. Because CP is identified as a strong risk factor for PDAC occurrence[3-5], detection of CP in patients is important for the identification of early stage PDAC patients. Our present study indicates that the measurement of serum Mac-2bp is a useful strategy for detection of CP patients in the general population.

Very recently, we reported that a dramatic change in oligosaccharides on serum haptoglobin occurs between CP and PDAC patients[22]. In PDAC patients, we previously reported that serum fucosylated haptoglobin levels are significantly increased and could be a useful serum biomarker[23,24]. We measured serum total fucosylated haptoglobin and core-fucosylated haptoglobin by our developed lectin-antibody ELISA systems using *Aleuria aurantia* lectin (AAL), which recognizes all types of fucosylation, and *Pholiota squarrosa* lectin (PhoSL), which specifically recognizes core-fucosylation[25], respectively. Using these ELISA systems, we found serum core-fucosylated haptoglobin levels were significantly elevated in CP patients compared with HV subjects and PDAC patients[22]. Although the precise mechanisms through which serum core-fucosylated haptoglobin levels increase in CP patients are still unclear, these findings

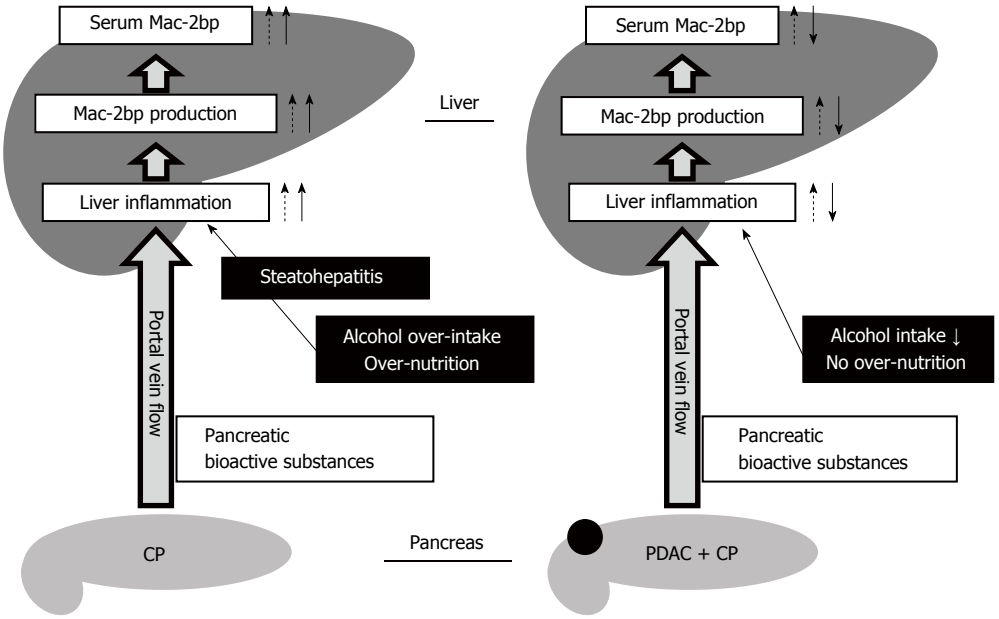

Figure 3 Putative mechanism of serum Mac-2bp changes in chronic pancreatitis and pancreatic ductal adenocarcinoma. In both chronic pancreatitis (CP) and pancreatic ductal adenocarcinoma (PDAC) patients, increased pancreatic bioactive substances produced in the pancreas flow into the liver through the portal vein and evoke inflammatory changes in the liver. This liver inflammation increases hepatic Mac-2bp production and serum Mac-2bp levels (Dotted arrows). Alcohol over-intake and/or relative over-nutrition induces steatohepatits in CP and further increases hepatic Mac-2bp production (left panel solid arrows). In contrast, the cessation of alcohol over-intake and no over-nutrition in PDAC would decrease hepatic Mac-2bp production and serum Mac-2bp levels would decrease in PDAC (right panel solid arrows).

indicate that core-fucosylation of glycoproteins would be enhanced in CP patients. Mac-2bp is a glycoprotein that we identified as one of the major fucosylated glycoproteins[12]. Therefore, using core-fucosylated Mac-2bp as a better biomarker is consistent with the findings of the present study.

To elucidate what cells produce Mac-2bp in the pancreas, we performed immunohistochemical staining for human Mac-2bp in PDAC and CP patients. However, Mac-2bp was expressed faintly in the pancreas tissues of both PDAC and CP patients (Supplementary Figure 1). These findings indicate that Mac-2bp was not produced in the pancreas. Previous reports demonstrate that tumor necrosis factor α and interferon γ can increase Mac-2bp expression in fibroblasts[26,27]. The blood stream carries abundant bioactive substances produced in the pancreas into the liver through the portal vein. Pancreatic inflammatory cytokines and cancer bioactive substances in CP and PDAC also flow into the liver and hepatic glycoprotein production, including Mac-2bp, would increase. Our previous reports demonstrate that serum Mac-2bp levels are significantly elevated in NASH patients compared to simple steatosis patients[12,13], and we found that serum Mac-2bp levels in CP patients were as high as those in NASH patients in the present study. Steatopancreatitis, induced by alcohol and/or energy over-intake, may promote the development of CP and is related to steatohepatitis[28-30]. Considering these findings, pancreatic bioactive substances would increase Mac-2bp production in the liver, and the presence of steatohepatitis under the condition of alcohol over-intake and/or relative over-nutrition further increases hepatic Mac-2bp production in CP patients. In contrast, no over-nutrition and cessation of alcohol over-intake in PDAC patients would contribute to the improvement of liver injury and might decrease the hepatic production of Mac-2bp (Figure 3). Indeed, our findings demonstrate that serum Mac-2bp levels were significantly and positively correlated with serum liver enzyme levels (AST, ALT, and GGT) and CRP (Table 2), but not with serum AMY levels. These results indicate that the liver may produce the elevated serum Mac-2bp in CP patients.

Our study has some limitations. Firstly, our CP and PDAC patients were clinically diagnosed with or without histological diagnosis. Therefore, the histological changes of noncancerous tissues of CP and PDAC patients were not fully assessed. In our future study, we would like to measure serum Mac-2bp levels in histologically diagnosed PDAC and CP patients. Secondly, age and gender among our study groups were significantly different. Ideally, age and gender would be matched among groups. However, the number of our study subjects was not enough to match these factors. Therefore, we performed multivariate analyses to adjust for these factors and found the significance of Mac-2bp even after adjusting for age and gender (Tables 3 and 4).

In conclusion, we find that serum Mac-2bp levels were significantly increased in CP patients compared with HV subjects and PDAC patients. This finding indicates that serum Mac-2bp can be used as a novel and useful CP biomarker. Measurement of serum Mac-2bp could

enable noninvasive screening for subclinical CP as well as chronic liver diseases in the general population.

COMMENTS

Background

Pancreatic ductal adenocarcinoma (PDAC) has the worst prognosis of all malignancies, and chronic pancreatitis (CP) is thought to be one of the main precursor diseases for PDAC occurrence. The authors recently found that inflammation and fibrosis are independent, characteristic histological changes in noncancerous lesions in PDAC patients despite the absence of a history of clinical CP. Therefore, the authors hypothesized that cryptogenic CP is an important predictive factor for PDAC occurrence. However, no useful biomarkers for the clinical diagnosis of CP have been identified.

Research frontiers

Recently, the authors identified Mac-2 binding protein (Mac-2bp) as a novel nonalcoholic steatohepatitis and fibrosis diagnostic serum biomarker. Mac-2bp is rarely detectable in normal liver, but strongly detected in hepatocytes from chronic hepatitis type C patients as liver fibrosis progresses. In the present study, we found that serum Mac-2bp levels were significantly increased in CP patients compared with healthy volunteers and PDAC patients. This finding indicates that serum Mac-2bp can be used as a CP biomarker.

Innovations and breakthroughs

In the present study, the authors found that serum Mac-2bp levels were increased in CP patients compared with in HV subjects and PDAC patients. Multivariate analyses demonstrated that Mac-2bp was an independent and significant determinant for CP discrimination from HV subjects and PDAC patients. Mac-2bp levels are known to increase in chronic liver diseases such as chronic hepatitis type C and NASH. The present results indicate that increased serum Mac-2bp in subjects without liver diseases should be evaluated for CP.

Applications

The present study found that serum Mac-2bp levels were significantly increased in CP patients compared with HV subjects and PDAC patients. This finding indicates that serum Mac-2bp can be used as a novel and useful CP biomarker. Measurement of serum Mac-2bp could enable noninvasive screening for subclinical CP as well as chronic liver diseases in the general population.

Peer-review

Very well written article, scientific content is important as conveying a new message using a novel biomarker for detection of subclinical Chronic pancreatitis. However the use of term subclinical CP in this study has been extrapolated to patient with CP as mentioned in methodology. This needs to be clarified whether these patients had any symptoms of CP or were detected incidentally from imaging findings. Also, author needs to define the term subclinical CP. Authors have also extrapolated their results in NASH patients but not mentioned whether these were same subjects with NASH and CP or PDAC, could they find a correlation?

Abstract

Sub capsular hepatic haematoma is a rare complication after endoscopic retrograde cholangiopancreatography (ERCP). Exact pathological mechanism is still unclear and few reports are nowadays available in literature. We report the case of a 58-year-old woman with recurrent episodes of upper abdominal pain, nausea and vomiting. On the basis of laboratory exams, abdomen ultrasound and magnetic resonance imaging she was diagnosed with a common bile duct stone. Endoscopic biliary sphincterotomy was performed. On the following day the patient complaint severe abdominal pain with rebound and hemodynamic instability. A computed tomography scan reveal a 14 cm × 6 cm × 19 cm sub-capsular hepatic haematoma on the right lobe that was successfully managed via percutaneous embolization. Sub capsular liver haematoma is a rare life threatening complication after ERCP that should be managed according to patients' haemodynamic and clinic.

Key words: Endoscopic guidewire; Endoscopic retrograde cholangiopancreatography; Abdominal pain; Subcapsular hepatic hematoma; Embolization

Core tip: Hepatic hematoma is a rare and potentially life threatening complication after endoscopic retrograde cholangiopancreatography (ERCP). Despite its severity, only few cases are described in current literature. The paper describe the management of a huge right lobe

hepatic hematoma following ERCP. An exhaustive literature analysis is made considering, signs and symptoms at presentation, time of presentation, diagnosis, and treatment. Awareness of this potential complication, high level of suspicion and prompt treatment are at the basis of better outcomes in such patients.

Subcapsular hepatic haematoma of the right lobe following endoscopic retrograde cholangiopancreatography: Case report and literature review. *World J Gastroenterol* 2016; 22(17): 4411-4415 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i17/4411.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i17.4411

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is a minimally invasive procedure for diagnosis and treatment of biliary and pancreatic disease. Complications occur in 2.5%-8% of cases with mortality rates ranging from 0.5%-1.0%[1]. Pancreatitis, cholangitis, perforation, and bleeding as a result of papillotomy are the most frequently described complications[2-3]. Sub capsular hepatic haematoma is a rare and potential life threatening condition[4]. We report the unusual case of a sub capsular hepatic haematoma after ERCP presenting with abdominal pain and hypotension.

CASE REPORT

A 58-year-old woman with recurrent episodes of upper abdominal pain was diagnosed with common bile duct stone by abdomen ultrasound and magnetic resonance imaging. She was admitted for ERCP and sphincterotomy. A proper drainage of the common bile duct was performed without complications. 12 h after the procedure the patient complaint a sudden abdominal pain with tenderness and rebound in the upper right quadrant without fever. Laboratory tests revealed a normal white blood cell count (7.44 × 10^9/L) and haemoglobin level (13.3 g/dL) with a slightly increased C-reactive protein (14.3 mg/dL). Total bilirubin, transaminases and amylases were within normal limits. Abdomen plain film was normal without signs of pneumoperitoneum. On the basis of such symptoms the patient was closely monitored. On the following 12 h she gradually develops hypotension (95/50 mmHg) and tachycardia (115 bpm) with a progressive haemoglobin decrease (8.6 g/dL). Urgent abdomen computed tomography (CT) scan demonstrated a large subcapsular hepatic haematoma of the right hepatic lobe supported by three peripheral parenchymal lacerations with contextual active bleeding and compression of the right and middle hepatic vein (Figure 1). On the basis of laboratory, clinical, and hemodynamic parameters the patient was urgently managed with percutaneous embolization of some small peripheral vessels on the sixth and seventh segment.

The post procedural course was uneventful with restoration of normal haemoglobin levels after transfusion (12.9 g/dL). Six days after embolization an abdomen CT scan shows the stability of the hematoma and the patient was discharged home.

DISCUSSION

Sub capsular hepatic haematoma is a rare and potentially life threatening complication after ERCP. Probably underestimated, only few cases are nowadays reported in literature and the exact pathological mechanism is unclear (Table 1). Accidental puncture of a peripheral intrahepatic biliar tree with consensual laceration of a small parenchymal vessels by endoscopic guide wire, may explain the phenomenon[2-4].

Sudden abdominal pain whenever associated with hypotension and tachycardia after ERCP should raise the suspicion of intrahepatic bleeding with Glisson's capsule distension. Different symptoms are described in literature: abdominal pain (91%), anemia (39.1%), hypotension (39.1%), fever (21.7%) and peritonism (13%) (Table 1). Laboratory tests did not provide major indicators of the development of a sub capsular hepatic haematoma, except for a decrease in the haemoglobin level[1]. Imaging modalities (ultrasound and CT) are the gold standard for diagnosis and surveillance of this emergent complication[9,15].

In the present case symptoms and signs started 12 h after the procedure with an early diagnosis and prompt treatment. Aspecific symptoms with a late onset from ERCP may occur with consequent delayed diagnosis and treatment (range 2-144 h) (Table 1).

Different treatment modalities are proposed in literature based on haemodynamic and clinics. The role of imaging in the assessment dimension and of ab extrinsic compression on hepatic vein is an important detail that should kept in mind whenever approaching such patients.

In stable patients with a limited, peripheral and non-compressive haematoma, a conservative management with prophylactic antibiotics should be suggested. Serial haemoglobin controls and abdomen CT verification is advisable[19]. Percutaneous drainage under CT guide and US should be proposed in case of abscess formation and fever[1].

Whenever hemodynamic instability is present with active bleeding and contrast extravasation, an immediate radiological or surgical approach should be taken into account. Minimally invasive radiological selective peripheral vessels embolization shows high success rates[21]. Surgical management should be reserved in case of general condition deterioration,

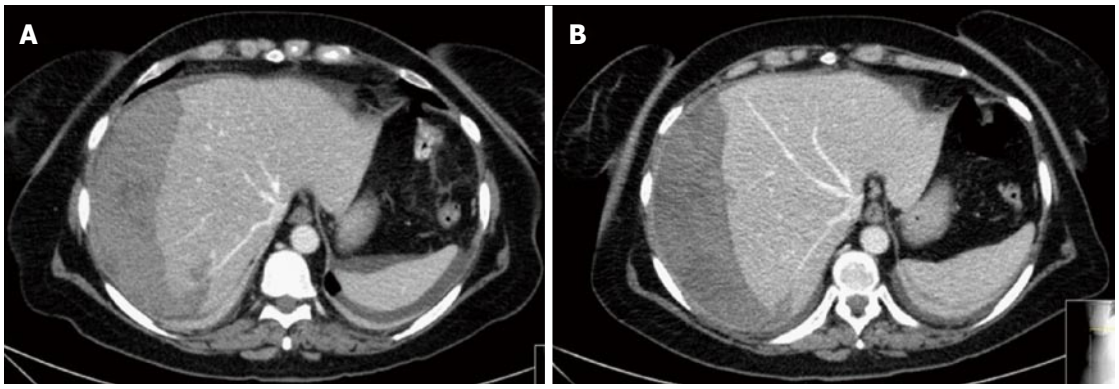

Figure 1 Urgent abdomen computed tomography scan. A: Hepatic subcapsular hematoma of the right lobe (14 cm × 6 cm × 19 cm) with peripheral parenchymal laceration. Ab-extrinsic compression of the right and middle hepatic vein with perisplenic free fluid; B: Six days after radiological selective embolization: note the stability of the haematoma dimension with disappearance of perisplenic free fluid.

haemodynamic instability with signs of consensual peritoneal and free abdominal fluid[9]. Surgical approach consist in hematoma evacuation, local haemostasis with electrocoagulation or haemostatic devices, or packing in case of massive haemorrhage[22]. Literature data are in favour with a conservative treatment (43.5%), percutaneous embolization (26%), drainage (17.4%) and surgical management (13%) as a first line treatment. Failure of the first approach occur in 3 different cases (13%) without severe consequences (Table 1). Sudden rupture of the haematoma with consequent haemoperitoneum is a dreaded complications with high risk of mortality if misdiagnosed. González-López *et al*[22] report the case of a 30 years-old patient with Glisson's capsule rupture and consequent haemoperitoneum with consequent hypotension and signs of peritonism. The patients was surgically managed with electrocautery and packing without success.

Sub capsular liver haematoma is a rare and potentially life threatening complication following ERCP. Conservative treatment will be sufficient in most hemodinamically stable patients with no signs of super infection or abscess formation. Selective embolization is adequate in case of peripheral small vessels bleeding determining hemodynamic instability. Surgical approach is advisable in case of rupture risk, signs of peritonism and free abdominal fluid. Serial follow up CT scan are essential for dimension monitoring. We recommend that for legal purposes this potential risk should be addressed in the preoperative informed consent.

COMMENTS

Case characteristics

A 58-year-old woman with recurrent episodes of upper abdominal pain was diagnosed with common bile duct stone by abdomen ultrasound and magnetic resonance imaging and admitted for endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy.

Clinical diagnosis

Hemodynamic instability, hypotension, and tachycardia were consistent with a post-procedural bleeding.

Differential diagnosis

Papillary bleeding after ERCP is one of the most common complications after the procedure. Splenic rupture, intrahepatic hematoma and visceral abdominal vessels rupture, related to instrumental looping with excessive traction, are exceptionally responsible for such situation.

Laboratory diagnosis

Laboratory tests did not provide major indicators in development of sub capsular hepatic haematoma.

Imaging diagnosis

Abdominal ultrasound and computed tomography (CT) scan are necessary for differential diagnosis.

Pathological diagnosis

A large sub capsular hepatic haematoma of the right lobe with active bleeding was evident on CT scan.

Treatment

On the basis of laboratory, clinical, and hemodynamic parameters the patient was urgently managed with percutaneous embolization of some small peripheral vessels.

Related reports

Probably underestimated, hepatic hematoma following ERCP is an extremely rare complication with few cases reported in current literature.

Experiences and lessons

Hepatic hematoma is a rare, potentially life threatening complication after ERCP. Awareness of such event is fundamental for early detection, diagnosis and treatment.

Peer-review

This report describe our experience in the management of a large hepatic hematoma after ERCP with an exhaustive literature review. Symptoms and signs at presentation, diagnosis, and management are reviewed in accordance to published literature. Limited number of literature reported cases is the major weakness of this study. Further studies are necessary to investigate the mechanism of injury and appropriate management of such complication.

Abstract

An inverted Meckel's diverticulum is a rare gastrointestinal congenital anomaly that is difficult to diagnose prior to surgery and presents with anemia, abdominal pain, or intussusception. Here, we report the case of 57-year-old men with an inverted Meckel's diverticulum, who was preoperatively diagnosed using double-balloon enteroscopy. He had repeatedly experienced epigastric pain for 2 mo. Ultrasonography and computed tomography showed intestinal wall thickening in the pelvis. Double-balloon enteroscopy via the anal route was performed for further examination, which demonstrated an approximately 8-cm, sausage-shaped, submucosal tumor located approximately 80 cm proximal to the ileocecal valve. A small depressed erosion was observed at the tip of this lesion. Forceps biopsy revealed heterotopic gastric mucosa. Thus, the patient was diagnosed with an inverted Meckel's diverticulum, and single-incision laparoscopic surgery was performed. This case suggests that an inverted Meckel's diverticulum should be considered as a differential diagnosis for a submucosal tumor in the ileum. Balloon-assisted enteroscopy with forceps biopsy facilitate a precise diagnosis of this condition.

Key words: Inverted Meckel's diverticulum; Double-balloon enteroscopy; Small bowel tumor; Epigastric pain; Heterotopic gastric mucosa

Core tip: An inverted Meckel's diverticulum is a rare congenital anomaly of the gastrointestinal tract which is difficult to diagnose prior to surgery. This case report represents the utility of double-balloon enteroscopy for the precise preoperative diagnosis of an inverted Meckel's diverticulum.

INTRODUCTION

Meckel's diverticulum is a common asymptomatic congenital, gastrointestinal anomaly that is a remnant of the omphalomesenteric duct[1]. The incidence of Meckel's diverticulum was between 0.3%-4% in an autopsy series[1-3]. This anomaly may present as an inverted diverticulum causing anemia, abdominal pain, or intussusception[4]. Small bowel series and abdominal computed tomography (CT) scans have been used for the diagnosis of an inverted Meckel's diverticulum. However, the preoperative diagnosis of an inverted Meckel's diverticulum is difficult because the clinical and imaging features overlap with those of other etiologies or acute abdomen or gastrointestinal bleeding[5]. The final diagnosis is often made either intra-operatively or based on postoperative pathology reports. A recent advance in diagnostic methods involves balloon-assisted enteroscopy, which enables both the endoscopic observation of the entire small intestine as well as biopsy collection[6-8]. Here we report the rare case of a 57-year-old man with an inverted Meckel's diverticulum that was preoperatively diagnosed using double-balloon enteroscopy.

CASE REPORT

A 57-year-old man who had been repeatedly experiencing epigastric pain for 2 mo consulted at a clinic. He was then referred to another hospital due to a thickened intestinal wall observed on abdominal ultrasonography. His past medical history included depression and a gallbladder polyp treated by cholecystectomy. Physical examination and laboratory findings were unremarkable. An abdominal contrast-enhanced CT also showed a thickened small intestinal wall, with an elongated, intraluminal, fat-attenuating lesion in the lower abdomen (Figure 1). An upper gastrointestinal endoscopy and total colonoscopy were performed, but no abnormalities were found within the observed area. The patient was subsequently referred to our hospital for further examination. Retrograde double-balloon enteroscopy (DBE) was performed, which demonstrated an 8-cm, sausage-shaped, polypoid lesion that was located approximately 80 cm proximal to the ileocecal valve. A small depressed erosion was seen at the tip of the polypoid lesion, and intestinal villous mucosa was seen on the surface of the lesion (Figure 2). Using selective contrast-enhanced radiography with DBE, an elongated polypoid lesion was demonstrated in the ileum (Figure 3). Although Tc-99m pertechnetate scintigraphy was negative, a forceps biopsy from the tip of the depressed lesion revealed heterotopic gastric mucosa. The patient was diagnosed with an inverted Meckel's diverticulum, and he underwent single-incision laparoscopic surgery 3 mo later. An excavation of the serosa was observed at the basal region of the polypoid lesion by laparoscopy. After a Hutchinson's maneuver, segmental resection was performed. Pathological examination of the specimen revealed an 8.0 cm × 1.4 cm, sausage-shaped, polypoid lesion. Histological examination showed heterotopic gastric mucosa mimicking the pyloric glands at the tip of the lesion (Figure 4). The patient was discharged on post-operative day 6 without complications.

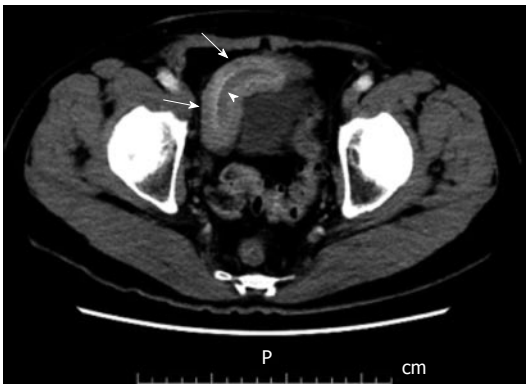

Figure 1 Contrast-enhanced computed tomography images of the lower abdomen. An abdominal computed tomography showed a thickened small intestinal wall (arrows) and an intraluminal, fat-attenuating lesion in the lower abdomen (arrowhead).

DISCUSSION

A Meckel's diverticulum is usually an asymptomatic condition, and many cases are incidentally discovered during a radiographic evaluation or during surgery performed for other reasons[1]. This condition causes symptoms in 4%-30% of patients[9], and possible complications include hemorrhage, bowel obstruction with or without intussusception, diverticulitis, and

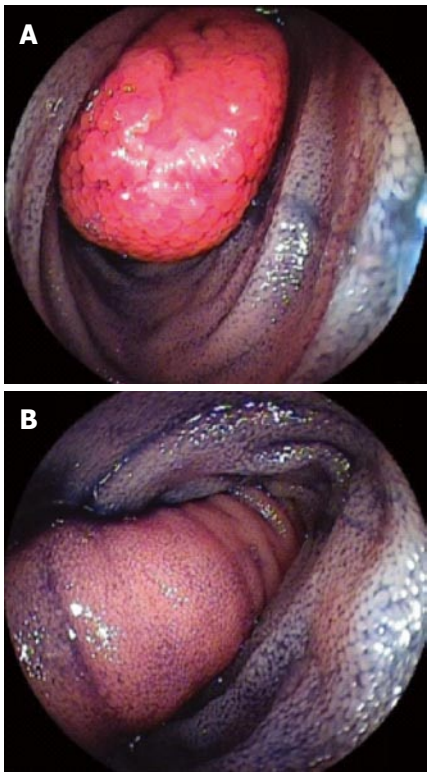

Figure 2 Double-balloon enteroscopy. A: Double-balloon enteroscopy revealed a sausage-shaped, elongated tumor with a depressed erosion at the tip in the ileum; B: Normal intestinal mucosa was seen on the surface of the tumor.

Figure 3 Selective contrast - enhanced radiography. An elongated, intraluminal polypoid lesion (arrows), approximately 8 cm in size, was seen in the terminal ileum.

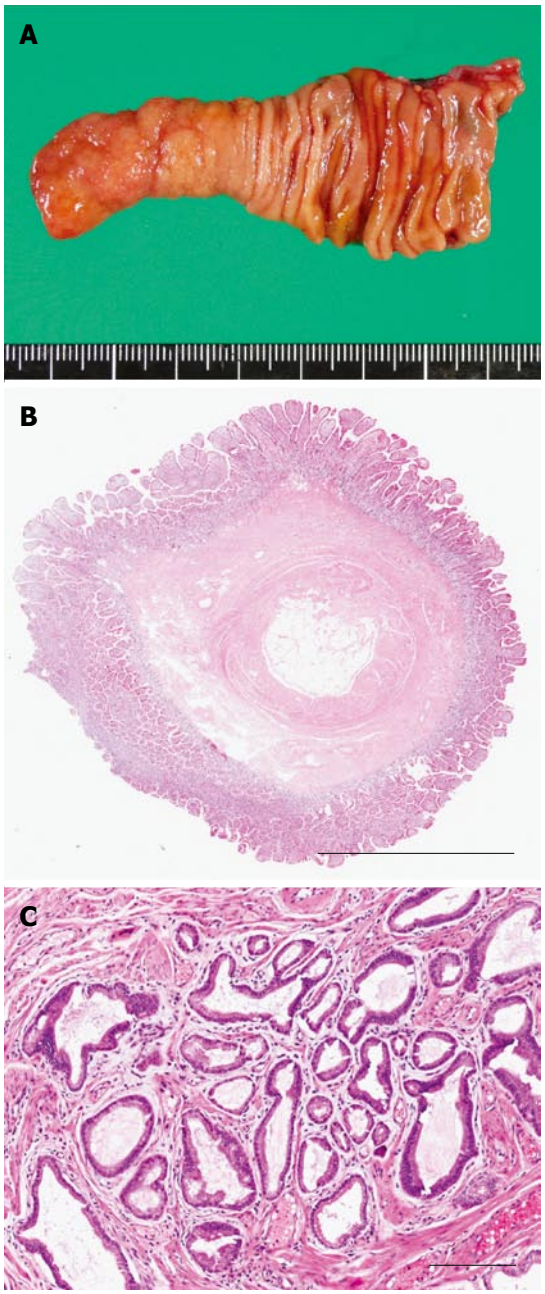

Figure 4 Pathological and histological examination. A: The opening of the specimen revealed an 8.0 cm × 1.4 cm polypoid lesion; B: Photomicrograph [hematoxylin and eosin (HE) stain] shows that the diverticulum was composed of all layers of the intestinal wall. Scale bars: 6 mm; C: Photomicrograph (HE stain) shows heterotopic gastric mucosa at the tip of the polypoid lesion. Scale bars: 600 μm.

inversion. According to a recent report, the most common complaint in an inverted Meckel's diverticulum is bleeding (80%), followed by anemia (78%) and abdominal pain (68%)[4]. The radiological features of an inverted Meckel's diverticulum are similar to that of a pedunculated intraluminal polyp, especially lipoma. Small bowel series reveal an elongated, smoothly margined, intraluminal mass that parallels the long axis of the intestine and frequently has a bulbous or club-sharped tip. Abdominal CT shows typical inverted cases as having a central core of fat attenuation[1].

This case seemed difficult to diagnose prior to surgery because the symptoms were mild and non-specific. Nevertheless, we could preoperatively diagnose the inverted Meckel's diverticulum using DBE. Recently, the reports of Meckel's diverticulum diagnosed using DBE are increasing[8]. DBE was developed by Yamamoto *et al*[6,7] in 2000 for the diagnosis and treatment of small intestinal disease. DBE is quite useful for diagnosis because it enables a biopsy of the entire small intestine[6]. Heterotopic gastric mucosa reportedly occurred in up to 50% of Meckel's diverticulum and up to 80% of symptomatic

patients[10]. Heterotopic pancreatic tissue was also found in 5%-16% of cases[1,11]. Meckel's diverticulum is typically located on the antimesenteric side of the distal ileum, within 20-100 cm proximal to the ileocecal valve[1]. Therefore, retrograde DBE is particularly recommended to diagnose Meckel's diverticulum[8,12].

The mechanism of inversion is not clearly understood. Levy *et al*[1] reported that 21% cases of Meckel's diverticulum were found to be inverted in the lumen of the small intestine. One theory is that abnormal peristaltic movement in proximity to the Meckel's diverticulum may cause it to invert[11,12]. Another theory is that because Meckel's diverticulum is not fixed to the mesentery or the intestine, it increases the likelihood of an inversion[4]. The mesenteric fat of the Meckel's diverticulum is pulled into the center of the diverticulum as it inverts in the small intestinal lumen. When the diverticulum is inverted, it may cause not only intestinal obstruction but also intussusception[1,4].

The preferred treatment for symptomatic Meckel's diverticulum is surgery. Whenever an inverted Meckel's diverticulum is diagnosed either pre-operatively or intra-operatively, the surgical procedure should be segmental resection. Laparoscopic resection is a safe and less invasive surgical procedure[1,4]. In this case, single-incision laparoscopic surgery was performed, which is a minimal access technique that can yield a reduction in scarring and consequently pain and suffering of the patients. Asymptomatic diverticula that are incidentally discovered remains controversial to date. The lifetime risk of developing complications is 4% up to the age of 20 years, 2% up to the age of 40 years, and 0% in the elderly population[1,4]. Therefore, preventive resection is recommended for patients younger than 40 years; for a diverticulum longer than 2 cm; diverticula with narrow necks, fibrous bands, or heterotopic gastric mucosa; or when the diverticula appears thickened and inflamed[4].

In the present case, an inverted Meckel's diverticulum with heterotopic gastric mucosa was clearly viewed using double-balloon enteroscopy. Therefore, an inverted Meckel's diverticulum should be considered as a differential diagnosis for a submucosal tumor in the ileum. Balloon-assisted enteroscopy combined with forceps biopsy enables a precise preoperative diagnosis.

COMMENTS

Case characteristics
A 57-year-old man had repeatedly experienced epigastric pain for 2 mo.

Clinical diagnosis
Physical examinations were unremarkable.

Differential diagnosis
Intestinal submucosal tumors: especially lipoma.

Laboratory diagnosis
All laboratory tests were within normal limits.

Imaging diagnosis
An abdominal contrast-enhanced computed tomography showed a thickened small intestinal wall, with an elongated, intraluminal, fat-attenuating lesion in the ileum, and retrograde double-balloon enteroscopy (DBE) demonstrated a sausage-shaped, polypoid lesion that was located approximately 80 cm proximal to the ileocecal valve. A small depressed erosion was seen at the tip of the polypoid lesion.

Pathological diagnosis
Histological examination showed that the diverticulum was composed of all layers of the intestinal wall, and heterotopic gastric mucosa was seen at the tip of the lesion.

Treatment
Single-incision laparoscopic surgery was performed.

Related reports
Although the reports of Meckel's diverticulum diagnosed using DBE are increasing, those of inverted situation is rare. DBE is quite useful for diagnosis.

Term explanation
An inverted Meckel's diverticulum is a condition where the Meckel's diverticulum literally inverts intraluminally on itself.

Experiences and lessons
An inverted Meckel's diverticulum is a rare congenital anomaly of the gastrointestinal tract which is difficult to diagnose prior to surgery. This case report represents the utility of double-balloon enteroscopy with biopsy for the precise preoperative diagnosis of an inverted Meckel's diverticulum.

Peer-review
The authors present a case report of inverted Meckel's diverticulum diagnosed pre-operatively. The report is well written.

Abstract

Laparoscopic cholecystectomy has become a standard treatment of symptomatic gallstone disease. Although spilled gallstones are considered harmless, unretrieved gallstones can result in intra-abdominal abscess. We report a case of abscess formation due to spilled gallstones after laparoscopic cholecystectomy mimicking a retroperitoneal sarcoma on radiologic imaging. A 59-year-old male with a surgical history of a laparoscopic cholecystectomy complicated by gallstones spillage presented with a 1 mo history of constant right-sided abdominal pain and tenderness. Computed tomography and magnetic resonance imaging demonstrated a retroperitoneal sarcoma at the sub-hepatic space. On open exploration a 5 cm × 5 cm retroperitoneal mass was excised. The mass contained purulent material and gallstones. Final pathology revealed abscess formation and foreign body granuloma. Vigilance concerning the possibility of lost gallstones during laparoscopic cholecystectomy is important. If possible, every spilled gallstone during surgery should be retrieved to prevent this rare complication.

Key words: Intra-abdominal abscess; Spilled gallstone; Laparoscopic cholecystectomy

Core tip: Gallstone abscess resulting from spilled gallstones is a rare complication following laparoscopic cholecystectomy. We report a rare presentation of gallstone abscess due to spilled gallstones following laparoscopic cholecystectomy, mimicking a retroperitoneal sarcoma in a 59-year-old male. Recognizing the patient information about a history of laparoscopic cholecystectomy and sharing the patient information with radiologists can make an accurate diagnosis and avoid misinterpretation when

the diagnosis is equivocal in radiologic imaging. Clear documentation of gallbladder perforation and gallstone can help with diagnosis of the complication and for correct management. Five noteworthy features are discussed in this paper.

INTRODUCTION

Laparoscopic cholecystectomy is a standard treatment for symptomatic gallstone disease. Gallbladder perforation and gallstones spillage during laparoscopic cholecystectomy occurs in up to 40% of cases[1-3]. The incidence of unretrieved spilled gallstones has been estimated at 16% to 50%[3-5]. Gallstone abscess following spilled gallstones is an extremely rare delayed complication of laparoscopic cholecystectomy[3,6]. Common locations of the abscess are in the abdominal wall followed by intra-abdominal cavity usually in the sub-hepatic or retroperitoneum inferior to sub-hepatic space[3]. We report a rare case of abscess formation due to spilled gallstones mimicking a retroperitoneal sarcoma following laparoscopic cholecystectomy.

CASE REPORT

Our institutional review board approved the reporting of this case. A 59-year-old male was admitted to our clinic with a 1-mo history of worsening right-sided constant abdominal pain. Outside abdominal sonography showed a 4.5 cm mass-like lesion in the sub-hepatic space. He had no significant past medical history apart from a history of laparoscopic cholecystectomy about 5 mo previously. Laboratory workup revealed a white blood cell count of 7500/mm^3. All other laboratory findings including liver function tests, amylase and lipase were within normal limits. Tumor makers were normal. The hepatitis serologic markers were all negative. Computed tomography (CT) scan of the abdomen revealed a 4.9 cm × 4.6 cm right retroperitoneal mass invading the muscle wall and a 2 cm mass abutting the right kidney (Figure 1A-C). Magnetic resonance imaging (MRI) detected an ill-defined mass in the sub-hepatic space with subtle high signal intensity in T2 weighted image, low signal intensity in T1 weighted image and high signal intensity in diffusion weighted image (Figure 2A-C). With the suspicion that this mass was a retroperitoneal sarcoma, an exploratory laparotomy was performed. It revealed a severe adhesion around the mass containing purulent material and gallstones in the sub-hepatic space. Examination of frozen sections revealed acute and chronic inflammation with abscess and foreign body granuloma. Small abscess cavity found in the sub-phrenic space was destroyed using suction. Purulent materials were removed and several remaining stones were retrieved and copious irrigation was performed. Final pathology showed acute and chronic inflammation with abscess and foreign body granuloma (Figure 3). Postoperative recovery was uneventful. Six months later, the patient remains in good condition without any complaints.

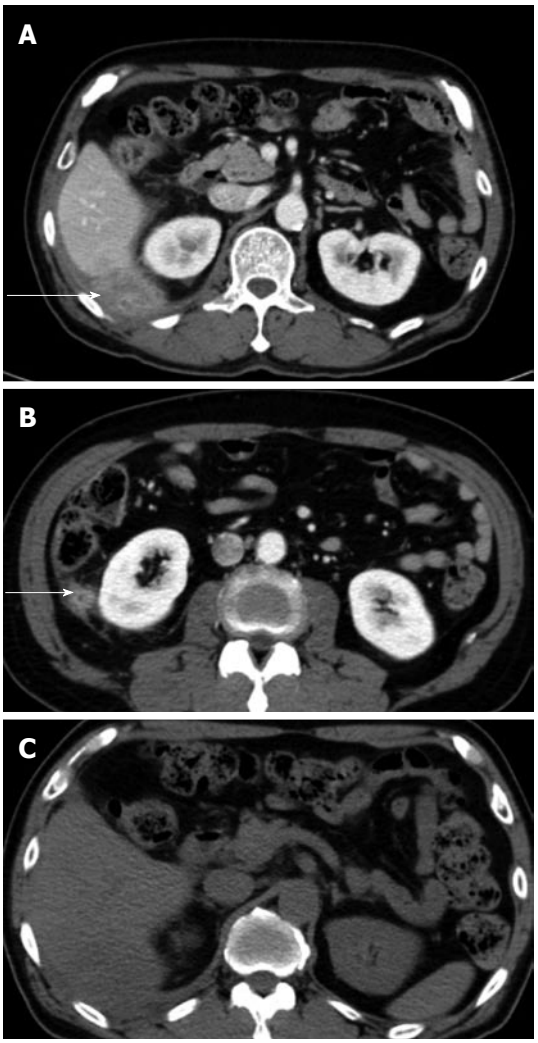

Figure 1 Five months after primary laparoscopic cholecystectomy, computed tomography scan was performed for evaluation of right upper quadrant pain. A and B: Abdominal CT scan revealed a 4.9 cm × 4.6 cm sized, ill-defined heterogenous retroperitoneal mass in posterolateral sub-hepatic and posterior perirenal space involving posterior abdominal wall (arrows); C: No calcified stone was seen to suggest spilled gallstones in the pre-contrast enhanced CT scan. CT: Computed tomography.

DISCUSSION

Gallbladder perforation and gallstone spillage during laparoscopic cholecystectomy occurs in up to 40% of cases[1-3]. The risk of gallbladder perforation leading to bile and gallstone spillage is more common during laparoscopic cholecystectomy than during

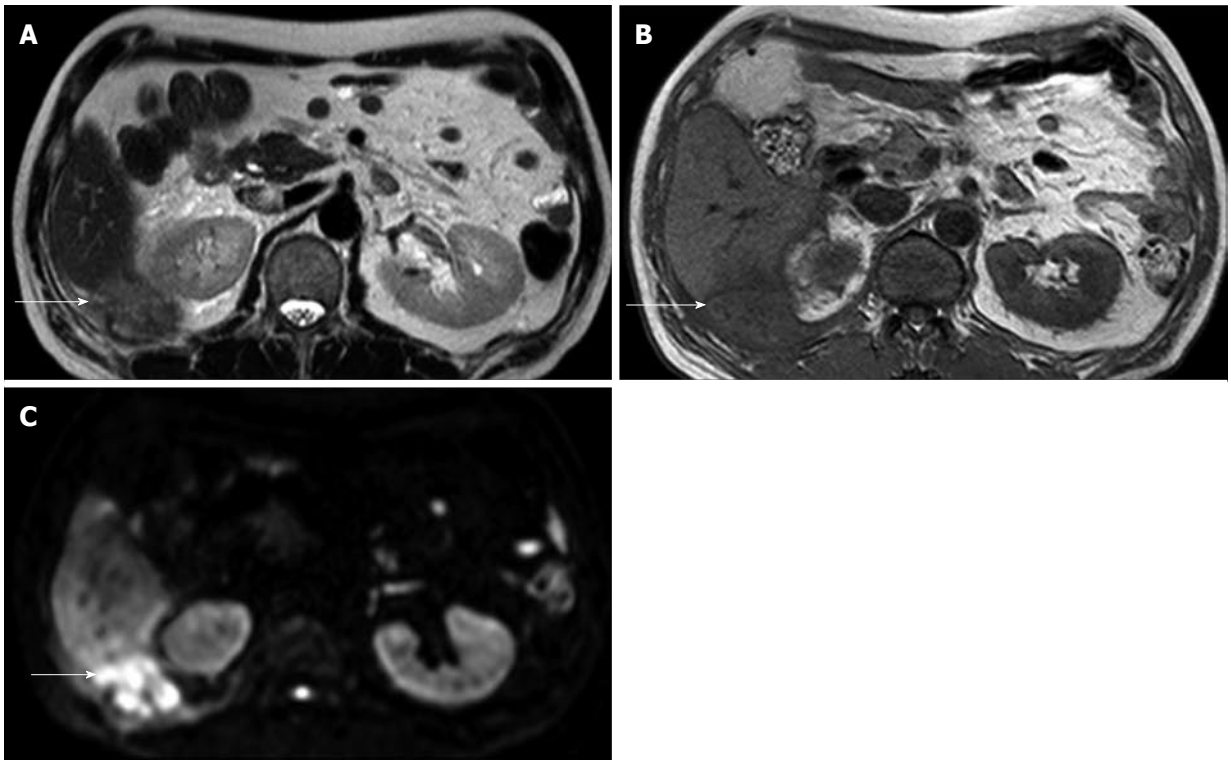

Figure 2 Magnetic resonance imaging showed ill-defined mass at right subhepatic space (arrows). A: Subtle high signal intensity in T2 weighted image; B: Low signal intensity in T1 weighted image; C: High signal intensity in diffusion weighted image.

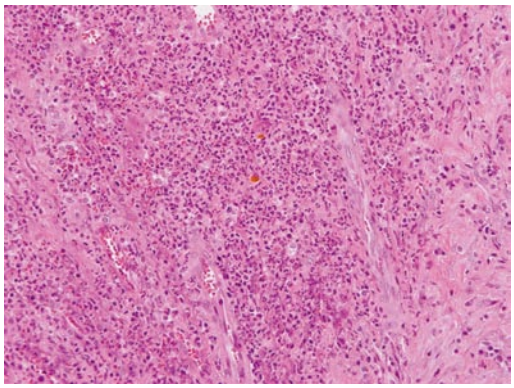

Figure 3 Numerous acute inflammatory cell and limphoplasma cell surrounding fibrosis and granulation tissue is seen. Bile stained gallstone sludge is seen in the center (haematoxylin and eosin staining, original magnification × 200).

open cholecystectomy. Gallbladder perforation most often occurs during the traction of the gallbladder or dissection from the gallbladder bed or extraction of the gallbladder through the port site, and it is more common in the presence of adhesions, inflammation around the gallbladder and in the early years of a surgical career[6,7]. The most important risk factor of gallbladder perforation is acute inflammation of the gallbladder with an edematous, friable or gangrenous wall[7,8]. However, gallstones spill into the abdominal cavity in only 7.3% of these cases[9,10].

Zehenter *et al*[10] reported all possible complications due to spilled gallstones during laparoscopic cholecystectomy. The most common complication is intra-abdominal abscesses that are located most often in the sub-hepatic space or its retroperitoneal region, as occurred presently. Fistula formations, hernia sacs, ovary and fallopian tubes containing lost gallstones are among some of the rare complications reported for gallstone abscess. These complications are rarely fatal. Thus, converting to an open procedure is not indicated, because only 8.5% of patients will lead to a complication[10].

An inflammatory response can be induced, which features walling off by omentum and local fibrosis. Inflammation and infection are more common with pigment stones[11]. This is postulated to be due to the release of bacteria from within the stones as the body breaks down the stone matrix[12]. In our case, preoperative CT in the primary procedure showed emphysematous cholecystitis with multiple stones (Figure 4). Operatively, gallbladder empyema with a friable wall was found (Figure 5). The edematous and friable wall hindered grasping of the gallbladder during the traction and the dissection of the gallbladder from the liver, which lead to gallbladder perforation and gallstones and infected bile spillage. Despite every effort to remove remaining stones including extensive peritoneal lavage and aspiration with a large suction tube (Figure 6), gallstone abscess due to spilled stones occurred 5 mo after laparoscopic cholecystectomy. This highlights that care must be taken not to spread gallstones into more inaccessible sites, making retrieval even more difficult. Spilled gallstones can be

Figure 4 Computed tomography scan showing emphysematous gallbladder and gallbladder stones.

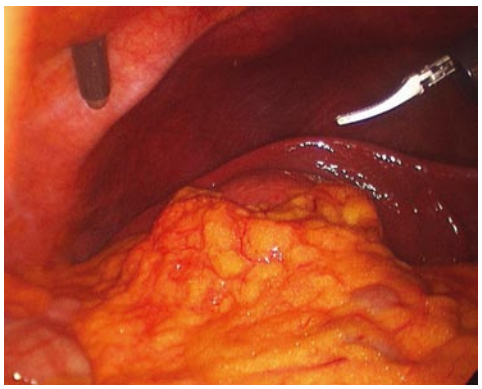

Figure 5 Operative findings in the primary procedure. Due to edematous, friable wall and gallbladder distension, it was hard to grasp the gallbladder during the traction and the dissection of the gallbladder from the liver.

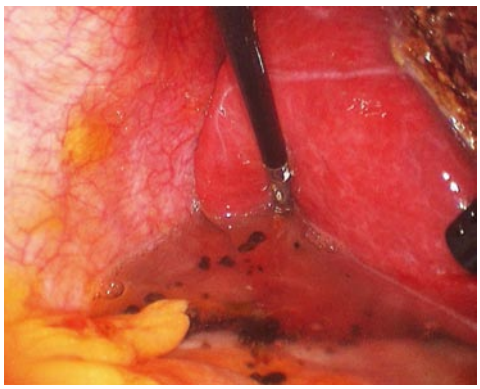

Figure 6 Multiple spilled gallstones. Copious irrigation of Morrison's pouch was applied.

retrieved easily in open cholecystectomy by irrigating the abdominal cavity and aspirating with a large suction tube or by collecting the stones with a sponge, which is difficult in laparoscopic cholecystectomy[13-15].

CT and MRI features of gallstones often include the presence of gallstones within the abscess, which is essential for a diagnosis[16]. Pigment stones with high calcium content are easily diagnosed with CT, whereas pure cholesterol stones and those with low calcium content may go undetected, as in our case[17]. Presently, CT and MRI were equivocal with the findings of retroperitoneal sarcoma. Spilled stones were not evident in radiologic imaging. Presence of the highly reflective echoes with posterior shadowing in the abscess cavity can be pathognomonic for gallstone abscess in patients with a history of laparoscopic cholecystectomy.

Abscess formation secondary to spilled stones mimicking a retroperitoneal sarcoma is rare. Despite their extreme rarity, the characteristic appearance of intra-abdominal abscesses from gallstones should be recognized because their radiographic appearance can mimic more severe disease, such as peritoneal metastasis[16,18]. Abscess formation from spilled stones after laparoscopic cholecystectomy has been reported to have an average duration of 4 mo to 10 years[19,20]. Presently, despite the history of laparoscopic cholecystectomy 5 mo before, gallstone abscess mimicking a retroperitoneal sarcoma in radiologic finding made the diagnosis difficult. Spilled gallstones around the liver may be confused with peritoneal metastasis or lymph nodes, having a similar appearance of round soft-tissue perihepatic nodules with a high attenuation peripheral rim on CT. Unenhanced CT may be useful in elucidating the calcified nature of these nodules. However, although the presence of calcification favours the diagnosis of spilled gallstones, some mucin producing tumours, such as tumours from the ovary and colon, can contain calcium[21]. Therefore, spilled gallstones should be considered in a patient with a history of LC presenting with an abdominal abscess.

The current case highlights five noteworthy features. Gallstone abscess resulting from spilled gallstones is a rare complication following laparoscopic cholecystectomy, but spilled gallstones should always be considered in a patient with a history of laparoscopic cholecystectomy presenting with an abdominal abscess. Secondly, a surgeon needs to share the patient information with radiologists to make an accurate diagnosis and avoid misinterpretation when the diagnosis is equivocal in radiologic imagings. Thirdly, careful manipulation of gallbladder with empyema, wall thickening and many gallstones during laparoscopic cholecystectomy should be made. Fourth, every effort to retrieve all spilled stones during laparoscopic cholecystectomy should be made to avoid late complications and the peritoneum should be irrigated with copious saline. Finally, it is important for the surgeon to clearly document in the operative record whether the gallbladder was perforated and whether stones spilled during laparoscopic cholecystectomy to help with diagnosis of the complication and for correct management.

In conclusion, retroperitoneal abscess formation secondary to spilled gallstones following laparoscopic cholecystectomy is a rare condition. If possible, every spilled gallstone during laparoscopic cholecystectomy

should be retrieved to prevent such a rare complication. As in our case, preoperative radiological investigations may be equivocal. Clear documentation of gallbladder perforation and gallstone spillage is important, as is being vigilant to the possibility of stones during surgery.

COMMENTS

Case characteristics

A 59-year-old male with a history of laparoscopic cholecystectomy 5 mo prior presented with a 1-mo history of worsening right-sided constant abdominal pain.

Clinical diagnosis

The patient presented with a 1-mo history of worsening right-sided constant abdominal pain.

Differential diagnosis

Retroperitoneal sarcoma, metastatic cancer.

Laboratory diagnosis

All labs were within normal limits.

Imaging diagnosis

Computed tomography showed a 4.9 cm × 4.6 cm right retroperitoneal mass invading the muscle wall and a 2 cm mass abutting the right kidney.

Pathological diagnosis

Acute and chronic inflammation with abscess and foreign body granuloma.

Treatment

Abscess cavity was destroyed using suction. Purulent materials were removed and several remaining stones were retrieved and copious irrigation was performed.

Related reports

Intra-abdominal abscesses secondary to spilled gallstones are located most often in the sub-hepatic space or its retroperitoneal region. Fistula formations, hernia sacs, ovary and fallopian tubes containing lost gallstones are among some of the rare complications reported for gallstone abscess.

Term explanation

The characteristic appearance of intra-abdominal abscesses from gallstones should be recognized because their radiographic appearance can mimic more severe disease, such as peritoneal metastasis and retroperitoneal sarcoma.

Experiences and lessons

Retroperitoneal abscess formation due to spilled gallstones following laparoscopic cholecystectomy is a rare condition. If possible, every spilled gallstone during laparoscopic cholecystectomy should be retrieved to prevent such a rare complication. Clear documentation of gallbladder perforation and gallstone spillage is important, as is being vigilant to the possibility of stones during surgery.

Peer-review

This case report is very useful to doctors in clinical practice. It is helpful to remind doctors to avoid the same mistake in clinical work.

Abstract

Hepatitis C virus (HCV) infection is associated with increased thrombotic risk. Several mechanisms are involved including direct endothelial damage by the HCV virus, with activation of tissue factor, altered fibrinolysis and increased platelet aggregation and activation. In advanced stages, chronic HCV infection may evolve to liver cirrhosis, a condition in which alterations in the portal microcirculation may also ultimately lead to thrombin activation, platelet aggregation, and clot formation. Therefore in advanced HCV liver disease there is an increased prevalence of thrombotic phenomena in portal vein radicles. Increased thrombin formation may activate hepatic stellate cells and promote liver fibrosis. In addition, ischemic changes derived from vascular occlusion by microthrombi favor the so called parenchymal extinction, a process that promotes collapse of hepatocytes and the formation of gross fibrous tracts. These reasons may explain why advanced HCV infection may evolve more rapidly to end-stage liver disease than other forms of cirrhosis.

Key words: Coagulation; Liver cirrhosis; Hepatitis C virus; Fibrogenesis; Parenchymal extinction; Portal thrombosis; Protein C

Core tip: Liver cirrhosis may be considered a pro-thrombotic condition despite it being associated with a low platelet count and deranged synthesis of clotting factors. When hepatitis C virus (HCV) is the etiological factor of liver cirrhosis, intrahepatic coagulation may

be enhanced by several direct actions of HCV on the clotting system, platelet aggregation, and altered anticoagulation. The excessive thrombin generation may be related to increased fibrogenesis both by a direct effect of thrombin on hepatic stellate cells and fibrosis related to ischemic parenchymal extinction.

Thrombin activation and liver inflammation in advanced hepatitis C virus infection. *World J Gastroenterol* 2016; 22(18): 4427-4437 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4427.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4427

INTRODUCTION

Liver damage in hepatitis C virus (HCV) infection includes a wide range of clinical entities. Chronic infection may lead to chronic hepatitis, with more or less marked steatosis and/or steatohepatitis, cirrhosis, and hepatocarcinoma. In advanced stages of HCV infection, recent research has pointed out the importance of thrombotic events and microcirculatory changes within the liver. As in other forms of cirrhosis, but probably with a higher prevalence, in HCV-infected patients thrombin formation with accompanying microthrombosis of portal vein radicles takes place, a phenomenon that may accelerate the natural history of the disease. The factors involved in this process, and the clinical relevance of this prothrombotic situation are reviewed in the present work.

HEMOSTATIC SYSTEM

Coagulant and anticoagulant pathways: A schematic overview

Hemostasis, in its wide sense, involves adhesion, aggregation, and activation of platelets (primary hemostasis), and the formation of a fibrin clot as the final product of an autocatalytic process initiated by the damaged endothelium. As shown in Figure 1, thrombin, a protein derived from the action of activated factor Ⅹ on prothrombin, plays a central role. Thrombin promotes platelet activation and aggregation, and activates factor XI, factor Ⅷ and factor Ⅴ, creating a positive feed-back loop that underscores the need of a counter-regulatory system. This is composed by antithrombin, tissue factor pathway inhibitor, thrombomodulin, liver synthesized vitamin-K dependent protein C and its endothelial receptor, and protein S. Thrombomodulin is a transmembrane protein located on endothelial cells, in intimate connection with endothelial protein C receptor (Figure 2). Thrombomodulin acts as a thrombin receptor. Once thrombin and protein C bind to thrombomodulin and protein C receptor, protein C becomes quickly activated by thrombin, a process highly dependent on thrombomodulin. Once activated, protein C binds to protein S. This complex inhibits activated factor Ⅴ and factor Ⅷ, leading to decreased thrombin generation (Figure 2). Thrombin generation is also quenched by the presence of antithrombin, a protease with many actions, also synthesized in the liver, and tissue factor pathway inhibitor (Figure 1), whose levels are not decreased, but even increased in cirrhosis[1]. Antithrombin strongly inhibits thrombin, but also inhibits the activated forms of factors XII, XI, Ⅹ, Ⅸ and Ⅶ; plasmin and kallikrein, trypsin and C1[2-4]. Tissue factor pathway inhibitor forms a complex with factor Xa, inactivating it; and also blocking the tissue factor-factor Ⅶa complex. Like thrombomodulin, tissue factor inhibitor is an endothelial product[5] and, as discussed later, both may become altered in hepatitis C-dependent endothelial damage.

Platelets constitute another key component of hemostasis. Endothelial disruption exposes subendothelial collagen to the bloodstream, and this is followed by an avid binding of collagen to collagen-specific Ia/Ⅱa platelet surface receptors. Another endothelial-derived multimeric protein, von Willebrand factor, firmly interacts with platelet glycoproteins Ib/Ⅸ/Ⅴ and collagen fibrils. The function of this multimeric protein is controlled by a metalloprotease (ADAMTS 13), synthesized by several cells, including hepatic stellate cells and endothelial cells, among others[6]. Binding of collagen to glycoprotein Ⅵ receptor activate the platelets - a process also facilitated by thrombin which activates platelets by binding to other types of receptors, namely specific G protein receptors. Activated platelets release several products contained in their granules, including potent proinflammatory mediators, and finally aggregate and form a hemostatic plug. Aggregated platelets efficiently anchor fibrin, forming a plug that stops bleeding. Platelet membrane phospholipids bind to the gamma carboxy residues of activated factors Ⅸ and Ⅹ, serving as a "platform" on which coagulation takes place. Calcium mediates this binding.

In order to avoid excessive thrombus formation, fibrinolysis is activated. This is also a tightly regulated process, by which an inactive protein - plasminogen - transforms into an active one - plasmin, which is able to destroy formed fibrin. A series of substances, such as tissue plasminogen activator, factor XIIa, and urokinase plasminogen activator transform plasminogen into plasmin, whereas several others block this effect. Indeed, plasminogen activator inhibitor, thrombin activatable fibrinolysis inhibitor (TAFI)[7], plasmin inhibitor, and histidine rich glycoprotein are all potent antifibrinolytic agents.

Thrombosis in HCV infection

There is considerable evidence that the hepatitis C

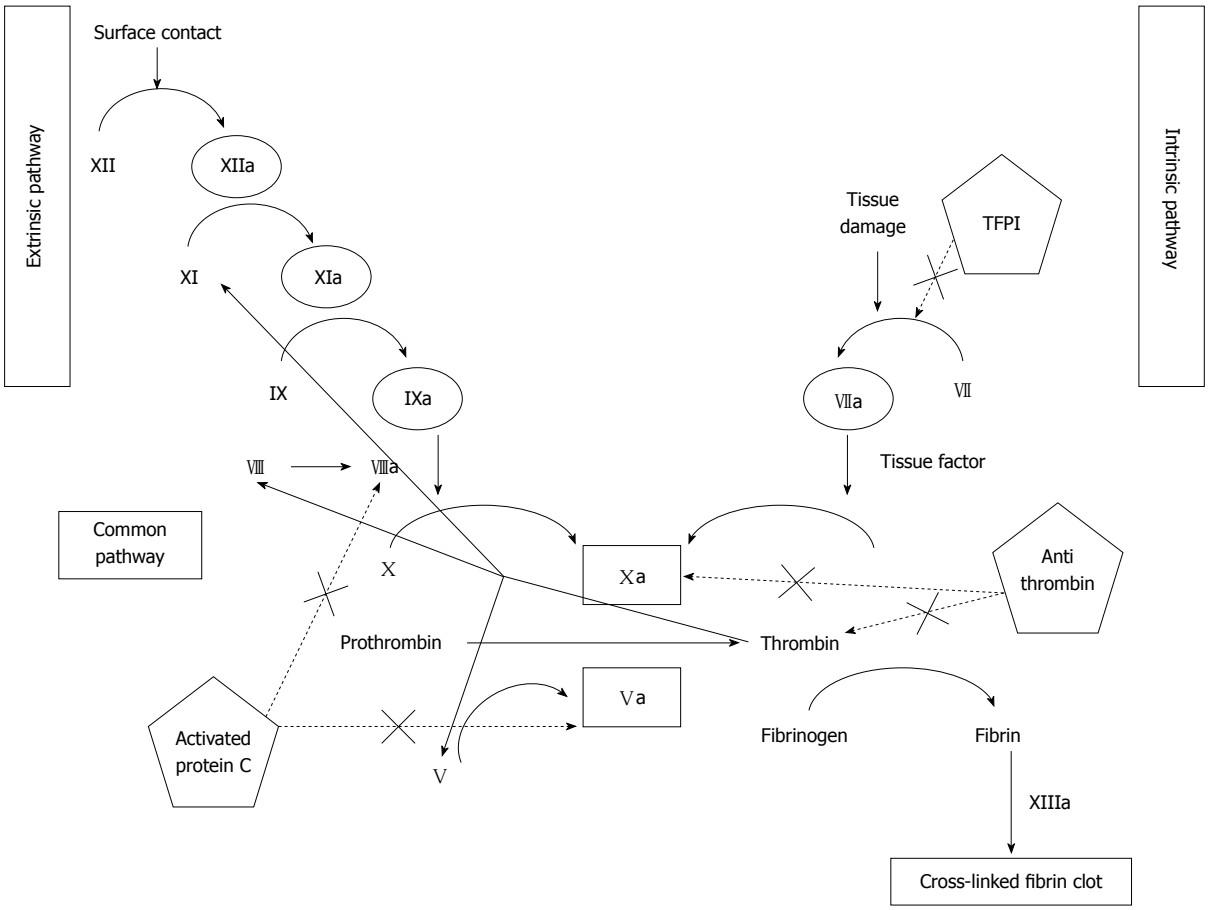

Figure 1 Coagulation cascade: Extrinsic, intrinsic, and common pathways. Coagulation factors are depicted in roman numerals with the suffix "a" denoting activated forms of the factors. Inhibitory pathways are shown in dotted lines. TFPI: Tissue factor pathway inhibitor.

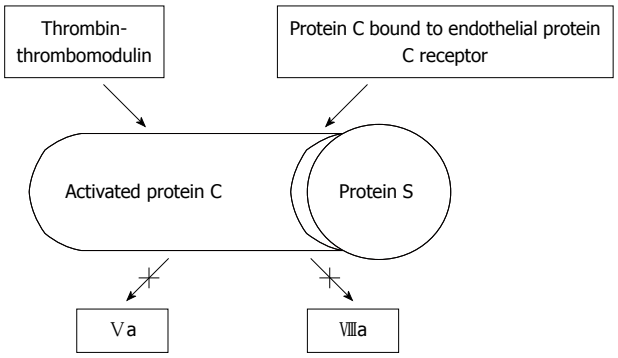

Figure 2 Anticoagulant effect of thrombomodulin, protein C, and protein S.

virus is able to activate hemostasis through several mechanisms, one of the main processes being HCV-induced endothelial damage and/or activation. Several clinical observations that are outlined below support this evidence (Figure 3).

In 1996, Prieto *et al*[8] reported an increased prevalence of anticardiolipin antibodies among HCV patients. This increased prevalence was related to prior thrombotic episodes, portal hypertension and thrombocytopenia. In a study on 201 patients, 124 of them with HCV infection, Biron *et al*[9] found a 33% prevalence of antiphospholipid antibodies that were significantly associated with increased liver fibrosis assessed by METAVIR fibrosis score. A relationship between HCV infection and prothrombotic state was also evidenced by Enger *et al*[10] (2014), who found that HCV infection was associated with various kinds of thromboembolic diseases in a cohort of 22733 HCV infected individuals in the United States. The incidence rate ratio among non-cirrhotic HCV infected patients was 1.44 (95%CI: 1.31-1.58) for any thrombotic event, and reached 6.06 (95%CI: 2.04-18.01) for portal vein thrombosis. Wang *et al*[11] compared 3686 HCV-infected patients with 14744 subjects without HCV or HBV infection and followed them during more than 5 years. They found that HCV infection was associated with a hazard ratio of deep vein thrombosis of 1.96 (95%CI: 1.03-3.73). Chen *et al*[12] in 2013 found a higher prevalence of pulmonary hypertension among HCV patients, portal vein thrombosis (a feature commonly present in their series of HCV patients) being an independent factor. However, other authors have failed to find a relationship between antiphospholipid antibodies and thrombotic episodes in HCV patients[13,14], although antiphospholipid antibodies were more frequently observed among HCV patients. Already in 1995, Violi *et al*[15] performed a study on 18 patients with liver cirrhosis and 36 controls and found that

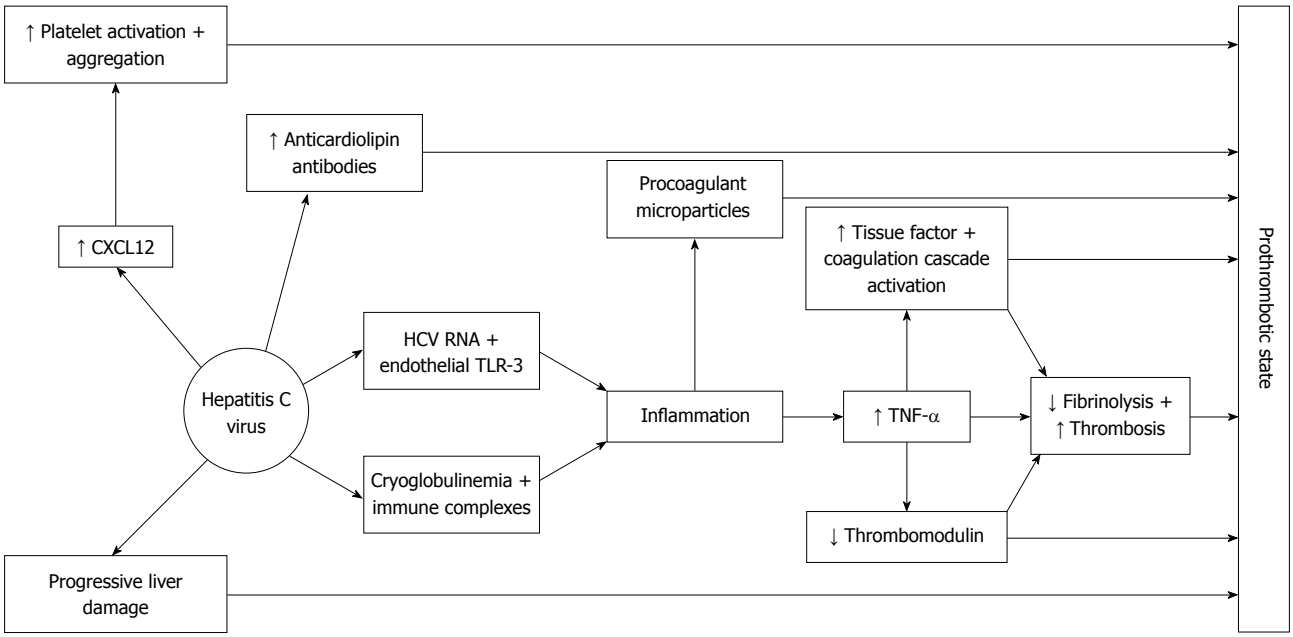

Figure 3 Hepatitis C virus has several effects on anticoagulant and procoagulant cascades, in addition to the effects on coagulation derived from liver cirrhosis development. (1) Hepatitis C virus (HCV) infection is associated with anticardiolipin antibodies which are related to thrombotic events; (2) Viral HCV RNA binds to toll-like receptors (TLR)-3 found in endothelial cells which leads to inflammation. Also, HCV infection is associated with cryoglobulinemia and thus immune complexes directed against viral RNA are formed. Inflammation generated by these two mechanisms lead to TNF-α secretion. TNF-α is an inducer of tissue factor expression, therefore exerting a prothrombotic effect by activating the coagulation cascade and also downregulates thrombomodulin expression; and (3) In HCV infection, CXCL12 is up-regulated in the endothelium of blood vessels formed in active inflammatory foci. CXCL12 is a potent promoter of platelet aggregation and adhesion.

venous thrombosis was associated with HCV infection, positive antiphospholipid antibodies, and increased rate of thrombin generation.

Main mechanisms involved

The mechanisms that may contribute to thrombosis in HCV infection include: systemic inflammation due to viral infection, direct infection of endothelial cells, viral-induced down regulation of physiological anticoagulant mechanisms, and alterations of fibrinolysis and thrombin generation dependent upon tissue factor generation by the infected endothelium[16]. The generation of antiphospholipid antibodies associated with HCV infection may also favor the generation of a procoagulant milieu[8], and immune complexes, usually in relation to cryoglobulinemia, may also trigger thrombotic phenomena[17].

Direct effect of HCV on anticoagulant and procoagulant pathways

Activation of tissue factor is of primary importance in the initiation of the coagulation cascade; and, as previously mentioned, damaged endothelium is the main source of tissue factor. Endothelial damage takes place in HCV infected patients, mainly by two main mechanisms. Firstly, today it is well known that HCV viral RNA binds to toll-like receptor (TLR)-3 in endothelial cells leading to inflammation[18] and generating enhanced expression of both tumor necrosis factor (TNF)-α and TNF receptor 2. In advanced stages of the disease, endothelial cells also express the chemokine CXCL 12 that recruits immune cells[19]. Additionally, endothelial damage associated with cryoglobulinemia is due to a type 3 hypersensitivity reaction with formation of immune complexes of antibodies directed against viral RNA. These immune complexes activate endothelial cells[20]. Inflammation generated by either of these mechanisms is accompanied by TNF-α secretion. TNF-α is an inducer of tissue factor expression, therefore exerting a prothrombotic effect[21] and also down-regulates thrombomodulin expression[22]. Cytokines decrease fibrinolytic properties of the endothelial cells[23]. In addition, tissue factor is present in increased amounts in microparticles in patients with chronic pure HCV infection[24], contributing in this way to enhanced coagulation.

HCV infection and platelets

Hemostatic platelet function is also enhanced. In patients affected by HCV infection, CXCL12 is up-regulated in the endothelium of blood vessels formed in active inflammatory foci. It is elevated in the plasma of patients with marked fibrosis and avidly binds to CXCR4 overexpressed by liver infiltrating lymphocytes[19]. CXCL12 is a potent promoter of platelet aggregation and adhesion[25], and, indeed, increased platelet activation and aggregation have been described among HCV patients[26,27].

Perhaps this increased platelet aggregation may explain some striking features described in HCV

patients regarding platelet count. Thrombocytopenia is more marked in HCV-infected patients than among those affected by other forms of chronic liver disease in a similar stage of severity[28]. The reasons are not well understood[29,30], and there are reports in which thrombocytopenia improves after treatment with interferon alpha[31]. This effect is seen despite the fact that thrombocytopenia is a well known side effect of interferon alpha, which strongly suggests a direct causal relationship between thrombocytopenia and HCV infection. Theoretically, thrombocytopenia could be due to decreased production, but results regarding thrombopoietin levels are disparate. Español *et al*[32], in 2000, found normal values in 23 HCV patients with chronic hepatitis compared with 43 controls, but there are also reports pointing to decreased thrombopoietin levels in relation with progression of liver disease[33,34], and restoration of megakariopoiesis after successful liver transplantation[35]. These data suggest that liver function is essential for the maintenance of normal thrombopoietin levels, although it has been also reported that thrombopoietin may be degraded in excess by the enlarged spleen[36]. Thrombocytopenia could also be related to hypersplenism, but although splenic sequestration surely plays a role in advanced stages of liver disease, thrombocytopenia is already evident before spleen enlargement ensues. Antiplatelet antibodies have been described in HCV infection[37], but their pathogenetic role in thrombocytopenia is debatable[38]. However, in some studies the severity of the disease is accompanied by a progressive decrease of platelet production and an increase in platelet antibodies. Platelet count was inversely related to liver fibrosis and directly to viral load[39].

In any case, increased coagulation and decreased fibrinolysis, together with enhanced platelet aggregation may underlie the aforementioned well described relationship between HCV infection and venous thrombosis. When liver damage evolves during the natural history of chronic HCV hepatitis, further mechanisms add to those described.

Prothrombotic alterations associated with liver cirrhosis

Complications of liver cirrhosis probably account for most of the hospital admissions of patients with advanced HCV liver disease. As other forms of liver cirrhosis, cirrhosis in patients affected by chronic HCV infection is characterized by progressive fibrous tissue deposition in the liver that separates groups of hepatocytes forming nodules with distorted vascular architecture and variable degrees of necrosis and liver cell regeneration[40].

Two syndromes converge in this disease: liver failure and portal hypertension, leading to a constellation of clinical and laboratory alterations, some of them theoretically associated with increased bleeding risk. Among these, the most outstanding features related to portal hypertension include the development of oesophageal varices, hypertensive gastritis, hemorrhoids, and hypersplenism; secondary thrombocytopenia is usually found in these patients. Liver failure impedes correct synthesis of clotting factors, such as prothrombin or, in later stages, fibrinogen. Therefore, both syndromes may cause bleeding diathesis. However, in stark contrast, thromboembolic events are not unusual in cirrhosis[41,42], with an overall incidence of 0.8% of non portal vein thrombosis in a study on 2074 cirrhotic patients[43]. In that study, although 5 out of the 17 affected patients showed antiphospholipid antibodies, none of them showed mutation of factor V and/or prothrombin, so no other classic prothrombotic abnormality was identified. On the other hand, the incidence of portal vein thrombosis is by far higher among cirrhotics than among the general population, reaching prevalence values of 0.6%-5%, increasing up to 40% among patients with advanced disease, or 10%-25% according to other reports[44]. Local factors, such as venous stasis and portal hypertension-related endothelial dysfunction are clearly involved in this type of venous thrombosis, but it is worth of note that considering all the forms of venous thromboembolic disease together, cirrhotic patients showed an increased risk, that was more marked among patients with cirrhosis categorized as Child class C, despite a more deranged prothrombin activity[45].

Therefore, liver cirrhosis, despite a usually observed low platelet count and deranged synthesis of some clotting factors, may be considered a prothrombotic condition.

Anticoagulant and procoagulant pathways in cirrhosis

Independent of etiology, recent research has pointed out that in liver cirrhosis several alterations predispose to an increased thrombotic risk, especially at the portal vein.

Synthesis of antithrombotic proteins, such as antithrombin, protein C and protein S is more intensely deranged than that of procoagulant proteins. As mentioned earlier, protein C plays a major role in controlling coagulation. In its active form it degrades several coagulation factors, especially factor V, leading to a decrease in thrombin production. Decreased synthesis of protein C by an impaired liver function may favor ongoing thrombin formation[46]. Binding of thrombomodulin to protein C increases the speed of protein C activation. Interestingly, in a previous study we found raised levels of thrombomodulin among cirrhotics, in the face of decreased protein C, protein S and antithrombin[47]. However, thrombomodulin-bound thrombin also shows a prothrombotic effect, since it inhibits fibrinolysis by cleaving TAFI into its active form[48]. Therefore, raised thrombomodulin, *via* its action on TAFI, can be viewed as another factor potentially involved in the procoagulant milieu of liver cirrhosis.

Thrombin activation may be aggravated in some

situations in which anticoagulant pathways are further impaired. Factor Ⅴ Leiden is a common (2%-15% prevalence among Caucasians) autosomal dominant trait[49]. It carries a single mutation at position 506 that makes it resistant to the degradative action of activated protein C. As a consequence, the action of factor Ⅴa on thrombin synthesis increases, leading to a procoagulant state. Indeed, factor Ⅴ Leiden is associated with an increased risk of portal vein thrombosis both in patients with and without cirrhosis[50]-although there are studies that do not support this finding[51]. In addition, in patients with HCV infection who also bear factor Ⅴ Leiden polymorphism there is an increased rate of liver fibrous tissue deposition[52], whose underlying mechanisms will be discussed later. Poujol-Robert *et al*[53], in 2004, reported an increased odds ratio for cirrhosis among patients with HCV infection and factor V Leiden mutation, and Papatheodoridis *et al*[54] (2003) found that the presence of activated protein C resistance was associated with more intense fibrosis in patients with chronic viral hepatitis. Moreover, factor Ⅴ Leiden also carries an increased risk of fibrosis in other tissues, as shown by Xu *et al*[55] (2001) in pulmonary fibrosis that developed in bleomycin-treated mice carrying the factor Ⅴ Leiden mutation: both homozygous and heterozygous animals showed a nearly 40% increase in hydroxyproline excretion compared to wild-type mice.

Other factors may contribute to this pro-coagulant effect. Persistent or chronic inflammation is a thrombophilic condition, characterized by raised fibrinogen and factor Ⅷ, which are main contributors to this procoagulant milieu. Cirrhotics show raised levels of factor Ⅷ[56]. Also, cirrhotics have raised von Willebrand factor, which may favor a greater platelet adhesion[57]. Lipoprotein receptor-related protein is responsible for catabolism of factor Ⅷ. Its expression is decreased in cirrhotics[58]. In a similar fashion, ADAMTS-13, a metalloprotease involved in the catabolism of von Willebrand factor, is reduced in patients with liver cirrhosis[59]. Increased fibrinolysis related to decreased PAI-1 levels in relation to t-PA were also reported in cirrhotics[60], and a parallel deficiency in other mediators, such as TAFI, probably contributes[61]. It is currently accepted that hyperfibrinolysis may affect 30%-50% of cirrhotics with advanced disease[62].

Endothelial alterations of the portal vein radicles are well described in liver cirrhosis[63]. Endotoxaemia possibly plays a relevant role in endothelial alterations[64], independent on the eventual direct effects of HCV infection. As mentioned above, altered endothelium promotes coagulation by activation of tissue factor. In cirrhotics there is also an increase in the expression of several adhesion molecules, including platelet-endothelial cell adhesion molecule-1 (PECAM-1), L-selectin and P-selectin[65], and, as just mentioned, increased levels of von Willebrand factor[57].

Activated endothelial cells, as well as monocytes and platelets, also lead to the formation of microparticles that also carry tissue factor. In addition, platelet derived microparticles are able to transfer the GⅡb-Ⅲa platelet receptor to leukocytes, a feature which leads to the activation of the nuclear transcription factor kappa B, inducing gene transcription of proinflammatory mediators[66]. In addition platelet microparticles are able to carry factor Ⅴ[67]. Some studies point to an increased production of microparticles derived from leukocytes, lymphocytes, erythrocytes or even hepatocytes in liver cirrhosis[68]; despite some assertions[69], other researchers have failed to find raised platelet-derived microparticles in cirrhotic patients[70].

In summary, cirrhotics show more depressed levels of anticoagulants than those of procoagulants; although the role of microparticles in liver cirrhosis is unclear, portal hypertension-related endothelial damage and endotoxin-mediated cytokine activation, together with altered fibrinolysis in some cases, all contribute to the prothrombotic state of these patients, with increased thrombin formation.

Platelets are also altered in liver cirrhosis, both in number and function. Decreased platelet number may be due to splenic pooling due to portal hypertension, lower thrombopoietin levels, and increased consumption due to endotoxaemia, increased antiplatelet antibody production, and increased coagulation activation[69], but no significant bleeding takes place if platelet count is over 60000/fl[71]. Qualitative platelet alterations include defective adhesion[72], partially compensated by increased von Willebrand factor; decreased aggregation in response to normal stimuli, such as ADP, ristocetin, thrombin, collagen or epinephrine[73] and altered function[26] which progresses as liver function worsens. The aforementioned increased production of prothrombotic platelet-derived microparticles may compensate for these defects, so that hemostasis does not become significantly altered. On the contrary, portal thrombotic events may occur if a thrombopoietin receptor agonist (Eltrombopag) is administered[74], despite a median maximum platelet count of 148000/fl.

All these factors add to the previously mentioned direct effects of HCV infection, explaining why in HCV liver cirrhosis the thrombotic complications are more frequently observed than in cirrhosis of other etiologies.

CONSEQUENCES OF INCREASED THROMBIN FORMATION

Thrombin and fibrous tissue deposition: Direct effects on fibrogenesis

Thrombin not only plays a central role in the coagulation system. The importance of increased thrombin activation in patients with liver cirrhosis resides in the fact that thrombin may be directly involved in fibrogenesis (Figure 4). Thrombin exerts this action after binding to a group of receptors called protease activator receptors (PAR). There are four of such

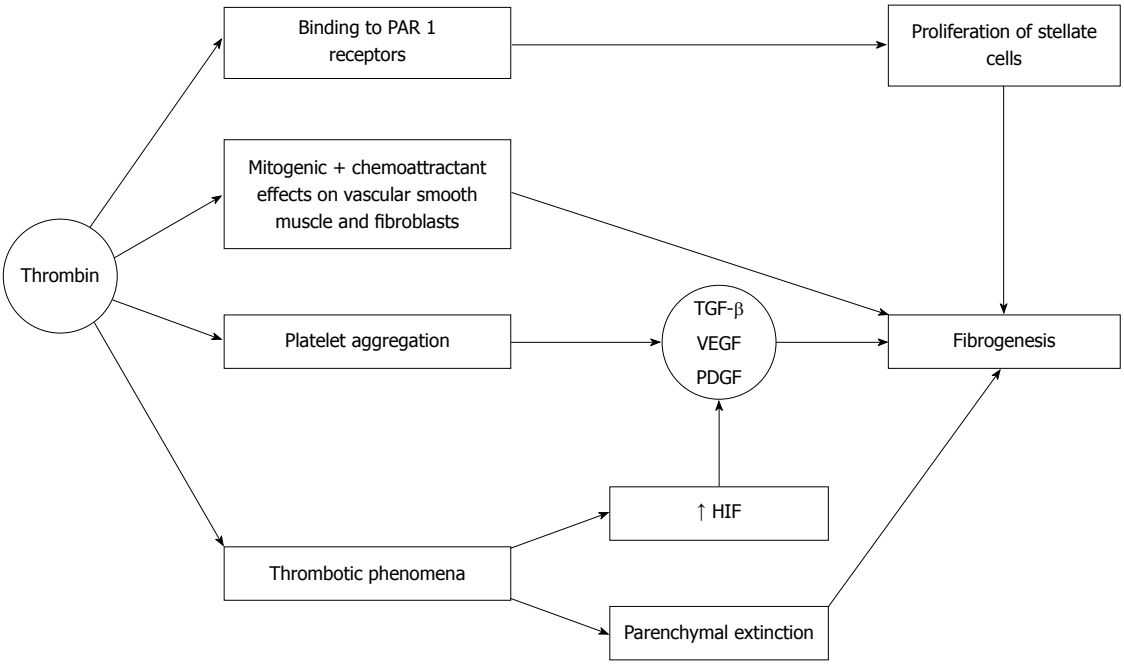

Figure 4 Effects on thrombin on fibrogenesis. Thrombin binds to PAR-1 receptors on hepatic stellate cells which leads to proliferaton and activation of these cells Thrombin also promotes platelet aggregation. Platelet alpha granules are rich in several growth factors, including TGF-β, which in turn promotes fibrogenesis. Vascular endothelial growth factor (VEGF) and PDGF also play contributory roles. Thrombin also exerts mitogenic and chemoattractant effects on vascular smooth muscle cells and fibroblasts. Finally, thrombotic phenomena also occur within the liver, leading to ischemic parenchymal injury, and substitution of parenchyma by fibrous tissue (the so called parenchymal extinction). When a clot provokes ischemia, VEGF, PDGF and TGF-β are activated probably *via* an increase in hypoxia-inducible-factor (HIF), which is raised in cirrhosis in relation to portal microthrombotic phenomena.

type of receptors (1-4), which become activated by several different proteases including thrombin (which activates PAR 1, 3, 4), and tryptase, which activates PAR-2, providing a rational basis to sustain the finding of liver fibrosis in the context of systemic mastocytosis[75]. PAR-1 receptors are present in the liver, and increase their expression in advanced liver disease[76] and along the transformation of stellate cells into myofibroblasts[77]. Indeed, hepatic stellate cells are one of the main cells in which these receptors become up-regulated in chronic liver disease. Binding of PAR with their ligands on stellate cells leads to proliferation and activation of these cells, that secrete monocyte chemoattractant protein 1 (MCP-1), increase deposition of extracellular matrix and the expression of receptors for platelet derived growth factor (PDGF) and transforming growth factor (TGF)-β[78]. In addition MCP-1 attracts monocytes, that produce tissue factor which contributes to more thrombin generation[79].

Another well known effect of thrombin is the ability to promote platelet aggregation. Platelet alpha granules are rich in several growth factors, including TGF-β, which in turn promotes fibrogenesis. Vascular endothelial growth factor (VEGF) and PDGF also play contributory roles. PDGF is a very strong mitogen for stellate cells and it also promotes fibrogenic activity by these cells[80]. PDGF upregulates the expression of matrix metalloproteinase (MMP)-2, MMP-9 and tissue inhibitor of metalloproteinase (TIMP)-1 and downregulates that of collagenase[40].

Thrombin also exerts mitogenic and chemoattractant effects on vascular smooth muscle cells and fibroblasts[81]. Factor Xa also activates PAR-1 and PAR-2, and may lead to fibrous tissue deposition. It was shown that incubation of fibroblasts with factor Xa led to a 12.6-fold increase in TGF-β expression, an increase which was by far more intense than that elicited when the cells were stimulated by thrombin[82].

Therefore, thrombin, both directly and indirectly, together with other activated coagulation factors, may play a role in the progression of liver cirrhosis, *via* the described effect on fibrogenesis.

Thrombin and clot formation: Parenchymal extinction and fibrogenesis

In addition to thrombosis of major veins, microthrombotic phenomena also occur within the liver, leading to ischemic parenchymal injury, and substitution of parenchyma by fibrous tissue (the so called parenchymal extinction[83]). This phenomenon consists in the ischemic collapse of hepatocytes between portal vein radicles and hepatic central venule, and becomes strongly exacerbated if congestive phenomena coexist, such as heart failure[84]. Coalescence of neighbouring tracts could lead to the formation of gross fibrous tracts and the evolution to cirrhosis[85]. When a clot provokes ischemia, VEGF, PDGF and TGF-β are activated[86] probably *via* an increase in hypoxia-inducible-factor (HIF), which is raised in cirrhosis due to increased portal resistance[87].

However, there are studies that do not support a pathogenetic role of portal vein thrombosis on progression of liver disease[88], but, as discussed above, factor V Leiden seems to accelerate progression of fibrosis in HCV infected patients. In other studies, other prothrombotic conditions such as hyperhomocysteinaemia[89] or mutations in factor XIII (both as an isolated finding or in combination with PAI-1 4G/5G mutation) also constitute a risk factor for an increased rate of liver fibrosis development in patients affected with HCV or chronic hepatitis B[90]. In other studies, the mutation associated with increased fibrosis progression rate was the prothrombin G20210 A mutation[91].

These data support the importance of microthrombotic phenomena in the progression of liver disease, especially in HCV-infected patients, in whom the endothelial changes promoted by HCV may be considered triggering factors, aggravated in later stages of the disease by the endothelial changes secondary to portal hypertension.

Therapeutic future prospects

Based on the aforementioned data, low molecular weight heparin has been advocated as a therapeutic option in patients with cirrhosis, with promising results: enoxaparin for 48 wk not only significantly prevented the development of portal vein thrombosis in patients with cirrhosis with Child-Pugh scores between 7 and 10, but it also associated with a decreased probability of decompensation of liver disease[92]. In that study, 18 out of 34 randomized to enoxaparin and 18 out of 36 in the placebo group were HCV-infected patients. Experimental research in rats has shown that treatment with heparin reduced severity of biochemical and histological changes induced in rats with oral carbon tetrachloride[93]. The possible role of anticoagulation in the treatment of advanced liver disease, especially in HCV-induced cirrhosis, is a promising idea that warrants confirmation[94].

Abstract

Great progress has been made in the field of liver transplantation over the past two decades. This progress, however, also brings up the next set of challenges: First, organ shortage remains a major limitation, and accounts for a large proportion of wait list mortality. While living donation has successfully increased the total number of liver transplants done in Asian countries, the total number of such transplants has been stagnant in the western hemisphere. As such, there has been a significant effort over the past decade to increase the existing deceased donor pool. This effort has resulted in a greater use of liver allografts following donation after cardiac death (DCD) along with marginal and extended criteria donors. Improved understanding of the pathophysiology of liver allografts procured after circulatory arrest has not only resulted in better selection and management of DCD donors, but has also helped in the development of mechanical perfusion strategies. Early outcomes demonstrating the clinical applicability of both hypothermic and normothermic perfusion and its potential to impact patient survival and allograft function have generated much interest. Second, long-term outcomes of liver transplant recipients have not improved significantly, as recipients continue to succumb to complications of long-term immunosuppression, such as infection, malignancy and renal failure. Furthermore, recent evidence suggests that chronic immune-mediated injury to the liver may also impact graft function.

Key words: Donation after cardiac death; Mechanical perfusion; Renal-sparing immunosuppression; Antibody-mediated rejection

Core tip: Organ shortage remains a major limitation in liver transplantation, and there has been a significant effort over the past decade to increase the existing deceased donor pool. Recent advances have included better selection and management

of donors after circulatory arrest, application of hypothermic and normothermic perfusion, minimization of standard immunosuppression and use of new immunosuppressive medications. Additionally, there has been renewed emphasis and understanding of liver immunology and the impact of antibody-mediated rejection. Together, these advances have allowed for expansion of the donor pool with concurrent improved patient outcomes.

INTRODUCTION

Over the last several decades, the field of transplantation has witnessed much change yet, among all solid organ transplants, arguably the greatest advances have been in liver transplantation. Today, liver transplantation is universally accepted as the only treatment option for end-stage liver disease, acute fulminant hepatic failure, hepatocellular carcinoma, hilar cholangiocarcinoma and several metabolic disorders. Advancements in surgical technique, perioperative management and immunosuppressive therapy have yielded excellent short-term graft and patient survival outcomes which have become the expected norm. With these advances comes the next set of challenges: organ shortage and improving long-term outcomes of the liver transplant recipients.

ORGAN SHORTAGE

The disparity between the number of available liver allografts and transplant candidates continue to grow worldwide. In Asia, this problem has been successfully addressed by ever-increasing numbers of living-donor liver transplantation (LDLT). In the western countries, however, the number of LDLT has not seen a significant change for over a decade, and the demand for deceased donor liver allografts continue to increase. Thus, substantial effort has been put in to expand the existing deceased donor pool.

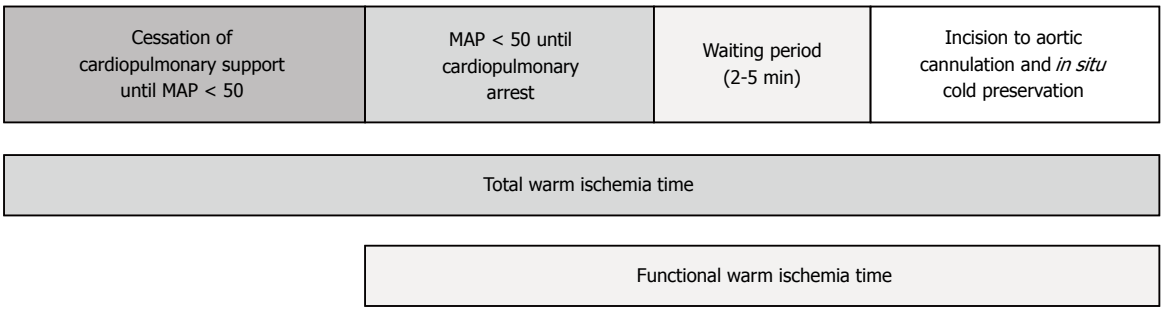
Use of donation after cardiac death liver allografts

In the early 1990s, the use of livers procured from donation after cardiac death (DCD) donors was an early attempt to narrow the disparity between organs and recipients in need[1]. The early experience with DCD livers was not favorable, as prolonged donor warm ischemia time and ischemia-reperfusion injury likely played a large role in the high rate of primary non-function, hepatic artery thrombosis, ischemic cholangiopathy, and allograft failure[2,3]. With increasing experience, however, factors associated with improved outcomes have been identified and more centers have begun to use these donors[4-6].

To date, there have been several large retrospective analyses which have identified DCD donor-related variables associated with recipient outcomes (Figure 1). Young age (45 ± 10 years old), short donor warm ischemia time (less than thirty minutes), and limited cold ischemia time (less than ten hours) have been shown to improve allograft outcomes[4-6]. In the Mayo Clinic experience, every minute added to the warm ischemia period between asystole and cross-clamp was found to be associated with a 16.1 percent increase in the odds of ischemic cholangiopathy[6]. Recipient factors associated with improved DCD outcomes generally concentrate on avoidance of sicker patients: excluding patients requiring retransplantation, patients with renal failure (creatinine > 2.0 mg/dL) and patients on life support[5]. The correlation between these factors and outcomes is likely related to minimization of both cold ischemia time and further allograft injury through recipient instability. As a result, by applying these donor and recipient criteria, DCD outcomes have improved considerably with recipient survival and allograft function similar to that of donation after brain death (DBD) donors[4-6].

Mechanical perfusion of deceased donor liver allografts

Despite these improved outcomes, many DCD livers continue to go unused as a result of unacceptable donor parameters and concern for poor allograft function. The concept of mechanical perfusion for solid organ transplantation was originally introduced in the late 1960s by Belzer *et al*[7] and renewed interest returned following a report by Moers *et al*[8] in 2000 which, through a prospective randomized control trial, demonstrated a decreased incidence of delayed graft function and improved graft survival in in kidney transplant recipients. Since then, hypothermic machine perfusion in kidney transplantation has gained a widespread use. Although suboptimal, static hypothermic cold storage remains the primary method for liver preservation, largely because of its cost effectiveness, simplicity, and logistics. At present, there is a large and apparent need to optimize preservation particularly for DCD, marginal, and extended-criteria donor organs. These allografts are subject to a greater risk of ischemia-reperfusion injury which occurs as a result of donor warm ischemia time, aortic cross-clamping and initiation of cold ischemia, rewarming during graft implantation, and finally full reperfusion (Figure 1). It is here that the utility of mechanical perfusion has emerged as potential solution to this problem.



Ref.	Txp Period	No. Patients	Donor Age	WIT	CIT	Asystole-to-cross clamp
4	1996-2006	874	⩽ 45 yr	⩽ 15 min[1]	⩽ 10 h	
5	1996-2003	367	-	< 30 min[1]	< 10 h	
6	1998-2010	200	-	-	-	Minimization of asystole-to-cross clamp time (1 min ≈ 16.1% IC)

Figure 1 Favorable donation after cardiac death donor criteria. [1]From time of cessation of cardiopulmonary support to with loss of hemodynamic and respiratory function up to the *in situ* initiation of cold preservation solution. MAP: Mean arterial pressure; WIT: Warm ischemia time; IC: Ischemia cholangiopathy.

Table 1 Comparison of hypothermic and normothermic mechanical perfusion

	Hypothermic mechanical perfusion	Normothermic mechanical perfusion
Temperature	4 ℃	37 ℃
Pathophysiology	Reduced cellular metabolism Non-functioning liver during preservation	Continued cellular metabolism Functioning liver during preservation
Perfusate	No specific requirements, oxygen can be used	Continuous delivery of nutrients and oxygen needs to be maintained
Logistics	Similar to that of hypothermic mechanical perfusion currently used for renal allografts	More complex
Benefits	Logistically easier May provide benefit in marginal livers	Allows for the assessment of metabolic and synthetic function during preservation May provide benefit in marginal livers Potential use in steatotic livers Felt to reduce ischemia reperfusion injury

Hypothermic perfusion

Hypothermia slows cellular metabolism and prolongs the amount of time an organ can be deprived of oxygen without loss of viability (Table 1). In liver transplantation, hypothermic perfusion has shown similar benefits. Authors Guarrera *et al*[9] have demonstrated that hypothermic perfusion decreases the extent of graft injury and subsequent clinical studies by the same group have shown improved allograft function, lower serum transaminases and decreased hospital stay as compared to matched historic cold storage liver allografts from DBD donors[10,11]. Equally beneficial results have been reported in DCD liver allografts[12,13]. In a trial using human DCD livers, Hypothermic Oxygenated PErfusion (HOPE) was applied for 1 to 2 h prior to implantation[12]. Functional warm ischemia time (MAP < 50 mmHg to cold flush) in this group ranged from 22 to 41 min and postoperative allograft function was normal in the entire cohort. In a follow-up period of 8.5 mo, no evidence of intrahepatic biliary complications was noted. As a continuation to this study, authors Dutkowski *et al*[13] recently published their results evaluating DCD livers treated with HOPE along with matched static cold storage DCD livers. As anticipated, results for DCD livers subjected to HOPE were superior with decreased graft injury, decreased intrahepatic cholangiopathy and biliary complications and improved 1-year graft survival[13]. Similarly, hypothermic machine perfusion has also been applied to extended criteria DBD donor liver allografts with encouraging outcomes, such as decreased allograft dysfunction (19% *vs* 30%), improved patient survival at one year (84% *vs* 80%) and a reduction in biliary complications (13% *vs* 43%)[11].

Normothermic perfusion

Normothermic perfusion is technically more demanding, as it requires a continuous delivery of nutrients and oxygen in order to maintain ongoing cellular metabolism[14]. In theory, this setup reduces the ischemia-reperfusion injury and may thereby allow for the safe transplantation of marginal liver allografts. Normothermic mechanical perfusion can also allow for the assessment of liver function during the pre-

implantation period (Table 1). Although these advantages are notable, historically, there have been difficulties in maintaining stable perfusion[15]. In a preclinical work by op den Dries *et al*[16], discarded DCD human donor livers were subjected to normothermic mechanical perfusion following cold ischemia times of 6.9 ± 1.9 h (WIT 15.5 ± 2.4 min). After six hours of normothermic perfusion (37 ℃), bile production was observed and histological examination showed well-preserved liver morphology without signs of hepatocellular ischemia, biliary injury, or sinusoidal damage[16]. Currently, there are several human trials underway comparing normothermic liver preservation with static cold storage. The first Phase I, non-randomized, prospective trial using the normothermic mechanical perfusion unit enrolled twenty transplanted livers in United Kingdom and was completed in 2014. Results from this trial demonstrated the safety and feasibility of normothermic machine preservation in human liver allografts (personal communication). In the interim, a multicenter, randomized controlled trial with enrollment plan for 260 liver allografts (130 using OrganOx©; 130 using static cold storage) is under way.

Steatotic liver allografts and mechanical perfusion

The application of mechanical perfusion to marginal donors is foreseeable as hepatic steatosis has become increasingly common in the United States and the incidence of deceased donors with steatotic livers has concurrently increased. Allografts with severe steatosis, defined as greater than sixty percent of the parenchyma, are known to carry a high risk of primary non-function[17,18]. On the contrary, liver allografts with mild steatosis (< 30%) yield results similar to those of non-steatotic liver allografts[17,18]. The outcomes of liver allografts with moderate steatosis (30% to 60%) remain variable, and often depend upon additional factors such as recipient stability, ischemia time, and mechanism of donation (*i.e.*, DBD *vs* DCD). Impaired microcirculation secondary to increased hepatocyte volume is theorized to be responsible for the relative susceptibility of steatotic livers to ischemia[19]. Cellular edema accompanying ischemia-reperfusion likely results in further obstruction of the sinusoids, thereby exacerbating this injury. Accordingly, steatotic DCD liver allografts are generally discarded as these scenarios combine several risk factors. As such, the application of mechanical perfusion may help salvage steatotic livers. At present, preclinical and clinical studies are lacking however Bessems *et al*[20] evaluated mechanical perfusion using a steatotic rat model in which they compared static cold storage and hypothermic oxygenated mechanical perfusion. Results from this animal model found that preservation of steatotic livers stored in standard cold storage resulted in more cellular injury. By comparison, the steatotic livers subjected to hypothermic oxygenated mechanical perfusion showed improved bile production and higher ATP levels[20].

IMPROVING LONG-TERM LIVER TRANSPLANTATION OUTCOMES

Although the short-term outcomes after liver transplantation have been excellent worldwide, long-term outcomes remain suboptimal. The top causes of late mortality after liver transplantation are allograft failure, cardiovascular events, infection, malignancy and renal failure[21]. There is a clear and direct link between these and the long-term use of immunosuppressive medications. As a result, in the past decade, a significant effort has been put forth to minimize immunosuppression in liver transplantation.

Renal sparing protocols

Renal insufficiency is the strongest predictor of late mortality following liver transplantation[21]. Because of this, the use of renal sparing immunosuppression protocols both during the induction and maintenance periods following liver transplantation has been introduced into the clinical practice over the past decade.

Mammalian target of rapamycin inhibitors: A number of large trials evaluated the role of mammalian target of rapamycin inhibitors (mTOR) in liver transplantation. The Preservation of Renal Function in Liver Transplant Recipients with Certican Therapy (PROTECT) study[22], a randomized controlled trial sought to evaluate the effect of conversion from calcineurin inhibitors (CNI) to everolimus starting four weeks following liver transplantation. Unfortunately, at one year, the study results proved to be inconclusive. No difference in glomerular filtration rater (GFR) was noted using the Cockcroft-Gault formula. Moreover, despite lack of clear benefit, the study did, however, observe a higher rate of infections, anemia, leukopenia and hyperlipidemia in the Everolimus treatment group[22].

By comparison, a second trial by Masetti *et al*[23] in 2010 showed some benefit in using mTOR inhibitors in liver transplantation. In this randomized control trial, cyclosporine (CsA) was used for ten days following liver transplantation. Patients were then randomized to Everolimus or cyclosporine plus mycophenolate mofetil (MMF). At twelve months, GFR was better in the Everolimus group and no differences were noted in patient survival, acute rejection or hepatic artery thrombosis[23]. Among the patients with a GFR less than 60 mL/min per 1.73 m^2, the Everolimus treatment group showed a benefit. Accordingly, conclusions of the study were that early withdrawal of CsA followed by Everolimus monotherapy in de novo liver transplant patients was associated with an improvement in renal function, although, a criticism of the study has been the baseline difference between

the two groups with regard to the starting GFR.

In Spare-the-Nephron Trial[24], patients on CNI/MMF for the first four weeks post-transplant were randomized to either continue the same regimen or convert to Sirolimus/MMF. A mean increase in patient GFR was noted in the Sirolimus group, however the composite endpoint demonstrated non-inferiority of Sirolimus to CNIs when used with MMF[24]. Review of other smaller studies evaluating the conversion from CNI to mTOR inhibitors in liver transplant patients with renal insufficiency reveals similar variable results[25-28]. A meta-analysis of the use of Sirolimus in liver transplant recipients with CNI-induced renal insufficiency found no significant improvement in GFR, risk of death or graft failure[29]. Findings were, however, significant for an increased risk of infection, mouth ulcers and treatment discontinuation[29]. Given this variability, the role of mTOR inhibitors continues to evolve with much indecision and hesitancy surrounding their use for renal insufficiency. Newer roles, specifically with regard to benefit in hepatocellular carcinoma, likewise remain to be fully realized.

Induction therapy and delayed introduction of calcineurin inhibitors: Delayed introduction of CNI following liver transplantation may, theoretically, help decrease the negative impact of CNI on renal function[30-33]. Among *de novo* liver transplant recipients who had pre-existing renal insufficiency, Thymoglobulin induction and delayed introduction of CNI resulted in lower serum creatinine, a higher estimated GFR, and less dependence on dialysis at twelve months[30]. Similar strategies have been employed using newer generation anti-interleukin-2-receptor antibodies (Basiliximab, Daclizumab) for induction[32,33]. The ReSpECT trial, comparing standard Tacrolimus *vs* reduced-dose Tacrolimus and Daclizumab induction and delayed reduced-dose Tacrolimus[34], demonstrated that the greatest decline in eGFR was seen in the standard Tacrolimus group with the least decline noted in the Daclizumab induction and delayed reduced-dose Tacrolimus group. Currently, at Mayo Clinic, Basiliximab induction is used in patients with renal insufficiency so as to delay initiation of CNI post-transplant.

Immunosuppression minimization/withdrawal: Of all the solid organs that are transplanted routinely, liver allograft appears to be unique, as approximately 19 percent of the recipients can achieve "operational" tolerance (off immunosuppression incidentally or obligatorily)[35,36]. Given these findings, several recent trials investigated elective withdrawal of immunosuppression (IS) in liver transplant recipients. In one such trial, 12 out of 20 (60%) pediatric liver transplant recipients were successfully weaned off IS, with no or minimal portal inflammation[37]. In a large European multi-center trial of 102 adult deceased donor liver transplant recipients, 41 (40%) achieved operational tolerance[38]. At present, more information is needed so as to better guide clinical decision making and similar trials with long-term follow-up will help identify parameters with predictive and diagnostic value regarding who could be successfully weaned off IS. Longitudinal follow-up of operationally tolerant patients will also further demonstrate whether long-term outcomes improve with limiting the recipients' cumulative exposure to IS, particularly CNI.

Chronic antibody-mediated injury

Historically, liver allografts were thought to be spared from the HLA antibody-mediated injury, however recent findings have challenged this concept. The Baylor group initially reported their observation in liver recipients with chronic rejection, who had circulating donor-specific HLA-antibody (DSA) more often than in patients with no rejection[39]. Subsequently, they found that multiple IgG subclasses were found in the sera of chronic rejection patients, and the IgG3 subclass was associated with increased risk of graft loss[40]. A definitive cause-and-effect relationship remains to be demonstrated however, as these studies used post-transplant DSA for analyses and did not include protocol biopsies. In our own observation at Mayo Clinic, we did not find any DSA-mediated graft injury in the first year after transplantation[41], and over the long term, de novo DSA formation was preceded by liver allograft dysfunction (*e.g.*, recurrent HCV cirrhosis)[42].

Based on these new observations, it appears that DSA may indeed cause chronic liver allograft injury, although less frequently than in kidney or hear transplantation. In order to better understand the impact of DSA on both early and late outcomes in liver transplantation, longitudinal prospective studies, similar to those done in kidney transplantation, correlating DSA (both pre- and posttransplant at routine intervals) with clinical outcomes and graft histology through protocol biopsies will need to be done. These studies will ideally be designed to analyze DSA in detail, target antigen expression in the allograft, and take into account immunosuppression and compliance issues in the recipients. In addition, histologic and genetic evidence of endothelial cell injury and microvascular inflammation (hallmark of DSA-mediated injury in kidney allografts) will need to be investigated in liver transplant recipients with circulating DSA (Table 2)[43-58].

CONCLUSION

Along with the advances made in liver transplantation over the past thirty years have come a new set of challenges. As the demand for liver transplantation continues to grow worldwide, more collaborative studies are needed to narrow the disparity between the number of available deceased donor liver allografts and wait-listed patients, and to improve the long-term

Table 2 Current data for donor-specific HLA-antibody-associated injuries in kidney and liver transplantation

	Kidney transplantation	Liver transplantation
DSA specificity and levels	↑ risk hyperacute rejection[44]; ↑ DSA in new onset late kidney allograft dysfunction[45]; acute AMR is associated with high posttransplant DSA levels[45]	↑ DSA in recipients with CR, presence of IgG3 subclass associated with ↑ risk of graft loss[40]
C4d deposition in microvasculature	Graft failure significantly worse in the presence of C4d+ staining[44]; C4d+ is a marker of antibody-mediated injury[44,46]	C4d+ staining nonspecific; In the presence of DSA, linear portal capillary and sinusoidal staining observed in ACR; DSA negative C4d+ staining found in biliary strictures and recurrent liver disease[47]
DSA subtypes, C1q binding	↓ graft survival and ↑ risk for AMR with C1q-binding DSA[48,49]	Limited data[50]
Microvascular inflammation	Peritubular capillaritis is a possible predictor of chronic AMR[51]; subclinical AMR may contribute to development of CAN[52]	No current data
EC activation by light microscopy	EC and BM ultrastructural abnormalities in glomerular and peritubular capillaries are early markers of TXG[53]	No current data
Gene expression profile of chronic AMR	Defined genetic profile in AMR[54,55]	No current data
Therapeutic-trials to prevent DSA-associated injury	Bortezomib (plasma cell-targeted therapy) as a possible antihumoral therapy[56]; plasma exchange for AMR[57,58]	No current data

Modified from Ref. 43. AMR: Antibody-mediated rejection; CAN: Chronic allograft nephropathy; EC: Endothelial cell; BM: Basement membrane; DSA: Donor-specific HLA-antibody; TXG: Transplant glomerulonephropathy.

outcomes of the liver recipients.

Abstract

The incidence of pancreatic ductal adenocarcinoma (PDA) is on the rise, and the prognosis is extremely poor because PDA is highly aggressive and notoriously difficult to treat. Although gemcitabine- or 5-fluorouracil-based chemotherapy is typically offered as a standard of care, most patients do not survive longer than 1 year. Therefore, the development of alternative therapeutic approaches for patients with PDA is imperative. As PDA cells express numerous tumor-associated antigens that are suitable vaccine targets, one promising treatment approach is cancer vaccines. During the last few decades, cell-based cancer vaccines have offered encouraging results in preclinical studies. Cell-based cancer vaccines are mainly generated by presenting whole tumor cells or dendritic cells to cells of the immune system. In particular, several clinical trials have explored cell-based cancer vaccines as a promising therapeutic approach for patients with PDA. Moreover, chemotherapy and cancer vaccines can synergize to result in increased efficacies in patients with PDA. In this review, we will discuss both the effect of cell-based cancer vaccines and advances in terms of future strategies of cancer vaccines for the treatment of PDA patients.

Key words: Pancreatic cancer; Dendritic cell; Whole tumor cell; Cancer vaccine; Cytotoxic T lymphocyte

Core tip: Chemotherapy and cell-based cancer vaccines such as dendritic cell- and whole tumor cell-based cancer vaccines can synergize to result in increased efficacies in patients with pancreatic ductal adenocarcinoma (PDA). Moreover, cell-based cancer vaccines and immune checkpoint inhibitors can be used to block inhibitory ligand/receptor interactions by acting on certain cancer cells or T cells, allowing an enhancement of the antitumor immune response in specific tumors, including PDA. Therefore, the blockade of immune regulatory checkpoints combined with cell-based cancer vaccines and/or chemotherapy may be effective in inducing adaptive antitumor immunity in patients with PDA.

Advances in inducing adaptive immunity using cell-based cancer vaccines: Clinical applications in pancreatic cancer. *World J Gastroenterol* 2016; 22(18): 4446-4458 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4446.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4446

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDA), which is derived from glandular tissue of the pancreas, accounts for approximately 95% of pancreatic cancer and is one of the most lethal cancers because of a propensity for metastatic spread[1,2]. Although the definitive treatment for early-stage PDA is surgical resection, this is only possible in approximately 15% of cases[3], as most patients with PDA present in an advanced stage at the time of diagnosis. Additionally, despite surgical resection, radiation and/or chemotherapy, patients with PDA have an overall 5-year survival of only 5% due to local recurrence and metastasis[1,2,4]. PDA cells grow rapidly and spread outside of the pancreas, including into the liver, lung, bone, and brain, through lymphatic and/or blood vessels. The current standard chemotherapy for patients with advanced PDA is gemcitabine. Gemcitabine can also be combined with nab-paclitaxel[5] or erlotinib[6], resulting in improved survival. Moreover, a multi-chemotherapy regimen (FOLFIRINOX) consisting of 5-fluorouracil, folinic acid, oxaliplatin and irinotecan has been associated with significant improvement in survival for patients with advanced PDA[7]. However, the currently used chemotherapeutic agents have still failed to demonstrate satisfactory clinical advantages in patients with advanced PDA. It has been well demonstrated that PDA is relatively resistant to chemotherapy, so new therapeutic strategies are urgently needed to improve pancreatic cancer treatment. Regarding potential targets for cancer vaccines, PDA cells express numerous tumor-associated antigens (TAAs), such as Wilms' tumor gene 1 (WT1)[8], mucin 1 (MUC1)[9], human telomerase reverse transcriptase (hTERT)[10], mutated K-Ras[11], survivin[12], carcinoembryonic antigen (CEA)[13], epidermal growth factor receptor 2 (HER-2)[14], and p53[15]. Therefore, cancer vaccines targeting these TAAs may be an alternative approach for treating patients with PDA.

INDUCTION OF ANTITUMOR IMMUNE RESPONSES

Cancer cells degrade endogenous antigens into short peptides (usually 8-10 amino acids) and present them *via* major histocompatibility complex (MHC) class Ⅰ molecules. These cells express numerous TAA-derived peptides on their cell surface as a result of malignant transformation. Meanwhile, T cells with the αβ T cell receptor (TCR) express CD4+ T cell or CD8+ T cell lineage markers[16]. Interaction of the TCR on CD8+ cytotoxic T lymphocytes (CTLs) with the complexes of antigenic peptides and MHC class Ⅰ molecules on tumor cells is a critical event in the T cell-mediated antitumor immune response. However, induction of CD8+ CTLs also requires antigenic peptides to be presented on the surface of antigen-presenting cells (APCs) in the context of MHC class Ⅰ molecules. It has become clear that dendritic cells (DCs) are the most potent APCs in the human body and play a pivotal role in the initiation, programming, and regulation of antitumor immune responses[17]. DCs can process endogenously synthesized antigens into peptides, which are presented on the cell surface as peptide/MHC class Ⅰ complexes, but require activation signals to differentiate and eventually migrate to the regional lymph nodes, where they are recognized by the αβ TCR on CD8+ T cells[17]. Moreover, DCs capture and process exogenous antigens and present peptide/MHC class Ⅰ complexes through an endogenous pathway *via* a process known as antigen cross-presentation[18]. This cross-presentation is essential for the initiation of $CD8^+$ CTL responses[19]. In contrast, exogenous antigens from the extracellular environment are captured and delivered to the compartments of the endosome/lysosome, where they are degraded into antigenic peptides, which are then complexed with MHC class Ⅱ and recognized by the αβ TCR of CD4+ T cells[17]. Finally, mature DCs can present TAAs to naive CD4+ and CD8+ T cells in the regional lymph nodes; these T cells then differentiate into activated T cells. It is well known that in the induction of efficient CD8+ CTL responses against cancer cells, CD4+ T cells are essential for the priming of CD8+ CTLs through activation of APCs and production of interleukin (IL)-2 and interferon (IFN)-γ[20]. CD4+ T cells also play an important role in the maintenance and infiltration of CD8+ CTLs at a tumor site[21]. Therefore, activation of antigen-specific CD4+ and CD8+ T cell responses by

cell-based cancer vaccines, such as either DCs loaded with TAAs or modified whole tumor cells, is essential to induce efficient antitumor immunity against pancreatic cancer cells[22].

PDA cells can evade immune control through several mechanisms. One major mechanism is the immunosuppressive tumor microenvironment. The microenvironment in pancreatic cancer in particular consists of PDA cells and stroma cells, such as cancer-associated fibroblasts (CAFs), tolerogenic DCs, myeloid-derived suppressor cells (MDSCs), immunosuppressive tumor-associated macrophages (TAMs), and regulatory T cells (Tregs). Importantly, PDA cells themselves induce immune suppression through production of immunosuppressive substances such as cytokines [*e.g.*, transforming growth factor (TGF)-β, IL-10, and IL-6, vascular endothelial growth factor (VEGF), Fas ligand (Fas-L), programmed cell death-1 (PD-1) ligand (PD-L1) and indoleamine-2, and 3-dioxygenase (IDO)][22,23]. These immunosuppressive cells inhibit antitumor immunity by various mechanisms, including depletion of arginine and elaboration of reactive oxygen species (ROS) and nitrogen oxide (NO)[22,23]. The pancreatic cancer microenvironment not only contributes to pancreatic cancer-induced immune suppression but also might be closely related to the extent of disease. For example, T cells producing IL-22 were significantly increased in PDA tissue, and this increase was significantly associated with tumor staging and poor prognosis[24]. Moreover, Tregs, MDSCs, and T helper 17 (Th17) cells in intratumoral tissue elicited strong immune suppression in patients[25,26]. As a result, CD8+ CTL function in patients with advanced PDA is impaired by IL-10 and TGF-β from Tregs. Therefore, DC-based cancer vaccines against PDA cells that cause induction of TAA-specific CD4+ and CD8+ T cells combined with depletion of immunosuppressive cells may tip the balance in favor of immunostimulation.

DC-BSAED CANCER VACCINES

The aim of cancer vaccines is to induce efficient antitumor immunity. Peptide vaccines are frequently used because they are simple, safe, and economical. However, certain obstacles prevent the use of peptide vaccines from becoming widespread. The drawbacks of peptide vaccines are related to numerous factors: (1) the limited number of known synthesized short peptides cannot be presented *via* many MHC molecules[27]; (2) monoclonal CD8+ CTLs may be ineffective in reacting to PDA cells[28]; (3) certain TAAs and MHC class Ⅰ molecules are occasionally down-regulated, which may occur during tumor progression[28]; and (4) DCs may have impaired function in patients with advanced PDA[29]. Therefore, *in vitro*-generated mature DCs have been developed as cancer vaccines because of their powerful ability to induce antigen-specific CD4+ T cells and CD8+ CTL responses in preclinical and clinical studies[30]. To date, the majority of DC-based cancer vaccines have been generated using monocyte-derived DCs. Immature DCs can be generated by a single leukapheresis after culture in the presence of granulocyte macrophage colony-stimulating factor (GM-CSF) and IL-4. In our laboratory, immature DCs are activated for vaccines by incubation with penicillin-killed and lyophilized preparations of a low-virulence strain (Su) of *Streptococcus pyogenes* (OK-432) and with prostaglandin E2 (PGE2), after which a large number of DCs can be cryopreserved in ready-for-use aliquots[31]. Several strategies have been used to develop DC-based cancer vaccines to elicit efficient antitumor immune responses (Table 1). To induce DC presentation of TAAs, DCs have been loaded with TAAs in the form of tumor lysates[32], antigenic peptides[33], dying or dead tumor cells[34], mRNA[35,36], cDNA[37], or exosomes[38] or have been fused with whole tumor cells to form hybrid cells[39]. The strategy of fusing DCs and whole tumor cells is based on the facts that DCs are potent APCs and that whole tumor cells express abundant TAAs, including both known and unidentified TAAs[40-42]. Therefore, DC-tumor fusion cells can process a broad array of TAAs and present them *via* MHC class Ⅰ and class Ⅱ in the context of co-stimulatory molecules[40-42]. Moreover, many adjuvants, including Toll-like receptor (TLR)3, TLR9, synthetic oligodeoxynucleotides (ODNs) containing unmethylated CpG, polyinosinic:polycytidylic acid (polyI:C), IL-2, IL-12, and IL-18, have been used in DC-based cancer vaccines to maximize antitumor immune responses in preclinical studies[43].

The field of cancer vaccines for PDA is currently in an active state of clinical investigation. In particular, the development of DC-based cancer treatments is of great importance. Clinical trials of DC-based cancer vaccines for PDA patients have been conducted (Table 2), including clinical trials for an MUC1-targeted DC-

Table 2 Clinical trials of dendritic cell-based cancer vaccines in pancreatic cancer patients

Cell-based cancer vaccines	Targets	Vaccines	Phase	Patients	Results	Ref.
Dendritic cells (DCs)	MUC1	DCs loaded with MUC1 peptide	Phase Ⅰ/Ⅱ	12 pancreatic or biliary cancer patients following surgical resection	These patients have been followed for more than 4 yr after vaccination, and 4 of them were alive without recurrence.	[46]
			Phase Ⅰ	16 patients with pancreatic cancer	2 of 15 patients with resected PDA were alive and disease free at 32 and 61 mo.	[47]
			Phase Ⅰ	7 patients with pancreatic cancer	These patients showed MUC1-specific immune responses; however, there was no significant clinical benefit.	[48]
		DCs transfected with MUC1 cDNA	Phase Ⅰ/Ⅱ	10 patients with pancreatic cancer	MUC1 specific immune responses were observed in 4 of 10 patients.	[49]
	WT1	DCs loaded with MHC class Ⅰ restricted WT1 peptides	Retrospective analysis	49 patients with pancreatic cancer refractory to standard treatment	The median survival time from vaccines was 360 d. Erythema reaction at the vaccination site was a prognostic factor for a significant survival benefit.	[56]
		DCs loaded with MHC class Ⅰ restricted WT1 peptides	Retrospective analysis	255 patients with pancreatic cancer refractory to standard treatment	The median survival time from diagnosis was 16.5 mo. Erythema reaction at the vaccination site was a prognostic factor for a significant survival benefit.	[60]
		DCs loaded with MHC class Ⅰ restricted WT1 peptides	Phase Ⅰ	10 patients with pancreatic cancer	The therapy was feasible, tolerable and effective in PDA patients without liver metastases.	[61]
		DCs loaded with MHC class Ⅰ and class Ⅱ restricted WT1 peptides	Phase Ⅰ	7 patients with pancreatic cancer	WT1 peptide-specific delayed-type hypersensitivity (DTH) was detected in 4 of 7 patients with PDA vaccinated with DC/WT1-Ⅰ/Ⅱ and in 0 of 3 patients with PDA vaccinated with DC/WT1-Ⅰ or DC/WT1-Ⅱ. All 3 PDA patients with strong WT1-specific DTH reactions had a median OS of 717 d. A patient with multiple liver metastases has remained alive for over 1000 d and received more than 71 vaccinations.	[31,62,63]
	hTERT	DCs transfected with hTERT mRNA	Phase Ⅰ	A patient who could not receive chemotherapy due to sever neutropenia	Vaccination was associated with induction of strong immune responses to multiple hTERT epitopes. The patient had been vaccinated with DC/hTERT mRNA alone for 3 yr and resulted in no evidence of active disease.	[66]
	CEA	DCs loaded with CEA mRNA	Phase Ⅰ	3 patients with resected pancreatic cancer following neoadjuvant vaccine therapy	All 3 PDA patients showed injection site reactivity and remained alive without recurrence at more than 2.5 yr from the original diagnosis	[68]
	DCs transfected with an adenovirus encoding IL-12		Phase Ⅰ	3 patients with pancreatic cancer	Intratumoral DC injections were guided by ultrasound. Vaccines induced a significantly increased infiltration of CD8+ T cells in some patients. A partial response was observed in 1 of 3 patients.	[73]
	penicillin-killed and lyophilized preparations of a low virulence strain (Su) of Streptococcus pyogenes (OK-432)-activated DCs and CD3-stimulated LAK cells		Phase Ⅰ	5 patients with pancreatic cancer	Intratumoral injection of OK432-activated DCs, followed by intravenous infusion of CD3-stimulated LAK cells. One patient had a partial response and 2 had stable disease for over 6 mo. The median OS was 478 d.	[75]
Peripheral blood mononuclear cells (PBMCs)	K-ras	irradiated PBMCs were used as antigen-presenting cells and loaded with K-ras peptide	Phase Ⅰ	9 patients with pancreatic cancer	Only one patient showed a positive cellular immune response. The worse prognosis of PDA patients on this immunization protocol using PBMCs as APCs may be associated with impaired induction of an antitumor immune responses.	[71]

MHC: Major histocompatibility complex; PDA: Pancreatic ductal adenocarcinoma; APC: Antigen-presenting cells; IL-12: Interleukin-12; WT1: Wilms' tumor gene 1; MUC1: Mucin 1; hTERT: Human telomerase reverse transcriptase; CEA: Carcinoembryonic antigen.

based cancer vaccination regimen. MUC1 is a TAA consisting of a polymorphic, glycosylated type Ⅰ transmembrane protein present in glandular epithelium and overexpressed in 90% of PDAs. Importantly, MUC1 is associated with poor prognosis, enhanced metastasis and chemoresistance[9,44]. It has been reported MUC1-

targeted cancer vaccines were effective in inducing antitumor immunity in murine pancreatic cancer models[45]. Therefore, several groups have conducted clinical trials with DCs loaded with MUC1 peptide (DCs/MUC1 peptide) or transfected with MUC1 cDNA (DCs/MUC1 cDNA). In a phase Ⅰ/Ⅱ clinical trial, following surgical resection, 12 patients with pancreatic or biliary cancer were vaccinated with MUC1 peptide-loaded DCs. These patients were followed for more than 4 years after vaccination, at which point 4 were alive and without recurrence[46]. In another phase Ⅰ study of 16 patients with PDA who were vaccinated with DCs/MUC1 peptide, 2 of 15 patients with resected PDA were alive and disease free at 32 or 61 mo[47]. Moreover, 7 PDA patients were vaccinated with DCs/MUC1 peptide in a phase Ⅰ trial[48]; these patients showed MUC1-specific immune responses, although there was no significant clinical benefit. MUC1-specific immune responses were also observed in 4 of 10 PDA patients following vaccination with DCs/MUC1 cDNA in a phase Ⅰ/Ⅱ trial[49]. Although the MUC1-targeted DC-based cancer vaccination regimen was safe and a significant MUC1-specific immune response was observed in several enrolled PDA patients, further investigation is warranted.

WT1

The WT1 antigen is also one of the most widely expressed TAAs in various tumor types, including PDA[50,51]. Importantly, WT1 has been ranked by the National Cancer Institute (NCI) as the number 1 target for cancer vaccines based on several factors: (1) therapeutic function; (2) immunogenicity; (3) the role of the antigen in oncogenicity; (4) specificity; (5) the expression level and percentage of antigen-positive cells; (6) stem cell expression; (7) the number of patients with antigen-positive cancers; (8) the number of antigenic epitopes; and (9) the cellular location of antigen expression[52]. WT1 has been found to be oncogenic, rather than tumor suppressive, in tumorigenesis[53]. Moreover, both cellular and humoral immune responses against the WT1 protein are naturally elicited in cancer patients, indicating that the *WT1* gene product is highly immunogenic[54,55]. Therefore, we and other groups have been performing clinical trials of the efficacy of WT1-targeted cancer vaccines for patients with PDA[31,56-63]. Four clinical reports about the use of DCs loaded with WT1 peptides combined with standard chemotherapy, such as gemcitabine, to treat advanced PDA patients have been published[31,56,60,61]. The vaccines can be mainly classified into 2 groups: (1) DCs loaded with MHC class I-restricted WT1 peptides (DC/WT1-I)[56,60,61] and (2) DCs loaded with multiple MHC class I- and class Ⅱ-restricted WT1 peptides (DC/WT1-I/Ⅱ)[31]. Both DC/WT1-I and DC/WT1-I/Ⅱ vaccinations are associated with significant induction of WT1-specific CD8+ T cells in circulating blood. In one study, Kobayashi *et al*[60] analyzed 255 PDA patients who received standard chemotherapy combined with DC-based cancer vaccines, including DC/WT1-I. The median survival time (MST) from diagnosis was 16.5 mo. Interestingly, an erythema reaction at the vaccination site was a prognostic factor for a significant survival benefit. DC/WT1-I-based cancer vaccines alone or combined with lymphokine-activated killer (LAK) cells were also retrospectively analyzed in 49 PDA patients[56]. Among all 49 patients, 2 had complete remission, 5 had a partial response, and 10 had stable disease. The survival of patients receiving DC-based cancer vaccines and standard chemotherapy (gemcitabine and/or S-1, an oral fluoropyridine) plus LAK cells was significantly longer than the survival of those receiving the vaccine in combination with chemotherapy but no LAK cells. Moreover, a prospective clinical trial using DC/WT1-I combined with gemcitabine demonstrated that the therapy was feasible, tolerable and effective in PDA patients without liver metastases[61]. We also conducted a phase Ⅰ study of chemoimmunotherapy using DC/WT1-I/Ⅱ vaccines and standard chemotherapy (gemcitabine and/or S-1) in 7 advanced PDA patients[31,57,62]. The combination therapy was well tolerated, and WT1-specific IFN-γ-producing CD4+ and CD8+ T cells were significantly increased following treatment with DC/WT1-I/Ⅱ. WT1 peptide-specific delayed-type hypersensitivity (DTH) was detected in 4 of the 7 patients with PDA who were vaccinated with DC/WT1-I/Ⅱ and in 0 of the 3 patients with PDA who were vaccinated with DC/WT1-I or DCs loaded with MHC class Ⅱ-restricted WT1 peptides (DC/WT1-Ⅱ). Moreover, the MST and the median progression-free survival (PFS) of the patients with PDA who were vaccinated with DC/WT1-I/Ⅱ were significantly longer than the MST and PFS of those receiving the DC/WT1-I or DC/WT1-Ⅱ vaccine. In addition, the WT1-specific DTH-positive patients who received DC/WT1-I/Ⅱ showed significantly improved overall survival (OS) and PFS compared with the negative-control patients. In particular, all 3 PDA patients with strong WT1-specific DTH reactions had a median OS of 717 d. Surprisingly, a patient with multiple liver metastases remained alive for more than 1000 d and received more than 71 vaccinations; this patient had strong WT1-specific DTH reactions throughout the vaccination period[63]. The combination of DC/WT1-I/Ⅱ and chemotherapy induced long-term WT1-specific CD4+ and CD8+ T cell responses. DC/WT1-I/Ⅱ may elicit not only effector but also long-lived effector memory and central memory T cells, all of which are capable of recognizing WT1-positive PDA cells and which are therefore associated with long-term stable disease[57].

hTERT

hTERT, the catalytic subunit of a functional telomerase complex, is also widely expressed in most human tumors and plays an essential role in tumor progre-

ssion[64]. Therapeutic strategies targeting such antigens involved in tumor growth resulted in antitumor immune responses in a mouse study[65]. As loss of telomerase activity may inhibit the progression of PDA cells, hTERT is a widely applicable target for triggering CTL responses. It was demonstrated that hTERT-specific immune responses were safely induced in a PDA patient vaccinated with DCs transfected with hTERT mRNA (DCs/hTERT mRNA)[66]. In this clinical study, DCs/hTERT mRNA vaccination was specifically administered to a PDA patient with relapsed disease[67]. The patient could not receive chemotherapy due to severe neutropenia and thus was vaccinated with DCs/hTERT mRNA alone for 3 years, which resulted in no evidence of active disease. The vaccinated patient also showed induction of strong immune responses to multiple hTERT epitopes. Therefore, hTERT-targeted DC-based cancer vaccines may be an effective approach for treating patients with PDA.

CEA

PDA cells widely express CEA, a glycosylated protein, so induction of CEA-specific immune responses may be associated with survival benefits[67]. In one clinical trial, 3 patients with resected PDA received neoadjuvant therapy, including DCs loaded with CEA mRNA (DCs/CEA mRNA), for 6 mo[68]. In this trial, all 3 PDA patients showed injection site reactivity and remained alive and without recurrence at more than 2.5 years from the original diagnosis. Although CEA-targeted cancer vaccinations induce strong CEA-specific immune responses, they usually fail to eradicate the tumor in most patients with advanced disease[67]. The results may be at least partly associated with the immunosuppressive effects of the tumor micro-environment. Therefore, to improve the clinical efficacy of CEA-targeted cancer vaccines, we need to design improved strategies that can overcome the immunosuppressive tumor microenvironment.

KRAS

As the *KRAS* gene is mutated in up to 95% of PDA cells[69], targeting mutant K-ras-specific immune responses may influence the clinical benefits of treatment for PDA patients[70]. To induce K-ras-specific antitumor immunity, irradiated peripheral blood mononuclear cells (PBMCs) were used as APCs and loaded with a K-ras epitope[71]. In this clinical trial, 9 patients with PDA, all with *KRAS* mutations, were vaccinated. Only one patient showed a positive cellular immune response, resulting in a median OS of 60 d. The worse prognosis of PDA patients subjected to an immunization protocol using PBMCs as APCs may be associated with impaired induction of antitumor immune responses per se. The vaccination protocol could be improved using mature DCs instead of PBMCs.

DCs combination therapy

The major cytokines currently in use or under evaluation for use in cancer vaccines are IFN-α, IL-2, GM-CSF, and IL-12[72]. An alternative strategy for clinical trials of DC-based cancer vaccines is use of IL-12-secreting DCs[73]. The main source of IL-12 in humans is DCs, and IL-12 acts as a major orchestrator of the T helper 1 (Th1)-type immune response against cancer when present directly in the tumor[74]. Therefore, 3 PDA patients were vaccinated with DCs transfected with an adenovirus encoding the IL-12 gene (DCs/IL-12)[73]. The intratumoral DC injections were mainly guided by ultrasound. DCs/IL-12 induced significantly increased infiltration of CD8+ T cells in certain patients, and a partial response was observed in 1 of the 3 patients with PDA[73]. As the DCs were not loaded with TAAs, cross-presentation of TAAs by the DCs in the patients must have been induced by IL-12. Another group reported administering gemcitabine and an endoscopic ultrasound-guided fine-needle injection of OK432-activated DCs into tumors in 5 PDA patients, followed by intravenous infusion of CD3-stimulated LAK cells[75]. Three of the 5 patients demonstrated effective responses: 1 had a partial response, and 2 had long-term stable disease for more than 6 mo[75]. The median OS was 478 d in this phase Ⅰ trial. In the patient with partial remission, induction of tumor antigen-specific CTLs was observed.

WHOLE TUMOR CELL-BASED CANCER VACCINES

Whole tumor cells can be genetically modified to produce cytokines to enhance antitumor responses. A GM-CSF-secreting, irradiated, allogeneic PDA cell line (GVAX) has been investigated in multiple phase Ⅰ and Ⅱ studies[76-82] (Table 3). GVAX recruits and activates DCs and promotes presentation of TAAs by DCs for activation of CD4+ and CD8+ T cells[83,84]. Early clinical trials demonstrated that vaccination with GVAX enhances CD8+ CTL responses against multiple mesothelin-specific epitopes that have been correlated with survival benefits[76-78]. As cancer vaccines alone have usually failed to demonstrate significant clinical activity in advanced PDA patients, PDAs are considered as non-immunogenic tumors, which is due to the immunosuppressive tumor microenvironment[80]. Recently, 39 PDA patients received GVAX alone or in combination with low-dose cyclophosphamide (Cy) to deplete Tregs[80]. Importantly, 33 of the 39 patients treated with GVAX showed the formation of vaccine-induced lymphoid aggregates. Moreover, the post-GVAX CTL infiltration and aggregate formation resulted in up-regulation of immunosuppressive regulatory mechanisms, including the PD-1/PD-L1 pathway. Therefore, GVAX-vaccinated PDA patients are better

Table 3 Clinical trials of whole tumor cell-based cancer vaccines in pancreatic cancer patients

Cell-based cancer vaccines	Vaccine	Phase	Patients	Results	Ref.
Whole tumor cell	GM-CSF-secreting allogeneic pancreatic cancer cell lines (GVAX) and chemoradiotherapy	Phase Ⅱ	14 patients with resected pancreatic cancer	3 patients were disease free at least 25 mo after diagnosis	[76]
	GVAX (arm A)/GM-CSF vaccine and cyclophosphamide (arm B)	Phase Ⅱ	50 patients with pancreatic cancer (2 arm)	Median OS: 2.3 mo in arm A, 4.3 mo in arm B	[77]
	GVAX and chemoradiotherapy	Phase Ⅱ	60 patients with resected pancreatic cancer	Induction of mesothelin-specific CD8+ T cells correlated with disease-free survival. Median OS: 24.8 mo	[78]
	Ipilimumab (anti-CTLA-4 monoclonal antibody) alone (arm 1), Ipilimumab and GVAX (arm 2)	Phase Ⅱ	30 patients with pancreatic cancer (2 arm: 1:1)	Three of 15 patients had evidence of prolonged disease stabilization (31, 71, and 81 wk) and 7 patients experienced CA19-9 declines (arm 1). In 2 of these patients, disease stabilization occurred after an initial period of progression. The median OS was 5.7 mo and 1 yr OS was 27%. Among patients with OS > 4.3 mo, there was an increase in the peak mesothelin-specific T cells and enhancement of the T-cell repertoire.	[79]
	GVAX	Phase Ⅱ	39 patients with pancreatic cancer	GVAX treatment was associated with the formation of vaccine-induced intratumoral tertiary lymphoid aggregates in 33 of 39 patients. Enhanced CD8+ CTL responses against multiple mesothelin-specific epitopes that have been correlated with survival benefits were also found.	[80]
	GVAX with low-dose cyclophosphamide (Cy) followed by CRS-207 (live-attenuated Listeria monocytogenes-expressing mesothelin) (arm A), GVAX + Cy (arm B)	Phase Ⅱ	90 patients with pancreatic cancer	Enhanced mesothelin-specific CD8+ CTL responses were associated with longer OS. Median OS was 9.7 mo (arm A, n = 61).	[81]
	Algenpantucel-L (2 pancreatic cancer cell lines that have been modified to express alpha-gal)	Phase Ⅱ	62 patients with resected pancreatic cancer	The 12-mo disease-free survival was 62%, and the 12-mo overall survival was 86%; the phase Ⅲ study is ongoing.	[82]

candidates for immune checkpoint therapies than vaccine-naive patients[79]. In a mouse study, a GVAX vaccine combined with anti-PD-1 antibody blockade improved murine survival compared with anti-PD-1 antibody or GVAX alone[85]. In a clinical trial, although GVAX alone also failed to show clinical benefits in PDA patients, infiltration of activated T cells expressing CTL-associated antigen 4 (CTLA-4) and PD-1 was induced by GVAX[80]. The efficiency of immune checkpoint-targeting agents is dependent on induction of adaptive immune responses[86]. Thus, they conducted combination therapy with inhibition of the CTLA-4 pathway using ipilimumab (anti-CTLA-4) and GVAX in metastatic PDA patients[79]. Three of 15 patients had evidence of prolonged disease stabilization (31, 71, or 81 wk), and 7 patients experienced a decline in carbohydrate antigen 19-9 (CA19-9). In 2 of these patients, disease stabilization occurred after an initial period of progression. The median OS was 5.7 mo, and 1-year OS was 27%. Among patients with OS > 4.3 mo, there was an increase in the peak mesothelin-specific T cell count and enhancement of the T cell repertoire[79]. Moreover, immunosuppressive pathways in the tumor microenvironment were overcome by the addition of the GVAX vaccine and low-dose Cy for PD-1 blockade. Therefore, combining anti-PD-1 or anti-PD-L1 antibody therapy with cancer vaccines such as GVAX may be effective therapy for PDA patients. In addition, they demonstrated that GVAX coupled with low-dose Cy followed by treatment with CRS-207 (live-attenuated *Listeria monocytogenes* expressing mesothelin) induced innate and adaptive immunity in 61 PDA patients. Mesothelin-specific CD8+ CTL responses enhanced by GVAX/Cy/CRS-207 were associated with longer OS (n = 61, 9.7 mo) compared with the responses enhanced by GVAX/Cy (n = 29, 4.6 mo)[81].

Whole tumor cells can be genetically modified to produce cytokines to inhibit tumor cell production of immunosuppressive cytokines, such as TGF-β, IL-10, IL-6, and VEGF. In particular, TGF-β has a critical role in immunosuppressive mechanisms, so down-regulation of TGF-β activates DCs and increases TAA-specific CTL induction. In mouse studies, several strategies to inhibit the production of TGF-β by cancer cells were developed. For example, TGF-β production by cancer cells was inhibited by the administration of neutralizing antibodies[87,88] and small interfering RNAs (siRNAs)[89] or constructs coding for a soluble variant of the TGF-β receptor[90]. We have previously demonstrated that the production of TGF-β, IL-10 and VEGF by human PDA cells is significantly limited upon exposure to

pharmaceutical-grade ethanol, without decreased expression of MHC class I and MUC1[91]. Therefore, whole tumor cells genetically modified to express immunosuppressive cytokines, such as GM-CSF, and to inhibit immunosuppressive cytokines, such as TGF-β, are better candidates for the generation of DC-based cancer vaccines for PDA patients.

CELL-BASED CANCER VACCINES COMBINED WITH CHEMOTHERAPY

Cytotoxic chemotherapy has been known to blunt immune responses because of the toxic effects of these treatments on dividing bone marrow progenitor cells, including lymphocytes. However, increasing evidence has suggested that cancer vaccines have the possibility of achieving better effects if combined with chemotherapy[92]. Cancer cells undergoing immunogenic apoptosis due to chemotherapy express calreticulin (CRT), which is a Ca2+-binding chaperone on the cell surface that mediates efficient phagocytosis by DCs[93,94]. In addition, high-mobility group box 1 (HMGB1)[95,96] and pentraxin-3 (PTX3)[97] are released from late-stage dying cancer cells to activate DCs and modulate immune responses *via* a TLR4-dependent signaling pathway. Therefore, necrotic or apoptotic tumor cells induced by chemotherapeutic agents enhance immunogenicity and can be effectively taken up by DCs, resulting in efficient processing of TAAs for presentation to T cells. For example, a standard cytotoxic agent for PDA, gemcitabine, can enhance the cross-presentation of TAAs by DCs as well as CTL induction[98]. Moreover, Cy and gemcitabine can each augment the antitumor effects by depleting immunosuppressive cells such as Tregs, B cells and MDSCs as well as by inducing the proliferation of DCs, all of which potentially enhances the antitumor immune response[98-101]. We also reported that up-regulated presentation of WT1 peptide *via* MHC class I molecules on PDA cells is induced by exposure of the cells to gemcitabine and/or S-1[102]. Importantly, WT1-specific CTLs can more efficiently lyse gemcitabine-treated PDA cells than untreated cells[102]. Certain TAAs that are not usually expressed on cancer cells may be uncovered by treating cancer cells with chemotherapeutic agents; these antigens are good targets for cancer vaccines because they can be effectively recognized by antigen-specific CTLs[103]. Therefore, cancer vaccines can synergize with chemotherapy in targeting PDA cells[104]. In addition, our recent reports indicate that the combination of gemcitabine and trastuzumab conjugated to a cytotoxic agent (T-DM1) may be a promising modality for the treatment of PDA cells with low human epidermal growth factor 2 (HER2) expression as a result of the unique HER2-up-regulating effect of gemcitabine[105]. Importantly, cancer patients who have previously received cancer vaccines could also benefit more from subsequent chemotherapy than those patients who are not vaccinated[106].

Although conventional treatments such as chemotherapy can eradicate certain cancer cells, the remaining cancer stem cells (CSCs) can lead to tumor relapse. Although CSCs have been implicated in chemoresistance, these remaining CSCs are still attractive targets for cancer vaccines[107,108]. Therefore, it is desirable to develop a novel therapy that selectively targets CSCs *via* cancer vaccines, which can be combined with conventional chemotherapy. Indeed, expression of TAAs such as MUC1 is up-regulated in CSCs by chemotherapy, and CSCs are efficiently lysed by MUC1-specific CTLs[108,109]. CSC-loaded DC-based cancer vaccines may be an alternative approach. We have reported that DCs fused with CSC cells induced CSC-specific CD4+ and CD8+ T cells with high production of IFN-γ, which is predominantly produced by Th1 cells[108]. Therefore, developing surgery/chemotherapy targeting the bulk of cancer cells combined with cell-based cancer vaccines targeting CSCs is highly desirable.

CONCLUSION

CTLA-4 and PD-1 are well-described co-inhibitory molecules that are highly expressed by TAAs-specific CTLs and associated with impaired antitumor immune responses. In contrast, PD-L1, which binds to PD-1, is not constitutively expressed in tumor cells but is induced in response to IFN-γ produced by activated T cells[110]. Therefore, immune checkpoint inhibitors, such as CTLA-4, PD-1 and anti-PD-L1 antibody, may be an efficient means for treating cancer patients[110]. Indeed, antibodies can be used to block inhibitory ligand/receptor interactions by acting on certain cancer cells (*e.g.*, anti-PD-L1) or T cells (*e.g.*, anti-CTLA-4 or anti-PD-1), allowing enhancement of the antitumor immune response in specific tumors[111]. However, single-agent immune checkpoint inhibitors, such as CTLA-4, PD-1, and anti-PD-L1 antibody, elicit limited adaptive immune responses in PDA patients due to the non-immunogenic tumor microenvironment, which provides a formidable barrier to CTL infiltration at baseline[85]. Therefore, cell-based cancer vaccines may prime PDA patients for treatment with better candidate checkpoint inhibitors[112]. Combining a blockade of multiple inhibitory pathways with cell-based cancer vaccines may synergistically decrease T cell anergy and improve clinical benefits.

Abstract

Combined hepatocellular cholangiocarcinoma (CHC) accounts for 0.4%-14.2% of primary liver cancer cases and possesses pathological features of both hepatocellular carcinoma and cholangiocarcinoma. Since this disease was first described and classified in 1949, the classification of CHC has continuously evolved. The latest definition and classification of CHC by the World Health Organization is based on the speculation that CHC arises from hepatic progenitor cells. However, there is no evidence demonstrating the common origin of different components of CHC. Furthermore, the definition of CHC subtypes is still ambiguous and the identification of CHC subtype when a single tumor contains many components has remained unresolved. In addition, there is no summary on the newly recognized histopathology features or the contribution of CHC components to prognosis and outcome of this disease. Here we provide a review of the current literature to address these questions.

Key words: Progenitor cell origin; Pathology classification; Combined hepatocellular cholangiocarcinoma

Core tip: This review article focuses on the current views about the histopathology and clinical characteristics of combined hepatocellular cholangiocarcinoma (CHC). Whether the different components of CHC share a common cell origin is still ambiguous. Furthermore, the definition of CHC subtype is still ambiguous and

the identification of CHC subtype when a single tumor contains many components has remained unresolved. The features between hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC) make CHC has better prognosis than CC but poorer than HCC.

INTRODUCTION

Combined hepatocellular cholangiocarcinoma (CHC) is a rare form of primary liver cancer with pathological features of both hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC). CHC accounts for 0.4%-14.2% of primary liver cancer cases in different regions[1-4]. It was first described and classified by Allen and Lisa in 1949[5], and Goodman updated the pathology classification in 1985[3]. Currently, according to the World Health Organization (WHO), CHC is classified into the classical subtype and subtype with stem-cell features[6].

Despite the extensive study on CHC over the past 60 years, many questions remain unresolved. Although many studies demonstrated that CHC originated from progenitor cells[7-9], whether all subtypes of CHC with stem-cell features share a common origin is unknown. Furthermore, how to classify the newly recognized histopathology features and how many effects on survival for CHC of the diversity of components and the properties of each component remain unclear. In addition, how to distinguish CHC form CK19(+)HCC and how to identify the subtype when a single tumor contains many components are still ambiguous. Finally, the clinical features of CHC including the risk factors, the role of liver transplantation and diagnosis are still controversial.

Therefore, here we review the current literature on CHC to address these issues.

EVOLUTION OF CHC CLASSIFICATION

Allen and Lisa first described CHC in 1949[5]. The authors classified this type of tumor into three subtypes including (1) separate masses composed of either HCC or CC; (2) contiguous but independent masses of HCC and CC; and (3) an intermingling of hepatocellular and glandular elements. In 1985, Goodman[3] updated the classification as (1) collision tumors, a coincidental occurrence of both HCC and CC in the same patient; (2) transitional tumors including areas of intermediate differentiation and an identifiable transition between HCC and CC; and (3) fibrolamellar tumors, which resemble the fibrolamellar variant of HCC but also contain mucin-producing pseudoglands. In 1989, The Liver Cancer Study Group of Japan[10] formulated its own classification of CHCs into three types: double cancer, combined type, and mixed type. In 1994[11], CHC was universally defined by the WHO as a tumor with intimate and unequivocal mixtures of both HCC and CC cells. However, these tumors should be distinguished from cases with separate HCC and CC arising in the same liver and in which HCC and CC are present at adjacent locations.

With the development of medicine, an increasing number of studies have demonstrated that hepatic progenitor cells play an important role in the development of CHC. Therefore, in 2010, the WHO updated the classification of CHC into the classical type and subtypes with stem cell features[6]. The subtypes were further subdivided into the typical subtype, intermediate cell subtype, and cholangiolocellular subtype. The classical type of CHC contains unequivocal components of HCC and CC, whereas subtypes with stem cell features possess special histopathology features (Table 1). This most recent classification system has been widely adopted.

Origin

Since the identification of CHC occurred, the debate on the origin of CHC has been ongoing. It is theoretically reasonable for CHC to originate from hepatocytes, cholangiocytes or hepatic progenitor cells. Many published studies have aimed to validate the origin of CHC at genetic and protein levels.

Genetic level

Multiple studies have been conducted to verify whether the HCC and CC components of CHC share the same origin and to identify the origin of the components. In 1996, Imai *et al*[12] investigated alterations of p53, K-ras and Rb-1 genes in seven CHC patients. The authors found that both components of CHC have the same genetic characteristics and speculated that they thus share the same origin. In 2000, Fujii *et al*[13] studied the allelic status of chromosome arms 1p, 1q, 3p, 4q, 5q, 6q, 8p, 9p, 10q, 11q, 13q, 16q, 17p, 17q, 18q, and 22q in HCC and CC foci of CHC. According to genetic patterns, they classified CHC origin into three possibilities: (1) a collision tumor in which two independent neoplastic clones develop at close proximity; (2) a single clonal tumor with divergent potential; and (3) a single clonal process in which genetic heterogeneity occur in the process of clonal evolution. This was the first unique classification of the origin of CHC at the genetic level. The authors considered that different types of CHCs had the same or different origins. Cazals-Hatem[14] screened for loss of heterozygosity (LOH) and for p53 and beta-catenin

Table 1 Evolution of classification of combined hepatocellular cholangiocarcinoma

Ref.	Classification
Allen *et al*[5], 1949	Separate masses
	Contiguous but independent masses
	Intimate intermingling of hepatocellular and glandular element
Goodman *et al*[3], 1985	Collision tumors, a coincidental occurrence of both HCC and CC in same patient
	Transitional tumors including areas of intermediate differentiation
	Fibrolamellar tumors, having features of fibrolamellar HCC and CC
Liver Cancer Study Group of Japan[10] 1989	Double cancer
	Combined type
	Mixed type
WHO[6] 2010	CHC-classical: typical HCC and typical CC
	CHC-SC
	CHC-SC-typical: nests of mature looking hepatocytes with peripheral clusters of small cells that have a high nucleus:cytoplasm ratio and hyperchromatic nuclei
	CHC-SC-int: tumor cells show features intermediate between hepatocytes and cholangiocytes. These tumor cells show strands, solid nests and/or trabeculae of small, uniform cells with scant cytoplasm and hyperchromatic nuclei
	CHC-SC-CLC: admixtures of small monotonous glands, antler-like anastomosing patterns. Each tumor cell is cuboidal, smaller in size than normal hepatocytes, with a high nucleus: cytoplasm ratio, and distinct nucleoli

CHC: Combined hepatocellular-cholangiocarcinoma; CHC-SC-typical: Combined hepatocellular-cholangiocarcinoma, stem cell features, typical subtype; CHC-SC-int: Combined hepatocellular-cholangiocarcinoma, stem cell features, intermediate cell subtype; CHC-SC-CLC: Combined hepatocellular-cholangiocarcinoma, stem cell features, cholangiolocellular subtype; HCC: Hepatocellular carcinoma; CC: Cholangiocarcinoma.

mutations in 9 CC, 15 CHC and 3 collision tumors compared with 137 HCC cases. Recurrent specific LOH was identified at 3p and 14q with significant differences among CHC, CC and HCC. The authors concluded that CHC is genetically more similar to CC compared with HCC. CHC shared frequent +1q (71%), +8q (57%), and 8p (57%) with HCC and higher numbers of imbalance with CC. The similar chromosomal changes with HCC and CC suggested that both share characteristics of CHC. These data also supported the same origin of different components of CHC. Although the genetic studies of CHC have provided some preliminary findings, whether HCC and CC components within CHC share the same origin should be further explored.

Protein level

Currently, the widely accepted origin of CHC is hepatic progenitor cells. However, it really takes a long time to get the conclusion. Many studies have used immunohistochemistry analyses to evaluate protein expression in CHC. A study by Okada *et al*[15] in 1987 reported the same levels of ABH, Lewis, and sialyl Lea antigens in CHC and HCC, indicating that CHC might have a hepatocellular origin. Imai *et al*[12] studied the expression patterns of carcinoembryonic antigen and keratin in seven CHC patients and demonstrated the same phenotypic characteristics in both components of CHC, suggesting a common origin of the hepatocellular and cholangiocarcinoma components. Zhang *et al*[8] performed immunohistochemical analysis of twelve CHC cases for hepatocytic (hepPar1, alpha-fetoprotein), cholangiocytic cytokeratin (CK7, CK19), hepatic progenitor cell (OV-6), hematopoietic stem cell (c-kit, CD34), as well as CD45 and chromogranin-A markers. The results suggested that CHC has the same hepatic progenitor cell origin. The same conclusion was also obtained by Akiba *et al*[16] who performed immunohistochemical analyses of biliary markers (CK7, CK19, and EMA), hepatocyte paraffin (hepPar-1), hepatic progenitor cell markers[17] (CD56, c-kit, CD133, and EpCAM), and vimentin. Kim *et al*[18] studied the expression of Yes-associated protein 1 (YAP1), a potential oncogene that can promote stem cell proliferation, among three groups comprising 36 HCCs with stem characteristics, 64 HCCs without stemness and 58 CHCs. Higher expression of YAP1 was observed in CHCs and HCCs with stemness than in HCCs without stemness. From the results of the expression of hepatocellular, cholangiocellular and progenitor cell markers, we speculate that the origin of CHC is hepatic progenitor cell.

UNSOLVED HISTOPATHOLOGY PROBLEMS

Although the classification of CHC has been widely accepted, there are still some special histopathology features that have not been classified. Nakajima[19] first described CHC with sarcomatous transformation in 1988, and several similar cases have since been reported[20-22]. In 2013, Terada[23] reported a CHC case with ductal plate malformation features that was characterized with CC cells forming markedly irregular tubules with intraluminal cell projections, bridge formations, and intraluminal tumor biliary cells. Jung *et al*[24] reported cholangiocellular carcinoma with satellite nodules showing intermediate differentiation.

Current studies have established that CHC contains various components. However, which component plays a more important role in the prognosis of CHC and whether the number of components could affect the recurrence and survival remain ambiguous. Akiba *et al*[16] investigated 54 CHC cases according to the WHO classification. The pathology type was defined by predominant histologic pattern (≥ 50%). CHC has wide histologic diversity, which poses a challenge for classification of CHC. Ikeda *et al*[25] divided 24 CHC cases into two groups: group A with less than 5% stem cell areas, and group B with more than 5% stem cell features. The expression level of delta-like 1 homolog was higher in group B than in group A. The postoperative overall survival rate was better in group A than in group B. These results suggest that the contribution of different components in CHC might be a significant factor that affects outcome. Sasaki *et al*[26] examined 62 CHC patients and found that the intermediate cell subtype was significantly associated with gender, tumor size, and histological grade of HCC and inversely correlated with the degree of stromal fibrosis. Significant associations were observed between cholangiocellular carcinoma and degree of fibrosis and inflammation, and an inverse association was observed with histological grade of HCC. The proportion of typical subtype was significantly inversely correlated with the degree of inflammation. Furthermore, the histological diversity score was also associated with vascular invasion. These data demonstrate a correlation between the proportion of each stem cell subtype and the histological diversity with clinicopathological factors, suggesting various properties of each component in the development of CHC. Although the WHO provided a clear definition and classification of CHC, the roles of newly recognized histopathology features, properties of each component, and the functions of diversity of components in recurrence and survival still need further exploration. In addition, the definition of CHC subtypes is still ambiguous, and how to distinguish CHC from CK19(+)HCC and how to identify the subtype of CHC when a single tumor contains many kinds of components require further research.

CLINICAL CHARACTERISTICS

Risk factors

Similar to other primary liver cancers, CHC could be induced by various factors impairing liver parenchyma. Compared with HCC, the relationship between HBV or HCV and CHC incidence is relatively weak[27]. A Japanese study revealed that the anti-HCV-positive rate was high in CHC as well as in HCC[28]. A hospital-based case-control study in China found that HBV infection and heavy alcohol intake might contribute to the development of CHC[29]. The percent of HCV-HBC infection was 37.3% and chronic liver disease was 38.3%, which suggested that viral infection and cirrhosis may be risk factors for ICC and CHC.

Clinical features

Whether the clinical features of CHC are similar to those of HCC or CCC is controversial. Compared with CC, the clinicopathological features of CHC include more advanced histological differentiation, increased prevalence in males, and lower levels of serum bilirubin and ALP. These features may make it possible to diagnose CHC in patients with suspected CC[30]. CHC is a hypovascular liver cancer with striking elevation of serum AFP and multiple regional lymphadenopathy[31]. These features are similar to both HCC and CC. The prevalence of hepatitis B positivity and cirrhosis in CHC was intermediate between HCC and CC[2,32]. CHCs were more likely to occur in males than CC[33]. Compared with HCC, CHC had lower incidence in Asian or Pacific patients with less distant spread. While clinical characteristics of CHC are similar to those of HCC, overall survival is more similar to that of ICC. Ng *et al*[34] investigated 21 cases of CHC and found that invasive characteristics with venous permeation, direct invasion into liver parenchyma and microsatellite formation were similar to those of HCC. The hypovascular features and regional lymphadenopathy features of CHC resemble those of CC. The elevations of serum AFP, venous permeation, and direct invasion and microsatellite formation in CHC are similar to those of HCC. The 75% positive rate of hepatitis B surface antigen and 61.5% AFP elevation rate detected in CHC were also closer to levels in HCC[34]. The features of both HCC and CC make CHC be a typical cancer having no special characters.

DIAGNOSIS

Imaging methods

The development of imaging methods has led to their important role in evaluating the properties of primary liver cancer. Dynamic computed tomography for CHC diagnosis has three enhancement patterns, including type Ⅰ hyper-enhancement in the early phase and hypo-enhancement due to washout of contrast medium in the late phase, resembling HCC; type Ⅱ peripheral enhancement in the early phase; and type Ⅲ late phases and an area of hyper-enhancement in the early phase and an area of slight delayed enhancement in the late phase. Type Ⅲ can be identified on the presentation of computed tomography[35]. Contrast-enhanced computed tomography could also predict the dominant component of CHC, which could optimize the treatment strategy for CHC patients[36]. Sensitivities and specificities for diagnosis of CHC range from 33% to 34% and 81% to 100%, respectively[37]. Therefore, tumor markers and risk factors should be used to improve the accuracy of diagnosis. Magnetic resonance imaging also contributes to the diagnosis of CHC[4].

Pathology

Before operation, it is difficult to accurately diagnose CHC. Although it is not entirely possible to confirm reliable diagnosis of CHC on cytologic preparations alone, cellblock or core biopsy for histochemical and immunohistochemical studies could be helpful for diagnosis[38,39]. Analysis of operative specimens is the gold standard for the diagnosis of CHC.

Treatment

Although the prognosis of CHC is poor, the development of hepatectomy, liver transplantation, and adjuvant chemotherapy and radiation therapy has improved the survival of patients.

Hepatectomy is the most important treatment for CHC, and can prolong the life of patients and even cure disease. Eguchi *et al*[40] reported successful hepatectomy for the intrahepatic recurrence of a CHC case and showed that resection of recurrent tumors could improve the poor prognosis of CHC.

Liver transplantation is another treatment for CHC. In CHC patients with liver transplantation, the 5-year survival was better than liver transplantation for intrahepatic CC but poorer than that of HCC meeting the Milan criteria[41-44]. The overall survival rates of CHC patients with liver transplantation at 1, 3 and 5 years were 79%, 66% and 16%, respectively[43]. Groeschl *et al*[45] showed that the survival benefit for localized CHC transplantation is similar to liver resection for CHC, but inferior to transplantation for HCC. Itoh *et al*[46] showed that better survival could be achieved after the living-donor liver transplantation for CHC meeting the Milan criteria or the Kyushu University criteria, similar to that of HCC.

Apart from operation, several adjuvant treatments are available, such as chemotherapy and radiation therapy. Disease-free survival of 42 mo after operation for a CHC case with lymph node metastasis was achieved through adjuvant chemotherapy and radiation therapy[47]. The case suggested an improved prognosis using multimodal therapy for CHC. Oral administration of UFT[48] effectively treated CHC with lymph node metastases. Systematic chemotherapy with fluorouracil, doxorubicin and cisplatin effectively suppressed the progression of CHC[49].

Together these findings suggest that for treatment of CHC, we should combine surgery with multimodal therapy to improve the survival of patients.

PROGNOSIS

The prognosis of primary liver cancer is poor. How about the prognosis of CHC? Tickoo investigated 27 CHCs with regard to their clinical features, which were different from those of pure HCC[50]. CHC showed disappointing prognosis, with overall 3- and 5-year survival rates of 30% and 18%, respectively. The 1- and 3-year survival rates in the CHC group (81.9% and 47%, respectively) were higher than those of the CC group and lower than those of the HCC group, which suggested a better prognosis of CHC compared with CC but worse compared with HCC[2]. In another center[4], the overall survival rates of CHC at 1, 3 and 5 years were 53%, 26% and 12%, respectively. Thus, the survival of CHC appears to be better than that of CC but worse than that of HCC[51]. Many factors could affect recurrence and survival after treatment. In a study of 30 CHC patients, Lin *et al*[4] found that major vascular branch invasion, regional organ invasion, nodal and distant metastases could affect prognosis. Park *et al*[52] concluded that the presence of portal vein thrombosis, distant metastasis and cholangiocellular component might be a poor prognosis indicator. Age, gender, transarterial chemoembolization and T stage were significant prognosis factors in CHC patients. The prognosis is poorer once the cholangiocellular components occur in liver cancer[52]. Sex, tumor-related factors (tumor number, major thrombus, and microvascular thrombus), serum gamma-glutamyl transpeptidase (GGT), and carbohydrate antigen 19-9 level seemed to be independent prognosis factors of long-term surgical survival for HBV-related CHC[53]. Disease-free survival could be affected by tumor size, major thrombus and serum GGT. The overall survival for CHC was associated with tumor size and lymph node metastasis. Poorer disease-free survival and similar overall survival rates were observed between CHCs and CCs[54]. The presence of cirrhosis, percent of serum hepatitis B or C marker positivity and the level of serum alpha-fetoprotein may be prognosis factors. Together these data indicate that CHC has a poor prognosis and many factors affecting the survival of HCC and CC could also be important prognostic factors for CHC.

Prospective

The obvious features between HCC and CC make CHC have better prognosis than CC but poorer than HCC. Owing to the limited therapy, the improvement of prognosis could be achieved by the development of basic science. With the development of sequencing techniques, it will soon be possible to demonstrate whether the different components of CHC share the same origin at the DNA level[55]. In addition, we could further explore whether CHC originates from hepatic progenitor cells at the RNA and protein levels. Finally, to address the unsolved pathology questions of CHC, many more studies are needed to clearly distinguish CHC from CK19(+)HCC and define the correct subtypes when a single mass has many different components. Owing to the variation of function in deciding the survival of different cancer components, perhaps a score system on the properties of each component and the numbers of components to predict the prognosis

could be established.

Abstract

AIM: To analyze the effect of three-dimensional (3D)-arrangement on the expression of epithelial-to-mesenchymal transition markers in pancreatic adenocarcinoma (PDAC) cells.

METHODS: HPAF-Ⅱ, HPAC, and PL45 PDAC cells were

cultured in either 2D-monolayers or 3D-spheroids. Ultrastructure was analyzed by transmission electron microscopy. The expression of E-cadherin, β-catenin, N-cadherin, collagen type I (COL-I), vimentin, α-smooth muscle actin (αSMA), and podoplanin was assayed by confocal microscopy in cells cultured on 12-mm diameter round coverslips and in 3D-spheroids. Gene expression for E-cadherin, Snail, Slug, Twist, Zeb1, and Zeb2 was quantified by real-time PCR. E-cadherin protein level and its electrophoretic pattern were studied by Western blot in cell lysates obtained from cells grown in 2D-monolayers and 3D-spheroids.

RESULTS: The E-cadherin/β-catenin complex was expressed in a similar way in plasma membrane cell boundaries in both 2D-monolayers and 3D-spheroids. E-cadherin increased in lysates obtained from 3D-spheroids, while cleavage fragments were more evident in 2D-monolayers. N-cadherin expression was observed in very few PDAC cells grown in 2D-monolayers, but was more evident in 3D-spheroids. Some cells expressing COL-I were observed in 3D-spheroids. Podoplanin, expressed in collectively migrating cells, and αSMA were similarly expressed in both experimental conditions. The concomitant maintenance of the E-cadherin/β-catenin complex at cell boundaries supports the hypothesis of a collective migration for these cells, which is consistent with podoplanin expression.

CONCLUSION: We show that a 3D-cell culture model could provide deeper insight into understanding the biology of PDAC and allow for the detection of marked differences in the phenotype of PDAC cells grown in 3D-spheroids.

Key words: Epithelial-to-mesenchymal transition; E-cadherin; 3D-spheroids; Podoplanin; Pancreatic ductal adenocarcinoma

Core tip: The functions of living tissue can be mimicked by three-dimensional (3D) cell cultures, thereby providing a method of decoding the information encoded in the tissue architecture. We aimed to analyze the effect of 3D-arrangement on the expression of some key markers of epithelial-to-mesenchymal transition in pancreatic adenocarcinoma (PDAC) cells cultured in either 2D-monolayers or 3D-spheroids. Our results show that a 3D-cell culture model could provide deeper insight into understanding the biology of PDAC and allow for the detection of marked differences in the phenotype of PDAC cells grown in 3D-spheroids.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is one of the most aggressive and lethal tumors, representing the fourth most common cause of cancer death in the Western world, with an estimated incidence of more than 40000 cases per year in the United States. The 5-year survival for all stages of the disease remains < 5%[1,2], due to the high incidence of recurrence and metastases dissemination[3].

During carcinogenesis, the "phenotypic switch" of pancreatic epithelial cells to mesenchymal cells, the so-called "epithelial-to-mesenchymal transition" (EMT), plays a pivotal role in PDAC progression, rendering tumor cells invasive and able to metastasize distant organs[4]. The EMT-related phenotype is characterized by the loss of epithelial features, including cell adhesion and polarity, following down-regulation of E-cadherin, cytoskeleton reorganization by expressing vimentin and α-smooth muscle actin (αSMA), and the motile properties and secretion of matrix metalloproteinases (MMPs)[5]. Several inducers of EMT transcription factors have been described, such as Snail, Slug, Twist, and Zeb, repressing E-cadherin expression *in vivo* and in various cancer cell lines, including lung, breast, colorectal, and ovarian cancer, thus inducing tumor malignancy[6-8]. It was demonstrated that Snail and Slug could increase invasion of breast, squamous, and pancreatic cancer cells[9-12]. The loss of E-cadherin is known to be a pivotal event, although experimental evidence demonstrates that 6 out of 7 PDAC commercial cell lines maintain E-cadherin expression in the cell membrane. Moreover, the similar expression of EMT markers in PDAC and benign pancreatic ducts[13] increases the relevance of studies aimed at definitively clarifying the role of EMT in PDAC development and progression, with particular attention paid to the expression of E-cadherin.

It is generally recognized that plastic or glass substrates commonly used for cell culture are not representative of the cellular environment found in organisms. Cells cultured as monolayers do not reproduce the structural organization or functional differentiation of the epithelium *in vivo*[14], and sometimes signaling pathways are fundamentally differently regulated than in polarized structures[15]. *In vitro* three-dimensional (3D) culture systems reduce the differences between 2D cell cultures and physiological tissues, thereby offering the possibility of investigating aspects of tumor biology and pathophysiology by maintaining a 3D cancer cell arrangement that reflects the *in vivo* tissue and tumor situation in relation to cell-cell interaction and differentiation patterns[16]. Therefore, 3D cultures, such as the well-established spheroid culture system,

could better reflect the *in vivo* behavior of cells in tumor tissues[17].

As PDAC remains currently one of the most lethal cancers, comprehension of its biology, development, and progression remains crucial for making inroads into this devastating human disease. The aim of this study was to investigate the expression of the main EMT markers in HPAF-Ⅱ, HPAC, and PL45 PDAC cell lines, grown in either 2D-monolayers or 3D-spheroids. Our goal was to use 3D cultures to bridge the gap between traditional cell cultures and *in vivo* settings with a method that mimics the 3D structure of living tissue in order to better characterize the phenotype of PDAC cells and, therefore, their behavior. We were particularly interested in understanding if the expression of E-cadherin is affected by these two different cell arrangements, in order to obtain new information on the effective role of this marker in PDAC.

MATERIALS AND METHODS

2D-monolayer cell culture and 3D-spheroid preparation

Three human pancreatic cancer cell lines (HPAF-Ⅱ, HPAC, and PL45) from pancreatic ductal adenocarcinoma (PDAC) (American Type Culture Collection, ATCC) were studied. PDAC cells were cultured in DMEM (Dulbecco's Modified Eagle Medium) supplemented with 10% heat-inactivated fetal bovine serum (FBS), 2 mmol/L glutamine, antibiotics (100 U/mL penicillin, 0.1 mg/mL streptomycin), and 0.25 μg/mL amphotericin B. Cell viability was determined by trypan blue staining.

To obtain 3D-spheroids, PDAC cells (5×10^4 cells) were seeded in 24-well multiwell plates coated with 1% agarose in DMEM.

Spheroid integrity was verified by phase-contrast imaging after 3 d, 1 wk, and 2 wk, and cell viability in 3D-spheroids was determined by calcein fluorescence. For this purpose, 3D-spheroids were incubated with calcein-AM (3 μg/mL in PBS) for 30 min at 37 ℃, 5% CO_2 and observed under a fluorescence inverted microscope. In live cells, the nonfluorescent calcein AM is converted to green-fluorescent calcein after acetoxymethyl ester hydrolysis by intracellular esterases. For morphological and molecular evaluations, spheroids were harvested after 10 d. Duplicate samples of PDAC cells grown in 2D-monolayers and 3D-spheroids were analyzed.

To understand the invasive behavior of 3D-spheroids, HPAF-Ⅱ spheroids were seeded in basement membrane extract (BME) (Geltrex, Life Technologies), following the manufacturer's instructions. Single 3D-spheroids were suspended in 2% BME in complete DMEM, and then seeded in a 96-well multiwell plate coated with a thick layer of BME. 3D-spheroids were observed under an inverted microscope at different time points and monitored for a 14 d period to detect whether or not they were able to invade the surrounding environment.

Ultrastructural characterization by transmission electron microscopy

HPAF-Ⅱ, HPAC, and PL45 cells were grown as 2D-monolayers on Petri dishes. At confluence, cells were fixed with a solution containing 2% freshly prepared paraformaldehyde and 2% glutaraldehyde in 0.1 mol/L sodium cacodylate buffer (pH 7.4). 3D-spheroids were harvested and fixed in the same fixative. Both 2D-monolayer cultures and 3D-spheroids, after fixation for 2-4 h at 4 ℃, were rinsed twice in cacodylate buffer for 20 min, post-fixed in 1% osmium tetroxide in the same buffer at 0 ℃ for 30 min, washed in distilled water, and stained *en bloc* with 2% aqueous uranyl acetate. After dehydration in graded ethanols, 2D-monolayer cultures (*in situ* on Petri dishes) and 3D-spheroids were embedded in Epon-Araldite resin.

Semi-thin sections 0.5 μm thick were stained with 0.5% toluidine blue in 1% sodium borate and examined using a light microscope (Zeiss Axiophot) for preliminary observations. Ultra-thin sections cut by a Leica Supernova ultramicrotome were stained with lead citrate and observed under a Zeiss EM10 electron microscope.

Immunofluorescence and confocal microscopy

HPAF-Ⅱ, HPAC, and PL45 cells were cultured on 12-mm diameter round coverslips into 24-well culture plates. When at the desired confluence, cells were washed in phosphate-buffered saline (PBS), fixed in 4% paraformaldehyde in PBS containing 2% sucrose for 10 min at room temperature, post-fixed in 70% ethanol, and stored at -20 ℃ until use. 3D-spheroids were fixed for 3 h in the same conditions. Cells grown in 2D-monolayers and 3D-spheroids were then washed in PBS three times and incubated overnight at 4 ℃ with the primary antibodies anti-E-cadherin (1:2500, Becton Dickinson), anti β-catenin (1:500, Novocastra), anti-N-cadherin (1:200, Santa Cruz), anti-collagen type Ⅰ (COL-I) (1:2000, Sigma Aldrich), anti-vimentin (1:200, Novocastra), anti-αSMA (1:400, Sigma Aldrich), and anti-podoplanin (15 μg/mL, Sigma Aldrich). Secondary antibodies conjugated with Alexa 488 (1:500, Molecular Probes, Invitrogen) were applied for 1 h at room temperature in PBS containing 25 μmol/L rhodamine-phalloidin in PBS and 0.2% triton X-100 in the dark. Negative controls were incubated that omitted the primary antibody. Finally, cells on coverslips and 3D-spheroids were incubated for 15 min with DAPI (1:100.000, Sigma Aldrich) and mounted onto glass slides using Mowiol. PDAC cells grown in 2D-monolayers or 3D-spheroids were analyzed by confocal microscopy (Olympus FV1000).

Real-time PCR

Total RNA was isolated by a modification of the acid guanidinium thiocyanate-phenol-chloroform method (Tri-Reagent, Sigma, Italy). One μg of total RNA was reverse-transcribed in 20 μL final volume of reaction

mix (Bio-Rad, Segrate-Milan, Italy). mRNA levels for E-cadherin, Snail, Slug, Twist, Zeb1, and Zeb2 were assessed. GAPDH was used as an endogenous control to normalize the differences in the amount of total RNA in each sample. The primer sequences were as follows: GAPDH: sense CCCTTCATTGACCTCAACTACATG, antisense TGGGATTTCCATTGATGACAAGC; E-cadherin: sense GAACGCATTGCCACATACAC, antisense GAATTCGGGCTTGTTGTCAT; Snail: sense CTTCCA GCAGCCCTACGAC, antisense CGGTGGGGTTG AGGATCT; Slug: sense TGTTTGCAAGATCTGCGGC, antisense TGCAGTCAGGGCAAGAAAAA; Twist: sense AGCAAGATTCAGACCCTCAAGCT, antisense CCTGGT-AGAGGAAGTCGATGTACCT; Zeb1: sense GAAAGTCAT-CCAGCCAAATGG, antisense ACTTGGTTCTCAGC TTGGGGAATCA; and Zeb2: sense GCTACACGTTTTGC-CTACCGC, antisense CGATTACCTGCTCCTTTGGGTT.

Amplification reactions were conducted in a 96-well plate in a final volume of 20 μL per well containing 10 μL of 1× SYBR Green Supermix (Bio-Rad, Italy), 2 μL of template, and 300 pmol of each primer. Each sample was analyzed in triplicate in a Bioer LineGene 9600. The cycle threshold (Ct) was determined and gene expression levels relative to that of GAPDH were calculated.

Western blot

Cell lysates were prepared in Tris-HCl 50 mmol/L pH 7.6, 150 mmol/L NaCl, 1% Triton X-100, 5 mmol/L EDTA, 1% SDS, proteases inhibitors, and 1 mmol/L sodium orthovanadate. Lysates were incubated on ice for 30 min and centrifuged at 14000 *g*, for 10 min at 4 ℃ to remove cell debris. Cell lysates (40 μg of total proteins) were diluted in SDS-sample buffer, loaded on 10% SDS-polyacrylamide gel, separated under reducing and denaturing conditions at 80 V according to Laemmli, and transferred at 90 V for 90 min to a nitrocellulose membrane in 0.025 mol/L Tris, 192 mmol/L glycine, 20% methanol, and pH 8.3. After electroblotting, the membranes were air dried and blocked for 1 h.

For E-cadherin evaluation on cell lysates, membranes were incubated for 1 h at room temperature in monoclonal antibody to E-cadherin (1:2500, Becton Dickinson) and, after washing, in HRP-conjugated rabbit anti-mouse serum (1:40000 dilution, Sigma, Italy). To confirm equal loading, membranes were reprobed by monoclonal antibody to α-tubulin (1:2000 dilution, Sigma Aldrich). Immunoreactive bands were revealed using the Amplified Opti-4CN or the Opti-4CN substrate Bio-Rad.

Analysis of results

Data are expressed as mean ± SD. Since the number of samples in each experimental group was low, we did not analyze our data by inferential statistics; rather, we aimed to measure differences between cells grown in 2D-monolayers or 3D-spheroids by calculating the effect size according to Cohen[18].

RESULTS

3D-spheroid morphology and viability

When seeded in agarose-coated wells, PDAC cells formed 3D aggregates that were evident after 40-72 h. HPAF-Ⅱ, HPAC, and PL45 cells cultured in 2D-monolayers were characterized by an epithelial morphology (Figure 1A). Inverted microscope observation of the 3D-spheroids at different time points showed that, after one week, cell density was increased and the spheroid exhibited a compact structure, with different morphologies in different cell types (Figure 1B). The size of the 3D-spheroids was approximately 300-500 μm. No evident differences were observed after two weeks, and so the spheroids were harvested for molecular and morphological evaluations after 10 d. To assess eventual necrosis in the inner part of the spheroids, possibly due to reduced delivery of nutrients, cells were stained with calcein-AM. Observations *via* fluorescent microscope revealed that all the cells were metabolically active, as they were all fluorescent (Figure 1C). Cell integrity in 3D-spheroids was also confirmed by transmission electron microscopy (TEM) (Figures 2-4).

Ultrastructural characterization by transmission electron microscopy

HPAF-Ⅱ cultured in 2D-monolayers grew as flat layers in which light or small dark cells partially overlapped and arranged with the basolateral membrane adhering to the plastic dish. Cells contained organelles and showed apical microvilli facing the culture medium (Figure 2A). HPAF-Ⅱ 3D-spheroids showed a compact structure consisting of multiple cell layers, with microvilli extensively covering the apical surfaces of the outer cellular layer (Figure 2B-D). Cells had variable shapes and cytoplasm amount, and sometimes contained mucin granules and small autophagic vacuoles. They also frequently exhibited a pale and markedly segmented nucleus (Figure 2B), with adjacent cells in the outer layer connected by junctional complexes located in the apical-lateral domain and by numerous interdigitations and desmosomes in their lateral domains (Figure 2C and D), which was consistent with cell polarity. The inner part of 3D-spheroid adjacent cells were separated by an evident intercellular space and linked by interdigitations. Additionally, some cells were arranged to delimit lumen-like structures (Figure 2B).

HPAC cells appeared as flat layers of light and dark cells that only partially overlapped and were interdigitated and connected by junctions in some cases. They exhibited short microvilli on the surface facing the culture medium. Cells contained organelles, autophagosomes, and showed other morphological similarities with HPAF-Ⅱ (Figure 3A). HPAC grown in 3D-spheroids showed a compact organization consisting of multicellular layers (Figure 3B). Epithelial cells of the outer layer presented their apical domain towards the

Original magnification: 20 ×; B: 3D-spheroids observed under inverted microscope after 3, 7, and 14 d. HPAF-Ⅱ spheroids were more rounded and uniformly dense; by contrast, HPAC and PL45 spheroids displayed an irregular shape. Original magnification: 10 ×; C: Representative 3D-spheroid under inverted microscope and after incubation with calcein-AM. Original magnification: 10 ×.

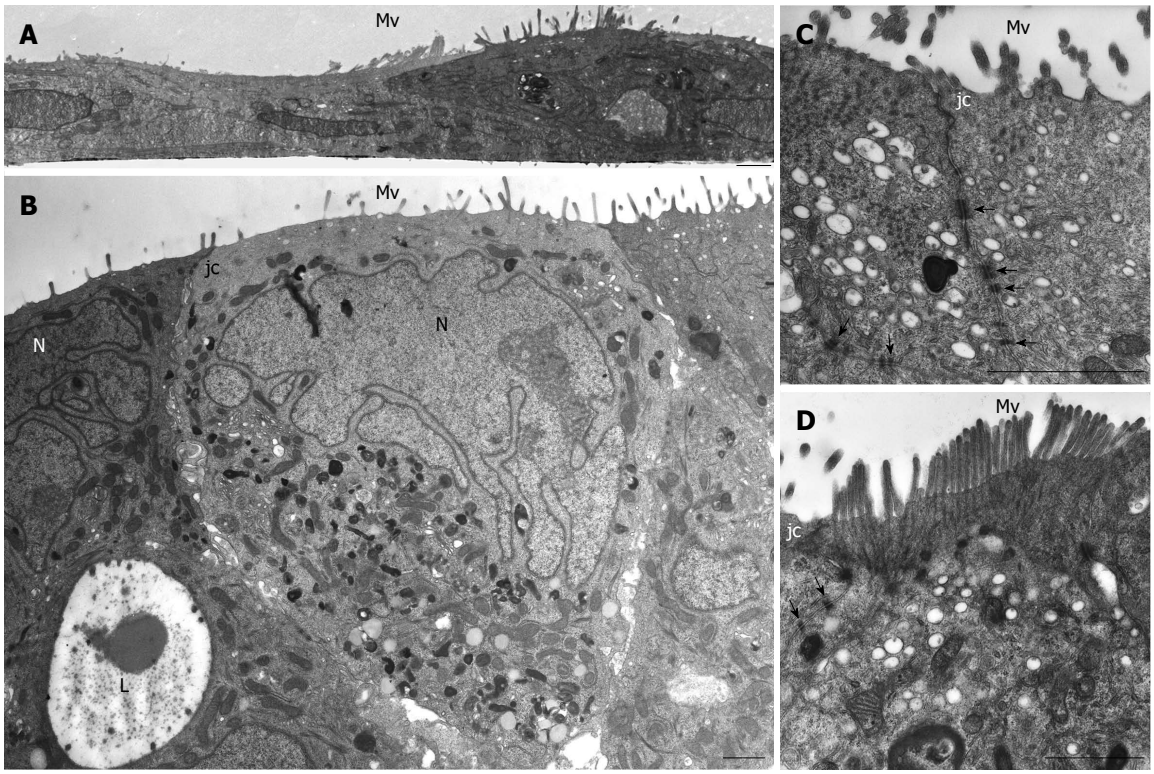

Figure 2 HPAF-Ⅱ ultrastructure. A: Electron microscopy of HPAF-Ⅱ culture grown in a 2D-monolayer showing two cells partially overlapping and exhibiting microvilli (Mv). Scale bar = 1 μm; B-D: Ultrastructural features of HPAF-Ⅱ cells grown in 3D-spheroids. Adjacent cells located at the periphery of the spheroid show microvilli (Mv) in the apical domain and junctional complexes (jc). In B, some cells exhibit a pale and markedly irregular nucleus (N). Some adjacent cells delimit a lumen-like structure (L). Scale bar = 1.5 μm. C, D**:** Adjoined cells are connected by junctional complexes (jc) in their apical-lateral domains and by numerous adherens junctions (arrows) in their lateral domains. In D, microvilli are densely packed; at their core, actin microfilaments can be seen extending into the apical cytoplasm. C, D: scale bar = 1.5 μm.

culture medium and were extensively covered with microvilli (Figure 3B2-D). Cell polarity was also evident as Golgi complexes and numerous mitochondria were present in the apical compartment (Figure 3B2 and C); moreover, the cytoplasm occasionally exhibited mucin granules at the apical pole (Figure 3C). Nuclei were located at the opposite side and characterized by widely dispersed chromatin and sometimes by a markedly irregular shape (Figure 3C). HPAC cells in 3D-spheroids exhibited a junctional complex consisting of tight junctions (zonulae occludentes), adherens junctions (zonulae adhaerentes), and desmosomes (maculae adhaerentes) in the apical-lateral domains (Figure 3D). In the internal region of 3D-spheroids, adjacent cells were separated by a more evident intercellular space and were interdigitated with neighboring cells by finger-like projections, without any evident junctional specializations (Figure 3B2). Notably, according to

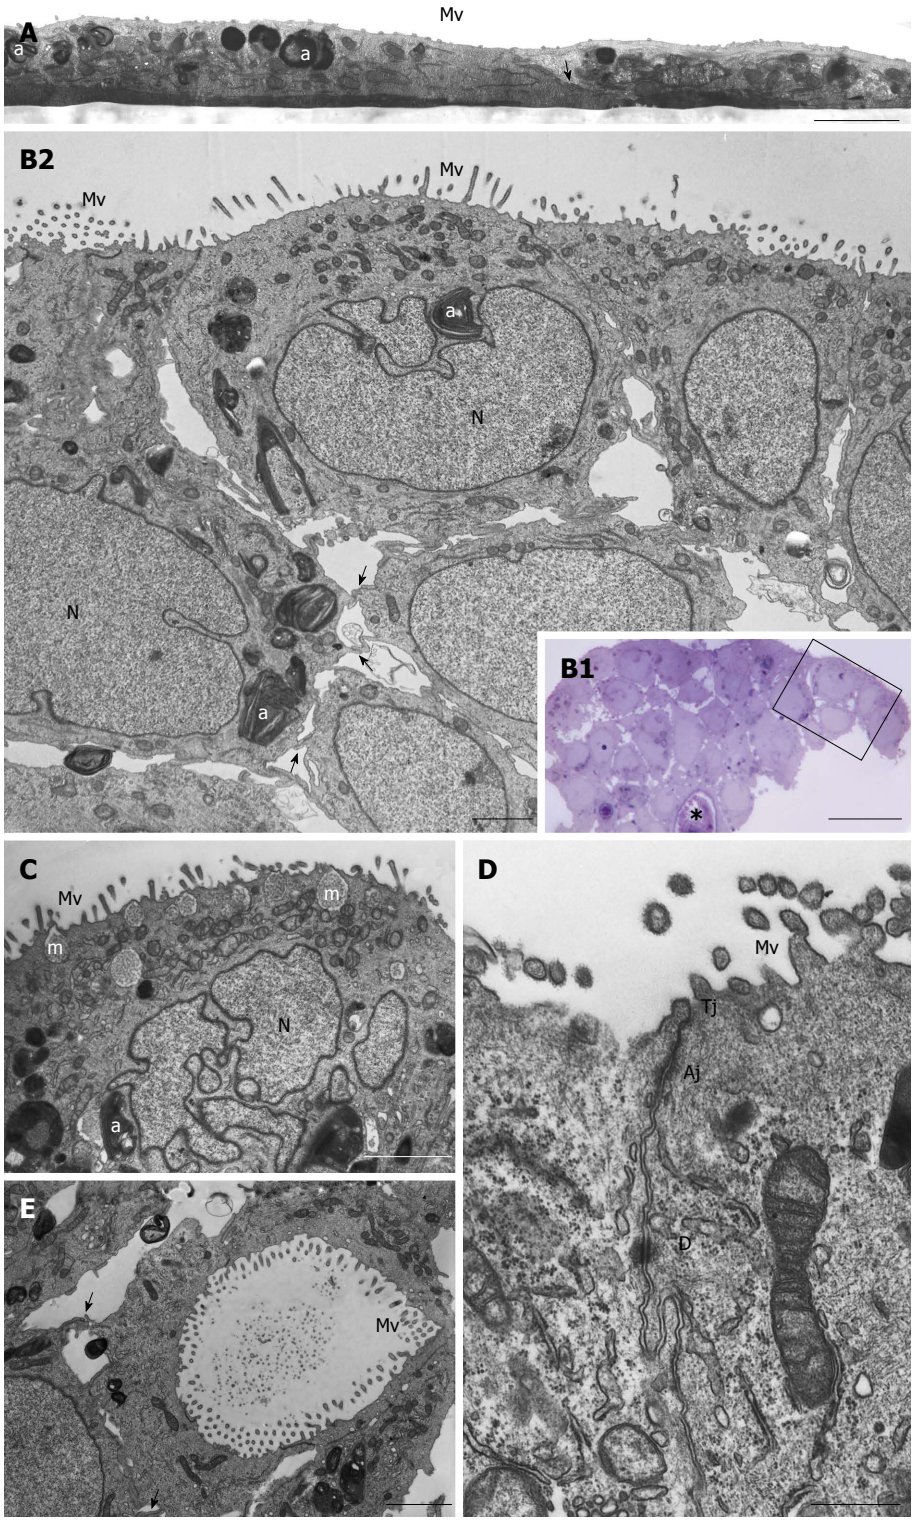

Figure 3 HPAC ultrastructure. A: Electron microscopy of a HPAC 2D-monolayer. Two cells having dark and light cytoplasm, respectively, are partially overlapped and interdigitated by finger-like projections (arrow); sparse and short microvilli (Mv) in the domain facing the culture medium and some autophagosomes (a) can be seen. Scale bar = 2 μm; B1: Light microscopy of a semi-thin section showing a representative area of a multilayered 3D-spheroid. The asterisk indicates a lumen-like structure. Ultrastructural features of the boxed area are shown in B2. Scale bar = 20 μm; B2: Electron microscopy of the thin section immediately adjacent to the semi-thin one, and corresponding to the boxed area in B1, shows cellular polarity and numerous microvilli (Mv) in the apical domain facing the culture medium. Several autophagosomes (a) can be observed in the cytoplasm. Cells of the lower region exhibit interdigitating finger-like processes (arrows) in the interstitial space. Nuclei (N) are euchromatic and frequently display more or less deep invaginations. Scale bar = 5 μm; C: Micrograph showing a cell with a markedly irregular nucleus (N) and several mucin granules (m) in the apical cytoplasm. Scale bar = 2 μm; D: Thin section of two adjacent cells located at the periphery of the spheroid and facing the culture medium. Microvilli (Mv) in the apical domain and a junctional complex, consisting of tight junction (Tj), adherens junction (Aj), and desmosome (D) in the lateral domain, can be observed. Scale bar = 0.5 μm; E: Micrograph of the inner part of a spheroid in which some adjacent interdigitated cells (arrows) delimiting a lumen-like structure exhibit numerous microvilli in their apical domains and junctional specializations (arrows). Scale bar = 2 μm

Figure 4 PL45 ultrastructure. N: Nucleus. Scale bar = 1 μm; B: Light microscopy of a semi-thin section showing a multilayered spheroid with 2 small groups of cells partially detached from the periphery of the spheroid (arrows). Scale bar = 40 μm; C: Electron microscopy of a thin section adjacent to the semi-thin one showing a group consisting of 3 cells joined to each other. The outlined areas are shown at greater enlargement in inserts C1 and C2; arrows indicate desmosomes. N: Nucleus. Scale bar = 5 μm. Inset scale bar = 0.25 μm.

the description of elevated basal autophagy of PDAC cells, numerous autophagosomes were present in the cytoplasm of both the outer and inner regions of 3D-spheroids (Figure 3B2 and C)[19]. In the internal part of HPAC spheroids, some adjoined cells were linked by junctional specializations and arranged in lumen-like structures which appeared polarized with numerous microvilli projecting into the lumen (Figure 3E).

PL45 cells cultured in 2D-monolayers showed a light or dark cytoplasm in a similar manner to HPAF-Ⅱ and HPAC cells. However, unlike HPAF-Ⅱ and HPAC grown in 2D-monolayers, some cells showed protrusions of the plasma membrane similar to invadopodia of about 6 μm in length that projected toward the culture medium (Figure 4A).

PL45 grown in 3D-spheroids were arranged in multiple layers (Figure 4B and C) and frequently had markedly irregular nuclei (Figure 4C). In the cytoplasm, lipid droplets, autophagosomes, and numerous mitochondria were mainly located close to the nucleus. Interestingly, small groups of cells linked to each other by desmosomes (Figure 4C; inserts C1 and C2) seemed partially detached from the peripheral area of the spheroid (Figure 4B and C).

E-cadherin and β-catenin expression, and actin arrangement

Immunofluorescence analysis revealed that E-cadherin and β-catenin were strongly expressed at cell boundaries in both PDAC 2D-monolayers and 3D-spheroids, suggesting the presence of functional adherens junctions (Figures 5-7). In 2D-monolayers, actin filaments were

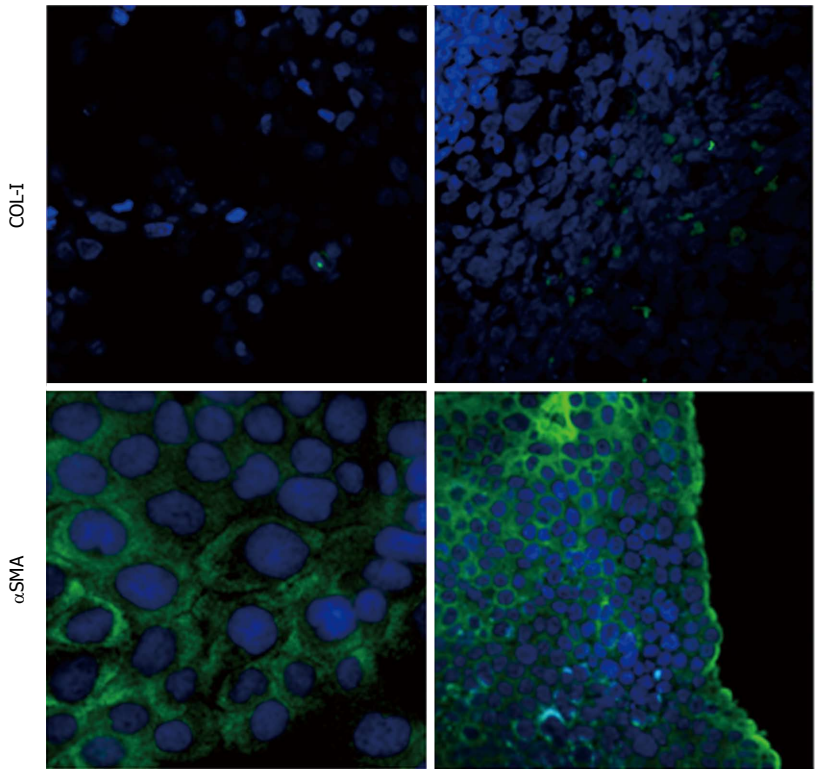

Figure 5 Expression of epithelial-to-mesenchymal transition-related markers in HPAF-Ⅱ cells. Micrographs using a confocal microscope showing epithelial (A) and mesenchymal markers (B) in HPAF-Ⅱ cells grown in 2D-monolayers and 3D-spheroids. Original magnification: 60 ×.

arranged just beneath the plasma membrane, forming the cortical actin, although actin fibers were also found in the cytoplasm. In HPAC and PL45, the presence of actin fibers was even more evident, suggesting focal adhesions which attach to the plastic substrate. In contrast, cortical actin filaments were much more evident in 3D-spheroids, as observed in differentiated epithelial cells (Figures 5A, 6A, and 7A). Gene expression analysis revealed that E-cadherin mRNA levels were highly expressed in 2D-monolayers compared to 3D-spheroids. This difference was evident since the effect size was > 2 (5.68 and 7 in HPAC and PL45 cells, respectively) (Figure 8A). In contrast, Western blot analysis showed that full-length E-cadherin (120 kDa) was expressed to a higher extent in 3D-spheroids (Figure 8B and C). In fact, lysates of HPAF-Ⅱ, HPAC, and PL45 cells grown in 3D-spheroids contained higher E-cadherin expression when compared to the relative 2D-monolayers (effect size: 6.15, 6.91, and 36.28, respectively), which was consistent with stronger cell adhesion. Moreover, in cells grown in 2D-monolayers, lower full-length E-cadherin levels were paralleled by an increase in E-cadherin degradation fragments that was consistent with cell junction disruption and lower cell adhesion. The molecular weight of some E-cadherin fragments were consistent with CT1, CT2, and CT3, as previously described[20,21].

Mesenchymal-related phenotype marker expression

Using immunofluorescence, the expression of EMT markers was analyzed with respect to the acquisition of a mesenchymal phenotype suggestive of EMT. N-cadherin was almost undetectable in PDAC cells grown as 2D-monolayers and immunoreactivity was mostly diffuse in the cytoplasm. N-cadherin immunoreactivity was more frequent in 3D-spheroids, mostly in the cytoplasm. In HPAC spheroids, N-cadherin was sometimes detected at cell boundaries, which was consistent with the presence of functional adherens junctions containing this "mesenchymal" transmembrane protein. Although COL-I was expressed by very few scattered PDAC cells grown in 2D-monolayers, its expression seemed more frequent in 3D-spheroids, particularly in HPAC cells (Figures 5B, 6B, and 7B). αSMA was evident in both experimental conditions (Figures 5B, 6B, and 7B) in the three considered cell lines. Vimentin was undetectable (data not shown).

The EMT markers Twist, Snail, Zeb1, and Zeb2 were almost undetectable in both experimental conditions (data not shown). Slug was expressed at very low levels in HPAF-Ⅱ, as well as in PL45 2D-monolayers and 3D-spheroids, and was detected in HPAC at a higher degree in cells grown in 2D-monolayers compared to HPAC in 3D-spheroids (Figure 8D). Low or undetectable mRNA levels of these EMT markers were consistent with a high expression of E-cadherin under both experimental conditions.

cells grown in either 2D-monolayers or 3D-spheroids (Figure 9A). Since podoplanin expression was described in cells undergoing collective migration, HPAF-Ⅱ 3D-spheroids were placed in BME to monitor their morphology during invasion of the surrounding matrix. We did not observe any evident spindle-like projections extending in the BME, but small clusters of cells did seem to detach from the spheroid surface to invade the surrounding environment (Figure 9B). These findings were confirmed by TEM analysis. In these experimental conditions we analyzed phalloidin-stained cells to detect invadopodia. Confocal microscopy revealed the presence of isolated invadopodia, mostly located in the perinuclear region of HPAF-Ⅱ 3D-spheroids grown without BME. Interestingly, invadopodia seemed more evident in the 3D-spheroids grown in BME (Figure 9C).

DISCUSSION

EMT is a complex step-wise process characterized by the loss of epithelial adhesion properties following changes in E-cadherin expression patterns, adherens junction disruption, induction of MMPs leading to the disruption of basement membranes, and enhanced migration and invasion[4]. Loss of intercellular adhesion and increased motility promote tumor cell invasion, allowing tumor cells to acquire the capacity to infiltrate surrounding tissue and metastasize at distant sites[22].

An early essential event of EMT is the loss of epithelial phenotype and cell-cell adhesion driven by the down-regulation of E-cadherin, a well-characterized adhesive junction protein expressed in differentiated and polarized epithelial cells. The graded loss of E-cadherin correlates with the aggressiveness of numerous carcinomas and a worsening prognosis, whereas the forced expression of E-cadherin suppresses tumor development in various *in vitro* and *in vivo* experimental tumor models[23]. E-cadherin down-regulation leads to the release of the E-cadherin/β-catenin complex from the plasma membrane, the disruption of cell-cell junctions[24], and to β-catenin nuclear translocation, where it may function as a transcriptional co-activator[25].

It has also been shown that pancreatic cancers display a reduced expression of E-cadherin and an increased expression of N-cadherin which, in primary tumors, are significantly related to histological grade[26] and the invasive/undifferentiated phenotype[27]. However, in 6 out of 7 PDAC commercial cell lines, the expression of E-cadherin was maintained in the cell membrane[13], increasing the relevance of studies aimed at characterizing the phenotype of PDAC cells in relation to the expression of EMT markers, in order to define the role of EMT in PDAC development and progression.

Our immunofluorescence analysis data show that HPAF-Ⅱ, HPAC, and PL45 cells grown in 2D-monolayers and 3D-spheroids are characterized by strong E-cadherin and β-catenin immunoreactivity at the cell-cell boundary, suggesting that adherent junctions are retained by PDAC cells under both experimental conditions. Original magnification: 60 ×; B: HPAF-Ⅱ 3D-spheroid grown in basement membrane extract (BME) monitored at different time points; C: HPAF-Ⅱ 3D-spheroids grown in the absence or presence of BME were stained using rhodamine-phalloidin to detect actin filaments. Invadopodia are evident boxed. Original magnification: 60 ×.

E-cadherin mRNA levels tended to increase in HPAF-Ⅱ cells grown in 3D-spheroids, but were decreased in HPAC and PL45 spheroids compared to 2D-monolayers. Conversely, E-cadherin was upregulated in PDAC 3D-spheroids at the protein level, suggesting that PDAC cells grown in 3D-spheroids have stronger cell adhesion. The electrophoretic pattern revealed cleavage fragments of E-cadherin in PDAC grown in monolayers, suggesting that the protein underwent partial digestion and was therefore less effective in providing strong cell-cell adhesion under these conditions. However, full length E-cadherin was detected in 3D-spheroids, supporting a stronger cohesion which likely allows and favors collective migration[28]. The presence of E-cadherin degradation fragments may explain the apparent discrepancy between E-cadherin mRNA and protein levels, since they can be generated by post-translational modifications.

The epithelial differentiated phenotype of HPAF-Ⅱ, HPAC, and PL45 was strongly confirmed, especially in 3D-spheroids, using a transmission electron microscope. In fact, PDAC cells grown in 3D-spheroids maintained the junctional complexes and cell polarity typical of columnar simple epithelium lining pancreatic secretory ducts, and exhibited many microvilli on the apical surface. This finding is not in conflict with the behavior of these cells; as previously demonstrated, PDAC cells, even if characterized by a well-differentiated phenotype, are highly malignant and invasive[29].

Our results point to new and important information in understanding the phenotype of these cancer cells in relation to the expression of mesenchymal markers. We showed that PDAC cells in 3D-spheroids retain the expression of the E-cadherin/β-catenin complex at cell boundaries, while N-cadherin is occasionally expressed at the plasma membrane. This finding suggests not only that PDAC cells in 3D-spheroids have undergone the "cadherin switch" typical for EMT, but also that E-cadherin-mediated cell adhesion is retained and probably strengthened by functional adherens cell junctions containing N-cadherin, especially in HPAC cells.

Confocal microscopy confirmed that HPAF-Ⅱ, HPAC, and PL45 exhibit a differentiated epithelial phenotype, as previously suggested[30,31], but some differences in the expression of EMT markers were detected. In particular, mesenchymal markers seemed more evident in HPAC and PL45 cells, with PL45 being the least differentiated. This differing profile could be responsible for the different behavior, but a relationship between differentiation grade, cell migration, and invasion potential has not yet been defined[32].

The concomitant expression of mesenchymal markers, such as αSMA, in both 2D-monolayers and 3D-spheroids supports the hypothesis that PDAC cells underwent EMT. The expression of EMT markers such as Twist, Snail, Zeb1, and Zeb2 was almost undetectable, in line with the high expression of E-cadherin and the maintenance of adherens junctions. Slug was detected in PDAC cells at low levels, particularly in HPAC cells, in both 2D-monolayers and 3D-spheroids. An inverse correlation between Snail and E-cadherin at the mRNA level in pancreatic cancer cells was previously reported, while Slug expression in pancreatic cancer was reported to have no evident relationship with decreased expression of E-cadherin[7]. To explain this apparent inconsistency, it was suggested that the transient expression of Snail might be involved in inducing the invasion process, whereas Slug might be involved in the maintenance of the migratory invasive phenotype[7].

Some cells in 3D-spheroids expressed COL-I, a protein typical of mesenchymal-like cells. We feel this is an interesting finding that demonstrates the relevance of the 3D arrangement in determining cell phenotype and, therefore, supports the importance of 3D experimental models in cancer research.

E-cadherin expression and functional adherens junctions seem more evident in 3D-spheroids, suggesting that higher cell adhesion could favor collective cell migration in PDAC cells by linking them together and ensuring tissue integrity during collective cell migration. The hypothesis of PDAC cells moving cohesively in a collective migration is also supported by the observation that no single invading cells were previously detected in 3D reconstructed models, indicating that single cell invasion does not occur in PDAC. Moreover, increased E-cadherin was shown in the leading edge of migrating epithelial sheets[33], supporting collective migration for these cancer cells. In contrast with individually migrating cells, during collective migration the rear of the front cell retains intact cell-cell junctions to the successor cell, thereby mechanically holding the cells together and augmenting the efficiency of paracrine cell-cell signaling and multicellular coordination[34,35].

Podoplanin is a small mucin-like protein up-regulated in a number of different cancers, suggesting a role in tumor progression[36-39]. Although the physiological function of podoplanin is still unknown and its functional contribution to tumor progression has remained elusive, podoplanin expression was observed in cells invaded by collective migration[40]. Results from immunofluorescence analysis show podoplanin expression in HPAF-Ⅱ, HPAC, and PL45, according to the hypothesis of collective invasion of PDAC cells. This is consistent with the evidence of small clusters of cells detaching from spheroid surfaces observed at TEM, and with the results of the behavior of HPAF-Ⅱ spheroids in BME, showing that spindle-like projections extending in the BME were not evident, but small groups of cells did detach from the spheroid surface to invade the surrounding matrix. Furthermore, we detected frequent invadopodia, known as specialized podosomes, which release matrix metalloproteinases and characterize collectively invading cancer cells[41]. These invadopodia were more evident in the presence

of BME, as well as being evident under TEM.

Considered as a whole, our data could contribute to clarifying the role of EMT in PDAC progression, provide additional correlative evidence that PDAC cells express EMT markers, and point to relevant differences in the phenotype of PDAC cells grown in 3D-spheroids. In fact, under these experimental conditions, PDAC cells are characterized by functional adherens junctions and concomitant expression of mesenchymal markers, such as N-cadherin and COL-I, which are almost undetectable in PDAC cells grown in 2D-monolayers.

Our results support the use of 3D cultures in biomedical research to bridge the gap between traditional cell cultures and *in vivo* settings in order to more clearly understand the biology of PDAC[14-17,42]. Since 3D cultures seem to provide excellent information on PDAC cell phenotype[43,44], they could represent a pre-clinical model for identifying and validating tumor markers, as well as allowing for the study of new therapeutic tools for PDAC.

COMMENTS

Background

The functions of living tissues can be mimicked in three-dimensional (3D) cell cultures, thereby providing a method of decoding the information encoded in the tissue architecture. The authors analyzed the effect of 3D-arrangement on the expression of some key markers of epithelial-to-mesenchymal transition (EMT) in pancreatic adenocarcinoma (PDAC) cells cultured in either 2D-monolayers or 3D-spheroids.

Research frontiers

Although 3D-cell cultures represent a well-established experimental condition to study the effect of 3D-arrangement on cell phenotype in different cell types, few studies have been performed using 3D-cell cultures of PDAC cells. Some discrepancies were described in the expression of E-cadherin in PDAC commercial cell lines and tissue fragments, increasing the relevance of studies aimed at characterizing the phenotype of PDAC cells in relation to the expression of EMT markers.

Innovations and breakthroughs

The overall information provided by this study supports the use of 3D-cultures in biomedical research to bridge the gap between traditional cell cultures and *in vivo* settings. This approach places cultured cells in an environment that more closely represents and mimics the complex 3D structure of living tissues, in order to more clearly understand the biology of PDAC. The results show that a 3D-cell culture model could provide deeper insight into understanding the biology of PDAC, thereby allowing for the detection of important differences in the phenotype of PDAC cells grown in 3D-spheroids. This study contributes to the clarification EMT's role in PDAC progression, and provides additional correlative evidence of EMT marker expression in PDAC cells.

Applications

3D cultures offer a potential pre-clinical model for identifying and validating tumor markers, as well as allowing for the study of new molecular tools to inhibit signaling pathways and target EMT transcription factors.

Peer-review

This manuscript describes EMT phenomena in 3D-cell cultures using three kinds of pancreatic cancer cell lines. The authors investigated ultrastructural characterization of EMT with transmission electron microscopy and expression of EMT-associated proteins, such as αSMA and E-cadherin. A marked EMT phenomenon was observed in 3D-cell cultures compared to 2D cultures. The results are very interesting.

Abstract

AIM: To investigate the role of diarylpropionitrile (DPN), a selective agonist of estrogen receptor β (ERβ), in liver cirrhosis with portal hypertension (PHT) and isolated hepatic stellate cells (HSCs).

METHODS: Female Sprague-Dawley rats were ovariectomized (OVX), and liver cirrhosis with PHT was induced by CCl_4 injection. DPN and PHTPP, the selective ERβ agonist and antagonist, were used as drug interventions. Liver fibrosis was assessed by hematoxylin and eosin (HE) and Masson's trichrome staining and by analyzing smooth muscle actin expression. Hemodynamic parameters were determined *in vivo* using colored microspheres technique. Protein expression and phosphorylation were determined by immunohistochemical staining and Western blot analysis. Messenger RNA levels were analyzed by quantitative real-time polymerase chain reaction (qRT-PCR). Collagen

gel contraction assay was performed using gel lattices containing HSCs treated with DPN, PHTPP, or Y-27632 prior to ET-1 addition.

RESULTS: Treatment with DPN *in vivo* greatly lowered portal pressure and improved hemodynamic parameters without affecting mean arterial pressure, which was associated with the attenuation of liver fibrosis and intrahepatic vascular resistance (IHVR). In CCl_4-treated rat livers, DPN significantly decreased the expression of RhoA and ROCK Ⅱ, and even suppressed ROCK Ⅱ activity. Moreover, DPN remarkedly increased the levels of endothelial nitric oxide synthase (eNOS) and phosphorylated eNOS, and promoted the activities of protein kinase G (PKG), which is an NO effector in the liver. Furthermore, DPN reduced the contractility of activated HSCs in the 3-dimensional stress-relaxed collagen lattices, and decreased the ROCK Ⅱ activity in activated HSCs. Finally, *in vivo*/*in vitro* experiments demonstrated that MLC activity was inhibited by DPN.

CONCLUSION: For OVX rats with liver cirrhosis, DPN suppressed liver RhoA/ROCK signal, facilitated NO/PKG pathways, and decreased IHVR, giving rise to reduced portal pressure. Therefore, DPN represents a relevant treatment choice against PHT in cirrhotic patients, especially postmenopausal women.

Key words: Portal hypertension; Estrogen receptor; Rho-kinase signaling; Nitric oxide; Hepatic stellate cells

Core tip: Liver cirrhosis and portal hypertension (PHT) are subject to gender and estrogen levels. The aim of the present study was to investigate whether estrogen receptor β selective agonists could ameliorate intrahepatic resistance and mitigate PHT in rats with CCl_4-induced cirrhosis, and uncover the underlying mechanism by investigating RhoA/ROCK and NO/PKG signaling. The authors propose that treatment with an estrogen receptor β selective agonist could improve cirrhotic PHT *via* regulating RhoA/ROCK and NO/PKG signaling.

Role of estrogen receptor β selective agonist in ameliorating portal hypertension in rats with CCl_4-induced liver cirrhosis. *World J Gastroenterol* 2016; 22(18): 4484-4500 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4484.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4484

INTRODUCTION

Increased intrahepatic vascular resistance (IHVR) to portal blood flow is a major contribution to portal hypertension (PHT) in liver cirrhosis[1,2], and decreased splanchnic vascular resistance worsens and maintains the increased portal pressure (PP)[2,3]. Over the past 20 years, with a keen grasp on hepatic microcirculation, a dynamic component involving changes in hepatic vascular tone has been demonstrated to contribute to IHVR; hence, increased vascular tone augments IHVR[4,5]. Apart from structural changes (fibrosis, vascular remodeling, vascular occlusion, and nodule formation), activated hepatic stellate cells (HSCs), contraction of intrahepatic vascular smooth muscle cells (VSMCs) and decreased levels of NO vasodilator, all play a critical role in contributing to increased IHVR[4,6]. It is well known that the intrahepatic upregulation of RhoA/ROCK signaling, as well as the inhibition of NO/PKG signaling, contributes to increased IHVR[7-9]. Furthermore, the two pathways regulate each other, maintaining the balance between phosphorylation and dephosphorylation of myosin light chains (MLC)[9-11]. Thus the two pathways are crucial therapeutic targets to inhibit the increased IHVR and PP occurring in cirrhosis.

Epidemiological studies have reported the male to female ratio among patients with cirrhosis is in the range of 2.3:1-2.6:1; moreover, menopause increases the susceptibility to cirrhosis and PHT[12,13]. Animal experiments and clinical trials have provided consistent evidence for the protective effect of endogenous and exogenous estrogen on liver fibrosis[12-16]. However, the administration of exogenous estrogen had its potential risks, causing their clinical use[17] to be impeded. Fortunately, previous studies regarding estrogen receptor (ER) subtypes have indicated that estrogen receptor β (ERβ) gives rise to few side effects of estrogen[18], while ERα mediates the majority effects of estrogen on classic estrogen target tissues, as well as their associated side effects[19]. Interestingly, high ERβ expression levels and low ERα expression levels were observed in both men's and women's normal and fibrotic livers, and HSCs had functional ERβ, rather than ERα, which responded directly to estradiol (E2) exposure[20]. ERβ selective agonists hold the key to producing protective effects of estrogens on liver cirrhosis and PHT, while reducing undesired side effects[21].

Therefore, this study investigated the effect of diarylpropionitrile (DPN), an ERβ selective agonist, on the intrahepatic RhoA/ROCK and NO/PKG pathways, and on hepatic hemodynamics systemically as well.

MATERIALS AND METHODS

Animals

Female SD rats - initially weighing 180-200 g - were acquired from the Laboratory Animal Center of School of Medicine, Shanghai Jiao Tong University, China. Under the constant temperature of 21 ℃, rats were exposed to a light/darkness cycle of 12 h/12 h, and accessed to water and standard rat chow. All animal

experiments conformed to guidelines on caring and using lab animals which were reviewed by the Research Ethics Committee of Renji Hospital (No. RJ-20151211).

Treatment regimens

Rats were assigned to a sham-operated control group (n = 15) or an ovariectomized (OVX) group (n = 45) in a random way. The rats were intraperitoneally injected with ketamine (100 mg/kg per body weight) and xylazine (12 mg/kg per body weight) for anesthesia. The surgical procedure was performed from a midline back incision and both ovaries were removed. The control group received the same incisions and the two ovaries were explored but not excised. The animals were allowed 2 wk for recovery. OVX rats were divided into three groups with 15 in each, as below: OVX + CCl_4 group, OVX + CCl_4 + DPN group and OVX + CCl_4 + DPN + PHTPP group.

CCl_4 administration

The rats needed to weigh and administer mixed food on a daily basis. For the OVX + CCl_4 group, the subcutaneous injection at a dose of 4 mL/kg was conducted twice a week while doubling dosage for the first injection, as 400 mL/L CCl_4 with olive oil needs to be done. After 14-16 mo, this procedure led to micro nodular cirrhosis with PHT. In addition to this, the OVX + CCl_4 + DPN group was treated subcutaneously with 30 nmol/100 g DPN in 1 mL dimethyl sulfoxide (DMSO), twice weekly. Along with CCl_4 and DPN, the OVX + CCl_4 + DPN + PHTPP group also received 30 nmol/100 g PHTPP in 1 mL DMSO, twice weekly. The control group was injected with 1 mL DMSO, twice weekly. After 14 to 16 mo, CCl_4 and drug injections were stopped within 6 d prior to the start of experiments. Although there were 15 rats in each group at the beginning of the study, the number of the rats decreased to 11, 13 and 12 in the OVX + CCl_4, OVX + DPN + CCl_4 and OVX + DPN + PHTPP + CCl_4 groups, respectively, due to death caused by illness. Five rats from each group were sacrificed for tissue harvesting. Sample livers were kept in formaldehyde or snap-frozen by liquid nitrogen under the temperature of -80 ℃. The mesenteric arteries were used to detect mesenteric arteriole reactivity. The other rats were used for hemodynamic studies and their blood was used to analyze biochemical parameters.

Hemodynamic studies

When rats were given ketamine anesthesia (100 mg/kg, imp), in a median laparotomy, a PE-50 catheter was inserted into a small ileocaecal vein and guided to the portal vein to measure PP. A PE-50 catheter was introduced to a left femoral artery to measure mean arterial pressure (MAP). An additional PE-50 catheter was inserted from a right carotid artery leading to the left ventricle, which was used for microsphere injection. The femoral artery catheters and the portal vein were in connection with a pressure transducer (M100613, United States Philips Corporation). The PP and MAP were recorded on a multi-channel recorder (COLIN, BP508, Japan). The zero reference point referred to the spot of 1 cm above the operating table.

The Dye-Trak microsphere technique was performed as per previous description. Briefly, the 1-min withdrawal (0.65 mL/min) of a reference sample was conducted with a continuous extraction pump (ALC-IP900, shanghai, china). Suspending in the solution of 0.3 mL saline with 0.05% Tween, approximately 300000 yellow microspheres of 15.5 μm in diameter (Triton Technologies, San Diego, California, United States) were injected into the left ventricle within 10 s of starting blood withdrawal. Suspending in a solution as same as yellow ones, 150000 blue microspheres was injected into an ileocaecal vein within 30 s to evaluate mesenteric portal-systemic shunt volume. Ten minutes later, the rats were sacrificed by injecting KCl intravenously. The blood and tissue samples were assimilated by a portion of 3.8 mL of 5.3 mol/L KOH and 0.5 mL Tween 80, and were subsequently boiled for 1 h. Then ready samples were processed by vortex and filtered with Whatman Nucleopore filters (Whatman International, Maidstone, United Kingdom). Colors were extracted from the filtered microspheres by using 0.2 mL dimethyl formamide and measured by absorption spectrophotometry. Hemodynamic parameters were measured and calculated according to standard methods[22,23]. Afterwards, with the software of Triton Technologies, cardiac output and organ blood flow were calculated and expressed based on 100 g per body weight. Splanchnic perfusion pressure was obtained by deducting PP from MAP. Splanchnic vascular resistance was rated by the splanchnic perfusion pressure to the splanchnic blood flow. Mesenteric portal-systemic shunt flow was derived from the fraction in the lung out of total injected blue microspheres. Hepatic portal-vascular resistance was estimated as PP divided by the sum of gastrointestinal and splenic perfusion minus mesenteric portal-systemic shunt flow. Systemic vascular resistance (SVR) was defined as the ratio of MAP to cardiac output.

Histological and immunohistochemical assessment

HE, immunohistochemical, and trichrome collagen staining were applied to examine liver sections (4 mm) on glass slides with silane coating. Liver sections were evaluated randomly by an accomplished liver pathologist yet unfamiliar with animal groups.

For immunohistochemistry, primary antibodies (Cell Signaling Technology, Danvers, MA) were used at a dilution of 1:200 (phosphor-Thr18/Ser19-PML) or 1:100 (α-SMA) to incubate liver sections, after the incubation in the streptavidin-peroxidase complex. Peroxidase conjugates were then viewed in diaminobenzidine (DAB) solution. Afterwards, the prepared livers were

processed by hematoxylin counterstaining and then covered with a plate.

Collagen contents were quantified using Masson's trichrome collagen stain, and the Masson-stained areas are reported to be its ratio to the total area. The positive areas were analyzed using Image J software. The liver sections were then averagely valued among five rats from each group.

Quantitative RT-PCR

An array of processes need to be done, including separating RNA from 30 mg shock-frozen hepatic tissue with TRIzol (Invitrogen), using MMLV reverse transcriptase (Invitrogen) to perform reverse transcription, conducting quantitative RT-PCR (qRT-PCR) with Platinum SYBR Green qPCR SuperMix-UDG (Invitrogen), and preparing primers and probes for RT-PCR with Primer Express Software (Applied Biosystems, Foster City, CA). 18S rRNA was used for the endogenous control. The used primer sequences were the following: GAPDH, (Forward) GGAGTCCACTGGCGTCTTC and (Reverse) GGCATTGCTGATGATCTTGAGG; RhoA, (Forward) GGCAGAGATATGGCAAACAGG and (Reverse) TCCGTCTTTGGTCTTTGCTGA; ROCK-Ⅱ, (Forward) CCCGATCATCCCCTAGAACC and (Reverse) TTGGAGCAAGCTGTCGACTG.

Western blot and antibodies

Shock-frozen section samples were processed by homogenization in buffer containing 25 mmol/L Tris/HCl, 5 mmol/L ethylenediamine tetraacetic acid, 10 μmol/L phenylmethanesulfonyl fluoride, 1 mmol/L benzamidine, and 10 μg/mL leupeptin. Liver samples were put in the buffer for dilution. Homogenate protein concentrations were determined using the BCA Protein Assay kit (Beyotime, Haimen, China). Samples (40 μg of protein/lane) were assayed by SDS-PAGE (15% gels for RhoA and p-MLC; 8% for ROCK, iNOS, eNOS, and p-eNOS; and 10% for moesin, p-moesin, VASP, p-VASP, and α-SMA). After electrophoresis, protein was shifted under the effect of a 250 mA current for 1.5 h to a polyvinylidene difluoride membrane which was stemmed by 5% BSA for 2 h and treated as below in primary antibodies at the temperature of 4 ℃ overnight: DAPDH, ERβ, α-SMA, iNOS, eNOS, and p-eNOS (Ser^{1177}) from Abcam (Cambridge, United Kingdom); RhoA, ROCKII, moesin, p-moesin (Thr^{558}), VASP, p-VASP (Ser^{239}), MLC, and p-MLC (Thr^{18}/Ser^{19}) from Santa Cruz Biotechnology (Santa Cruz, CA). The membrane was then processed for 1 h with appropriate secondary antibodies (Abcam) at a 1:5000 dilution. Fluorescent signals were detected with an Odyssey Imaging System (Li-Cor Biosciences, Lincoln, NE). GAPDH served as an internal control.

Assessment of PKG, ROCK and MLC activities

PKG activity was assessed and indicated by the phosphorylation level of endogenous substrate VASP at $Ser239$[8,22]. ROCK activity was evaluated by measuring the phosphorylation of endogenous substrate, moesin, at Thr^{558}[8,22]. MLC activity was assessed by measuring the phosphorylation of MLC at Thr^{18}/Ser^{19}[24]. The analysis was performed by Western blot with site- and phosphor-specific antibodies.

Cell culture

HSCs were separated from male SD rats with the weights of 300-400 g as per previous description[24]. Technically, after in situ sequential perfusion of the solutions of collagenase IV (Sigma, St. Louis, United States) and pronase E (Merck, Darmstadt, Germany) to hepatic samples, decentralized cells were separated by density gradient centrifugation with Optiprep (Nycomed, Sweden). Cells were obtained at a density less than 1.053 (9% Optiprep). Viability and purity were determined to be higher than 95% as per Trypan blue exclusion and morphological characteristics. Then cells were plated onto uncovered plastic culture plates, being cultivated with Dulbecco's Modified Eagle Medium without Phenol Red (DMEM; Invitrogen), which was complemented with 10% fetal bovine serum, 0.6 IU/mL insulin, 2 mmol/L glutamine, and 1% antibiotic-antimycotic solution (Invitrogen), and was renewed every 48-72 h.

Collagen gel contraction assay

Collagen gel contraction experiments were conducted upon slight modifications[25] as per previous descriptions. Briefly, hydrated collagen gels were produced with rat tail tendon collagen I (Becton Dickinson Labware, Bedford, MA) and made adjustments with 0.1 N NaOH and 10 × PBS, to a final collagen concentration of 1.2 mg/mL and pH 7.4 at 4 ℃. A 500 μL portion of collagen solution was put into wells of a 24-well tissue culture dish for 1 h incubation at 37 ℃. Then HSCs were layered on top of the collagen lattice of 5×10^5 cells/mL. Twenty-four hours after adding 1 mL/well of serum free culture medium and the starvation process, lattices in stability were flushed twice with 1 × PBS. After pretreatment with DPN (10^{-7} mol/L), DPN (10^{-7} mol/L) + PHTPP (10^{-7} mol/L), or Y-27632 (10^{-5} mol/L) for 30 min, HSCs were exposed to ET-1 (10^{-8} mol/L, Roche Diagnostics, Brussels, Belgium). Buffer without ET-1 was used as a control. Gels were immediately detached with the tip of a 100 μL pipette from the plates in the pattern of gentle circumferential dislodgment. Digital photos were obtained to monitor the change in lattice area 4 h after addition of the contractile agonist. All information was drawn from studies of more than three sets of triple collagen lattices by cultured HSCs out of three different rat HSC separations.

Analysis of Rho kinase and MLC activity in HSCs

Activated HSCs grown on culture dishes were starved for 24 h. HSCs were pretreated with DPN (10^{-7} mol/L), DPN (10^{-7} mol/L) + PHTPP (10^{-7} mol/L), or Y-27632

Table 1 Biochemical parameters of the different treatment groups

Group	ALT (U/L)	AST (U/L)	Bilirubin (mg/dL)	Albumin (g/L)	BUN (mmol/L)	Scr (μmol/L)
Control (n = 8)	43.3 ± 7.7	124 ± 14	0.3 ± 0.1	34.1 ± 3.4	8.7 ± 1.2	22.4 ± 4.0
OVX + CCl_4 (n = 6)	166 ± 10.1[a,b]	439 ± 19[a,b]	3.4 ± 0.3[a,b]	21.5 ± 2.8[a,b]	16.7 ± 1.8[a,b]	35.0 ± 4.7[a,b]

(10^{-5} mol/L) for 30 min, prior to exposure to ET-1 (10^{-8} mol/L) for 4 h. Buffer without ET-1 was used as a control. ROCK and MLC activities were assessed by monitoring the phosphorylation levels of moesin at Thr^{558} and MLC at Thr^{18}/Ser^{19}, respectively[22,26].

Statistical analysis

Data are expressed as mean ± SE. After the Bonferroni/Dunn or Mann-Whitney *U* test, ANOVA was applied to compare among groups (SPSS 21 for Windows, SPSS Inc., Chicago, IL). A *P*-value < 0.05 had great statistical significance. With regards to analyzing concentration response curves, the information was seated by nonlinear regression in the Prism computing project (Graph Pad Software Inc., San Diego, CA).

RESULTS

Biochemical parameters

CCl_4 caused a great increase of the analyzed biochemical parameters, including ALT, AST and bilirubin, and a significant decrease in albumin. However, treatment with DPN decreased the ALT, AST and bilirubin levels, and increased the albumin levels in PHT rats. PHTPP counteracted the effect of DPN (Table 1).

Morphological characteristics of the rat livers

CCl_4 caused significant hepatocyte steatosis, fibrous proliferation of interlobular portal areas, and formation of pseudolobules and tubercles, whereas DPN attenuated these phenomena (Figure 1A). This could be verified by trichrome staining (Figure 1B) from a histological perspective. Collagen content quantification demonstrated that the collagen volume fraction increased in CCl_4-induced cirrhotic rats (24.8% ± 4.8%) in comparison with the control group (2.1% ± 0.5%), however, DPN treatment played a significant role in inhibiting the secretion of collagen (17.0% ± 4.0%). There was no statistically significant difference in collagen content between the PHTPP group (22.9% ± 4.9%) and the CCl_4-induced group (Figure 1C).

Expression of α-SMA in rat livers

The expression of α-SMA correlated with the activity of HSCs and the degree of cirrhosis. Immunohistochemical staining and Western blot analysis against α-SMA consistently showed a significant increase in α-SMA expression in the OVX + CCl_4 and OVX + CCl_4 + DPN + PHTPP groups, while DPN treatment greatly decreased the expression of hepatic α-SMA in CCl_4-treated rats (Figure 2A-D).

Expression of ERβ in rat livers

ERβ expression was present in the rat livers of all of four groups. The expression of ERβ in DPN treated rats was slightly higher than that in the other three groups, although there was no statistically significant difference between all groups (Figure 3A-B)

In vivo hemodynamic studies

In the OVX + CCl_4 group there were markedly increased PP and IHVR compared to the control group. However, treatment with DPN significantly decreased PP and IHVR, while PHTPP counteracted the effect of DPN (Table 2). With regards to hyperdynamic circulation, the OVX + CCl_4 treated rats presented markedly increased CO and PVI, and decreased MAP, TPR and SVR. Nevertheless, DPN significantly decreased CO and PVI, and increased SVR, but did not affect MAP and TPR. PHTPP counteracted the effect of DPN on CO, PVI and SVR (Table 2).

Effect of DPN on the RhoA/ROCK pathway in rat livers

In comparison with those sham-operated non-cirrhotic rats, both RhoA and ROCK protein levels were dramatically improved in the OVX + CCl_4 rat livers. Treatment with DPN significantly down-regulated RhoA and ROCK protein levels, though they remained higher than those in sham-operated rats. In contrast, treatment with PHTPP counteracted DPN (Figure 4A-B). In all four groups, the mRNA expression levels of both RhoA and ROCK were consistent with RhoA and ROCK protein levels (Figure 4C). As a ROCK activity indicator, the moesin phosphorylation was examined by Western blot. Western blot analysis showed that p-moesin (Thr^{558}) levels were significantly enhanced in OVX + CCl_4 rat livers. DPN treatment significantly decreased the level of p-moesin (Thr^{558}), while PHTPP treatment counteracted the effect of DPN. These differences were not in association with variation of overall moesin levels, alike in all groups (Figure 4D-E).

Effect of DPN on the NO/PKG pathway in rat livers

There was no distinction between the intrahepatic eNOS expression levels of the OVX + CCl_4 group and the control group, but there was an important decrease in

DPN: Diarylpropionitrile.

intrahepatic eNOS phosphorylation amount. Treatment with DPN not only markedly increased the expression of eNOS, but also significantly up-regulated p-eNOS (Ser^{1177}) levels in the cirrhotic livers of OVX rats (Figure 5A-B).

PKG activity was evaluated by measuring the phosphorylation of its endogenous substrate, VASP at Ser^{239}. Western blot analysis using p-VASP (Ser^{239}) antibodies revealed that p-VASP (Ser^{239}) levels remained unchanged in the OVX + CCl_4 and PHTPP treated rats, compared to the control group. However, DPN treatment significantly enhanced intrahepatic p-VASP (Ser^{239}) levels. No differences in total VASP expression were found between treatment groups. Therefore, it can be said that DPN increases PKG activity in the livers of OVX + CCl_4 rats (Figure 5A-B).

Regarding the expression of iNOS, Western blot analysis revealed that the marked increase in iNOS expression seen in the cirrhotic livers OVX rats could be inhibited by DPN (Figure 5A-B).

MLC activity

The RhoA/ROCK and NO/PKG pathways maintain the balance between phosphorylation and dephosphorylation of MLC[9-11]. Thus, we investigated the level of p-MLC (Thr^{18}/Ser^{19}) using Western blot analysis. The results revealed that p-MLC (Thr^{18}/Ser^{19}) levels greatly increased in the OVX + CCl_4 rat livers compared to control rats. However, treatment with DPN significantly decreased the level of p-MLC (Thr^{18}/Ser^{19}), while the addition of PHTPP increased the level of p-MLC (Thr^{18}/Ser^{19}) once more (Figure 6A-B). Therefore, DPN inhibited MLC activity in the OVX + CCl_4 rat livers, which reduced the contraction of intrahepatic VSMCs.

Collagen gel contraction assay

The contraction was assessed using a model in which subcultured cells were grown on top of gel lattices composed of type 1 collagen. The lattice contraction in ET-1 processed cells registered stronger than in normal cells, producing gels by 51.8% ± 7.1% and 82.6% ± 8.9% of the original size, respectively. Pretreatment with 10^{-7} mol/L DPN or 10^{-5} mol/L Y-27632 significantly reduced the contraction of HSCs, reducing the gel areas to only 73.8% ± 8.3% and 77.7% ± 9.6%, respectively. However, pretreatment with both 10^{-7} mol/L DPN and 10^{-7} mol/L PHTPP produced HSC contraction similar to that of the ET-1 control, 54.4% ± 7.2% of the initial gel area (Figure 7A-B). Thus, DPN inhibited the ET-1-induced HSC contraction, and the inhibitory capacity of DPN was similar to that of the ROCK inhibitor Y-27632.

Expression of ERβ in HSCs

Expression of ERβ existed in all of the five cell treatment groups. Furthermore, there were no statistically significant differences in the ERβ expression of the five groups (Figure 7C-D).

Effect of DPN on ROCK activity in HSCs

Western blot analysis showed that ET-1-induced activation significantly increased the level of p-moesin (Thr^{558}) in HSCs compared to the control group. Treatment with DPN reduced the phosphorylation of moesin in HSCs, while addition of PHTPP returned the p-moesin (Thr^{558}) level to that seen in the ET-1 group. Treatment with Y-27632 was more effective than DPN in inhibiting the level of p-moesin (Thr^{558}) (Figure 7A-B). Thus, the results revealed that DPN could inhibit the activity of ROCK in HSCs, but its capacity was less than that of the classic ROCK inhibitor Y-27632 (Figure 7E-F).

Effect of DPN on MLC activity in HSCs

We also investigated the phosphorylation of MLC in the five cell treatment groups. As a result, DPN played a more powerful role in inhibiting p-MLC (Thr^{18}/Ser^{19}) than inhibiting p-moesin (Thr^{558}). The role of DPN in

inhibiting p-MLC (Thr^{18}/Ser^{19}) was similar to that of Y-27632 (Figure 7E-F).

DISCUSSION

Our study shows that DPN, an ERβ selective agonist, not only postpones the development of liver cirrhosis, but also decreases the PP and IHVR in OVX CCl_4-induced cirrhotic rats. Furthermore, our data demonstrate that DPN inhibits the RhoA/ROCK pathway and activates the NO/PKG pathway, leading to the inactivation of p-MLC in the cirrhotic livers of OVX rats. Furthermore, the *in vitro* studies demonstrate that DPN suppresses the contraction of HSCs, which is associated with the inhibition of ROCK and phosphorylation of MLC.

In the previous studies, estrogen therapy was indicated to improve hepatic fibrosis[12-15]. Thus, we first examined the effect of DPN on CCl_4-induced liver cirrhosis in OVX rats by histological and immunochemical assessments. Furthermore, we examined α-SMA expression. HE staining and computerized collagen volume fraction analysis using trichrome staining indicated that DPN significantly inhibited CCl_4-induced liver cirrhosis in OVX rats (Figure 1). α-SMA expression markedly activated HSCs, which play a critical role in liver fibrogenesis[26]. Immunohistochemical staining and Western blot analysis against α-SMA confirmed that DPN downregulated α-SMA expression in CCl_4-induced cirrhotic livers. However, an ERβ antagonist, PHTPP, counteracted the effect of DPN (Figure 2). This indicates that DPN may improve liver cirrhosis in an HSC-dependent manner. The results of the liver and renal examinations affirmed the conclusion above (Table 1).

To investigate the effect of DPN on PP, IHVR and hyperdynamic circulation, we measured *in vivo* hemodynamic parameters using the microspheres

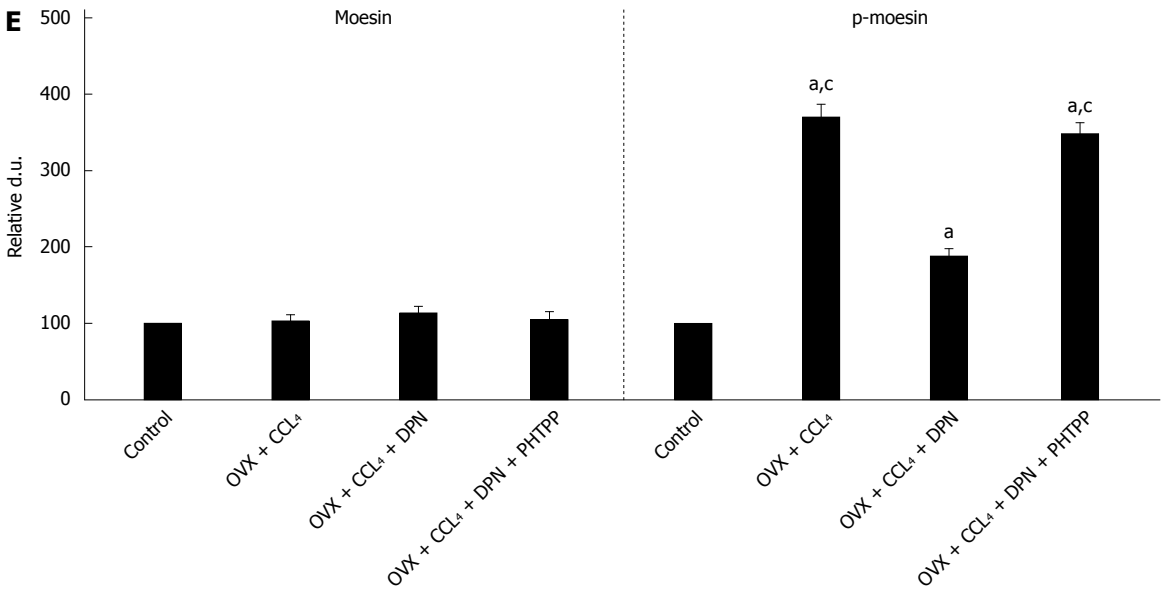

Figure 4 Diarylpropionitrile inhibits the protein (A, B) and mRNA (C, D) expression of RhoA and ROCKII, and even suppresses the site-specific phosphorylation of moesin (Thr^{558}) in CCl_4-treated rats (D, E). Shown are the relative densitometric quantifications of all experiments (mean ± SE), with values from the sham-operated controls set to 100 DU. $^aP < 0.05$ *vs* control group; $^cP < 0.05$ *vs* DPN group. DPN: Diarylpropionitrile.

technique. Interestingly, our data indicated that DPN markedly decreased the PP and IHVR in CCl_4-induced cirrhotic OVX rats, but PHTPP counteracted the effects of DPN. This suggested that DPN played an important role in decreasing the PP and IHVR *via* ERβ in the liver. Moreover, DPN improved the hyperdynamic circulation of cirrhotic rats without effecting the MAP or TPR (Table 2). In this regard, DPN is clearly different from other vasodilators, such as nitrates and ROCK antagonists, as these medicines have a risk of decreasing MAP and TRP[27,28]. This characteristic of DPN is worth intensively exploring.

Although the liver did not work as the estrogen's classic target organ, in our present experiment, Western blot analysis showed that there indeed existed ERβ expression in the livers of all of four rat groups. This result is consistent with a previous study[20], and is the basis of DPN having an effective role in the liver (Figure 3).

More and more evidence indicates that the high responsiveness of the intrahepatic vascular bed is closely related to increased expression and activation of ROCK in cirrhotic livers, which leads to increased IHVR[7]. Furthermore, ROCK antagonists, such as Y-27632 and fasudil, significantly decrease the IHVR[28]. As described in previous studies[29-31], estrogen could attenuate vascular contraction through inhibition of the RhoA/ROCK pathway. Thus, we further investigated the effect of DPN on the RhoA/ROCK pathway in the CCl_4-induced cirrhotic livers of rats. Our data indicate that treatment with DPN greatly reduced the mRNA and protein expression levels of RhoA and ROCKⅡ (Figure 4A-C). Moreover, DPN inhibited the increase in moesin phosphorylation typically seen in the cirrhotic livers, without altering the levels of total moesin (Figure 4D-E). This means that DPN not only inhibited the expression of RhoA and ROCK, but also blocked hepatic ROCK activity as seen by the suppression of moesin phosphorylation, which is a common measure of ROCK activity. Therefore, it can be said that besides improving liver fibrosis, DPN can decrease intrahepatic vasoconstriction, thus decreasing intrahepatic vascular tone.

RhoA/ROCK signaling and NO/PKG signaling regulated each other and maintained the balance between intrahepatic vasocontraction and vasodilatation[9-11]. Hence, we explored the effect of DPN treatment on NO/PKG signaling in the cirrhotic livers of OVX rats. It has been reported that although eNOS protein levels may appear unchanged, eNOS activity and NO production can decrease in sinusoidal endothelial cells (SECs)[16,32]. It was also been reported that estrogen stimulated eNOS expression in SECs and increased NO production in both normal and cirrhotic rats[32,33]. Our experiment revealed unchanged eNOS expression in cirrhotic OVX rats compared to the control group, although the levels of p-eNOS (Ser^{1177}) were noticeably lower (Figure 5). However, DPN might not only increase eNOS expression, but also increase p-eNOS (Ser^{1177}) levels (Figure 5). Hence, DPN could not only increase the expression of eNOS in SECs, but also upregulate the activation of eNOS, ultimately augmenting eNOS-derived NO generation. In addition, we investigated iNOS expression, and found that the markedly increased iNOS expression seen in the cirrhotic livers of OVX rats could be inhibited by DPN, which could in turn be blocked by PHTPP (Figure 5). It was reported that estrogen, which has potent antioxidant properties, could significantly attenuate cytokine-induced iNOS production in rat hepatocytes[34]. Thus, we speculate

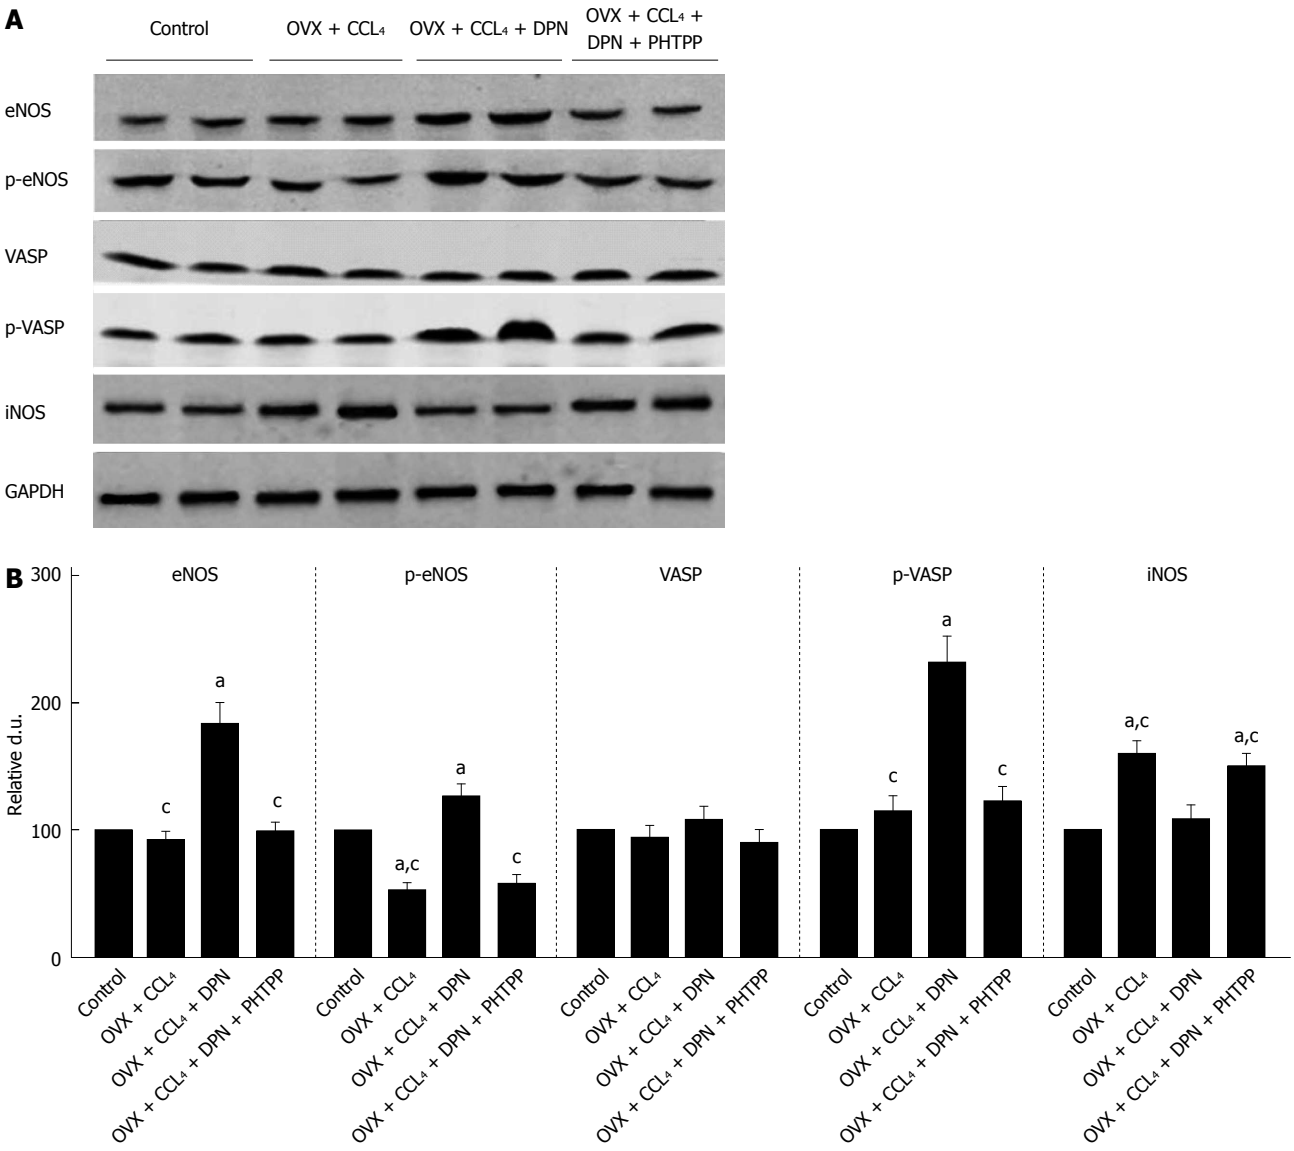

Figure 5 Diarylpropionitrile increases the hepatic expression of NO/PKG pathway proteins and increases their activity but inhibits hepatic iNOS expression in CCl_4-treated rats. A: Western blot analysis of eNOS, p-eNOS, VASP, p-VASP, and iNOS protein expression; B: Relative densitometric quantifications of all experiments (mean ± SE), with the values from the controls set to 100 DU (each group $n = 5$). $^aP < 0.05$ *vs* control group; $^cP < 0.05$ *vs* DPN group.

that DPN might negatively regulate protein nitrosylation and enhance NO bioavailability *via* inhibiting iNOS, which is closely associated with oxidative stress and cytokines[35,36]. To further understand the role of DPN in the activation of PKG, we detected phosphorylation levels of VSAP, an endogenous PKG substrate[8,22]. Our data indicate that DPN upregulates p-VASP (Ser239) and ultimately mediates NO-induced vasodilatation (Figure 5). There is evidence that defective eNOS signaling is mediated by ROCK activation in rats with secondary biliary cirrhosis[12], and that PKG-dependent RhoA deactivation would lead to a perpetuating loop in the effect of statins on RhoA/ROCK activity[37]. In our current study, we also found that inhibition of the RhoA/ROCK pathway might contribute to the activity of NO/PKG pathway in CCl_4-induced cirrhotic OVX rats, and vice versa. Taken together, we concluded that DPN could simultaneously play an important role in the inhibition of the RhoA/ROCK and the activation of the NO/PKG pathways in the intrahepatic vascular system of cirrhotic rats. In VSMCs, both inhibition of the RhoA/ROCK pathway and activation of the NO/PKG pathways commonly attribute to the activity of myosin light chain phosphatase (MLCP), causing inhibited myosin light chain phosphorylation and vasodilatation[38]. As both pathways converge at this step, the level of MLC phosphorylation was detected. The results indicated that treatment with DPN significantly decreased the level of p-MLC (Thr^{18}/Ser^{19}), however, PHTPP can offset this effect (Figure 5). In conclusion, it can be said that DPN attenuates vasoconstriction in the cirrhotic livers of OVX rats by inhibiting MLC activity *via* regulation of the RhoA/ROCK and NO/PKG pathways.

HSCs have crucial importance in the development of liver cirrhosis[26]. Activated HSCs transform into myofibroblast-like cells, and acquire contractility. Their

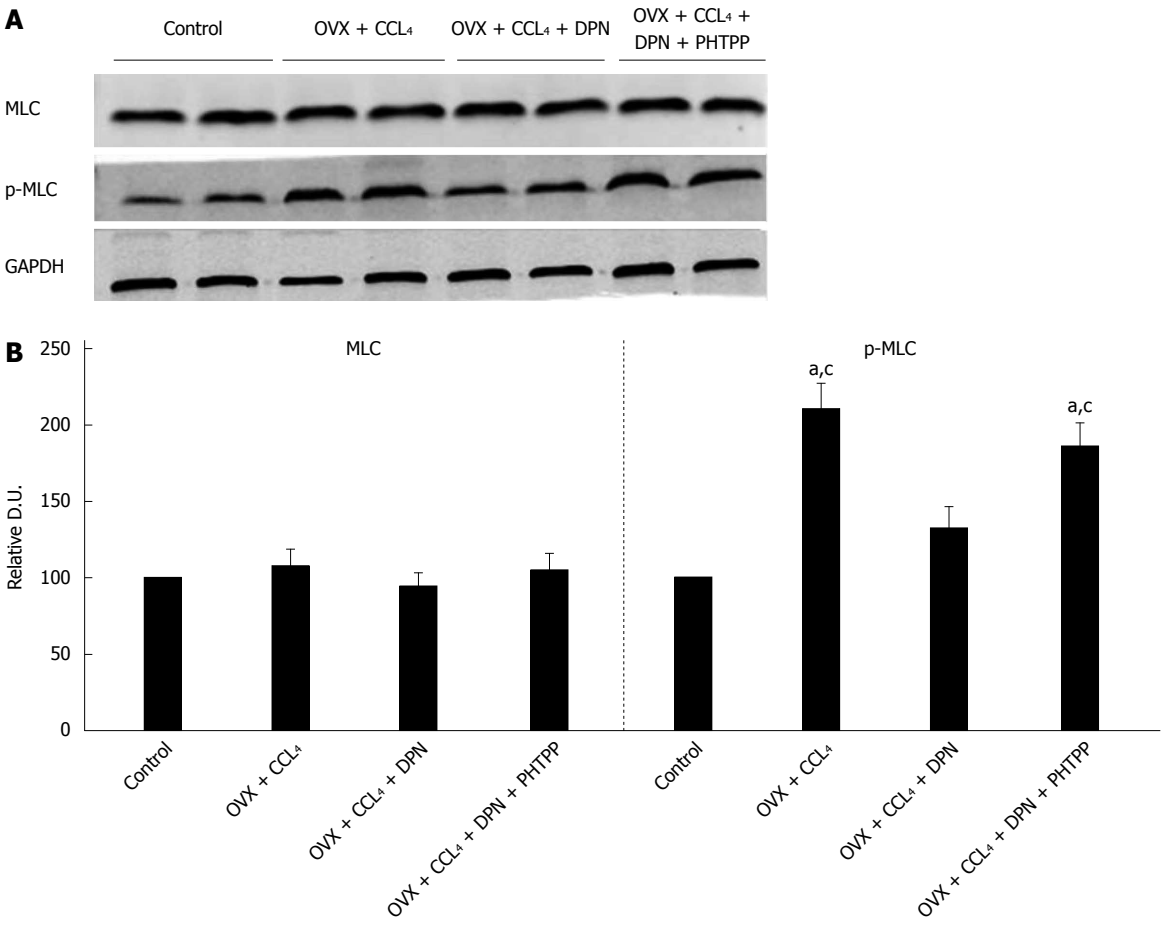

Figure 6 Diarylpropionitrile inhibits the phosphorylation of MLC in the livers of CCl_4-treated rats. A: Western blot analysis of total MLC and p-MLC; B: Relative densitometric quantifications of all experiments (mean ± SE), with the values of the controls set to 100 DU (each group $n = 5$) $^aP < 0.05$ *vs* control group; $^cP < 0.05$ *vs* DPN group. DPN: Diarylpropionitrile.

shrinkage is reported to be conditioned mainly through a Ca^{2+}-sensitization mechanism which is analogous to the contraction in VSMCs[39,40]. Therefore, HSCs were considered the key cells in IHVR regulation. Recently, selective inhibition of the RhoA/ROCK pathway in activated HSCs has been regarded as a potential novel therapeutic target to reduce PHT[41,42]. Our *in vivo* studies suggest that DPN treatment in OVX cirrhotic rats significantly reduced hepatic α-SMA expression, thus we hypothesized that DPN negatively regulates the activation of HSCs. Nonetheless, the effect of DPN on the contraction of HSCs required more extensive investigation. First, we verified that ERβ expression was truly present in HSCs (Figure 7C-D). With regard to the physiological role of DPN in the regulation of HSC contractility, a collagen gel contraction assay was performed. We observed that 10^{-7} mol/L DPN could significantly inhibit the 10^{-7} mol/L ET-1-induced contraction of the HSC containing gel lattices. This was also observed with 10^{-5} mol/L Y-27632, while 10^{-7} mol/L PHTPP counteracted the effect of DPN (Figure 7A-B). Hence, it can be said that 10^{-7} mol/L DPN has a similar efficacy to 10^{-5} mol/L Y-27632 in blocking the HSC contraction.

To further specify the role of DPN in the regulation of ROCK activity in HSCs, the phosphorylation of moesin was examined. Although 10^{-7} mol/L DPN was less effective than 10^{-5} mol/L Y-17632 in downregulating p-moesin (Thr^{558}), treatment with 10^{-7} mol/L DPN still significantly decreased p-moesin (Thr^{558}) levels compared to HSCs stimulated with 10^{-7} mol/L ET-1 (Figure 7D-E). We therefore concluded that DPN could be a novel ROCK inhibitor used to block the contraction of activated HSCs. To our knowledge, in HSCs the inactivation of MLCP is mainly regulated by the RhoA/ROCK pathway[43]. So we investigated the effect of DPN on the phosphorylation of MLC in HSCs. Interestingly, 10^{-7} mol/L DPN distinctly inhibited the ET-1-induced overexpression of p-MLC (Thr^{18}/Ser^{19}), and 10^{-7} mol/L DPN was equally effective in inhibiting p-MLC (Thr^{18}/Ser^{19}) as 10^{-5} mol/L Y-27632 (Figure 7D-E). Although DPN was less potent than Y-27632 in blocking the moesin phosphorylation (Thr^{558}), its final effect on p-MLC (Thr^{18}/Ser^{19}) and HSC contraction was no different than that of Y-27632. Further research is needed to fully explore the mechanisms involved. As a final note, it has been shown that HSCs contain functional ERβ but no ERα[20]; therefore, DPN could be used as a targeted ROCK inhibitor without causing severe systemic side effects.

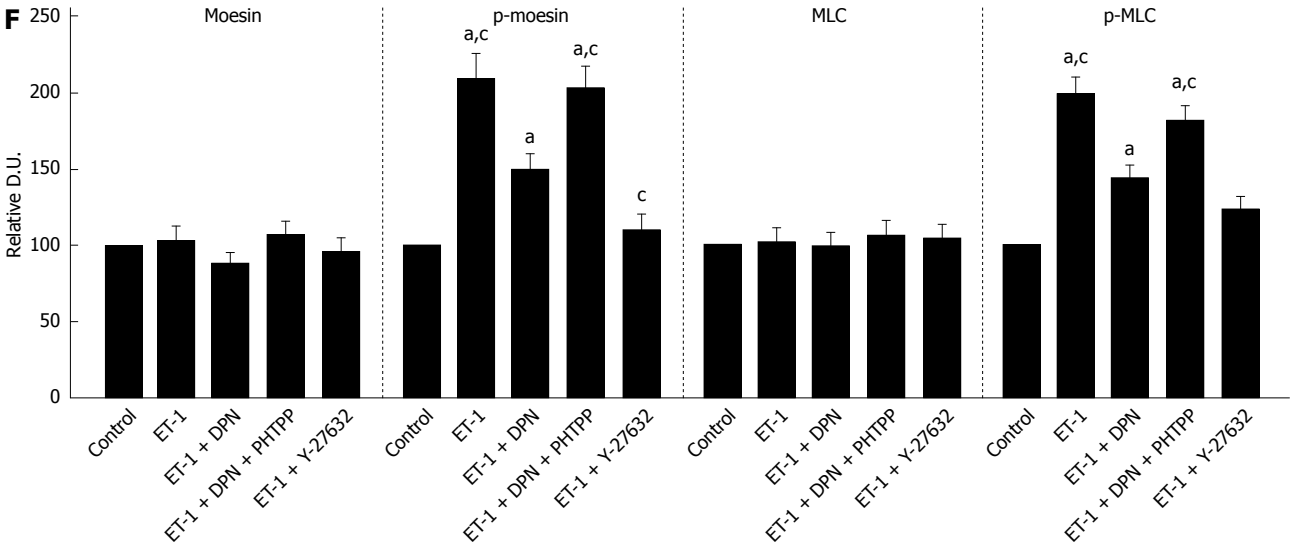

Figure 7 Diarylpropionitrile inhibits collagen lattice contraction in hepatic stellate cells and decreases ET-1 induced moesin and MLC phosphorylation. A: Appearance of collagen lattices 4 h after drug treatment; B: The percentage of remaining lattice area 4 h after drug treatment (each group n = 12); C, D: Western blot analysis of ERβ protein expression in hepatic stellate cells (HSCs) (each group n = 5); E: Western blot analysis of the total and phosphorylated moesin and MLC in HSCs; F: Relative densitometric quantifications of moesin and MLC experiments (mean ± SE), with the values of the controls set to 100 DU (each group n = 5). $^{a}P < 0.05$ *vs* control group; $^{c}P < 0.05$ *vs* DPN group. OVX: ovariectomized; SVR: Systemic vascular resistance; DPN: Diarylpropionitrile.

In summary, treatment with DPN was effective in lowering PHT in CCl_4-induced cirrhotic OVX rats, which was attributed to its anti-hepatic fibrosis effect and its ability to decrease IHVR *via* inhibition of the RhoA/ROCK and activation of the NO/PKG signaling pathways. DPN also significantly reduced HSC contractility by inhibiting ROCK activation and downstream MLC phosphorylation. This study suggests that DPN could be a potential candidate for estrogen replacement therapy, benefiting menopausal women with liver cirrhosis and PHT.

COMMENTS

Background

Increased intrahepatic vascular resistance (IHVR) is a major cause for portal hypertension (PHT), and activated hepatic stellate cells (HSCs), contraction of intrahepatic vascular smooth muscle cells, and reduced vasodilator nitric oxide levels all play a critical role in contributing to increased IHVR. NO is of great significance in increasing IHVR levels. Animal experiments and clinical trials provide consistent evidence for the protective effect of endogenous and exogenous estrogens on liver fibrosis. However, exogenous estrogens give rise to a number of potential risks, which restrain them from clinical uses.

Research frontiers

Evidence indicates the intrahepatic upregulation of RhoA and Rho-kinase signaling and inhibition of NO/PKG signaling from increasing IHVR. For these reasons, the two pathways serve as the crucial therapeutic target to ameliorate PHT. High estrogen receptor (ER) β expression levels and low ERα expression levels were observed in livers, moreover, HSCs have functional ERβ, rather than ERα. Therefore, this paper studied the effect of DPN - an ERβ selective agonist - on the two pathways, and also on hepatic hemodynamics systemically.

Innovations and breakthroughs

DPN treatment is effective in lowering PHT in CCl_4-induced cirrhosis of the OVX rats, contributes to its anti-hepatic fibrosis effect, and is capable of decreasing IHVR by the inhibition of RhoA/ROCK and activation of the NO/PKG signaling pathways. DPN also significantly reduced HSC shrinkage by restraining ROCK activation and down-streaming MLC phosphorylation *via* ERβ.

Applications

The ERβ selective agonist may be a potential therapeutic approach to managing PHT and liver fibrosis, particularly for those menopausal women and patients with low estrogen levels.

Terminology

ER subtypes play a distinct role in exerting different biological effects with tissue-specific responses. ERβ selective agonists may produce biological effects without causing any classic side effects of estrogens.

Peer-review

This is a well-done experimental study concerning the efficacy of ER agonist against cirrhosis-related portal hypertension. Clinically practical benefits will not come into effect within a short time. However, the study suggests that the ERβ selective agonist be a potential therapeutic method to manage PHT and liver fibrosis.

Abstract

AIM: To explore the role and potential mechanism of miR-30b regulation of autophagy in hepatic ischemia-reperfusion injury (IRI).

METHODS: An animal model of hepatic IRI was generated in C57BL/6 mice. For *in vitro* studies, AML12 cells were immersed in mineral oil for 1 h and then cultured in complete Dulbecco's Modified Eagle's Medium

(DMEM)/F12 to simulate IRI. Mice and cells were transfected with miR-30b agomir/mimics or antagomir/inhibitor to examine the effect of miR-30b on autophagy to promote hepatic IRI. The expression of miR-30b was measured by real-time polymerase chain reaction. Apoptotic cells were detected by terminal uridine nick-end labeling (TUNEL) staining, and cell viability was detected by methylthiazole tetrazolium assay. The expression of light chain 3, autophagy-related gene (Atg)12, Atg5, P62, and caspase-3 were detected by western blotting analysis.

RESULTS: miR-30b levels were significantly down-regulated after hepatic IRI, and the numbers of autophagosomes were increased in response to IRI both *in vivo* and *in vitro*. These findings demonstrate that low levels of miR-30b could promote hepatic IRI. Furthermore, we found that miR-30b interacted with Atg12-Atg5 conjugate by binding to Atg12. Overexpression of miR-30b diminished Atg12 and Atg12-Atg5 conjugate levels, which promoted autophagy in response to IR. In contrast, downregulation of miR-30b was associated with increased Atg12-Atg5 conjugate levels and increased autophagy.

CONCLUSION: miR-30b inhibited autophagy to alleviate hepatic ischemia-reperfusion injury *via* decreasing the Atg12-Atg5 conjugate.

Key words: miR-30b; Autophagy; Atg12-Atg5 conjugate; Hepatic ischemia-reperfusion injury

Core tip: miR-30b levels were significantly down-regulated after hepatic ischemia-reperfusion injury (IRI) in mice. The number of autophagosomes was increased in response to IRI both *in vivo* and *in vitro*. Decreased levels of miR-30b could promote hepatic IRI, as revealed by reductions in cells viability *in vitro*. Overexpression of miR-30b diminished autophagy-related gene (Atg)12 and Atg12-Atg5 conjugate levels which promoted autophagy in response to hepatic IRI. Therefore, miR-30b inhibits autophagy to alleviate hepatic IRI *via* decreasing the Atg12-Atg5 conjugate.

Li SP, He JD, Wang Z, Yu Y, Fu SY, Zhang HM, Zhang JJ, Shen ZY. miR-30b inhibits autophagy to alleviate hepatic ischemia-reperfusion injury *via* decreasing the Atg12-Atg5 conjugate. *World J Gastroenterol* 2016; 22(18): 4501-4514 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4501.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4501

INTRODUCTION

Hepatic ischemia-reperfusion injury (IRI) is an important factor for the prognosis of surgical outcomes and patient survival as well as the protection of hepatic cells[1]. A key consideration regarding liver function was revealed from a recent study demonstrating that autophagy represents a principal component of hepatology[2]. Autophagy consists of a tightly regulated intracellular catabolic pathway involving lysosomal degradation of cytoplasmic organelles and proteins[3]. miRNAs are closely linked to virtually all fundamental biological pathways[4], and they play critical roles in a broad range of biological processes including proliferation, differentiation, apoptosis, and stress responses[5].

Recent findings have indicated some novel roles for miRNAs in the regulation of autophagy[6,7]. In this report, we focused on miRNAs with direct autophagic implications, as exerted either through putative core components of autophagy machinery or through less well-characterized mechanisms. The 3′-untranslated region (UTR) of the autophagy associated gene 12 (Atg12) contains the predicated target sites for miRNA-30b (miR-30b), which were identified by luciferase reporter gene assays. The possibility exists that miR-30b might contribute to alleviating IRI *via* modulating autophagy through targeting Atg12. In this study, we attempted to determine whether miR-30b modulates autophagy and thus alleviate hepatic IRI. Specifically, we upregulated or downregulated expression of miR-30b to examine the effects of miR-30b on Atg12 and Atg12-Atg5 conjugate levels that regulate autophagy in hepatic IRI. Our data indicate that miR-30b might serve as a novel therapeutic target regulating autophagy in hepatic IRI.

MATERIALS AND METHODS

Animals and cell line

Male C57BL/6 mice (7-8-wk-old, 23 ± 3 g) were purchased from the experimental animal center of the PLA Military Medical Science Academy. All animals received humane care according to established standards and were maintained in an air-conditioned animal room at 25 ℃ with free access to water and food. All protocols conformed to the National Institute of Health (NIH) guidelines and all animals received care in compliance with the principles of laboratory animal care. The AML12 cell line (mouse hepatic cell) was purchased from the American Type Culture Collection (ATCC, Manassas, VA, United States). The study was performed according to Tianjin Medical University Institutional Review Board guidelines, and the protocol was approved by the Institutional Review Board.

Reagents and antibodies

Dulbecco's Modified Eagle's Medium (DMEM)/F12 medium and fetal bovine serum (FBS) were purchased from Gibco (Grand Island, NY, United States); miR-30b-5p mimics/agomir, miR-30b-5p inhibitor/antagomir,

miR-NC, Atg12 siRNA and RiboFECTTM CP Reagent were purchased from RiboBio Co., Ltd. (Guangzhou, China); rapamycin and 3-MA were purchased from Selleck Inc (Houston, TX, United States). The In Situ Cell Death Detection Kit, TMR red and SYBR Green quantitative real time polymerase chain reaction (qRT-PCR) Master Mix were purchased from Roche Diagnostics GmbH (Mannheim, Germany); Trizol and Lipofectamine 2000 were obtained from Invitrogen (Carlsbad, CA, United States). Antibody Atg12, light chain 3 (LC3), P62, caspase-3, cleave caspase-3, poly ADP-ribose polymerase 1 (PARP1), β-actin, and horseradish peroxidase (HRP)-conjugated secondary antibodies were purchased from Cell Signaling Technology Inc (Beverly, MA, United States).

Animal model and treatment

The segmental (70%) hepatic ischemia model was performed as previously described[1]. There were six mice in the sham group, and the 24 mice in the IR group were divided by reperfusion times, consisting of 2, 6, 12, and 24 h. Mice in the miR-30b-5p agomir group (n = 6), miR-30b-5p antagomir group (n = 6), and miR-NC group (n = 6) received miR-30b-5p agomir (10 nmol/L), antagomir (10 nmol/L), or miR-NC (10 nmol/L), respectively, by tail intravenous injection 24 h prior to ischemia.

Serology detection

Serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels of the mice in all groups were determined with use of a commercial assay kit (Nanjing Jiancheng Biological Technology, Nanjing, China). Enzyme activities were expressed as international units per liter (U/L).

Histology and transmission electron microscopy

Samples of liver were fixed in 4% mediosilicic isotonic formaldehyde for 24 h, dehydrated, and embedded in paraffin. Five micrometer-thick sections were cut from each paraffin embedded tissue and stained with hematoxylin and eosin (HE) to evaluate the degree of liver damage. In addition, liver and cell samples were placed in 1% glutaraldehyde and post-fixed with 2% osmium tetroxide. The cell pellets or sections were embedded in epon resin. The data were quantified by counting the number of autophagosomes per cross-sectioned cell.

Cell culture and treatment

AML12 cells were plated at a density of 2 × 10^5 cells/mL in 6-well plates and divided into seven groups[8]: (1) Control group, cells were cultured in DMEM/F12 without treatment; (2) IR group, cells were immersed in mineral oil (1 mL/well) for 1 h to simulate ischemia then cultured in DMEM/F12 for 12 h to simulate reperfusion; (3) miR-30b-5p mimics group, cells were transfected with 50 nmol/L miR-30b-5p mimics or miR-NC using RiboFECTTM CP Reagent for 24 h according to the manufacturer's protocol, followed by reperfusion as described above; (4) miR-30b-5p inhibitor group, cells were transfected with 50 nmol/L miR-30b-5p inhibitor or miR-NC, followed by reperfusion; (5) Atg12 siRNA group, cells were treated with Atg12 siRNA or siRNA-NC for 24 h, followed by reperfusion; (6) Rapamycin group, cells were treated with 40 nmol/L rapamycin for 2 h, followed by reperfusion; and (7) 3-MA group, cells were treated with 60 μM 3-MA for 2 h, followed by reperfusion.

Methylthiazole tetrazolium bioassay

Cells were seeded onto 96-well plates (5 × 10^4 cells/well) and after culture for 24 h at 37 ℃, subjected to reperfusion as described above. Fresh medium was then added to each well together with 20 μL methylthiazole tetrazolium solution (5 mg/mL), and the plate was incubated at 37 ℃ for 4 h. The medium was then removed, and 200 μL dimethylsulfoxide was added per well. The optical density of each well was determined with a test wavelength of 490 nm.

Confocal fluorescent microscopic detecting autophagy

AML12 cells were cultured in 6-well plates to 60%-70% confluence. The cells were transfected with tandem GFP-RFP-LC3 adenovirus (Hanbio, Shanghai, China) according to the GFP-RFP-LC3 instruction manual to further confirm autophagy induction.

Immunocytochemistry

The streptavidin-peroxidase staining technique was used to detect protein following antigen retrieval by microwave treatment. After blocking endogenous peroxidase activity by incubating in 3% H_2O_2 for 15 min, specimens were incubated with antibodies [proliferating cell nuclear antigen (PCNA) and caspase-3] at 4 ℃ overnight. Specimens were incubated at room temperature for 1 h with the secondary antibody, then diaminobenzidine solution was used. Counterstaining was performed with hematoxylin.

qRT-PCR

Total RNA was isolated by Trizol and 1 μg of RNA for reverse transcription was prepared as described above. RT-PCR was performed in a total volume of 25 μL reaction mixture. U6 or GAPDH was used as an internal control and the expression levels was calculated using MxPro software (Version 4.0, Stratagene, La Jolla, CA, United States).

Luciferase reporter gene assays

The miRWalk database was used to predict the binding site on the 3'-UTR of miR-30b, and this database combines several bioinformatic platforms including TargetScan 4.2, miRBase, and miRanda. Luciferase reporter gene assay was performed using the Dual-Luciferase Reporter Assay System (Promega, Madison,

WI, United States) according to the manufacturer's instructions[9-11]. Cells were transferred into 24-well plates at 3 × 10^4 cells/well. After 24 h, the cells were transiently co-transfected with pRL-TK plasmid (Promega), and various constructs containing different lengths of the Atg12 5′-flanking region or pGL3-Basic. The luciferase activities were measured according to the manufacturer's instructions.

Western blot analysis

Protein samples were harvested from mice livers and AML12 cells. The proteins were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and then transferred to the nitrocellulose membranes. Membranes were probed with the antibodies to Atg12, LC3, P62, caspase-3, cleave caspase-3, RARP1 and β-actin. Bound antibodies were then visualized using an enhanced chemiluminescence (ECL) detection kit with an appropriate HRP-conjugated secondary antibody.

Apoptosis analysis using terminal uridine nick-end labeling

Terminal uridine nick-end labeling (TUNEL) reactions were performed using an In Situ Cell Death Detection Kit, TMR red. For quantification, the mean number of TUNEL-positive cells, as determined using 200 ×, in five different fields was determined.

Statistical analysis

All data are presented as mean ± SD. Differences among groups were analyzed using a one-way analysis of variance followed by the Student-Newman-Keuls post-hoc test. The SPSS software 19.0 (Armonk, NY, United States) was used for these analyses, where $P < 0.05$ was considered to be statistically significant.

RESULTS

Hepatic IRI alters miR-30b, Atg12, and Atg5 mRNA expression in mice livers

With the IR mouse model, miR-30b-5p expression levels gradually decreased ($P < 0.05$) after reperfusion, however, levels of Atg12 and Atg5 mRNA increased thereafter ($P < 0.05$), as compared with the Sham group (Figure 1A).

Alterations of autophagy in mice livers induced by IRI

As shown in Figure 1B, the expression of Atg12, Atg12-Atg5 conjugate, and LC3II was upregulated as a function of time following reperfusion ($P < 0.05$). Meanwhile, cleave caspase-3 expression increased as a function of time after reperfusion.

Alterations of liver pathological changes and serum AST and ALT levels

Pathological analyses as presented in Figure 1C, revealed considerable hepatocyte edema, congestion and apoptosis at 6-24 h post-reperfusion as compared with the Sham group. The time-dependent changes in serum AST and ALT levels of mice are illustrated in Figure 1D. Serum AST and ALT levels gradually increased ($P < 0.05$), reaching a peak at 12 h ($P < 0.001$) following reperfusion. Next, we evaluated autophagic vacuoles using Transmission Electron Microscopy (TEM). Autophagosomes, which contained partially degraded cytoplasmic material, were clearly observed with TEM (Figure 1E). The basal number of autophagosomes within the IR group was increased relative to the Sham group ($P < 0.001$).

miR-30b can alleviate mouse hepatic IRI

To clarify whether miR-30b can alleviate hepatic IRI, we either upregulated or downregulated the expression of miR-30b in mice after tail intravenous injection of miR-30b-5p agomir or antagomir, respectively, at 12 h following reperfusion. As shown in Figure 2A, we found that miR-30b-5p agomir significantly decreased the histopathologic changes of liver induced by IR treatment, but miR-30b-5p antagomir aggravated these changes. Compared with the miR-NC group, serum AST and ALT levels in the miR-30b-5p agomir group mice were decreased while those of the miR-30b-5p antagomir group mice were increased as a function of time following reperfusion ($P < 0.05$, Figure 2B). As illustrated in Figure 2C, the number of TUNEL-positive cells was significantly decreased compared with that of the miR-NC group ($P < 0.05$); however, miR-30b-5p antagomir increased the number of TUNEL-positive cells compared with that of the miR-NC group ($P < 0.01$). When compared with the miR-NC group at 12 h reperfusion, the miR-30b-5p agomir resulted in a significant increase in PCNA expression but a decrease in caspase-3, cleave caspase-3, and PARP1 expression. In contrast, the miR-30b-5p antagomir decreased in PCNA expression but increased in caspase-3, cleave caspase-3, and PARP1 expression (Figure 2D and E). These findings demonstrate that miR-30b can alleviate hepatic IRI.

miR-30b inhibits autophagy by sequestering Atg12

Based upon information contained within the bioinformatics database, we hypothesized that the miR-30b binding site was at the 3′-UTR of Atg12, and a luciferase reporter assay was performed to determine the effects of miR-30b on the 3′-UTR of Atg12 (Figure 3A). When examined at 12 h post-reperfusion, overexpression of miR-30b with miR-30b-5p mimics in AML12 cells significantly reduced Atg12 mRNA and protein levels compared with those cells transfected with the miR-NC ($P < 0.05$, Figure 3B). Moreover, levels of Atg12-Atg5 conjugate and LC3II decreased after transfection of miR-30b-5p mimics when compared with that of miR-NC ($P < 0.05$, Figure 3C). In contrast, the results in AML12 cells treated with miR-30b-5p inhibitor were opposite. Our findings

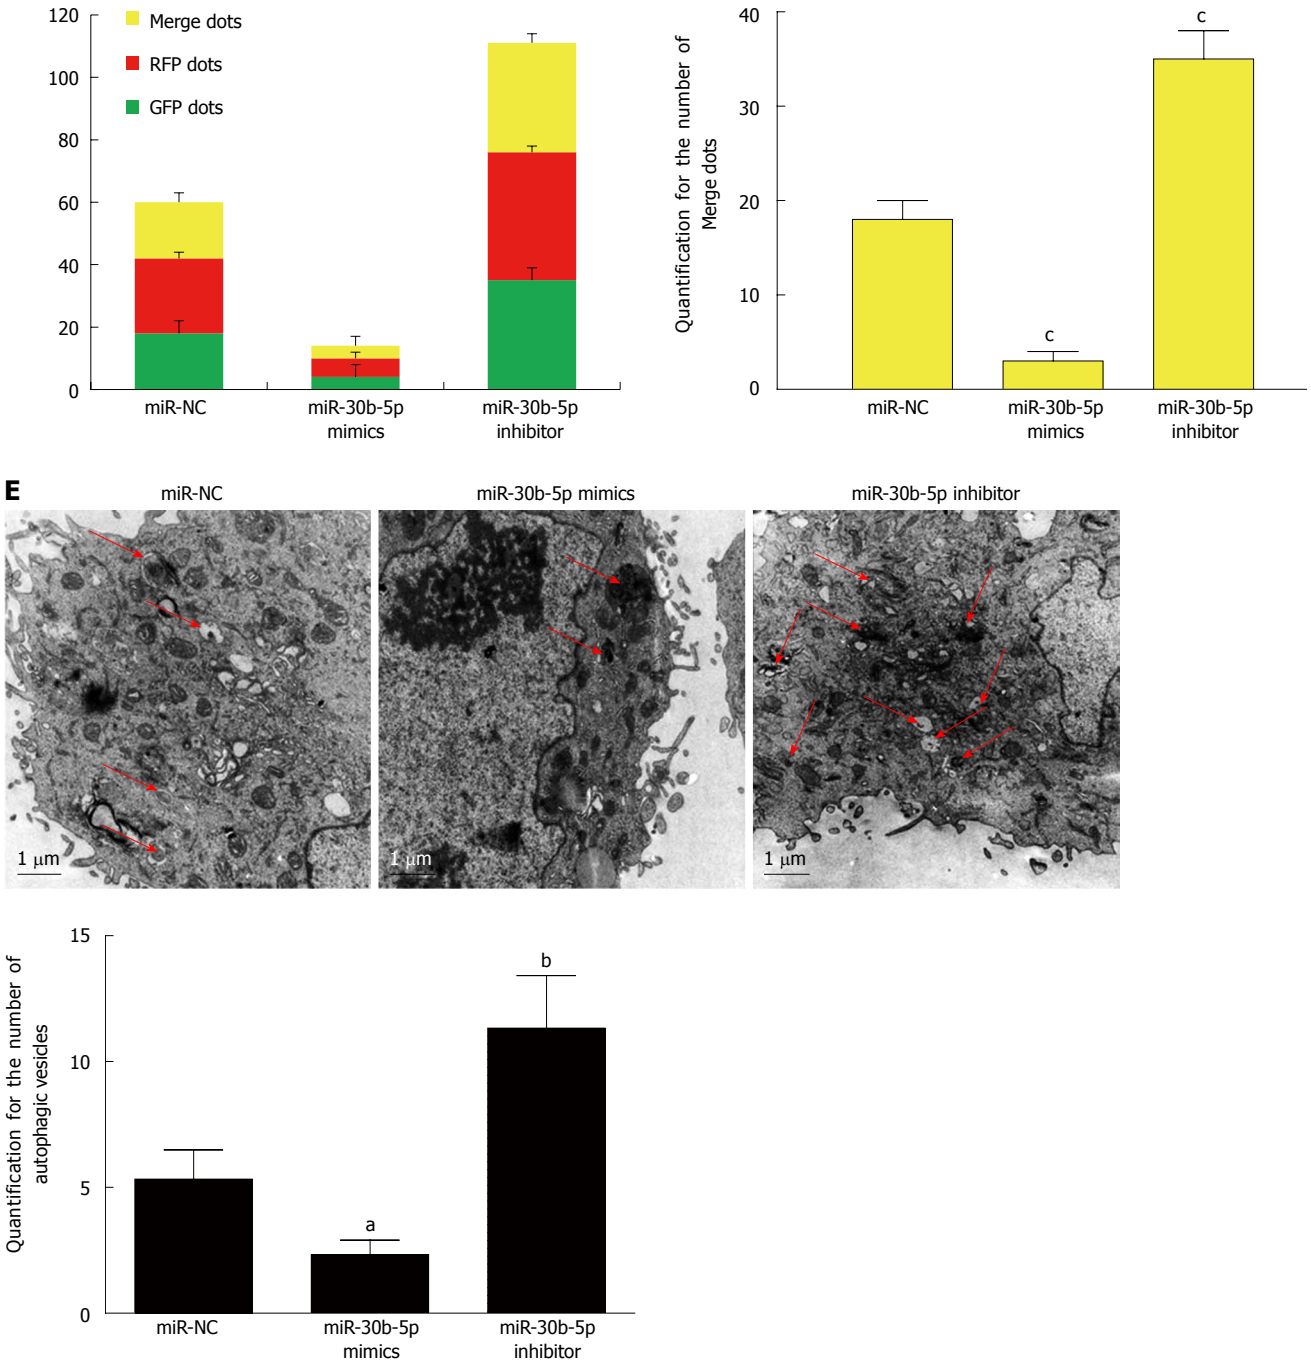

Figure 3 miR-30b inhibits autophagy by sequestering Atg12 in AML12 cells. A and B: The predicted miR-30b binding site on the Atg12 mRNA 3'-untranslated region (UTR) is shown, and a luciferase reporter assay was performed to determine the effects of miR-30b on the Atg12 mRNA 3'-UTR; C: Western blot was used to detect expression of Atg12 and LC3 in AML12 cells treated with miR-30b mimics or inhibitor; D: Confocal immunofluorescence of AML12 cells demonstrated increased numbers of GFP-RFP-LC3 dots in the IR group; when autophagy is induced, both GFP and RFP are expressed as yellow dots (autophagosomes). Red dots represent autolysosomes as the GFP degrades in an acid environment. Scale bars = 20 μm; E: TEM images of AML12 cells after ischemia followed by reperfusion at 12 h. TEM images show representative examples of autophagosomes (red arrows). Scale bars = 1.0 μm. And the data were quantified by counting the number of autophagosomes per cross-sectioned cell; $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* miR-NC group. Every experiment was repeated three times.

indicate that miR-30b could decrease Atg12 and Atg12-Atg5 conjugate levels in AML12 cells.

We performed a Ad-GFP-RFP-LC3 to examine the potential role of miR-30b in autophagy after IRI in AML12 cells. The appearance of GFP- or RFP-LC3 dots within the cytoplasm reflects the recruitment of LC3 proteins to autophagosomes. Upon activation of autophagy, both GFP and RFP are expressed as yellow dots when merged, representing autophagosomes. When autophagosomes fuse with lysosomes and form autolysosomes, the GFP degrades in an acid environment, but the RFP-LC3 remains showing as red dots. A confocal immunofluorescence experiment was performed to demonstrate an increase of LC3. The Ad-GFP-RFP-LC3 was transfected into AML12 cells to confirm the induction of autophagy. As shown in

Figure 3D, miR-30b inhibited significantly the induction of autophagosomes. We observed both fluorescent proteins were expressed after the infection with Ad-GFP-RFP-LC3. There were significant decreases in yellow dots with marginal elevations in red dots in the miR-30b-5p mimics group compared to the miR-NC or miR-30b-5p inhibitor groups ($P < 0.001$). Next, we evaluated autophagic vacuoles using TEM, an Autophagosomes were clearly visualized with TEM (Figure 3E). The basal number of autophagosomes within the miR-30b-5p mimics group was decreased relative to the miR-30b-5p inhibitor or miR-NC group ($P < 0.001$). Taken together, the results show that miR-30b inhibits autophagic flux by sequestering Atg12.

miR-30b inhibits autophagy to alleviate AML12 cell ischemia-reperfusion injury by targeting Atg12

In order to assess whether cells become more resistant to IRI depending on autophagy status in a hepatic IRI model, we examined the effects of rapamycin and 3-MA, an activator and inhibitor of autophagy, respectively. Rapamycin decreased the survival ratio of AML12 cells induced by IR treatment, and 3-MA inhibited this change ($P < 0.05$, Figure 4A). Moreover, rapamycin increased the levels of LC3Ⅱ and decreased P62 expression, whereas 3-MA decreased the levels of LC3Ⅱ and increased P62 expression (Figure 4B). These data found that activating autophagy could aggravate hepatic IRI. miR-30b-5p mimics increased viability of IRI AML12 cells treated responding to IR ($P < 0.05$), but viability of IRI AML12 cells treated with miR-30b-5p inhibitor was decreased ($P < 0.05$, Figure 4C). As demonstrated in Figure 4D, Atg12 siRNAs significantly down-regulated Atg12 expression in AML12 cells. The viability of IRI AML12 cells treated with miR-30b-5p mimics or inhibitor (Figure 4E) was enhanced by siRNA knockdown of Atg12. AML12 cells were also treated with miR-30b-5p mimics/inhibitor or Atg12 siRNA to investigate potential interactions between the miR-30b and Atg12-Atg5 conjugate during IR. At 12 h post-reperfusion, siRNA-mediated knockdown of Atg12 contributed to Atg12-Atg5 conjugate and LC3II protein levels inhibited by miR-30b-5p mimics, while Atg12 siRNA decreased the levels of Atg12-Atg5 conjugate and LC3II induced by miR-30b-5p inhibitor (Figure 4F). These data suggest that miR-30b inhibits autophagy to alleviate hepatic IRI by targeting Atg12.

DISCUSSION

Autophagy plays a pivotal role in cellular homeostasis and adaptation to adverse environments[12,13], and although the regulation of this process remains incompletely understood[14], it is known to provide a cytoprotective role important for survival[15]. Autophagy is regarded as a natural and essential defense mechanism against inflammatory, damnification, and oncotherapy[16]. Hence, regulation of the autophagy pathway has been implicated in the pathogenesis of numerous human diseases. Recently, a growing number of studies on autophagy and liver diseases have focused on liver ischemia reperfusion[17-20]. miR-30b, a member of the miR-30 family, has been suggested to play a role in the differentiation of several cell types[21]. The miR-30 family is also involved in the control of structural changes in the extracellular matrix of the myocardium[22] and in the regulation of the apoptosis[23].

In this study, we discovered that miR-30b was downregulated in mice livers subjected to IR. In addition, the expression of Atg12 and LC3II was upregulated, and the numbers of autophagosomes observed in the IR group increased as a function of time following reperfusion. miR-30b expression was decreased in response to hepatic IRI and was accompanied by a corresponding activation of autophagy. The induction of autophagy represents an initial response to IR in mice livers, while Atg12 and Atg12-Atg5 conjugate expression decreased as a function of time following reperfusion. To clarify whether miR-30b can alleviate hepatic IRI, we upregulated or downregulated expression of miR-30b in mice after tail intravenous injection of miR-30b-5p agomir or antagomir, respectively. miR-30b-5p agomir significantly decreased the histopathologic changes of livers induced by IR treatment, and the number of TUNEL-positive cells were significantly decreased. However, downregulated expression of miR-30b could aggravate the histopathologic changes. PCNA, a subunit of the mammalian DNA polymerase delta, is synthesized primarily during the S phase of the cell cycle[24]. PCNA is a relay molecule that functions as a molecular integrator for proteins involved in the control of the cell cycle, DNA repair, and cell death[25]. Therefore, PCNA is a convincing marker to distinguish proliferating cells. The miR-30b-5p agomir resulted in a significant increase in PCNA expression but a decrease in caspase-3, cleave caspase-3 and PARP1 expression. In contrast, down-regulated expression of miR-30b decreased in PCNA expression but increase in caspase-3, Cleave caspase-3 and PARP1 expression. These findings demonstrate that miR-30b can alleviate hepatic ischemia-reperfusion injury.

Autophagosome formation requires two ubiquitin-like conjugation systems, the Atg12 and LC3 systems[26]. The Atg12 system is located upstream of the LC3 system in the context of Atg protein organization. Atg12 is conjugated to Atg5, forming the irreversible Atg12-Atg5 complex, which strongly enhances the formation of LC3-phosphatidylethanolamine conjugation[27]. caveolin-1 also regulated Atg12-Atg5 conjugate during autophagosome formation, and caveolin-1 competitively interacts with the Atg12-Atg5 system to suppress the formation and function of the latter in lung epithelial cells[28]. Based upon miRNA target gene prediction, we identified the 3′-UTR area of the Atg12 gene as a match of miR-30b.

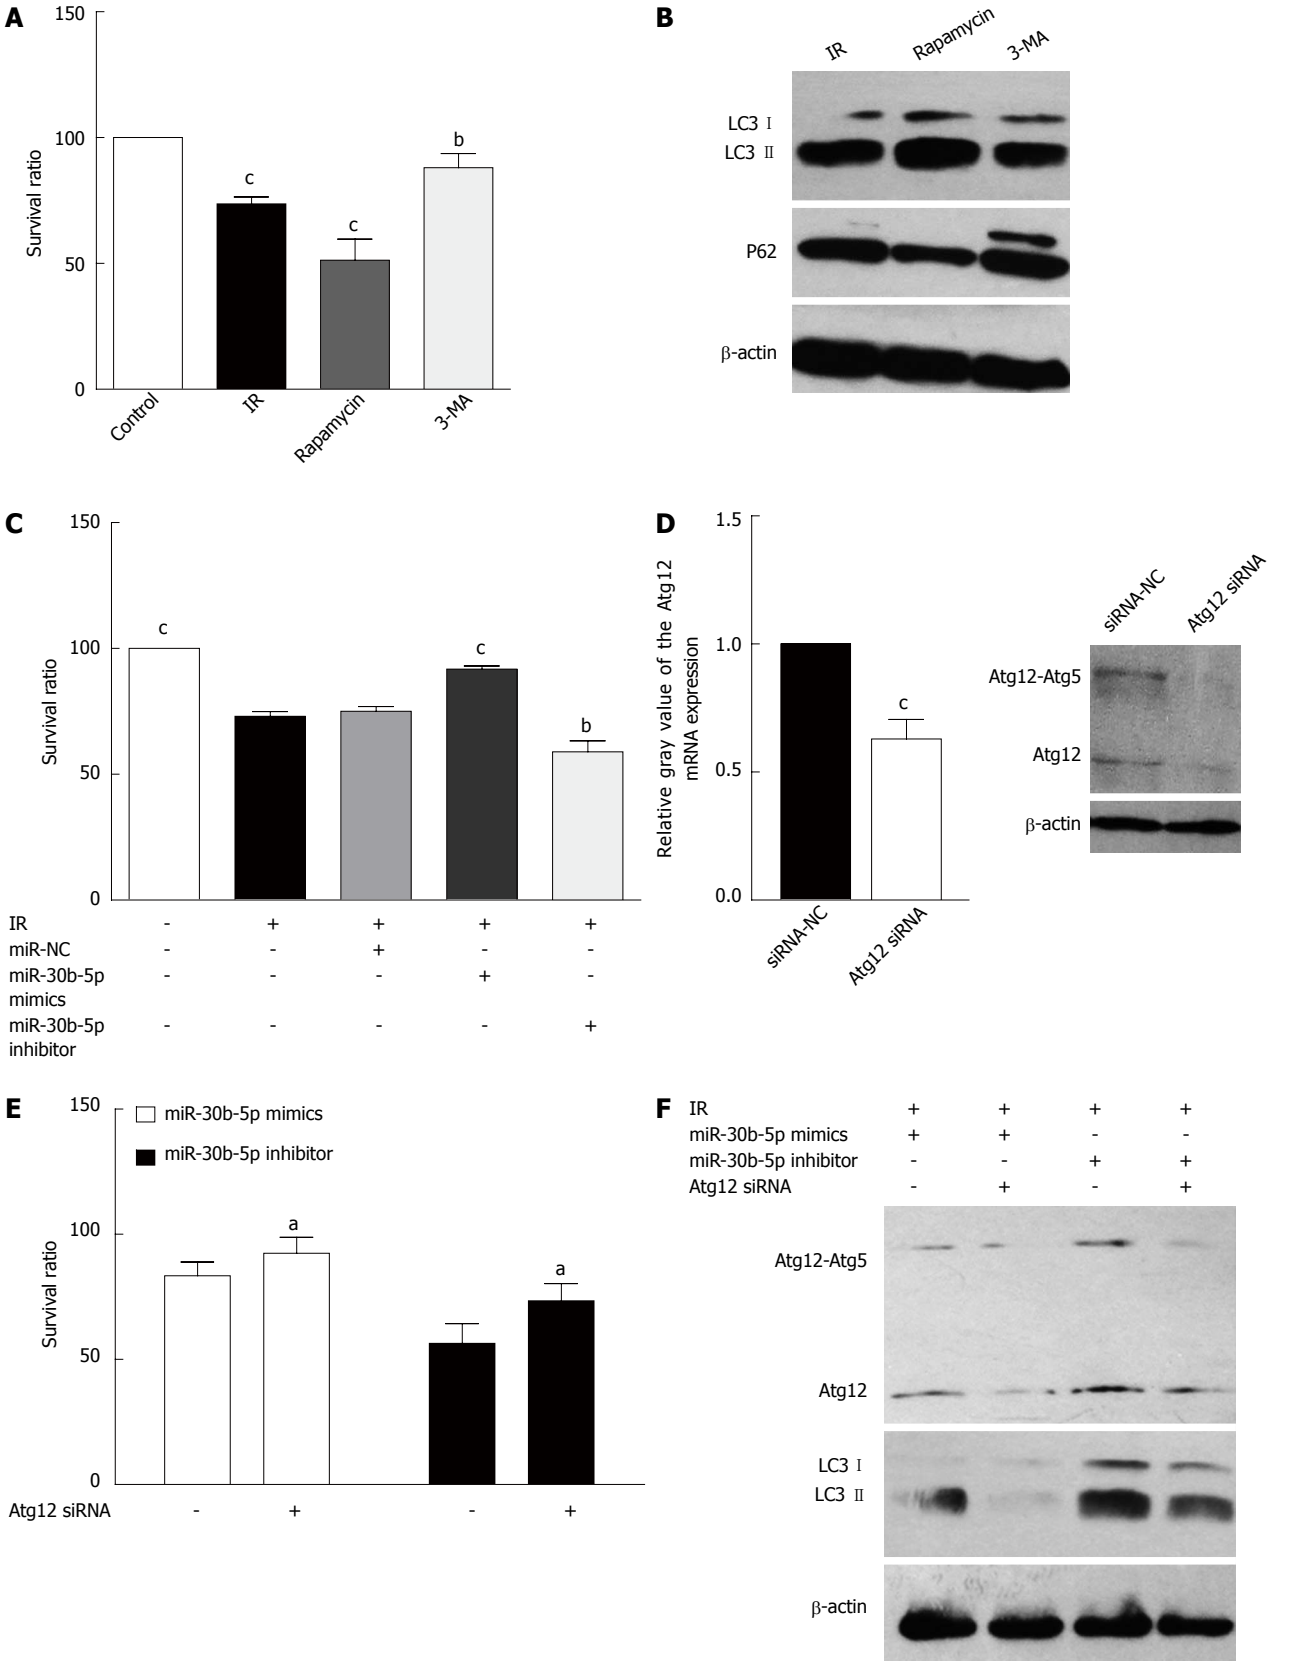

Figure 4 miR-30b alleviate AML12 cell ischemia-reperfusion injury by targeting Atg12 *in vitro*. A: The survival ratio of AML12 cells was measured after treatment with rapamycin or 3-MA; B: Western blot was used to detect the expression of LC3 and P62 in AML12 cells treated with Rapamycin or 3-MA; C: The survival ratio of AML12 cells was measured after treatment with miR-30b mimics or inhibitor; D: AML12 cells were transfected with Atg12 siRNAs, and the Atg12 mRNA and protein level of the target were evaluated using quantitative real time polymerase chain reaction or western blot analysis, respectively; E: The survival ratio of AML12 cells was measured at 12 h post-reperfusion in the absence or presence of miR-30b mimics, the miR-30b inhibitor, or Atg12 siRNA; F: Protein levels of Atg12 and LC3 were analyzed using western blot in AML12 cells at 12 h post-reperfusion in the absence or presence of miR-30b mimics, the miR-30b inhibitor, or Atg12 siRNA; $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* IR/miR-NC group. Every experiment was repeated three times.

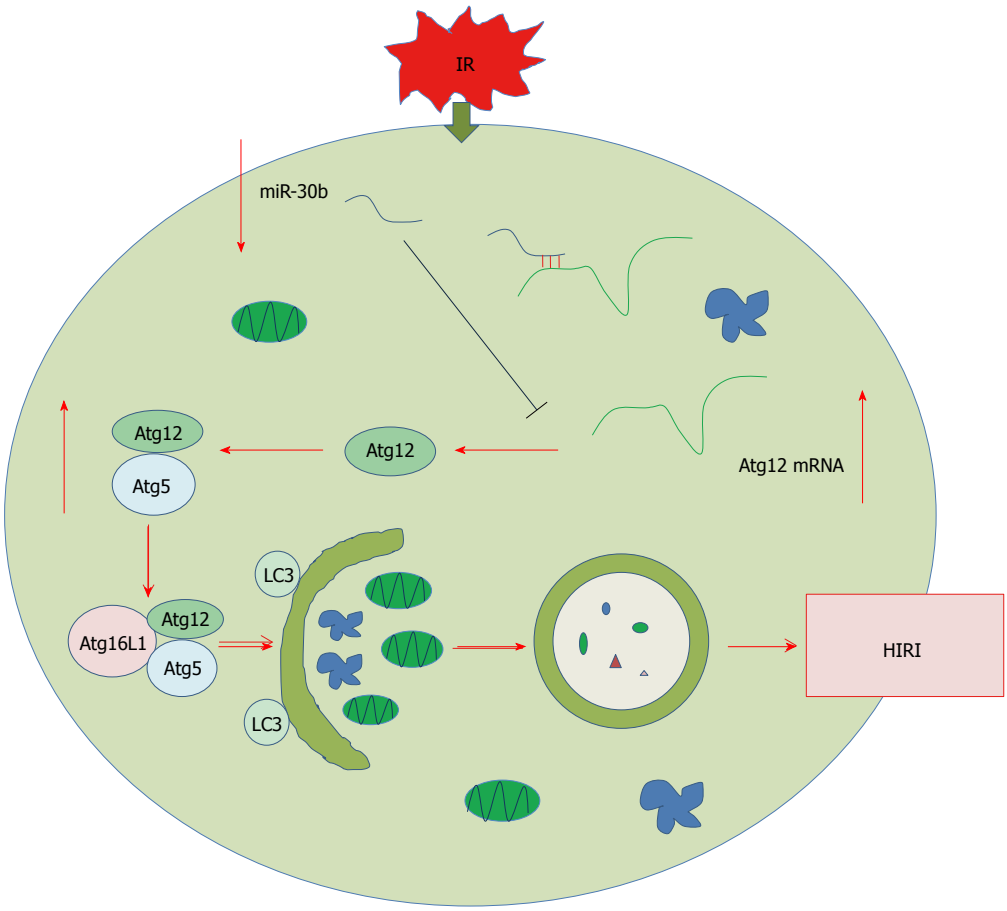

Figure 5 Model of miR-30b inhibition of autophagy to alleviate hepatic ischemia-reperfusion injury *via* decreasing the Atg12-Atg5 conjugate. The expression of miR-30b, which binds the 3'-UTR of Atg12, was significantly down-regulated after HIRI. Levels of Atg12 and Atg12-Atg5 conjugate then increased and promoted autophagy, leading to apoptotic cell death. Therefore, miR-30b can inhibit autophagy to alleviate hepatic IRI by decreasing levels of Atg12-Atg5 conjugate. HIRI: Hepatic ischemia-reperfusion injury.

Our data showed that up-regulation of the expression of miR-30b significantly increased cell viability as a function of time following reperfusion, while the miR-30b inhibitor significantly decreased cell viability. Related to these findings, a significant decrease of LC3 dots in AML12 transfected with miR-30b-5p mimics compared with miR-NC group. The number of LC3 dots increased in the miR-30b inhibitor group relative to the miR-30b mimics group. These results indicate that miR-30b increased the viability of hepatocytes induced by IR *via* inhibiting autophagy. Over-expression of miR-30b significantly reduced Atg12 and Atg12-Atg5 conjugate protein levels after AML12 cells transfected with miR-30b mimics; and LC3II expression was decreased in these cells. The expression of Atg12 and Atg12-Atg5 conjugate protein levels increased after AML12 cells were transfected with the miR-30b inhibitor, while LC3II was also increased at the same time. Taken together, it seems clear that miR-30b can decrease Atg12 and Atg12-Atg5 conjugate expression, thereby down-regulating autophagy to alleviate hepatic IRI.

Autophagy is a self-digesting process that occurs in response to stress and plays important roles in the pathogenesis of a variety of diseases[15]. Autophagy functions mainly in a pro-survival capacity for cells to cope with nutrient starvation and anoxia[29,30], however, excessive levels of autophagy within impaired cells can contrarily induce cell death[31]. Oxidative stress may lead to autophagy which induces cell death in cisplatin-induced AKI[32]. In our study, we found that activation of autophagy aggravated hepatic IRI, an effect that was dependent on Atg12 and Atg12-Atg5 conjugate. We also treated AML12 cells with the miR-30b mimics, miR-30b inhibitor, or Atg12 siRNA to investigate whether any potential interaction may exist between miR-30b and Atg12 during IR. Our findings suggest that miR-30b mediated apoptosis to alleviate hepatic IRI, an effect that was dependent on Atg12 activity. As was shown in Figure 5, we found that miR-30b inhibited autophagy to alleviate hepatic IRI by decreasing the Atg12-Atg5 conjugate. This finding may serve as a guide to prevent hepatic IRI and provide a future strategy in research areas of IRI.

COMMENTS

Background

Hepatic ischemia reperfusion injury (IRI) represents an important clinical problem as related to liver resection or transplantation. miRNAs participate in various hepatic pathophysiological processes *via* regulating autophagy. miR-30b, a member of the miR-30 family, is involved in the control of structural changes in the regulation of the apoptosis. However, the importance and function of miR-30b and whether miR-30b regulate autophagy to alleviate hepatic IRI have not yet been elucidated.

Research frontiers

It was reported that overexpression of miR-30b had an anti-apoptotic effect on the early phase of rat myocardial ischemia injury model through targeting Kirsten ras sarcoma (KRAS) and activating the Ras/Akt pathway. E2F1-regulated miR-30b suppressed Cyclophilin D to protect the heart from IRI and necrotic cell death.

Innovations and breakthroughs

This is the first study to investigate the role of miR-30b in inhibiting autophagy to alleviate hepatic IRI, and we found that miR-30b decreases the level of Atg12-Atg5 conjugate. This study provides the basis for a future research strategy in hepatic ischemia reperfusion injury.

Applications

This study provides insight into the role of miR-30b in the inhibition of autophagy to alleviate hepatic IRI by decreasing the autophagy-related gene Atg12-Atg5 conjugate. Understanding how miR-30b regulates autophagy during hepatic IRI may facilitate the design of new therapeutic approaches to prevent and cure hepatic IRI.

Terminology

Atg12 ubiquitin-like conjugation systems are required in autophagosome formation, and the Atg12 system is located upstream of the light chain 3 (LC3) system in the context of Atg protein organization. Atg12 is conjugated to Atg5, forming the irreversible Atg12-Atg5 complex, which strongly enhances the formation of LC3-phosphatidylethanolamine conjugation.

Peer-review

This is an interesting paper, providing important information on the expression of miR-30b and its role in autophagy during hepatic IRI. This study found that the miR-30b inhibited autophagy to alleviate hepatic IRI *via* decreasing the Atg12-Atg5 conjugate. The result is very important for advanced research studies on hepatic IRI.

Abstract

AIM: To discover novel biomarkers for early diagnosis, prognosis or treatment of human colorectal cancer.

METHODS: iTRAQ 2D LC-MS/MS analysis was used to identify differentially expressed proteins (DEPs) in

the human colonic epithelial carcinogenic process using laser capture microdissection-purified colonic epithelial cells from normal colon, adenoma, carcinoma *in situ* and invasive carcinoma tissues.

RESULTS: A total of 326 DEPs were identified, and four DEPs (DMBT1, S100A9, Galectin-10, and S100A8) with progressive alteration in the carcinogenic process were further validated by immunohistochemistry. The DEPs were involved in multiple biological processes including cell cycle, cell adhesion, translation, mRNA processing, and protein synthesis. Some of the DEPs involved in cellular process such as "translation" and "mRNA splicing" were progressively up-regulated, while some DEPs involved in other processes such as "metabolism" and "cell response to stress" was progressively down-regulated. Other proteins with up- or down-regulation at certain stages of carcinogenesis may play various roles at different stages of the colorectal carcinogenic process.

CONCLUSION: These findings give insights into our understanding of the mechanisms of colorectal carcinogenesis and provide clues for further investigation of carcinogenesis and identification of biomarkers.

Key words: Colorectal Cancer; Proteome; Biomarker; Carcinogenesis

Core tip: In this study, we used iTRAQ 2D LC-MS/MS analysis to identify differentially expressed proteins (DEPs) in the human colonic epithelial carcinogenic process using laser capture microdissection-purified colonic epithelial cells from normal colon, adenoma, carcinoma *in situ* and invasive carcinoma tissues. A total of 326 DEPs were identified. Four DEPs (DMBT1, S100A9, Galectin-10, and S100A8) with progressive alteration in the carcinogenic process were further validated using immunohistochemistry. The DEPs were involved in multiple biological processes including cell cycle, cell adhesion, translation, mRNA processing, and protein synthesis. These findings give insights into our understanding of the mechanisms of colorectal carcinogenesis and provide clues for further investigation of carcinogenesis and identification of biomarkers.

INTRODUCTION

Colorectal cancer (CRC) is the third leading cause of cancer death, affecting over a million people worldwide per year in recent years[1,2]. The World Health Organization estimates a 77% increase in the number of newly diagnosed cases of CRC and an 80% increase in deaths from CRC by 2030[3]. Despite an improvement in relative survival of CRC at 5 years due to early diagnosis at initial stages and breakthroughs in treatment of stages Ⅱ and Ⅲ disease, CRC is still one of the most lethal malignancies and the 5-year survival rate for patients with metastasis is < 5%[4]. Most patients are diagnosed at an advanced stage and have a poor prognosis. At present, CRC diagnosis and therapy are still dependent upon descriptive classification and staging systems based on morphology/histology[5]. Remarkable achievements in the understanding of cellular and molecular mechanisms of colorectal carcinogenesis have been made in recent years. However, therapy for advanced colorectal cancer remains limited, and current screening methods including sigmoidoscopy and colonoscopy lack the required sensitivity and specificity[6,7]. Therefore, a comprehensive understanding of the mechanisms behind colorectal carcinogenesis will contribute to the improvement in early detection and prognosis and provide novel therapeutic targets.

Carcinogenesis is a multistep and complicated process characterized by genetic alterations, including chromosomal abnormalities, gene mutations, and epigenetic changes that disrupt normal cell growth and division[8]. A genetic model describing the transition from healthy colonic epithelia through dysplastic adenoma to malignant cancer has been proposed[9]. According to the model[10], the colonic carcinogenic process originates from normal colonic mucosa (NC) and then transforms sequentially from adenoma (AD), carcinoma *in situ* (CIS, equivalent to high-grade intraepithelial neoplasia), and ultimately to invasive colorectal cancer (ICC)[11]. A number of sequential genetic abnormalities, including gene mutations in APC, K-ras, and p53 and epigenetic changes, were identified at different stages of colorectal carcinogenesis[11,12].

In recent years, much progress has been made in understanding genetic changes in the colonic carcinogenesis process, and many studies have been conducted to analyze differentially expressed proteins (DEPs) between certain stages of colorectal carcinogenesis[13-15]. However, there has been no systematic comparison between typical stages across the carcinogenic process, and much less is known about dynamic alterations at the proteome level during the process. Tissue heterogeneity is the main problem for analysis of biological samples in the study of disease. Recent technological progress using laser

capture microdissection (LCM) has made it possible to overcome this problem and to enrich the desired populations of cells from heterogeneous tissues[16-18].

Isobaric tags for relative and absolute quantification (iTRAQ) combined with two-dimensional liquid chromatography-tandem mass spectrometry (2D LC-MS/MS) is a highly sensitive and practical technology[19-21]. Compared to conventional proteomic technology such as 2D electrophoresis, the iTRAQ method has the following advantages. First, it can label proteins from up to eight samples in a single experiment. Second, it can resolve large proteins (> 200 kD), small proteins (< 10 kD), and proteins with extremes in isoelectric point[22]. Therefore, iTRAQ technology offered us a feasible method to simultaneously compare the proteomes of successive stages of colorectal carcinogenesis.

To clarify the dynamic patterns of DEPs during colorectal carcinogenesis and provide valuable information for further identification of biomarkers for prevention, treatment or early diagnosis of CRC, iTRAQ tagging followed by 2D LC-MS/MS was performed to identify DEPs among LCM-purified colonic epithelial carcinogenic tissues and explore their dynamic expression patterns. A total of 326 DEPs were identified among different stages to have distinct expression patterns during the carcinogenic process, and four top-ranked DEPs (DMBT1, S100A9, Galectin-10, and S100A8) were further validated by immunohistochemistry. To our knowledge, this is the first comprehensive study that systematically compares the dynamic alterations of proteins during the process of colorectal carcinogenesis by comparative proteomics.

MATERIALS AND METHODS

Sample collection

Twenty-seven cases of fresh colonic tissues (5 cases of NC, 8 cases of AD, 5 cases of CIS, 9 cases of ICC) collected between January 2011 and December 2012 were obtained from the Department of Surgery, Xiangya Hospital, Central South University, China and used for iTRAQ-labelling. The patients received neither chemotherapy nor radiotherapy before curative surgery and signed an informed consent form for the study, which was approved by the local ethical committee. All tissue specimens were obtained from surgical resection, and the normal colonic tissue samples were acquired from the resection edge furthest away from the lesion (≥ 10 cm). The tissue samples in the ICC group were from CRC patients with lymph node metastasis. All of the tissues were flash frozen in liquid nitrogen and stored at -80 ℃ until further use.

An independent set of formalin-fixed and paraffin-embedded archival tissue specimens, including 50 cases of NC, 50 cases of AD, 30 cases of CIS, and 63 cases of ICC, were obtained from colonoscopic or surgical resection at Xiangya Hospital, Central South University, China, and used for immunohistochemical staining. The parameters of patients and tissue specimens are shown in Supplementary Table 1.

Tissue processing and LCM

To exclude the interference of stromal elements and adjoining cells, LCM[18] was used to purify the target cells. All NC, AD, CIS and ICC tissues were stained with haematoxylin and eosin and independently evaluated by two experienced pathologists. LCM was performed to purify the cells of interest from each type of tissue according to our previous procedure[17]. Briefly, frozen sections (8 μm thick) of all tissues were prepared using a Leica CM 1900 cryostat at -25 ℃. The sections were placed on membrane-coated glass slides (Leica), fixed in 75% alcohol for 30 s, and stained with 0.5% violet-free methyl green (Sigma). The stained sections were air-dried and then subjected to LCM. Each cell population was determined to be 95% homogeneous by microscopic visualization of the captured cells (Supplementary Figure 1).

Protein extraction

The microdissected cells were dissolved in lysis buffer (7 mol/L urea, 2 mol/L thiourea, 65 mmol/L dithiothreitol, 0.1 mmol/L phenylmethylsulfonyl fluoride) at 4 ℃ for 1 h and then centrifuged at 12000 rpm for 30 min at 4 ℃. The supernatant was collected, and the protein concentration was determined by the 2D Quantification Kit (Amersham Biosciences). To diminish the effects of biological variation on the proteomic results, equal amounts of proteins from each individual sample in various types of tissue (NC, AD, CIS and ICC) were pooled to generate a sample for the corresponding type of tissue. Four pooled protein samples (corresponding to the four types of tissues) were obtained for iTRAQ labelling.

Protein digestion and labelling with iTRAQ reagents

Trypsin digestion and iTRAQ labelling were performed according to the manufacturer's protocol (Applied Biosystems). In brief, 100 μg protein of each pooled sample was reduced, alkylated, and then digested overnight at 37 ℃ with trypsin (mass spectrometry grade; Promega). The samples were then labelled with iTRAQ reagents as follows: iTRAQ reagent 113, AD; iTRAQ reagent 114, NC; iTRAQ reagent 115, CIS; and iTRAQ reagent 116, ICC. The labelled digests were then mixed and dried.

Off-line 2D LC-MS/MS

The mixed peptides were fractionated according to the procedure described in our previous study[23]. A total of 10 SCX fractions were collected. Each fraction was dried down by the rotary vacuum concentrator, dissolved in buffer C (5% acetonitrile, 0.1% formic acid), and analysed on Triple TOF 5600 systems (Applied Biosystems) in information dependent mode. Briefly, peptides were separated on reverse-phase

columns (ZORBAX 300SB-C18 column, 5 μm, 300 Å, 0.1 mm × 15 mm; Micromass) using an Eksigent 1D PLUS system (Applied Biosystems). Peptides were separated by a linear gradient mobile phase A (5% acetonitrile, 0.1% formic acid) and mobile phase B (95% acetonitrile, 0.1% formic acid) from 5 to 40 of mobile phase B in 120 min at a flow rate of 300 nL/min. Survey scans were acquired from 400-1500 with up to 15 precursors selected for MS/MS and dynamic exclusion for 20 s. Each SCX fraction was analysed in duplicate.

Data analysis

Analyst QS 1.1 (Applied Biosystems) was used for data acquisition, and ProteinPilot 4.2 (Applied Biosystems) was used for protein identification and quantification. The precursor tolerance and the iTRAQ fragment tolerance were both set at 0.2 Da. The data analysis parameters were set as follows: Sample type, Itraq 4 plex (peptide labelled); Cys alkylation, MMTS; Digestion, Trypsin; Instrument, Triple TOF 5600; Species, Homo sapiens; ID Focus, Biological modifications; Database, Uniprot human database (release Apr 2013); Search Effort, Thorough; Max missed cleavages, 2; FDR Analysis, Yes; User Modified Parameter Files, No; Bias Correction, Auto; Background Correction, Yes. Identified proteins were grouped by the software to minimize redundancy. All peptides used for the calculation of protein ratios were unique to the given protein or proteins within the group, and peptides that were common to other isoforms or proteins of the same family were ignored.

The protein confidence threshold cutoff was 1.3 (unused ProtScore) with at least one peptide with 95% confidence. The average iTRAQ ratios from the duplicate experiments were calculated for each protein[23,24]. The confidence level of the altered expression of proteins was calculated by ProteinPilot as a *P*-value, which allows the results to be evaluated based on the confidence level of expression change. In addition, false discovery rate (FDR) for the protein identification was calculated by searching against a concatenated reversed database[25].

Determination of cutoff threshold for significant fold changes in iTRAQ experiments

In a comprehensive iTRAQ experiment, the variations are composed of technical, experimental and biological variations[26]. According to previous reports[26-28], the cutoff threshold for meaningful fold changes over experimental errors can be determined by using the experimental replicate method. Particularly, the main variation in this study was experimental variation, whereas the biological variation was minimized by sample pooling effect. The variations in our method using experimental replicates are considered to be the actual variations in the iTRAQ experiment.

The number of shared quantified proteins in the 2 iTRAQ experiments was 379 based on the following selection criteria: containing more than 2 unique peptides (> 95%), *P*-value < 0.05, and EF < 2. These 379 proteins were used initially to determine the experimental variations and to confirm the threshold for meaningful fold changes.

Experimental variations for the 113/114, 115/114, and 116/114 reporter ions were calculated using the ratios of the 379 common quantified proteins between the first and second iTRAQ experiments; the experimental variations for the reporter ions were r^2 = 0.8499, r^2 = 0.8382, and r^2 = 0.9283, respectively (Supplementary Figure 2A). In addition, the cutoff threshold for meaningful fold changes (cutoff for DEPs) in the expression ratios of 113/114, 115/114, and 116/114 were determined using the experimental replicate method described in previous studies[27,28]. Accordingly, 90% of the identified proteins in the 2 iTRAQ experiments fell within 50% of the respective experimental variation (Supplementary Figure 2B). Therefore, only fold changes > 1.5 or < 0.67 were considered significant.

Differential proteome expression during colorectal carcinogenesis

To identify the DEPs in the colorectal carcinogenic process, protein expression profiles between two stages of this process (AD, CIS or ICC *vs* NC; CIS *vs* AD; ICC *vs* CIS) were compared. The proteins that met the following criteria were confidently considered as DEPs: (1) proteins were repeatedly identified by the two experiments; (2) proteins were identified based on ⩾ 2 peptides; (3) an averaged ratio-fold change > 1.5 or < 0.67 between two stages; (4) proteins in CIS or ICC should be differentially expressed compared with NC; and (5) proteins should be differentially expressed in at least one of the three comparisons between adjacent stages (AD *vs* NC, CIS *vs* AD and ICC *vs* CIS).

Cluster analysis of differential protein expression profiles

The averaged iTRAQ values obtained in two experimental replicates for each protein of the four types of tissues (NC, AD, CIS, and ICC) were log2-transformed. Total DEPs were normalized and clustered with J-express 2012 (http://jexpress.bioinfo.no) into nine categories by using the K-means algorithm with the Pearson correlation distance.

Bioinformatics analysis

The DEPs were first annotated by GO from Biological Process using David software (http://david.abcc.ncifcrf.gov/). The GO terms were considered to be significantly enriched when the corrected *P*-value was less than 0.05. Pathway analyses of each K-means cluster of proteins were performed using REACTOME software (http://www.reactome.org/). The REACTOME

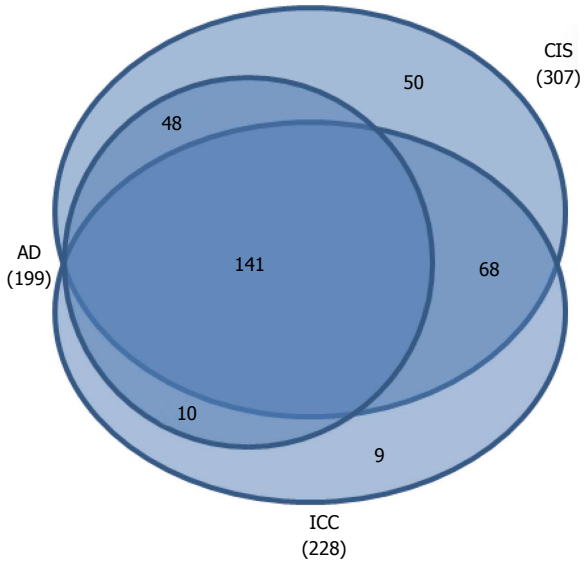

Figure 1 Venn diagrams of comparisons of the differentially expressed proteins from the different stages compared to the NC group.

performs an enrichment test to determine whether any Reactome pathways are enriched in the submitted data. A binomial test was used to calculate the probability. The *P*-values are corrected for multiple testing (Benjamini-Hochberg procedure) that arises from evaluating the submitted list of identifiers against every pathway. The pathway with the corrected *P*-value less than 0.05 was considered to be significantly enriched.

Immunohistochemistry and evaluation of staining

Immunohistochemistry was performed according to the procedure described in our previous study[26]. Briefly, the sections were incubated with anti-DMBT1 (1:200; Santa Cruz), anti-S100A9 (1:200; Santa Cruz), anti-Galectin-10 (1:200; Abcam), or anti-S100A8 (1:200; Santa Cruz) antibody overnight at 4 ℃, and they were then incubated with a biotinylated secondary antibody followed by avidin-biotin peroxidase complex (DAKO) according to the manufacturer's instructions. Finally, tissue sections were incubated with 3',3'-diaminobenzidine until a brown colour developed and were then counterstained with Harris' modified haematoxylin. The evaluation of immunostaining was performed as previously described[29]. A score (ranging from 0-6) was obtained for each case. A combined staining score of $\leqslant$ 2 was considered to be negative staining (no expression); a score between 3 and 4 was considered to be moderate staining (expression); and a score between 5 and 6 was considered to be strong staining (high expression).

Statistical analysis

SPSS software (IBM, v19) was used for statistical analyses. Numerical variables with normal distribution were compared using unpaired *t*-tests or paired *t*-tests. Non-normal distribution data were compared using Wilcoxon rank sum tests. A *P*-value less than 0.05 was considered statistically significant.

Table 1 Number of protein expression changes in comparison between adjacent stages of colon carcinogenesis process

Comparison	Protein expression	
	Downregulated	Upregulated
AD:NC (113:114)	113	86
CIS:AD (115:113)	137	102
ICC:CIS (116:115)	103	141

RESULTS

Identification of quantified proteins during colorectal carcinogenesis

A total of 3211 non-redundant proteins were identified at a minimum confidence level of 95% (unused ProtScore > 1.3) in two iTRAQ experiments. Among these, 2374 proteins were repeatedly identified in the two experiments. In total, 3123 proteins were quantified, and 2319 of them were commonly quantified in the two iTRAQ experiments (Supplementary Figure 3). The detailed protein identification and quantification data are shown in Supplementary Table 2. Using the concatenated target-decoy database search strategy as detailed by Elias and Gygi[25], a 0% rate of false positives was estimated, which further strengthened the reliability of our data.

To define significant changes in protein expression, fold-changes > 1.5 or < 0.66 were established as cutoff values, which were determined using the experimental replicate method as described in the Methods section. A total of 326 DEPs were found according to the selection criteria, of which 199 were found in AD/NC, 307 in CIS/NC, and 228 were in ICC/NC. There were 141 (43%) common DEPs among all three tumor stages compared to NC. All the DEPs in AD/NC group were found in CIS/NC or ICC/NC groups, while there were 50 DEPs specific to CIS/NC, and 9 DEPs specific to ICC/NC (Figure 1). Out of 326 DEPs, 199 were found in AD/NC (86 upregulated and 113 downregulated), 239 were found in CIS/AD (102 upregulated and 137 downregulated), and 244 in ICC/CIS (141 upregulated and 103 downregulated) (Table 1).

To obtain a biological view of the DEPs, GO enrichment analysis was employed to discover the significant biological processes. In the comparison of proteome expression in AD (113 reporter) *vs* NC (114 reporter), out of 199 DEPs, 86 up-regulated proteins were involved in gene expression processes such as "DNA replication", "DNA metabolic process" and "translation", whereas 113 down-regulated proteins were involved in energy and metabolism processes such as "blood coagulation", "response to external stimulus" and "complement activation" (Figure 2A).

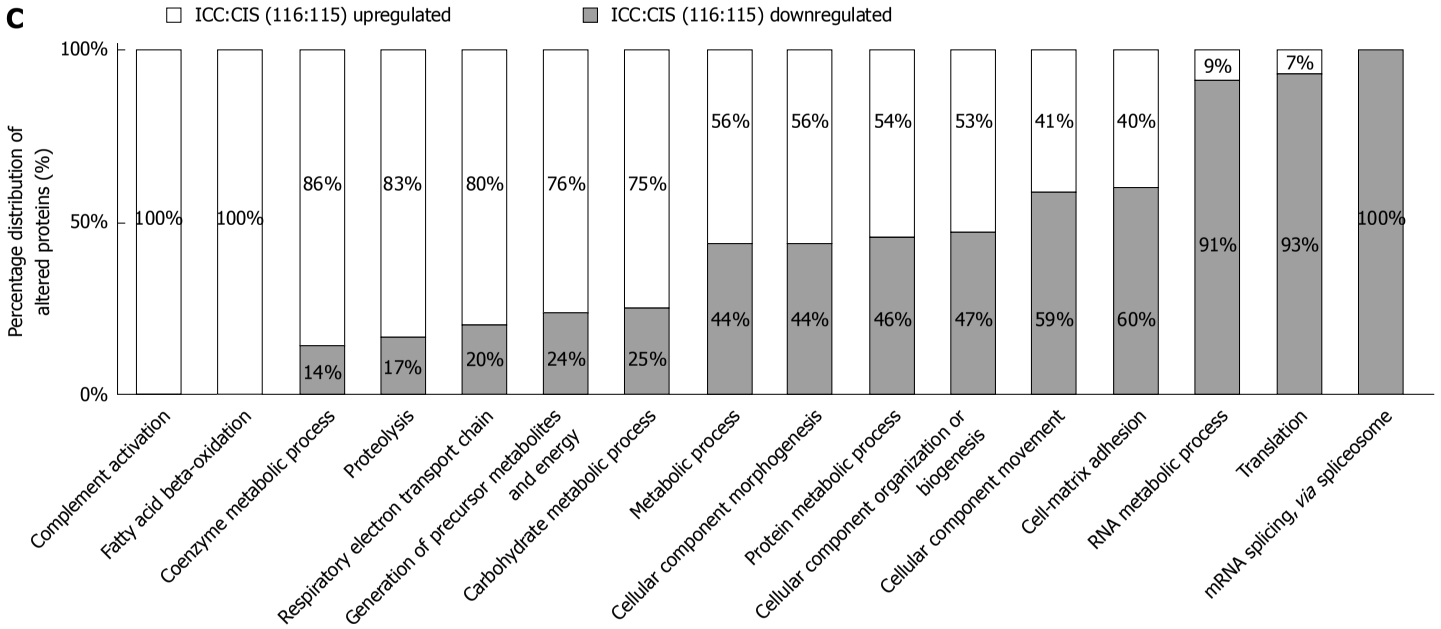

Figure 2 Functional distribution of differentially expressed proteins between adjacent stages of the colon carcinogenesis process. Functional classification of differentially expressed proteins from AD *vs* NC, CIS *vs* AD and ICC *vs* CIS were assigned to "biological process" subcategories. Only significant subcategories for "biological process" are presented. Each subcategory is presented as the percentage of up- and down-regulated proteins.

reporter) *vs* AD (113 reporter), we identified 239 DEPs, 102 and 137 of which were up-regulated and down-regulated, respectively. Notably, the down-regulated proteins were involved in energy metabolism pathways such as "respiratory electron transport chain", "fatty acid beta-oxidation" and "generation of precursor metabolites and energy", whereas the up-regulated proteins were involved in biological process such as "cell cycle", "cell-cell adhesion" and "cell-matrix adhesion" (Figure 2B).

Between the expression patterns of ICC (116 reporter) *vs* CIS (115 reporter), 244 DEPs included 141 up-regulated and 103 down-regulated proteins. The bioinformatics analysis indicated that the up-regulated proteins mainly participate in "complement activation", "fatty acid beta-oxidation" and "coenzyme metabolic processes", whereas the down-regulated proteins participate in biological processes associated with "mRNA splicing", "translation" and "cell-matrix adhesion" (Figure 2C).

Cluster analysis of DEPs and functional analysis

Among the DEPs, some were only differentially expressed in one stage, while others were differentially expressed in multiple stages. To explore the dynamics of DEPs and gain more insights into their biological significance in colorectal carcinogenic processes, K-means clustering and REACTOME pathway analysis were performed. The expression pattern K-means clustering analysis of DEPs showed stage-specific and co-regulated expression profiles.

The 326 DEPs were classified into 9 clusters by the K-means clustering algorithm (Figure 3, Supplementary Table 3). According to the overall tendency, the nine clusters were arbitrarily categorized into three groups. Group 1 consists of clusters 1 and 5, in which the abundance of DEPs increased at all three stages of AD, CIS and IC, and exhibited the highest expression in CIS or IC. Group 2 consists of cluster 2 and 7, in which the abundance of DEPs decreased at all three stages of AD, CIS

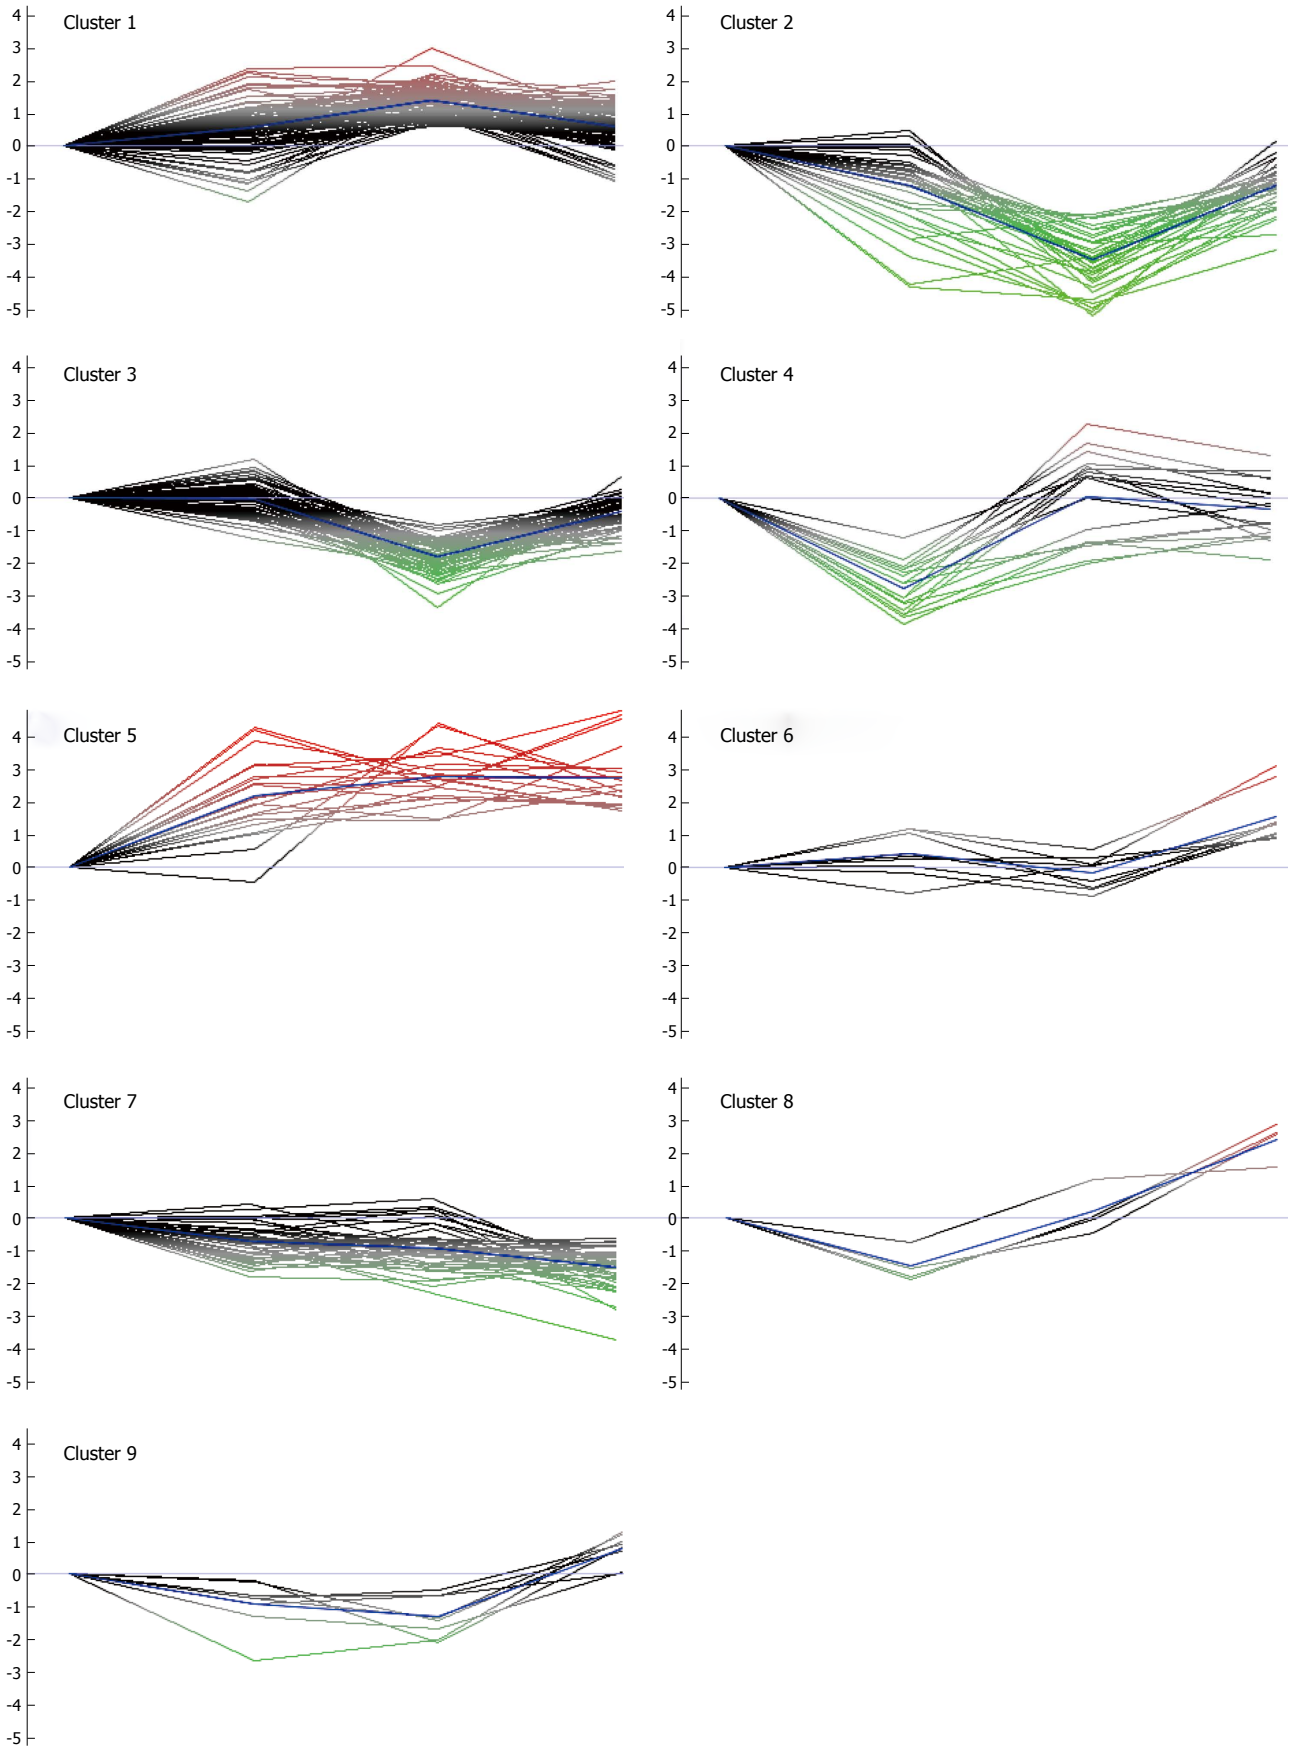

Figure 3 K-mean clusters of differentially expressed proteins. These proteins could be clustered into nine clusters. According to the average tendency, the nine clusters can be arbitrarily categorized into three groups. Group 1 includes clusters 1 and 5, in which the abundance of proteins progressively increased during the colon carcinogenic process. Group 2 consists of clusters 2 and 7, in which the abundance of proteins progressively decreased during the process. Group 3 consists of clusters 3, 4, 6, 8 and 9, in which the abundance of proteins was significantly up-regulated or down-regulated in certain stages of the process.

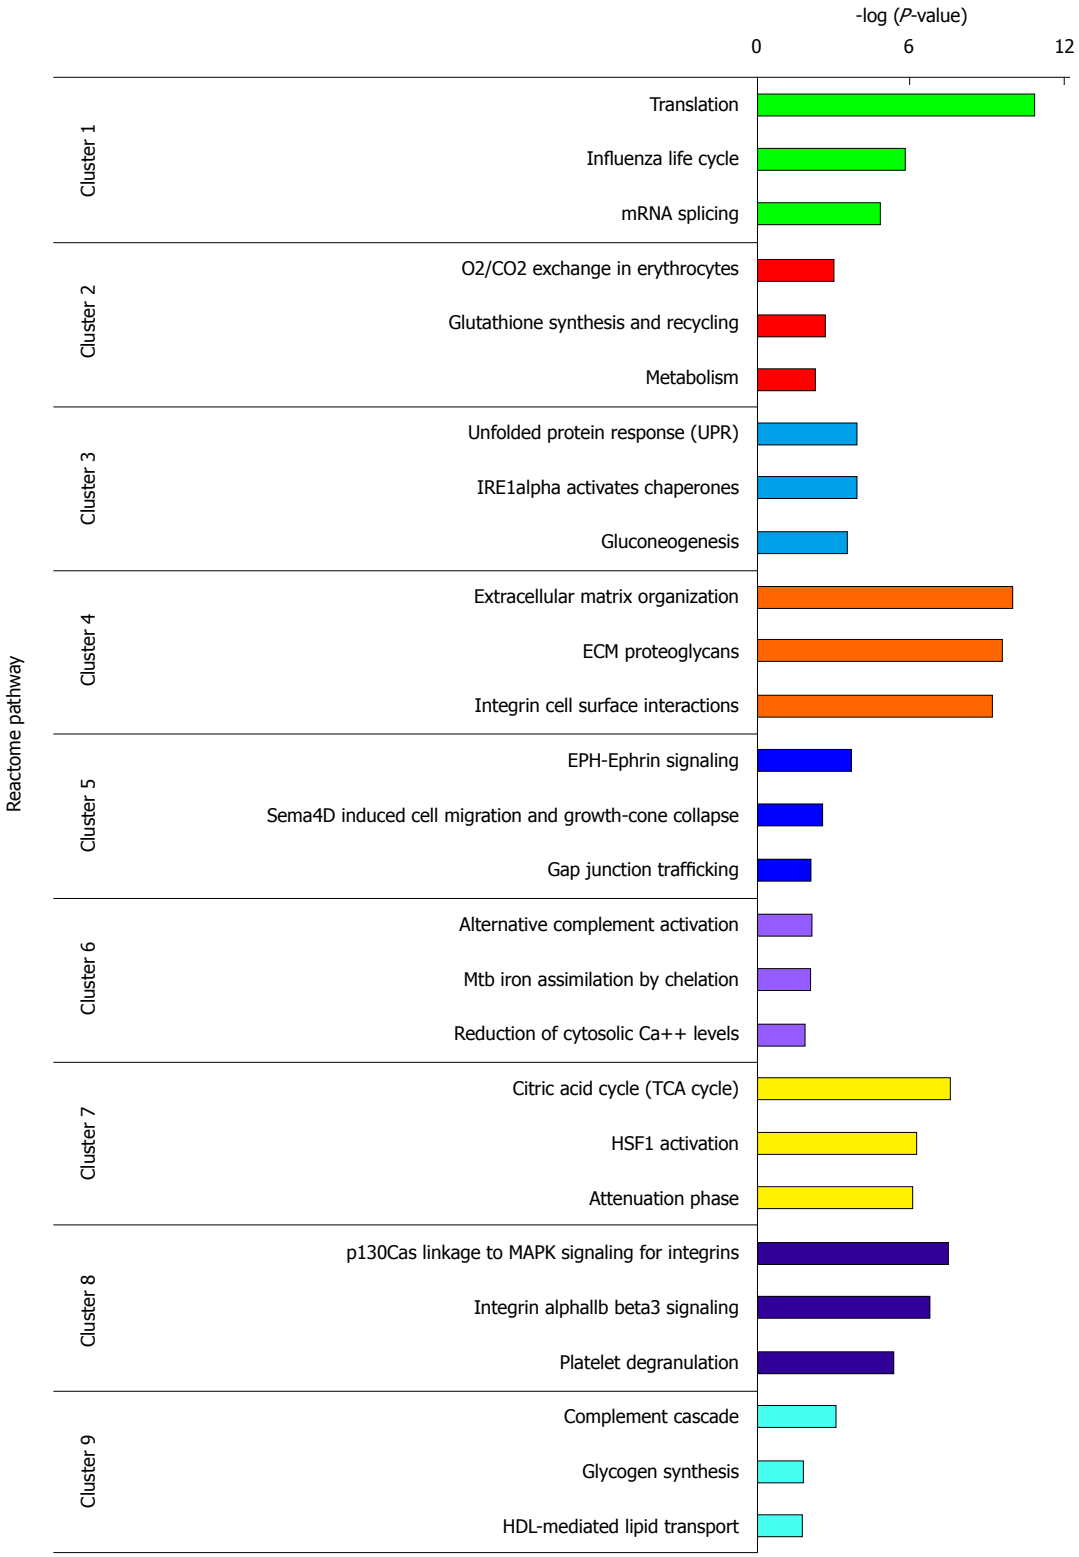

Figure 4 REACTOME pathway analysis of differential expressed proteins in each cluster. Only top 3 significant pathways are presented. Each pathway is presented as negative logarithm of *P*-value.

and IC, and exhibited the lowest expression in CIS or IC. Group 3 consists of clusters 3, 4, 6, 8 and 9, in which the abundance of proteins fluctuated during the colorectal carcinogenic process and was significantly up-regulated or down-regulated only in certain stages. Ideally, the proteins within each cluster are co-regulated proteins, and may have similar biological functions during colorectal carcinogenesis. Pathway analysis with REACTOME revealed that proteins in clusters 1 and 5 were mainly involved in "translation", "EPH-Ephrin signaling" and "Sema4D induced cell migration and growth-cone collapse", *etc*., whereas

the proteins in clusters 2 and 7 were associated with "O_2/CO_2 exchange in erythrocytes", "glutathione synthesis and recycling," and "TCA cycle" (Figure 4, Supplementary Tables 4 and 5). Interestingly, the abundance of proteins in clusters 8 and 9, which were mainly involved in pathways related with integrin and complement, were reduced first, and then increased. These proteins may exert different or even opposite functions at different stages of colorectal carcinogenesis through the associated pathways. The DEPs in each cluster were involved in multiple pathways, which indicated that multiple cellular pathways participated in the carcinogenic process, implying the complexity of the process.

Immunohistochemistry

Four of the top ranked proteins (DMBT1, S100A9, Galectin-10, and S100A8), which had expression levels that were progressively up-regulated during colorectal carcinogenic process, were chosen for immunohistochemical verification (Table 2). An independent set of archival tissue specimens including NC, AD, CIS and ICC were used for detection of the expression levels of the four proteins by immunohistochemistry. As shown in Figure 5 and Supplementary Table 3, expression levels of the four proteins significantly increased from early stage, AD, until late stage, ICC, but their expression patterns were not identical. For example, although Galectin-10 expression increased in all pathological stages ($P < 0.05$ for AD *vs* NC, CIS *vs* NC, and ICC *vs* NC), the expression level was lower at CIS than at AD or ($P < 0.05$ for CIS *vs* AD and ICC *vs* CIS). As another example, S100A8 expression was significantly higher at ICC than at AD or CIS ($P < 0.05$ for ICC *vs* AD and ICC *vs* CIS), although it also increased in all three pathological stages ($P < 0.05$ for AD *vs* NC, CIS *vs* NC and ICC *vs* AD).

DISCUSSION

Colorectal carcinogenesis has been a typical model for multistage carcinogenesis. The colorectal carcinogenic process includes several typical pathological stages: AD, CIS and ICC. Previous studies mostly focused on genes and acquired a great deal of information supporting the multistage model of colorectal carcinogenesis. With the advent of proteomics, researchers have made efforts to study alterations of the proteomes between certain stages of carcinogenesis[30,31]. Compared to previous reports on colorectal carcinogenesis, our current study mainly investigated the characteristics and dynamics of DEPs throughout multiple typical stages of the colorectal carcinogenic processes. Protein quantification by iTRAQ is a very useful technique to monitor relative changes in proteins in a variety of settings, such as multiple stages of cancer development. Some limitations of iTRAQ technique include underestimation of ratios, limited dynamic range (fold changes of < 2 orders of magnitude), and relatively expensive reagents[32,33]. Since iTRAQ underestimates ratios, we expect that the actual ratio change of up-regulation or down-regulation would be more than that we reported.

There were 199 DEPs founded between AD *vs* NC. GO enrichment analysis indicated that proteins

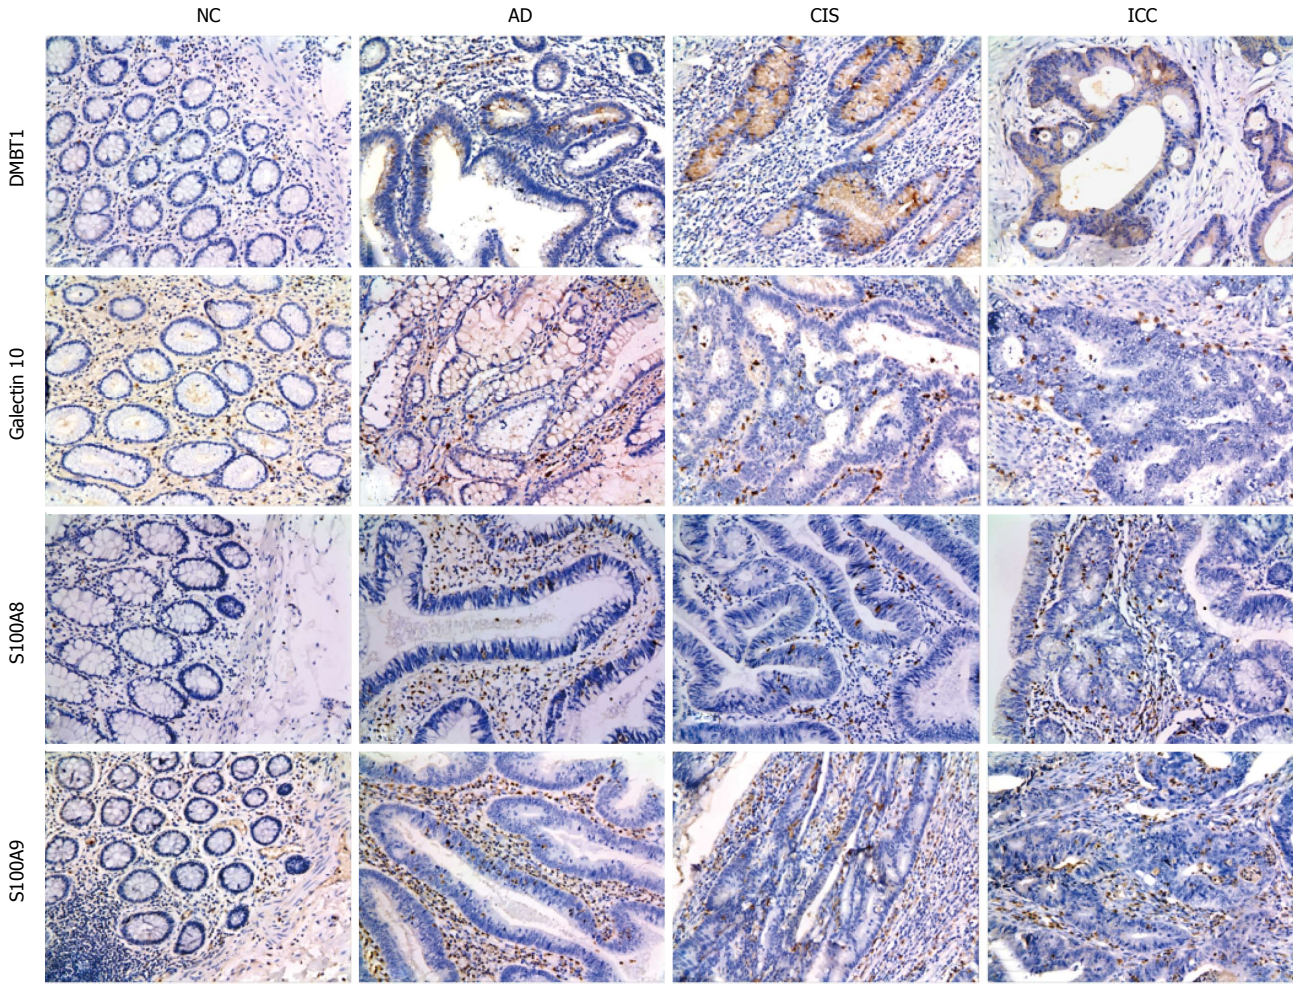

Figure 5 Representative results of immunohistochemistry show the expression of DMBT1, S100A9, Galectin-10 and S100A8 in the NC, AD, CIS and ICC (Original magnification, × 200). DMBT1 immunostaining in NC, AD, CIS and ICC. Negative staining was observed in NC, moderate in AD tissues, and strong cytoplasmic staining in CIS and ICC tissues. S100A9 immunostaining in NC, AD, CIS and ICC. Negative staining was found in NC, weak intralesional staining in AD, moderate intralesional staining in CIS and strong intralesional staining in ICC. Galectin-10 immunostaining in NC, AD, CIS and ICC. Negative staining was found in NC, weak staining in AD and CIS, and moderate staining in ICC. S100A8 immunostaining in NC, AD, CIS and ICC. Negative staining was observed in NC, moderate intralesional staining in AD and CIS, and strong intralesional staining in ICC.

associated with DNA replication, translation, protein complex biogenesis and assembly were significantly up-regulated in AD, whereas proteins associated with blood coagulation, response to external stimulus, complement activation and cell adhesion, *etc.*, were down-regulated in AD. Previous genetic analysis by Suppression Subtractive Hybridization (SSH) also found that genes involved in DNA replication, complement activation and cell adhesion were significantly differentially expressed in AD[34]. This is in accordance with our findings at the protein level.

Previous studies compared the proteomes between colorectal adenomas and carcinomas, and found that the DEPs participated in RNA processing, translation, and cell adhesion[35,36]. In the present study, we also showed that during the transition from AD to CIS, the DEPs were associated with cell-cell adhesion, cell-matrix adhesion, translation and RNA metabolic processing. In addition, our results showed that the up-regulated proteins were associated with cell cycle and cellular component movement, while the down-regulated proteins were associated with respiratory electron transport chain and fatty acid beta-oxidation. Previous studies using genome-wide mRNA expression profile analysis showed that the pathway of fatty acid metabolism is down-regulated in CRC compared to adenomas[37]. In addition to CRC, proteins involved in fatty acid β-oxidation were also found to be down-regulated in pancreatic cancer cells[38,39].

Between CIS and ICC, the proteins associated with complement activation were up-regulated in ICC. The multiple roles that complement proteins play in carcinogenesis, including functions that facilitate cancer metastasis such as promotion of angiogenesis, invasion and migration, have been reviewed[40,41]. Furthermore, recent studies demonstrate that activation of the complement C5 component C5a and its receptor C5aR can promote cancer cell invasion[42,43].

DMBT1 (deleted in malignant brain tumours 1) gene is located in 10q25.3-q26.1, a region with frequent LOH

in many types of human cancers. Therefore, DMBT1 was proposed to be a tumour suppressor[44]. DMBT1 deletion occurs in brain tumours[45], and down-regulation of DMBT1 was reported in mammary tumours, oral squamous cell carcinoma, skin cancers and other tumour types[46,47]. However, there are also a number of reports showing that DMBT1 was up-regulated in cancers. For example, Dolznig *et al*[48] found that DMBT1 expression was increased in colonic samples compared to normal controls. In our present study, we also found that DMBT1 expression was up-regulated from early to late stages of colonic carcinogenesis. In addition to CRC, DMBT1 expression was also up-regulated during oesophageal carcinogenesis[49]. Since DMBT1 expression was up-regulated in some cancer types while down-regulated in others, the mechanism by which DMBT1 contributes to carcinogenesis could be tissue-specific, and needs more investigation.

S100A9 and S100A8 proteins are members of a family of Ca2+ binding proteins. Both proteins are often co-expressed and form a heterodimer to exert their biological functions. Overexpression of S100A8 and S100A9 has been associated with carcinogenesis[50-52]. For example, Stulík *et al*[53] reported that S100A9/A8 were up-regulated in human colon carcinoma. S100A9/A8 could activate MAPK and NF-κB pathways in colon tumour progression[50]. Our results showed that S100A9/A8 expression was gradually up-regulated during carcinogenesis. The tendency of both protein expression levels during colonic carcinogenesis was similar, which was consistent with the performance of their biological function as a heterodimer. Our study suggested that both proteins are associated with colorectal carcinoma progression, which supported the therapeutic strategies of blocking S100A9/A8 activity for either inflammatory diseases or cancer[52].

Galectins are a family of proteins characterized by their binding specificity for β-galactoside sugars. The best understood galectin in cancer is Galectin-3. Galectin-3 has been shown to play important roles in tumorigenesis processes, including transformation, metastasis and invasion[54,55]. As for Galectin-10, Ågesen *et al*[56] demonstrated that Galectin-10 was the most differentially expressed gene, with 10-fold higher expression in early- *vs* late-onset CRC, and was important in the development of early-onset CRC.

The present work investigated for the first time the dynamic expression patterns of DEPs in multistage carcinogenesis of CRC using quantitative proteomic methods. We systematically compared the characteristics and dynamics of the expressed proteins across the various stages of colorectal carcinogenesis. The findings reported here provide a basis for discovery of candidate biomarkers for early diagnosis of CRC, and give clues for further investigation of the mechanisms of colorectal carcinogenesis and for discovery of new therapeutic targets.

COMMENTS

Background

Colorectal cancer is the third leading cause of cancer death in the world. Colorectal carcinogenesis is a multistep and complicated process, from normal colonic mucosa, adenoma, carcinoma *in situ*, and ultimately to invasive colorectal carcinoma.

Research frontiers

In recent years, much progress has been made in understanding genetic changes in the colonic carcinogenesis process, and many studies have been conducted to analyze differentially expressed proteins between certain stages of colorectal carcinogenesis

Innovations and breakthroughs

In this study, proteomic analysis was used to identify differentially expressed proteins in the human colonic epithelial carcinogenic process, including normal colon, adenoma, carcinoma *in situ* and invasive carcinomas tissues. A total of 326 proteins were identified to be differentially expressed. The differential expression of four proteins (DMBT1, S100A9, Galectin-10, and S100A8) was validated using immunohistochemistry.

Applications

These findings give insights into our understanding of the mechanisms of colorectal carcinogenesis. In addition, these studies provide a list of differentially expressed protein as potential biomarkers.

Peer-review

This paper provides practical and novel proteomic information that is currently not known with respect to the expression of various proteins during colon carcinogenesis. It is well written, and data presented are interesting.

Abstract

AIM: To investigate serum interleukin (IL)-38 level and its clinical role in predicting virological response (VR) to telbivudine (LdT) in patients with chronic hepatitis B (CHB).

METHODS: The study participants were divided into two groups; one group consisted of 43 healthy controls (HCs) and the other group consisted of 46 patients with hepatitis B e antigen-positive CHB. All patients were administered 600 mg of oral LdT daily for 52 wk, and they visited physicians every 12 wk for physical examination and laboratory tests. Serum IL-38 levels were determined using ELISA. The concentrations of serum Th1- and Th2-type cytokines were measured using the cytometric bead array (CBA) method.

RESULTS: Serum levels of IL-38 at baseline in all patients were higher than those in HCs [306.97 (123.26-492.79) pg/mL *vs* 184.50 (135.56-292.16) pg/mL, $P = 0.019$]; the levels returned to normal after the first 12 wk of treatment with LdT [175.51

(103.90-331.91) pg/mL *vs* 184.50 (135.56-292.16) pg/mL, $P > 0.05$]. Serum IL-38 levels at baseline were positively associated with serum aspartate aminotransferase levels in patients with CHB ($r = 0.311$, $P = 0.036$). Higher levels of serum IL-38 at baseline were associated with a greater probability of VR to LdT treatment at 24 wk (48.15% *vs* 15.79%, $P = 0.023$) and 52 wk (66.67% *vs* 36.84%, $P = 0.044$). The levels of serum IL-38 in patients with primary non-response at week 12 after treatment initiation were lower than those in patients with primary response [64.44 (49.85-172.08) pg/mL *vs* 190.54 (121.35-355.28) pg/mL, $P = 0.036$]. Serum IL-38 levels were correlated with serum IL-6 and IL-12 levels in patients with CHB during treatment with LdT.

CONCLUSION: Elevated serum IL-38 levels in untreated CHB patients reflect ongoing liver injury. Higher serum IL-38 levels before treatment indicate a greater probability of VR to LdT treatment.

Key words: Alanine aminotransferase; Aspartate aminotransferase; Interleukin-6; Interleukin-12; Interleukin-38; Chronic hepatitis B; Primary non-response; Virological response

Core tip: This is the first study detailing kinetic changes in serum interleukin-38 (IL-38) levels during chronic hepatitis B (CHB). Higher pretreatment serum IL-38 levels are associated with a greater probability of virological response to telbivudine treatment. Elevated levels of serum IL-38 in untreated patients with CHB reflect ongoing liver injury, which is an indirect indicator of vigorous endogenous clearance of hepatitis B virus infection. Our findings suggest that clear signs of viral clearance at baseline may predict a favorable response to treatment of CHB using nucleoside analogs.

Wang HJ, Jiang YF, Wang XR, Zhang ML, Gao PJ. Elevated serum interleukin-38 level at baseline predicts virological response in telbivudine-treated patients with chronic hepatitis B. *World J Gastroenterol* 2016; 22(18): 4529-4537 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4529.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4529

INTRODUCTION

Hepatitis B virus (HBV) infection is a serious global health concern, and approximately 240 million people have been chronically infected with HBV[1]. Patients with chronic hepatitis B (CHB) have a high risk of developing liver cirrhosis and hepatocellular carcinoma[2].

Previous studies have revealed that HBV infection may suppress the immune system, and that Th1 and Th2 cells and their respective cytokines are possibly involved in the pathogenesis of CHB[3,4]. Telbivudine (LdT), a nucleoside analog (NA), not only inhibits viral replication, but also increases cytokine production by the Th1 cell subpopulation, which could contribute to its antiviral efficacy[5]. Th2 cells secrete interleukin (IL)-10 and IL-6, which are involved in liver inflammation in CHB[6,7]. Members of the IL-1 cytokine family are also associated with acute and chronic inflammation, and they facilitate the differentiation and function of polarized innate and adaptive lymphoid cells[8,9]; they likely participate in CHB infection. For example, it has been reported that IL-37, an anti-inflammatory cytokine, was a part of the immune response in patients with CHB who showed hepatitis B e antigen (HBeAg) seroconversion, and that both serum IL-33 and IL-37 levels are associated with liver injury in these patients[10,11].

IL-38 (IL-1F10) is a newly characterized cytokine of the IL-1 family, and it is expressed in the basal epithelia of the skin and in the proliferating tonsillar B cells[12]. It was suggested that IL-38 may have anti-inflammatory properties, since it shares some sequence homology with IL-1Ra (41%) and IL-36Ra (43%)[8]. This assumption was first supported by a study that showed that a recombinant IL-38 bound to the IL-36 receptor and inhibited the expression of IL-17, IL-22, and IL-8 in human peripheral blood mononuclear cells (PBMCs) under inflammatory conditions. It was further suggested that IL-38 might function as a partial IL-36 receptor antagonist[13]. Another study observed a marked increase in lupus-associated pro-inflammatory mediators following silencing of endogenous IL-38 in PBMCs, which supported the assumed anti-inflammatory function of IL-38[14]. Furthermore, IL-38 was upregulated in patients with primary Sjogren's syndrome, and it was suggested to counteract the imbalanced activation of IL-36[15]. Genetic association studies indicated that IL-38 polymorphisms are linked with a high frequency of psoriatic arthritis, ankylosing spondylitis, and rheumatoid arthritis in the population, suggesting that IL-38 is a likely component in the pathogenesis of these inflammatory diseases[8,16,17].

NAs and interferons (IFNs) are the currently available antiviral agents for treating CHB[18]. LdT is a synthetic thymidine NA that shows potent inhibition of HBV replication[19]. Recent studies have shown that treatment with LdT not only suppresses HBV replication, but also modulates the immune response in treated CHB patients[20].

To our knowledge, there are no available data regarding the expression or function of IL-38 in CHB. In this study, we quantified the kinetic changes in serum IL-38 level and investigated the potential correlation between the levels of HBV-related biochemical markers, Th1/Th2 type cytokines, and serum IL-38 levels during LdT treatment of patients with CHB. In addition, we discussed the implications of our findings.

MATERIALS AND METHODS

Patients

A total of 46 patients with CHB were recruited at the First Hospital of Jilin University from September 2012 to October 2014. Patients with CHB showed positive results for hepatitis B surface antigen (HBsAg), HBeAg, and HBV DNA for at least 12 mo. Another 43 gender-, age- and ethnicity-matched healthy controls (HCs) were recruited from the Physical Examination Center of our hospital during the same period. Individuals who showed seropositivity of hepatitis C, G, or D virus, those infected by HIV-1 or those with autoimmune liver disease were excluded from the study. None of the participants had received immunosuppressive or antiviral therapy during the 12 mo preceding their inclusion in the study, and none of them reported a history of exposure to known hepatotoxins. The demographic and clinical characteristics of the patients are summarized in Table 1. Written informed consent was obtained from each study participant; the experimental protocol was established according to the guidelines of the 1975 Declaration of Helsinki and was approved by the Human Ethics Committee of Jilin University, China.

Patients were administered 600 mg LdT (Novartis Pharmaceuticals, Beijing, China) daily for 52 wk, and they visited the outpatient department of the hospital every 12 wk for physical examination and laboratory tests. All patients were followed up for one year. Peripheral blood samples were obtained and serum samples were separated; the samples were stored at -80 ℃ until use.

Measurement of serum IL-38 by enzyme-linked immunosorbent assay

Serum concentrations of IL-38 in patients and HCs were determined by enzyme-linked immunosorbent assay [human IL-38 enzyme-linked immunosorbent assay (ELISA) kit; CUSABIO Life Sciences, Wuhan, Hunan province, China]. Briefly, individual sera were subjected to ELISA, and the concentrations of serum IL-38 in individual samples were calculated using the standard curve established with the recombinant IL-38 provided. The detection limit of IL-38 ranged between 31.25 and 2000 pg/mL.

Cytometric bead array of serum Th1- and Th2-type cytokines

The concentrations of serum Th1- and Th2-type cytokines (IFN-γ, TNF-α, IL-2, IL-4, IL-12, IL-10, and IL-6) were determined by cytometric bead array (CBA) according to the manufacturer's protocol (BD Biosciences, San Jose, CA, United States), with minor modifications. Briefly, 25 μL of individual serum was used in duplicate for analysis. The concentrations of serum cytokines were quantified using the CellQuest Pro and CBA software (Becton Dickinson, San Jose, CA, United States) on an FACSAria Ⅱ flow cytometer (BD Biosciences).

Table 1 Demographic and clinical characteristics of study subjects at baseline

Parameters	Patients with CHB (n = 46)	Healthy controls (n = 43)
Age (yr)	34.5 (23.75-38.25)	34 (22-40)
Sex (M/F)	38/8	34/9
HBV DNA load (log_{10} IU/mL)	7.71 (6.98-8.10)	NA
ALT level (U/L)	117.35[a] (74.50-241.48)	14 (6-22)
AST level (U/L)	96.75[a] (57.25-176.25)	12 (10-30)
HBsAg level (IU/mL)	7821.43 (3337.23-20737.14)	NA
HBsAg, pos/neg	46/0	0/43
HBeAg, pos/neg	46/0	0/43

Data are represented as median and interquartile range (IQR) or real case number. Normal values: ALT ≤ 50 IU/L; AST ≤ 40 IU/L; HBV DNA ≤ 1.78 log_{10} IU/mL (60 IU/mL). [a]$P < 0.05$ *vs* the HCs. The undetectable HBV DNA loads were recorded as those ≤ 60 IU/mL. CHB: Chronic hepatitis B; HBV: Hepatitis B virus; NA: Not applicable; ALT: Alanine transferase; AST: Aspartate transferase; HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; pos: Positive; neg: Negative.

Serological analysis of HBV markers

Serum HBsAg, hepatitis B surface antibody (HBsAb), HBeAg, and hepatitis B e antibody (HBeAb) were detected by chemiluminescent microparticle immunoassay (CMIA), using an Abbott i2000 automated chemiluminescent immunoassay analyzer (Abbott Laboratories, Abbott Park, IL, United States). The levels of serum alanine transferase (ALT) and aspartate transferase (AST) were detected using a Biochemistry Automated Analyzer (Roche Diagnostics, Branchburg, New Jersey, United States). Serum HBV DNA was measured by quantitative PCR using a luciferase-based detection kit, following the manufacturer's protocols (Roche). The detection limit of viral DNA was 60 IU/mL (HBV DNA ≤ 60 IU/mL was considered undetectable).

Statistical analysis

Quantitative data were expressed as median and interquartile range (IQR). Differences between independent groups were analyzed by Mann-Whitney *U* test or Student's *t*-test when appropriate and differences between related groups were analyzed by Wilcoxon signed ranks test. The correlation between variables was evaluated using Spearman's rank correlation test. Receiver operating characteristic curves were constructed to identify optimal cutoff values for predicting virological response (VR) to treatment. Fisher's exact tests were carried out to compare the rates of VR, HBeAg loss, ALT normalization and HBsAg loss. Binary logistic regression was used to determine predictors of VR. All statistical analyses were performed by the SPSS software (version 18.0). *P*-value < 0.05 was considered as statistically significant.

Table 2 Dynamics of clinical parameters in patients with chronic hepatitis B during LdT treatment

Parameters	Baseline	3 mo	6 mo	9 mo	13 mo
HBV DNA load (log_{10} IU/mL)	8.41 (7.68-8.80)	3.79[a] (3.20-5.14)	3.04[a] (2.48-3.98)	2.81[a] (2.48-3.10)	2.48[a] (2.48-3.50)
ALT level (U/L)	117.35 (74.50-241.48)	36.00[a] (23.93-85.50)	27.00[a] (22.00-38.00)	27.50[a] (23.00-34.25)	29.50[a] (24.00-55.00)
AST level (U/L)	96.75 (57.25-176.25)	34.00[a] (28.00-55.25)	26.00[a] (22.00-31.25)	24.50[a] (19.75-30.00)	27.00[a] (22.75-43.25)
HBsAg level (IU/mL)	7821.43 (3337.23-20737.14)	4214.99[a] (2034.48-10170.46)	5153.19[a] (2039.45-10671.30)	4414.88[a] (2317.96-10084.21)	4210.48[a] (1664.73-9823.78)

Data are represented as median and interquartile range (IQR). Normal values: ALT ≤ 50 IU/L; AST ≤ 40 IU/L; HBV DNA ≤ 1.78 log_{10} IU/mL (60 IU/mL). [a]$P < 0.05$ *vs* baseline value. The undetectable HBV DNA loads were recorded as those ≤ 60 IU/mL. CHB: Chronic hepatitis B; HBV: Hepatitis B virus; ALT: Alanine transferase; AST: Aspartate transferase; HBsAg: Hepatitis B surface antigen.

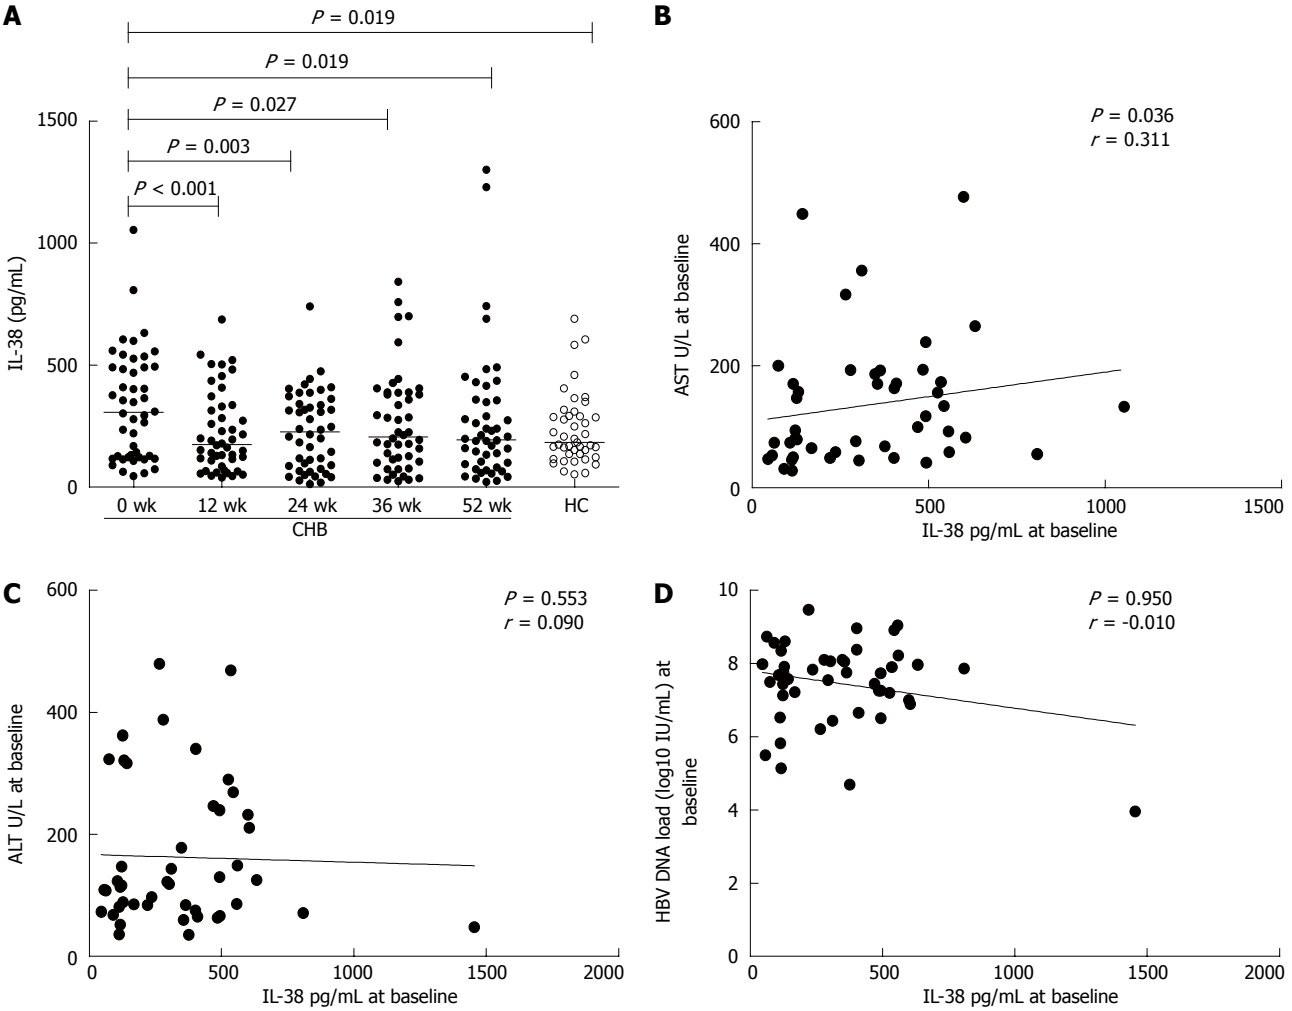

Figure 1 Kinetic changes in serum interleukin-38 levels of patients with chronic hepatitis B during treatment with telbivudine and association of serum interleukin-38 with serum aspartate transferase, alanine transferase, hepatitis B virus DNA loads prior to treatment. A: Kinetic changes in the levels of serum IL-38 in HCs and patients with CHB at baseline and at 12, 24, 36, and 52 wk of LdT treatment. IL-38 levels were higher in patients with CHB compared with HCs at baseline [306.97 (123.26-492.79) pg/mL *vs* 184.50 (135.56-292.16) pg/mL; $P = 0.019$]. They were reduced at week 12, 24, 36, and 52 of LdT treatment ($P < 0.001$, $P = 0.003$, $P = 0.027$, $P = 0.019$), and the levels of serum IL-38 in patients with CHB were no longer different from that of the HCs after 12 wk of LdT treatment. B: Serum AST levels correlated with serum IL-38 levels at baseline. C and D: Serum IL-38 levels did not correlate with serum ALT levels or with serum HBV DNA loads at baseline. IL-38: Interleukin-38; HCs: Healthy controls; CHB: Chronic hepatitis B; LdT: Telbivudine; ALT: Alanine transferase; AST: Aspartate transferase; HBV: Hepatitis B virus.

RESULTS

HBV-related biochemical markers in patients with CHB before and during treatment with LdT

There was no significant difference in the distribution of age or gender between patients with CHB and HCs (Table 1).

HBV DNA and HBsAg levels gradually decreased in response to the LdT treatment and were lower than the levels before treatment. Both ALT and AST

Table 3 Comparison of demographic and clinical characteristics of patients with high and low interleukin-38 levels before treatment

Parameter	High IL-38 level before treatment (n = 27)	Low IL-38 level before treatment (n = 19)
Age (yr)	35 (23-38)	34 (25-40)
Sex (M/F)	22/5	16/3
HBV DNA load (log_{10} IU/mL)	7.74 (6.89-8.10)	7.69 (7.14-8.36)
ALT level (U/L)	130.00 (71.00-246.50)	108.00 (81.00-147.00)
AST level (U/L)	156.00[c] (76.00-193.00)	74.00 (49.00-147.00)
HBsAg level (IU/mL)	6641.55 (4437.10-18631.33)	10222.92 (2657.06-24877.19)

Data are represented as median and interquartile range (IQR) or real case number. Normal values: ALT ⩽ 50 IU/L; AST ⩽ 40 IU/L; HBV DNA ⩽ 1.78 log_{10} IU/mL (60 IU/mL). [c]P < 0.05 *vs* the group of patients with low serum IL-38 levels before LdT treatment. The undetectable HBV DNA loads were recorded as those ⩽ 60 IU/mL. High IL-38 level: Serum IL-38 ⩾ 250 pg/mL; Low IL-38 level: Serum IL-38 < 250 pg/mL; IL-38: Interleukin-38; HBV: Hepatitis B virus; ALT: Alanine transferase; AST: Aspartate transferase; HBsAg: Hepatitis B surface antigen; M: Male; F: Female.

levels also decreased during treatment (Table 2). VR was defined as undetectable HBV DNA (⩽ 60 IU/mL). Primary non-response (PNR) was defined as a decrease in HBV DNA of less than 1 log10 IU/mL from baseline at 12 wk after treatment initiation[21]. Of the 46 patients, 5 showed PNR and the remaining 41 patients showed primary response (PR) at week 12. At weeks 24 and 52 of LdT therapy, 16 (35%) and 25 (54%) patients with CHB showed VR, respectively.

Kinetic changes in serum IL-38 levels of patients with CHB during treatment with LdT and association of serum IL-38 with serum AST prior to treatment

The kinetic changes in serum IL-38 levels during treatment were determined. Serum IL-38 levels at the baseline and at 12, 24, 36, and 52 wk were 306.97 (123.26-492.79) pg/mL, 175.51 (103.90-331.91) pg/mL, 226.53 (84.33-346.47) pg/mL, 205.91 (103.48-387.16) pg/mL, and 194.79 (90.71-356.48) pg/mL, respectively. As shown in Figure 1, IL-38 levels were higher in patients with CHB compared with HCs at baseline [306.97 (123.26-492.79) pg/mL *vs* 184.50 (135.56-292.16) pg/mL, P = 0.019, Figure 1A], and they were reduced at week 12, 24, 36, and 52 of LdT treatment (P < 0.001, P = 0.003, P = 0.027, P = 0.019, Figure 1A). In addition, the levels of serum IL-38 in patients with CHB were no longer different from that of the HCs after 12 wk of LdT treatment, since a quick reduction was observed only during the first 12 wk.

Correlation analysis of serum IL-38 with ALT and AST levels showed that serum IL-38 levels at baseline were positively associated with serum AST levels (P = 0.036, r = 0.311, Figure 1B) but not with serum ALT levels (P > 0.05, Figure 1C) in patients with CHB. No significant correlation was found between serum IL-38 and serum AST or ALT values during LdT therapy (data not shown).

In addition, there was no significant association between serum IL-38 and HBV DNA levels prior to LdT treatment (P > 0.05, Figure 1D), and no significant correlation during LdT therapy (data not shown).

Pretreatment serum IL-38 levels in patients with CHB were associated with antiviral therapy outcomes

We generated receiver operating characteristic curves to decide optimal cut-off values of serum IL-38 at baseline to predict VR. Using the serum IL-38 levels at baseline, we divided the 46 patients with CHB into two groups: high level group (HG; serum IL-38 ⩾ 250 pg/mL, n = 27) and low level group (LG; serum IL-38 < 250 pg/mL, n = 19). The pretreatment characteristics of the two groups are shown in Table 3. There was no significant difference in the distribution of age or gender, and serum HBV DNA, ALT, and HBsAg levels between HG and LG. However, the serum AST levels differed between the groups. Interestingly, the serum HBV DNA loads in HG were lower than those in LG at week 12, 24, 36, and 52 post initial LdT treatment (P = 0.041, 0.003, 0.003, 0.020, Figure 2A), suggesting a better response in patients with high serum levels of IL-38. No significant difference in serum HBsAg levels was noted between the groups during LdT therapy (P > 0.05 at week 12, 24, 36, and 52, Figure 2B).

The VR rates were compared between HG and LG, and it was observed that at 24 wk, VR was achieved in 13 patients (48.15%) in HG and 3 patients (15.79%) in LG. Higher serum IL-38 levels at baseline were associated with greater VR (OR = 4.95, 95%CI: 1.17-21.03, P = 0.023). At 52 wk, 18 patients (66.67%) in HG and 7 patients (36.84%) in LG achieved VR. The IL-38 levels at baseline elicited different responses to therapy (OR = 3.43, 95%CI: 1.00-11.71, P = 0.044). Treatment outcomes, including HBeAg elimination, ALT normalization and HBsAg loss, between patients with high and low baseline IL-38 levels were also compared. As shown in Table 4, there were no significant differences in HBeAg elimination, ALT normalization and HBsAg loss between HG and LG. According to our data, an elevated serum IL-38 level at baseline could predict better virological response.

The serum AST, ALT, HBsAg, and HBV DNA levels at baseline were analyzed by binary logistic regression and they were not associated with VR at week 24 or 52 of LdT treatment (data not shown).

Primary response was associated with high serum IL-38 levels

The levels of serum IL-38 in patients with CHB who showed PR were higher than those of CHB patients who showed PNR at 12 wk after LdT treatment [190.54 (121.35-355.28) pg/mL *vs* 64.44 (49.85-172.08) pg/mL, P = 0.036, Figure 3], while they did not differ at baseline.

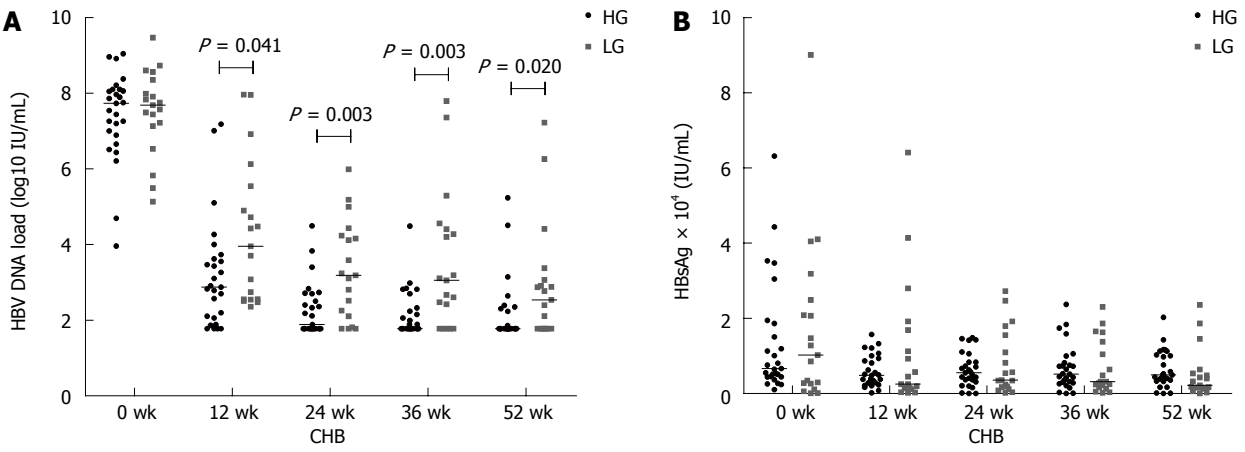

Figure 2 Comparison of serum hepatitis B virus DNA loads (A) and hepatitis B surface antigen levels (B) between high level group and low level group at baseline and at 12, 24, 36, and 52 wk of LdT treatment. A: The serum HBV DNA loads in HG were lower than those in LG at week 12, 24, 36, and 52 post initial LdT treatment (P = 0.041, 0.003, 0.003, 0.020). B: No significant difference in serum HBsAg levels was noted between the groups during LdT therapy. LdT: Telbivudine; HBV: Hepatitis B virus; HG: High level group; LG: Low level group; HBsAg: Hepatitis B surface antigen.

Table 4 Comparison of treatment outcomes between patients with high and low baseline interleukin-38 levels

Parameters	Week 24			Week 52		
	HG (n = 27)	LG (n = 19)	P value	HG (n = 27)	LG (n = 19)	P value
HBV DNA ≤ 60 IU/mL	13 (48.1)	3 (15.8)	0.023	18 (66.7)	7 (36.8)	0.044
HBeAg seroconversion	4 (14.8)	2 (10.5)	0.516	8 (29.6)	4 (21.1)	0.382
ALT normalization	25 (92.6)	15 (78.9)	0.182	21 (77.8)	12 (63.2)	0.225
HBsAg loss	0 (0.0)	0 (0.0)	NA	1 (3.7)	1 (5.3)	0.661

Normal values: ALT ≤ 50 IU/L; AST ≤ 40 IU/L; HBV DNA ≤ 1.78 log10 IU/mL (60 IU/mL). The undetectable HBV DNA loads were recorded as those ≤ 60 IU/mL. HG: High IL-38 level group, basement serum IL-38 ≥ 250 pg/mL; LG: Low IL-38 level, basement serum IL-38 < 250 pg/mL; IL-38: Interleukin-38; HBV: Hepatitis B virus; ALT: Alanine transferase; AST: Aspartate transferase; HBsAg: Hepatitis B surface antigen; HBeAg: Hepatitis B e antigen; NA: Not applicable.

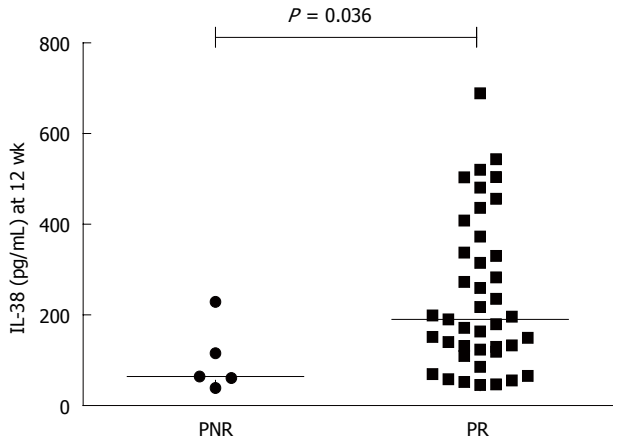

Figure 3 Comparison of serum interleukin-38 levels between patients with primary non-response and primary response at 12 wk post initial telbivudine treatment. The levels of serum IL-38 in patients with CHB who showed PR were higher than those of CHB patients showed PNR at 12 wk after LdT treatment [190.54 (121.35-355.28) pg/mL *vs* 64.44 (49.85-172.08) pg/mL, P = 0.036]. IL-38: Interleukin-38; CHB: Chronic hepatitis B; LdT: Telbivudine; ALT: Alanine transferase; AST: Aspartate transferase; HBV: Hepatitis B virus; PNR: Primary non-response; PR: Primary response.

Serum IL-38 levels correlated with IL-6 and IL-12 levels in patients with CHB during LdT treatment

As shown in Figure 4, the serum levels of IL-38 were positively associated with the levels of serum IL-6 at baseline, week 12, 24, 36, and 52 after starting LdT treatment (P = 0.003, r = 0.435; P = 0.002, r = 0.436; P = 0.001, r = 0.481; P < 0.001, r = 0.552; P = 0.008, r = 0.386; Figure 4A-E). The levels of serum IL-38 were positively associated with the levels of serum IL-12 at week 24, 36, and 52 of LdT treatment (P = 0.042, r = 0.301; P < 0.001, r = 0.515; P = 0.002, r = 0.451; Figure 4F-H).

DISCUSSION

To our knowledge, this is the first study detailing kinetic changes in serum IL-38 levels during CHB. We found that the levels of serum IL-38 at baseline in patients with CHB were higher than in HCs, which declined and returned to normal after 12 wk of LdT treatment. There was a positive correlation between IL-38 and AST levels at baseline. Patients with high serum levels of IL-38 showed a higher probability of VR than patients with low serum levels of IL-38. Further, the serum HBV DNA level in patients with high baseline IL-38 levels was reduced after 12 wk of LdT treatment as compared to patients with low baseline IL-38 levels.

Our findings indicated that IL-38 level may be a

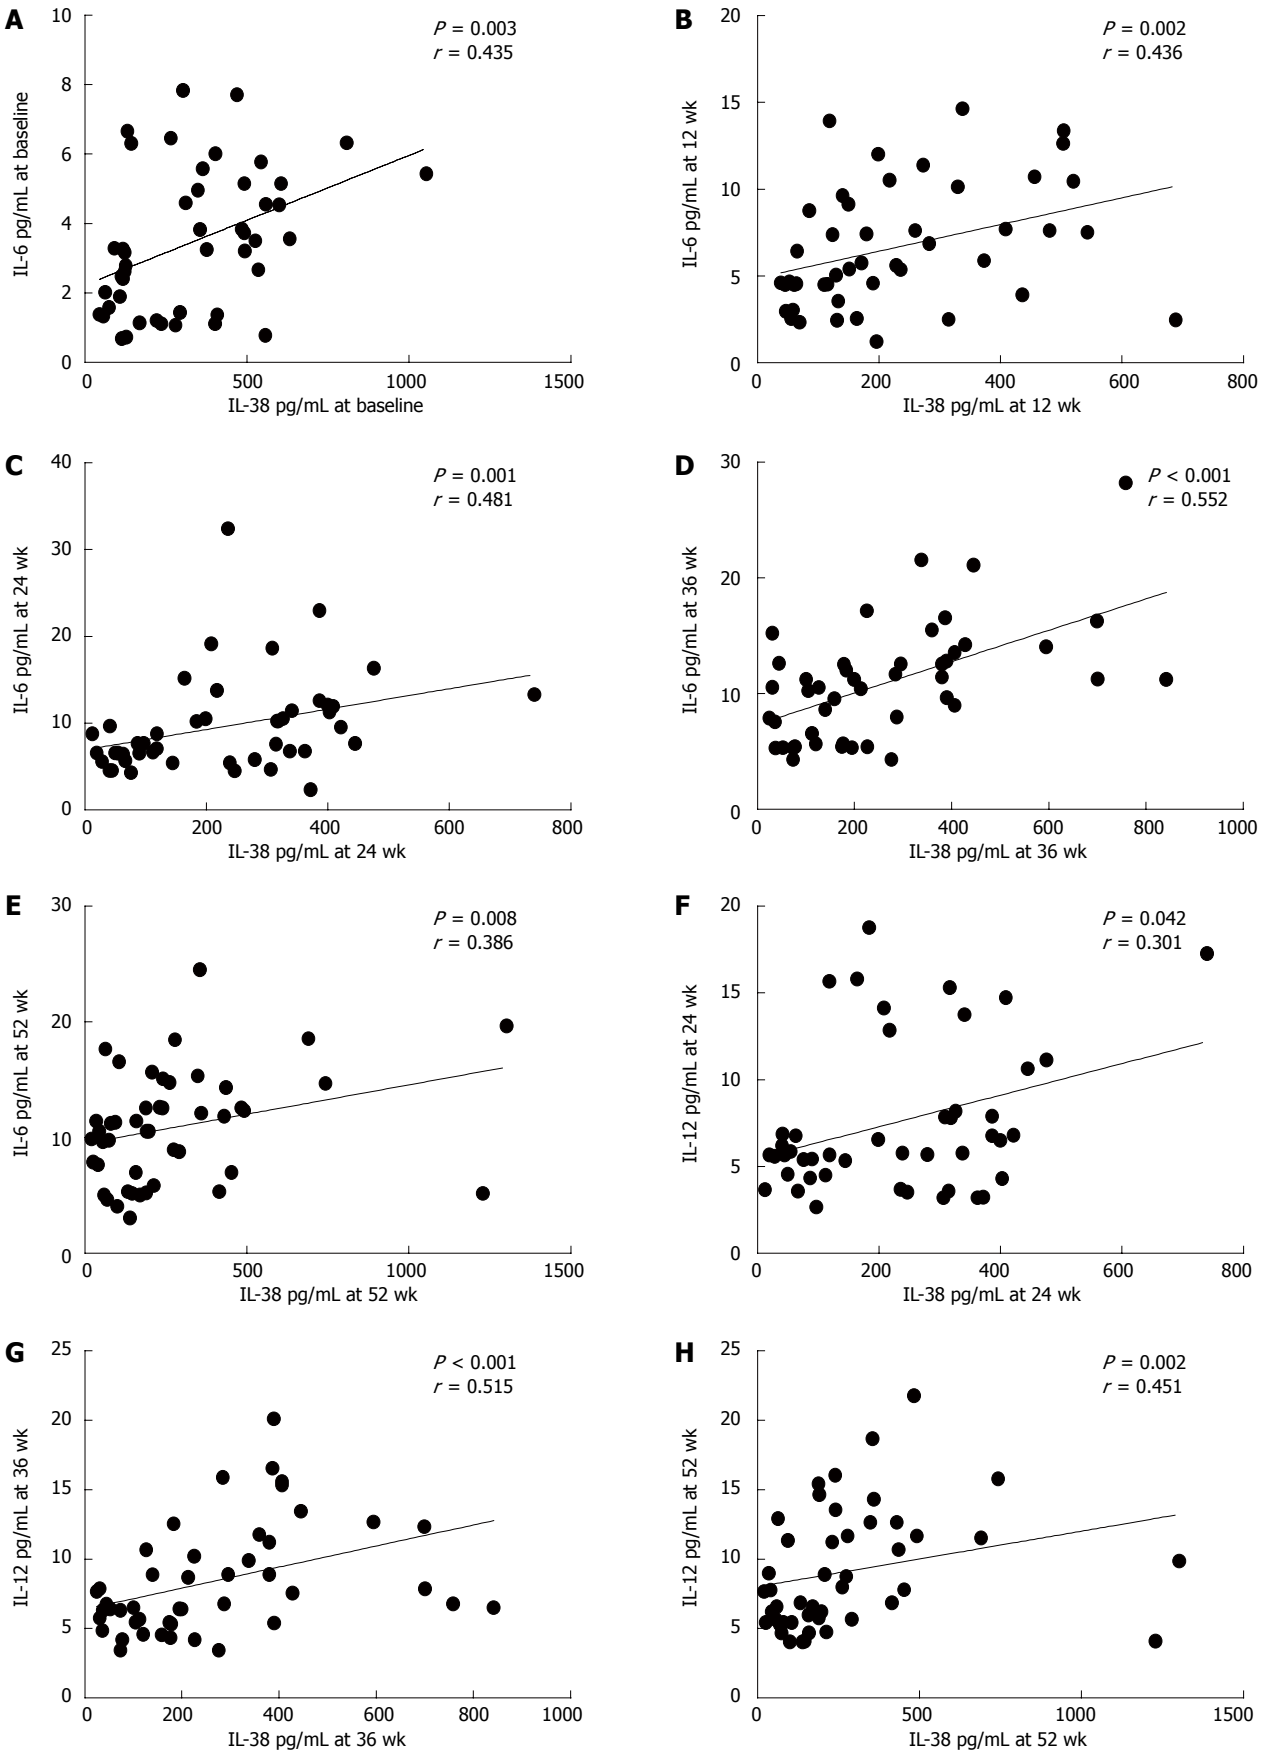

Figure 4 Correlation of serum interleukin-38, Th1- and Th2-type cytokines levels. A-E: Serum IL-38 levels correlated with serum IL-6 levels in patients with CHB during LdT treatment at baseline, and at 12, 24, 36, and 52 wk, respectively; F-H: Serum IL-38 levels correlated with serum IL-12 levels in patients with CHB during LdT treatment at 24, 36, and 52 wk, respectively. IL-38: Interleukin-38; CHB: Chronic hepatitis B; LdT: Telbivudine.

marker reflecting liver injury, since elevated IL-38 at baseline was in parallel with elevated AST, an indicator of liver injury[22]. However, we could not confirm whether elevated IL-38 level was a primary trigger for the liver injury or a response to it. Nevertheless, the elevated IL-38 level indicates hepatic necroinflammation to a certain extent. An active hepatic necroinflammation is a result of destruction of infected hepatocytes, and it can be viewed as viral clearance. Based on this information, we can explain why patients with high IL-38 and AST levels at baseline showed much better VR to LdT treatment, because these patients showed more vigorous endogenous clearance of HBV infection in addition to the antiviral effect of LdT. In contrast, patients with lower IL-38 and AST levels likely indicated a weak endogenous clearance of HBV infection. NAs such as LdT may not show potent antiviral efficacy without a strong endogenous clearance.

PNR suggests failure of antiviral treatment. Thus, in a compliant patient with PNR, more potent antiviral therapy might be necessary[21]. At 12 wk of LdT therapy, serum IL-38 levels of patients with PNR were lower than those of patients with PR, suggesting that patients with high IL-38 levels at baseline show a more effective clearance of HBV infection, which supports our speculation of more vigorous endogenous viral clearance in patients with a high serum level of IL-38.

Previous studies indicated that cytokines were involved in the noncytopathic suppression of HBV replication[23]. IL-6 is reported to be responsible for early suppression of HBV in infected hepatocytes[24]. IL-6 exerted its inhibitory effect through reducing HBV transcripts/core protein and decreasing the level of HBV genome-containing nucleocapsids[25]. IL-6 also inhibits HBV entry through down regulation of sodium taurocholate cotransporting polypeptide[26]. IL-12 plays an important role in the defense against viral infections through promoting naive T cells differentiation into Th1 cells and inhibiting viral replication[27]. Cytokine IL-12 can rescue the anti-viral function of exhausted HBV-specific CD8 T cells[28]. Our data showed positive correlations between IL-38 and IL-6 or IL-12, suggesting the functional association between cytokine IL-38 and Th1/Th2 type cytokines IL-6 and IL-12. Further studies are required to uncover the underlying molecular links between these cytokines.

Accurate prediction of response to antivirals in treating chronic HBV infection remains challenging. However, our findings strongly suggest that a favorable response does not completely depend on the antiviral efficacy of the agent, but also relies on the vigorous endogenous viral clearance. Thus, our study provides a clue for predicting VR by looking for signs of endogenous viral clearance.

In conclusion, our study demonstrated that higher pretreatment serum IL-38 levels are associated with a greater probability of VR to LdT treatment. Elevated levels of serum IL-38 in untreated patients with CHB reflect ongoing liver injury, which is an indirect indicator of vigorous endogenous clearance of HBV infection. A favorable response may be observed if the LdT antiviral effect is combined with a strong endogenous viral clearance. Therefore, our findings suggest that clear signs of viral clearance at baseline may predict a favorable response to treatment of CHB using NAs.

COMMENTS

Background

Hepatitis B virus (HBV) infection is a serious global health concern. Interleukin (IL)-38 is a new anti-inflammatory cytokine of the IL-1 family, and its polymorphisms are associated with inflammatory diseases.

Research frontiers

The clinical outcome of HBV infection is a complex process between viral replication and host immune response. Cytokines are involved in the regulation of immune responses against HBV infection. Many investigators attempt to find ideal immunological indicators for response to antiviral therapy of chronic hepatitis B (CHB).

Innovations and breakthroughs

To date, there are no available data regarding the expression or function of IL-38 in CHB. This study demonstrated that higher serum IL-38 levels at pretreatment were associated with a greater probability of VR to LdT treatment. Elevated levels of serum IL-38 in untreated patients with CHB reflect ongoing liver injury, which is an indirect indicator of vigorous endogenous clearance of HBV infection. A favorable response could be observed if the LdT antiviral effect is combined with a strong endogenous viral clearance.

Applications

The findings suggest that clear signs of viral clearance at baseline may predict a favorable response to NAs treatment of CHB.

Peer-review

This manuscript demonstrated that higher pretreatment serum IL-38 levels are associated with a greater probability of VR to LdT treatment. The authors suggested that elevated serum IL-38 levels reflect ongoing liver injury, which is an indicator of endogenous clearance of HBV infection. These findings are interesting because it might provide novel predictors for good response to antiviral therapy.

Abstract

AIM: To investigate the expression and clinical significance of B7-H4 and hepatitis B virus X (HBx) protein in hepatitis B virus-related hepatocellular carcinoma (HBV-HCC).

METHODS: The expression of B7-H4 in the human

HCC cell lines HepG2 and HepG2.2.15 were detected by western blot, flow cytometry, and immunofluorescence. The expression of B7-H4 and HBx in 83 HBV-HCC was detected by immunohistochemistry, and the relationship with clinicopathological features was analyzed. Paraffin sections were generated from 83 HBV-HCC patients (22 females and 61 males) enrolled in this study. The age of these patients ranged from 35 to 77 years, with an average of 52.5 ± 11.3 years. All experiments were approved by the Ethics Committees of the Second Affiliated Hospital, Zhejiang University School of Medicine.

RESULTS: B7-H4 was significantly upregulated in HepG2.2.15 cells compared to HepG2 cells. Specifically, the protein expression of B7-H4 in the lysates of HepG2 cells was more than that in HepG2.2.15 cells. In addition, HBx was expressed only in HepG2.2.15 cells. Similar data were obtained by flow cytometry. The positive rates of B7-H4 and HBx in the tissues of 83 HBV-HCC patients were 68.67% (57/83) and 59.04% (49/83), respectively. The expression of HBx was correlated with tumor node metastases (TNM) stage, and the expression of B7-H4 was positively correlated with HBx (r_s = 0.388; P < 0.01). The expression level of B7-H4 in HBx-positive HBV-HCC tissues was substantially higher than that in HBx-negative HBV-HCC tissues. The expression level of B7H4 was negatively related to tumor TNM stage.

CONCLUSION: Higher expression of HBx and B7-H4 was correlated with tumor progression of HBV-HCC, suggesting that B7-H4 may be involved in facilitating HBV-related hepatocarcinogenesis.

Key words: Hepatocellular carcinoma; Hepatitis B virus; Hepatitis B virus X; B7-H4; Immunohistochemistry

Core tip: Hepatitis B virus (HBV) is a major public health problem, and HBV-related hepatocellular carcinoma (HBV-HCC) has an extremely poor prognosis due to the lack of effective treatments. B7-H4 is a newly characterized member of the B7 superfamily that is actively involved in regulating the pathogenesis of tumors. However, the intrahepatic expression of B7-H4 in HBV-HCC patients has not been described. In this study, we found that the higher expression of HBx and B7-H4 was correlated with tumor progression of HBV-HCC. Therefore, B7-H4 may be involved in facilitating HBV-related hepatocarcinogenesis.

INTRODUCTION

More than 350 million people worldwide suffer from a persistent hepatitis B virus (HBV) infection and are at an increased risk of developing hepatitis, cirrhosis, and hepatocellular carcinoma (HCC)[1]. HCC is the fifth most common cancer and the third most common cause of death due to cancer worldwide[2]. No systemic therapy has been shown to improve survival, and recurrence is common, even for curative treatment. Therefore, there is a need to identify prognostic biomarkers and new therapeutic strategies. It has been shown that the majority of HBV-related HCC tissue samples contain integrated viral DNA[3]. Hepatitis B virus X (HBx) originates from the HBV genome and is a multifunctional regulatory protein. Although HBx does not bind directly to DNA, it can *trans*-activate gene transcription through multiple *cis*-acting elements[4,5]. HBx may be associated with the development of human HCC[6,7], but the precise mechanism of HBx in tumorigenic transformation of hepatocytes remains unclear.

The coregulatory molecules of the B7 family have an indispensable role in the immune regulation of several pathologies[8]. It has been reported that B7-H1 and B7-H4 are expressed in human tumors and that they may act as coregulatory inhibitors to inhibit T cell activation or to induce T cell apoptosis[9-11]. Furthermore, the expression of B7-H1 in hepatocarcinoma cells can be initiated by HBx, leading to T cell apoptosis and potentially facilitating the genesis of HCC[12].

B7-H4 (also named B7S1 or B7x), a member of the B7 superfamily[13,14], has been demonstrated to inhibit T cell activation, proliferation, and differentiation and to be inversely correlated with tumor T cell infiltration[15,16]. B7-H4 is widely prevalent in a variety of tumor tissues[10,17-21], but it is absent on the cell surface of most human normal somatic tissues[13]. Multiple studies have revealed that B7-H4 can downregulate tumor-reactive cytotoxic T lymphocyte (CTL) function[13] and that inhibition of B7-H4 with small interference RNA (siRNA) led to antitumor immunity and inhibition of tumor growth[17,22]. Therefore, B7-H4 has been suggested to play a key role in tumor progression and immune escape. Interestingly, recent data have demonstrated that B7-H4 expression was enhanced in cells infected with a virus, such as Epstein-Barr virus (EBV)[23] and HBV[24]. These results indicate that B7-H4 signaling may affect the pathogenesis of a viral infection, and a clear understanding of its functional role may further elucidate the disease process. Although the presence of B7-H4 in human tumors appears to be a general phenomenon, there are no clinical data available on the expression levels of B7-H4 in human HBV-HCC.

It is evident that both HBx and B7-H4 are involved in the pathogenesis of HBV-HCC. However, the relationship between these two proteins remains unknown. Therefore, we speculated that both HBx and B7-H4 would promote the survival of hepatocytes transfected with HBV malignant transformation and tumor development. To test this hypothesis, HepG2 cells, a human HCC cell line, were transfected with HBV (HepG2.2.15). We investigated the prognostic significance and clinical relevance of HBx and B7-H4 expression in a cohort of 83 HCC patients treated by a curative resection.

MATERIALS AND METHODS

Cell lines

HepG2 cells derived from human HCC were purchased from American Type Culture Collection (ATCC, Manassas, VA, United States) and were grown in Dulbecco's Modified Eagle' Medium (DMEM) culture media (Life Technologies Corporation, Gaithersburg, MD, United States) containing 100 IU/mL penicillin, 100 μg/mL streptomycin (Life Technologies Corporation), and 10% fetal bovine serum (FBS, PAA, Morningside, Australia) at 37 ℃ in a humidified incubator with 5% CO_2.

HepG2.2.15 cells transfected with the complete HBV DNA and stably HBV-expressing hepatoma cells derived from HepG2 cells (firstly described by Sells et at 1987 and 1988)[25,26] were purchased from the Chinese Center For Type Culture Collection (CCTCC, Wuhan, China) and were grown in DMEM culture media containing 300 μg/mL G418 (Promega, Madison, WI, United States), 100 IU/mL penicillin, 100 μg/mL streptomycin, and 10% FBS at 37 ℃ in a humidified incubator with 5% CO_2.

Antibodies

Mouse monoclonal antibody (3E8 mAb) specific for human B7-H4 was previously described[27]. Rabbit anti-HBx antibody was purchased from Abcam (Cambridge, MA, United States). Horseradish peroxidase (HRP)-conjugated rabbit anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) monoclonal antibody was purchased from Cell Signaling Technology (Danvers, MA, United States). HRP-conjugated goat anti-mouse IgM, goat anti-mouse IgG, and goat anti-rabbit IgG antibodies were purchased from Santa Cruz Biotechnology (Dallas, TX, United States). Alexa Fluor® 488 goat anti-mouse IgM antibody was purchased from Invitrogen (Life Technologies Corporation).

Cell lysis

Cells were lysed using cell lysis buffer containing 2 mmol/L Tris-HCl, pH 7.5, 15 mmol/L NaCl, 0.1 mmol/L Na_2EDTA, 0.1 mmol/L EGTA, 0.1% Triton X-100, 0.25 mmol/L sodium pyrophosphate, 0.1 mmol/L beta-glycerophosphate, 0.1 mmol/L Na_3VO_4, and 0.1 μg/mL leupeptin (Cell Signaling Technology). Samples containing 1 × 10^6 cells were lysed in 200 μL cell lysis buffer for 30 min at 4 ℃ and then clarified by centrifugation at 8000 *g* for 10 min. Protein concentration was determined using a bicinchoninic acid (BCA) protein assay kit (Pierce, Rockford, IL, United States), with bovine serum albumin (BSA) as the standard.

Western blot analysis

Cell lysate preparation and western blot were performed as described previously[27]. Briefly, cell lysates were denatured for 10 min at 95 ℃ with sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) sample buffer, electrophoresed on 10% SDS-PAGE gels, and transferred to polyvinylidene difluoride (PVDF) membranes. Membranes were blocked with 5% nonfat milk in Tris-buffered saline with Tween [TBST 20 mmol/L Tris-HCl, pH 7.5, 150 mmol/L NaCl, and 0.05% (v/v) Tween 20] and then incubated with specific antibodies at 4 ℃ overnight. After thoroughly washing, blots were incubated with HRP-conjugated secondary antibody for 1 h at room temperature. Protein band intensity was analyzed using enhanced chemiluminescence (ECL) reagents (Millipore, Billerica, MA, United States) and a VersaDoc MP5000 imaging system (Bio-Rad, Hercules, CA, United States).

Flow cytometry analysis

Each sample of cells (2 × 10^6) was incubated with 3E8 mAb for 1 h at 4 ℃, followed with Alexa Fluor® 488 goat anti-mouse IgM antibody for 30 min at 4 ℃. Normal mouse IgM was used as an antibody control. Cells were washed twice, and samples were analyzed using a flow cytometer (FACScan, San Jose, CA, United States) by flowjo7.6.

Immunofluorescence detection

Cell samples were fixed in ice-cold 3%-4% paraformaldehyde in phosphate buffered saline (PBS) (pH 7.4) for 15 min at room temperature, incubated for 10 min with PBS containing 0.25% Triton X-100, and then incubated with 1% BSA in PBS with Tween (PBST) for 30 min. Cells were then incubated in the diluted 3E8 mAb in 1% BSA in PBST in a humidified chamber overnight at 4 ℃. Normal mouse IgM was used as an antibody control. After thorough washing, cells were incubated with Alexa Fluor® 488 goat anti-mouse IgM antibody in 1% BSA for 1 h at room temperature in the dark and then rinsed with PBS. Cells were incubated with 3 ng/mL 4',6-diamidino-2-phenylindole (DAPI, Invitrogen, Life Technologies Corporation) for 10 min, mounted with ProLong Gold Antifade Reagent (Invitrogen, Life Technologies Corporation), and observed under an Olympus 1X81 fluorescence microscope (Center Valley, PA, United States) microscopy using filters for fluorescein isothiocyanate (FITC) and DAPI.

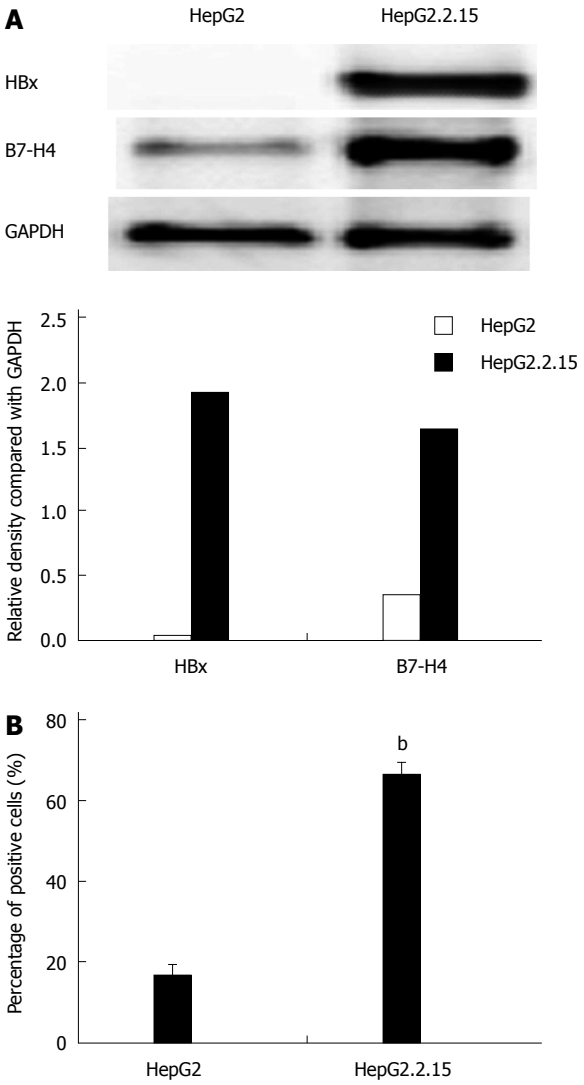

Figure 1 Expression of B7-H4 in HepG2 and HepG2.2.15 cells. A: Detection of B7-H4 expression by western blot. The expression level of B7-H4 and HBx was shown by the relative density ratio of B7-H4 and GAPDH; B: Detection of B7-H4 expression by flow cytometry. $^{b}P < 0.01$, HepG2.2.15 *vs* HepG2 cells. HBx: Hepatitis B virus X; GAPDH: Reduced glyceraldehyde-phosphate dehydrogenase.

Immunohistochemical staining

HBV-HCC tissue microarrays were obtained from Alenabio Biotechnology Co., LTD (Shanxi, China) for immunohistochemical (IHC) staining. Clinical and pathological information for individual cancer samples was provided by the array manufacturers (for details see www.alenabio.com). Paraffin sections of tumors were obtained from 83 HBV-HCC patients (22 females and 61 males) enrolled in this study. Informed consent for this study was obtained from each patient. The age of these patients ranged from 35 to 77 years, with an average of 52.5 ± 11.3 years. Tumor grade was divided into three categories: tumor grade Ⅰ is well-differentiated, low grade malignant; tumor grade Ⅱ is moderately-differentiated, intermediate grade malignant; tumor grade Ⅲ is poorly-differentiated, high grade malignant. TNM stage refers to the Tumor Node Metastasis stage. All of these experiments were approved by the Ethics Committees of the Second Affiliated Hospital, Zhejiang University School of Medicine. IHC staining was performed on mouse tumor tissues as previously described[27]. Briefly, tissues were labeled using primary antibodies specific for B7-H4 and HBx, and antibody binding was detected using EnVision System reagents (DAKO, Glostrup, Denmark). Semi-quantitative measurements of staining intensity (0-3, least intense to most intense), and the proportion of stained cells (0-4, no cells stained to more than 70% cells stained) were determined as previously described[27]. A combined score of $\geqslant 2$ was considered to indicate positive expression. All slides were scored by two researchers blinded to the pathological and clinical features.

Statistical analysis

All experiments were performed in triplicate. Differences in positive rates between groups were determined using a χ^2 test (SPSS 18, IBM Corporation, New York, NY, United States). Differences of B7-H4 expression between groups were determined using a Student's *t*-test. A correlation analysis was determined using Spearman correlation coefficients. Statistical significance was set at $P < 0.05$.

RESULTS

Detection of B7-H4 expression by Western blot and flow cytometry

The expression of B7-H4 in lysates of HepG2 and HepG2.2.15 cells was determined by western blot (Figure 1A). The results revealed that HBx was expressed in HepG2.2.15 cells but not in HepG2 cells. Moreover, the expression level of B7-H4 was significantly higher in HepG2.2.15 cells compared with HepG2 cells, consistent with results from the flow cytometry analysis ($P < 0.01$, Figure 1B).

Detection of B7-H4 expression by immunofluorescence staining

The immunofluorescence assay confirmed that the immunoreactivity for B7-H4 was strong in HepG2.2.15 cells. In contrast, the immunoreactivity for B7-H4 was virtually absent in HepG2 cells (Figure 2). Moreover, B7-H4 was diffusely expressed either in the membrane or the cytoplasm of HepG2.2.15 cells.

Expression and clinical significance of B7-H4 and HBx in HBV-related hepatocellular carcinoma

Immunohistochemical analysis detected the expression of B7-H4 and HBx in HBV-HCC tissues. Among the 83 HBV-HCC tissue samples examined, the positive rates of B7-H4 and HBx were 68.67% (57/83) and 59.04% (49/83), respectively. Statistical analysis revealed that the positive rates of HBx were correlated with the tumor TNM stage ($P < 0.01$) but not with

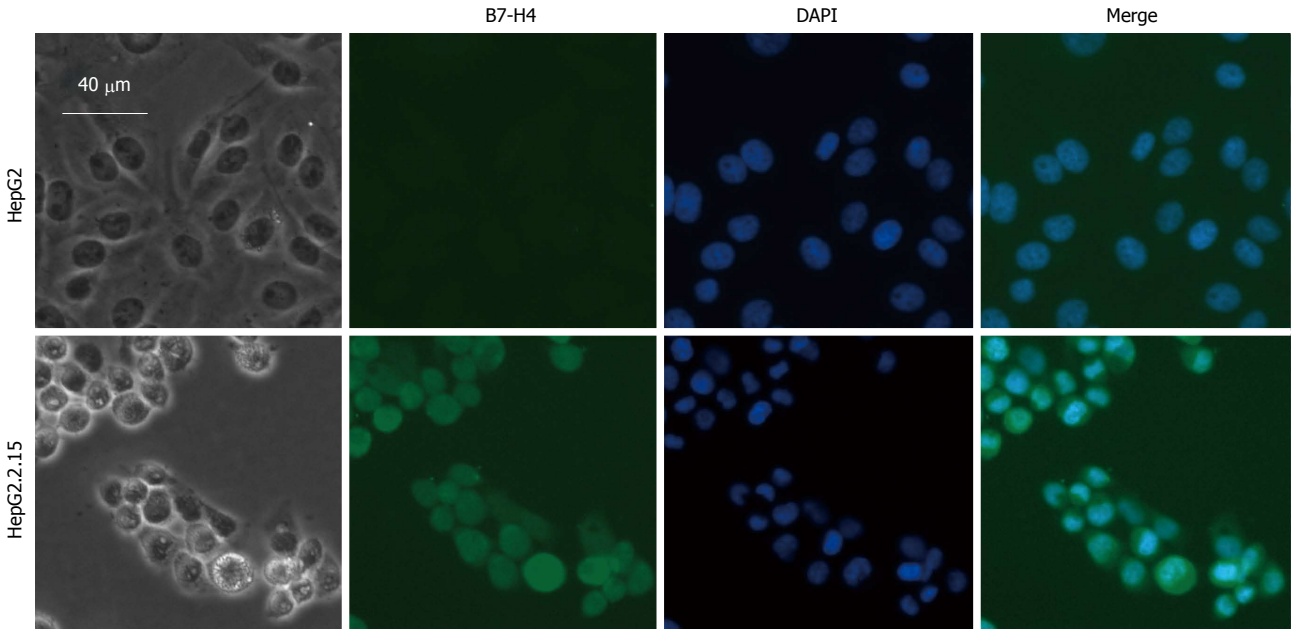

Figure 2 Expression of B7-H4 in HepG2 and HepG2.2.15 cells determined by immunofluorescence staining. Immunofluorescence detection of B7-H4 in HepG2 and HepG2.2.15 cells was stained with 3E8 mAb followed with Alexa Fluor® 488 goat anti-mouse IgM antibody (green). Nuclei were stained with DAPI (blue). Changes in cell morphology were recorded with a light microscope at 200 × magnification.

Table 1 Expression and clinical significance of B7-H4 and hepatitis B virus X in hepatitis B virus-related hepatocellular carcinoma

	HBx		χ^2/P	B7-H4		χ^2/P
	No. of positive	No. of negative		No. of positive	No. of negative	
Gender						
Male	39	22	$\chi^2 = 2.28$	42	19	$\chi^2 = 0.00$
Female	10	12	$P > 0.05$	15	7	$P > 0.05$
Age (yr)						
≤ 50	21	21	$\chi^2 = 2.87$	25	17	$\chi^2 = 3.31$
> 50	28	13	$P > 0.05$	32	9	$P > 0.05$

HBx: Hepatitis B virus X; HBV: Hepatitis B virus.

patient's age, sex, or tumor grade. The positive rate of HBx expression in TNM stage Ⅲ/Ⅳ tissues was 75.56% (34/45), substantially higher than the 39.47% in TNM stage Ⅰ/Ⅱ tissues (15/38, $P < 0.01$; Table 1). The positive rates of B7-H4 expression in HBV-HCC tissues were not correlated with patient's age, sex, tumor grade, or tumor TNM stage.

Correlation between B7-H4 and HBx in HBV-related hepatocellular carcinoma

The positive rate of B7-H4 in HBx-positive HBV-HCC tissues 83.67% (41/49) was significantly higher than the 47.06% in HBx-negative HBV-HCC tissues (16/34, $P < 0.01$). The expression of B7-H4 was positively correlated with HBx ($r_s = 0.388$, $P < 0.01$).

Furthermore, the effect of HBx on the expression level of B7-H4 in HBV-HCC tissues was analyzed (Table 2). B7-H4 expression with scores of 3.43 ± 1.68 in HBx-positive HBV-HCC tissues was substantially higher than that in HBx-negative HBV-HCC tissue scores of 1.81 ± 1.30 ($P < 0.01$). The expression level of B7-H4 in HBx-positive HBV-HCC tissues was not related to patient's age, sex, or tumor grade. However, a slight decrease was seen in TNM Ⅲ/Ⅳ samples (3.12 ± 1.63), and this difference was statistically significant in comparison with that of the TNM Ⅰ/Ⅱ samples (4.13 ± 1.51, $P < 0.05$; Figure 3).

DISCUSSION

HBV infection is the primary cause of liver disease that has the potential to develop HCC[3,28]. Although the

pathogenic mechanisms of HBV-HCC are not clear, it has been reported in many studies that immune-mediated hepatocyte malignant transformation might play a key role. HCC has poor immunogenicity, partly due to poor antigen expression, the lack of costimulatory molecules to positively regulate T cell immune responses[29], and an increased number of costimulatory molecules that negatively regulate T cell immune response[30].

There is accumulating evidence that immunotherapy may become a powerful therapeutic option for HCC patients[31]. Stimulating or eliminating inhibitory T cell signaling to enforce antitumor responses is central to immune-based therapies to eradicate human cancers. It is clear that costimulatory molecules play pivotal roles in regulating the immune response and are engaged in the pathogenesis of many diseases, especially chronic virus infection and tumor development[32]. B7-H4 is a member of the B7 family, and its mRNA is broadly expressed in many tissues[13,14]. In addition to the inhibition of T cell tolerance, our previous data showed that B7-H4 was also involved in the regulation of cellular tumor apoptosis[22]. More importantly, after performing a multivariate adjustment for conventional prognostic factors, elevation in B7-H4 expression was a significant predictor of tumor recurrence[33]. The expression and distribution of B7-H4 in HCC tissues from HBV patients has not been previously reported. In this study, we found that the expression of B7-H4 was significantly increased in HCC cells transfected with HBV compared with control HCC cells. A high percentage of B7-H4 positive staining was observed in a subset of HBx-positive HBV-HCC tissues and was significantly associated with the TNM stage of HCC and level of HBx expression. Thus, HBx and B7-H4 may jointly promote the development of HBV-HCC and prove useful for the clinical evaluation of HBV-HCC patients, especially to identify high-risk patients who are at increased risk of cancer progression.

Although several studies have examined the role of B7-H4 in tumor immunity, the pathophysiologic function of B7-H4 has yet to be fully elucidated. In the present study, we found a detrimental role for B7-H4 in HBV-HCC patients. Costimulatory molecules, including vascular cell adhesion molecule (VCAM)-1[34], cluster of differentiation (CD)40[35], CD28, and programmed death (PD)-1[36] as well as several members of the B7 superfamily (*e.g.*, B7-1, B7-2[29], B7-H1[12,30], and B7-H3[37]), have been reported to be expressed in HCC tissues. These costimulatory molecules could provide positive (VCAM-1, CD28, CD40, B7-1, and B7-2) or negative (PD-1 and B7-H1) signals to local T cells response and regulate the pathogenesis of HCC. It has been reported that HBeAg suppresses the specific cellular immunity that clears the virus by upregulating B7-H1 expression, eventually leading to immune tolerance to HBV infection[38]. B7-H4 was described to be a membrane costimulatory ligand of the B7 superfamily, which is involved in the downregulation of T cell activation under certain circumstances. Ectopic B7-H4-Ig may protect animals from liver injury induced by concanavalin A (ConA), which could be associated with reduced serum levels of interleukin (IL)-2, interferon (IFN)-gamma, and IL-4 as well as enhanced IL-10 production[39]. Thus, B7-H4 may lead to immune tolerance to HBV infection and play an important role in immune suppression in chronic HBV-HCC patients. In addition to surface location, intracellular expression of B7-H4 has been reported in primary ovarian tumor cells[9], with similar expression levels to what we observed here in HBV-HCC (Figures 2 and 3). However, we also found that B7-H4 was an intracellular protein that was upregulated in HBV-HCC patients. This expression pattern suggests that B7-H4 might possess functions that are different from other cell surface molecules of the B7 family, which were previously reported to a play role in the pathogenesis of cancers by inhibiting the T cell-mediated immune response. Our previous results indicated that intracellular B7-H4 enhanced oncogenicity and inhibited apoptosis in pancreatic cancer cells[22]. In addition, Salceda *et al*[17] suggested that the expression of B7-H4 on breast cancer cell surface acts as an anti-apoptosis molecule that inhibits tumor apoptosis and ultimately protects tumors from cell-mediated immune surveillance. Furthermore, B7-H4 expression was enhanced in B cells infected with EBV, and the engagement of B7-H4 initially increased the levels of intracellular ROS, which induced the expression of FasL and subsequently aroused Fas-mediated and caspase-dependent apoptosis of EBV-transformed B cells[23]. These results together with our previous data indicate that B7-H4 signaling is involved in regulating cell apoptosis and that intracellular B7-H4 might possess an anti-apoptotic effect in HCC cells. Additional research is needed to determine if this effect is a function of B7-H4.

Interestingly, the expression of B7-H4 in HBx-

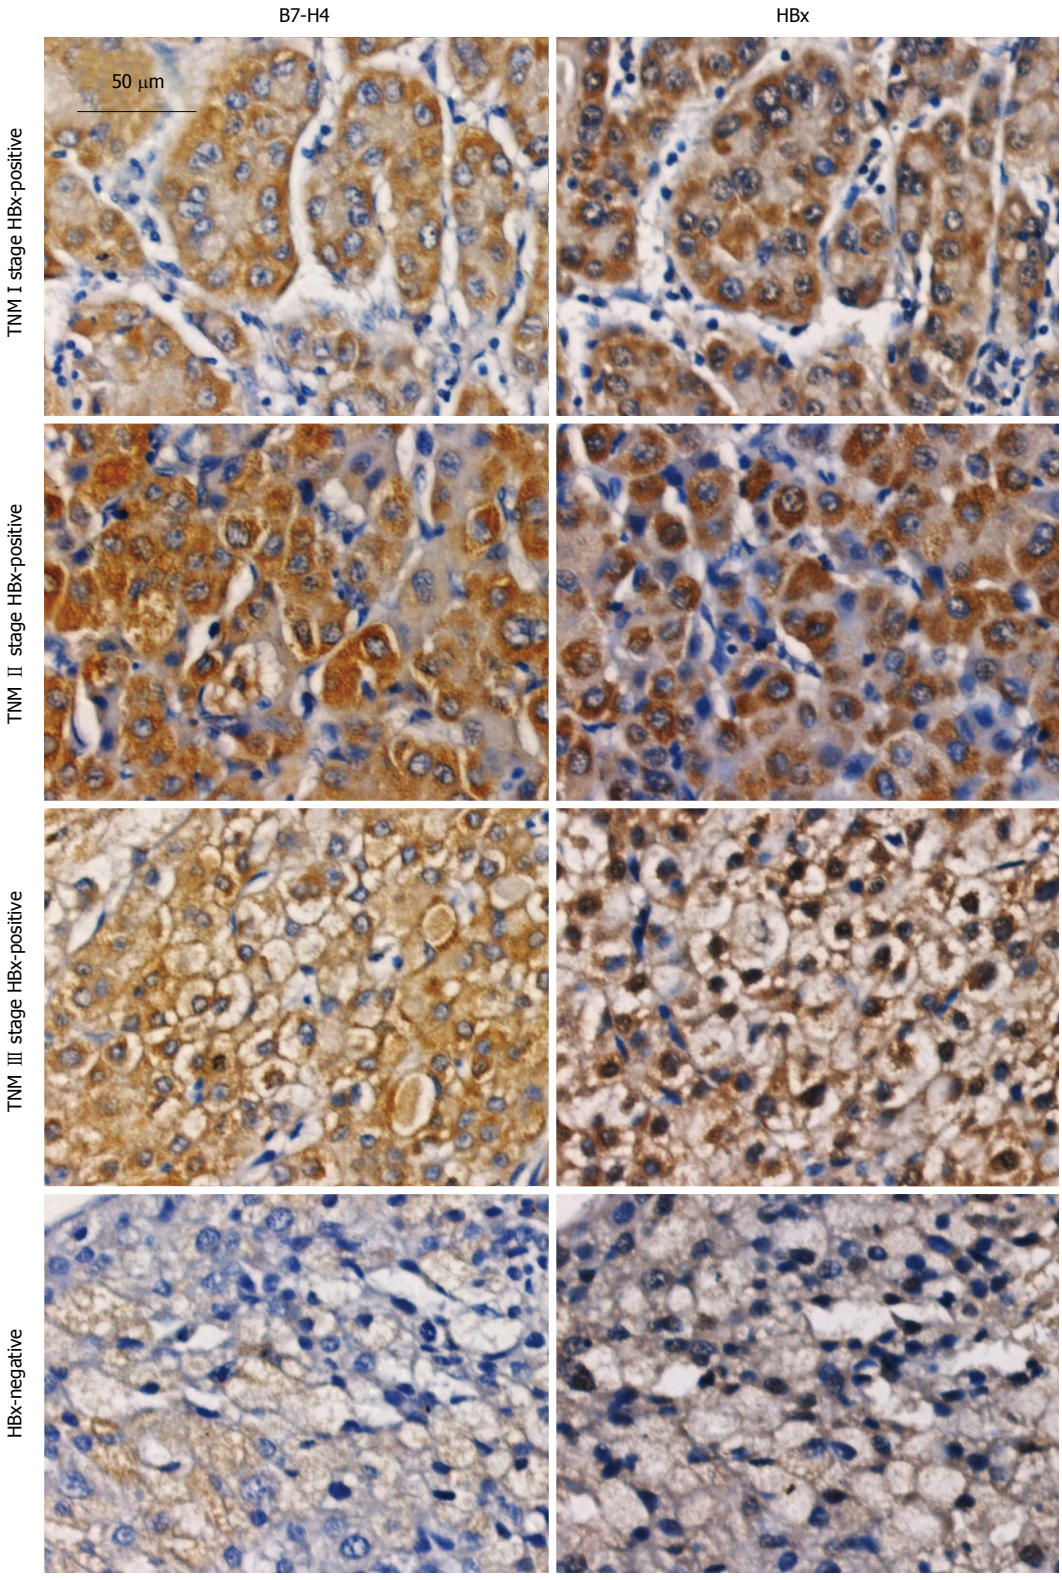

Figure 3 Expression of B7-H4 and hepatitis B virus X in hepatitis B virus related hepatocellular carcinoma tissues detected by immunohistochemical staining. Paraffin sections were generated from 83 hepatitis B virus related hepatocellular carcinoma (HBV-HCC) patients (22 females and 61 males) were enrolled in this study. The age of these patients ranged from 35 to 77 years, with an average of 52.5 ± 11.3 years. HBV-HCC tissues were subjected to IHC staining using antibodies specific for B7-H4 and HBx and recorded with a light microscope at 200 × magnification. HBx: Hepatitis B virus X; IHC: Immunohistochemical.

positive HBV-HCC tissues was negatively correlated with the TNM stage. The epitope binding to the 3E8 mAb of B7-H4 may be altered. It has been reported that some cell surface adhesive proteins, such as mucin 4 (MUC4), can mask the human epidermal growth factor receptor (HER)2 receptor and inhibit

Herceptin binding to HER2 through a stereospecific blockade, leading to Herceptin resistance[40]. Genetic mutations of epidermal growth factor receptor lead to gefitinib resistance[41]. Thus, we suspected that an epitope change of B7-H4 might be involved in immune-mediated tumor escape, thereby contributing to tumor development. Moreover, there was extensive necrosis in the advanced stage HBV-HCC tissues, leading to a decrease in the expression level of B7-H4. The mechanism by which this process occurs will be persued as an anvenue of future research.

In conclusion, our results indicate that B7-H4 is highly expressed in human HBx-positive HBV-HCC tissues and is associated with the TNM stage. Therefore, HBx and B7-H4 may play important roles in the development of HBV-HCC. In addition, B7-H4 may be involved in HBx-induced hepatocarcinogenesis, and an increased understanding of the functional roles of B7-H4 could aid in clarifying the mechanism of HBx in HBV-HCC. Furthermore, targeting B7-H4 may present a novel strategy by which disease diagnosis or immunotherapy against HBV infection can be achieved.

COMMENTS

Background

Hepatitis B virus-related hepatocellular carcinoma (HBV-HCC) has an extremely poor prognosis due to the lack of effective treatments. B7-H4 is a newly characterized member of the B7 superfamily of proteins, which are actively involved in regulating the pathogenesis of tumors. It is clear that both hepatitis B virus X (HBx) and B7-H4 are involved in the pathogenesis of HBV-HCC. However, the intrahepatic expression of B7-H4 in HBV-HCC patients has not been described.

Research frontiers

HBx originates from the HBV genome and is a multifunctional regulatory protein. Although HBx does not bind directly to DNA, it can *trans*-activate gene transcription through multiple *cis*-acting elements. HBx was thought to be associated with the development of human HCC. It has been reported that B7-H4 is expressed in human tumors and is implicated as coregulatory inhibitors that may inhibit T cell activation or induce T cell apoptosis upon antigen recognition. B7-H4 expression was enhanced in cells infected with a virus, such as Epstein-Barr virus (EBV) and HBV. B7-H4 signaling is most likely to affect the pathogenesis of a viral infection and a clear understanding of its functional role may further elucidate the disease process. Although the presence of B7-H4 in human tumors appears to be a general phenomenon, there is little available on the expression level of B7-H4 in human HBV-HCC.

Innovations and breakthroughs

In this article, the authors reached the conclusion that co-inhibitory molecules, such as B7-H4, are always involved in HBx-induced hepatocarcinogenesis. Targeting B7-H4 may represent a novel strategy by which disease diagnosis or immunotherapy against HBV infection can be achieved.

Applications

Based on these data, the authors concluded that B7-H4 is highly expressed in human HBx-positive HBV-HCC tissues and is associated with TNM stage. Therefore, HBx and B7-H4 may play an important role in the development of HBV-HCC. In addition, B7-H4 may be involved in HBx-induced hepatocarcinogenesis, and an increased understanding of the functional roles of B7-H4 could aid in clarifying the mechanism of HBx in HBV-HCC. This study provides new insight into the function of a coinhibitory signaling pathway during the clinical course of HBV-HCC.

Peer-review

The authors have presented a highly interesting study. The design, interpretation, and presentation of their study are well performed.

Abstract

AIM: To identify risk factors associated with survival in patients retransplanted for hepatitis C virus (HCV) recurrence and to apply a survival score to this population.

METHODS: We retrospectively identified 108 patients retransplanted for HCV recurrence in eight European liver transplantation centers (seven in France, one in Spain). Data collection comprised clinical and laboratory variables, including virological and antiviral treatment data. We then analyzed the factors associated with survival in this population. A recently published score that predicts survival in retransplantation in patients with hepatitis C was applied. Because there are currently no uniform recommendations regarding selection of the best candidates for retransplantation in this setting, we also described the clinical characteristics of 164 patients not retransplanted, with F3, F4, or fibrosing cholestatic hepatitis (FCH) post-first graft presenting with hepatic decompensation.

RESULTS: Overall retransplantation patient survival rates were 55%, 47%, and 43% at 3, 5, and 10 years, respectively. Patients who were retransplanted for advanced cirrhosis had survival rates of 59%, 52%, and 49% at 3, 5, and 10 years, while those retransplanted for FCH had survival rates of 34%, 29%, and 11%, respectively. Under multivariate analysis, and adjusting for the center effect and the occurrence of FCH, factors associated with better survival after retransplantation were: negative HCV viremia before retransplantation, antiviral therapy after retransplantation, non-genotype 1, a Model for End-stage Liver Disease (MELD) score < 25 when replaced on the waiting list, and a retransplantation donor age < 60 years. Although the numbers were small, in the context of the new antivirals era, we showed that outcomes in patients who underwent retransplantation with undetectable HCV viremia did not depend on donor age and MELD score. The Andrés score was applied to 102 patients for whom all score variables were available, producing a mean score of 43.4 (SD = 6.6). Survival rates after the date of the first decompensation post-first liver transplantation (LT1) in the liver retransplantation (reLT) group (94 patients decompensated) at 3, 5, and 10 years were 62%, 59%, and 51%, respectively, among 78 retransplanted individuals with advanced cirrhosis, and 42%, 32%, and 16% among 16 retransplanted individuals with FCH. In the non-reLT group with hepatic decompensation, survival rates were 27%, 18%, and 9% at 3, 5, and 10 years, respectively (P < 0.0001). Compared with non-retransplanted patients, retransplanted patients were younger at LT1 (mean age 48 ± 8 years compared to 53 ± 9 years in the no reLT group, P < 0.0001), less likely to have human immunodeficiency virus (HIV) co-infection (4% *vs* 14% among no reLT patients, P = 0.005), more likely to have received corticosteroid bolus therapy after LT1 (25% in reLT *vs* 12% in the no reLT group, P = 0.01), and more likely to have presented with sustained virological response (SVR) after the first transplantation (20% in the reLT group *vs* 7% in the no reLT group, P = 0.028).

CONCLUSION: Antiviral therapy before and after retransplantation had a substantial impact on survival in the context of retransplantation for HCV recurrence, and with the new direct-acting antivirals now available, outcomes should be even better in the future.

Key words: Antivirals; Hepatitis C; Mortality; Prognosis; Retransplantation; Risk factors

Core tip: Liver retransplantation for hepatitis C recurrence may be a subject of debate. This study was performed in order to assist patient selection for retransplantation in a context of donor scarcity. This retrospective multicenter study analyzed predictive factors for survival in a population of patients retransplanted for hepatitis C virus recurrence, including virological and antiviral treatment data. We also applied a previously published score to this population.

Predictive factors for survival and score application in liver retransplantation for hepatitis C recurrence. *World J Gastroenterol* 2016; 22(18): 4547-4558 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4547.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4547

INTRODUCTION

Advanced liver disease caused by hepatitis C virus (HCV) is the leading cause of liver transplantation (LT) in Western countries[1,2]. The post-transplant detection of HCV ribonucleic acid (RNA) in the serum or graft is universal in pre-LT viremic patients[3,4]. Histologically documented chronic hepatitis C develops in approximately 70% of patients during the first year after LT[5]. Progression of this disease is particularly aggressive in transplanted patients, with a rapid evolution towards fibrosis (cirrhosis within approximately 9 to 12 years) when compared to immunocompetent individuals (cirrhosis within approximately 20-30 years)[4], resulting in graft loss due to recurrent disease[6]. A previous study showed that patients with clinically compensated graft cirrhosis achieved a 1-year survival rate of 74%, but this rate fell to 41% in those with clinical decompensation[7]. In patients with established cirrhosis and graft failure, retransplantation (reLT) is the only therapeutic option[8]. However, because of organ shortages, cost issues, and poorer survival, the indications for reLT must be appropriate[9]. In previous studies, HCV-related disease did not indicate a poorer prognosis following reLT[9-21], while other studies identified HCV recurrence as an independent predictive factor of mortality[22-24]. Few studies have evaluated risk factors for mortality among patients retransplanted for HCV recurrence[25-29].

Predictive models for retransplantation

In order to predict post-reLT survival and, therefore, aid in patient selection, several scores have been developed[30,31]. That most widely employed is the Rosen score[32]. However, like many others, this model was based on reLT cases in general and not just on cases of HCV recurrence.

The first score specifically designed for HCV-positive patients was published recently by Andres *et al*[29]. This study analyzed registry data from the Scientific Registry of Transplant Recipients on 1422 individuals transplanted for HCV and retransplanted at least 30 d after the first transplant. In order to design a score that could predict survival after reLT, they identified six predictive variables associated with survival: recipient age at the time of the first transplant, interval elapsing between the two transplants, donor age, creatinine levels, international normalized ratio (INR), and serum albumin values before the second transplant.

Several factors currently influence the decision to retransplant patients who have experienced a recurrence of HCV after transplantation. These include factors related to the individual patient, the physician' s judgement, transplant cent policies and experience, and geographic donor organ availability. There are no uniform guidelines to indicate which patients with HCV recurrence should undergo reLT. A survey in 2003 showed that nearly all transplant centers in the United States were likely to offer reLT to patients experiencing an HCV recurrence[33]. The scenario is likely to change radically with the development of new direct-acting antivirals (DAA). However, these drugs may not be available in some countries in the short- or medium-term.

The present study was performed in order to identify predictive survival factors in patients with HCV-related graft failure undergoing liver reLT before the era of new antivirals and to apply a previously published score[29] that predicts survival after reLT in recipients with HCV recurrence. Secondary objectives were to describe the natural history of HCV in retransplanted patients compared to their first transplantation and to describe a group of patients experiencing graft failure due to HCV recurrence who were not retransplanted in order to clarify which patients were selected for reLT, as there are no uniform criteria for reLT in the setting of HCV recurrence.

MATERIALS AND METHODS

Study design and population

This was a retrospective and multicenter study involving seven liver transplantation centers in France (Paul Brousse, Edouard Herriot, Beaujon, Saint Antoine, Pitié-Salpétrière, Rennes and Henri Mondor Hospitals), and one center in Spain (La Fe Hospital). There were no specific recommendations regarding reLT criteria for HCV-related recurrence, and the indication for reLT depended on each center's policies. However, all centers generally indicated reLT in patients with graft failure, using the same criteria as those applied for the first transplantation. Protocol biopsies were performed yearly in all French centers, but not in the Spanish center. Immunosuppression protocols were similar, with the use of cyclosporine or tacrolimus, corticosteroids during the first 6-12 mo, and/or mycophenolate mofetil. Antiviral treatment policies were also similar; treatment was initiated with any degree of fibrosis or fibrosing cholestatic hepatitis, given that the clinical conditions were sufficient to undergo antiviral therapy.

We included patients aged 18 or older who had undergone LT for HCV-related disease and then reLT with HCV recurrence as the main indication between January 1994 and June 2012 (reLT group). HCV recurrence was confirmed histologically as the principal reason for reLT by prior biopsies or an explant displaying cirrhosis or fibrosing cholestatic hepatitis. Patients with hepatitis B (HBV) co-infection with positive HBV DNA after the first LT (LT1) were excluded.

In order to describe which patients were selected for reLT in the absence of uniform criteria for reLT in the setting of HCV recurrence, we also identified those transplanted for HCV-related disease and presenting with graft failure but who were not retransplanted (no reLT group). This group represented the population in whom reLT may have been indicated, as opposed to those with cirrhosis and no clinical decompensation, in whom reLT would not have been indicated. The

inclusion criteria were: patients aged 18 or older receiving LT between January 1994 and June 2012 for HCV-related disease and experiencing HCV recurrence in the form of Metavir F3, F4, or fibrosing cholestatic hepatitis (FCH) (confirmed histologically), presenting with clinical hepatic decompensation (defined as the presence of ascites, encephalopathy, variceal hemorrhage, or jaundice), who had not undergone reLT, and with positive serum HCV RNA after the first transplantation. Exclusion criteria were patients with HBV co-infection with positive HBV DNA after transplantation.

Case identification

Retransplanted patients were identified by consulting prospectively maintained databases in the Spanish center and in five of the French centers or the database operated by the French Biomedicine Agency (Agence de la Biomédecine), which covered the two other French centers. This agency is a public organization under the supervision of the French Ministry of Health, whose responsibilities include organizing the procurement and transplantation of organs, tissues, and cells. All transplant centers in France are required to report all their cases to this agency.

To identify cases of non-retransplanted patients with advanced liver disease/FCH and graft failure in all centers, all patients transplanted for HCV-related disease were identified first. Subsequently, all post-LT biopsies revealing F3, F4, or FCH were included, and a chart review was performed in order to identify those patients presenting with hepatic decompensation (defined as the presence of ascites, encephalopathy, variceal hemorrhage, or jaundice).

Data collection and definitions

After case identification, data were collected by consulting the prospectively maintained databases when available, which included several variables. Variables not available in the databases were collected through chart review in all centers.

Regarding the first and second transplantations: Donor age and gender, living or deceased donor, donor HCV serology, recipient age and gender, concomitant kidney transplantation, acute rejection episodes after LT, receipt of corticosteroid bolus, receipt of OKT3, maintenance immunosuppressive regimen, HCV treatment (medication and duration), reason for treatment discontinuation, HCV treatment response (as previously defined[34]), presence of hepatocellular carcinoma (HCC) prior to LT1, presence of alcoholic disease prior to LT1, human immunodeficiency virus (HIV) co-infection, diabetes mellitus pre or post-LT, Metavir fibrosis score on biopsies post-transplant, presence and timing of FCH, HCV viremia levels before LT1 and before reLT, HCV genotype, date and type of hepatic decompensation, biochemical data 20-30 d after decompensation, fibrosis progression rate[35], date and cause of death, reason for no reLT, and patient and graft survival (the latter being defined as the interval between the date of transplant and the date of hepatic decompensation or death).

Regarding the second transplantation: MELD score prior to transplant, pre-reLT bilirubin, pre-reLT creatinine, pre-reLT INR, pre-reLT albumin, date and type of decompensation, number of days of intensive care unit (ICU) hospitalization prior to reLT, date of graft failure (defined as clinical hepatic decompensation), and date and cause of death.

Survival score

The survival score published previously by Andres *et al*[29] was applied to all reLT cases for which such score variables were available. This score was calculated as follows:

(0.23 × donor age) + (4.86 × creatinine log) - (2.45 × interval between the first and second transplant log) + (2.69 × INR) - (0.10 × recipient age) + (3.27 × albumin + 40).

Statistical analysis

The primary endpoint was to determine predictive factors for survival after reLT for a recurrence of hepatitis C. Graft and patient survival probabilities were determined using the Kaplan-Meier method and compared using the log-rank test. A Cox model with a likelihood ratio test was used to compare the difference in survival for continuous variables. Variables with a *P* value below 0.15 under univariate analysis were included in order to enable a stepwise multivariate evaluation using the Cox multivariate model, with the calculation of hazard ratios and corresponding 95%CI. Under multivariate analysis, a *P* value of 0.05 or lower was considered to be significant. A predictive model was constructed with the aim of predicting survival in individual patients retransplanted for hepatitis C recurrence according to the presence of prognostic factors[36]. For this, donor age was categorized as more or less than 60 years considering the scarcity of young donors, and MELD score superior or inferior to 25[37]. Data were compared between retransplanted and non-retransplanted patients using the χ^2 test for categorical data and the independent samples *t*-test for continuous data. Survival comparisons between the two groups were performed by taking account of the date of the first decompensation, considering that this could be the moment at which re-listing would be discussed. Differences between fibrosis progression rates were calculated using a paired *t* test. A *P* value of 0.05 or lower was considered to be significant. Statistical analyses were performed using SAS software version 9.1.3 (SAS Institute Inc., Cary, NC, United States).

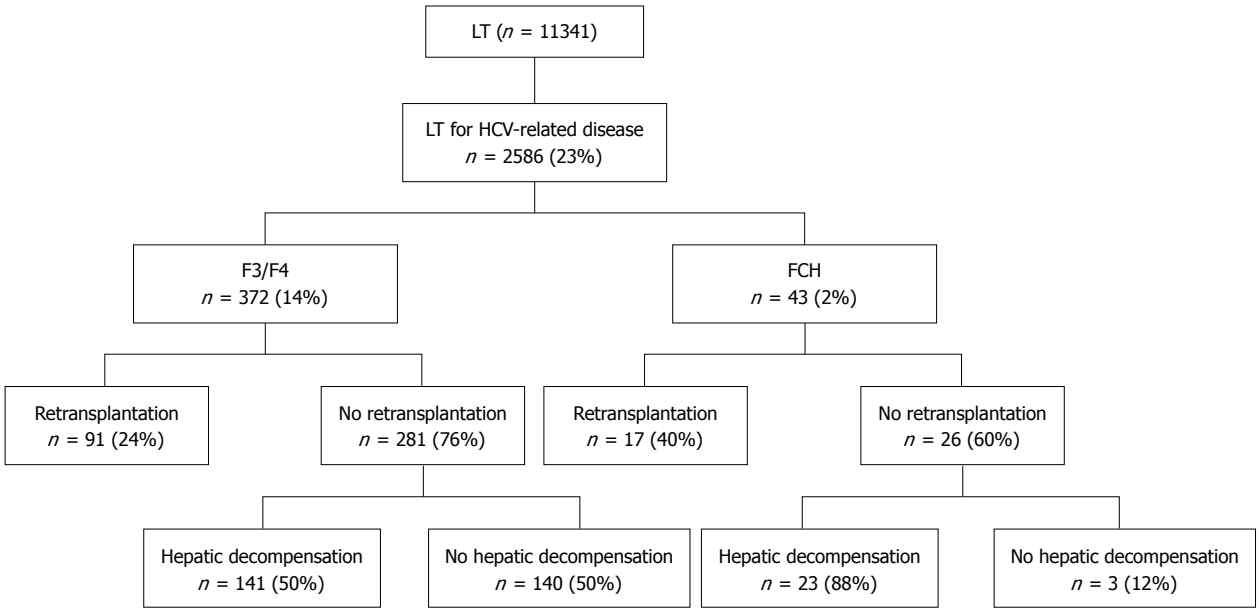

Figure 1 One hundred and eight retransplanted cases for hepatitis C virus recurrence and 164 not retransplanted F3/F4/ fibrosing cholestatic hepatitis cases presenting hepatic decompensation (in italics) after inclusion and exclusion criteria were applied. HCV: Hepatitis C virus; F3/F4: Metavir fibrosis score 3/4; FCH: Fibrosing cholestatic hepatitis.

RESULTS

Between January 1994 and June 2012, 11341 LTs were performed in the eight study centers, and in 2586 (23%) patients, the main indication was HCV-related disease. Of these, 372 (14%) patients progressed to F3 or F4, and 91 patients were retransplanted. Forty-three patients (2%) presented FCH, and 17 of these were retransplanted, totaling 108 retransplanted patients. Figure 1 shows all cases that led to the final case selection. We also identified 164 patients with hepatic decompensation who did not undergo reLT (141 with F3 or F4 and 23 with FCH) prior to the data collection period. The center-based distribution of advanced fibrosis and FCH cases with and without reLT is described in Table 1. The mean interval elapsing between reLT re-listing and actual reLT was 151 d (1-1393), with no statistical difference between the groups (P = 0.22). Explants revealed concomitant chronic rejection in three cases, non-alcoholic steatohepatitis in one case, and hepatocarcinoma in one case. In all other cases, HCV recurrence was the only diagnosis that led to reLT.

Demographic and clinical characteristics

The principal clinical and demographic characteristics of the reLT patients were: mean age at LT1 of 48 ± 8 years; mean age at reLT of 54 ± 8 years; 81 (75%) were men; mean donor age at LT1 of 51 ± 15 years; mean donor age at reLT of 44 ± 16 years; none of the donors were seropositive for HCV; concomitant alcoholic disease in 20 patients (18%); HIV co-infection in four (4%); HCC at LT1 in 40 (37%); 84 patients (78%) presented with F4 after LT1, 18 (17%) presented with FCH, and six (5%) presented with F3 and clinical hepatic decompensation; and 26 patients (25%) received corticosteroid bolus after LT1. The mean interval between LT1 and decompensation was 4.4 years (0.1-16.0). The mean interval between LT1 and reLT was 5.5 years (0.1-17.8). The mean MELD score 20-30 d after decompensation was 21 ± 7, and the mean MELD score before reLT was 24.5 ± 8.4. The first decompensation presented as ascites in 68 patients (68%), encephalopathy in 12 (12%), jaundice in 10 (10%), and variceal hemorrhage in 9 (9%).

Survival and prognostic factors

Patient survival rates in the reLT group were 55%, 47%, and 43% at 3, 5, and 10 years, respectively, after the date of reLT. Patients who were retransplanted for advanced cirrhosis had survival rates of 59%, 52%, and 49% at 3, 5, and 10 years, while those retransplanted for FCH had survival rates of 34%, 29%, and 11%, respectively.

There were 28 cases of reLT before 2003, and 80 cases between 2003 and 2012. There was no statistical difference when survival was compared between these two periods (P = 0.26).

Fourteen patients presented with a sustained virological response (SVR) after LT1. The survival rate in this group of patients was 86% at 5 years (12/14 patients), with a median reLT donor age of 44 years (14-62) and a median MELD score of 24 (14-38) (Table 2).

The risk factors associated with better survival under univariate analysis are shown in Tables 3 and 4. An Andrés score lower than 40 was significantly associated with better survival under univariate

analysis but not under multivariate analysis. Factors associated with survival under multivariate analysis are shown in Table 5, which concerns the 83 patients for whom all variables found to be significant under univariate analysis were available. Data were adjusted for the center effect and for the occurrence of FCH after LT1.

The causes of death among the 55/108 patients (51%) in the reLT group were as follows: septic shock of bacterial origin in 17 (31%), liver failure due to HCV recurrence in nine (16%), surgical complications during the perioperative period in seven (13%), hemorrhage in five (9%), multiorgan failure in four (7%), heart failure in two (4%), septic shock of fungal origin in two (4%), and other causes in eight (16%) (one case each of lymphoproliferative disorder, pulmonary embolism, renal insufficiency, septic shock of mycobacterial origin, non-liver solid cancer, and four unknown).

Estimation of survival

An estimate of survival was calculated, based on the presence of the five independent predictors of survival (Table 6). This table highlights two situations that underline the importance of HCV therapy after reLT. If modifiable factors were taken into account and a donor younger than 60 years was used, with the patient receiving antiviral treatment after reLT, estimated survival at 3 years was 73%. In contrast, the same situation but with no treatment after reLT generated a survival rate of only 18% at 3 years.

Application of the score

The Andrés score was applied to the 102 patients for whom all score variables were available (in six patients, pre-reLT albumin values were not available), and this produced a mean score of 43.4 (SD = 6.6).

Natural history

In the reLT group, 18/108 patients (17%) presented with FCH after the first LT. Of these, 5/18 (28%) progressed to FCH after reLT (P = 0.11). Of the remaining 90/108 (83%) who did not present with FCH after LT1, six (7%) progressed to FCH after reLT.

In 52 patients with available pre and post-reLT biopsies, the mean fibrosis progression rate was 2.28 (0.27-16) Metavir units/year after LT1, compared to 1.49 (0-6.0) Metavir units/year after reLT (P = 0.051). Of these, 13 (25%) received antiviral therapy before reLT (four patients presented with an SVR), and 11 (21%) received antiviral therapy after reLT (seven presented with an SVR).

Fifty-six of the remaining patients were not included in the analysis for the fibrosis progression rate for the following reasons: five did not undergo biopsies before reLT (so that the precise timing of fibrosis was not determined), 51 did not present biopsies with fibrosis after reLT (23 died within 90 d of reLT, six underwent biopsies that revealed lobular hepatitis, five had biopsies showing FCH, five had undetectable levels of HCV viremia before reLT, two presented with a sustained virological response after antiviral therapy following reLT, and ten for unknown reasons).

HIV: Human immunodeficiency virus; IS: Immunosuppression; LT1: First liver transplantation; MMF: Mycophenolate mophetil; HCV: Hepatitis C virus; reLT: Liver retransplantation; SVR: Sustained virological response; NR: Non-responder; FCH: Fibrosing cholestatic hepatitis; MELD: Model for End-stage Liver Disease.

No reLT group

Survival rates after the date of the first decompensation post-LT1 in the reLT group (94 patients decompensated) at 3, 5, and 10 years, were 59%, 55%, and 46%, respectively. In the non-reLT group with hepatic decompensation, survival rates were 27%, 18%, and 9% at 3, 5, and 10 years, respectively ($P < 0.0001$).

Compared to non-retransplanted patients, retransplanted patients were younger at LT1 (mean age 48 ± 8 years compared to 53 ± 9 in the no reLT group, $P < 0.0001$), less likely to have HIV co-infection (4% compared to 14% in the no reLT group, $P = 0.005$), more likely to have received corticosteroid bolus after LT1 (25% in the reLT *vs* 12% in the no reLT group, $P = 0.01$), and more likely to have presented with an SVR after the first transplantation (20% in reLT group *vs* 7% in no reLT group, $P = 0.028$) (the data refer to 71 treatments in reLT group and 87 treatments in the no reLT group). Variables found to be similar in both groups included: acute rejection episodes after LT1, use of OKT3 after LT1, number of antiviral treatments, results of biochemical and hematological investigations up to 30 d after hepatic decompensation following LT1 (bilirubin, creatinine, INR, hemoglobin, platelets, sodium and albumin), genotype distribution, type of antiviral treatment, treatment duration, and rate of treatment discontinuation.

Table 4 Univariate analysis of quantitative variables associated with survival in retransplanted patients for hepatitis C virus recurrence

Risk factor	Hazard ratio	95%CI	*P* value
Less days under MV pre-reLT	1.25	1.02-1.52	0.031
Lower reLT donor age	1.02	1.00-1.04	0.017

Non-genotype 1	3.94	1.35-11.57	0.010
Reinscription MELD ⩽ 25	2.45	1.23-4.88	0.010

HCV: Hepatitis C virus; reLT: Liver retransplantation; MELD: Model for End-stage Liver Disease.

In the non-reLT group with hepatic decompensation, 20 (12.1%) of the 164 patients were re-listed or were undergoing a pre-reLT work-up for relisting at the time of data collection. The reasons for not replacing the remaining 144 patients on the waiting list were: death due to hepatic decompensation before relisting (30.6%), clinically considered as unsuitable because of hepatic, cardiac, renal, neurological, psychiatric or other systemic diseases (22.9%), advanced age (over 70 years) (11.8%), *de novo* cancer or HCC recurrence (6.9%), alcohol consumption (4.9%), stable without further decompensation (4.2%), under antiviral therapy at the time of data collection and would be considered for reLT depending on outcome (2.4%), poor compliance (2.8%), stabilized after a SVR (1.4%),

patient refused reLT (0.7%), reLT not possible due to surgical impediments (0.7%), and unknown (10.8%). The mean follow-up period was of 5796 d (62-9541).

DISCUSSION

Because of the large number of patients with HCV recurrence seen at our transplantation centers, this multicenter and retrospective study is the first non-registry study to have been performed on reLT. Furthermore, it is also the first to have analyzed detailed virological data and antiviral therapies in this population, giving great importance to this factor when selecting patients with HCV recurrence for reLT, especially in the current era of direct-acting antivirals. In this context, the principal prognostic factors associated with the survival in our cohort were: negative HCV viremia before reLT, antiviral therapy after reLT, non-genotype 1, re-listing at MELD below 25, and a reLT donor age < 60 years. The non-retransplanted group was helpful in trying to explain the selection bias for and against an indication for reLT, as the decision to retransplant a patient with HCV recurrence depended on each center's policies.

The most important contribution of our study is the evidence concerning the considerable influence of antiviral therapy before and after reLT. Previous studies had demonstrated the importance of treating HCV before and after LT1[38-47]. During the period of our study, the new drugs that became available were protease inhibitors, and we included only one patient under sofosbuvir, one of the newer direct-acting antivirals. In the modern era of direct-acting antivirals, encouraging results have been achieved using interferon-free HCV regimens in the population of patients with advanced cirrhosis on the waiting list, with high SVR rates and low rates of serious adverse events requiring treatment discontinuation[48,49]. Studies of post-LT treatment with the new DAAs studies have demonstrated SVR rates ranging from 70%-94%[49-53]. Although the numbers in our study were small, we were also able to show that in the 14 patients undergoing reLT with undetectable HCV viremia, the reLT donor age and MELD score did not influence outcome. In the long-term, early antiviral treatment post-LT may become the standard-of-care and reduce the occurrence of advanced graft cirrhosis. However, the subpopulations of individuals presenting with genotype 3, end-stage renal disease, and resistance to DAAs remain a concern.

Several early studies had described high mortality rates in individuals retransplanted for HCV recurrence[25,26], with more recent studies producing survival rates similar to ours[27,54]. Our reLT survival rates of 55%, 47%, and 43% at 3, 5, and 10 years, respectively, were not excessively disappointing given the LT survival rates for HCV cirrhosis alone reported in the literature, which average 75%, 65%, and 52% at 1, 3, and 5 years[55]. A minimum acceptable threshold for graft survival is difficult to define[56]. Previous meetings have suggested a minimum 5-year survival of 50% for reLT[57]. At 5 years, the patients in our cohort achieved a 47% survival rate, but no defined criteria for re-listing were applied. Better patient selection should, therefore, improve survival. Although the survival of the four HIV co-infected patients after reLT was extremely poor (no patient was alive at 3 years), in the context of new DAA, the response rates are promising in the non-transplanted population[58,59]. In a recent multicenter study on reLT in HIV-infected individuals, only four patients experienced an HCV recurrence requiring reLT, even though DAAs were not yet available[60]. Regarding the disappointing survival rates seen in non retransplanted patients compared to those undergoing reLT, many factors may have influenced this result, such as higher rates of SVR in the reLT group and possibly higher rates of comorbidities leading to contraindications for reLT.

In McCashland's study[27], although the MELD score was not predictive of survival, higher MELD scores pre-reLT (> 25) were associated with mortality rates. However, that study was not designed to analyze predictive factors for survival. Our data analyses found that relisting with a MELD > 25 was associated with a poor prognosis but not the MELD score before reLT. In their no-reLT group with decompensated HCV recurrence, survival reached 47% at 3 years, compared to 27% in our study. The percentage of relisted patients in their study was similar to our findings (15% *vs* 12%).

One known factor to improve survival in the setting of HCV-related diseases is donor age[61], and our data confirmed this finding in the context of reLT. Our estimation of survival not only demonstrated the importance of antiviral therapy but also the impact of donor age. This finding triggers another discussion regarding the futility of the procedure in an era of young donor shortages[62]. Although the numbers are small, we also showed that outcomes in patients who underwent reLT with undetectable HCV viremia did not depend on donor age. This issue warrants future evaluation in the context of the availability of new antivirals.

In the registry study by Andres *et al*[29], which proposed the score applied to our patients, several variables were not available from this registry, such as HCV genotype, level of viremia, type of anti-HCV treatment, and biopsy scores, all of which could have markedly affected survival. In our study, patients with an Andres score over 40 had a 5-year survival rate of 40%, compared to an estimated survival of 27% in their cohort. One possible explanation for these discrepant results may have been their inclusion criteria (more than 30 d after reLT for all HCV-positive retransplanted cases), so that they did not solely include patients with HCV recurrence. In addition, our cohort may have included more severely ill patients. Our study was not designed to validate the score, as statistically the number of cases was still too small to offer new thresholds. Other previously published scores had either not been designed specifically for reLT in the event of HCV recurrence[12,32] or were derived from LT1 cases and then extended to reLT and, therefore, did not focus on this population[14].

Our study did have some limitations. Considering that surgical techniques, immunosuppression regimens, antiviral treatment, anesthesiology, and intensive care have changed over the years, the long period we covered could have influenced survival. Notably, the survival rates were similar when our analysis compared reLT before and after 2003. Although our study included data from eight different liver transplantation centers, two of them contributed more than half of the reLT cases (57/108; 53%). As these two centers could be considered more experienced in this technique, an analysis was performed after adjusting for the center effect. No uniform criteria exist for reLT indication in HCV recurrence, and each center adopted its own policies. This analysis also applied to antiviral therapy before and after reLT. Another limitation was that the identification of cases for the non-reLT group was based on histological biopsies post-LT1, but because one center did not perform protocol biopsies, this group may have been under-represented. Furthermore, FCH was defined according to the pathologist's report, and, hence, may not have strictly followed previously accepted definitions of FCH[63-65].

In conclusion, reLT in the context of HCV recurrence requires careful patient selection. From this present study, the first to analyze such detailed virological and treatment data, we can conclude that antiviral therapy both before and after reLT can play an important role when deciding whether to retransplant or not. In an era of new direct-acting antivirals agents, the scenario of retransplantation for HCV recurrence will most likely change dramatically in the future. The findings of our study could nevertheless be useful in the medium term while HCV recurrence is still prevalent, especially in limited-resource settings where direct-acting antivirals are not yet available.

COMMENTS

Background

Advanced liver disease caused by hepatitis C virus (HCV) is the leading cause of liver transplantation (LT) in Western countries. Histologically documented chronic hepatitis C develops in approximately 70% of patients during the first year after LT. Progression of this disease is particularly aggressive in transplanted patients, with a rapid evolution towards fibrosis when compared to immunocompetent individuals, resulting in graft loss due to recurrent disease. In patients with established cirrhosis and graft failure, retransplantation (reLT) is the only therapeutic option. Because of organ shortages, cost issues, and poor survival, the indications for reLT must be appropriate. In previous studies, HCV-related disease did not indicate a poorer prognosis following reLT, while other studies have identified HCV recurrence as an independent predictive factor for mortality. Few studies, however, have evaluated risk factors for mortality among patients retransplanted for HCV recurrence.

Research frontiers

Retransplantation for HCV recurrence has been a controversial issue because of the possibility of poorer survival compared to other indications. The published literature is scarce on this topic, as there are currently no formal recommendations as to which patients should undergo retransplantation in this context. A multicenter study was performed in order to analyze survival factors in this population.

Innovations and breakthroughs

This is the first published study with a fair number of retransplantations for HCV recurrence to analyze, in terms of virological findings and HCV antiviral therapy, risk factors for improving better prognosis. In view of the new era of direct-acting antivirals and donor scarcity, the results of this study should aid in decision-making in the context of indications for retransplantation.

Applications

In this new era of direct-acting antivirals and donor scarcity, the results of this study should aid with decision-making in the context of indications for retransplantation.

Terminology

The recurrence of hepatitis C is universal among individuals transplanted for HCV-related cirrhosis and with a positive viral load prior to transplantation. Retransplantation may be indicated in those patients who progress to cirrhosis after HCV recurrence on the graft.

Peer-review

This article addresses is a very important topic in the era of chronic organ shortage. The authors have very nicely written a review of 108 patients retransplanted for HCV recurrence in eight European liver transplantation centers and analyzed the factors associated with survival in this population.

Abstract

AIM: To assess whether video capsule endoscopy (VCE) affects the outcomes of left ventricular assist devices (LVADs) recipients with gastrointestinal bleeding.

METHODS: This is a retrospective study of LVAD recipients with obscure gastrointestinal bleeding (OGIB) who underwent VCE at a tertiary medical center between 2005 and 2013. All patients were admitted and monitored with telemetry and all VCE and subsequent endoscopic procedures were performed as inpatients. A VCE study was considered positive only when P2 lesions were found and was regarded as negative if P1 or P0 were identified. All patients were followed until heart transplant, death, or the end of the study.

RESULTS: Between 2005 and 2013, 30 patients with LVAD underwent VCE. Completion rate of VCE was 93.3% and there was no capsule retention. No interference of VCE recording or the function of LVAD was found. VCE was positive in 40% of patients (n = 12). The most common finding was active small intestinal bleeding (50%) and small intestinal angiodysplasia (33.3%). There was no difference in the rate of recurrent bleeding between patients with positive and negative VCE study (50.0% *vs* 55.6%,

P = 1.00) during an average of 11.6 ± 9.6 mo follow up. Among patients with positive VCE, the recurrent bleeding rate did not differ whether subsequent endoscopy was performed (50% *vs* 50%, *P* = 1.00).

CONCLUSION: VCE can be safely performed in LVAD recipients with a diagnostic yield of 40%. VCE does not affect recurrent bleeding in LVAD patients regardless of findings.

Key words: Heart-assist devices; Capsule endoscopy; Gastrointestinal hemorrhage; Heart failure; Endoscopy; Digestive system

Core tip: Obscure gastrointestinal bleeding (OGIB) is a common complication for patients receiving left ventricular assist device (LVAD). Although video capsule endoscopy (VCE) is frequently used to investigate OGIB, there is limited data on the safety and usefulness of VCE in LVAD recipients. We found that VCE can be safely performed in LVAD recipients with OGIB and with a 40% diagnostic yield. However, the results of VCE and the subsequent management driven by VCE did not affect the rate of recurrent GIB. Endoscopic intervention thus should be used judiciously, and alternative ways of management should be considered in LVAD patients with OGIB.

Video capsule endoscopy in left ventricular assist device recipients with obscure gastrointestinal bleeding. *World J Gastroenterol* 2016; 22(18): 4559-4566 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4559.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4559

INTRODUCTION

Approximately 50000 patients die from advanced heart failure in the United States each year, with a high mortality rate and life expectancy < 2 years when only medical therapies are utilized[1]. Although heart transplantation is a definitive therapeutic option for advanced heart failure, only 2200 heart transplants are performed annually due to donor shortage, leaving a large proportion of heart failure patients in need of an alternative therapy[2]. In recent years, Left Ventricular Assist Devices (LVADs) are used increasingly in this setting as destination therapy, bridge to transplantation, bridge to recovery, or bridge to decision in patients with advanced heart failure[3]. This approach has increased survival and improved quality of life in advanced heart failure patients[4].

Since the initial introduction of LVAD therapy, it is well documented that LVADs increase the risk of gastrointestinal bleeding (GIB), with as many as 20%-40% of LVAD recipients manifesting GIB[5-7]. The mechanism of GIB in LVAD recipients remains incompletely understood, but it is thought to be contributed to by development of angiodysplasia, acquired von Willebrand disease, persistent right ventricular dysfunction, and mucosal ischemia secondary to low pulse pressure[8,9]. GIB is further exacerbated by the use of anticoagulation in LVAD patients. Although previous reports found that upper GI tract is the most common site of GIB in LVAD recipients[10], obscure gastrointestinal bleeding (OGIB) remains a frustrating condition frequently encountered in this population.

Video capsule endoscopy (VCE) has made a significant impact on the evaluation of patients with OGIB, with a diagnostic yield of approximately 60%-70%[11]. However, it is a relative contraindication to use VCE in the setting of implanted electrical medical devices[12], and there is limited data on both the usage of VCE in LVAD associated OGIB, as well as the safety of VCE in LVAD patients[13-19].

We retrospectively evaluated our experience with VCE in LVAD patients with OGIB. The aims of our study were to determine the safety and diagnostic yield of VCE, and to assess the outcomes based on management driven by VCE in LVAD recipients.

MATERIALS AND METHODS

Patients

All patients undergoing VCE following implantation of LVAD at Washington University Medical Center between January 2005 and September 2013 were eligible for inclusion in this retrospective study. For inclusion, all subjects were required to have obscure GI bleeding, which was defined as hematemesis, melena, hematochezia, or anemia with positive fecal occult blood, without a definitive source identified on upper endoscopy (EGD) and colonoscopy, thereby requiring VCE for further localization of the bleeding source. Exclusion criteria consisted of patients aged less than 18 years, patients who did not have both EGD and colonoscopy performed prior to VCE, incomplete data collection and studies with unintelligible data. This study protocol was approved by the Institutional Review Board at Washington University in St. Louis.

Data collection

Inpatient and outpatient charts were reviewed in the institution's electronic medical records to extract demographic data, indications for LVAD, types of LVAD implanted, follow-up and GIB data. Patients were followed until heart transplant, death or the last point of contact in the electronic medical records. Patients lost to follow up were not included in the final analyses. Episodes of recurrent GIB were identified and recorded. Recurrent GIB was defined as any recurrence of overt GIB or anemia with positive fecal occult blood. Medical records were reviewed to

GIB: Gastrointestinal bleeding; LVAD: Left ventricular assist device; VCE: Video capsule endoscopy.

determine cause of death, and to determine if death was related to GIB when relevant. The Charlson comorbidity index was calculated based on the review of medical records[20].

Procedures

All VCE studies were performed using PillCam (Given Imaging, Duluth, GA, United States) as inpatients. The risk of capsule retention was assessed by history and radiological imaging studies such as small bowel follow-through or CT enterography per the discretion of GI consult service. Patients were given a half gallon of Golytely (Braintree Laboratories, Braintree, MA, United States) the evening before the procedure and were kept nothing by mouth after midnight. On the day of the procedure, the capsule endoscope was ingested or endoscopically placed in the duodenum if patients had dysphagia or delayed gastric emptying. Patients were monitored by continuous telemetry and evaluated serially by staff. LVADs were monitored continuously by the system controller and interrogated immediately after the VCE *via* the system monitor to evaluate for any changes in function. VCE reports were evaluated for possible LVAD interference and medical records were evaluated for possible LVAD dysfunction related to VCE interference.

Outcomes

The findings on VCE were categorized into 3 types of mucosal abnormalities as previously reported[21]. P0 lesions were those considered to have no bleeding potential such as normal study, submucosal vein, diverticula without bleeding, or nodule without mucosal break. P1 lesions were those having uncertain bleeding potential such as erosions or red spots. P2 lesions were those thought to have high bleeding potential such as ulcers, angiodysplasias, tumors, as well as active bleeding without lesions identified. The diagnostic yield of the study was assessed by the frequency of P2 lesions. Positive VCE studies were defined as VCE findings with P2 lesions. VCE findings reported P0 or P1 lesions were considered as negative VCE studies. If VCE did not reach the cecum at the end of recording, it was considered an incomplete study. Safety endpoints included interference of VCE with LVAD function, interference of LVAD with VCE reports, and other previously described adverse events associated with VCE.

Statistical analysis

For statistical analysis, data is reported as mean ± SD unless otherwise indicated. Fisher's exact test and Student's *t*-test were used for categorical variables and continuous variables, respectively. A *P*-value less than 0.05 was required for statistical significance. Logistic regression was used to examine predictors for VCE outcomes.

RESULTS

Thirty LVAD patients underwent VCE over the 8-year study period. No patient was lost to follow up or excluded in this study. All patients were treated and all procedures were performed as inpatients. The mean age was 60.1 ± 10.2 years, and 20% of patients were female (Table 1). Thoratec HeartMate Ⅱ LVADs were implanted in all of the patients except one patient who had a HeartWare HVAD. The Charlson comorbidity index, the history of GIB prior to LVAD implantation, the interval between LVAD implantation and GIB, and the history of overt GIB did not differ between patients with positive *vs* negative VCE studies. Twenty-three out of the thirty patients (76.7%) presented with overt OGIB: 21 with melena (70%), 2 with hematochezia (6.7%); whereas 7 patients (23.3%) presented with occult OGIB. Most of our patients received antiplatelets (86.7%) or anticoagulants (93.3%) on presentation. On average 3.2 ± 1.7 endoscopic procedures were performed within 4.1 ± 5.0 d prior to VCE, including 37 EGDs, 17 push enteroscopies, 40 colonoscopies,

Table 2 Locations and findings of positive video capsule endoscopy studies *n* (%)

	Patients (*n* = 12)
Locations of positive VCE findings	
Stomach and duodenum	2 (16.7)
Small intestine	9 (75.0)
Colon	1 (8.3)
Findings of positive VCE studies	
Small intestinal bleeding with no source or lesion identified (2 in the duodenum, 4 in the jejunum)	6 (50.0)
Angiodysplasia (1 in the duodenum, 3 in the small bowel)	4 (33.3)
Colonic bleeding with no source or lesion identified	1 (8.3)
Gastric ulcer	1 (8.3)

VCE: Video capsule endoscopy.

and 2 sigmoidoscopies. VCE was performed 6.2 ± 2.6 d after the presentation of GIB. VCE was placed endoscopically in 2 patients (6.7%) because one patient had a history of pyloric stenosis, and the other patient failed the swallow study. The mean small bowel transit time of VCE was 3.2 ± 1.1 h. VCE did not reach the cecum in 2 patients (6.7%) over the 8 h recording period, but there was no capsule retention. There was no electromagnetic interference of either VCE or LVAD identified in any patients.

Patients with positive VCE study stayed in the hospital longer than patients with negative VCE study (20.3 d *vs* 8.3 d, $P = 0.04$). Over the average 11.6 mo follow-up period, there was no statistically significant difference in the recurrent bleeding rate (50% *vs* 55.6%, $P = 1.00$), the number of endoscopies performed after VCE (1.8 ± 1.8 *vs* 1.7 ± 2.5, $P = 0.97$), or mortality rate (33.3% *vs* 33.3%, $P = 0.90$) between patients with positive and negative VCE. The total recurrent bleeding rate in this population was 53.3% ($n = 16$) and the presentation included melena ($n = 12$), hematochezia ($n = 3$) and anemia with positive fecal occult blood ($n = 1$). All 16 patients with recurrent bleeding were hospitalized and underwent transfusion and endoscopic procedures for managing recurrent GIB. The overall mortality rate in this study was 33.3% ($n = 10$): 7 patients died from underlying heart failure, 2 patients died from septic shock, one patient died from subdural hematoma, and none of the patients died from GIB. Four LVAD recipients underwent heart transplantation on average 4.3 mo after VCE and did not develop recurrent GIB afterwards. Before heart transplantation, VCE studies were positive in 2 patients (1 duodenal angiodysplasia and 1 jejunal angiodysplasia) and negative in 2 others.

The diagnostic yield of VCE to detect P2 lesions in this study was 40%. Table 2 demonstrates the locations and the findings of positive VCE studies. Small intestine was the most common site of positive VCE findings (75%). The predominant positive VCE findings in our study were small intestinal bleeding with no source or lesion identified (50%) and small intestinal angiodysplasias (33.3%). Eighteen VCE studies (60%) were negative, including 13 P0 lesions (12 normal, 1 small nodule) and 5 P1 lesions (red spots). The only patient who had a HeartWare HVAD implanted had a normal VCE study. Despite prior negative upper endoscopies performed 2 and 24 d prior to VCE, two lesions were found within reach of EGD by VCE: one gastric ulcer and one duodenal angiodysplasia (neither VCE was placed endoscopically). One VCE found active bleeding in the colon without the cause of bleeding identified. Angiodysplasia were found in 4 patients: 1 in the duodenum and 3 in the small intestine. In 2 patients where VCE failed to reach the cecum at the end of recording, VCE still detected the cause of GIB: one with gastric ulcer and one with small intestine angiodysplasia. Using logistic regression, we found that higher INR on presentation was associated with a higher probability of positive findings in VCE (OR = 3.62, 95%CI: 1.03-12.7, $P = 0.04$), adjusted for age, gender, and hemoglobin level.

Positive VCE studies led to further endoscopic evaluations in 6 patients out of 12 (50%): 6 push endoscopies and 3 single balloon enteroscopies. The other 6 patients with positive VCE did not have further endoscopies because they had no further bleeding and their hemoglobin had stabilized. During follow-up the overall recurrent bleeding rate in patients with positive VCE was 50% (6 out of 12). In addition, there was no difference in the recurrent bleeding rate whether subsequent endoscopic procedures were performed following positive VCE (3 out of 6 or 50% in each group, $P = 1.00$). Furthermore, after VCE, medications were adjusted in 7 out of 12 patients with positive VCE, and 8 out of 18 patients with negative VCE. These changes included discontinuation or decrease in the dose of aspirin and initiation of proton pump inhibitors. The change of medical management did not affect the rate of recurrent bleeding regardless of whether patients had a positive VCE (40% *vs* 57.1%, $P = 1.00$), or negative VCE (60% *vs* 50%, $P = 1.00$). The presentations of recurrent GIB were melena ($n = 4$), hematochezia ($n = 1$) and anemia with positive fecal occult blood ($n = 1$). The clinical course and management of LVAD recipients with positive VCE studies are detailed in Table 3.

DISCUSSION

In this retrospective study spanning 8 years, we demonstrated the safety of VCE and a 40% diagnostic yield of P2 lesions in LVAD recipients with OGIB. We found that the results of VCE were not associated with the rate of recurrent GIB, the number of endoscopic procedures performed, or mortality rate. In addition, the findings of VCE and the subsequent management did not affect the rate of recurrent GIB in LVAD patients.

This study identified 30 LVAD recipients undergoing

VCE for OGIB. To our knowledge, this is the largest available series of VCE in LVAD patients in the literature[6,13-19,22] (Table 4). Our results show that VCE is safe to perform in LVAD recipients, without interference between VCE and LVAD and without capsule retention. One prior study found 2 cases of LVAD possibly interfering with capsule images, and suggested that the leads of VCE be placed away from LVAD[23]. Based on the results of this and other previous studies, the interference between VCE and LVAD is uncommon[14,16,23]. Consistent with our experience, a recent review article reported that VCE is unlikely to impair the function of cardiac pacemakers, implantable cardioverter defibrillators, and LVAD, although the authors cautioned that wireless telemetry may interfere with VCE recordings[24].

The diagnostic yield of VCE in LVAD patients in two previous reports was 31% (n = 13) and 80% (n = 5) (Table 4)[6,22]. With a larger sample size of 30, the diagnostic yield in our study is 40%. Since only P2 lesions were considered positive, our diagnostic yield reflects true clinically relevant findings. It is known that the diagnostic yield of VCE is higher when it is performed closer to the presenting GIB event[25,26], or in patients with overt GIB than with occult GIB[27,28]. It is also known that the diagnostic yield of VCE is comparable to double balloon enteroscopy (DBE) according to a meta-analysis[29]. A recent study of DBE in LVAD recipients who presented with overt OGIB found that the diagnostic yield of DBE was 69% when DBE was performed within 24 h of initial presentation[30]. We suspect that VCE would have a similar diagnostic yield if it is performed within 24 h of overt OGIB. In our study, VCE was performed on average 6.2 d after admission- after coagulopathy was corrected and after other endoscopic procedures failed to identify the cause of OGIB. Using logistic regression, we found that higher INR on presentation was associated with a higher probability of positive VCE. If OGIB is highly suspected in an LVAD patient with a supra-therapeutic INR on presentation, expediting VCE, possibly before coagulopathy is corrected and

DBE: Double balloon enteroscopy; GIB: Gastrointestinal bleeding; N/A: Not applicable; SBE: Single balloon enteroscopy; VCE: Video capsule endoscopy.

other endoscopies performed, may improve the diagnostic yield of VCE in this population.

In a general population with OGIB, > 80% of the bleeding sites are in the small bowel[11]. The most common location of positive VCE finding in our LVAD patients with OGIB is also small bowel (75%). The most common finding of positive VCE in our study was small bowel bleeding without the cause of bleeding identified, whereas small bowel angiodysplasia was the second most common finding. The source of bleeding can be difficult to identify by VCE in the setting of active bleeding since blood can obscure visualization and VCE cannot clear the visual field with water irrigation. Nevertheless, we surmise that angiodysplasia is the most likely cause of GIB in those with small bowel bleeding without lesions identified given that it has been shown to be the most common cause of GIB in LVAD patients[6,7,22]. Indeed, 3 patients with small bowel bleeding without lesion identified on VCE were later found to have bleeding small bowel angiodysplasias on subsequent enteroscopies. Of note, in our study 25% of positive VCE findings were within reach of EGD or colonoscopy, underscoring the elusive nature of these lesions and the importance of repeat examinations if necessary.

Our study is the first to report recurrent GIB rate in LVAD recipients after VCE. Although LVAD is thought to predispose patients to GIB through various mechanisms, the recurrent GIB rate (53%) in our LVAD population is similar to OGIB in non-LVAD patients[31]. Furthermore, there was no difference in the rate of recurrent GIB, the number of endoscopies performed after VCE, and the mortality rate, whether VCE studies were positive or negative. Even among patients with a positive VCE, further endoscopic intervention did not affect recurrent bleeding- the recurrent bleeding rate was 50% regardless of endoscopic intervention (Table 3). On the other hand, the negative VCE study in our cohort was not associated with lower recurrent bleeding rate. It is possible that OGIB may merely be a reflection of the underlying condition or hemodynamics of LVAD patients, and endoscopic procedures do not necessarily impact their natural courses. Endoscopic evaluation or therapy in this population therefore should be used judiciously, especially given that medical therapy with thalidomide or Octreotide has recently been reported to be effective in LVAD recipients with OGIB[32,33]. Further study is required to identify the characteristics of patients who may benefit from endoscopic intervention *vs* supportive care.

Of the 12 patients with positive VCE studies, only 6 patients had subsequent endoscopic procedures because the other 6 patients had no further GI bleeding and their hemoglobin had stabilized, again indicating a dissociation of VCE findings with patients' clinical courses. Given that only 50% of patients with positive VCE had persistent GIB requiring further endoscopic intervention, one possible approach to treat LVAD recipients with OGIB based on our finding is to defer VCE and endoscopies until persistent GIB is observed. The current health care environment creates tremendous pressure on hospitals to shorten patients' stay and expedite diagnostic procedures and treatment. For certain patients in this population, however, it may be more cost-effective to observe and provide supportive medical care without endoscopies. Future studies are needed to test this hypothesis and to determine which subset of LVAD recipients with OGIB would benefit from VCE and subsequent endoscopies.

None of LVAD recipients in this study died from GIB, consistent with a prior report[34]. All 4 patients who received heart transplantation in our study did not have recurrent bleeding episodes during the study period, which is similar to the result in a recent systematic review that reported 12 patients without recurrent GIB after heart transplantation[7]. All together, the data indicates that the changes of physiology and hemodynamics associated with LVAD are the causes of GIB, and this process and GIB can

be reversed when LVAD is removed. Consistent with this concept, a previous study found that all LVAD recipients had reduced high molecular weight von Willebrand factor multimers which were normalized after patients received heart transplants[35].

Our study has limitations. Given that this is a retrospective study from a single tertiary medical center, it has weaknesses similar to other retrospective studies and should be carefully interpreted or generalized. In addition, although this study provides the largest series of VCE in LVAD recipients with OGIB, the sample size of 30 is still limited. We might underestimate the true rate of recurrent bleeding because the follow-up duration may not be long enough. Lastly, in our study VCE were interpreted by several gastroenterologists and the management of patients was not standardized. These variations may affect the results of our study.

In conclusion, our study shows that VCE can be safely performed in LVAD recipients with OGIB and with a 40% diagnostic yield. However, the results of VCE and the subsequent management driven by VCE did not affect the rate of recurrent GIB. Endoscopic intervention thus should be used judiciously in this patient population. An observation-and-supportive care approach could be an alternative way to treat LVAD patients with OGIB. Future studies should answer the questions of what subset of LVAD recipients with OGIB would benefits from endoscopic therapy, and what the most cost-effective way is to take care of this challenging group of patients.

COMMENTS

Background

Gastrointestinal bleeding (GIB) is one of the most common complications in Left Ventricular Assist Devices (LVADs) recipients. The mechanism of GIB in this setting is still unclear, but it is thought to be the results of development of angiodysplasia, acquired von Willebrand disease, persistent right ventricular dysfunction, and mucosal ischemia secondary to low pulse pressure. Moreover, managements of GIB in patients with LVAD are challenging. It is quite difficult to determine the source of GIB and it is not uncommon to not be able to identify the site of bleeding despite extensive workup. Video capsule endoscopy (VCE) has been used extensively for evaluating patients with obscure GIB (OGIB). In this study, we determined the safety and diagnostic yield of VCE, and assessed the outcomes of GIB based on management driven by VCE in LVAD recipients.

Research frontiers

There is limited data on the usage of VCE in LVAD patients. The results of this study provide evidence on the utility and safety of VCE in LVAD patients.

Innovations and breakthroughs

This study showed that VCE can be safely performed in LVAD recipients and the diagnostic yield of VCE was 40%. However, the results of VCE and the subsequent management driven by VCE did not affect the rate of recurrent GIB.

Applications

Although VCE is relatively safe to perform in LVAD recipients, VCE does not necessarily change the course of OGIB in LVAD recipients. Thus, endoscopic intervention should be used carefully in these patients. An observation-and-supportive care approach could be an alternative way to treat LVAD patients with OGIB.

Terminology

LVAD, an implantable mechanical device that helps a heart pumps blood throughout the body. OGIB, gastrointestinal bleeding that is unable to identify the cause after upper endoscopy and colonoscopy are performed. VCE, a small wireless camera that is ingested to examine parts of GI tract.

Peer-review

This is an interesting study for patients with obscure GI bleeding and LVAD receiving VCE.

Abstract

AIM: To explore methylation of *DAPK*, *THBS1*, *CDH-1*, and *p14* genes, and *Helicobacter pylori* (*H. pylori*) status in individuals harboring esophageal columnar metaplasia.

METHODS: Distal esophageal mucosal samples obtained by endoscopy and histologically diagnosed as gastric-type (non-specialized) columnar metaplasia, were studied thoroughly. DNA was extracted from paraffin blocks, and methylation status of death-associated protein kinase (*DAPK*), thrombospondin-1 (*THBS1*), cadherin-1 (*CDH1*), and *p14* genes, was examined using a methyl-sensitive polymerase chain reaction (MS-PCR) and sodium bisulfite modification protocol. *H. pylori cagA* status was determined by PCR.

RESULTS: In total, 68 subjects (33 females and 35 males), with a mean age of 52 years, were included. *H. pylori cagA* positive was present in the esophageal gastric-type metaplastic mucosa of 18 individuals. *DAPK*, *THSB1*, *CDH1*, and *p14* gene promoters were methylated by MS-PCR in 40 (58.8%), 33 (48.5%), 46

(67.6%), and 23 (33.8%) cases of the 68 esophageal samples. *H. pylori* status was associated with methylation of *DAPK* (P = 0.003) and *THBS1* (P = 0.019).

CONCLUSION: DNA methylation occurs in cases of gastric-type (non-specialized) columnar metaplasia of the esophagus, and this modification is associated with *H. pylori cagA* positive infection.

Key words: DNA methylation; Esophageal columnar metaplasia; Thrombospondin-1; Death-associated protein kinase; *Helicobacter pylori*; *cagA*

Core tip: Columnar metaplasia of the esophagus, whether specialized or not, is a hallmark of gastroesophageal reflux disease. Current information suggests that intestinal metaplasia in the esophagus arises from gastric-type metaplasia. In this study, we have demonstrated that *Helicobacter pylori* (*H. pylori*) *cagA*$^+$ can colonize esophageal gastric-type metaplastic mucosa, and that DNA methylation of tumor suppressor genes could be related to *H. pylori cagA*$^+$ infection, which in turn, may predispose to precancerous lesions, including intestinal metaplasia.

Methylation of *DAPK* and *THBS1* genes in esophageal gastric-type columnar metaplasia. *World J Gastroenterol* 2016; 22(18): 4567-4575 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4567.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4567

INTRODUCTION

Columnar metaplasia of the esophagus is defined as the replacement of the normal settled squamous epithelium in the distal portion of the esophagus with columnar epithelium, either with goblet cells [specialized columnar metaplasia, *i.e*., complete or incomplete intestinal metaplasia, Barrett esophagus (BE)], or without goblet cells (non-specialized columnar metaplasia or gastric-type metaplasia; *i.e*., oxyntocardiac and cardiac mucosa)[1]. The importance of such a distinction is found in the higher risk of developing adenocarcinoma of the distal esophagus in patients harboring specialized columnar metaplasia; the incidence of adenocarcinoma originating in BE has been reported as approximately 0.5% per year, with higher risk when long-segment BE is present[2]. However, it is now recognized that the presence of specialized columnar metaplastic cells (goblet cells) is not an essential requirement for the development of such adenocarcinomas[3]. Columnar metaplasia of the esophagus, whether specialized or not, is a hallmark of gastroesophageal reflux disease (GERD), and current information suggests that intestinal metaplasia in the esophagus arises from gastric-type, oxyntocardiac and/or cardiac (non-specialized) metaplasia[4]. Histologically, the non-specialized metaplastic mucosa of the esophagus may display any of the changes commonly observed in settled gastric mucosa, including the changes observed during *Helicobacter pylori* (*H. pylori*) infection[5].

Neoplastic transformation and progression in BE are related with genetic and epigenetic events that ultimately favor abnormal expression of the genes responsible for the intrinsic control mechanisms regulating cellular proliferation and/or apoptosis. DNA methylation is involved in the epigenetic regulation of gene expression (primarily through gene repression) when it occurs predominantly in regions containing CpG islands, which are often concentrated in the promoter regions of genes. In the case of esophageal adenocarcinoma, abnormal methylation patterns are not only detected in neoplastic tissue but also in premalignant Barrett mucosa. These results suggest that hypermethylation of DNA is an early epigenetic event in the multistep process of esophageal carcinogenesis[6].

Recent reports suggested that *H. pylori* is an initiator of the inflammatory microenvironment which might promote carcinogenesis and progression of gastric cancer[7]; in gastric diseases, chronic inflammation and alterations in DNA and histone methylation, especially at promoter regions, are frequently associated with *H. pylori* infection[8,9]. Such epigenetic alteration could be promoted in part by activation of NF-κB and PI3K/AKT-Sp1-RBP2-Cyclin D1 pathways triggered by *H. pylori* Cytotoxin-associated gene product [cytotoxin-associated gene A (*cagA*)] positive[7,9,10]. In addition to aging, increased methylation of several genes has also been described in chronic gastritis and premalignant stages of gastric carcinoma, irrespective of *H. pylori* status[11]. Moreover, *H. pylori* infection induces an overexpression of DNA methyltransferases (DNMTs), which has been associated with CpG island methylation of multiple gene promoters involved in cell growth, differentiation and tumor suppression, like *Ndrg2*, *p14*, *DAPK* and cadherin-1 (*CDH1*), as in chronic gastritis as in gastric cancer[7,12-14].

Consequently, the aim of this retrospective and descriptive study, was to explore the relationship between methylation of the death-associated protein kinase (*DAPK*), thrombospondin-1 (*THBS1*), *CDH1*, and *p14* genes, and the presence of *H. pylori cagA* positive, in the non-specialized, gastric-type columnar metaplastic mucosa of the distal esophagus, in a group of Mexican patients.

MATERIALS AND METHODS

Patients

This is a retrospective and descriptive study of consecutive cases with the histopathological diagnosis of non-specialized (gastric-type), but not specialized (complete or incomplete intestinal metaplasia), columnar metaplasia of the distal esophagus. Biopsies of the distal esophagus, as well as gastric biopsies, were retrieved from the files of the Department of Pathology at the Instituto Nacional de Cancerología (INCan) in Mexico City during the period between January 2003 and December 2008. Inclusion criteria were females and males, aged > 18 years. All biopsies were obtained by means of the panendoscopy procedure at the Endoscopy Service outpatient clinic, in patients with upper gastrointestinal complaints and with endoscopic suspicion of columnar metaplasia. Relevant demographic and clinical data for each patient were retrospectively retrieved from their clinical records. Non-specialized columnar metaplasia of the esophagus was operationally defined as the presence of cardiac and/or oxyntocardiac gastric mucosa lacking goblet cells and intermingled with recognizable islets of non-keratinized squamous epithelium and/or immersed duct structures lined by multilayered epithelium. Slides stained with hematoxylin and eosin (HE) from each case were thoroughly reviewed, and histological criteria for gastritis (mononuclear cells and neutrophils) and *H. pylori* density were applied to grade the samples according to the Visual analog scales (VAS) proposed by the Updated Sydney System[15]. Giemsa staining was also performed to confirm the presence of *H. pylori*. Finally, cases with sufficient tissue were selected for morphological and molecular analysis. DNA was extracted from paraffin-embedded tissue samples.

DNA extraction and bisulfite modification

DNA was extracted from histological sections of 20 μm in thickness by phenol/chloroform/isoamyl alcohol. One μg of genomic DNA extracted from samples was subjected to sodium bisulfite modification using a Zymo Kit (EZ DNA Methylation™ Kit; Zymo Research Co., United States) following manufacturer's instructions for small samples. As a control, we employed human lymphocyte DNA, known to be unmethylated in the promoter regions of our genes-of-interest.

Methylation-specific polymerase chain reaction

Bisulfite-modified DNA was amplified with primers specific for either methylated or unmethylated sequences[11] (Table 1). PCR products were subjected to electrophoresis on 3% agarose gels and were then visualized under ultraviolet (UV) illumination using ethidium bromide.

H. pylori detection by PCR

The presence of *H. pylori* was corroborated by PCR using the following primers from the conserved region of the *cagA* gene: forward, 5'-TT CAT GGG CGT GTT TGA TG-3', and reverse, 5'-AGC GAC TCC CTC AAC ATC TAA-3'. The fragments were amplified with 30 cycles utilizing a 55 ℃ annealing temperature.

Statistical analysis

Statistical review of the study was performed by a biomedical statistician. The association of tested variables with the presence of *H. pylori* infection was assessed using the χ^2 test. OR with their corresponding 95%CIs were calculated as a measure of association using logistic regression analysis. Two-sided statistics were used in all cases, and a probability (*P*) value of 0.05 was considered as significant. SPSS ver. 19 software (2010; IBM Corp., Armonk, NY, United States) was used for computations.

RESULTS

A total of 68 subjects (33 females and 35 males) with a mean age of 52 years (range, 25-88 years) fulfilled the histological criteria and were thus eligible for the study. In 35 subjects, gastric mucosa samples were insufficient for the molecular study, and in the remaining 33 (48.5%) subjects, the gastric samples were processed for final analysis. Endoscopic findings at the distal esophagus included variable degrees of mucosal erosion, salmon-colored mucosal tongues and irregular Z line. Histologically, all cases showed chronic inflammation. In the esophageal samples, the

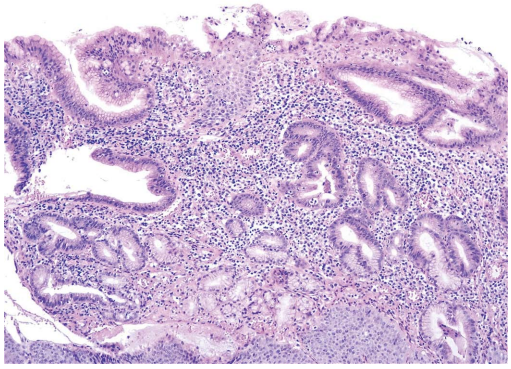

Figure 1 Islets of non-keratinized squamous epithelium can be observed intermingling with cardiac-type gastric mucosa. Superficial and glandular gastric epithelial linings demonstrate infiltration by polymorphonuclear leukocytes (Hematoxylin-eosin staining; original magnification × 10).

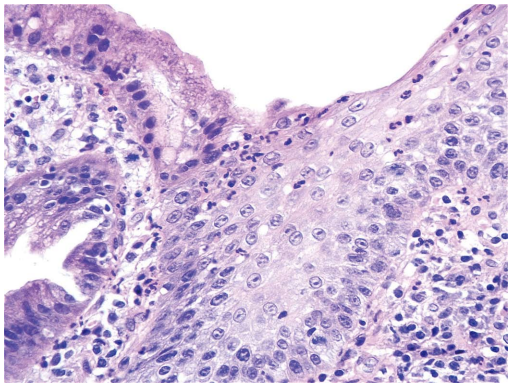

Figure 2 Histological section of gastric-type columnar mucosa of the esophagus. Moderate mononuclear infiltrate in the lamina propria and polymorphonuclear leukocytes infiltrating the mucosa layer can be observed (Hematoxylin-eosin staining stain; original magnification × 40).

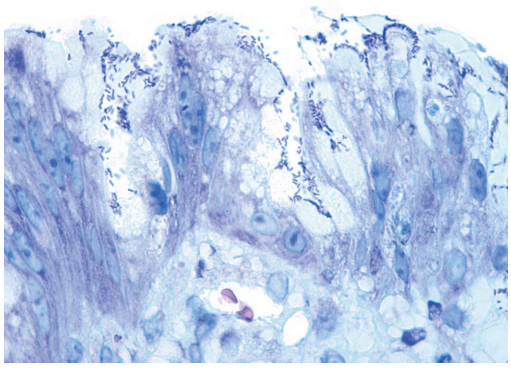

Figure 3 Numerous rod-shape bacilli can be seen attached to the gastric-type metaplastic columnar epithelium (Giemsa staining; original magnification × 100).

intensity of the mononuclear infiltrate was moderate in 43 (63.2%) cases, mild in 18 (26.5%), and marked in 7 (10.3%). Forty (58.8%) of the cases displayed polymorphonuclear leukocyte activity in the gastric-type metaplastic mucosa, which was graded as mild in 33 (82.5%) cases, moderate in 5 (12.5%), and marked in 2 (5%) (Figures 1 and 2). In 22 (32.3%) cases, *H. pylori* microorganisms were identified at the luminal surface of the gastric-type metaplastic mucosa. *H. pylori* density was graded as mild in 17 (77.3%) cases, moderate in 3 (13.6%), and marked in 2 (9.1%) (Figure 3). Regarding the 33 gastric biopsies, mononuclear infiltrate intensity was moderate in 16 (48.5%) cases, mild in 14 (42.4%), and marked in 3 (9.1%). Polymorphonuclear leukocyte activity was present in 17 (51.5%) cases and graded as moderate in 8 (47%), mild in 7 (41.2%), and marked in two (11.8%). *H. pylori* microorganisms were found in 17 (51.5%) cases and graded according to density, as moderate in 10 (58.8%), mild in 5 (29.4%), and marked in two (11.8%). In addition, four (12.1%) and two (6%) of the 33 cases displayed mild and moderate complete intestinal metaplasia, respectively. In one (3%) case, there was also mild atrophy of the gastric mucosa.

Table 2 Association of *Helicobacter pylori cagA*$^+$ infection as detected by PCR, with DNA methylation of the promoter regions of target genes in the esophageal biopsies

		Helicobacter pylori infection by PCR		*P* value
		Negative	Positive	
DAPK	Unmethylated	26	2	0.003[1]
	Methylated	24	16	
THBS1	Unmethylated	30	5	0.019[1]
	Methylated	20	13	
CDH1	Unmethylated	19	3	0.097
	Methylated	31	15	
p14	Unmethylated	36	9	0.091
	Methylated	14	9	

[1]*Helicobacter pylori cagA*$^+$ status was significantly associated with methylation.

CagA$^+$ *H. pylori* was detected in the esophageal non-specialized metaplastic mucosa and in the gastric mucosa of 18 (26.5%) of 68 individuals, and in 10 (30.3%) of 33, respectively, by means of Polymerase chain reaction (PCR) (Figure 4A). *DAPK*, *THSB1*, *CDH1*, and *p14* gene promoters were methylated by MS-PCR in 40 (58.8%), 33 (48.5%), 46 (67.6%), and 23 (33.8%) cases of the 68 esophageal samples and in 10 (30.3%), 14 (43.8%), 26 (78.8%), and 10 (31.3%) of the gastric biopsies, respectively. In the remaining cases, these genes were not methylated (Figure 4B). *H. pylori cagA*$^+$ status was significantly associated with methylation of *DAPK* (P = 0.003) and *THBS1* (P = 0.019) in the 68 esophageal samples (Table 2), and bivariate analysis confirmed the significance of this association (Table 3). In the comparative analysis between the 33 gastric and 33 esophageal paired samples, the trend for the association between *H. pylori cagA*$^+$ and methylation of *THBS1* and *DAPK* genes was maintained (Table 4). Methylation of the *CDH1* and *p14* gene promoters did not exhibit statistically significant differences between *H. pylori cagA*$^+$ and *cagA*$^-$ cases, in both the esophageal and

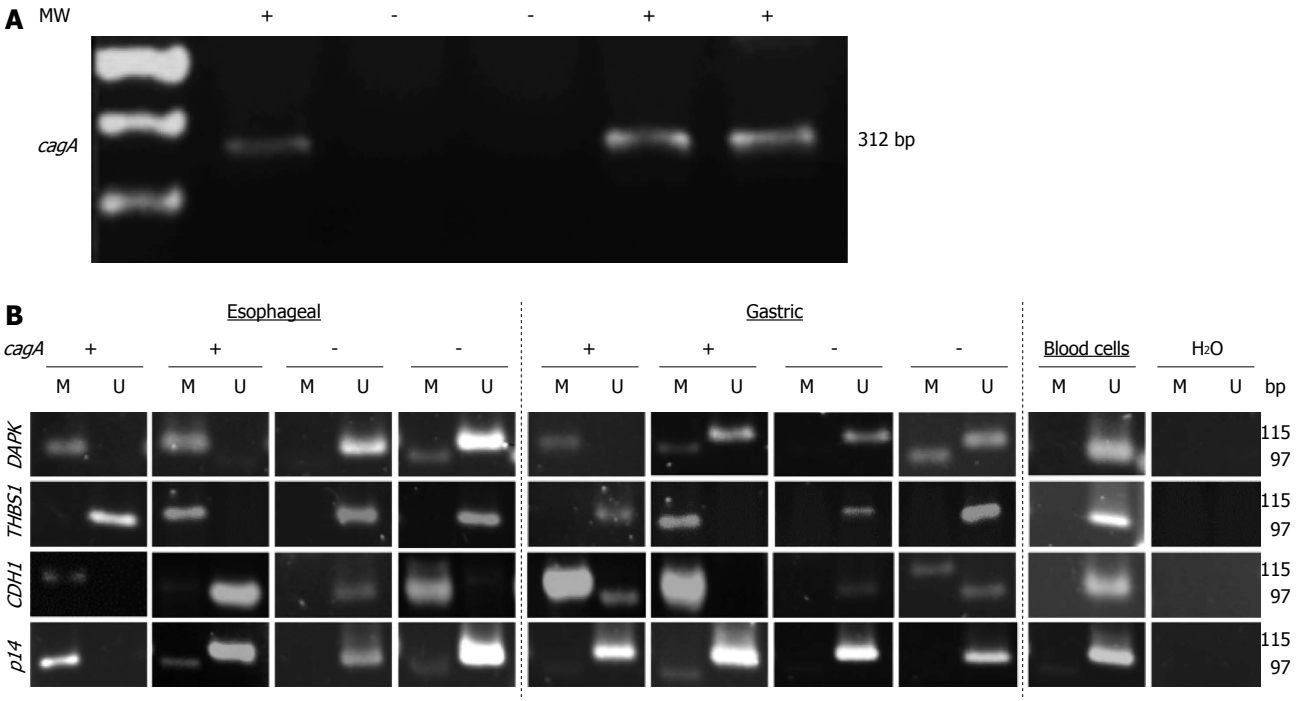

Figure 4 *cagA* detection and DNA promoter methylation status of *DAPK*, *THBS1*, *CDH1* and *p14* genes in esophageal and gastric mucosa tissue samples. A: *Helicobacter pylori cagA*$^+$ detection by polymerase chain reaction (PCR) amplification in tissue samples, (+) positive and (-) negative; B: Analysis of methylation status of *DAPK*, *THBS1*, *CDH1*, and *p14* genes promoters in esophageal mucosa and gastric biopsies tissue samples detected by methyl-sensitive PCR. Blood cells were used as control of unmethylated promoter regions. M represents methylated and U represent unmethylated; the status of *Helicobacter pylori cagA* is indicated as (+) positive and (-) negative.

the gastric biopsies. Among the esophageal biopsies, there were no significant differences regarding the age (P = 0.39) or gender (P = 0.34) of the subjects and *H. pylori* status by means of PCR; histopathological variables according to the Updated Sydney System for the classification and grading of gastritis were significantly associated with *H. pylori cagA*$^+$ status (Table 5). On the other hand, *H. pylori* density, mononuclear cells, and neutrophils, as histologically graded according to the Updated Sidney System for the classification of gastritis, did not show correlation with methylation status of the genes-under-study (data not shown).

DISCUSSION

Allison *et al*[16,17] first described and correctly interpreted the histopathological changes occurring in the distal esophagus of subjects suffering from GERD, and Paull *et al*[18], defined the histological subsets of the columnar lined esophagus. The subsets were then renamed the oxyntocardiac mucosa (formerly the fundic epithelium), cardiac mucosa (formerly the junctional epithelium), and intestinal metaplastic

mucosa (formerly the specialized columnar epithelium) by Chandrasoma *et al*[19].

Although *H. pylori* infection of the gastric mucosa has been proposed as a beneficial factor for GERD and BE[20,21], nearly nothing has been published regarding the potential effects of *H. pylori* colonization on the esophageal non-specialized (gastric-type) metaplastic mucosa. To the best of our knowledge, this study is the first to examine the presence of *H. pylori cagA*$^+$ in columnar metaplastic mucosa of the esophagus and to correlate such bacterial presence with the appearance of early epigenetic events. We selected cases with gastric-type (non-specialized) columnar metaplasia of the esophagus because, in addition to being considered an early morphological change in the evolution of Barrett's esophagus[21], intestinal metaplastic cells are infrequently colonized by *H. pylori*[22]. Given the limited and random sampling of the columnar esophagus, we cannot yet rule out the presence of specialized columnar epithelium in areas other than those analyzed in the present study. However, our goal was to explore the methylation status of select genes and the relationship of methylation with *H. pylori cagA*$^+$ infection in gastric-type metaplastic mucosa of the esophagus.

The majority of these studies, however, have been planned and conducted employing normal settled esophageal mucosa or tissues displaying intestinal metaplasia and not considering non-specialized (gastric-type) metaplastic mucosa. In this study, we explored the methylation status of four genes, *DAPK* (proapoptotic; tumor suppressor), *THBS1* (angiogenesis inhibitor), *CDH1* (cell adhesion), and *p14ARF* (cell cycle regulator; tumor suppressor), in patients harboring gastric-type (non-specialized) columnar metaplasia of the esophagus. Of these, *DAPK* and *THBS1* methylation was significantly associated with *H. pylori cagA*$^+$ infection of the esophageal gastric-type metaplastic mucosa, whereas *CDH1* and *p14* genes methylation was not. In specialized columnar metaplasia of the esophagus (BE), *DAPK*, *CDH1*, and *p14* have been reported to be methylated in 50%, 8%, and 7%, respectively[23], whereas *THBS1* is infrequently methylated[6]. On the other hand, we did not find a statistically significant association between *H. pylori cagA* positive and methylation of any of these genes, in the gastric mucosa. Our findings could be interpreted as the result of the smaller sampling of the gastric mucosa than of the columnar lined esophagus, therefore, with a loss of any potential statistic association. Another plausible explanation is that metaplastic gastric mucosa, in the distal esophagus, is more susceptible to, or predisposes to, the methylation of certain genes than the normal settled gastric mucosa due to disturbances induced by the gastroesophageal reflux, in addition to the *H. pylori* infection.

It is widely recognized that *H. pylori* is able to colonize gastric mucosa along the entire gastrointestinal tract, including areas as proximal as the upper esophagus[24] and as distal as the rectum[25], as well as all sites in between, such as the duodenum[26] and Meckel's diverticulum[27]. Previously, colonization of gastric-type mucosa in BE was also described; however, its clinicopathological significance has been underestimated[5]. Recently, employing a rat experimental model of chronic gastroesophageal reflux, Liu *et al*[28] demonstrated that severity of inflammation and incidence of Barrett esophagus and esophageal adenocarcinoma are increased when *H. pylori* colonizes the esophagus. In the gastric mucosa, *H. pylori* causes a complex immune and inflammatory process that is largely determined by the virulence of strains carrying the cytotoxin-associated gene (*cag*) pathogenicity island (PAI)[29]. Thus, *H. pylori* is responsible for several molecular events that ultimately play a significant role in gastric carcinogenesis. Interestingly, *H. pylori* infection has been suggested as an initiator of gastric carcinogenesis by upregulation of DNA methyltransferase 3B (DNMT3B)[7], and it has been also reported to induce expression of DNMT1 and DNMT3A in gastrointestinal stromal tumors[30]; therefore, *H. pylori* DNMT-induced *de novo* methylation could promote aberrant CpG island methylation, thus increasing the risk of gastric cancer[31,32].

Dysregulation of *DAPK* is implicated in the development and progression of cancer through gene silencing. DAP kinase function is closely related with the *p*53-dependent pathway for apoptosis[33]. In the gastric mucosa, hypermethylation of the *DAPK* promoter has been associated with aging and chronic inflammation[11], as well as premalignant stages of gastric carcinoma[34]. Hypermethylation of the *DAPK* gene in noncancerous gastric and chronic gastritis mucosa has been associated

with the risk of gastric cancer and neutrophil infiltration activity, but not aging, in a *H. pylori*-infected population[10,12,35]. In the esophageal mucosa, decreases in DAPK protein expression correlate with the severity of reflux esophagitis and tumor progression in Barrett carcinogenesis[36].

Moreover, a field effect of *DAPK* has been detected in normal esophageal mucosa of patients with adenocarcinoma and Barrett esophagus[37]. Indeed, possible silencing of *DAPK* by methylation could be an early event in columnar metaplasia of the esophagus, and this silencing remains throughout the process of neoplastic transformation. The association between *DAPK* silencing and *H. pylori* infection has been previously reported in gastric mucosa[12]. It is noteworthy that *H. pylori* infection of the columnar mucosa could be exerting an additive effect on *DAPK* gene promoter methylation, in addition to the reflux.

On the other hand, *THBS1* is an inhibitor of angiogenesis and its expression is regulated by tumor-suppressor genes such as *p*53 and *Rb*. Additionally, *THBS1* possesses tumor suppressive properties *in vivo*. It has been demonstrated that *THBS1* methylation inactivates its expression in several normal and neoplastic cell lines[38].

DAPK and *THBS1* have been found to be methylated in the gastric mucosa in patients with diseases ranging from chronic gastritis to carcinoma, with a rising frequency of *DAPK* methylation encountered in advanced stages of carcinogenesis[36]. *THBS1* promoter methylation has been associated with *DAPK* methylation from early-onset sporadic gastric carcinoma[39]. In this way, our findings are in agreement with previous studies that demonstrated that the early steps of Barrett's progression may involve DNA methylation of genes linked with apoptosis and tumor suppressor properties, particularly *DAPK* and *THBS1*. Our findings are also consistent with those reported by Ferrández *et al*[40], who performed a large case-control study and observed that *H. pylori* CagA$^+$ infection does not reduce the risk of BE.

Finally, we are aware that our study has some limitations, regarding its retrospective design, the small number of patients under study, and the inevitable sampling bias due to the varied and random distribution of the histological changes among the columnar lined esophagus. Further prospective studies are warranted to adequately identify patients with GERD with higher risks for developing severe disorders including BE as well as adenocarcinoma and its precursor lesions.

In this study, we showed that CpG methylation occurs in non-specialized, gastric-type columnar metaplasia of the esophagus and is closely related to *H. pylori cagA*$^+$ infection. Given this effect on gastric-type metaplastic mucosa, a conscious search for *H. pylori* and its eradication may be essential for halting the early mechanisms potentially involved in BE development and BE-associated carcinogenesis, among subjects suffering from GERD.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is a highly prevalent condition among worldwide population, and gives rise to esophageal columnar metaplasia, among others. Nowadays, columnar metaplasia of the esophagus is classified into non-specialized (gastric-type) and specialized [intestinal-type; Barrett's esophagus (BE)] neoplastic transformation and progression in BE, are related to genetic and epigenetic events that ultimately favor abnormal expression of the genes responsible for the intrinsic control mechanisms regulating cellular proliferation and/or apoptosis.

Research frontiers

Current information suggests that intestinal metaplasia arises from gastric-type, non-specialized metaplasia. In the stomach, *Helicobacter pylori* (*H. pylori*) infection has been associated with methylation of multiple gene promoters involved in cell growth, differentiation and tumor suppression, as in chronic gastritis as in gastric cancer. In this study, the authors report the methylation of two genes and its relation to *H. pylori cagA* status, in gastric- type columnar metaplasia of the esophagus.

Innovations and breakthroughs

DNA methylation of the promoter regions of genes containing CpG islands is involved in the epigenetic regulation of gene expression (predominantly through gene repression), and it is an early event in the multistep process of esophageal carcinogenesis. The authors performed the first study to assess the methylation of some genes involved in neoplastic transformation and progression in several organs, and its correlation with *H. pylori cagA*$^+$ infection, in the esophageal gastric-type metaplastic mucosa.

Applications

This study provides evidence that CpG methylation occurs in non-specialized columnar metaplasia of the esophagus and is closely related to *H. pylori cagA*$^+$ infection. Given this effect on gastric-type metaplastic mucosa, a conscious search for *H. pylori* and its eradication may be essential for halting the early mechanisms potentially involved in BE development and BE-associated carcinogenesis, among subjects suffering from GERD.

Peer-review

Herrera-Goepfert *et al* explored gene methylation in esophageal columnar metaplasia, and correlated these findings with the status of *H. pylori cagA*$^+$. It is well written and contains information which readers may be interested. Because it is suggested that intestinal metaplasia in the esophagus arises from gastric-type metaplasia, authors should include intestinal metaplasia in the study.

Abstract

AIM: To explore the correlation between *Helicobacter pylori* (*H. pylori*)-associated gastric diseases and colorectal neoplasia.

METHODS: Patients included in this study underwent a colonoscopy and esophago-gastro-duodenoscopy (EGD) along with histopathological measurement between March 2012 and March 2015 at Qi-Lu Hospital of Shandong University, who also had results of *H. pylori* detection. A total of 233 cases were selected. Demographic data, *H. pylori* infection status (including results of rapid urease tests and gastric mucosa pathological examinations) and histopathological examination results of gastric and colorectal mucosa were gathered and analyzed. The statistical analysis focused on the prevalence of colorectal neoplasms among patients with various histopathological categories of the stomach. ORs and their 95%CI were calculated to describe the strengths of the associations.

RESULTS: The incidence rates of colorectal adenoma without high-grade intraepithelial neoplasia (HGIEN) (OR = 2.400, 95%CI: 0.969-5.941), adenoma with HGIEN (5.333, 1.025-27.758) and adenocarcinoma (1.455, 0.382-5.543) were all higher for patients with *H. pylori*-associated gastritis than for those in the control group. The incidence rate of colorectal adenoma with HGIEN (3.218, 0.767-13.509) was higher in patients with intestinal metaplasia than in the control group, while the incidence rates of adenoma without HGIEN (0.874, 0.414-1.845) and adenocarcinoma (0.376, 0.096-1.470) were lower in the intestinal metaplasia group than in the control group. The incidence rate of colorectal adenoma without HGIEN (3.111, 1.248-7.753) was significantly higher in the gastric intraepithelial neoplasia group than in the control group, while the rates of adenoma with HGIEN (1.481, 0.138-15.941) and adenocarcinoma (2.020, 0.561-7.272) were higher in the gastric intraepithelial neoplasia group. Incidence rates of colorectal adenoma without HGIEN (1.067, 0.264-4.314), adenoma with HGIEN (2.667, 0.231-30.800) and adenocarcinoma (2.182, 0.450-10.585) were all higher in the gastric adenocarcinoma group than in the control group.

CONCLUSION: *H. pylori* infection as well as *H. pylori*-associated gastric diseases are risk factors for colorectal neoplasia.

Key words: *Helicobacter pylori*; *Helicobacter pylori*-associated gastric diseases; Colorectal neoplasia; Endoscopy with pathological biopsy; Chinese population

Core tip: Few studies have investigated the relationship between *Helicobacter pylori* (*H. pylori*)-associated gastric diseases and colorectal neoplasia. In particular, no such research on the Chinese population has been reported so far. To explore this correlation in the Chinese population, demographic data, *H. pylori* infection status and histopathological data of gastric and colorectal mucosa of 233 Chinese patients were gathered and analyzed. The results demonstrated that *H. pylori*-associated gastric diseases might increase the risk of colorectal neoplasia regardless of the number, size and location of the neoplasm. Therefore, we can assume that *H. pylori*-associated gastric diseases are potential risk factors for colorectal neoplasia in the Chinese population.

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies worldwide. In China, the incidence and mortality rates of CRC have increased in recent years[1]. Due to the lack of specific clinical manifestations, the early diagnosis of CRC is relatively difficult, leading to the poor prognosis. Therefore, it is of great importance to elucidate the pathogenesis and risk factors of CRC, and develop relevant prevention and early detection strategies. During the development of CRC, the mucosa will progress from normal mucosa to adenoma first, and then to adenocarcinoma. This process provides the chance for early detection and intervention of CRC, and colorectal adenoma is considered the most important precancerous lesion for CRC. These two diseases, colorectal adenoma and CRC, are collectively called colorectal neoplasia.

It is believed that the development of colorectal neoplasia is associated with *Helicobacter pylori* (*H. pylori*) infection[2,3], although the pathophysiological mechanism underlying the correlation remains unclear. Most scholars believed that *H. pylori* might induce colorectal neoplasia by regulating the expression of serum gastrin[4,5]. Persistent *H. pylori* infection can lead to various gastric diseases, including gastritis, gastric intestinal metaplasia, gastric intraepithelial neoplasia and gastric adenocarcinoma. Chronic atrophic gastritis (CAG), which may progress to intestinal metaplasia, intraepithelial neoplasia and adenocarcinoma, can lead to decreased gastric acid secretion by extensive glandular atrophy. Serum gastrin level will increase accordingly through the negative feedback regulation, which shall then act as a trophic factor for colorectal mucosa. Therefore, different kinds of *H. pylori*-associated gastric diseases may be correlated with different levels of colorectal neoplasia depending on the serum gastrin level. Although several previous studies concluded that *H. pylori* seropositivity was associated with colorectal neoplasia[4,6-8], few have investigated the relationship between *H. pylori*-associated gastric diseases and colorectal neoplasia. In particular, no such research on the Chinese population has been reported so far.

In this research, we carried out a retrospective analysis of a database of 60501 Chinese patients who underwent esophago-gastro-duodenoscopy (EGD) and/or colonoscopy, trying to explore the possible correlation between *H. pylori*-associated gastric diseases and colorectal neoplasia.

MATERIALS AND METHODS

Patient selection

A total of 60501 Chinese patients underwent EGD and/or colonoscopy between March 2012 and March 2015 at Qi-Lu Hospital of Shandong University. Out

Table 1 Clinical indications for esophago-gastro-duodenoscopy and colonoscopy *n* (%)

Indication for EGD and colonoscopy	EGD	Colonoscopy
Abdominal discomfort	78 (33.5)	65 (27.9)

Hematochezia	12 (5.2)	34 (14.6)
Weight loss	10 (4.3)	13 (5.6)
Others	58 (24.9)	39 (16.7)
Dyspepsia	33 (14.2)	
Reflux esophagitis	42 (18.0)	
Emesis	21 (9.0)	
Colorectal cancer screening		25 (10.7)
Polypectomy following-up		24 (10.3)

EGD: Esophago-gastro-duodenoscopy.

of those 60501 patients, those who had both EGD and complete colonoscopy (including the colonoscopy of the entire large intestine) were selected in the study. Histopathological results of gastric mucosa and colorectal mucosa as well as the results of *H. pylori* measurement were taken for all subjects. None of those patients in this study had a previous history of inflammatory bowel diseases (IBS), hereditary non-polyposis colorectal cancer (HNPCC) or familial adenomatous polyposis (FAP). None of them received *H. pylori* eradication therapy, gastrointestinal surgery, radiotherapy, chemotherapy, or other biotherapies targeting the cancer. No patients had a long-term drug use history. Based on the aforementioned criteria, a total of 233 patients were chosen.

Data collection

Demographic data, *H. pylori* infection status and histopathological results of gastric and colorectal mucosa were collected for all subjects. *H. pylori* infection status was determined by rapid urease test (RUT) and histopathological examination of gastric mucosa. *H. pylori* positivity was defined as results from one or both examinations were positive. EGD and colonoscopy were performed with EG-2990i electronic gastroscopes and EC-3890Fi electronic colonoscopes (Pentax, Tokyo, Japan), respectively. The location, number, and size of polyps were recorded during the colonoscopy.

All data were from existing records and personal identities were removed before the data were used in this study. Therefore, there was no need to obtain informed consent from patients.

Diagnostic criteria

Among the 233 patients, 159 (68.2%) had gastric antrum biopsies, 59 (25.3%) had gastric body and fundus biopsies, 29 (12.4%) had cardia biopsies, and 20 (8.6%) had multiple-site biopsies. The diagnostic criteria of the gastric biopsies were set according to the updated Sydney system[9]. Based on the sample size of this study, patients were divided into four groups according to their histopathological results of gastric mucosa: chronic gastritis group (including chronic non-atrophic gastritis and CAG), gastric intestinal metaplasia group, gastric intraepithelial neoplasia group and gastric adenocarcinoma group.

The following four histopathological categories were used for the colorectal mucosa: inflammation or non-adenomatous polyps (including hyperplastic polyps, inflammatory polyps, *etc.*), adenoma (including tubular adenoma, tubulovillous adenoma and villous adenoma) without high-grade intraepithelial neoplasia (HGIEN), adenoma with HGIEN and colorectal adenocarcinoma. Polyps were grouped based on their location such as rectum (including rectosigmoid junction), sigmoid colon, descending colon, transverse colon and ascending colon (including ileocecal junction). Polyps were also grouped based on the number: 1-3, 4-9 and > 10. Adenomas were grouped based on their size: 0-9 mm, 10-19 mm and > 20 mm.

Statistical analysis

The degree of correlations between *H. pylori*-associated gastric diseases and colorectal neoplasia was measured by ORs and their 95%CIs. χ^2 test was applied to calculate *P*-values. When the expected frequency was less than 5, Fisher's exact test was used to calculate *P*-values. *P*-values less than 0.05 were considered statistically significant. All statistical analyses were performed using Excel 2013 (Microsoft, Redmond, WA, United States) and SPSS 20.0 (SPSS, Chicago, IL, United States). The statistical methods of this study were reviewed by Dr. Jing Liu from Department of Epidemiology and Biostatistics, School of Public Health, Shandong University.

RESULTS

General characteristics of the study population

All 233 Chinese patients were between 16 and 89 years old, with the mean age at 56.85 ± 12.38 years. Of the 233 patients, 70.4% were males (164 patients), aged between 16 and 83 years with the mean at 56.69 ± 12.06 years, and 29.6% were females (69 patients), aged between 16 and 89 years with the mean at 57.22 ± 13.19 years. The clinical indications for EGD and colonoscopy are listed in Table 1.

Correlation between H. pylori-associated gastritis and colorectal neoplasia

H. pylori-associated gastritis is a gastric disease while the histopathological type was chronic gastritis (including chronic non-atrophic gastritis and CAG) with *H. pylori* infection (the infection status was determined by RUT and histopathological examination). Because no patient included in this research had completely normal histopathological results of gastric mucosa, patients with chronic gastritis and negative *H. pylori* were used as control group 1 in this research. For the

HGIEN: High-grade intraepithelial neoplasia; *H. pylori*: *Helicobacter pylori*.

same reason, patients with colorectal inflammation or non-adenomatous polyps were used as control group 2.

As shown in Table 2, compared to the patients in the control group 1, patients with *H. pylori*-associated gastritis were younger and had a higher rate of males. The incidence rates of colorectal adenoma without HGIEN, colorectal adenoma with HGIEN or colorectal adenocarcinoma were higher in the *H. pylori*-associated gastritis group than in the control group 1. The incidence rate of *H. pylori*-associated gastritis was much lower for patients in the control group 2 than for those in the other three groups (the colorectal adenoma group without HGIEN, the colorectal adenoma group with HGIEN and the colorectal adenocarcinoma group). The correlation between *H. pylori*-associated gastritis and colorectal neoplasms was the highest when the number of polyps was between 4 and 9 (OR = 2.857, 95%CI: 0.983-8.306, $P = 0.049$). In addition, the association of *H. pylori*-associated gastritis with colorectal neoplasms was independent of colorectal neoplasms size, with OR values greater than 1. The association was highest when the polyps were located at the descending colon (OR = 2.737, 95%CI: 1.018-7.357, $P = 0.043$).

Correlation between gastric intestinal metaplasia and colorectal neoplasia

There were more old people and males in the gastric intestinal metaplasia group than in the control group 1 (Table 3). The incidence rate of colorectal adenoma with HGIEN was higher in the gastric intestinal metaplasia group than in the control group 1, while the incidence rates of colorectal adenoma without HGIEN and colorectal adenocarcinoma were lower in the gastric intestinal metaplasia group. The inconsistency may be due to the small sample size, as there were only three patients with both gastric intestinal metaplasia and colorectal adenocarcinoma. Therefore, each individual case had a big impact on the OR value, leading to poor reliability of the final conclusion.

The association of gastric intestinal metaplasia with the number of colorectal neoplasms was also impacted by the small sample size, as the OR values varied considerably. The OR value was greater than 1 when the number of polyps was between 1 and 3 or between 4 and 9, while the OR value was smaller than 1 when the number of polyps was greater than 10. There were only five patients with both gastric intestinal metaplasia and more than 10 colorectal polyps. Also affected by the small sample size, the association of gastric intestinal metaplasia with the size of colorectal neoplasms was inconsistent. Since there was only one patient with both gastric intestinal metaplasia and colorectal adenoma larger than 20 mm, the analysis result could hardly be representative. This was also the case for the association of gastric intestinal metaplasia with the location of colorectal neoplasms.

Correlation between gastric intraepithelial neoplasia and colorectal neoplasia

Compared to patients in the control group 1, patients in the gastric intraepithelial neoplasia group were slightly older and had a significantly higher proportion of males ($P = 0.002$, Table 4). The incidence rate of colorectal adenoma without HGIEN was significantly higher in the gastric intraepithelial neoplasia group than in the control group 1 ($P = 0.013$). Similarly, the incidence rates of colorectal adenoma with HGIEN

Table 3 Correlation between gastric intestinal metaplasia and colorectal neoplasia *n* (%)

HGIEN: High-grade intraepithelial neoplasia.

and colorectal adenocarcinoma were also higher in the gastric intraepithelial neoplasia group. Gastric intraepithelial neoplasia was found more frequently in all other three groups (the colorectal adenoma group without HGIEN, the colorectal adenoma group with HGIEN and the colorectal adenocarcinoma group) than in the control group 2.

The association of gastric intraepithelial neoplasia with the number of colorectal neoplasia was similar to that of *H. pylori*-associated gastritis, as the OR values were all greater than 1. The association was the highest when the number of polyps was between 4 and 9 (OR = 3.175, 95%CI: 1.071-9.413, $P = 0.033$). The associations of gastric intraepithelial neoplasia with the size of colorectal neoplasia were also similar, with the association being strongest when the size of adenoma was 0-9 mm (OR = 2.844, 95%CI: 1.092-7.410, $P = 0.029$). Compared to that of *H.*

HGIEN: High-grade intraepithelial neoplasia.

pylori-associated gastritis, the association of gastric intraepithelial neoplasia with the location of colorectal neoplasms was even stronger. The association was statistically significant when the polyps were located at the sigmoid colon, descending colon, transverse colon and ascending colon.

Correlation between gastric adenocarcinoma and colorectal neoplasia

Fourteen gastric adenocarcinoma patients were enrolled in the study (Table 5). Their average age (62.36 ± 16.31 years) was significantly higher than that of the control group 1 (56.42 ± 14.90 years). There was also a higher percentage of males in the gastric adenocarcinoma group than in the control group 1. The incidence rates of colorectal adenoma without HGIEN, colorectal adenoma with HGIEN and colorectal adenocarcinoma were higher in the gastric adenocarcinoma group than in the control group 1. However, the results were not statistically significant due to the small sample size. The incidence rate of gastric adenocarcinoma was higher in all three case groups than in the control group 2.

The relationship of gastric adenocarcinoma with the number of colorectal neoplasia varied widely because of the small sample size. There was no patient with both gastric adenocarcinoma and more than 10 colorectal polyps in this study. Also because of the small sample size, the association of gastric adenocarcinoma with the size of colorectal neoplasms was inconsistent, leading to low reliability. It was the same situation for the association of gastric adenocarcinoma with the location of colorectal neoplasia.

DISCUSSION

The first report that *H. pylori* infection might be associated with colorectal neoplasia (particularly colorectal adenomas) could be traced back to 1997[10]. Several previous studies have shown a positive correlation between *H. pylori* infection and colorectal neoplasia in different populations, such as African American[11], German[6,8], and Israelite[12]. However, other studies did not support the idea that *H. pylori* infection was associated with the development of colorectal neoplasia. For example, Strofilas *et al*[4] found that there was no significant difference of anti-*H. pylori* IgG antibodies between the colorectal cancer group and the control group in Greeks. A recent meta-analysis also failed to find a statistical association between *H. pylori* infection and colorectal neoplasia among the East Asian population[13]. In addition, such lack of association between *H. pylori* and colorectal adenomas was also reported in the United States Hispanic population[14]. Therefore, it was speculated that the relationship between *H. pylori* infection and colorectal neoplasia was race dependent[15], making it important to analyze data based on race.

Most previous studies used positive serology as the indicator of *H. pylori* infection[16-19], while others used the presence of *H. pylori*-associated gastritis as the indicator[20-22]. Yet very few studies used other *H. pylori*-associated gastric diseases as indicators during the investigation of the association of colorectal neoplasia with *H. pylori*-associated gastric diseases as well as their severity. In particular, to our knowledge, no such study has been performed on the Chinese population. Since Chinese represent more than one fifth of the

world total population, it is of great significance to investigate the relationship between *H. pylori*-associated gastric diseases and colorectal neoplasia in the Chinese population.

Our study demonstrated that *H. pylori*-associated gastric diseases might increase the risk of colorectal neoplasia regardless of the number, size and location of the neoplasm, although some results were not statistically significant as the sample size was too small. Generally we can assume that *H. pylori* infection as well as *H. pylori*-associated gastric diseases are potential risk factors for colorectal neoplasia.

Chinese population has a high prevalence of *H. pylori* infection and *H. pylori*-associated gastric diseases[23]. The incidence rate of colorectal adenocarcinoma is also high in China[24]. Early diagnosis of colorectal adenocarcinoma is relatively low even though early diagnosis is very important to lower the mortality[25]. Our research showed that people who had *H. pylori*-associated gastric diseases did have high risk of colorectal neoplasia. It is important to encourage patients with *H. pylori*-associated gastric diseases to undergo colonoscopy earlier and more frequently, to improve the early diagnostic rate of colorectal adenocarcinoma. In addition, people in the high-risk group should receive some interventions, such as lifestyle changes, which may lower the risk of developing cancer.

One advantage of this study was that RUT and histopathological results were used to determine the *H. pylori* infection status. As the gold standard for *H. pylori* infection diagnosis[26], histopathological examination can diagnose the *H. pylori* infection and pathologic changes of the stomach at the same time. Compared to serological tests that cannot differentiate existing infections from historical ones, RUT and histopathological tests diagnose only existing *H. pylori* infection. Such a distinction is vital since only existing *H. pylori* infection stimulates immune responses that can induce or perpetuate chronic inflammation in the gastrointestinal tract, and many malignancies are associated with epigenetic alterations induced by chronic inflammation[27,28].

How *H. pylori* infection increases the risk of colorectal neoplasia has not yet been elucidated. One common hypothesis is that hypergastrinemia induced by *H. pylori* infection contributes to the colorectal carcinogenesis, as high levels of gastrin can promote colorectal cell growth *in vitro* and increase colorectal cancer rates in animal models[29-31]. Since serum gastrin levels increase significantly as the healthy stomach progresses to malignancy[32], it could be inferred that the correlation between *H. pylori*-associated gastric diseases and colorectal neoplasia should be higher as the severity of the gastric lesions increases. However, our study showed that there was little association of the type of *H. pylori*-associated gastric diseases with colorectal neoplasia. This negative result might be due to the small sample size. As no gastrin level data was included in the study, it might also be because the gastrin levels were similar in different *H. pylori*-associated gastric diseases, as gastrin levels could be influenced by many factors. Yet other studies did show that gastrin levels were not related to colorectal neoplasia[6]. That being said, more studies are needed to clarify this issue. The relatively small sample size of our study also made it impossible to perform multivariate logistic analysis to eliminate possible confounding factors, restricting the research conclusion. Another limitation is that since all data were collected from the same center, some bias such as environmental factor might impact the results.

In conclusion, our study revealed that *H. pylori* infection and *H. pylori*-associated gastric diseases are potential risk factors of colorectal neoplasia. Early colonoscopy and interventions should be taken to reduce the risk of colorectal neoplasia for people with *H. pylori*-associated gastric diseases. Studies with larger sample size and multi-center data collection for Chinese population are needed to further clarify this association and to understand the underlying pathophysiological mechanism.

COMMENTS

Background

Colorectal cancer (CRC) is one of the most common malignancies worldwide. Colorectal adenoma is considered the most important precancerous lesion for CRC, and these two diseases are collectively called colorectal neoplasia. Accumulating evidence indicates that in addition to being a major risk factor of gastric cancer, *Helicobacter pylori* (*H. pylori*) infection is also associated with colorectal neoplasia. Although several previous studies concluded that *H. pylori* seropositivity was associated with colorectal neoplasia, few have investigated the relationship between *H. pylori*-associated gastric diseases and colorectal neoplasia. In particular, no such research on the Chinese population has been reported so far. In this study, we carried out a retrospective analysis of a database of 60501 Chinese patients who underwent esophago-gastro-duodenoscopy and/or colonoscopy, trying to explore the possible correlation between *H. pylori*-associated gastric diseases and colorectal neoplasia.

Research frontiers

Early diagnosis of colorectal cancer is very important to lower the mortality. Based on these results, it is critical for patients with *H. pylori*-associated gastric diseases to receive colonoscopy and interventions earlier to improve prognosis.

Innovations and breakthroughs

In this study, the authors investigated the possible correlation between *H. pylori*-associated gastric diseases and colorectal neoplasia in the Chinese population for the first time. Since the relationship between *H. pylori* infection and colorectal neoplasia was considered race dependent, these results supplemented the hypothesis that *H. pylori*-associated gastric diseases are potential risk factors of colorectal neoplasia with evidence from the Chinese population.

Applications

These results suggest that *H. pylori* infection and *H. pylori*-associated gastric diseases are potential risk factors of colorectal neoplasia, encouraging people in the high-risk group to receive colonoscopy and some interventions earlier and more frequently, thus improve the early diagnostic rate of colorectal adenocarcinoma.

Peer-review

It is an interesting study, but includes too few subjects to have such a conclusion. It is in the text that *H. pylori* infection may affect colorectal neoplasm formation differently in different races. And this study reported for the first time how *H. pylori*-associated gastric diseases are correlated with colorectal neoplasm in the Chinese people, representing its innovation.

Abstract

AIM: To investigate the changes in clinical symptoms and gastric emptying and their association in functional dyspepsia (FD) patients.

METHODS: Seventy FD patients were enrolled and divided into 2 groups *Helicobacter pylori* (*H. pylori*)-negative group (28 patients), and *H. pylori*-positive group (42 patients). Patients in the *H. pylori*-positive group were further randomly divided into groups: *H. pylori*-treatment group (21 patients) and conventional treatment group (21 patients). Seventy two healthy subjects were selected as the control group. The proximal and distal stomach area was measured by ultrasound immediately after patients took the test meal, and at 20, 40, 60 and 90 min; then, gastric half-emptying time was calculated. The incidence of symptoms and gastric half-emptying time between the FD and control groups were compared. The *H. pylori*-negative and conventional treatment groups were given

conventional treatment: domperidone 0.6 mg/(kg/d) for 1 mo. The *H. pylori*-treatment group was given *H. pylori* eradication treatment + conventional treatment: lansoprazole 30 mg once daily, clarithromycin 0.5 g twice daily and amoxicillin 1.0 g twice daily for 1 wk, then domperidone 0.6 mg/(kg/d) for 1 mo. The incidence of symptoms and gastric emptying were compared between the FD and control groups. The relationship between dyspeptic symptoms and gastric half-emptying time in the FD and control groups were analyzed. Then total symptom scores before and after treatment and gastric half-emptying time were compared among the 3 groups.

RESULTS: The incidence of abdominal pain, epigastric burning sensation, abdominal distension, nausea, belching, and early satiety symptoms in the FD group were significantly higher than in the control group (50.0% *vs* 20.8%; 37.1% *vs* 12.5%; 78.6% *vs* 44.4%; 45.7% *vs* 22.2%; 52.9% *vs* 15.3%; 57.1% *vs* 19.4%; all $P < 0.05$). The gastric half-emptying times of the proximal end, distal end, and the whole stomach in the FD group were slower than in the control group (93.7 ± 26.2 *vs* 72.0 ± 14.3; 102.2 ± 26.4 *vs* 87.5 ± 18.2; 102.1 ± 28.6 *vs* 78.3 ± 14.1; all $P < 0.05$). Abdominal distension, belching and early satiety had an effect on distal gastric half-emptying time ($P < 0.05$). Abdominal distension and abdominal pain had an effect on the gastric half-emptying time of the whole stomach ($P < 0.05$). All were risk factors (odds ratio > 1). The total symptom score of the 3 groups after treatment was lower than before treatment ($P < 0.05$). Total symptom scores after treatment in the *H. pylori*-treatment group and *H. pylori*-negative group were lower than in the conventional treatment group (5.15 ± 2.27 *vs* 7.02 ± 3.04, 4.93 ± 3.22 *vs* 7.02 ± 3.04, All $P < 0.05$). The gastric half-emptying times of the proximal end, distal end, and the whole stomach in the *H. pylori*-negative and *H. pylori*-treatment groups were shorter than in the conventional treatment group ($P < 0.05$).

CONCLUSION: FD patients have delayed gastric emptying. *H. pylori* infection treatment helps to improve symptoms of dyspepsia and is a reasonable choice for treatment in clinical practice.

Key words: Functional dyspepsia; Gastric emptying; Ultrasound

Core tip: Stomach half-emptying time was determined in *Helicobacter pylori* (*H. pylori*) patients and healthy controls. The half-emptying times at the proximal end, distal end, and the whole stomach in the functional dyspepsia (FD) group were slower than in the control group. Total symptom scores in the *H. pylori*-treatment group and *H. pylori*-negative group were lower than in the conventional treatment group after treatment. Patients with FD have delayed gastric emptying. Treatment of *H. pylori* infection helps to improve symptoms of dyspepsia and is a reasonable choice for therapy in clinical practice.

INTRODUCTION

Functional dyspepsia (FD) is the most common functional gastrointestinal disorder, but its etiology remains unclear[1-3]. However, it is generally believed that an abnormality in gastric motility is an important factor[4]. Patients with FD often appear to have abdominal distension, belching, nausea, and other symptoms of dyspepsia. In severe cases, it has a major impact on daily life, and treatment is required to alleviate the symptoms[5-7]. FD is associated with a variety of factors that include gastrointestinal motility disorders, gastrointestinal hormone secretion abnormalities, or *Helicobacter pylori* (*H. pylori*) infection[8]. Among them, *H. pylori* infection probably induces symptoms by increasing the sensitivity to mechanical distension or increasing gastric acid secretion[9]. Clinically, gastric motility drug treatment is primarily given to these patients. However, whether there is a need for eradication therapy for *H. pylori* in FD patients remains controversial[10]. Furthermore, determination of gastric emptying by ultrasound is convenient for observation, has economic advantages, is easy for patients, and is suitable for widespread or repeated use[11,12]. Therefore, this study compared symptoms of dyspepsia, gastric emptying time, and other indicators before and after *H. pylori* treatment in patients with FD in our hospital, and in healthy volunteers. The relationship between the symptoms of dyspepsia and gastric half-emptying time were observed in FD patients, and whether *H. pylori* treatment could alleviate the symptoms was investigated, with the aim of providing a basis for the clinical treatment.

MATERIALS AND METHODS

Study population

A total of 70 adult FD patients admitted to our hospital from January 2013 to March 2015 were included in this study as the FD group, and were divided into 2 groups: *H. pylori*-negative group ($n = 28$) and *H. pylori*-positive group ($n = 42$). The *H. pylori*-positive group was further randomly divided into 2 groups: an *H. pylori* treatment group and a conventional treatment group ($n = 21$ each group). Patients with

FD met the following criteria[13]: (1) the Rome Ⅲ diagnostic criteria of FD; (2) duration of disease 1-3 years, with no gastrointestinal motility or *H. pylori* drug treatment in the previous month; (3) had not been treated with systematic FD or *H. pylori* drugs; and (4) underwent pathological examination by gastroscopy and a ^{13}C-urea breath test. *H. pylori*- positive patients were required to have 2 positive checks, and excluded single-positive patients. In addition, 72 healthy adults were selected from the Medical center as the control group. None of the subjects had the following exclusion criteria[13]: (1) organic lesions in the stomach and duodenum revealed by endoscopic examinations; (2) history of gastrointestinal surgery; (3) diabetes or connective tissue diseases; and (4) long-term smoking or alcoholism. Age and other characteristics were similar between the FD group and control group (P > 0.05, Table 1).

Methods

A GE Voluson E8 ultrasound with a C1-5 transducer was used for examination of all subjects by an experienced sonographer. Subjects were not allowed to drink and eat 12 h before the ultrasound examination, and the empty state of the stomach was confirmed before examination[14]. Patients were asked to finish a 500 mL standard test meal within 4-5 min (500 mL of 80 g black sesame paste in boiled water, cooled to about 25 ℃; about 1960 kJ)[15]. With patients in a sitting position, the abdomen between the xiphoid and navel was first scanned by an ultrasound 4C1 convex array probe The "figure-of-eight-like" double ring sign (Figure 1) junction is the angulus, which is the boundary between the proximal end and distal ends of the stomach. The proximal and distal stomach areas were measured immediately after patients took the test meal and at 20, 40, 60, and 90 min thereafter, and gastric half-emptying time was obtained by computer analysis.

FD patients in the *H. pylori*-negative group and conventional treatment group were given domperidone 0.6 mg/kg/d 30 min before a meal for 1 mo; while patients in the *H. pylori* treatment group took a combination of 3 drugs as eradication therapy for *H. pylori*, including lansoprazole tablets 30 mg once daily, clarithromycin tablets 0.5 g twice daily, and amoxicillin 1.0 g twice daily for 1 wk. Confirmation of *H. pylori* eradication was performed with a gastroscope and ^{13}C-urea breath test. Then domperidone 0.6 mg/kg per day) was given 30 min before a meal for 1 mo. Dyspepsia symptoms pre-and-post treatment were scored in all these groups. Gastric half-emptying time was determined after the end of treatment.

Evaluation index

Dyspepsia symptoms of all subjects were statistically compared, and the correlation with gastric half-emptying time was analyzed. Total dyspepsia symptom scores before and after treatment were compared and analyzed among the 3 groups of patients with FD. Symptom scores for abdominal pain, epigastric burning sensation, abdominal distension, nausea, belching, vomiting, and early satiety were scored according to the severity of symptoms: 0, asymptomatic; 1, mild (between asymptomatic and moderate); 2, moderate (symptoms that can be tolerated); 3, severe (symptoms that are intolerable and have a serious impact on daily life)[16,17]. Then, gastric half-emptying time after treatment was compared among the 3 groups of patients with FD.

Statistical analysis

SPSS 20.0 was used to analyze all data (IBM Corp., Armonk, NY, United States). P < 0.05 was considered statistically significant. The incidence of epigastric abdominal pain, epigastric burning sensation, abdominal distension, nausea, belching, vomiting, and early satiety symptoms was compared between the FD group and control group using the χ^2 test. Gastric half-emptying time: Gastric half-emptying time of the proximal end, distal end, and the whole gastric region was compared between the FD group and control group using the t-test. The relationship between dyspepsia symptoms and gastric half-emptying was determined using logistic regression analysis, with gastric half-emptying time as the dependent variable and the symptoms of dyspepsia as the independent variables. Total symptom scores before and after treat-

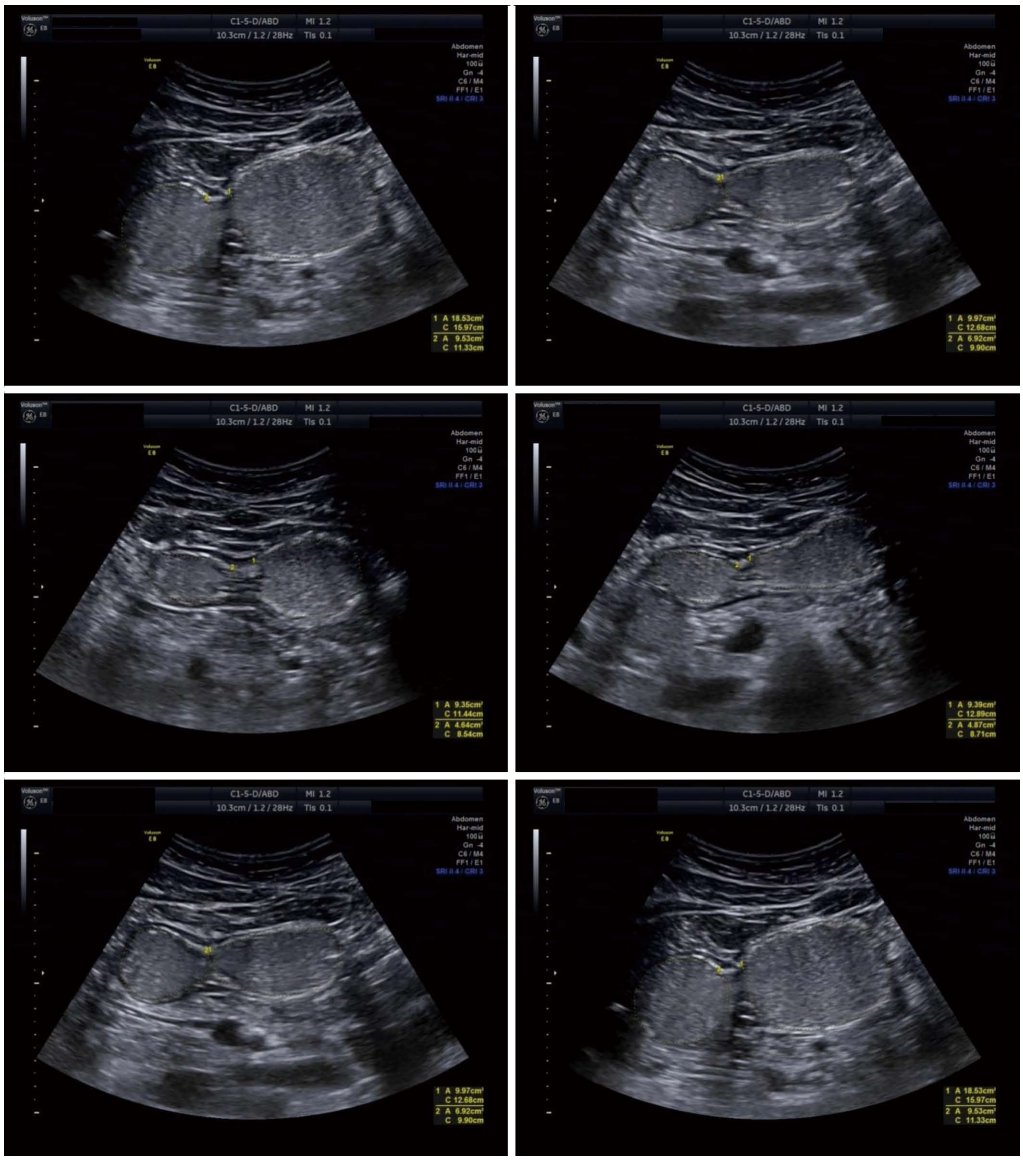

Figure 1 Gastric "figure-of-eight-like" double ring sign in different patients.

ment in the 3 groups of FD patients were compared by one-way analysis of variance (ANOVA test). The SNK-*Q* test was then performed for paired comparisons when the difference between groups was statistically significant. The gastric half-emptying times at the proximal end, distal end, and the whole gastric region after treatment among the 3 groups of patients were compared by ANOVA, followed by the SNK-*Q* test for paired comparisons.

RESULTS

Comparison of dyspepsia symptoms

The incidence of abdominal pain, epigastric burning sensation, abdominal distension, nausea, belching, and early satiety symptoms was significantly higher in patients in the FD group compared with the control group ($P < 0.05$). However, there was no significant difference in the incidence of vomiting between the 2 groups ($\chi^2 = 1.624$, $P = 0.203$), as shown in Table 2.

Comparison of gastric half-emptying conditions

Gastric half-emptying times at the proximal end, distal end, and the whole gastric region were significantly slower in the FD group than in the control group ($P < 0.05$, Table 3). As observed from the gastric emptying curve for the 2 groups, gastric contents in the proximal end presented a gradual downward trend in the control group, which slowed down between 40 min and 60 min. However, the rate of decline was slower in the FD group compared with the control group, and the decline between 40 and 60 min time points was significantly slower, presenting a plateau phase. The control group continued to present a slow downward trend in the gastric emptying curve at the distal end. However, the curve presented an upward and a downward trend in the FD group within the first 20 min after eating, and was slower than that in the

Groups	Gastric half-emptying time at the proximal end (min)	Gastric half-emptying time at the distal end (min)	Gastric half-emptying time at the whole gastric region (min)
FD group (n = 70)	93.7 ± 26.2	102.2 ± 26.4	102.1 ± 28.6
Control group (n = 72)	72.0 ± 14.3	87.5 ± 18.2	78.3 ± 14.1
t value	6.149	3.782	6.316
P value	0.000	0.000	0.000

FD: Functional dyspepsia.

control group. In the gastric emptying curve of the whole gastric region, the control group continued to present a slow downward trend. However, the curve for the FD group declined at different rates (Figure 2).

Relationship between symptoms of dyspepsia and gastric half-emptying time

There was no significant association of any of the symptoms with prolonged gastric half-emptying time at the proximal end (P > 0.05). However, abdominal distension, belching, and early satiety was associated with abdominal distension at the distal end (P < 0.05), and were risk factors for delayed gastric half-emptying time at the distal end (OR > 1). Abdominal distension and abdominal pain were associated with gastric half-emptying time of the whole gastric region (P < 0.05), and were risk factors for delayed gastric half-emptying of the whole gastric region (OR > 1, Table 4).

Total score of patients with symptoms of dyspepsia occurring before and after treatment

There was no statistically significant difference in total patient symptom scores before treatment among the 3 groups (F = 3.021, P = 0.291). However, the scores were lower after treatment than before treatment, and the difference was statistically significant (P < 0.05). There was a statistically significant difference in scores after treatment among the 3 groups (F = 3.162, P = 0.014). Pairwise comparisons showed total symptom scores after treatment were significantly lower in the *H. pylori* treatment group and *H. pylori*-negative group than in the conventional treatment group (*H. pylori* treatment group: Q = 2.259, P = 0.029; *H. pylori*-negative group: Q = 2.163, P = 0.037); however, there was no significant difference between the *H. pylori* treatment group and *H. pylori*-negative group (Q = 0.270, P = 0.791; Table 5).

Gastric half-emptying time after treatment

There was a statistically significant difference in gastric half-emptying time at the proximal end, distal end, and whole gastric region after treatment among the 3 groups ($P < 0.05$). Pairwise comparisons showed that gastric half-emptying times at the proximal end, distal end, and whole gastric region were significantly shorter in the *H. pylori*-negative group and *H. pylori* treatment group compared with the conventional treatment group ($P < 0.05$); while there was no significant difference between the *H. pylori* treatment group and *H. pylori*-negative group ($P > 0.05$, Table 6).

DISCUSSION

In patients with FD, although there is no organic disease, belching, nausea, abdominal pain, and other symptoms of dyspepsia can continue for more than 6 mo, and if symptoms persist for 3 mo or more, there is a greater impact on the quality of life[17-20]. The incidence of FD is about 20%, and is mostly caused by gastric motility disorders, including abnormal gastric emptying, stomach discomfort from reduced capacity, and gastric electrical rhythm abnormalities[21-24]. The stomach can be divided into 2 regions at the angulus, and the proximal and distal regions function differently to some extent. The proximal region mainly functions to receive and store food, and control liquid emptying. The distal region may conduct peristalsis to grind the food and mix it with the gastric juice[25-29]. Observation of gastric emptying by ultrasound is a simple method, does not cause injury, and is easily accepted by patients. Therefore, gastric emptying studies by ultrasound observation enable the comparison of the relationship between the symptoms of patients with FD. In this study, a comparative analysis was performed for gastric emptying and various common FD symptoms in the proximal end, distal end and full stomach. *H. pylori* infection affects the endocrine aspects of the smooth muscle in the human gastro-

intestinal tract, and this is generally considered to have a significant impact on the symptoms in patients with FD[30-32]. Therefore, in this study, *H. pylori*-positive and -negative symptoms and gastric emptying between healthy subjects and patients with FD were compared in order to observe the effects of *H. pylori* infection in FD patients.

The study revealed that the incidence of symptoms in the FD group, except vomiting, was high compared with the control group. Gastric half-emptying time at the proximal end, distal end, and the whole gastric region was slower in the FD group than in the control group. Abdominal distension, belching, and early satiety were associated with gastric half-emptying time at the distal end. Abdominal distension and abdominal pain were associated with gastric half-emptying time of the whole gastric region. Total symptom scores of patients in the 3 groups decreased after treatment. In the *H. pylori*-negative group and *H. pylori* treatment group, total symptom scores after treatment were lower compared with the conventional treatment group; and gastric half-emptying times at the proximal end, distal end, and the whole gastric region were shorter than in the conventional treatment group. However, there was no difference between the *H. pylori* treatment group and *H. pylori*-negative group. It can be observed that delayed gastric emptying and *H. pylori* infection have an important impact on the occurrence of symptoms in FD patients. As observed from the gastric emptying curve at the distal end after eating, the amount of food inside the stomach at the distal end increased and slowly declined. It is considered that this is because the proximal end of the stomach suffers from receptive dysfunction for food. When food increases, relaxation is delayed, resulting in regurgitation or the rapid discharge of food into the distal end, causing FD patients to have early satiety, abdominal distension, and other symptoms[33-36]. In addition, the abnormal distribution of food at the proximal and distal end of the stomach further affects the emptying of food, resulting in the occurrence of symptoms of dyspepsia[37].

After administration of drugs promoting gastric motility to patients, the clinical symptoms of FD patients were alleviated regardless of whether *H. pylori* infection was present or not. As observed, abnormal gastric motility is an important reason for the occurrence of FD symptoms. *H. pylori* eradication treatment to improve symptoms and gastric emptying of *H. pylori*-positive patients is better than no *H. pylori* eradication treatment. It has been considered that *H. pylori* participate in the occurrence of FD symptoms through a variety of mechanisms[9]. This includes *H. pylori* infections in the gastrointestinal tract causing an increase in mechanical expansion sensitivity[38,39]. *H. pylori* infection can directly lead to increased gastric acid secretion or promote gastric acid secretion by increasing gastrin, leading to abdominal pain, epigastric burning sensations, and other symptoms[40]. *H. pylori* infection can cause gastrointestinal hormone secretion disorders, such as increased somatostatin and cholecystokinin, leading to an increase in the incidence of symptoms in patients with FD[41-44]. *H. pylori* infection affects gastric emptying, and influencing factors include increased release of leukotrienes[45,46], or nitric oxide and other substances. This leads to gastrointestinal smooth muscle relaxation and delayed gastric emptying, or an increase in 5-HT and other substances affecting gastrointestinal smooth muscle contraction, resulting in gastrointestinal tract motility disorders[47-50].

As the amount of samples collected in this study was small and it was a single center study, the relationship between symptoms of dyspepsia in patients with FD, gastrointestinal tract motility disorders, and *H. pylori* infections requires further larger scale investigations to further determine the pathophysiological mechanisms in order to provide good guidance for clinical diagnosis and treatment of patients with FD.

In summary, gastric emptying is delayed to some extent in patients with FD. For patients infected with *H. pylori*, *H. pylori* eradication treatment helps to improve dyspepsia symptoms. This may be a reasonable choice for therapy in clinical practice.

COMMENTS

Background

Functional dyspepsia (FD) is the most common functional gastrointestinal disorder, but the etiology remains unclear. Patients with FD often appear to have abdominal distension, belching, nausea, and other symptoms of dyspepsia. In severe cases, it seriously impacts their daily life. FD is related to a variety of causes that include gastrointestinal motility disorders, gastrointestinal hormone secretion abnormalities, or *Helicobacter pylori* (*H. pylori*) infection. However whether there is a need for eradication therapy for *H. pylori* in FD patients remains controversial. Therefore, the study investigated the relationship between symptoms of dyspepsia and gastric half-emptying time in FD patients, and whether *H. pylori* treatment could alleviate the symptoms, to provide a basis for clinical treatment.

Research frontiers

In recent years, FD incidence has gradually increased and its cause is unknown. Studies have reported that *H. pylori* infection can cause gastrointestinal hormone secretion disorders such as increased somatostatin and cholecystokinin secretion, leading to a corresponding increase in the incidence of symptoms in patients with FD. The symptoms of FD are mostly caused by gastric motility disorders, including abnormal gastric emptying, stomach discomfort from reduced capacity, and gastric electrical rhythm abnormalities. The use of ultrasound to observe gastric emptying, and compare symptoms score, is a simple and effective method.

Innovations and breakthroughs

FD is mostly caused by gastric motility disorders including abnormal gastric emptying. Gastric emptying observation by ultrasound is a simple and effective method, does not cause injury, and is easily accepted by patients. Using symptom scoring for a variety of FD symptoms, a more comprehensive evaluation of symptoms can be made.

Applications

This study demonstrated that patients with FD have delayed gastric emptying. *H. pylori* infection treatment helps to improve symptoms of dyspepsia. FD is closely associated with abnormal gastric emptying and *H. pylori* infection. This provides a basis for clinical treatment with gastrointestinal motility drugs and *H.*

pylori eradication therapy in FD patients.

Peer-review

This study compared and analyzed the gastric emptying and symptoms between FD patients and healthy people; *H. pylori* positive group, *H. pylori*-negative group and the conventional treatment. It demonstrates that patients with FD have delayed gastric emptying. *H. pylori* infection treatment helps to improve symptoms of dyspepsia. Provide a reliable basis to applications gastrointestinal drugs and drugs to cure *H. pylori* for the treatment of patients with *H. pylori*.

Abstract

AIM: To determine the efficacy of calcium supplementation in reducing the recurrence of colorectal adenomas.

METHODS: We conducted a systematic review and meta-analysis of published studies. We searched PubMed, Scopus, the Cochrane Library, the WHO International Clinical Trials Registry Platform, and the ClinicalTrials.gov website, through December 2015. Randomized, placebo-controlled trials assessing supplemental calcium intake for the prevention of recurrence of adenomas were eligible for inclusion. Two reviewers independently selected studies based on predefined criteria, extracted data and outcomes (recurrence of colorectal adenomas, and advanced or "high-risk" adenomas), and rated each trial's risk-of-bias. Between-study heterogeneity was assessed, and pooled risk ratio (RR) estimates with their 95% confidence intervals (95%CI) were calculated using fixed- and random-effects models. To express the treatment effect in clinical terms, we calculated the number needed to treat (NNT) to prevent one adenoma recurrence. We also assessed the quality of evidence using GRADE.

RESULTS: Four randomized, placebo-controlled trials met the eligibility criteria and were included. Daily doses of elemental calcium ranged from 1200 to 2000 mg, while the duration of treatment and follow-up of participants ranged from 36 to 60 mo. Synthesis of intention-to-treat data, for participants who had undergone follow-up colonoscopies, indicated a modest protective effect of calcium in prevention of adenomas (fixed-effects, RR = 0.89, 95%CI: 0.82-0.96; random-effects, RR = 0.87, 95%CI: 0.77-0.98; high quality of evidence). The NNT was 20 (95%CI: 12-61) to prevent one colorectal adenoma recurrence within a period of 3 to 5 years. On the other hand, the association between calcium treatment and advanced adenomas did not reach statistical significance (fixed-effects, RR = 0.92, 95%CI: 0.75-1.13; random-effects, RR = 0.92, 95%CI: 0.71-1.18; moderate quality of evidence).

CONCLUSION: Our results suggest a modest chemopreventive effect of calcium supplements against recurrent colorectal adenomas over a period of 36 to 60 mo. Further research is warranted.

Key words: Calcium; Colorectal adenoma; Recurrence; Cancer chemoprevention; Colorectal cancer; Systematic review; Meta-analysis; Polyp

Core tip: To assess the efficacy of calcium supplementation in reducing the recurrence of colorectal adenomas, we conducted a systematic review and meta-analysis of randomized, placebo-controlled trials. We found a modest protective effect of calcium in prevention of adenomas (fixed-effects, RR = 0.89, 95%CI: 0.82-0.96; random-effects, RR = 0.87, 95%CI: 0.77-0.98; high quality of evidence). On the other hand, the association between calcium treatment and advanced ("high-risk") colorectal adenomas was not statistically significant (fixed-effects, RR = 0.92, 95%CI: 0.75-1.13; random-effects, RR = 0.92, 95%CI: 0.71-1.18; moderate quality of evidence). Further targeted research is warranted.

Calcium supplementation for the prevention of colorectal adenomas: A systematic review and meta-analysis of randomized controlled trials. *World J Gastroenterol* 2016; 22(18): 4594-4603 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4594.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4594

INTRODUCTION

Colorectal cancer is a tumour resulting from a complex interaction between inherited susceptibility and environmental factors, as demonstrated by genetic, experimental, and epidemiological studies[1-3]. It represents the third most common malignancy, and the fourth most common cause of cancer deaths globally, accounting for 1.35 million new cases and 0.7 million deaths annually[4].

The magnitude of the colorectal cancer problem, and the failure of advanced disease chemotherapy to effect significant reductions in the respective mortality rates, indicate that an intensive approach to the prevention of this disease is necessary. Accordingly, research on chemopreventive agents for colorectal cancer has received much attention over the last 30 years. Among several promising compounds (including vitamins A, C, and E, folate and other B vitamins, aspirin, sulindac and other non-aspirin non-steroidal anti-inflammatory drugs, statins, bisphosphonates, selenium, and fiber)[5-16], calcium has also been studied. It was proposed by Newmark *et al*[17] that calcium binds bile acids in the bowel lumen, inhibiting their well-known proliferative and carcinogenic effects. In addition, calcium has demonstrated a direct antiproliferative effect on cells, as well as promoting cellular differentiation and death (apoptosis)[18]. Evidence from epidemiologic studies also suggests that higher calcium intake may reduce the risk of colorectal cancer[19].

Most colorectal tumors develop from adenomas arising from the lining of the intestine. Progression - described as the adenoma-cancer (or polyp-cancer) sequence - is characterized by morphological and histological changes[20]. For instance, a small tubular adenoma acquires villoglandular characteristics as it grows. On the molecular level, the adenoma-cancer sequence reflects an accumulation of genomic defects. Generally, a single adenoma has a risk of progressing into neoplasia of 0.25% per year[21], depending on its size, location, histological type, and the presence of dysplasia.

The standard treatment for colorectal adenomas is endoscopic resection that interrupts the progression to invasive disease[22]. However, even after polypectomy, rates of adenoma recurrence may be up to 50% within 3 years of follow-up[23,24]. That is why research on colorectal cancer prevention has often focused on prevention of recurrent adenomas. Assuming that the effects of chemopreventive agents on adenomas reflect those on cancer, this endpoint provides a convenient surrogate for the study of colorectal cancer prevention[25,26].

Contrary to expectations, the recent randomized placebo-controlled trial published by Baron *et al*[27] showed that daily supplementation with 1200 mg of calcium did not significantly reduce the risk of colorectal adenomas over a time period of 3 to 5 years. In view of earlier promising clinical trial data[28,29], we sought to obtain a comprehensive snapshot of the existing evidence on the clinical efficacy of calcium supplementation for the prevention of colorectal adenomas. Therefore, we carried out an updated

systematic review and meta-analysis of randomized controlled trials (RCTs) published in the peer-reviewed literature.

MATERIALS AND METHODS

Data sources and search strategy

To identify the studies of interest, we systematically searched the PubMed and Scopus bibliographic databases from their inception to 15 December 2015 (date of final search). Search terms included: "calcium" combined with "adenoma" or "polyp". The search was limited to RCTs and human studies. No language restrictions were applied.

We also searched the Cochrane Library for any recently published systematic review on the subject, the WHO International Clinical Trials Registry Platform, and the *ClinicalTrials.gov* website, for completed but unpublished studies.

Two authors (Bonovas S and Lytras T) independently reviewed titles and abstracts to identify studies for inclusion. The full texts of the selected articles were carefully examined for eligibility, and their reference lists (as well as those of relevant systematic reviews[30-33]) were also investigated to identify any studies missed by the electronic database search.

Selection criteria

Studies were eligible for inclusion if they were randomized, placebo-controlled trials assessing supplemental calcium intake for the prevention of recurrent colorectal adenomas. All studies had to include follow-up evaluation (*i.e.*, endoscopy) to confirm the presence or absence of adenomas. If the results of a study were reported in multiple publications and/or at multiple time-points, we selected the most updated publication and extracted the data for the maximum follow-up time reported, as long as it remained a randomized trial and fully reported the outcomes of interest.

Studies were excluded if they were observational; did not report (or provided insufficient data to calculate) the outcomes of interest; or evaluated multi-interventional therapies, in which the effect of calcium treatment could not be separated out. We did not apply restrictions on eligibility according to dosage, or duration of calcium supplementation.

Types of outcomes and data extraction

We analyzed the following two outcomes: (1) recurrence of colorectal adenomas (at least one adenoma detected during follow-up colonoscopies); and (2) recurrence of advanced or "high-risk" adenomas (defined as those that have a diameter $\geqslant$ 10 mm, villous or tubulovillous features, or severe dysplasia).

Data extraction was independently undertaken by two authors (Bonovas S and Lytras T) using a predesigned form. The following information was extracted from each study: first author, journal and year of publication, study design and duration, number and characteristics of participants, intervention parameters, and number of subjects with the outcomes of interest reported for the intervention and control groups.

Disagreements were resolved *via* consensus, referring back to the original articles.

Assessment of risk of bias

We assessed the risk of bias (RoB) in included studies using the Cochrane Collaboration's tool[34], which addresses the following key-domains: sequence generation; allocation concealment; blinding; incomplete outcome data; selective outcome reporting; and other sources of bias, such as extreme baseline imbalances in prognostic factors, etc. These items were considered for RoB assessment and were classified as "adequate" (low RoB), "inadequate" (high RoB), or "unclear" (uncertain RoB).

Studies reporting adequate procedures in all domains were classified as "low RoB", studies with inadequate procedures in at least one domain were classified as "high RoB", and those with unclear procedures in one or more domains were classified as "uncertain RoB". Discrepancies among reviewers were discussed and agreement was reached by consensus.

Data synthesis and analysis

The risk ratio (RR) was used to measure treatment effects. Study-level RRs along with their 95%CI were calculated using intention-to-treat data for study participants who completed the follow-up evaluation (*i.e.*, follow-up colonoscopies).

Meta-analyses were performed twice, assuming a fixed-effects model (Mantel-Haenszel approach[35]) and a random-effects model (DerSimonian-Laird approach[36]). Under a fixed-effects model, we assume that the included studies share a common true effect, and the pooled effect is an estimate of the common effect size. Under a random-effects model, we assume that the true effects vary between the studies, and the pooled effect is a weighted average of the effects reported in the different studies. The random-effects model often leads to broader confidence intervals (*i.e.*, it is a more conservative approach)[37].

The between-study heterogeneity was evaluated using the Cochran's Q test[38], with a 0.10 level of significance, and the I-squared metric[39], which describes the percentage of variation across studies that is due to heterogeneity rather than chance. I-squared values of less than 25%, 25%-50%, or higher than 50% indicate low, moderate, or high heterogeneity, respectively[40].

Publication bias was not assessed, because the relevant statistical tests lack power when the number of included studies is limited[41].

To express the treatment effect in clinical terms, we calculated the number needed to treat (NNT) to prevent one adenoma recurrence using the Mantel-Haenszel

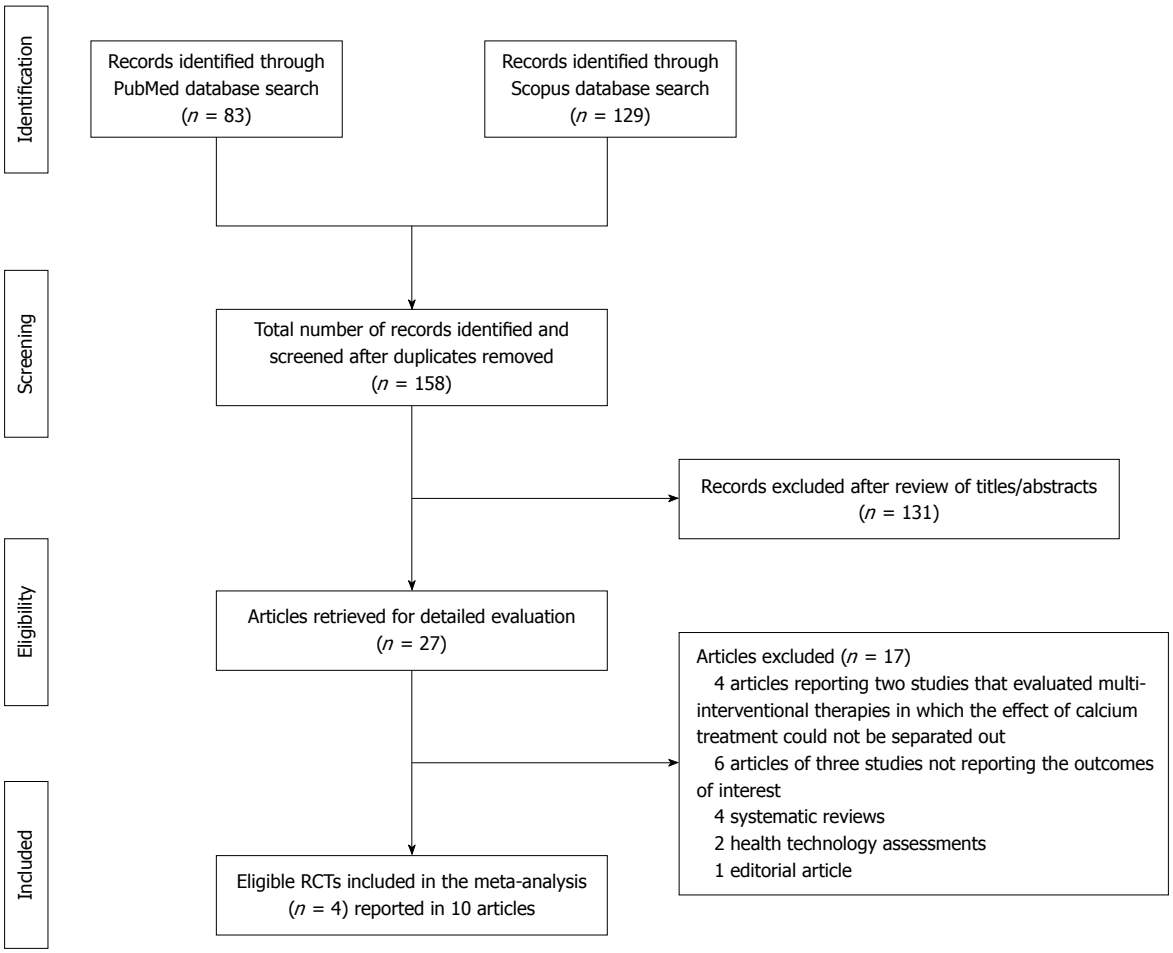

Figure 1 Summary of the evidence search and selection process (flow diagram). RCTs: Randomized controlled trials.

fixed-effects risk difference (risk in the placebo group minus risk in the calcium group), in cases in which a statistically significant RR was detected. The NNT is the inverse of this risk difference.

The quality of evidence (confidence in the synthesized effect estimates) was assessed using GRADE (Grading of Recommendations Assessment, Development and Evaluation)[42].

For all statistical analyses, we used the R software[43], version 3.2.2, and the "meta" package for R[44], version 4.3-0. All *P*-values are two-tailed. For all tests (except for heterogeneity), a *P*-value less than 0.05 indicates statistical significance.

Our study was performed in accordance with the Cochrane Handbook for intervention reviews[41], and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) statement[45].

The study did not involve any experiment on humans or animals, thus an ethical approval was not required.

RESULTS

Search results

A summary of the literature search and selection process is shown in Figure 1 (Flow diagram). Four randomized studies of calcium supplementation met the eligibility criteria and were included: (1) the Vitamin D/Calcium Polyp Prevention Study[27,46]; (2) the Southwest Oncology Group (SWOG) Calcium Chemoprevention Pilot Study[47,48]; (3) the European Cancer Prevention Organisation (ECP) Calcium Fibre Polyp Prevention Study[28,49,50]; and (4) the Calcium Polyp Prevention Study[29,51,52].

They were multicenter, randomized, placebo-controlled trials of supplementation with calcium for the prevention of colorectal adenomas. Daily doses of elemental calcium ranged from 1200 to 2000 mg, while the duration of treatment and follow-up of patients ranged from 36 to 60 mo. A summary of the trials' characteristics is given in Table 1.

Patients underwent endoscopy at baseline; subsequent colonoscopies were then undertaken to assess adenoma recurrence during the follow-up. The studies differ in that the SWOG Calcium Chemoprevention Pilot Study[47,48] recruited patients with completely resected colorectal cancer, while all the other studies included participants with colorectal adenomas removed before enrollment. All studies reported the number of subjects with adenomas (and advanced adenomas) identified during the follow-up

Table 1 Randomized, double-blind, placebo-controlled trials of calcium supplementation for prevention of colorectal adenomas

Study or subgroup[1]	Participants randomized	Mean age (yr)	Women	Follow-up (mo)	Amount of elemental calcium supplemented (mg/d)
Vitamin D/Calcium Polyp Prevention Study[27]	1675	59	15%	36 or 60	1200
SWOG Calcium Chemoprevention Pilot Study[47]	220	68[2]	37%	60	1800
ECP Calcium Fibre Polyp Prevention Study[28]	439	59	37%	36	2000
Calcium Polyp Prevention Study[51,52]	930	61	28%	48	1200

[1]For the Vitamin D/Calcium Polyp Prevention Study, only a subgroup was taken into account in the analysis; [2]Median value. ECP: European Cancer Prevention Organisation; SWOG: Southwest Oncology Group.

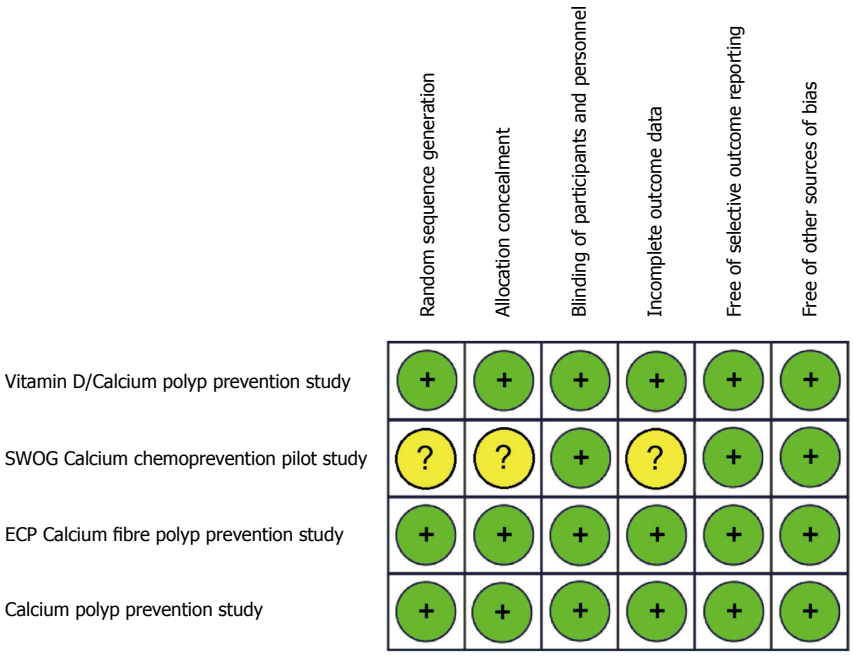

Figure 2 Risk-of-bias assessment for the studies included in the meta-analysis. Green (+): Low risk-of-bias; Yellow (?): Unclear risk-of-bias. ECP: European Cancer Prevention Organisation; SWOG: Southwest Oncology Group.

endoscopies; thus, we were able to conduct a post hoc analysis of these clinical trials, calculate RRs for the outcomes of interest, and incorporate them in the meta-analyses.

Another two clinical trials were identified, but did not meet the eligibility criteria, and were excluded. The first study - included in two previous systematic reviews[31,32] - examined a mixed intervention consisting of calcium, β-carotene, vitamin C, vitamin E, and selenium, compared with placebo[53,54]. The second clinical trial, which was evaluating a combination treatment of aspirin, calcitriol, and calcium, compared with placebo, was terminated early because no positive tendency was shown in a preplanned interim analysis[55,56]. In both studies, the effect of calcium could not be separated out; thus, they were not included in the evidence synthesis.

Risk of bias in included studies

The Vitamin D/Calcium Polyp Prevention Study[27,46], the ECP Calcium Fibre Polyp Prevention Study[28,49,50], and the Calcium Polyp Prevention Study[29,51,52], were judged to be at low RoB: their allocation sequences appeared to be adequately generated and concealed; patients and staff were masked; participants excluded from the analyses (those who had not undergone follow-up colonoscopy) were balanced in numbers and reasons across intervention groups; and the outcomes of interest for this review were fully reported.

The SWOG Calcium Chemoprevention Pilot Study[47,48] was considered to have uncertain RoB, because information was insufficient to permit judgement about the sequence generation process, the method used to conceal allocation, and attritions/exclusions.

Quality assessment items are presented in Figure 2.

Results of quantitative synthesis

Recurrence of colorectal adenomas: Intention-to-treat data for 2984 participants, who underwent follow-up colonoscopies, were analyzed. Each one of the four included trials reported a lower recurrence rate of colorectal adenomas in the calcium group, as compared to the placebo group; however, the results only from two studies (the Calcium Polyp Prevention

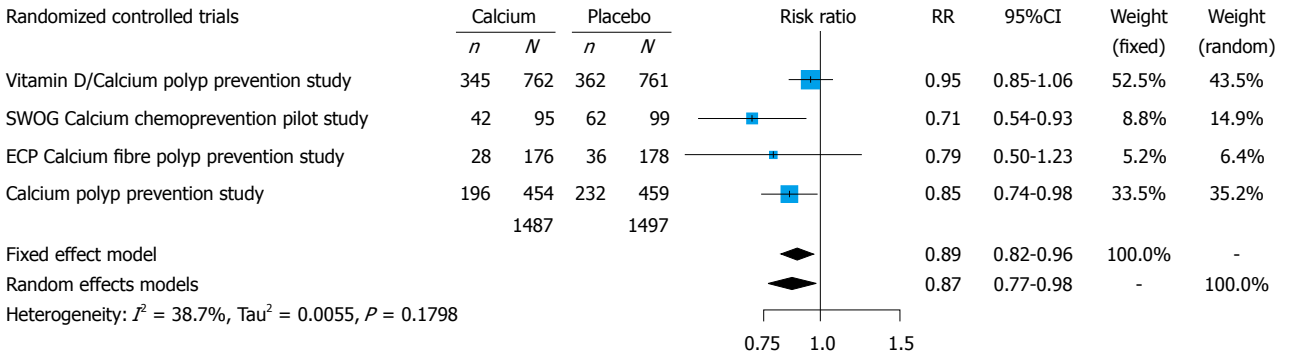

Figure 3 Forest plot for adenomas: results from individual studies and meta-analysis. For the analysis we used intention-to-treat data for patients who underwent follow-up evaluation (follow-up colonoscopies). ECP: European Cancer Prevention Organisation; SWOG: Southwest Oncology Group; *n*: Number of subjects with at least one adenoma detected during the follow-up evaluation; *N*: Number of subjects who underwent follow-up evaluation; RR: Risk ratio.

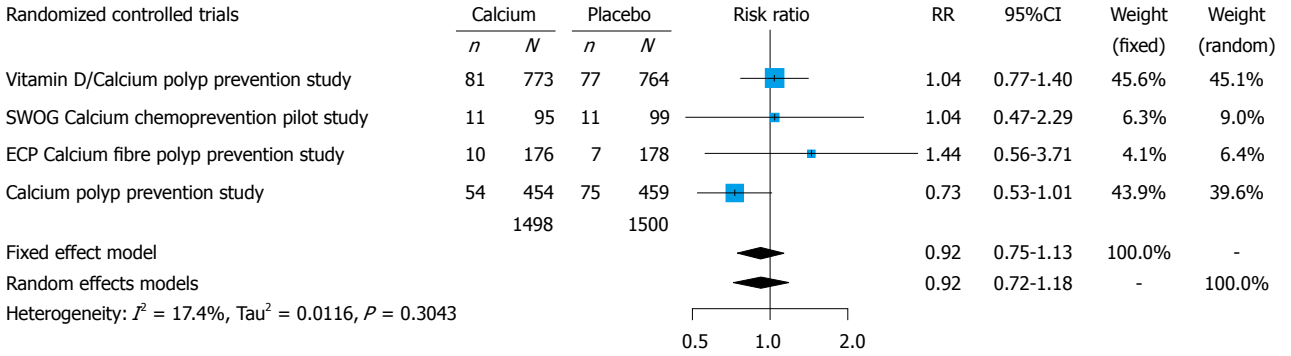

Figure 4 Forest plot for advanced adenomas: results from individual studies and meta-analysis. For the analysis we used intention-to-treat data for patients who underwent follow-up evaluation (follow-up colonoscopies). ECP: European Cancer Prevention Organisation; SWOG: Southwest Oncology Group; *n*: Number of subjects with at least one adenoma detected during the follow-up evaluation; *N*: Number of subjects who underwent follow-up evaluation; RR: Risk ratio.

Study[29,51,52] and the SWOG Calcium Chemoprevention Pilot Study[47,48]) were statistically significant. The overall recurrence rate, on all four RCTs, was 41.1% in calcium groups and 46.2% in placebo groups, over a treatment and follow-up period of 3 to 5 years.

We found a statistically significant modest protective effect (about 10%-15% risk reduction) of calcium supplements in the prevention of colorectal adenomas, both under the assumption of a fixed-effects model (RR = 0.89, 95%CI: 0.82-0.96) and a random-effects model (RR = 0.87, 95%CI: 0.77-0.98). The RRs with their 95%CIs for the individual studies, and the pooled results, are shown in Figure 3. The Cochran's *Q* test had a *P*-value of 0.18 and the corresponding I-squared value was 39%, indicating moderate heterogeneity between the studies.

For patients treated with calcium supplements in the included trials, the NNT was 20 (95%CI: 12-61) to prevent one colorectal adenoma recurrence within a period of 3 to 5 years.

Recurrence of advanced (high-risk) adenomas: We analyzed data for 2998 participants, who completed their follow-up evaluations (colonoscopies). None of the studies reported statistically significant results for advanced adenomas. Their overall occurrence, on all four RCTs, was 10.4% in calcium groups and 11.3% in placebo groups.

In meta-analysis, the association between calcium treatment and advanced adenomas did not reach statistical significance, either assuming a fixed-effects model (RR = 0.92, 95%CI: 0.75-1.13) or a random-effects model (RR = 0.92, 95%CI: 0.71-1.18). The RRs with their 95%CIs for the individual studies, and the pooled results, are presented in Figure 4. The Cochran's *Q* test had a *P*-value of 0.30 and the corresponding I-squared value was 17%, indicating low heterogeneity between the studies.

Quality of the evidence

Using the GRADE approach[42], our confidence in the synthesized evidence is "high" for the first outcome (adenomas), but "moderate" for the second one (advanced adenomas), for the following reasons: (1) the data were derived from RCTs, which are considered as the gold standard for assessing drugs[57]; (2) the synthesized effect estimates are precise for adenomas, but imprecise for advanced adenomas; (3) heterogeneity is low-to-moderate across studies; and (4) publication bias is not likely.

A high quality of evidence means that "we are very confident that the true effect lies close to that of the

Table 2 Summary of findings

	Illustrative comparative risks (95%CI)		
	Assumed risk Placebo	Corresponding risk Calcium	
Recurrence of adenomas (follow-up: 3 to 5 yr)	462 per 1000	411 per 1000 (379 to 444)	Relative effect (95%CI): RR = 0.89 (0.82-0.96) No. of patients with follow-up evaluation: 2984 No. of RCTs: 4 Quality of evidence (GRADE): ++++ (high)
Advanced adenomas (follow-up: 3 to 5 yr)	113 per 1000	104 per 1000 (85 to 128)	Relative effect (95%CI): RR = 0.92 (0.75-1.13) No. of patients with follow-up evaluation: 2998 No. of RCTs: 4 Quality of evidence (GRADE): +++- (moderate)

(1) the basis for calculating the assumed risk is the overall event rate across the trial groups receiving placebo; (2) the corresponding risk (calcium group) is based on the assumed risk and the relative effect estimate (risk ratio); (3) the relative effect estimate and its 95%CI come from a Mantel-Haenszel fixed-effects meta-analytic model; and (4) the overall quality of evidence is judged as "high" for recurrence of adenomas, and "moderate" for advanced adenomas. A high quality of evidence means that "we are very confident that the true effect lies close to that of the estimate of the effect", while a moderate quality of evidence means that "we are moderately confident in the effect estimate. The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different"[58]. Population: Patients with colorectal adenomas removed before enrollment. Intervention: Calcium supplementation (1200-2000 mg/d) to prevent recurrence of adenomas. Comparison: Placebo. RR: Risk ratio; GRADE; Grading of Recommendations Assessment, Development and Evaluation; RCTs: Randomized controlled trials.

estimate of the effect", while a moderate quality of evidence means that "we are moderately confident in the effect estimate. The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different"[58].

A summary of findings and strength of evidence is shown in Table 2.

DISCUSSION

Chemoprevention is a promising area of cancer research focusing on prevention of malignancies through pharmacological, biological, and nutritional interventions[59]. As first defined by Sporn[60], cancer chemoprevention uses natural, synthetic, or biologic agents to reverse, suppress, or prevent either the initial phase of carcinogenesis or the progression of malignant cells to cancer[61-65]. Regarding chemoprevention of colorectal cancer, several studies suggest that calcium may have chemopreventive potential[66-72]. Our knowledge on the underlying mechanism is incomplete. It has been proposed that calcium may protect against neoplasia in the large bowel by binding bile and fatty acids, thus decreasing their proliferative and carcinogenic effects on colonic epithelial cells[17].

Meta-analysis is a statistical methodology for combining the findings from independent studies[73]. We undertook this systematic review and meta-analysis to assess and synthesize the existing evidence on the efficacy of calcium supplements in prevention of colorectal adenomas.

In the recent literature, we have identified three systematic reviews with meta-analyses of RCTs examining the efficacy of calcium supplementation for the prevention of colorectal adenomas[31-33]. Carroll *et al*[31] and Shaukat *et al*[32] performed similar three-trial meta-analyses including the ECP Calcium Fibre Polyp Prevention Study[28,49,50], the Calcium Polyp Prevention Study[29,51,52], as well as the Hofstad *et al*[53,54] study that examined a mixed intervention consisting of calcium, β-carotene, vitamin C, vitamin E, and selenium, compared with placebo. Both meta-analyses found a significant 20% risk reduction associated with calcium. On the other hand, the third meta-analysis by Weingarten *et al*[33] reported a larger protective effect for calcium (OR = 0.74, 95%CI: 0.58-0.95) including only the ECP Calcium Fibre Polyp Prevention Study[28,49,50] and the Calcium Polyp Prevention Study[29,51,52], and excluding the Hofstad *et al*[53,54] study because of the use of antioxidants as a co-intervention. However, Weingarten *et al*[33] used the numbers of randomized subjects, rather than the numbers of subjects who completed the follow-up evaluation (colonoscopy), as the denominator in the analysis. This approach assumes that none of the subjects lost to follow-up experienced the outcomes[74,75]; however, this assumption does not appear to be valid.

In our study, a rigorous and extensive literature search was conducted; four eligible randomized trials were identified (the Vitamin D/Calcium Polyp Prevention Study[27,46], the SWOG Calcium Chemoprevention Pilot Study[47,48], the ECP Calcium Fibre Polyp Prevention Study[28,49,50], and the Calcium Polyp Prevention Study[29,51,52]); two further trials were excluded (the Hofstad *et al*[53,54] study and the Pommergaard *et al*[55] study[56]) because they evaluated multi-interventional treatments where the effect of calcium could not be separated out; data extraction was carefully undertaken by two independent investigators; and the evidence was synthesized using appropriate statistical techniques. Our results indicate a modest chemopreventive effect of calcium supplements against colorectal adenomas (approximately 10%-15% risk reduction; high quality

of evidence). However, this effect was not statistically significant for the advanced (high-risk) adenomas (imprecise pooled effect estimates; moderate quality of evidence). These findings extend the results of the primary trials and have important implications for future research.

The strengths of this systematic review should be weighed against a number of limitations. Firstly, the number of available studies was limited. Secondly, a colorectal adenoma typically requires 10-15 years to evolve into clinically invasive cancer[76]. Therefore, we did not examine whether calcium supplementation affects the progression of adenomas into invasive cancer. To address this question, studies with longer durations of treatment and follow-up are necessary. Thirdly, we could not analyze whether the dose of calcium affected the results; however, the dose range was relatively narrow in the included trials (range: 1200-2000 mg of elemental calcium daily).

Despite these limitations, our study is the most up-to-date meta-analysis on the topic and adheres to the recommended PRISMA reporting standards. Calcium does not appear to strongly reduce the risk of adenomas; however, there is high quality evidence suggesting a modest overall risk reduction, which might be a composite of an effect of calcium supplements in some populations (*e.g.*, the non-obese[27]) and some adenoma types (*e.g.*, the right-colon adenomas[28]), and lack of effect in others. Therefore, we consider that the recent negative results published by Baron et *al*[27] is not the end of the road for calcium as a potential chemopreventive agent against colorectal carcinoma; rather a new research approach is warranted. There is good reason to focus again on basic research, and perform clinical and epidemiologic studies to answer questions related to dosing and duration of treatment, and identify populations for whom calcium might be particularly beneficial for prevention of adenomas and colorectal cancer.

ACKNOWLEDGMENTS

We would like to thank Dr. Petros Kopterides, MD, PhD, University of Pittsburgh, for language revision.

COMMENTS

Background

Colorectal cancer is the 3rd most common malignancy and the 4th most common cause of cancer deaths globally, with 1.35 million new cases and 0.7 million deaths annually. Most colorectal malignancies develop from adenomas arising from the lining of the intestine. That is why research on colorectal cancer prevention has often focused on prevention of recurrent adenomas.

Research frontiers

It has been suggested that calcium binds bile acids in the bowel lumen, inhibiting their well-known proliferative and carcinogenic effects. Calcium has also demonstrated a direct antiproliferative effect on cells, as well as promoting cellular differentiation and apoptosis.

Innovations and breakthroughs

Contrary to expectations, the recent randomized controlled trial published by Baron *et al* showed that daily supplementation with 1200 mg of calcium did not significantly reduce the risk of colorectal adenomas over a period of 3 to 5 years. In view of earlier promising clinical data, the authors sought to obtain a comprehensive picture of the evidence by conducting a systematic review and meta-analysis of randomized controlled trials.

Applications

The results show a modest chemopreventive effect of calcium supplements against recurrent colorectal adenomas. Further clinical and epidemiological research is warranted to answer questions related to dosing and duration of treatment, and identify populations for whom calcium might be particularly beneficial.

Terminology

Meta-analysis is a statistical methodology for combining the findings from independent studies.

Peer-review

This study presented the effect of calcium supplementation on colorectal adenoma recurrence through a meta-analysis of clinical trials. This is a valuable paper on secondary adenoma prevention in the colon. The authors give a comprehensive view of an important clinical topic.

Abstract

Pseudo-Meigs' syndrome associated with colorectal cancer is extremely rare. We report here a case of pseudo-Meigs' syndrome secondary to metachronous ovarian metastases from colon cancer. A 65-year-old female with a history of surgery for transverse colon cancer and peritoneal dissemination suffered from metachronous ovarian metastases during treatment with systemic chemotherapy. At first, neither ascites nor pleural effusion was observed, but she later complained of progressive abdominal distention and dyspnea caused by rapidly increasing ascites and pleural effusion and rapidly enlarging ovarian metastases. Abdominocenteses were repeated, and cytological examinations of the fluids were all negative for malignant cells. We suspected pseudo-Meigs' syndrome, and bilateral oophorectomies were performed after thorough informed consent. The patient's postoperative condition improved rapidly after surgery. We conclude that pseudo-Meigs' syndrome should be included in the differential diagnosis of massive or rapidly increasing ascites and pleural effusion associated with large or rapidly enlarging ovarian tumors.

Key words: Pseudo-Meigs' syndrome; Colon cancer; Ascites; Pleural effusion; Ovarian metastasis

Core tip: Pseudo-Meigs' syndrome associated with colorectal cancer is extremely rare. Here, we report a case of this syndrome secondary to metachronous

ovarian metastases from transverse colon cancer. This patient complained of progressive abdominal distention and dyspnea preoperatively, but her postoperative condition improved rapidly after bilateral oophorectomies. We conclude that pseudo-Meigs' syndrome should be included in the differential diagnosis of massive or rapidly increasing ascites and pleural effusion associated with large or rapidly enlarging ovarian tumors.

Pseudo-Meigs' syndrome secondary to metachronous ovarian metastases from transverse colon cancer. *World J Gastroenterol* 2016; 22(18): 4604-4609 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4604.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4604

INTRODUCTION

Meigs' syndrome is defined by the presence of a benign ovarian tumor with ascites and pleural effusion that resolve after removal of the tumor[1]. The ovarian tumors in Meigs' syndrome are fibromas or fibroma-like tumors, and other benign or malignant pelvic tumors associated with ascites and pleural effusion are described as pseudo-Meigs' syndrome[2]. Pseudo-Meigs' syndrome associated with colorectal cancer is extremely rare, and the etiology of ascites and pleural effusion in this syndrome remains unknown. We describe here a case of pseudo-Meigs' syndrome secondary to metachronous ovarian metastases from transverse colon cancer and discuss the etiology of the ascites and pleural effusion in this syndrome.

CASE REPORT

A 65-year-old female with a history of surgery for ileus due to transverse colon cancer was admitted to our department for the induction of oxaliplatin-based chemotherapy. During the previous surgery, we had found numerous nodules of peritoneal dissemination, each 1 mm in size under the right diaphragm and in the pelvis, as well as sparsely distributed nodules of similar size on the mesentery of the small intestine. Furthermore, a disseminated nodule 5 mm in size had been observed in the greater omentum. We had performed right hemicolectomy with ileocolic anastomosis and omentectomy. Pathologically, moderately differentiated adenocarcinoma had been observed in the colonic tumor and in the resected nodule in the omentum, and no lymph node metastasis had been observed. After 1 year and 3 mo of treatment with irinotecan-based chemotherapy, computed tomography (CT) examination performed 22 d before admission revealed bilateral enlarged ovaries with solid and cystic components, suggesting bilateral ovarian metastases (Figure 1A). Although neither ascites nor pleural effusion had been observed in the CT examination, the patient had already gained more than 4 kg, and a moderate amount of ascites had been identified by an abdominal ultrasound examination performed 9 d before admission. Four days after admission, she complained of abdominal distention and bilateral edema of the legs, and an abdominal ultrasound examination completed on the same day identified massive ascites and a small amount of bilateral pleural effusion. She soon became unable to eat because of abdominal distention. She also complained of progressive dyspnea, and at worst, her oxygen saturation was 88% in room air. CT examination performed 26 d after admission showed a large amount of ascites and pleural effusion with left-side predominance (Figure 1B and C). Bilateral

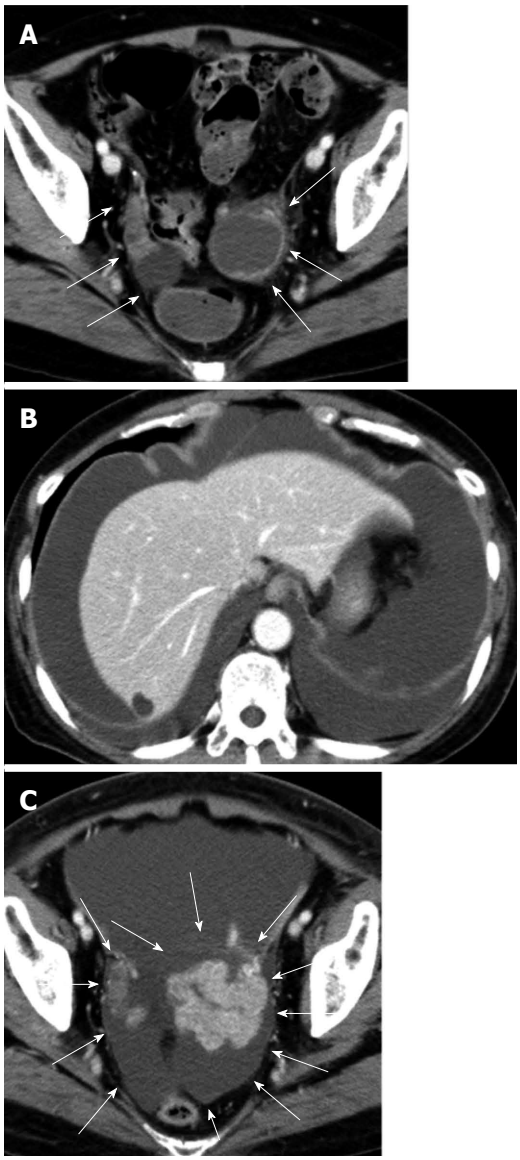

Figure 1 Computed tomography of the abdomen. A: The examination performed 22 d before admission showed bilateral enlarged ovaries with solid and cystic components (arrows). Ascites was not visible; B and C: The examination performed 26 d after admission revealed massive ascites and pleural effusion and rapid enlargement of ovarian tumors (arrows).

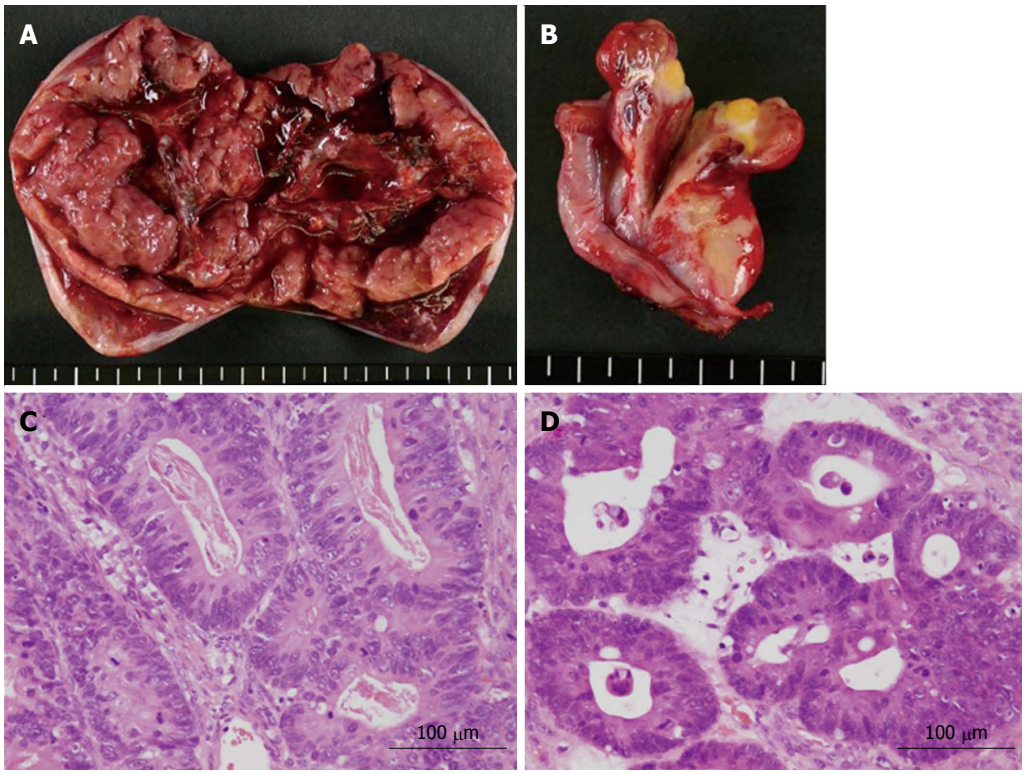

Figure 2 Pathological analysis. A, B: Cross-sectional views of the left and right ovarian tumors, respectively. The left ovarian tumor measured 90 mm × 55 mm, and the right ovarian tumor measured 30 mm × 30 mm. Both tumors contained solid and cystic components; C, D: Microscopic views of the left and right ovarian tumors, respectively, showing moderately differentiated adenocarcinoma.

ovarian tumors showed a rapid increase in size, and the left and right ovaries measured 97 mm × 66 mm and 80 mm × 29 mm, respectively (Figure 1B and C). Abdominocenteses were performed three times, and cytological examinations of the fluids were all negative for malignant cells. Despite the diffuse peritoneal dissemination observed during the previous surgery, we suspected pseudo-Meigs' syndrome caused by metastatic ovarian tumors and recommended the patient for surgery. Laboratory tests prior to surgery showed carcinoembryonic antigen (CEA) levels at 2.9 ng/mL (normal, < 5 ng/mL), carbohydrate antigen (CA) 19-9 levels at 51.4 U/mL (normal, < 37 U/mL), and CA 125 levels at 1150.0 U/mL (normal, < 35 U/mL). After thorough informed consent, a laparotomy was performed by lower abdominal incision, and more than 3.6 L of serous fluid was removed. Bilateral oophorectomies were performed, and a drainage tube was inserted into the Douglas' pouch. Although we could not inspect the right subphrenic region from the incision, we did not find any of the peritoneal nodules formerly observed on the mesentery of the small intestine and in the pelvis. The resected tumors from the left and right ovaries measured 90 mm × 55 mm and 30 mm × 30 mm, respectively (Figure 2A and B). Pathological examination revealed moderately differentiated adenocarcinoma of the ovaries that had negative immunohistochemical staining for cytokeratin (CK) 7 but positive staining for CK18, CK19 and CK20, leading to the diagnosis of bilateral ovarian metastases from colon cancer (Figure 2C and D). The patient's postoperative condition improved rapidly after surgery. The amount of fluid drained through the abdominal tube during postoperative day 1 was 150 mL, and the tube was removed 2 d after the surgery. Although the feeling of abdominal distention diminished soon after the surgery, both body weight and abdominal girth did not change for 3 d after the surgery but rapidly decreased thereafter (Figure 3). After hospital discharge, she was treated with chemotherapy, and a pulmonary metastasis was resected 1 year after the oophorectomies. Recurrence of peritoneal dissemination was suspected by CT examination 2 years and 4 mo after the oophorectomies, and jejuno-jejunal bypass was performed for jejunal obstruction 5 years and 2 mo after the oophorectomies. She died of cancer 6 years and 11 mo after the first operation and 5 years and 6 mo after the oophorectomies.

DISCUSSION

In 1937, Meigs and Cass[1] described 7 cases of ovarian fibromas associated with ascites and pleural effusion, and these manifestations were subsequently termed Meigs' syndrome[3]. Pseudo-Meigs' syndrome associated with colorectal cancers is extremely rare, and only 11 cases, including the present case, have been reported in the English literature (Table 1)[4-13]. Eight out of these 11 cases were reported in Japan, and most of the patients were under 60 years of age,

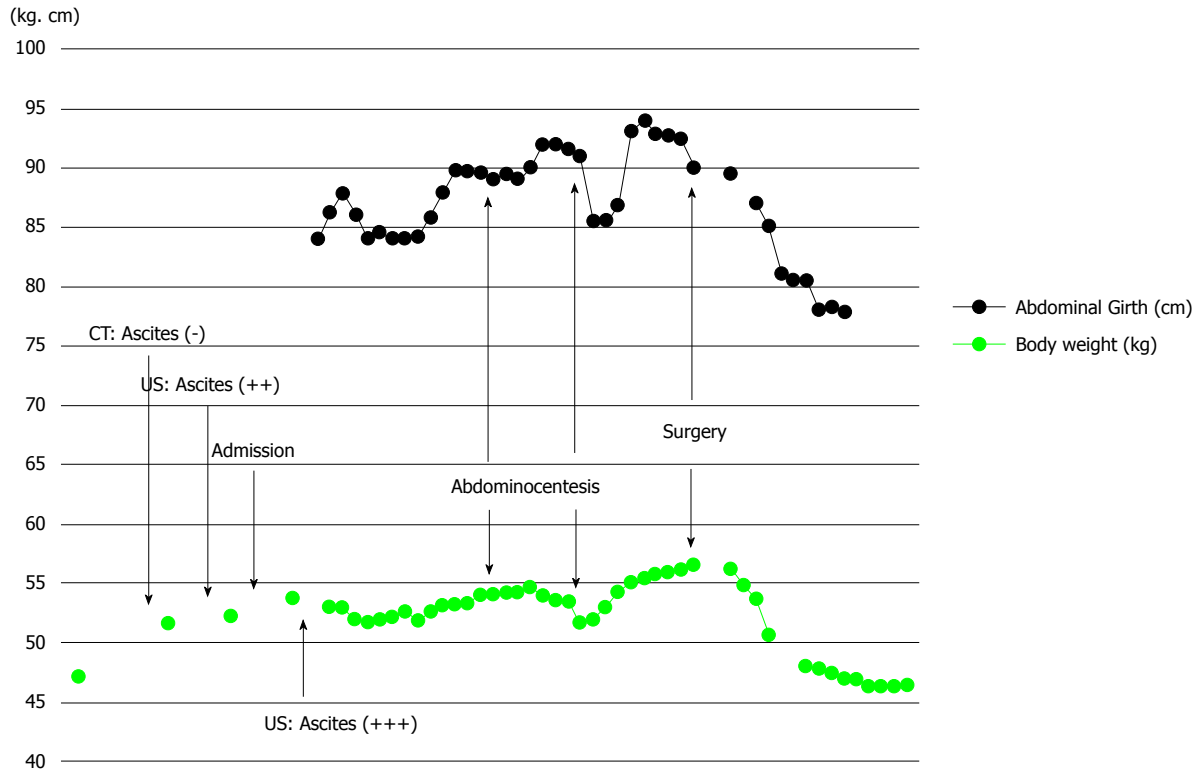

Figure 3 Line graphs showing changes in body weight and abdominal girth. Note that the body weight increased more than 4 kg before the emergence of ascites and that both the body weight and abdominal girth did not change for 3 d after surgery but thereafter decreased rapidly. CT: Computed tomography; US: Ultrasound.

Table 1 Characteristics of reported cases of pseudo-Meigs' syndrome associated with colorectal cancers

Ref.	Year	Age (yr)	Primary site	Onset of syndrome
Ryan[4]	1972	35	Transverse colon	Synchronous
Matsuzaki *et al*[5]	1992	39	Rectum	Synchronous
Nagakura *et al*[6]	2000	53	Sigmoid colon	Synchronous
Ohsawa *et al*[7]	2003	41	Sigmoid colon	Synchronous
Feldman *et al*[8]	2004	49	Cecum	Metachronous
Rubinstein *et al*[9]	2009	61	Cecum	Synchronous
Hosogi *et al*[10]	2009	44	Ascending colon	Synchronous
Okuchi *et al*[11]	2010	42	Rectum	Metachronous
Maeda *et al*[12]	2011	58	Sigmoid colon	Synchronous
Saito *et al*[13]	2012	44	Sigmoid colon	Synchronous
Present case	2016	65	Ascending colon	Metachronous

which is younger than the mean age for the development of colorectal cancers in the general population. There seems to be no preponderance in the locations of the primary lesions, and the associated ovarian metastases were metachronous in only 3 cases, including this case. Because of the metachronous development of this syndrome, we could observe the patient in detail from its early phase.

The etiology of ascites in this syndrome is unclear, although several theories have been proposed. First, Meigs suggested that irritation of the peritoneal surface by a hard solid ovarian tumor could stimulate the production of peritoneal fluid[14]. A second theory is that ascites develops due to pressure on the superficial lymphatics of the tumor[3]. A third theory is that stromal edema and transudation may occur as a result of a discrepancy between the arterial supply to a large tumor and the venous and lymphatic drainage of the same mass[15]. A fourth theory suggests that excessive production of fluid by the peritoneum leads to ascites in this syndrome[16]. The last but probably the most plausible theory is that increased capillary permeability and the resultant third-space fluid shift occur due to increased levels of inflammatory cytokines and vascular endothelial growth factor (VEGF)[17]. Abramov *et al*[17,18] reported high levels of interleukin (IL)-1beta, IL-6, IL-8, VEGF and fibroblast growth factor in serum, ascites and pleural effusion and a decline in serum levels of these inflammatory cytokines and vasoactive factors after removal of the ovarian tumor and suggested that the release of these factors from the tumor should be involved in the clinical manifestations of this syndrome by inducing capillary leakage and third-space fluid accumulation. The clinical manifestations of Meigs' syndrome show great similarity with a severe form of ovarian hyperstimulation syndrome (OHSS) that is associated with injection of human chorionic gonadotropin (hCG) and is also characterized by massive cystic enlargement of the ovaries, ascites and pleural effusion[19]. In severe OHSS, ascites and pleural effusion develop due to increased capillary permeability and resultant third-space fluid shift, and VEGF produced from ovarian follicles under the prolonged effects of hCG is thought to play a key

role[19,20]. The site of VEGF production in patients with pseudo-Meigs' syndrome is currently unclear. Okuchi *et al*[11] reported that immunohistochemical staining examinations showed increased VEGF expression in oviduct epithelial cells of both metastatic and non-metastatic sides rather than in tumor cells. Given that increased capillary permeability and resultant third-space fluid shift form part of the etiology of ascites in this syndrome, this may explain why the body weight of the present patient had increased well before the emergence of ascites and why both body weight and abdominal girth did not change for 3 d after removal of the ovarian tumors and insertion of a drainage tube.

The etiology of pleural effusion also remains unclear, but the prevailing theory is that the transfer of ascites occurs through transdiaphragmatic lymphatics, which was demonstrated by the flow of intraperitoneally injected India ink from the peritoneum to the pleural cavity[21]. Terada *et al*[22] also demonstrated that labeled albumin injected into the peritoneum was detected in the right pleura in maximum concentration within 3 h. However, considering the similarity of this syndrome to severe OHSS, increased capillary permeability may also be involved in the etiology of pleural effusion.

While it may be difficult, it is very important to distinguish the clinical manifestations of pseudo-Meigs' syndrome with those of disseminated malignant disease because in the case of this syndrome, removal of ovarian tumors will markedly improve not only the quality of life but also the prognosis of the patient. Thus, pseudo-Meigs' syndrome should be included in the differential diagnosis of massive or rapidly increasing ascites and pleural effusion associated with large or rapidly enlarging ovarian tumors.

COMMENTS

Case characteristics
The patient was a 65-year-old female who had surgery for ileus caused by transverse colon cancer.

Clinical diagnosis
Pseudo-Meigs' syndrome.

Differential diagnosis
Peritoneal carcinomatosis.

Laboratory diagnosis
Laboratory tests before oophorectomies showed carcinoembryonic antigen (CEA) levels at 2.9 ng/mL (normal, < 5 ng/mL), carbohydrate antigen (CA) 19-9 levels at 51.4 U/mL (normal, < 37 U/mL), and CA 125 levels at 1150.0 U/mL (normal, < 35 U/mL).

Imaging diagnosis
Bilateral ovarian metastases with massive ascites and pleural effusion.

Pathological diagnosis
Moderately differentiated adenocarcinoma in the ovaries, compatible with metastases from transverse colon cancer.

Treatment
Bilateral oophorectomies.

Related reports
Pseudo-Meigs' syndrome associated with colorectal cancer is extremely rare, and the etiology of ascites and pleural effusion in this syndrome remains unknown.

Term explanation
Meigs' syndrome is defined by the presence of a benign ovarian tumor with ascites and pleural effusion that resolve after removal of the tumor. The ovarian tumors in Meigs' syndrome are fibromas or fibroma-like tumors, and other benign or malignant pelvic tumors associated with ascites and pleural effusion are described as pseudo-Meigs' syndrome.

Experiences and lessons
This case report may provide supporting evidence for the etiology of ascites and pleural effusion in pseudo-Meigs' syndrome; our observations that the body weight of the patient had increased well before the emergence of ascites and that both the body weight and abdominal girth did not change for 3 d after removal of the ovarian tumors support the idea that increased capillary permeability and the resultant third-space fluid shift explain the etiology of ascites and pleural effusion in this syndrome.

Peer-review
The authors conclude that pseudo-Meigs' syndrome should be included in the differential diagnosis of massive or rapidly increasing ascites and pleural effusion associated with large or rapidly enlarging ovarian tumors.

Abstract

Isolated splenic metastases from colorectal cancer are very rare clinical entities and when they are present, they usually manifest widely disseminated disease. In this paper we report a case of metachronous solitary isolated splenic metastasis from colon cancer in a 64-year-old woman who was successfully treated by laparoscopic splenectomy. We discuss the pathological and clinical aspects of this condition. We furthermore comment on the diagnostic and therapeutic options of this rare entity through our observation of the case and consideration of the 31 case reports published in the literature.

Key words: Isolated splenic metastases; Colon cancer; Splenectomy

Core tip: Isolated splenic metastases from colon cancer are very rare, reporting of such cases was encouraged and recommended in several publications of this clinical entity to improve the management and survival of patients on stronger well-founded evidence.

Abdou J, Omor Y, Boutayeb S, Elkhannoussi B, Errihani H. Isolated splenic metastasis from colon cancer: Case report. *World J Gastroenterol* 2016; 22(18): 4610-4614 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i18/4610.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i18.4610

INTRODUCTION

Isolated Splenic metastases from colorectal cancer are very rare clinical entity and when they are present, they are usually a manifestation of widely disseminated disease[1]. This rareness can be explained by the anatomical, histological and functional characteristics of spleen which is usually considered an infertile soil for metastases[2]. We report a case of isolated splenic metastasis 16 mo after right Hemicolectomy for stage Ⅰ of colon adenocarcinoma which was successfully treated by Laparoscopic splenectomy. We discuss the clinical and pathological aspects of this rare entity, and consider the diagnostic and therapeutic options based on our observation of the case, and 31 cases reports published in the literature.

CASE REPORT

A healthy 64-year-old woman presented in July 2012, with abdominal pain and "heaviness". A colonoscopy was performed and demonstrated a budding tumor in the cecum that easily bleeds. A histological exam showed moderately differentiated adenocarcinoma. A computed tomography (CT) scan of the chest, abdomen and pelvis revealed a Wall-thickening of the cecum without others abnormalities. She underwent a right hemicolectomy with a histopathological finding of a moderately differentiated adenocarcinoma invading the muscularis propria. Twelve lymph nodes were removed and none showed metastases (pT2N0M0, Stage Ⅰ), with no blood vessel invasion. The status of MSI proteins and BRAF were not verified. she was on regular fallow-up every 3 mo with a serum carcinoembrionic antigen (CEA) and CT scan of the chest, abdomen and pelvis. Sixteen months after her colectomy, a serum CEA level was 38 ng/mL, CT Scan demonstrated a single low-density lesion in the spleen which measures 4.9 cm of diameter (Figure 1). At Laparoscopic exam, no intra-abdominal lesions and no peritoneum or liver metastases were detected. Splenectomy was performed at that time. The Histological exam demonstrated an adenocarcinoma with spread the splenic parenchyma (Figure 2). The following appointment, delayed at 6 mo post splenectomy, revealed no recurrences. CT scanning showed no recurrence in the spleen area, liver, abdomen or the chest; CEA level was 12 ng/mL, however a fluorodeoxyglucose-positron emission tomography (FDG-PET) scan revealed a high metabolic activity in the abdominal cavity, mediastinum and left inguinal lymph nodes suggesting diseases recurrences (Figure 3). Chemotherapy was therefore commenced consisting of Fluorouracil (5FU), Leucovorin, oxaliplatine and Bevacizumab. After 6 cycles, there was no evidence of progression disease.

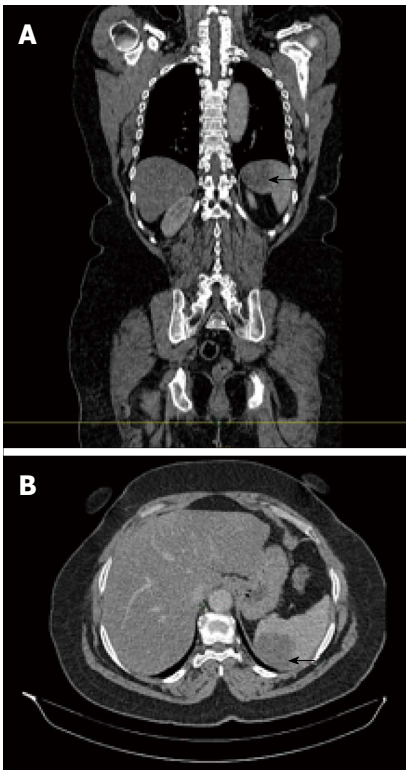

Figure 1 Abdominal computed scan demonstrating, in sagittal (A) and axial (B) views, a single low-density lesion of the spleen which measures 4.9 cm in diameter.

DISCUSSION

Splenic metastases from colorectal cancer are very rare. The incidence of this clinical entity was reported by Berge[2] to be 4.4% in 7165 autopsy cases, but he did not mention the incidence of Isolated Splenic metastases.

We found only 31 cases of isolated solitary Splenic metastasis from colorectal cancer in the English-language literature published in PubMed. dates searched were from 1969, date of the first case reported, to October 2015 (Table 1[3-31]). The cases consisted of 18 men and 13 Women, ranging in age from 33 to 84 years (mean, 62.7 years). The splenic metastasis was synchronous in five cases and metachronous in others 26 cases. The majority of cases were asymptomatic and the diagnosis was performed in follow-up of patients by imaging studies evaluation of increased CEA level which was elevated in 81% of cases ranging between 4.6 and 223 ng/mL, in our patient CEA level was 38 ng/mL. The interval between the primary tumor treatment and the detection of spleen metastasis varying from 3 to 144 mo (16 mo in our case). Splenic metastases were detected by Computed tomography scan, alone in 18 cases, or combined with other imaging studies such as Ultrosonography (5 cases), positron emission tomography (4 cases) and

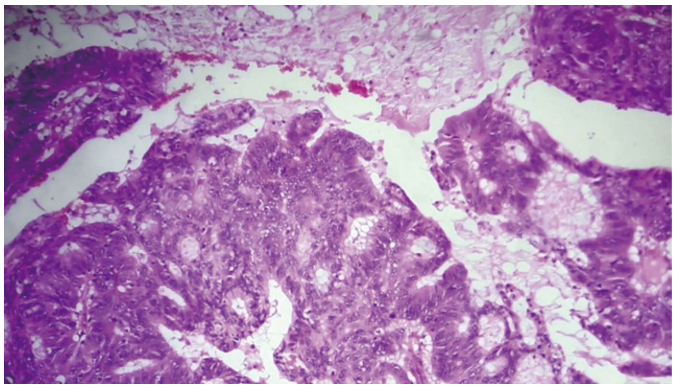

Figure 2 Adenocarcinoma spread the splenic parenchyma (hematoxylin-eosin staining, magnification × 20).

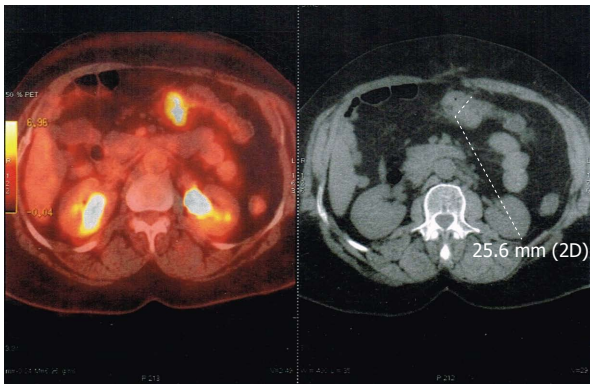

Figure 3 Fluorodeoxyglucose-positron emission tomography with high metabolic activity in the abdominal cavity.

Magnetic Resonance Imagery (1 case); 2 cases were detected by Liver-spleen scintigraphy; and 1 case by fluorodeoxyglucose-positron emission tomography (FDG-PET) scan[25]. The size of splenic lesions varied from 1.5 to 18 cm. In the cases reported the primary tumor was located in the sigmoid colon in 8 cases, in the ascending colon in 6 cases, in the descending colon in 5 cases, and in the rectum and Splenic flexure in 3 cases each; in the cecum in 2 cases as in our case, 1 case in the hepatic flexure and transverse colon each; In 2 patients the primary tumor localization was not specified. So the most frequent site of primary tumor is the left colon (61% of cases). Metastases are classically spread through either hematological or lymphatic pathways, however there is no lymphatic afferent in the spleen[1] and therefore the spread is *via* the blood vessels. in the cases of splenic metastasis, the regional lymph nodes were involved in 17 cases of primary tumor (16 cases with Sage Ⅲ, 1 case with Stage Ⅳ); in 9 cases the regional lymph nodes were negatives (7 cases with stage Ⅱ, 2 cases with stage Ⅳ), in 5 patients the regional lymph nodes was not specified; in our case the primary tumor was stage Ⅰ with no blood vessels invasion, it is the first in the literature. The diagnosis of spleen metastasis was confirmed by fine-needle aspiration in two cases[14,27] and in others cases by splenectomy.

Therapeutics options of metastatic colorectal cancer include surgery, chemotherapy with or without target therapy and radiotherapy. In all cases reported of Isolated Splenic metastases from colon cancer, splenectomy was performed, with Laparoscopic approach in only one case[25] as in our patient. This surgical technique remains controversial in Splenic malignancies because the risk of peritoneal dissemination and the few data in the literature. Lopez Monclova *et al*[31] reports 6 cases of Laparoscopic splenectomy for splenic metastasis from melanoma, ovarian cancer, colorectal cancer and malignant fibrous histiocytoma without surgical complications with a survival ranged from 2 mo to 11 years. Moreover, studies have demonstrated that laparoscopic techniques used in surgery of colorectal and gynecological cancer were not associated with a greater risk of intraperitoneal dissemination than conventional techniques[32]. Despite the fact that Chemotherapy is the most appropriate options of metastatic colon cancer by improving symptoms and survival, it was given in only 5 cases, as neoadjuvant in 2 cases and adjuvant in 3 cases. Target therapy was given only for 1 patient[23]. Interval survival after splenectomy ranging from 3 to 84 mo (mean, 22.5 mo). in patients with metachronous splenic metastasis only 2 cases were relapsed between 9 and 11 mo, in contrast 3 of 5 cases of synchronous splenic metastases were relapsed. Our patient was relapsed 6 mo post splenectomy, we suggest that this early relapse could be explained by lack of adjuvant chemotherapy post splenectomy rather than the surgical technique.

In conclusion, isolated splenic metastases from colorectal cancer are very rare clinical entity. A strict monitoring of patients with colon cancer after primary treatment should lead to early diagnosis of such metastasis. Splenectomy followed by adjuvant chemotherapy seems the optimal approach that can improve survival, despite small number of cases in the literature.

This is the first case in our institution and the first case of metachronous isolated splenic metastasis from colon cancer of which the primary tumor was stage Ⅰ.

[1]Spleen metastases; 1st DFI disease-free interval between treatment of primary tumor and diagnosis of the spleen metastasis; 2nd DFI disease- free interval after splenectomy. CEA: Carcinoembrionic antigen; N: Normal; LN: Lymph node; NL: Not listed; CT: Computed tomography; US: Ultrasonography; LSS: Liver splenic scintigraphy; PET: Positron emission tomography; MRI: Magnetic resonance imagery; S: Surgery; Cmt: Chemotherapy; TT: Target therapy.

We report this case for enrich the database of this rare clinical entity and to improve the management and survival of patients with isolated splenic metastases from colorectal cancer as was recommended and encouraged in similar publications.

COMMENTS

Case characteristics

A 64-years-old woman was on regular fallow-up post right hemicolectomy for stage I adenocarcinoma of the cecum. Computed tomography (CT) scan demonstrated a single low-density lesion in the spleen sixteen months post her hemicolectomy.

Clinical diagnosis

The patient was no symptoms; the spleen metastasis was detected after routine monitoring.

Differential diagnosis

Splenic infraction or abscess, lymphoma.

Laboratory diagnosis

A serum carcinoembrionic antigen level was 38 ng/mL.

Imaging diagnosis

CT scan demonstrated a single low-density lesion in the spleen which measures 4.9 cm of diameter.

Pathological diagnosis

An adenocarcinoma with spread the splenic parenchyma.

Treatment

Laparoscopic splenectomy.

Term explanation

Microsatellite instability (MSI) result in a defect of DNA mismatch repair, MSI/BRAF testing had a prognostic factor in colon cancer.

Experiences and lessons

A strict monitoring of patients with colon cancer after primary treatment should lead to early diagnosis of such metastasis and the properly treatment.

Peer-review

This paper is informative and is suitable for publishing.

Abstract

Major advances have been made in the treatment of chronic hepatitis C virus (HCV) infection with the advent of direct-acting antiviral agents (DAAs). China has the most cases of HCV infection worldwide, but none of the DAAs has been approved in mainland China so far, and interferon (IFN)-α-based treatment remains the standard of care. HCV patients without response or with contraindications to IFN-based therapy have no alternative options. However, many patients buy DAAs, especially the generic forms of sofosbuvir, from other countries or areas. Under these circumstances, the use of these drugs may cause many predictable and unpredictable problems in ethics, law and medical practice. Given the obstacles of legal accessibility to DAAs and the potential problems of obtaining and using DAAs in China, the early launching of the DAAs in China or the legalization of buying drugs from areas outside China and using these drugs in China is an urgent issue and needs to be dealt with as soon as possible, in the interest of the patients.

Key words: Hepatitis C virus infection; Treatment; Direct-acting antiviral agent; Generics; China

Core tip: This article describes the current treatment situation of chronic hepatitis C virus infection in China and discusses the potential problems pertinent to the access and the use of direct-acting antiviral agents (DAAs), especially the use of generic DAAs from various sources.

INTRODUCTION

Infection with hepatitis C virus (HCV) is a leading

cause of liver disease. Worldwide, an estimated 130-170 million people have HCV infection, and China has the most cases of HCV infection worldwide, with an estimated 29.8 million people[1]. A high proportion of people with HCV infection have developed advanced chronic liver diseases, including chronic hepatitis, liver cirrhosis and hepatocellular carcinoma (HCC).

The primary goal of treating chronic HCV infection is to achieve a sustained virologic response (SVR), which is defined as the absence of serum HCV RNA 12-24 wk after cessation of treatment. Patients achieving an SVR are considered cured in that 99% of patients who achieve an SVR remain undetectable for virus during long-term follow-up[2]. Achievement of SVR is associated with improved clinical outcomes. Pegylated interferon (Peg-IFN)-α 2a or 2b in combination with ribavirin (RBV) has been the standard of care for chronic HCV infection. However, treatment with Peg-IFN-α and RBV has limited efficacy. For instance, 48 wk of Peg-IFN and RBV therapy may achieve SVR in only 40% of patients with HCV genotype 1 infection[3]. Significant adverse events may accompany the duration of treatment[3-5], resulting in poor adherence and premature treatment discontinuation. Moreover, patients with decompensated liver disease, patients with HIV/HCV co-infection, patients who have comorbidity such as heart disease or chronic kidney diseases, patients who have had renal failure and renal transplantation, and patients who have undergone liver transplantation for HCV-associated liver disease may be contraindicated to or ineligible for the regimen of IFN and RBV. Patients who have a null or low response to the regimen of IFN and RBV and patients who are unwilling to take the drugs have no alternative effective treatments. Therefore, novel treatments that have more potent antiviral activity and fewer adverse effects and are eligible and compatible for patients with complex comorbidity in real life settings are urgently required.

Fortunately, major advances have been made in the treatment of chronic HCV infection, with the advent of direct-acting antiviral agents (DAAs) in recent years. Many regimens free of IFN or free of both IFN and RBV have been devised based on combination of new DAAs. These new regimens provide excellent efficacy with higher SVR rates and good safety profile with fewer side effects, and are of shorter duration of treatment. The patients also have a better treatment experience, higher adherence to treatment, and substantial improvement of health-related quality of life during treatment[6]. DAA combination regimens also provide high SVR rates in patients with various HCV genotypes, disease conditions and treatment experiences, including cirrhosis associated with HCV genotype 1[7,8], liver and kidney transplant recipients[9], HCV-genotype-1-infected patients with compensated cirrhosis who had not achieved SVR after successive treatments with Peg-IFN and protease-inhibitor regimens[10], and treatment-naïve and treatment-experienced patients co-infected with HIV and HCV genotypes 1-4[11].

CURRENT TREATMENT OF CHRONIC HCV INFECTION IN CHINA

Because of the unavailability of the novel DAAs, IFN-α or Peg-IFN-α in combination with RBV remains the current standard of care for chronic HCV infection in mainland China. Under these circumstances, HCV patients, especially some important and difficult to treat HCV patients, such as nonresponders to IFN and RBV treatment and those with relapse; patients with renal failure or heart disease; patients intolerant to the adverse events of and with contraindications to INF and RBV; patients with HCV-related cirrhosis and/or HCC; and patients with HIV/HCV co-infection have no other treatment options. In reality, however, the patients themselves are pragmatic. They try to seek help from other sources and find ways possible to obtain the drugs for the treatment of their disease. The high cost used to be one of the obstacles for some patients because of the unaffordability, but the cost is not an issue with the launching of generic drugs in some countries such as India. The price of the generic drugs is much lower than their brand-name counterparts. As a result, many HCV patients have bought or are going to buy DAAs, mainly sofosbuvir, a "blockbuster drug", from various regions or countries such as India and Bangladesh through different means, including through brokers, relatives and friends who have the opportunity to buy the drugs. The HCV patient population using DAAs, mainly sofosbuvir, from the above-mentioned sources is rapidly increasing in China.

DISCUSSION

Undoubtedly, most patients may benefit from the use of these drugs. Ethically and responsibly, doctors would be pleased to see that the patients have access to effective medicines and the probable cure of their disease. However, some problems may be encountered.

First, none of the DAAs including sofosbuvir, whether generics or brand name, has been approved by the China Food and Drug Administration. In this respect, the use of these drugs appears to be illegal in China. There is a similar but not identical example. Lu Yong, a Chinese man, who was diagnosed with chronic myeloid leukemia when he was aged 34 years in 2002, was arrested, jailed and then released by the police authorities in China early this year because of purchasing the Indian generic drug imatinib mesylate for himself and other patients. Although he appeared to be accused of selling "fake drugs", he knows nothing about the reasons for either being arrested or being released[12]. It is suggested that there are some legal issues and gaps.

Second, physicians may feel frustrated and embarrassed when they are consulted by patients with chronic HCV infection regarding the treatment of the disease. The doctors may tell the patients that there are many new drugs that are effective and have fewer adverse effects and may be suitable for their condition when they advise patients who are unsuitable for IFN and RVB, but none of the drugs is lawfully available in China. Of course, the doctors can let the patients wait for the availability of these drugs. However, some of the patients, such as those with decompensated liver disease and those awaiting organ transplantation, cannot wait because of the rapid progress of their disease and its life-threatening potential. Another situation is that the patients consult doctors about using drugs that they have bought from other countries, mostly from illegal sources and by illegal means, and the drugs may thus be regarded as "fake drugs". Additionally, the quality of the drugs may also not be guaranteed. In this situation, the doctors may place themselves at risk because they appear to guide their patients to use "fake drugs".

Third, because of the lack of other DAAs for rational combination, most of the patients take sofosbuvir in combination with RBV and some patients even use sofosbuvir alone for the treatment of their HCV infection with various treatment durations, irrespective of the HCV genotypes involved, the underlying liver disease (hepatitis or cirrhosis) and comorbidity. In reality, the situation may be rather more complex than expected. HCV genotype 1 infection accounts for most cases of HCV infection in China, but there are also other genotypes in China, including 2, 3 and 6[13].

Although the combination of sofosbuvir and RBV is a pan-genotypic regimen and may be applied for HCV genotypes 1-6, and this regimen remains the standard of care for genotypes 2 and 3, its efficacy was suboptimal in patients with HCV genotype 1, with an SVR of 54% for genotype 1b treatment-naïve hepatitis and 60% for genotype 1 treatment-naïve cirrhosis after 24 wk of treatment[14]. In the United States, the regimen of sofosbuvir and RBV for 24 wk in patients with genotype 1 infection is not recommended because of the longer treatment duration and lower expected SVR rates compared with other regimens[15]. The efficacy of this regimen for treatment-experienced genotypes 2 and 3 infection, with or without cirrhosis, was also suboptimal, with an SVR of 72% for genotype 2 treatment-experienced cirrhosis after 12 wk of treatment, an SVR of 77% for genotype 3 treatment-experienced hepatitis after 24 wk of treatment, and an SVR of 60% for genotype 3 treatment-experienced cirrhosis after 24 wk of treatment[14]. Based on these data, it is indicated that a proportion of patients with HCV genotype 1 or genotypes 2 and 3 treatment-experienced hepatitis or cirrhosis is using an non-optimal regimen for treatment. Therefore, it is anticipated that higher non-response and relapse rates may result from the use of this regimen.

Another concern is the possibility of treatment-emergent variants that may confer resistance to the antiviral treatment, although sofosbuvir has high genetic barriers to resistance[14]. Of note, a DAA used as monotherapy is not recommended because of the strong likelihood of treatment failure and the potential to induce resistance[15].

Moreover, the drug safety and drug-drug interactions pertinent to the use of sofosbuvir and RBV or sofosbuvir alone cannot be completely ignored. Sofosbuvir has a good safe profile and few drug-drug interactions. However, the safety of sofosbuvir in patients with some comorbidity, such as severe renal impairment (an estimated glomerular filtration rate < 30 mL/min/1.73 m^2) or end-stage renal disease on dialysis, is not well established, in that the levels of sofosbuvir and its metabolite are substantially elevated in such patients[15]. In contrast, co-administration of P-glycoprotein inhibitors, including anticonvulsants such as phenobarbital, antimycobacterials such as rifampin, ritonavir-boosted tipranavir, and St John's wort can decrease sofosbuvir concentrations[16]. Additionally, although sofosbuvir is not supposed to have significant pharmacological interactions with tacrolimus or cyclosporine[17], unexpected tacrolimus/cyclosporine reduction, which needs dosage adjustment, was observed in transplant recipients during sofosbuvir/RBV treatment for severe HCV infection recurrence. This raises the importance of awareness in the post-transplant HCV-recurrence setting when sofosbuvir is administered[18]. All these may place the patients with some comorbidity in unsafe conditions or bring new problems for the retreatment of patients if necessary.

CONCLUSION

As doctors, we hope for early launching of the DAAs, not only sofosbuvir but also other agents that can be rationally combined with sofosbuvir, in China, and the legalization of buying drugs including generic drugs from areas outside China and using these drugs in China, without further delay, in the interest of the patients. Presently, regulations concerning the usage of drugs, including generic drugs from other areas and international routes, should be established by the health authorities in China to meet the urgent needs. In the long run, China's health authorities need to reform fully their drug import policy and distribution system to satisfy legitimately and sensibly the therapeutic requirement of patients. In particular, the authorities need to guarantee the timely availability of novel drugs, even if they may be generics, for the urgent need of severely ill patients to improve survival and quality of life. At the same time, doctors may become confident to advise the use of such drugs without fear of violating the law or regulations concerning the quality of the drugs. We wish for the early arrival of a time when patients can easily and legally have access to effective drugs, and doctors can lawfully and

unimpeachably play their role in the treatment of HCV infection.

Abstract

Human epidermal growth factor receptor 2 (HER2) overexpression is increasingly recognized as a frequent molecular abnormality in gastric and gastroesophageal cancer. With the recent introduction of HER2 molecular targeted therapy for patients with advanced gastric cancer, determination of HER2 status is crucial in order to select patients who may benefit from this treatment. This paper provides an update on our knowledge of HER2 in gastric and gastroesophageal cancer, including the prognostic relevance of HER2, the key differences between HER2 protein expression interpretation in breast and gastric cancer, the detection methods and the immunohistochemistry scoring system.

Key words: Human epidermal growth factor receptor 2 testing; Gastric cancer; Immunohistochemistry; Scoring system; Trastuzumab

Core tip: It is clear that human epidermal growth factor receptor 2 (HER2) protein over-expression and gene amplification are much more heterogeneous in gastric cancer compared to breast cancer. Gastric and gastroesophageal tumors require a unique immunohistochemistry scoring system and interpretation expertise. We aimed to clarify the key differences in immunohistochemistry interpretation of gastric cancer, providing a practical update on HER2 testing and scoring.

Abrahao-Machado LF, Scapulatempo-Neto C. HER2 testing in gastric cancer: An update. *World J Gastroenterol* 2016; 22(19): 4619-4625 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i19/4619.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i19.4619

INTRODUCTION

Human epidermal growth factor receptor 2 (HER2), also known as CerbB-2 and ERBB2, is a proto-oncogene located on chromosome 17q21 that encodes a transmembrane protein with tyrosine kinase activity,

a member of the HER receptor family and is involved in signal transduction pathways, leading to cell growth and differentiation[1].

Amplification of the HER2 gene and overexpression of its product were first discovered in breast cancer and are significantly associated with worse outcomes[2]. Many studies have demonstrated that HER2 is also present in several other malignancies, including colorectal cancer, ovarian cancer, prostate cancer, lung cancer and, particularly, gastric and gastroesophageal cancer[3].

In gastric and gastroesophageal cancer, the frequency of HER2 overexpression varies widely in the literature; studies have yielded inconsistent findings regarding its prognostic relevance[4-12]. With the recent introduction of trastuzumab for the treatment of patients with advanced gastric cancer, the clinical demand for HER2 assessment is rapidly increasing. However, HER2 testing in gastric cancer differs from testing in breast cancer because of inherent differences in tumor biology, intratumoral heterogeneity of HER2 expression and incomplete membrane staining that are commonly observed in gastric tumors[13].

This paper aims to summarize the current evidence regarding HER2 in gastric and gastroesophageal cancer and to provide a practical update on HER2 testing and scoring that is essential for appropriate selection of patients who are eligible for treatment with trastuzumab.

RELEVANCE OF HER2 IN GASTRIC AND GASTROESOPHAGEAL CANCER

The frequency of HER2 overexpression in gastric and gastroesophageal cancer ranges from 4.4% to 53.4%, with a mean of 17.9%[4-14].

Although some small-scale studies have not demonstrated the prognostic properties of HER2[4,5,9,12], a larger number of studies indicate that HER2 is a negative prognostic factor, showing more aggressive biological behavior and higher frequencies of recurrence in HER2-positive tumors[1,6-8,11,14].

Given this controversy of HER2 prognostic values, a systematic review of a large number of studies was recently conducted in order to address this issue[14]. Forty-two publications with a total of 12749 patients were reviewed; the majority (71%) of the publications showed that a HER2-positive status was associated with decreased survival and clinicopathological features of tumor progression, such as serosal invasion, metastases and higher disease stage[14]. The results clearly set HER2 as a negative prognostic factor, suggesting that HER2 overexpression/amplification is a molecular abnormality that might be associated with the development of gastric cancer[7,14].

HER2 MOLECULAR TARGETED THERAPY

Trastuzumab is a monoclonal antibody directed against HER2; as one of the first molecular-targeted drugs to be developed, it was first introduced for the treatment of HER2-positive advanced breast cancer[2].

There is no consensus on the mechanism in which trastuzumab acts in cancer cells, but the evidence is that in addition to preventing dimerization of HER2 with other HER family members and stimulating endocytosis, it seems to induce cell mediated immunity and inhibit angiogenesis[15].

In the ToGA trial, patients with HER2-expressing unresectable gastric and gastroesophageal tumors were treated with chemotherapy and trastuzumab or with chemotherapy alone. A statistically significant increase in overall survival was observed in patients who received trastuzumab[16].

Although only a modest improvement of 2.7 mo in the median overall survival was observed in HER2-positive patients with the addition of trastuzumab, according to the ToGA trial, there was an improvement of 4.2 mo in the median overall survival in a post-hoc analysis[14,16-18].

Other molecular HER2-targeted agents have been tested or are currently being tested such as pertuzumab, lapatinib, the antibody-drug conjugate trastuzumab-emtansine (TDM-1)[19-23] and afatinib (NIH study trial registration number NCT01522768; ClinicalTrials.gov). However, the efficacy of these agents has been shown to be either unsatisfactory or as modest as trastuzumab[22,24]. Trastuzumab is the first molecular targeted agent approved as a standard treatment in gastric cancer, but it remains under investigation for more potent utilization.

Thus, it is imperative to determine the HER2 status in advanced gastric or gastroesophageal junction adenocarcinoma in order to select patients who may benefit from this promising treatment.

HER2 TESTING METHODS

HER2 status is mainly assessed by immunohistochemistry (IHC) or *in situ* hybridization (ISH) assays. Both methods can be done on formalin-fixed and paraffin-embedded biopsy tissues or surgical specimens and occasionally, cytological samples[25]. Fluorescent *in situ* hybridization (FISH) is regarded to be the gold standard; however, because of its higher cost and time consumption, as well as the need for a fluorescence microscope, generally only equivocal cases are subjected to this technique. Furthermore, the high concordance between FISH and IHC that is reported in the literature supports the use of IHC, the most familiar and readily accommodated method in most surgical pathology laboratories[26-29].

Thus, IHC should be used as the first screening method for HER2 evaluation and those cases with results considered equivocal for HER2 overexpression (2+) should be referred for FISH analysis or other alternative *in situ* hybridization method[28] (Figure 1). A simple and practical alternative to FISH for these

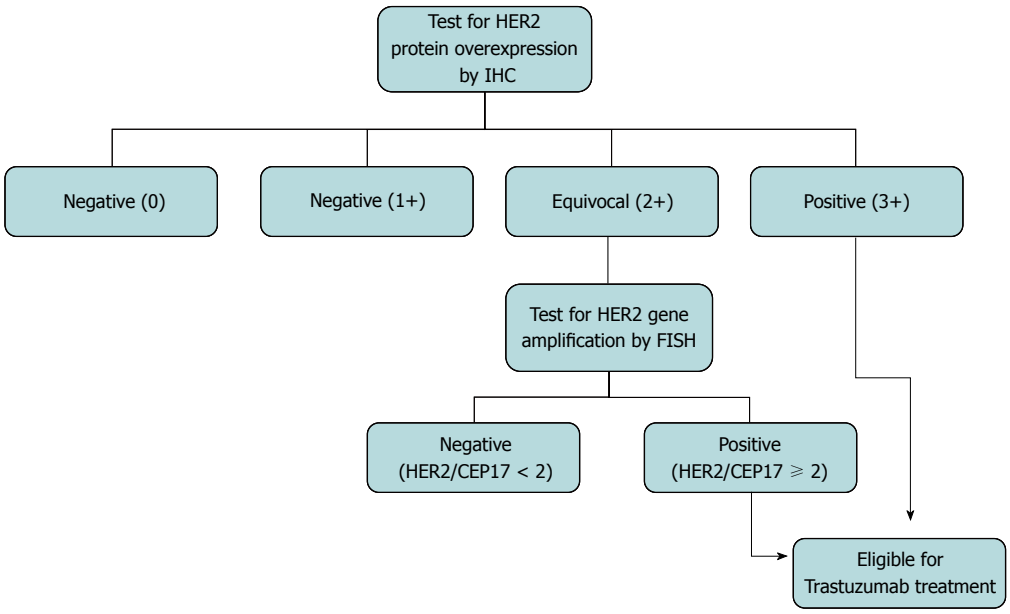

Figure 1 Human epidermal growth factor receptor 2 testing algorithm. HER2: Human epidermal growth factor receptor 2; IHC: Immunohistochemistry; FISH: Fluorescent *in situ* hybridization; CEP17: Chromosome 17.

Table 1 Advantages and disadvantages of the human epidermal growth factor receptor 2 testing methods

Method	Advantages	Disadvantages
IHC	Quick to perform; Most laboratories use fully automated processes; Widely used and familiar to all pathologists; Results can be viewed using a conventional bright-field microscope; Permits parallel viewing of tumor cell morphological features; Stained tissues do not degrade over time	Equivocal cases (2+) need another method for conclusion; Accuracy is more dependent on pre-analytic variables
FISH	Very objective and accurate; Actual copies of HER2 genes can be counted; Considered the golden standard of HER2 testing	Technically more demanding; Usually performed only in large laboratories/institutions; Costs are substantially high; Requires the use of fluorescence microscope and dark room; Comparatively more time consuming; Reagents degrade over time
SISH/CISH/ DDISH	Quick to perform; Very objective and accurate; Technique is fully automated; Results can be viewed using a conventional bright-field microscope; Permits parallel viewing of tumor cell morphological features; Slides can be stored because the signal is stable; Double-stranded probes labeled with two haptens can detect both markers on a single slide (DDISH)	More expensive than IHC; Unfamiliar to non-specialist pathologists

IHC: Immunohistochemistry; FISH: Fluorescent *in situ* hybridization; SISH: Silver *in situ* hybridization; CISH: Chromogenic *in situ* hybridization; DDISH: Dual-color dual-hapten *in situ* hybridization.

equivocal cases is provided by the employment of other *in situ* hybridization techniques such as silver *in situ* hybridization (SISH), chromogenic *in situ* hybridization and dual-color dual-hapten *in situ* hybridization. These three methods can be easily analyzed under a conventional bright field microscope and have shown excellent correlation with results obtained by FISH[30-32].

Because IHC is the easiest, least expensive and most widespread method of HER2 assessment, this paper focuses on IHC. Table 1 shows the different HER2 methods and their advantages and disadvantages.

Differences between HER2 expression in breast and gastric cancer

The key differences between HER2 expression in breast and gastric and gastroesophageal cancer are listed[17,30]: (1) the membranous distribution of the antibody in the neoplastic cells of breast cancer is

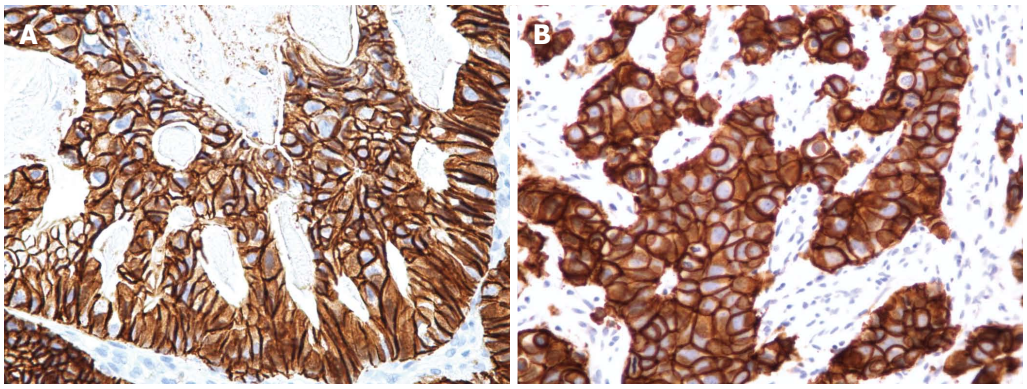

Figure 2 Human epidermal growth factor receptor 2 expression in gastric and breast tumors. A: A HER2-positive (3+) case of gastric adenocarcinoma; the cytoplasmic membranous immunostaining is incomplete and predominantly basolateral (× 400); B: A HER2-positive (3+) case of invasive ductal carcinoma of the breast; the cytoplasmic membranous staining is fully circumferential (× 400). HER2: Human epidermal growth factor receptor 2.

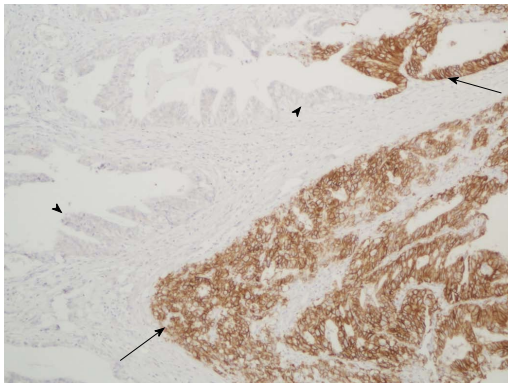

Figure 3 Representative image of the intratumoral heterogeneity of HER2 expression. Arrows indicate areas with strong continuous membranous staining (score 3+) and arrowheads indicate negative areas (score 0) (× 100). HER2: Human epidermal growth factor receptor 2.

predominantly circumferential, whereas in gastric cancer, it is generally incomplete, predominantly basolateral ("U"-shaped) or lateral (parallel lines) (Figure 2). Thus, unlike for breast cancer, circularity of IHC staining is not a criterion for HER2 IHC scoring in gastric cancer; (2) intratumoral heterogeneity, defined as the presence of areas with different HER2 scores within the same tumor, *i.e.*, focal or patchy positivity, is a common pattern encountered in gastric tumors but is only rarely seen in breast cancer (Figure 3). It may cause sampling errors when randomly sampled biopsies are examined (see below). Although the causes of intratumoral heterogeneity of HER2 expression are not yet fully understood, some studies indicate that it could be explained merely by tumor inherent genetic heterogeneity[33,34]. Since *Helicobacter pylori* (*H. pylori*) is widely accepted as the main causative agent of gastric cancer[35], we speculate whether among the diverse bacterial factors, concomitant infection with different strains and diverse host responses there could be a reasonable link with HER2 intratumoral heterogeneity. Interestingly, Tegtmeyer *et al*[36] showed that some *H. pylori* strains could in fact activate HER2, while infection with other strains suppressed HER2 activity. However, this correlation of the bacterium with HER2 intratumoral heterogeneity is still a matter of debate and requires further studies; and (3) variation of the incidence of HER2 expression with anatomic location does not occur in breast cancer, whereas it is more frequent in the proximal stomach, including the esophageal-gastric junction, than in the distal stomach. With the introduction of the seventh edition of TNM classification, a large number of tumors that were formerly categorized as gastric are now considered as esophageal and gastroesophageal junction tumors instead, with relatively high HER2-positivity rates in these primary neoplasms[37].

IHC score system

Given these differences between HER2 expression in breast and gastric cancer, an appropriate scoring system, exclusive for gastric tumors, was developed, because just transferring the breast cancer IHC scoring roles to gastric cancer could lead to a significant loss of patients. The system proposed by Hofmann *et al*[38] that has been assimilated by CAP and FDA, besides being specific for gastric tumors, also distinguishes biopsies from surgical specimens[17]. Table 2 shows the IHC score system for HER2 in gastric cancer and Figure 4 illustrates it.

Differences among samples

As mentioned above, mainly because of intratumoral heterogeneity, the size of the tissue sample might interfere in HER2 analysis. Although Hofmann's HER2 scoring system was formulated for evaluating HER2 status in biopsy and surgical specimens, discordant HER2 results in paired specimens were observed in a small percentage of tumors[39]. Intratumoral heterogeneity appears likewise to be the subject of conflicting results of HER2 expression in primary and metastatic tumor samples[33]. Moreover, in a previous study, we showed a significant difference in sensibility when analyzing HER2 expression in whole-tissue sections and in tissue microarrays[13]. Our personal

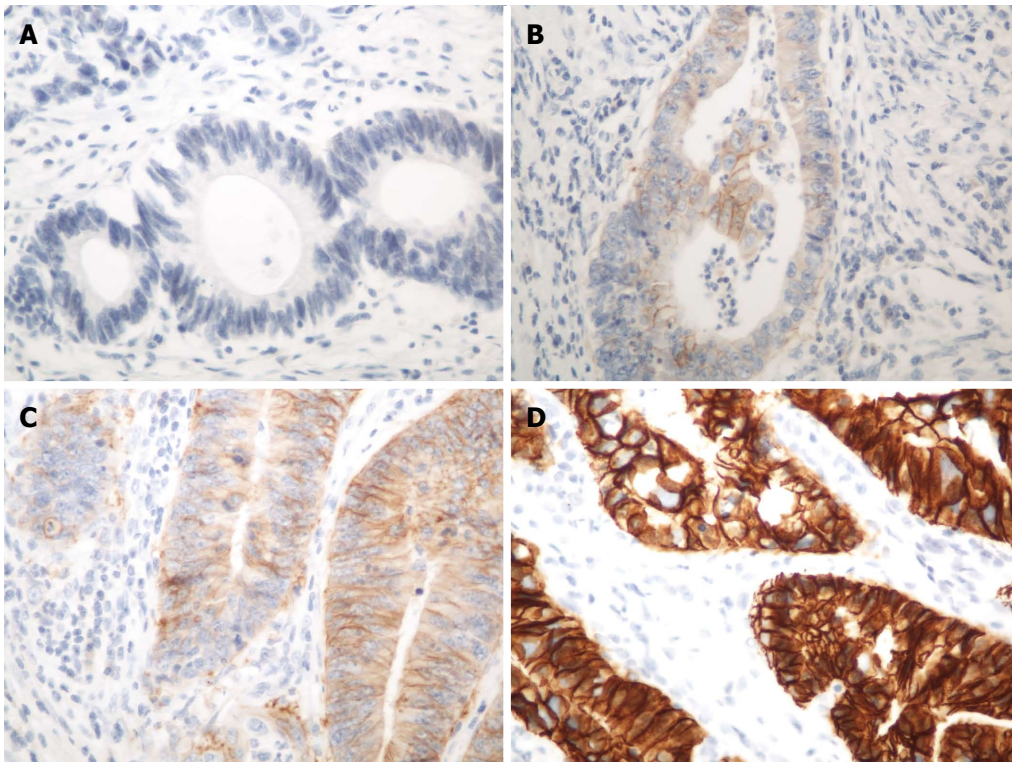

Figure 4 Human epidermal growth factor receptor 2 protein expression in gastric and gastroesophageal tumors. A: A negative (0) case; B: A negative (+1) case; C: An equivocal (2+) case; D: A positive (3+) case. HER2: Human epidermal growth factor receptor 2.

Table 2 Immunohistochemistry scoring for human epidermal growth factor receptor 2 expression in gastric and gastroesophageal junction cancer[17]

Score	Surgical specimen	Biopsy	HER2 overexpression assessment
0	No membranous staining or staining of < 10% of the tumor cells	No membranous staining or staining only in rare cells (less than 5 cohesive cells)	Negative
1+	Staining is weak or detected in only one part of the membrane in ⩾ 10% of the cells	Staining is weak or detected in only one part of the membrane of at least 5 cohesive cells	Negative
2+	Moderate/weak complete or basolateral membranous staining in ⩾ 10% of the cells	Moderate/weak complete or basolateral membranous staining of at least 5 cohesive cells	Equivocal
3+	Strong complete or basolateral membranous staining in ⩾ 10% of the neoplastic cells	Strong complete or basolateral membranous staining of at least 5 cohesive cells	Positive

HER2: Human epidermal growth factor receptor 2.

experience suggests that it is prudent to extend the evaluation to more than one sample and, if feasible, to also evaluate metastatic foci. In fact, testing all available specimens should be considered so that discrepancies can be excluded. When only biopsies are available, it is recommended to have at least four fragments containing tumor cells[40]. We also recommend that all surgical specimens from patients that previously obtained HER2-negative results in biopsies should also be tested to increase the chance of finding HER2-positive tumors.

IHC antibodies

The results of the HER2 test might differ according to the antibody used and, consequently, the antibody might considerably influence therapeutic decisions. An optimal IHC antibody should be adequately sensitive to select the greatest possible number of candidates for treatment and should have the lowest possible false-positive rate in order to avoid overtreatment.

The commercial antibodies currently available are the HercepTest and A0485 (Dako, Glostrup, Denmark), SP3 (Labvision; Thermo Fisher Scientific, Fremont, CA, United States), 4B5 (Ventana Medical Systems, Tucson, AZ, United States) and CB11 (Novocastra, Newcastle upon Tyne, England). Some studies have shown substantial divergence among the antibodies regarding the results of HER2 expression in gastric tumors[13,29,41]. Our previous study compared HercepTest, SP3 and 4B5. We observed that the 4B5 and SP3 antibodies showed similar good performance, with high NPV (negative predictive value) and AUC (area under the ROC curve) values that indicated higher accuracy compared to the HercepTest[13]. Based

on these results and on our personal experience, we believe that 4B5 and SP3 antibodies are more reasonable for first-line tests than the HercepTest in gastric tumors.

CONCLUSION

Given the recent introduction of trastuzumab for the treatment of patients with advanced gastric cancer, assessment of HER2 status is now mandatory for selecting patients eligible for this treatment. Although the development of automated platforms and image analysis should broaden the availability of *in situ* hybridization technologies, immunohistochemistry continues to play an essential role in HER2 status assessment. The overall reliability of HER2 evaluation by IHC, however, can be affected by diverse pre-analytical, analytical and post-analytical variables. Therefore, gastric and gastroesophageal cancer requires a unique scoring system, but above all, it requires expertise in interpretation.

Abstract

Minimally invasive surgery (MIS) for upper gastrointestinal (GI) cancer, characterized by minimal access, has been increasingly performed worldwide. It not only results in better cosmetic outcomes, but also reduces intraoperative blood loss and postoperative pain, leading to faster recovery; however, endoscopically enhanced anatomy and improved hemostasis *via* positive intracorporeal pressure generated by CO_2 insufflation have not contributed to reduction in early postoperative complications or improvement in long-term outcomes. Since 1995, we have been actively using MIS for operable patients with resectable upper GI cancer and have developed stable and robust methodology in conducting totally laparoscopic gastrectomy for advanced gastric cancer and prone thoracoscopic esophagectomy for esophageal cancer using novel technology including da Vinci Surgical System (DVSS). We have recently demonstrated that use of DVSS might reduce postoperative local complications including pancreatic fistula after gastrectomy and recurrent laryngeal nerve palsy after esophagectomy. In this article, we present the current status and future perspectives on MIS for gastric and esophageal cancer based on our experience and a review of the literature.

Key words: Stomach neoplasms; Esophageal neoplasms; Minimally invasive surgical procedures; Postoperative complications; Robotic surgical procedures

Core tip: Minimally invasive surgery (MIS) for upper gastrointestinal cancer reduces intraoperative blood loss and postoperative pain, leading to faster recovery. It also results in better cosmetic outcomes. The impact of MIS on postoperative complications and long-term outcomes has been under debate. We have recently demonstrated that use of da Vinci Surgical System might reduce postoperative local complications including pancreatic fistula after gastrectomy and recurrent laryngeal nerve palsy after esophagectomy.

INTRODUCTION

Gastric cancer (GC) is the fifth most common malignancy and the third leading cause of cancer death in the world in 2012[1]. Surgical resection remains the only curative treatment option, and regional lymphadenectomy is recommended as part of radical gastrectomy[2]. According to the Japanese Gastric Cancer Association (JGCA) Gastric Cancer Treatment Guidelines, D2 gastrectomy is recommended for advanced gastric cancer (AGC)[3,4]; however, D2 lymphadenectomy, especially when combined with splenectomy or pancreaticosplenectomy, has been reported to increase morbidity and mortality[5-8].

Esophageal cancer (EC) is the eighth most common malignancy and the sixth leading cause of cancer death in the world in 2012[1]. Similar to GC, surgical resection remains the primary curative treatment option, and regional lymphadenectomy is recommended as part of radical esophagectomy[9-12]. Esophagectomy, which requires thoracolaparotomic manipulation, is one of the most invasive operations in gastrointestinal (GI) surgery, being associated with significant morbidity and mortality[13,14].

Minimally invasive surgery (MIS), which was launched in the late 80's[15], has been characterized by minimal access using laparoscope or thoracoscope with CO_2 insufflation[16]. Although the impact of MIS on postoperative inflammatory response has still been unclear, it has been increasingly used for upper GI malignancies in an attempt to improve postoperative outcomes[13,17,18].

This article provides the updates on laparoscopic gastrectomy (LG) for GC and video-assisted thoracoscopic surgery esophagectomy (VATS-E) for EC, particularly focusing on our twenty-year experience in this field along with a review of previously reported and ongoing large prospective studies.

GASTRIC CANCER

LG for early gastric cancer

Since the first report of LG by Kitano *et al*[19] in 1994, LG for GC has gained popularity because of its beneficial short-term effects leading to improved quality of life (QoL) in comparison with open gastrectomy (OG), although many controversies still exist due to the lack of solid evidence on its long-term outcomes[20-24]. Therefore, LG had long been recognized as an investigational treatment even for early gastric cancer (EGC) but not as a standard procedure in Japan[25]. However, based on the results of the following multicenter phase Ⅱ trial conducted by the Japanese Clinical Oncology Group (JCOG) (JCOG0703)[26], the new Japanese Gastric Cancer Treatment Guidelines (ver. 4, issued in 2014) has turned to allow laparoscopic distal gastrectomy (LDG) for clinical stage Ⅰ disease as a standard treatment option[4].

JCOG0703

JCOG0703[26] was conducted to assess the safety of LDG with D1+ lymph node (LN) dissection for clinical stage Ⅰ GC. In this well-designed phase Ⅱ study, to control for the quality of surgery, only surgeons who had performed 30 or more LDGs and 30 or more open distal gastrectomies (ODGs) participated. A central review of the surgical procedure in all the patients was conducted by evaluating photographs taken during the procedure. Between 2007 and 2008, 176 eligible patients from 14 hospitals were enrolled. The incidence of anastomotic leakage or pancreatic fistula was primarily determined, resulting in only 1.7 % (3/173), which was much lower than the pre-specified threshold of 8%. Moreover, morbidity (Common Terminology Criteria for Adverse Events, CTCAE v3.0 Grade 3 or 4)[27] was 5.1%. Thus, the safety of LDG for clinical stage IA/IB disease was securely confirmed.

JCOG0912

On the basis of JCOG0703, a multicenter phase Ⅲ RCT of LDG *vs* ODG with D1+ nodal dissection for clinical stage Ⅰ GC (JCOG0912) has currently been conducted to determine the non-inferiority of LDG to ODG in terms of overall survival[28,29]. For quality control of surgery, surgeons were required to have experience with at least 30 LDGs as well as certification (or its equivalent) from the Japan Society for Endoscopic Surgery (JSES) according to the Endoscopic Surgical Skill Qualification System[30]. Between 2010 and 2013, 921 patients (LDG 462, ODG 459) were enrolled from 33 institutions. Regarding short-term outcomes of this study, LDG significantly improved blood loss, postoperative pain and recovery of bowel movement irrespective of extended operative time. There were no grade 3 or 4 (CTCAE v4.0[31]) intraoperative adverse events in either arm. No difference was observed in the overall proportion of in-hospital, non-hematological

Table 1 Ongoing randomised controlled trials on laparoscopic distal gastrectomy for advanced gastric cancer

	JLSSG0901	KLASS02	CLASS01
Country	Japan	Korea	China
Start year	2010	2011	2012
Phase	Ⅱ/Ⅲ	Ⅲ	Ⅲ
Intervention	LDG *vs* ODG	LDG *vs* ODG	LDG *vs* ODG
Inclusion criteria	cT2-4a cN0-2 (except bulky N2)	cT2-4a cN0/1	cT2-4a cN0-3 (except bulky LN)
Sample size	Ⅱ:180, Ⅲ:500	1050	1056
Primary endpoint	Ⅱ: morbidity Ⅲ: 3-year RFS	3-year RFS	3-year RFS

JLSSG: Japanese Laparoscopic Surgery Study Group; KLASS: Korean Laparoscopic Gastrointestinal Surgery Study; CLASS: Chinese Laparoscopic Gastrointestinal Surgery Study; LDG: Laparoscopic distal gastrectomy; ODG: Open distal gastrectomy; LN: Lymph node; RFS: Relapse-free survival.

grade 3 or 4 adverse events excluding biochemical data (LDG *vs* ODG, 3.3% *vs* 3.7%). The proportion of grade 3 or 4 serum AST/ALT increased was higher in LDG than ODG (16.4% *vs* 5.3%, $P < 0.001$). Thus, this trial has so far demonstrated that LDG performed by the credentialed surgeons was at least as safe as ODG in terms of adverse event and short-term clinical outcomes. The primary analysis of the long-term outcomes including overall survival and relapse-free survival is planned in 2018[29].

KLASS01

The Korean Laparoscopic Gastrointestinal Surgery Study (KLASS) group 01 trial is another multicenter (13 institutions) RCT to confirm oncological safety of LDG for EGC in comparison with ODG[32,33]. The primary endpoint of this study is 5-year overall survival. Surgeons had to have performed at least 50 cases of both LDG and ODG, and their institution should have performed more than 80 cases of both LDG and ODG, respectively. Between 2006 and 2010, 1416 patients (705 LDGs and 711 ODGs) were enrolled. Regarding short-term outcomes, LDG improved the overall complication rate (LDG *vs* ODG, 13.0% *vs* 19.9%, $P = 0.001$), particularly wound complication (LDG *vs* ODG, 3.1% *vs* 7.7%, $P < 0.001$). The major intra-abdominal complication (LDG *vs* ODG, 7.6% *vs* 10.3%, $P = 0.095$) and mortality rates (LDG *vs* ODG, 0.6% *vs* 0.3%, $P = 0.687$) were similar between the groups. Thus, this trial has so far demonstrated that LDG for patients with clinical stage Ⅰ GC was sufficiently safe and has a benefit of lower occurrence of wound complication compared with conventional ODG. The long-term outcomes are being awaited.

Laparoscopic total gastrectomy for EGC

These multicenter prospective studies only cover distal gastrectomy. At this moment, both JGCA and JSES have commented that Laparoscopic total gastrectomy (LTG) should be cautiously introduced because of its technical difficulties in complicated alimentary tract reconstruction as well as the LN dissection at the splenic hilum or along the short gastric arteries[4,34]. Since techniques for laparoscopic esophagojejunostomy has recently been established among expert laparoscopic surgeons[35,36], JCOG is planning a phase Ⅱ study to determine the safety of LTG with D1+ LN dissection for clinical stage Ⅰ disease[37]. KLASS group has already been conducting a similar phase Ⅱ trial (KLASS03) to properly evaluate the perioperative morbidity and mortality of LTG for EGC since 2012[17].

LG for AGC

Application of LG for AGC remains to be debated not only because of the lack of evidence on long-term outcomes, but also because of the technical difficulty in performing complete D2 LN dissection and a concern for the innate risk of cancer cell dissemination to the peritoneal cavity[5,16,17,38]. Having said that, acceptable short- and long-term outcomes of the LG for AGC have been reported by a couple of experienced surgeons including us[38-41]. Currently, large-scale multicenter RCTs have been conducted in Japan (The Japanese Laparoscopic Surgery Study Group, JLSSG 0901[42]), Korea (KLASS02[17,43]), and China (The Chinese Laparoscopic Gastrointestinal Surgery Study, CLASS 01[17]) in order to determine the feasibility of LDG for locally AGC (Table 1).

LG for AGC at our institute

History: Laparoscopic surgery was launched in the early 90's in our country[44]. At that time, most laparoscopic surgeons applied laparoscopic surgery, using its minimally invasive nature, to less extended surgery[45]. However, we assumed from the beginning that laparoscopic surgery should be suitable for meticulous LN dissection using laparoscopically enhanced anatomy and reduced venous bleeding *via* pneumoperitoneum irrespective of the limited range of motion, poor depth perception, and limited tactile sensation[5,46]. Then, we introduced laparoscopic assistance into moderate to advanced GI surgery in combination with a caudocranial and mediolateral approach to overcome those limitations in 1995, and developed techniques for LDG and LTG with D2 dissection for AGC, which were published for the first time in the world[47,48]. Since then, we have performed

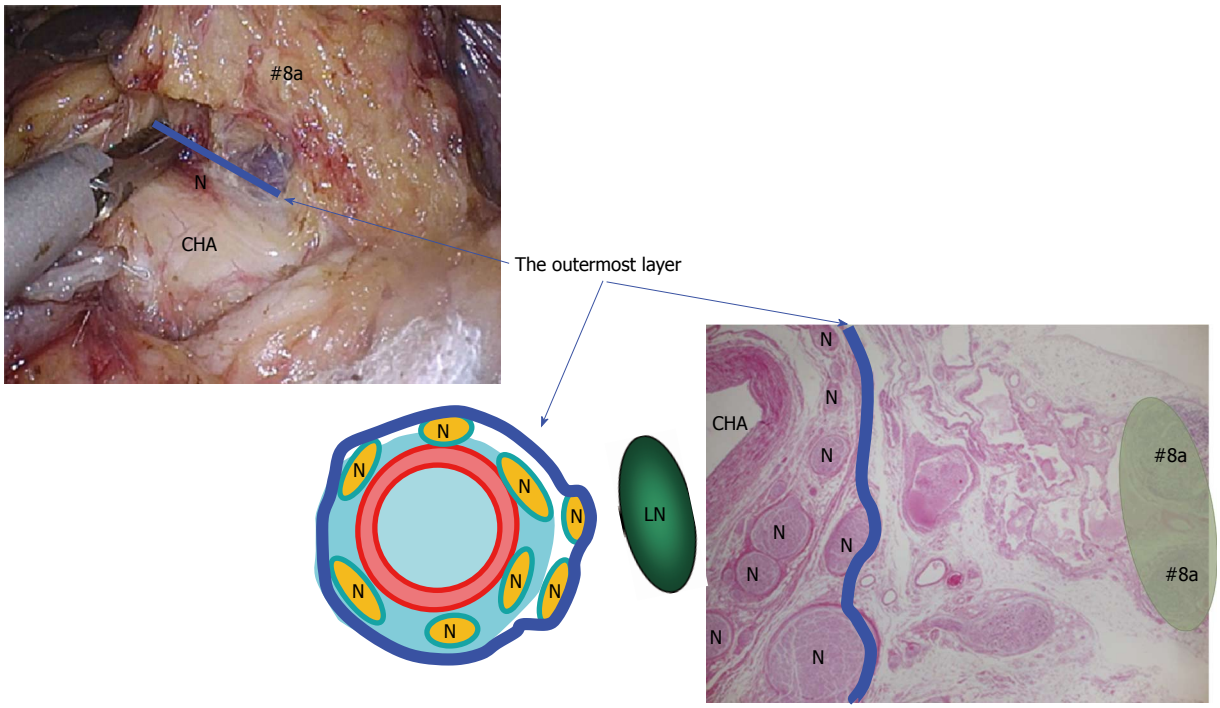

Figure 1 Outermost layer of the autonomic nerve. Shown in the blue line, lies between the vascular sheath of the major arteries and the fat tissue including lymph nodes. Appropriate tension given to this thin loose connective tissue layer generates sufficient space for safe, adequate and reproducible prophylactic lymph node dissection along the major arteries. LN: Lymph node; N: Nerve; CHA: Common hepatic artery.

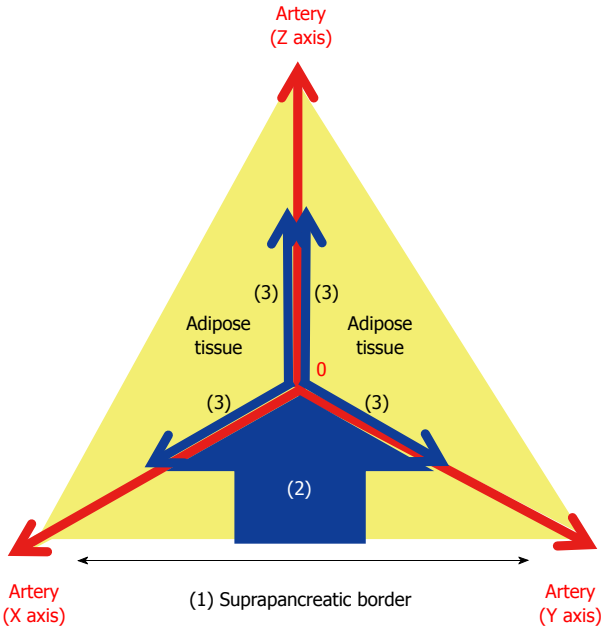

Figure 2 XYZ-axis theory. The following three steps result in effective probing of the outermost layer: (1) dissection of the serosal membrane on the suprapancreatic border; (2) dissection of the fat tissue in the caudo-cranial direction towards the zero point; and (3) dissection of the fat tissue bearing the target LNs in the medio-lateral direction along the outermost layer on the XZ and YZ axes. The outermost layer adjacent to the zero point should be exposed during the 2nd step.

more than 1500 LGs. At present, the standard type of operation for curable GC at our institute is totally laparoscopic D2 gastrectomy[5].

Suprapancreatic lymph node dissection: Outermost-layer oriented medial approach: D2 dissection entails removal of the LNs in the suprapancreatic area in distal and total gastrectomy[4]. Dissection of this area is technically demanding due to the serious risk of bleeding and/or pancreatic leakage derived from a major vessel or organ injury[49,50]. To improve the safety, efficacy, and reproducibility of suprapancreatic LN dissection, we developed our original methodology called outermost layer-oriented medial approach[46,50]. In this approach, the thin loose connective tissue layer between the autonomic nerve sheaths of the major arteries and the adipose tissue bearing lymphatic tissue is dissected[46,50]. We termed this layer as the outermost layer of the autonomic nerve (Figure 1)[46]. To identify this layer throughout the dissection process, we developed an original surgical theory, "XYZ-axis" theory (Figure 2), consisting of the following three steps: (1) cut the serosal membrane on the suprapancreatic border; (2) dissect suprapancreatic adipose tissue caudocranially towards the junction of the three arteries (zero point) to find the outermost layer; and (3) dissect the target adipose tissue mediolaterally along the outermost layer spreading on the XZ and YZ axes. Using this theory, the outermost layer could easily be found not only at the junction of left gastric, common hepatic, and splenic arteries (Figure 3A), but also at that of gastroduodenal, right gastroepiploic, and anterior superior pancreaticoduodenal arteries (Figure 3B) and that of proper hepatic and right gastric arteries (Figure 3C).

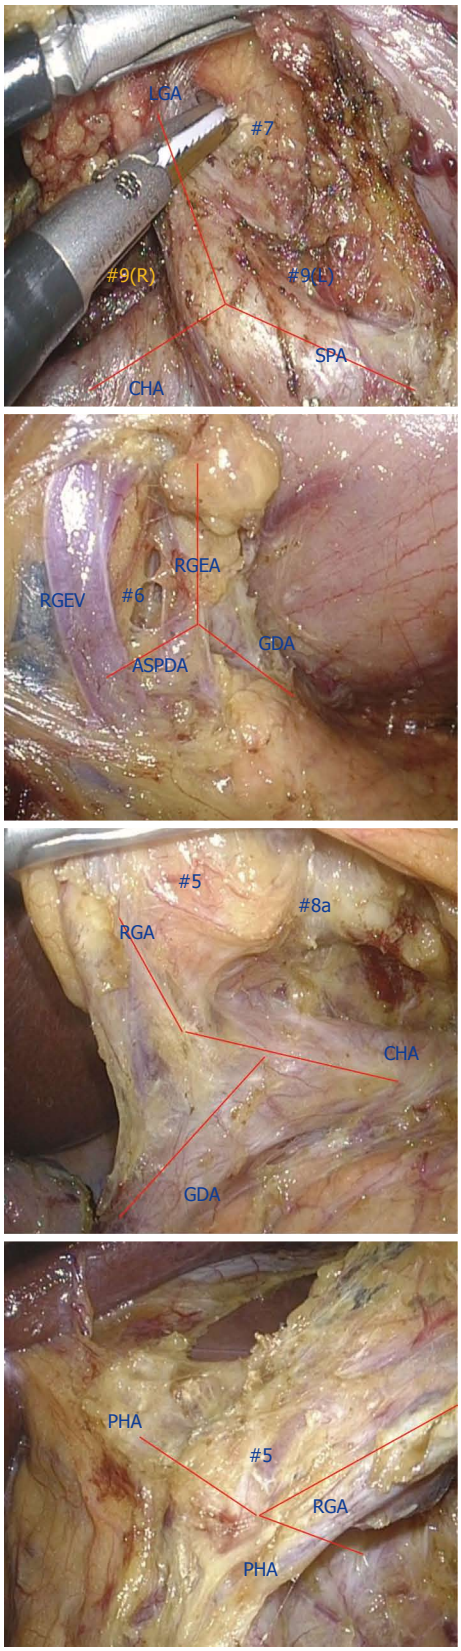

Figure 3 Lymph node dissection along the outermost layer using the XYZ-axis theory. A: No. 7 and 9 dissection, B: No. 6 dissection, C: No. 5 dissection.

LTG for AGC: Splenic hilar lymph node dissection: According to the JGCA guidelines, D2 total gastrectomy is recommended for advanced proximal GC[3,4]; however, as mentioned before, D2 lymphadenectomy combined with splenectomy or pancreaticosplenectomy has been reported to increase morbidity and mortality[5,51,52]. Therefore, the practical importance of station 10 LN dissection and splenectomy in D2 total gastrectomy is controversial[6-8].

We started totally LTG (TLTG) for AGC in 1997[47] and have established a stable and robust methodology, including splenic hilar LN (SHLN) dissection, even though LTG but not LDG has still been one of the independent risk factors for postoperative complications of LG[53,54]. Regarding the extent of SHLN dissection, D2 lymphadenectomy combined with distal pancreaticosplenectomy (D2 + PS) is performed in patients with tumors infiltrating into the pancreatic body or tail. D2 lymphadenectomy combined with splenectomy (D2 + S) is performed in patients with LN metastasis at the station 11 d or 10 or in those with greater curvature invasion. Spleen-preserving D2 lymphadenectomy (D2-S) is performed in patients with tumor depths cT $\geqslant$ 3 without LN metastasis at the station 11 d or 10, whereas D2 lymphadenectomy with preservation of station 10 LNs and the spleen (D2-10) is performed in patients without greater curvature invasion and with tumor depths cT2 (Figure 4)[55].

Regarding the operating procedures, additional care to control the extent of SHLN dissection in TLTG was given to: (1) the layer on the fusion fascia at the infrapancreatic border of the pancreatic tail; (2) the layer on the subretroperitoneal fascia on the left diaphragmatic crus around the upper pole of the spleen; and (3) the outermost layer of the splenic artery. Using these layers, the aforementioned four different types of SHLN dissection could easily be performed. Procedural details are summarized in our previous literature[55]. In this previous study, multivariate analysis revealed that operative time was the only significant factor associated with postoperative complications. Operative time, morbidity, and pancreatic fistula increased with increasing extent of SHLN dissection. Therefore, the extent of SHLN dissection should be appropriately attenuated if this is allowed by oncological factors. At present, according to the latest JGCA guidelines[4], complete clearance of station 10 nodes by splenectomy should still be considered for potentially curable T2-4 tumors invading the greater curvature of the upper stomach. However, in patients with T2-4/N0-2/M0 GC not invading the greater curvature, the JCOG0110 trial demonstrated that prophylactic splenectomy should be avoided to improve operative safety and survival[2,56].

Intracorporeal anastomosis: To fully utilize the advantages of LG, totally laparoscopic gastrectomy with intracorporeal anastomosis is promising. We have preferred intracorporeal anastomosis with linear staplers because of its handy, quick visible, and reproducible natures. In LDG, we have used delta-shaped anastomosis for Billroth-Ⅰ reconstruction[57-59],

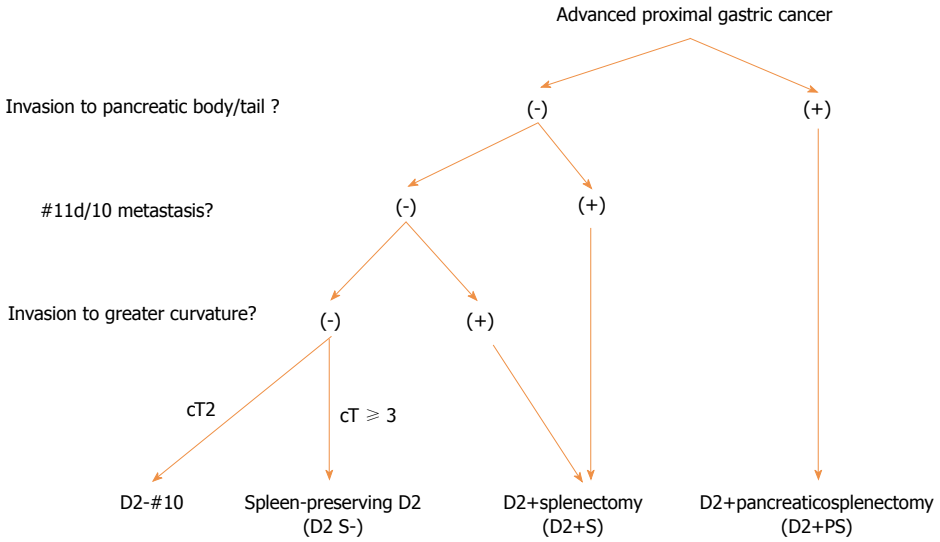

Figure 4 Indication for splenic hilar lymph node dissection at FHU.

antiperistaltic side-to-side anastomosis for Billroth-Ⅱ reconstruction, and functional end to end anastomosis for Roux-en-Y reconstruction[5]. In total gastrectomy, we have used functional end to end anastomosis[36] and overlap method[35] for intraabdominal and intrathoracic esophagojejunostomy, respectively. In proximal gastrectomy, modified overlap method with no-knife stapler has been used[60]. The details on intracorporeal anastomosis in LG are well summarized in the review article by Hosogi *et al*[60].

Outcomes: The short-term and long-term outcomes of LG for AGC at our institute have been satisfactory from both technical and oncological point of view (LG *vs* OG: mortality, 1.1% *vs* 0%, $P = 0.519$; morbidity, 24.2% *vs* 28.5%, $P = 0.402$; 5-year disease free survival, 65.8% *vs* 62.0%, $P = 0.737$; overall survival, 68.1% *vs* 63.7%, $P = 0.968$). Details are demonstrated in our previous reports[38,55].

Robotic gastrectomy

In Japan, da Vinci S HD Surgical System received approval by the Drugs, Cosmetics and Medical Instruments Act in November, 2009. We introduced da Vinci S to our institution in 2009 for the first time in our county, and have been actively using this system for operable patients with resectable upper GI cancer who agreed to uninsured use of the robot[46,53,61].

According to the latest meta-analysis of robotic gastrectomy (RG) *vs* LG, combining the findings from previous observational studies with small sample size, use of the robot significantly increased operative time and cost, whereas there were no significant differences in other short-term outcomes including blood loss, number of dissected lymph nodes, surgical margins, postoperative complications and duration of hospital stay[62]. The only large non-randomized prospective study (NCT01309256), recently reported from Korea, demonstrated similar outcomes[63]. These reports suggested that use of the robot might even deteriorate the cost-effectiveness[62,63]. In other words, the greatest issue around RG is a lack of clear benefits of the robotic system which corroborate the longer duration of operation and higher cost[63]. However, most of the patients enrolled in these previous studies had pathological stage Ⅰ diseases, and these studies failed to eliminate the learning effect or the selection bias at least partly generated by more expensive copayment in RG[62,63]. The impact of RG on long-term outcomes has largely been unclear[64,65]. Thus, the advantages of RG for AGC conducted by fully-trained robotic surgeons have never been clarified. In addition, several reports have demonstrated the short learning curve of RG[66-69].

Since 2009, we have performed RG for more than 250 patients not only with EGC but with AGC. Then, according to our retrospective analyses in comparison with LG (EGC *vs* AGC, 57% *vs* 43%), RG reduced morbidity down to one fifth including pancreatic fistula, leading to further improvement in short-term postoperative courses, although it slightly increased blood loss and operative time[53,70]. Multivariate analyses clearly demonstrated that conventional LG (non-use of the surgical robot), total gastrectomy (*vs* distal) and D2 lymphadenectomy (*vs* D1+) were the significant independent risk factors determining postoperative complications[53]. Moreover, the greater the extent of gastric resection and LN dissection, the more effective the use of the robot[53]. In terms of long-term results, 3-year overall survival did not change between RG and LG[71]. Not only oncological factors including tumor size and clinical stage but also surgical factors including pancreatic fistula were found to be associated with three-year recurrence free survival, indicating the oncological as well as surgical importance of preventing pancreatic fistula[71,72]. These

data suggest that the best indication for the use of the robot might be RG for AGC with D2 dissection[53]. Thus, multi-institutional prospective studies conducted by experienced robotic surgeons, in which considerable number of patients with AGC are enrolled, should be required to determine whether use of the robotic system for AGC truly attenuates pancreatic fistula, possibly leading to improvement in long-term outcomes[70].

Since the beginning of October, 2014, we have been conducting a multi-institutional single-arm prospective study (UMIN000015388), which Japanese Ministery of Health, Labor, and Welfare has recently approved for Advanced Medical Technology ("senshiniryo")[70]. This study was designed to determine the impact of the use of the robot, for minimally invasive radical gastrectomy to treat resectable GC, on short-term outcomes, mainly focusing on postoperative complications, as well as long-term outcomes and cost. The specific hypothesis of this study was that the use of the robot in patients with cStage Ⅰ or Ⅱ diseases reduces the morbidity (Clavien-Dindo Classification Grade ≥ Ⅲ[73]) of 6.4% in conventional LG down to 3.2%. The sufficient sample size was calculated to be 330. All the patients will be registered in 2 years after starting this study and followed up for 3 years, thus the expected study period should be 5 years in total. Interim analyses will be done once the initial 220 cases are registered. As of January 31, 2016, 122 patients from 5 institutions have been registered.

ESOPHAGEAL CANCER

History

Since 1992, when Cuschieri *et al*[74] first reported on VATS-E, many groups have described various methods[75-79]. In Japan, Akaishi *et al*[75] first reported on thoracoscopic total esophagectomy with en bloc mediastinal lymphadenectomy in 1996. Kawahara *et al*[76] demonstrated the details of VATS-E with extended lymphadenectomy in 1999, and Osugi *et al*[80] clarified the long-term outcomes of VATS-E. We performed prone VATS-E with CO2 insufflation in 2006 for the first time in our country[61].

Indication

The indication for VATS-E is relatively wider than that for LG[10]. VATS-E has currently been applied up to locally advanced EC even after neoadjuvant chemoradiotherapy[9,10]. Only some conditions including T4 tumor, severe intrathoracic adhesion, and one-lung ventilation failure are considered to be excluded from the indication for VATS-E[10,77,81].

Left lateral decubitus vs prone position

Regarding the patient positions used for VATS-E, similar to right transthoracic open esophagectomy (OE), the left lateral decubitus position had been mostly used[75,82]. However, the prone position has increasingly been used recently[74,83-85]. Prone VATS-E is characterized by operating surgeon-friendly sense of use brought by more ergonomic set up as well as a drier operative field given by gravity in combination with the positive intrathoracic pressure generated by CO_2 insufflation[61]. To enjoy these advantages of the prone position as well as those of laparoscopic horizontal magnified view with overcoming the laparoscopic limited range of motion, we fully mobilize the "meso-oesophagus"[86] from lower up to upper mediastinum prior to the LN dissection of station 106 recR, 106 recL+tbL, and 112 (Japanese Classification of Esophageal Cancer, the 11th ed[87]) using the 6-trocar system in the hemi-prone position (Figure 5).

Outcomes

To date, a number of single-institution studies have demonstrated acceptable short-term outcomes of VATS-E for thoracic EC regarding operative time, blood loss and postoperative complications, which are comparable with those of conventional OE[13,81]. According to a meta-analysis based on these small case-control studies, VATS-E reduced blood loss, total morbidity and respiratory complications, leading to shorter intensive care unit and hospital stay in comparison with OE[88-90]. In terms of long-term outcomes, a limited number of case-control studies have demonstrated the comparable results with conventional OE[80,89,91,92]. Therefore, to determine the feasibility and beneficial effects of VATS-E, multicenter prospective RCTs are warranted.

ECOG2202: The Eastern Cooperative Oncology Group (ECOG) performed the first prospective phase Ⅱ multicenter trial (ECOG2202[93]) to assess the feasibility of VATS-E. A total of 110 patients were enrolled at 17 credentialed sites. The primary endpoint was 30-d mortality. 30-d and perioperative mortality was 2.1% and 2.9%, respectively. Grade 3 or 4 (CTCAE v3.0[27]) adverse effects occurred in 49.5% of the eligible 105 patients. Estimated 3-year overall survival was 58.4% (95%CI: 47.7%-67.6%). These data suggested that VATS-E was feasible and safe with acceptable perioperative and oncological outcomes.

Traditional Invasive *vs* Minimally Invasive Esophagectomy trial: Traditional Invasive *vs* Minimally Invasive Esophagectomy (TIME) trial is the first multicenter RCT comparing short-term outcomes of prone VATS-E and those of OE, which was conducted by a study group in Europe[77,94]. In this study, 56 and 59 patients were randomly assigned to the OE and the VATS-E group, respectively. As a result, VATS-E reduced, intraoperative blood loss, postoperative pain, postoperative pulmonary infection, and vocal cord palsy, leading to reduced hospital stay and improved postoperative QoL. No siginificant difference was observed in mortality and the number of

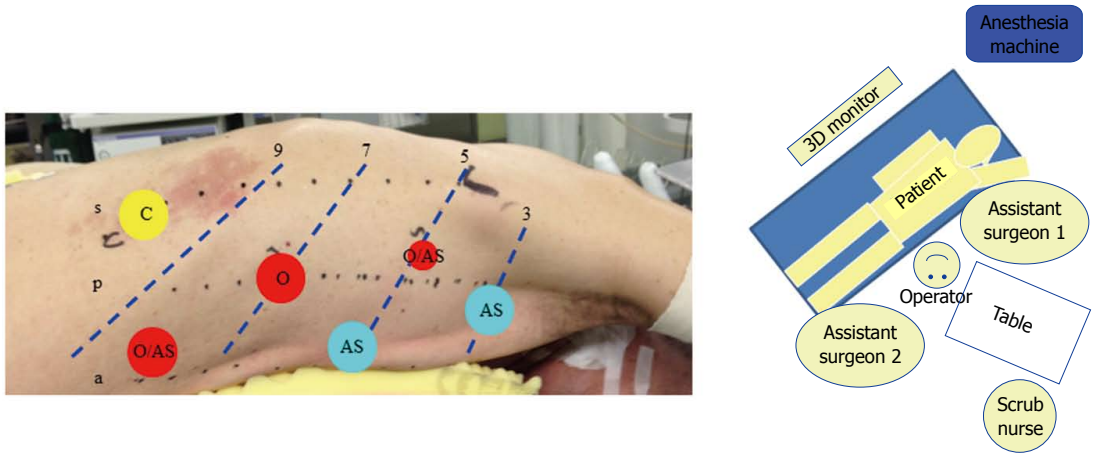

Figure 5 Setup for prone VATS-E at Fujita Health University. A: The patient in the hemi-prone position using the six-trocar system. 12 mm trocars are used except for the trocar in the 5th intercostal space (ICS) behind the posterior axillary line; B: OR setup. s: Scapula angle line; p: Posterior axillary line; a: Anterior axillary line; 3: 3rd ICS; 5: 5th ICS; 7: 7th ICS; 9: 9th ICS; O: Operating surgeon; AS: Assistant surgeon.

dissected lymph nodes. These findings suggested the advantages of VATS-E over OE in terms of short-term outcomes.

Robotic esophagectomy

The robotic esophagectomy has been less commonly performed than robotic gastrectomy. Thus, the impact of the use of D*VSS* on esophagectomy has been assessed mostly in case-series with small sample size[61,95-109]. Various groups have reported on feasibility and safety with good short-term outcomes in a wide-range of approaches to esophagectomy[110]. Van der Sluis *et al*[111] have reported sufficient oncological long-term outcomes of robotic esophagectomy for advanced esophageal cancer (5-year overall survival, 42%). Hernandez *et al*[100] demonstrated that the learning curve for a robotic-assisted procedure appears to begin near proficiency after 20 cases for surgeons experienced in conventional minimally invasive approach. Further studies are warranted to determine advantages and disadvantages of robotic esophagectomy.

Since 2009, we have performed robotic radical esophagectomy in the prone position for more than 40 patients. Then, compared to conventional MIS, robotic approach significantly reduced incidence of vocal cord palsy and hoarseness, suggesting that the use of the robot, which promotes more accurate recurrent laryngeal nerve identification and dissection[95], should reduce the chances of recurrent laryngeal nerve injury, resulting in preserved laryngopharyngeal function[61].

DISCUSSION

Although MIS for upper GI cancer has consistently appeared to improve short-term outcomes and at least preserve long-term outcomes, solid evidences that verify feasibility of MIS and even superiority to open surgery have still been lacking. Advantages and disadvantages of LDG for EGC and AGC over ODG will soon be clarified after the ongoing multicenter RCTs are concluded, however, those of LTG and VATS-E will have been unclear for the time being.

One of the principal reasons why surgeons have been attracted to MIS must be the laparoscopically enhanced anatomy provided by the magnified vivid image with high definition in combination with the horizontal view. To fully utilize these advantages of MIS, the disadvantages of MIS including limited range of motion has to be overcome. We believe one of the solutions may be the laparoscopic manipulation in the caudocranial and/or mediolateral manner, and another may be the use of the surgical robot as indicated in our previous reports[46,50,53,55,61].

We wish to further develop MIS for advanced cancer and that requiring advanced skills by actively utilizing novel technologies including the surgical robot, based on the principles and methods grown through conventional MIS and open surgeries.

In conclusion, technical advancements and development of endoscopic instruments will continue to evolve MIS for upper GI cancer. The outcomes should be validated in a scientific fashion.

ACKNOWLEDGMENTS

The authors thank Dr Seiichiro Kanaya for his wonderful contribution to establishing our original method of minimally invasive gastrectomy and esophagectomy.

Abstract

Signaling pathways of gastric carcinogenesis and gastric cancer progression are being avidly studied to seek optimal treatment of gastric cancer. Among them, hepatocyte growth factor (HGF)/c-MET, phosphoinositide 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) and janus kinase 2/signal transducer and activator of transcription 3 (JAK2/STAT3) pathways have been widely investigated. Their aberrant expression or mutation has been significantly associated with advanced stage or poor prognosis of gastric cancer. Recently, aberrations of immune checkpoints including programmed cell death-1/programmed cell death ligand-1 (PD-1/PD-L1) have been suggested as an important step in the formation of a microenvironment favorable for gastric cancer. Accomplishments in basic research have led to the development of novel agents targeting these signaling pathways. However, phase Ⅲ studies of selective anti-HGF/c-MET antibodies and mTOR inhibitor failed to show significant benefits in terms of overall survival and progression-free survival. Few agents directly targeting STAT3 have been developed. However, this target is still critical issue in terms of chemoresistance, and SH2-containing protein tyrosine phosphatase 1 might be a significant link to effectively inhibit STAT3 activity. Inhibition of PD-1/PD-L1 showed durable efficacy in phase Ⅰ studies, and phase Ⅲ evaluation is warranted. Therapeutic strategy to concurrently inhibit multiple tyrosine kinases is a reasonable option, however, lapatinib needs to be further evaluated to identify good responders. Regorafenib has shown promising effectiveness in prolonging progression-free survival in a phase Ⅱ study. In this topic highlight, we review the biologic roles and outcomes of clinical studies targeting these signaling pathways.

Key words: Gastric cancer; Hepatocyte growth factor; Mammalian target of rapamycin; Signal transducer and activator of transcription 3; Programmed cell death ligand-1

Core tip: Among various cellular signaling pathways, hepatocyte growth factor/c-MET, phosphoinositide 3-kinase/Akt/mammalian target of rapamycin and janus kinase 2/signal transducer and activator of transcription 3 pathways are reportedly important in gastric carcinogenesis and metastasis. Aberrations of immune checkpoints have been vigorously investigated. However, clinical results of their target agents have not always matched the theoretical expectations of efficacy. In this review, we summarize the biologic impacts of the aforementioned signaling pathways, and their recent clinical outcomes including those of multiple kinase inhibitors in gastric cancer.

INTRODUCTION

Gastric cancer is the fourth common malignant tumor worldwide, and the second most common cause of cancer-related mortality[1]. The progress in therapeutic approaches has allowed complete remission of early gastric cancer by surgical or even endoscopic resection of tumors. However, if gastric cancer is advanced when diagnosed, the prognosis is generally poor and survival time is short even after surgical complete resection. Therefore, highly selective and effective chemotherapy remains an important issue for appropriate management of advanced gastric cancer.

A recent notable study provided a comprehensive molecular evaluation of primary gastric adenocarcinoma tissues as part of The Cancer Genome Atlas project[2]. The authors proposed four subtypes of gastric cancer according to the molecular characteristics: Epstein-Barr virus positive tumors, microsatellite instability tumors, genomically stable tumors and chromosomal unstable tumors. This study is a prime example of efforts to develop optimal classification of gastric cancer by analyzing common dysregulated pathways and to provide distinct tailored therapy for individual patients. Since the report of significant clinical benefits of trastuzumab in human epidermal growth factor receptor 2 (HER2)-positive gastric and esophagogastric junction (EGJ) adenocarcinoma[3], various targets have been investigated in the treatment of advanced gastric cancer. These targets include epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), hepatocyte growth factor(HGF)/c-MET and mammalian target of rapamycin (mTOR)[4]. However, we still have a long way to go before complete conquest of gastric cancer.

In this topic highlights, we aimed to review the biologic roles of several molecular signaling pathways on the basis of recent trials of targeted therapies in advanced gastric cancer. These include the HGF/c-MET, phosphoinositide 3-kinase (PI3K)/Akt/mTOR, janus kinase 2/signal transducer and activator of transcription 3 (JAK2/STAT3) and programmed cell death-1/programmed cell death ligand-1 (PD-1/PD-L1) pathways. In the latter part, we focus on clinical outcomes of newly developed agents targeting the aforementioned pathways and summarize the findings of some clinical studies of multi-kinase inhibitors (MKIs), which can simultaneously multiple receptor tyrosine kinases (RTKs) in advanced gastric cancer.

CELLULAR SIGNALING PATHWAYS OF GASTRIC CANCER

HGF/c-MET pathway

c-MET is a heterodimeric subfamily of RTK. c-MET is composed of an α-chain, which possesses only an extracellular domain, and a β-chain composed of extracellular, transmembrane and intracellular domains[5]. The ligand of c-MET, HGF, is converted into an active form that causes dimerization and activation of the c-MET receptor. The activated HGF/c-MET signal leads to autophosphorylation of multiple tyrosine residues of the intracellular region of c-MET, such as Y1230, Y1234, Y1235, Y1349 and Y1356, which form multi-functional docking sites to recruit several intracellular adaptor proteins[6]. Among them, Grb2-associated binder 1 (GAB1) can directly bind to c-MET or forms a complex with growth factor-bound protein 2 (GRB2) to indirectly interact with c-MET. The c-MET association recruits several main adaptor proteins including STAT3 and PI3K, which in turn activate downstream biologic effects including cellular proliferation, migration/invasion and induction of epithelial-mesenchymal transition (EMT) (Figure 1)[7].

Clinical impact of the HGF/c-MET pathway in gastric cancer has been well documented. High protein expression rate of c-MET in gastric carcinoma tissue has been demonstrated by immunohistochemistry (IHC; 43%-82%)[8,9] and by gene amplification rate (2%-10%)[9-12]. In both approaches, the elevated expression of c-MET has been positively associated with advanced tumor stage and poor survival rate. Consequently, multiple agents targeting the HGF/c-MET signaling pathway are being evaluated. Tivantinib, an anti-c-MET tyrosine kinase inhibitor (TKI), used in combination with the EGFR TKI, erlotinib, has extended progression-free survival (PFS) in patients

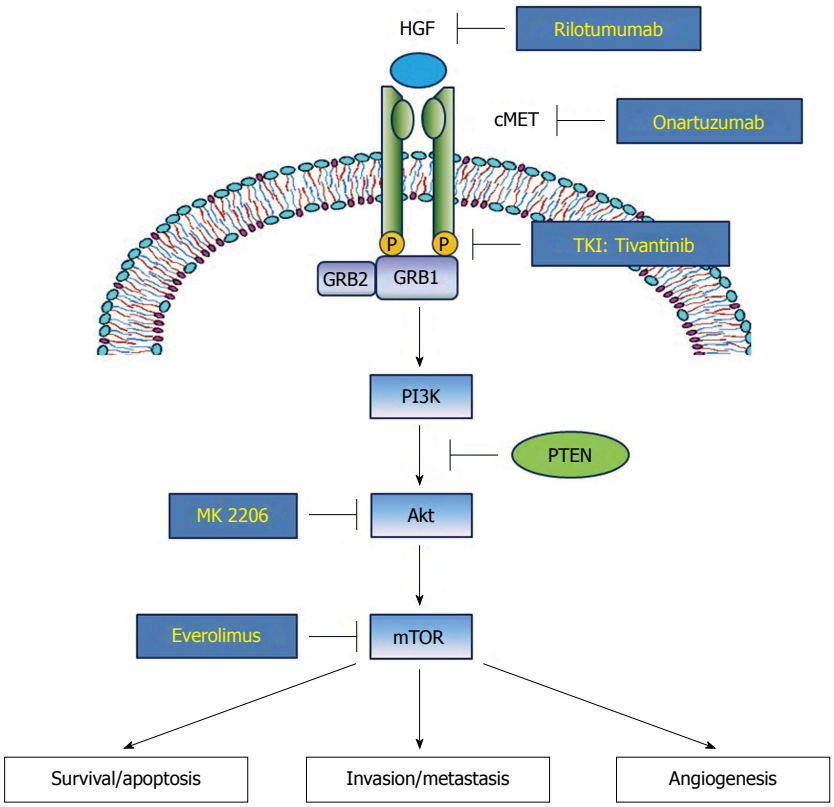

Figure 1 Hepatocyte growth factor/mesenchymal epithelial transition factor and phosphoinositide 3-kinase/Akt/mammalian target of rapamycin pathway, and their inhibitors evaluated in gastric cancer patients. HGF: Hepatocyte growth factor; cMET: Mesenchymal epithelial transition factor; GAB1: Grb2-associated binder 1; GRB2: Growth factor-bound protein 2; PI3K: Phosphoinositide 3-kinase; PTEN: Phosphatase and tensin homolog; mTOR: Mammalian target of rapamycin.

with locally advanced or metastatic non-squamous non-small-cell lung cancer in a phase Ⅲ trial[13]. In gastric cancer, phase Ⅲ studies for rilotumumab, an anti-HGF monoclonal antibody, and onartuzumab, an anti-c-MET monoclonal antibody, have been completed, and clinical outcomes of tivantinib were recently reported[14].

PI3K/Akt/mTOR pathway

The PI3K-Akt-mTOR pathway plays a pivotal role in oncogenesis and progression including cell growth, survival, invasion/metastasis and angiogenesis, and gastric cancer is no exception. PI3K is usually activated through binding and stimulation of various RTKs by growth factors including HGF and c-MET. Activated PI3K subsequently phosophorylates and activates phosphatidylinositol 3,4-biphosphate (PIP2), phosphatidylinositol 3,4,5-triphosphate (PIP3), phosphoinositide-dependent protein kinase 1 and Akt[15]. Akt, which is also termed protein kinase B, is a major effector protein of the PI3K pathway. Phosphorylated Akt (p-Akt) modulates various biologic functions like cell survival, migration/invasion and angiogenesis through downstream adaptor molecules including mTOR (Figure 1)[16].

Genetic alteration of biological signals involving the PI3K/Akt/mTOR pathway has been frequently detected in gastric carcinoma. For example, a point mutation of *PIK3CA* encoding p110 (a class IA subunit of PI3K) is often observed in gastric carcinoma tissues, ranging from 4.3%-25%[17-21], with the point mutation mostly seen in exon 9 and exon 20[17]. Their mutation or gene amplification is positively associated with the T stage of gastric cancer[20,22]. In contrast, *PTEN*, which encodes phosphatase and tensin homolog and inactivates Akt by converting PIP3 to PIP2, is deleted in 4%-23% of gastric cancers[21,23,24] and loss of heterozygosity (LOH) is observed in 17%-47% cases of gastric cancer. LOH of PTEN is significantly associated with p-Akt level in gastric carcinoma tissues, TNM stage and poor prognosis of survival[25-29]. Activated Akt signaling promotes mTOR protein complexes 1 and 2 (mTORC1 and mTORC2), which can play pivotal roles in cancer cell migration and metastasis. Prevalence of mTOR expression is reported as approximately 50% in gastric cancer tissues, and is negatively associated with PTEN expression[30,31].

Clinical and laboratory evidence indicates the promising potential of targeting the PI3K-Akt-mTOR signaling pathway for efficacious treatment of gastric cancer, and various kinds of inhibitors or antibodies acting on this pathway have been developed and tried. These inhibitors are classified into several categories that include PI3K inhibitors, dual mTOR1/mTOR2 inhibitors, Akt inhibitors, mTOR1 inhibitors and dual PI3K/mTOR inhibitors[15]. Among them, a phase Ⅰ study

of isoform specific PI3K inhibitor (p110α) BYL719 is ongoing (NCT01613950)[32], and clinical outcomes of Akt inhibitor MK 2206 and mTOR1 inhibitor everolimus and rapamycin were previously reported, and are dealt with more fully in the latter part of this review.

JAK2/STAT3 pathway and inhibitory role of SH2-containing protein tyrosine phosphatase 1

The most established stimulator of STAT3 signaling pathway is the interleukin (IL)-6 family that includes IL-6, IL-11 and leukemia inhibitory factor, which bind to their receptors, and then phosphorylate and activate JAK2. Activated JAK2 recruits and activates STAT3 by phosphorylation, which can dimerize and translocate into the nucleus to act as a transcription factor and up-regulate various target genes involving cellular proliferation, migration/invasion and angiogenesis[33]. Indeed, persistent constitutive activation of JAK2/STAT3 in cancer cells is closely associated with gastric carcinogenesis and poor prognosis[34]. Besides this classic effect of JAK2/STAT3 pathway in cancer development, another pivotal role of STAT3 protein is the tumor microenvironment, where immune cells can be recruited and STAT3 can mediate various interactions with cancer cells to generate tumor progression. In gastric cancer, *Helicobacter pylori* (*H. pylori*)-induced cytotoxin-associated antigen (CagA) is closely associated with STAT3 activity in both gastric epithelial cells and mucosal immune cells. For example, *H. pylori* infection and CagA secretion can lead to IL-23 release from dendritic cells, which binds to their receptor and activates JAK2/STAT3 transmembrane signaling of naïve $CD4^+$ T-cells, and causes differentiation of T-helper (Th)-17 specific lineages to release associated cytokines including IL-17[35]. Up-regulated IL-17 can promote pro-inflammatory and oncogenic environment. Expression level of IL-17 is positively correlated with depth of tumor, lymphovascular invasion and lymph node involvement in gastric cancer tissues[36,37], and IL-17 mediates angiogenesis *via* up-regulation of VEGF *in vivo* and *in vitro*[38]. In gastric epithelial cells, CagA is translocated *via* the type-Ⅳ secretion system and releases IL-11. The released IL-11 bind to their receptor and activate the JAK2/STAT3 cascade[39]. Activated STAT3 functions as a transcription factor to induce many target genes involved in proliferation, invasion/metastasis and angiogenesis including cyclin D1, surviving, matrix metalloproteinase-9, CD44v6 and VEGF[34,40].

Thus, a therapeutic strategy to target the STAT3 signaling pathway appears to be reasonable. Routes of inhibition include blockade of JAK activation by dephosphorylation, inhibition of STAT3 phosphorylation, dimerization or gene transcription[35]. In terms of dephosphorylation, several phosphatases have been reported to be associated with STAT3 activity. Among them, SH2-containing protein tyrosine phosphatase 1 (SHP1) may be crucial in the down-regulation of the JAK2/STAT3 pathway by dephosphorylation[41-43]. Several candidate agents including natural compounds were reported to induce SHP1 and inhibit STAT3 activity. Sorafenib and its synthetic analogues also can act as a SHP1 agonist to inhibit phosphor-STAT3 activity and show various anti-cancer effects, such as promotion of apoptosis, overcoming of radio- or chemo-resistance and inhibition of EMT or fibrosis on hepatocellular carcinoma cell lines[44-51]. However, the exact inhibitory role of SHP1 in gastric cancer development and progress is unknown. We recently showed that expression of SHP1 is reduced or ameliorated in various gastric cancer cell lines due to epigenetic silencing, and that reinforced SHP1 expression significantly inhibits cellular proliferation, migration/invasion and induce apoptosis[52]. SHP1 might be a promising target to effectively inhibit JAK2/STAT3 activity in gastric cancer cells (Figure 2).

Immune checkpoints

Immune checkpoints regarding tumor infiltrating lymphocytes and immune evasion mechanism associated with carcinogenesis have been studied in the search for alternative therapeutic targets. Among them, cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) and PD-1, which are minimally expressed on the surface of resting T-lymphocytes but are widely expressed on activated T-lymphocytes, have been intensively studied for gastric carcinogenesis, and anti-PD-1 antibodies are already in clinical trials of gastric cancer chemotherapy[53]. Ligands for PD-1 (PD-L1) and CTLA-4 (B7-1/B7-2), which are expressed on the surface of tumor cells, bind to PD-1 and CTLA-4 respectively, inhibit pivotal function of effector T-cells for immune surveillance and consequently promote the growth of gastric cancer cells (Figure 3)[54].

PD-1 expression differs between gastric cancer tissues and non-cancerous tissues, with the significantly up-regulated PD-1 level in gastric cancer tissues being significantly correlated with poor clinical parameters including increased tumor size, advanced stage, metastasis and patient survival[55-58]. Furthermore, PD-1 expression on $CD4^+$ and $CD8^+$ T cells from gastric cancer tissues is higher than non-cancer tissues or peripheral blood mononuclear cells from normal subjects, and is significantly associated with disease progression[59]. However, a recent Korean study demonstrated that expression rate of PD-L1 on gastric cancer tissues was 43.6%, and was related to less advanced stage, intestinal type, well/moderately differentiated adenocarcinoma rather than poor differentiation and better overall survival (OS) and disease-free survival[60]. A recent Chinese study investigated PD-L1 expression level using large number of gastric cancer tissues (almost 400 specimens); PD-L1 expression was significantly associated with TIL density, and moderate to high TIL density was closely correlated with better prognosis[61]. Thus, the

exact relationship between PD-1/PD-L1 expression and clinical parameters needs to be further evaluated.

RECENT TRIALS OF TARGET THERAPY FOR GASTRIC CANCER

The pivotal ToGA study of targeted therapy for the treatment of unresectable gastric/EGJ cancer investigated the synergistic effects of trastuzumab, a monoclonal anti-HER2 antibody, with capecitabine/cisplatin or fluorouracil/cisplatin regimen. OS and PFS were significantly prolonged[3]. Since then, various target agents have been tried for the optimal treatment of advanced gastric cancer. Among them, newly developed drugs targeting the HGF/c-MET, PI3K/Akt/mTOR, JAK2/STAT3 and PD-1/PD-L1 pathways are dealt with here, and MKIs that simultaneously target multiple tyrosine kinases is also introduced in this section. A portion of these studies were presented at the 2015 annual meeting of the American Society of Clinical Oncology (ASCO); their outcomes are summarized in Table 1.

Phase Ⅲ studies of anti-HGF/c-MET antibodies

Rilotumumab, an anti-HGF monoclonal antibody, and onartuzumab, an anti-c-MET monoclonal antibody,

have been tried as first-line treatments for gastric or EGJ adenocarcinoma in phase Ⅲ studies. Their clinical outcomes were presented at the ASCO 2015 meeting. Rilotumumab significantly increased PFS when combined with ECX (epirubicin/cisplatin/capecitabine) regimen in a phase Ⅰb/Ⅱ study[62]. From this background, the phase Ⅲ RILOMET-1 study of first-line therapy of MET-positive, HER2-negative gastric/EGJ cancer compared rilotumumab (15 mg/kg) plus ECX with placebo plus ECX was performed. OS (9.6 mo *vs* 11.5 mo, HR = 1.37, *P* = 0.021) and objective response rate (ORR: 30.0% *vs* 39.2%, OR = 0.67, *P* = 0.027) were significantly inferior in the rilotumumab group, and subgroup analysis also showed that no subgroups appeared to be benefit with rilotumumab arm regardless of the degree of MET positivity[63]. This result is contrary to that of a phase Ⅰ/Ⅱa study, which contained a larger number of Asian patients (18%) than the RILOMET-1 population (1%). The different racial distribution may have contributed to the opposite outcomes between the two studies. Thus, the phase Ⅲ RILOMET-2 study has been performed to investigate the efficacy of rilotumumab in combination with cisplatin/capecitabine regimen as the first line chemotherapy among Asian patients with unresectable gastric/EGJ cancer[64].

The METGastric study of onartuzumab (10 mg/kg) for the treatment of HER2-negative, MET-positive metastatic gastric or EGJ adenocarcinoma without prior treatment, used onartuzumab in combination with the 5-fluorouracil (5-FU)/leukovorin/oxaliplatin (FOLFOX) regimen and compared outcomes with FOLFOX alone[65]. The addition of onartuzumab to FOLFOX was ineffective in the intention-to-treat analysis and OS, PFS and ORR were not significantly different between the two groups. However, addition of onartuzumab showed a marginal effect in OS for the moderate-to-strong MET positive subgroup (9.7 mo *vs* 11.0 mo, HR = 0.64, *P* = 0.062). Grade 3 or 4 adverse events were more common in the onartuzumab arm. Furthermore, a French phase Ⅱ study that compared FOLFOX plus rilotumumab or panitumumab, an anti-EGFR antibody, with FOLFOX alone for first-line treatment of metastatic, HER2-negative gastric or EGJ adenocarcinoma showed that adding panitumumab or rilotumumab seemed more toxic and was not more effective than mFOLFOX6 alone[66]. Considering recent outcomes of phase Ⅱ/Ⅲ studies of rilotumumab and ornatuzumab, targeting HGF/c-MET in gastric cancer has little rationale for further evaluation. However, cMET still has potential for promising biomarkers considering that c-MET-positive gastric/EGJ cancers have strong association with shorter OS and poor prognosis[67], and future research needs to search for other significant predictive factors for response to anti-HGF/c-MET therapy.

Akt and mTOR inhibitors

A phase Ⅰ study evaluated the combinatory effect of MK-2206, a potent pan-Akt inhibitor, with trastuzumab for treatment of HER2-positive, refractory gastric carcinoma. The rational was that the PI3K/Akt pathway is a main downstream signaling pathway of HER2 and is closely related with trastuzumab resistance. Oral MKN-2206 was given either 135 mg every week or 60 mg every other day with trastuzumab 8 mg/kg intravenously on day 1 every 3 wk. Clinical benefit response rate including stable disease more than 4 mo was 24%, and median time to progression was 72 d[68].

The PI3K/Akt pathway might be successfully inhibited by targeting mTORC1 kinase, and the development of rapamycin analogs (*e.g*., everolimus, temsirolimus) have been promoted[15]. A multicenter phase Ⅱ study of everolimus, an oral inhibitor of mTOR, in patients with refractory metastatic gastric cancer showed a disease control rate of 56.0%, PFS of 2.7 mo (95%CI: 1.6-3.0 mo) and OS of 10.1 mo (95%CI: 6.5-12.1 mo), which warrant further phase Ⅲ evaluation[69]. However, results of the phase Ⅲ GRANITE-1 study comparing everolimus with best supportive care for previously treated advanced gastric cancer were disappointing, and researchers failed to demonstrated significant benefit in OS (5.4 mo *vs* 4.3 mo, HR = 0.90, *P* = 0.124); indeed, PFS was significantly increased in the everolimus arm (1.7 mo *vs* 1.4 mo, HR = 0.66, *P* < 0.001)[70]. A phase Ⅱ multicenter study of low dose everolimus (10 mg on days 1, 8 and 15) plus cisplatin and a weekly 24-h infusion of high-dose 5-FU and leucovorin (cisplatin 35 mg/m^2 intravenous infusion for 24 h on days 1 and 8, 5-FU 2000 mg/m^2 and leucovorin 300 mg/m^2 intravenous infusion for 24 h on days 1, 8 and 15) for treatment-naïve gastric cancer was conducted but failed to increase ORR as in a preplanned statistical assumption (52.5%)[71]. However, in one case everolimus was tried after failure of 1st and 2nd line chemotherapy for a young male metastatic gastric cancer patient with multiple liver metastases. A subsequent mutational analysis revealed a PIK3CA hotspot mutation and pS6 overexpression in the primary tumor. The patient achieved stable disease for 1 year and pS6 expression was nearly abolished after two cycles of everolimus treatment[72]. Furthermore, a phase Ⅱ study of everolimus for refractory metastatic gastric and EGJ adenocarcinoma showed that a subgroup with strong pS6 expression (≥ 2 + IHC staining) was significantly correlated with better PFS and disease control rate[73]. Therefore, subgroup analysis for finding of positive predictive biomarkers in patients treated with everolimus needs to be performed.

STAT3 inhibitors and effect of SHP1 inducers

Few agents capable of directly targeting STAT3 have been developed, and clinical trials of STAT3 inhibitors in the treatment of gastric cancer are lacking. A recent phase Ⅰ study reported that OPB-31121, an oral STAT3 inhibitor, showed an overall response rate

Table 2 Ongoing clinical trials of target therapy in advanced gastric and esophagogastric junction adenocarcinoma

Trial identifier	Line of treatment	Phase of study	Treatment arms	Primary endpoint

NCT01913639[108]	First	Ⅱ	FOLFOX + regorafenib	PFS

PFS: Progression free survival; OS: Overall survival; MTD: Maximum tolerated dose; 5-FU: 5-fluorouracin; ORR: Objective response rate; XELOX: Capecitabine/oxaliplatin; FOLFOX: 5-fluorouracil/leucovorin/oxaliplatin; mTOR: Mammalian target of rapamycin.

of 44.4% assessed as stable disease in advanced solid tumors including gastric cancer[74]. However, STAT3 not only up-regulates various target oncogenes associated with gastric carcinogenesis and metastasis, but is closely related with drug resistance of standard chemotherapeutic agents including 5-FU, cisplatin and adriamycin in gastric cancer[75-77]. In this regard, targeting of STAT3 remains a critical issue in the treatment of gastric cancer, and development of specific and effective inhibitors of STAT3 should be further investigated. Several natural compounds[76,78-80] and pharmacologic medicines, such as proton pump inhibitors[75,81], inhibit STAT3 activity in *in vitro* and *in vivo* studies of gastric cancer. These agents are expected to show a synergetic effect or enhance chemosensitivity when combined with standard chemotherapy agents.

Several natural compounds inhibit the STAT3 activation pathway through induction of SHP1 in hematopoietic cancer cell lines[42,43,82-85] and hepatoceullar carcinoma (HCC) cell lines[86,87]. We recently showed that plumbagin (5-hydroxy-2-methyl-1,4-naphthoquinone), a quinonoid constituent extracted from the roots of the medical plant *Plumbago zeylanica* L, suppresses STAT3 activity and consequently targets gene expression *via* induction of SHP1 in gastric cancer cells[88]. Because most gastric cancer cells showed reduced or lack of expression of SHP1, a therapeutic strategy to indirectly inhibit STAT3 pathway might be an alternative option in pharmacologic treatment of gastric cancer and SHP1 may play pivotal roles in this signaling pathway. As mentioned above, several MKIs, such as sorafenib and sunitinib, show a significant link between SHP1 and suppression of STAT3 activity in HCC cells.

Immune checkpoint inhibitors: anti-PD-1/PD-L1 antibodies

The anti-CTLA-4 monoclonal antibody tremelimumab was developed and a phase Ⅱ study was performed to evaluate its use in second-line chemotherapy in advanced gastric and esophageal adenocarcinoma. However, the results were disappointing and only one patient achieved partial response among 18 enrolled patients, and stable disease was observed only in four patients[89]. Concerning the PD-1/PD-L1 pathway, pembrolizumab (MK-3475), an anti-PD-1 monoclonal antibody, and avelumab (MS0010718C), an anti-PD-L1 monoclonal antibody, have been developed. Pembrolizumab was tried for rescue therapy of recurrent or metastatic gastric or EGJ adenocarcinoma, which were positive for PD-L1, in the KEYNOTE-012 study[90]. ORR by central review was 22.2%, PFS 1.9 mo and OS 11.4 mo, and pembrolizumab showed durable efficacy and manageable safety profile for the heavily pre-treated, PD-L1 positive population. Further studies to support the efficacy of pembrolizumab in advanced gastric cancer are now in progress. For example, KEYNOTE-059 (NCT02335411) is a phase Ⅱ study of pembrolizumab monotherapy or in combination with standard chemotherapy[91] and KEYNOTE-061 (NCT02370498) is a phase Ⅲ study to compare pembrolizumab monotherapy with paclitaxel as the second-line therapy[92] (Table 2).

In Japan, avelumab was tried for refractory stage Ⅳ gastric and EGJ adenocarcinoma. A dose of 10 mg/kg was administered intravenously every 2 wk until progression. Most of adverse events were grade 1 or 2, ORR was 15.0% and PFS was 11.9 wk. Additional studies to evaluate the efficacy of avelumab and biomarkers from tumor tissue and blood samples including PD-L1 expression need to be evaluated[93].

MKIs

RTKs play crucial roles in the development of proliferation, differentiation, migration/invasion and apoptosis in gastric cancer. Currently, various inhibitors targeting the tyrosine kinase motif have been developed, and some display concurrent inhibitory effects of multiple tyrosine kinases. One of the first generation MKIs was sorafenib, which can inhibit BRAF, VEGF receptor (VEGFR) and platelet-derived growth factor receptor (PDGFR)[94]. A phase Ⅱ study investigated the efficacy of sorafenib in combination with docetaxel and cisplatin as the first-line chemotherapy in metastatic gastric or EGJ adenocarcinoma. Partial response was achieved in

41% (90%CI: 28%-54%), and the median PFS was 5.8 mo (90%CI: 5.4-7.4 mo) and median OS was 13.6 mo (90%CI: 8.6-16.1 mo). No additional toxicities were observed by adding sorafenib to docetaxel/cisplatin regimen. The results of this study warranted further evaluation of sorafenib in chemotherapy of gastric cancer[95]. However, another multicenter phase Ⅱ study of oxaliplatin and sorafenib as the second-line chemotherapy after failure of cisplatin/fluoropyrimidine regimen in advanced gastric adenocarcinoma revealed a median PFS of 3.0 mo (95%CI: 2.3-4.1 mo) and median OS of 6.5 mo (95%CI: 5.2-9.7 mo), which failed to support the implementation of a phase Ⅲ study[96]. Sorafenib was also evaluated for combination therapy with oral fluoropyrimidine and cisplatin, such as S-1/cisplatin[97] and capecitabine/cisplatin[98], in phase Ⅰ studies. Both studies showed tolerable safety profile and acceptable efficacy.

Lapatinib is a MKI that competitively inhibits ATP binding of tyrosine kinase in both HER2 and EGFR, and which is approved for the treatment of HER2-positive breast cancer[99]. Two large-scale, randomized, phase Ⅲ trials were recently reported. The researchers evaluated the efficacy and safety of lapatinib in HER2-positive, advanced or metastatic gastric and EGJ adenocarcinoma. The LOGiC study addressed lapatinib as the first-line chemotherapy in combination with capecitabine/oxaliplatin, and lapatinib arm was compared with capecitabine/oxaliplatin alone[100]. Median OS was not significant between both arms (12.2 mo *vs* 10.5 mo, P = 0.349), while PFS was significantly longer (6.0 mo *vs* 5.3 mo, P = 0.0381) and ORR was higher (53% *vs* 39%, P = 0.0031) in the lapatinib arm. Subgroup analysis for OS revealed that Asians and younger patients (< 60 years) showed significant benefit. The TyTAN study compared lapatinib plus paclitaxel with paclitaxel alone in the second-line treatment of gastric cancer in an Asian population[101]. This study showed no significant difference of median OS and PFS between both arms (11.0 mo *vs* 8.9 mo, P = 0.1044; 5.4 mo *vs* 4.4 mo, P = 0.2441; respectively). However, better efficacy was observed in the lapatinib arm in HER2-3+ subgroup. Further studies are warranted to examine the factors predicting good responders to lapatinib therapy.

Several novel MKIs have been investigated for the treatment of refractory gastric cancer. Findings were presented at the ASCO 2015 meeting. Among them, regorafenib, which inhibits multiple tyrosine kinases related to angiogenesis (VEGFR1-3), tumor microenvironment [PDGFR-β, fibroblast growth factor receptor (FGFR)] and oncogenesis (KIT), was previously developed and reported as effective in colon cancer and gastrointestinal stromal tumors (GISTs)[102]. The phase Ⅱ INTEGRATE study was designed and performed to investigate the efficacy of regorafenib in refractory, metastatic gastric and EGJ adenocarcinoma by comparing regorafenib 160 mg/d with placebo[103]. PFS was significantly increased in regrafenib group (2.6 mo *vs* 0.9 mo, HR = 0.40, P < 0.0001), however, OS was not significantly different between two groups (5.8 mo *vs* 4.5 mo, HR = 0.74, P = 0.11). An interesting thing is that HR = for PFS was significantly lower in Korean patients than in Western patients from Canada and Australia, which indicates that regorafenib might be more effective in Asian patients. Pazopanib is another potent MKI of VEGFR1-3, PDGFRα/β and FGFR1/3, and was previously approved by the United States Food and Drug Administration for the treatment of patients with advanced renal cell carcinoma[104]. A phase Ⅱ study was performed and reported the combinatory effect of pazopanib with capecitabine/oxaliplatin regimen as the first-line chemotherapy in metastatic gastric and EGJ cancer. ORR was 57.6% and adverse events of grade 3-4 were neutropenia (15.1%), anemia and thrombocytopenia (both 10.6%)[105].

CONCLUSION

Many studies have focused on revealing biologic relevant mechanism of development and progression of gastric cancer, and many medical agents targeting these pathways have been validated in clinical trials. However, most of them failed to reach significant benefits in phase Ⅲ trials, and novel therapeutic strategies are necessary in the future. To achieve this goal, individualized and precise target therapy should be planned on the basis of exploration of biologic characteristics of individual gastric cancer patients. In addition, targeting multiple RTKs rather than focusing on single pathway and attempts to overcome chemoresistance and enhance synergism with standard chemotherapeutic agents are expected to be prevalent. These approaches will hopefully lead to a more effective treatment, perhaps even conquest, of gastric cancer.

Abstract

To provide an update of the latest trends in epidemiology, clinical course, diagnostics, complications and treatment of auto immune hepatitis (AIH). A search of the MEDLINE database was performed using the search terms: "auto immune hepatitis", "clinical presentation", "symptoms", "signs", "diagnosis", "auto antibodies", "laboratory values", "serology", "histopathology", "histology", "genetics", "*HLA* genes", "*non-HLA* genes", "environment", "epidemiology", "prevalence", "incidence", "demographics", "complications", "HCC", "PBC", "PSC", "corticosteroid", "therapy", "treatment", "alternative treatment". English-language full-text articles and abstracts were considered. Articles included reviews, meta-analysis, prospective retrospective studies. No publication date restrictions were applied. AIH is an immune meditated progressive inflammatory liver disease that predominantly affects middle-aged females but may affect people of all ages. The clinical spectrum of AIH is wide, ranging from absent or mild symptoms to fulminant hepatic failure. The aetiology of AIH is still unknown, but is believed to occur as the consequence of an aberrant immune response towards an un-known trigger in a genetically susceptible host. In the absence of a gold standard, diagnosis is based on the combination of clinical, biochemical and histopathological criteria. Immunosuppressive treatment has been the cornerstone of treatment since the earliest description of the disease in 1950 by Waldenström. Such treatment is often successful at inducing remission and generally leads to normal life expectancy. Nevertheless, there remain significant areas of unmet aetiological a clinical needs including fundamental insight in disease pathogenesis, optimal therapy, duration of treatment and treatment alternatives in those patients unresponsive to standard treatment regimens.

Key words: Auto immune hepatitis; Diagnosis; Liver; Epidemiology; Treatment

Core tip: Autoimmune hepatitis (AIH) is a chronic inflammatory liver disorder of unknown aetiology, which can lead to hepatic failure and premature

death when untreated. In AIH there is no existence of a pathognomonic feature and therefore the diagnosis rests on a combination of immunological, biochemical, and histological features together with exclusion of other liver diseases. Due to large heterogeneity of the disease, AIH might be unrecognised. Immunosuppressive treatment has been the cornerstone of treatment. Such treatment is often successful at inducing remission. For most patients life long treatment is indicated. In patients in whom all treatments fail, liver transplantation remains a final option.

van Gerven NMF, de Boer YS, Mulder CJJ, van Nieuwkerk CMJ, Bouma G. Auto immune hepatitis. *World J Gastroenterol* 2016; 22(19): 4651-4661 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i19/4651.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i19.4651

INTRODUCTION

The first to describe a chronic form of hepatitis in young women was Jan Waldenström in 1950[1]. Later, the disease was associated with other autoimmune diseases and was termed "lupoid hepatitis" because of the presence of antinuclear antibodies and lupus erythematosus cells[2]. These observations led to the idea that the foundation of this disease was a loss of immunological tolerance. The term Auto Immune Hepatitis (AIH) in its current meaning was introduced by Mackay and colleagues in 1965 when the concept of autoimmunity was acknowledged at an international meeting[3].

AIH is now recognized as a relatively rare chronic inflammatory liver disease predominantly affecting females in which a loss of tolerance against hepatic tissue is assumed. Based on the type of serum auto-antibodies, AIH can be subdivided into two types: type 1 AIH, identifiable by antinuclear antibodies (ANA) and/or anti-smooth muscle antibodies (SMA), and type 2 AIH, predominantly found in children and defined by antibodies against liver kidney microsomes type 1 (anti-LKM-1) or for anti-liver cytosol type 1 antibodies[4,5].

EPIDEMIOLOGY

There are few studies that have investigated the epidemiology of AIH. The majority of these studies are hampered by the fact that no predefined criteria for disease diagnosis were applied. In some older studies there has been admixture of patients with chronic hepatitis C and finally some of the studies may have been subject to tertiary referral bias (Table 1).

Nevertheless, incidence data are more or less comparable in Western Europe, ranging from 0.8 to 3 per 100000 with a prevalence ranging from 11 to 24 per 100000[5-9]. In Asia AIH seems to be less frequent, with incidence numbers ranging between 0.08 and 0.15 in Japan[10].

Substantially higher prevalence data of 42.9 cases per 100000 were found in a well defined native Alaskan population, although it should be noted that this study involved a small catchment area and a very limited number of patients[11]. Based on the available studies it is estimated that 11%-20% of all cases of chronic hepatitis in Western countries is caused by AIH[12]. The prevalence of AIH is still gradually increasing. Whether or not this reflects a true rise in incidence, as seen in other immune-mediated diseases like Crohn's disease, increased awareness of the disease or different diagnostic criteria is unknown.

Women are affected more frequently than men with a sex ratio of around 4:1[8]. In women a bimodal age pattern is usually seen, one in the late teens and one around the menopause but it should be stressed that disease can develop in all age groups and both genders[4,13].

PATHOGENESIS

The etiology of AIH remains unknown and fundamental questions regarding disease pathogenesis remain to be resolved. It is generally believed that AIH occurs in a genetically susceptible host as the consequence of an exaggerated immune reaction towards hepatic tissue[14]. Such a response can occur when effector lymphocyte responses are abundant and inappropriate leading to tissue damage, or, alternatively, when there is a numerical and/or functional defect in regulatory T cells (Treg) controlling such responses. This defect is more obvious at disease presentation than during treatment induced remission, where a partial recovery is observed.

Whilst abundant pro-inflammatory responses have been identified in most, if not all immune-mediated diseases, it has been very difficult to gain evidence for a primary defect in regulatory T cells in the majority of these diseases. Tregs isolated from children and adults with AIH were profoundly dysfunctional, suggesting that an underlying Treg deficiency plays a permissive role in the pathogenesis of AIH[15-17].

More recent studies omitted to find either functional or numerical Treg impairments in AIH patients and thus the question as to whether AIH is the result of defective immunoregulation warrants further investigation.

A third, not mutually exclusive mechanism may relate to molecular mimicry, which has been proposed as a mechanism by which exogenous substances may trigger an immune response against autoantigens. Such a response may spark an inflammatory reaction and the resulting hepatocellular injury may give rise to the release of other previously hidden antigens that may further fuel the inflammatory reaction. Exogenous pathogens implicated in this process include,

Table 1 Studies of incidence and prevalence of autoimmune hepatitis

amongst others, the hepatitis C virus. A sequence homology between HCV polyprotein and cytochrome P4502D6 (CYP2D6) was previously reported, which was identified as anti-LKM-1 autoantibodies[18,19]. Indeed, anti-LKM-1 is seropositive in up to 10% of HCV patients. Other proposed triggers include other hepatotrophic viruses, as well as drug induced liver injury caused by antibiotics (including nitrofurantoin and minocycline), statins and anti-TNF agents[20-25].

GENETIC FACTORS

Genetic factors have long been implicated in disease pathogenesis yet systematic studies addressing the genetic epidemiology of AIH including familial occurrence, disease concordance in twins or ethnic differences in disease prevalence are lacking. Nevertheless, there are several observations that support a genetic basis for AIH. These include the association with other autoimmune diseases with a known genetic basis in up to a quarter of patients[8]. Additionally, associations with alleles of the Major Histocompatibility Complex (MHC) that encode the Human Leucocyte Antigens (HLA) were already described in the late seventies and confirmed and refined thereafter in numerous studies in different ethnic groups[26-28]. Such associations are found with most autoimmune diseases, most likely because they contribute to the specificity of immune reactions. HLA typing of patients with AIH reveals strong association with the HLA-DRB1 locus, with the haplotypes DRB1*0301 (HLA-DR3) and DRB1*0401 (HLA-DR4) as the main susceptibility factor in white Northern Europeans and North Americans[27,29-31]. Intriguingly there is evidence for substantial genetic heterogeneity in AIH with different MHC associations in different ethnic populations. Thus, in Japanese patients HLA-DRB1*0405 is the most important susceptibility allele[32,33] whereas primary associations with DRB1*0404 were found in Mexican patients[34].

The HLA alleles not only determine overall disease susceptibility but appear also to act as modifiers of the clinical phenotype. For instance, HLA-DR4 was found to be associated with female gender, less severe disease, more common autoimmune disease, and older age of onset[35-40].

Despite the fact that the MHC loci confer a 6 to 7 fold increased disease risk, these variants alone cannot explain the genetic predisposition for AIH. Genes outside the MHC have only been studied in candidate gene approaches involving limited numbers, making them prone to overestimation of significance. Most extensively studied is the cytotoxic T lymphocyte antigen-4 (*CTLA-4*) gene[41,42]. A recent study in the Netherlands involving a substantial number of patients however observed no significant differences in allele and genotype frequencies of the *CTLA-4* gene between AIH patients and controls[43].

More recently, genome-wide association studies have emerged as a powerful and unbiased approach for the identification of new genetic susceptibility loci in autoimmune diseases. Very recently this methodology was applied in a multicentre cohort of type 1 AIH patients. This study confirmed the involvement of the MHC region and identified *SH2B3* as the first genetic risk factor outside the MHC region. In addition, several other loci were identified supporting the thesis that AIH has a complex genetic basis[27].

CLINICAL FEATURES

The clinical manifestation of AIH can range from mild or severe symptoms to fulminant hepatic failure[44]. In all patients with liver disease AIH should be considered, so that that appropriate treatment can be instituted without delay. Up to 40 percent of patients presents with acute hepatitis, characterizes by right upper-quadrant abdominal pain, fatigue, jaundice and arthralgia[45]. However a fulminant manifestation or a long sub clinical course with only minimal increase of liver enzymes and non specific symptoms, such as arthralgia or fatigue, may be seen[12,46-49] (Table 2).

Clinical manifestations of AIH may vary among ethnic groups. Thus, non-Caucasian patients (the majority being from African-American descent) had more aggressive disease at initial presentation, lower reaction to immunosuppressive therapy, and worse outcomes when compared to Caucasian patients[44]. Higher rates of cirrhosis were found in Hispanic *vs* Caucasian patients, and a trend towards worse survival among Asians[50].

Other autoimmune diseases are common in up to

Table 2 Presentation and symptoms in auto immune hepatitis

Acute hepatitis	
Chronic hepatitis	
Hepatomegaly	
Splenomegaly	
Spider naevi	
Palmar erythema	
Non specific symptoms:	
Tiredness	
Fever	
Loss of appetite	
Upper abdominal pain	
Arthralgia	
Extrahepatic autoimmune disease (most common mentioned):	
Thyroiditis	10%-23%
Primary biliary cirrhosis	10%-20%
Diabetes	7%-9%
Primary sclerosing cholangitis	2%-8%
Rheumatoid arthritis	2%-5%
Celiac disease	1%-2%

40% of AIH patients. They included, among others thyroid disease, diabetes, inflammatory bowel disease and rheumatoid arthritis. A recent study demonstrates that celiac disease is more prevalent among AIH patients compared to the general population[51]. In addition AIH may have cholestatic features that can resemble primary sclerosing cholangitis (PSC) and primary biliary cirrhosis (PBC) and overlap with these diseases have been described in 10%-20% and 2%-8% of cases, respectively[9,14,52-55] (Table 2). So far, there have not been uniform definitions or diagnostic criteria for the overlap of AIH with PBC or PSC. It is still under debate as to whether these overlap syndromes represent variants of the main autoimmune liver diseases or hallmarks of a separate entity[56]. The presence of features of different diseases can occur simultaneously as well as sequentially in each form of overlap syndromes. AIH and PBC are the most frequently described autoimmune liver diseases. The pattern of abnormalities in laboratory tests can help determine the origin of the disease. In AIH a hepatic pattern is found, and a primarily cholestatic pattern in PBC; in addition, elevation of IgG is characteristic of AIH, an increase in IgM is commonly found in PBC patients.

Due to an absence of a well validated scoring system for the diagnosis of PBC-AIH overlap, the criteria developed by Chazouillères *et al*[57] are commonly applied.

In various reports AIH-PSC overlap syndrome has been described and is characterised by ANA and/or SMA seropositivity, hypergammaglobulinaemia and interface hepatitis - all features typical of "classical" AIH - in conjunction with cholestatic biochemical changes, frequently associated with inflammatory bowel disease, and histological evolution to fibrous obliterative cholangitis, ductopenia, portal tract oedema and/or bile stasis[58].

DIAGNOSIS

The diagnosis is based on the combination of clinical and laboratory features and histological changes after exclusion of other causes of hepatitis[59].

Laboratory abnormalities

AIH is suggested by a patient with elevated Alanine-aminotransferase (ALT) and Aspartate transaminase (AST) activity, raised Immunoglobulin G (IgG), high titres of circulating antibodies, negative serum tests and exclusion of toxic hepatitis. However not all these laboratory findings need to be present in an individual patient.

Elevation of serum IgG is a common finding in AIH[60], but normal IgG levels may be found in up to 30% of patients[61,62].

Auto antibodies are the hallmark of AIH and can constitute an important part of the diagnostic work up. The classic antibodies associated with AIH are Antinuclear antibodies (ANA), anti-smooth-muscle antibodies (ASMA) and Anti Liver kidney microsomal (LKM-1). About 70%-80% of AIH patients have significant titres ($\geqslant$ 1:40) of ANA or ASMA and overall 3%-4% have anti LKM-1, while up to 20% are seronegative for these antibodies[60].

ANA are the most commonly found auto antibodies in AIH, yet are rather non-specific since they can be found in a large variety of diseases as well as in healthy individuals[63]. ANA may be the only antibody present or may occur in conjunction with ASMA. ASMA are the second major class of antibodies which have proved useful in the diagnosis of AIH. Although less prevalent than ANA they are more specific[64].

Autoantibody detection not only supports in the diagnosis but also classifies between type 1 and type 2 AIH. Type 1 AIH is associated with the presence of ANA and/or SMA and type 2 with the presence of anti-LKM-1 and/or anti-liver cytosolic-1 (LC-1). In Northern Europe and North America type 2 AIH accounts for less than 10% of all patients[55].

Antibodies to soluble liver antigen (SLA) or liver pancreas antigen (LP) are found in 10%-30% of patients with AIH. These antibodies are specific for AIH and may proof useful in the diagnosis[65]. Antibodies to actin and atypical peripheral anti-neutrophilic cytoplasm are also commonly seen in type 1 AIH, however their applicability is limited due to lack in specificity[59].

Liver histology

A liver biopsy is usually necessary to confirm the diagnosis, provide histological assessment of disease severity and exclude other causes of hepatitis. There are no individual histological criteria that prove the diagnosis of AIH[66]. Interface hepatitis (or piecemeal necrose) is the histological hallmark of AIH and is a process of inflammatory infiltration and erosion of the hepatic parenchyma at the junction of the portal

Table 3 Simplified diagnostic criteria for auto immune hepatitis[75]

Variable	Cutoff	Points
ANA or ASMA	⩾ 1:40	1
ANA or ASMA	⩾ 1:80	
or LKM-1	⩾ 1:40	2
or SLA	Positive	
IgG	> Upper normal limit	1
	> 1.10 times upper normal limit	2
Liver histology (evidence of hepatitis is a necessary condition)	Compatible with AIH	1
	Typical AIH	2
Absence of viral hepatitis	Yes	2
		⩾ 6: probable AIH
		⩾ 7: definite AIH

ANA: Antinuclear antibodies; ASMA: Anti-smooth-muscle antibodies; LKM-1: Anti Liver kidney microsomal; IgG: Immunoglobulin G.

tract[67]. It is found in 84%-98% of patients[13,45,68], but can also be seen in patients with drug-induced and viral hepatitis[68]. The infiltrates consist of hepatic mesenchymal cells containing lymphocytes, plasma cells and histiocytes that typically accompany these cells. Patients presenting with chronic AIH typically have plasma cells infiltrated at the interface and throughout the lobule. Plasma cells are not invariability present and paucity of plasma cells does not therefore exclude a diagnosis of AIH. They may be absent in up to one third of the patients[68,69].

In a recent study, emperipolesis and rosette formation appear superior histological predictors of AIH when compared to the typical histological features of interface hepatitis and plasma cells[70].

Diagnosis scoring system

Because there is no golden standard for the diagnosis of AIH, diagnostic scoring systems have been established that support the diagnosis in most of patients. The IAIHG scoring system, originally published in 1993[71] and revised in 1999[60], was developed as a search tool to ensure comparability of study populations. Despite a high degree of sensitivity (100%) and specificity (90%)[72-74], these criteria have been proven impractical in the day to day clinical practice.

In 2008 the IAIHG produced a simplified system for the diagnosis of AIH which is less complex and enhances applicability in clinical practice[75]. This system is based on four variables: presence and level of anti bodies, IgG concentration, typical histological features and absence of viral markers (Table 3). Recently three studies report that the simplified scoring system performs with high specificity (97%-99%) and lower sensitivity (81%-88%) when compared to the original diagnostic criteria yet requires further prospective validation[72,76,77].

TREATMENT

Indication of treatment

The short and long term efficacious of immune suppression in patients with AIH has been described unequivocally. When left untreated, an estimated 40% of patients will die within six months of diagnosis[78]. When treated adequately, the 20-year survival rate for all treated patients exceeds 80%, and life expectancy is similar to that of age and sex matched normal subjects from the same geographical area[79].

Updated treatment guidelines have recently been emerged by the European Association for the Study of the Liver (EASL) in 2015, the British Society of Gastroenterology in 2011 and the American Association for the Study of Liver Diseases (AASLD) in 2010[4,80,81]. Patients with AST levels 10-fold the upper normal limit, or fivefold the upper normal limit in concurrence with IgG levels at least twice the upper normal limit, or histological features of bridging necrosis or multiacinar necrosis, should be offered immunosuppressive treatment because of clear survival benefit (Table 4). Patients not satisfying these criteria must be personalized and treatment should be based on clinical judgement[4].

Standard treatment

Current therapeutic strategies for AIH consist of an induction with prednisone and frequently include subsequent addition of azathioprine (AZA) as steroid-sparing maintenance therapy[80]. Prednisone is introduced at a dose of 1 mg/kg with a maximum of 60 mg/d in monotherapy or a maximum of 30 mg/d in combination treatment[4,12]. After AST and ALT normalize, prednisone alone can be reduced by 10 mg/wk until a dose of 20 mg.

Patients treated with combination therapy can reduce prednisone by 5 mg/wk until 15 mg. A slower reduction is advised after this point[4,82]. For maintenance treatment AZA can be used at a dose 1-2 mg/kg per day either alone or in combination with low dose prednisone[4,83]. A recent review based on available randomised controlled trials found that prednisone monotherapy and prednisone in combination wit AZA are both feasible induction therapies for AIH, while maintenance therapy prednisone and AZA and Monotherapy AZA are superior to prednisone monotherapy[84]. AIH patients

Table 4 Indication for treatment of auto immune hepatitis (adapted from Manns *et al*[4])

Absolute	Relative
Serum AST ⩾ 10 fold ULN	Symptoms (fatigue, arthralgia, jaundice)
Serum AST ⩾ 5 fold ULN and IgG level ⩾ twice normal	Serum AST and/or IgG less than absolute criteria
Bridging necrosis or multiacinar necrosis on histological examination	Interface hepatitis

AST: Aspartate transaminase; ULN: Upper limit normal; IgG: Immunoglobulin G.

treated with corticosteroids and/or AZA have the risk of many side effects on both drugs. The side effects of long term treatment with corticosteroids are well known; acne, moon shape face, striae, weight gain and loss of bone density. Adverse effects of thiopurines are common and generally occur shortly after the start of therapy. They include allergic reactions, flu-like illness, nausea fever, malaise, rash, abdominal pain, hepatotoxicity, pancreatitis and myelosuppression[83,85-87]. The principal side effects of AZA are cytopenia and liver test abnormalities, which may be difficult to distinguish from inherent AIH disease activity.

Remission and relapse

Remission of previously symptomatic patients is defined as a complete normalisation of all inflammatory parameters, including AST, ALT, bilirubine, IgG, recovery from symptoms and inactive liver histology[4,9,82]. In 80%-90% of patients with moderate/severe AIH, serum ALT decreases after starting treatment. Usually a decrease is seen within two weeks. As transaminase decrease, clinical symptoms revolve and liver functions shows marked improvement within 3-6 mo after starting prednisone treatment either with or without AZA[81].

There is no prescribed duration of the length of treatment. Because histological restore lags behind clinical and biochemical improvement by 3-8 mo, treatment should be continued for at least this period[88,89]. Proper patient selection including sustained remission on immunosuppressive Monotherapy for a minimum of 2 years can markedly improve the success rate of treatment withdrawal[90]. The AASLD and EASL guidelines recommend treatment withdrawal, when serum liver and immunoglobulin levels have been repeatedly normal for a period of at least two years. Liver biopsy prior to termination of treatment is preferred[4,80]. Relapse is characterized by an increase in ALT levels (three times upper normal limit) and/or increase of serum IgG level to more than 2 g/L following tapering of steroid doses or after complete withdrawal of immunosuppression[4]. Literature from the 1970s showed a high risk of relapse after drug withdrawal[88,91], but this was later disputed and it was recommended that drugs withdrawal should be attempted[92]. A more recent retrospective analysis found that relapse occurred in almost all patients with AIH when immunosuppressive medication was discontinued or tapered[4,92,93]. Relapse occurred despite prior attainment of complete remission, including a histological inactive follow up biopsy prior to tapering in a subgroup of patients. In patients who have relapsed once, a subsequent attempt to withdrawal therapy was invariably associated with the re-occurrence of a relapse[93]. Since repeated relapses were associated with a poorer long term prognosis patients should receive life long treatment[94,95]. A lifelong follow up should occur in patients who successfully stopped immunosuppression, while a relapse can occur 10 years later[93].

Alternative treatment

In up to 10% of AIH patients, the therapeutic strategy of prednisone and AZA is unsuccessful, due to intolerable side effects or lack of clinical response[4,81]. In patients who fail on standard therapy, alternative immunosuppressive treatments have been tried with encouraging results. Cyclosporine[96-98], tacrolimus[99,100], methotrexate[101], cyclophosphamide[102] and mycophenolate mofetil[103-105] have been tried, with varying degrees of success, as a replacement for AZA.

In a small recent study allopurinol was added to the AZA or mercaptopurine treatment in patients who fail treatment due to ineffectiveness or intolerance, due to skewed thiopurine metabolism. The combination of low dose thioprines and allopurinol proved an effective and well-tolerated alternative in the treatment of AIH. Larger and controlled studies are needed to confirm these outcomes[106]. As an alternative for prednisone, budesonide is receiving considerable attention.

In two recent studies in patients with noncirrhotic AIH oral budesonide, in combination with azathioprine, induces and maintains remission. This treatment causes fewer steroid-specific side effects[107,108]. Routine use is not currently recommended, while the trial duration is short and the fact that no follow up date were presented[81]. AZA is the prodrug of 6-mercaptopurin (6-MP) and is converted into 6-MP in a nonenzymatic manner before exhibiting its antiproliferative and immunosuppressive properties. In patients with ulcerative colitis and Crohn's disease 6-MP has a beneficial role in AZA-intolerant patients[109]. In patients with AIH and AZA intolerance, 6-MP seems to be an effective and well-tolerated second line treatment[110]. The use of 6-thioguanine 6-TG), an agent more directly leading to down-stream active metabolites of AZA, showed clinical improvement in

three AIH patients intolerant to AZA. A prospective evaluation of 6-TG as possible immunosuppressive drug in AIH patients is warranted[111].

COMPLICATIONS AND PROGNOSIS

Complications in AIH are comparable to those seen in other liver diseases and in rare cases AIH presents by the occurrence of hepatic encephalopathy[112,113].

Liver fibrosis is often presence at diagnosis and a subgroup of patients have already cirrhosis at presentation[4,68] suggesting that the disease has gone unrecognized for a significant period prior to diagnosis. When left untreated, an etsimated 40% of patients will die within 6 mo of diagnosis[88,91,114]. In some patients without proper treatment, AIH progresses to cirrhosis and eventually Hepatocellular carcinoma (HCC). The presence of cirrhosis at diagnosis or during treatment and the need for long-term immunosuppressive therapy have been observed as risk factors for malignant transformation[115]. In addition risk factors for HCC furthermore include male gender, advanced stage disease, portal hypertension as ascites and esophageal varices[116]. HCC occurs in 1%-9% of AIH patients[116-118], which is less frequently compared to patients with chronic viral hepatitis[119]. Imaging with ultrasonography or computed tomography should be conducted every 6-12 mo. In patients who develop liver failure, liver transplantation needs to be considered[48,120]. When AIH is indicated for transplantation, transplanted patients, practically compared to other chronic liver diseases, have an excellent 5 year survival of between 78%-91%[121-123]. The recurrence rate of AIH after initial successful transplantation is problematic and occurs in around 30% of patients[124].

CONCLUSION

AIH is a relatively rare disease of unknown aetiology. Many factors contribute to the diagnosis, which is characterized by a female predominance, histologically evidence of periportal hepatitis in the absence of viral markers, hypergammaglobulinaemia, the presence of auto antibodies in serum, plasmacellular infiltrates and an optimal response to steroids in most patients. In AIH there is no existence of a pathognomonic feature and therefore the diagnosis rests on a combination of immunological, biochemical, and histological features together with exclusion of other liver diseases. Due to large heterogeneity of the disease, AIH might be unrecognised. The clinical manifestation of AIH can range from mild or severe symptoms to fulminant hepatic failure. AIH generally responds to immunosuppressive treatment and treatment is required as soon as the diagnosis is made. For most patients lifelong treatment is indicated. In patients in whom all treatment attempts fail liver transplantation needs to be considered.

AIH remains a major diagnostic and therapeutic challenge. Growing insights into the clinical presentation of AIH highlights the importance of evaluation of the current diagnostic criteria, role of genetic and environmental factors, as well as the development of new treatment strategies.

Abstract

AIM: To determine if expression of colonic tryptophan hydroxylase-2 (TPH2), a surrogate marker of neuronal 5-hydroxytryptamine, is altered in Hirschsprung's-associated enterocolitis.

METHODS: Entire resected colonic specimens were collected at the time of pull-through operation in children with Hirschsprung's disease (HSCR, n = 12). Five of these patients had a history of pre-operative Hirschsprung's-associated enterocolitis (HAEC). Controls were collected at colostomy closure in children with anorectal malformation (n = 10). The distribution of expression of TPH2 was evaluated using immunofluorescence and confocal microscopy. Protein expression of TPH2 was quantified using western blot analysis in the deep smooth muscle layers.

RESULTS: TPH2 was co-expressed in nitrergic and cholinergic ganglia in the myenteric and submucosal plexuses in ganglionic colon in HSCR and healthy controls. Co-expression was also seen in submucosal interstitial cells of Cajal and PDGFRα^+ cells. The density of TPH2 immuno-positive fibers decreased incrementally from ganglionic bowel to transition zone

bowel to aganglionic bowel in the myenteric plexus. Expression of TPH2 was reduced in ganglionic bowel in those affected by pre-operative HAEC compared to those without HAEC and healthy controls. However, expression of TPH2 was similar or high compared to controls in the colons of children who had undergone diverting colostomy for medically refractory HAEC.

CONCLUSION: Altered TPH2 expression in colonic serotonergic nerves of patients with HSCR complicated by HAEC may contribute to intestinal secretory and motor disturbances, including recurrent HAEC.

Key words: Serotonin; Tryptophan hydroxylase 2; Hirschsprung; Enterocolitis; Ganglionic

Core tip: Despite optimal surgery, children with a history of Hirschsprung's disease (HSCR) complicated by Hirschsprung's-associated enterocolitis (HAEC) are at higher risk of long-term colonic dysfunction. Tryptophan hydroxylase-2 (TPH2) is a surrogate marker for neuronal 5-hydroxytryptamine (5-HT). We hypothesized that expression of TPH2 is altered in the colon of children with HAEC. We found the density of serotonergic nerves to be differentially reduced in the ganglionic colon of children with HSCR and HAEC compared to those without HAEC compared to controls, although expression is normalized in those with diverting colostomy. Abnormal neuronal 5-HT expression may contribute to post-operative colonic dysfunction in HSCR.

Altered tryptophan hydroxylase 2 expression in enteric serotonergic nerves in Hirschsprung's-associated enterocolitis. *World J Gastroenterol* 2016; 22(19): 4662-4672 Available from: URL: http://www.wjgnet.com/1007-9327/full/v22/i19/4662.htm DOI: http://dx.doi.org/10.3748/wjg.v22.i19.4662

INTRODUCTION

Hirschsprung's-associated enterocolitis (HAEC) is the most serious complication of Hirschsprung's disease (HSCR) and is the leading cause of disease-related mortality. It occurs in 17%-50% of patients with HSCR and may occur before or after a pull-through operation[1,2]. Although a scoring system for HAEC exists, there is no agreed definition of this condition. It is typically described as an inflammatory disease of the colon leading to a spectrum of symptoms ranging from abdominal distension and loose stools to life-threatening toxic megacolon[3,4]. The etiology and pathogenesis of HAEC are still incompletely understood. It has been proposed that intestinal barrier dysfunction, abnormal innate immunity and the presence of a disturbed microbiome are all potential contributors to its etiology[1]. However, given that the primary abnormality in HSCR is the absence of enteric ganglia in the distal colon, it follows that the enteric nervous system may have a role in the pathogenesis.

5-Hydroxytryptamine (5-HT), also commonly known as serotonin, is a major neuroendocrine signaling molecule. While the gut is the single largest reservoir of 5-HT, the wide range of its functions therein have only been elucidated relatively recently. The majority of enteric serotonin is stored in the mucosa in the enterochromaffin (EC) cells. Approximately 1%-5% of enteric serotonin is stored in the serotonergic enteric nerves, where it acts as a neurotransmitter[5,6]. The rate limiting step in the synthesis of 5-HT is the conversion of L-tryptophan to 5-hydroxytryptophan by tryptophan hydroxylase (TPH). The conversion of 5-hydroxytryptophan to 5-HT then occurs rapidly through the actions of L-amino acid decarboxylase[7]. However, the synthesis pathway of enteric 5-HT differs depending on whether 5-HT is being synthesized in EC cells, where the TPH1 isozyme of TPH predominates, or in serotonergic neurons, where TPH2 predominates. In this way, it is possible to indirectly evaluate the expression of neuronal 5-HT separately from that produced in EC cells[5,7].

5-HT has many roles, including activation of intrinsic reflexes such as peristalsis, vasodilation, and secretion. When released from EC cells, mucosal 5-HT has been demonstrated to promote inflammation - an activity which is counterbalanced by its re-uptake *via* the serotonin transporter (SERT)[5,8]. Abnormal mucosal 5-HT activity has been demonstrated in inflammatory and functional bowel disorders such as ulcerative colitis and irritable bowel syndrome[9]. Conversely, enteric neuronal 5-HT is anti-inflammatory and neuroprotective, an activity which has obvious importance in the setting of inflammation and enterocolitis, as neuronal damage can frequently result[8]. It has previously been reported that populations of mucosal EC cells are deficient in the ganglionic bowel of children with HSCR who have previously had HAEC. It is unclear if this is a facilitator or an effect of HAEC[10].

We hypothesized that, in children who had previously been treated for HAEC, neuronal 5-HT expression is altered compared to those who did not require treatment for HAEC. In this study we aimed to investigate the distribution of 5-HT in the aganglionic and ganglionic colon of children with HSCR and in healthy controls and to quantify expression of TPH2 in serotonergic enteric nerves of these patients.

MATERIALS AND METHODS

Specimen collection

The study was approved by the ethics committees of both centers (Our Lady's Children's Hospital Ethics Committee, GEN292.12; Temple Street Children's

University Hospital Research and Ethics Committee, 13.003). Informed written consent was obtained from parents/legal guardians prior to specimen collection. The procedures carried out during the study were in conformance with the principles expressed in the Declaration of Helsinki.

Full-length colonic specimens resected during pull-through operations for HSCR were obtained fresh from 12 patients, incorporating aganglionic, transition zone and ganglionic bowel (age range 3 mo-14 mo). Colonic control specimens were similarly obtained from the proximal colostomy limb of 10 patients at the time of descending/sigmoid colostomy closure in children following surgical correction of anorectal malformation (age range 7 mo-21 mo). The level of the most proximal extent of the transition zone was routinely confirmed by 3,3'-diaminobenzidine (DAB) immunohistochemistry probing for protein gene product 9.5 (PGP 9.5), which stains nerve cells. All experiments incorporated comparison of ganglionic bowel in HSCR with transition zone and aganglionic bowel as well as healthy controls.

Double-label immunofluorescence

Colonic sections were embedded in OCT compound [VWR, Ireland (361603E)] and snap frozen in liquid nitrogen. Twenty micron sections were cut and were fixed in 10% neutral buffered formalin (Sigma-Aldrich, Ireland [HT501128-4L]). Cell membranes were permeabilized by rinsing in 1% w/v PBS with 1% Triton X-100. Sections were blocked in 10% bovine serum albumin [BSA, Sigma-Aldrich, Ireland (A2153-50G)] diluted in 1% w/v PBS with 0.05% Tween® [Sigma-Aldrich, Ireland (P1379)] (PBST) for 90 min at room temperature to prevent non-specific antibody binding. Samples were incubated simultaneously in both primary antibodies of interest, diluted in 10% BSA, at 4 ℃ overnight. Antibodies to the following antigens were used to label specific cell types in the colonic wall: HuD (PGP 9.5) was used to label nerve cells; TMEM16A [anoctamin-1 (ANO1)])was used to label interstitial cells of Cajal (ICCs); platelet derived growth factor receptor-α (PDGFRα) was used to label PDGFRα$^+$ cells, neuronal nitric oxide synthase (nNOS) was used to label nitrergic neurons, vasoactive intestinal peptide (VIP) was used to label peptidergic neurons, and choline acetyltransferase was used to label cholinergic neurons. A detailed description of the primary antibodies used in the study is seen in Table 1. Following incubation in primary antibody solution, samples were rinsed intensively in 1% PBST, following which they were incubated in a solution containing both secondary antibodies specific to the host species of each primary antibody (Table 1), diluted in 10% BSA, for 90 min at room temperature. After intensive rinsing in 1% PBST, samples were counterstained with 4',6-diamidino-2-phenylindole (DAPI) nuclear counterstain [Thermo Scientific, Ireland (EN62248)]. Sections were mounted with glass coverslips using Mowiol® 4-88 fluorescence mounting medium [Sigma Aldrich, Ireland (81381-50G)], which was constituted according to manufacturer's specifications. Specimens were visualized using laser scanning confocal microscopy (LSM700 Confocal Microscope, Carl Zeiss MicroImaging GmbH, Jena, Germany). Resulting images were processed, including calculation of TPH2 immuno-positive cell counts, using ImageJ - an open-access software available from http://imagej.nih.gov/ij/.

Protein extraction and Western blot analysis

The mucosa was dissected from the deep smooth muscle layers at the time of specimen collection. Protein was extracted from the tunica muscularis layers to limit the probability of unwanted antibody binding to tryptophan hydroxylase 1 (TPH1), of which the mucosa is a substantial reservoir. Bowel tissue fragments were homogenised using a tissue homogeniser in radioimmunoprecipitation (RIPA) buffer containing 1% protease inhibitor cocktail [Sigma Aldrich, Ireland (P2714)]. Soluble and insoluble fractions were then separated by centrifugation at 4 ℃ at 3000 *g* over 30 min. The concentration of the supernatant was determined by means of a Bradford assay [Sigma-Aldrich Ltd., Arklow, Ireland (B6916)] using a standard curve generated from known concentrations of BSA. Novex® Bolt® LDS sample buffer and reducing agent [Biosciences, Dublin, Ireland (B0007 and B0009 respectively)] were added to each protein aliquot according to manufacturer's protocols. The protein concentration of each sample was then equilibrated with the addition of deionised water. Samples were denatured at 70 ℃ for 10 min and were then loaded onto an SDS polyacrylamide gel [Bolt® Novex 4%-12% Bis-Tris gel: Biosciences, Dublin, Ireland (NW04120BOX)] in NuPAGE® MES SDS running buffer [Biosciences, Dublin, Ireland (NP0002)] and separated by electrophoresis at 150 V. Proteins were then transferred from the gel to a 0.45 μm PVDF membrane at 30 V for 90 min.

Membranes were blocked in 3% dried skimmed milk dissolved in 1% PBST for 1 h to prevent non-specific antibody binding and were then incubated in primary antibody (Table 1) diluted in 10% BSA overnight at 4 ℃. Membranes were rinsed in 1% PBST for 4 h and were then incubated in species-specific secondary antibody (Table 1) for 90 min at room temperature. Following further rinses with 1% PBST for a minimum of 1 h, membranes were incubated in chemiluminescent substrate [SuperSignal™ West Pico Chemiluminescent Substrate, Thermo-Fischer, Ireland (34079)] for 5 min at room temperature before transfer to a chemiluminescence cassette for blot visualization. Protein expression levels were semi-quantitatively evaluated by densitometric analysis using the open-access image processing software

Table 2 Clinical details of patients with Hirschsprung's disease included in the study

Characteristic	*n* = 12	
Gender	Male (*n* = 11)	Female (*n* = 1)
Median age at pull-through operation	5 mo	3-14 mo
Associated syndromes	Trisomy 21	*n* = 5 (2 with HAEC)
Pre-operative HAEC	Yes (*n* = 5)	No (*n* = 7)
Diverting/levelling stoma	Yes (*n* = 3)	No (*n* = 9)

HAEC: Hirschsprung's-associated enterocolitis.

ImageJ. Statistical analysis was performed using a statistical software package (SPSS v20.0). Non-parametric analysis including Mann-Whitney *U*-test was utilized in testing for differences in TPH2 protein expression between ganglionic and aganglionic colon in HSCR and healthy controls.

RESULTS

Double-labelled immunofluorescence

Basic clinical details regarding patients whose specimens were used in this study can be seen in Table 2. The specificity of our antibody to detect neuronal TPH2 was confirmed by the presence of TPH2 co-expression with HuD, a specific marker of nerve cell bodies, seen in the myenteric plexus of normally ganglionated bowel in HSCR and in healthy controls, while no evidence of expression of either was seen in the myenteric plexus of aganglionic bowel in HSCR (Figure 1A and B). There was a dense network of ANO1-immuno-positive ICC fibers seen in the myenteric plexus. There was no co-expression of TPH2 with ANO1 (Figure 1C), although the processes of ICCs did form dense network around ganglia immuno-positive for TPH2. Of interest, there was partial co-expression of TPH2 with PDGFRα in the cell bodies of PDGFRα$^+$ fibroblast-like cells in the myenteric plexus (Figure 1D).

In the submucosa of aganglionic bowel, HuD-positive nerve cell bodies were absent, although TPH2-positive fibers were still present in reduced density (Figure 2A). Confirmation of the presence of TPH2-immuno-positive nerve cell bodies in the submucosa of ganglionated bowel is seen in Figure 2B. TPH2 was co-expressed with ANO1 in the cell processes of submucosal ICCs (Figure 2C) and with PDGFRα in the cell bodies of PDGFRα$^+$ cells (Figure 2D).

The density of TPH2-immuno-positive cells reduced incrementally from colonic controls (Figure 3A) to ganglionic bowel in HSCR (Figure 3B), transition zone (Figure 3C) and aganglionic bowel (Figure 3D), where expression of TPH2 appeared markedly reduced in the myenteric and submucosal plexuses (Figure 3E). TPH2 was found to be co-expressed with ChAT-positive cholinergic nerve cell bodies in the myenteric plexus (Figure 4A), as well as with nNOS in nitrergic ganglia (Figure 4B). VIP-immuno-positive neurons did not co-express TPH2 in the myenteric plexus (Figure 4C) or in the submucosa (data not shown). Cholinergic nerve fibers in the circular muscle co-expressed TPH2 (Figure 4D).

Western blot analysis

A specific band was detected at approximately 60 kDa, consistent with the molecular weight of TPH2. No doublet bands were observed, confirming specific antibody binding to the TPH2 isozyme, as occurred when Western blot analysis was performed using whole tissue protein extract, which contains significant quantities of TPH1. In patients who had HAEC, TPH2 expression was reduced in the aganglionic bowel, transition zone and ganglionic bowel in HSCR compared to controls ($P = 0.044$) while there was a trend towards lower expression of TPH2 patients with HSCR who had never been treated for HAEC ($n = 7$) in aganglionic bowel compared to healthy controls ($P = 0.056$) (Figure

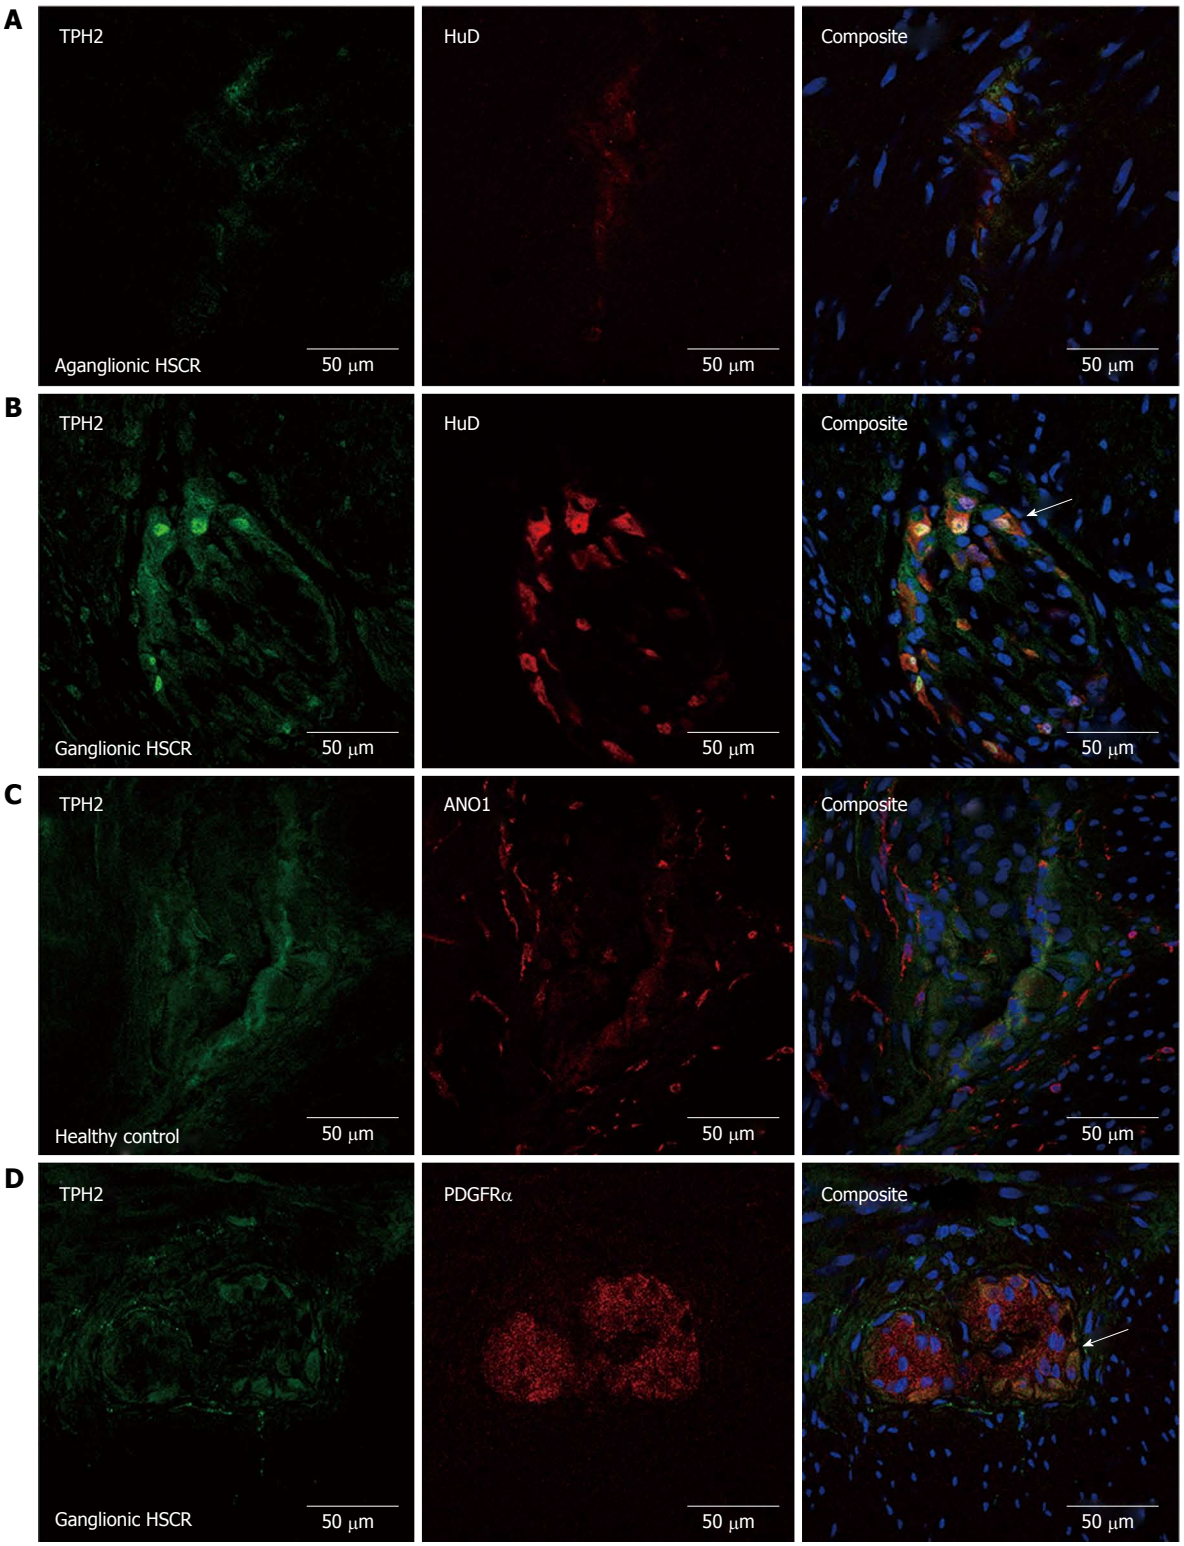

Figure 1 Confocal micrograph series demonstrating pattern of tryptophan hydroxylase-2 expression in the myenteric plexus of the colon. There is almost no HuD or TPH2 immunofluorescence seen in aganglionic colon in HSCR in (A), while there is clear co-expression (arrow head) in the nerve cell bodies in (B). While TPH2 and anoctamin-1 (ANO1) are not co-expressed in (C), the interstitial cells of Cajal (ICC) fibers form a dense network around TPH2-immuno-positive ganglia. TPH2 was co-expressed with PDGFRα cell bodies in the myenteric plexus, seen in (D). TPH2: Tryptophan hydroxylase-2; HSCR: Hirschsprung's disease.

5A). However, consistent marked recovery of TPH2 expression levels was noted in the colon of patients with HSCR, who had been treated for HAEC, but who had undergone formation of a diverting stoma due to failure of medical management (P = 0.002, n = 3). Such was the recovery that expression levels were even higher than in patients who had HSCR but who did not have a history of pre-operative HAEC (Figure 5B).

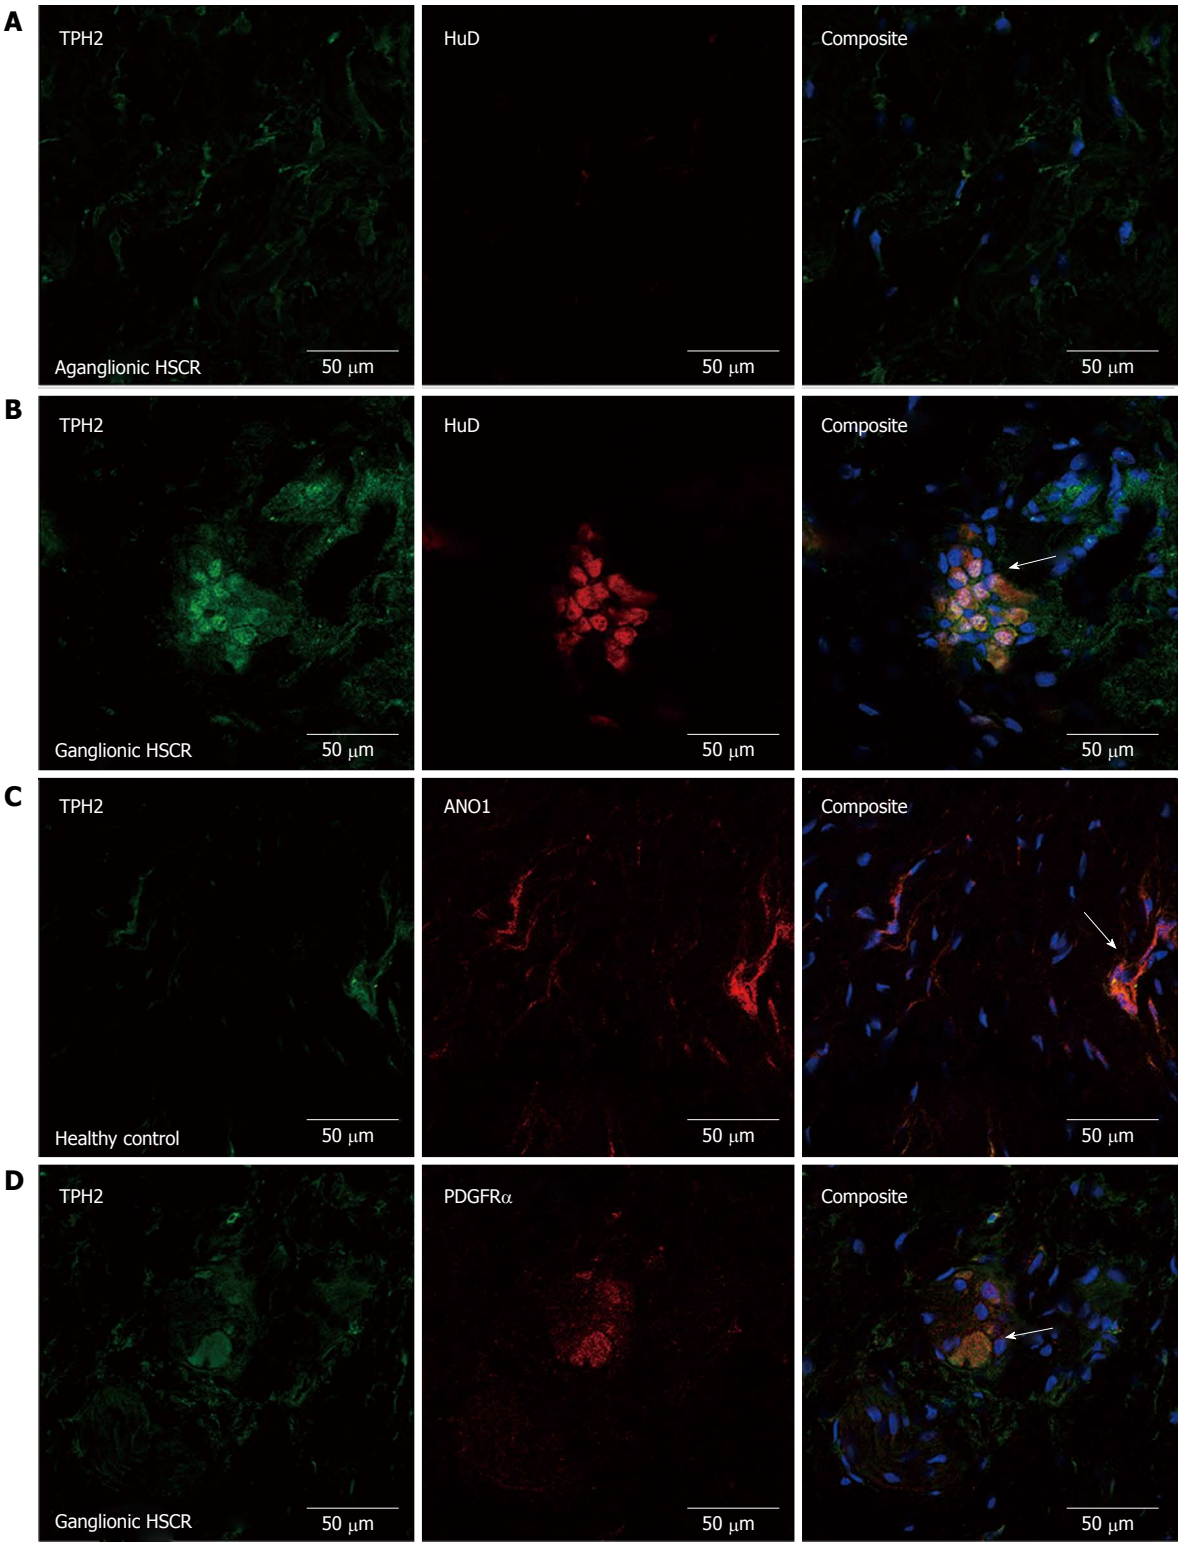

Figure 2 Confocal micrograph series demonstrating tryptophan hydroxylase-2 expression pattern in the submucosal plexus. Again, no HuD expression is seen in the aganglionic bowel, although there are some TPH2 immuno-positive fibres seen in (A). In ganglionic bowel in HSCR (B), TPH2 co-expressed with HuD (white arrow) in ganglion cells. There was co-expression of TPH2 with anoctamin (ANO)-positive submucosal interstitial cells of Cajals (ICCs) and PDGFRα^+ cells, seen in (C) and (D) respectively (white arrow). TPH2: Tryptophan hydroxylase-2; HSCR: Hirschsprung's disease.

DISCUSSION

Enterocolitis is reported as the presenting feature of HSCR in between 12.5% and 40.5% of cases, with many of these cases occurring in the neonatal period[2,11]. The histopathological changes seen in HAEC range from cryptitis to mucosal ulceration, transmural necrosis and colonic perforation[1]. Only recently has an understanding of the processes contributing to the pathogenesis of enterocolitis been developed. In the

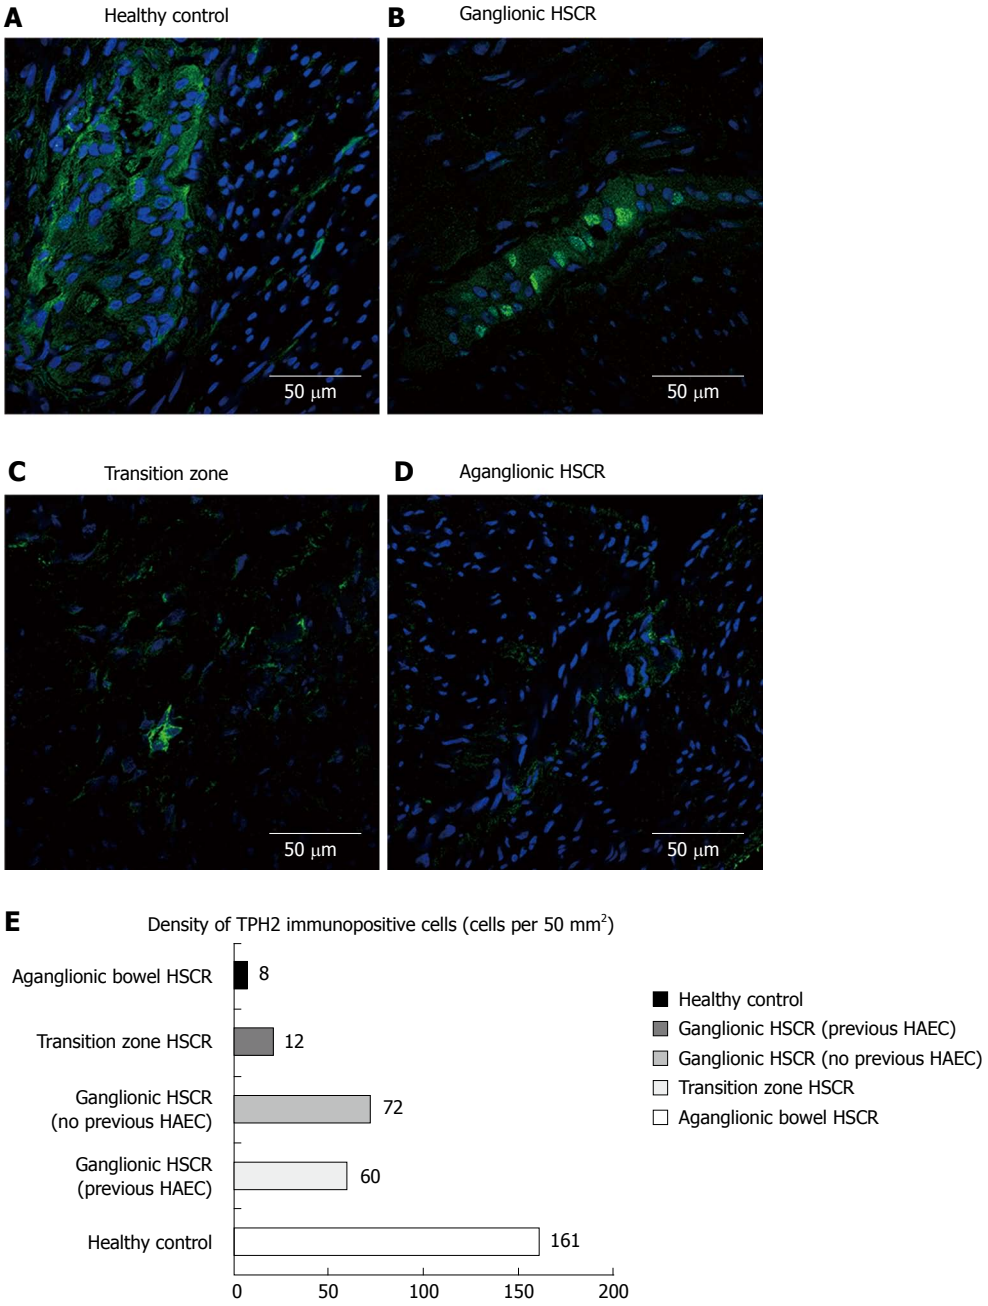

Figure 3 Double-labelled immunofluorescence. Series (A) to (D) demonstrate the incremental reduction in tryptophan hydroxylase-2 immuno-positive cells in the myenteric plexus from healthy control, to ganglionic bowel in HSCR through to aganglionic bowel. The bar graph in (E) demonstrates the mean cell counts of TPH2 immuno-positive cells, with a reduction seen particularly in transition zone and aganglionic bowel, and slight variation seen in the ganglionic bowel of those with pre-operative HAEC *vs* those who did not. TPH2: Tryptophan hydroxylase-2; HSCR: Hirschsprung's disease; HAEC: Hirschsprung's-associated enterocolitis.

colon, the enteric nervous system (ENS) is arranged into two plexuses: a submucosal plexus and a plexus that lies between the two deep smooth muscle layers, known as the myenteric plexus. The role of the myenteric plexus primarily concerns intestinal motility while the submucosal plexus regulates a myriad of epithelial functions such as enteric blood flow, immunity, release of enteric peptides from enteroendocrine cells, and epithelial transport[1,12]. It follows that the absence of a functioning ENS in the colon of those with HSCR will lead to dysregulation of these processes and, consequently, enterocolitis.

Although only 5% of 5-HT in the colon is neuronal in origin, it is notable that, in TPH1 knockout mice, gastrointestinal motility is preserved, even with stripping of the mucosa, indicating that only neuronal 5-HT is involved in gastrointestinal motility[5]. Additionally, animal models have demonstrated that neuronal 5-HT acts as a growth factor during enteric neurogenesis, promoting the development and survival of dopaminergic and GABAergic neurons[5,13]. It is thought that serotonergic neurons are large descending interneurons which, as well as being calbindin-positive, are cholinergic[14]. Our

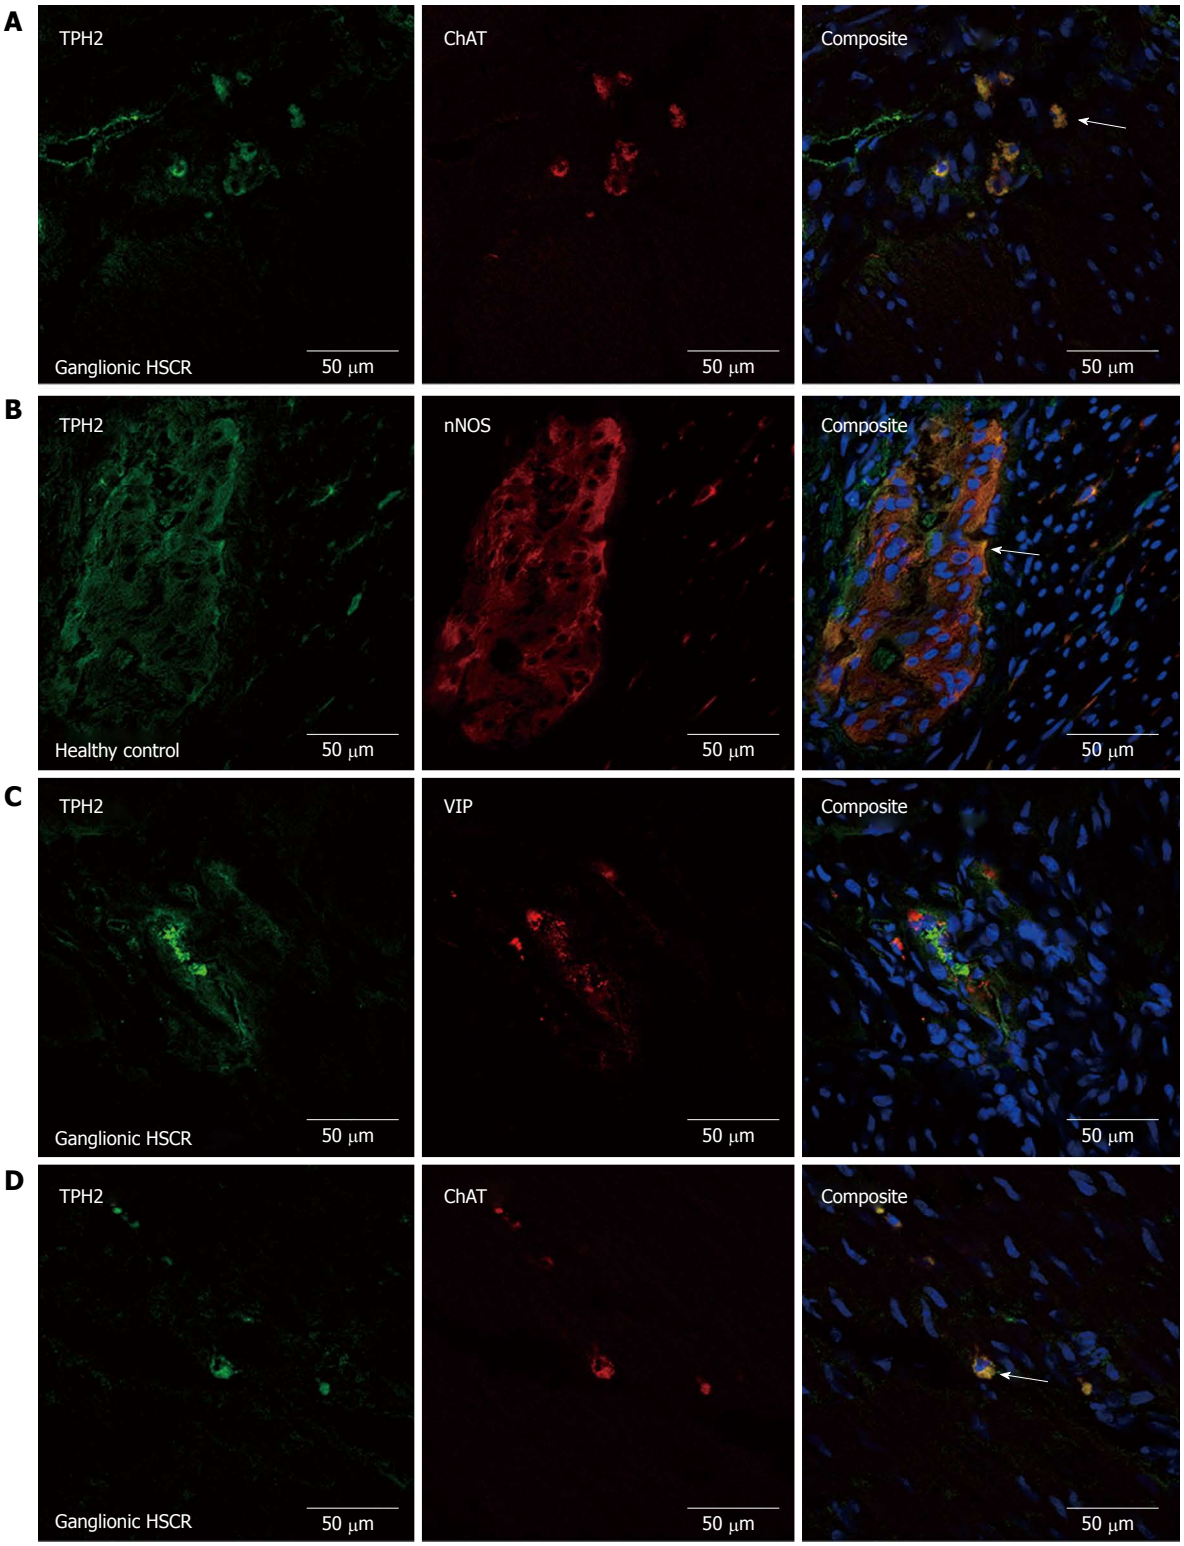

Figure 4 Confocal micrograph series. Confocal micrograph series demonstrating the cholinergic nature of TPH2 immuno-positive neurons in the myenteric plexus (A), with ChAT-TPH2 co-expression (white arrow). There was also co-expression of nNOS and TPH2 in the myenteric plexus (B) (white arrow) and submucosal plexus (not shown). VIPergic neurons did not express TPH2 in the myenteric plexus (C). Image (D) shows ChAT immune-positive cholinergic nerve fibres in the circular muscle layer, co-expressing TPH2. TPH2: Tryptophan hydroxylase-2.

findings concur with this observation, as we observed consistent co-expression of TPH2 with ChAT, a key enzyme in acetyl choline synthesis, in circular muscle nerve fibers.

Serotonergic nerves have previously been shown to make extensive synapses with myenteric ICCs, as well as nitrergic neurons. This indicates a functional role for serotonergic neurons in modulating nitrergic neurotransmission and pacemaker activity. Okamoto *et al*[15] has also observed that most colonic nitrergic

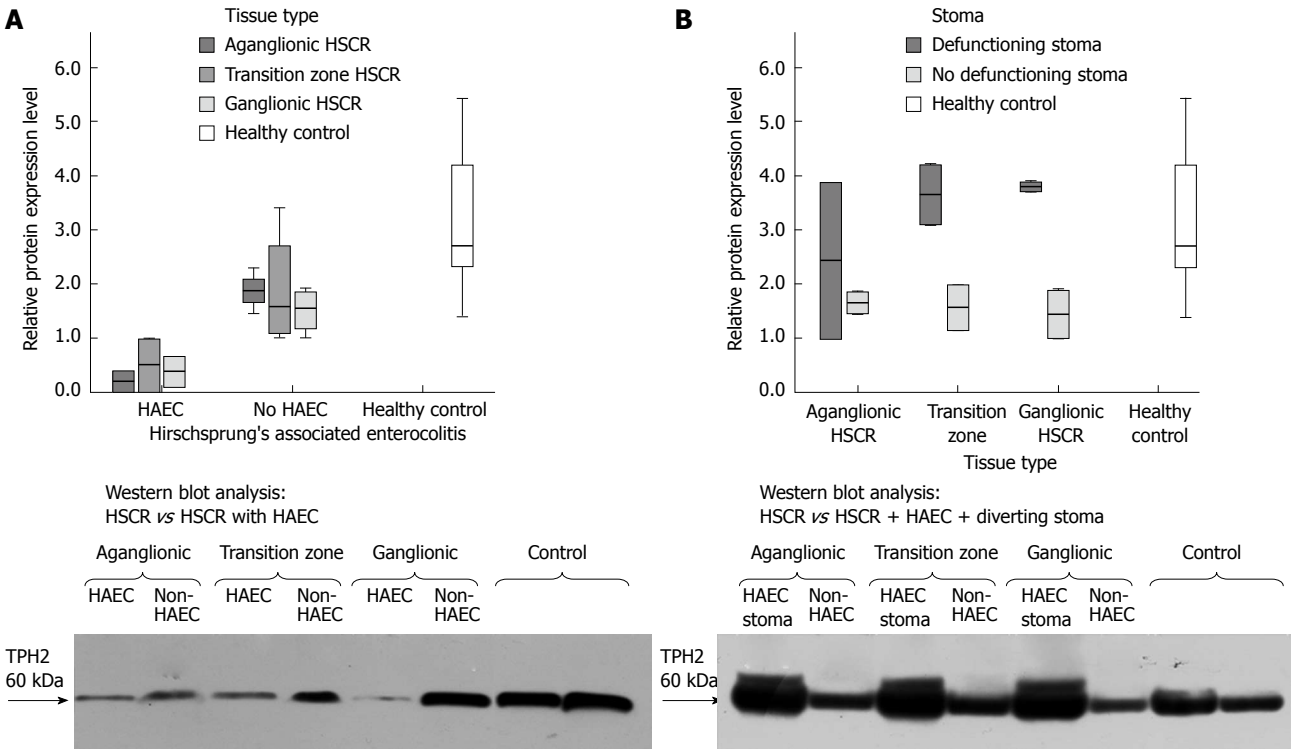

Figure 5 Western blot analysis. Western blot analysis is seen in (A) showing reduced expression of TPH2 in the colon of children with HSCR complicated by HAEC, who were managed non-operatively prior to pull-through surgery. The reduction in expression is seen across the aganglionic and ganglionic bowel of these patients. Image (B) shows the impact of diverting stoma formation on TPH2 expression in children with HSCR and pre-operative HAEC, with increased expression seen when compared to children without a history of HAEC and no stoma. In both (A) and (B), protein expression has been normalized against the loading control, GAPDH (36kDa). TPH2: Tryptophan hydroxylase-2; HSCR: Hirschsprung's disease; HAEC: Hirschsprung's-associated enterocolitis.

neurons and submucosal ICCs were richly supplied by serotonergic varicosities in murine colon and suggested a potential role for neuronal 5-HT in the regulation of slow wave electrical activity. Liu *et al*[16] demonstrated that 5-HT acts on the 5-HT$_3$ receptor on ICCs, wherein the receptor functions as a Ca^{2+}-influx mechanism to augment pacemaker activity in ICCs. The intimate spatial arrangement of serotonergic nerves with nNOS-positive nerves is also important as it is thought that, through the intercession of descending inhibitory serotonergic neuronal activity, the release of nitric oxide from nNOS-positive neurons suppresses excitatory cholinergic activity and limits the rate at which colonic migrating motor complexes (CMMC) are propagated in mice[14]. The equivalent peristaltic activity to the CMMC in humans is the high-amplitude propagating contraction.

A close spatial arrangement of myenteric ICC fibers with TPH2-positive ganglia was demonstrated in our study, with co-expression of TPH2 and nNOS in myenteric and submucosal nitrergic ganglia and submucosal ANO-1 positive ICCs. In addition, we have demonstrated co-expression of TPH2 in the relatively recently described PDGFRα^+ cells. These fibroblast-like cells share morphological similarities with ICCs but are c-kit negative[17]. It is thought that they play a role in transducing purinergic neurotransmission through the activity of apamin-sensitive small-conductance Ca^{2+}-activated K^+ (SK3) channels[18]. Our immunofluorescence findings suggest a possible functional role for serotonergic neurons in modulating PDGFRα^+ cell function. It is inferable from the current evidence in the literature, that reduced density of serotonergic nerves in aganglionic and transition zone bowel and, in some patients, the ganglionic bowel, in HSCR, would disturb the inhibitory mechanisms required to maintain normal colonic motility. This is of particular relevance in patients with HAEC.

Mucosal 5-HT, secreted by EC cells, has been demonstrated in animal models to be pro-inflammatory, probably due to its activation of 5-HT receptors on dendritic cells in the lamina propria[8]. In other inflammatory conditions of the bowel, such as ulcerative colitis, reduced levels of the SERT have been reported, leading to increased 5-HT availability[8]. Conversely, neuronal 5-HT has been shown to be neuroprotective. *In vitro* and *in vivo* studies have demonstrated that neuronal 5-HT acts *via* 5-HT$_{2B}$ and 5-HT$_{4A}$ receptors respectively to promote survival of ICCs and enteric neurons respectively[7,8].

It has long been recognized that significant enteric neural damage occurs in severe inflammatory conditions of the colon, particularly in the setting of necrotizing enterocolitis[19-21]. Our finding of reduced expression of TPH2 in the aganglionic, transition zone and ganglionic bowel in HSCR complicated by

HAEC, compared with patients unaffected by HAEC and controls, is probably reflective of enterocolitis-mediated neuronal damage. The vicious circle of enterocolitis and loss of neuroprotective serotonergic neurons may thus occur. We have previously reported on the outcomes of children with HSCR complicated by HAEC. It was found that approximately one third of patients in the series experienced enterocolitis both pre- and post-operatively[2]. Disturbances in colonic function were also more common in these patients at long-term follow-up[2]. That our findings represent effect rather than cause is supported by the finding that levels of TPH2 greatly recover in the defunctioned colon of children with HSCR complicated by HAEC who were treated with diverting colostomy due to failure of medical management.

One striking characteristic of the population from whom pull-through specimens were collected for this study is the high proportion of children with trisomy 21 at 41.2%. The incidence of trisomy 21 in Ireland, at 1 in 546 live births, is the highest in Europe[22]. Children with trisomy 21 are recognized to be at a considerably higher risk of developing HAEC (approximately 51%) compared to those without trisomy 21[23]. In our study 2 of the 5 patients who developed pre-operative HAEC had trisomy 21, both of whom were treated with a diverting stoma, indicating the severe nature of their enterocolitis.

In conclusion, we have demonstrated that serotonergic neurons co-express TPH2 with ANO1-immuno-positive ICCs in the submucosa, even in aganglionic bowel. We have also shown, for the first time, co-expression of TPH2 in PDGFRα^+ cells, suggesting a possible role for serotonergic modulation of their function. TPH2 expression was reduced in the myenteric plexus and deep smooth muscle layers of aganglionic colon in children with HSCR unaffected by pre-operative HAEC. However, in children with HSCR complicated by HAEC, TPH2 expression was reduced in both aganglionic and ganglionic bowel - a finding that was reversed in the colon of children treated with diverting stoma formation due to HAEC refractory to non-operative strategies. HAEC-mediated serotonergic neuronal damage may contribute to ongoing problems with colonic function and recurrent enterocolitis despite properly performed corrective pull-through surgery.

ACKNOWLEDGMENTS

We wish to thank Dr. Luiz Alvarez and Dr. Caroline King for their experimental support. We also acknowledge the contribution of the Departments of Histopathology in Our Lady's Children's Hospital and Temple Street Children's University Hospital for their logistical support in specimen collection. This study is supported by grants from the National Children's Research Centre/ Children's Medical and Research Foundation and from the Temple Street Foundation.

COMMENTS

Background

Hirschsprung's disease (HSCR) is the most common congenital gut motility disorder. It may be complicated by a severe pancolitis known as Hirschsprung's-associated enterocolitis (HAEC). Despite constituting only approximately 1%-5% of total intestinal serotonin (5-HT), neuronal 5-HT plays a key role in modulating gut motility and is thought to have an anti-inflammatory, neuroprotective role, in contrast to mucosal 5-HT which is pro-inflammatory.

Research frontiers

Dysregulation of mucosal 5-HT transport has already been implicated in ulcerative colitis and other inflammatory disorders of the human colon. While a previous study has described a reduction of enterochromaffin cells, which produce mucosal 5-HT, in the ganglionic colon of children with a history of HAEC, neuronal 5-HT expression has yet to be evaluated in HSCR. In mice, knockout of tryptophan hydroxylase 2 (TPH2), the key enzyme in the synthesis pathway of neuronal 5-HT, leads to slow gastrointestinal transit and severe intestinal inflammation. Conversely, knockout of TPH1, the key enzyme in the synthesis of mucosal 5-HT, has no effect on gastrointestinal motility.

Innovations and breakthroughs

It is known that patients with HSCR who experience pre-operative HAEC are at an increased risk of poor functional outcome despite optimal surgical treatment, with some patients continuing to experience severe constipation and recurrent enterocolitis even in the absence of a mechanical obstruction. The causes for this have yet to be fully elucidated. Current findings by the authors suggest that neuronal 5-HT is deficient in the ganglionic colon of children with a history of pre-operative HAEC. Given its anti-inflammatory, neuroprotective roles, our findings suggest a mechanism by which post-operative enterocolitis may occur.

Applications

5-HT and its receptors are some of the most important current pharmacological targets in the alteration of gut motility. While the authors have indirectly shown a reduction in neuronal 5-HT in the healthy ganglionic colon in HSCR after HAEC, it is unclear if this finding would persist at follow-up after a pull-through operation, as expression of TPH2 appeared to have recovered in patients who underwent levelling or defunctioning colostomy. These findings lay the foundation for future work examining whether the abnormalities detected in this study persist at follow-up, as well an empiric evaluation of the functional outcomes of patients in this study.

Terminology

Tryptophan hydroxylase 2 (TPH2) is an enzyme which catalyzes the conversion of L-tryptophan to 5-hydroxytryptophan, which is the critical rate-limiting step of neuronal 5-HT synthesis. It is an isozyme of TPH1, which catalyzes the same reaction in the synthesis of mucosal 5-HT in enterochromaffin cells.

Peer-review

This is a clearly presented study, addressing an important aspect of the role of neuronal 5-HT in Hirschprung's disease.

Abstract

AIM: To assess the effects of ischemic preconditioning (IPC, 10-min ischemia/10-min reperfusion) on steatotic liver mitochondrial function after normothermic ischemia-reperfusion injury (IRI).

METHODS: Sixty male Sprague-Dawley rats were fed

8-wk with either control chow or high-fat/high-sucrose diet inducing > 60% mixed steatosis. Three groups (n = 10/group) for each dietary state were tested: (1) the IRI group underwent 60 min partial hepatic ischemia and 4 h reperfusion; (2) the IPC group underwent IPC prior to same standard IRI; and (3) sham underwent the same surgery without IRI or IPC. Hepatic mitochondrial function was analyzed by oxygraphs. Mitochondrial Complex-Ⅰ, Complex-Ⅱ enzyme activity, serum alanine aminotransferase (ALT), and histological injury were measured.

RESULTS: Steatotic-IRI livers had a greater increase in ALT (2476 ± 166 *vs* 1457 ± 103 IU/L, P < 0.01) and histological injury following IRI compared to the lean liver group. Steatotic-IRI demonstrated lower Complex-Ⅰ activity at baseline [78.4 ± 2.5 *vs* 116.4 ± 6.0 nmol/(min·mg protein), P < 0.001] and following IRI [28.0 ± 6.2 *vs* 104.3 ± 12.6 nmol/(min·mg protein), P < 0.001]. Steatotic-IRI also demonstrated impaired Complex-Ⅰ function post-IRI compared to the lean liver IRI group. Complex-Ⅱ activity was unaffected by hepatic steatosis or IRI. Lean liver mitochondrial function was unchanged following IRI. IPC normalized ALT and histological injury in steatotic livers but had no effect on overall steatotic liver mitochondrial function or individual mitochondrial complex enzyme activities.
